Reduction of complex **2** with 1 equivalent of $Co(Cp)_2$ in CH_2Cl_2 and toluene gave the tautomers [$Co(Cp)_2$][Co^{III}(3,5-DTBCat)$_2$(phen)] (**4**,*ls*-Co^{III}) and [$Co(Cp)_2$][Co^{III}(3,5-DTBSQ)(3,5-DTBCat)(phen)] (**4**,*hs*-Co^{II}).† The magnetic and spectroscopic characterization as well as the variable-temperature UV–VIS spectra of acetone solutions of these two phen $Co(Cp)_2^+$ salts were also found to be similar to those obtained for the corresponding bpy complexes. In short, the neutral phen complex **2** can be reduced and the reduced Co^{III} and Co^{II} species are involved in a valence-tautomeric equilibrium, *i.e.* **4**,*ls*-Co^{III-} ⇌ **4**,*hs*-Co^{II-}, establishing a similar array of four states for the phen complex.

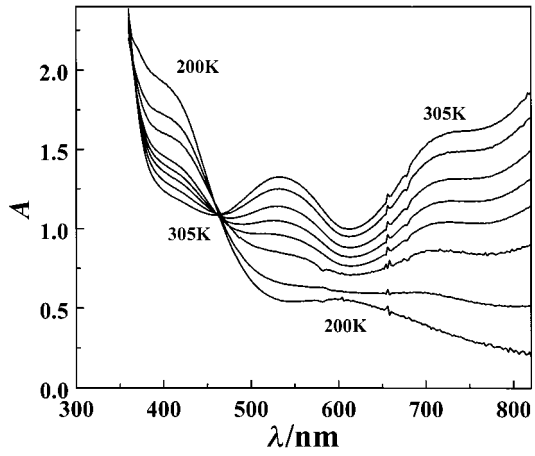

Fig. 2 Temperature dependence of the electronic absorption spectrum of an acetone solution of complex **3**

Oxidation of complex **1** could also establish another valence-tautomeric equilibrium, in addition to the two pictured in Fig. 1. Toward this goal, complex **1** was oxidized in 95% ethanol at 273 K (where complex **1** is mostly in the **1**,*ls*-Co^{III} form) by a H_2O_2–HCl mixture, following a procedure described by Wicklund *et al*.[8] for the oxidation of catecholate ligands. This oxidation gave [Co^{III}(3,5-DTBSQ)$_2$(bpy)]Cl, the Cl^- salt of (**5**,*ls*-Co^{III})$^+$.† Variable-temperature UV–VIS spectroscopy provides convincing evidence of the presence of a valence-tautomeric equilibrium for the oxidized form of the bpy complex in EtOH, *i.e*. for the equilibrium of **5**,*ls*-Co^{III+} ⇌ **5**,*hs*-Co^{II+}. At low temperatures (200 K) an intense band at 570 nm is seen that is characteristic of the (**5**,*ls*-Co^{III})$^+$ tautomer. An increase in temperature to 300 K leads to a decrease in the intensity of this band as a band at 720 nm, that is characteristic of (**5**,*hs*-Co^{II})$^+$, grows in. Two isosbestic points are seen. However, we must emphasize that when the temperature of the EtOH solution of (**5**,*hs*-Co^{II})$^+$ is increased above 300 K, the intensity of the 720 nm band does not increase. Instead, the intensities of both the 720 and 570 nm bands decreased as the temperature was increased above 300 K. We attribute this thermal instability of (**5**,*hs*-Co^{II})$^+$ to loss of the quinone ligand.

In summary, complexes of the composition [$Co(Cp_2)$]-[Co^{III}(3,5-DTBCat)$_2$(NN)] have been shown to undergo valence tautomerism. In addition, the reversibility of the tautomeric equilibria permitted the establishment of an array of four states with different magnetic and optical properties, reversibly interconvertible by means of electrochemical and thermal switching. Such an array of states is suitable to be used in the future as a building block for molecular electronic devices.

Phosphazene P_4-Bu^t base for the Ullmann biaryl ether synthesis

Claudio Palomo,*† Mikel Oiarbide, Rosa López and Enrique Gómez-Bengoa

Departamento de Química Orgánica, Facultad de Química, Universidad del País Vasco, Apdo. 1072, 20080 San Sebastián, Spain

In the presence of phosphazene P_4-Bu^t base and CuBr, aryl halides couple with phenols to give biaryl ethers at *ca.* 100 °C

The reaction of aryl halides with sodium or potassium aryloxides promoted by copper additives results in the formation of aryl ethers, the classical Ullmann biaryl ether synthesis.[1] The major problems of this reaction are the competitive reduction of the aryl halide to the dehalogenated arene[2] and the requirement for extremely harsh conditions, *i.e.* 200–300 °C, long reaction times and strong polar and often toxic solvents.[3] These reaction conditions probably account for an additional problem, namely the formation of isomeric biaryl compounds *via* substitution through an elimination-addition mechanism. On the other hand, the reductive homocoupling of the aryl halide component is also another inherent problem of this reaction.[4] Despite considerable success to date, these efforts have identified the same solution to these problems, namely, the preactivation of the aryl halide component *via*, for instance, the use of transition metals[5] or by placing an electron-withdrawing substituent *ortho* or *para* to the leaving group.[6] Although these variants have a prevalent position in the synthesis of complex macrocyclic peptides,[6,7] there exists no general solution for the direct coupling of aryl halides with phenols.[8]

Recently Buchwald *et al.*[9] described the first case of biaryl ether synthesis with unactivated aryl halides. The reaction occurs at *ca.* 110 °C using Cs_2CO_3 as the key reaction element.

We describe here an efficient method for the direct coupling of aryl halides with phenols that is based on the so-called 'naked anion' phenomenon.[10] Our procedure‡ combines this concept with the use of Schwesinger's phosphazene bases.[11] The synthesis and properties of these bases have been described recently.[12] We have found that P_4-Bu^t base in combination with Cu^I salts in either dioxane or toluene effects the Ullmann reaction of electron-rich, electron-neutral and electron-poor aryl halides with a variety of phenols (Scheme 1). For example, iodobenzene reacted with 2,4-dimethylphenol to produce the corresponding biaryl ether in 81% isolated yield under conditions where the use of other conceptually different bases produced only traces of the expected product, if at all.§ Other copper salts such as CuCl, CuI and $(CuOTf)_2$–benzene were also effective, but Cu^{II} salts did not give the coupling product. As shown in Table 1, the best results were attained using stoichiometric quantities of CuBr, although in some cases the reaction also proceeded well under CuBr catalysis (entries 1, 4, 5 and 8). The method is particularly suitable for electron-neutral aryl halides and *ortho*-substituted phenols. For example 2,6-dimethylphenol (entry 2) provided the corresponding biaryl ether in good yield and even the *o*-*tert*-butyl phenol (entry 3) coupled with *p*-iodotoluene to give the desired biaryl ether in 56% yield. The coupling reaction of *o*-iodotoluene and *o*-cresol (entry 4) also proceeded well to afford the corresponding biaryl ether in 69% yield. In these two latter cases, once again, no coupling reaction was observed when either DBU or TBD§ were used. Under the established reaction conditions, both electron-rich (entry 6) and electron-poor (entries 7–9) aryl halides also were effective in their coupling with phenols.

On the other hand, from the examples in Table 1 it also seems that the reaction conditions used are compatible with various functional groups. Nevertheless, neither the amino or the amido functionalities were inert under these reaction conditions. In fact, treatment of 3,5-dimethyliodobenzene with both aniline and *p*-toluidine afforded, under the above reaction conditions, the corresponding biaryl amines in 78 and 71% yield,

[a] Reactions conducted on a 1 mmol scale; aryl halide:phenol:CuBr = 1:2:2 in toluene as solvent unless otherwise stated. [b] Yields in parentheses refer to the reaction under catalytic conditions for Cu^I (20 mol% of CuBr). [c] Dioxane as solvent. [d] Reaction carried out in the presence of DMF (10% v/v). [e] Reaction carried out in the presence of galvinoxyl radical (10 mol%); in the absence of this radical inhibitor undesired byproducts were dominant. [f] Under catalytic conditions a mixture of isomeric biaryl ethers was formed.

respectively.[13] Although the precise role played by the phosphazene P_4-Bu^t base in the outcome of the reaction is not clear at present, two observations may give some clue: (i) the well-known ability of such a base to form highly nucleophilic 'naked' anions and, (ii) the complete solubility that the otherwise insoluble CuBr exhibits in the presence of P_4-Bu^t. Both factors may facilitate the formation of the reactive intermediate aryloxycopper species,[14] which can then react with the aryl halide under essentially homogeneous conditions. In any case, the use of this phosphazene base appears to be critical for performing the coupling reaction under reaction conditions that are unsuitable for conventional bases.

‡ General procedure: A mixture of the aryl halide (1 mmol), the corresponding phenol (2 mmol), P_4-Bu^t (2 mmol) and CuBr (2 mmol or 0.2 mmol for the catalytic version) in dry, deoxygenated toluene or dioxane (3 ml) was refluxed under a nitrogen atmosphere until the aryl halide was consumed as determined by GC analysis (typically 16–20 h). The reaction mixture was then allowed to cool to room temperature, diluted with EtOAc and washed sequentially with saturated aq. NH_4Cl (25 ml), 0.1 M NaOH (25 ml) and water (25 ml). The organic layer was dried over Na_2SO_4 and concentrated *in vacuo*. Purification by flash chromatography on silica gel using hexane afforded the analytically pure product.

§ Among the bases tested, Na_2CO_3, K_2CO_3 and 3,3,6,9,9-pentamethyl-2,10-diazabicyclo[4.4.0]dec-1-ene (PMDBD) were completely uneffective; 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) and 1,5,7-triazabicyclo[4.4.0]-dec-5-ene (TBD) afforded the coupling product in less than 20% yield along with the starting material and unidentified side products.

Control of reaction course of the excited state of charge-transfer complexes by the free energy of backward electron transfer

Naoki Haga,*[a] Hiroaki Takayanagi[a] and Katsumi Tokumaru[b]

[a] *School of Pharmaceutical Sciences, Kitasato University, Minato-ku, Tokyo 108, Japan. E-mail: hagan@pharm.kitasato-u.ac.jp*
[b] *University of Tsukuba, Tsukuba, Ibaraki 305, Japan*

Selective excitation of charge-transfer (CT) complexes between acenaphthylene and various electron acceptors gives net reaction products when the resulting radical ion pairs lie at sufficiently higher energy than the ground state (large $-\Delta G_{BET}$); however, with decrease of $-\Delta G_{BET}$, these tend to become less reactive and finally non-reactive.

During active works on photoinduced electron transfer reactions, attention has been paid to the behavior of the excited states of charge-transfer complexes.[1–9] It was found that, for the combination of aromatic hydrocarbons with electron acceptors, contact radical ion pairs (CIPs) produced on excitation of their charge-transfer complexes facilely undergo backward electron-transfer (BET), the rate constant of which, k_{BET}, increases with decrease of the net free energy difference, $-\Delta G_{BET}$, between the ground state and the radical ion pair, whereas solvent separated radical ion pairs (SSIPs) resulting from encounters of excited states of either donors or acceptors with counterparts follow a bell-shaped k_{BET} *versus* $-\Delta G_{BET}$ relationship.[1–5] The above difference in behavior between CIPs and SSIPs might reflect a much smaller reorganization energy for BET from the former than from the latter.[8] However, the above energy gap effect on the reactivity of CT complexes has been investigated mostly by means of transient absorption spectroscopy, therefore whether the excited states of the CT complexes do or do not give the final reaction products remains unclear. Previously, we found that selective excitation of the CT complex of acenaphthylene (ACN) and TCNE with 546.1 nm light in acetonitrile or dichloroethane did not give any product, whereas excitation of ACN with 435.8 nm light in the presence of TCNE afforded products by way of electron transfer.[10,11]

This finding has led us to examine how $-\Delta G_{BET}$ affects the net chemical reactivity of the excited states of CT complexes between ACN and a series of electron acceptors such as nitriles, acid anhydrides, and quinones,† and we found that the $-\Delta G_{BET}$ value very dramatically controls the net reactivity of the excited state as reported below. The CT complexes‡ were selectively excited in dichloromethane with 546.1 nm light to determine the quantum yields of the reaction, or with >500 nm light to investigate the reaction products, since the CT complexes show absorption at wavelengths longer than 500 nm but ACN shows absorption at wavelengths shorter than 500 nm.

Fig. 1 plots the quantum yields of reaction, Φ_R, against $-\Delta G_{BET}$.§ This indicates that CT complexes with large $-\Delta G_{BET}$ values give net products; however, with lowering of $-\Delta G_{BET}$, Φ_R tends to decrease and finally reaches zero when $-\Delta G_{BET}$ is lower than 1.7 eV.¶ When $-\Delta G_{BET}$ is lower than the threshold, excitation of the CT complexes of ACN with acceptors did not result in any reaction products but excitation of ACN in the presence of the same acceptors afforded reaction products. In these cases, for the same combination of ACN and an acceptor, the SSIP resulting from excitation of ACN is reactive but either the excited state of the CT complex or the CIP resulting therefrom is unreactive. On the other hand, the CIP resulting from the excited CT complex, when lying with $-\Delta G_{BET}$ larger than the threshold, can undergo charge separation to give definite products *via* SSIPs competing with BET.

The Φ_R is composed of efficiencies for charge separation from the excited CT complex, Φ_{CS}, and for the generation of products from the dissociated radical ions, Φ'_R, according to $\Phi_R = \Phi_{CS} \times \Phi'_R$. Therefore, the above results certainly indicate that charge separation practically does not occur when $-\Delta G_{BET}$ is smaller than the above threshold, and the efficiency for charge separation tends to increase with increase of $-\Delta G_{BET}$ as shown in Scheme 1, since the radical ions, once produced from the SSIP, can give reaction products; *i.e.* Φ'_R is always > 0. In fact, excitation of ACN in the presence of the electron acceptors examined afforded reaction products and these were essentially the same as those resulting from excitation of CT complexes when they gave net reaction products.‖ In Scheme 1, A and A′ represent, for example, TCNB and TCNE, respectively.

When the CT complexes afford net reaction products, the resulting products are classified into two classes, *i.e.* those derived from benzoquinones (BQs) and those from non-BQs as shown in Scheme 2. Selective excitation of the CT complexes between ACN and non-BQs, namely acid anhydrides or nitriles, gave mainly two isomeric dimers of ACN, *cisoid*-**1** and *transoid*-**1**, in a ratio of 3–7 : 1, as observed in the excitation of ACN in the presence of electron acceptors such as TCNE which results in electron transfer from the excited ACN to the acceptors followed by the formation of a dimeric radical cation of ACN ($ACN_2^{+\cdot}$) affording *cisoid*- and *transoid*-**1** in the same ratio as above (Scheme 2).[10]

Excitation of the CT complexes of BQs, when affording products, gave addition products (**2**, **3**, and **4**), together with *cisoid*-**1** and *transoid*-**1** (Scheme 2), but no reduction products of BQs such as hydroquinones. For example, selective excitation of the CT complex between ACN and 2-CBQ gave **2**, **3**, and **4** in 13, 32, 7% yields, respectively, together with 20% of **1** with a *cisoid* : *transoid* ratio of 4.0 : 1 on consumption of 21% of

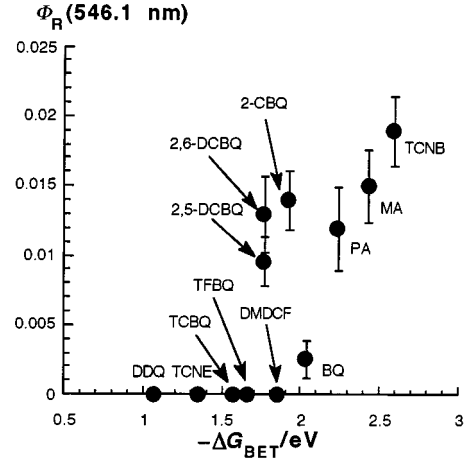

Fig. 1 Plots of quantum yield (Φ_R) at 546.1 nm for the reaction of ACN with various acceptors *versus* the energy gap between the ground state and the CIP ($-\Delta G_{BET}$)

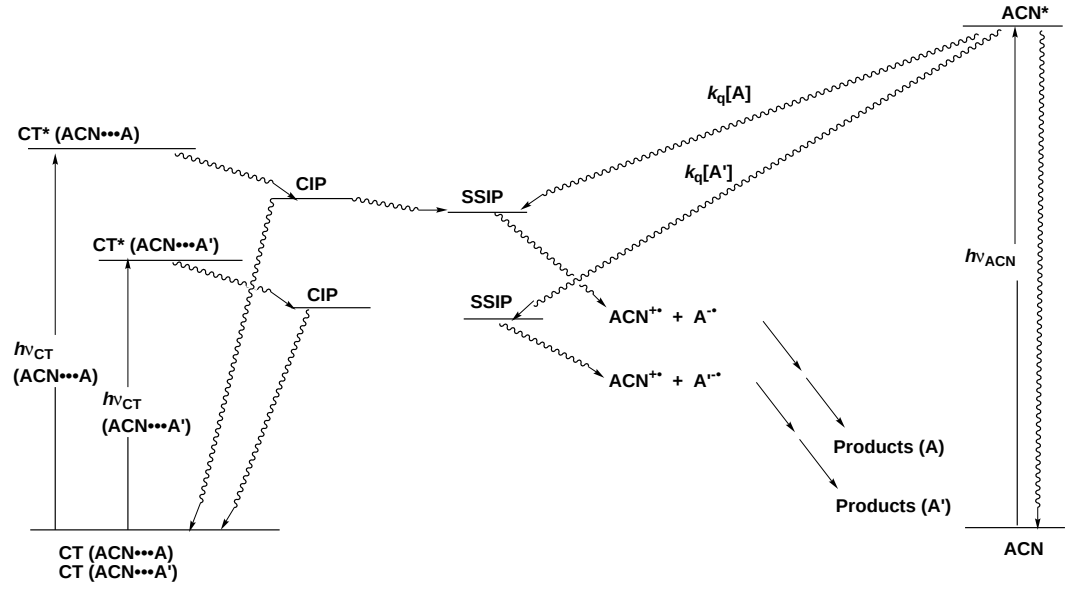
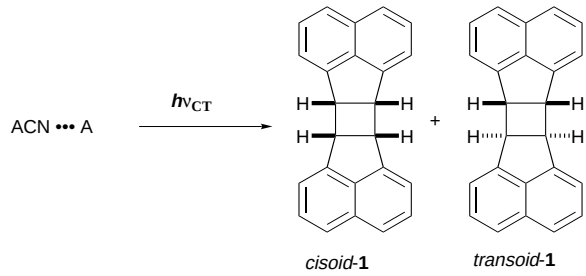
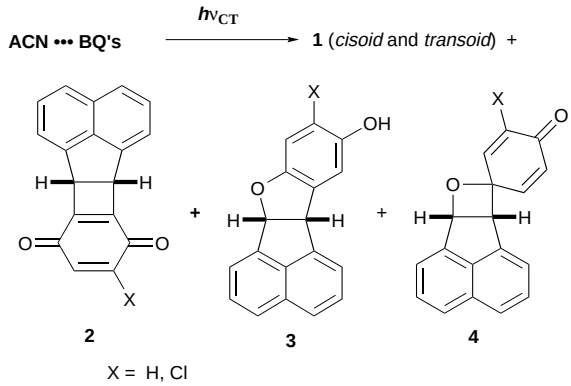


Scheme 1

(1) Acceptors: non-benzoquinones (nitriles and acid anhydrides)



(2) Acceptors: benzoquinones



Scheme 2

ACN. Similarly, direct excitation of ACN with > 400 nm light gave *cisoid*-**1**, *transoid*-**1**, **2**, **3**, and **4** in 9, 4, 18, 36, 8% yields, respectively, on consumption of 94% of ACN.

In conclusion, $-\Delta G_{BET}$ clearly controls the reactivity of excited CT complexes by affecting the BET rate from the resulting CIP as schematically drawn in Scheme 1. Details of the present study will be published elsewhere.

To our knowledge, this is the first report to show, in a series of CT complexes between an electron donor with various acceptors, $-\Delta G_{BET}$ dramatically controls the course of reaction leading to final isolable products.

This work was partly supported by a Grant-in Aid for Scientific Research (No. 08640696) from the Ministry of Education, Science, and Culture, Japan, and Kitasato University Research Grant for Young Researchers (N. H.).

Notes and References

† Abbreviations of acceptors in this study: TCNB, tetracyanobenzene; DMDCF, dimethyl dicyanofumarate; MA, maleic anhydride; PA, pyromellitic dianhydride; BQ, 1,4-benzoquinone; 2-CBQ, 2-chloro-1,4-benzoquinone; 2,5-DCBQ, 2,5-dichloro-1,4-benzoquinone; 2,6-DCBQ, 2,6-dichloro-1,4-benzoquinone; TCBQ, chloranil; TFBQ, fluoranil.

‡ The CT complexes show absorptions extending to 400–700 nm in organic solvents depending on the acceptors. The equilibrium constants, K_{eq}, for formation of the 1 : 1 CT complex were spectrophotometrically[12] determined in DCE in the range 1.6–6.2 M^{-1} depending on the acceptors.

§ The quantum yields, Φ_R, for reaction on selective excitation of the CT complexes were determined based on the amount of converted ACN under irradiation by 546.1 nm monochromatic light in DCE.[13]

¶ In the threshold region, 2-CBQ ($-\Delta G_{BET}$ 1.92 eV) showed higher Φ_R than BQ (2.03 eV), and moreover 2,6-DCBQ (1.76 eV) and 2,5-DCBQ (1.76 eV) exhibited much larger Φ_R values than DMDCF (1.85 eV). This fact might be attributed to the heavy atom effect of the chlorine atom in these chloroquinones to enhance conversion of the initially resulting singlet radical ion pair (RIP) to a triplet RIP which will more effectively lead to separation of free radical ions.

‖ An equimolar mixture (0.005–0.02 M) of ACN and an acceptor in DCE was irradiated using a 400 W high pressure mercury lamp in a merry-go-round apparatus at 20 °C as described for TCNE.[10] The products were isolated by flash column chromatography and identified by spectral properties and/or elemental analysis.

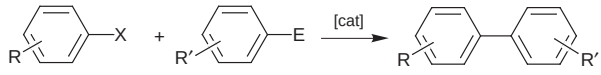
Orthopalladation of inexpensive, commercially available tris(2,4-di-*tert*-butylphenyl) phosphite gives a dimeric complex 3 which proves to be an extremely active catalyst in biaryl coupling reactions, giving unprecedented turnover numbers of up to 1 000 000 [mol product (mol Pd)$^{-1}$] and turnover frequencies of nearly 900 000 [mol product (mol Pd)$^{-1}$ h^{-1}] in the Suzuki reaction and turnover numbers of up to 830 000 in the Stille reaction.

The use of triaryl phosphite complexes in catalysis has recently enjoyed a renaissance as a result of the activity they show in hydroformylation,[1] asymmetric hydrocyanation[2] and enantioselective alternating co-polymerisation of CO and propene.[3] Our interest lies in the synthesis and catalytic behaviour of orthometallated triaryl phosphite complexes and the role that the metallation plays in their activities.[4] So far the exploitation of such systems has been limited to a few catalytic reductions[4b,5] and only one example of catalytic C–C bond formation.[6]

One particularly important class of C–C coupling reaction is the catalytic formation of non-symmetric biaryls (Scheme 1) by the coupling of aryl halides with either arylboronic acids (the Suzuki reaction) or aryltin reagents (the Stille reaction). In general, catalyst loadings in such reactions are high (1–10 mol%) which imposes financial constraints on scaling up reactions and problems associated with catalyst removal. Therefore the synthesis of high activity catalysts which can be used in low concentrations is a desirable goal. Recently, Beller and co-workers reported the use of the metallated tris(2-



Scheme 1 Suzuki [E = $B(OH)_2$] and Stille (E = SnR_3) biaryl coupling reactions

methylphenyl)phosphinepalladium(II) complex **1** as an efficient catalyst for the Suzuki reaction.[7] The ready ability of triaryl phosphites to undergo analogous metallation reactions as well as their ease of synthesis, commercial availability and very low cost prompted us to examine the possibility of designing well-defined orthometallated Pd^{II}–triaryl phosphite complexes capable of catalysing biaryl coupling reactions.

The reaction of bulky tris(2,4-di-*tert*-butylphenyl)phosphite **2** with $PdCl_2$ gives the orthometallated dimer **3** in 96% yield. Compound **3** has been characterised by satisfactory elemental analysis, ^{1}H and ^{31}P NMR spectroscopy and by single crystal X-ray analysis (Fig. 1).§ Compound **3** shows remarkable stability to air and moisture—in solution it shows no sign of decomposition after several weeks, whilst solid samples can be kept in air for at least six months. No decomposition is observed when **3** is heated at 130 °C in toluene for 24 h, demonstrating that the catalyst also shows good thermal stability.

The coupling of aryl halides and phenylboronic acid catalysed by **3** was investigated and representative results are summarised in Table 1. With 4-bromoacetophenone as substrate, extraordinarily high turnover numbers (TONs) of up to 1 000 000 [mol product (mol Pd)$^{-1}$] and turnover frequencies (TOFs) of nearly 900 000 [mol product (mol Pd)$^{-1}$ h^{-1}] were obtained at 110 °C. The previous highest activity with this substrate was achieved with complex **1** which gave a TON of 74 000 at the higher temperature of 130 °C over 16 h.[7] In the present reaction, lowering the temperature to 70 °C leads to a reduction in activity, but even at 20 °C high levels of activity are observed relative to previous reports of ambient temperature reactions.[8] The reaction is strongly influenced by a change of solvent or base, thus replacing toluene with THF at 70 °C leads to a substantial drop in rate. Similarly, with NaOAc as the base in DMA lower rates are observed.

With 4-bromobenzophenone as substrate high rates and ultimate conversions are also seen. As expected, activity decreases with increasing electron density on the aryl bromide. For instance, when 4-bromoanisole is employed TOFs are about two orders of magnitude lower than with 4-bromoacetophenone, however the ultimate TONs—up to 30 000—are, we believe, without precedent.

[a] Determined by GC and/or ^{1}H NMR analysis of reaction mixture samples, based on aryl halide.

In the coupling reactions with higher catalyst concentrations ($\geqslant$0.1 mol% Pd) deposition of palladium is observed in the later stages of the reaction. Similarly, reaction of **3** with 1 equiv. of $PhB(OH)_2$ and K_2CO_3 in the absence of an aryl bromide leads to deposition. When this reaction was repeated with 1 equiv. of **2** included, decomposition was inhibited and it was possible to monitor the reaction by ^{31}P NMR spectroscopy. The spectrum after 30 min showed the mixture to be predominantly **2** and **3** but amongst other minor peaks two relatively major low field double doublets were apparent.¶ We have tentatively assigned these to the two isomers of [Pd(Ph){P(OC$_6$H$_2$-2,4-Bu$^t_2$)-(OC$_6$H$_3$-2,4-Bu$^t_2$)$_2$}{P(OC$_6$H$_3$-2,4-Bu$^t_2$)$_3$}] in which the P atoms are disposed *trans* (major) or *cis* (minor). Also apparent is a small peak at δ −18.3. Such a high field shift is consistent with the formation of a Pd^0–phosphite complex. We postulate that reductive elimination of the orthometallated phosphite aryl and a phenyl groups occurs, yielding a catalytically active zero valent palladium species. This is in accord with findings for the use of **1** in the Stille reaction.[9] However, a Pd^{II}/Pd^{IV} couple has recently been suggested to be active in the Heck arylation of alkenes catalysed by **1** and related complexes[10] and at this stage we cannot rule out a related pathway.

Encouraged by the results obtained in the Suzuki reaction we decided to investigate the application of **3** to the Stille reaction. Representative results for the coupling of tributylphenyltin with aryl bromides are summarised in Table 2. With 4-bromoacetophenone as substrate TONs of up to 840 000 were achieved within 18 h at 120 °C. To the best of our knowledge this is the highest reported activity to date, comparing well with that obtained with **1** which gives a TON of 1650 in the coupling of 4-bromoacetophenone with $PhSnMe_3$ at the same temperature.[9] The reaction is again somewhat more sluggish with 4-bromoanisole, but useful conversions are still obtained.

In summary the complex **3** is extremely active in biaryl coupling reactions under both Suzuki and Stille conditions and consequently can be used in very low concentrations. In view of this unprecedented activity and the low cost of **2**—at least two orders of magnitude cheaper than tris(2-methylphenyl)phosphine—we believe that it will be the catalyst of choice in such reactions. We are currently investigating its application to further catalytic processes. Preliminary investigations show it to be extremely active in the Heck arylation of alkenes, showing TONs of up to 5.75 million for activated aryl bromides, and these findings will be published elsewhere.

This work was supported by Forbairt and the Trinity Trust Foundation. We thank Johnson-Matthey for the generous loan of palladium salts and Cork University Foundation for the purchase of an X-ray diffractometer.

Friedel–Crafts reactions in the ionic liquid system 1-methyl-3-ethylimidazolium chloride–aluminium(III) chloride can be performed with excellent yields and selectivities, and in the case of anthracene, have been found to be reversible.

The possibility of carrying out chemical transformations in low temperature ionic liquids has, to date, received little attention.[1] Ionic liquids such as the [emim]Cl–$AlCl_3$ ([emim]$^+$ = 1-methyl-3-ethylimidazolium cation) system have been shown to demonstrate catalytic activity in reactions such as Friedel–Crafts acylations,[2,3] alkylation reactions,[4] isomerisation of alkanes,[5] and the alkylation of isobutane with butene.[6] Here, we present a series of reactions of AcCl with carbocyclic aromatic compounds in acidic compositions (X = 0.67)‡ of [emim]Cl–$AlCl_3$ (Fig. 1) and compare their performance with similar reactions in 'conventional' molecular solvents.

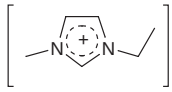

Fig. 1 The structure of the [emim]$^+$ cation

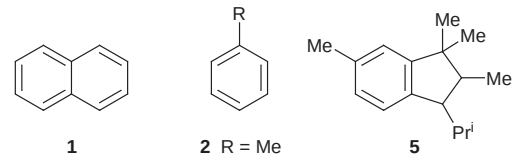
To date, there have been very few publications detailing reactive chemistry in ionic liquids.[1] With the development of ambient temperature ionic liquids, the possibility of investigating chemical processes in these new solvents provides an interesting challenge. One of the most studied ionic liquids is the [emim]Cl–$AlCl_3$ system.[7,8] An investigation of the Friedel–Crafts reactions of simple benzene derivatives in this medium has been performed by Wilkes.[3] With a view towards developing reactions for clean synthesis in ionic liquids, a number of Friedel–Crafts acetylation reactions have now been performed. The Friedel–Crafts reactions of five simple aromatic compounds has been investigated and are shown in Table 1.

The reactions work efficiently, giving the stereoelectronically-favoured product. In the acetylation reaction of naphthalene **1**, the major product was the thermodynamically unfavoured 1-isomer, with a 2% yield of the 2-isomer. This is in accordance with best literature yield and selectivity.[9,10] It has been suggested that the position of attack on naphthalene is determined to a large extent by steric factors.[11] For example, if the reaction is carried out in nitrobenzene or nitromethane,[11] the 2-isomer is the major product and the acylating agent is thought to be an AcCl–$AlCl_3$–nitrobenzene complex. In the ionic liquid, the acylation agent is thought to be the free acylium ion.[3,12,13] Since the acylium ion is much smaller than the adduct, attack at sterically more hindered positions can occur.[3,13] In the ionic liquid, subsequent rearrangement of 1- or 2-acetylnaphthalene was not observed to occur. This was confirmed when the products were heated to 100 °C and in the presence of added hydrogen chloride,[14] and no further reaction was observed. In the acetylations of toluene **2**, chlorobenzene **3** and anisole **4**, all the major products were the 4-isomers. In these cases, the 2-isomers were present, but at levels less than 2%. These yields and selectivities were as good as the best published results.[15–17] With the reaction of 1,1,2,6-tetramethyl-3-isopropylindane **5**, the fragrance traseolide (5-acetyl-1,1,2,6-tetramethyl-3-isopropylindane) was obtained in 99% yield as a single isomer. The stereochemical arrangement of the indane ring was unaffected by the reaction.



1 **2** R = Me, **3** R = Cl, **4** R = OMe, **5**

The acetylation reactions of anthracene were found to behave in a different manner to those of simpler aromatic compounds. Anthracene is generally considered to undergo acetylation reactions primarily at the 9-position.[18] Furthermore, the possibility of diacetylation exists, and deacetylation reactions complicate the chemistry, leading to a complex mixture of products. Owing to the complexity of the reaction, it was decided to monitor the variation of composition of the reaction mixture with time by gas chromatographic analysis.

It can be seen from Table 2 that 9-acetylanthracene **7** is the initial product in the reaction, formed rapidly in under 5 min, but this subsequently undergoes a slow disproportionation to anthracene and the two isomers of diacetylanthracene, **10** and **11**. Also, small amounts of 1- and 2-acetylanthracene are formed transiently. This implies that the monoacetylation of anthracene is reversible. Since the 1,5- and 1,8-diacetylanthracenes are the only isomers found in the final products, only the 1-acetylacthracene intermediate can undergo diacetylation. A plausible mechanistic scheme for this reaction is given in Scheme 1.

Table 1 Friedel–Crafts acylation of aromatic compounds **1–5** with AcCl in [emim]Cl–$AlCl_3$ (X = 0.67)

Aromatic compound	T/°C	t/h	Products (% yield)
1	0	1	1-AcAr (89), 2-AcAr (2)

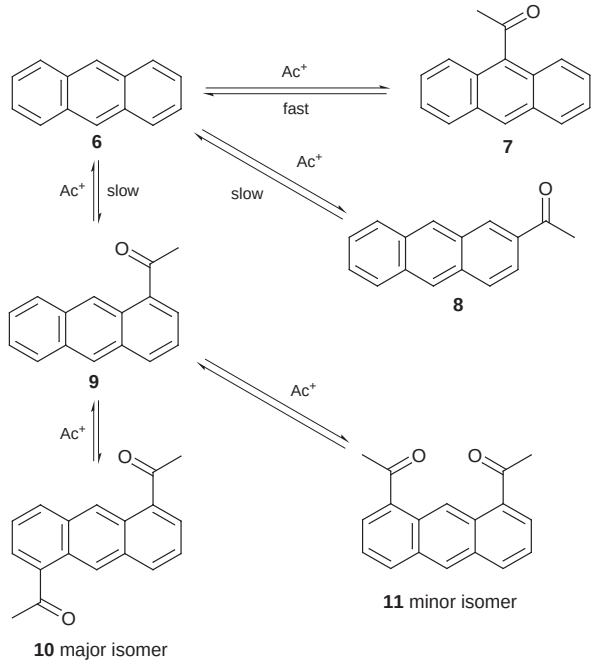
5 min	1.5	15	73	3	1
24 h	1.5	25	0	42	33
5 min	2.1	13	69	5	3
24 h	2.1	1	1	57	42

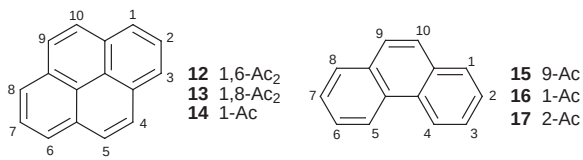


Scheme 1

It was decided to investigate the behaviour of 9-acetylanthracene in the ionic liquid. 9-Acetylanthracene dissolves in the [emim]Cl–$AlCl_3$ (X = 0.67) ionic liquid at 0 °C, and undergoes a slow conversion to anthracene (33%), **8** (12%), **10** (31%) and **11** (22%) (Scheme 1). Initially, a very slow reaction was observed. When a proton source (water) was introduced to the reaction vessel, a more rapid reaction occurred suggesting a proton-catalysed mechanism. The addition of small quantities of water to the reaction vessel leads to the formation of hydrogen chloride, which in chloroaluminate ionic liquids behaves in a superacidic manner.[14]

From these observations, it is possible to propose a plausible mechanism for the behaviour of 9-acetylanthracene in [emim]Cl–$AlCl_3$ (X = 0.67). It behaves in a manner that is very similar to that shown in Scheme 1. The key initial step must involve the protonation of **7** followed by loss of the acylium ion.

The acetylation reactions of pyrene and phenanthrene were also investigated (Table 3). The reaction of pyrene with AcCl in the ionic liquid appeared to behave in a similar manner to that of anthracene. The major products were the 1,6- and 1,8-isomers of diacetylpyrene, **12** and **13**, and the minor product was identified as 1-acetylpyrene **14**. This behaviour has not been reported in previous acetylation studies.[19] In the acetylation of phenanthrene, the mono-acetyl derivatives are the major products, with very little of the diacetyl products formed. As expected, 9-acetylphenanthrene **15** is the major product, and the minor products are the 1- and 2-isomers, **16** and **17**. This is very similar to conventional $AlCl_3$ catalysed reactions of AcCl with phenanthrene.[20]



Based on these initial results, ionic liquids appear to provide an excellent medium for performing Friedel–Crafts reactions. Simple aromatic compounds, such as toluene, anisole or chlorobenzene are easily acetylated in yields that are equal to the best literature yields.[9–14] In addition, the regiochemical control of these reactions is excellent. In the acetylation of electron-rich polyaromatics, there is evidence that the reaction is reversible and that deacetylation reactions are proton catalysed. As for the mechanism of these reactions, the reaction of naphthalene appears to show that the acetylating agent is sterically small, and is probably the free acylium ion. It should also be noted that carbocyclic aromatics, such as naphthalene, phenanthrene and pyrene, form highly coloured compounds in acidic [emim]Cl–$AlCl_3$, probably π-complexes as they are paramagnetic.[21,22] The fact that paramagnetic species are present, and that protons play a significant part in these reactions, suggests that the classical mechanisms proposed for the Friedel–Crafts reaction may need modification.

Table 3 The acetylation of pyrene and phenanthrene in [emim]Cl–$AlCl_3$

Aromatic compound	T/°C	Time	AcCl/ equiv.	Starting material	Composition (%) Products
Pyrene	20	2 h	1.2	32	13 (**14**), 55 (**12** + **13**)
Phenanthrene	−10	5 min	1.5	0	55 (**15**), < 5 (**17**), 30 (**16**)

Characterization of chlorine atom adducts of dimethyl and diphenyl sulfide in CCl_4

John E. Chateauneuf

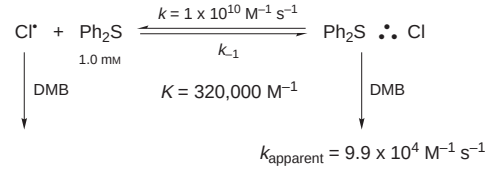
Department of Chemistry, Western Michigan University, Kalamazoo, MI 49008, USA and the Radiation Laboratory, University of Notre Dame, Notre Dame, IN 46556, USA. E-mail: chateauneuf@wmich.edu

The equilibrium constants for the association of chlorine atom with dimethyl and diphenyl sulfide to form chlorine atom adducts have been determined spectroscopically and indicate that both adducts should be considered three electron bond complexes.

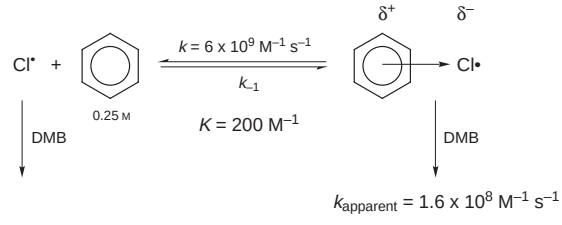
Dimethyl sulfide (Me_2S) is known to be the major natural source of sulfur in the atmosphere.[1] Removal of Me_2S from the atmosphere is believed to occur by the reaction of Me_2S with photolytically generated free radicals and halogen atoms. Therefore, there has been considerable interest recently in kinetic and mechanistic investigations of halogen atom reactivity with sulfur containing species.[2–6] An important aspect of these investigations is the possibility of forming chlorine atom adducts to sulfides. It is also important to understand the physiochemical nature of the chlorine adducts in differing physical environments, *e.g.* gas, interfacial and liquid phases. This report presents a spectroscopic and kinetic methodology for the determination of equilibrium constants (K_{eq}) for the formation of chlorine atom molecular complexes in carbon tetrachloride solution. The equilibrium constants determined in this work were compared to values of K_{eq} for known π- and σ-chlorine atom complexes to determine the bonding nature of the dimethyl sulfide and diphenyl sulfide chlorine atom adducts.

The reason it is important to understand the strength of interaction of chlorine atom adducts is that K_{eq} will influence subsequent reactivity of the individual components of the system. Recently, in reports describing the photochemistry of the diphenyl sulfide/chlorine atom adduct ($Ph_2S/Cl^{\bullet}$), the complex was assigned to a π-molecular complex[7] owing to similarities in its absorption spectrum to $Cl^{\bullet}$/arene π-complexes.[8] The assignment is extremely intriguing in that the dimethyl sulfide/chlorine adduct ($Me_2S\therefore Cl$) has been characterized as a sulfur–chlorine three electron bond (2c–3e) adduct by matrix isolation EPR spectroscopy,[9] and in aqueous solution by pulse radiolysis.[10] Therefore, the question arises as to whether $Ph_2S/Cl^{\bullet}$ may demonstrate dual complexation, that is, π-interaction of $Cl^{\bullet}$ with the aromatic rings and σ-bond formation with the sulfur center. This question may be addressed by measuring the apparent reactivity of the $Ph_2S/Cl^{\bullet}$ adduct with 2,3-dimethylbutane (DMB) at low concentrations of complexing agent,[11,12] and in turn determining K_{eq}. The results obtained then may be compared with the reactivity of the known $Cl^{\bullet}$/benzene π-complex[8] and the $Cl^{\bullet}$/pyridine σ-complex.[11,12]

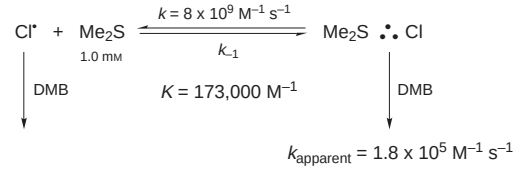
Chlorine atoms, and in turn $Ph_2S/Cl^{\bullet}$, were independently generated by both pulse radiolysis† and 266 nm laser flash photolysis (LFP) of CCl_4‡ containing 1×10^{-3} M Ph_2S. Each method of generation produced the same result, namely absorption spectra containing two absorption bands (λ_{max} = 340 nm, 500 nm; see graphical abstract) that were consistent with the absorption spectrum of $Ph_2S/Cl^{\bullet}$ previously reported.[7] Also consistent with the previous report was 1×10^{10} M^{-1} s^{-1} rate of formation of the $Ph_2S/Cl^{\bullet}$ complex and the 340 nm and 500 nm absorption bands of the $Ph_2S/Cl^{\bullet}$ complex demonstrated identical kinetic behavior. From a detailed kinetic analysis of selectivity in the photochlorination of DMB in the presence and absence of benzene, Ingold and coworkers[8] determined K_{eq} = 200 M^{-1} for the $Cl^{\bullet}$/benzene π-complex, *i.e.* $K_{benzene}$ = 200 M^{-1}. It has been demonstrated[11,12] that K_{eq} of other $Cl^{\bullet}$ complexes ($Cl^{\bullet}$/M) may then be determined by monitoring the apparent reactivity ($k_{apparent}$) of the complex with DMB using time resolved spectroscopy and the relationship, $K_M = K_{benzene} \times k_{apparent}(benzene)/k_{apparent}(M)$. By directly monitoring the formed complex, $Cl^{\bullet}$/M, the apparent reactivity reflects the extent of reversible dissociation§ to free $Cl^{\bullet}$, which then may be scavenged by DMB. The $Ph_2S/Cl^{\bullet}$ complex demonstrated little reactivity towards DMB, $k_{apparent} = 9.9 \times 10^4$ M^{-1} s^{-1}. This results in K_{eq} for formation of the adduct (K_{Ph_2S}) to be 3.2×10^{-5} M^{-1} according to Scheme 1 and the equation above with $K_{benzene}$ and $k_{apparent}$(benzene), see Scheme 2, being 200 M^{-1} and 1.6×10^8 M^{-1} s^{-1}, respectively. For comparison, K_{eq} for formation of the $Cl^{\bullet}$/pyridine σ-complex is 1.2×10^5 M^{-1} and $k_{apparent}$(pyridine) = 2.6×10^5 M^{-1} s^{-1}.[11] The $Me_2S/Cl^{\bullet}$ adduct was also generated by both pulse radiolysis and LFP of CCl_4 (λ_{max} = 365 nm, see graphical abstract). Similar to the $Ph_2S/Cl^{\bullet}$ results, $Me_2S/Cl^{\bullet}$ also demonstrted little reactivity toward DMB, $k_{apparent} = 1.8 \times 10^{-5}$ M^{-1} s^{-1}, yielding $K_{eq} = 1.73 \times 10^5$ M^{-1}, Scheme 3. This is true even at $[Me_2S] = 5 \times 10^{-4}$ M. It should also be noted that in aqueous solution K for neutral disssociation of $Me_2S\therefore Cl \rightarrow Me_2S + Cl^{\bullet}$ is $\ll 10^{-10}$ M^{-1}, whereas $K \approx 4$ M^{-1} for the ionic dissociation to $Me_2S^{\bullet+} + Cl^-$.[10] In CCl_4 there was no spectroscopic evidence of $Me_2S^{\bullet+}$



Scheme 1



Scheme 2



Scheme 3

formation, owing to the lack of solvating power of this solvent.

In summary, the values of K_{eq} for the Cl$^{\bullet}$ adducts with benzene, pyridine, Me_2S and Ph_2S in CCl_4 are: 200 M^{-1}, 120000 M^{-1}, 173000 M^{-1} and 320000 M^{-1}, respectively. Gratifyingly, these results are in accordance with recent theoretical determinations of the 0 *K* binding energies[5,6] of 11.4 kcal mol^{-1} for the Cl$^{\bullet}$/pyridine complex [Table 2 in ref 5; method used G2 (MP2, SVP)] and 12.32 kcal mol^{-1} for the $Me_2S^{\therefore}Cl$ complex [Table 5 in ref. 6; method used QCISD (T)/DZP + ZPC]. The results presented demonstrate that the bonding nature of the Ph_2S/Cl adduct is not consistent with a loosely bound π-molecular complex, and should be considered a three-electron bond $Ph_2S^{\therefore}Cl$ adduct, as is the $Me_2S^{\therefore}Cl$ complex. The methodology presented may prove useful in future characterizations of $R_2S^{\therefore}Cl$ complexes in interfacial and mixed-solvent systems.

The work described herein was supported in part by the Office of Basic Energy Sciences of the U.S. Department of Energy (Contribution No. NDRL-4075) and by Western Michigan University. I would also like to thank Professor Yi-Ping Liu for helpful discussions.

Notes and References

† Pulse radiolysis experiments were performed using a 10 ns pulse of 8 MeV electrons from the Notre Dame Radiation Laboratory linear accelerator (LINAC). The pulse radiolysis apparatus has been described elsewhere.[13]

‡ CCl_4 (Fisher Spectranalyzed) was distilled from K_2CO_3 (35 cm Vigreux column) prior to use.

§ This methodology is only valid in the absence of radical chain regeneration of Cl$^{\bullet}$ which is not possible in the present experiments.

A blue photoluminescent $[Zn(L)(CN)_2]$ (L = 2,2′-dipyridylamine) material with a supramolecular one-dimensional chain structure

Kin-Ying Ho, Wing-Yiu Yu, Kung-Kai Cheung and Chi-Ming Che*

Department of Chemistry, The University of Hong Kong, Pokfulam Road, Hong Kong

A novel blue luminescent $[Zn(L)(CN)_2]$ complex (L = 2,2′-dipyridylamine) is synthesized and characterized by an X-ray diffraction study; the crystal packing in the Zn complex reveals that the molecules self-assemble by intermolecular hydrogen bonds [N–H···N≡C distance = 2.965(7) Å] and face-to-face π–π aromatic stacking interactions to form two-dimensional sheets.

Cyanometallates are useful motifs for the construction of supramolecular structures having novel photoelectronic properties; the superstructure formation is usually achieved through bridging linear covalent M–C≡N–M bonding interactions.[1] There have been relatively few attempts to harness terminal cyanide ligand as a binding site for hydrogen bonding in the synthesis of supramolecular assemblies. As part of our endeavour to explore the potential application of some blue luminescent metal complexes for molecular light-emitting diode device fabrications,[2] we are interested in the coordination chemistry of zinc(II) cyanides,[3] the luminescence properties of which have been little studied. Herein is decribed a blue luminescent cyanozinc(II) complex with 2,2′-dipyridylamine ligand L, $[Zn(L)(CN)_2]$, and the solid state structure of which shows cooperative N–H···N≡C hydrogen bonding and π–π stacking interactions.

The zinc(II) complex was prepared by prolonged reflux of a methanolic suspension of $Zn(CN)_2$ with L.† Using hot methanol the product was isolated as pale yellow crystals suitable for an X-ray crystallographic study.‡ Fig. 1 depicts a perspective view with atom numbering of the molecule. The Zn atom adopts a distorted tetrahedral coordination geometry and the measured Zn–N(1)/(3) distances are 2.037(4) and 2.046(4) Å, and the Zn–C(1)/(2) distances are found to be 1.987(6) and 2.007(6) Å. The observed Zn–N distances are comparable to the corresponding bond distances [2.148(9) and 2.082(9) Å] found for a related

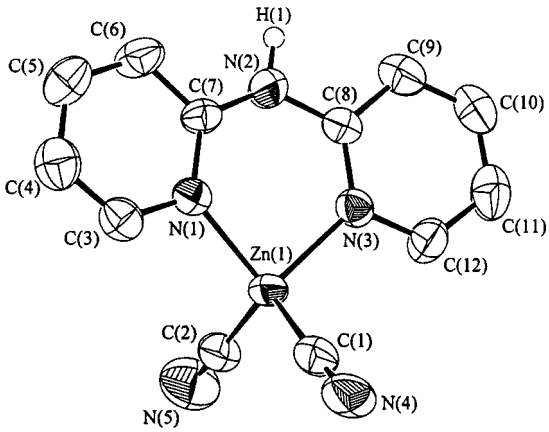

Fig. 1 Perspective view of $[Zn(L)(CN)_2]$ [50% thermal ellipsoids except for H(1)] and atom-numbering scheme. Significant bond distances (Å) and angles (°): Zn(1)–N(1) 2.037(4); Zn(1)–N(3) 2.046(4); Zn(1)–C(1) 1.987(6); Zn(1)–C(2) 2.007(6); N(2)–H(1) 0.91(6). N(1)–Zn(1)–N(3) 92.3(2); N(1)–Zn(1)–C(1) 116.3(2), N(1)–Zn(1)–C(2) 108.4(2); N(3)–Zn(1)–C(1) 108.4(2); N(3)–Zn(1)–C(2) 110.0(2); C(1)–Zn(1)–C(2) 118.3(2).

$[Zn(L)(dien)](NO_3)_2$ complex [dien = bis(2-aminoethyl)-amine].[4] The C(1)–Zn–C(2) bond angle is 108.3(2)°, whereas the N(1)–Zn–N(3) angle is 92.3(2)°.

As shown by the crystal packing (Fig. 2), the molecules are self-organized by extensive intermolecular hydrogen bonds between the amino and the cyano groups (N–H···N≡C) of the adjacent molecules, with obvious directionality and short intermolecular contact between successive nitrogen atoms [N···N distance = 2.965(7) Å]. The N(2)–H(1)···N(4) bond angle is 154(5)°, therefore a polymeric one-dimensional zigzag chain results. A related report by Cotton and co-workers[5] also revealed that the pseudo-tetrahedral $[Co(L)_2]$ molecules stack together to form a one-dimensional ribbon with molecules linked through intermolecular hydrogen bonding. In the present $[Zn(L)(CN)_2]$ complex face-to-face π–π stacking interactions between the aromatic rings of the 2,2′-dipyridylamine ligand are also evident, the interplanar separations are in the range 3.5–3.7 Å, and the glide-related complexes are linked in a head-to-head fashion to generate a supramolecular architecture of an infinite two-dimensional sheet. Inspection of the crystal packing shows that there are two kinds of two-dimensional sheets constituted by the same array of intermolecular forces but having the π–π stacking interactions aligning along different directions, hence a herringbone-type pattern is created.[6]

The spectroscopic and emission data of $[Zn(L)(CN)_2]$ complex are listed in Table 1. In MeOH, the absorption spectrum of the complex is dominated by intraligand π–π* transitions at 255 and 315 nm. In solution, the complex displays a high energy emission with λ_{max} = 359 nm and τ = 10 ns at 298 K. Because there is no significant shift in emission energy for the related $[Zn(L)X_2]$ (X = CN, OAc, Cl) complexes,† the emission is neither MLCT (metal-to-ligand charge transfer) nor LMCT (ligand-to-metal charge transfer) in nature. We tentatively assign it to the intraligand $^1(\pi–\pi^*)$ fluoresence since a similar emission with λ_{max} at 357 nm is also observed for the free ligand. Interestingly, in both solid state and in 77 K MeOH–EtOH glassy solution, the corresponding intraligand $^3(\pi–\pi^*)$

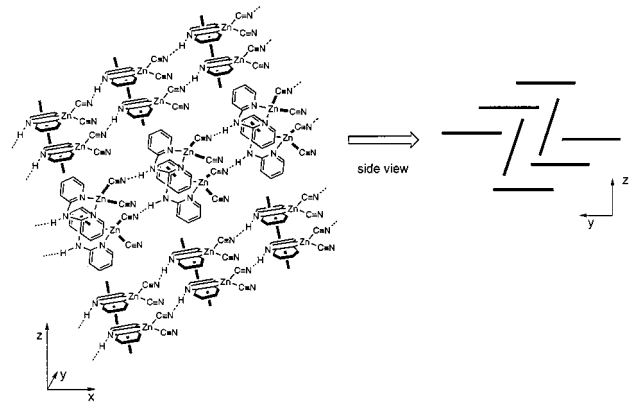

Fig. 2 Herringbone-type crystal packing pattern of $[Zn(L)(CN)_2]$ molecules. The molecules are self-assembled to form extended 2-D sheets by cooperative π–π stacking interactions and extensive intermolecular hydrogen (N–H···N≡C) bonds.

Table 1 Photophysical data for $[Zn(L)(CN)_2]$ and derivatives

Complex	UV–VIS λ/nm (ε/dm^3 mol^{-1} cm^{-1})[a]	Emission λ/nm		
		298 K[b]	77 K[c]	Solid state[d]
$[Zn(L)(CN)_2]$	257 (18000), 316 (16000)	359	351, 392	363, 418
$[Zn(L)(OAc)_2]$	257 (20000), 315 (18000)	359	349, 389	378
$[Zn(L)Cl_2]$	255 (18000), 315 (17000)	360	348, 390	378

[a] In MeOH at 298 K. [b] In degassed MeOH. [c] In MeOH–EtOH (1 : 2). [d] At 298 K.

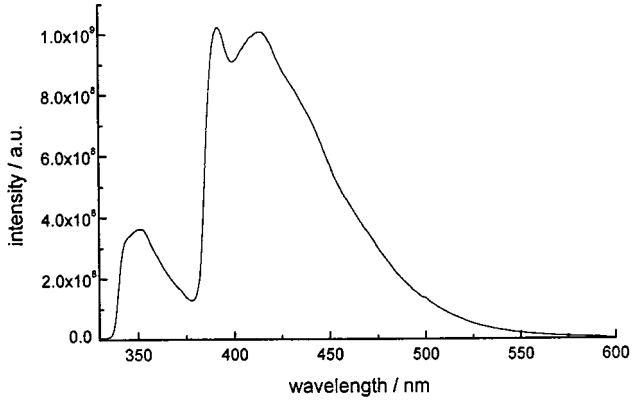

Fig. 3 Emission spectrum of $[Zn(L)(CN)_2]$ (excited at 315 nm) in MeOH–EtOH (1 : 2) glassy solution at 77 K.

phosphorescence has also been observed. As shown in Fig. 3, the lower energy $^3(\pi$–$\pi^*)$ emission at 392 nm (lifetime = 0.33 μs) shows a well resolved vibronic structure with a vibrational spacing of *ca.* 1350 cm^{-1} that is assigned to the skeletal stretching of the ligand.

The $[Zn(L)(CN)_2]$ complex shows an extended two-dimensional structure through cooperative hydrogen bonding and π–π stacking interactions. Its polymeric structure and the blue photoluminescence highlight the potential application of the zinc(II) cyanide complex as an advanced material for blue-light emitting diode devices.

Notes and References

† *Preparation* of $[Zn(L)(CN)_2]$. A methanolic solution (20 cm^3) of L (0.17 g, 1 mmol) was added to a refluxing suspension of $Zn(CN)_2$ (0.12 g, 1 mmol) in MeOH (30 cm^3). The mixture was refluxed overnight. After cooling to room temperature, the white solid was collected by filtration. The product complex was extracted from the white solid into boiling methanol, and pale yellow crystals were obtained on cooling of the hot methanolic extract (overall yield: 60%). FT-Raman: 2164, 2153, 1619, 1587 and 1436 cm^{-1}. ^{1}H NMR (270 MHz, CD_3OD, TMS): δ 10.11 (s, 1H), 8.20 (d, 2H, ^3J = 4.3 Hz), 781 (t, 2H, ^3J = 7.3 Hz), 7.56 (d, 2H, ^3J = 7.2 Hz), 7.02 (t, 2H, ^3J = 6.0). FAB-MS: *m*/*z* 289 $[M]^+$, 261 $[M - CN]^+$. Anal. Calc. for $C_{12}H_9N_5Zn$ (M_r = 288.62): C, 49.94; H, 3.14; N, 24.27. Found: C, 49.99; H, 3.02; N, 24.41%.

Preparation of $[Zn(L)(OAc)_2]$. A methanolic solution (20 cm^3) of L (0.17 g, 1 mmol) was added to a refluxing solution of $Zn(OAc)_2 \cdot 2H_2O$ (0.22 g, 1 mmol) in MeOH (30 cm^3). The mixture was refluxed overnight. After cooling to room temperature, the solvent was removed by rotary evaporation, and the white residue was recrystallized by slow diffusion of diethyl ether into methanolic solution to afford colorless crystals (overall yield: 85%). ^{1}H NMR (270 MHz, CD_3OD, TMS): δ 8.38 (dd, 2H, ^4J = 1.2 Hz, ^3J = 5.6 Hz), 7.93 (td, 2H, ^4J = 1.9 Hz, ^3J = 7.9 Hz), 7.20 (d, 2H, ^3J = 8.6 Hz), 7.16 (td, 2H, ^3J = 6.5, ^4J = 1.0 Hz). FAB-MS: *m*/*z*: 294 $[M - OAc]^+$. Anal. Calc. for $C_{14}H_{15}N_3O_4Zn$ (M_r = 354.67): C, 47.41; H, 4.26; N, 11.85. Found: C, 47.25; H, 4.21; N, 11.92%.

Preparation of $[Zn(L)Cl_2]$. A similar procedure as for $[Zn(L)(OAc)_2]$ was employed, except that hot DMF was used for recrystallization (overall yield: 80%). ^{1}H NMR (270 MHz, CD_3OD, TMS): δ 8.20 (d, 2H, ^3J = 2.6 Hz), 7.80 (m, 2H), 7.58 (d, 2H, ^3J = 8.4 Hz), 7.01 (t, 2H, ^3J = 6.3 Hz). FAB-MS: *m*/*z* = 270 $[M - Cl]^+$. Anal. Calc. for $C_{10}H_9Cl_2N_3Zn$ (M_r = 307.49): C, 39.06; H, 2.95; N, 13.67. Found: C, 38.93; H, 2.99; N, 13.75%.

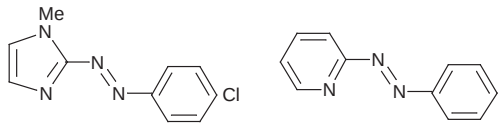
Synthesis and characterisation of a pair of azo anion radicals bonded to ruthenium(II)

Maya Shivakumar, Kausikisankar Pramanik, Prasanta Ghosh and Animesh Chakravorty*

Department of Inorganic Chemistry, Indian Association for the Cultivation of Science, Calcutta 700 032, India. E-mail: icac@iacs.ernet.in

The reactions of 1-methyl-2-(*p*-chlorophenylazo)imidazole (L^1) and 2-(phenylazo)pyridine (L^2) with [Ru(H)(X)(CO)(PPh_3)$_3$] (X = Cl, Br) have afforded the green paramagnetic (S = ½) and EPR-active ($g \approx 2.00$) title anion radical complexes [Ru($L^{1\cdot-}$)(Cl)(CO)(PPh_3)$_2$] **1 and [Ru($L^{2\cdot-}$)(Br)(CO)(PPh_3)$_2$] **2** in which the N–N bond lengths lie near 1.35 Å.**

Familiar systems with nitrogen–nitrogen single and double bonds are hydrazines and azobenzenes. One-electron reduction[1–3] of the azo group can lead to a bond order of 1.5 due to population of the azo π* orbital, but no such species have so far been isolated in pure form. Herein we describe the successful synthesis and structural characterisation of a pair of azo anion radicals bonded to bivalent ruthenium. The specific azo ligands used are the 2-(arylazo)heterocycles L^1 [3] and L^2 (general



L^1 L^2

abbreviation, L).[4,5] The corresponding radical anions will be represented as $L^{1\cdot-}$ and $L^{2\cdot-}$ respectively.

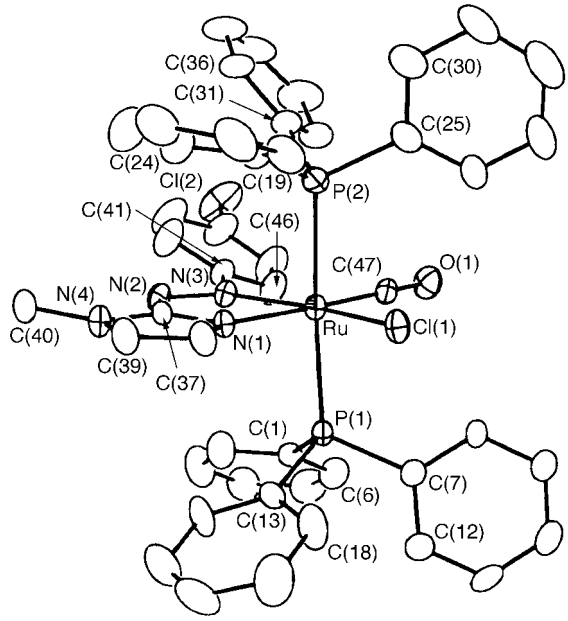


Fig. 1 ORTEP diagram of [Ru($L^{1\cdot-}$)(Cl)(CO)(PPh_3)$_2$] **1** (hydrogen atoms are omitted for clarity). Selected bond distances (Å) and angles (°): Ru–Cl(1) 2.416(2), Ru–P(1) 2.385(2), Ru–P(2) 2.393(2), Ru–N(1) 2.093(6), Ru–N(3) 2.107(6), Ru–C(47) 1.854(8), N(2)–N(3) 1.369(8), O(1)–C(47) 1.116(8), P(1)–Ru–P(2) 175.25(8), Cl(1)–Ru–N(3) 162.6(2), N(1)–Ru–C(47) 175.8(3), N(1)–Ru–N(3) 76.0(2), Ru–C(47)–O(1) 179.5(8).

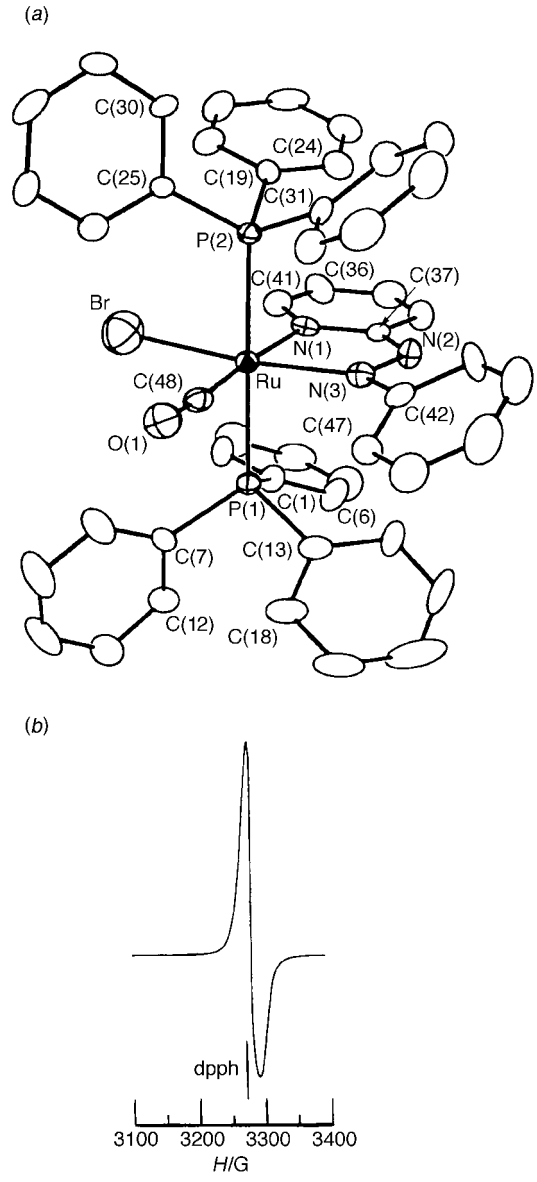

Fig. 2 (*a*) ORTEP diagram of [Ru($L^{2\cdot-}$)(Br)(CO)(PPh_3)$_2$] **2** (hydrogen atoms are omitted for clarity). Selected bond distances (Å) and angles (°): Ru–Br 2.521(3), Ru–P(1) 2.415(4), Ru–P(2) 2.399(4), Ru–N(1) 2.111(13), Ru–N(3) 2.069(13), Ru–C(48) 1.843(17), N(2)–N(3) 1.341(17), O(1)–C(48) 1.125(18), P(1)–Ru–P(2) 176.3(2), Br–Ru–N(3) 168.8(3), N(1)–Ru–C(48) 175.5(6), N(1)–Ru–N(3) 76.3(5), Ru–C(48)–O(1) 175.3(14). (*b*) Powder EPR spectrum of **2** in the X-band (9.11 GHz) at 298 K. Instrument settings: power, 28 dB; modulation, 100 kHz; sweep center, 3200 G; sweep width, 1000 G; sweep time 240 s.

Addition of [Ru(H)(Cl)(CO)(PPh_3)$_3$][6] (0.1 mmol) to a solution of L^1 (0.26 mmol) in dry benzene (10 ml) followed by heating

to reflux for 1 h and subsequent cooling afforded the deep green crystalline complex $[Ru(L^{1\cdot-})(Cl)(CO)(PPh_3)_2]$ **1** in 85% yield (all operations were carried out in an oxygen free environment).† A similar reaction of L^2 with $[Ru(H)(Br)(CO)(PPh_3)_3]$ [6] in dry heptane furnished $[Ru(L^{2\cdot-})(Br)(CO)(PPh_3)_2]$ **2**.† The key to our success is the use of hydridic starting materials which provide the reducing equivalent that is necessary for anion radical generation, eqn. (1), *via* Ru–H bond cleavage.

$$[Ru(H)(X)(CO)(PPh_3)_3] + L \rightarrow [Ru(L^{\cdot-})(X)(CO)(PPh_3)_2] + \tfrac{1}{2} H_2 + PPh_3 \quad (1)$$

The solid complexes which are quite stable in dry air behave as one-electron paramagnets (μ_{eff}: **1**, 1.80 μ_B and **2**, 1.78 μ_B) and display a single-line strong powder EPR signal (298 K) with g = 2.000 for **1** and g = 1.999 for **2**, the respective peak-to-peak line-widths being 9 G and 18 G. This is consistent with the azo anion radical description. The expected small ^{14}N hyperfine splitting is not resolved probably due to dominant anisotropic contributions.[2,7]

The X-ray structures‡ of **1** and **2** are shown in Fig. 1 and 2; Fig. 2 also displays the EPR spectrum of **2**. In each case the L ligand forms a planar five-membered chelate ring to which the *trans*-$Ru^{II}(PPh_3)_2$ fragment lies nearly orthogonally. The halide and carbon monoxide ligands are positioned *trans* to the azo and heterocyclic nitrogen atoms respectively. The N–N distances, 1.369(8) Å in **1** and 1.341(17) Å in **2**, are intermediate between those of double (≈1.25 Å[8]) and single (≈1.45 Å[9]) bonds as expected for the radical anion description.

Aerial oxidation of **1** and **2** in polar solvents gives $[Ru(L^1)(Cl)(CO)(PPh_3)_2]^+$ $\mathbf{1}^+$ and $[Ru(L^2)(Br)(CO)(PPh_3)_2]^+$ $\mathbf{2}^+$ which have been isolated as diamagnetic PF_6^- salts.† In dichloromethane solutions the $E_{\frac{1}{2}}$ values of the $\mathbf{1}^+/\mathbf{1}$ and $\mathbf{2}^+/\mathbf{2}$ couples are respectively −0.47 V and −0.39 V *vs.* SCE. Reversible coulometric recycling between **1** and $\mathbf{1}^+$ and between **2** and $\mathbf{2}^+$ can be repeatedly performed in an inert atmosphere. A wider application of our synthetic procedure for anion radical generation is under scrutiny.

Selective synthesis of MeCHO by C_2H_4–(O_2+NO) cell system

I. Yamanaka,† A. Nishi and K. Otsuka

Department of Chemical Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152-8552, Japan

The formation rate of MeCHO and current for the C_2H_4 | Pd | H_3PO_4 | graphite | O_2 + NO (NO_2) cell are ten times higher than those for the C_2H_4 | Pd | H_3PO_4 | Pt | O_2 cell.

The selective synthesis of MeCHO has been demonstrated by a C_2H_4–O_2 cell system that was assembled as [C_2H_4, H_2O(g) | Pd-black/graphite/PTFE anode | aq. H_3PO_4 in silica wool | Pt-black/graphite/PTFE cathode | O_2].[1] Oxidation of C_2H_4 to MeCHO at the anode [eqn. (1)] and reduction of O_2 to H_2O at the cathode [eqn. (2)] proceeded respectively.

$$C_2H_4 + H_2O \rightarrow MeCHO + 2\,H^+ + 2e^- \quad (1)$$

$$1/2\,O_2 + 2\,H^+ + 2\,e^- \rightarrow H_2O \quad (2)$$

The cell system has several advantages compared with the current Wacker process using a mixture of C_2H_4 and O_2 catalysed by $PdCl_2$ and $CuCl_2$ in HCl solution.[2] For example, (i) the cell system is chloride free, and (ii) no separation processes for products and catalysts are required. Recent attractive heterogeneous catalytic systems have the same advantages.[3,4] The cell system has additional advantages, (iii) the reaction rate and the current are easily controlled by variable resistance, and (iv) the danger of explosion is reduced because C_2H_4 and O_2 are separated by the membrane.[1,5–7] However, the rate of MeCHO formation attained in this C_2H_4–O_2 cell system (1 ~ 2 TON per Pd atom in 1 h)[1] has to be improved dramatically. The TON obtained in the current Wacker process is greater than 10.[2] Therefore, the purpose of this work is to demonstrate the enhancement of the formation rate of MeCHO by one order of magnitude for the C_2H_4–O_2 cell system.

First, the potentials at the anode and the cathode for the C_2H_4–O_2 cell were measured at 353 K. The details of electrochemical measurement have been described elsewhere.[8] The potentials at the anode and the cathode were +0.26 V (*vs.* Ag | AgCl) and +0.86 V respectively under open circuit conditions: the electromotive force (EMF) was 0.60 V. The potentials were changed to +0.65 and +0.67 V under short circuit conditions. The difference in the anode and the cathode potentials under short circuit conditions is due to an Ohm resistance. Thus, the over-potential at the anode was larger than that at the cathode. However, it should be noted that a considerable over-potential existed at the cathode, 32% of the EMF, for the electrochemical reduction of O_2.

If the over-potential at the cathode could be decreased by some means, an additional electrochemical potential could be applied at the anode which should increase the formation rate of MeCHO and the current. On the basis of this concept, many trials were performed for improving the rate of MeCHO formation. In conclusion, it is found that the addition of nitric oxide in a stream of O_2 dramatically enhances the current and the formation rate of MeCHO.

Fig. 1 shows a time profile for the formations of MeCHO and CO_2 [Fig. 1(*a*)] and for the current [Fig. 1(*b*)] with and without addition of NO into an O_2 stream. The apparent surface areas of the electrodes were 2 cm^2. The content of Pd in the anode was 120 μmol. When the circuit was shorted, a current of 3 mA cm^{-2} flowed and MeCHO was selectively produced (> 97%). When NO was added to the stream of O_2, a drastic increase in the current (35 mA cm^{-2}) and the formation rate of MeCHO were observed. When the NO addition was stopped, the current and the formation rate of MeCHO immediately decreased. Then, the current and the formation rate of MeCHO increased again with the addition of NO. It is clear that the addition of NO to the O_2 stream reversibly accelerates both the current and the formation rate of MeCHO. Although the formation rate of CO_2 was also increased by the addition of NO, the selectivity to MeCHO was still quite high (> 95%).

The cathode and anode potentials for the C_2H_4–(O_2+NO) cell system were measured. The cathode potential under open circuit conditions is 1.0 V, which was considerably higher than the value (0.86 V) for the C_2H_4–O_2 cell. A separate experiment showed that the cathode potential for the C_2H_4–NO cell was 0.85 V. When NO was added to the O_2 stream in the cathode compartment, formation of a dark brown gas was observed, indicating the formation of NO_2 [eqn. (3)]. The increase in the cathode potential by the addition of NO and O_2 must be due to the formation of NO_2, which could be a stronger oxidant than O_2 or NO.

$$NO + 1/2\,O_2 \rightarrow NO_2 \quad (3)$$

The anode potential under open circuit conditions is 0.26 V. The EMF for the C_2H_4–(O_2+NO) cell is 0.74 V, which is larger than the value (0.60 V) for the C_2H_4–O_2 cell. When the circuit was shorted, the potentials of the anode and the cathode were changing to 0.88 and 0.93 V, respectively. The over-potentials at the anode and cathode were 0.62 and 0.07 V. The over-potential of 0.07 V at the cathode was smaller than that of 0.19 V for the C_2H_4–O_2 cell, although the current was one order of

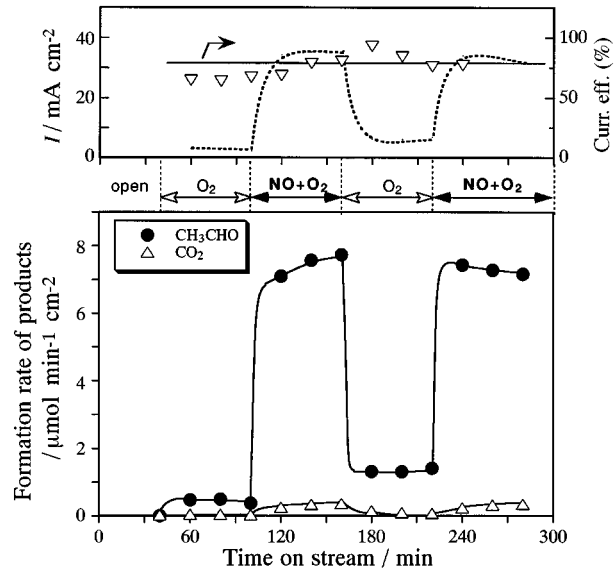

Fig. 1 Effects of NO addition into the O_2 stream at the cathode on the formation of MeCHO with the C_2H_4–O_2 cell: (●) MeCHO and (△) CO_2. C_2H_4 (39 kPa), H_2O (13 kPa), anode | aq. H_3PO_4 in silica wool | cathode, O_2 (51 kPa), He (50 kPa) or NO (50 kPa). T = 353 K. Anode: Pd-black/CF/PTFE, total flow rate = 32 ml min^{-1}. Cathode: Pt-black/graphite/PTFE, total flow rate = 32 ml min^{-1}.

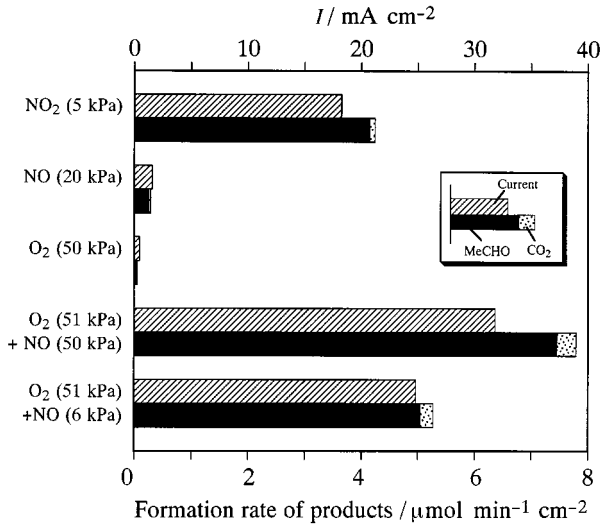

Fig. 2 Effects of some oxidants of the C_2H_4–oxidant cell with graphite/PTFE cathode on the Wacker oxidation. C_2H_4 (39 kPa), H_2O (13 kPa), anode | aq. H_3PO_4 in silica wool | cathode, oxidants. Oxidants: NO_2 (5 kPa), NO (20 kPa), O_2 (50 kPa), NO (50 kPa) + O_2 (51 kPa), and NO (6 kPa) + O_2 (51 kPa). T = 353 K.

magnitude larger than that for the C_2H_4–O_2 cell. This fact suggests that the electrochemical reduction of NO_2 is very easy compared with that of O_2.

The cathode used so far in this work was Pt-black/graphite/PTFE. If the reduction of NO_2 occurs quite easily, we may exclude Pt-black from the cathode. In fact, a cathode without Pt-black (graphite/PTFE cathode) showed very good electrocatalytic performance; a high current of 40 mA cm^{-2} and selective MeCHO formation (3% yield and 8 TON in 1 h). The optimum reaction conditions were studied for the C_2H_4–(O_2+NO) cell using the graphite/PTFE cathode. Then, a maximum yield of 15% and 31 TON in 1 h were obtained, which is fairly good productivity for MeCHO formation.

The results for the oxidation of C_2H_4 using different oxidants are compared in Fig. 2. The cathode in these experiments was graphite/PTFE. A current of 18.5 mA cm^{-2} flowed and MeCHO was selectively produced with the C_2H_4–NO_2 cell, although the pressure of NO_2 was only 5 kPa. A mixture of O_2 and NO was an excellent oxidant but O_2 or NO alone were not effective oxidant at the graphite cathode. When P_{NO} was reduced from 50 to 6 kPa for the C_2H_4–(O_2+NO) cell, the formation rate of MeCHO and the current were slightly decreased. The influences of P_{NO} on the formation rate and the current were small. When NO_2 (5 kPa) was introduced into the anode compartment, catalytic oxidation of C_2H_4 to CO_2 (1.2 μmol min^{-1} cm^{-2}) and MeCHO (0.4 μmol min^{-1} cm^{-2}) proceeded under open circuit conditions. The selective synthesis of MeCHO from C_2H_4 with NO_2 catalysed by the Pd anode does not proceeed. No enhancing effects due to the addition of NO_2 into the anode compartment on the formation of MeCHO and the current were observed under short circuit conditions. These facts confirm that NO_2 produced from a mixture of O_2 and NO works as a strong oxidant at the cathode.

The products for the reduction of NO_2 and NO at the cathode were trace formation of N_2 and N_2O in the gas phase and a small amount of NH_2OH or NH_3 (< 4% current efficiency) in the diaphragm. There are no other products containing nitrogen. These observations suggest that NO_2 is being reduced to NO and H_2O [eqn. (4)].

$$NO_2 + 2\ H^+ + 2\ e^- \rightarrow NO + H_2O \qquad (4)$$

The NO produced here would regenerate NO_2 according to [eqn. (3)]. Thus, NO works as a mediator (or catalyst) for the electrochemical reduction of O_2.

Simultaneous determination of dopamine, uric acid and ascorbic acid at an ultrathin film modified gold electrode

Zhiqiang Gao*† and Hai Huang

Department of Chemistry, National University of Singapore, Kent Ridge, Singapore 119260, Republic of Singapore

Well-separated square wave voltammetric peaks for uric acid, dopamine and ascorbic acid were observed at an ultrathin polypyrrole–tetradecyl sulfate film modified gold electrode, which can be used for simultaneous determination of these species in the range of 1 to 500 μM with good reproducibility.

Recently there has been a considerable effort in the development of voltammetric methods for the determination of uric acid (UA), dopamine (DA) and ascorbic acid (AA) in biological samples. It is generally believed that direct redox reactions of these species at bare electrodes are irreversible and therefore require high overpotentials.[1] Moreover the direct redox reactions of these species at the bare electrodes take place at very similar potentials and often suffer from a pronounced fouling effect, which results in rather poor selectivity and reproducibility. The ability to determine UA, DA and AA selectively has been a major goal of electroanalytical research.[2] Since the basal concentrations of UA, DA and AA in biological samples vary from species to species in an extremely wide range, from 1.0×10^{-7} to 1.0×10^{-3} M,[3] both sensitivity and selectivity are of equal importance in developing voltammetric procedures. Various approaches, mainly based on ion-exchange membrane coated electrodes, have been attempted to solve the UA, DA and AA determination problems.[4–8] Ion exchange membranes of both anionic and cationic nature have been developed to electrostatically accumulate/trap oppositely charged analyte molecules. Among them are Nafion,[5] poly(ester sulfonic acid),[6] poly(4-vinylpyridine)[7] *etc*. However, the drawbacks of these ion exchange membrane modified electrodes are their memory effect, non-uniform thickness and poor reproducibility arising from the solvent evaporation method used in the film preparation. Moreover, some of the valuable information is lost when working with these ion exchange membrane modified electrodes because the membranes only allow oppositely charged species access to the electrode.

The electropolymerization of conducting polymers generally results in polymer films which are uniform and strongly adherent to the electrode surface. In addition the polymer films can be deposited onto a small area with a high degree of geometrical conformity and controllable thickness; this aspect is particularly important in the manufacture of microsensors. In short, fabrication of conducting polymer films is flexible and easily controlled, hence provides an attractive means of overcoming the problems caused by the solvent evaporation method.

In this work, the feasibility of modifying gold electrodes in an attempt to develop a sensitive voltammetric procedure for UA, DA and AA was studied. A remarkable improvement in square wave voltammetric responses of UA, DA and AA (voltammetric peaks were separated by about 150 mV from each other) and a noticeable enhancement of voltammetric sensitivity were observed at the polypyrrole–tetradecyl sulfate (PPy–TDS) film modified gold electrode. All of these were brought about by the combined catalytic function of the PPy–TDS film and the minimized background current in square wave voltammetry.

The PPy–TDS film was deposited onto the gold electrode galvanostatically in a deaerated solution saturated with pyrrole and sodium tetradecyl sulfate. The film thickness was controlled in the range of 20–25 nm by measuring the charge passed during electrodeposition. The electrode was then rinsed thoroughly with water and conditioned by cycling the potential for 2 min between –0.20 and 0.50 V at a scan rate of 50 mV s^{-1} (*vs.* Ag/AgCl) in a 0.10 M pH 7.0 phosphate buffer solution. The electrode was ready after a final rinse with water. Under optimum experimental conditions for the deposition of PPy–TDS film, the gold electrode was perfectly covered with an ultrathin PPy–TDS film, confirmed by surface coverage measurement using the copper under potential deposition method.[9]

Fig. 1 shows square wave voltammograms of 0.50 mM DA, UA and AA at both bare gold and the PPy–TDS film coated gold electrodes. As can be seen in Fig. 1(*a*), a rather broad oxidation peak appeared at about 0.32V at the bare gold electrode and the peak potentials for UA, DA and AA were indistinguishable. It is impossible to deduce any conclusive information from the broad voltammetric peak. Depending on the history of the electrode surface and the concentration ratios of UA, DA and AA, the peak potential could vary from 0.30 to 0.5 V. As shown in Fig. 1(*b*), the presence of the PPy–TDS film at the electrode surface resolved the mixed voltammetric response into three well-defined voltammetric peaks at potentials of 0.32, 0.17 and 0.015 V, corresponding to the oxidations of UA, DA and AA, respectively. Furthermore, as indicated in Fig. 1(*b*), substantial increases in peak currents were observed due to the improvements in the reversibilities of the electron transfer processes.[10] This suggests an efficient catalytic reaction between the modified electrode and the three species in solution. When cyclic voltammetry was conducted with the modified gold electrode at different scan rates, good linearities between the peak currents and the square roots of the scan rates for UA, DA and AA were obtained, indicating diffusion-controlled processes in solution. Rotating disk electrode experiments also reached the same conclusions as those obtained by voltammetry for all modified electrodes. No

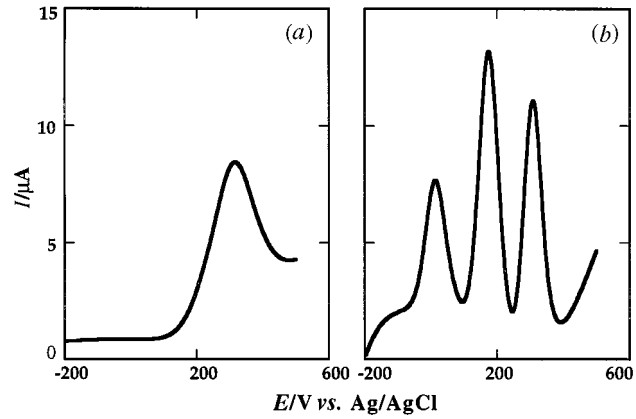

Fig. 1 Square wave voltammograms of 0.50 mM UA, DA and AA at (*a*) a bare gold and (b) a PPy–TDS film modified gold electrode (0.10 M pH 7.0 phosphate buffer, initial potential = −0.2 V, SW amplitude = 25 mV, SW frequency = 15 Hz, SW step = 2 mV)

obvious changes in the peak currents were observed when increasing the film thickness from 20 nm to 1.0 μm, suggesting that the PPy–TDS film has genuine catalytic function towards the oxidation of UA, DA and AA, and that the electron transfer processes within the film and at the film–solution interface are sufficiently fast that they do not affect the catalytic currents of UA, DA and AA. However, the charging current increased with increasing film thickness, thus preventing us from determining UA, DA and AA at micromolar levels. A similar catalytic effect was also observed at PPy films doped with other anions, but large charging currents were observed at PPy films doped with small anions such as chloride, nitrate and sulfate.[11] For practical purpose, in order to minimize the charging current, the PPy–TDS film should be kept as thin as possible, as long as the electrode is completely covered by the PPy–TDS film. Moreover, there is no memory effect at all since analytes cannot penetrate into the highly compact and conductive PPy–TDS film and the electron exchange process takes places at the PPy–TDS film–solution interface.

The overall facility of the modified electrode for simultaneous determinations of UA, DA and AA was demonstrated in solutions with simultaneous changes of concentrations. The peak currents obtained increased linearly with increasing UA, DA and AA concentrations in the range of 1.0 to 500 μM with a correlation coefficient of 0.997–0.998. The detection limits (signal-to-noise ratio = 3.0) for UA, DA and AA were found to be 0.4, 0.4 and 0.6 μM respectively. The modified electrode showed excellent anti-fouling properties. A series of 50 repetitive voltammetric determinations of sample solutions containing 25 μM UA, DA and AA were used to evaluate the stability of the modified electrode. The coefficient of variation was found to be 5.5%, indicating that the modified electrode is not subject to surface fouling by the oxidation products, which are notorious for their surface fouling effects at the bare electrodes.[12] High stability was also observed in phosphate buffer solutions containing high concentrations of chloride. For example, no obvious deterioration was observed after 50 repetitive voltammetric runs in a 0.10 M pH 7.0 phosphate buffer solution containing 0.15 M NaCl. The advantages accruing from the catalytic function of the film improved the selectivity of the voltammetric measurement of UA, DA or AA in the presence of the other two. As demonstrated in Table 1, the peak current obtained for a 25 μM of UA, DA or AA sample solution was practically constant in the presence of a wide range of concentrations of the other two species. In addition the slopes of the calibration curves were almost the same as those obtained with simultaneously changing concentrations of UA, DA and AA.

Table 1 Square wave voltammetric data (SW amplitude = 25 mV, SW frequency = 15 Hz, SW step = 2 mV) for 25 μM UA, DA and AA in mixed solutions at the PPy–TDS film modified gold electrode

AA		DA		UA	
DA + UA/ μM	ip_{AA}/μA	UA + AA/ μM	ip_{DA}/μA	DA + AA/ μM	ip_{UA}/ μA
0.0 + 0.0	0.250	0.0 + 0.0	0.600	0.0 + 0.0	0.510
10 + 10	0.247	10 + 10	0.590	10 + 10	0.512
50 + 50	0.248	50 + 50	0.608	50 + 50	0.505
200 + 200	0.247	200 + 200	0.575	200 + 200	0.498
500 + 500	0.245	500 + 500	0.580	500 + 500	0.490
1000 + 500	0.225	500 + 1000	0.535	1000 + 1000	0.445

In conclusion, we have demonstrated the possibility of using the PPy–TDS film modified electrode for the simultaneous determination of UA, DA and AA. The modified electrode showed excellent sensitivity, selectivity and anti-fouling properties. The high selectivity was proved to be mainly attributed to the catalytic function of the PPy–TDS film.

Deep cavity [CpFe(arene)]$^+$ derivatized cyclotriveratrylenes as anion hosts

K. Travis Holman,[a] G. William Orr,[a] Jonathan W. Steed[b] and Jerry L. Atwood*[a]

Even in the absence of hydrogen bonding functionality, [CpFe(arene)]$^+$ derivatized cyclotriveratrylenes 5 will bind anionic substrates (*i.e.* [PF_6]$^-$, halides) deep within their preorganized molecular cavities. The crystal structure of 5b[PF_6]$_3$·($CH_3CH_2OCH_2CH_3$)$_{1.5}$·(H_2O) demonstrates the [5b⊂(PF_6)]$^{2+}$ complex and solution halide binding is monitored by ^{1}H NMR spectroscopy.

The development of receptor molecules for the specific complexation and/or detection of anions has over the years proven to be a formidable task. In consequence, a rather large and diverse array of supramolecular anion hosts has appeared.[1] Currently, work in our group is aimed at designing anion hosts by arranging positively charged organometallic moieties around the bowl shaped cavities of polyaromatic macrocycles such as calix[*n*]arenes and cyclotriveratrylene (CTV).[2] Similar organometallic anion receptors, including an amide functionalized [CpFe(arene)]$^+$ host,[3c] have been used extensively by Beer *et al.* for the sensing of anionic species with remarkable selectivity, although these hosts typically couple the function of charge pairing interactions with hydrogen bonding residues.[3] We have found that the tetrametallated calixarene [{(*p*-cymene)Ru}$_4$(calix[4]arene − 2H)]$^{6+}$ **1**, the dimetallated CTV [{(*p*-cymene)Ru}$_2$CTV]$^{4+}$ **2**, and related derivatives can function as anion receptors, despite the absence of hydrogen bonding functionality. The solution anion binding properties of hosts such as **1** and **2**, however, are typically complicated by the ability of the host to bind anions at sites exterior to the host cavity, as well as within.[2] We herein report new deep-cavity [CpFe(arene)]$^+$-based anion hosts whose upper rim charge preorganization allows binding of anions exclusively within the host cavity, and without the use of hydrogen bonding residues.

Racemic cyclotriveratrylene-based hosts **5** were synthesized as their [PF_6]$^-$ salts in good yield (75–85%) by S_NAr substitution of the respective [CpFe(chloroarene)][PF_6]**3a–c** complex with *rac*-cyclotriguaiacylene (CTG)[4] **4** in DMF containing excess K_2CO_3 (Scheme 1).[5] Neutralization of the reaction mixture with 2 M HCl(aq.) followed by addition of NH_4PF_6(aq.) and precipitation with water led to the products, which were further purified by passing through a short column of neutral alumina with acetone and reprecipitating with diethyl ether.

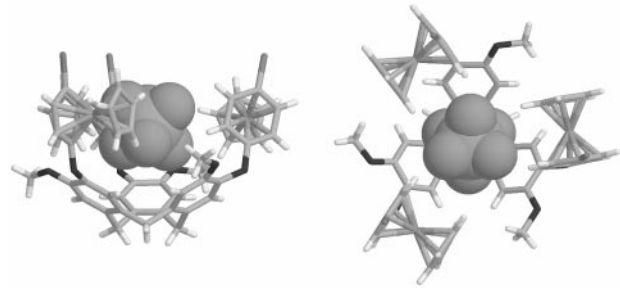

Fig. 1 X-Ray crystal structure of **5b**[PF_6]$_3$·($CH_3CH_2OCH_2CH_3$)$_{1.5}$·(H_2O)† depicting side and top views of [**5b**⊂(PF_6)]$^{2+}$ (see http://www.rsc.org/suppdata/cc/1998/2109 for full colour version of this figure)

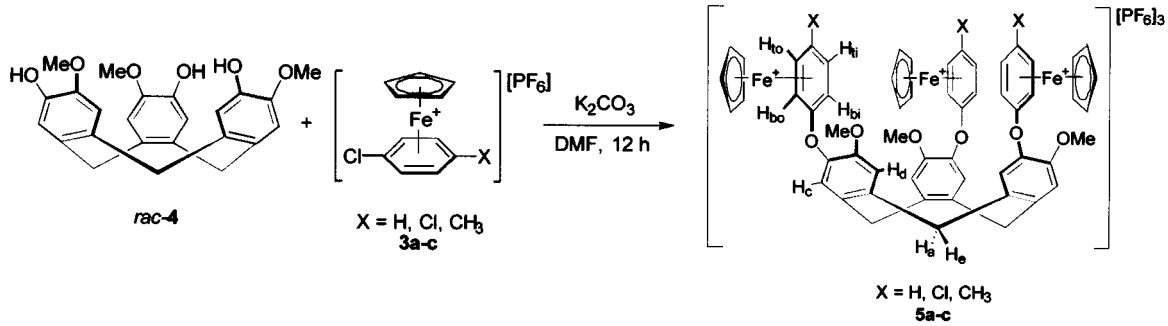
The crystal structure of **5b** [PF_6]$_3$·($CH_3CH_2OCH_2CH_3$)$_{1.5}$·(H_2O)† demonstrates an approximate C_3 symmetric host conformation, with all of the [CpFe(arene)]$^+$ substituents directed up from the rim of the CTG moiety, and exemplifies the ability of these new hosts to complex large anions deep within their cavities (Fig. 1). One [PF_6]$^-$ ion is located central to the host cavity with its three-fold symmetry axis matching that of the pseudo three-fold axis of the host cation. The depth of cavity penetration is highlighted by the fact that the phosphorus atom lies approximately 0.6 Å below the plane defined by the iron atoms. Short P···Fe distances of 5.16, 5.14, and 5.08 Å to the three iron atoms of the host are representative of significant charge pairing interactions between the included [PF_6]$^-$ anion and all three metal centers of the host, whereas the other two [PF_6]$^-$ anions each only exhibit similar close contacts to one iron atom at 5.09 and 5.12 Å respectively.

The solution anion binding properties of hosts **5** become evident upon examination of the ^{1}H NMR spectrum of [**5b**][PF_6]$_3$. In NO_2CD_3 the *para* substituted aromatic rings of the upper rim [CpFe(arene)]$^+$ moieties appear as a typical AB pattern, indicative of fast rotation of this group on the NMR timescale. Addition of [NBu_4]Br results in the concomitant splitting of this AB pattern into two separate patterns as the rotation of the [CpFe(arene)]$^+$ moieties is slowed as a consequence of bromide binding. Thus, separate signals are observed for sets of protons on the inside and outside of the molecular cavity of **5b**. In acetone-d_6,‡ **5b** displays inhibited [CpFe(arene)]$^+$ rotation even in the absence of bromide,



Scheme 1 Synthesis of deep cavity [CpFe(arene)]$^+$-based hosts **5**

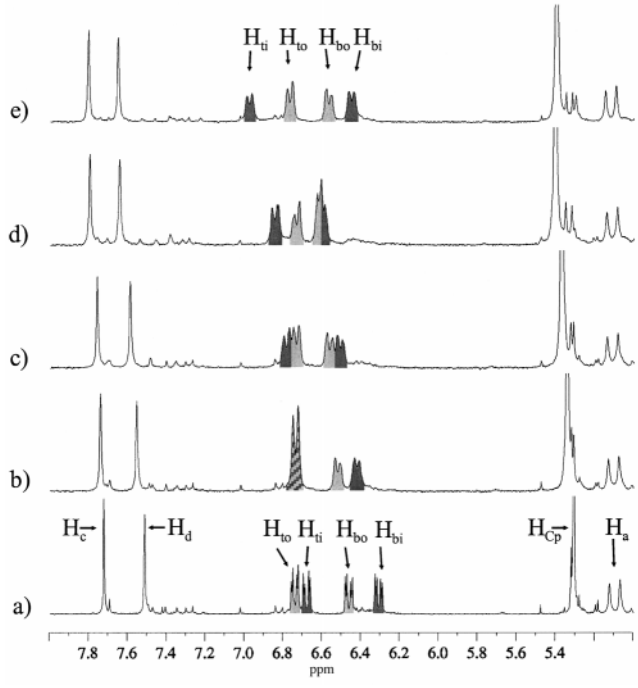


Fig. 2. ^{1}H NMR spectrum of **5b**$[PF_6]_3$ (acetone-d_6, 2.5 mM) with: (a) 0; (b) 0.35; (c) 0.60; (d) 1.00 equivalent of added NBu_4Br; (e) 1.00 equivalent of added NBu_4Cl

probably indicating binding of the $[PF_6]^-$ anion in a fashion similar to that observed in the crystal structure. A ^{1}H–^{1}H NOESY experiment allows assignment of the four unique protons according to Scheme 1 (*e.g.* $H_{top,inside} = H_{ti}$). Although, from this experiment, it is not possible to determine which set of top ($H_{t\_}$) and bottom ($H_{b\_}$) protons (dark or light shaded) correspond to the inside ($H_{\_i}$) of the cavity and which correspond to the outside ($H_{\_o}$), ^{1}H NMR titration experiments with $[NBu_4]Br$ make this apparent. Fig. 2 shows that as up to one equivalent of bromide is added, the chemical shifts of one top/bottom set (dark shaded) of protons are more dramatically affected than the other ($\Delta\delta_{max}$ = 0.17, 0.29 ppm for H_{ti} and H_{bi}). This behavior is indicative of the difference in $[PF_6]^-$ and bromide binding and these protons are thus assigned as those corresponding to the inside of the molecular cavity (H_{ti} and H_{bi}). Similar effects are observed with the addition of NBu_4Cl ($\Delta\delta_{max}$ = 0.30, 0.14 ppm for H_{ti} and H_{bi}) although the magnitude of the chemical shift change is larger for H_{ti} than H_{bi}. Conversely, addition of iodide affects H_{bi} more than H_{ti} and also more than the addition of bromide ($\Delta\delta_{max} \geqslant 0.07$, 0.35 ppm for H_{ti} and H_{bi}). No changes in chemical shifts are observed with the addition of $[NBu_4][PF_6]$.

In all instances precipitation of **5b**$[X]_3$ onsets when any amount greater than one equivalent of halide is added and association constants could not be determined due to these constraints. This in itself is a significant feature of hosts **5**, however, since typical non-preorganized $[CpFe(arene)]^+$ cations are acetone soluble and display essentially no ^{1}H chemical shift changes even in the presence of a large excess of halide. Furthermore, the near linear dependence of the chemical shifts of $H_{\_i}$ on the amount of added halide suggests large association constants and extremely efficient complexation of halides (*vs.* $[PF_6]^-$) by the host in this solvent. That precipitation onsets when more than one equivalent of halide is present is indicative of a soluble $[\mathbf{5b}\subset X]^{2+}$ (X = Cl^-, Br^-, I^-) species which will precipitate in the presence of significant concentrations of unbound halide. It is difficult to interpret the differences in chemical shift behavior of H_{ti} and H_{bi} with the different halides but it is likely an artifact of the relative differences in host conformations of $[\mathbf{5b}\subset(PF_6)]^{2+}$ and the $[\mathbf{5b}\subset X]^{2+}$ species. On the basis of these data, the relative preference of **5b** for the different sized halides cannot be definitively established, but the overall greater changes in chemical shift for iodide complexation may suggest a preference for the larger halide.

The new anion hosts reported represent a new class of anion receptor molecules whose binding properties are a direct consequence of only appropriately arranged sites of positive charge in the molecule. **5a**–**c** have distinct advantages over molecules such as **1** and **2** in that they do not possess significant binding sites exterior to the molecular cavity. We anticipate that the reactive chlorine substituents at the upper rim of **5b** will allow extension of the host cavity. Moreover, we are currently investigating the distinct possibility of synthesizing new metallated cryptophane[6] host molecules by capping off **5b** with another cyclotriguaiacylene moiety. Finally, the chiral nature of **4**, which can be resolved into its two optically active forms,[4] may provide a unique opportunity to investigate enantioselective binding of anionic species using chiral hosts similar to **5**.

We are grateful to the U.S. National Science Foundation for support and NATO for the award of a Collaborative Research Grant (ref. CRG 960320).

Large interlayer repeat distances observed for montmorillonites treated by mixed Al–Fe and Fe pillaring solutions

T. Mandalia, M. Crespin, D. Messad and F. Bergaya*

CRMD-CNRS, 1b Rue de la Férollerie, 45 071 Orléans Cedex 2, France. E-mail: f.bergaya@cnrs-orleans.fr

Raw montmorillonites treated with mixed Al–Fe pillaring solutions, with Fe/(Al + Fe) molar ratio between 0.1 and 1, and heated at 300 °C lead to large *d*-spacings according to XRD which increase from 52 Å for the sample with the lowest iron content to 76 Å for the pure Fe-treated clay sample.

Pillared clay minerals (PILCs) are usually obtained by intercalation of large inorganic polymeric cations which exchange the compensating cations from the clay, then dehydration and dehydroxylation occur upon calcination to give metal oxide clusters which act as pillars. These pillars separate adjacent silicate layers which then increases the interlayer distance and creates a permanent porosity between them.[1]

The synthesis of pillared clays has been investigated extensively in the past two decades as a function of the nature of the clays, the nature of the pillars and the conditions of pillaring. Usually, polyoxo-cations of Al, Zr, Ti, Fe, *etc*. are incorporated as pillars. Many reviews have been published.[2,3] The synthesis of pillared clays from mixed pillaring species is less common and the formation of truly mixed pillars is not easy to confirm when two cationic species are simultaneously intercalated.[4]

In most of the pillared clays reported to date the free height is comparable to the van der Waals thickness of the host layers. The term 'supergallery' has been used previously to describe some pillared clays having high basal spacing and where the thickness of the layer ($\approx$10 Å) is smaller than the free interlamellar heights. For example, iron-pillared clays are obtained with basal spacing of *ca.* 23–27 Å[5] and free heights of *ca.* 13–17 Å. In an international patent, McCauley claimed larger basal spacings (>40 Å) of pillared clays obtained by incorporation of various rare earth metals in the trivalent state with aluminium polycations in the clay layers.[6] However claims for gallery heights have never exceeded 40 Å.

In the present work, addition of Al and Fe pillaring solutions, with Fe/(Al + Fe) molar ratio of 0–1 leads to a series of modified Al–Fe-clays with very high distances according to XRD. The products were obtained without incorporation of any non-ionic surfactant or other organic polymeric compounds. The nature of the iron pillaring oligomers is still not well known. In addition, methods for preparing thermally stable Fe-PILCs have not been established.

To study the diffraction patterns of the materials having peaks at very low 2θ angle, proper alignment and calibration of the diffraction instrument is necessary to obtain a good accuracy in the diffraction analysis. To verify that the following obtained results are not an artefact, a low-angle diffraction calibration standard product[7] (silver behenate), considered as a standard which has a set of well-defined (00*l*) diffraction peaks at 2θ angles down to 1.5° with Cu-Kα radiation, was used to calibrate the XRD Siemens D 500 instrument (Fig. 1). The raw Wyoming montmorillonite was received from Comptoir des Minéraux (France). The elemental analyses of this crude montmorillonite obtained by XRF, and corrected by the weight loss which is *ca.* 15%, are: 66.35% SiO_2, 21.61% Al_2O_3, 4.29% Fe_2O_3, 2.70% MgO, 0.02% MnO, 0.21% TiO_2, 2.23% Na_2O, 1.58% CaO, 0.61% K_2O and 0.09% P_2O_5. The cation exchange capacity of this clay was *ca.* 80 mequiv. per 100 g of calcined clay. This material was used without further purification.

The oligomeric pillaring solutions were prepared by the following methods: (i) Al_{13} oligomer: a solution containing hydroxy-Al oligocations with OH : Al ratio of 2.2, was prepared from 0.4 M $AlCl_3 \cdot 6H_2O$ and 0.4 M NaOH. Seven days ageing was carried out at room temperature before use. (ii) Fe oligomer: following the procedure of Rightor *et al.*,[5] Na_2CO_3 powder was added gradually to an aqueous solution of 0.2 M $FeCl_3$, up to a base : Fe ratio of 2. The freshly resulting oligomer was used immediately without ageing.

A 2% suspension of raw clay was prepared by dispersing 2 g of montmorillonite in deionized water. Different amounts of Al and Fe oligomers (Al + Fe = 100%), prepared by the methods described above, were then added simultaneously to this clay slurry to give the ratio of M : clay = 10 mmol (g of clay)$^{-1}$. The suspension was aged for one day at room temperature. The clay products were centrifuged and then washed by successive agitations/centrifugations with deionized water until Cl^- free. Specimens of the clay suspensions were dried on glass slides at room temp. The samples were heated at 300 °C for 3 h. XRD patterns were recorded using Ni-filtered Cu-Kα radiation.

XRD patterns of the various clay samples are shown in Fig. 2. The *d*(001) spacing of the Al-sample is nearly 18 Å [Fig. 2(a)]. This value is similar to those generally reported for Al-PILCs and indicates the success of pillaring. The mixed Al–Fe sample [Fe/(Al + Fe) = 0.1] shows an additional peak at 52 Å which is lower in intensity than the peak at 18 Å. The *d*(004) of this first peak which must appear at nearly 13 Å, could be the origin of the assymetrical behaviour of this reflection [Fig. 2(b)]. The Al–Fe sample [Fe/(Al + Fe) = 0.2] gives two better defined peaks, one at *ca.* 64 Å which indicates that increasing the amount of Fe results in an increase in the *d*-value for the peak appearing at low angle and the other at 16.7 Å with high intensity [Fig. 2(c)]. The position of this second peak coincides with the fourth order (*ca.* 16 Å) of the 64 Å reflection, this again could explain the high intensity of this second peak. The mixed Al : Fe sample [Fe/(Al + Fe) = 0.5] has one peak at 72 Å and a second less intense broad peak centered at *ca.* 15.7 Å [Fig. 2(d)]. In the pure

Table 1 XRD spacings and textural properties: surface area, porous (V_P) and microporous ($V_{\mu P}$) volumes of the treated montmorillonites (Mt) as a function of Fe/(Al + Fe) molar ratio in the initial solutions, and of the starting raw clay heated at 300 °C. Mesoporous volume (V_{mP}) is obtained by subtracting microporous volume from total porous volume

Clay sample	Fe/(Al + Fe) initial molar ratio	First peak *d*/Å	Specific surface area/ $m^2\ g^{-1}$	$V_P/cm^3\ g^{-1}$	$V_{\mu P}/cm^3\ g^{-1}$	$V_{mP}/cm^3\ g^{-1}$
Mt.Al	0	18.3	246	0.18	0.104	0.076
Mt.Al-Fe	0.1	52	230	0.22	0.082	0.138
Mt.Al-Fe	0.2	64	210	0.23	0.047	0.183
Mt.Al-Fe	0.5	72	202	0.24	0.034	0.206
Mt.Fe	1	76	148	0.22	0.002	0.218
raw Mt heated at 300 °C	0	~10	18.5	0.06	0.004	0.056

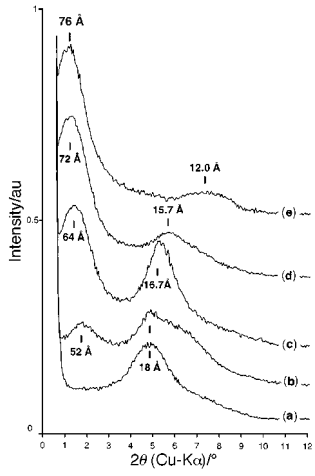

Fig. 2 XRD patterns with oriented specimen, heated at 300 °C, of the clays initially treated by the Al and Fe oligomer solutions in different ratios: (a) Fe/(Al + Fe) = 0; (b) Fe/(Al + Fe) = 0.1; (c) Fe/(Al + Fe) = 0.2; (d) Fe/(Al + Fe) = 0.5 and (e) Fe/(Al + Fe) = 1

Fe sample, the distance of the first peak reaches its maximum at *ca.* 76 Å and the second very broad peak position shifts to a lower distance of *ca.* 12 Å [Fig. 2(e)]. The general observation in all these spectra is that increasing the amount of iron in the initial solutions leads to (i) a shift of the first peak to lower angle and (ii) to a shift of the second peak in the opposite direction with an almost linear decrease in this case of the corresponding basal spacing from 18 to 12 Å.

The high distance observed here for the iron pillared sample was previously suspected by Yamanaka and Hattori,[8] but not shown by XRD. In fact, these authors comparing the adsorption isotherms of different molecules by Al-, Zr- and Fe-PILCs noticed that even though the basal spacings were similar in all these pillared samples, a BET isotherm (presumably, type IV or II) was observed for Fe whereas Langmuir isotherms (type I) were obtained for Zr and Al. From this, they concluded that the pore dimensions of the iron oxide pillared clay are probably larger than those expected from the 16.7 Å obtained basal spacing. They suggested that XRD analysis only reflects the partial well-ordered stacking of the silicate layers, since the remaining disordered parts are not revealed by XRD.

At this stage, the questions are what kind of iron species lead to these high distances of the peaks and do these increasing distances correspond to the interlamellar spaces between the layers? TEM studies are in progress to answer to these questions. In a study on partial hydrolysis of $FeCl_3$, Tchoubar *et al.*[9] have shown in similar experimental conditions that the sizes, which varied with time, of the obtained iron polymers, were centered around 100 Å: thus our *d* values are perhaps not so surprising. However, it is the first time, to our knowledge, that the synthesis of montmorillonites treated by pillaring solutions leading to such unexpectedly large distances of *ca.* 70 Å (XRD) is reported from a regular smectite clay.

The N_2 BET specific surface areas, pore, mesopore and micropore volumes of the treated clays are presented in Table 1. The starting raw montmorillonite clay, heated at 300 °C, exhibits a low surface area of 18.5 $m^2\ g^{-1}$, a low pore volume of 0.06 $cm^3\ g^{-1}$ and a microporosity of 0.004 $cm^3\ g^{-1}$. Al-PILC has, as expected, a surface area of 246 $m^2\ g^{-1}$, a pore volume of 0.18 $cm^3\ g^{-1}$ and a microporosity of 0.104 $cm^3\ g^{-1}$. With increasing Fe/(Al + Fe) initial ratio, the surface areas of the mixed treated clays decrease and reach 148 $m^2\ g^{-1}$ for the pure Fe sample which is still 7 times higher than the surface area of the heated starting clay. Here, the situation is very complex because as shown in our previous studies,[10] some precipitated oxyhydroxide Fe species are retained by the clay outside the interlamellar spaces and the intrinsic surface area is difficult to define. Rather, a comparative global evolution has to be taken into account in these clay materials. Moreover, the total pore volumes of the mixed treated clays remain almost constant, *ca.* 0.23 ± 0.01 $cm^3\ g^{-1}$, while the microporosity of these clays decreases with increased iron content and the residual microporosity value of the iron clay is very low. This indicates that montmorillonite treated with Al–Fe pillared species, creates essentially some mesoporosity between the clay particles, which could be at the origin of these high distances. The pillars may prevent access to the interlamellar spaces and the microporosity decreases to zero, and other unknown species of Al and Fe compounds could be obtained. All these possibilities have to be quantitatively analysed and interpreted from TEM images.

In conclusion, in this work unexpectedly large interlayer distances for montmorillonites treated by mixed Al–Fe and Fe-pillaring solutions are observed by XRD. These distances vary from 52 to 72 Å and reach a maximum at 76 Å in the pure Fe sample. Nevertheless, increasing the amount of iron leads to an increase of mesoporosity instead of microporosity.

This work was supported by an Avicenne European Programme No. 83. We thank D. Tchoubar and B. Jones for helpful discussion.

Stereoselective debromination of aryl-substituted *vic*-dibromide with indium metal

Brindaban C. Ranu,*† Sankar K. Guchhait and Arunkanti Sarkar

Department of Organic Chemistry, Indian Association for the Cultivation of Science, Jadavpur, Calcutta 700 032, India

Debromination of both *meso* and *dl* (*erythro* and *threo*) aryl-substituted *vic*-dibromides with indium metal in MeOH leads to *trans*-alkenes exclusively.

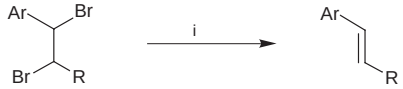
The protection-deprotection of olefins *via* bromination-debromination is an important process in organic synthesis. Although bromination generally proceeds smoothly and stereospecifically to give high yields of dibromides, debromination at a later stage in the synthesis often proves more difficult. This is primarily because the efficiency of this process greatly depends upon the stereoselectivity in the debromination step and compatibility of the reagent with the carbon–carbon double bond formed and other functionalities present in the substrates. Many reagents[1] including metals like Zn,[1d] Mg[1d] and Sm,[1h] have been reported in the literature for this reaction, but most of them are also associated with the limitations regarding selectivity and compatibility. Thus, an efficient and selective procedure for debromination of *vic*-dibromides is needed.

In recent times there has been increasing interest in indium-mediated transformations because of certain unique properties inherent to indium.[2] However, although indium has been used extensively in carbonyl addition reactions,[2,3] its potential in other domains has not been explored to any great extent.[4] Because of the close resemblance of indium to magnesium and zinc in several respects, including first ionization potential, indium could also be a potential reducing agent. This prompted us to initiate an investigation of indium-promoted reductive debromination of *vic*-dibromides. We have observed that aryl-substituted *vic*-dibromides undergo smooth debromination to produce the corresponding (*E*)-alkenes when treated with indium metal in MeOH (Scheme 1).

The experimental procedure is very simple. A mixture of *vic*-dibromide (1 mmol) and indium metal (1 mmol,‡ cut into small pieces) in dry MeOH (10 ml) was refluxed for a certain period of time (Table 1) until completion of the reaction (TLC). MeOH was removed and the residue was extracted with Et_2O. Evaporation of solvent followed by purification by silica gel chromatography furnished the pure alkene in high yields.

A wide range of structurally varied aryl-substituted *vic*-dibromides underwent debrominations by this procedure to provide the corresponding alkenes. The results are summarised in Table 1. Very interestingly, only *trans* olefins are obtained from all the substrates, whether they are *meso*/*erythro* or *dl*/*threo* (entries 1, 2, 4, 5, 8, 9). If debromination occurs by the usual *trans*-elimination, *meso*/*erythro*- or *dl*/*threo*-*vic*-dibromides would give *trans*- or *cis*-alkenes, respectively. It is therefore suggested that the reaction occurs *via* a common, relatively stable radical or anion intermediate which directly collapses to (*E*)-alkene. This speculation gains support from the observations that *cis*-stilbene does not undergo isomerisation to the *trans* isomer upon reflux with indium metal or oxidised indium products§ from debromonation of *erythro*-1,2-dibromo-1-phenyl-2-benzoylethane in MeOH, even after 8 h. The presence of *cis*-stilbene was also not detected upon quenching the debromination reaction of *vic*-dibromides of stilbene at an intermediate stage.

In general, the reactions are very clean and high-yielding. MeOH has been found to be the best solvent for this reaction; in pure MeCN the debromination does not proceed at all. Several sensitive functional groups, such as ketone carbonyl, carboxylic ester, hydroxy, methoxy and chloro groups on aromatic rings, remained unaffected under the present reaction conditions. No over-reduction of the produced alkene was observed with any



Scheme 1 *Reagents and conditions*: i, In, MeOH, reflux

Table 1 Debromination of aryl-substituted *vic*-dibromides with indium metal in MeOH

Entry	Substrate	*t*/h	Product	Yield (%)[a]

substrate, unlike those reactions reported using Sm[1h] and Mg.[5] As this reagent is inert to alkyl-substituted dibromides (entries 14, 15), selective debromination of aryl-substituted *vic*-dibromide moieties is achieved in the presence of alkyl-substituted dibromide moieties (entry 16). This procedure is also effective for the debromination of *vic*-dibromoalkenes to the corresponding alkynes (entries 17, 18).

In conclusion, the present procedure provides an efficient and general methodology for reductive debromination of aryl-substituted *vic*-dibromides to the corresponding (*E*)-alkenes; to the best of our knowledge this is the first report of indium-promoted debromination of *vic*-dibromides.[6] The significant improvements offered by this method over other existing debromination procedures[1] are: no overreduction of the double or triple bond formed, tolerance to several reducible functionalities, exclusive formation of (*E*)-alkenes from *cis*- as well as *trans*-dibromides, selective debromination of aryl-substituted dibromide moieties in presence of alkyl-substituted ones, and the easy availability and apparently nontoxic nature of indium metal.¶ Thus, this reaction is endowed with considerable synthetic potential and may provide a new method for reductive debromination and conversion of a *cis*-alkene to its *trans*-isomer. Further investigations of more useful applications are in progress.

We gratefully acknowledge financial support from CSIR, New Delhi [Grant No. 01(1504)/98] for this investigation. S. K. G. and A. S. are also thankful to CSIR for their fellowships. We thank Mr A. Som for his help with this work during his tenure as a summer project student in this laboratory from IIT, Kanpur.

‡ Debromination also proceeds in the presence of < 1 equiv. of indium; however, the reaction is very slow, *e.g. erythro*-1,2-dibromo-1-phenyl-2-benzoylethane (entry 8) takes 9 h with 0.5 equiv of In compared to 1 h with 1 equiv under identical reaction conditions.

§ We thank one of the referees for this suggestion.

¶ Indium metal is not affected by air and moisture and thus does not require any activation before reaction. Indium can be handled easily without any special precautionary measures and is relatively inexpensive.

A copper(I)-catalysed template synthesis of solvatochromic aryl-arsonium and -stibonium systems and a synchrotron structural study of a tetraarylstibonium di-iodocuprate

David W. Allen,*[a] Joanne P. L. Mifflin[a] and Simon Coles[b]†

[a] *Division of Chemistry, Sheffield Hallam University, Sheffield, UK S1 1WB*
[b] *Department of Chemistry, University of Wales, Cardiff, Cardiff, UK CF1 3TB*

A route to solvatochromic tetraaryl-arsonium and -stibonium phenolate betaines is described, together with a synchrotron structural study of a precursor arylstibonium di-iodocuprate salt in which both cation and anion have unusual geometries.

Methods for the synthesis of aryl-arsonium or -stibonium salts from tertiary arsines or stibines and aryl halides are limited, the usual route being the reaction of the tertiary arsine or stibine, commonly the triphenyl derivative, and an aryl halide, in the presence of aluminium chloride at > 200 °C.[1] We have shown that tertiary phosphines react with aryl halides bearing appropriate donor atoms in the *ortho* position to the halogen in the presence of catalytic quantities of nickel(II) or copper(II) compounds under mild conditions in refluxing ethanol,[2] and were interested in exploring similar template-assisted reactions of triaryl-arsines and -stibines. As triaryl-arsines and -stibines coordinate readily to copper(I) halides to form complexes which are labile in solution,[3] we have investigated their reactions with a series of template aryl halides in the presence of copper(I) iodide, in acetonitrile, and wish to report the formation of tetraaryl-arsonium and -stibonium systems in high yield under these remarkably mild conditions. We have also applied this procedure in the synthesis of the first solvatochromic tetraaryl-arsonium and -stibonium iminophenolate betaines, the properties of which are compared with those of the related phosphonium system. A synchrotron structural study of one tetraarylstibonium salt is also reported, which reveals a significant intramolecular coordinative interaction between the onium centre and the donor atom in the *ortho* position of the template system, and also the presence of a di-iodocuprate(I) anion which interacts with a second di-iodocuprate anion *via* a short copper–copper interaction to give a dinuclear anion.

The reaction of the aryl halides **1** (X = H, Z = OMe; X = Cl, Br, or Ph, Z = OH) with triphenylarsine and copper(I) iodide in acetonitrile under reflux for several hours gave, after pouring into aqueous potassium iodide solution and solvent extraction into dichloromethane, the tetraarylarsonium salts **2** (E = As, Y = I or CuI_2) as yellow-brown crystalline solids. ^1H and ^{13}C NMR spectra were consistent with the proposed structures. Under FABMS conditions, the arsonium salts gave a characteristic molecular ion for the cation present. The structure of the salt **2** (X = H, Z = OMe, E = As, Ar = Ph, Y = I) was also confirmed by a full X-ray crystallographic study.[4] Similarly, treatment of the aryl halides **1** (X = H, Z = OMe; X = Cl, Br, or Ph, Z = OH) and **3** with triphenyl- or tri-*p*-tolyl-stibine and copper(I) iodide in acetonitrile under reflux gave the related arylstibonium salts **2** (E = Sb; Ar = Ph or *p*-tolyl, Y = CuI_2) and **4** (Ar = Ph or *p*-tolyl, Y = CuI_2). Again, ^1H and ^{13}C NMR spectra were consistent with the proposed structures, and under FABMS conditions, each stibonium salt gave a characteristic molecular ion for the cation present. The nature of the anion present was confirmed by negative ion mass spectrometry. The stibonium salts formed more quickly than the related arsonium salts under the same conditions. Attempts to prepare the related phosphonium salts using copper(I) iodide as catalyst in acetonitrile were unsuccessful. Clearly, the group 15 ligand must influence crucial stages of the reaction, for which the mechanism is uncertain. A kinetic study of related nickel(II)-catalysed reactions of phosphines with template aryl halides supported a mechanism in which oxidative insertion of an intermediate phosphine–nickel complex into the carbon–halogen bond was the key step, followed by reductive elimination of the arylphosphonium salt and regeneration of the effective catalyst.[5] It is likely that a similar mechanism applies in the above reactions, perhaps involving a copper(I)–copper(III) redox cycle, in which the triaryl-arsine and -stibine ligands are able to stabilise intermediate organometallic species more effectively than the related triarylphosphines.

A structural study‡ has been made of the stibonium salt **2** (E = Sb; Ar = Ph; X = Br; Z = OH, Y = CuI_2). Routine investigations, using a rotating anode X-ray source, failed to provide data of sufficient intensity to produce a fully refinable structure. Data were therefore collected, upon a crystal of dimensions 200 × 20 × 20 μm, using station 9.8 of the Daresbury SRS.[6] The cation of the observed structure is displayed in Fig. 1 (together with selected bond lengths and angles for both cation and anion). Significant points of interest are the close intramolecular approach of the imino nitrogen to the stibonium centre, the antimony–nitrogen distance (2.65 Å), lying well within the sum of the van der Waals' radii (3.75 Å),[7] and the consequent distortion of the bond angles at antimony from the idealised tetrahedral angle towards a five-coordinate arrangement, consistent with an intramolecular coordinative interaction from nitrogen to antimony to form a five-membered ring. Tetraarylstibonium halides also show considerable distortion from idealised tetrahedral geometry as a result of weak interactions of the stibonium centre with the halide ion, resulting in essentially trigonal bipyramidal structures in which the antimony–halogen bond is unusually long.[8,9] The structure co-crystallises with a 50% occupied CH_2Cl_2 solvent and the counter-ion, which was found to be di-iodocuprate(I). The CuI_2

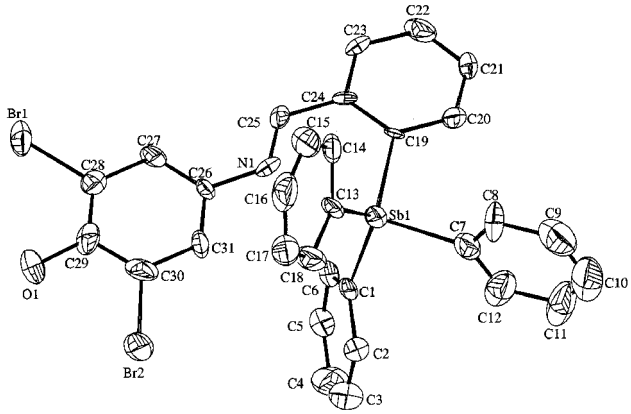

Fig. 1 Structure of the tetraarylstibonium cation with selected bond lengths (Å) and angles (°) for cation and di-iodocuprate anion: Sb–N1 2.65(4), Sb–C1 2.09(2), Sb–C7 2.13(2), Sb–C13 2.13(2), Sb–C19 2.114(14), C25–N1 1.28(2), Cu1–I1 2.508(2), Cu1–I2 2.576(2), Cu–Cu 2.732(4); C1–Sb–C7 106.7(7), C1–Sb–C13 119.2(6), C1–Sb–C19 113.6(6), C7–Sb–C13 102.0(7), C7–Sb–C19 101.4(6), C13–Sb–C19 115.9(6), C19–C24–C25 121.2(14), N1–C25–C24 118.9(13), N1–Sb–C1 83.9(7).

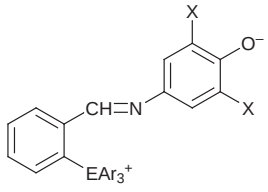
moiety shows a considerable distortion from the expected linear arrangement as a result of a very short copper–copper interaction (2.73 Å) with a second di-iodocuprate anion in the lattice. The stabilisation of poly[dihalocuprate(I)] anions by large phosphonium cations has been documented,[10,11] but the only stibonium salt involving a related anion is that of the copper(II) complex, $(SbPh_4)_2{\cdot}Cu_2Cl_6$.[12] However the Cu–Cu separation in this structure is much greater (3.394 Å) than that in the di-iodocuprate(I) counter-ion discussed here. Comparison with other di-iodocuprate(I) anions crystallizing in the same manner shows the Cu–Cu separation to be somewhat greater than in our example (average = 2.95 Å).[13,14]

Treatment of the salts **2** (E = As or Sb; Ar = Ph; X = Cl, Br, or Ph), dissolved in dichloromethane, with aqueous sodium hydroxide solution, resulted in a marked colour change from yellow to red-purple with formation of the related betaines **5**,



5

which were subsequently isolated and purified by trituration with diethyl ether. Again, ^1H and ^{13}C NMR spectra were consistent with the proposed structures, showing some significant chemical shift changes compared to the parent salts. Under FABMS conditions, cationic molecular ions were again observed. Conversion to the betaines resulted in a significant shift of the visible absorption maximum to longer wavelength. Thus, *e.g.* λ_{max} for the salt **2** (E = Sb; Ar = Ph; X = Cl, Y = CuI_2) in dichloromethane was observed at 358 nm, whereas for the related betaine **5** in the same solvent, λ_{max} = 536 nm. Significantly, in view of the potential link with non-linear optical properties, the betaines exhibited negative solvatochromism, the visible absorption maximum moving to longer wavelength on moving to a solvent of lower polarity. In the case of the above betaine, λ_{max} moved from 536 nm in dichloromethane to 576 nm in THF. The solvatochromic behaviour of the arsonium and stibonium betaines is almost identical to that of the related phosphonium betaines **5** (E = P, Ar = Ph; X = Cl, Br, or Ph) which we reported recently.[15] There is currently growing interest in the optical properties of organic derivatives of the main group 15 elements.[16,17]

We thank the EPSRC National Mass Spectrometry Service Centre, University of Wales, Swansea, for high resolution FABMS determinations, and also Neotronics Scientific Ltd for financial support.

New and improved catalysts for transition metal catalysed radical reactions

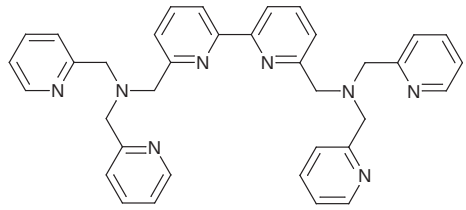
Floryan de Campo, Dominique Lastécouères and Jean-Baptiste Verlhac*†

Laboratoire de Chimie Organique et Organométallique (UMR 5802 CNRS), Université Bordeaux I, 351 cours de la Libération, 33405 Talence Cedex, France

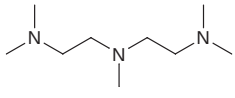
New Cu^{I} and Fe^{II} complexes displayed considerable improvements in atom transfer radical addition reactions.

Inter- and intra-molecular radical addition reactions are powerful tools for synthetic organic chemistry. In particular, those reactions initiated by reductive methods such as organotin hydride reduction of ω-haloolefins are well-known processes for the promotion of carbon–carbon bond formation for intramolecular addition and ring construction.[1,2] In contrast, atom transfer radical addition (ATRA) reactions make use of the redox properties of transition metal complexes in order to initiate the reaction by homolytic cleavage of a carbon–halogen bond. As a result, and in contrast to the Kharash addition, the termination step introduces a versatile halogen atom into the product which is then useful for further functionalisation. Thus, a new class of catalysts, most commonly transition metal complexes such as $RuCl_2(PPh_3)_2$,[3] $FeCl_2(P(OEt)_3)_3$,[4] Co(Di-Meglyoxime)$_2$,[5] CuCl(bpy)[3] or a mixture of iron metal and copper bromide,[6] can be used in ATRA reactions. However, only limited success has been reported and only a few examples have appeared which describe cyclisations of allylic trichloroacetates[7] or trichloroacetamides[8] to produce γ-lactones and lactams, respectively, or additions of trihalo compounds such as CCl_4,[9] trichloroacetic acid or esters[10] to olefins. Competing telomerisation is often considered to be a drawback.

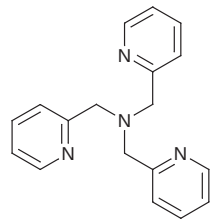
Here we report that the use of new copper and iron complexes, for such reactions as the addition of CCl_4 to oct-1-ene and the cyclization of unsaturated trichloroacetates, which lead to a considerable improvement in terms of catalytic activity.



L1

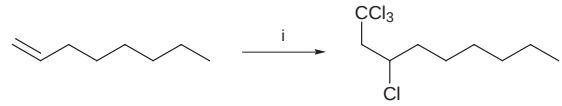


L2



L3

Ligands **L1**, **L2** and **L3** were synthesised according to literature procedures.[11] The catalyst was prepared *in situ* by reacting copper(I) or iron(II) chloride with 1 equiv. of ligand. Whatever the ligand used, the addition of CCl_4 to oct-1-ene proceeds smoothly and affords the corresponding 1:1 adduct. In a typical procedure, oct-1-ene (0.2 M in 1,2-dichloroethane) and CCl_4 (1.1 equiv.) were allowed to react under argon with various amounts of complex (from 30 to 3%) at 80 °C for 18–48 h. Flash chromatography through a short silica gel column and distillation under reduce pressure afforded 1,1,1,3-tetrachlorononane in almost quantitative yield (Scheme 1).



94% [**L1** or **L3** (0.03 mol%, 48 h)]
75% [bpy (0.3 mol%, 48 h)]
70% [**L2** (0.003 mol%, 18 h)]

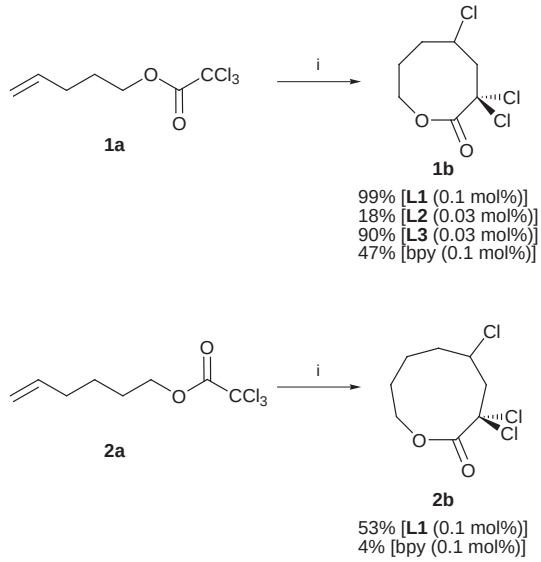
Scheme 1 *Reagents and conditions*: i, CuCl–ligand, CCl_4

The remarkable solubility of the catalysts, even in concentrated mixtures, and the low quantity of catalyst required in order to complete the reaction represent the major improvement. Thus, even with only 0.003 equiv. of an equimolar mixture of CuCl and ligand **L2**, the tetrachloro adduct is formed in 70% yield, making these systems truly catalytic.

The most significant result was the possibility of using a simple tridentate polyamine (**L2**). This ligand is obtained in a one step procedure from a very cheap starting material. These new complexes induce a faster addition reaction than the widely used Cu(I)Cl/bpy complex. In order to find a catalyst which is less oxygen and water sensitive, we have also investigated the activity of the corresponding iron(II) complexes. Although the iron(II)(bpy) complex was almost inactive, those obtained with **L1** and **L2** exhibit good catalytic activity.‡

Emboldened by these results, we then studied the ability of these catalysts to induce the cyclisation of unsaturated trichloroacetates and particularly pent-4-enyl trichloroacetate **1a** and hex-5-enyl trichloroacetate **2a**. We report herein the synthesis of the eight- and higher-membered lactones by a cyclisation process *via* an *endo* mechanism (Scheme 2). The trichloroacetates were treated at 80 °C (0.1 M in 1,2-dichloroethane) with various amounts of catalyst under argon.

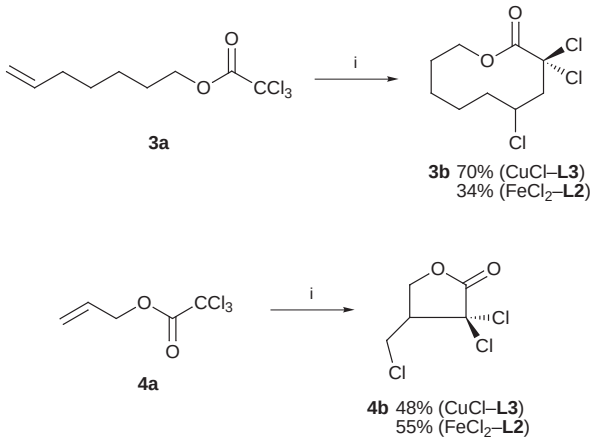
The complexes reported herein are far better catalysts than the previously described CuCl–bpy system.[3] For instance, ligand **L1** in the presence of copper(I) (0.1 mol%) converted quantitatively pent-4-enyl trichloroacetate **1a** into lactone **1b**. Using the same conditions the yield reached only 47% with CuCl–bpy. The CuCl–**L2** system proved to be not as effective in the catalysis of intramolecular reactions, but when $FeCl_2$ was used instead of CuCl, it was possible to obtain a good yield of cyclisation product.§ In all of the experiments described, no significant amount of telomers could be detected. It has been previously reported that with a high stoichiometric ratio of $Cu^{I}Cl$–bpy (30%), significant telomer formation occurs. The lactone formation yield remains average (60%), but all the ester is consumed. The same phenomena could be observed when more that 10% catalyst was used, whatever the final concentration. These results indicate that the concentration of radicals (free or metal-bonded) remains high during the reaction and that the kinetic constant of cyclisation might be smaller than the telomerisation constant.



Scheme 2 *Reagents and conditions*: i, CuCl–ligand, 1,2-dichloroethane, 80 °C

The cyclisation of hex-5-enyl trichloroacetate **2a** gave only a low yield of lactone **2b** in the presence of CuCl–bpy (0.1 mol%), but this yield is subsequently improved by the use of either the CuCl–L1 or the $FeCl_2$–L2 systems.¶ In the cyclisation experiments with **2a**, a substantial difference between the yield of cyclisation products and the total conversion, based on the disappearance of **2a**, was noted. The difference in mass balance is probably due to the tendency for **2a** to give oligomers and particularly dimers, which have been characterised by mass spectrometry, because of the increase in ring size.

We have also observed reactions which were impossible to perform with CuCl–bpy;[7] for instance the cyclisation of hept-6-enyl trichloroacetate **3a** afforded the cyclic *endo* lactone **3b** in 70% yield in the presence of CuCl–**L3** (Scheme 3). It was also possible to catalyse the *exo* cyclisation of prop-2-enyl trichloroacetate **4a** with 48% yield in the presence of the same catalyst. In the latter case the $FeCl_2$–**L2** system also proved to be effective.



Scheme 3 *Reagents and conditions*: 1,2-dichloroethane, 80 °C, CuCl–**L3** or $FeCl_2$–**L2** catalysts (0.1 mol%)

As previously observed,[3,12] the cyclisation of esters with long unsaturated chains (**1a**, **2a**, **3a**) proceeds *via* an *endo* pathway. This is due to the fact that the most stable conformation for the ester function (s-*trans*) does not impede the cyclisation process if the carbon chain is long enough. With the unsaturated ester **4a**, only the less favourable conformation (s-*cis*) can give rise to the cyclisation product. In this case the formation of a five-membered ring *via* an *exo* pathway is preferred. The but-3-enyl trichloroacetate lies in an intermediate position. It was impossible for us to obtain cyclisation products, we could only detect cyclic dimers and telomers by mass spectrometry. The formation of a six-membered ring lactone *via* the s-*cis* conformation is not favourable and the butenyl chain is not long enough to allow a cyclisation process *via* the s-*trans* conformation. These results are consistent with those reported by O-Yang in the case of α-iodo esters.[12]

As a conclusion, the use of new ligands represents a significant improvement for the catalytic activity of copper(I) and iron(II) complexes in ATRA reactions by reducing the required amount of complex by a factor of 10 to 100. Moreover, they are soluble in the reaction mixture and catalyse reactions which are impossible to perform with the $Cu^{I}Cl$–bpy complex. The metal could also act as a template and allow the notoriously difficult cyclisation of eight- and nine-membered ring lactone precursors as suggested previously.[7] We are currently trying to relate the redox potentials of these complexes to their catalytic activity.

We are indebted to Dr B. Maillard for fruitful discussion and to the Région Aquitaine for financial support.

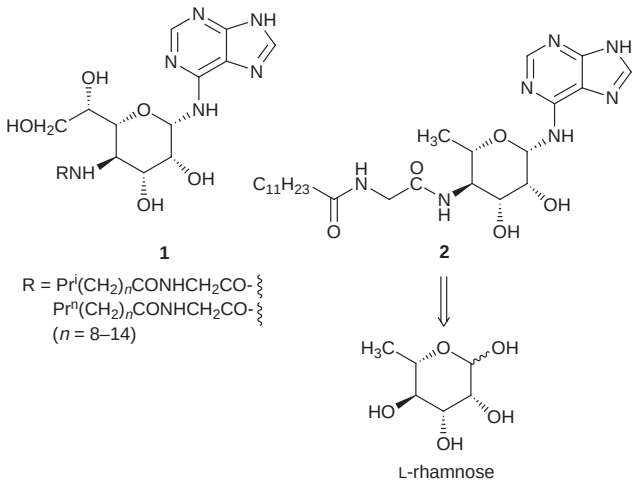
A highly cytotoxic L-rhamnose analogue of the antitumour agent spicamycin

Angeles Martín,[a] Terry D. Butters[b] and George W. J. Fleet*[a]†

[a] *Dyson Perrins Laboratory, University of Oxford, South Parks Road, Oxford, UK OX1 3QY*
[b] *Oxford Glycobiology Institute, Department of Biochemistry, University of Oxford, South Parks Road, Oxford, UK OX1 3QU*

Rhamnospicamycin 2, a rhamnose analogue (containing adenine, a carbohydrate, an amino acid and a fatty acid) of the naturally occurring combinatorial library spicamycin 1, is prepared from L-rhamnose and shown to be highly cytotoxic towards human myeloma cells (IC_{50} = 120 nM).

Nucleoside analogues linked to a sugar through the NH_2 group of adenine are very rare.[1] Spicamycin **1**, an antitumour



antibiotic isolated from *Streptomyces alanosinicus*,[2] is a naturally occurring combinatorial library of fatty acids linked through glycine to a seven carbon sugar and then through the anomeric position of the carbohydrate to the amino group of adenine.[3] The potential of spicamycin as a new class of antitumour agent[4] stimulated structure activity studies[5] that found that the dodecanoyl derivative **1** (R = decanoyl) had antitumour activity against human gastric cancer SC-9 superior to that of mitomycin C, which is clinically used for many kinds of tumours.[6] A semi-synthetic analogue of spicamycin **1** with a tetradecadienoyl side chain[7] potently inhibits the growth of certain human tumour lines *in vitro* and displays marked *in vivo* activity in Colo 205 colon carcinoma xenografts;[8] it will shortly be available for Phase 1 clinical trials in the USA. Exposure of cells to spicamycin at low concentrations of the drug alters glycoprotein processing and induces some accumulation of oligomannosides; while the molecular mechanism for the activity of spicamycin needs to be clarified, the effects of the compound are consistent with a prominent early effect on the enzymatic machinery or organelles important for proper glycoprotein processing and emphasise the novelty of this agent's likely mechanism of action.[9]

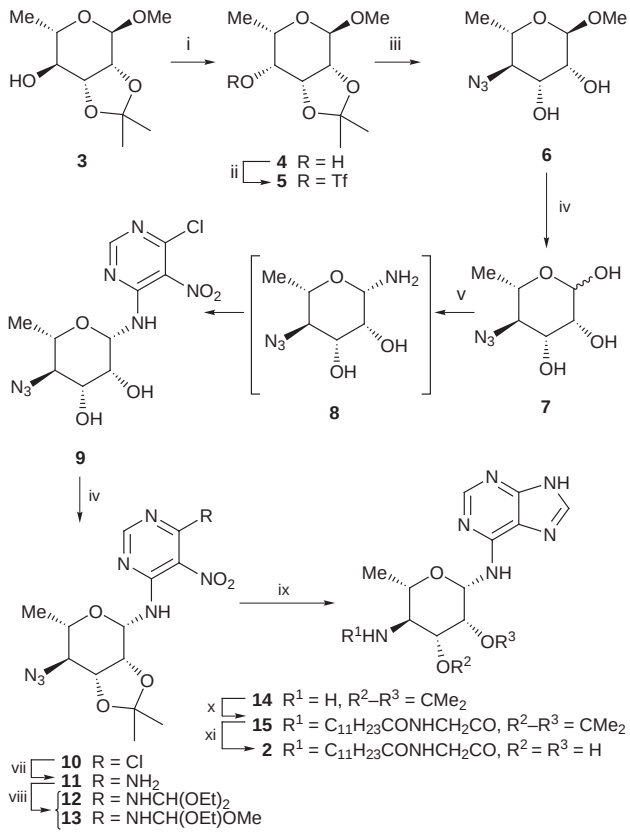
Spicamycin **1** contains a nucleoside base, a carbohydrate, an amino acid and a lipid fragment and thus provides an interesting target for synthesis, and for constructing a wide range of combinatorial libraries from suitable building blocks in which of these components may be varied. No studies on the total synthesis of spicamycin have been reported, all modifications to the structure arising from semi-synthetic procedures from degradation of the natural material. The absolute configuration of the carbohydrate component in **1** was determined by X-ray crystallographic analysis;[10] **1** is a seven carbon sugar analogue of L-mannose, and is thus closely related to L-rhamnose. The total synthesis of closely related carbohydrate analogues of spicamycin would allow the importance of structural features of the carbohydrate to be determined and provide materials for the elucidation of the mechanism of activity of this class of antitumour agent.

Here we report the synthesis of the spicamycin analogue **2** from L-rhamnose and its cytotoxicity against human myeloma cells. The synthesis of rhamnospicamycin **2** requires introduction of nitrogen with retention of configuration at C-4 of L-rhamnose, following by elaboration at the anomeric position of the sugar and at the nitrogen group in C-4. Introduction of the nitrogen as an azide at C-4 permits flexibility in the approach to spicamycin analogues by allowing development of the amino acid side chain or the introduction of the adenine moiety at the anomeric position of rhamnose in either order. Here, the purine is introduced first, but there are clearly many approaches with opportunities for the development of libraries at different stages of the synthesis.

The acetonide **3**, prepared from L-rhamnose in 87% overall yield as previously described,[11] has only the hydroxy group at C-4 of rhamnose unprotected. Oxidation of **3** with PCC in CH_2Cl_2 and subsequent reduction of the resulting ketone with $NaBH_4$ afforded the inverted alcohol **4** in 95% yield over the two steps. Esterification of **4** with Tf_2O and pyridine in CH_2Cl_2 gave the triflate **5** in 82% as a relatively unstable oil. Treatment of **5** with NaN_3 in DMF, followed by cleavage of the acetonide with aqueous TFA, gave the 4-azidorhamnose derivative **6** [mp 81–82 °C (acetone–hexane) $[\alpha]_D^{21}$ −123.5 (*c* 0.72, MeOH)] in 60% yield over two steps (40% from rhamnose). More vigorous hydrolysis of **6** with aqueous TFA at reflux yielded the azido lactols **7**[12] in 86% as a mixture of anomers (α:β, 2:1).

The anomeric amine **8** was obtained from treatment of **7** with aqueous NH_3. All attempts to introduce the adenine moiety directly by addition of 6-chloropurine to **8** were unsuccessful; the principal products were dimeric amines derived from **8**. Accordingly, **8** was reacted with the more electrophilic 4,6-dichloro-5-nitropyrimidine (in the presence of Et_3N as base) to afford the pyrimidine derivative **9** [mp 142–144 °C; $[\alpha]_D^{21}$ +23.2 (*c* 0.59, MeOH)] in 20% yield from **7**, which was converted into the more easily manipulated acetonide **10** [mp 127–129 °C; $[\alpha]_D^{21}$ +50.9 (*c* 0.55, Me_2CO)] in 70% yield. Studies to improve the yield of this key step are in progress.

Reaction of **10** with aqueous NH_3 resulted in nucleophilic displacement of the chloride to give the corresponding amine **11** [mp 180–182 °C, $[\alpha]_D^{21}$ +3.5 (*c* 0.60, Me_2CO)] in 97% yield. Investigation of the activity of a range of reducing agents with the nitro azide **11** failed to identify any reagent with significant selectivity for the nitro group over the azide. Accordingly, the additional carbon necessary for purine formation was added to the free amino group in **11** prior to reduction; treatment of **11** with triethyl orthoformate gave, after work-up in the presence of MeOH, a mixture of the compounds **12** and **13** in a ratio of 1:1 in 65% yield. Hydrogenation of the azides **12** and **13** in MeOH in the presence of Pd/C effected the reduction of the azide and nitro groups to the corresponding diamines which sponta-



Scheme 1 *Reagents and conditions:* i, PCC, molecular sieves 3Å, CH_2Cl_2, then $NaBH_4$, EtOH–H_2O, 0 °C; ii, Tf_2O, Py, CH_2Cl_2, −10 °C; iii, NaN_3, DMF, then TFA–H_2O 3:7; iv, TFA–H_2O 1:1, 1,4-dioxane, reflux; v, NH_3 (aq), then 4,6-dichloro-5-nitropyrimidine, Et_3N, DMF; vi, $Me_2C(OMe)_2$, CSA, acetone; vii, NH_3 (aq), MeOH, 60 °C; viii, $HC(OEt)_3$, 140 °C, then MeOH, silica; ix, H_2, Pd/C, MeOH; x, dodecanoylglycine, DMF, *N*-hydroxysuccinimide, WSC·HCl; xi, 70% AcOH (aq), 60 °C

neously cyclised to give the purine **14**[13] [oil; $[\alpha]_D^{21}$ +25.4 (*c* 0.22, MeOH)] in 53% yield.

Condensation of the amine **14** with dodecanoylglycine[5] in DMF in the presence of *N*-hydroxysuccinimide and 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride (WSC·HCl) gave the glycopeptide **15** in 71% yield.[14] Finally, removal of the acetonide in **14** with aq. AcOH gave rhamnospicamycin **2**, mp 224–226 °C (decomp.) $[\alpha]_D^{21}$ +9.71 (*c* 0.35 MeOH) in 82% yield; rhamnospicamycin is columnable in organic solvents and easy to purify. The NMR of **2** in DMSO is temperature dependent (in contrast to the NMR in CD_3OD) and may indicate some propensity for intramolecular hydrogen bonding between the carbohydrate hydroxy protons and the adenine nucleus.[15]

In a preliminary study rhamnospicamycin **2** was found to be highly cytotoxic with an IC_{50} value for cell growth (assessed over 15 h in culture using human myeloma cells, HL60 cells) is 120 nM; thus **2** displays much the same potency as that reported for the dodecanoyl derivative of spicamycin **1**.

While there are a number of steps in the synthesis that have yet to be optimised, we have shown that variation in the carbohydrate fragment of spicamycin may allow a wide range of novel materials with cytotoxic activity to be prepared. Spicamycin incorporates a nucleoside, a fatty acid, a sugar and an amino acid all into one component; the potent cytotoxicity with the possibility of a novel mode of action as an anti-cancer agent in regard to modification of glycoprotein processing, together with the opportunity to generate combinatorial libraries, makes this class of compound an attractive one for further synthetic study and biological evaluation of the mechanism.

Financial support from the European Community for a post-doctoral fellowship (Programme Training and Mobility Research) to A. M. (contract no. ERBFMBICT961664) is gratefully acknowledged.

Synthesis and luminescence behaviour of rhenium(I) diynyl complexes. X-Ray crystal structures of [Re(CO)$_3$(^{t}Bu$_2$bpy)(C≡C–C≡CH)] and [Re(CO)$_3$(^{t}Bu$_2$bpy)(C≡C–C≡CPh)]

Vivian Wing-Wah Yam,* Samuel Hung-Fai Chong and Kung-Kai Cheung

Department of Chemistry, The University of Hong Kong, Pokfulam Road, Hong Kong SAR, People's Republic of China. E-mail: wwyam@hkucc.hku.hk

Luminescent rhenium(I) diynyl complexes [Re(CO)$_3$(^{t}Bu$_2$bpy)(C≡C–C≡CH)] and [Re(CO)$_3$(^{t}Bu$_2$bpy)(C≡C–C≡CPh)] were synthesized and their photophysical properties studied; the crystal structures have also been determined.

There has been a rapidly growing interest in the chemical and physical properties of C$_n$-bridged metal-containing materials,[1] in view of their potential applications as nonlinear optical materials, molecular wires, and molecular electronics. With the recent reports on the successful isolation of acetylide-bridged rhenium(I) organometallics[1a–g,2] and our recent efforts in incorporating metal-to-ligand charge transfer (MLCT) excited states into rhenium(I) acetylide units to make luminescent rigid-rod materials,[3] we have extended our work to employ the diynyl unit as the ligand to extend the carbon chain. Herein are reported the synthesis, structure and luminescence behaviour of two rhenium(I) diynyl complexes, [Re(CO)$_3$(^{t}Bu$_2$bpy)(C≡C–C≡CH)] **1** and [Re(CO)$_3$(^{t}Bu$_2$bpy)(C≡C–C≡CPh)] **2**.

Reaction of a mixture of [Re(CO)$_3$(^{t}Bu$_2$bpy)Cl],[4] KF, AgOTf and Me$_3$SiC≡C–C≡CSiMe$_3$ in a 1 : 1 : 1 : 3 ratio in MeOH under reflux conditions in an inert atmosphere of nitrogen for 24 h afforded [Re(CO)$_3$(^{t}Bu$_2$bpy)(C≡C–C≡CH)], which was isolated as orange crystals after purification by column chromatography on silica gel using dichloromethane as eluent, followed by recrystallization from dichloromethane–diethyl ether. On the other hand, reaction of a mixture of [Re(CO)$_3$(^{t}Bu$_2$bpy)Cl], AgOTf, NEt$_3$ and PhC≡C–C≡CH[5] in a 1 : 1 : 2 : 1.5 ratio in refluxing THF under nitrogen for 24 h afforded [Re(CO)$_3$(^{t}Bu$_2$bpy)(C≡C–C≡CPh)]. Purification by column chromatography on silica gel using dichloromethane–light petroleum (1 : 1 v/v) as eluent, followed by subsequent recrystallization from dichloromethane–light petroleum yielded [Re(CO)$_3$(^{t}Bu$_2$bpy)(C≡C–C≡CPh)] as yellow crystals. The identities of both complexes **1** and **2** have been confirmed by satisfactory elemental analyses, ^{1}H NMR spectroscopy, FAB-MS,† and X-ray crystallography.‡

Fig. 1 and 2 depict the perspective drawings of complexes **1** and **2** with atomic numbering, respectively. Both structures show a slightly distorted octahedral geometry about Re with the three carbonyl ligands arranged in a facial fashion. The N–Re–N bond angles of 74.6(2) and 73.9(1)° for **1** and **2**, respectively, are less than 90°, as required by the bite distance exerted by the steric demand of the chelating bipyridine ligand. The two C≡C bond lengths are 1.199(10) and 1.19(1) Å for **1** and 1.198(7) and 1.189(7) Å for **2**, which are comparable to those found for diynyl systems.[1d,6] The Re–C≡C–C≡C units are essentially linear with bond angles of 175.2(6)–179.8(10) and 175.7(5)–178.6(6)° for **1** and **2**, respectively.

The electronic absorption spectra of **1** and **2** show intense absorption bands at *ca.* 404 and 416 nm, respectively, in tetrahydrofuran. With reference to previous spectroscopic work on rhenium(I) diimine systems,[3,4,7] the intense low energy absorption is tentatively assigned as the dπ(Re) → π*(^{t}Bu$_2$bpy) MLCT transition. The lower MLCT absorption energy for **2** than **1** is consistent with the better σ- and π-donating abilities of PhC≡C–C≡C than HC≡C–C≡C,[1j,8,9] which render the Re(I) centre more electron rich, and raise the Re dπ orbital energy. Similar trends have been observed in the related alkynyl system [Re(CO)$_3$(^{t}Bu$_2$bpy)X],[3] in which the MLCT absorption band occurs at higher energy for X = HC≡C than when X = PhC≡C.

Excitation of **1** and **2** both in the solid state and in fluid solutions at room temperature at λ > 400 nm resulted in strong orange luminescence, attributed to the ^{3}MLCT phosphorescence. The excitation spectra of **1** and **2** in THF show excitation bands at *ca.* 400 nm and 410 nm, respectively, which closely resemble those of the MLCT absorption maxima. The photophysical data are summarized in Table 1. The slightly lower MLCT emission energy of **2** than **1** in THF is in line with the stronger σ- and π-donating abilities of the phenyldiynyl unit than the butadiynyl ligand, *i.e.* PhC≡C–C≡C (625 nm) < HC≡C–C≡C (620 nm). Similar trends have been observed in the monoacetylide analogues [PhC≡C (688 nm) < HC≡C (670 nm)].[3] It is interesting to note that both **1** and **2** emit at higher energies than their respective monoacetylide counterparts, *i.e.* in the [Re(CO)$_3$(^{t}Bu$_2$bpy)X] system, the emission energies in THF follow the order: HC≡C–C≡C (620 nm) > HC≡C (670 nm); PhC≡C–C≡C (625 nm) > PhC≡C (688 nm). The observation of a blue shift in emission energies upon increasing

Table 1 Photophysical data for complexes **1** and **2**

Complex	Medium (T/K)	Emission, λ_{em}/nm (τ_o/μs)
1	THF (298)	620 (< 0.1)
	CH_2Cl_2 (298)	604 (< 0.1)
	Solid (298)	565 (< 0.1)
	Solid (77)	580
	EtOH–MeOH glass (4 : 1 v/v) (77)	540
2	THF (298)	625 (< 0.1)
	Solid (298)	570 (< 0.1)
	Solid (77)	570

the C≡C unit is in line with the assignment of a ^{3}MLCT [dπ(Re) → π*(^{t}Bu$_2$bpy)] origin and disfavours the assignment of a ^{3}MLCT [dπ(Re) → π*(C≡C–C≡CR)] or a metal-perturbed ^{3}IL [π(C≡C–C≡CR) → π*(C≡C–C≡CR)] origin. Given the similar σ-donating properties of the monoacetylide *versus* the diynyl unit,[9] the much better π-accepting ability of RC≡C–C≡C than RC≡C would become the dominating factor, stabilizing the Re dπ orbitals to a greater extent, and hence give rise to a higher energy ^{3}MLCT emission.

Atomic nitrogen attachment to an sp³ carbon during the electrospray ionization process was proved by experiments using $^{15}N_2$ and other evidence.

Electrospray ionization (ESI) has been adopted for the study of various small organic compounds as well as large biomolecules in recent years.[1–5] In the course of our mass spectrometric studies of unstable organic compounds in solution, we have found some unexpected mass shifts of 14 atomic mass units (u).‡ This phenomenon was observed in some aliphatic and aliphatic ether compounds containing sp³ carbons (Fig. 1). Since this shift was found in compounds that mainly consisted of aliphatic moieties, the participation of a CH_2 unit was the most promising hypothesis to explain this mass difference. However, we propose here that atomic nitrogen attachment in the ESI process is the reason for this shift, based on several electrospray mass spectrometric studies including an $^{15}N_2$ experiment.

An electrospray is produced under atmospheric pressure using a strong electric field. This field induces a charge accumulation at the liquid surface located at the end of the nebulizing capillary, which will break to form highly charged droplets.[6–8] In this process, N_2 is frequently used as a sheath gas and sometimes as a drying gas to evaporate the droplets. Ionspray (IS), a form of electrospray using the sheath gas as a pneumatic nebulizer, made it possible to introduce relatively large amounts of solution.[9] The ionization of non-polar compounds is also possible using IS. This method was adopted for our study using N_2 as the sheath gas. A double focus tandem mass spectrometer equipped with an atmospheric ESI source was used for this experiment in order to obtain detailed characteristics of the single charged ion species to be discussed here. Typical conditions for the ESI measurement were as follows: acceleration voltage; 5 kV, resolution; 2000–5000, needle voltage (current); 2.5–5.0 kV (700 to > 20000 nA), desolvation chamber temperature; 100 °C, sample flow; 7 mL h^{-1} and sheath gas flow; 1.5 l min^{-1} (JEOL, JMS–700T). The neat chemicals were sprayed without dilution. In the case of THF, for instance, the $[M + 14]^+$ ion is clearly detected using molecular nitrogen as a pneumatic nebulizing gas in the atmospheric ESI source, as can be seen in Fig. 1(*b*). The ions of *m/z* 71 $[THF - H]^+$ and 145 $[(THF)_2 + H]^+$ are also observed[10] in this spectrum. The results from ESI-MS experiments using $[^2H_{12}]$cyclohexane proved that the mass shift is not ascribed to the elimination and intermolecular attachment of CH_2 (14u) in cyclohexane itself [Fig. 2(*a*)]. A similar result was obtained from the experiment using $[^2H_8]$THF [Fig. 2(*b*)]. We could not help but consider that this shift might be caused by a nitrogen atom at this point.

It is strongly suggested that the attached nitrogen atom comes from the nebulizing gas because no ion signals corresponding to the atomic nitrogen adducts were observed in the experiment using Ar as a nebulizing gas. Moreover, using $^{15}N_2$ as the nebulizing gas (99.7 atom% ^{15}N), a clear mass shift of 15u was observed based on the generation of the $[THF + {}^{15}N]^+$ ion [Fig. 3(*b*)]. The ions assigned as monomeric and dimeric THF were not interfered with. The $^{15}N_2$ experiments for cyclohexane, Et_2O and n-hexane are also shown in Fig. 3.

These results prove the formation of an atomic nitrogen adduct during the ESI process. How does it happen? Does the generation of atomic nitrogen species under atmospheric electric discharge[11] constantly occur? Although this behavior is

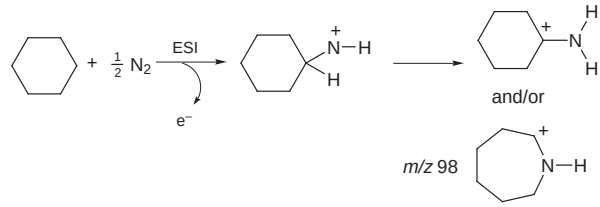
thought to be similar to that of the singlet nitrene,[12] a detailed mechanism and the structures of the products are unknown. A methoscopic cluster ion generated from an associative ionization is one of the possible adducts obtained from this process. However, this species is thought to contain a covalently bonded nitrogen because of the potent reactivity of absolute atomic nitrogen. Our result that atomic nitrogen attachment isn't observed in similar compounds that do not contain sp^3 carbons, such as furan and benzene, suggests particular reactivity of this species. In addition, we obtained an ESI mass spectrum of cyclohexylamine, which is identical to the spectrum of nitrogen-attached cyclohexane [Fig. 1(*a*)]. Thus, one of the probable structures of the nitrogen adduct in the case of cyclohexane is cyclohexylamine (Scheme 1).



Scheme 1

Detailed structure determination of this cation generated from the nitrogen attachment is our current task. We believe that the interpretation of various mass spectra displaying the unexpected mass shift of 14u will be made easier if the participation of atomic nitrogen attachment is taken into account.

In summary, atomic nitrogen attachment to sp^3 carbons in positive electrospray ionization mass spectrometry was observed. Experiments using $^{15}N_2$ and other evidence definitely suggest that the mass shift of 14u comes from an absolute nitrogen atom. This result points to a facile nitrogen fixation which will be useful in synthetic organic chemistry.[13]

Polymers containing backbone acetylene, anthracene and tetra-, penta- or hexa-coordinate silicon units: UV–visible, photoluminescence and solution $\chi^{(3)}$ non-linear optical properties

William E. Douglas,*[a]† Daniel M. H. Guy,[a] Ajoy K. Kar*[b] and Changhai Wang[b]

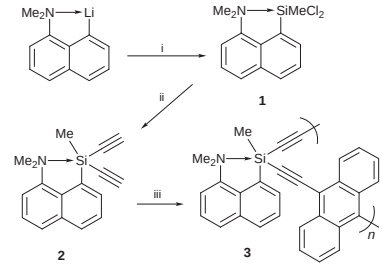
[a] *CNRS UMR 5637, Université Montpellier II, 34095 Montpellier cedex 5, France*
[b] *Department of Physics, Heriot-Watt University, Riccarton, Edinburgh, Scotland, UK EH14 4AS*

Poly(aryleneethynylenesilylene)s of general structure $(C{\equiv}CSiR_2C{\equiv}CX)_n$ (X = 9,10-anthrylene) containing tetra-, penta- or hexa-coordinate silicon exhibit high $\chi^{(3)}$ values, the absorbance and emission spectra being red-shifted with respect to those for the corresponding monomers $R_2Si(C{\equiv}CAr)_2$ (Ar = 9-anthryl); these properties are consistent with extensive through-Si conjugation along the backbone.

As recently reviewed, conjugated poly(aryleneethynylene)s are of current interest on account of their photo- and electroluminescent properties and large third order harmonic generation, the $\chi^{(3)}$ values being similar to those for poly(diacetylene)s.[1] The incorporation of electron-rich anthracene units into poly(aryleneethynylene)s has been found to have a marked influence on the luminescence properties,[2] and is particularly effective in π-electron delocalisation along the backbone of such polymers containing Pt.[3] The silicon-containing analogues $(C{\equiv}CSiR_2C{\equiv}CX)_n$ [poly(aryleneethynylenesilylene)s] have been known for some years,[4] those where X is phenylene exhibiting blue photoluminescence[5] with a solution Re($\chi^{(3)}$) value of -9.3×10^{-13} esu.[6] Few polymers containing hypercoordinate silicon are known although the latter exhibits very different chemical and electronic behaviour from tetracoordinate silicon.[7] Recently we prepared poly(aryleneethynylenesilylene)s containing backbone hexacoordinate silicon groups,[8] and the series has now been extended to the corresponding polymers with pentacoordinate silicon incorporating the 8-dimethylamino-1-naphthyl (NpN) ligand known to give stable hypercoordinate species.[9]

The pentacoordinate compounds were obtained from the previously characterized[10] dichlorosilane **1** which was treated with monoethynyl Grignard reagent (Scheme 1) to give the new (4 + 1)-coordinate[11] diethynylsilane **2**.‡ Likewise, tetracoordinate monomer **5** with two 1-naphthyl groups was prepared from dichlorosilane **4** (Scheme 2), the spectral data being similar to those for $Ph_2Si(C{\equiv}CH)_2$.[4,12]

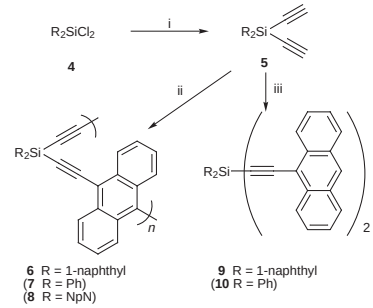
Monomers **2** and **5** undergo palladium-catalysed cross-coupling polymerization with 9,10-dibromoanthracene affording, respectively, **3** containing pentacoordinate Si (Scheme 1) and **6** with tetracoordinate $(1\text{-Np})_2Si$ groups (Scheme 2), the latter being similar to the Ph_2Si analogue **7**.[13] Size exclusion chromatography (SEC) showed both materials to be low molecular weight polymers (Table 1) similar to previously



Scheme 1 *Reagents and conditions*: i, excess $MeSiCl_3$, Et_2O, room temp., 5 h; ii, HC≡CMgBr, THF, −78 °C to room temp.; iii, 9,10-dibromoanthracene, $(PPh_3)_2PdCl_2$, CuI, PPh_3, Et_3N, PhMe, 4 h, 89 °C

reported polymer **8** containing hexacoordinate Si.[8] Reflecting the change in the electronic environment, the Si*C*≡C ^{13}C and ^{29}Si NMR resonances are shifted upfield with increasing coordination number, there being little effect on the $\nu_{C\equiv C}$ IR absorbance (Table 1).

Model monomers **9** and **10** containing tetracoordinate Si were prepared by palladium-catalysed cross-coupling with 9-bromoanthracene (Scheme 2, Table 2). The spectral data are similar to those for the analogous polymers (Table 1), the second IR $\nu_{C\equiv C}$ band in the polymers appearing in the monomers as an ill-defined shoulder around 2150 cm^{-1}.



Scheme 2 *Reagents and conditions*: i, HC≡CMgBr, THF, −78 °C to room temp.; ii, 9,10-dibromoanthracene, $(PPh_3)_2PdCl_2$, CuI, PPh_3, Et_3N, PhMe, 16 h, 89 °C; iii, 9-bromoanthracene, $(PPh_3)_2PdCl_2$, CuI, PPh_3, Et_3N, PhMe, 4 d, 89 °C

10	orange–red	2122, 2148	−47.2	100.1	106.6	0.88

[a] In Nujol mull. [b] In $CDCl_3$ solution. [c] Assigned by analogy with results of ^{13}C–^1H coupling experiments on $(1\text{-Np})_2Si(C\equiv CPh)_2$. [d] Quantum yield, Φ_f, determined in THF solution at an excitation wavelength of 370 nm with reference to 9,10-diphenylanthracene standard.

The UV–VIS spectra in CH_2Cl_2 solution [Fig. 1(A)] show intense absorption bands with fine structure most probably arising from transitions similar to those for anthracene. With respect to the bands in anthracene, those for **9** and **10** are red-shifted with increased extinction coefficients, the bathochromic shift being greater than for 9-ethynylanthracene.[14,15] The corresponding bands in the polymers are further red-shifted with respect to those in (i) **9** and **10**, (ii) 9,10-diethynylanthracene (λ_{max}, 356, 377, 423 nm),[16] and (iii) 9,10-bis(trimethylsilylethynyl)anthracene (λ_{max}, 391, 414, 439 nm). In addition, the polymers (except **6**) show a new broad absorption peak around 520 nm tailing off towards 575 nm, corresponding to an optical gap of *ca.* 2.2 eV. Monomers **9** and **10** show a similar new absorption occurring at lower wavelength than for the polymers (*e.g.* **9**: λ_{max} 451 nm). These properties suggest the presence of through-Si conjugation.

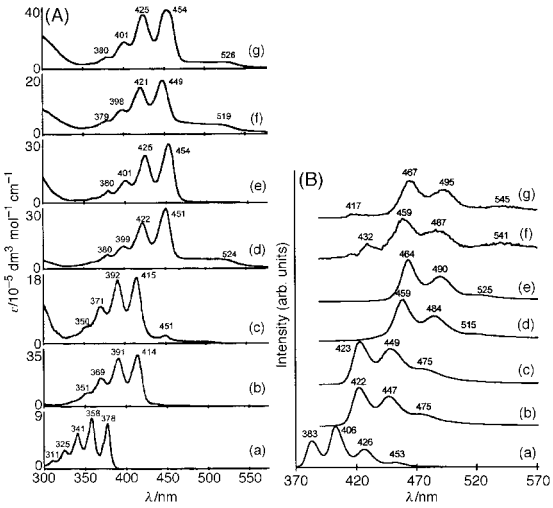

Fig. 1 (A) UV–VIS spectra in CH_2Cl_2 solution and (B) fluorescence spectra in THF solution at an excitation wavelength of 370 nm of (*a*) anthracene, (*b*) **10**, (*c*) **9**, (*d*) **7**, (*e*) **6**, (*f*) **3** and (*g*) **8**

Likewise, the fluorescence spectra [Fig. 1(B)] show a red-shift on going from anthracene to **9** and **10** and then a further such shift on going to the polymers, the apparent Stokes shifts[17] lying in the range 8–13 nm (*cf.* anthracene 5 nm). For the polymers, the low energy band at *ca.* 540 nm is probably due to excimer formation since (i) the relative intensity is concentration dependent, and (ii) anthracene compounds are known to dimerize on absorbing 320–400 nm light.[18] A picosecond time-resolved photoluminescence study of **7** (1 g l^{-1} in THF) at 532 nm showed maximum emission at 470 nm and a decay time constant of *ca.* 6 ns. Unlike polymers **3**, **7**, **8** and poly(*p*-phenyleneanthryleneethynylene)s,[19] **9** and **10** are highly emissive (*cf.* anthracene: Φ_f = 0.32[20]).

The sign and the magnitude of the real and imaginary parts of $\chi^{(3)}$ were determined for polymers **3**, **7** and **8** by solution Z-scan measurements[21] in the near-resonant region at 1064 nm (Table 3),§ the polymers being of sufficient chain length for the $\chi^{(3)}$ effects to be at a maximum.[22] High activity was found [in particular Im($\chi^{(3)}$) for **3** containing pentacoordinate Si], the value of Re($\chi^{(3)}$) being comparable to that determined in the resonant region at 590 nm for poly(phenyleneethynylenesilylene).[6] At 595 nm, a rather fast dominant relaxation time of *ca.* 20 ps was observed for the three polymers;¶ under non-resonant conditions the materials are expected to be considerably faster.

Table 3 Solution $\chi^{(3)}$ properties[a]

Si Coord. no.	Polymer	β/cm GW^{-1}	Im($\chi^{(3)}$)/esu	n_2/cm^2 W^{-1}	Re($\chi^{(3)}$)/esu
4	**7**	0.27	1.8×10^{-13}	5.0×10^{-15}	4.0×10^{-13}
5	**3**	1.20	8.0×10^{-13}	—	—
6	**8**	0.27	1.8×10^{-13}	5.0×10^{-15}	4.0×10^{-13}

[a] Z-scan measurements in $CHCl_3$ solution (50 g l^{-1}) at 1064 nm, pulse duration 140 ps, intensity 20 GW cm^{-2}.

In conclusion, the UV–VIS, photoluminescence and high $\chi^{(3)}$ properties of the polymers are consistent with extensive through-Si conjugation along the backbone.

Stereoselective radical aryl migrations from sulfur to carbon

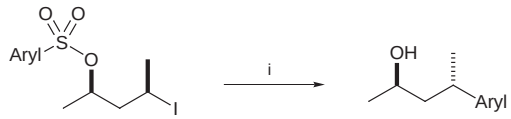
Armido Studer*† and Martin Bossart

Laboratorium für Organische Chemie, Eidgenössische Technische Hochschule, ETH-Zentrum, Universitätstrasse 16, CH-8092 Zürich, Switzerland

Stereoselective radical 1,5 aryl migrations from sulfur (in arenesulfonates) to carbon with diastereoselectivities of up to 14:1 are presented.

$C(sp^2)$–$C(sp^3)$ bonds occur in many natural products and new methods for their stereoselective formation are important. In the literature, there are only a very few methods for stereoselective $C(sp^3)$–aryl bond formation. The Heck[1] and Michael[2] reactions have to be mentioned at this point. Numerous examples of radical aryl transfers (C→C,[3] N→C,[4] O→C[5] and S→C[6]) have been published, however, we were surprised to find only three reports of stereoselective radical aryl migrations.[7] Herein we describe highly diastereoselective 1,5 aryl migrations from sulfur to carbon.

Motherwell, in his pioneering studies, has shown that intramolecular *ipso* substitution in arenesulfonates by aryl radicals is an efficient method for biaryl synthesis.[6] Based on our work on the stereoselective phenyl migration from Si to C[8] we decided to test arenesulfonates as possible 'arene sources' in the intramolecular stereoselective radical *ipso* substitution reaction. To this end, arenesulfonates **1–5** were prepared in moderate to good yields (50–90%) from (*like*)-4-iodopentan-2-ol and the corresponding commercially available sulfonyl chlorides in pyridine.[9] The racemic‡ iodo alcohol was easily prepared from (*meso*)-pentan-2,4-diol according to established procedures.[10] We were pleased to find that *ipso* substitution occurs smoothly (Scheme 1, Table 1). Slow addition of tin hydride to **1** in refluxing benzene under optimized conditions§ afforded the known[11] alcohol **6** in 76% yield with high selectivity (*u*:*l* = 13:1, entry 1). Both electron poor and electron rich arenes can be stereoselectively transferred. Thus, the *p*-fluorophenyl derivative **7** was obtained in 59% yield with a slightly lower selectivity (10:1, entry 2).¶ In the case of the electron rich anisyl and dansyl derivatives a lower yield was observed (**8**, 50%, 9:1; **10**, 52%, 11:1, entries 3 and 5). Even heteroarenes can be used in the *ipso* substitution as shown for the thienyl transfer (**9**, 74%, 9:1, entry 4). As a side product, the corresponding reduced (dehalogenated) sulfonate was always observed in these aryl migration reactions.



1–5 **6–10**

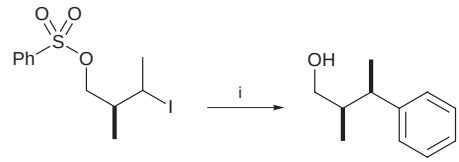
Scheme 1 *Reagents and conditions*: i, Bu_3SnH, AIBN, syringe pump, benzene (0.03 M)

Table 1 Stereoselective aryl transfer from sulfur to carbon

Entry	Sulfonate	Aryl	Product	Yield (%)	Ratio (*u*:*l*)[a]
1	**1**	Ph	**6**	76	13:1
2	**2**	4-FC_6H_4	**7**	59	10:1
3	**3**	4-$MeOC_6H_4$	**8**	50	9:1
4	**4**	thienyl	**9**	74	9:1
5	**5**	5-Me_2N-naphthyl	**10**	52	11:1[b]

[a] Determined by GC analysis. [b] Determined by ^1H NMR spectroscopy.

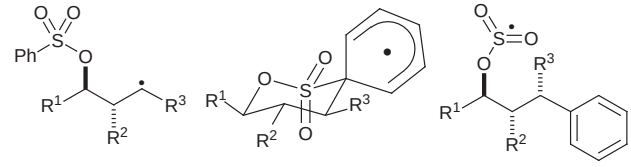
In order to study the 1,2-stereoinduction, sulfonate **11** was prepared as a 1:1 mixture of diastereoisomers. Aryl migration under analoguous conditions provided alcohol **12** in 49% yield (*l*:*u* = 7:1, Scheme 2). The relative configuration of the major isomer was assigned after oxidation (Swern) to the corresponding known[12] aldehyde.



11 **12** (49%, *l* : *u* = 7 : 1)

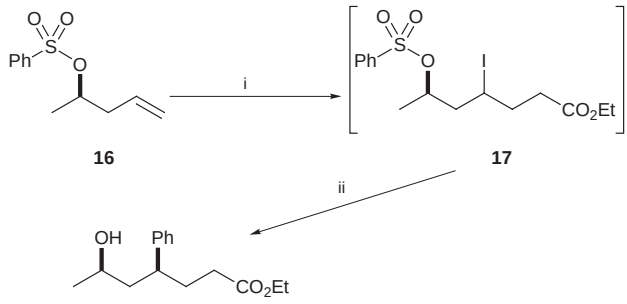
Scheme 2 *Reagents and conditions*: i, Bu_3SnH, AIBN, syringe pump, benzene (0.05 M)

From the stereochemical outcome of the reactions discussed above, we suggest the following model to explain the observed selectivities: radical **13** undergoes intramolecular *ipso* attack at the aryl group of the sulfonate to form cyclohexadienyl radical **14**. Products derived from 1,7 addition were not observed. We assume that the low energy transition state for the formation of **14** resembles a chair with the substituents in equatorial positions. Fragmentation (re-aromatization) then affords radical **15** which after SO_2 extrusion and reduction leads to the corresponding alcohol. It is not clear how fast the SO_2 extrusion process is by which the corresponding alkoxyl radical is formed. However, in the crude product mixture of the aryl migration reactions, we never observed sulfur-containing products derived from **15**; therefore, we assume that the SO_2 extrusion is faster than trapping of the intermediate radical **15** with Bu_3SnH.‖ According to this model, the observed 1,3- (→ *unlike* products) and 1,2-selectivity (→ *like* product) can be readily understood.



13 **14** **15**

As a first application of this method we studied a one pot reaction sequence where a radical addition reaction is followed by a stereoselective phenyl migration. Sulfonate **16** was prepared from the corresponding homoallylic alcohol and benzenesulfonyl chloride as described above (43%).[9] Radical acceptor **16** and ethyl iodoacetate (1.5 equiv.) were reacted under atom transfer conditions[13] in benzene [$Bu_3SnSnBu_3$ (10%), *hν*, 300 W sun lamp, 0.1 M] to afford iodide **17**, which after dilution (→ 0.05 M) was directly transformed upon slow addition of Bu_3SnH (1.8 equiv. over 7 h) and AIBN (0.25



18 (24%, *u* : *l* = 14 : 1)

Scheme 3 *Reagents and conditions*: i, $Bu_3SnSnBu_3$ (10%), *hν*, ICH_2CO_2Et, benzene (0.1 M); ii, Bu_3SnH, AIBN, syringe pump, benzene (0.05 M)

equiv.) to **18** (Scheme 3). Hydroxy ester **18** was isolated in 24% yield (unoptimized) as a 14:1 (*u*:*l*) mixture of diastereoisomers. The intermediate iodide **17** was formed with no selectivity, as shown in a separate experiment by ^{1}H NMR analysis of a sample taken after the iodine transfer reaction.

In summary, we have shown that the intramolecular *ipso* substitution is an efficient method for the stereoselective C(sp^2)–C(sp^3) bond formation. Since many sulfonyl chlorides are commercially available, a variety of aryl groups can be stereoselectively transferred to form products which are difficult to prepare by any other method.

We are grateful to Professor Dr D. Seebach for generous financial support and to Professor Dr D. P. Curran for helpful discussions.

‡ All the compounds described herein were prepared as racemic mixtures. In the schemes only one enantiomer is shown.

§ *General procedure*: Bu_3SnH (1.5 equiv.) and AIBN (0.3 equiv.) in benzene (0.8–1.2 M) were added over 7 h (syringe pump) to a refluxing solution of the iodide in benzene (0.03 M). After complete addition the reaction mixture was stirred under reflux for additional 30 min. The mixture was then allowed to cool to room temperature and MeLi (5 equiv.) was slowly added. After stirring for 30 min the reaction mixture was hydrolyzed with saturated aq. NH_4Cl. Extraction with Et_2O and washing of the organic phase with brine afforded, after drying ($MgSO_4$) and purification by flash column chromatography (SiO_2, pentane–Et_2O), the corresponding alcohol. (MeLi treatment is not neccessary but advantageous since the tin halide formed is transformed to the corresponding methylated compound which is easily removed.)

¶ The relative configurations of the alcohols **7–10**, and **18** were assigned by analogy to **6** based on the characteristic chemical shift of the hydrogen atom (of the major isomer) at the newly formed stereogenic center.

‖ We believe that the products are formed under kinetic control; however, Motherwell has shown that SO_2 extrusion is rather slow in his systems and that in the biaryl synthesis the entire process is probably reversible [ref. 6(*c*)]. Experiments to elucidate the mechanism are planned.

Stereoselective *O*-glycosylation reactions employing diphenylphosphinate and propane-1,3-diyl phosphate as anomeric leaving groups

Vankayalapati Hariprasad, Gurdial Singh*† and Isabelle Tranoy

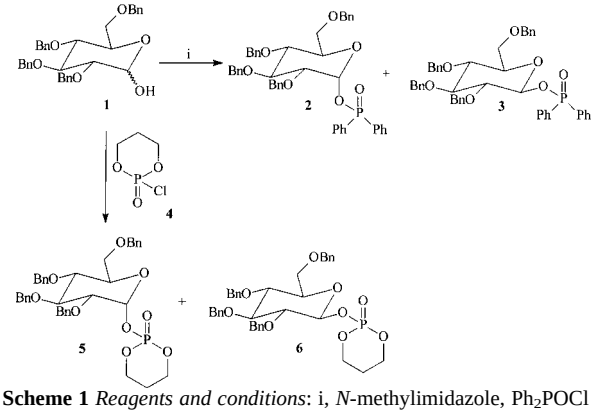
Department of Chemistry, University of Sunderland, Sunderland, UK SR1 3SD

Glycosidation of tetra-*O*-benzyl-D-glucose using diphenylphosphinate as the leaving group afforded β-*O*-linked glycosides as the major products, whilst the use of propane-1,3-diyl phosphate as the leaving group resulted in the exclusive formation of β-*O*-linked glycoside.

The essential role that glycoconjugates play in a large number of molecular processes is now well recognised. The impact of these complex molecules in biological processes such as neuronal development, fertilisation, proliferation of cells and the organisation into specific tissues is truly remarkable.[1] Furthermore in tumours there are changes in the carbohydrate structures found at the cell surface and these appear to be intimately involved with metastasis.[2] Carbohydrates are also important in inducing protective antibody response which is responsible for the protection of the organism during infection.[3] As a direct consequence of these properties there has been a resurgence of interest in the chemistry of carbohydrates by both chemists and biologists and thus an enormous amount of methodology has been developed for *O*-glycosylation.[4] In particular there have been a number of reports regarding glycosyl donors that have a phosphorus atom in the leaving group at the anomeric centre. Interest in this has arisen due to the fact that phosphorus compounds can be readily modified by several other atoms allowing the preparation of a range of leaving groups. The coupling reactions of glycosyl diphenyl phosphates, glycosyl diphenylphosphinimidates and glycosyl phosphoramidates have received much attention;[5] in all of these reports 1,2-*trans*-β-linked glycosides are formed with a stereoselectivity of *ca.* 3 : 1 in favour of the β-isomer. The employment of *S*-glycosyl phosphorodimidothioates has also been reported and affords 1,2-*cis*-glycosidic linkages,[6] and the use of dimethylphosphinothioate as glycosyl donors has also been investigated.[7]

In order to extend the scope of this methodology we decided to investigate the possibility of using the diphenylphosphinyl group for coupling of sugars with peptides/amino acids. Our attraction to this approach was derived from the fact that its use had been elegantly demonstrated for the coupling and *N*-protection of amino acids.[8] One of the major considerations in adopting this approach was the principle that one should be able to utilise the same coupling reagent for the synthesis of oligosaccharides and peptides, although in the former case we are forming a glycosidic bond rather than an amide bond; however the leaving group is the same in both reactions. In addition the employment of the diphenylphosphinate and propane-1,3-diyl phosphate groups[9] should result in the preparation of *O*-glycosides with improved stability, enabling ready isolation and storage of these compounds. Additionally we chose to study propane-1,3-diyl phosphate as the leaving group as this would provide a comparison of the effect of pK_a on leaving group ability. Furthermore the introduction of the cyclic phosphate group would allow us to assess the influence of steric requirements at the anomeric centre.

We chose to investigate the coupling at the anomeric centre of tetra-*O*-benzyl-D-glucopyranose. Our attraction to this was multi-faceted, with the major consideration being that there would be no participation by the C-2 substituent in the coupling reaction; furthermore, these processes had received scant attention in the literature and in addition we would have a flexible method that would allow the synthesis of *O*-glycopyranosides.



Scheme 1 *Reagents and conditions*: i, *N*-methylimidazole, Ph_2POCl

Treatment of tetra-*O*-benzyl-D-glucopyranose **1** with diphenylphosphinyl chloride and *N*-methylimidazole resulted in the formation of the phosphinates **2**‡ and **3** (ratio 10 : 1) in 95% yield (Scheme 1), which could be separated by column chromatography. However for ease we conducted all of our reactions with this anomeric mixture, which could be stored at −20 °C for 3–4 months without decomposition.[10] Similar treatment of **1** with the cyclic phosphoryl chloride **4** resulted in formation of the phosphates **5**‡ and **6**, which were inseparable by chromatography, in 65% yield, (ratio *ca.* 10 : 1).

We thus proceeded to study the reactions of the phosphinates **2** and **3** and also of the cyclic phosphates **5** and **6** with a range of nucleophiles (Scheme 2, Table 1). In the case of the reaction of n-butanol with pure **2** there was little difference in the stereochemical outcome of the reaction to that found using the anomeric mixture. In general the chemical yield was excellent, however the observed stereoselectivity in these cases was poor, being in the order of 3 : 1 in favour of the desired β-isomer. The stereochemistry of products was established by ^{1}H and ^{13}C NMR analysis. The ^{13}C NMR spectra were particularly useful as the β-isomers **7** had chemical shifts above δ 100 whilst the α-isomers **8** had a resonance at *ca.* δ 96,[11] allowing assignment of the newly formed stereocentre.

In the case where we employed propane-1,3-diyl phosphate as the leaving group the stereoselectivity was improved, with the β-isomer being the major compound in the case of oxygen nucleophiles. To our surprise the use of serine- and thereonine-derived nucleophiles resulted in the formation of **8** as the major isomer; this may be as a result of a hydrogen bonding interaction with the N–H, resulting in delivery from the α-face of the

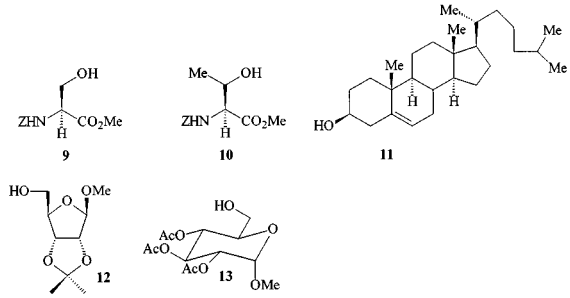
[a] All yields are for isolated products.



glucose. We were gratified to observe that we had attained our goal of excellent selectivity in the formation of **7** in the cases where we employed sugar-derived nucleophiles. This is particularly encouraing as we have a 2-*O*-benzyl protecting group which is non-participating in glycosylation reactions and would be expected to result in the formation of the α-glycosides. As a result of these findings one could, in principle, use *O*-benzyl protected sugars as starting materials and by changing the activating group of the glycosyl donor either desired stereoisomer can be obtained, thus alleviating the need for differentially protected starting sugars.

We have thus established that tetra-*O*-benzyl-D-glucopyranose can be converted into *O*-linked glycosides with high stereoselectivity in the cases where we employed propane-1,3-diyl phosphate as the leaving group, adding to the methodology available for the synthesis of complex carbohydrates.

We thank Professor R. Ramage (Edinburgh University) for helpful discussions and encouragement. We also thank the EPSRC for access to the mass spectrometry service at the University of Wales, Swansea (Director, Dr J. A. Ballantine).

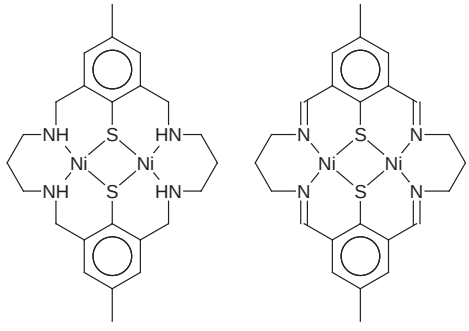
Reduction of a dinickel(II) dithiolate Schiff-base macrocyclic complex with sodium borohydride results in a 'bowl'-shaped dinickel(II) dithiolate amine macrocyclic complex which exhibits four separate one-electron redox processes.

The active site of the [Ni,Fe]-hydrogenases, metalloenzymes which catalyse $H_2 = 2H^+ + 2e^-$, has only recently been established to be dimetallic.[1] There has been considerable debate as to the oxidation state(s) of the nickel centre during the catalytic cycle.[2] As the overall reaction is a redox process it seems likely that either one or both of the doubly cysteinate-bridged metal ions, nickel and iron, change oxidation state during the catalytic cycle, although a third possibility, of the thiolate residues being non-innocent, has yet to be ruled out. Early studies of mononickel thiolate model compounds established many important chemical and electrochemical points,[2] and indicated that interactions with species such as carbon monoxide and hydrogen occur in the Ni(I) oxidation state.[2,3] In order to better mimic the dimetallic active site, studies are now probing the impact of the presence of a second metal ion, doubly bridged to the nickel ion by thiolate residues, on the properties of the complexes.[4–8] We have prepared a family of dinickel thiolate model complexes in which the two incorporated nickel(II) ions are bridged by thiolate(s): the polydentate ligands employed supply N_2S_2 or $N_2X_1S_1$ (X = O or N) coordination to each nickel ion.[5–7] Here we present the substantial effects on structure and electrochemistry of varying the nature of the nitrogen donors from imine to amine in a dinucleating macrocycle which provides N_2S_2 coordination environments to each of the pair of bound nickel(II) ions.

The red, diamagnetic, tetraimine macrocyclic complex **2** was prepared as reported (**CAUTION**: Perchlorate salts are potentially explosive and should therefore be handled with appropriate care).[6] The first of this new generation of tetraamine macrocyclic complexes, complex **1**, was prepared from **2** by sodium borohydride reduction in MeOH in air followed by an acid workup.[9] Red single crystals of **1** were obtained in 60–80% yield by recrystallisation of the crude product from MeCN by vapour diffusion of diethyl ether and an X-ray structure determination carried out.†‡ The nickel(II) ions in **1** have an N_2S_2 square planar environment (Fig. 1) as observed in the tetraimine complex **2**.[6] However, in complex **1** the overall shape of the complex is very different to that of **2**. Specifically, in addition to the folding of the two phenyl planes, which is observed in both complexes (angles between phenyl planes: 98.8 and 105.9° in **2** *vs.* 111.5° in **1**), the ligand in complex **1** exhibits a second folding at right angles to the first, which leads to a 'bowl'-shaped complex overall (Fig. 1) rather than the 'bowed' shape observed for **2**.[6] This additional fold is possible in **1** because of the change from conjugated trigonal imine groups in **2** to flexible tetrahedral amine groups in **1**, and this is readily seen by comparison of the distances of the nitrogen atoms from the plane of the respective phenyl rings (**2**, N 0.25–0.52 Å out-of-plane; **1**, N 1.10 and 1.11 Å oop). This leads



as $[Ni_2L1][ClO_4]_2$ **1** as $[Ni_2L2][ClO_4]_2$ **2**

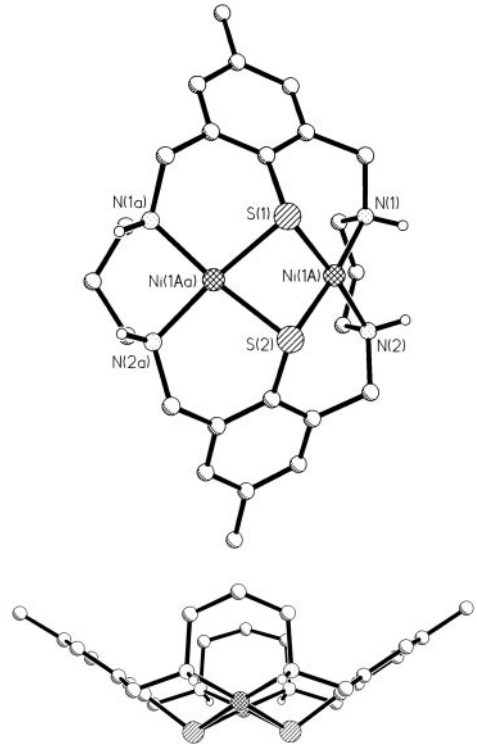


Fig. 1 Perspective diagrams of the cation of **1**, $[Ni_2L1]^{2+}$. No hydrogen atoms, except those on the amine nitrogen atoms, are shown. Selected bond lengths (Å) and angles (°): Ni(1A)–N(2) 1.951(4), Ni(1A)–N(1) 1.951(4), Ni(1A)–S(1) 2.1685(18), Ni(1A)–S(2) 2.177(2), N(2)–Ni(1A)–N(1) 88.72(18), N(2)–Ni(1A)–S(1) 174.37(14), N(1)–Ni(1A)–S(1) 96.45(14), N(2)–Ni(1A)–S(2) 96.62(14), N(1)–Ni(1A)–S(2) 174.22(14), S(1)–Ni(1A)–S(2) 78.13(8), C(15)–S(1)–Ni(1A) 107.3(2), C(15)–S(1)–Ni(1Aa) 107.3(2), Ni(1A)–S(1)–Ni(1Aa) 88.19(9), C(25)–S(2)–Ni(1Aa) 106.8(2), C(25)–S(2)–Ni(1A) 106.8(2), Ni(1Aa)–S(2)–Ni(1A) 87.76(12), where symmetry transformation a is $x, -y - 1/2, z$.

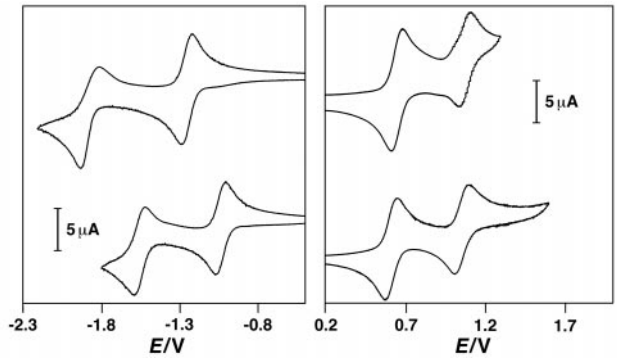

Fig. 2 Cyclic voltammograms of **1** (top) and **2** (bottom). Conditions: 1 mM complex in MeCN, 200 mV s^{-1}, 0.1 M NBu_4ClO_4 electrolyte, referenced to Ag/0.01 M $AgNO_3$ (the Fc/Fc^+ couple occurred at +0.13 V). Reduction potentials (V) for the dinickel complexes **1** (L*n* = L1) and **2** (L*n* = L2) respectively: $E_{1/2}$ $[Ni_2Ln]^{3+/4+}$ $+1.10^{QR}$, $+1.07^{QR}$; $E_{1/2}$ $[Ni_2Ln]^{2+/3+}$ $+0.69^{R}$, $+0.63^{R}$; $E_{1/2}$ $[Ni_2Ln]^{+/2+}$ -1.18^{R}, -1.01^{R}; $E_{1/2}$ $[Ni_2Ln]^{0/+}$ -1.86^{QR}, -1.46^{R}. K_d (**1**, ox) = 1.2×10^{-7}, K_d (**1**, red) = 1.1×10^{-11}, K_d (**2**, ox) = 3.6×10^{-8}, K_d (**2**, red) = 2.5×10^{-8}; ^{R} reversible, ^{QR} quasi-reversible.[14]

to the N_2S_2 mean planes of the two encircled nickel atoms intersecting at an angle much closer to 90° in **1** (124°) than is observed in **2** (146.3 and 146.4°), which in turn results in shorter Ni···Ni separations in **1** (3.14 and 3.15 Å in **2** *vs.* 3.02 Å in **1**): a shortening of the S···S separations (2.84 and 2.85 Å in **2** *vs.* 2.74 Å in **1**) is also observed in **1**, along with changes in the angles at sulfur (Fig. 1 caption).[6] The 'bowl' created by this new macrocyclic ligand distinguishes the two axial sites on the nickel atoms, producing an 'inside' and 'outside' surface which may lead to interesting features when reactivity studies are carried out. All of the amine hydrogen atoms point in the same direction (*cis*) with respect to the macrocyclic 'bowl'.

The cyclic voltammograms obtained for complexes **1** and **2** are shown in Fig. 2. In both cases a series consisting of four separate one-electron steps is readily identified: the dinickel(II) complexes can be oxidised in two steps or reduced in two steps. From EPR studies and comparisons with related $N_2X_1S_1$ (X = O or N) square planar dinickel thiolate complexes and dizinc complexes these processes are believed to be largely metal-centred (*i.e.* $Ni^{I}_2 \leftrightarrow Ni^{I}Ni^{II} \leftrightarrow Ni^{II}_2 \leftrightarrow Ni^{II}Ni^{III} \leftrightarrow Ni^{III}_2$).[6,7] The mixed valent forms of the complexes prepared by electrochemical oxidation or reduction exhibit axial EPR spectra consistent with metal-based Ni(III) or Ni(I) species respectively. In the former, *g* values are of the order of $g_{\|}$ 2.02 and $g_{\perp}$ 2.20 and in the latter, $g_{\|}$ 2.01 and $g_{\perp}$ 2.08. These values are consistent with those derived for the oxidised and reduced forms of the metal with equatorial tetraaza-donors. Precise data will be reported elsewhere.[7] Interestingly the potentials at which the two sequential oxidation processes of $[Ni^{II}_2Ln]^{2+}$ (*n* = 1 or 2) occur do not vary much with the change from imine to amine nitrogen donors. In contrast the potentials of the two sequential reduction processes of $[Ni^{II}_2Ln]^{2+}$ (*n* = 1 or 2) differ significantly: there is a substantial shift to more negative potentials on changing from imine to amine nitrogen donors, as expected given that this equates to a reduction of π-acceptor ability.[10] A second feature is that the two waves have a greater ΔE, corresponding to the mixed valent species $[Ni_2L1]^{+}$ being more stable with respect to disproportionation. It is curious that the dramatic differences in the reductive processes of **1** when compared with **2** are not reflected in the oxidative processes and we are further investigating this point.[7]

The successful synthesis of this tetraamine complex, **1**, represents a major step towards the production of stable dimetallic species suitable for redox and binding studies as the macrocycle is hydrolytically stable in contrast to the parent Schiff base. The nature and reactivity of the redox products are of considerable interest both in their own right and due to their relevance to the redox process catalysed by [Ni,Fe]-hydrogenases.[11] Further work is under way to explore these exciting aspects of our dinickel thiolates.[7]

This work was supported by grants from the University of Otago. We thank Professor W. T. Robinson (University of Canterbury) for the X-ray data collections and C. Beck (University of Sydney), Professor A. McAuley and Dr S. Subramanian (University of Victoria) for the EPR spectra.[7] This work is dedicated to Professor W. Roper on the occasion of his 60th birthday.

Notes and References

† Satisfactory C,H,N,S analyses were obtained for **1** and **2**. NMR (300 MHz, CD_3CN, ref. ext. TMS): **1** δ_H (298 K) 7.18 (4H, s), 3.64 (8H, d), 3.47 (4H, d), 2.92 (4H, dd), 2.47 (4H, d), 2.27 (6H, s); **2** δ_H (343 K) 9.48 (4H, s, br), 7.54 (4H, s), *ca*. 4.50 (4H, br), *ca*. 4.31 (4H, br), 2.46 (6H, s), 2.24 (2H, d, br), 1.64 (2H, br).

‡ *Crystal data* for **1**: $C_{28}H_{40}Cl_2N_6Ni_2O_{10}S_2$, dark red square block, crystal dimensions 0.40 × 0.35 × 0.13 mm, orthorhombic, *Pnma*, a = 16.825(3), b = 11.190(2), c = 19.160(4) Å, U = 3607.3(12) $Å^3$, μ = 1.37 mm^{-1}. Data were collected at 149 K on a Bruker SMART diffractometer using graphite-monochromated Mo-Kα, λ = 0.71073 Å. A total of 26349 reflections were collected in the range $3 < 2\theta < 53°$ and the 3900 independent reflections were used in the structural analysis after a semi-empirical absorption correction had been applied. The structure was solved by direct methods (SHELXS-86),[12] and after resolution of severe disorder problems (electronic supplementary information: see http://www.rsc.org/suppdata/cc/1998/2131) the refinement on F^2 against all data (SHELXL-97)[13] converged satisfactorily to $R1$ = 0.068 [for $3036F > 4\sigma(F)$; $wR2$ = 0.191 and goodness of fit = 1.14 for all 3900 F^2; 390 parameters; 230 restraints; +0.70/−0.57 $eÅ^{-3}$]. Organisation of long aliphatic monocarboxylic acids in β-cyclodextrin channels: crystal structures of the inclusion complexes of tridecanoic acid and (*Z*)-tetradec-7-enoic acid in β-cyclodextrin

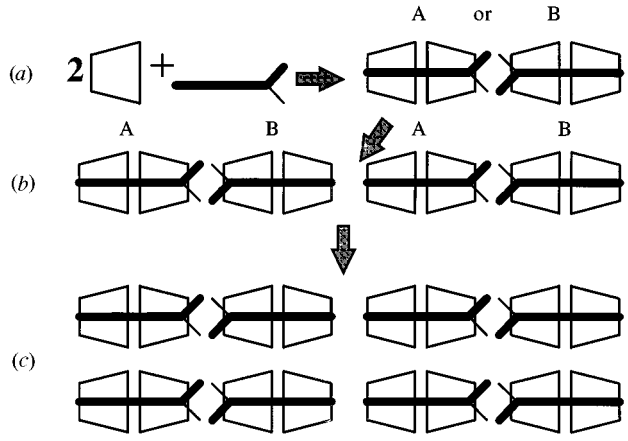
Stella Makedonopoulou,[a] Irene M. Mavridis,*[a]† Konstantina Yannakopoulou[a] and John Papaioannou[b]

[a] *Institute of Physical Chemistry, National Centre for Scientific Research 'Demokritos', Aghia Paraskevi 153 10, Athens, Greece*
[b] *Laboratory of Physical Chemistry, University of Athens, Panepistimiopolis 157 71, Greece*

In the crystalline state, infinite channels of β-cyclodextrin dimers host infinite arrays of self associated linear aliphatic monocarboxylic acids, thus enclosing the hydrophilic carboxy ends inside the hydrophobic channels.

Non-bonding interactions like H-bonds and hydrophobic interactions comprise the main routes for the assembly of supermolecules,[1a,b] entities detectable as distinct from the constituent molecules. Since the non-covalent bonding interactions are at least an order of magnitude weaker than covalent bonds, stable supermolecules require a large number of such interactions, *i.e.* the presence of a large area of complementary surface[1c,d] in order to compensate for the entropic loss due to organisation. This requirement is fulfilled in the formation of host–guest assemblies. Moreover, if the supermolecules possess groups capable of aggregation *via* non-covalent bonds, it is possible to synthesise supramolecular assemblies. Thus the latter can be generated by introducing groups with a tendency for specific interactions into strategic parts of the supermolecules.[2]

The systems reported here, which involve inclusion of one molecule of a long aliphatic mono-carboxylic acid (tridecanoic acid **1** and (*Z*)-tetradec-7-enoic acid **2**) into two molecules of β-cyclodextrin (β-CD), combine host–guest interactions and supramolecular synthon association of both host and guest to form supramolecular assemblies. They were designed to form three-component pseudo-rotaxanes and subsequent stacking of those into infinite channels. Indeed, such systems were prepared through precipitation from aqueous solutions of β-CD after the addition of a two-fold excess of the aliphatic acids at room temperature. The crystallographic analyses‡ revealed that the above simple process allowed the formation of systems exhibiting many levels of supramolecular organisation.



Scheme 1 Schematic representation of (*a*) the self-assembly of two β-cyclodextrin molecules and an aliphatic acid molecule into [3]pseudorotaxanes, (*b*) the formation of a channel supramolecular array and (*c*) supramolecular arrays of higher order by channel association

Firstly, β-CD forms dimers *via* H-bonds between the O3 secondary hydroxy groups of the two monomers, as is common in β-CD inclusion complexes.[3] Each molecule of aliphatic acid threads into the long cavity of a β-CD dimer to form a [3]pseudorotaxane [Scheme 1(*a*)]. The aliphatic guests span the entire length of the β-CD dimer with the carboxylic groups slightly protruding from one primary face and the terminal methyl groups protected at the other end. Threading of two cyclodextrin units (α-CD, permethylated α-CD) onto one long aliphatic molecule has also been observed[4] in aqueous solutions and inter-cyclodextrin H-bonds have been invoked to account for the thermodynamic parameter measurements in solution studies of polypseudorotaxanes.[5]

At a second level, the supramolecular units align along the crystallographic *c* axis to form channels (Fig. 1). The crystallographic asymmetric unit contains one [3]pseudorotaxane in

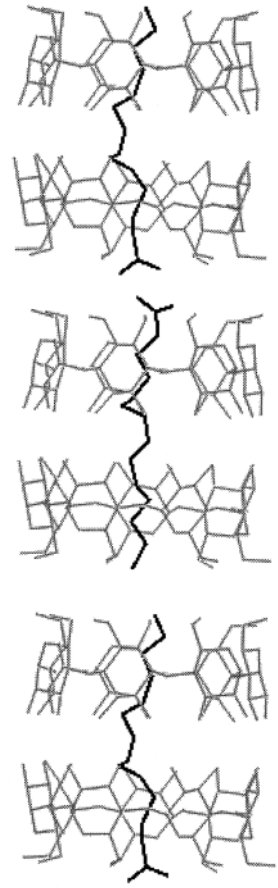


Fig. 1 Channel formation in the β-cyclodextrin complex of (*Z*)-tetradec-7-enoic acid. The two terminal guest molecules have the A orientation and the middle one the B orientation.

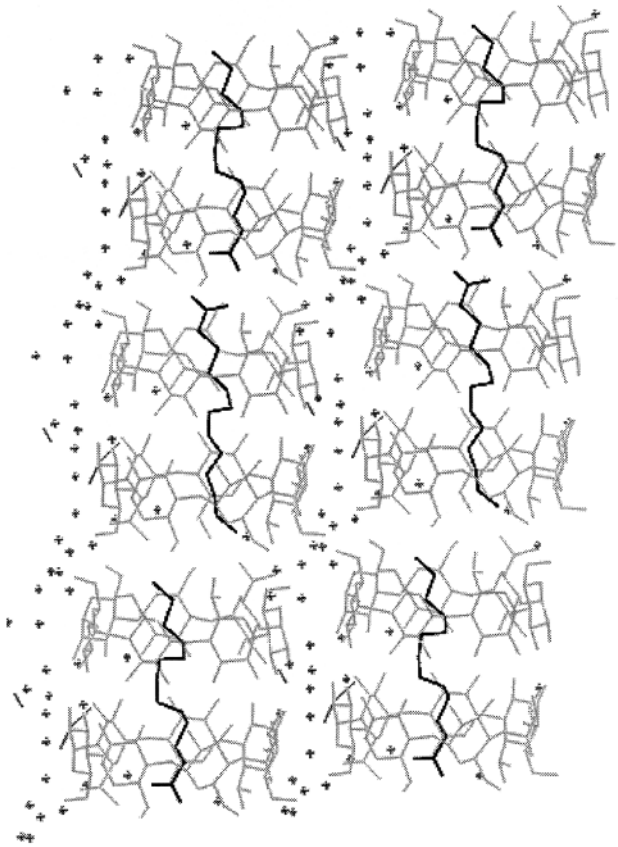

Fig. 2 Organisation in three-dimensions of channels of β-cyclodextrin–tridecanoic acid complexes

which the aliphatic acid is disordered over two orientations (A and B) of almost equal probability (occupation factors for orientations A and B refined to: A = 52%, B = 48% for **1**, and A = 51%, B = 49% for **2**; considered as 50% each from the accuracy of the present data). Therefore, a β-CD dimer encloses one molecule of the acid in orientation A and the adjacent dimer along the channel in orientation B in order to form conventional carboxylic dimers [Scheme 1(*b*)]. The observed distances between the adjacent carboxylic oxygen atoms of orientations A and B are O1A···O1B = 2.50 and OA2···OB2 = 2.74 Å for **1** and OA1···OB1 = 2.70 and O2A···O2B 2.71 Å for **2**. The overall formation of the channel resembles an infinite poly-pseudorotaxane where the β-CD molecules are not threaded onto a polymer chain but onto an linear assembly of aliphatic carboxylic acids held together by intermolecular interactions. In addition, the β-CD host assists in the formation of the supramolecular assembly *via* H-bonds between two primary hydroxy groups of consecutive dimers (O···O distances 2.93 and 2.98 Å for **1** and **2** respectively) that further strengthen the channel.

The supramolecular organisation extends to a third level, since the channels associate *via* H-bonds along the **a** and **b** axes [Scheme 1(c), Fig. 2]. The H-bonding interactions are either through direct association of primary and secondary hydroxy groups (five H-bonds at O···O distances 2.77–2.89 and 2.76–2.91 Å for **1** and **2** respectively) or through intervening water molecules.

Determination of the unit cells of crystals of β-CD complexes of aliphatic mono-acids with 12–16 carbon atoms show that they are isomorphous with the complexes reported here, showing that they also form [3]pseudorotaxanes aligned in channels. In contrast, β-CD complexes of aliphatic di-acids with 10–16 carbon atoms also form [3]pseudorotaxanes but they do not align in channels,[6] preferring to interact with the polar environment. Therefore, in the case of the monocarboxylic acids we observe the remarkable fact that the carboxylic groups prefer to be enclosed inside the hydrophobic environment of the channel rather than interact with the aqueous environment in the periphery of the β-CD dimers, as in the case of the di-acids. We believe that what forces them inside the channel is the presence of the terminal methyl groups of the guest in the other primary face of the β-CD dimers. Due to the presence of the solvent in the lattice, these methyl groups would be exposed to the aqueous environment if channels were not formed. On the other hand, although the carboxylic groups prefer the polar environment, they can be stabilised by self-association into carboxylic dimers. The formation of the latter corresponds to an overall non-polar moiety[7] that can stay inside the hydrophobic channel.

Summarising, we have achieved the construction of an infinite channel structure, based on specific features of simple building blocks, with aliphatic mono-carboxylic acids threaded through two β-CD molecules. The tendency of cyclodextrins to form inclusion complexes and simultaneously to self-associate and form dimers is combined with the tendency of the guest molecules for self association through a very well known synthon, the carboxylic dimer. It is shown that the channel forming ability of similar systems is directly related to the degree of hydrophobicity/hydrophilicity of the end groups of the guest emerging from the primary faces, due to one more variable, the solvent, that influences the packing of the building blocks. Currently, we are exploiting the properties of the systems in order to design transitions between the packing modes[8] of dimeric β-CD complexes *via* the interplay of the aliphatic chain length and the nature of the end groups.

Synthesis of a novel supported solid acid BF_3 catalyst

Karen Wilson and James H. Clark*

Green Chemistry Group, Department of Chemistry, University of York, Heslington, York, UK YO1 5DD. E-mail: jhc1@york.ac.uk

A novel and active form of supported boron trifluoride has been prepared and the active sites identified.

Tightening environmental legislation on the production of waste during homogeneously acid catalysed reactions has led to a demand for heterogenised systems that will aid recovery of the catalyst and minimise pollution. BF_3 is widely used as a Lewis acid catalyst in many organic reactions, including alkylation, acylation, polymerisation, isomerisation and addition reactions,[1] and may be used directly from the gas phase, or complexed with an organic or inorganic ligand (*e.g.* $BF_3{\cdot}OEt_2$ or $BF_3{\cdot}H_3PO_4$). Recovery of boron from the reaction however results in the formation of large amounts of waste, which on an industrial scale is environmentally unacceptable.

The use of a heterogeneous BF_3 system would offer ease of catalyst recovery and reuse, and minimise the production of waste currently formed during BF_3 recovery. However a suitable replacement supported system must also exhibit activities/selectivities comparable to the existing homogeneous route. To date previous attempts to produce oxide supported BF_3 has focused on the use of gaseous BF_3.[2–4] In this paper we report the synthesis, characterisation and reactive properties of a novel mesoporous SiO_2 supported solid acid catalyst prepared using liquid BF_3 precursors. The activity of the catalyst towards the alkylation of phenol with oct-1-ene to form octyl phenyl ether or octylphenol (important in the production of lubricants) was examined.

A range of SiO_2 supported BF_3 catalysts (4 mmol g^{-1} loading) were prepared from $BF_3(H_2O)_2$ (Aldrich 96%) and $BF_3{\cdot}OEt_2$ (Aldrich 99%) precursors. Mesoporous SiO_2 (K100-Merck) of surface area 310 m^2 g^{-1} was dried for 24 hours at 300 °C, then stirred under a N_2 atmosphere with a mixture of the precursor diluted in 100 ml of ethanol or toluene at 20 °C or reflux respectively. The catalyst slurry was stirred for 2 hours, then dried slowly on a rotary evaporator at 50 °C.

Characterisation of the acid sites present on the surface was performed by recording DRIFT spectra following titration of the supported BF_3 catalysts with pyridine as shown in Fig. 1.

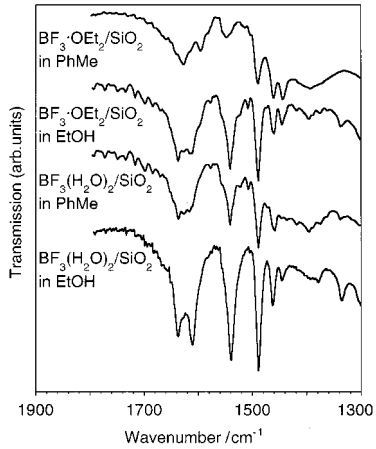

Fig. 1 DRIFTS following pyridine titration of 4 mmol g^{-1} BF_3/SiO_2 catalysts prepared using $BF_3(H_2O)_2$ and $BF_3{\cdot}OEt_2$ precursors in ethanol or toluene

These show that all the catalysts exhibit both Lewis and Brønsted acidity, as indicated by the absorption bands at 1445 and 1461 cm^{-1}, (Lewis sites), and those at 1638 and 1539 cm^{-1} (Brønsted sites). The remaining bands at 1611 and 1489 cm^{-1} are assigned to pyridine bound at either Lewis or Brønsted sites. There is a striking difference in the nature of the acid sites depending on catalyst preparation, with the catalyst prepared from the $BF_3(H_2O)_2$ precursor in ethanol exhibiting the most intense Brønsted bands. Brønsted acidity in solid acid catalysts normally arises from polarised $^{\delta-}O–H^{\delta+}$ sites. The observation of strong Brønsted acidity following attachment of a Lewis acid centre to an oxide support has been reported in other systems,[4,5] and might be attributed to polarisation of surface hydroxyl groups *via* an inductive effect of the electronegative F atoms on BF_3. However what is remarkable in this instance is how the Brønsted acidity varies with catalyst preparation, with the catalysts prepared in ethanol exhibiting higher concentrations of Brønsted acid sites than those prepared in toluene.

The origin of the acid sites on the ethanol prepared $BF_3(H_2O)_2/SiO_2$ catalyst was investigated using thermogravimetric analysis coupled with evolved gas FTIR (TGIR), which allows molecules desorbing from the catalyst during thermal analysis to be identifed by their vibrational spectrum. Fig. 2 shows the thermal analysis results for supported $BF_3(H_2O)_2$ and $BF_3{\cdot}OEt_2$ catalysts which had been prepared in ethanol. Heating both catalysts above 100 °C results in significant weight loss and the observation of ethanol desorption in the IR. However the differential mass lost indicates that the ethanol desorption temperature from $BF_3(H_2O)_2/SiO_2$ is 10 °C higher than from $BF_3{\cdot}OEt_2/SiO_2$, and approximately twice the amount of ethanol is evolved. This corresponds to approximately 4 and 2.5 mmol g^{-1} of ethanol present on each catalyst respectively. The uptake of short chain alcohols has been used as an indication of the strength and concentration of Brønsted acid sites on zeolites.[6] These results therefore suggest that $BF_3(H_2O)_2/SiO_2$ possesses a higher coverage of stronger Brønsted acid sites compared to $BF_3{\cdot}OEt_2/SiO_2$.

Further heating beyond 400 °C results in an additional weight loss which is accompanied by the evolution of HF from the

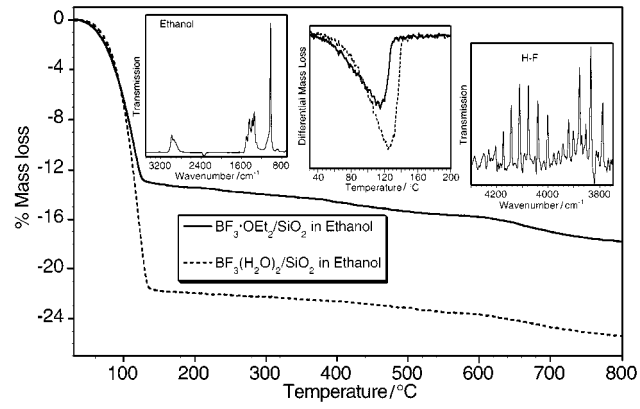

Fig. 2 TGIR comparing 4 mmol g^{-1} $BF_3(H_2O)_2/SiO_2$ and $BF_3{\cdot}OEt_2/SiO_2$. IR spectra recorded during decomposition reveal the evolution of ethanol and HF. The differential mass loss is also shown to indicate the peak ethanol desorption temperature.

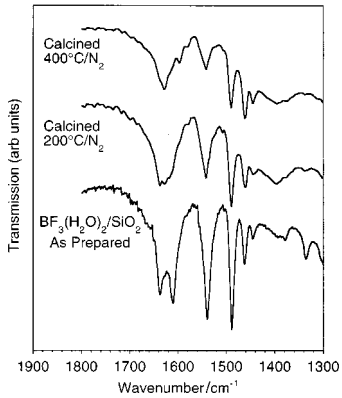

Fig. 3 DRIFTS following pyridine titration of 4 mmol g^{-1} $BF_3(H_2O)_2/SiO_2$ after calcination to 200 °C and 400 °C under N_2. All spectra were recorded at 20 °C.

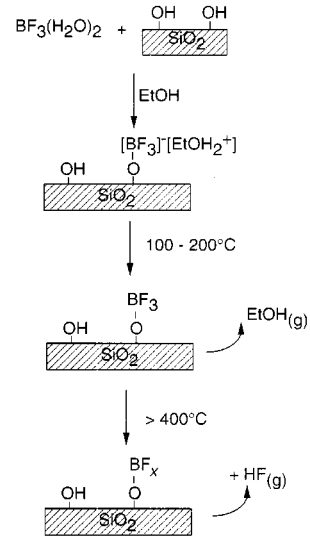
catalyst. Corresponding DRIFTS/pyridine titrations of catalysts calcined to 200 and 400 °C under N_2, shown in Fig. 3**,** indicate that the Brønsted sites are gradually lost as the calcination temperature is increased.

While BF_3 alone is a Lewis acid, it is often used catalytically when bound to organic ligands to form strong proton donating complexes.[1] The evolution of ethanol at 120 °C coupled with the loss of Brønsted acidity indicates that Brønsted acid sites in the $BF_3(H_2O)_2/SiO_2$ catalyst may arise from the binding of ethanol to supported BF_3 centres resulting in the formation of a $[SiOBF_3]^-[EtOH_2]^+$ complex. Further evidence in support of this model comes from ^1H MAS NMR of the as prepared catalyst which show resonances at 1.343, 4.009 and 8.160 ppm which are consistent with CH_3, CH_2 and OH_2^+ of protonated ethanol respectively.[6] Previous studies have reported that ligand exchange between $BF_3{\cdot}OEt_2$ and ethanol results in the formation of $H^+[BF_3OEt]^-$ complexes.[7] However, to form the protonated ethanol complex proposed in this model interaction with a more protic BF_3 complex is required, *e.g.* $BF_3(H_2O)_2$, which can exist as $[H_3O]^+[BF_3OH]^-$.[1] The trend in Brønsted acidity observed between $BF_3{\cdot}OEt_2$ and $BF_3(H_2O)_2$ precursors can thus be understood in these terms.

Desorption of ethanol from the $BF_3(H_2O)_2/SiO_2$ catalyst following 200 °C calcination lowers the number of Brønsted sites titratable by pyridine (Fig. 3). We atttribute those remaining to the polarisation of surface hydroxyl groups on the support by the BF_x centres. By 400 °C dehydroxylation of the support further reduces the number of Brønsted sites leaving predominantly Lewis acid character, as evidenced by the DRIFTS bands at 1627 and 1462 cm^{-1} which are attributed to the BF_x sites. The evolution of HF above 400 °C observed by TGIR indicates that these BF_x groups start to decompose above this temperature, and by 600 °C no titratable acid sites remain indicating complete decomposition of the BF_x centres. Likewise BET measurements on calcined $BF_3(H_2O)_2/SiO_2$ catalysts reveal the surface area is maintained at 258 m^2 g^{-1} up to 200 °C, indicating that the BF_3 sites are stable to this temperature. An increase in surface area to 266 m^2 g^{-1} is observed on calcining to 400 °C, consistent with the decomposition of BF_3. It should be noted that due to outgassing procedures prior to BET measurements changes in surface area due to ethanol desorption cannot be observed. We believe that these spectroscopic results can be summarised by the model presented in Scheme 1.

The catalytic activity of these supported BF_3 samples was tested using the reaction of oct-1-ene with phenol (performed at 85 °C using 0.05 M of each reactant, in 100 ml of 1,2-dichloroethane with 1 g of supported BF_3 catalyst). Table 1 shows the phenol conversion and selectivities towards octyl phenyl ether obtained after 23 hours reaction time. It is clear that the activity of the $BF_3(H_2O)_2/SiO_2$ catalyst prepared in ethanol is superior to the other samples. The activity can thus be correlated with the



Scheme 1

Table 1 Phenol conversion and selectivities towards octyl phenyl ether after 23 h reaction for the different catalysts

Catalyst	Phenol conversion (%)	Ether selectivity (%)
$BF_3(H_2O)_2/SiO_2$ (EtOH)	30	61
$BF_3(H_2O)_2/SiO_2$ recycled	6	97
$BF_3(H_2O)_2/SiO_2$ ($PhCH_3$)	4	78
$BF_3{\cdot}OEt_2/SiO_2$ (EtOH)	3	85
$BF_3{\cdot}OEt_2/SiO_2$ ($PhCH_3$)	< 1	92

number and strength of Brønsted acid sites identified on these catalysts using TGIR.

Following reuse of $BF_3(H_2O)_2/SiO_2$ samples, a decrease in conversion and selectivity towards ring alkylation products is observed relative to the fresh catalyst. Preliminary characterisation of used catalyst, by DRIFTS and pyridine titration, indicates the nature of the acid sites remains essentially unchanged. The loss of activity on recycling the catalyst may result from organic residue deposited on the catalyst during reaction causing pore blocking and/or poisoning of active sites.

In conclusion, we have synthesised a novel form of supported boron trifluoride which is easy to prepare and handle, shows unusually high Brønsted acidity which can be controlled by activation temperature, and exhibits considerable catalytic activity.

We thank the EPSRC for funding the project, EPSRC/RAEng for a Clean Technology Fellowship (to J. H. C.), and colleagues at York and the University of Newcastle Chemical and Process Engineering Department for helpful discussions.

Syntheses and structures of $W_2(\mu\text{-}Cl)_3Cl_6^-$ and $W_2(\mu\text{-}Cl)_2Cl_8^{2-}$, new d^2–d^2 confacial and edge-sharing bioctahedral ditungsten compounds, and a convenient synthesis of $W_2(\mu\text{-}Cl)_3Cl_6^{2-}$

Vladimir Kolesnichenko, Dale C. Swenson and Louis Messerle*

Department of Chemistry, The University of Iowa, Iowa City, IA 52242, USA. E-mail: lou-messerle@uiowa.edu

$(NR_4)W_2Cl_9$ and $(NR_4)_2W_2Cl_{10}$, prepared by addition of NR_4Cl (R = alkyl) to $(WCl_4)_x$ powder in CH_2Cl_2, have confacial [W=W, 2.689(1) Å] and edge-sharing bioctahedral [W=W, 2.792(1) Å] structures, respectively, as $NBnEt_3^+$ salts, and convert with added NR_4Cl to $(NR_4)_2W_2Cl_9$ and $(NR_4)WCl_6$ and eventually $(NR_4)_2WCl_6$; $(NR_4)W_2Cl_9$ can be converted to $(NR_4)_2W_2Cl_{10}$ by NR_4Cl at −30 °C.

High symmetry confacial [$M_2(\mu\text{-}L)_3L_6$, D_{3h}; L = ligand] and edge-sharing [$M_2(\mu\text{-}L)_2L_8$, D_{2h}] bioctahedral complexes are known for many transition metals and are of considerable importance for understanding metal–metal single and multiple bonding.[1] The effect of orbital population on M–M distance can be understood by studying isostructural compounds with various d-electron counts. Confacial bioctahedral congeners with differing d-electron counts are known for few metals (*e.g.* Re,[2] W). For tungsten, $W_2(\mu\text{-}Cl)_3Cl_6^{3-}$ (d^3–d^3; one of the first[3] metal–metal bonded compounds to be recognized[4] as such) and d^2–d^3 $W_2(\mu\text{-}Cl)_3Cl_6^{2-}$ have been reported.[5,6] The W–W distance in the former, which has been studied theoretically,[7] is a short 2.409(7)–2.4329(6) Å,[6,8,9] (depending on cation), and increases[6] by 0.12 Å upon oxidation to $W_2(\mu\text{-}Cl)_3Cl_6^{2-}$. While there are many preparations[10] of $W_2(\mu\text{-}Cl)_3Cl_6^{3-}$, few are known for the dianion;[5,6,11] $W_2(\mu\text{-}Br)_3Br_6^{2-}$ is also known.[12]

We recently developed new syntheses of powdered and crystalline $(WCl_4)_x$ and showed that its structure was a linear polymer of edge-sharing bioctahedra with alternating short (double bond) and long (no bond) W···W separations![13] The unusually reactive powder form, prepared from Sn reduction of WCl_6 in $ClCH_2CH_2Cl$, reacts with NR_4Cl to give the new chloroditungstates $W_2(\mu\text{-}Cl)_2Cl_8^{2-}$ **1** and $W_2(\mu\text{-}Cl)_3Cl_6^-$ **2** as well as $W_2(\mu\text{-}Cl)_3Cl_6^{2-}$ **3**. We report synthetic and structural details.

The reaction of NR_4Cl (R_4 = $BnEt_3$, $BnBu_3$, Bu_4) with $(WCl_4)_x$ leads to scission of dinuclear fragments, disproportionation, and then comproportionation depending on stoichiometry and temperature. At 25 °C, reaction of $(WCl_4)_x$ with one equiv. of $NBnEt_3Cl$ (a cation which facilitates product separation) in CH_2Cl_2 leads to $(NBnEt_3)_2(W_2Cl_9)$ [**3**; 96% isolated yield, eqn. (1)]† and $(NBnEt_3)WCl_6$. The mixture is comproportionated by $NBnEt_3Cl$ to $(NBnEt_3)_2WCl_6$ [94% yield, eqn. (1)]. UV–VIS spectra of products matched literature data.[11,14]

$$3\ WCl_4 \xrightarrow[-(NR_4)WCl_6]{3\ NR_4Cl} \underset{\mathbf{3}}{(NR_4)_2[W_2(\mu\text{-}Cl)_3Cl_6]} \xrightarrow{3\ NR_4Cl} 3\ (NR_4)_2WCl_6 \quad (1)$$

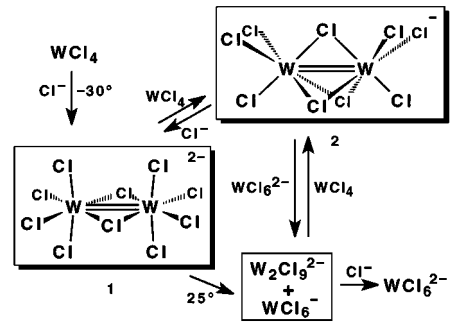
The reaction between $(WCl_4)_x$ and $NBnEt_3Cl$ in CH_2Cl_2 at −30 °C yields $(NBnEt_3)_2[W_2(\mu\text{-}Cl)_2Cl_8]$ **1** which crystallizes along with undissolved $(WCl_4)_x$. Upon warming to 25 °C, **1** redissolves and disproportionates to **3** and $(NBnEt_3)WCl_6$ [eqn. (2)], thus establishing that **1** is an intermediate in eqn. (1). With additional $(WCl_4)_x$, **3** and $(NR_4)WCl_6$ comproportionate to emerald green $(NBnEt_3)[W_2(\mu\text{-}Cl)_3Cl_6]$ [**2**; eqn. (2)]. Compound **2** can be prepared conveniently‡ in one step (90% isolated yield) by combining $(WCl_4)_x$ with 0.5 equiv. $NBnEt_3Cl$ in CH_2Cl_2 at 25 °C, and can be converted§ back to **1** (95% isolated yield) at −30 °C by $NBnEt_3Cl$ in CH_2Cl_2; isolation is possible because of the low solubility of the $NBnEt_3^+$ salt. We believe that **1** and **2** have not been observed in previous studies[5,6,14] because they disproportionate in solution (**1**) or in the presence of Cl^- (**2**). Compound **2** is reduced to **3** by either $(NBnEt_3)_2WCl_6$ or Cp_2Fe in CH_2Cl_2. Scheme 1 summarizes the principal transformations.

$$3\ \underset{\mathbf{1}}{(NR_4)_2[W_2(\mu\text{-}Cl)_2Cl_8]} \longrightarrow 2\ \underset{\mathbf{3}}{(NR_4)_2[W_2(\mu\text{-}Cl)_3Cl_6]} + 2\ (NR_4)WCl_6$$

$$\downarrow 6\ WCl_4$$

$$6\ (NR_4)[W_2(\mu\text{-}Cl)_3Cl_6] \quad (2)$$

$$\underset{\mathbf{2}}{}$$



Scheme 1

The syntheses of **1**, **2**, and **3** are facilitated by the use of $(WCl_4)_x$ powder.[13] Reactions of $(WCl_4)_x$, as prepared by reduction of WCl_6 with red phosphorus, $W(CO)_6$, or Sb,[13] with NR_4Cl proceed more slowly and lead to lower purity materials because the lower solubility of these $(WCl_4)_x$ materials results in an excess of NR_4Cl in the early stages of the reactions.

Single crystals of $(NBnEt_3)_2[W_2(\mu\text{-}Cl)_2Cl_8]\cdot 3CH_2Cl_2$ **1** were obtained from −35 °C CH_2Cl_2 solution. The solid-state structure¶ of the centrosymmetric ditungstate portion of **1** (Fig. 1) consists of an edge-sharing bioctahedron with a W(1)–W(1A) distance of 2.792(1) Å, a W(1)–Cl(1)–W(1A) angle of 71.88(6)°, and a Cl(1)–W(1)–Cl(1A) angle of 108.12(6)°. The crystallographically independent axial Cl(2) and Cl(3) in each bioctahedral hemisphere are bent away from Cl(3A) and Cl(2A) with Cl(2)–W(1)–W(1A) and Cl(3)–W(1)–W(1A) angles of

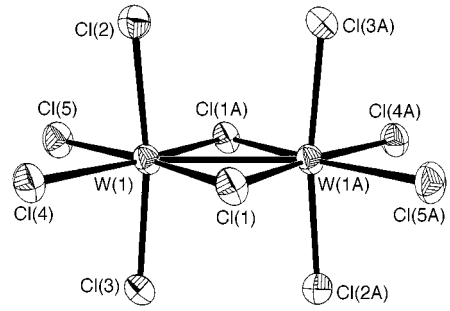


Fig. 1 Thermal ellipsoid plot of the molecular structure of the ditungsten anion portion of **1**

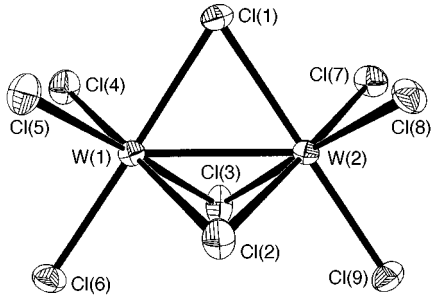

Fig. 2 Thermal ellipsoid plot of the molecular structure of the ditungsten anion portion of **2**

94.38(6)° and 93.98(6)°, respectively, and a Cl(2)···Cl(3A) nonbonded distance which is appreciably closer [3.131(3) Å] than twice the Cl van der Waals (VDW) radius of 1.70–1.90 Å.[15]

The anion in **1** is similar to that of the W≡W bonded portion of $(WCl_4)_x$, and can be formally viewed as the scission of that edge-sharing bioctahedral portion of the polymeric structure[13] and addition of two Cl^- endcaps. The W≡W distance in crystalline $(WCl_4)_x$ is 2.688(2) Å, with W–Cl–W bridge angles of 69.4(2)° and bent-back axial Cl [W–W–Cl(axial), 94.99(12)°]. The axial Cl in each bioctahedral hemisphere of $(WCl_4)_x$ are also closer [3.085(10) Å] than twice the Cl VDW radius. There is no similarity between the structures of **1** and W_2Cl_{10} [*i.e*. $W_2(\mu\text{-}Cl)_2Cl_8$] which has a long W···W separation of 3.814(2) Å and a Cl_μ–W–Cl_μ angle of 81.5(1)°.[16]

The only other Group 6 $M_2(\mu\text{-}Cl)_2Cl_8^{2-}$ compound is edge-sharing bioctahedral $(PPh_4)_2[Mo_2Cl_{10}]$,[17] with no Mo–Mo bond (Mo···Mo, 3.80 Å). The reason(s) for the substantial differences between $Mo_2(\mu\text{-}Cl)_2Cl_8^{2-}$ and $W_2(\mu\text{-}Cl)_2Cl_8^{2-}$ **1** are presently unknown, though the difference in degree of metal–metal bonding parallels that for $Mo_2(\mu\text{-}Cl)_3Cl_6^{3-}$ and $W_2(\mu\text{-}Cl)_3Cl_6^{3-}$.

Single crystals of $(NBnEt_3)[W_2(\mu\text{-}Cl)_3Cl_6]$ **2** were obtained from cooled (−35 °C) $CH_2Cl_2/CHCl_3$ solutions. Single-crystal X-ray diffractometry‖ confirmed that the anion portion of **2** possesses a confacial bioctahedral structure (Fig. 2) with a W(1)–W(2) distance of 2.696(3) Å and an acute W(1)–Cl(μ)–W(2) average angle of 66.6(1)° which is smaller than the bridge angle of 70.53° for an idealized confacial bioctahedron. The W–W distance and W–Cl_μ–W angles are consistent with a formal W(1)–W(2) double-bonding ($a_1'^2e'^2$) interaction.

The W–W distance in $W_2(\mu\text{-}Cl)_3Cl_6^{n-}$ (n = 3, 2, 1) thus increases from 2.409(7) to 2.4329(6) Å for n = 3, to 2.540(1) Å for n = 2, and to 2.696(3) Å for n = 1 (compound **2**), as would be expected from σ-bond weakening with increasing nuclear charge and/or the decrease in formal bond order from 3 to 2.5 to 2.[6] The UV–VIS data for **2** correspond to those reported[11] for $(Bu_4N)_2(W_4Cl_{17})$, whose structure was not determined. The analytical accuracy, as the authors noted, did not rule out an alternative formulation such as $NBu_4(W_2Cl_9)$. It is interesting that $W_4Cl_{17}^{2-}$ was reported[11] to react with excess Cl^- to give products including $W_2Cl_9^{2-}$, as does **2**.

The mechanism of formation of **1**, **2**, and **3** from chloride attack on $(WCl_4)_x$, the solid-state and solution magnetochemistry of **1** and **2** (which exhibits a surprisingly low moment of ⩽ 1.3 μ_B in solution by the Evans method), theoretical studies using the GAMESS program,[18] and the reactivity of the new ditungsten(IV) perchloroanions are under investigation.

The support of Nycomed, Inc. and the University of Iowa Biosciences Initiative Research Program is gratefully acknowledged, as are the useful comments of a reviewer.

Notes and References

† Synthesis of **3**: a stirred mixture of 0.500 g (1.535 mmol) WCl_4 and 0.350 g (1.537 mmol) $NBnEt_3Cl$ in 10 mL CH_2Cl_2 converted in 10 min from a gray suspension to a deep purple-brown suspension with microcrystals, and eventually to a deep blue-purple precipitate in a green-brown solution. After several days, the precipitate was filtered off, washed with CH_2Cl_2 until the wash became light blue-purple, and dried *in vacuo*. Weight = 0.525 g (96% yield). The UV–VIS spectrum (CH_2Cl_2) matched those of known $W_2Cl_9^{2-}$ salts. Anal: W, 33.7; Cl, 29.01. Calc. for $(NBnEt_3)_2W_2Cl_9$: W, 34.32; Cl, 29.78%. The supernatant was cooled to −30 °C for one day and a first crop of the brown crystalline product was isolated by filtration for analysis and dried *in vacuo*; weight 0.110 g (37% yield) $(NBnEt_3)WCl_6$. Anal: W, 31.2; Cl, 36.43. Calc. for $(NBnEt_3)WCl_6$: W, 31.22; Cl, 36.12%.

‡ Synthesis of **2**: a stirred mixture of WCl_4 (1.00 g, 3.07 mmol), $NBnEt_3Cl$ (0.350 g, 1.54 mmol), and CH_2Cl_2 (15 mL) gave a deep blue-green solution after 10–30 min. After one day, the deep blue-green solution was filtered and rotary-evaporated to a viscous oil, which crystallized to 1.218 g dark emerald-green product (90% yield). Anal: W, 41.1; Cl, 35.58. Calc. for $(NBnEt_3)W_2Cl_9$: W, 41.83; Cl, 36.29%. UV–VIS, λ/nm (ε/dm^3 mol^{-1} cm^{-1}): 650 (825), 530 (370), 360 (shoulder), and 305 (22600). MS (FAB, negative ion mode, m/z): 687 (M^+, base peak for $W_2Cl_9^-$ isotope pattern).

§ Synthesis of **1** *via* Cl^- addition to $W_2Cl_9^-$: pre-cooled (−30 °C) solutions of 0.052 g (0.228 mmol) $NBnEt_3Cl$ in 2 mL of CH_2Cl_2 and 0.200 g (0.228 mmol) $(NBnEt_3)(W_2Cl_9)$ in 4 mL of CH_2Cl_2 were mixed. Deep purple-brown microcrystals formed immediately. After aging at −30 °C for 1 day, the crystals were filtered off cold, washed with cold CH_2Cl_2 (*ca*. 5 mL) and dried *in vacuo*. Weight = 0.257 g (95% yield). Anal: W, 30.8. Calc. for $(NBnEt_3)_2W_2Cl_{10}\cdot CH_2Cl_2$: W, 30.85%.

Colloid-roughened surfaces as templates for the heterogeneous nucleation of lepidocrocite γ-FeO(OH) nanoparticles

Marc Nagtegaal, Ram Seshadri and Wolfgang Tremel*

Institut für Anorganische und Analytische Chemie, Johannes Gutenberg-Universität Mainz, Becher Weg 24 D-55099 Mainz, Germany. E-mail: tremel@indigotrem1.chemie.uni-mainz.de

Lepidocrocite γ-FeO(OH) crystals can be specifically nucleated by sulfonate-terminated SAM/gold surfaces from solutions at room temperature; previously 'roughening' the gold surface through the tethering of gold colloids increases yields.

Extensive studies by Rieke and coworkers[1] have established the propensity of sulfonate modified surfaces (of polymers and of self-assembled monolayers (SAMs) of alkylsilyl compounds on silicon) to heterogeneously nucleate the formation of FeO(OH) crystallites from Fe^{III} solutions. We have been interested in extending this chemistry to the use of SAMs of ω-substituted alkylthiols on gold as substrates for such heterogeneous nucleation. This would simultaneously permit greater freedom for manipulation of the surface chemistry of the nucleating substrate, facilitate atomic force microscopic (AFM) investigations and most importantly, permit the use of surface plasmon spectroscopy (SPS) to monitor *in situ*, the accretion of material on the substrate. In the course of these investigations, we have been able to unambiguously confirm that only on sulfonate-terminated substrates is there significant nucleation of FeO(OH) (in the γ modification) at room temperature from Fe^{III} solutions that are otherwise stable to hydrolysis.

Primarily the influence of the sulfonate head-group on the nucleation of FeO(OH) is acidity; nucleation usually being carried out from acidic solutions at pH < 3. Under these conditions, of the typical ω substituents used by us (carboxylates, phosphonates, *etc*.) only the sulfonate group is ionised, permitting its binding to Fe^{III} ions. Size is not a consideration since the O–O distances in SO_3 groups are about 20% smaller than O–O distances in the FeO_6 octahedra that are the principal structural motifs in the different FeO(OH). These points have been discussed extensively by Reeves and Mann who have examined binding between different tetrahedral anions and the iron oxides.[2] Epitaxis between substrate and crystallite is thus not an issue. A strategem to increase the number of nucleation sites on the substrate would then be to chemically tether (using alkyl dithiols) nanometre-sized gold colloids to the substrates in order to microscopically roughen their surfaces. This has previously proved useful in stabilising aragonite.[3]

Gold-coated glass substrates were placed overnight in 1 mM solutions of 1,12-dodecanedithiol (DDDT) in ethanol. After this, they were dipped in toluene sols of gold colloids† for 2 min. Placing these substrates in solutions of iron(III) nitrate resulted in nearly no deposition of material. FeO(OH) does in fact nucleate heterogeneously on bare gold substrates (because the high conductivity and surface energy of gold permits ions that attach initially to be discharged) so we could conclude that the lack of a deposit on the untreated colloid-tethered surface arises from the continued presence of amphiphiles (left over from the colloid preparation). Further treatment of the colloid-covered gold surfaces through exposure to 1 mM ethanolic solutions of the sodium salt of 3-mercaptopropane sulfonic acid (MPS) results in their being able to nucleate the deposition of thin films of orange–brown powders from the Fe^{III} solutions.‡ The use of MPS/colloid/DDDT/gold architectures resulted in significantly greater amounts of the orange–brown powders being deposited than when only MPS/gold substrates are used.

As at least eighteen different crystalline compounds are formed in the Fe–O–H system,[4] it is important to unambiguously establish the nature of the orange brown powders. This could be achieved using grazing-incidence X-ray diffraction, combined with Rietveld profile fitting. Fig. 1 displays experimental and fitted X-ray diffraction profiles,§ acquired with a fixed grazing angle of $\Omega = 0.5°$. The lepidocrocite structure[5] was used in the fit, refining scale, profile and preferred orientation parameters. The various parameters of gold (peaks indicated using asterisks) as a second phase were also refined. Below the fitted profile is a simulation of crystalline lepidocrocite with the *hkl* indices marked.

Fig. 2(a) displays tapping mode AFM images¶ of the gold substrate to which colloids were tethered with DDT. The image is displayed at a magnification wherein it is difficult to distinguish the individual colloid particles, but is necessary for comparison with the other images. The crystals were nucleated under identical conditions on two different substrates, (b) MPS/gold and (c) MPS/colloid/DDDT/gold. The crystals are lath-like. On the MPS/gold substrate, they have typical dimensions of 100 nm × 20 nm in the plane of the substrate. On the colloid modified surface (c) the density of crystals is larger presumably as a result of a greater nucleation,‖ and the crystals are simultaneously bigger, extending to about 200 nm. The

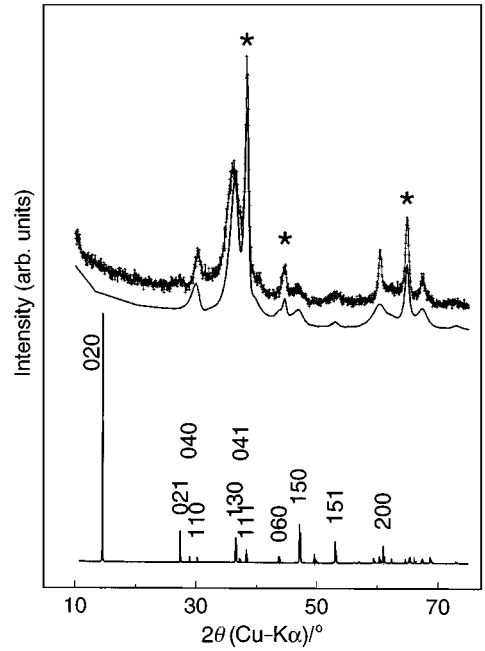

Fig. 1 Experimental and fitted grazing incidence xrd pattern of the FeO(OH) crystals on the MPS/colloid/DDDT/gold assembly. The two profiles have been slightly offset for clarity. The asterisks mark the peaks due to the gold substrate. At the bottom is a simulation of isotropic crystalline lepidocrocite with the *hkl* indices marked.

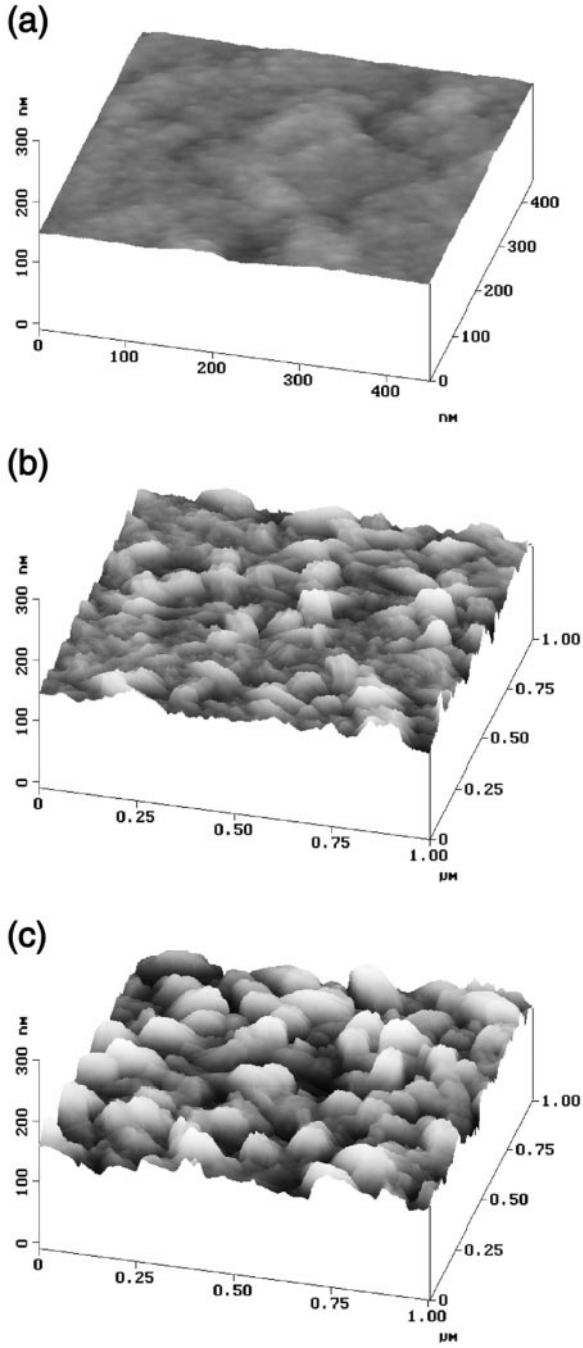

Fig. 2 AFM images of (a) the colloid/DDDT/gold substrate, (b) lepidocrocite crystals grown on MPS/gold and (c) on MPS/colloid/DDDT/gold. The shading is indicative of the height with black referring to the bottom of the scanned image, through gray to white referring to a relative height of 150 nm.

morphology is slightly altered, being a little more rounded. Lepidocrocite is layered,[4] and possesses sheets of FeO_6 double octahedra. An analysis of the structure does not reveal any mode of epitaxy between the O atoms in the structure and a model sulfonate terminated thiol SAM. The layering however suggests that the expected growth direction of the crystals with reference to the substrate would be the direction normal to the sheets namely [010]. The 0*k*0 lines are supressed in the XRD pattern, rather than being enhanced, as one would expect in this case. This arises from two causes. The first is that employing the small grazing Ω angles used in the measurements, one would expect that the incident X-ray will not sample very many 0*k*0 layers. The other is that the pattern clearly displays crystalline correlation lengths that are *hkl* dependent; the peaks with a finite *h* index are more narrow while along those with finite *k*, the peaks are broad, reflecting the poor crystallinity along this direction.

We thank Dr B. Baumgartner of STOE & Cie., Darmstadt for the grazing incidence X-ray diffraction data, and Professor H.-J. Butt for providing access to his AFM facilities. The gold used here was part of a generous gift from Degussa, Hanau, and the dithiol was provided by Mr J. Küther.

Notes and References

† Gold colloids were prepared in two-phase toluene/water systems following the procedure of Brust *et al*.[6] Details on the formation and nature of colloid-tethered gold surfaces can be found in ref. 3.

‡ FeO(OH) crystallisations were performed by placing the substrates in polypropylene flasks containing 2 mM solutions (freshly prepared) of iron(III) nitrate for a period of 48 h at room temperature.

§ X-Ray diffraction data were acquired on a STOE θ–2θ diffractometer and were treated using the XND Rietveld program (version 1.16, J.-F. Bérar, ESRF, Grenoble, France, 1997).

¶ Tapping mode AFM images were acquired using a Nanoscope IIIa, employing Si cantilevers.

‖ From the present data, we infer that higher initial nucleation results in greater deposition on the colloid-roughened surfaces. That the FeO(OH) crystals are simultaneously larger suggests that the small crystals formed initially could anneal into larger ones. Initial X-ray measurements indeed suggest that crystallinity increases (linewidths narrow) with time even on keeping deposited Fe oxides and oxide–hydroxides at room temperature.

Enantioselective synthesis of an axially chiral 1,7-naphthyridine-6-carboxamide derivative having potent antagonist activity at the NK_1 receptor

Yoshinori Ikeura,[a] Takenori Ishimaru,[b] Takayuki Doi,[a] Mitsuru Kawada,[c] Akira Fujishima[a] and Hideaki Natsugari*[a]†

[a] Pharmaceutical Research Division, [b] Discovery Research Division and [c] Technology Development Department, Takeda Chemical Industries, Ltd., 2-17-85, Jusohonmachi, Yodogawa-ku, Osaka 532-8686, Japan

A new and highly potent NK_1 antagonist, (*aR*,9*R*)-3 [(*aR*,9*R*)-7-[3,5-bis(trifluoromethyl)benzyl]-8,9,10,11-tetrahydro-9-methyl-5-(4-methylphenyl)-7*H*-[1,4]diazocino[2,1-*g*][1,7]naphthyridine-6,13-dione], was atropdiastereoselectively synthesized in good yield by cyclization of the chiral intermediate 6b.

In our preceding papers,[1] we described the discovery[1a,b] and stereochemical characterization[1c] of the potent NK_1 antagonist[2] **1** {*N*-[3,5-bis(trifluoromethyl)benzyl]-7,8-dihydro-*N*,7-dimethyl-5-(4-methylphenyl)-8-oxo-1,7-naphthyridine-6-carboxamide}. Since **1** has a tertiary carboxamide group at the sterically hindered C_6-position, it exhibits two notable stereochemical properties (Fig. 1). First, the *trans* and *cis* amide conformational isomers (rotamers) of **1** are separable at room temperature;[1a] the compound isolated by conventional work-up is the *trans*-isomer (*trans*-**1**), while the thermodynamically unstable *cis*-isomer (*cis*-**1**) can also be isolated as a minor product by careful separation procedures. Both isomers interconvert and reach an equilibrium state of a *ca.* 7:1 ratio in solution. Second, *trans*-**1** and *cis*-**1** exist as a mixture of two separable and stable enantiomers [(*trans*,*aR*)-**1**, (*trans*,*aS*)-**1** and (*cis*,*aR*)-**1**, (*cis*,*aS*)-**1**, respectively][3] arising from restricted rotation around the C_6–C(O) bond (Fig. 1).[1c] Such stereoisomerism due to restricted rotation is known as atropisomerism among biaryl compounds and some sterically hindered aromatic carboxamides.[4] The atropisomers, (*trans*,*aR*)-**1** and (*trans*,*aS*)-**1**, which were separated by preparative high performance liquid chromatography (HPLC) using a chiral column,‡ have significant stability in solution; *e.g.* they were not interconverted in DMSO at 37 °C for 16 h and underwent racemization only after storage at 50 °C for *ca.* 70 h. Among these four isomers of **1**, the active isomer was shown to be (*trans*,*aR*)-**1**. From a practical perspective, however, separation of the active isomer (*trans*,*aR*)-**1** is difficult, and further studies using *trans*-**1** as a racemate would encounter difficulties, especially at the stage of pharmaceutical development.

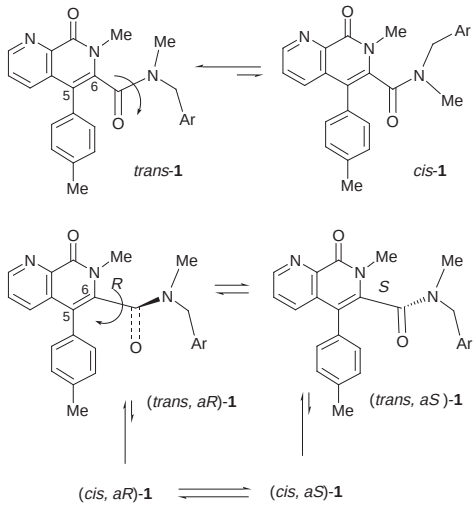

Fig. 1 The stereoisomers of **1**

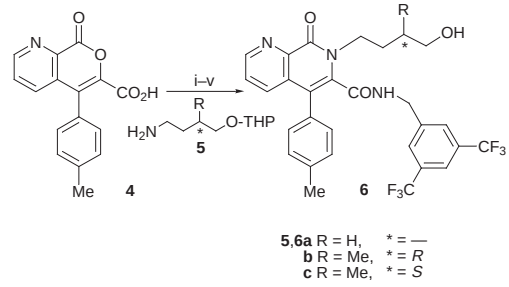
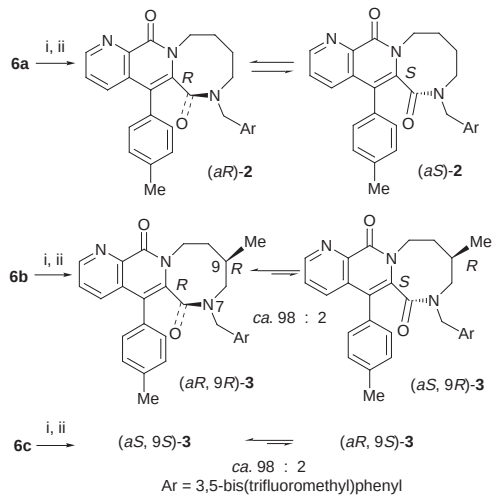
Thus, in the search for new compounds with an improved stereochemical profile, we designed cyclic analogues of **1**, and analogues with an eight-membered ring (*e.g.* **2** and **3**) (Scheme 2) became target molecules based on the results of conformational studies on *trans*-**1**. Here we describe the atropdiastereoselective synthesis of the potent NK_1 receptor antagonist (*aR*,9*R*)-**3** {(*aR*,9*R*)-7-[3,5-bis(trifluoromethyl)benzyl]-8,9,10,11-tetrahydro-9-methyl-5-(4-methylphenyl)-7*H*-[1,4]-diazocino[2,1-*g*][1,7]naphthyridine-6,13-dione} by cyclization of the chiral intermediate **6b**.

General synthesis of tricyclic analogues of **1** (**2** and **3**) is outlined in Schemes 1 and 2. The key intermediates **6a–c** [7-(hydroxyalkyl)-1,7-naphthyridine-6-carboxamide derivatives] were prepared from the pyrano[3,4-*b*]pyridine-6-carboxylic acid **4**.[5] First, the acid **4** was amidated with 3,5-bis(trifluoromethyl)benzylamine *via* the acid chloride to provide the amide. Treatment of the amide with the appropriate amines **5a–c**,[6] followed by deprotection with TsOH and dehydration with DBU gave **6a–c** (Scheme 1). Cyclization of **6a–c** was accomplished by mesylation followed by treatment with NaH in THF to give **2** and **3** in good yields (Scheme 2).

For the atropisomers in the cyclic analogues of **1** (**2** and **3**), we initially supposed that the flipping of this new ring would be too rapid to enable the separation of stable isomers at room temperature.[7] However, chiral HPLC analysis of **2** showed two peaks at room temperature, and **2** was separated by preparative HPLC using a chiral column to give the atropisomers (*aR*)-**2** and (*aS*)-**2**, which have opposite $[\alpha]_D$ values (+45.6 and −41.3, respectively) and show considerable stability in solution; *e.g.* they are gradually interconverted in DMSO to *ca*. 70% ee at 37 °C over 40 h and undergo racemization after storage at 50 °C for *ca.* 60 h. These results indicate that **2** exists as a racemate, making development as a clinical candidate difficult. Thus, we



Scheme 1 *Reagents and conditions*: i, $SOCl_2$, THF, reflux, 1.5 h; ii, 3,5-bis(trifluoromethyl)benzylamine, Et_3N, THF, room temp., 0.5 h (71% from **4**); iii, **5**, THF–MeOH, room temp., 16 h ; iv, DBU, toluene–MeCN, reflux, 1 h; v, TsOH, MeOH, room temp., 0.5 h



Scheme 2 *Reagents and conditions*: i, MsCl, Et_3N, THF, 0 °C, 0.5 h; ii, NaH, THF, reflux, 1 h [isolated yields from **6**: 79% for **2**, 69% for (*aR*,9*R*)-**3** and 66% for (*aS*,9*S*)-**3**]

next designed the C_9 methyl analogues of **2** (*i.e.* **3**) as target compounds, expecting asymmetric induction from the C_9 chiral center to obtain the desirable chirality arising from atropisomerism, and achieved the stereoselective synthesis of the atropisomer by cyclization of an intermediate with a chiral methyl group, **6b** (Scheme 2). The product ratio of the atropisomer (*aR*,9*R*)-**3** to its isomer (*aS*,9*R*)-**3** was *ca.* 98:2, and a single recrystallization step gave (*aR*,9*R*)-**3** with > 99% de. The minor isomer (*aS*,9*R*)-**3**, with 98.6% de, was isolated as a powdery substance by repeated preparative HPLC at 0 °C using the mother liquor. Both atropisomers, (*aR*,9*R*)-**3** and (*aS*,9*R*)-**3**, were found to be gradually interconverted in solution to reach the same equilibrium state [(*aR*,9*R*)-**3**:(*aS*,9*R*)-**3** = *ca.* 98:2] (*e.g.* in EtOH at 37 °C in *ca.* 60 h).

Single crystal X-ray analysis of (*aR*,9*R*)-**3**[8] revealed that the N_7–C_8–C_9–C_{10} moiety in the eight-membered ring is disposed above the plane of the adjacent 1,7-naphthyridine ring, while the amide oxygen (C_6=O) is below the ring (*i.e. aR* stereochemistry). The relative spatial orientation of the C_9 methyl group and the *N*-[3,5-bis(trifluoromethyl)benzyl] group in (*aR*,9*R*)-**3** was shown to be such that the two groups are disposed in opposite directions. This is presumed to be a thermodynamically stable form which is important for the high atropdiastereoselectivity in the cyclization of **6b**.

The enantiomer of (*aR*,9*R*)-**3** [*i.e.* (*aS*,9*S*)-**3**], with > 99% de, was similarly obtained by the cyclization of the corresponding enantiomeric intermediate **6c** followed by a single recrystallization step (Scheme 2).

Compound (*aR*,9*R*)-**3** exhibited excellent NK_1 antagonistic activities§ both *in vitro* (IC_{50} = 0.45 nM) and *in vivo* (ED_{50} = 4.3 μg kg^{-1}). The structure–activity relationships in the isomers of **3** [for the atropisomer (*aS*,9*R*)-**3**: IC_{50} = 20 nM and ED_{50} = 26 μg kg^{-1}¶ and for the enantiomer (*aS*,9*S*)-**3**: IC_{50} = 340 nM and ED_{50} = > 300 μg kg^{-1}] indicate that the stereochemistry around C_{5a}–C_6(O)–N_7–CH_2Ar is the important factor for receptor recognition.

In summary, the axially chiral compound (*aR*,9*R*)-**3** and its enantiomer (*aS*,9*S*)-**3** were atropdiastereoselectively synthesized by cyclization of the chiral intermediates **6b** and **6c**, respectively. Compound (*aR*,9*R*)-**3** exhibited excellent NK_1 antagonistic activities both *in vitro* and *in vivo*.

The authors thank Mr T. Tanaka for conformational analysis, Ms F. Kasahara for NMR analysis, Mr I. Kamo for *in vivo* screening and Mr Y. Tajima for *in vitro* screening.

Dramatic rate acceleration in titanocene catalyzed epoxide openings: cofactors and Lewis acid cocatalysis

Andreas Gansäuer*† and Harald Bluhm

Institut für Organische Chemie der Georg-August-Universität, Tammannstr. 2, D-37077 Göttingen, Germany

High synthetic efficiency concerning yield and catalytic turn-over in intermolecular C–C bond forming reactions of radicals derived from epoxides can be achieved by means of hydrogen bonding with cofactors or by Lewis acid cocatalysis.

Catalytic reactions emerging from stoichiometric transformations have become increasingly important over the last three years.[1,2] We have developed protonation of carbon–titanium and oxygen–titanium bonds as an alternative to silylation for achieving catalytic turnover.[3] This has allowed highly diastereoselective pinacol couplings and chemo- and regioselective reductive openings of epoxides. Here we describe an efficient method for the addition of radicals derived from epoxides to α,β-unsaturated carbonyl compounds yielding synthetically important δ-lactones, hydroxy esters and hydroxy nitriles in high yield, with low catalyst loading in short times.

Under the standard conditions for the reductive opening of epoxides with hydrogen atom donors[3a] dodec-1-ene oxide gives only 21 and 40% yield of the addition products to methyl acrylate (**7**) and acrylonitrile (**6**), respectively, after 72 h in the presence of 5 mol% Cp_2TiCl_2 (Scheme 1). Moreover, the products are contaminated with polymeric material derived from the radical acceptor. We reasoned that low yields and turnovers are due to product inhibition. Compound **6** and MeOH formed after lactonization seemed to be able to efficiently complex at least one of the titanocene species in the catalytic cycle. Similar problems were noticed in reactions of higher substituted epoxides as well as in addition reactions to *tert*-butyl acrylate. Since this type of product inhibition could be a general problem in the *de novo* design of catalytic electron transfer reactions with densely functionalized molecules, a widely applicable solution is of interest for this rapidly expanding field.

Two conceptually different and novel approaches towards binding of the reaction products and thus catalyst activation seemed to be at hand. Since alcohols are formed during the course of the reaction, complexation of the products by hydrogen bond formation with a suitable acceptor, *e.g.* a sterically demanding amine, should be possible.[4] On the other hand a Lewis acid stronger than Cp_2TiCl_2[5] should be complexed by the reaction products and thus allow for catalyst activation and thus higher turnover.[6] Table 1 summarizes the results of our initial optimization studies. Other Lewis acids not included, *e.g.* $AlCl_3$, gave vastly inferior results.

Gratifyingly, using Zn as stoichiometric reductant[7] led to a distinct acceleration of the reaction. It seems that $ZnCl_2$ formed during the course of the reduction of Cp_2TiCl_2 acts as a Lewis acid strong enough to bind MeOH and restore catalyst activity. This effect is even more pronounced when 1 equiv of $ZnCl_2$ is added to the reaction mixture. The same effect could be observed in addition reactions to *tert*-butyl acrylate. Interestingly in the reaction of **1** with **3**, lactone **7** is isolated as the sole product of the reaction in high yield after aqueous work-up when Zn is used as stoichiometric reductant. A detailed kinetic analysis reveals formation of 85% of **6** after 3 h. Subsequently, $ZnCl_2$-initiated cyclization occurs. Thus, it seems that $ZnCl_2$ first allows for efficient formation of **6** and then activates the nitrile strongly towards intramolecular attack by the hydroxy group. The resulting imino ester is hydrolyzed during work-up. Compared to other methods of lactone formation from hydroxy nitriles[8,9] our reaction conditions are clearly milder and a wider variety of functional groups is tolerated. Also the product is formed in a one step procedure without the necessity of isolating and purifing any intermediates.[10] However, with Mn as reductant and $ZnCl_2$ as an additional Lewis acid only **6** is formed after 8 h. Thus, $MnCl_2$ seems to coordinate the nitrile group without allowing activation towards cyclization. Accordingly, the beneficial role of $ZnCl_2$ involves prevention of product inhibition by complexation of the hydroxy group. The utility of our approach was further demonstrated by the fact that catalyst loading in these reactions can be reduced to 1 mol% without significant decrease in yields when reaction times are prolonged.

Table 2 summarizes some of the examples conducted under the optimized reaction conditions. While sterically more

3	Zn[b]	—	43	**7**	73
3	Zn	$ZnCl_2$	12	**7**	88
3	Mn	$ZnCl_2$	14	**6**	80
4	Mn	—	65	**7**	21
4	Zn	$ZnCl_2$	16	**7**	72

[a] As 94:6 mixture of 5-substituted pyran-2-one **7** and 6-substituted pyranone or 94:6 mixture of 4-hydroxymethyltetradecanenitrile or ester **6** or **5** and 5-hydroxypentadecanenitrile or ester. [b] 1 mol% of catalyst employed.

Table 2 Addition reactions of other epoxides to α,β-unsaturated carbonyl compounds with Lewis acid cocatalysis

Substrate	Reductant/ additive	*t*/h	Product	Yield (%)
	$Zn/ZnCl_2$	24		86
	$Zn/ZnCl_2$	16		78
	Zn	64		93[a]
	$Zn/ZnCl_2$	12		91
	Zn	10		65[b]

[a] Reaction performed in the presence of 4-phenyl-2-butanone (95% recovery). [b] Compound **3** as acceptor, 12 h reflux to complete the reaction.

demanding hydroxy nitriles can be readily obtained in the presence of $ZnCl_2$, refluxing of the reaction mixture yields the lactones in good yields. The reaction conditions tolerate a number of functional groups, *e.g.* ketones and halides, sensitive to stronger SET reagents, *e.g.* SmI_2.[11]

Lewis acid cocatalysis thus offers an attractive means for catalyst activation and alteration of selectivity in titanocene-catalyzed addition reactions of radicals derived from epoxides to α,β-unsaturated carbonyl compounds. Compared to the stoichiometric parent system[12] the amount of Cp_2TiCl_2 to be utilized is reduced by a factor of 200 and only 1.2 equiv. of radical acceptor have to be used compared to the 10 equiv. usually employed under stoichiometric conditions. No significant reduction in isolated yields is observed. Also deoxygenation, constituting a major side reaction under stoichiometric conditions especially for monosubstituted epoxides, was never observed.[12] Our catalytic conditions are therefore clearly superior to the stoichiometric conditions.

Hydrogen bonding also constitutes a convenient way to achieve catalyst activation and to obtain the desired products under mild conditions. However, care has to be taken in choosing the appropriate hydrogen bond acceptor. If the acceptor represents a powerful ligand, *e.g.* DMPU, catalyst deactivation was observed. If a base is chosen as acceptor instead, it should not constitute a sterically accessible ligand and its hydrochloride must not have a higher pK_a[13] than collidine hydrochloride. Otherwise proton transfer precludes catalytic turnover.[3]

Accordingly we decided to test collidine and ran the reaction under buffered protic conditions. Table 3 summarizes the results of our investigations. Clearly collidine has a beneficial role on both catalytic activity and yields of the products.

Table 3 Collidine as cofactor in addition reactions

Substrate	*t*/h	Product	Yield (%)
1	36	**6**	75
	36		73
	36		73

Addition to **3** proceeded smoothly to give the desired product **6** in good yields and in reasonable reaction times. It seems that collidine is indeed able to bind hydroxy groups of the reaction products *via* hydrogen bonding. Thus, collidine acts as a cofactor to restore catalytic activity *via* hydrogen bonding.

MTO catalyzed oxidation of aldehyde *N*,*N*-dimethylhydrazones with hydrogen peroxide: high yield formation of nitriles and *N*-methylene-*N*-methyl *N*-oxide

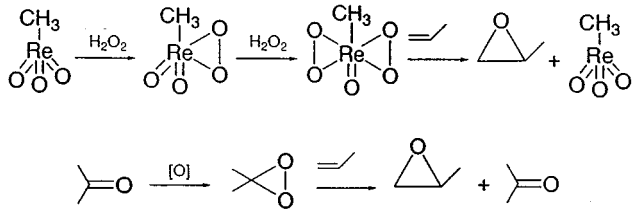
Henri Rudler*† and Bernard Denise

Laboratoire de Synthèse Organique et Organométallique, UMR 7311, Université Pierre et Marie Curie, Tour 44-45, 4 Place Jussieu, 75252 Paris Cedex 5, France

***N*,*N*-Dimethylhydrazones of aldehydes react with hydrogen peroxide at −50 °C in the presence of catalytic amounts of methyltrioxorhenium (MTO) to give in high yield the corresponding nitriles and *N*-methylene-*N*-methyl *N*-oxide.**

The transformation of aldehydes into nitriles is an important process in organic synthesis.[1,2] Several procedures are available for that purpose and very recently the oxidative conversion of *N*,*N*-dimethylhydrazones of aldehydes using dimethyldioxirane has been described.[3] Such a transformation has also been achieved by the use of peracids.[4] Both methods suffer from serious drawbacks: they both use stoichiometric amounts of oxidants which are either expensive (low yield formation of dimethyldioxirane from potassium peroxysulfate) and/or are waste-forming processes (acids from peracids). The use of hydrogen peroxide alone[2] or associated with a catalyst (either phosphomolybdic acid or sodium tungstate)[5] has also drawbacks: in the first case satisfactory yields were observed only in the case of hydrazones derived from aromatic aldehydes, whereas in the second case side reactions took place.

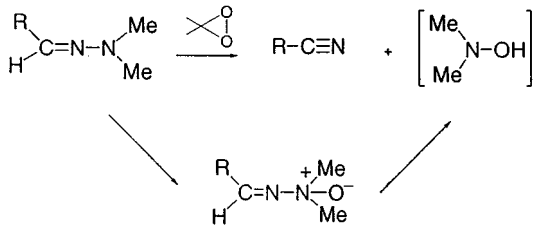
During our search for new applications of MTO[6] in organic synthesis, mainly based on the analogy which exists between dimethyldioxirane and the peroxo derivatives obtained upon oxidation of MTO with hydrogen peroxide (*e.g.* the epoxidation of olefins, Scheme 1),[7–11] we surmised that this system might be a good and efficient candidate for the catalytic transformation of *N*,*N*-dimethylhydrazones of aldehydes into nitriles.



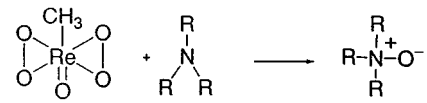
Scheme 1

Indeed, the mechanism which was suggested for the oxidative cleavage of dimethylhydrazones involved an electrophilic oxygen transfer from dioxirane to the terminal nitrogen atom leading to an *N*-oxide.[3] An intramolecular elimination of dimethylhydroxylamine was then supposed to lead to the nitrile (Scheme 2).

It is known that MTO catalyzes the oxidation of tertiary amines to *N*-oxides (Scheme 3).[12] Moreover, hydroxylamines

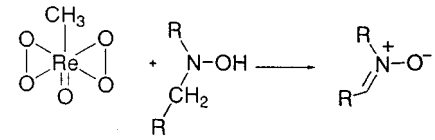


Scheme 2

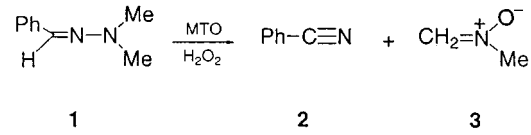


Scheme 3

are also catalytically converted into nitrones by the same system (Scheme 4).[13,14] Taken together, these two reactions would imply the formation of nitriles and *N*-methylene-*N*-methyl *N*-oxide from *N*,*N*-dimethylhydrazones of aldehydes. This indeed turned out to be the case (Scheme 5).



Scheme 4



1 **2** **3**

Scheme 5

Thus, an ethanolic solution of the *N*,*N*-dimethylhydrazone of heptanal[15] (0.45 g, 2 ml of EtOH) was added dropwise to a yellow solution of MTO and H_2O_2 (1.5%, 2 equiv. of 35% H_2O_2) in EtOH at −50 °C. The solution was then allowed to warm to room temperature over 1 h. Evaporation of most of the solvent followed by the addition of water and extraction with Et_2O gave, after evaporation of the organic solvent, the expected nitrile (0.29 g, 90%). The aqueous layer was also evaporated *in vacuo* to give an oily yellow liquid, which was also soluble in CH_2Cl_2. The mass spectrum of this product confirmed the molecular formula C_2H_5NO (*m*/*z* 59). The ^{1}H NMR spectrum disclosed two signals: a singlet at δ 3.60 for the NMe group and an AB system for two hydrogens at δ 6.67. The ^{13}C NMR spectrum confirmed the presence of a methyl and a methylene group (DEPT experiment), respectively, at δ 132.5 and 50.85.[11]

An NMR experiment with stoichiometric amounts of preformed MTO diperoxide[9] and the *N*,*N*-dimethylhydrazone of benzaldehyde clearly demonstrated the formation of the expected nitrone. It appears therefore that the transformation of the hydrazones into a mixture of nitriles and nitrone **3**‡ *via* dimethylhydroxylamine requires indeed 2 equiv. of H_2O_2.

Similar results, shown in Table 1, were observed under the same experimental conditions, starting from a series of hydrazones, and giving high yields of the expected nitriles.

Interestingly, epoxidation of the carbon–carbon double bonds of the hydrazones **4**–**7** was not observed under these precise reaction conditions. However, addition of an excess of H_2O_2 (3–4 equiv.) led, in the case of **6**, to the expected epoxy-nitrile

Table 1 Synthesis of nitriles *via* oxidation of *N*,*N*-dimethylhydrazones with MTO and H_2O_2 yield (%)[a]

[a] Isolated yield.

arising from the oxidation of the non-conjugated double bond. Thus, the low temperature formation of the nitriles in the presence of stoichiometric amounts of H_2O_2 is compatible with the presence of less reactive functional groups.

Under the same conditions, *N*,*N*-dimethylhydrazones of ketones (*e.g.* phenyl ethyl ketone) led to the corresponding ketones, whereas imines derived from aldehydes (*e.g.* *N*-benzylidenemethylamine) gave essentially the corresponding amides (55%) and those derived from ketones (*e.g.* *N*-cyclohexylidenepropylamine), mixtures of oxaziridines and nitrones. Work is in progress to assess the scope of these latter transformations.

Mesoporous MCM-48 membrane synthesized on a porous stainless steel support

Norikazu Nishiyama,* Akihiro Koide, Yasuyuki Egashira and Korekazu Ueyama

Department of Chemical Engineering, Faculty of Engineering Science, Osaka University, 1-3 Machikaneyama, Toyonaka, Osaka 560-8531, Japan. E-mail: nisiyama@cheng.es.osaka-u.ac.jp

A mesoporous MCM-48 membrane with high thermal stability has been synthesized on a porous stainless steel support by hydrothermal treatment.

Inorganic membranes made of ceramics or metals have been of interest for separation processes owing to their superior characteristics of thermal stability, structural stability and chemical resistance. Mesoporous inorganic membranes with an average pore diameter of 2–10 nm have been studied, mainly with respect to γ-alumina, titania and zirconia membranes prepared by the sol–gel method. However, since they have a wide pore size distribution, other inorganic membranes possessing uniform pore channels have been in demand for high performance applications in nanofiltration, ultrafiltration, pervaporation and membrane reactors.

Mobil scientists discovered a new family of mesoporous molecular sieves designated as M41S in 1992.[1,2] The M41S family includes members having uniform pore structures of hexagonal (MCM-41), cubic (MCM-48) and lamellar (MCM-50) symmetry. In their method, surfactant liquid-crystal structures serve as an organic template for the polymerization of silicates. Parallel to the discovery of M41S materials, Yanagisawa *et al.*[3] and Inagaki *et al.*[4] treated a layered kanemite polysilicate in an aqueous solution of a quaternary ammonium bromide surfactant and prepared a mesoporous silicate designated as FSM-16.

Recently, Ogawa[5,6] developed a rapid synthesis route for mesoporous films under acidic conditions using a mixture of tetramethoxysilane and an aqueous solution of a trimethylammonium salt. The products were transparent films of the hexagonal phase of periodic silica–surfactant composites with a unidimensional pore structure parallel to the surface of a glass substrate. Yang *et al.*[7] fabricated continuous mesoporous silica films on mica under acid conditions. They stated that the surface structure and reactivity of the mica surface controls the orientation of the micellar precursor species.

Straight pores should be oriented perpendicularly to the membrane surface in order to utilize the materials with unidimensional pores for separations. Tolbert *et al.*[8] have synthesized mesostructured silica (MCM-41) particles with orientated hexagonal pores from a hexagonal silicate–surfactant liquid crystal in a high magnetic field. This method has promise for the production of oriented mesopores in thin membranes for use in separations and in chemical sensors. On the other hand, MCM-48 has a three-dimensionally ordered pore structure. Therefore, the MCM-48 membrane is a promising material showing great potential applications such as in filtration, pervaporation and membrane reactors. In this study, a mesoporous membrane made of MCM-48 was synthesized on a porous stainless steel support by hydrothermal treatment.

The MCM-48 membrane was prepared as follows: a stainless steel support with an average pore diameter of 1 μm was placed in tetraethylorthosilicate (TEOS). Then, a solution which consisted of the quaternary ammonium surfactant $C_{16}H_{33}(CH_3)_3NBr$, NaOH and deionized water was added to the TEOS. The molar composition of the mixture was 0.6 $C_{16}H_{33}(CH_3)_3NBr$: 1.0 TEOS : 0.5 NaOH : 60 H_2O. Although a clear solution was obtained after mixing, the solution became inhomogeneous after 30 min of stirring. After the mixture was stirred for 90 more minutes, the mixture and support were transferred to an autoclave. The stainless steel support was placed horizontally in the bottom of the autoclave. The reaction was carried out without stirring at 363 K for 96 h. The product was rinsed with deionized water and calcined at 773 K for 4 h. Powder and a membrane were simultaneously obtained after the reaction. The BET surface area of the powder was measured by nitrogen adsorption at 77 K.

With respect to the mechanical strength of the membrane, it is preferable that the MCM-48 grows in the pores of the support. When the support was covered with a silica layer *ca*. 0.5 mm thick, the layer was removed from the surface of the support by polishing with a spatula until the surface of the stainless steel support appeared. Fig. 1 shows the SEM images for the surface

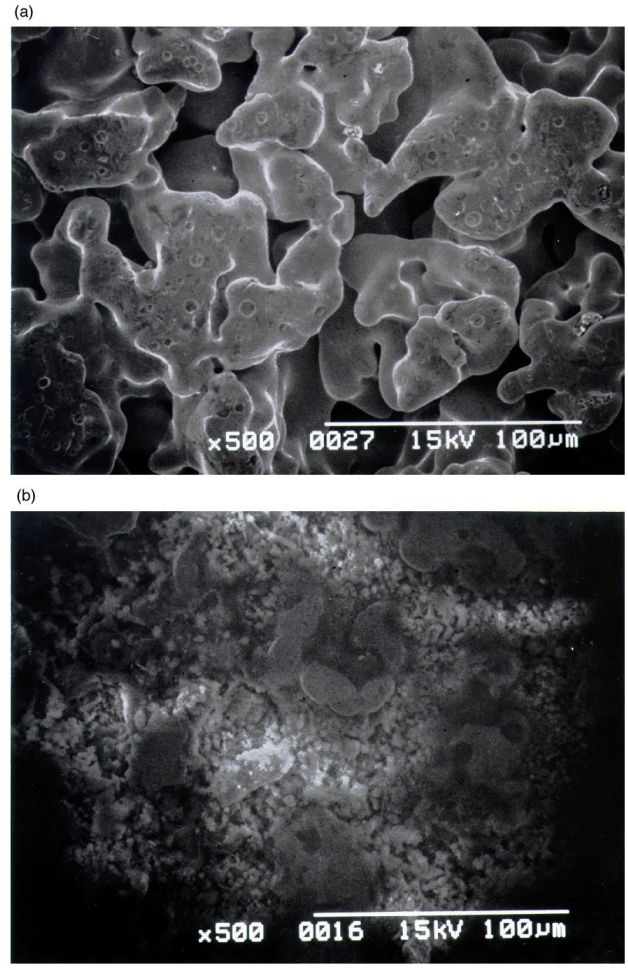

Fig. 1 Scanning electron micrographs of (a) the stainless steel support and (b) the MCM-48 membrane

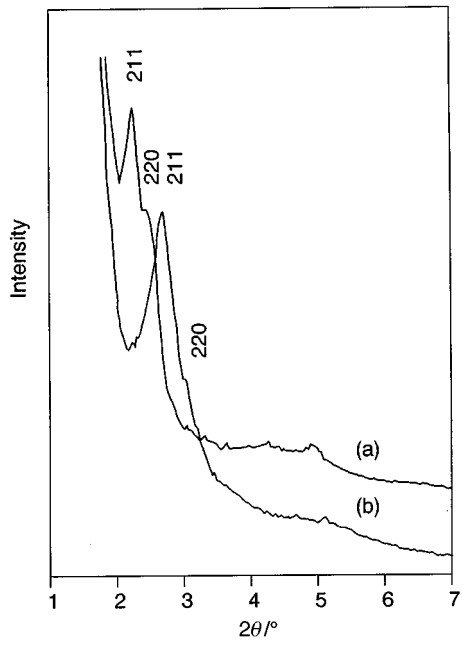

Fig. 2 X-Ray diffraction patterns of MCM-48 membranes (a) before calcination and (b) after calcination

of the original stainless steel support and the polished membrane before calcination. Particles with diameters of about 1 μm can be observed in the pores of the stainless steel.

The X-ray diffraction pattern of the polished membrane before calcination is shown in Fig. 2(a). The peaks for MCM-48 were found in the X-ray diffraction pattern even after the removal of the MCM-48 layer on the support, which indicates that MCM-48 grew in the pores of the stainless steel support. Fig. 2(b) shows the X-ray diffraction pattern of the polished membrane after calcination. The d_{211} values decreased from 3.9 nm to 3.3 nm after calcination because of the shrinkage of the structure. However, the peak intensity was not reduced even after calcination, showing that the ordered structure was maintained even after the removal of the surfactant. This result shows that the MCM-48 membrane prepared in this study has high thermal stability up to 773 K. The powder formed in the solution was MCM-48 with a BET surface area of 1025 $m^2\ g^{-1}$, showing its high quality.

We performed gas permeation tests using the MCM-48 membrane before and after calcination. The tests were carried out using a pressure drop of 100 kPa at room temperature. The permeances of nitrogen are shown in Table 1. Only pinholes and cracks between the MCM-48 particles can be gas permeable before calcination because the mesopores of MCM-48 are blocked by surfactant molecules. The MCM-48 membrane before calcination was impermeable to nitrogen gas. This result shows that MCM-48 particles were densely packed in the pores of the support and formed a compact composite membrane before calcination. The calcined membrane was permeable to nitrogen gas. The compactness of the MCM-48 membrane and the effect of the shrinkage of the structure by calcination on permeation properties will be reported in the near future.

Table 1 The permeance of N_2 through MCM-48 membranes

	Permeance/10^{-5} mol $m^{-2}\ s^{-1}\ Pa^{-1}$
Before calcination	0.0
After calcination	1.5

In conclusion, we have prepared a mesoporous inorganic membrane made of MCM-48 which has a three-dimensionally ordered pore system. A composite layer of stainless steel/MCM-48 was obtained in a compact form.

We thank GHAS at the Department of Chemical Engineering at Osaka University for SEM and XRD measurements. This study was partly supported by the Shimadzu Science Foundation.

Formation of separated *versus* contact ion triples in heavy alkaline-earth thiolates

Scott Chadwick, Ulrich Englich and Karin Ruhlandt-Senge*

Department of Chemistry, 1-014 Center for Science and Technology, Syracuse University, Syracuse NY 13244-4100, USA. E-mail. Kruhland@syr.edu.

The synthesis and structural characterization of the alkaline-earth thiolates [Sr(18-crown-6)(hmpa)$_2$][SMes*]$_2$ and [Ba(18-crown-6)(hmpa)(SMes*)][SMes*], displaying rare ion association modes with only one or no cation–thiolate linkages are presented.

In contrast to the well explored chemistry of separated organometallic lithium and sodium derivatives, little is known about the ionic association in heteroatomic systems. To date no separated alkoxide or aryloxide ion pairs have been described, and, to the best of our knowledge, only one thiolate, [Li(12-crown-4)$_2$][SMes*] (Mes* = $C_6H_2Bu^t_3$-2,4,6), has been reported.[1] The ion association chemistry of alkaline-earth derivatives is even less explored, which might be explained by the potentially more complex chemistry with three different types of ion association: contact triples with two cation–anion linkages, separated ion triples with no contacts between cation and anions, and semi-separated ion triples displaying one cation–anion contact, while the second anion does not interact with the metal center.

Only few examples of separated heteroatomic alkaline-earth derivatives such as [Mg(12-crown-4)$_2$][TeSi(SiMe$_3$)$_3$]$_2$,[2] and [Ca(18-crown-6)(NH$_3$)$_3$][SMes*]$_2$ have been reported.[3] All known strontium and barium chalcogenolates are contract triples, as observed in [Sr(thf)$_4$(=EMes*)$_2$] (E = S, Se),[4] [Sr(NH$_3$)(Py)(μ-SCEt$_3$)$_2$]$_\infty$,[5] [Sr(tmen)$_2$\{SeSi(SiMe$_3$)$_3$\}$_2$],[2] and [Ba(Py)$_5$\{TeSi(SiMe$_3$)$_3$\}$_2$].[2] We present herein the synthesis and structural characterization of the separated [Sr(18-crown-6)(hmpa)$_2$][SMes*]$_2$ **1** (Fig. 1), and the semi-separated [Ba(18-crown-6)(hmpa)(SMes*)][SMes*] **2** (Fig. 2). Compounds **1** and **2** represent examples of the least known association modes for alkaline-earth derivatives.

Several synthetic routes can be utilized for the synthesis of heavy alkaline-earth chalcogenolates, the most efficient of which is the treatment of the ammonia solvated metals with thiol. The insoluble powders, obtained after evaporation of ammonia and addition of thf can be transferred into soluble species by addition of a slight excess of hmpa.†

The Sr center in **1** is eight coordinate, with two strong hmpa donor interactions [2.420(2) Å] in addition to six crown-ether linkages in the range of 2.712(1)–2.736(1) Å. Both, the Sr–hmpa and the crown-ether connections compare well with literature data.[10] The S–C bond length in **1** is observed at 1.771(2) Å, which is slightly shorter than in [Sr(thf)$_4$(SMes*)$_2$],[4] but compares well with Li(12-crown-4)$_2$][SMes*][1] and [Ca(18-crown-6)(NH$_3$)$_3$][SMes*]$_2$.[3]

The comparison of **1** with [Sr(thf)$_4$(SMes*)$_2$] and [Sr(NH$_3$)(Py)(μ-SCEt$_3$)$_2$]$_\infty$ clearly shows that the presence of a multidentate donor (18-crown-6) in combination with a very strong donor (hmpa) greatly affects the ionic association of the resulting complexes. To make the rupture of a Sr–S bond thermodynamically favorable, a significant amount of solvation energy must be provided. Apparently, the donors thf, pyridine or NH$_3$ which are present in the reaction mixtures resulting in the contact triples, do not provide sufficient solvation energy to stabilize a separated Sr cation.

The Ba derivative **2**, which crystallizes with two independent molecules per asymmetric unit, consists of a monocation [Ba(18-crown-6)(hmpa)(SMes*)], and a separated SMes* anion. The Ba centers are eight coordinate with one thiolate [Ba–S 3.012(2) and 3.025(2) Å] and one hmpa contact [Ba–O 2.592(5), 2.594(5) Å], in addition to six crown-ether linkages [2.772(5)–2.807(5) Å]. The Ba atom is slightly displaced from the plane of the six crown-ether oxygen atoms [0.256 and 0.264 Å] towards the hmpa donor, indicating a strong Ba–hmpa interaction. The Ba–S–C angles are observed at 150.8(2) and 153.7(3)°, S–C distances in the contact thiolate are observed at 1.792(7) and 1.805(7); those for the separated anion are identified at 1.777(7) and 1.753(7) Å. The shortest Ba–S distance for the non-coordinating anion is observed at 6.533 Å.

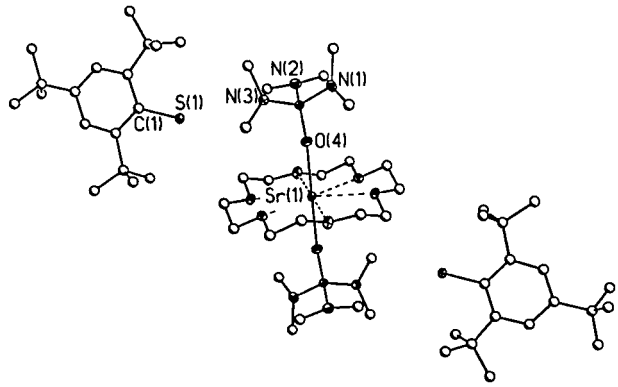

Fig. 1 Computer generated plot of [Sr(18-crown-6)(hmpa)$_2$][SMes*]$_2$ **1**. H atoms have been eliminated for clarity. Sr–O(hmpa) 2.420(2) Å; Sr–O(crown) 2.712(1), 2.718(1), 2.736(1) Å; S–C 1.771(2) Å.

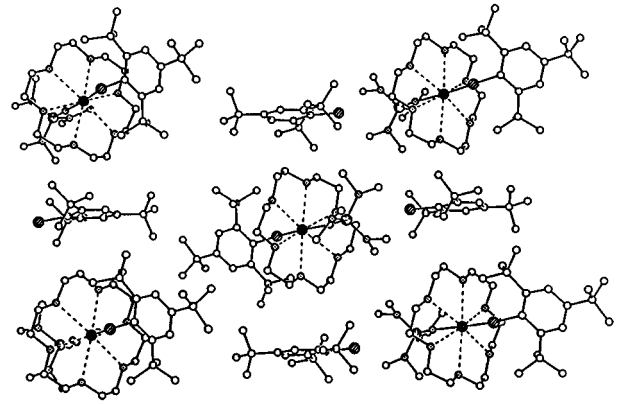

Fig. 2 Computer generated plot showing part of the unit cell in **2**. Ba–S 3.012(2), 3.025(2) Å; Ba–O(hmpa) 2.592(5), 2.594(5) Å; Ba–O(crown) 2.772(5)–2.807(5) Å; S–C (contact) 1.792(7), 1.805(7) Å; S–C (separated) 1.777(7), 1.753(7) Å; Ba–S–C 153.7(3), 150.8(2)°; O(hmpa)–Ba–S 172.8(1), 174.1(1)°.

Several complexes containing Ba–S moieties, where the S atom is part of a S–C–N resonance delocalized system are available for structural comparison to **2**.[6] While the Ba–crown-ether or –hmpa interactions fall in expected ranges,[7] significant differences are observed in the Ba–S distances. The Ba–S lengths in a series of seven-coordinate compounds bearing the 2-mercaptobenzoxazole ligand were observed at a mean value of 3.31(1) Å,[8] while Ba–S interactions in a ten-coordinate trimercaptotriazine derivative are displayed over a range of 3.396(2)–3.692(2) Å.[9] The shorter Ba–S bonds in **2** can be attributed in part to the absence of a second thiolate ligand in the coordination environment of the cation. In addition, the chelating nature of both the mercaptotriazine and the 2-mercaptobenzoxazole ligands might result in the lengthening of the Ba–S bond. The strong Ba–S bond in **2** is further demonstrated by the repeated isolation of **2**, even if very large excesses (up to 12 fold) of hmpa was added to the reaction mixture. The unusually wide Ba–S–C angles of 150.8(2) and 153.7(3)° compare well with those observed in [Ca(18-crown-6)(SMes*)$_2$], where one strong [2.785(2) Å] and one weaker [2.859(2) Å] Ca–S interaction was observed.[7] The environment at the S atom involved in the stronger bond is very similar to that in **2** [Ca–S–C 154.1(2)°].

Several factors affect the ion association in alkali and alkaline-earth chalcogenolates. The balance between steric congestion about the cation and tendency towards maximization of cation–anion interactions is nicely demonstrated in the ion triples [Sr(18-crown-6)(hmpa)$_2$][SMes*]$_2$ **1** and [Ba(18-crown-6)(hmpa)(SMes*)][SMes*] **2**. The smaller Sr cation (CN 8: 1.40 Å)[10] is unable to accommodate one SMes* ligand while maintaining strong crown ether coordination. In the presence of the strong donor hmpa, the Sr–S bond is ruptured (shortest resulting Sr–S 6.301 and 7.252 Å), and hmpa donor molecules occupy the coordination sites perpendicular to the crown ether plane. Ligation by hmpa provides the needed cation coordination while being sterically less demanding than the thiolate anions. This result might be compared to [Ca(18-crown-6)(SMes*)$_2$],[3] isolated in the absence of hmpa. This reaction was carried out in thf, which is apparently unable to provide the necessary solvation energy for the stabilization of a separated cation. The addition of hmpa to the corresponding Ba reaction, results in **2**: the larger Ba cation (CN 8: 1.56 Å)[10] enables the close approach of one thiolate ligand and one hmpa donor.

The synthesis and characterization of the first Sr separated ion triple, **1**, and the novel, unusual intermediate between a contact and a separated ion triple **2**, contributes significantly to the understanding of the association chemistry of the alkaline-earth elements. The detailed analysis of structural parameters gives important insight into the nature and strength of alkaline-earth metal–ligand and –donor interactions, while providing information about the preferred alkaline-earth metal environment. Our work in this area of chemistry is continuing and will be subject of forthcoming publications.

This work was supported by the National Science Foundation (CHE-9702246) and the Deutsche Forschungsgemeinschaft (Postdoctoral stipend for U. E.). Purchase of the X-ray diffractometer was made possible with grants from NSF (CHE-95-27898), the W. M. Keck Foundation and Syracuse University.

Notes and References

† *Synthetic procedures*: all reactions were performed under anaerobic and anhydrous conditions. HSMes* was prepared by published procedures.[11] **CAUTION**: hmpa [hexamethylphosphoramide, P(O)(NMe$_2$)$_3$] is a suspected carcinogen and should be handled in a well ventilated fumehood using gloves. *General procedure* for **1** and **2**: a 100 ml Schlenk flask was charged with 1.0 mmol of metal, 0.26 g (1.0 mmol) of 18-crown-6 and 0.56 g (2.0 mmol) of HSMes*. Approximately 25 ml of predried $NH_{3(l)}$ was condensed into the flask. The deep-blue solution was stirred at −78 °C for 1 h and then warmed up to room temp. 25 ml of thf was added. A heavy yellow–white suspension persisted even after brief heating. As hmpa was added dropwise (0.70 ml, 4.0 mmol), the reaction gradually cleared then became cloudy-white once again. The solution was heated briefly to reflux and immediately filtered through a Celite padded frit. **1**: colorless blocks formed on cooling to room temperature in 16% yield (0.20 g). Mp: shrinking at approximately 215 °C and an irreversible melt at 245–250 °C. ^{1}H NMR ([$^2H_8$]thf), δ 7.06 (s, 4H), 3.83 (s, 24H), 2.62 (d, 36H), 1.74 (s, 36H), 1.24 (s, 18H); ^{13}C{^{1}H}NMR ([$^2H_8$]thf), δ 150.16, 150.10, 120.77, 71.01, 39.15, 37.34, 32.44, 32.03; IR (Nujol), 2920s, 1592w, 1461s, 1377s, 1354m, 1285s, 1190m, 1155s, 1095s, 1024m, 981s, 966s, 876w, 839w, 757s, 616w, 483m cm^{-1}. **2**: colorless crystals formed almost instantly out of a yellow filtrate in 19% yield (0.21 g). Melting to an oily residue at 175–180 °C, decomposition above 200 °C. ^{1}H NMR ([$^2H_5$]py) δ 7.59 (s, 4H), 3.82 (s, 24H), 2.58 (d, 18H), 2.19 (s, 36H), 1.46 (s, 18H); ^{13}C{^{1}H}NMR ([$^2H_5$]py), δ 139.37, 121.37, 70.98, 39.52, 37.31, 34.80, 32.61, 32.03; IR (Nujol), 2854s, 1593w, 1462s, 1377s, 1349w, 1283w, 1246w, 1195w, 1166w, 1087m, 1042w, 979w, 957m, 875w, 833w, 723m, 480w cm^{-1}.

‡ The crystals were mounted as described earlier.[12a] Crystal data for **1** and **2**·0.5C$_7$H$_8$ were collected at 150 K with Mo-Kα radiation (λ = 0.710 73 Å), Bruker SMART CCD diffractometer, graphite monochromator, Oxford Instruments Cryojet low temperature device. Both structures were solved and refined using the SHELXTL program package.[12b] An absorption correction was applied using the program system SADABS.[12c] **1**: M = 632.64, crystal dimensions 0.20 × 0.15 × 0.15 mm, μ = 0.882 mm^{-1}, scan range 3° < 2θ < 57°, monoclinic, space group $P2_1/n$, a = 10.5771(3), b = 17.5403(5), c = 19.8293(7) Å, β = 91.152(1)°, V = 3678.1(2) Å^3, Z = 2, D_c = 1.142 g cm^{-3}, 22232 measured, 8569 independent reflections (R_{int} = 0.0329), 358 refined parameters. R_1 [$I > 2\sigma(I)$] = 0.0441, R_1 (all data) = 0.0667. **2**·0.5C$_7$H$_8$: M = 2363.73, crystal dimensions 0.30 × 0.30 × 0.30 mm, μ = 0.744 mm^{-1}, scan range 2 < 2θ < 50°, monoclinic, space group $P2_1/n$, two independent molecules per asymmetric unit, one disordered solvent toluene molecule, a = 21.2127(3), b = 14.2323(2), c = 43.2258(1) Å, β = 90.613(1)°, V = 13049.4(3) Å^3, Z = 4, D_c = 1.203 g cm^{-3}, 63 151 measured, 22 564 independent reflections (R_{int} = 0.0681), 1222 refined parameters, R_1[$I > 2\sigma(I)$] = 0.0855, R_1 (all data) = 0.1436. Some of the hmpa donors and Bu^t groups in **2** are disordered and have been refined utilizing split positions and a set of restraints. CCDC 182/1005.

Characterization of poly(carbon monofluoride) by ^{19}F and ^{19}F to ^{13}C cross polarization MAS NMR spectroscopy

Thomas R. Krawietz and James F. Haw*†

Department of Chemistry, Texas A&M University, PO Box 300012, College Station, TX 77842-3012, USA

High speed ^{19}F MAS NMR and ^{13}C MAS NMR with ^{19}F to ^{13}C cross polarization allows spectroscopic identification of monofluorinated and geminally difluorinated carbon species in poly(carbon monofluoride).

Poly(carbon monofluoride), $(CF_x)_n$, is a stable, hydrophobic material prepared from graphite and elemental fluorine at high temperatures.[1] $(CF_x)_n$ materials, where x is greater than 0.60, are currently being produced on an industrial scale for use in Li/$(CF_x)_n$ batteries, and these are characterized by high energy density, wide operating temperatures and long storage life.[2] Poly(carbon monofluoride) is also used as a solid lubricant with wear performance better than that of graphite or MoS_2, especially in high temperature or oxidizing environments.[3,4] It is agreed that covalent incorporation of fluorine results in a puckering of the graphite structure into extended sheets of fused cyclohexane rings,[5–8] but other details of the structure of $(CF_x)_n$, including defect sites, are more poorly understood. Previous applications of NMR to this material have been wide-line ^{19}F investigations. One such study concluded that $(CF_x)_n$ is an array of *cis-trans*-linked boats, with all fluorine in axial positions. A more recent student used similar methods to support a *trans-trans*-linked chair structure, and that conclusion is supported by the available X-ray data.[6–9] The availability of technology for very rapid sample rotation has made possible high resolution NMR analysis of solids,[10,11] and several such ^{19}F magic angle spinning (MAS) NMR investigations have appeared in the literature.[12–15] Here we have used high speed MAS to obtain ^{19}F NMR spectra of $(CF_x)_n$ materials that are dominated by the isotropic chemical shifts of bulk and defect structures. Furthermore, we have confirmed our assignments by acquiring ^{13}C NMR spectra of the same materials using cross polarization from ^{19}F and fluorine decoupling.

Two samples of carbon monofluoride were obtained from Aldrich. Fast neutron activation determined the empirical formulae to be $(CF_{0.87})_n$ and $(CF_{1.12})_n$. Samples for NMR investigation were loaded and sealed under an inert nitrogen atmosphere in 4.0 and 5.0 mm zirconia MAS rotors using Delrin [poly(oxymethylene)] endcaps. High speed ^{19}F MAS NMR was performed on a home built spectrometer operating at a fluorine resonance of 188.8 MHz utilizing a 4.0 mm spinning module from Otsuka Electronics. The fluorine chemical shift was externally referenced to an ampoule of trichlorofluoromethane at 0 ppm. $\pi/2$ pulses of 3 μs or less were used. Reported spectra are the result of 1024 transients, utilizing a composite Bloch decay sequence[16] for probe background suppression and a 1 s recycle delay. ^{19}F to ^{13}C CP MAS NMR spectra were acquired on a Chemagnetics CMX-360 operating at 337.8 (^{19}F) and 90.5 MHz (^{13}C) using a probe from Otsuka Electronics spinning 5.0 mm rotors. The magic angle was optimized using the ^{79}Br resonance of KBr.[17] The ^{13}C chemical shift was referenced (17.4 ppm) and the ^{1}H–^{13}C Hartmann–Hahn matching condition was set using hexamethylbenzene. The ^{19}F–^{13}C match was then optimized on polytetrafluoroethylene (PTFE) by adjustment of the ^{19}F power level to coincide with the previously determined ^{13}C $\pi/2$ pulse width. The double-resonance NMR probe contained sufficient fluoropolymer that ^{13}C Bloch decay spectra obtained with ^{19}F decoupling were dominated by background signals, even with background-suppression pulse sequences. Fortunately, probe background was greatly diminished with ^{19}F–^{13}C cross polarization, and background was negligible when the ^{13}C magnetization was generated using composite CP sequences. We optimized the CP contact time by measuring the important relaxation rates. For a sample of $(CF_{0.87})_n$ we measured a ^{19}F $T_{1\rho}$ of 33.4 ± 5.0 ms and 147 ± 18 μs for T_{FC}.[18] We selected a 1.5 ms contact time to provide excellent CP efficiency without unnecessary radio-frequency heating. The ^{13}C $\pi/2$ pulse width was 4.3 μs and high-power ^{19}F decoupling was used. Each ^{13}C NMR spectrum is the result of 2048 transients and a 3 s recycle delay.

Fig. 1 reports ^{19}F MAS NMR spectra of samples of $(CF_{0.87})_n$ and $(CF_{1.12})_n$ obtained with a spinning speed of 18 kHz. This spinning speed was necessary to average the ^{19}F–^{19}F homonuclear dipolar interaction as well as to place spinning sidebands away from spectral regions of interest. The most intense peak in both spectra, at −187 ppm, is assigned by comparison to the fluorines on C9 and C10 of either *trans*- or *cis*-perfluorodecalin, each at −186 ppm. Therefore, the −187 ppm resonance in Fig. 1 is confidently assigned to C–F groups.[19] A second isotropic peak, at −116 ppm, is present in both samples but is clearly larger for the sample with the higher fluorine content. This signal can also be assigned by comparison to perfluorodecalins, for which both the axial and equatorial fluorines in CF_2 groups in the 1, 4, 5, and 8 positions have shifts of −124 ppm.[19] The line widths of both ^{19}F resonances are likely due to chemical heterogeneity, as modest variations in sample temperature or spinning speed suggested no further line narrowing.

Further evidence for these assignments came from the ^{19}F to ^{13}C CP MAS spectra (Fig. 2). Both spectra have a majority resonance at 89 ppm and a shoulder that spectral deconvolution shows to be centered at 111 ppm. The latter feature is distinctly larger in the sample with the higher fluorine content. We assign the ^{13}C resonances by comparison to an earlier study of graphite hydrofluoride, $C_xF_{1-\delta}(HF)_\delta$, by Mallouk and co-workers.[20] $C_xF_{1-\delta}(HF)_\delta$ has a resonance at 88 ppm that was assigned to

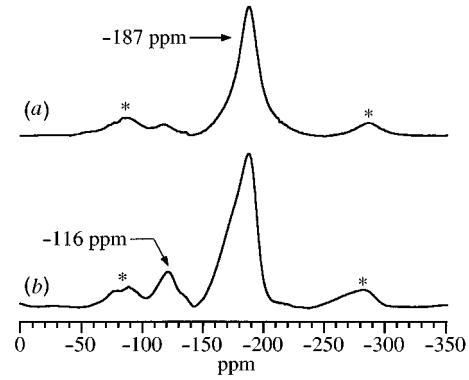

Fig. 1 188.8 MHz ^{19}F MAS NMR spectra of graphite monofluoride having empirical stoichiometries of (*a*) $(CF_{0.87})_n$ and (*b*) $(CF_{1.12})_n$. Spectra were acquired at 298 K using a spinning speed of 18 kHz. Asterisks denote spinning sidebands.

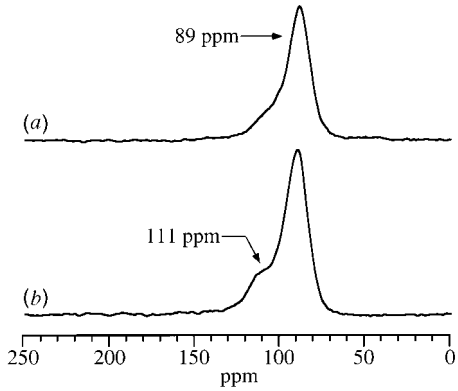

Fig. 2 90.5 MHz ^{13}C MAS NMR spectra of graphite monofluoride obtained with ^{19}F to ^{13}C cross polarization and high power ^{19}F decoupling. Spectra were acquired at 298 K with a spinning speed of 8 kHz. (*a*) $(CF_{0.87})_n$ and (*b*) $(CF_{1.12})_n$.

monofluorinated carbons, and this strongly supports a similar assignment for $(CF_x)_n$. $C_xF_{1-\delta}(HF)_\delta$ also showed a small ^{13}C signal at 112 ppm which Mallouk and co-workers assigned to CF_2 groups at the edge of grains. This supports assignment of the 111 ppm shoulder in Fig. 2 to the carbons in CF_2 groups. Our spectra clearly show that CF_2 groups are enhanced at higher fluorine incorporation, in agreement with Lagow's proposal for the fluorine siting in 'superstoichiometric' poly(carbon monofluoride).[21] However, we have also demonstrated the presence of smaller amounts of CF_2 in a sub-stoichiometric material. In this case, CF_2 groups are still reasonable as peripheral groups at sheet edges or in other defected structures. In principal, we should be able to establish a quantitative relationship between the levels of CF_2 in the ^{19}F and ^{13}C spectra, but the use of cross polarization in the latter case prevents such a comparison.

In conclusion, ^{19}F high speed MAS NMR analysis has permitted resolution of majority and defect sites in highly fluorinated graphite derivatives, and the interpretation of these experiments is supported by ^{13}C MAS NMR with ^{19}F to ^{13}C cross polarization and high power ^{19}F decoupling.

This work was supported by the National Science Foundation (Grant No. CHE-9528959). We would also like to thank Judith A. Sharp and R. Malcolm Brown, Jr. at the University of Texas in Austin for providing transmission electron microscopy and discussions of sample morphology.

Stable [60]fullerene carbocations

Anthony G. Avent, Paul R. Birkett,*† Harold W. Kroto, Roger Taylor and David R. M. Walton

The Fullerene Science Centre, School of Chemistry, Physics and Environmental Science, University of Sussex, Brighton, Sussex, UK BN1 9QJ

[60]Fullerene derivatives, $C_{60}Ar_5Cl$ (Ar = Ph or 4-FC_6H_4), react with $AlCl_3$ in solution at room temperature to form C_s symmetrical pentaaryl[60]fullerene carbocations, $C_{60}(Ar)_5^+$.

A number of stable [60]fullerene derivatives which are anions have been synthesised and characterised in solution.[1] In contrast no carbocationic [60]fullerene derivatives have been described to date. However, the non-functionalised [60]fullerene radical carbocation, $C_{60}^{+\cdot}$, has been identified by *in situ* EPR and NMR spectroscopy in super acid media[2] and the fullerene cationic salt $[C_{76}^+][CB_{11}H_6Br_6^-]$ has been fully characterised.[3] Photo-induced electron transfer (PET) has recently been used to generate $C_{60}^{+\cdot}$ which was functionalised *in situ* by reaction with hydrogen donor molecules, such as alcohols, resulting in the formation of 1-substituted 1,2-dihydro[60]fullerene derivatives.[4] Our studies of Friedel–Crafts reactions between chlorofullerenes and aromatic compounds with $FeCl_3$,[5] a moderately strong Lewis acid, imply the formation of either fullerene carbocation intermediates (or of donor–acceptor complexes which subsequently undergo front-side displacement by an aromatic group, which is unlikely). We have now prepared and characterised the first examples of [60]fullerene derivative carbocations, $C_{60}Ar_5^+$ (Ar = Ph or 4-FC_6H_4), which are formed by cleaving the fullerene–Cl bond of $C_{60}Ar_5Cl$ (Ar = Ph **1**;[5a] 4-FC_6H_4 **2**[5c]) using a strong Lewis acid, $AlCl_3$.

The reaction of either **1** or **2** in CH_2Cl_2, $CHCl_3$ or CS_2 with $AlCl_3$ at room temperature over 30 min results in a change from an orange solution to an intense purple–red indicating the formation of new [60]fullerene derivatives. *In situ* ^{1}H NMR spectra (CS_2–CD_2Cl_2) of the above reactions showed that, in each case, complete conversion to a new C_s symmetric pentaarylated [60]fullerene derivative occurs as each spectrum has the same number and intensities of signals as the C_s symmetric starting material; however, the chemical shifts of the signals are significantly different. For example, in the reaction of **2** with $AlCl_3$ the two multiplets due to the Hs of the unique aryl ring (A) are shifted downfield in the reaction product (Fig. 1). Unequivocal assignments for the signals of the pairs of aryl rings (BC and DE) are not possible as NOE experiments result in equal saturation transfer to all similar signals in the spectrum. Irradiation of the highest field 3-H multiplet of the spectrum in Fig. 1(*a*), which is due to one of the two pairs of aryl rings of the reaction product from **2**, results in the equal collapse of the two other 3-H signals (including that of the unique aryl ring). The foregoing data is consistent with the proposal that the $AlCl_3$ is able to abstract the chlorine atom from **1** or **2** generating the carbocations **3** or **4** which are expected to have considerable anti-aromatic character due to their 4π electron systems (Scheme 1). 1,2-Phenyl migration then occurs producing the carbocations **7**‡ and **8**.§ The fact that the NOE data shows equal saturation transfer to all five aryl rings in both of the reaction products implies that there is a dynamic equilibrium between the initial carbocation formed, which can be viewed as the C_5 symmetric anti-aromatic cyclopentadienyl carbocations, **5** and **6**, and the subsequent major reaction products, **7** and **8**, respectively. However, variable temperature NMR spectra of both reaction products to 233 K failed to produce any evidence for the presence of **5** or **6**.

The *in situ* ^{13}C NMR spectra of both **7** and **8** have the required number of signals due to the fullerene carbon atoms [28 sp^2 (26 × 2C and 2 × 1C), three sp^3 (2 × 2C and 1 × 1C) and one carbocationic carbon (1 × 1C$^+$)] in addition to those of the aryl carbons. The signal due to the *ipso*-carbon attached to the fullerene cage of the unique aryl ring A is not observed in the spectrum of **8** and is most probably masked by one of the other *ipso*-signals. The formation of donor–acceptor type complexes can be ruled out as the chemical shifts, δ 173.74 and 171.67, of the signals due to the carbon atoms bearing the positive charge in **7** and **8** respectively are much too low field. However, these values are relatively high-field for carbocationic centres and reflect the exchange of the aryl groups detected by ^{1}H NMR spectroscopy. Other factors, such as the positively charged carbon atom having an empty sp^3-like orbital due to the strained ring system being unable to rehybridise to form a planar sp^2 orbital, should however also be considered. The positive charge is localised mostly at or near to the site of its generation in both **7** and **8**. Consequently the carbon atoms immediately adjacent to the carbon atom bearing the positive charge undergo a large downfield shift (> δ 4) compared with those more remote to the positive centre. This situation is analagous to the observed localisation of either the negative charge in the monoaddended fullerene anions[1a–e] or to the radical electron in mono-radical addition to fullerenes.[7] The signals due to the readily identifi-

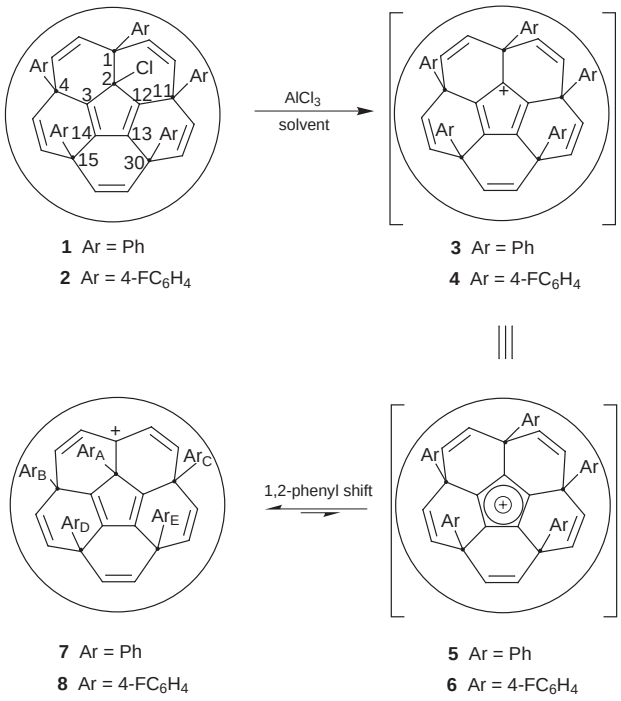

Scheme 1 The proposed reaction sequence for the formation of the carbocations **7** and **8**. Only the five-membered ring around which the phenyl groups are situated in [60]fullerene is shown; the C atoms are numbered using the IUPAC system[6] and the aromatic labels, *e.g.* Ar_A, in **7** and **8** correspond to those used in the text.

able (single intensity) symmetry plane sp^2 carbon atoms (C55/C60 carbons), which are located at the opposite pole of the [60]fullerene cage, undergo anomalously large downfield shifts of δ 2.67 and 2.66 in **7** and δ 1.86 and 1.72 in **8** probably due to the presence of endohedral homoconjugation, *i.e.* overlap of the rear nodes of the orbitals of the sp^2 carbons C55 and C60 with those of the carbocationic carbon C1 and the sp^3 carbon C2 through the interior of the cage. A transannular interaction of this type was first suggested by Olah *et al*. to explain the observed downfield shift of the bridgehead Hs in the ^{1}H NMR spectrum of the 1-adamantyl carbocation.[8] Moreover, endohedral homoconjugation has recently been observed by cyclic voltammetry in the pentaphenylcyclopentadienyl[60]fullerene anion, $C_{60}Ph_5^-$.[9]

Further studies to examine the scope, nature, properties, spectroscopy and chemical reactivity of this new fullerene species are in progress.

We thank the EPSRC (for an Advanced Fellowship to P. R. B.) and the Royal Society for financial support.

Anomalous rearrangements in the reaction of acylpolysilanes with $TMSNTf_2$

Malcolm B. Berry,[b] Russell. J. Griffiths,[a] Dmitrii S. Yufit[a] and Patrick G. Steel*[a]†

Reaction of acylpolysilanes with silylbistriflimides (R_3SiNTf_2) leads to novel silanols *via* a pathway involving two 1,2-migrations of Me_3Si groups from silicon to carbon and one migration of a R_3SiO unit from carbon to silicon; the X-ray structure of one example is reported.

In the course of an investigation of the use of silenes as reagents for novel transformations in organic synthesis we had need to generate silenes from acylpolysilanes in what is effectively a 1,3 silyl migration.[1] This is normally achieved through either thermal (T = *ca*. 180 °C) or photochemical initiation.[1,2] Neither of these methods is compatible with the range of functionality which we wished to explore. Consequently, in order to determine whether it was possible to generate silenes through the Lewis acid promoted 1,3-silyl shift of acylpolysilanes, we investigated the reaction of benzoylpolysilane with silyl based Lewis acids (TMSOTf, $TMSNTf_2$). Here we report that there is no evidence for the formation of silenes in this process (neither silene adducts nor silene dimers are detected) but rather a series of 1,2-migrations occurs to generate a silenium ion intermediate which subsequently undergoes nucleophilic capture.

Initial experiments involved the addition of trimethylsilyl triflate (TMSOTf) to a mixture of the polysilane and piperylene. However, these reactions were complicated by extensive diene polymerisation. Consequently we turned to the use of the corresponding silylbistriflimides (R_3SiNTf_2), readily available from the corresponding allylsilane and bis(trifluoromethylsulfonyl)imide, which has been reported to be more tolerant with respect to alkene polymerisation.[3] Whilst this strategy proved to be no more successful than TMSOTf in inhibiting diene degradation, addition of $TMSNTf_2$ to a solution of the polysilane in CH_2Cl_2 at −78 °C afforded a deep red colour. After stirring at this temperature for 12 h, aqueous workup followed by flash column chromatography afforded a colourless crystalline material in near quantitative yield. Infra-red spectroscopy revealed the presence of an OH group, whilst mass spectroscopy showed a molecular ion at *m/z* 442 which corresponded to the starting material plus Me_3SiOH. Chemical analysis confirmed this formula. However it proved difficult to fit this data with the NMR spectra which showed four $SiMe_3$ units and five different silicon signals. Fortunately it proved possible to grow crystals suitable for X-ray diffraction,‡ which revealed the structure as the silanol **2a** (Fig. 1).§

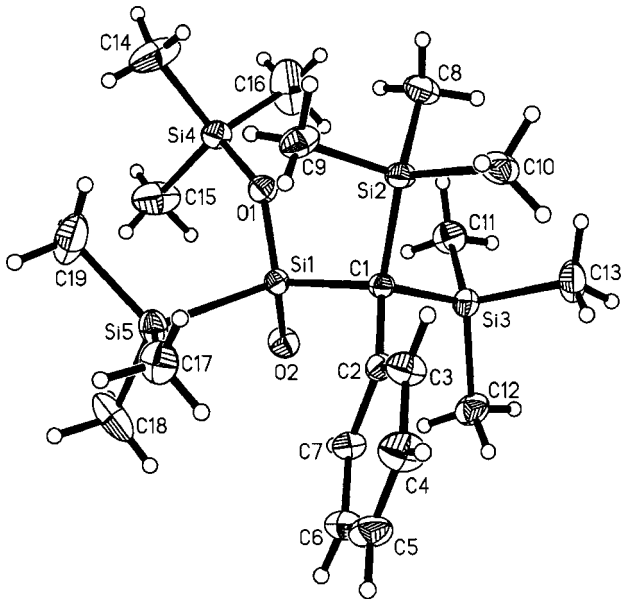

Fig. 1 Molecular structure of **2a**

In order to verify that this was a general procedure we then repeated this experiment with various other acylpolysilanes (Table 1). Whilst 4-trifluoromethylbenzoylpolysilane **1b** and acetylpolysilane **1d** gave similar products, pivaloylpolysilane **1e** failed to react and the 4-methoxyphenyl analogue **2c** underwent rapid decomposition on attempted isolation. To account for these observations we suggest that the reaction follows the pathway outlined in Scheme 1. Initial activation of the carbonyl group by the Lewis acid generates the oxacarbenium ion **5** which is stabilised by three β-Me_3Si units and R^1. In the situation in which the neighbouring alkyl group provides no stabilisation there is no reaction (R = Bu^t). Two successive 1,2 migrations of a trimethylsilyl group from silicon to carbon accompanied by a 1,2 shift of a trimethylsilyloxy group from carbon to silicon then occur. Similar migrations of trimethylsilyl groups from silicon to an adjacent cationic centre are precedented.[4–7] The precise order of these events is not clear and these may be either concerted or stepwise pathways. Whilst a silyl cation may be invoked as an intermediate in this process we have obtained no evidence for this and Lewis base coordinated species **6** and **8** (X = NTf_2^- or $RCOSiR'_3$) are probably more plausible. The resultant 'silenium ion' complex **8** is then hydrolysed by water on aqueous workup to produce the observed silanol. Use of MeOH in this final step leads to the

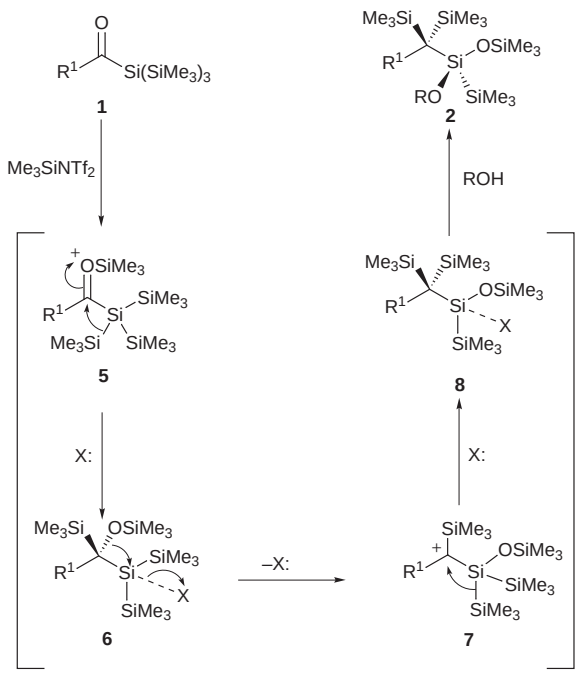
[a] Yields refer to purified isolated compounds. [b] All products gave satisfactory spectroscopic and analytical data. [c] 10 mol% of $TMSNTf_2$ was used. [d] MeOH was added as the quenching agent. [e] Product decomposed on attempted isolation.



Scheme 1 Mechanistic pathway for the reaction of acylpolysilanes **1** with trialkylsilylbistriflimides

corresponding methoxide analogue **3a** in equally good yield (Table 1, entry 3). Further evidence in support of this pathway come from the use of TBMSOTf as the Lewis acid. As predicted this leads to complete incorporation of the TBDMS group at the silyloxy position (Table 1, entry 4) as confimed by ^{29}Si NMR spectroscopy (**4a**: OSiBu^{t}Me$_2$ δ 9.48; **2a**: OSiMe$_3$ δ 5.44). Furthermore, use of substoichiometric quantities of the initiator produces the same product in a corresponding yield together with recovered starting material (Table 1, entry 2).

Similar structures have been reported by Brook in the reaction of tertiary alkyl acylpolysilanes (R = Bu^t, adamantyl and bicyclo[2.2.2]octyl) with $TiCl_4$.[4] This was accounted for by a similar mechanistic pathway although, in this latter case, a 1,3 methyl shift from one of the trimethylsilyl groups to the 'silenium ion' also occurs. The reason for this difference between the $TiCl_4$ and the bistriflimide promoted pathways is not obvious at the present time.

In conclusion we report a novel rearrangement of acylpolysilanes on reaction with silyl triflates. Attempts to tune this reactivity to generate silenes in a convenient fashion are in progress and will be reported in due course.

We thank GlaxoWellcome and the EPSRC for financial support of this work (studentship to R. J. G. and funding for D. S. Y., repectively), the EPSRC mass spectrometry service at Swansea for accurate mass determinations, Dr A. M. Kenwright and Mr I. H. McKeag for assistance with NMR experiments and Dr M. Jones for mass spectra. The referees are thanked for helpful comments regarding the mechanism of this transformation.

Electrorheological behaviour at low applied electric fields of microcrystalline cellulose in BP oils

Jayne L. Davies, Ian S. Blagbrough*† and John N. Staniforth

Department of Pharmacy and Pharmacology, University of Bath, Bath, UK BA2 7AY

Electrorheological fluids have been prepared at low applied electric fields from BP oils containing microcrystalline cellulose (MCC); even at a low applied electric field of 500 V mm^{-1}, 10% MCC in oils rich in linoleic or oleic acids behave as electrorheological fluids with the latter displaying significantly higher yield stresses.

Electrorheology describes the rapid and reversible change in viscosity exhibited by certain suspensions of solid particles in electrically non-conducting liquids upon application of an electric field. Electrorheological (ER) fluids can run freely like water, ooze like honey or solidify like gelatine, depending upon the applied electric field. Winslow pioneered the use of ER fluids in the 1940s, with mechanical engineering applications ranging from a simple hydraulic valve[1] to a complex tracking device for copying machines.[2] The appeal of ER fluids is the rapid response, usually on the millisecond time scale, upon application of an electric field,[3–5] and this response is completely reversible upon removal of the electric field.[5,6] Although typically the electric fields necessary to provide an ER effect are in the region of 1–5 kV mm^{-1}, the power consumption is small (mW).[7]

Traditionally, ER fluids are composed of a dispersed particulate phase,[7,8] in the size range 0.5 to 100 μm, in an insulating base fluid.[9–11] In the absence of an electric field, most ER fluids behave, to a first approximation, as Newtonian fluids. When a continuous DC electric field E is applied to an ER fluid and the fluid is sheared in a direction perpendicular to the field, the relationship between the stress τ and the shear rate γ can be described by the Bingham model. According to this equation, flow only occurs once the applied stress exceeds the static yield stress $\tau_\gamma(E)$. The flow equation is given in eqn. (1), where η_B is

$$\tau(E) = \tau_\gamma(E) + \eta_B\gamma \quad (1)$$

termed the Bingham viscosity. We are investigating the feasibility of using ER fluids as controllable drug delivery systems. In the absence of an electric field, a basal level of drug release will occur by diffusion across a mesh electrode. It is envisaged that upon application of an electric field, drug release will be controlled (hindered or halted).

We initially selected the pharmaceutically acceptable tablet excipient microcrystalline cellulose (MCC) in silicone oil as our ER fluid. This ER fluid has been recently reported, but only under high electric fields (in the range 1–3 kV mm^{-1}).[12,13] This project encompasses the search for pharmaceutically acceptable alternatives to traditional (engineering based) ER base fluid components. Thus, silicone oil (100 cS) or an alternative oil was used as the base fluid, together with sieved MCC (size fraction below 45 μm).‡ We have investigated the use of super refined BP oils as substitutes for silicone oil.‡ Oleic acid [(*Z*)-octadec-9-enoic acid] is the major constituent of apricot kernel (68%),[14] safflower (63%),‡ peanut (56%),[15] and sesame seed oils (45%).[15] Linoleic acid [(*Z*,*Z*)-octadeca-9,12-dienoic acid) is the primary constituent of sweet almond oil (75%)[16] and soyabean oil (50%).[15] In pharmaceutics, peanut and sesame seed oils find their uses as vehicles for sustained-release intramuscular injections.[16] Almond oil is also used as a vehicle for injections[17] and soyabean oil has replaced peanut oil in total parenteral nutrition regimens.[15]

A CSL^2 rheometer (TA Instruments, Leatherhead, UK) has been specially modified to allow the application of an electric field across the test fluid. A small electrolyte reservoir (approximately 0.5 ml) containing a 0.1% w/v solution of aq. KCl was used to form the electrical connection between the power supply (Model PS350 High Voltage Power Supply, Stanford Research Systems, Sunnyvale, CA, USA) and the rheometer geometry. The draw rod is insulated except for the threaded portion at the tip which makes contact with the geometry. In our experiments, we used a small volume (*ca*. 3.5 ml) concentric cylinder where the diameters of the cup and bob were 9.33 and 8.60 mm, respectively, resulting in a gap of 730 μm. All ER fluids were prepared using 10% w/w MCC (sieve fraction below 45 μm) in the appropriate oil, then sonicated (Decon FS300b) for two periods of 15 min prior to analysis. Temperature equilibration (37 ± 0.1 °C) of the sample was carried out for 15 min under the influence of an applied electric field (500 V mm^{-1}) prior to measurement. A continuous ramp of shear stresses from 0 to 50 Pa at a rate of 0.1 Pa s^{-1} was applied to each ER fluid with the resultant shear rate measured. A flow curve was plotted (Fig. 1) and the yield stress was determined by extrapolation of the experimental shear stress–shear rate data to zero shear rate using the Bingham model. Five measurements from each sample were taken and the associated mean and standard deviation were calculated (see Table 1).

In these studies, we have shown that, at a low applied electric field of 500 V mm^{-1}, suspensions of 10% w/w MCC in a range of BP oils behave as ER fluids. Furthermore, in general, BP oils afforded a higher Bingham yield stress than silicone oil (see Table 1), typically 12 Pa compared to 9 Pa. Using the ANOVA

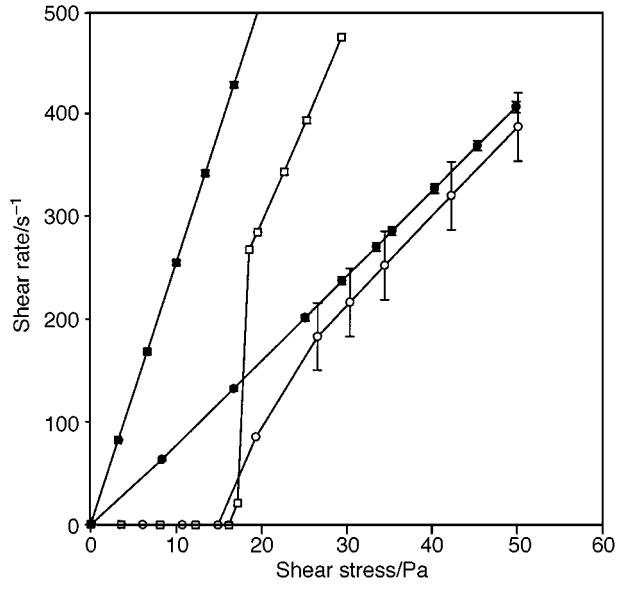

Fig. 1 Comparison of the flow behaviour at 0 V mm^{-1} [(●) silicone oil; (■) sesame seed oil] and 500 V mm^{-1} [(○) silicone oil; (□) sesame seed oil]

Table 1 The Bingham yield stress values for 10% w/w MCC in various oils at 500 V mm^{-1} (n = 5)

Oil	Bingham yield stress/Pa	Standard deviation
Almond	8.79	0.29
Apricot	12.54	0.39
Peanut	12.78	0.33
Safflower	12.17	0.47
Sesame seed	12.27	0.12
Silicone	8.94	0.26
Soyabean	10.53	0.37

test (one way), it was found that there were statistical differences ($p < 0.05$) between the oils. A Fisher analysis was carried out to highlight where differences were present. No significant difference ($p < 0.05$) was found between almond oil and silicone oil. Apricot oil, peanut oil, safflower oil, and sesame seed oils were also found not to be significantly different. In the light of these findings, we conclude that the BP oils which have oleic acid as the major constituent have significantly higher yield stress values compared with the BP oils having linoleic acid as their major constituent. Preliminary studies, using a parallel plate geometry, with 10% MCC in oleic and linoleic acids (*ca.* 95%)‡ also exhibited an ER response at 250 V mm^{-1}. This demonstration of ER responses below 1 kV mm^{-1}, using pharmaceutically acceptable oils, should find ready applications.[18–22]

We thank Hoechst Marion Roussel (Swindon, UK, and Kansas City, USA) for funding this studentship (to J. L. D.). We gratefully acknowledge the support and interest of Dr David Jordan (HMR, Swindon) in our studies.

Bismuth(III) thioether chemistry: the synthesis and structure of $[Bi_4Cl_{12}(MeSCH_2CH_2CH_2SMe)_4]_n{\cdot}nH_2O$, a highly unusual network involving Bi_4Cl_4 rings and bridging dithioether ligands

Anthony R. J. Genge, William Levason and Gillian Reid*

Department of Chemistry, University of Southampton, Highfield, Southampton, UK SO17 1BJ. E-mail: gr@soton.ac.uk

The structure of $[Bi_4Cl_{12}(MeSCH_2CH_2CH_2SMe)_4]_n{\cdot}nH_2O$ involves $Bi_4Cl_{12}(\eta^1\text{-}MeSCH_2CH_2CH_2SMe)_4$ tetrameric units which are linked by bridging dithioether ligands to give a three-dimensional polymeric network; the Bi_4Cl_4 core is an eight-membered heterocycle which adopts an open cradle conformation.

With the exception of complexes with phosphine and amine ligands,[1,2] the coordination chemistry of the heavier p-block elements such as bismuth is rather poorly developed. A small number of Bi^{III} complexes involving macrocyclic thioethers has been described, including $[BiCl_3([9]aneS_3)]$ ([9]aneS$_3$ = 1,4,7-trithiacyclononane),[3] $[BiCl_3([12]aneS_4)]$ ([12]aneS$_4$ = 1,4,7,10-tetrathiacyclododecane)[4] and $[BiCl_3([18]aneS_6)]$ ([18]aneS$_6$ = 1,4,7,10,13,16-hexathiacyclooctadecane).[5] Macrocyclic ligands however offer enhanced binding properties over acyclic ligands, are conformationally less flexible than their acyclic counterparts and often exhibit different binding modes. Structural studies have shown that these macrocyclic Bi species are discrete molecular entities, with coordination numbers varying from six to nine. As part of our investigation into thio-, seleno- and telluro-ether complexes with p-block elements we report here the preparation and structure of a very unusual Bi^{III} compound $[Bi_4Cl_{12}(MeSCH_2CH_2CH_2SMe)_4]_n{\cdot}nH_2O$. Other than the macrocyclic compounds described above, the only structurally characterised Bi^{III} thioether complex is $[Bi_2I_8(SMe_2)_2][SMe_3]_2$.[6]

Reaction of $BiCl_3$ with 1 mol equiv. of $MeSCH_2CH_2CH_2SMe$ in CH_2Cl_2 affords a light yellow solution. Following filtration and concentration of the solution, the flask was left to stand for several days during which yellow crystals of a compound with the formula $[BiCl_3(MeSCH_2CH_2CH_2SMe)]{\cdot}H_2O$ were isolated in *ca.* 20% yield. The IR spectrum shows the presence of the dithioether, as well as several peaks in the range 300–230 cm^{-1} assigned to Bi–Cl stretching vibrations. Microanalyses are also consistent with the above formulation. Traces of moisture in the CH_2Cl_2 probably account for the associated water. A single crystal X-ray structure determination† revealed a three-dimensional polymeric network with the structural formula $[Bi_4Cl_{12}(MeSCH_2CH_2CH_2SMe)_4]_n{\cdot}nH_2O$. The structure involves $Bi_4Cl_{12}(MeSCH_2CH_2CH_2SMe)_4$ tetrameric units (related by crystallographic $\bar{4}$ symmetry) which are linked by bridging dithioether ligands to give a three-dimensional polymeric network [Fig. 1(a) and (b)]. Each Bi^{III} ion is therefore coordinated to two terminal Cl atoms, Bi–Cl(2) 2.538(7), Bi–Cl(3) 2.533(7) Å, two μ_2 bridging Cl atoms, Bi–Cl(1) 2.913(7), Bi–Cl(1*) 2.969(6) Å, and two S-donors from different bridging dithioether ligands, Bi–S(1) 2.857(7), Bi–S(2*) 2.977(7) Å. The geometry at each Bi atom therefore approximates to a severely distorted octahedron, with an open triangular face which we assume is occupied by the Bi lone pair. The μ_2-bridging Bi–Cl distances are much longer than the terminal distances and are themselves only slightly different, hence an alternative description is that the structure comprises of $[BiCl_2(\eta^1\text{-}MeSCH_2CH_2CH_2SMe)_2]^+$ cations loosely associated into tetramers through interactions with chloride anions, Cl(1) and Cl(1*). There are additional long range, weak interactions which link the μ_2-bridging Cl atoms to Bi centres across the Bi_4Cl_4 ring, forming a pseudo-cuboid arrangement, Bi···Cl(1*) 3.268(7) Å. This interaction is significantly longer than one would expect for a genuine μ_3-bridging Cl.[7] The

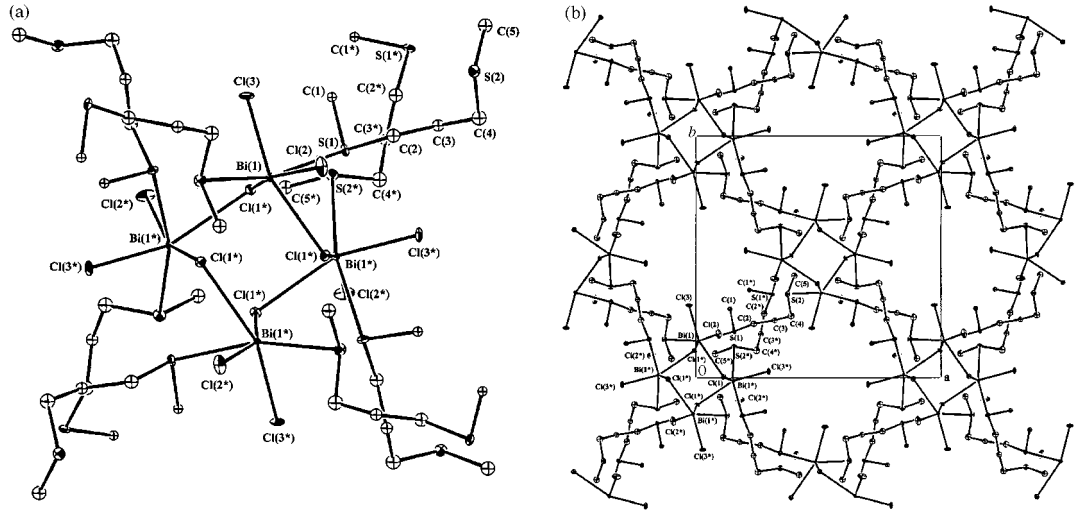

Fig. 1 (*a*) View of a portion of the $[Bi_4Cl_{12}(MeSCH_2CH_2CH_2SMe)_4]_n$ structure with the numbering scheme adopted (H atoms are omitted for clarity and atoms marked with an asterisk are related by a crystallographic $\bar{4}$ operation). Selected bond lengths (Å): Bi–Cl(1) 2.913(7), Bi–Cl(2) 2.538(7), Bi–Cl(3) 2.533(7), Bi–S(1) 2.857(7), Bi–S(2*) 2.977(7) Å. (*b*) View down the *c*-axis of the three-dimensional polymer, illustrating the channels running through the structure.

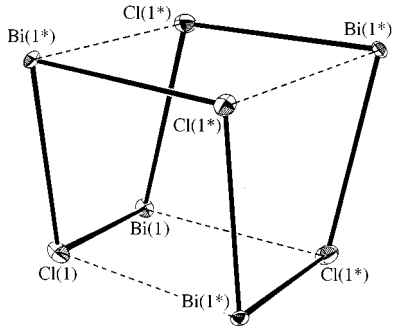

Fig. 2 View of the Bi_4Cl_4 core, illustrating the open cradle conformation. The dashed lines indicate the secondary Bi···Cl interactions.

Bi_4Cl_4 core forms an eight-membered heterocyclic ring which, as a result of the weak Bi···Cl interactions adopts an open cradle conformation (Fig. 2). The secondary Bi···Cl(1*) interaction is in the general direction of the void assumed to be occupied by the lone pair, but not in the direction of the maximum electron density. This behaviour is commonly observed in Bi^{III} and Sb^{III} chemistry.[8]

Bismuth halides often form compounds incorporating partially condensed Bi_4X_4 polyhedra,[7] however, the open cradle or pseudo-cuboid arrangement adopted in the title compound is very unusual. The Bi–S and $Bi–Cl_{terminal}$ bond lengths are similar to those observed in the reported macrocyclic thioether complexes of Bi^{III}, *e.g.* seven-coordinate $[BiCl_3([12]aneS_4)]$ [Bi–S 2.987(3)–3.072(3), Bi–Cl 2.569(4)–2.575(3) Å] and nine-coordinate $[BiCl_3([18]aneS_6)]$ [Bi–S 3.146(4)–3.225(4), Bi–Cl 2.607(4) Å]. The polymeric network arises due to incorporation of bridging $MeSCH_2CH_2CH_2SMe$ ligands. We have shown previously that this and other related group 16 donor ligands can bind to Cu^{I} and Ag^{I} centres and in a small number of cases also yield complex polymeric arrays, although quite different in detail from the title compound.[9]

Further work is underway to establish whether this highly unexpected structural motif is replicated in other Bi^{III} complexes with group 16 donor ligands, and to understand the factors which influence the assembly of supramolecular arrays of this type.

We thank the University of Southampton and the EPSRC for support and thank one of the referees for helpful comments on the structural description.

Notes and References

† *Crystal data* for $C_5H_{12}BiCl_3S_2·H_2O$, M = 469.62, tetragonal, space group $P\bar{4}2_1c$, a = 16.440(10), c = 11.843(7) Å, V = 3200 Å^3, Z = 8, D_c = 1.949 g cm^{-3}, μ(Mo-Kα) = 117.26 cm^{-1}. A pale yellow block (0.40 × 0.35 × 0.10 mm) grown by slow evaporation of a solution of the compound in CH_2Cl_2 was mounted on a Rigaku AFC7S four-circle diffractometer. Data collection at 150 K using Mo-Kα X-radiation (λ = 0.710 73 Å), gave 1668 unique reflections of which 1183 with $F \geqslant 4\sigma(F)$ were used in all calculations. The structure was solved using direct methods[10] and developed by iterative cycles of least-squares refinement[11] and difference Fourier synthesis which revealed a $BiCl_3(MeSCH_2CH_2CH_2SMe)$ unit and a water molecule in the asymmetric unit. Crystallographic $\bar{4}$ symmetry generates the tetrameric unit and the three-dimensional array. The data were corrected for absorption using DIFABS[12] with the model at isotropic convergence (max., min. transmission factors = 1.000, 0.309, respectively). Some of the C atoms in the ligand backbone show quite high thermal motion, although alternative sites could not be identified, hence these were refined isotropically. Anisotropic thermal parameters were refined for the Bi, Cl and S atoms and H atoms associated with the dithioether were included in fixed, calculated positions (the H atoms associated with the H_2O solvent molecule were not located). At final convergence, R = 0.050, R_w = 0.066, S = 1.80 for 79 parameters. CCDC 182/1002.

Satisfactory spectroscopic and analytical data were obtained.

On the efficacy of propeller-shaped, C_3-symmetric triarylphosphines in asymmetric catalysis

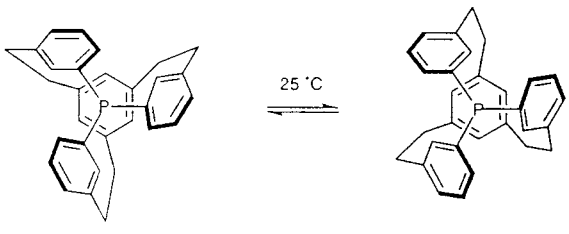
Mark T. Powell, Alexander M. Porte and Kevin Burgess*

Department of Chemistry, Texas A & M University, PO Box 300012, College Station, TX 77842-3012, USA.
E-mail: burgess@chemvx.tamu.edu

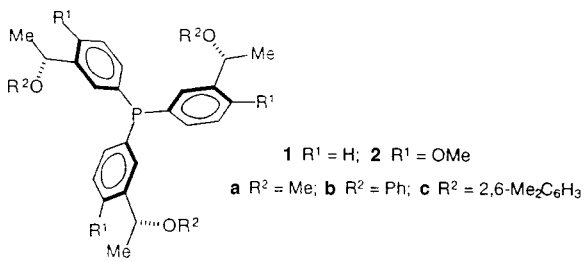
Ligand sets 1 and 2 were prepared and examined for evidence of C_3-symmetric propeller-shaped conformations in solution, and for their ability to induce enantioselectivity in an allylation reaction.

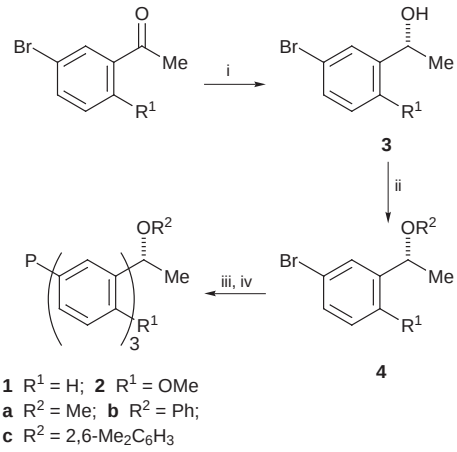
There are conflicting arguments with regard to the potential of optically pure, C_3-symmetric triarylphosphines in asymmetric syntheses. Some researchers may correctly point to the value of C_2-ligands[1] and claim that application of C_3-ligands is a logical extrapolation of the field. C_3-Symmetric arrangements of three aromatic groups around a central atom can adopt stable enantiomeric propeller-shaped conformations that might provide chiral pockets to facilitate enantiodiscrimination.[2] However, the contrary argument is also convincing. Asymmetric induction cannot increase indefinitely with the symmetry of the chiral directing group because a perfectly spherical object would be useless for inducing a chiral environment.

Experimentally, the value of optically active, propeller-shaped, C_3-symmetric phosphines is hard to assess. This is because of synthetic difficulties associated with obtaining the requisite ligands, and due to a lack of techniques to recognize rigid propeller conformations in solution. Sharpless and co-workers, for instance, prepared triarylphosphine cage structures (an example is shown below) by relatively difficult synthetic routes.[3,4] They then found that in an optically active complex, this ligand stereomutates between enantiomeric propeller-shaped conformations at room temperature. This ligand design therefore did not facilitate a test of the efficacy of propeller-shaped C_3-symmetric ligands, hence their value remained questionable. The work described in this manuscript deals with attempts to address this issue using phosphines **1** and **2**. The tenet of this project is that a chiral substituent on the aromatic rings could be easily installed, and may lead to stable C_3-symmetric propeller-shaped aryl arrays in the ligand.



an easily racemized C_3 ligand from Sharpless





Scheme 1 *Reagents and conditions*: i, $BH_3{\cdot}SMe_2$, 5 mol% 4,5,6,7-tetrahydro-1-methyl-3,3-diphenyl-1*H*,3*H*-pyrrolo[1,2]-[1,3,2]oxazaborolebornane (CBS),[8] CH_2Cl_2, −25 °C, 12 h (94% and 96.2% ee for **1**; 85%, 99% ee for **2**); ii, alkylation (yields range from 70 to 99%, *e.g.* MeI, NaH, DMF for **1a**); iii, ^{t}BuLi, Et_2O, −30 °C, 1 h; iv, PCl_3, Et_2O, −30 to 25 °C (yields typically 30–50% for steps iii and iv)

Scheme 1 outlines the route by which the ligand set **1a–1c** (and later **2a–2c**) was obtained. The route diverges from the common chiral alcohol intermediate **3** hence this strategy is more efficient than ones that rely on different starting materials for each phosphine prepared.

Evidence for preferred stereoisomeric propeller-shaped conformations in solution is hard to obtain. Crystallographic studies of derivatives such as complex **5a** (Fig. 1) indicated the desired conformations exist in the solid state, but these observations can give no indication of their dynamic behavior in solution. Consequently, a set of circular dichroism (CD) spectra was recorded to elucidate solution state conformations. Chiral ordering of the aromatic groups should be accompanied by

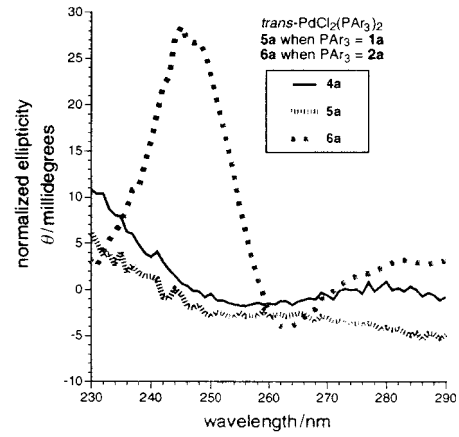


Fig. 1 Comparison of normalized ellipticities (*i.e.* ellipticities per mole of aromatic ring) for compounds **4a**, **5a** and **6a**

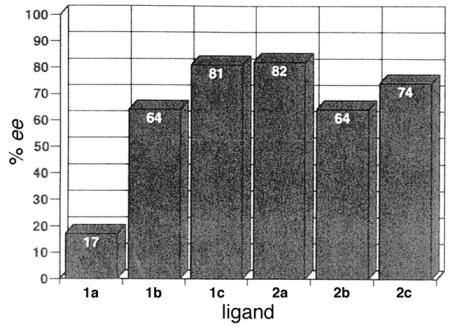

Fig. 2 Phosphines **1** and **2** in an allylation reaction (unoptimized yields, measured by GC using an internal standard: **1a**, 72%; **1b**, 33%; **1c**, 54%; **2a**, 50%; **2b**, 51%; **2c**, 47%)

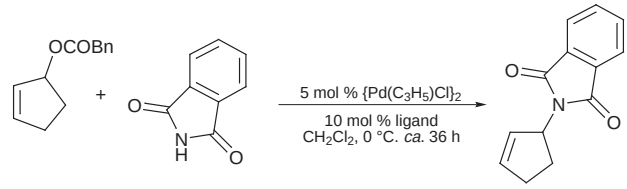
increased molar ellipticities at wavelengths corresponding to aromatic absorptions for palladium complex **5a** relative to the aryl bromide starting material **4a**.[5] Fig. 1 shows that an increased ellipticity was not observed for complex **5a** derived from ligand **1a**. This led us to suppose that conformational rigidity could be increased by incorporation of a *para*-substituent to disfavor free rotation about the bond to the *meta*-chiral center. Consequently, ligand set **2** was prepared and selected derivatives were examined by CD. Fig. 1 indicates that complex **6a** derived from ligand **2a** does indeed show an enhanced ellipticity relative to intermediate **4a**.

High throughput parallel screens[6] were used to test ligands **1** and **2** in the palladium mediated allylation reaction illustrated below. Thus reactions were run simultaneously in wells contained in a cooled aluminium block, then analyzed using an autosampler/chiral HPLC apparatus. Details of this approach applied in other studies from our group have been documented.[7] Fig. 2 shows the data obtained. The enantioselectivities reached an optimum value of 82%. We think that this level of induction by the distal chiral *meta*-substituents would not be possible unless ordering of the aromatic rings were operative. Enhanced ellipticities when a *para*-substituent is present (*i.e.* **2a** *vs.* **1a**) correlates with dramatically increased enantioselectivities. On average, higher enantioselectivities tend to be observed for the ligands **2** than for series **1**.



The data presented here suggest that phosphines **2** can exist in conformations in which the aromatic groups are ordered in propeller-shaped arrays, and that these same phosphines give significant induction in an allylation reaction. However, it is unlikely that perfectly C_3-symmetric conformations predominate for ligand **2** in complexes because the *meta*-substituent can adopt orientations that are *exo* and *endo* with respect to the metal. Work now in progress concerns a ligand system for which this is not a possibility.

We thank Marcel Jaspars for some informative preliminary experiments. Formation of oligomers of methyl- and phenyl-pyrrole at an electrified liquid/liquid interface

Vincent J. Cunnane*† and Una Evans

Advanced Sensors Research Unit, Department of Chemical and Environmental Sciences, University of Limerick, Limerick, Ireland

The formation of oligomers of 1-methylpyrrole and 1-phenylpyrrole has been initiated by a heterogeneous electron transfer (HET) step at the interface of two immiscible electrolyte solutions; the HET leads to the formation of a radical cation of the monomer in the organic phase.

In 1975 Guainazzi *et al.*[1] reported that a direct current applied across the liquid/liquid interface of a heterogeneous, unreactive $Cu^{2+}/[V(CO)_6]^-$ redox system, with $CuSO_4$ in the aqueous phase and tetrabutylammonium hexacarbonylvanadate in a 1,2-dichloroethane (DCE) phase, led to the deposition of a copper layer at the interface. More recently electrochemical–chemical (EC) type mechanisms have been reported for such liquid/liquid interfaces.[2,3] Here we report on a novel EC type reaction between an aqueous redox couple and a monomer in DCE leading to oligomer formation in the organic phase, where for the first time the electrochemical step is an electron transfer.

A general scheme for the equilibrium condition for the two phase electron transfer reaction [eqn. (1)] where a reducible

$$n^2O^{1(w)} + n^1R^{2(o)} \leftrightarrow n^1O^{2(o)} + n^2R^{1(w)} \quad (1)$$

species O^1 in the aqueous phase reacts with an oxidisable species R^2 in the organic phase can be expressed in terms of individual ionic activities and the Galvani potential of each phase, leading to a Nernst type equation of the form shown in eqn. (2), where $E°_i$ is the standard potential of the couples in

$$\Delta^w{}_o\phi = E°_{R^2/O^2} - E°_{R^1/O^1} + (RT/n^1n^2F)\ln J_a \quad (2)$$

each phase, R is the gas constant, T is the absolute temperature, F the Faraday constant and J_a is given by eqn. (3), where a is the

$$J_a = a^{n^2}{}_{R^1}a^{n^1}{}_{O^2}/a^{n^2}{}_{O^1}a^{n^1}{}_{R^2} \quad (3)$$

activity of the species in each phase. As such, the position of equilibrium in a two phase redox system is dependent on the values of the standard potentials and also on the interfacial Galvani potential difference.[4] Hence for a given system the position of equilibrium can be determined by an externally imposed Galvani potential difference, using standard electrochemical instrumentation. A HET reaction can thus be observed in the available potential window by careful matching of the standard potentials of the redox couples in each phase.

Cyclic voltammetry (CV) was the main technique used. A flat water/1,2-DCE interface with an area of 0.125 cm^2 was formed in a four electrode cell. The potential difference at the interface was controlled using a four electrode potentiostat (Model 2000, Sycopel Scientific Ltd., Boldon).

DCE (Fluka 99.5% GC grade) was used as received as the organic solvent in all experiments. 18.2 MΩ water used throughout and was prepared using the Maxima ultra pure water system. Li_2SO_4 (Fluka > 98.0%) was used as received as the aqueous supporting electrolyte. Tetraphenylarsonium chloride (TPAsCl) (Fluka, 95%) was used as received in the organic reference phase. Tetraphenylarsonium tetrakis(4-chlorophenyl)borate (TPAsTCPB) was the supporting electrolyte in the organic phase and was prepared using TPAsCl and sodium tetrakis(4-chlorophenyl)borate (NaTCPB) (Fluka > 98.0%). Ferrous sulfate·$7H_2O$(Aldrich 99+%), ferric sulfate·$5H_2O$(Aldrich 97%), 1-methylpyrrole (MPy, Aldrich 99%) and 1-phenylpyrrole (PPy, Aldrich 99%) were also used as received.

To measure the half-wave potentials ($E_{1/2}$) of the aqueous redox couples and the oxidation potentials of the monomers in DCE a 10 μm platinum microelectrode was used. The $E_{1/2}$ of oxidation of 1-methylpyrrole and 1-phenylpyrrole, in the organic electrolyte system, were found to be 750 and 720 mV *vs.* SCE, respectively. Fe^{2+}/Fe^{3+} in the form of $Fe_2(SO_4)_3$/$Fe(SO_4)$ was chosen as the aqueous redox couple as it has a closely matching halfwave potential, with an $E_{1/2}$ of 650 mV *vs.* SCE in the aqueous electrolyte system.

The cell used to observe the electron transfer is shown in Scheme 1,where the monomer is 1-methylpyrrole or 1-phenylpyrrole and δ represents the interface.

Pt/10 mmol Li_2SO_4 + 10 mmol $Fe_2(SO_4)_3$ and 10 mmol $FeSO_4$ (aq)/δ/1 mmol TPAsTCPB + 0.5 mmol monomer (DCE)/1 mmol TPAsCl (aq)/AgCl/Ag

Scheme 1

When the aqueous redox couple is present and in the absence of monomer in the organic phase no charge transfer is observed in the potential window of interest and also no charge transfer is observed when the monomer is present but in the absence of the aqueous redox couple.

When both the aqueous redox couple and monomer are present a charge transfer reaction occurs, this is shown in Fig. 1(*a*). It was found that on continuous cycling the shape of the CV trace changes to give a characteristic S-shaped curve [Fig 1 (*b*)].

From eqn. (2) it can be seen that for a HET reaction, changing the ratio of concentrations of the aqueous redox couple should change the $E_{1/2}$ of the electron transfer reaction and, as can be seen from Tables 1 and 2, this is indeed the case.

Table 1 shows the variation of $E_{1/2}$ for the charge transfer reaction with varying Fe^{III}:Fe^{II} when the cell is: Pt/10 mmol Li_2SO_4 + *x* mmol $Fe_2(SO_4)_3$ and *y* mmol $FeSO_4$ (aq)/δ/1 mmol TPAsTCPB + 0.5 mmol MPy (DCE)/1 mmol TPAsCl (aq)/AgCl/Ag.

Table 2 shows the variation of $E_{1/2}$ for the electron transfer reaction with varying Fe^{III}:Fe^{II} when the cell is: Pt/10 mmol Li_2SO_4 + *x* mmol $Fe_2(SO_4)_3$ and *y* mmol $FeSO_4$ (aq)/δ/1 mmol TPAsTCPB + 0.5 mmol PPy (DCE)/1 mmol TPAsCl (aq)/AgCl/Ag.

Table 1 Variation of $E_{1/2}$ with varying Fe^{III}:Fe^{II} for the charge transfer reaction with MPy

Ratio Fe^{3+}:Fe^{2+}	$Fe_2(SO_4)_3$/ mmol	$Fe(SO_4)$/ mmol	$E_{1/2}$/mV
1:5	1	10	565
2:1	10	10	640
4:1	10	5	660
10:1	10	2	No e-transfer

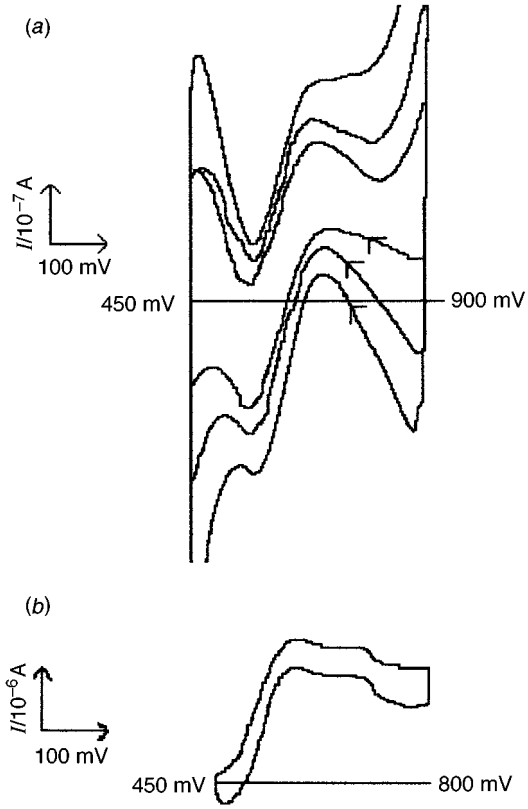

Fig. 1 (*a*) Cyclic voltammograms of the system: Pt/10 mmol Li_2SO_4 + 10 mmol $Fe_2(SO_4)_3$ and 10 mmol $FeSO_4$ (aq)/δ/1 mmol TPAsTCPB + 0.5 mmol MP (DCE)/1 mmol TPAsCl (aq)/AgCl/Ag. Sweep rates: 10, 25 and 50 mV s^{-1}. (*b*) Cyclic voltammogram of the system: Pt/10 mmol Li_2SO_4 + 10 mmol $Fe_2(SO_4)_3$ and 10 mmol $FeSO_4$ (aq)/δ/1 mmol TPAsTCPB + 5 mmol MP (DCE)/1 mmol TPAsCl (aq)/AgCl/Ag after cycling for 30 min at a sweep rate of 100 mV s^{-1}.

The changing shape of the cyclic voltammogram suggested that the electron transfer reaction is not reversible and that the organic phase changes throughout the experiment. UV–VIS spectroscopy was used to study the organic phase. The organic phase was removed from the cell and transferred to a quartz cuvette.

The 1-methylpyrrole monomer shows a characteristic peak at 247 nm when dissolved in DCE. On addition of the base electrolyte salt TPAsTCPB this characteristic monomer peak disappears and a new peak is detected at 271 nm. The disappearance of the monomer peak is probably due to the fact that this sample is blanked using 10 mmol TPAsTCPB, which absorbs in the region below 300 nm. After cycling for 10 min a peak is detected at 293 nm and after 20 min of cycling a peak is detected at 309 nm.

Table 2 Variation of $E_{1/2}$ with varying Fe^{III}:Fe^{II} for the electron transfer reaction with PPy

Fe^{3+}:Fe^{2+}	$Fe_2(SO_4)_3$/ mmol	$Fe(SO_4)$/ mmol	$E_{1/2}$/mV
1:5	1	10	No e-transfer
2:1	10	10	630
20:1	10	1	690

The 1-phenylpyrrole monomer shows a characteristic peak at 260 nm when dissolved in DCE. On addition of the base electrolyte salt TPAsTCPB a peak is observed at 292 nm. After cycling for 10 min a peak is detected at 304 nm, which does not change significantly with further cycling.

Rohde *et al*.[5] reported that the absorbtion maxima of oligomers of 1-methylpyrrole increase with increasing chain length. They found that 1-methylpyrrole monomer has a λ_{max} value of 250 nm increasing to λ_{max} of 290 nm for oligomers with eight methylpyrrole units. They extrapolated the λ_{max} of the insulating polymer, an oligomer of infinite chain length, to be 310 nm.

This change in λ_{max} is observed here for 1-methylpyrrole (and 1-phenylpyrrole) with increasing cycling time. This is an indication that oligomers are being formed in the organic phase.

We have shown for the first time that an electron transfer reaction can be brought about between an aqueous-based redox system and an organic-based monomer unit at an electrified liquid/liquid interface. It is presumed that the electron transfer results in the formation of a radical cation in the organic phase. This radical cation will then undergo various chemical steps leading to the formation of oligomers in the organic phase. Further research is investigating the nature of the oligomers formed and their conducting properties. The system is being expanded to look at other electroactive monomer and organic systems.

This work was supported by Forbairt Scientific Programme (SC/95/255) and by the EU-TMR Network, ODRELLI (ERBFMRXCT960078).

FEATURE ARTICLE

‘Oxo-hydroxo tautomerism’ as useful mechanistic tool in oxygenation reactions catalysed by water-soluble metalloporphyrins

Jean Bernadou*† and Bernard Meunier*†

Laboratoire de Chimie de Coordination du CNRS, 205 route de Narbonne, 31077 Toulouse cedex 4, France

High valent metal–oxo species have been evoked as active intermediates in many different oxidation reactions using manganese or iron porphyrin complexes as catalysts and oxygen atom donors (H_2O_2, PhIO, NaOCl, $KHSO_5$, ... *etc*.) or dioxygen associated to a reductant as oxygen atom source. When these metalloporphyrin-catalysed oxidations are performed in water, such metal–oxo species are able to transfer an oxygen atom coming from either the oxygen source or from bulk water. This fact has been explained by the so-called oxo–hydroxo tautomerism, a mechanism involving a rapid shift of two electrons and one proton from a hydroxo ligand (electron-rich ligand formed by deprotonation of an aqua ligand) to the trans oxo species (electron-poor ligand) leading to the transformation of the hydroxo ligand into an electrophilic oxo entity on the opposite side of the initial oxo. This ‘oxo–hydroxo tautomerism’, evidenced by using ^{18}O-labelled water, has been used as mechanistic tool to unambiguously characterize oxygen atom transfer mechanisms mediated by metal–oxo species in opposition to mechanisms related to free radical oxidation reactions.

Introduction

High-valent metal–oxo intermediates play an important role in catalytic processes involving dioxygen activation and O-atom transfer reactions performed by hemoproteins such as cytochromes P-450 and some peroxidases.[1,2] For example, the so-called Compound I of peroxidases (Cpd I), with two oxidizing equivalents above the ferric state, has been characterised in horseradish peroxidase as an iron(IV)–oxo porphyrin π cation radical, and the great reactivity of P-450 is believed to derive from a formal iron(V)–oxo porphyrin species acting as ultimate oxidant.[3–6] Compound II (Cpd II), the second catalytic intermediate of peroxidases, is an iron(IV)–oxo with only one oxidizing equivalent above the resting state of the corresponding native heme–enzyme. There is no Cpd II intermediate in the catalytic cycle of cytochrome P-450.

$Por\text{-}Fe^{III}$
native state of P-450 or peroxidase

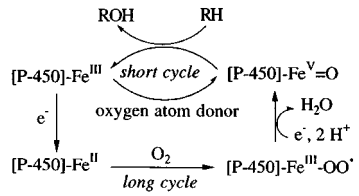
$Por\text{-}Fe^{V}{=}O$ or $(Por^{\bullet+})Fe^{IV}{=}O$ — P-450 active species or Cpd I

$Por\text{-}Fe^{IV}{=}O$ — Cpd II

The recent discovery of oxo–hydroxo tautomerism can contribute to a better characterisation and an improved understanding of chemical reactivities of these high-valent metal–oxo species, not only important for the knowledge of heme-enzymes catalyzing oxidations, but also in the design of efficient biomimetic or bioinspired oxidation catalysts. After a short survey on the characteristics of high-valent metal–oxo complexes, this Feature Article will be focused on the oxo–hydroxo tautomerism.

High-valent metal–oxo species in heme-enzymes and related chemical models

The oxidative reactions mediated by cytochrome P-450 are better described with an iron(V)–oxo as active entity than with any other putative species. Taking in consideration all the different experimental data accumulated for the last three decades on cytochrome P-450, it is reasonable to assume that hydroxylation of alkanes, epoxidation of electron-rich alkenes and formation of *N*-oxides are performed by an electrophilic high-valent iron(V)–oxo rather than by a nucleophilic Fe^{III}–OOH intermediate. The high oxidation state of iron in the perferryl $Fe^{V}{=}O$ species might be reduced by transfering one electron from the sulfur atom of the cysteinato proximal ligand, or from the porphyrin ligand like in peroxidases [ferryl is used for an iron(IV)–oxo species; perferryl is used for an iron(V)–oxo species or an iron(IV)–oxo with a radical cation on the macrocyclic ligand, like in Cpd I of peroxidases].[5b,7] This audacious hypothesis has been supported by establishing in 1975 that a single oxygen atom donor, namely iodosylbenzene PhIO, was a suitable co-factor for a P-450 mediated O-dealkylation reaction.[8] Then, the modeling of peroxide shunt in the catalytic cycle of cytochrome P-450 (short cycle in Scheme 1)



Scheme 1 Catalytic cycle of cytochrome P-450 with the formation of an iron(V)–oxo species (or an iron(IV) radical-cation as in Cpd I of peroxidases) *via* a ‘long catalytic cycle’ with dioxygen, two electrons and two protons or *via* a ‘short cycle’ (peroxide shunt) with oxygen atom donors (PhIO, NaOCl, $KHSO_5$, H_2O_2)

was demonstrated with synthetic metalloporphyrins using PhIO, NaOCl, $KHSO_5$ or H_2O_2.[2,5b,9–12] There is no physical characterisation of the putative iron(V)–oxo for cytochrome P-450 itself because of its very short lifetime, but its orbital diagram based on different calculations has been described by several groups.[13,14] The reactive high-valent iron or manganese–oxo species are usually depicted with a double-bond between the metal and the oxygen atom [complex **A** in Scheme 2, case of an iron(V)–oxo species]. This classical way to represent a metal–oxo bond is convenient to describe the oxidation state of the metal, but one drawback is that the same formalism is used for the non-labile $Ti^{IV}{=}O$ derivative as for the highly reactive $Fe^{V}{=}O$ or $Mn^{V}{=}O$ complex. In fact, the electronic structure of the form **A** with a metal–oxygen double bond is probably higher in energy than the diradical form **B**, an iron(IV)–oxoid species, in a similar way as singlet dioxygen, with a double bond, is higher in energy by 23 kcal mol^{-1} (1 cal = 4.184 J) compared to the triplet ground state, with a single O–O bond and two unpaired electrons (the name ‘oxoid’ underlines the reduction of the bond order between the metal

Form **A** ('singlet state') Form **B** ('triplet state')
d^3 iron(V)–oxo d^4 iron(IV)–oxoid

Scheme 2 Different representations of high-valent iron–oxo entities: form **A** with a double Fe–O bond and form **B** with a diradical and a single Fe–O bond (for a discussion on these two different electronic configurations of iron–oxo species, see ref. 13). X = anionic axial ligand.

center and the oxygen atom). So, the ground state of the high-valent iron–oxo species of cytochrome P-450 will ressemble the diradical Fe^{IV}–O· (for **B**) whereas Fe^{V}=O with a formal double bond (form **A**) represents an excited state. However, Schwarz and coworkers have recently proposed that both states of the perferryl entity will be involved in catalytic hydroxylations, with a spin inversion during the reaction.[13]

The high-valent iron–oxo species of Cpd I of peroxidases (horseradish peroxidase HRP, ligninase, . . . *etc.*) has a lifetime which is long enough to allow the collection of physical data by different methods: UV–VIS, EPR, magnetism, resonance Raman, X-ray absorption and Mössbauer.[2] All these different methods confirmed that Cpd I of horseradish peroxidase is a perferryl species with a radical-cation on the porphyrin ligand $(Por^{\cdot+})Fe^{IV}$=O. X-Ray absorption[15] and resonance Raman[16] studies respectively indicated that the Fe=O bond distance was 1.6 Å with a vibration at 737 cm^{-1}. The π-radical-cation of Cpd I has a predominant $^2A_{2u}$ character, indicative of an electron abstraction from the a_{2u} orbital of the porphyrin ligand.[17] This porphyrin radical is weackly ferromagnetically coupled with the spin $S = 1$ of the ferryl state.[18] It should be noted that HRP is unable to catalyze O-atom transfer reactions, in contrast to chloroperoxidase, suggesting that the lability of the high-valent iron–oxo is mainly controlled by the axial ligand (both chloroperoxidase and cytochrome P-450 have a cysteine as proximal ligand, instead of a histidine for a horseradish peroxidase).[19,20] The reduced accessibility for substrates in HRP can not be the only factor to explain the absence of oxygenation activity for this enzyme, since the amino acids of the distal site responsible for the heterolytic cleavage of the peroxidic O–O bond are not oxidized during the catalytic cycle of HRP despite their close interactions with the active site.

Since the pioneering work of Groves *et al.*[3] on the characterisation of an iron(IV)–oxo radical-cation porphyrin complex, many groups have focused their efforts on the isolation and the description of chemical models of heme-enzymes. In all these model systems, the exchange between the spin $S = 1$ of the ferryl group with the spin $S' = 1/2$ of the porphyrin radical-cation was found to be strongly ferromagnetic in contrast to the weak ferromagnetic coupling usually observed with Cpd I derivatives.[21] The one-electron reduced complex, namely $(Por)Fe^{IV}$=O equivalent to a peroxidase Cpd II, which was described early in the cases of six-coordinate[22*a*] and five-coordinate[22*b*] porphyrin complexes, can be isolated by a reductive chromatography of $(Por^{\cdot+})Fe^{IV}$=O over basic alumina and is stable at room temperature.[22*c*] A $(Por)Mn^{IV}$=O complex has been characterised by X-ray absorption spectroscopy.[23] The Mn–O bond distance is 1.69 Å and the complex has a $S = 3/2$ spin state corresponding to a high spin d^3 configuration. Recently, it has been reported the detection and the characterization of a manganese(V)–oxo porphyrin complex by rapid-mixing stopped-flow spectrophotometry.[24]

High-valent iron–oxo complexes can be prepared with peracids *via* the intermediate formation of a acylperoxo–iron(III) porphyrin complex. This latter compound undergoes a heterolytic cleavage of the O–O bond in dichloromethane to provide the iron–oxo or a homolytic cleavage in toluene to give rise to a bridged *N*-oxide porphyrin.[25] It must be noted that all the high-valent metal–oxo porphyrin complexes are highly electrophilic and as such react with alkanes, alkenes or heteroatoms in contrast to the nucleophilic $(Por)Fe^{III}$–OOH complexes[26] (see also ref. 27 for the use of thianthrene-5-oxide as a probe to distinguish between electrophilic and nucleophilic oxidants).

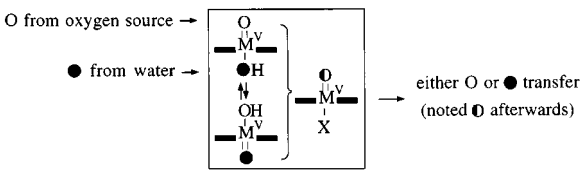
The stability of high-valent iron– or manganese–oxo species is highly dependent on the nature of the ligands. An inert d^2 square-pyramidal manganese(V)–oxo stable at room temperature has been prepared with a diamido ligand[28] (see also ref. 29 for the design of robust ligands for oxidizing complexes). An additional example of lability *versus* stability of high-valent species is the case of nitrido–manganese(V) porphyrin complexes which is kinetically inert with organic substrates, but able to transfer the nitrido motif to chromium(III) porphyrin *via* a two-electron redox process mediated by a heterobimetallic μ-nitrido intermediate.[30] The same nitrido–manganese(V) porphyrin complexes can be transformed into nitrogen atom-transfer agents after acylation of the nitrido ligand to generate a labile acylimido–manganese(V) porphyrin complex.[31]

At the present stage of knowledge, the design of metal–oxo complexes able to efficiently catalyse oxygenations is still challenging, since all the parameters involved in the different O-atom transfer steps are not fully understood.

A new type of tautomerism: the oxo–hydroxo tautomerism

After the above reminders on high-valent metal-oxo porphyrin complexes, we wish now to report the recent discovery of an oxo–hydroxo tautomerism[32,33] and its utilisation as mechanistic tool in oxygenation reactions catalysed by water-soluble metalloporphyrins.

Using isotopically labelled oxidants or labelled water, it has been shown that the oxygen of the metal–oxo porphyrin complex can be quickly exchanged with water *via* the axial hydroxo ligand with reaction rates depending on the experimental conditions (pH, temperature, composition of the medium, nature of the axial ligands, . . .). We shall see that, using the label distribution in oxidation products modulated by this oxo–hydroxo tautomerism, it is possible to unambiguously distinguish between oxygenation reactions occurring *via* an oxygen transfer from a high-valent metal–oxo complex or *via* an autoxidation mechanism (see ref. 34 for a review on this controversial debate) in metalloporphyrin-catalysed oxygenations carried out in the presence of $H_2{}^{18}O$. For short, the phenomenon termed oxo–hydroxo tautomerism corresponds to a rapid shift of two electrons and one proton from a hydroxo ligand (electron-rich ligand) to the *trans* oxo species (electron-poor ligand) leading to the transformation of the hydroxo ligand into an electrophilic oxo entity on the opposite side of the initial oxo (Scheme 3). The main consequence of this tautomerism is the incorporation within the substrate of an oxygen atom coming from either the oxidant or from bulk water, respectively in the ratio 1 : 1. the degree of ^{18}O-exchange observed into the product (epoxide, alcohol, . . .) is then mechanistically informative.



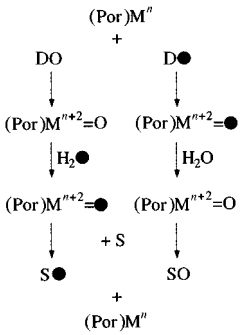
Scheme 3 The oxo–hydroxo tautomerism mediates the incorporation into the oxidation product of 50% of oxygen coming from the primary oxidant and 50% from water. X = hydroxo ligand.

Some previous data on O-exchange of metal–oxo species with bulk water

In the last fifteen years, several reports mentioned the use of ^{18}O-labelling experiments in order to characterize high-valent

metal–oxo species or to elucidate the mechanism of O-transfer by these reactive species. For reactions performed in the presence of water, results varied from 0 to 100% of O-incorporation form water, depending on the experimental conditions. Most of these results can be understood by reference to the oxo–hydroxo tautomerism (for detailed comments, see the paragraph on required conditions to observe oxo–hydroxo tautomerism) or on the basis of a direct O-exchange of the oxo ligand with the bulk water.

Most of the studies to determine the origin of the incorporated oxygen atom in alkene epoxidations or alkane hydroxylation catalysed by metalloporphyrins have been performed in organic solvents or biphasic media with hydrophobic complexes. From these data, it has been concluded that the oxygen atom originated from the primary oxidant (PhIO,[35] LiOCl,[36] $KHSO_5$[37]). When experiments are performed in water or in an organic solvent containing a sufficient amount of water, several reports suggested that high-valent metal–oxo complexes exchanged the coordinated oxygen atom with water (using either labelled water or labelled oxygen atom donor). As indicated in Scheme 4 for a theoretical 100% O-exchange with water, these



Scheme 4 Principle of labelling studies: case of theoretical 100% O-exchange with water. Unlabelled or ^{18}O-labelled water (H_2O and H_2●) and oxygen atom donor (DO and D●). [Por] = porphyrin ligand; S = substrate.

experiments were usually based on generating the active species with ^{18}O-labelled activating agent [H_2O_2; *m*-chloroperoxybenzoic acid (*m*-CPBA); O_2 in the presence of a reductant] and washing the label in the presence of unlabelled water, or at the reverse, using unlabelled oxidant and performing the reaction in ^{18}O-labelled water.

Resonance Raman investigations on Cpd II of HRP at pH 7, based on isotopic shift of the Fe^{IV}=O stretching mode of Cpd II ($\nu_{Fe=O}$ was observed at 774 cm^{-1} after activation with either $H_2{}^{16}O_2$ or $H_2{}^{18}O_2$ in $H_2{}^{16}O$, at 740 cm^{-1} for activation with either $H_2{}^{16}O_2$ or $H_2{}^{18}O_2$ in $H_2{}^{18}O$), provided evidence for the oxygen atom exchange between the heme-Fe^{IV}=O and bulk water (Table 1).[38] In a controversial manner, this exchange was

Table 1 Resonance Raman data on the possible exchange of the oxygen atom of high-valent metal–oxo species with bulk water

not observed in the case of stable species of diacetylheme or manganese substituted HRP: the Raman spectrum of Cpd II generated with $H_2{}^{16}O_2$ or $H2^{18}O_2$ presented lines at 781 or 745 cm^{-1} (diacetylheme HRP), at 626 or 596 cm^{-1} (Mn–HRP), respectively. No isotope-induced change was observed at neutral pH for 1 h at 4 °C in the presence of $H_2{}^{16}O$ or $H_2{}^{18}O$, indicating no appreciable exchange of the oxo entity with bulk water.[39] In studies performed at −80 °C on a ferryl porphyrin π-cation-radical derived from the synthetic (*meso*-tetramesitylporphyrinato)iron(III) chloride [(TMP)Fe^{III}Cl], the $\nu_{Fe=O}$ band was observed at 828 cm^{-1} (activation with [^{16}O]*m*-CPBA) or 792 cm^{-1} (activation with [^{18}O]*m*-CPBA), the first one remaining unshifted in the presence of $H_2{}^{18}O$; therefore the oxo oxygen atom was not easily exchanged with water under these conditions (Table 1).[40]

The O-exchange of metal–oxo with bulk water can also be monitored by analysing the label content of oxygenation products of reactions catalysed by synthetic metalloporphyrins. Groves *et al.*[3] reported that the high-valent iron–oxo complex generated in a first step from (TMP)Fe^{III}Cl with *m*-CPBA in an organic medium containing 1% $H_2{}^{18}O$ was able, in a second step, to epoxidize norbornene with a 99% ^{18}O-incorporation. This result allowed to discard the hypothesis of either free or metal coordinated peroxyacid as the oxygen transfer agent and support an high-valent iron–oxo intermediate with an oxygen exchangeable with added $H_2{}^{18}O_2$. Incorporation of ^{18}O from bulk water was further noticed[41] in the course of epoxidation of β-methylstyrene by manganese(V)–oxo porphyrin in CH_2Cl_2 saturated in $H_2{}^{18}O$, indicating here also a rather fast exchange of the oxo ligand with water. This ^{18}O-exchange was clearly slower in the case of manganese(IV) species and was inhibited by the presence of pyridine as axial ligand.[41,42]

Oxo-hydroxo tautomerism with water-soluble metalloporphyrins

Epoxidation reaction

We initially reported oxo–hydroxo tautomerism to explain isotopic results observed in aqueous phase during $KHSO_5$ epoxidation of carbamazepine (CBZ), an analgesic and anticonvulsivant drug, catalysed by a cationic water-soluble manganese porphyrin.[33] In such reaction performed at pH 5 in aqueous solution with various contents of $H_2{}^{18}O$, it was shown that half of the oxygen atoms incorporated in the epoxide came from the solvent (Fig. 1(*a*)]. It was checked that neither CBZ-

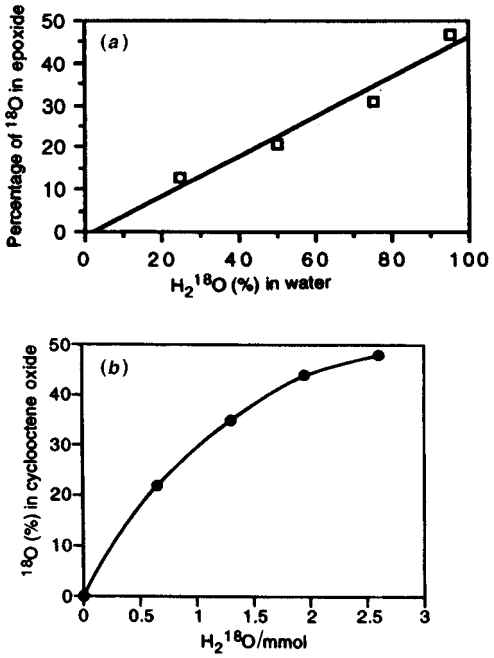

Fig. 1 (*a*) The amount of labelled oxygen found in CBZ oxide correlates with half the content of ^{18}O-label of water present in the reaction mixture. In abscisse: content (%) of $H_2{}^{18}O$ in water (from ref. 33 with permission from the American Chemical Society; see also ref. 44 for a similar correlation). (*b*) Dependence on a sufficient concentration of water in non-aqueous solvent to observe oxo-hydroxo tautomerism. In abscisse: 0.5, 1.0, 1.5, 2.0 and 2.5 mmol of $H_2{}^{18}O$ correspond to 1, 2, 3, 4 and 5 M $H_2{}^{18}O$ concentration, respectively; substrate concentration was 20 mM (from ref. 44 with permission from the American Chemical Society).

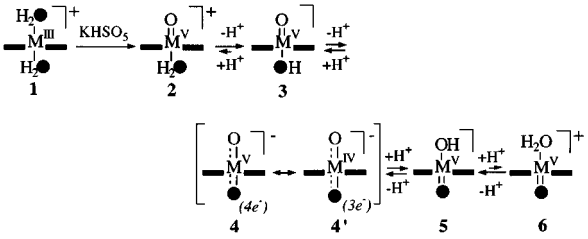
oxide[33] nor $KHSO_5$[37,43] exchanged oxygen atoms with water in the reaction conditions.

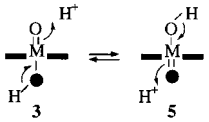
To explain the constant ratio of 0.5 for the incorporation of oxygen from the solvent, we proposed an oxo–hydroxo tautomerism mechanism[32] (formerly named 'redox tautomerism' in refs. 33, 43–47) involving a coordinated water molecule on the manganese(III) porphyrin precursor **1** (Scheme 5). It must



Scheme 5 General scheme for the oxo–hydroxo tautomerism

be noted that a 50% O-exchange corresponds only to the oxo–hydroxo tautomerism involving the hydroxo ligand *trans* to the high-valent metal–oxo complex, but not to a direct exchange of the oxo ligand with bulk water.

Mn(TMPyP), the pentaacetate of the diaquamanganese(III) derivative of *meso*-tetrakis(1-methyl-pyridinium-4-yl)porphyrin, can exist in aqueous medium with one or two metal-bound water molecules as axial ligands (**1** in Scheme 5; see ref. 48 for a X-ray structure of the bis-aqua-MnTMPyP complex). Increasing the metal oxidation state from III to V (going from the Mn^{III} complex **1** to the Mn^{V}=O **2**) should lower sufficiently the pK_a value of the ligated water to allow, at the pH of the reaction, its conversion into a hydroxo ligand (**3**; see ref. 49 for a discussion on the pK_a values of aqua and hydroxo ligands in high-valent metalloporphyrins). Removal of a proton from this hydroxo ligands results in the formation of the stabilized anion **4** with four electrons delocalized on both metal–oxygen bonds (**4′** is a mesomeric form with three delocalized electrons and manganese in the formal oxidation state IV). This anion can be protonated with the same probability at the end of one of the two metal–oxo-like bonds, giving rise to either form **3** or **5**, which reacts with CBZ to produce CBZ-oxide containing either ^{16}O or ^{18}O, respectively, in the ratio 1 : 1. The conversion of **3** to **5** does not necessarily involve **4** and **4′** as discrete deprotonated intermediates but might also proceed *via* a hydrogen-bonded water molecule in a more concerted fashion (Scheme 6).

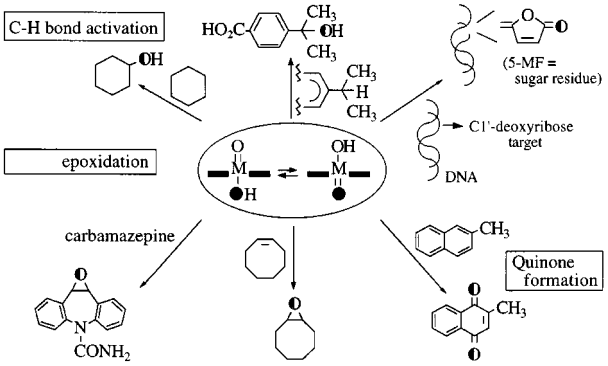


Scheme 6 Key step of the oxo–hydroxo tautomerism

Other recent reports support the concept of oxo–hydroxo tautomerism.[24,44,47] Groves *et al.*[24] reported also the ^{18}O-incorporation in CBZ-oxide in a Mn(TMPyP)-catalysed oxidation of CBZ *via* an oxo–hydroxo interconversion. Lee and Nam described similar ^{18}O-incorporation in cyclooctene epoxidation by either *m*-CPBA, H_2O_2 or Bu^tOOH catalysed by [*meso*-tetrakis(pentafluorophenyl)porphyrinato]iron(III) chloride $Fe^{III}(F_{20}TPP)Cl$, the reaction being performed in a MeOH–CH_2Cl_2 mixture containing 10% H_2O.[44] Even at low pH values, CBZ epoxidation data obtained in aqueous solutions by H_2O_2, Bu^tOOH or $KHSO_5$ in the presence of [*meso*-tetrakis(2,6-dichloro-3-sulfonatophenyl)porphyrinato]iron(III) chloride indicated that the oxo–hydroxo tautomerism was involved.[47] In these latter cases, the experiment strongly supported that a common high-valent iron–oxo species was generated from the different oxidants and was the reactive intermediate responsible for alkene epoxidation.

Hydroxylation reactions (Scheme 7)

The oxo–hydroxo tautomerism was further characterized in the oxidation of deoxyribose C–H bonds of DNA by the Mn(TMPyP)–$KHSO_5$ system.[45] Hydroxylation at carbon-1′ of



Scheme 7 Examples of oxo–hydroxo tautomerism from literature data. ○: unlabelled oxygen; ●: labelled oxygen; ◐: mixed labelled oxygen.

deoxyribose gave in several steps 5-methylene-2-furanone (5-MF), as final sugar residue. In the presence of labelled $H_2{}^{18}O$, 50% of oxygen coming from the primary oxidant (^{16}O from $KHSO_5$) and 50% from the solvent (^{18}O from $H_2{}^{18}O$) were incorporated in 5-MF, strongly supporting a metal–oxo mediated DNA cleavage with an oxo–hydroxo tautomerism to explain the ^{18}O-incorporation in the desoxyribose oxidation product. Another example came from the monopersulfate oxidation of 4-isopropylbenzoic acid performed in $H_2{}^{18}O$ and catalysed by the same water-soluble metalloporphyrin Mn(TMPyP).[43] In the primary hydroxylation product, 4-(1-hydroxy-1-methylethyl)benzoic acid, nearly half of the oxygen atoms incorporated in the alcohol function came from water. In the cyclohexane hydroxylation by *m*-CPBA catalysed by $Fe(F_{20}TPP)Cl$, the percentage of ^{18}O incorporated in cyclohexanol was also found to be close to 50%, with a reaction mixture containing only 10% of water.[44]

Quinone formation (Scheme 7)

In an aqueous solution the metalloporphyrin-catalysed oxidation of 2-methylnaphthalene to *p*-quinones involves two consecutive oxygen transfers from an intermediate metal–oxo entity responsible for 30 to 55% indirect incorporation of ^{18}O from water into the generated quinones.[46]

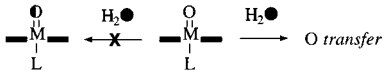
Required conditions to observed oxo-hydroxo tautomerism

An axial ligand competitive to the hydroxo ligand inhibits oxo–hydroxo tautomerism

In heme-enzymes, the presence of a cysteinato ligand (cytochrome P-450 or chloroperoxidase) or an imidazole from an histidine (peroxidase) prevents water from coordinating to iron. This implies that there is no possible exchange between high valent metal–oxo intermediates and water through an oxo–hydroxo tautomerism. From this point of view, the experimental data presented above in Table 1 on Cpd II of HRP is rather controversial and suggests that an exchange of the oxygen of the metal-oxo with bulk water on the distal side may occur in some conditions (probably *via* a *cis*-dihydroxo complex and not *via* a prototropy betwen the metal–oxo oxygen and the hydroxo ligand as in the oxo–hydroxo tautomerism).

With synthetic metalloporphyrins the situation is different. Iron and manganese porphyrins are known to form imidazole and pyridine complexes when these heterocycles are present in reaction mixtures. In the epoxidation of *cis*-β-methylstyrene with *m*-CPBA catalysed by $Mn^{III}(TMP)Cl$, the presence of pyridine completely prevents isotopic enrichment of epoxide products when the reaction is performed in the presence of

$H_2{}^{18}O$.[41] In the epoxidation of cyclooctene by Fe(F_{20}TPP)Cl and H_2O_2, it was found that effectively the ^{18}O-incorporation into the product diminished as the amount of 5-chloro-1-methylimidazole added to the reaction mixture increased.[44] So when the axial position opposition to the oxo group is blocked by a ligand (not derived from water), the oxo–hydroxo tautomerism cannot occur and consequently the oxygen incorporated in the oxidation product is 100% from the oxidant, instead of 50% from the oxidant and 50% from water (Scheme 8).

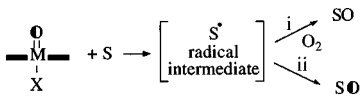


Scheme 8 Inhibition of the oxo–hydroxo tautomerism equilibrium in the presence of strong axial ligands. L = neutral ligand, *e.g.* pyridine or imidazole.

When there is no *trans* ligand, evidently the oxo–hydroxo tautomerism does not occur. But, when the *trans* ligand is a water molecule instead of an hydroxo ligand [see hereafter for a discussion on the case of metal(IV)–oxo species], the tautomerism is largely reduced. This may be an explanation why the oxo–hydroxo tautomerism was not observed during the oxidation of polycyclic aromatic hydrocarbons catalysed by iron tetrasulfophthalocyanine performed in the presence of $H_2{}^{18}O$ (the reactive species was shown to be Fe^{IV}=O)[50] or in cobalt-mediated alkene epoxidations with potassium monopersulfate[51] where the oxygen atom was coming only from the oxidant.

Competitive autoxidation route lowers incorporation of oxygen from water

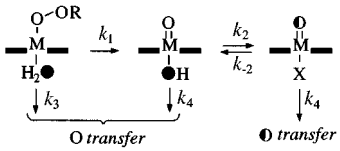
Groves *et al.* noticed that during cyclooctene[41] or *cis*-β-methylstyrene[42] epoxidation by manganese(IV)–oxo porphyrin under aerobic conditions, dioxygen was intimately involved in the oxidation process with oxidation products partially resulting from an autoxidation process. Evidently, the consequence is a lowering in isotopic enrichment from solvent. During the monopersulfate oxidation of ketoprofen catalysed by Mn(TMPyP),[43] trapping of radical intermediates by molecular oxygen (route i, Scheme 9) was shown to compete with the oxygen rebound mechanism (route ii), explaining the observed reduction of ^{18}O-incorporation from solvent in the final product when ketoprofen was oxidised under air by the system Mn(TMPyP)–$KHSO_5$–$H_2{}^{18}O$ system.



Scheme 9 Diverted autoxidation route lowers the oxygen incorporation rate. Route i: radical escaping from the solvent cage (autoxidation route); route ii: recombination within solvent cage (oxygen rebound mechanism).

Temperature effect

In order to characterize the high-valent reactive species formed by oxidative activation of metalloporphyrins, many experiments have been performed at low temperature with some of them concerning ^{18}O-incorporation into the products in the presence of $H_2{}^{18}O$. In the more extensive study, Lee and Nam[44] described the cyclooctene epoxidation by H_2O_2 or *m*-CPBA in the presence of Fe(F_{20}TPP)Cl at different temperatures. The ^{18}O-enrichment in the epoxide gradually increased as the reaction temperature raised from −78 to 45 °C. The authors suggested that an Fe^{III}–OOR species was involved at low temperature, with a rate of the O–O bond cleavage (leading to the high-valent iron–oxo porphyrin complex) lower than the oxygen atom transfer rate ($k_1 < k_3$ in Scheme 10). At higher

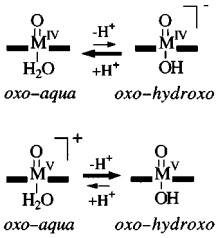


Scheme 10 Kinetic parameters depending on temperature. X = hydroxo ligand.

temperature the formation of the high-valent iron oxo porphyrin should be favored (increase of k_1). However, since tautomerism is a phenomenon highly dependent on temperature, the present results might alternatively be re-interpreted as a fast formation of the iron–oxo species ($k_1 > k_3$), even at low temperature, but with a slow prototropy ($k_2 < k_4$) at this teperature and a faster one ($k_2 > k_4$) at higher temperature (k_3 and k_4 = oxygen atom transfer rates; the best conditions to observe the oxo–hydroxo tautomerism correspond to $k_1 > k_3$ and $k_2 > k_4$). We must note that even at low temperature (−78 °C) iron–oxo porphyrin species have been detected and characterized.[3,21,22]

Differences in exchange kinetics for metal(IV)–oxo and metal(V)–oxo

From experiments conducted on *cis*-β-methylstyrene with manganese(V)–oxo and manganese(IV)–oxo porphyrin complexes, Groves *et al.* concluded from the ^{18}O results that, in addition to differences in oxygen transfer occurring with retention or loss of the stereochemistry, the manganese(IV)–oxo slowly exchanged its oxo ligand with $H_2{}^{18}O$, while the exchange was very fast for the manganese(V)–oxo complex.[41] These data are consistent with Schemes 5 and 11 and with



Scheme 11 Equilibria between oxo–aqua and oxo–hydroxo forms depending on the oxidation state of the metal center

literature data on the proton acidity of coordinated water in high-valent species:[49,52,53] going from **3** to **5** only needs a prototropy in the case of a manganese(V)–oxo species (Scheme 5 and 11; the oxo–hydroxo is the major form), whereas in the case of manganese(IV)–oxo (Scheme 11) the ligand *trans* to the oxo is mainly a water molecule owing to the lower acidity of the ligated water when the metal oxidation state is reduced. So, for manganese(IV)–oxo complexes, the oxo–hydroxo tautomerism can only affect the small fraction of metal–oxo species with an hydroxo ligand, the oxo–aqua form being dominant in this case.

Role of the ratio water/substrate concentrations

The percentage of ^{18}O incorporated in oxidation products might be governed by the relative rate to reach the tautomerism equilibrium (k_2 in Scheme 10) which is a function of the water concentration, and the rate of oxygen transfer (k_4) which depends on the substrate concentration. For reaction performed in an essentially aqueous medium (a 90% aqueous solution is 50 M in water) and a substrate rather diluted (*e.g.* 1 mM), the competition between the tautomerism and the oxygen transfer was not observed: the water/substrate molar ratio ($\approx 5 \times 10^4$) was largely in favor of the oxo–hydroxo tautomerism.[33] In an organic medium containing only a small amount of water and at high substrate concentrations, the situation is opposite and can affect the tautomerism equilibrium and consequently the level of ^{18}O-incorporation.[44] An example of such an extreme

condition concerns the epoxidation of 1 M cyclohexene solution in CH_2Cl_2–MeOH containing 5% of $H_2{}^{18}O$ with a metalloporphyrin catalyst and H_2O_2, Bu^{t}OOH or *m*-CPBA as oxygen donor. In these conditions, no ^{18}O-incorporation was observed in the epoxide (water/substrate molar ratio ≈ 3).[35] In intermediate conditions, such as in epoxidation of 20 mM cyclooctene with H_2O_2 catalysed by Fe(F_{20}TPP)Cl in an organic medium containing increasing amounts of water, the 50% O-incorporation from water was observed for a reaction mixture containing at least 10% of water [water/substrate molar ratio above 250; Fig. 1(*b*)].[44] In the rare case of a very small concentration of substrate, then the reaction becomes very slow and the aqua ligand (form **2** or **6** in Scheme 5) can exchange with water from solvent and the ^{18}O incorporation from solvent can raise above 50%.[44]

Other parameters to take into account

Probably several other parameters may influence the oxo–hydroxo tautomerism but no systematic study has been done up to now. Among them, the pH value of the reaction mixture plays surely a key role in this prototropy mechanism as also the nature of the metal and the ligand in the metalloporphyrins through their capacity to form differently coordinated complexes. In addition, some reported variations of the ^{18}O rate of incorporation around 50% suggest that the oxo-hydroxo tautomerism equilibrium is probably tuned by small variations of kinetic parameters, including solvent effect or differences in the kinetic parameters of the oxygen transfer from the metal–oxo to the substrate.

Conclusion

Among the different methods to study the mechanism of oxidation mediated by high-valent metal–oxo complexes, the recent discovery of the 'oxo–hydroxo tautomerism' provides an additional useful tool to discuss the mechanism of catalytic O-atom transfer reactions, the nature of the axial ligand *trans* to the oxo species and the oxidation state of these metal–oxo entities. In particular, when the required conditions to observe the oxo–hydroxo tautomerism are respected, it appears that the incorporation into the oxidation product of 50% of oxygen coming from water constitutes a strong evidence of an oxygen atom transfer involving an high-valent metal–oxo intermediate.

In the future, it might be possible to generalize this oxo–hydroxo tautomerism to other complexes having both the oxo and hydroxo ligands in a *trans* configuration as reported in the present survey for water-soluble metalloporphyrins but also for complexes having these two ligands in a *cis* configuration.

Systematic analysis of metal coordination sphere geometry from crystallographic data: a general method for detecting geometrical preferences, deformations and interconversion pathways

Judith A. K. Howard,*[a] Royston C. B. Copley,[a] Jing Wen Yao[a] and Frank H. Allen*[b]

[a] *Department of Chemistry, University of Durham, South Road, Durham, UK DH1 3LE. E-mail: J.A.K.Howard@durham.ac.uk*
[b] *Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge, UK CB2 1EZ. E-mail: allen@ccdc.cam.ac.uk*

A simple and general computational procedure using the L–M–L angles for all crystallographic observations of an ML_n coordination sphere generates mappings which reveal geometrical preferences, deformations from standard polyhedral geometries, and interconversions between polyhedral forms; a systematic analysis of the geometry of seven-coordination is described.

Systematic knowledge about geometries, deformations and interconversion pathways of metal coordination spheres is fundamental to inorganic chemistry.[1] For ML_n coordination, where L is any ligand, much knowledge is implicit in the $N_a = n(n-1)/2$ values of the L–M–L valence angles. This has been demonstrated[2] for the lower coordination numbers, $n = 3$, 4, using crystallographic data retrieved from the Cambridge Structural Database (CSD),[3] and using data analysis methods analogous to those applied to conformational studies of organic systems based on torsional metrics.[4]

However, the high topological symmetry of generalised ML_n systems having $n \geqslant 5$ has so far prevented routine systematic studies of the associated angular data sets. For a given system, the topological symmetry gives rise to $n!$ possible enumerations of the chemically equivalent L atoms, hence to $n!$ permutations of the valence angle sequence. There are two ways of addressing this problem so that we can properly visualise and analyse a data matrix of N_a valence angles for N_f occurrences of an ML_n substructure in the CSD, *viz.*: (*a*) By completely filling the parameter space spanned by the valence angles, *i.e.* by including all $n!N_f$ permutationally equivalent angular sequences in the data matrix. This method has frequently been used in the conformational (torsional) analysis of *k*-membered cyclic systems where topological symmetry requires a maximum $2k$-fold data expansion.[4] Given that $n! = 120, 720, 5040, 40320$ for $n = 5, 6, 7, 8$-coordination, visualisation and analysis of permutationally complete valence angle matrices for ML_n systems becomes increasingly intractable.

(*b*) By placing each angular sequence into a single asymmetric unit of the valence angle parameter space. This can be effected by comparing all permutations of each angular sequence with some predefined set of standard values, so as to locate the permuted sequence that provides the best numerical fit to the standard sequence. The numerical overlay therefore assigns a unique atomic enumeration of the L-atoms to each example of ML_n coordination retrieved from the CSD with respect to the atomic enumeration chosen for the standard. The resulting data matrix comprises the N_a valence angles for the basic number (N_f) of fragments retrieved from the database: a much more tractable proposition for visual display and numerical analysis.

In this communication, we describe a general computational procedure in which the topological problem is dealt with according to method (*b*), and which also addresses the problems of data analysis inherent in the dimensionality of the angular description, *i.e.* the fact that $n(n-1)/2$ angles are needed to provide a full description of each coordination sphere. We illustrate the application of the method to a systematic study of the geometrical characteristics of the 372 examples of 7-coordination available in the CSD.

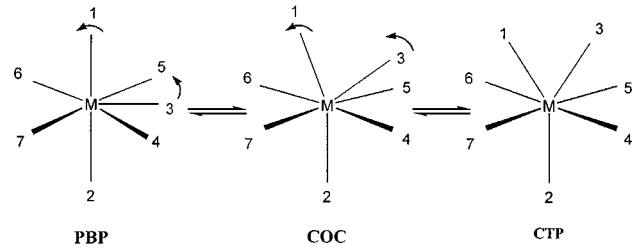
Standard and symmetric *n*-polyhedra [*e.g.* the tetrahedron (T), octahedron (O), pentagonal bipyramid (PBP), capped trigonal prism (CTP), *etc.*] are archetypal reference frames that are used to describe coordination sphere geometries. In many cases, the N_a valence angles for the standard are fixed by symmetry, irrespective of the M–L (or L–L edge) distances. In others, and notably some of the higher-coordination archetypes, valence angle sequences may vary under the symmetry of the archetype. Here, it is necessary to select a set of angles for use as a standard. This does not obviate our method in any way, since the purpose of the standard is to provide a fixed origin in valence angle space that represents an idealised *n*-polyhedron appropriate to the problem under investigation.

We denote the standard set of L–M–L angles as $\theta_{k(\mathrm{std})}$ [$k = 1 \rightarrow N_a$], and determine how far an observed geometry, defined by angles $\theta_{k(\mathrm{obs})}$ derived from the CSD, is distorted from an appropriate archetype, by computing the Euclidean dissimilarity:

$$\mathrm{Rc}(x) = 100 \min_p \left\{ \frac{\Sigma_k [\theta_{k(\mathrm{obs})} - \theta_{k(\mathrm{std})}]^2}{\Sigma_k \theta_{k(\mathrm{std})}^2} \right\}^{\frac{1}{2}} \qquad (1)$$

in which (x) identifies the archetypal standard, and the subscript p indicates that Rc(x) is the minimum value obtained through application of eqn. (1) to all possible sequences of the $\theta_{k(\mathrm{obs})}$ that arise from the $n!$ permutational ligand enumerations. Local FORTRAN77 code derives and applies the permuted L–M–L angle sequences and, for each CSD observation, identifies the specific permutation that is closest to the standard angular description used for archetype (x). Thus, the procedure implicitly identifies the specific labelling of the CSD atoms, L, that best matches the labelling used for the standard.

For 7-coordination, the three common archetypal polyhedra (Scheme 1) are the pentagonal bipyramid (PBP), capped



Scheme 1 The PBP ⇔ COC ⇔ CTP interconversion path: atomic movements in 7-coordination. The unique standard angles (°) for CTP: L^1–M–L^2 141.8, L^1–M–L^3 76.4, L^1–M–L^4 127.3, L^1–M–L^5 127.3, L^1–M–L^6 76.4, L^1–M–L^7 76.4, L^2–M–L^4 76.4, L^2–M–L^5 76.4, L^4–M–L^5 87.7, L^4–M–L^6 152.7, L^4–M–L^7 85.9.

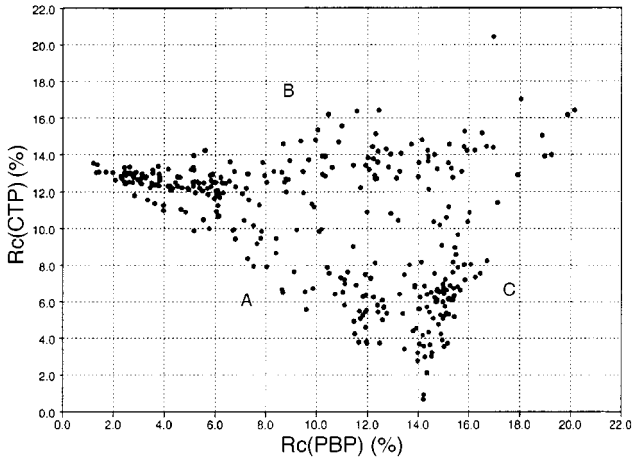


Fig. 1 Rc(CTP) *vs.* Rc(PBP) for all 372 fragments having 7-coordination

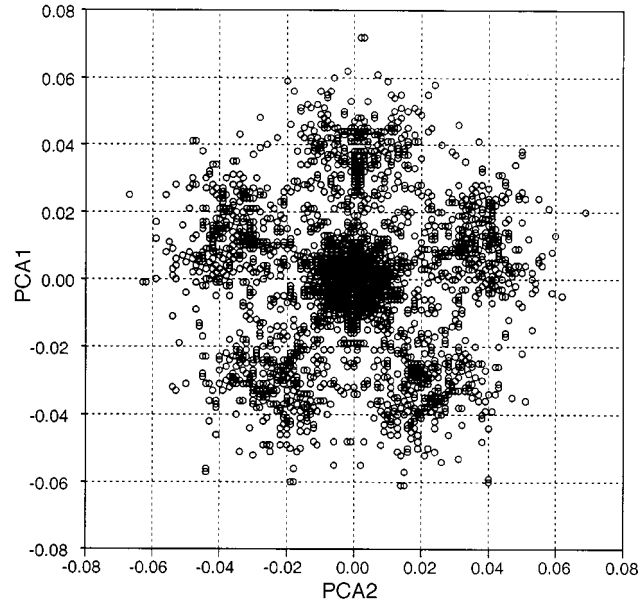

Fig. 2 D_{5h} expanded PCA: PC_1 *vs.* PC_2 for all 372 fragments (7440 observations after expansion)

octahedron (COC), and the capped trigonal prism (CTP). The COC can be considered as an intermediate form on the PBP ⇔ CTP interconversion pathway.[1] Starting from PBP, one of the five equatorial ligands (3 in Scheme 1) moves out of the plane towards apical ligand 1, which then moves away from its apical position. Small relocations of equatorial ligands 4–7 then generate the COC geometry, and further small movements of atoms 3 and 1 generate the CTP polyhedron. The standard CTP angles used in the present report are given in Scheme 1. In practice, users may choose their own standard (origin) angles for the CTP case.

The CSD System program QUEST3D[3] was used to locate 372 examples of ML_7 coordination (L = any non-H atom), and to output the (permutationally random) sequence of 21 L–M–L valence angles for each example. The local code was used to minimise both Rc(PBP) and Rc(CTP) over the 5040 possible permutations using eqn. (1). The dataset was visualised by plotting Rc(PBP) *vs.* Rc(CTP), and Fig. 1 immediately reveals a number of significant features: (*a*) a well populated cluster of PBP geometries having Rc(PBP) up to *ca.* 7%, (*b*) a linear PBP ⇔ CTP interconversion pathway (A in Fig. 1) that passes through a populated COC area, and (*c*) interconversion pathways B and C that connect the PBP and CTP examples with a loose cluster of observations for which both Rc(*x*) values are *ca.* 15% or higher. Examination of individual structures in these areas shows that they arise almost entirely from ML_7 fragments having small ligand bite angles. Conversely, the PBP area is dominated by ML_7 species having either seven or two unidentate ligands. The COC/CTP area is structurally diverse and requires further detailed study.

Because the Rc(*x*) minimisation process does assign standard atomic labels to the seven equivalent ligands in ML_7 systems, we can use this information as a basis for more detailed multivariate data analyses, *e.g.* the principal component analysis (PCA) technique[5] that is commonly applied to conformational problems.[4] In the ML_7 case however, we are now starting with data that defines a single asymmetric unit of parameter space. Thus, we can expand the data set in a controlled manner to reflect full or partial topological symmetries in the resultant PCA plots. Based on previous PCA studies of the conformations of five-membered rings,[4] we may treat the five ligands that most closely map to their coplanar equatorial counterparts in the PBP standard as a cyclic system, which would have exact D_{5h} symmetry in the planar form (a perfect PBP form). To examine the deformations in this system exhibited in real structures, we apply a D_{5h}-expansion to the angular dataset prior to application of PCA. The analysis generates PC_1 and PC_2 as a degenerate pair and Fig. 2, which shows a plot of the PC scores along these orthogonal axes for the expanded dataset, is a readily interpretable visualisation of the dataset: the central cluster of Fig. 2 maps the PBP examples (five equatorial ligands closely coplanar), while the five symmetric 'spokes' map the PBP ⇔ COC ⇔ CTP pathways that arise from each of the equatorial atoms of the PBP standard being designated, in turn and according to the D_{5h} topology, as the mobile ligand 3 in Scheme 1.

An extraordinary richness of information is immediately apparent in the simple two-dimensional visual representation of a 21-dimensional parameter space shown in Fig. 1, while Fig. 2 shows how the analysis can be further enhanced through use of standard multivariate techniques. We stress that any interpretation of structural diversity, in terms of geometrical arrangements, distortions from symmetrical forms, and interconversion pathways, is wholly dependent on the investigator and, as in most structural data mining experiments, a full interpretation (currently in preparation) involves a close examination of individual structures. The technique reported here provides the essential underpinning for such data mining experiments by treating the most difficult problem of atomic permutational symmetry that has, until now, presented a serious disincentive to knowledge discovery in coordination chemistry. Further, the fact that eqn. (1) generates a one-dimensional metric, Rc(*x*), that quantifies how far the shape of an observed coordination sphere deviates from some idealised standard (*x*), raises the possibility of including such metrics in the CSD itself, to form the basis for simple and rapid searches for coordination sphere geometries that are close to (or even far from) a particular reference frame.

Is the metallocene (3-THF-CH_2-Cp)$_2ZrCl_2$ a better catalyst than the corresponding 2-THF derivative for olefin polymerisation? A molecular modelling study

Edward A. H. Griffiths, Ian R. Gould and Subramaniam Ramdas*

Department of Chemistry, Imperial College of Science, Technology and Medicine, South Kensington, London, UK SW7 2AY. E-mail: s.ramdas@ic.ac.ukur

Semi-empirical, *ab initio* and density functional calculations performed on the active intermediates (2-THF-CH_2-Cp)$_2Zr^+$-CH_3 and (3-THF-CH_2-Cp)$_2Zr^+$-CH_3 indicate that the former is more stable as an intra-molecular complex by up to 21.6 kcal mol^{-1} and is, therefore, a less efficient catalyst for olefin polymerisation.

Incorporating metallocenes onto inorganic supports ($TiCl_3$ on $MgCl_2$) for industrial polymerisation of olefins is a major technical challenge. Anchoring traditional Group IV metallic catalysts, *e.g.* Cp_2ZrCl_2, to the support by mono-substitution of each Cp ring with an appropriate 'tethering' group containing a Lewis base is an attractive strategy. Experimentally, in the homogeneous polymerisation of ethylene[1] by (2-THF-CH_2-Cp)$_2ZrCl_2$ (Fig. 1), the activity was found to be low compared

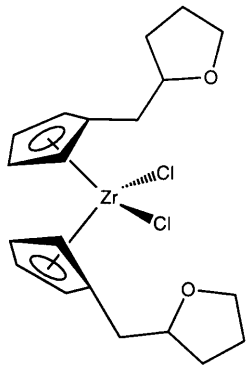

Fig. 1 The structure of (2-THF-CH_2-Cp)$_2ZrCl_2$

to the parent Kaminsky[2,3] catalyst. This was rather surprising in view of the fact that any C-substitution in the Cp rings usually gives rise to a marginal increase in the activity of the catalyst. It was, therefore, suspected that the active catalytic site (2-THF-CH_2-Cp)$_2Zr^+$-CH_3 (generated by MAO alkylation and Cl^- abstraction from the dichloride derivative), could suffer from an intra-molecular complexation of the ether group to the electrophilic Zr centre (see Fig. 2). Ether co-ordination would, of course, compete with ethylene insertion and result in slow polymerisation.

To verify this hypothesis, we have carried out semi-empirical,† *ab initio*‡ and density functional (DFT)§ calculation on the proposed catalytically active intermediate (Fig. 2). Since the evidence for or against internal complexation is unlikely from the study of a single intermediate, we have carried out these calculations on both the 2-THF and 3-THF (see Fig. 3) complexes. The results on the optimised energies and geometries are shown in Tables 1 and 2 respectively.

Semi-empirical calculations yielded on geometry optimisation an energy difference of only 2.9 kcal mol^{-1} between the 2-THF and 3-THF complexes. This is too small a difference to preclude the formation of an internal complex by one of the

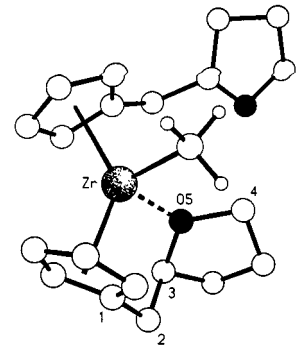

Fig. 2 The structure of the 2-THF cation

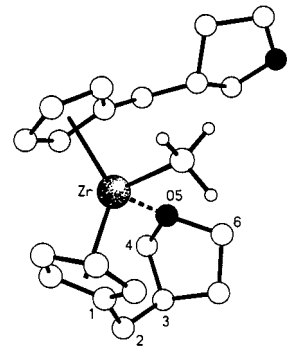

Fig. 3 The structure of the 3-THF cation

Table 1 Energies (kcal mol^{-1}) of the two cations at the semi-empirical (PM3), uncorrelated (HF) and correlated (DFT) levels. The bottom row shows the energy differences

Cation	PM3	HF	DFT
2-THF	-68.5	-629093.9	-677570.5
3-THF	-65.4	-629074.5	-677548.9
ΔE	2.9	19.4	21.6

Table 2 Selected geometry values for the two cations: angles shown in degrees and distances in Å. The figures in brackets refer to the corresponding results from semi-empirical (PM3) calculations. Atom numbering as shown in Fig. 2 and 3

Cation	$Zr–O_5$	$C_1–C_3–C_5$	Angle between $Zr–O_5$ and plane $C_3–C_5–C_4$ (2-THF), $C_4–C_5–C_6$ (3-THF)
2-THF	2.18 (2.27)	110.5 (112.9)	10.9 (50.8)
3-THF	2.19 (2.29)	117.2 (113.0)	30.8 (65.0)

systems. On the other hand, the *ab initio* HF calculations (with geometry optimisation) carried out gave rise to an energy difference of 19.4 kcal mol^{-1}, clearly indicating that the 3-THF complex cation is less stable and, therefore, should remain an active catalytic site. To examine the effects of electron correlation, non-local single-point DFT calculations were undertaken on the optimised geometries obtained above. These DFT calculations indicated a further increase in the energy difference to 21.6 kcal mol^{-1} between the two cations. Thus all the above levels of theory and calculations show that the 2-THF cationic complex is more stable than the 3-THF complex—clearly predicting that the (3-THF-CH_2-Cp)$_2ZrCl_2$ is a better choice between the catalysts. The 3-THF derivative has now been synthesised and its activity for ethylene polymerisation was found to be 9.25 g h^{-1} compared to zero activity for the 2-THF complex.[1]

The results (Table 2) on the optimised geometries reveal the origin of the relative stabilities of the two cationic complexes. In both the systems the Zr and O atoms are within bonding distances of 2.18–2.19 Å. Inspection of the frontier orbitals of both the systems, particularly the LUMO, shows very little difference, indicating the same degree of overlap between the lone pairs of the O and the orbitals of the Zr. We, therefore, conclude that in the 3-THF complex, the increased internal strain is steric in origin and arises from the required distortions in the bond angle between C_1–C_2–C_3 atoms as well as in the angle between the Zr–O bond and the plane of the THF ring.¶

In summary, we have successfully rationalised the poorer activity of the (2-THF-CH_2-Cp)$_2ZrCl_2$ catalyst for ethylene polymerisation compared to the 3-THF variant (not a common experimental choice).

We thank Dr Peter Maddox and Dr John McNally for useful discussions and their contribution to this paper. We thank the EPSRC for a grant (E. A. H. G.) and BP Chemicals for support and permission to publish this work.

Notes and References

† Semi-empirical: The MNDO[4] module provided within SPARTAN[5] employs PM3 parameters, including PM3™ that incorporates d functions for transition metals. The optimised geometries of several organometallic molecules have reproduced the X-ray structures of zirconocenes to within 0.04–0.05 Å on bond lengths and 3–5° on bond angles around the metal atom. Though the optimum energies are unreliable for the purposes of ligand design, the method does provide a useful starting geometry for subsequent *ab initio*/DFT studies.

‡ *Ab initio*: All *ab initio*/DFT calculations were carried out using the GAUSSIAN94 package.[6] Geometry optimisations of the two cationic species were performed at the HF level of theory using the 3-21G basis set.[7] The LanL2DZ effective core potential[8] was placed upon the zirconium atom.

§ DFT: Single point DFT calculations using B3LYP[9,10] were performed with the same basis sets as used for the HF optimisations described above.

¶ It is interesting to note that the crystal structure of the stable tetrahydrofurylcyclopentadienyltitanium trichloride[11] (Fig. 4) is in line with our results from the *ab initio*/DFT methods. The results from the semi-empirical calculations are, however, less reliable for predicting the geometries of such cationic complexes.

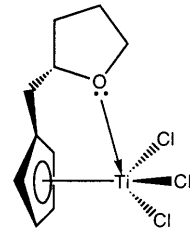

Fig. 4 The structure of tetrahydrofurylcyclopentadienyltitanium trichloride

1 BP Patent No: EP 608054. In a laboratory scale experiment it was found that 1.9 mg (4.1×10^{-3} mmol) of the catalyst (2-THF-CH_2-Cp)$_2ZrCl_2$ in the presence of MAO in toluene (100 ml, 0.41 M) at an ethylene pressure of 4 psig shows no polymerisation activity at room temperature—addition of Cp_2ZrCl_2 to the mixture, however, restored immediate polymerisation activity. In comparison, the catalyst (3-THF-CH_2-Cp)$_2ZrCl_2$ gave 9.25 g h^{-1} of the polymer, under similar experimental conditions.

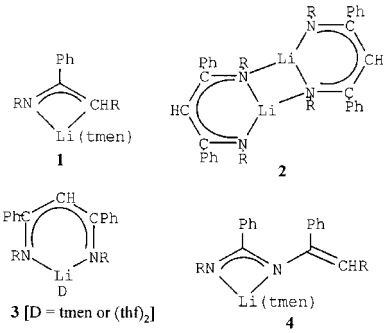
Novel lithium 3-sila- and 3-germa-β-diketiminates†‡

Peter B. Hitchcock, Michael F. Lappert* and Marcus Layh

The Chemistry Laboratory, University of Sussex, Brighton, UK BN1 9QJ. E-mail: m.f.lappert@sussex.ac.uk

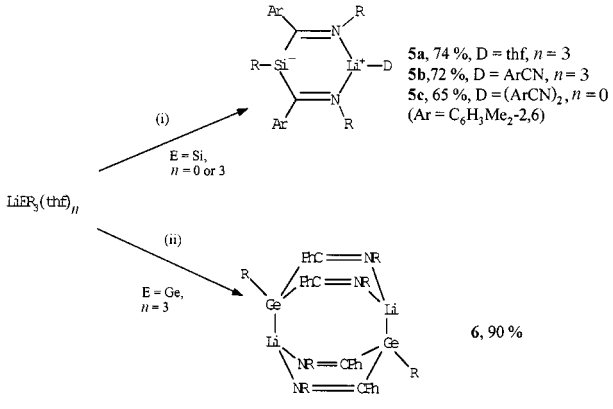
The novel 3-sila- and 3-germa-β-diketiminates [Li{N(R)-C(Ar)E(R)C(Ar)N(R)}(D)$_n$] (R = SiMe$_3$, Ar = C$_6$H$_3$Me$_2$-2,6 or Ph, E = Si or Ge, D = thf or ArCN and n = 1 or 2) were obtained from the reaction of [Li(ER$_3$)(thf)$_3$] with PhCN or ArCN; the X-ray crystal structures of two representatives of this new class of compounds were determined and shown to have, in contrast to related carbon analogues, the anionic charge localised at Si or Ge.

We have recently reported on the diverse outcome of the reaction of a trimethylsilylmethyllithium reagent, *e.g.* Li(CHR$_2$) or Li(CR$_3$), with an α-H-free nitrile (R = SiMe$_3$).[1] *E.g.* from Li(CHR$_2$) and PhCN, depending on stoichiometry and conditions the product was the crystalline lithium 1-azaallyl **1**,[2] β-diketiminate **2**[3] or **3**,[4] or the isomeric 1,3-diazaallyl **4**.[2]



We now focus on the behaviour of the silicon or germanium congener Li(ER$_3$) of Li(CR$_3$) towards PhCN or ArCN (E = Si or Ge, Ar = 2,6-Me$_2$C$_6$H$_3$). This study has led to the isolation (Scheme 1) and characterisation of the novel crystalline compounds **5a**–**c** and **6**, which are 3-sila (**5a**–**c**) or 3-germa (**6**) analogues of the ketiminates **3** or **2**, respectively. Whereas the anionic ligands in **2** and **3** are N,N′-centred, in **5** and **6** they are E-centred.

While [Li(SiR$_3$)(thf)$_3$][5] in pentane with 1 or 2 equiv. of PhCN yielded a mixture, using the bulkier and less reactive ArCN afforded (i in Scheme 1) the red, crystalline lithium 3-sila-β-diketiminate [Li{N(R)C(Ar)Si(R)C(Ar)N(R)}(D)$_n$] **5a** or **5b** in high yield. The exact nature of the product was strongly influenced by the choice of starting material and work-up procedure. When thf-free LiSiR$_3$ was treated with 3.5 equiv. of ArCN, **5c** [(D)$_n$ = (ArCN)$_2$] was isolated, whereas [Li(SiR$_3$)(thf)$_3$] with 2 equiv. of ArCN gave either **5b** [(D)$_n$ = ArCN; removal of volatiles prior to recrystallisation] or **5a** [(D)$_n$ = thf; product directly crystallised from the reaction mixture].



Scheme 1 Some reactions of LiER$_3$ with aryl nitriles (R = SiMe$_3$). *Reagents* (ArCN for i or PhCN for ii) *and conditions*: reagents were mixed in C$_5$H$_{12}$ at −78 °C (i) or −50 °C (ii) and the mixture was then warmed to *ca*. 25 °C and stirred for 12 h.

The germyllithium compound [Li(GeR$_3$)(thf)$_3$][6] was less reactive than its silicon analogue, as evident from its different behaviour towards the two nitriles. Treatment with ArCN gave a stable Lewis acid/base adduct by partial replacement of thf by ArCN. The more reactive PhCN yielded (ii in Scheme 1) bright yellow, crystalline [LiGe(R){C(Ph)=NR}$_2$]$_2$ **6**.

Each of **5a**, **5b**, **5c** and **6** gave satisfactory microanalytical and NMR spectroscopic data.§ In order to investigate the nature of the bonding, and make comparisons with carbon analogues such as the β-diketiminates **2** and **3** and a series of alkali metal cyclopentadienyls M[η^5-C$_4$Me$_4$(ER)] (M = Na or K, E = Si or Ge),[7] the X-ray crystal structures of **5b** (which is structurally similar to **5c**, to be described in the full paper), **5c** (Fig. 1)¶ and **6** (Fig. 2)¶ were determined.

Crystalline **5c** is a monomer; the Li atom is surrounded in an approximately tetrahedral fashion by two nitrogens N(1) and N(2) from the ligand and two from the coordinated nitriles. The atoms Li, N(1), C(1), Si(3), C(2) and N(2) are arranged in a six-membered ring of boat conformation [the angles between the planes N(1)N(2)C(1)C(2) and LiN(1)N(2) or C(1)Si(3)C(2) are 44.3(3) or 28.2(3)°, respectively]. The negative charge is probably mainly localised at the silicon Si(3) [see also δ(^{29}Si{^{1}H}) −15.5 in **5b**], as is indicated by its pyramidal configuration [Σ°Si(3) 336.4(2)°] and the Si(3)–C(1) [1.874(4)

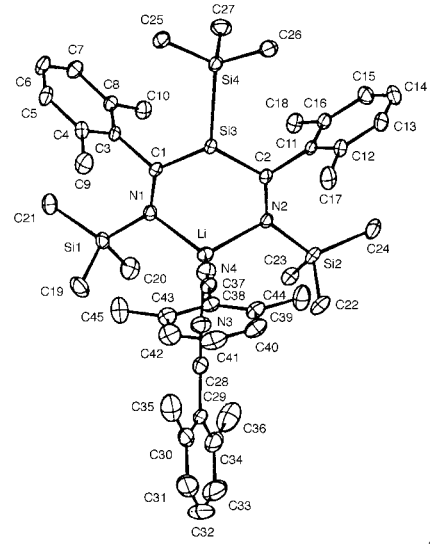


Fig. 1 Molecular structure of **5c** with selected bond distances (Å): Li–N(1) 2.000(7), Li–N(2) 1.995(7), Li–N(3) 2.106(8), Li–N(4) 2.106(9), Si(3)–Si(4) 2.334(5), Si(3)–C(1) 1.874(4), Si(3)–C(2) 1.878(5), N(1)–C(1) 1.303(5), N(2)–C(2) 1.308(5)

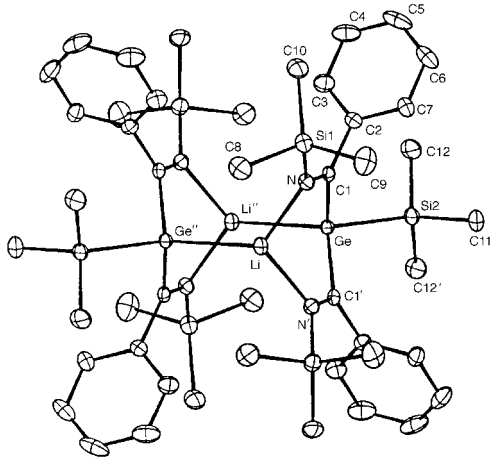

Fig. 2 Molecular structure of **6** with selected bond distances (Å): Li–N 1.954(5), Li–Ge″ 2.657(8), Ge–Si(2) 2.401(1), Ge–C(1) 2.008(3), N–C(1) 1.288(4)

Å], Si(3)–C(2) [1.878(5) Å], C(1)–N(1) [1.303(5) Å] and C(2)–N(2) [1.308(5) Å] bond lengths which are appropriate for SiC single and CN double bonds. The distance between Si(3) and Li of 3.125 Å is much longer than the Si–Li bond in, for example, $[LiSiMe_3)(tmen)_{1.5}]$ [2.70(1) Å],[8] $[\{Li(\mu\text{-}SiMe_3)\}_6]$ [2.62(1)–2.78(1) Å],[9] $[Li(SiR_3)(thf)_3]$ [2.67(1) Å],[5] $[Li(SiR_3)(dme)_{1.5}\}$ [2.630(5) Å],[10] or $[(Li\{\mu\text{-}Si(Me)(SiMe_2Ph)_2\}\})_2]$ [2.664(5), 2.778(7) Å].[11] We conclude that **5c** has a zwitterionic structure with only a weak (hence boat) interaction between the anionic Si(3) and the cationic Li.

The germanium derivative **6**, in contrast to **5c**, is neutral donor-free. Crystalline **6** is a dimer, Fig. 2, in which two six-membered $\overline{LiNC(1)GeC(1')N'}$ rings in boat conformation are connected by a direct Ge–Li bond of 2.657(8) Å. Similar values are reported for $[Li(GeR_3)(thf)_3]$ [2.666(6) Å] and $[Li(GeR_3)(pmdeta)]$ [2.653(9) Å].[6] The Ge atoms are in an approximately tetrahedral environment and the Ge–C(1) and C(1)–N bond distances of 2.008(3) and 1.288(4) Å are typical for Ge^{II}–C single (*e.g.*[12] 2.042(8) Å in $\{Ge(CHR_2)_2\}_2$ or 1.961(8) and 2.007(9) Å in $[Li(12\text{-crown-}4)_2][C_4Me_4\text{-}GeC_6H_2Me_5\text{-}2,4,6]$[7]) and C=N double bonds.

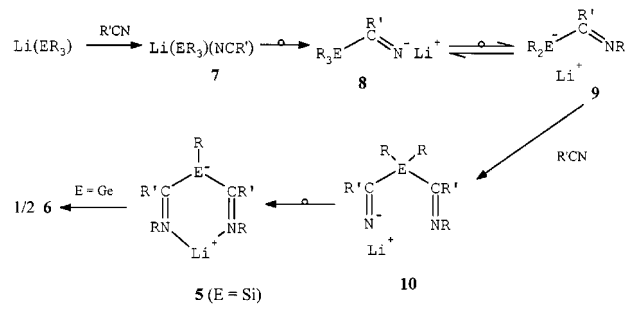
The presence of distinct E–C single and C=N double bonds in crystalline **5c** (E = Si) and **6** (E = Ge) contrasts with the situation in the carbon analogues such as **3**, which have an essentially planar central carbon [E(H), E = C]; this, and the E⋯C (E = C) and C⋯N distances of *ca*. 1.40 and 1.33 Å, respectively,[4] indicates that in **3** there is significant delocalisation in the β-diketiminate ligand.

Whereas studies on the Si and Ge analogues of cyclopentadienyls $[E(R')C_4Me_4]^-$ in $M\{E(R')C_4Me_4\}$ (crown ether) (M = Li, Na or K; E = Si or Ge; R′ = Me, SiR_3 or $C_6H_2Me_3$-2,4,6) showed that in these systems Si and Ge are similarly reluctant to form delocalised aromatic anions, the monoanion of $[Si(Bu^t)C_4Ph_4]^-$ [13*a*] and the dianion $[GeC_4Ph_4]^{2-}$ [13*b*] are aromatic.

The $^{13}C\{^1H\}$ NMR chemical shifts of the skeletal carbon [E*C*(Ph)N] in **5c** (δ 219.4) and **6** (δ 238.0) differ considerably from those in the carbon analogues **2** (δ 177.5)[2] and **3** (D = tmen, δ 174.9),[4] which indicates that the bonding in the crystalline molecules is retained in solution. This is further supported by δ [$^{29}Si\{^1H\}$] −15.5 in **5b** [*cf.* refs. 7 and 13(*a*)].

Compounds **5**, unlike **6**, were soluble in aliphatic hydrocarbons. Attempts to convert the dimer **6** into a monomeric Lewis base (*e.g.* thf or py) adduct have not provided isolable products, but colour changes (red) indicated that reactions had occurred.

It is evident that in the formation of compounds **5** and **6** two successive E–C couplings, followed by unprecedented 1,3-Me_3Si migrations from E to N, are implicated. We propose that the reactions involve intermediates **7**–**10** of Scheme 2.



Scheme 2

Anionic 1,3-Me_3Si shifts from N → N,[14] C → N,[1–3] and P → N[15] in reactions with nitriles were previously documented.

Complexes **5** and **6** are of interest for the novelty of their formation and their structures and have potential as ligand transfer reagents.

A simple ladder tin phosphate built up of the 4-membered cyclic tecton, $[Sn_2P_2O_4]$, is described along with a related layered material.

A variety of open-framework metal phosphate materials have been synthesized and their structures elucidated in the last few years. Of particular interest to us are the recently-discovered open-framework tin(II) phosphates containing trigonal-pyramidal SnO_3 and or square-pyramidal SnO_4 units linked to tetrahedral PO_4 units.[1–4] The tin phosphates reported so far possess three-dimensional,[1,2] layered[3] or monomeric structures[4] and the Sn/P ratios in these materials are generally greater than unity. To our knowledge, a pure tin(II) phosphate with a chain structure has not yet been discovered, although a tin(II) phosphanate with a chain structure is known.[5] Based on a study of a tin phosphate monomer unit stabilized by hydrogen bonding with the template amine,[4] we suggested recently that the basic building unit present in all the tin(II) phosphate materials is the $[Sn_2P_2O_4]$ moiety, forming a four-membered ring. We, therefore, considered it important to explore the possibility of synthesizing a simple chain tin(II) phosphate formed by the $[Sn_2P_2O_4]$ tecton. A systematic study of Sn(II) phosphates prepared hydrothermally in the presence of various structure-directing agents has enabled us to obtain two very simple materials with a Sn/P ratio of unity. One of the tin(II) phosphates, **I**, containing only four- and eight-membered rings forms a layered structure, whereas the second material, **II**, contains only four-membered rings forming a ladder structure. We can, however, show how **I** can be generated from **II**, by a mere shifting of Sn–O–P bonds. Furthermore, the ladder structure, **II**, fills the gap left by the absence of one-dimensional chain structures in the tin phosphate family.

Compounds **I** and **II** were synthesized hydrothermally by employing DABCO (1,4-diazobicyclo[2,2,2]octane) and DEED (*N*,*N*′-diethylethylenediamine) as the structure-directing agents[6a,b] and characterized by single crystal X-ray diffraction studies,[7a,b] using the Siemens SMART system. The structure of **I**, $[C_6N_2H_{14}]^{2+}2[SnPO_4]^-\cdot H_2O$, is made up of layers constructed by the networking of SnO_3 and PO_4 units. The connectivity between these units creates 4- and 8-membered rings, forming a layer along the *bc* plane (Fig. 1). The individual layers are held together by the protonated DABCO molecules which occupy spaces in between the layers [Fig. 1(b)] along with a water molecule. This is clearly a simple structure compared to the known Sn(II) phosphates.[1–4] The tin(II) phosphate, **II**, $[C_6N_2H_{18}]^{2+}2[SnPO_4]^-$ formed by DEED, however, is even simpler in that its structure involves edge sharing of 4-membered $Sn_2P_2O_4$ rings, forming one-dimensional chains in the form of ladders (Fig. 2). The amine molecule is situated between the ladders. Indeed, **II** can be considered to be an inorganic ladderane, not unlike the organic counterpart.[8] In both **I** and **II**, there are strong hydrogen bond interactions between the anionic framework (layer in the case of **I**, and chain in the case of **II**) and the protonated amine molecules. The Sn–O distances and angles in both the phosphates are as expected for 3-coordinated tin(II) atoms, and the P–O distances and angles are in agreement with those in the previously reported phosphate structures. The P–O [P(1)–O(4) for **I** and P(1)–O(1) for **II**] distance of *ca.*1.5 Å corresponds to the P=O double bond which takes part in hydrogen bonding with the amine.

The two structures formed by the $Sn_2P_2O_4$ tecton described here are the simplest open-framework tin phosphate structures known so far. The layered structure of **I** can be made from the chain structure of **II** by the scheme shown in Fig. 3 [compare this with Fig. 1(a)]. In the proposed transformation, every second alternate 4-membered ring of **II** is broken (Sn–O–P bond—forming a new P=O), accompanied by a simple rotation of the existing P=O group about a P–O single bond giving rise to a Sn–O–P bond and new 4- and 8-membered rings. The broken line in Fig. 3 represents the new Sn–O–P bond formed. Such a formulation is consistent with the doubling of the *b* axis in **I** compared to **II**. In general, *n*-edge-sharing 4-membered rings can give rise to a ring with $4n - 2(n - 1)$ atoms. Or, if we add *n* 4-membered rings to a *m*-membered ring, we get a ring with $m + 2n$ atoms (*m* and *n* represent T atoms; T = Si, P in aluminosilicate zeolites and Sn, P in the present case). We thus

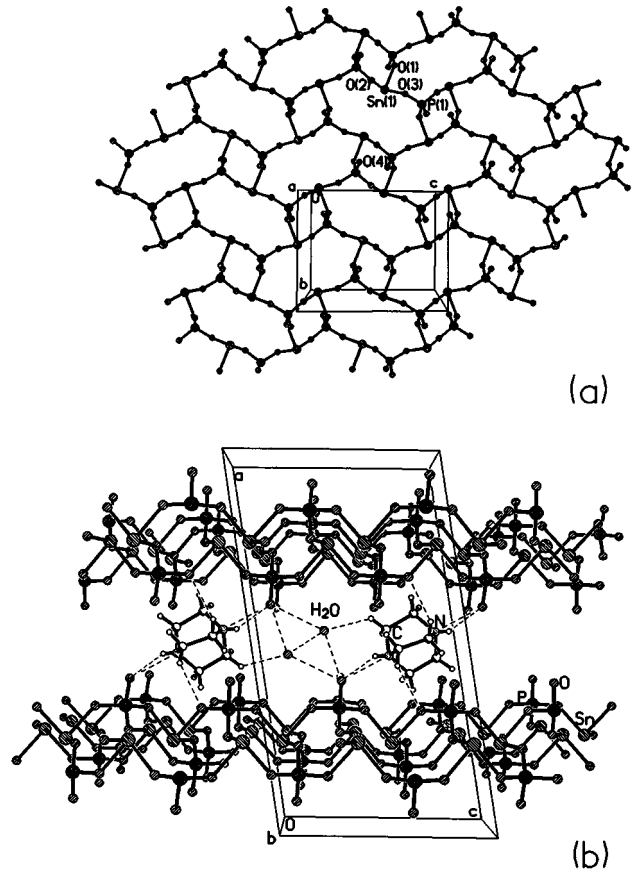

Fig. 1 Structure of **I**, $[C_6N_2H_{14}]^{2+}2[SnPO_4]^-\cdot H_2O$ showing (a) the 4- and 8-membered rings and the connectivity within the layer, and (b) the arrangement of anionic layers, the amine and the water molecules

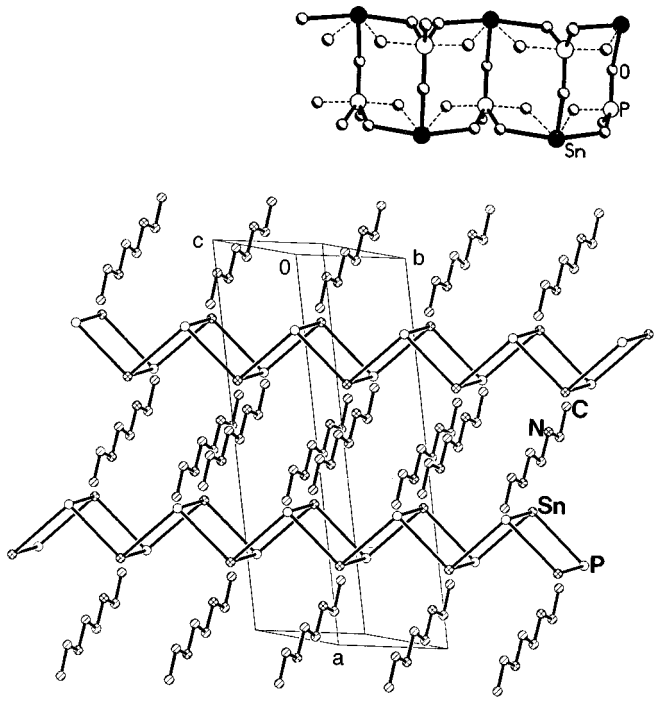

Fig. 2 Structure of **II**, $[C_6N_2H_{18}]^{2+}2[SnPO_4]^-$ showing the ladders and the amine (inset shows oxygen positions and the dotted lines represent the bonding with the disordered oxygens)

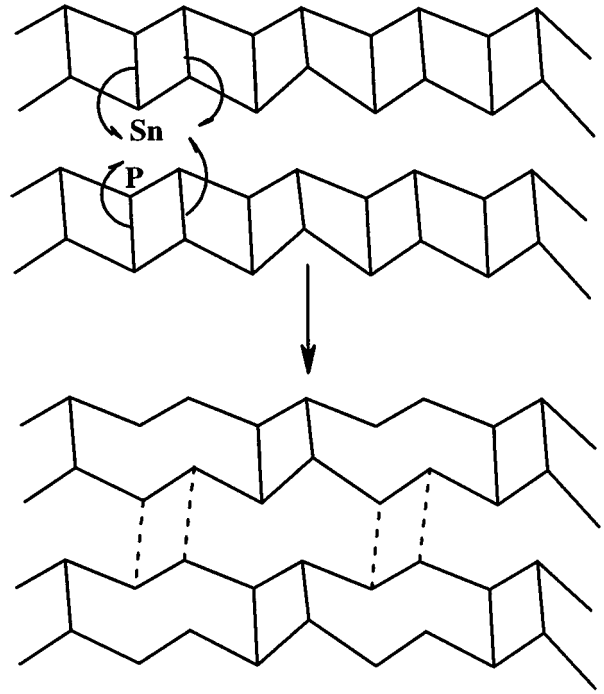

Fig. 3 Conversion of the chain (**II**) into the layered structure shown schematically. Note that the 4-membered rings are broken to form the 8-membered rings. The dotted lines represent the new 4- and 8-membered rings that are formed due to the Sn–O–P bonding and subsequently the layer (oxygens are not shown).

see how 6-, 8-, 10- and 12-membered rings can be formed from the 4-membered units.

The authors thank Unilever Plc for support of a joint research project between MRL, UCSB and JNCASR.

6 (*a*) 2.06 g of tin(II) oxalate were dispersed in 10 ml of water and 1.8 g of 85 wt% H_3PO_4 were added to the mixture under continuous stirring. 2 g of DABCO were added to the above and stirred until homogeneous. The composition of the mixture was SnC_2O_4 : $1.5H_3PO_4$: 1.8DABCO : $45H_2O$. The mixture was heated initially at 150 °C for 2 days and finally at 180 °C for 2 days and the product contained large quantities of plate-like single crystals. (*b*) 2.06 g of tin(II) oxalate, 2.81 ml of DEED, 5 ml of water and 5 ml of ethylene glycol were mixed together and stirred for 10 min. To this mixture 1.53 g of 85 wt% H_3PO_4 were added and the mixture homogenized and heated at 150 °C for 2 days. The final composition of the mixture was SnC_2O_4 : 1.95DEED : $27.5H_2O$: 8glycol : $1.3H_3PO_4$.

First three-component addition reaction in a series of 1,5-bis(dialkylamino)pentamethinium salts: a simple and efficient approach to tridentate chelating ligand systems

Vadim D. Romanenko,*[a,b] Jean-François Colom Toro,[a] François Rivière,[a] Jean-Gérard Wolf[a] and Michel Sanchez*[a]†

[a] *Université Paul Sabatier, Synthèse et Physicochimie Organique, UPR ESA 5068, 118 Route de Narbonne F-31062, Toulouse Cedex 4, France*
[b] *Institute of Biochemistry and Petrochemistry, Academy of Sciences of the Ukraine, Kiev-94, 253660, Ukraine*

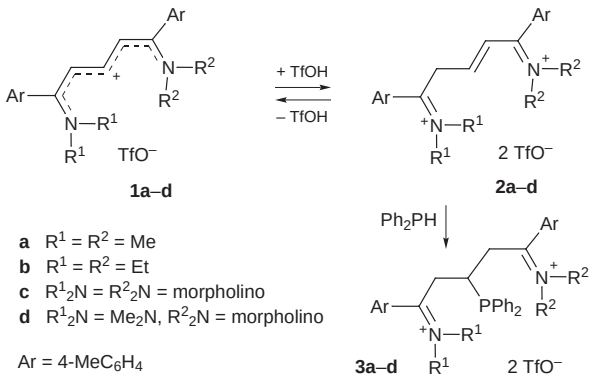
A new approach to tridentate chelating NPN, NPO and OPO ligand systems is described *via* a tandem reaction of easily available 1,5-bis(dialkylamino)pentamethinium salts (streptocyanine dyes) with diphenylphosphine in the presence of TfOH.

The role of polymethine dyes as components of industrially important technologies has long been acknowledged.[1] It is surprising, therefore, that the reported chemistry of polymethine salts is rather sparse.[2,3] This is due to the relatively high thermodynamic stability of the polymethine chain and its tendency to be regenerated after reaction. In the pentamethinium series this enables introduction of nucleophilic or electrophilic groups into the chain by substitution rather than addition to the double bonds.

To exploit the synthetic potential of easily available pentamethinium salts[2,4] we now report the application of tandem methodology in the preparation of chelating polyheteroatomic compounds,[5] starting from 1,5-diaryl-substituted pentamethinium salts **1**.

Since non-ionic protic nucleophiles are not capable of direct addition to pentamethinium salts, activation of the latter towards the addition of phosphines might be achieved in the presence of strong protic acid, thus facilitating nucleophilic attack on the intermediate dicationic species.

Treatment of the pentamethinium salts **1** with the Ph_2PH and TfOH in the molar ratio 1:1:1 in a CH_2Cl_2 solution at −35 °C resulted in the quantitative formation of the diiminium salts **3** (Scheme 1). We obtained **3**‡ as colorless crystals in 83–95% yield. NMR signals at *ca.* δ 1.9 (HCP) and 3.2 (CH_2CHP, d, $^3J_{HH}$ 7 Hz) in the ^{1}H NMR spectra and *ca.* δ 187 (C=N$^+$), 35 (C3, $^1J_{CP}$ 22 Hz) and 39 (C2, C4, $^2J_{CP}$ 9 Hz) in the ^{13}C NMR spectra are diagnostic for structure **3**. The ^{31}P NMR signal is observed as a singlet in the range expected for alkyldiphenylphosphines (δ_P *ca.* 3).



Scheme 1

Single crystals of salt **3b** were obtained from MeCN at 20 °C and X-ray data were collected at 160 K.§ The compound crystallizes along with 1 equiv. of MeCN in space group *P*1 Fig. 1. The C(3) atom in **3b** displays a slightly distorted tetrahedral geometry. The P–C(3) bond length [1.873(2) Å] lies at the higher limit of the normal P–C(sp^3) range, as in the sterically overcrowded compound $HC(PPh_2)_3$ (av. 1.872 Å).[6] Iminium nitrogens are sp^2-hybridized. The distances between the C(sp^2) atoms and nitrogen atoms [C(1)–N(1) and C(5)–N(2), av. 1.294 Å] are considerably shorter than in 1,5-diaryl-substituted pentamethinium salts (*ca.* 1.325 Å)[7] but comparable with those observed in other iminium salts.[8] The C(1)–C(2) and C(4)–C(5) distances are 1.498(3) and 1.507(3) Å, approximately 0.035 Å shorter than the C(2)–C(3) and C(3)–C(4) bonds. This may imply hyperconjugation in the $[HCC(Ar)N]^+$ bond system.

To gain some insight into possible intermediates leading to **3**, we treated **1b** with TfOH in CH_2Cl_2 at −50 °C. Monitoring the reaction *via* ^{13}C NMR spectroscopy clearly showed the reversible build-up of **2b** [δ 186.7 and 176.3 (C^1, C^5), 155.8 (C^3), 128.3 (C^4), 40.1 (C^2)]. The protonation of **1b** was achieved when 1.5-fold molar excess of TfOH was added. Subsequent warming of the solution in the NMR probe resulted in the disappearance of the signals due to **2b** due to its degradation with the loss of the $[Et_2NH_2^+TfO^-]$ salt. The yield of **3** sharply decreased if Ph_2PH was not added to the pentamethinium salt at the same time as the TfOH. The reaction pathway begins with an attack of the proton at the C^2 methine carbon of the substrate. The non-isolable dicationic intermediate **2** allows the efficient trapping of Ph_2PH in the subsequent nucleophilic addition.

An important aspect of salts **3** is their ability to release Ph_2PH. According a variable-temperature ^{31}P NMR study, the reversible cleavage of **3** in MeCN occurs above 50 °C. The

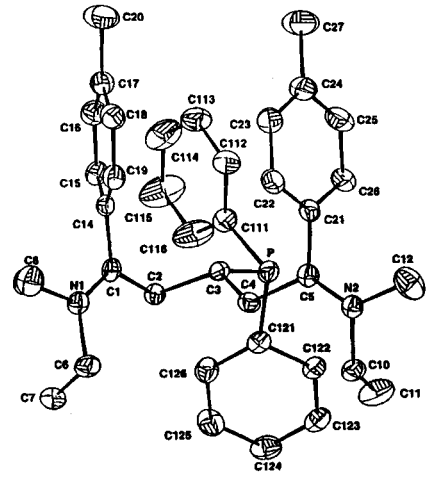


Fig. 1 Molecular structure of **3b** with atomic numbering scheme

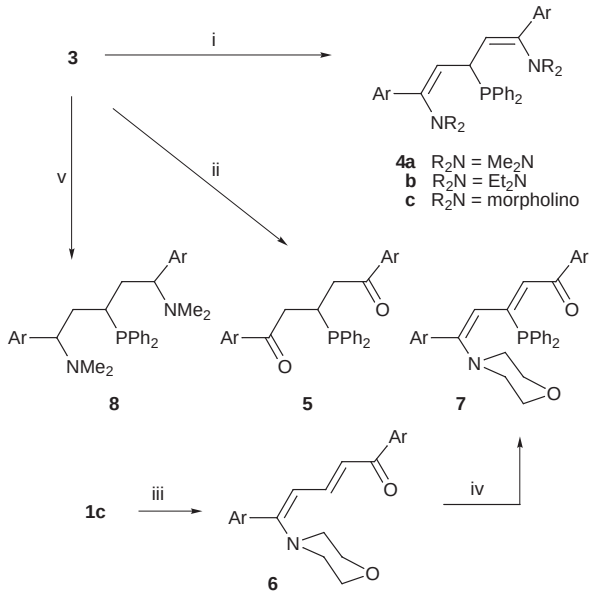

Scheme 2 *Reagents and conditions*: i, KOH, EtOH, 20 °C, 1 h; ii, KOH, EtOH–H_2O (5:1), 70 °C; iii, KOH EtOH–H_2O (5:1), 20 °C, 1 h; iv, Ph_2PH, KOH (cat.), MeCN, 20 °C, 24 h; v, $NaBH_4$, EtOH, −20 °C

addition of 3 mol% TfOH or an equimolar amount of pyridine to a CH_2Cl_2 solution of **3** promotes rupture of the C–P bond and the appearance of a broadened singlet at δ_P −38, indicating a fast proton exchange for the three-component system (**1**/Ph_2PH/TfOH). The cleavage of **3** proceeds slowly at 20 °C in alcohols and very fast in highly polar basic solvents such as HMPA, DMF or NMP. Evaporation of the solvent allows the recovery of **3**. Strong acids (catalytically) and weak bases tend to cleave the P–C(3) bond in **3** due to reversible protonation at the P centre and deprotonation of the chain methylene group. The treatment of **3** in EtOH at 20 °C with 2 equiv. of KOH affords the neutral compounds **4**¶ (Scheme 2). The deprotonation of the dication **3** and the formation of **4** is a highly regioselective reaction if the alternative pathway including protonation of the P atom and subsequent splitting up Ph_2PH is blocked or inhibited. The products **4** were isolated as crystalline materials and, in the case of **4c**, characterised by single-crystal X-ray structure determination.§ The most interesting difference between **3b** and **4c** is a lengthening of the P–C(3) bond [1.892(2) Å for **4c** *vs*. 1.873(2) Å for **3b**]. Meanwhile, compounds **4** do not display evidence for structural lability. Thus factors favouring P–C bond scission in **3** are of electronic rather than steric character.

When **3** was allowed to react with 2 equiv. of KOH in aq. EtOH at 60 °C for 2 h (Scheme 2) the dicarbonyl derivative **5**¶ was obtained. The conversion includes the intermediate formation of **4** and its subsequent hydrolysis. Efforts to synthesize **7** under similar conditions (1 equiv. of KOH, EtOH–H_2O, 60 °C) were not successful. However, reaction of **1c** with 1 equiv. of KOH in EtOH gave a yellow microcrystalline precipitate **6** (78%). Compound **7** was then constructed *via* treatment of **6** with Ph_2PH.¶ Finally, the reduction of **3a** with $NaBH_4$ proceeded smoothly in EtOH at −20 °C to give **8** (62%).¶

In summary, these results illustrate the ability of strong electrophiles to interact with the electron deficient pentamethinium chain, leading to the formation of adducts which are stabilised by addition of proton-donor nucleophiles. Polymethine salts are prospective starting materials for organoelement and coordination chemistry.

Mechano-catalysis, a novel and simple method to decompose water into H_2 and O_2 in which mechanical energy is directly converted into chemical energy, is demonstrated.

H_2 production from water decomposition is one of the most attractive candidates for future clean energy resources. Electrolysis of water is a familiar way to accomplish overall water splitting. Photoelectrochemical and/or photocatalytic decomposition of water have also been pursued from the viewpoint of solar energy utilization.[1–4] Recently, the authors have been studying the decomposition of water on magnetically stirred Cu_2O powder under visible light irradiation.[5] At the stage when H_2 and O_2 evolved steadily in a stoichiometric ratio, we tentatively concluded that the reaction proceeded 'photocatalytically'.[5] In the subsequent study of the system, however, we found several characteristics of the reaction which are unusual for conventional photocatalytic ones. The most striking aspect of the reaction was the continuous evolution of H_2 and O_2 even after the light was turned off. This cannot be understood by the model of a semiconductor photocatalyst in which photoexcited electrons and holes are postulated to directly react with reactant water molecules (or H^+ and OH^- ions).[1] The lifetime of the photoexcited electronic states is at most of the order of milliseconds. We then hypothesized that photon energy was stored in the Cu_2O particle as some chemical species and the excess energy was gradually released to decompose water. To our surprise, however, the evolution of H_2 and O_2 in the dark continued for several hundred hours, and eventually the amounts of evolved H_2 and O_2 exceeded that of Cu_2O used. Another noticeable feature of this reaction is the marked dependence of the H_2 and O_2 evolution rates on the rate of stirring, *i.e.* the rate of H_2O decomposition increases monotonically with the rate of rotation. Without stirring, no H_2 and O_2 evolution occurred.

From these observations, we ended up with the following working hypothesis: the mechanical energy supplied by stirring was converted to chemical energy of H_2 and O_2 with Cu_2O functioning as a mediator or a catalyst. To work out this hypothesis, we have carried out rather extensive experiments by using various binary oxides. Here we report some phenomenological results which seem to be enough to prove our hypothesis. The detailed and atomic scale mechanism is an open question.

The reaction was carried out in a flat-bottomed reaction vessel made of Pyrex glass. Typically 0.1 g of oxide powder was suspended by magnetic stirring (F205, Tokyo Garasu Kikai) in 200 cm^3 of distilled water. The stirring rod was sealed by PTFE (polytetrafluoroethylene, Teflon®). The reaction vessel was attached to a closed gas circulation system (about 800 cm^3) equipped with an evacuation line. Before the reaction, the gas phase was completely evacuated and only water vapor remained. The evolved gas was accumulated and was analyzed by gas chromatography (TCD, Ar carrier, MS 5A column). When performing reactions in the dark, the reaction vessel was completely covered with aluminium foil, and when performing the reaction under photoirradiation, a 500 W Xe lamp placed at the side of the reaction vessel was used. The reaction temperature was at or somewhat lower than room temperature.

Various kinds of binary metal oxides which are stable in water were surveyed in the dark reaction. Cu_2O, NiO, Co_3O_4, and Fe_3O_4 exhibited H_2 and O_2 evolution. Much lower yet definite activity was also exhibited by RuO_2 and IrO_2. Specifically, CuO and Fe_2O_3 did not show activity for the reaction. Typical photocatalysts such as TiO_2, ZnO and WO_3 were also completely inert.

Fig. 1 shows a typical time course of H_2 and O_2 evolution on NiO in the dark. The NiO sample used was a yellow green powder with a BET surface area of about 1 $m^2\ g^{-1}$ and the particle size was about 0.5 μm [purchased from Kanto Chemical, high purity reagent (3 N)]. H_2 and O_2 kept evolving exactly in the stoichiometric ratio of water decomposition. The rate of H_2 and O_2 evolution gradually decreased with the accumulation of the evolved gas probably due to the effect of O_2 pressure. A similar effect was observed for the other three active oxides, *i.e.* Cu_2O, Co_3O_4 and Fe_3O_4. Almost the same time course was reproduced in the second run after evacuation. The total amount of evolved H_2 after the second run was 1.7 mmol, which exceeded the amount of NiO used, *i.e.* 1.3 mmol (0.1 g). No appreciable degradation of the activity was observed even after the second run. It was thus confirmed that this dark reaction proceeds catalytically.

Another point worth noting is the effect of the shape of the stirring rod: when a stirring rod with a flat bottom was used, the rate of H_2 and O_2 evolution was increased by more than an order of magnitude compared with that obtained when a round bottomed rod was used. This indicates that a mechanical effect such as the rubbing of the catalyst powder by the stirring rod is essential for the decomposition of water.

Two further experiments were conducted. First, double-sided adhesive tape was stuck to the flat bottom of the stirring rod and

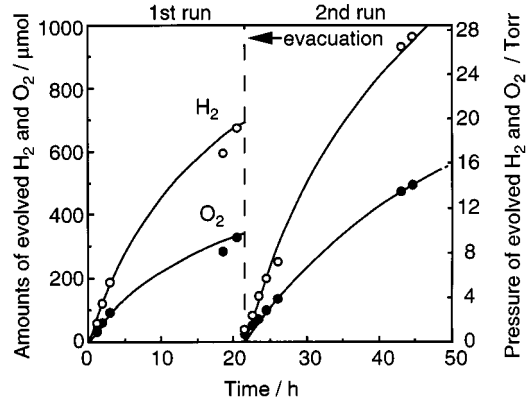

Fig. 1 Time course of H_2 (open circles) and O_2 (filled circles) evolution on NiO in the dark. The gas phase was evacuated at a reaction time of 22 h. Catalyst (NiO): 0.1 g, H_2O: 200 cm^3.

ca. 0.01 g of NiO powder was stuck onto the other side of the tape. The stirring rod was rotated in distilled water without any suspended NiO powder in it, and almost the same rate of H_2 and O_2 evolution as seen in Fig. 1 was achieved. This indicates that at least the major part of the water splitting reaction proceeded in between the stirring rod and the bottom of the glass reaction vessel. This result also excluded the possibility that the Teflon which coated the stirring rod took part in the reaction. Second, a Ni metal foil (35 mm × 9 mm × 0.2 mm) was oxidized at 800 °C for 1 h in air and was rotated in distilled water at the bottom of the reaction vessel by using a stirring rod attached on top of the foil. Again H_2 and O_2 evolution was observed with a rate of about half that obtained in the above experiment using adhesive tape. These results suggest that the rubbing of the oxide materials against the bottom wall of the glass reaction vessel is essential, but the collisions between the oxide particles or at the stirrer surface are not.

In the above experiments, we did not pay much attention to the influence of magnetic fields generated by the stirring device. To avoid magnetic field effects, a motor driven mechanical stirrer was used for the abrasive stirring. The motor rotated the catalyst powder (NiO) stuck on the tip of the driving shaft, which was pressed on the bottom of the reaction vessel. Even in the reaction cell, stoichiometric H_2 and O_2 evolution was observed. Therefore, the magnetic field exerted by the stirrer has nothing to do with the present phenomenon.

From all the above experimental results, we conclude that the H_2 and O_2 evolution is regarded as 'mechano-catalytic' overall water splitting. Because of the first and second laws of thermodynamics, it is not probable that heat of friction leads to the observed water decomposition. We, therefore, consider that these catalysts directly convert mechanical energy to chemical energy.

We now turn to the influence of photoirradiation. When the reaction vessel containing a suspended powder catalyst was irradiated with a Xe lamp, essentially no appreciable change in H_2 and O_2 evolution rate was observed for NiO, Co_3O_4, and Fe_3O_4. However, in the case of Cu_2O, a difference of the rate of H_2 and O_2 evolution was observed as shown in Fig. 2. During the first 50 h, the reaction was carried out under irradiation (> 460 nm) and then the reaction was continued in the dark for another 50 h after the evacuation of the gas phase. The rate of H_2 and O_2 evolution under the irradiation was faster by about 3 times than that in the dark. Because of the difference of the activity between reaction in the dark and under photoirradiation, we previously concluded the observed phenomenon as photocatalysis, which should be corrected. At present, we do not have a satisfactory explanation for the effect of photoirradiation on Cu_2O.

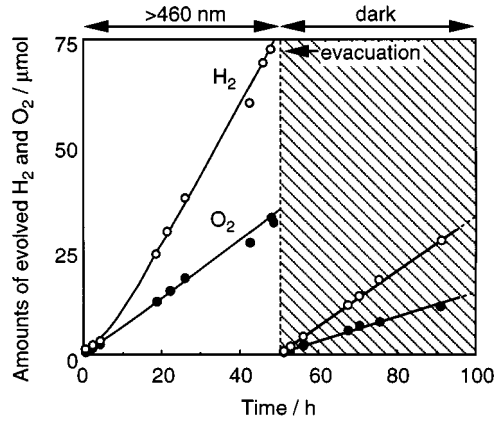

Fig. 2 Time course of H_2 (open circles) and O_2 (filled circles) evolution on Cu_2O under visible light (> 460 nm) irradiation and in the dark. The reaction system was evacuated at a reaction time of 50 h. Catalyst (Cu_2O): 0.1 g, H_2O: 200 cm^3.

As we have shown, the rate of H_2 and O_2 evolution strongly depends on the rubbing method of the catalytic materials, and thus much more efficient systems could be constructed by a suitable reactor design.

This work was partly supported by the Research Institute of Innovative Technology for the Earth (RITE), and also by a Grant-in-Aid for Scientific Research on Priority Area of 'Catalytic Chemistry of Unique Reaction Fields-Extreme Environment Catalysts' from the Ministry of Education, Science, Sports and Culture, Japan, and also by the Research for the Future Program, the Japan Society for the Promotion of Science.

Hydrothermal synthesis and structural characterization of a tubular oxovanadium organophosphonate, $(H_3O)[(V_3O_4)(H_2O)(PhPO_3)_3]\cdot xH_2O$ (x = 2.33)

Grant Bonavia,[a] Robert C. Haushalter,[b] Charles J. O'Connor,[c] Claudio Sangregorio[c] and Jon Zubieta*[a]

The hydrothermal reaction of KVO_3, $PhPO_3H_2$ and water at 180 °C for 116 h yields the tubular mixed valence V^V/V^{IV} polymer $(H_3O)[(V_3O_4)(H_2O)(PhPO_3)_3]\cdot xH_2O$ (x = 2.33).

The widespread contemporary interest in metal phosphonate materials[1–3] reflects their potential applications as sorbents, ion exchangers,[4] ionic conductors,[5] nonlinear optical materials,[6] sensors[7] and catalysts.[8] The vanadyl organophosphonate system has proved particularly fruitful and is represented by molecular clusters of various nuclearities, and one-, two- and three-dimensional phases.[9–11] In common with metal organophosphonates in general, lamellar structures predominate for the vanadyl organophosphonate subclass, with $[(VO)(H_2O)(PhPO_3)]$[12] providing the structural prototype. Lamellar vanadyl organophosphonates possess structurally well defined internal void spaces and coordination sites which allow intercalation of substrate molecules. Modifications of organic substituents, introduction of templating reagents, and variations in metal–phosphonate compositions can be exploited to change substrate-specific recognition and to design novel phases. It is also apparent that variations in reaction conditions can result in significant structural reorganization.[13–15] Thus, the novel tubular material $(H_3O)[(V_3O_4)(H_2O)(PhPO_3)_3]\cdot xH_2O$ **1** (x = 2.33) was prepared by relatively minor modification of the synthetic procedure employed in the isolation of the lamellar $[(VO)(H_2O)(PhPO_3)]$.[12]

The reaction of MVO_3 (M = NH_4^+, Na^+, K^+), $PhPO_3H_2$ and water in the mole ratio 1 : 2.33 : 340 at 180 °C for 116 h yielded dark green hexagonal rods of $(H_3O)[(V_3O_4)(H_2O)(PhPO_3)_3]\cdot xH_2O$ **1** (x = 2.33)† in 75% yield. Although the inorganic cation of the vanadate starting material does not appear in the product, it is absolutely required for the synthesis of **1**, an observation which highlights the often critical role of sacrificial cations in hydrothermal synthesis. Consequently, the reaction of V_2O_5 with $PhPO_3H_2$ under identical conditions yields only $[VO(H_2O)(PhPO_3)]$. It is noteworthy that hydrothermal treatment of $[VO(H_2O)(PhPO_3)]$ with Na^+ at pH 2 results in quantitative conversion to **1**. However, compound **1** was not isolated in more basic environments, where an undefinable powder was observed to form. Attempts to prepare **1** from oxovanadium phenylphosphonate clusters such as $[V_5O_7(OMe)_2(PhPO_3)_5]^-$,[16] and Na^+ in nonaqueous solvents proved fruitless. However, such clusters proved perfectly adequate for synthesis under hydrothermal conditions, suggesting that a solvent of a high dielectric constant is required and that the synthesis of **1** occurs through disassembly of oxovanadium phosphonate units rather than fusion of discrete clusters or unzipping of layered structures into infinite chains which subsequently fuse into the tubular form.

As illustrated in Fig. 1, the structure of **1**‡ consists of $[(V_3O_4)(H_2O)(PhPO_3)_3]_n^{n-}$ tubes running parallel to the *c*-axis. The phenyl groups extend outward from the periphery of the tube, while the vanadyl oxo groups are directed both to the interior and exterior of the cavity. The hydronium cation and the water molecules are contained within the hydrophilic interior of the tube, while the phenyl groups of the tube interdigitate with phenyl groups from adjacent tubes to provide a hydrophobic exterior.

The walls of the tube are constructed from three independent oxovanadium centers, an aqua group and three phosphonate bridging ligands, shown in Fig. 2. Two of the vanadium sites

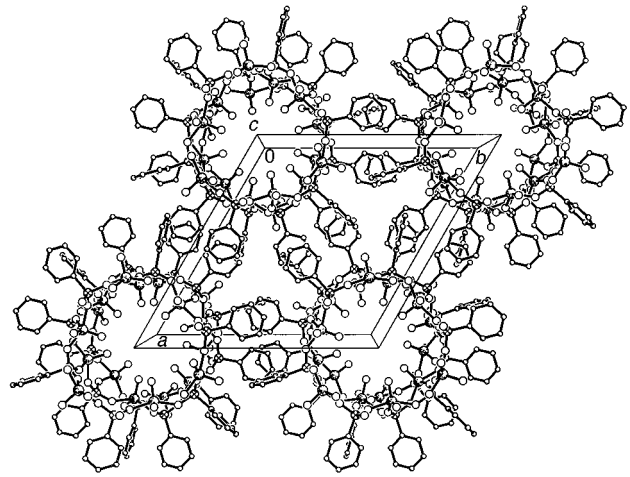

Fig. 1 A view along the crystallographic *c* axis of the tubular structure of the anions of **1**. The hydronium cations and water molecules of crystallization occupy the hydrophilic interior of the tube. The phenyl groups project outward from the tubes and interdigitate in the hydrophobic domains outside the tubes.

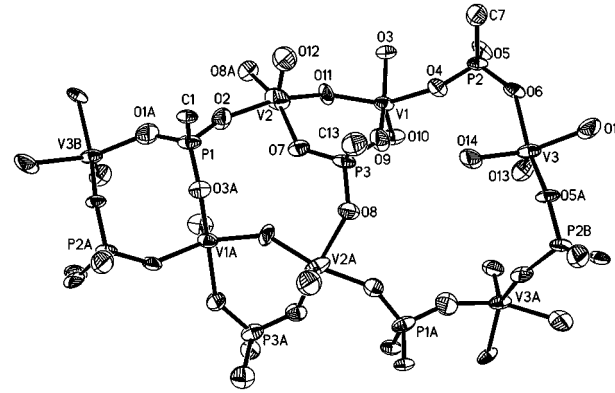

Fig. 2 A view of the V–O–P building blocks of the tube walls, showing the atom-labeling scheme and 50% probability ellipsoids. Selected bond lengths (Å): V1–O10 1.563(3), V1–O11 1.928(3), V1–O3 1.946(3), V1–O9 1.974(3), V1–O4 1.979(3), V2–O12 1.621(4), V2–O11 1.880(3), V2–O7 1.905(3), V2–O2 1.929(3), V2–O8 1.987(3), V3–O13 1.596(4), V3–O5 1.902(3), V3–O6 1.955(3), V3–O1 1.970(4), V3–O14 2.005(4).

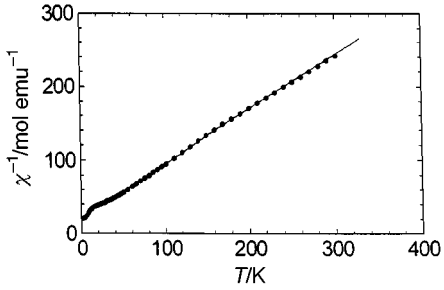

Fig. 3 A plot of $1/\chi$ *vs*. temperature, showing the Curie fit to the data

form a binuclear unit of corner-sharing square pyramids with the terminal oxo-groups in *anti*-orientation with respect to the V–O–V bridge. The remaining three coordination sites on each vanadium center are occupied by oxygen donors from the phosphonate ligands. The third vanadium site V3 is an isolated square pyramid (no V–O–V interactions). The oxo-group is directed toward the interior of the tube, while the coordinated aqua ligand forms parts of the tube wall. The complex pattern of phosphonate bridging of metal centers provides four distinct heteronuclear ring motifs as fundamental building blocks[18] of the tube wall: six atom (VOVOPO), eight atom $(VOPO)_2$, ten atom (VOVOPOVOPO) and sixteen atom $(VOPO)_4$ cycles.

The temperature dependence of the magnetic susceptibility of **1** is shown in Fig. 3. Above 40 K, the magnetic susceptibility conforms to the Curie–Weiss law with a Curie constant corresponding to 3.27 μ_B and a Θ value of −27 K. The effective moment for each of two V^{IV} ions is 2.33 μ_B, indicating a significant orbital contribution to the moment as anticipated for the $^2T_{2g}$ ground state. The negative Θ value indicates the presence of antiferromagnetic spin interactions, and the deviation from Curie–Weiss behavior below 40 K can be ascribed to the coupling of the spins of the d^1 V^{IV} sites. These observations are consistent with charge balance and valence sum calculations[17] which give an average oxidation state of 4.33 per vanadium site, or 1 V^V and 2 V^{IV} centers.

Thermogravimetric analysis of **1** shows weight losses corresponding to 1 and *ca*. 1.5 water molecules of crystallization at 50–60 and 120–140 °C, respectively. A weight loss corresponding to two additional water molecules occurs between 245 and 275 °C. The material decomposes sharply at 305 °C with an additional 30% weight loss to produce a blue amorphous material.

While **1** represents the first example of a tubular structure for the vanadium–organophosphonate system, tubular uranyl phosphonates have been reported recently.[13–15] However, the structure of the wall of **1** is quite distinct from the uranyl species which do not form U–O–U bonds. When viewed down the tube axis, the structure of **1** presents the circular projection also observed for $(UO_2)(PhPO_3)\cdot 0.7H_2O$, whereas $[(UO_2)_3(PhPO_3H)_2]\cdot H_2O$ exhibits a rectangular profile. Although the uranyl materials exhibit neutral tubes, the tube in **1** is anionic with charge compensation provided by hydroxonium cations, which occupy the interior of the tube and hydrogen bond to oxo-groups of the tube wall and water molecules which stuff the tube interior. Furthermore, the vanadyl sites of **1** are five coordinate, a geometry achieved through coordination to terminal and bridging oxo-groups and η^3,μ_3-phosphonate ligation. In contrast, the uranyl centers of the circular tubular material $(UO_2)(PhPO_3)\cdot 0.7H_2O$ are seven coordinate, exhibiting the common *trans* dioxo unit and requiring that the phosphonate adopt the η^3, μ_5-coordination mode. The structure of **1** exhibits two of the phenomena that critically influence the organization of organic–inorganic composite materials, namely, multipoint hydrogen bonding and hydrophilic–hydrophobic interactions.[18]

The research was supported by NSF grant CHE9617232.

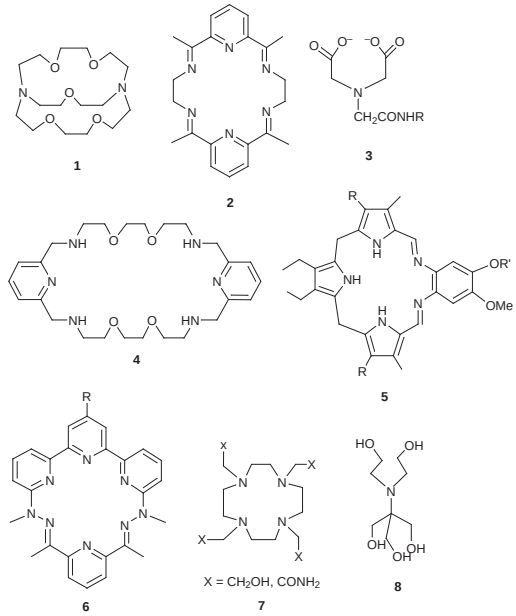
Structure and phosphodiesterase activity of Bis-Tris coordinated lanthanide(III) complexes

Soon Jin Oh, Young-Seo Choi, Seok Hwangbo, Sung Chul Bae, Ja Kang Ku, and Joon Won Park*

Department of Chemistry, Center for Biofunctional Molecules, Pohang University of Science and Technology, San 31 Hyoja-dong, Pohang, 790-784, Korea. E-mail: jwpark@vision.postech.ac.kr

A commonly used buffer, 2,2-bis(hydroxymethyl)-2,2′,2″-nitrilotriethanol (Bis-Tris) coordinates lanthanide(III) ion strongly in water to form molecular species that are highly active for the hydrolysis of a phosphate diester, bis(4-nitrophenyl) phosphate.

Ligand free lanthanide ions have been shown to be highly reactive for hydrolyzing phosphate esters including RNA and DNA.[1] There has been considerable interest in developing organic ligands that bind tightly around lanthanide ions in order to increase the solubility of the metal ions, and to develop artificial restriction enzymes by covalently anchoring the metal to molecules that bind nucleic acids sequence specifically.[2] Over the last several years, many elegant ligands (**1**–**7**) that bind



lanthanide ions have been developed for the purpose of hydrolyzing phosphates.[2–5] Negatively charged ligands tend to bind tightly to lanthanide ions but greatly lower the reactivity of the metal ions for hydrolyzing phosphates.† On the other hand, neutral ligands tend to release the lanthanide ions by deligation (**1**, **2**).[3,4] Here we report a remarkably simple neutral ligand (**8**)[6]‡ that binds tightly around lanthanide ions without lowering their reactivity for hydrolyzing phosphates.

Compound **8** is a commonly used buffer 2,2-bis(hydroxymethyl)-2,2′,2″-nitrilotriethanol (Bis-Tris). An equimolar mixture of $LaCl_3$ and Bis-Tris in methanol yielded white crystals. The structure of $[La(\mathbf{8})_2]Cl_3$ (Fig. 1) reveals that the metal has ten coordination sites occupied by two molecules of Bis-Tris.§ Each molecule of Bis-Tris acts as a pentacoordinate ligand with four of its oxygen atoms and its nitrogen atom. The remaining oxygen of Bis-Tris cannot coordinate due to its structural position. Although the crystal structure is that of a 2 : 1 ligand to metal complex, other data shown below indicate that the major species in aqueous solution of an equimolar mixture of $LaCl_3$ and Bis-Tris is a 1 : 1 ligand to metal complex.

Potentiometric titration of an equimolar mixture of $LaCl_3$ and Bis-Tris in water showed that there is no ligand-free La(III) ion or metal-free Bis-Tris. The pK_a of Bis-Tris shifts from 6.5 to 4.0 in the presence of an equivalent of $LaCl_3$ (24 mM), indicating that the formation of the complex is quite favorable in the aqueous solution ($K_f = 5 \times 10^4$ M^{-1}).¶ It is rather surprising to observe such a large binding constant for the neutral ligand, given that the formation constant of the europium(III) cryptand 221 complex is smaller than 0.5 M^{-1}.[3a]‖ Other buffers of the similar structure such as Tris, Bis-Tris Propane, Taps, Tapso, and Tes do not bind to lanthanide ions as well as Bis-Tris. In particular, a binding constant of 2.75×10^2 M^{-1} for Tris has been reported.[7]

In the titration of the equimolar mixture, consumption of 2 equiv. OH^- is observed at around pH 9.8. The low steepness of the titration curve suggest that a dimer **9** is formed at the pH. In the absence of any organic ligands, $LaCl_3$ itself also gives a curve of the similar shape. Based on the slope of the titration curve, it has been suggested that ligand-free lanthanide ions also form dimers or higher order aggregates under alkaline conditions. Thus lanthanide ions tend to form gels under alkaline conditions (pH > 9) even at low concentrations (0.5 mM). Interestingly, equimolar mixtures of $LaCl_3$ and Bis-Tris remain in solution even at 40 mM $LaCl_3$ and pH 11.5. It may be that Bis-Tris prevents aggregation of La(III) ions and enhances solubility by capping the two ends of the dimer **9** (Scheme 1).

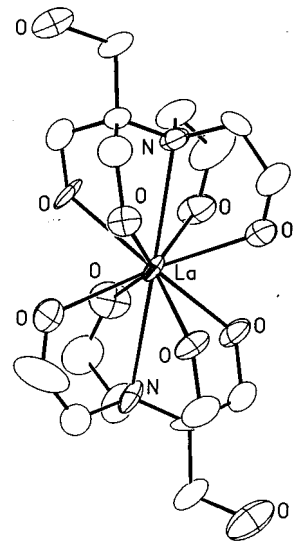


Fig. 1 ORTEP diagram of the lanthanum(III) complex coordinating two molecules of Bis-Tris. Distances between the coordinated oxygen atoms and the metal center are between 2.515(14) and 2.622(13) Å. Distances between the nitrogen atoms and the metal center are between 2.863(14) and 2.948(13) Å. Hydrogen atoms and non-coordinating chloride anions are removed for clarity.

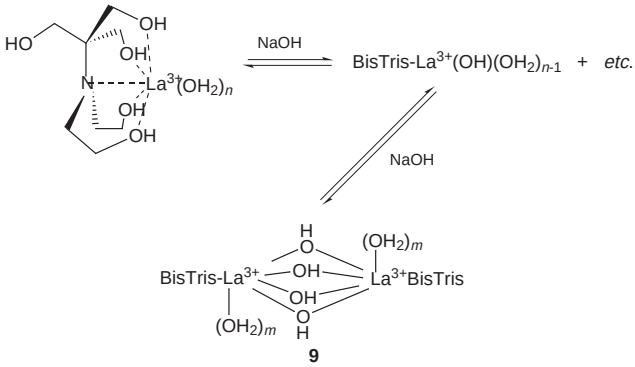

9

Scheme 1

Time-resolved luminescence spectroscopy is a valuable method for investigating Eu(III) complexes in aqueous solution.[8] The number of coordinating waters (q) per Eu(III) center in solution can be obtained by measuring the luminescence lifetimes of each species in water and deuterated water. Fig. 2 shows the excitation spectra of an equimolar mixture of $EuCl_3$ and Bis-Tris in water with 0–2.5 equiv. NaOH added. In the absence of any added NaOH, a single sharp peak at 579.7 nm with the q value of 6 suggests an 1 : 1 Eu to Bis-Tris complex with less than six coordinating water molecules. When two equiv. OH^- is added, a major peak at 580.4 nm with a significantly reduced q (2.5) value appears, which is consistent with structure **9**.

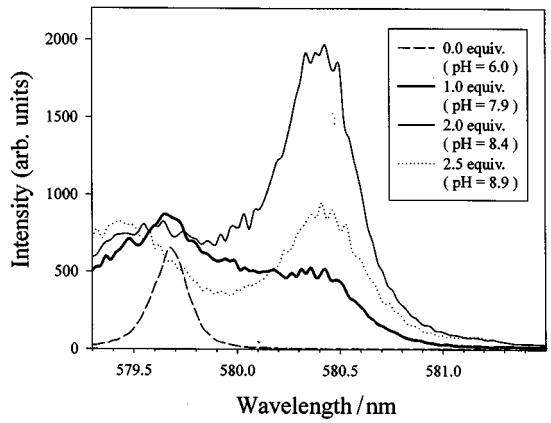

Fig. 2 Excitation spectra of the europium(III) complex in the presence of 1 equiv. of Bis-Tris. Spectra were recorded in water upon addition of (a) 0, (b) 1.0, (c) 2.0 and (d) 2.5 equiv. NaOH.

The reactivity of a 1 : 1 $LaCl_3$ to Bis-Tris solution for hydrolyzing bis(4-nitrophenyl)phosphate (BNPP) initially increases with added NaOH but reaches a maximum at 2 equiv. NaOH. Therefore, complex **9** or its kinetic equivalent is the active species for hydrolyzing BNPP. The phenomenon is observed at a wide range of concentration (0.5–20 mM). Although Bis-Tris increases the solubility of lanthanide ions by tightly complexing them, it does not reduce the reactivity of the metal center for hydrolyzing BNPP. For comparison, the activities were measured at low concentration, where precipitation of free lanthanide ions is not problematic. The hydrolytic activity of a 1 : 1 $LaCl_3$ to Bis-Tris solution (0.5 mM) with 2 equiv. NaOH ($k = 7.3 \times 10^{-3}$ s^{-1}) is comparable to a solution of $LaCl_3$ (0.5 mM) with 2 equiv. NaOH ($k = 8.2 \times 10^{-3}$ s^{-1}). We propose that the hydrolytic mechanism involves nucleophilic attack of the phosphate bridging the two metal centers by one of the bridging hydroxides (**10**).[9]

The generation and trapping of organozinc carbenoids from orthoformates: a novel alkoxycyclopropanation reaction

Rodney J. Fletcher, William B. Motherwell* and Matthew E. Popkin

Department of Chemistry, Christopher Ingold Laboratories, University College London, 20 Gordon Street, London, UK WC1H OAJ

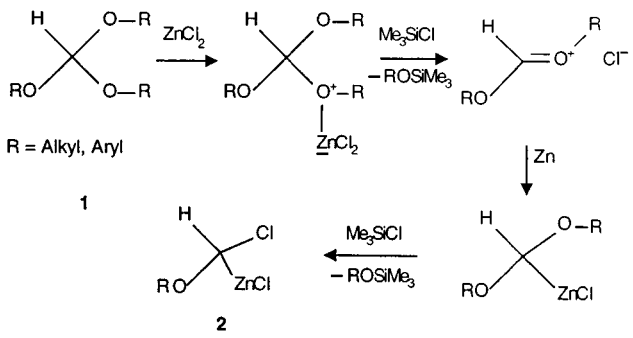
Alkoxycyclopropanes are readily prepared by reaction of an orthoformate with an alkene in the presence of Me_3SiCl and zinc.

We have previously shown that a useful range of organozinc carbenoids[1] can be generated from the reaction of simple carbonyl compounds with zinc in the presence of a silicon electrophile and that these intermediates can then undergo a variety of reactions including C–H insertion to give alkenes,[2] dicarbonyl coupling[3] and cyclopropanation.[4] More recently, in the light of reports on the preparation of isolable organochromium[5] and organoiron[6] carbenoids *via* two-electron delivery from a metal salt to a preformed carboxonium salt, we have demonstrated that acetals and ketals may be used as precursors for the formation of related organozinc carbenoids *via* reduction of their derived oxonium ions, once again with zinc in the presence of Me_3SiCl.[7]

As a logical consequence of the above sequence, and in view of the proven versatility of alkoxycyclopropanes as highly useful intermediates for organic synthesis,[8] we therefore reasoned, as outlined in Scheme 1, that the Lewis acid assisted cleavage of an orthoformate **1** could give rise, in similar fashion, to hitherto unknown α-alkoxy and α-aryloxy organozinc carbenoids **2**.

A preliminary study using allylbenzene and trimethyl orthoformate as a convenient methoxycarbenoid source served to confirm the above hypothesis (Table 1, entry 1) and also allowed us to develop a convenient experimental method. Thus, a typical experimental procedure would involve slow addition over 24 h of two separate portions of trimethyl orthoformate (1.4 ml, 8 mmol) and Me_3SiCl (1.0 ml, 8 mmol) in Et_2O to a vigorously stirred mixture of the alkene (2 mmol), Me_3SiCl (1.2 ml, 0.9 mmol) and zinc amalgam (2.5 g, 50 mmol) in refluxing Et_2O, each completed addition being followed by a 24 h reflux.

Further inspection of the results in Table 1 using a series of simple alkenes not only emphasises that preparatively useful yields of methoxycyclopropanes can be obtained under mild conditions, but also confirms that cyclopropanation occurs with retention of the original stereochemistry of the alkene (entries 3 and 4), that mono-, di- and tri-substituted alkenes can be used (entries 1–5) and that, as for other organozinc carbenoids,[1,4] there is a distinct stereochemical preference for formation of the more hindered *cis* (or *endo*) isomer (entries 1, 3 and 5).



Scheme 1

Our attention was then directed towards the use of a variety of readily available orthoformates in order to assess their relative efficiencies for alkoxy- and aryloxy-carbenoid generation. Comparison of the results in Table 2 using allylbenzene as the standard alkene trap reveals several features of interest. Thus, the selection of tripropyl orthoformate (entry 1) led to a significant decrease in the isolated yield when compared with its trimethyl congener (Table 1, entry 1), presumably as a result of increased steric hindrance for incipient oxonium ion formation and/or electron delivery. However, the ability to preselect an unsymmetrical orthoformate with improved leaving group ability can be advantageous, as in the case of diethyl phenyl orthoformate (entry 2) which afforded only the ethoxycyclopropane in good yield. Furthermore, the obvious parallel which can be drawn in terms of the relative contributions of relief of ring strain and entropic factors involved in the

hydrolysis of acetals, ketals and orthoesters[9] can be used to exercise some degree of predictive power, as evidenced by the selective transfers involved in the use of the 2-methoxydioxolane (entry 3) and the catechol derivative (entry 4).

Clearly a useful range of functionalised alkoxy- and aryloxycyclopropanes can now be constructed in this way.

Finally, we have also carried out a preliminary study in order to probe the electronic character of α-alkoxyorganozinc carbenoids. *A priori* it might be argued that such species could be more nucleophilic, and exhibit a chemoselective preference for an electron-deficient alkene. In the event however, as shown by some representative examples in Table 3, the enol ester (entry 1) and the acrylate (entry 2) give comparable yields of cyclopropanated product. However, the result of a direct competition experiment using the monoterpene ester (entry 3) clearly demonstrates that the more electron-rich alkene is favoured over the acrylate.

From a practical standpoint, as in the classical Simmons–Smith reaction,[10] the above method clearly requires the use of an excess of reagents for efficient organozinc carbenoid generation and trapping. This is reflected in the (potentially intramolecular) aryloxycyclopropanation of the unsaturated orthoformate **4** (Scheme 2), where of course only 1 equiv. of alkoxycarbenoid can be produced.

In summary, the above results exemplify a simple and inexpensive method for the preparation of alkoxy- and aryloxycyclopropanes under mild neutral conditions *via* a novel class of organozinc carbenoids. Furthermore, in comparison to traditional methods for the generation of alkoxycarbenoids, the present method obviates the necessity for handling toxic α-halo

Table 3 Alkoxycyclopropanation of various alkenes with orthoformates

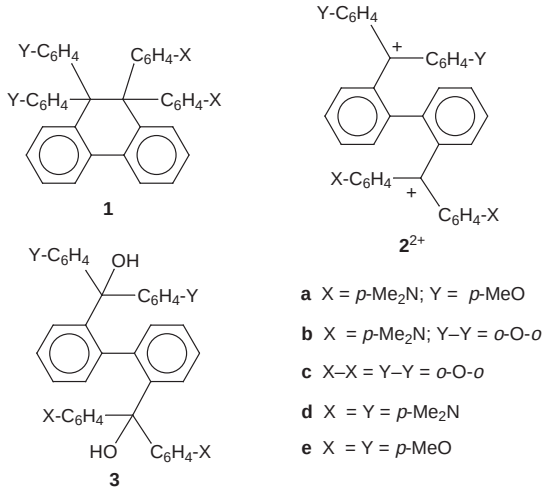
A new type of tricolor electrochromic system based on the dynamic redox properties of hexaarylethane derivatives

Takanori Suzuki,*† Jun-ichi Nishida and Takashi Tsuji

Division of Chemistry, Graduate School of Science, Hokkaido University, Sapporo 060-0810, Japan

Electrochemical interconversion between 9,9,10,10-tetraaryldihydrophenanthrene 1 and 2,2′-bis(triarylmethylium) 2^{2+} has been proven to proceed *via* open form cation radical $2^{+\cdot}$ as a stable intermediate; using these three species, a novel tricolor electrochromic system that exhibits hysteretic color change (color 1 → color 2 → color 3 → color 1) is formed.

Molecular systems whose properties can be controlled electrochemically are attracting much attention because they might be applicable to the construction of molecular devices such as redox switches.[1] From this point of view the redox couples of hexaarylethanes **1d**,**e** and bis(triarylmethane) dyes **2d**,**e**$^{2+}$ are



interesting;[2] their noteworthy features include electrochromic behaviour with vivid changes in color and very high bistability due to reversible C–C bond making/breaking[3] upon two-electron transfer (dynamic redox properties). During the course of our mechanistic investigation on the interconversion between **1** and $\mathbf{2}^{2+}$, we have found that a unique tricolor electrochromic system could be achieved using **1a**,**b** and **2a**,**b**$^{2+}$ possessing two different triarylmethane moieties, whose properties are reported herein. Although several multi-color electrochromic systems have been reported (color 1 ↔ color 2 ↔ color 3 ↔ *etc*.),[4] the hysteretic chromicity of the present systems (color 1 → color 2 → color 3 → color 1) is unprecedented.

Unsymmetric diols **3a**‡ and **3b**‡ were prepared in 12 and 8% yield, respectively, by the reaction of 2,2′-dilithiobiphenyl[5] with a mixture of the corresponding two ketones followed by chromatographic separation on SiO_2 from the symmetric diols **3c–e**. Deeply colored dication salts **2a**$^{2+}(BF_4^-)_2$‡ [λ_{max}(MeCN)/nm (log ε) 632 (4.93), 519 (4.72), 319 (4.25), 272 (4.24)] and **2b**$^{2+}(BF_4^-)_2$‡ [632 (4.92), 488 sh (3.76), 425 (4.22), 377 (4.46), 321 (4.23), 261 (4.63)] were obtained in 91 and 93% yield, respectively, by treating these diols with 42% HBF_4–$(EtCO)_2O$. Reduction of the dication salts with SmI_2 in THF gave colorless ethanes **1a**‡ [λ_{max}(MeCN)/nm (log ε) 268 (4.61)] and **1b**‡ [270 (4.58)] in 97 and 78% yield. X-Ray analysis§ has

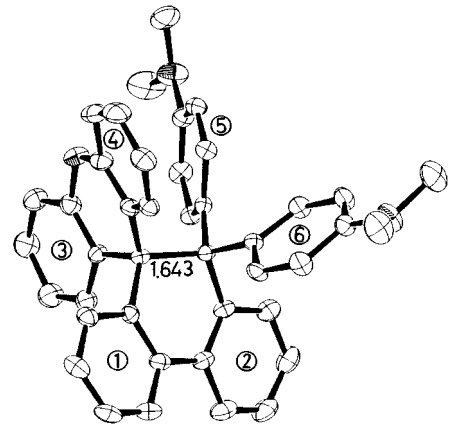


Fig. 1 Molecular geometry of ethane **1b** determined by X-ray analysis. The bipheny skeleton is nearly planar (the dihedral angle between planes 1 and 2: 16.2°), and the central six-membered ring adopts a pseudo-half chair conformation (planes 3 and 6: axial; 4 and 5: equatorial). The xanthene moiety is deformed slightly into the butterfly shape (the dihedral angle between planes 3 and 4: 15.2°). There is no disorder around the ethane bond in **1b**, unlike the symmetric ethane **1e** (ref. 2).

revealed that **1b** has a very long C–C bond [1.643(6) Å] (Fig. 1).¶ Thus, oxidation of **1a**,**b** with 2 equiv. of $(p\text{-}BrC_6H_4)_3N^{+\cdot}SbCl_6^-$ in CH_2Cl_2 led to the fission of the weak bonds to regenerate the dications **2a**,**b**$^{2+}$, which were isolated as $SbCl_6^-$ salts‡ in 82 and 79% yield, respectively. C_2-Symmetric ethane **1c**‡ [λ_{max}(MeCN)/nm (log ε) 282 (4.27), 230 sh (4.71)] and orange-colored **2c**$^{2+}(BF_4^-)_2$‡ [495 sh (3.62), 460 (3.79), 382 (4.56), 263 (4.82)] containing two xanthene moieties were also prepared from diol **3c**‡ for comparisons.

The cyclic voltammogram of **1c** is quite similar to those of **1d**,**e**; it shows irreversible 2e oxidation peak at +1.42 V, and the corresponding cathodic peak is largely shifted to +0.50 V, which was assigned to the 2e reduction peak of **2c**$^{2+}$ (Table 1). In contrast, unsymmetric ethanes **1a**,**b** behave rather differently from **1c–e**. Although their oxidation potentials are close to that of the tetrakis(dimethylamino) derivative **1d**, in the return cycle of the voltammograms there appeared two cathodic peaks (Fig. 2). From independent measurements on **2a**,**b**$^{2+}$ it was confirmed that these peaks are due to two-stage 1e reduction

[a] 0.1 mol dm^{-3} $Bu^n_4NBF_4$, Pt electrode, scan rate 100 mV s^{-1}. [b] Two-electron process. [c] Irreversible wave, values were calculated as $E^{ox} = E_{peak} - 0.03$ and $E^{red} = E_{peak} + 0.03$, respectively. [d] Ref. 2.

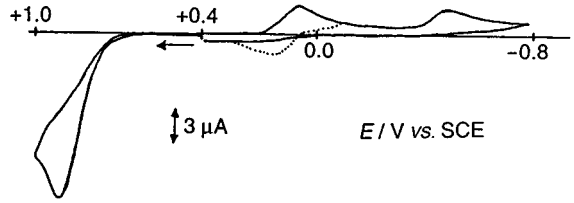

Fig. 2 Cyclic voltammogram of ethane **1a** (10^{-3} mol dm^{-3}) in CH_2Cl_2 (*E*/V *vs.* SCE 0.1 mol dm^{-3} $Bu^n_4NBF_4$, Pt electrode, scan rate 500 mV s^{-1}). The reduction peaks are absent when the voltammogram is first scanned cathodically. As shown by the dotted line, the first reduction wave at +0.07 V is reversible when the scanning was reversed at −0.10 V.

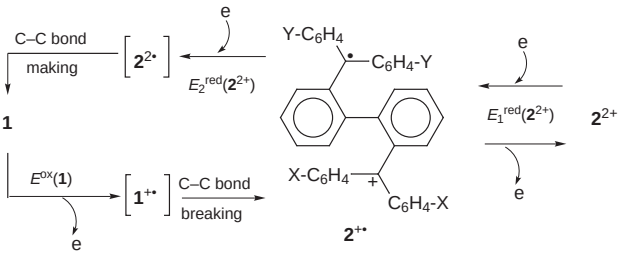
processes of the dications; the first one corresponding to the Y-C_6H_4-C^+-C_6H_4-Y moiety is completely reversible. Furthermore, the anodic peak due to the oxidation of **1a**,**b** appears in the voltammograms of **2a**,**b**$^{2+}$ after scanning the irreversible second 1e reduction wave. Such redox properties can be accounted for only by assuming the reaction mechanism shown in Scheme 1, in which the weakened C–C bond of hexaarylethane **1** is cleaved after 1e oxidation‖ to **1**$^{+\cdot}$ whereas two-fold 1e reduction of **2**$^{2+}$ to **2**$^{2\cdot}$ is necessary before the ring closure to **1**. It should be noted that **2**$^{+\cdot}$ produced from **1**$^{+\cdot}$ is more easily oxidized than **1** [E^{ox}(**1a**,**b**) is much more positive than E^{ox}(**2a**,**b**$^{+\cdot}$) = E_1^{red}(**2a**,**b**$^{2+}$)], thus the steady-state concentration of **2**$^{+\cdot}$ is negligible during the electrochemical oxidation of **1**, although the same specimen is a long-lived intermediate in the reduction process of **2**$^{2+}$.



Scheme 1

Thanks to the hysteretic interconversion between **1**, **2**$^{+\cdot}$ and **2**$^{2+}$, novel tricolor electrochromic systems could be constructed using the unsymmetric derivatives. Thus, upon electrochemical oxidation of colorless **1a**, both the blue (X = *p*-Me_2N) and red (Y = *p*-MeO) triarylmethylium chromophores grow simultaneously to develop the violet color of **2a**$^{2+}$ [Fig. 3(*a*)]. On the other hand, the red chromophore disappears first upon reduction of **2a**$^{2+}$ [Fig. 3(*b*), stage 1], and next the blue cation radical **2a**$^{+\cdot}$ is converted to colorless **1a** [Fig. 3(*c*), stage 2] even under the constant-current electrolytic conditions. Similar behaviour but with a different color was observed for the interconversion of **2b**$^{2+}$ (green) (isosbestic points: 248, 270, 300 nm) → **2b**$^{+\cdot}$ (blue) (296 nm) → **1b** (colorless) (309 nm) → **2b**$^{2+}$ (green), showing the generality of the unprecedented pattern of color change.

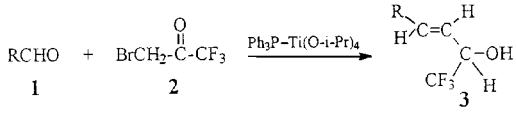
Novel reductive olefination mediated by Ti(O-i-Pr)$_4$ and Ph$_3$P. One-pot synthesis of trifluoromethylated *trans*-allylic alcohols

Yanchang Shen,*† Yuming Zhang and Yuefen Zhou

Shanghai Institute of Organic Chemistry, Academia Sinica, 354 Fenglin Lu, Shanghai 200032, China

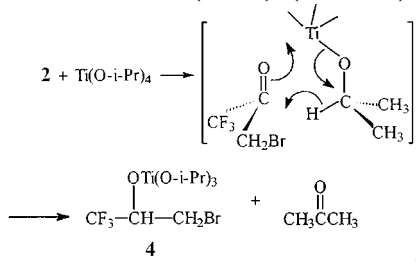
A novel reductive olefination mediated by Ti(O-i-Pr)$_4$ and Ph$_3$P and its application to the 'one-pot' synthesis of perfluoroalkylated *trans*-allylic alcohols are described.

One-pot synthesis has attracted much interest in recent years because it provides a simple and efficient route to compounds by including two or more transformations in a single operation to increase the complexity of a substrate starting from commercially available, relatively simple precusors.[1] In our laboratory 'one-pot' carbon–carbon double bond formation has been observed between α-bromo carboxylic derivatives (esters, amides and nitriles) and aldehydes in the presence of n-Bu$_3$P(As) and catalyst (Pd, Zn, Cd) forming α,β-unsaturated esters, amides and nitriles.[2] This reaction greatly simplifies the traditional Wittig reaction into a stereospecific alkenylation methodology and compresses the three steps of a Wittig reaction to a one-step, one-pot synthesis.[3] Allylic alcohols are employed as useful building blocks in many synthetic applications, particularly in the synthesis of biologically active compounds.[4] Therefore there has been much interest in the development of an effective 'one-pot' method for the preparation of allylic alcohols, especially fluoro species. Numerous methods by which to prepare allylic alcohols are known,[5] but either multiple steps are necessary or the starting materials are not commercially available. Very recently a new stereoselective method for the preparation of allylic alcohols using nickel catalyzed alkylative cyclization of ynals or coupling of aldehydes, alkynes and organozincs has been reported.[6] However, the syntheses of trifluoromethylated allylic alcohols[7a–d] and difluoro species[7e–h] are still limited. Herein we report a novel reductive olefination mediated by Ti(O-i-Pr)$_4$ and Ph$_3$P and its application to the 'one-pot' synthesis of trifluoromethylated *trans*-allylic alcohols (Scheme 1). The results are summarized in Table 1.



Scheme 1

At present, the tentative hypothesis shown in Schemes 2–4 appears to be consistent with the information currently available. The reaction is postulated to be initiated by the Meerwein–Pondorf–Verley-like reduction of 3-bromo-1,1,1-trifluoroacetone with Ti(O-i-Pr)$_4$ (Scheme 2).[8]



Scheme 2

The halophilic reaction occurred between intermediate **4** and the Ph$_3$P forming ion pair **5** and **6** as reported in the literature (Scheme 3).[9] Compound **6** might be stabilized by a strong electron-withdrawing trifluoromethyl group. Subsequently the active species **5** and **6** reacted with the aldehyde forming the six-membered intermediate **7**. After elimination of triphenylphosphine oxide and HBr the intermediate **8** was formed which was hydrolysed to give the product **3** (Scheme 4).[10]

Table 1 Preparation of perfluoroalkylated allylic alcohols[a] mediated by Ti(O-i-Pr)$_4$ and Ph$_3$P

Compound	R	(Bp/°C)/(*p*/torr)	Yield (%)[b]
3a	C_6H_5	114–115/2.5[c]	90
3b	4-$CH_3C_6H_4$	110/2.5	99
3c	4-FC_6H_4	102–104/2.6	87

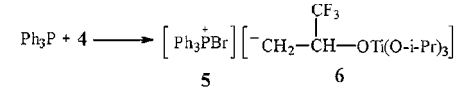
3g	3-BrC_6H_4	105/2.0	71
3h	3-ClC_6H_4	110/2.0	78
3i	2-BrC_6H_4	81/2.5	95
3j	(*E*)-C_6H_5CH=CH	118/2.5	81

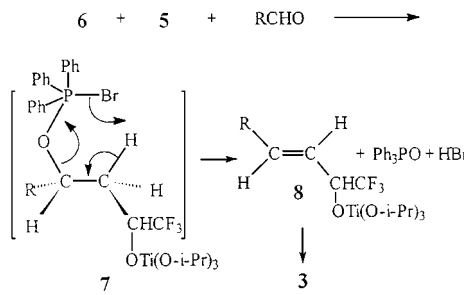
[a] All reactions were carried out neat at 80 °C for 24 h, using 1.0 equiv. of Ti(O-i-Pr)$_4$, Ph$_3$P, 3-bromo-1,1,1-trifluoroacetone and aldehyde. [b] Isolated yields. All new compounds were characterized by microanalyses, IR, NMR and mass spectroscopy. [c] Lit.[7a] data 76–77 °C/1 torr. [d] Mp.

3-Bromo-1,1,1-trifluoroacetone was proved to be able to react with Ti(O-i-Pr)$_4$ by independent experiment. When **2** was reacted with Ti(O-i-Pr)$_4$ at 80 °C for 2 h, **4** was isolated and characterized, [11] and further reacted with 4-chlorobenzaldehyde in the presence of Ph$_3$P giving the desired product **3d**.‡

A possible mechanism involving Ph$_3$P attack on 3-bromo-1,1,1-trifluoroacetone to give the enolate, followed by an aldol condensation, transferring the Ph$_3$PBr onto the hydroxylic oxygen, followed by elimination of HBr from **7,** and a Merrwein–Pondorf–Verley 1,2-reduction of the enone product, seems to be discounted, since in the absence of Ti(O-i-Pr)$_4$, no olefination occurred under the same conditions. If the above mentioned mechanism does occur, the olefination product



Scheme 3



Scheme 4

should be obtained in the absence of $Ti(O\text{-}i\text{-}Pr)_4$. The detailed mechanism is being pursued.

These studies provide, to our knowledge, the first example of organotitanium compounds combined with Ph_3P mediated reductive olefination giving trifluoromethylated *trans*-allylic alcohols efficiently and stereoselectively. This 'one-pot' synthesis is a very convenient starting point using commercially available substances for the preparation of trifluoromethylated allylic alcohols, and the widespread use of these allylic alcohols is quite important in organic synthesis. They are interesting fluorinated building blocks, not easily available by existing synthetic methods.

‡ General experimental procedure: To a mixture of 3-bromo-1,1,1-trifluoroacetone (1 mmol), aldehyde (1 mmol) and Ph_3P (1 mmol) in a capped vessel under nitrogen was injected $Ti(O\text{-}i\text{-}Pr)_4$ (1 mmol). After stirring at 80 °C for 24 h, the reaction mixture was treated with 5% HCl (10 ml) and extracted with Et_2O (3 × 20 ml). The organic layer was washed with water (3 × 10 ml), dried and evaporated to remove the solvent. The residue was chromatographed on silica gel, and eluted with petroleum ether (60–90 °C)–ethyl acetate (95:5) to give the product.

Novel highly extended and sulfur rich tetrathiafulvalene (TTF) derivatives through an unprecedented TTF core building process

C. Boulle,[a,b] O. Desmars,[b] N. Gautier,[b] P. Hudhomme,*[a,b]† M. Cariou[a] and A. Gorgues*[a]

[a] *Ingénierie Moléculaire et Matériaux Organiques, UMR-CNRS 6501, 2 Boulevard Lavoisier, 49045 Angers Cedex, France*
[b] *Laboratoire de Synthèse Organique, UMR-CNRS 6513, 2 rue de la Houssinière, 44322 Nantes Cedex 03, France*

A new and unexpected tetrathiafulvalene (TTF) core building process is observed *via* reaction of a 1,3-dithiole phosphonate anion with a 2-oxo-1,3-dithiole functionality.

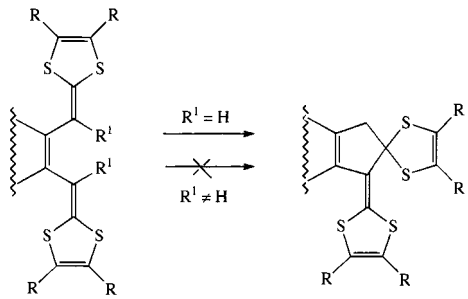
Since their discovery, the transport properties of the charge-transfer salts related to the TTF series have been improved.[1] In particular, chemical modifications[2] of the donor have allowed enhancement of the dimensionality of the related materials, thus preventing metal-to-insulator transitions (Peierls distorsions). With this aim, space extended and sulfur-rich analogs of TTF as the donors constitute very good candidates.[3] Thus, bis(1,4-dithiafulven-6-yl)TTFs were found able to afford interesting 2D electroconductive materials thanks to intermolecular intra- and inter-chain S···S contacts. Unfortunately, under acidic or oxidative conditions, these donors may undergo unwanted internal cyclization reactions when R^1 = H (Scheme 1).[4]

Following our efforts to suppress such side reactions, which have a spoiling effect during the slow electrooxidation process,[3c,d] we have designed new donors **1** related to benzoTTF, bearing no hydrogen atom in the R^1 position, in which the 1,3-dithiol-2-ylidene moieties are connected *via* the R^1–R^1 vinylene substituent. We report here on their straightforward synthesis and on their electrochemical properties.

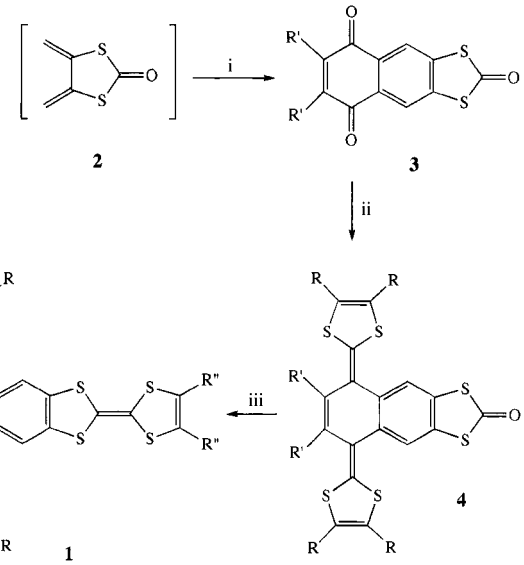
As outlined in Scheme 2, our synthetic strategy was based on three main steps: (i) a Diels–Alder cycloaddition between 2-oxo-4,5-bis(methylene)-1,3-dithiole **2** and paraquinonic dienophiles with further aromatization of the cycloadduct, (ii) a bis-Horner–Wadsworth–Emmons olefination of the quinonic carbonyl functionalities of **3** with Akiba's reagents,[5] and (iii) a final coupling reaction of the resulting compound **4** with 2-(thi)oxo-1,3-dithioles.

Thus, in the first step, diene **2** was generated *via* two independent routes,[6] either by an annulating reaction involving the thermal decomposition of *S*-propargyl xanthate[7] (Route **A**), or by an iodide induced reductive elimination on 2-oxo-4,5-bis(bromomethyl)-1,3-dithiole[8] (Route **B**). This diene was trapped with a quinone (*p*-benzoquinone or 1,4-naphthoquinone) and further addition of DDQ[9] to perform the aromatization, furnished the corresponding target compounds **3a** and **3b** (Scheme 3).

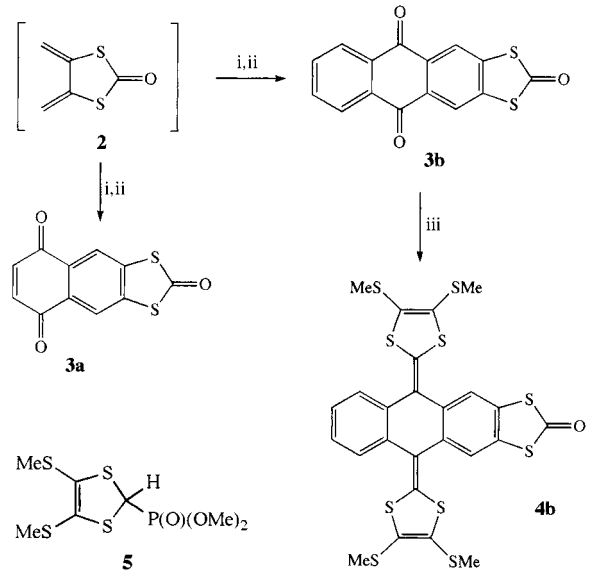
For the second step, we checked the behaviour of **3a** and **3b** with the anion of **5** generated upon treatment of the corresponding phosphonate with BuLi in THF at −78 °C. From **3a**, the olefination was unsuccessful, this failure being interpreted as resulting from an electron transfer between the quinonic compound acting as the π-acceptor (Ep^1_{red} = −0.56 V *vs.* SCE)[10] and the phosphonate anion acting as the donor.[3d] From



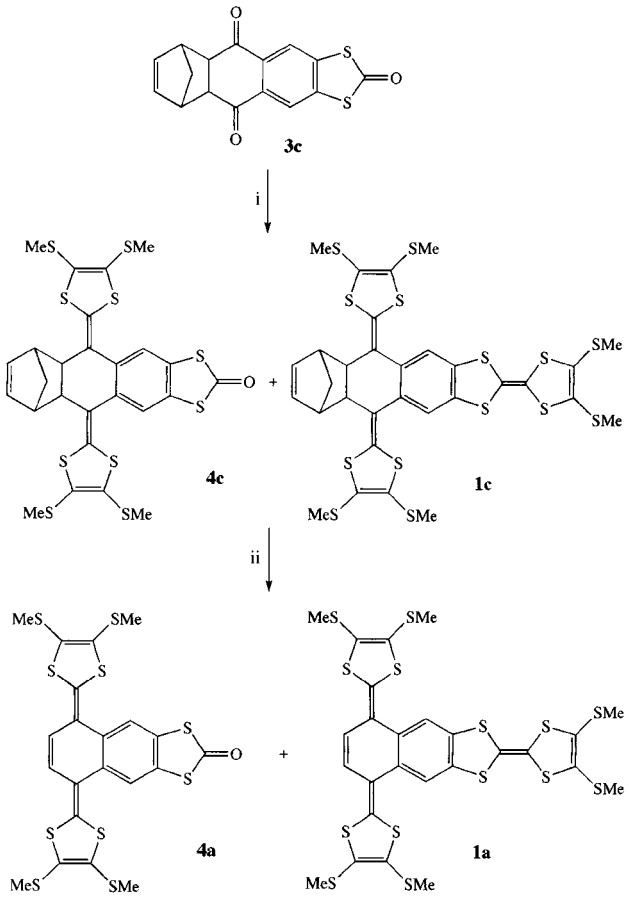
Scheme 1



Scheme 2 *Reagents and conditions*: i, Diels–Alder cycloaddition with further aromatization; ii, bis-Horner–Wadsworth–Emmons olefination; iii, coupling reaction



Scheme 3 *Reagents and conditions*: (Route **A**): i, reflux, chlorobenzene, *p*-benzoquinone or 1,4-naphthoquinone; ii, DDQ (**3a**: 30%, **3b**: 46%); (Route **B**): i, $Et_4N^+I^-$, MeCN, *p*-benzoquinone or 1,4-naphthoquinone; ii, DDQ (**3a**: 83%, **3b**: 54%); iii, **5**, BuLi, THF, −78 °C



Scheme 4 *Reagents and conditions*: i, **5**, BuLi, THF, −78 °C; ii, thermal treatment

the less oxidizing compound **3b** (Ep^1_{red} = −0.84 V *vs.* SCE), upon treatment with a large excess of the anion of **5**, the bis-olefinated product **4b** could be isolated in 28% yield after silica gel column chromatography (hexane–CH_2Cl_2 1 : 1).

In order to perform the required olefination of **3a**, we decided to suppress the accepting quinonic character thanks to a prior Diels–Alder cycloaddition of cyclopentadiene, this latter being possibly subsequently removed (Yamashita's methodology[11]). Thus, cyclic voltammetry confirmed that the corresponding cycloadduct **3c** is a poor π-acceptor (Ep^1_{red} = −1.42 V *vs.* SCE). Unexpectedly, after reaction of **3c** (0.33 mmol) with a large excess of the anion of **5** (1.98 mmol) in THF (35 ml) and silica gel column chromatography (CS_2–CH_2Cl_2 8 : 1), we observed that the bis-olefinated compound **4c** appearing as the main product (50% yield) was accompanied by the tris-olefinated compound **1c** (25% yield), this latter corresponding to a TTF core building through an unprecedented Horner–Wadsworth–Emmons olefination of the 2-oxo-1,3-dithiole functionality with Akiba's reagent (Scheme 4). We also noted the partial decomposition of the phosphonate anion of **5** to tetrakis(methylsulfanyl)TTF and elimination of dimethyl phosphite.[12] The yield of **1c** was increased to 43% by using 10 equiv. of Akiba's reagent and BuLi. Cyclic voltammetry of **1c** exhibited an irreversible process, suggesting the possible loss of cyclopentadiene which obviously could be induced electrochemically. Nevertheless, this reaction was more readily performed by classical thermal treatment of **1c** in *o*-dichlorobenzene or, directly, in the dry state, in a Kugelrohr apparatus[13] in quantitative yield.

Cyclic voltammetry of **1a** exhibited three reversible oxidation peaks (Table 1), the first one corresponding to a 2e$^-$ process arising from the π-extended *p*-quinodimethane analog of TTF (by analogy with the voltammogram of **4a** and similar observations on such conjugated quinonic systems[3g,11a]) followed by two 1e$^-$ oxidation peaks related to the TTF moiety. These features are in agreement with the sequence: **1a** ⇌ $\mathbf{1a}^{2+}$ ⇌ $\mathbf{1a}^{3+\cdot}$ ⇌ $\mathbf{1a}^{4+}$.

[a] 1.5 mM in solvent–Bu_4NPF_6 (0.1 M), v = 100 mV s^{-1}.

Given the good π-donor ability of **1a**, efforts are now in progress to generalize this methodology to the synthesis of varied compounds **1** and formation of their corresponding cation radical salts.

The reaction of *cis*-$[PtCl_2(PEt_3)_2]$ with 2 equiv. of $[\{[Li\{\eta^2\text{-}OC(Bu^t)EC(Bu^t)O\}(DME)_{0.5}]_2\}_\infty]$, E = Sb or As, affords either the first distibene-dione complex, *cis*-$[Pt(PEt_3)_2\{\eta^2\text{-}Bu^tC(O)Sb{=}SbC(O)Bu^t\}]$, or the related diarsenide-dione bridged complex, *trans*-$[\{Pt(PEt_3)Cl\}_2\{\mu\text{-}\eta^1,\eta^1\text{-}Bu^tC(O)AsAsC(O)Bu^t\}]$, the X-ray crystal structures of which are described.

Since the preparation of the first diphosphene, Mes*P=PMes*, Mes* = $C_6H_2Bu^t_3$-2,4,6; by Yoshifuji in 1981[1] the chemistry of these species has developed into a well explored field.[2] By contrast, the heavier Group 15 analogues of diphosphenes have remained scarce and in the case of distibenes can be confined to one very sterically protected example, (Tbt)Sb=Sb(Tbt) **1** {Tbt = $C_6H_2[CH(SiMe_3)_2]_3$-2,4,6}.[3] In addition, three structurally characterised distibene complexes have been reported, *viz.* $[Fe(CO)_4\{\eta^2\text{-}[(SiMe_3)_2CHSb]_2\}]$ **2**[4] and $[\{W(CO)_5\}_3(\eta^2\text{-},\eta^1\text{-},\eta^1\text{-}RSb{=}SbR)]$ R = Ph,[5] Bu^t;[6] none of which contain functionalised distibene substituents. Our interest in low co-ordination antimony chemistry has recently led to us reporting the first example of a 2-stiba-1,3-dionatolithium complex **3** (E = Sb),[7] which we have begun to investigate as a possible transfer reagent in the formation of transition metal–stibadionate complexes (*cf.* β-diketonate chemistry). This work has led to some unexpected results which include the metal mediated synthesis of the first distibene-dione complex which is reported herein. Several related complexes are also described.

Treatment of *cis*-$[PtCl_2(PEt_3)_2]$ with 2 equiv. of **3** (E = Sb) in DME led to a moderate yield (39%) of **4** after recrystallisation from hexane (Scheme 1). Following this reaction by ^{31}P NMR revealed that the formation of **4** occurs over 5 h without any observable intermediate in the process. The orange crystalline material is air stable, thermally robust in the solid state (mp 112–114 °C decomp.) and stable in solution for days at 25 °C. If the reaction is carried out in a 1 : 1 stoichiometry, compound **4** is the only observable product, and *ca.* 50% of the platinum starting material remains unreacted. Interestingly, when the analogous 2 : 1 reactions of **3** (E = Sb) with *cis*-$[MCl_2(PEt_3)_2]$ (M = Ni, Pd) were carried out antimony mirrors were deposited from the reaction mixtures and the mono-acyl nickel or palladium complexes were isolated in moderate yields, **5** (39%) and **6** (56%), respectively.[8] It is noteworthy that none of the platinum analogue of **5** and **6** was found in the preparation of **4**, and similarly no distibene-dione complexes were identified in the preparations of **5** and **6**. Finally, in an attempt to form the arsenic counterpart of **4** the 2 : 1 reaction of **3** (E = As) with *cis*-$[PtCl_2(PEt_3)_2]$ was carried out but in this case the only tractable product was the diarsenide-dione bridged complex, **7**, which was formed in a low yield (5%, mp 124–126 °C decomp.).

The spectroscopic data† for **4** and **7** support their proposed structures. Of note are the ^{31}P NMR spectra of each complex which display one signal with $^1J_{PtP}$ satellites in the normal coupling range, thus suggesting the equivalence of all phosphine ligands in both complexes in solution. No molecular ions were seen in the mass spectra of **4** and **7**, but in the case of **4** a cluster of signals corresponding to the free distibene-dione ligand was observed. In contrast, the base peak in the mass spectrum of **7** coincides with the loss of a chloride ligand, while a signal relating to the cleavage of the As–As bond (monomer formation) was also detected.

The molecular structures‡ of **4** and **7** are depicted in Figs 1 and 2, respectively. The Pt centres in each have a distorted square planar coordination environment with the PEt_3 ligands *cis*- in **4** and *trans*- in **7**. Not surprisingly, the acyl substituents are *trans*- to each other in both compounds. The Sb–Sb distance in **4** lies almost midway between those for uncoordinated Sb–Sb double and single bonds [*e.g.* 2.642(1) Å in **1**[3] and 2.837 Å in Ph_4Sb_2,[9] respectively] and is slightly shorter than in the only other η^2-distibene complex **2**, 2.774(1) Å.[4] As has been described for **2** and closely related diphosphene complexes, *e.g.* *cis*-$[Pt(dppe)(\eta^2\text{-}PhP{=}PPh)]$,[10] the bonding in **4** can be thought of as lying somewhere between two canonical forms, one an η^2-distibene-Pt(0) complex and the other a three membered σ-bonded metallacycle containing a Pt(II) centre. Consistent with this description is the CSbSbC torsion angle of 173° (*cf.* 153° in **2**) which shows the ligand to be slightly distorted from planarity. In contrast to the distibene-dione ligand in **4**, the ligand in **7** can be thought of as a diarsenide-dione, the As centres of which have distorted trigonal pyramidal geometries (Σ angles = 311.8°). The As–As distance is in the expected region for single bonds and compares well with that in the only other structurally characterised example of a dinuclear complex containing a bridging diarsenide ligand, 2.456(2) Å in *trans*-

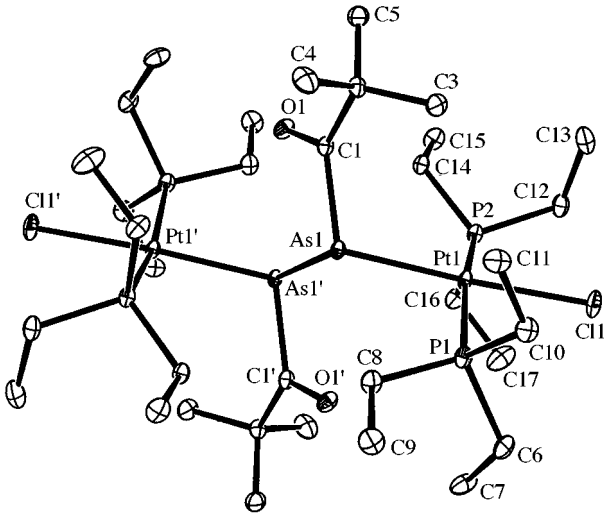

Fig. 2 Molecular structure of *trans*-[{Pt(PEt$_3$)Cl}$_2${μ-η^1,η^1-Bu^{t}C(O)As-AsC(O)Bu^t}] **7**. Selected bond lengths (Å) and angles (°): As(1)–As(1′) 2.4595(9), Pt(1)–As(1) 2.4425(5), As(1)–C(1) 2.010(5), Pt(1)–P(1) 2.3320(13), Pt(1)–P(2) 2.3078(13), Pt(1)–Cl(1) 2.4003(13); C(1)–As(1)–As(1′) 91.86(14), O(1)–C(1)–As(1) 119.3(4), Pt(1)–As(1)–As(1′) 110.63(3), C(1)–As(1)–Pt(1) 109.23(14), Cl(1)–Pt(1)–As(1) 170.95(4), P(1)–Pt(1)–P(2) 166.49(5).

[{CpFe(CO)$_2$}$_2$(μ-η^1,η^1-Ph$_2$As$_2$)].[11] All other bond lengths and angles in **4** and **7** lie in the expected regions.

At present the mechanism of formation of **4** can only be speculated upon but it seems that the likely intermediate is *cis*-[Pt(PEt$_3$)$_2${η^1-Sb[C(O)Bu^t]$_2$}$_2$] **8**, from which each η^1-Sb coordinated stibadionate ligand eliminates an acyl fragment, ·C(O)Bu^t, in a homolytic process. This would leave two coordinated [·SbC(O)Bu^t]$^-$ fragments which could couple, with an accompanying electron transfer to the Pt(II) centre, to give **4**. Although there is no spectroscopic evidence for the Sb-coordinated intermediate, **8**, its existence seems feasible considering that related 2-arsa-1,3-dionato ligands generally prefer η^1-As coordination over η^2-O,O-chelation in late transition metal complexes.[12] The fate of the acyl fragment is also a coupling reaction to give the known diketone, Bu^{t}C(O)C(O)-Bu^t, which was detected as the major product in the GC–MS analysis of the reaction volatiles.

We are currently investigating the mechanisms of formation of **4**–**7** which, when elucidated, should shed light on why such a variety of products result from supposedly similar reactions. These studies will form the basis of a forthcoming publication.

We acknowledge funding from the Leverhulme Trust (for S. J. B.), and King's College London and the EPSRC for provision of the diffractometer systems.

Naphthalene intercalation into molybdenum disulfide

Laura Kosidowski and Anthony V. Powell*

Department of Chemistry, Heriot-Watt University, Edinburgh, UK EH14 4AS. E-mail: a.v.powell@hw.ac.uk

Exfoliation of $LiMoS_2$ followed by reflocculation permits the intercalation of naphthalene guest molecules into the van der Waals gap of MoS_2.

Layered transition-metal disulfides are versatile intercalation hosts which can accommodate the steric demands of a wide variety of guest species.[1] Their ability to form intercalation compounds is known to be strongly dependent on the electronic structure of the dichalcogenide.[2] This may be traced to the requirement for the host structure to possess low-lying empty electronic states, as a result of the redox process which accompanies the intercalation reaction. Hence, dichalcogenides of group 4 and group 5 transition metals readily form intercalation compounds with a wide variety of guest species. This may be achieved electrochemically or chemically, either by direct reaction with electron donors such as organic Lewis bases or with chemical reducing agents. In contrast, the presence of a low-lying d_{z^2} band in the group 6 materials results in a more limited intercalation chemistry, mainly restricted to alkali metals as guest species.[3]

An alternative route to intercalation compounds of transition-metal disulfides *via* 'single' molecular layers, involving reaction of a colloidal dispersion of the layered host with a solution containing the guest species, has been described.[4] This has successfully been applied to the insertion of sterically disfavoured molecules[5] and those which are poor electron donors including substituted aromatics,[6] polymers[7] and ferrocene.[8] This route potentially provides access to a wide range of intercalation compounds of layered materials and in particular, affords a means of extending the intercalation chemistry of group 6 dichalcogenides to encompass novel guest species. In this work, by describing the synthesis and initial characterisation of a novel naphthalene intercalation compound of MoS_2, we illustrate that guest molecules which are both poor electron donors and non-polar may be introduced by this method.

$LiMoS_2$ was prepared by adding three equivalents of standardised 1.6 M *n*-butyllithium to a dispersion of 2H-MoS_2 in distilled light petroleum (bp 60–80 °C) and stirring for 48 h under N_2. The product, Li_xMoS_2, was washed with several 20 ml portions of light petroleum and dried under vacuum. Powder X-ray diffraction showed it to be single phase with a hexagonal unit cell; a = 3.312(45), c = 6.394(18) Å. The lithium content, x, was determined to be 1.02(2), by flame emission spectroscopy.

All further stages of the reaction were carried out in air. Sufficient de-ionized water was added to $LiMoS_2$ to produce a suspension of 0.08 g ml^{-1} exfoliated MoS_2 (denoted $\{MoS_2\}_{exf}$). The suspension was sonicated for 30 min, a saturated solution of naphthalene in dichloromethane added (in the molar ratio of $C_{10}H_8$: $\{MoS_2\}_{exf}$ = 5 : 1) and the mixture stirred for 24 h. The single layer dispersion reflocculated after acidification to pH = 2 using concentrated HCl. Stirring was then continued for periods between one day and three weeks, after which the solid was separated, washed with water and dichloromethane and vacuum dried. The degree of intercalation was found to vary with the length of stirring time following acidification. It was found that repetition of this method consistently led to intercalation providing the reaction was stirred for 7 days or more following acidification.

Upon exposure of $LiMoS_2$ to water, gas evolution was observed together with the formation of a black opaque suspension. This is consistent with a proposed mechanism for exfoliation.[9] Spontaneous movement of the exfoliated material up the walls of the reaction vessel was also seen to occur.

The powder X-ray diffraction pattern of the intercalated material [Fig. 1(a)] shows two strong lines corresponding to the 001 and 002 reflections, whose shift to lower angle indicates an increase in interlayer spacing. It exhibits a characteristic saw-tooth shape comprising asymmetrically broadened peaks. This is a consequence of the Warren effect[10] which arises from the fact that for a two-dimensional layer, the reciprocal lattice becomes a line perpendicular to the layer and so, for higher diffraction angles, a continuous distribution of diffraction intensity appears. The broadness of the Bragg peaks results from the small particle size, estimated from the degree of broadening to be < 150 Å. Omission of naphthalene from the final preparative step produced a material whose powder X-ray diffraction pattern [Fig. 1(b)] is consistent with the formation of poorly crystalline restacked MoS_2.

The content of the intercalated naphthalene in all product materials was determined by C, H elemental microanalysis and by thermogravimetry. A hydrogen content slightly in excess of that required for a C : H ratio corresponding to naphthalene, was found by C, H analysis. This suggested that some residual water was present. An initial low-temperature mass loss observed in thermogravimetric analysis was consistent with this conclusion, and was used to determine the water content independently. This residual water appears to be on the surface of the product

1	2.43	$(C_{10}H_8)_{0.07}(H_2O)_{0.11}MoS_2$	$(C_{10}H_8)_{0.07}(H_2O)_{0.06}MoS_2$
7	2.91	$(C_{10}H_8)_{0.08}(H_2O)_{0.33}MoS_2$	$(C_{10}H_8)_{0.08}(H_2O)_{0.28}MoS_2$
9	3.74	$(C_{10}H_8)_{0.11}(H_2O)_{0.26}MoS_2$	$(C_{10}H_8)_{0.11}(H_2O)_{0.20}MoS_2$
13	3.53	$(C_{10}H_8)_{0.13}(H_2O)_{0.19}MoS_2$	$(C_{10}H_8)_{0.13}(H_2O)_{0.14}MoS_2$
14	3.81	$(C_{10}H_8)_{0.13}(H_2O)_{0.05}MoS_2$	$(C_{10}H_8)_{0.13}(H_2O)_{0.05}MoS_2$
14	4.26	$(C_{10}H_8)_{0.20}(H_2O)_{0.19}MoS_2$	$(C_{10}H_8)_{0.20}(H_2O)_{0.12}MoS_2$

material since repeated preparation of samples indicated that there was no relationship between the interlayer expansion and the water content of the sample (Table 1). DSC measurements showed an endothermic transition at 100 °C, again consistent with surface water. It is also unlikely that naphthalene, a hydrophobic molecule, would co-intercalate with water. Atomic absorption analysis of the intercalation product showed it to be free of significant amounts of lithium (< 0.005 moles of Li per mole of MoS_2).

Table 1 shows repeated preparations, only varying in the period of stirring following acidification; their corresponding final interlayer expansion and composition. The length of stirring was found to affect the degree of intercalation observed such that no significant change in the extent of intercalation was observed for stirring times of less than seven days. Beyond this, the extent of intercalation of naphthalene increased with stirring time up to a maximum of 0.20 mole of naphthalene per mole of MoS_2 at 14 days stirring. Longer stirring times did not lead to any increase in the degree of intercalation beyond this value.

The interlayer expansion with respect to MoS_2 is *ca.* 3.8 Å. Molecular modelling calculations[11] indicate the van der Waals size of naphthalene to be *ca.* 6.8 × 5.1 Å. Hence the observed Δc value would suggest that the plane of the aromatic species is parallel to the MoS_2 layers. The smaller values of Δ_c observed at short reaction times may indicate the occurrence of staging. Further evidence for naphthalene intercalation with this orientation is provided by the fact that the p_z orbitals in naphthalene project above and below the plane of the ring in such a way as to give the ring an effective thickness of *ca.* 3.7 Å[12] which is consistent with the interlayer expansion observed in the product reported here. The area of a naphthalene molecule is *ca.* 35 Å^2 which compares with an interlayer area of *ca.* 8.6 Å^2 per molybdenum atom in MoS_2. Such a geometric constraint suggests that the maximum uptake of naphthalene is approximately 0.25 per molybdenum atom: the maximum guest content observed is 0.20. Steric repulsion between neighbouring naphthalene molecules is likely to prevent maximum occupancy of the interlayer spacing from being attained.

Insertion of a non-polar species into a group 6 disulfide has been achieved using the synthetic method reported here. An organic/inorganic composite material is obtained with a limiting content of 0.20 moles of naphthalene per molybdenum atom. The interaction of the organic and inorganic fragments of this material would be expected to lead to changes in the physical properties of the host. Studies of the structural, transport and magnetic properties of the material are currently in progress and will be reported in due course.

Ozone treatment for the removal of surfactant to form MCM-41 type materials

Matthew T. J. Keene, Renaud Denoyel and Philip L. Llewellyn*

Centre de Thermodynamique et de Microcalorimétrie du CNRS, 26 rue du 141ème RIA, 13331 Marseilles, cedex 3, France. E-mail: pllew@ctm.cnrs-mrs.fr

Ozone has been used to remove the organic surfactant species at 250 °C from as synthesised organic/inorganic composite (or mesophase) materials to form mesoporous MCM-41 type solids with higher surface area, larger pores and narrower pore size distribution than those obtained by conventional calcination at 550 °C.

The relatively large interest of MCM-type mesoporous materials that has arisen since 1992[1,2] lies in the fact that they can be tailored to form pores of narrow distribution, from 2 to 10 nm. This opens up a field of fundamental and applied science where a narrow mesopore size distribution and high surface area could be required. Surprisingly for these tailor-made materials where a control of the pore size can be important, a limited number of studies have been published concerning the specific removal of organic material from the as synthesised organic/inorganic composite or mesophase.[3–6] In effect, the removal of the 'templating' surfactant molecules, occluded within this material during the synthesis, is quite often carried out by thermal methods. Commonly, a heating ramp of 1 °C min^{-1} up to a plateau temperature of 550 °C in air is used.[1,2] However, methods such as plasma and supercritical fluid extraction[3] are other possible means to remove this organic material. Several studies have also used washing or ionic exchange of the surfactant.[4–7]

Ozone, is commonly used as a treatment in numerous applications ranging from environmental technology (*e.g.* ozone in water treatment[8]) to physics (*e.g.* cleaning of polished flat surfaces). To date, however, ozone treatment has not been used to eliminate organic species from porous materials. For microporous materials such as zeolites, the elimination of the organic template could be hampered by the steric hindrance of the micropores themselves. This is not the case for slightly larger pores where the elimination of the organic moieties from the pores is hindered to a far lesser extent. The present preliminary study has used ozone at room temperature to remove the organic surfactant to form mesoporous MCM-41 type materials.

The silica mesophase was prepared using the synthesis outlined by Grün *et al.*[9] This particular synthesis route uses tetraethoxysilicate as the silica source and is carried out at 25 °C. The surfactant used was cetyltrimethylammonium bromide (CTABr). After filtering and washing in distilled water, the sample was dried in air at 20 °C overnight. For comparison, part of the sample was calcined under a nitrogen flow, at a heating rate of 1 °C min^{-1}, up to a 550 °C plateau for 4 h. For the ozone treatment, around 0.1 g of sample was placed on a watch glass which was then placed for 24 h under a UV lamp (electrical power 20W : UV power 6.8 W at 254 and 180 nm) whose wavelength is known to create ozone from atmospheric oxygen. To verify the effect of the UV light on the sample, a separate sample was treated by a flow of gaseous ozone produced by an electric arc. Both samples showed similar results on further characterisation. The sample was characterised by X-ray diffraction (Fig. 1), DRIFT (Fig. 2) and argon adsorption manometry at 77 K (Fig. 3). The ozone treated sample was also treated by thermogravimetry up to 1000 °C that showed a 1% weight loss, essentially from silanol condensation forming water.

The XRD patterns shown in Fig. 1 are typical for hexagonal mesoporous materials. For the ozone treated sample, the d_{100} spacing of 4.15 nm is surprising in that it is the same as that found in the initial mesophase. Normally, thermal extraction and ion exchange of the template leads to an appreciable shrinkage of the structure of up to 25%.[4] This is illustrated in the lower pattern obtained for a traditionally calcined sample with a d_{100} spacing of 3.67 nm.

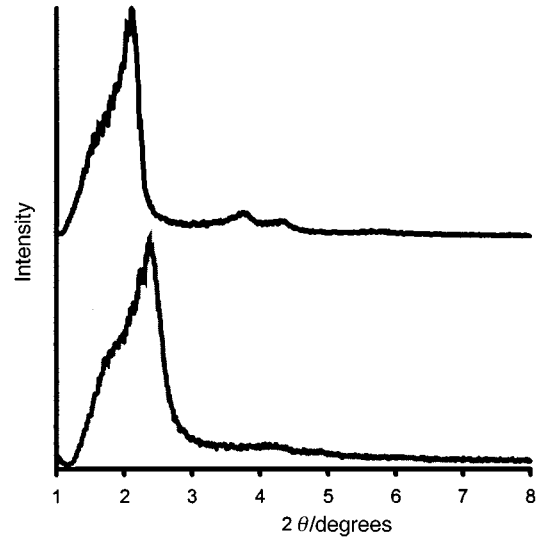

Fig. 1 X-Ray powder diffraction patterns of an ozone treated sample (upper curve) and a sample calcined to 550 °C (lower curve)

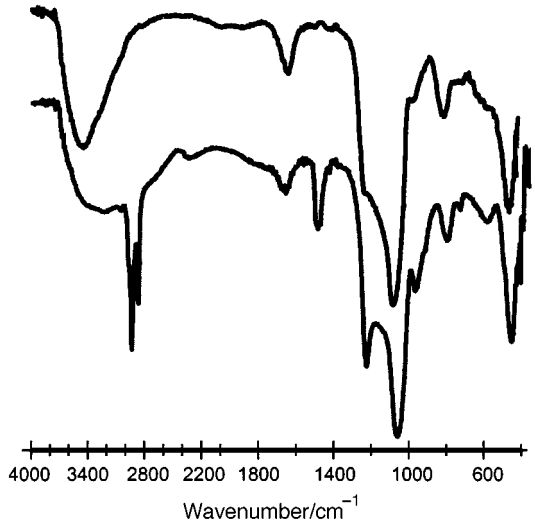

Fig. 2 DRIFT spectra of an ozone treated sample (upper curve) and original mesophase (lower curve)

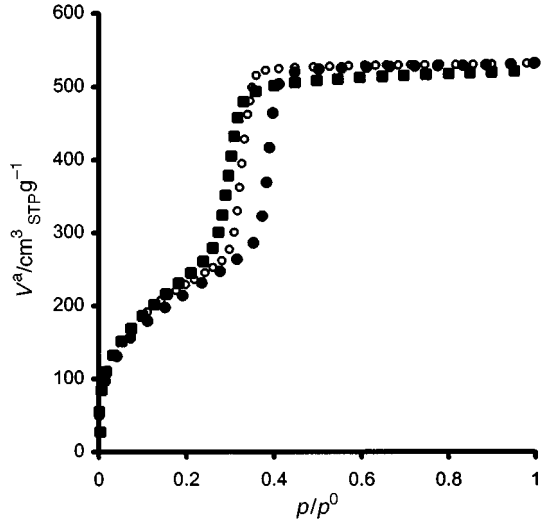

Fig. 3 Argon adsorption–desorption isotherm obtained at 77 K for (i) an ozone treated sample: (●) adsorption, (○) desorption, and (ii) a sample calcined at 550 °C: (■) adsorption

The IR spectrum of the silica mesophase before ozone treatment (lower curve, Fig. 2) clearly shows the peaks resulting from C–H stretching (2924 and 2854 cm^{-1}) as well as a broad signal (3600–3200 cm^{-1}) assigned to hydrogen bonded Si–OH groups.[10] After ozone treatment (upper spectrum, Fig. 2), the C–H peaks are no longer observed whereas a large signal assigned to hydrogen bonded Si–OH persists.

The argon adsorption isotherms at 77 K obtained with the ozone treated sample (circles) and a traditionally calcined sample (squares) (Fig. 3) are both of type IV character[11] and show distinct capillary condensation steps. The capillary condensation step obtained with the ozone treated sample is in reality sharper and slightly higher in relative pressure (p/p^0 = 0.37 compared with 0.30) than that obtained for a sample calcined using a standard thermal treatment. This would seem to indicate that a larger pore size and a narrower pore size distribution can be obtained for MCM41 using ozone treatment. The *t*-plot analysis shows that there are no micropores and relatively little external surface area (*ca.* 25 $m^2\ g^{-1}$) when compared to the calcined sample (*ca.* 40 $m^2\ g^{-1}$). The argon BET surface area obtained is 710 $m^2\ g^{-1}$ for the ozone treated sample, which is similar for the same sample calcined using a standard treatment. Using the geometric formula for the diameter $d = 4V/A$, leads to a pore diameter of 3.6 nm for the ozone treated material.

These results highlight that for mesoporous materials, such as MCM-41, treating by ozone could prove interesting from several points of view. First of all, such treatment is relatively strightforward, as a simple UV lamp can be used. Secondly, it could be envisaged that samples *in situ* can be treated after the synthesis of the mesophase. That is to say that, the elimination of the organic template can be possible within the synthesis medium limiting the total number of synthesis steps required. Thirdly, the ozone treatment is carried out at room temperature, although the temperature reached within the pores themselves could be higher. For this reason ozone treatment could prove well adapted to materials with a fragile structure where, for example, the nature of metal species occluded within the walls during synthesis could be altered on thermal treatment. Finally, this ozone treatment is a clean technology for the removal of organic species as the majority of products formed are thought only to be water and carbon dioxide. However, questions remain of in what forms the nitrogen and bromine are eliminated from the pores. From these points of view ozone treatment could prove more cost effective with respect to thermal treatment for the removal of organic species from these materials.

The authors would like to thank Dr J. Blanchard at the University of Frankfurt for the XRD spectra and the EC TMR program (ERB FM RX CT 960084) for financial support of M. T. J. K.

Unusual reactivity and isomerisation in dicobalt *s*-indacene complexes

Paul Roussel, Mark J. Drewitt, Douglas R. Cary, Catherine G. Webster and Dermot O'Hare*

Inorganic Chemistry Laboratory, South Parks Road, Oxford, UK OX1 3QR. E-mail: dermot.ohare@chem.ox.ac.uk

Di-{Co(Cp)} derivatives of Bu^t_4-*s*-indacene (Ic′) have been prepared, they exist as both *cis* and *trans* isomers which can interconvert in solution; the solution electrochemistry of these complexes show that these bimetallic complexes can exhibit up to four redox events; unusually, attempted oxidation by a protic oxidising agent of $(CoCp)_2$Ic results in attack at the central carbons of the indacene rings.

Organometallic polymers are known to show interesting magnetic and electronic properties arising from the communication of adjacent metal centres. For example, polyferrocenophanes exhibit two oxidation waves for the alternate iron sites.[1] Manriquez *et al*. have reported substantial intramolecular metal–metal communication for bimetallic complexes containing bridging indacene and pentalene ligands,[2] however attempts at synthesis of oligo- and poly-meric transition metal complexes incorporating these ligands have met with limited success owing to their insolubility.

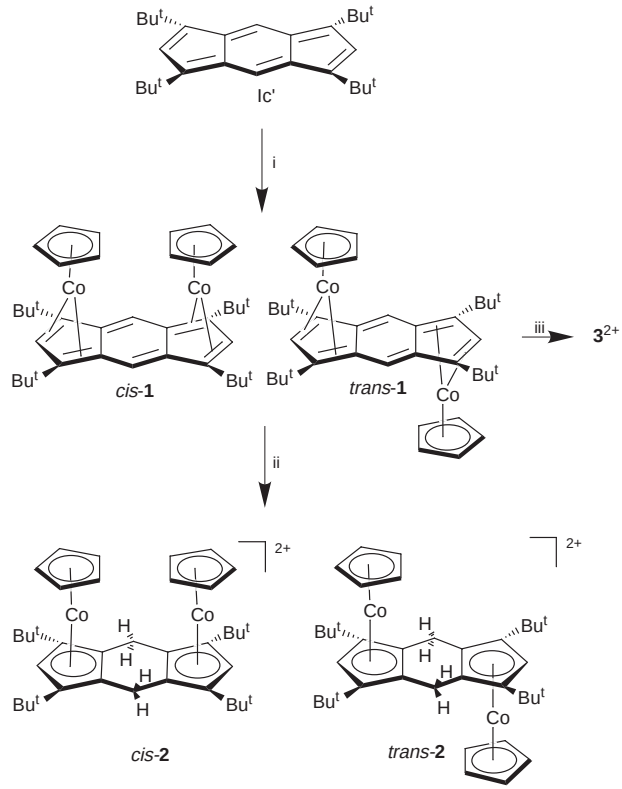
We have been investigating the organometallic chemistry of Ic′ (Ic′ = 1,3,5,7-tetra-*tert*-butyl-*s*-indacene)[3] with the view of making soluble oligomeric complexes with significant intramolecular electron–electron correlation.[4] So far, bimetallic transition metal complexes of Ic′ have only exhibited *cis* coordination of the two metal centres to the planar ligand, however, the transition metal starting materials were dimeric thus favouring this geometry. Thus, syntheses involving suitable monomeric transition metal starting materials should afford a mixture of both *cis* and *trans* bimetallic Ic′ complexes.

Reaction of Ic′ and 2 equiv. of monomeric $[CoCp(C_2H_4)_2]$ gave a brown solution, from which analytically pure $[(CoCp)_2Ic']$ **1**† can be isolated (Scheme 1). The room temperature ^1H NMR spectrum of a solution of **1** in $[^2H_8]$toluene shows two sets of uncorrelated resonances in the ratio 8 : 1, upon cooling the solution to 233 K this ratio changes to 5 : 1. We believe the resonances attributable to the major species are due to the *cis* isomer of **1** (Scheme 1) *vide infra*. In fact, on warming a solution of **1** in $[^2H_8]$toluene we can observe exchange broadening and eventual coalescence of some of the proton resonances due to the *cis* and *trans* isomers for **1** indicating rapid interconversion on the NMR timescale. The mechanism for this interconversion is presently under investigation. The fact that compound **1** is diamagnetic suggests that we should consider the Ic ligand as an L_4 donor in this case coordinated to two monovalent CoCp moieties.[5]

The cyclic voltammetric response of a tetrahydrofuran solution of **1** and tetrabutylammonium hexafluorophosphate (0.1 M) gave four quasi reversible waves at −0.12, −0.75, −1.18 and −1.49 V *vs* F_c–F_c^+.[6] $[Fv(CoCp^*)_2]$[7] (Fv = fulvalene) is reported to give a cyclic voltammogram containing four waves, attributable to the mono- and di-anionic, neutral, mono- and di-cationic species. The fact that we observe stepwise redox events indicates significant intramolecular interaction between the cobalt centres. Astruc and coworkers have demonstrated that $[Fv(CoCp^*)_2]$ may be conveniently oxidised to the dication with HPF_6.[7] We therefore employed a similar approach to the synthesis of the dication of **1**.

Reaction of **1** with 2 equiv. of ammonium tetrafluoroborate at room temperature, after work up, afforded a yellow air stable crystalline powder characterised as $[(CoCp)_2(Ic'H_2)][BF_4]_2$ **2**. The ^1H and ^{13}C NMR spectra of **2** showed that the Ic′ ligand has been protonated at the 4,8 carbon positions (Scheme 1) giving a mixture of *cis* and *trans* isomers. However, in this case the ^1H NMR does allow us to assign the resonances due to the *cis* isomer, since the two protons on each of the 4,8 carbon atoms are now chemically inequivalent. We observe no evidence for any interconversion on the ^1H NMR timescale between the *cis* and *trans* isomers in the temperature range 223–322 K. When the reaction is carried out at room temperature the *cis* : *trans* ratio of **2** is 8 : 1, which reduces to 5 : 1 when the reaction temperature is lowered to 233 K. The reaction of **1** with ND_4BF_4 affords $[^2H_2]$**2**, the ^1H NMR spectrum of the *cis* isomer indicates exclusive deuteration at one site. Geiger has showed that the protonation of $[CoCp_2]^-$ proceeds exclusively at the *exo* position, implying that it does not occur *via* the metal centre.[8]

Suitable crystals for single crystal X-ray diffraction analysis of *trans*-**2** were grown from a concentrated mixture of dichloromethane and acetonitrile. The molecular structure of *trans*-**2** (Fig. 1)‡ contains a crystallographic inversion centre at the middle of the six membered ring of the $Ic'H_2$ ligand and cocrystallised with one molecule of each of acetonitrile, dichloromethane and tetrafluoroborate in the asymmetric unit. The Cp moiety is only slightly staggered with respect to the



Scheme 1. *Reagents and conditions*: i, $[CoCp(C_2H_4)_2]$ (2.2 mol. equiv.), THF, 24 h, room temp.; ii, NH_4BF_4 (2 mol. equiv.), THF, room temp.; iii, Ag(OTf) (2 mol. equiv.), THF, room temp.

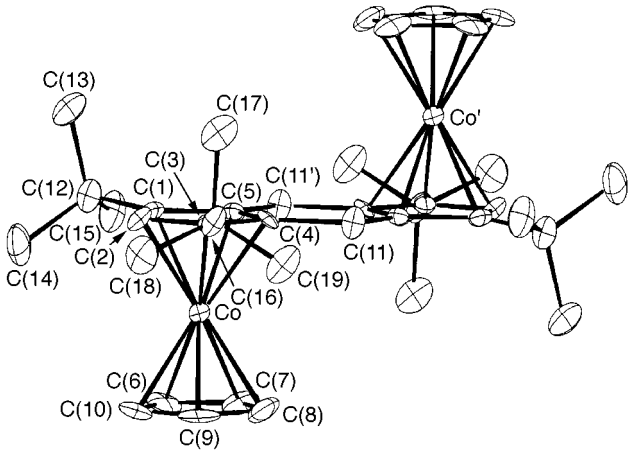


Fig. 1. Molecular structure of the *trans* isomer of **2** (CH_2Cl_2, MeCN, BF_4^- and H atoms have been omitted for clarity). Selected bond lengths (Å): Co–Ic′(centroid) 1.647(1), Co–Cp(centroid) 1.633(1), Co–C(1) 2.055(7), Co–C(2) 2.018(8), Co–C(3) 2.035(8), Co–C(4) 2.028(7), Co–C(5) 2.035(7), Co–C(6) 2.034(9), Co–C(7) 2.028(8), Co–C(8) 2.022(8), Co–C(9) 2.025(8), Co–C(10) 2.022(9).

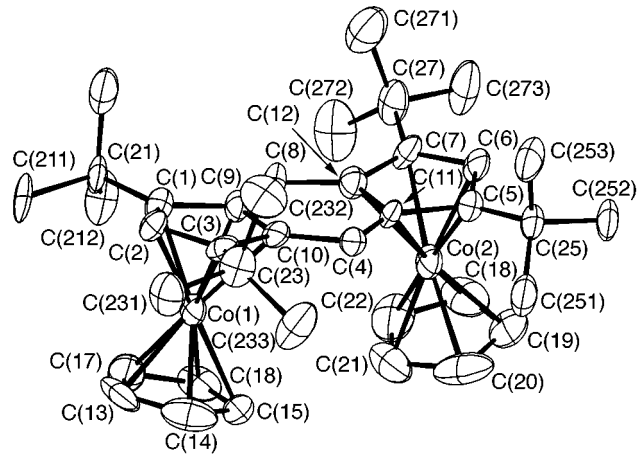

Fig. 2. Molecular structure of the *cis*-isomer of **3** (CH_2Cl_2, $CF_3SO_3^-$ and H atoms have been omitted for clarity). Selected bond lengths (Å): Co(2)–Cp(centroid) 1.66(1), Co(1)–C(1) 2.05(1), Co(1)–C(2) 2.03(1), Co(1)–C(3) 2.04(1), Co(1)–C(9) 2.15(1), Co(1)–C(10) 2.11(1), Co(1)–C(13) 2.04(1), Co(2)–C(5) 2.05(1), Co(2)–C(6) 2.01(1), Co(2)–C(7) 2.06(1), Co(2)–C(11) 2.18(1), Co(2)–C(12) 2.14(1), C(4)–C(10) 2.03(1).

IcH_2 ligand being out of phase by 7.8°, compared to cobaltocene and cobaltocenium cation which are staggered by 30°.[9] Thus **2** can be considered as two doubly bridged cobaltocenium cations. In contrast to the reported dimethyl silyl doubly bridged cyclopentadienyl complexes which are bent, the $Ic'H_2$ fragment is planar.[10] The cyclic voltammetric response of a tetrahydrofuran solution of **2** and tetrabutylammonium hexafluorophosphate (0.1 M) gave an irreversible oxidation wave at 0.65 V and an irreversible reduction wave at −1.31 V *vs* F_c–Fc^+.

Typically, electrophilic addition of a proton to cobaltocene occurs with a one electron reduction to afford the monovalent complex [Co(η^5-Cp)(η^4-C_5H_6)].[11] However the synthesis of **2** proceeds with a two electron oxidation at the cobalt atom. This is possible as the Ic′ undergoes electrophilic addition at the 4,8 carbon positions, which appear to be more reactive than the carbon atoms in the five membered rings.

The successful synthesis of the dication of **1** was achieved by employing aprotic oxidising reagents. Reaction of **1** with 2 equiv. of silver triflate afforded dark red crystalline [$(CoCp)_2$-Ic′]$^{2+}$[OTf]$_2$ **3**. We presume that compound exists as both *cis* and *trans* isomers. Compound **3** is paramagnetic, solutions in CD_3CN give a magnetic moment of 2.1 μ_B per cobalt atom. The molecular structure of *cis*-**3** (Fig. 2) shows the Ic′ ligand is slightly distorted to a convex structure with respect to the two CoCp fragments, thus reducing their steric interaction. The Co–C(Cp) bond lengths are all essentially equivalent [2.02(1)–2.05(1) Å], however, the Co–Ic′ bond lengths vary slightly, shifting the cobalt atoms towards the outside carbon atoms [*cf.* Co(1)–C(1–3) 2.03–2.05 Å, Co(1)–C(9,10) 2.11–2.15 Å]. This is similar to that found in *trans*-[(CoCp*)$_2$(*s*-indacene)]. The Cp(centroid)–Co–Ic′ bond angle of 175° further reducing the steric interaction between the CoCp moieties.

The *cis* isomer of **1** displays greater thermodynamic stability in solution over the *trans* isomer as indicated by the NMR experiments. The prevalence of the *cis* isomer seems somewhat strange from the distortion observed of the Ic ligand in the molecular structure of **3** and that only *trans* isomers are observed in unsubstituted *s*-indacene bimetallic transition metal complexes. We are presently undertaking density functional theory calculations on **1** in an effort to explain this unusual phenomenon.

We thank the EPSRC for financial support and a studentship (M. J. D.).

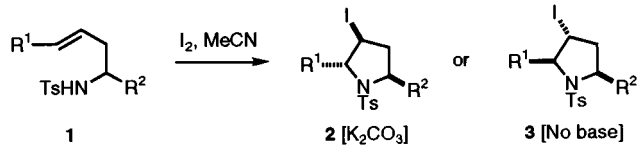
5-*endo-dig* Cyclisations of homopropargylic sulfonamides: a new route to 2,3-dihydropyrroles and β-iodopyrroles

David W. Knight,*[a]† Adele L. Redfern[a] and Jeremy Gilmore[b]

[a] *Chemistry Department, Cardiff University, PO Box 912, Cardiff, UK CF1 3TB*
[b] *Eli Lilly and Co. Ltd., Lilly Research Centre, Erl Wood Manor, Windlesham, Surrey, UK GU20 6PH*

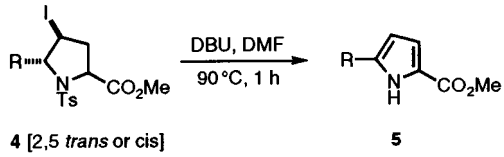
5-*endo-dig* Iodocyclisations of the homopropargylic sulfonamides 12a–c and 13 give excellent yields of the iododihydropyrroles 14a–d and thence the β-iodopyrroles 15a–d, following base-catalysed elimination of sulfinic acid.

We have recently reported that (*E*)-homoallylic tosylamides **1** (R^1, R^2 = alkyl, aryl) undergo highly efficient and stereoselective iodocyclisations to give the 2,5-*trans* iodopyrrolidines **2** in the presence of a base such as K_2CO_3, seemingly *via* a well-defined chair-like transition state conformation. In contrast, in the absence of a base, the corresponding 2,5-*cis* diastereoisomers **3** are obtained exclusively by acid-catalysed isomerization of the initial products **2** (Scheme 1).[1] Although apparently



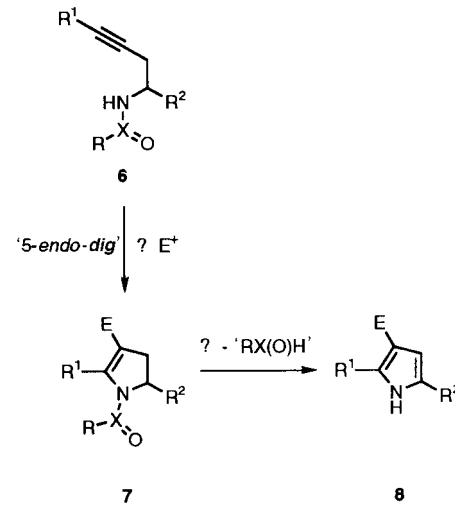
Scheme 1

5-*endo-trig* cyclisations, we do not regard these as exceptions to Baldwin's rules[2] as the process is electrophile- rather than nucleophile-driven; other aspects of our own studies and those of other research groups appear to substantiate this principle.[3] More recently, we have found that the method can be readily extended to include preparations of both 2,5-*trans* and 2,5-*cis* isomers of the substituted prolines **4** and that these undergo a double elimination of both HI and toluene-*p*-sulfinic acid upon warming with DBU in DMF, giving excellent yields of the pyrrole-2-carboxylates **5** (Scheme 2).[4]



Scheme 2

While this is a useful route to such pyrroles and is related to the established Kenner method, we felt that it was something of a backward step to lose this degree of functionality during the elimination, especially the iodine atom which could otherwise provide a handle for further elaboration. It was with this in mind that we wondered if it might be possible to effect similar cyclisations of related *homopropargylic* amine derivatives, inspired by our recent success in an approach to highly substituted furans.[5] The idea of working at this higher oxidation state is outlined in Scheme 3. If a suitably protected propargylic (prop-2-ynylic) amine **6** were to undergo a 5-*endo-dig* cyclisation, the resulting dihydropyrroles **7** might then be amenable to elimination of the protecting group, leading to pyrroles **8**, in which the electrophilic species used to trigger cyclisation is retained and hence would be available for additional reactions. Further, the dihydropyrrole species **7** might well be useful for



Scheme 3

further elaboration; however, at the outset, we had no idea whether these would be stable compounds. We were encouraged by the fact that, perhaps at first sight surprisingly and in direct contrast to the 5-*endo-trig* mode, 5-*endo-dig* cyclisations are favoured under Baldwin's rules.[2] Herein, we report on a first successful implementation of the approach shown in Scheme 3.

The success of the pyrrolidine and pyrrole syntheses (Schemes 1 and 2) naturally led us to choose as a first option the toluene-*p*-sulfonyl (tosyl) group to mask the amine nitrogen; the routes used to obtain representative substrates are shown in Scheme 4. The benzophenone imine of methyl glycinate **9**[6] was

Scheme 6

alkylated[7] with propargyl bromide and the *N*-protecting group of the resulting propargyl glycine **10** exchanged for a tosyl group. Sonogashira coupling[8] of the sulfonamide **11** so obtained with representative iodides provided excellent yields of the cyclisation substrates **12**. An alkyl derivative **13** was obtained using 1-bromopent-2-yne as the alkylating agent, followed by protecting group exchange.‡ An alternative strategy involving couplings between aryl iodides and the imine **10** was unsuccessful. We were delighted to find that exposure of the sulfonamides **12** and **13** to 3 equiv. of I_2 and K_2CO_3 in dry MeCN at ambient temperature resulted in slow but clean cyclisation to give excellent isolated yields of the iododihydropyrroles **14** (Scheme 5).[9] The aryl derivatives **14a–c** turned out to be stable crystalline solids with sharp melting points, whereas the alkyl derivative **14d** was a somewhat sensitive oil which nevertheless could be fully characterized.‡ Further, by stirring these dihydropyrroles **14** with DBU in DMF at ambient temperature, excellent yields of the corresponding iodopyrroles **15** were obtained by elimination of toluene-*p*-sulfinic acid (Scheme 5).‡ It was important to use 2 equiv. of the base; if only 1 equiv. was used, then approximately 50% of the product was the deiodopyrrole **16**, along with the expected product **15** (Scheme 6). We assume that the released sulfinic acid is responsible for this deiodination, perhaps by attack at iodine by sulfur, leading to the sulfonyl iodide, a process greatly reduced by the presence of an additional equivalent of base. Proton-catalysed cycloreversion, with loss of iodine, cyclisation and elimination is another possibility.

Both iodinated species **14** and **15** have potential for further elaboration, especially using one of the many transition metal-catalysed coupling procedures currently available. β-Iodopyrroles have recently been shown to undergo both Stille[10] and Sonogashira couplings.[11] In the present work we have established that the iododihydropyrroles **14** are compatible with palladium catalysts. Thus, a rapid Sonogashira coupling between dihydropyrrole **14a** and phenylacetylene [CuI (0.2 equiv.), $Pd(PPh_3)_4$ (0.1 equiv.), Et_2NH, 20 °C, 2 h] delivered an 82% isolated yield of the enyne **17**, suggesting that they will prove to be useful synthetic intermediates. These aspects and further studies of the scope and limitations of this chemistry are currently being pursued.

We thank the EPSRC Mass Spectrometry Centre, Swansea University, for the provision of high resolution MS data and Eli Lilly and Co. Ltd and the EPSRC for financial support through the CASE Scheme.

A Ru-allenylidene complex with an appended redox-active substituent: spectroscopic characterization of three oxidation states†

Rainer F. Winter*

Institut für Anorganische Chemie der Universität Stuttgart, Pfaffenwaldring 55, D-70569 Stuttgart, Germany. E-mail: winter@iac.uni-stuttgart.de

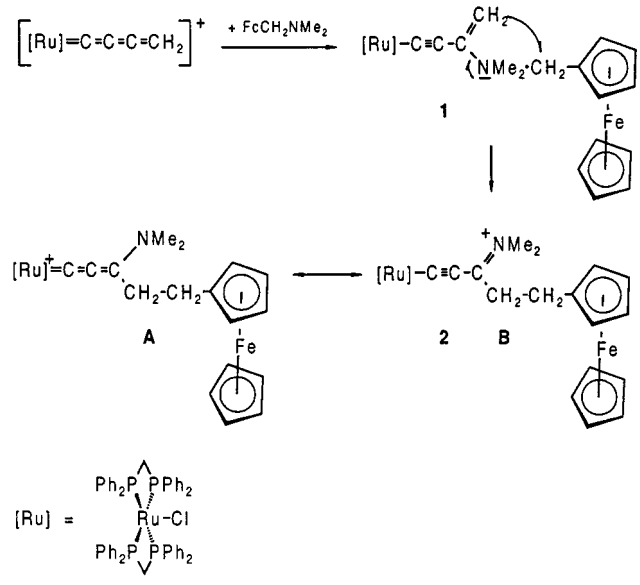
A Ru allenylidene complex with a ferrocenyl substituent in the aliphatic side chain has been prepared and the effects of the consecutive oxidations of the ferrocenyl group and the Ru have been probed by IR and UV/VIS spectroelectrochemistry.

The reactivity of metal-vinylidene and −allenylidene complexes is now well established and may be employed in a variety of useful transformations.[1,2] In contrast, it is only recently that a similar chemistry of the butatrienylidene ligand has begun to emerge. The reactions of the C_4H_2 ligand present in cationic $[Ru]=C=C=C=CH_2^+$ intermediates include the addition of aprotic nucleophiles to the electrophilic C_γ[3,4] and the addition of protic nucleophiles to the terminal double bond generating methyl substituted allenylidene complexes. Some interesting cycloaddition/cycloreversion chemistry[5] as well as an unusual Aza-Cope rearrangement following the addition of allyl substituted tertiary amines were also reported.[4]

We have initiated a program aimed at synthesizing novel heteroatom substituted Ru-allenylidene complexes $[Ru]=C=C=C(ER_n)R'^+$ from butatrienylidene precursors *trans*-$[ClRu(L_2)_2=C=C=C=CH_2]^+$ (L_2 = chelating diphosphine) and investigating their spectroscopic and electrochemical properties as a function of the heteroatom and the oxidation state of Ru. In this context we are striving for model compounds which allow us to reversibly alter the electronic properties of the unsaturated ligand by attaching redox active substituents to the allenylidene side chain. Here we report our findings on *trans*-$[ClRu(dppm)_2=C=C=C(NMe_2)C_2H_4Fc]^+$ SbF_6^-, **2** [dppm = bis(diphenylphosphino)methane; Fc = ferrocenyl, $(C_5H_4)Fe(C_5H_5)$], which constitutes the first example of such compounds. **2** was prepared in good yield by trapping the *in situ* generated $[ClRu(dppm)_2=C=C=C=CH_2]^+$ with ferrocenylmethyldimethylamine, $FcCH_2NMe_2$. Due to the inherent reactivity of the organometallic amine toward dichloromethane,[6] chlorobenzene had to be employed as solvent. As to the formation of **2**, we assume that the initially generated addition product **1** evolves to the title compound by migration of the resonance stabilized ferrocenylcarbenium ion[7] from the quaternary nitrogen to the neighbouring nucleophilic C_δ (Scheme 1). Thus, the overall reaction closely resembles that observed for Ph_2NH with $FcCH_2^+$ instead of a proton. In the crude reaction mixture, **1** was identified as a minor product along with a third, as yet unidentified component.‡ Although numerous attempts to obtain X-ray quality crystals failed the spectroscopic data leave no doubt as to the identity of **2**.‡ The most characteristic features are the intense allenylidene IR stretch at 1992 cm^{-1} (KBr pellet), the low field quintet in the ^{13}C NMR spectrum at δ 201.8 with a $^2J_{P\text{-}C}$ coupling of 13.6 Hz and the two triplets for the ethylene spacer as well as the signals of a monosubstituted ferrocenyl unit in the ^1H NMR spectrum. The methyl groups attached to the nitrogen give rise to two separate resonance signals in the ^1H and ^{13}C NMR spectra, indicating a double bond character of the C=N bond. Even at 368 K these signals remain separate without any indication of exchange broadening. The energy barrier for rotation must therefore well exceed 73 kJ mol^{-1}. These data are in agreement with the iminiumalkynyl resonance form **B** being the predominant contributor to the electronic structure of **2** as was noted before for other aminoallenylidene complexes.[4,8]

Cyclic and square wave voltammetry of **2** in CH_3CN§ reveal three electrochemical processes within the solvent window, one reduction and two oxidations. At room temperature the reduction is essentially irreversible. At lower temperatures, just above the melting point of the solvent, the chemical decomposition is slowed to a degree that allows us to determine the $E_{1/2}$ of this couple as −2.13 V *vs.* the ferrocene/ferrocenium standard. The first oxidation is a chemically and electrochemically reversible Nernstian process with an $E_{1/2}$ of + 0.02 V, *i.e.* close to that of ferrocene itself. We attribute this feature to the oxidation of the appended ferrocenyl substituent, which is further supported by spectroelectrochemistry (*vide infra*). The second oxidation occurs on the Ru fragment. Under appropriate experimental conditions, the Ru(II/III) couple constitutes a chemically reversible one electron step at $E_{1/2}$ = + 0.62 V which suffers, however, from somewhat slow electron transfer kinetics. Quasireversible behavior has been observed for the Ru(II/III) couples in similar systems.[9] Most significantly, the $E_{1/2}$ of this couple is shifted anodically by 50 mV with respect to otherwise identical complexes but containing a butenyl[4] or $CHEtC=CH_2$ side chain[10] instead of the ferrocenylethyl group. We attribute this shift to the increasing electron withdrawing ability of the allenylidene side chain as the appended ferrocenyl substituent is oxidized.

This effect is also evident from following the stepwise *in situ* oxidation of **2** by UV/VIS and IR spectroscopy. The first oxidation is accompanied by the growth of an absorption band at 642 nm, a region which is characteristic of the ferrocenium chromophore (see insert of Fig. 1). At the same time the intense metal-to-ligand charge transfer absorption band of the [Ru]=C



Scheme 1

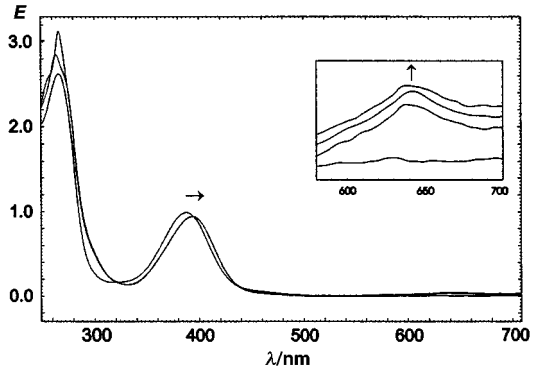


Fig. 1 Spectroscopic changes during the first electrochemical oxidation (Fc/Fc$^+$) of **2** in the UV/VIS region

=C=C(NR$_2$)R′$^{+}$ chromophore experiences a bathochromic shift from 386 nm to 394 nm (Fig. 1). A similar, albeit smaller effect just above the resolution power of our spectrometer is seen during IR monitoring of the first oxidation. Here, the intense allenylidene absorption band moves from 1999 cm^{-1} to 1997 cm^{-1}. Essentially no metal–metal coupling is observed over the partially saturated carbon spacer in the formally mixed valent heterobimetallic monooxidation product as shown by the absence of any absorption in the near IR region.

A larger effect is obtained when **2** is further oxidized. Both the UV/VIS and IR absorption bands exhibit a shift in the opposite direction to that found for the first oxidation process. In the fully oxidized trication the visible band is now positioned at 348 nm (Fig. 2). Another weak, broad band centered at 580 nm does also appear, which we attribute to a d–d transition within the Ru(III) fragment (insert of Fig. 2). The ferrocenium band remains essentially unchanged. In IR spectroelectrochemical experiments the intense absorption of the dication is replaced by a much weaker band at 2022 cm^{-1} as the oxidation of Ru(II) proceeds. We wish to emphasize that under our *in situ* conditions all oxidized species are reasonably stable. In fact, rereducing **2**$^{2+}$ reproduced the starting material in near quantitative (UV/VIS) and about 80% yields (IR). The lesser reversibility in the IR experiment is due to the longer electrolysis time required to convert the higher concentrated samples. We can therefore exclude that the loss of intensity in the IR experiment is caused by extensive decomposition rather than being an intrinsic characteristic of our system. Both the decrease in absorptivity of the IR band as well as its blue shift upon oxidation have also been observed in Ru(II)-cyanide complexes[11] thus emphasizing that, in this special situation, there may indeed be an analogy between the CN$^-$ and an electron poor acetylide ligand.[12] The shifts of the visible and the infrared bands do also point to an increase in bond order of the C$_\alpha$–C$_\beta$ entity as the ruthenium is oxidized.

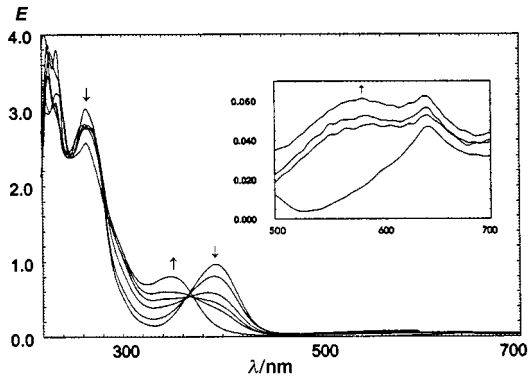

Fig. 2 Spectroscopic changes during the second electrochemical oxidation [Ru(II/III)] of **2** in the UV/VIS region

In summary, we have generated a novel functionalized aminoallenylidene complex by trapping a still elusive [Ru]=C=C=C=CH$_2^+$ intermediate with a suitable tertiary amine. The appended ferrocenyl substituent allows us to reversibly alter the electronic properties of the allenylidene ligand. Ferrocenyl oxidation influences both the Ru(II/III) oxidation potential and the spectroscopic properties of the allenylidene chromophore despite the rather remoteness of the ferrocenyl group and the saturated nature of the connecting bridge. Much larger effects are to be expected if the redox-active tag is attached directly to the delocalized allenylidene system. Work along these lines is in progress.

I am indebted to the Deutsche Forschungsgemeinschaft, DFG, for financial support of this work. The contributions of Stephan Hartmann are also gratefully acknowledged.

Two strategies to improve the catalytic activity of Ti-MCM-41 materials in the epoxidation of olefins are described; the first approach involves silylation of the surface of Ti-MCM-41 which produces a very hydrophobic catalyst whereas the second approach is based on removal of water from the reaction media; the increase in activity is not due to a change in the intrinsic activity of the Ti sites, but rather to a decrease of the catalyst deactivation by reducing the formation of diols produced by ring opening of the epoxide.

The discovery of TS-1,[1] and its extension to Ti-beta[2] and Ti-MCM-41[3] have broadened the scope of these interesting catalysts to include the oxidation of large hydrocarbon molecules.[3–6] It has been shown with these catalytic systems that the hydrophobic/hydrophilic properties of the surface are just as important as the number of active sites. Control of the hydrophobicity of the molecular sieve allows the optimization of the adsorption of reactants and products.[7,8] This is especially true for the epoxidation of olefins where, irrespective of the nature of the oxidant, the epoxide has higher polarity than the olefinic substrate. Consequently, the epoxide competes more favorably for adsorption on the hydroxylated surfaces of the Ti-silicates.[5] In this respect, the presence of silanol groups as well as the presence of =Ti–OH groups allows adsorption of the epoxide and results in ring opening of the epoxide and the formation of diols. As discussed later, the diols tend to strongly adsorb on the Ti sites and lead to partial deactivation of the catalyst.

We have shown that by decreasing the concentration of the internal silanol groups in Ti-beta, it is possible to significantly increase the selectivity to the epoxide.[7] In the case of materials such as Ti-silica and Ti-MCM-41, which contain a large number of silanol groups, the silanol content can be reduced by reaction with organosilanes[9,10] or by introducing organosilanes directly to the synthesis gel of mesoporous materials,[11–13] and this modification is reflected in the final properties of the catalyst.[13,14] In this manner it has recently been shown that silylated Ti-MCM-41 gives better selectivity to the epoxide when hydrogen peroxide is used as an oxidant.[14] However, the cyclohexene conversion was 13% of the maximum conversion achievable and the selectivity to the epoxide was only 13%. Thus, as shown previously by us,[15] hydrogen peroxide is not an appropriate oxidant for Ti-MCM-41 and consequently the poor performance is not surprising.

It appears that Ti-MCM-41 has the greatest potential as an epoxidation catalyst when organic hydroperoxides are used as the oxidant.[16] Here we will describe two different strategies that give results superior to those that have been reported up to now. In this way, two different samples of Ti-MCM-41 were prepared. The first sample was obtained from a gel having the following molar composition: $SiO_2 : 0.015\ Ti(OEt)_4 : 0.26$ CTABr : 0.26 TMAOH : 24.3 H_2O where CTABr is cetyltrimethylammonium bromide and TMAOH is tetramethylammonium hydroxide. The silica source, Aerosil-200, was obtained from Degussa. The crystallization was performed at 100 °C for 48 h in Teflon lined stainless steel autoclaves. The occluded surfactant was completely removed following a two step extraction procedure.

Ti-MCM-41 was silylated with hexamethyldisilazane (HMDS) as the silylating agent. The silylated samples are referred to as Ti-MCM-41S. The silylation was carried out at 120 °C with a solution of HMDS in toluene under inert atmosphere.

The MCM-41 structure was preserved after silylation and the surface area of the silylated sample was close to 1000 $m^2\ g^{-1}$.

Samples with different levels of silylation were obtained by changing the HDMS/Ti-MCM-41 ratio as shown in Table 1. The carbon content, determined by elemental analysis, was used to calculate the degree of surface coverage (Table 1).

The catalytic activity of these materials was measured in the epoxidation reaction of cyclohexene with *tert*-butylhydroperoxide (TBHP) at 60 °C. The olefin/TBHP ratio was to 4 mol mol^{-1} and the liquid/catalyst ratio was 20 g g^{-1}.

The results shown in Fig. 1 clearly indicate that the catalyst activity and selectivity increase with the level of silylation and much higher conversions and selectivities than those reported up to now have been achieved in this work. It is of interest that relatively low levels of silylation significantly improve the catalyst selectivity to the epoxide, but that over the range of silylation there is very little influence on the catalytic conversion. On the other hand, a significant improvement in catalytic activity is observed when the silylation gives rise to a surface coverage of > 40%. In this case, the selectivity to the epoxide is close to 100%.

The hydrophobicity of Ti-MCM-41S materials was estimated from the weight loss of the fully hydrated sample at 150 °C. We found that there is a linear correlation between the hydrophobicity and the surface coverage with trimethylsilyl groups as shown in Fig. 2. Therefore, one can conclude from Figs. 1 and 2 that in order to obtain a highly active and selective catalyst for epoxidation it is necessary to silylate Ti-MCM-41 above 40% or preferably close to 100%.

Table 1 Silylation conditions and degree of silylation achieved on Ti-MCM-41 catalysts

Sample	Ti content (wt.% TiO_2)	HMDS/ sample	C content (wt.%)	Surface coverage[a] (%)
Ti-MCM-41	1.9	—	—	0
Ti-MCM-41S1	1.9	0.026	4.2	33
Ti-MCM-41S2	1.8	0.034	7.9	63
Ti-MCM-41S3	2.1	0.123	10.3	82
Ti-MCM-41S4	2.0	0.260	11.9	95

[a] The calculated surface coverage per trimethylsilyl group is 47.6 $Å^2$ $molecule^{-1}$.[17]

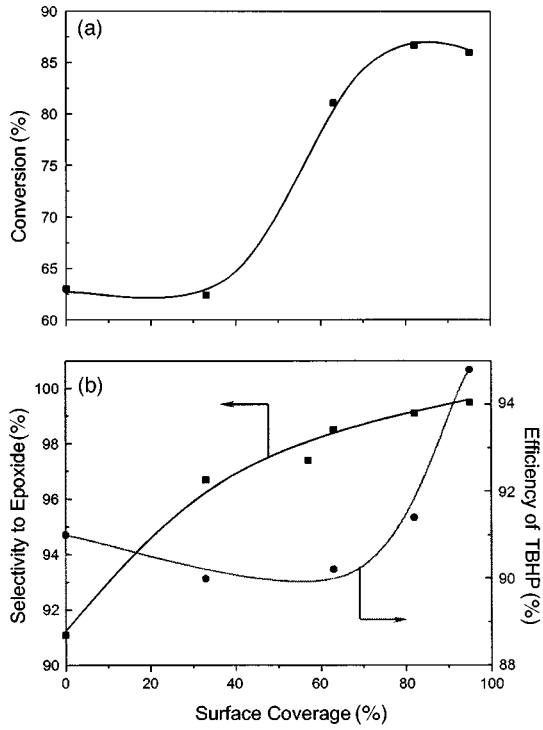

Fig. 1 Catalytic activity in the epoxidation of cyclohexene with TBHP of silylated Ti-MCM-41 at different degrees of surface coverage; (a) catalytic conversion after 30 min of reaction, (b) selectivity to epoxide and efficiency of TBHP at 85% cyclohexene conversion

Nevertheless, it was surprising to find that every hydrophobic Ti-MCM-41 catalysts were required in order to have highly active and selective epoxidation catalysts even when only organic reactants were used. This motivated us to analyze the amount of water contained in the reactants, and it was found by means of ^{1}H NMR that the TBHP contained 8 wt.% water. Then, we carried out the epoxidation of cyclohexene with TBHP which was dried using 4 Å molecular sieves. With ^{1}H NMR we determined that no decomposition of TBHP occurred and the remaining amount of water was below the detection limit of ^{1}H NMR. Under these conditions and using the non-silylated catalyst Ti-MCM-41, which contains 13.5 wt.% water adsorbed on the catalyst, the total conversion and selectivity to the epoxide obtained after 30 min of reaction were 85 and 97%, respectively. These results are very similar to those obtained with the completely silylated sample Ti-MCM-41S4 when using the as-received commercial TBHP.

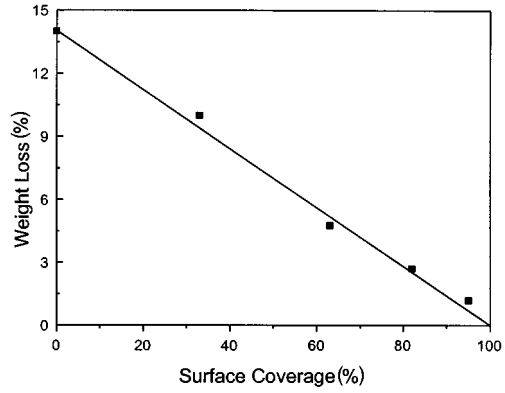

Fig. 2 Variation of the hydrophobicity, calculated as the weight loss at 150 °C by thermogravimetry, with the degree of silylation of Ti-MCM-41 catalysts

An additional experiment was carried out with dry TBHP and dry catalyst Ti-MCM-41. After 30 min the conversion was 91% and the selectivity was 100%. These results are the best conversion and selectivity to epoxide ever reported using Ti-based catalysts for epoxidation processes.

We conclude that the presence of water is responsible for the ring opening of the epoxide. However, its influence goes beyond the selectivity effect, since the diols resulting from the ring opening of the epoxide strongly decrease the catalytic conversion. We have seen this effect by performing the epoxidation reaction using dried TBHP, but adding 3.07 mmol of cyclohexanediol which corresponds to a typical amount of the diol formed during the catalytic experiments when non-dried TBHP is used. Under these conditions, the conversion is significantly reduced to 13% after 30 min of reaction. This result suggests that the increase in activity observed when using either silylated Ti-MCM-41 or non silylated Ti-MCM-41 with dry reactants is due to the significant decrease in the formation of diols which act as catalyst poisons for the Ti sites.

In conclusion we have presented two different strategies that can be used to obtain remarkably active and selective epoxidation catalysts based on Ti-MCM-41. The first strategy relies on the use of highly silylated samples and greater than 40% silylation coverage is required. In this case water can be present in the reaction media up to levels of 3 wt.%. On the other hand, one can use non-silylated catalysts, but in this case water must be removed from the reaction media.

It is also concluded in this work that the increase in activity observed with the silylated hydrophobic catalyst or with the absence of water in the reaction medium, is probably not due to a change of the intrinsic activity of the Ti catalytic sites but rather to a decrease in catalyst deactivation. An increase in catalyst stability is obtained by reducing the formation of diols that are produced by ring opening of the epoxide in the above conditions.

Financial support by the Spanish MAT97-1016-CO2-01 and MAT97-1207-CO3-01 is gratefully acknowledged. J. L. J. and M. D. thank the M.E.C. and M.E.A., respectively, for supporting their doctoral fellowships. M. T. N. thanks the CSIC for the postdoctoral grant. B. M. C. and L. T. N. acknowledge UOP for financial support.

Cyclodepolymerisation of bisphenol A polysulfone: evidence for self-complementarity in macrocyclic poly(ether sulfones)

Ian Baxter,[a] Abderrazak Ben-Haida,[b] Howard M. Colquhoun,*[c]† Philip Hodge,*[b]‡ Franz H. Kohnke[b]§ and David J. Williams*[a]¶

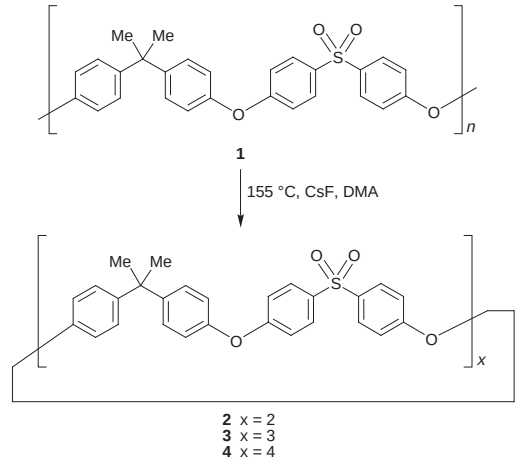
The engineering thermoplastic generally referred to as 'bisphenol A polysulfone' undergoes fluoride-promoted cyclodepolymerisation; high molar mass polymer is thus transformed into a series of macrocyclic oligomers containing up to at least 72 aromatic rings; those containing up to 24 rings have been isolated as pure compounds, and single-crystal X-ray studies of the cyclotrimer and cyclotetramer reveal shape-complementary pairs and chains of macrocyles, respectively.

Polycondensation reactions generally afford not only high molar mass linear polymers, but also (in amounts depending on reaction conditions) homologous series of macrocyclic oligomers.[1] As a result, significant quantities of cyclic materials are found in many important commercial polymers. Under equilibrium conditions, linear and cyclic species can interconvert *via* ring-opening polymerisation of macrocyclic oligomers and/or ring-closing depolymerisation (cyclodepolymerisation) of linear chains. Such interconversions have recently been demonstrated for polyesters,[2] polycarbonates,[3] and certain aromatic polyethers.[4] A theoretical framework for ring–chain equilibria in dilute solution has been developed by Mandolini and coworkers, indicating the existence of a threshold concentration below which *only* cyclic species should be present.[5]

Here we report that the high-performance engineering thermoplastic **1**, generally referred to as 'bisphenol A polysulfone' (formed by polycondensation of bisphenol A with 4,4′-dichlorodiphenyl sulfone, and trademarked as *Udel* by the Amoco Corporation and *Ultrason-S* by BASF) undergoes clean cyclodepolymerisation at high temperatures in the presence of fluoride ion. The polymer is transformed, *via* fluoride-promoted ether interchange reactions,[6] into a series of macrocyclic oligomers, ranging from the [2+2] cyclodimer to the [18+18] cyclooctadecamer (Scheme 1).

Heating a 0.5 wt% solution of bisphenol A polysulfone at reflux in DMA with 0.5 equiv. of CsF per polymer repeat unit leads to the disappearance of high molar mass polymer and formation (as evidenced by GPC and HPLC) of a well-defined series of oligomeric compounds.‖ Analysis of the isolated products by MALDI-TOF mass spectrometry (Fig. 1) demonstrates that the oligomers comprise exclusively *macrocyclic* species, with molar masses in the range *m/z* 906 (cyclodimer) to 7980 (cyclooctadecamer). Chromatographic fractionation yielded a series of pure, monodisperse oligomers from cyclodimer (**2**) to cyclohexamer, characterised by elemental analysis, ^{1}H and ^{13}C NMR spectroscopy, mass spectrometry and, in the cases of the cyclotrimer (**3**) and cyclotetramer (**4**), by single crystal X-ray diffraction.**

The cyclodimer (**2**), which crystallises spontaneously from solutions of the commercial polymer, has already been characterised in some detail;[7] the higher macrocycles were however previously unknown. The macrocyclic oligomers from cyclotrimer to cyclohexamer may be isolated as crystalline solvates from solvents such as $CHCl_3$ and CH_2Cl_2, but these



Scheme 1

readily lose solvent on heating to give amorphous, glassy materials. Single crystal X-ray analysis of the cyclotrimer **3**, as its MeCN solvate, shows the molecule to adopt a folded geometry, reminiscent of a tennis ball seam (Fig. 2). As with the cyclodimer,[7] the diphenyl sulfone units adopt 'open book' type conformations, while the diphenylisopropylidene rings are skewed. The diphenyl ether linkages on the other hand appear to be conformationally rather flexible, here adopting both near-orthogonal *and* skewed geometries.

Remarkably, it appears that centrosymmetrically-related pairs of cyclotrimers have self-complementary surfaces, since these interact in the solid state to create supramolecular 'dimers' as shown in Fig. 3. Isopropylidene groups centred on C(71) mutually insert through the loops of complementary oligomer chains between O(8) and S(57). Residual clefts in the surface of the dimer are populated by included MeCN solvent molecules. Dimer stabilisation appears to be achieved through a combination of electronically-complementary face-to-face π-stacking

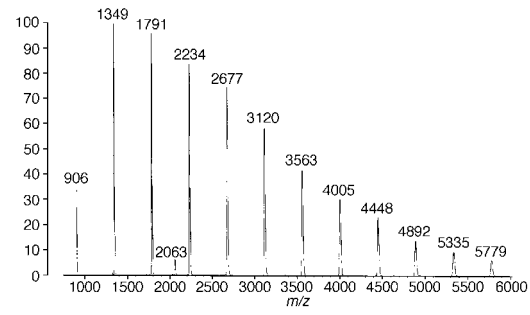


Fig. 1 Partial MALDI-TOF mass spectrum of the macrocyclic products (M + Na^+) formed by cyclodepolymerisation of bisphenol A polysulfone (the small peak at *m/z* 2063 is due to an impurity in the dithranol matrix.)

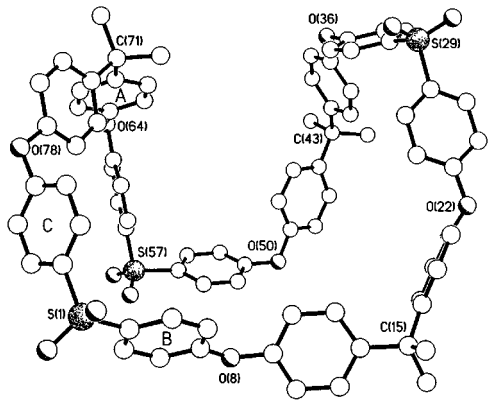

Fig. 2 Structure of **3**, illustrating the tennis ball seam-like conformation adopted in the solid state. Ring torsion angles relative to the plane of the C–X–C bridge (X = S, C, or O) are: at S(1), 86 and 86°; at S(29), 85 and 81°; at S(57), 84 and 79°; at C(15), 76 and 19°; at C(43), 62 and 31°; at C(71), 49 and 46°; at O(8), 79 and 7°; at O(22), 64 and 13°; at O(36), 73 and 4°; at O(50), 60 and 29°; at O(64), 85 and 3°; at O(78), 74 and 28°.

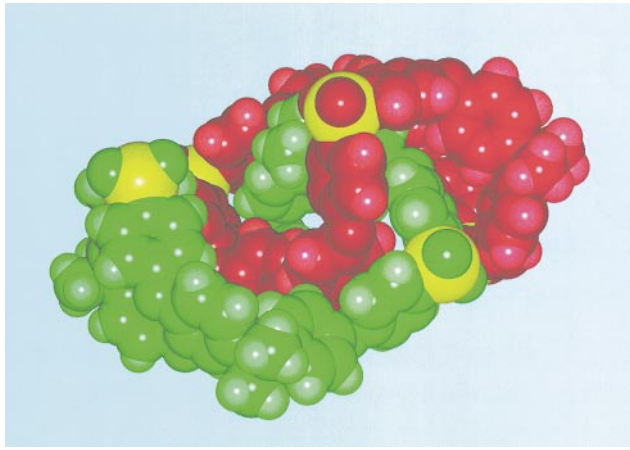

Fig. 3 Space-filling representation of **3**, showing the mutual interpenetration of enantiomeric macrocycles. The centroid···centroid and mean interplanar spacings between rings 'A' and 'B' in centrosymmetrically related molecules of the cyclotrimer are 3.96 and 3.57 Å respectively; the H··π distance and C–H··π angle are 2.71 Å and 175°, respectively; and the H···centroid vector is inclined by 82° to the 'C' ring plane.

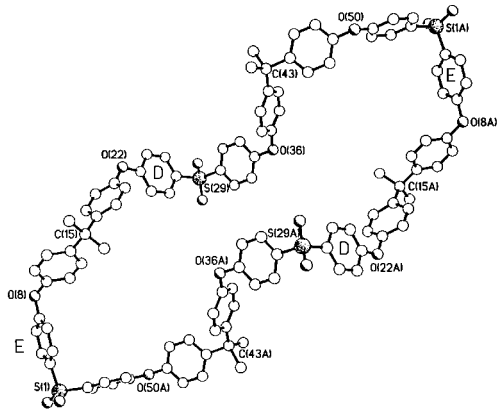

Fig. 4 Structure of **4**. Ring torsion angles relative to the plane of the C–X–C bridge (X = S, C, or O) are: at S(1), 89 and 84°; at S(29), 89 and 76°; at C(15), 57 and 26°; at C(43), 62 and 34°; at O(8), 70 and 27°; at O(22), 76 and 1°; at O(36), 79 and 33°; at O(50), 79 and 2°.

between ring 'A' of one molecule and ring 'B' of another, as well as a C–H··π interaction between the *ortho*-hydrogen *syn* to O(64) and the 'C' ring of an adjacent molecule.

The X-ray structure of the cyclo-tetramer **4** (Fig. 4) shows it to possess crystallographic inversion symmetry. The individual conformational features closely resemble those of the cyclotrimer and generate an elongated macrocycle, of approximately 33.6 × 15.5 Å, containing two distinct cavities. Again there is significant interpenetration of the isopropylidene unit of one macrocycle into the cavity of an adjacent molecule but here, instead of generating isolated pairs of cyclic oligomers, continuous chains of intertwined macrocycles are created.

A valuable new approach to the structural characterisation of non-crystalline polymers emerges from the present work, as it is becoming clear that even *very large* cyclic oligomers of such materials, *when monodisperse*, can afford single crystals of a size and morphology suitable for X-ray analysis. The position is somewhat analogous to that in protein crystallography, where macromolecules are monodisperse for genetic reasons and where strong intramolecular interactions lead to the adoption of compact conformations, allowing macroscopic single crystals to be obtained.

We wish to thank Mr P. R. Ashton of the University of Birmingham for the MALDI-TOF mass spectrometric analysis, and the EPSRC for financial support.

Effective biocatalytic transgalactosylation in a supercritical fluid using a lipid-coated enzyme

Toshiaki Mori and Yoshio Okahata*†

Department of Biomolecular Engineering, Tokyo Institute of Technology, Nagatsuda, Midori-ku, Yokohama 226-8501, Japan

A lipid-coated β-D-galactosidase is soluble and acts as an efficient trangalactosylation catalyst (the reverse hydrolysis reaction) in supercritical carbon dioxide ($scCO_2$).

Supercritical fluids (scFs) have become attractive as media for chemical reactions, as well as for extraction and chromatography, in the last decade;[1] their physical properties can be manipulated by small changes in pressure or temperature, and several of these properties (*e.g.* density, diffusion and viscosity) are intermediate between those of gases and liquids.[2] The larger diffusion rate in a scF compared to a liquid can be expected to increase the reaction rate.

Several organic reactions in scF have been achieved using homogeneously soluble organometallic complexes as catalysts.[3] Application of scFs for enzymatic reactions has also been reported using immobilized enzymes, as well as native enzymes.[4] However, since the immobilized and native enzymes are not soluble or particularly not stable in scFs, results comparable to those found in aqueous or organic solvents have not been obtained.[4] We have reported that the lipid-coated enzymes such as lipases,[5] phospholipases[6] and glycosidases[7] are soluble in most organic solvents and can catalyze reverse hydrolysis reactions such as esterification and transglycosylation in homogeneous organic media. We expected that lipid-coated enzymes would be homogeneously soluble in scFs as well as organic media, and would show efficient catalytic activity due to the high diffusion rates and the low viscosity found in scFs.

Here we report the high catalytic activity of transgalactosylation using a lipid-coated β-D-galactosidase in supercritical carbon dioxide ($scCO_2$). The reasons carbon dioxide was chosen as the scF are as follows: (i) CO_2 becomes a scF above 31.0 °C and 73.8 atm, conditions which are easily accomplished with gentle heating from ambient temperature and a commercial liquid chromatography pump, (ii) the solvent properties of $scCO_2$ can be continuously varied by changing the pressure or temperature, and (iii) CO_2 is non-toxic and the medium is easily removed by decompression to atmospheric pressure.

A lipid-coated β-D-galactosidase (from *Bacillus circulans*) was prepared by mixing aqueous solutions of enzyme and lipid molecules in the same way as reported previously.[5–7] It was confirmed from elemental analysis, UV absorption, and gel chromatography in CH_2Cl_2 that one enzyme is covered by about 200 ± 50 lipid molecules as a monolayer and that the protein content in the complex is 7 ± 1 wt%.[5–7] The lipid-coated enzyme was also found to be soluble (*ca.* 0.1 mg ml^{-1}) in $scCO_2$ in the range of 32–60 °C and 74–200 atm, by the observation using a pressure-resistant glass vessel (Taiatsu Techno, Co., Tokyo, volume: 10 ml), but not very soluble in liquid CO_2 (at 20 °C and 100 atm) and insoluble in gaseous CO_2 (at 40 °C and 40 atm).

Transgalactosylation reactions were carried out as follows. In a stainless steel or pressure-resistant glass vessel, both the substrates (1-*O*-*p*-nitrophenyl-β-D-galactopyranoside and 5-phenylpentan-1-ol) and a lipid-coated β-D-galactosidase were added, then liquid CO_2 was injected at 100–150 atm using a LC pump (Jasco PU-980 HPLC pump) connected to a CO_2 gas cylinder. The vessel was warmed with magnetic stirring above 40 °C to create the supercritical state, and the pressure was kept constant (±0.1 atm) by a back pressure regulator (JASCO 880–81). At the appointed time, the vessel was degassed carefully under cooling at 0 °C. The residual powder was solubilized in MeCN and analyzed by a HPLC.

Fig. 1 shows typical time courses of the transgalactosylation from 1-*O*-*p*-nitrophenyl-β-D-galactopyranoside (0.1 mM) to 5-phenylpentan-1-ol (1.0 mM) catalyzed by a lipid-coated β-D-galactosidase at 40 °C both in $scCO_2$ at 150 atm and in isopropyl ether at atmospheric pressure. In $scCO_2$, 1-*O*-(5-phenylpentyl)-β-D-galactopyranoside was obtained as the only transgalactosylated product in 72% yield after 3 h, at which point the reaction reached equilibrium. We have reported that the lipid-coated β-D-galactosidase can catalyze the same transgalactosylation in conventional organic solvents such as isopropyl ether.[7] The transgalactosylation in $scCO_2$ was 15-fold faster than in isopropyl ether. In this case, both the enzyme and the substrate

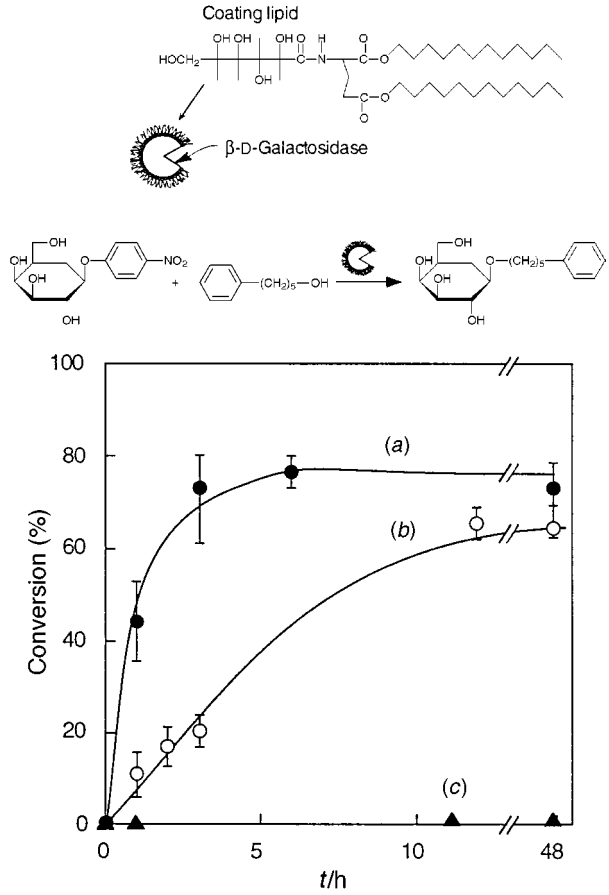

Fig. 1 A schematic illustration of a lipid-coated β-D-galactosidase and time-courses of transgalactosylation from 1-*O*-*p*-nitrophenyl-β-D-galactopyranoside (0.1 mM) to 5-phenylpentan-1-ol (1 mM) at 40 °C catalyzed by β-D-galactosidase (1 mg of protein) in 10 ml: (*a*) a lipid-coated enzyme in $scCO_2$ with 150 atm, (*b*) a lipid-coated enzyme in isopropyl ether, and (*c*) a native enzyme in $scCO_2$ with 150 atm

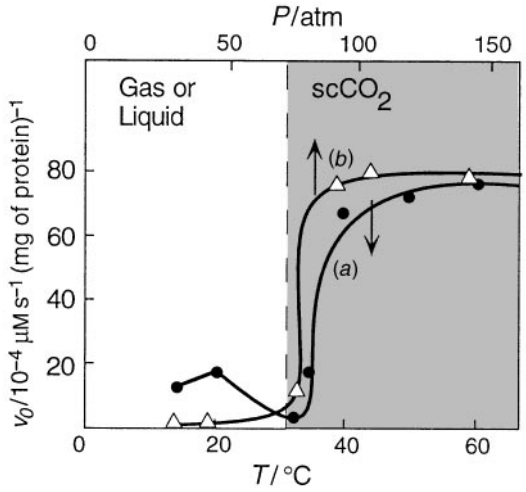

Fig. 2 Effect of (*a*) changing temperature at 150 atm and (*b*) changing pressure at 40 °C on the initial rate of transgalactosylation

were soluble in $scCO_2$, so the increase in the rate may be due to a decrease in the degree of solvation of the substrate. Transgalactosylations also occurred rapidly with acceptor alcohols having large alkyl groups, such as 1,2-*O*-bis(dodecyl)glycerol (conversion 45%) and cholesterol (conversion 15%).

When a lipid-coated lipase (from *Rhizopus delemar*) was prepared and applied as an esterification catalyst for monolaurin and lauric acid, the esterification rate increased 10-fold in $scCO_2$ over that in atmospheric isooctane (data not shown).[8] Although several studies on enzyme reactions in $scCO_2$ using native or immobilized enzymes have been performed, an improvement of reactivity over the reaction in atmospheric liquid media has not been reported.[4] Actually, the native β-D-galactosidase was observed to hardly catalyze the transglycosylation in $scCO_2$, as shown in Fig. 1(*c*). This is due to the insolubility and instability of native enzymes in $scCO_2$.

FT-IR spectra usually provide information about secondary structures, such as the content of α-helix and β-sheet domains in proteins.[9] FT-IR spectra were taken of the lipid-coated β-D-galactosidase in $scCO_2$[10] and a native β-D-galactosidase in D_2O solution. It was indicated from the peak strength of the amide I band at 1600–1700 cm^{-1} that the content of α-helix (21%) and β-sheet (26%) structures of the lipid-coated enzyme in $scCO_2$ agreed reasonably well with those (α-helix: 19%; β-sheet: 30%) of a native enzyme in D_2O solution. Thus, the structure of the lipid-coated enzyme in $scCO_2$ is not significantly changed from that in aqueous buffer solution.

One of the advantages of scFs as reaction media is that their physicochemical properties, such as diffusiion rate, density, polarity and viscosity, can be continuously changed by varying the temperature or pressure of the $scCO_2$ state.[2] The effects of changing temperature and pressure on the initial rates of the transgalactosylation catalyzed by a lipid-coated enzyme are shown in Fig. 2.[11] When the temperature was changed at a constant pressure of 150 atm [Fig. 2(*a*)], galactosylations were very slow below 31 °C, where the medium exists as liquid CO_2 and the lipid-coated enzyme is barely solubilized. The reactivity increased above 31 °C, where the lipid-coated enzyme is solubilized. Since the enzyme activity in aqueous buffer solution increased gradually with increasing temperature from 20 to 60 °C, this activity change depending on temperature is explained by the special physical property changes of $scCO_2$. A similar tendency was observed when the pressure was changed from 50 to 150 atm at 40 °C [Fig. 2(*b*)]. Gaseous CO_2 could not solubilize the lipid-coated enzyme below 72.9 atm (the critical pressure) and the enzyme activity drastically increased in $scCO_2$ depending on the pressure. When the temperature and pressure were changed repeatedly in the region in Fig. 2, the enzyme activity could be controlled reversibly over at least 10 cycles.

In conclusion, lipid-coated enzymes such as β-D-galactosidase and lipase are soluble and can catalyze transgalactosylation and esterification in supercritical CO_2. The enzyme activity was 10–15 times larger than that in conventional organic media. We could switch the enzyme activity on and off by adjusting the pressure or temperature of the CO_2 media across or within the $scCO_2$. In addition, compared with organic solvents $scCO_2$ is non-toxic and easily removed by decompression to atmospheric pressure, and thus is suitable for the biotransformation of food products and drugs. We believe that the combination of a lipid-coated enzyme and a $scCO_2$ reaction medium will form a versatile new system for biotransformation studies.

Depending on the reaction conditions and the ionic radius of the lanthanide ion, tetraphenyldisiloxanediol, $(Ph_2SiOH)_2O$, reacts with $[Ln\{N(SiMe_3)_2\}_3\{LiCl(thf)_3\}_3]$ (Ln = Eu, Gd, Sm) to afford novel heterobimetallic rare earth disiloxanediolates, some of which can be regarded as 'inorganic lanthanide metallocenes'; a ring expanded uranium(VI) derivative, $[U\{Ph_2Si(OSiPh_2O)_2\}_2\{(Ph_2SiO)_2O\}]$ 4, is formed upon treatment of uranocene, $[U(\eta^8\text{-}C_8H_8)_2]$, with $(Ph_2SiOH)_2O$.

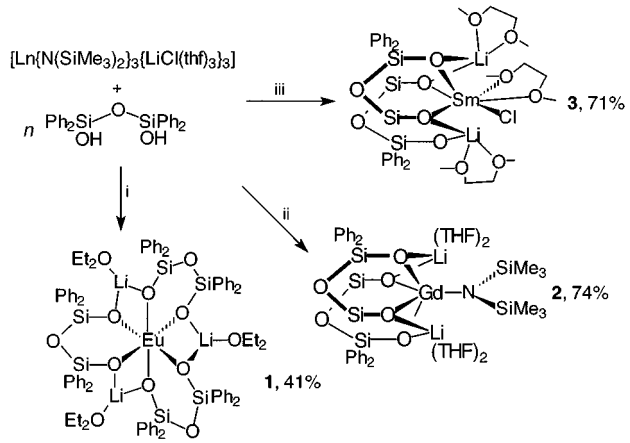
The chemistry of metallasiloxanes derived from silanediols, disiloxanediols and related Si–OH species is an area of active research[1] because such compounds are valuable precursors for metal oxides and silicates[2,3] as well as models for silica-supported heterogeneous catalysts.[1,4,5] A particularly useful ligand is the tetraphenyldisiloxanediolate dianion, $[(Ph_2SiO)_2O]^{2-}$, which gives rise to a variety of unusual and unexpected structures especially when combined with alkali metals[6] and early transition metals.[2b,6,7] Apparently this ligand has not yet been employed in f-element chemistry, with $[(C_5Me_5)_2Sm(thf)(\mu\text{-}OSiMe_2OSiMe_2O)Sm(C_5Me_5)_2(thf)]$[8] being the only closely related rare earth siloxane derivative. We report here the synthesis of novel lanthanide and uranium complexes derived from $[(Ph_2SiO)_2O]^{2-}$.

Treatment of $[Ln\{N(SiMe_3)_2\}_3\{LiCl(thf)_3\}_3]$ (Ln = Eu, Gd, Sm) (prepared from $LnCl_3$ and 3 equiv. of $LiN(SiMe_3)_2$ in thf solution[9]) with $(Ph_2SiOH)_2O$[10] in different stoichiometries afforded the new lanthanide disiloxanediolates **1**–**3** (Scheme 1). The use of *in situ* prepared lanthanide silylamide reagents in order to maintain the necessary high Li ion concentration is essential for the success of the preparations. The colorless crystalline solids have been fully characterized by elemental analyses, spectroscopic data and X-ray crystallography.§

The X-ray structure of **1** (Fig. 1) shows a heterobimetallic metallasiloxane, in which the central Eu ion is octahedrally surrounded by three mono-anionic chelating $(Et_2O)Li\{Ph_2SiO)_2O\}^-$ units.

The molecular structures of **2** and **3** (Figs. 2 and 3) are especially remarkable. Both complexes are disubstituted lanthanide metallasiloxanes comprising two lithium disiloxanediolate ligands while retaining one functional ligand [Cl or $N(SiMe_3)_2$, respectively]. The latter should make these compounds susceptible for further reactions. It is noteworthy that the outcome of these preparations depends not only on the stoichiometry but also on the size of the Ln^{3+} ion (Gd *vs.* Sm). In each case the coordination sphere of lithium is completed by addition of solvent molecules. The most striking feature of the gadolinium and samarium complexes, however, is their similarity with certain lanthanide metallocenes such as $(C_5Me_5)_2LnN(SiMe_3)_2$[11] (*cf.* **2**) or $(C_5Me_5)_2LnCl(thf)$[12] (*cf.* **3**). There is only one other report on Li-containing anionic ligands formally replacing the cyclopentadienyls in lanthanide metallocenes, *i.e.* the $[(dad)Li]^-$ units (dad = 1,4-diazadiene dianion).[13] It can be anticipated that the lithium disiloxanediolate units in the 'inorganic lanthanide metallocenes' **1**–**3** are quite robust spectator ligands owing to the presence of only Ln–O bonds.

For the synthesis of a related uranium cyclometallasiloxane the long-known sandwich complex uranocene, $[U(\eta^8\text{-}C_8H_8)_2]$,[14] was chosen as soluble starting material. Replacement of both cyclooctatetraenyl ligands upon treatment with an excess of $[(Ph_2SiOH)_2O]$ (an unprecedented reaction pathway



Scheme 1 Synthesis of complexes **1**–**3**. *Reagents and conditions*: i, Ln = Eu, n = 3, toluene–Et_2O; ii, Ln = Gd, n = 2, thf; iii, Ln = Sm, n = 2, DME (four phenyl groups in **2** and **3** have been omitted for clarity).

for uranocene) resulted in the formation of colorless [U{Ph_2-Si($OSiPh_2O$)$_2$}$_2${(Ph_2SiO)$_2$O}] **4** in 80% yield.

An X-ray structure analysis (Fig. 4) revealed the presence of a hexacoordinated uranium(VI) cyclometallasiloxane containing expanded trisiloxanediolate chelating ligands. This type of ring expansion has been reported earlier and studied in detail by Sullivan and coworkers.[7c] However, compound **4** represents the first example of a mixed-ligand complex containing both the ring expanded ligand and the original tetraphenyldisiloxanediolate dianion.

We conclude that siloxanediolate ligands derived from ($Ph_2SiOH)_2O$ are interesting new spectator ligands for f-elements which in the case of the lanthanides make inorganic analogues of synthetically useful lanthanide metallocenes available.

Infinite linear chains of Sb atoms in the novel metal-rich polyantimonides $Zr_{7.5}V_{5.5}Sb_{10}$ and $Zr_{6.5}V_{6.5}Sb_{10}$

Holger Kleinke*

FB Chemie, Philipps-Universität Marburg, D-35032 Marburg, Germany. E-mail: kleinke@mailer.uni-marburg.de

The structures of the title compounds exhibit short Sb–Sb bonds besides a multitude of bonding M–M interactions, *i.e.* the M atoms (Zr and V) in low valent states.

Partial electron transfer from the anionic to the cationic component has been used for a variety of so-called '*chimie-douce*' reactions.[1] Whereas the distances between the tellurium atoms decrease in the structures of the ditellurides from $ZrTe_2$ to $PdTe_2$ with increasing electronegativity of the metal atoms, the systematics of the Sb–Sb distances of the monoantimonides is less clear.

No Sb–Sb contacts < 350 pm occur in the structures of many monoantimonides of valence-electron poor transition metals like ScSb[2] and YSb[3] (both NaCl type), TiSb,[4] VSb[5] and NbSb[6] (all NiAs type). This may be considered as a hint to completely reduced Sb(-III). On the other hand, the structure of ZrSb[7] consists in part of puckered layers containing Sb_6 units with Sb–Sb distances of *ca*. 325 pm, which point to weak bonding interactions. This was the motivation to study Zr-rich antimonides. Here, the most metal-rich polyantimonides are presented, whose structures exhibit Sb–Sb bonds besides bonding metal–metal interactions. This observation is in contrast to related metal-rich tellurides[8] and arsenides[9] where neither Te–Te nor As–As bonds were found.

The isostructural pnictides $Zr_{7.5}V_{5.5}Sb_{10}$ and $Zr_{6.5}V_{6.5}Sb_{10}$[10] were synthesized by arc-melting of stoichiometric cold-pressed mixtures of Zr, V, and previously prepared $ZrSb_2$.[11] The metal sites are in part statistically mixed occupied by Zr and V in different ratios. The configurational entropy provides a significant contribution to the stability of these phases, which decompose during annealing at lower temperatures, namely at 900 and 1100 °C. The metal sites may be devided into two classes: the seven independent sites of the first class (white circles in Fig. 1) consist mainly of Zr atoms and form alternating triangles and rectangles parallel to the *b* axis. Five of these positions are surrounded by seven Sb atoms forming distorted pentagonal bipyramides, whereas the other two are located in pentagonal Sb_6 pyramides. The three independent positions of the second class (black circles in Fig. 1, mainly V atoms) are situated in distorted Sb_6 octahedra and Sb_5 square prisms, respectively.

Considering to a first approximation the sites of the first class solely as Zr sites and those of the second class as V sites, corresponding to a hypothetical '$Zr_7V_6Sb_{10}$', the Zr/V ratio per metal site decreases with increasing total M–Sb Pauling bond order, calculated with r_{Zr} = 145 pm, r_V = 122 pm.[12] It is concluded that the site preferences of Zr and V are mainly dominated by the different radii of the M atoms rather than by the different number of valence electrons which should influence basically only the metal–metal interactions.[13] Given the fact that $Zr_{7.7}V_{5.3}Sb_{10}$ and $Zr_{6.5}V_{6.5}Sb_{10}$ crystallize in a new structure type in addition to the occurrence of differential fractional site occupancies, these phases may be classified as typical DFSO stabilized materials,[14] being the first with the very different metal atoms, Zr and V. However, only three ($Zr_{6.5}V_{6.5}Sb_{10}$) or four ($Zr_{7.5}V_{5.5}Sb_{10}$) of the ten M sites show mixed Zr/V occupancies. On the other hand, complete ordering of the Zr and V atoms is observed in the structure of $Zr_2V_6Sb_9$.[15]

The metal atoms are interconnected *via* short metal–metal bonds with lengths between 260 and 310 pm. The majority of these interactions are found between atoms of class II parallel to [010] and between the atoms of the classes I and II, whereas only one of these relatively short bonds connects two atoms of class I, being situated in the *ac* plane [thick line in Fig. 2(a)]. The atoms of the first class form channels which include linear chains of Sb atoms with short alternating Sb–Sb distances of 280 and 288 pm for $Zr_{7.5}V_{5.5}Sb_{10}$ ($Zr_{6.5}V_{6.5}Sb_{10}$: 281 and 288 pm). It is interesting that the surrounding electropositive Zr

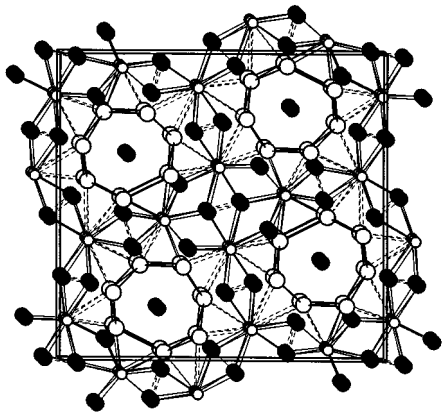

Fig. 1 Projection of the structure of $Zr_{7.5}V_{5.5}Sb_{10}$ along [010]. Large white circles: M atoms of class I (mainly Zr); small white: M atoms of class II (mainly V); medium black: Sb.

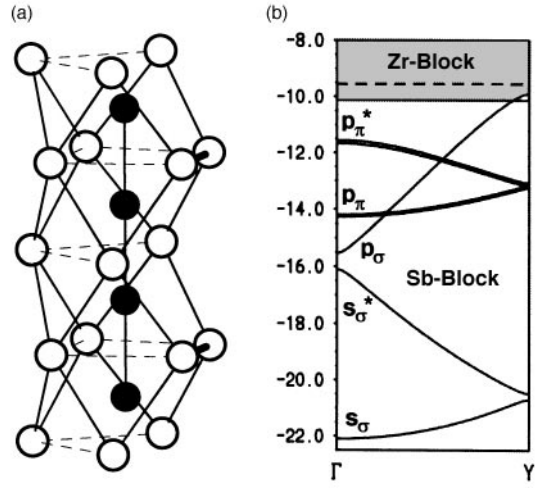

Fig. 2 (a) Part of the infinite $(Zr, V)_7Sb_2$ chain. Thick solid line between M atoms: distance d = 305 pm, thinner lines: 350 pm < d < 370 pm; dashed lines: 380 pm < d < 430 pm. (b) Schematic band structure of an infinite Zr_7Sb_2 unit.

atoms use some electrons for Zr–Zr bonds instead of reducing antimony to Sb(-III). Other Sb–Sb distances in this structure range from 330 to 350 pm (dashed lines in Fig. 1) which is comparable to the second shortest Sb–Sb bonds in elemental antimony (336 pm). Whereas the bonding character of these interactions remains questionable, the shorter distances, being shorter than in elemental antimony (291 pm), may be compared to the lengths of two-electron–two-center bonds found in other polyantimonides, namely in KSb (283 and 285 pm),[16] cyclo-Sb_5^{5-} (between 281 and 291 pm),[17] and Sb_{11}^{3-} (between 276 and 285 pm).[18]

However, the linearity of the Sb chain stands against two-electron–two-center bonds, as can be derived from a comparison with the zigzag Sb(-I) chains in KSb or the Te chains in elemental tellurium. In order to obtain more information about bonding in the Sb chain, the band structure of an infinite Zr_7Sb_2 chain with the atomic positions of the structure of $Zr_{7.5}V_{5.5}Sb_{10}$ (Fig. 2) was calculated using an extended Hückel approximation[19] with parameters listed previously.[15] As a consequence of the Peierls distortion, a gap occurs between the highly disperse p_σ and the p_σ* band of the Sb atoms. With the exception of the p_σ* band, all p states of the Sb atoms are located well below the Zr centered states [Fig. 2(b)]. Since the Zr states are partially occupied because of the bonding Zr–Zr interactions, seven bands of the two Sb atoms of the unit are completely filled, *i.e.* with two electrons per band. This leads to a formal consideration of these Sb atoms being Sb^{2-} which form (delocalized) one-electron–two-center Sb–Sb σ bonds. The latter gives a straightforward explanation for the linearity of the $^1_\infty[Sb^{2-}]$ chain, but not for the short bond lengths. The shortness of the Sb–Sb bonds is most likely a consequence of matrix effects, enabling a relatively short *b* axis and thus strong bonding metal–metal interactions parallel to the *b* axis. In a crude approximation, the formal electron counting schemes (ignoring the Sb–Sb interactions > 330 pm) of $(Zr^{4+})_{7.5}(V^{5+})_{5.5}(Sb^{2-})_2(Sb^{3-})_8(e^-)_{29.5}$ and $(Zr^{4+})_{6.5}(V^{5+})_{6.5}(Sb^{2-})_2(Sb^{3-})_8(e^-)_{30.5}$ show a multitude of electrons (*ca.* 2.3 per M atom) being available for (delocalized) M–M bonds and result in a reasonable averaged oxidation state of −2.8 for the Sb atoms.

This work was financially supported by the Bundesministerium für Bildung, Wissenschaft, Forschung und Technologie, the Deutsche Forschungsgemeinschaft, and the Fonds der Chemischen Industrie. I am grateful to Professor Dr B. Harbrecht for his interest and support.

Unexpected formation of a sterically protected nitrogen pentasulfide $ArNS_5$ (Ar = 2,6-dimesityl-4-methylphenyl) and the X-ray crystallographic analysis

Shigeru Sasaki, Hiroya Hatsushiba and Masaaki Yoshifuji*

Department of Chemistry, Graduate School of Science, Tohoku University, Aoba, Sendai 980-8578, Japan.
E-mail: yoshifj@mail.cc.tohoku.ac.jp

A stable cyclic nitrogen pentasulfide $ArNS_5$ (Ar = 2,6-dimesityl-4-methylphenyl) was unexpectedly obtained by passing the corresponding *N*-thiosulfinylaniline through a silica gel column and the chair form of the six-membered ring was revealed by X-ray crystallographic analysis.

Cyclic nitrogen polysulfides NS_x other than the eight-membered ring were not known for many years due to the lack of an appropriate method of preparation and their instability. Recently, Steudel *et al*. discovered a route to NS_x heterocycles (x = 5, 6, 8, 9, 11)[1] by using titanocene complexes, but most of them turned out to be unstable materials. On the other hand, introduction of sterically demanding groups has played an important role in the isolation of several cyclic polysulfides such as CS_x,[2] but such an attempt at kinetic stabilization of cyclic nitrogen polysulfides has not been reported. Recently, we[3] and Protasiewicz[4] have reported the synthesis of group15 element compounds such as diphosphenes and phosphaarsene possessing sterically protecting groups of the 2,6-diarylphenyl type, which have been successfully used by Power *et al.* for the stabilization of a wide range of compounds from low valent transition metals to main-group element compounds.[5] One of the noteworthy points of the 2,6-dimesityl-4-methylphenyl group is the difference of reactivity of the *ortho* substituents as compared with the widely used 2,4,6-tri-*tert*-butylphenyl group, in spite of the comparable sterically protecting effect.[3] During our systematic study on group 15 compounds possessing the 2,6-dimesityl-4-methylphenyl group, we became interested in *N*-thiosulfinylaniline **3**, since the 2,4,6-tri-*tert*-butylphenyl derivative cyclizes to form a five membered heterocycle despite the bulkiness of the *tert*-butyl group.[6] However, **3** was not so stable as expected and we obtained the stable cyclic nitrogen pentasulfide $ArNS_5$ **1** unexpectedly (Scheme 1).

2,6-Dimesityl-4-methylaniline (**2**) was prepared by $LiAlH_4$ reduction of the corresponding phenyl azide in 96%, which was synthesized from the corresponding iodobenzene by lithiation followed by quenching with *p*-toluenesulfonyl azide in 95%. Oxidation of **2** with MCPBA afforded the corresponding nitrosobenzene‡ as a stable pale green solid in 72% yield similarly to other sterically protected anilines.[7] Sulfurization of **2**† with S_2Cl_2 in the presence of triethylamine[6,8] gave a reddish purple oil, which was assigned as *N*-thiosulfinylaniline **3**. Almost quantitative formation of **3** was confirmed by ^1H NMR. However, **3** decomposed during attempted purification by column chromatography (SiO_2–*n*-hexane) and cyclic nitrogen pentasulfide **1** was isolated in 21% as a yellow solid. *N*,*N*′-Bis(2,6-dimesityl-4-methylphenyl)sulfurdiimide **4** (10%) was another identified product and 61% of aniline **2** was recovered. Pale yellow prisms suitable for X-ray crystallographic analysis were obtained after recrystallization from *n*-hexane.§

Fig. 1 shows the molecular structure of **1**. The NS_5 ring takes a chair form like CS_5,[9] S_6,[10] and TiS_5[11] heterocycles and the torsion angles within the six-membered ring range from 67.42(5) to 74.88(8)°, which deviate markedly from values of *ca.* 100° of the stable eight-membered rings such as HNS_7[12] and S_8.[13] On the other hand, the bond lengths and angles do not differ greatly from those for HNS_7.[12] The nitrogen atom takes almost planar geometry with the sum of the bond angles around N(1) as 359.57°, and the dihedral angle between the plane

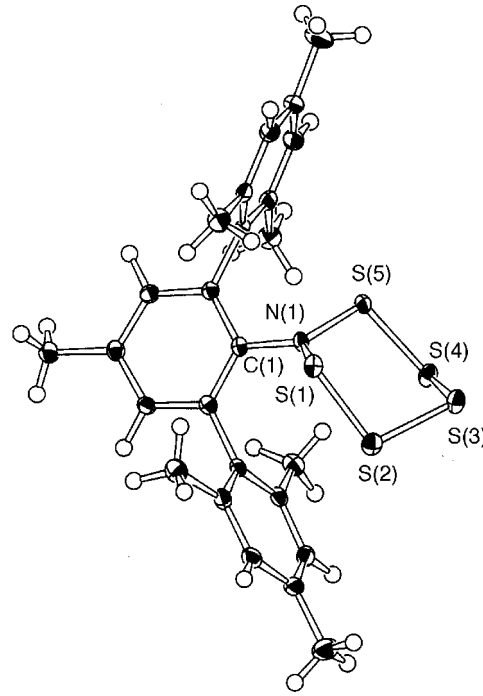

Fig. 1 Molecular structure of **1** in the crystal. ORTEP drawing with 50% probability ellipsoids. Selected bond lengths (Å), bond angles (°), and torsion angles (°): S(1)–N(1) 1.699(1), S(1)–S(2) 2.0612(7), S(2)–S(3) 2.0803(6), S(3)–S(4) 2.0718(6), S(4)–S(5) 2.0704(7), S(5)–N(1) 1.700(1), N(1)–C(1) 1.442(2), S(2)–S(1)–N(1) 104.40(5), S(1)–S(2)–S(3) 100.89(3), S(2)–S(3)–S(4) 99.14(2), S(3)–S(4)–S(5) 102.12(2), S(4)–S(5)–N(1) 104.01(5), S(1)–N(1)–S(5) 116.01(8), S(1)–N(1)–C(1) 121.61(10), S(5)–N(1)–C(1) 121.95(10), S(1)–S(2)–S(3)–S(4) –70.01(3), S(1)–N(1)–S(5)–S(4) 73.29(8), S(2)–S(1)–N(1)–S(5) –74.88(8), S(2)–S(3)–S(4)–S(5) 69.64(3), S(3)–S(2)–S(1)–N(1) 69.20(5), S(3)–S(4)–S(5)–N(1) 69.20(5).

defined by N(1), S(1), S(5), and C(1) and the central benzene ring is 55.07°. The NS_5 ring aligns in the direction of the *b* axis with the short contact less than the sum of van der Waals radii between S(2) and S(5*), S(1) and S(4*) of the neighboring molecules (marked with*), being 3.4102(6) and 3.6219(6) Å, respectively. Although the mechanism of the formation of **1** is not clear at present, oligomerization (stoichiometrically trimerization) of *N*-thiosulfinylaniline **3** followed by elimination of a stable sulfurdiimide **4** might afford **1**, since the electrophilicity of **3** might be enhanced by an acid on the silica gel surface. The ring size could depend on the steric demand or the cavity size made by the two mesityl groups.

The authors are grateful for financial support in part from The Japan Securities Scholarship Foundation and Grants-in-Aid for Scientific Research from the Ministry of Education, Science, Sports and Culture (Nos. 08454193 and 09239101). The authors also thank Instrumental Analysis Center for Chemistry, Graduate School of Science, Tohoku University for the measurement of mass spectra.

Notes and References

† To a solution of **2** (300 mg, 0.873 mmol) in a mixture of triethylamine (0.3 ml, 2.15 mmol) and diethyl ether (15 ml), a solution of disulfur dichloride (0.09 ml, 1.13 mmol) in diethyl ether (10 ml) was added dropwise at 0 °C to give a red mixture. After being stirred for 1 h at 0 °C, the reaction mixture was poured into ice-water, extracted with diethyl ether, dried over $MgSO_4$, and concentrated to give crude **3** as a red oil almost quantitatively. The oil was submitted to silica-gel column chromatography (gradient elution with *n*-hexane and chloroform) to give **1** (21%) and **4** (10%), together with recovery of **2** (61%). Further recrystallization of **1** from *n*-hexane afforded pure **1** as yellow prisms. **3**: reddish brown oil; ^{1}H NMR (200 MHz, $CDCl_3$) δ 7.05 (2H, s, arom.), 6.87 (4H, s, Mes-arom.), 2.43 (3H, s, CH_3), 2.28 (6H, s, Mes-*p*-CH_3), 2.10 (12H, s, Mes-*o*-CH_3); LRMS (EI, 70 eV) *m/z* 405 (M^+, 8), 341 ($M^+ - 2S$, 62), 326 ($M^+ - 2S - CH_3$, 100), 311 ($M^+ - 2S - 2CH_3$, 25); UV–VIS (CH_2Cl_2) λ_{max} 465 nm. **1**: yellow prisms; mp 133.0–134.0 °C; ^{1}H NMR (200 MHz, $CDCl_3$) δ 7.04 (4H, s, Mes-arom.), 6.84 (2H, s, arom.), 2.37 (6H, s, Mes-*p*-CH_3), 2.34 (3H, s, CH_3), 2.10 (12H, s, Mes-*o*-CH_3); ^{13}C NMR (50 MHz, $CDCl_3$) δ 145.3, 137.6, 137.5, 137.5, 136.4 , 130.7, 128.7, 21.3, 21.2, 20.9 (one quarternary carbon peak was missing at 295 and 323 K, probably due to dynamic behavior); IR (KBr) 3016, 2947, 2916, 2854, 1612, 1452, 1444, 1423, 1375, 1205, 1182, 1039, 1030, 870, 849, 758 cm^{-1}; UV–VIS (hexanes) $\lambda_{max}(\varepsilon)$ 246.4 (17900) nm ; LRMS (EI, 70 eV) *m/z* 501 (M^+, 0.4), 405 ($M^+ - 3S$, 6), 373 ($M^+ - 4S$, 5), 341 ($M^+ - 5S$, 58), 326 ($M^+ - 5S - CH_3$, 100), 311 ($M^+ - 5S - 2CH_3$, 24), 296 ($M^+ - 5S - 3CH_3$, 11); HRMS (EI, 70 eV) Found: *m/z* 501.0757, calc. for $C_{25}H_{27}NS_5$: *M* 501.0748.

Cleavage of a phosphorus carbon triple bond in the reaction of 2,2-dimethylpropylidynephosphine with $[Os_3(CO)_{10}(\mu_3\text{-}\eta^1:\eta^2:\eta^1\text{-}C_2Me)]$

Mathias Nowotny,[a] Brian F. G. Johnson,*[a] John F. Nixon[b] and Simon Parsons[c]

[a] *University Chemical Laboratories, Lensfield Road, Cambridge, UK CB2 1EW. E-mail: bfgj1@cam.ac.uk*

[c] *Department of Chemistry, University of Edinburgh, West Mains Road, Edinburgh, UK EH9 3JJ*

The reaction of 2,2-dimethylpropylidynephosphine with the cluster $[Os_3(CO)_{10}(\mu_3\text{-}\eta^1:\eta^2:\eta^1\text{-}C_2Me)]$ 1 results in P–C bond cleavage and an insertion of the precoordinated but-2-yne ligand into the phosphorus carbon triple bond of the incoming phosphaalkyne with formation of a novel bridging C_3P-moiety in the structurally characterised complex $[Os_3(CO)_8(\mu_2\text{-}PCBu^t)\{\mu_3\text{-}PC(Me)C(Me)C(Bu^t)\}]$ 2, together with a second $\mu_2\text{-}\eta^2,\eta^2$-ligated phosphaalkyne.

The coordination chemistry of phosphaalkynes RC≡P is of current interest and its similarity to the coordination behaviour of alkynes has been summarised in several recent reviews.[1] In particular, the use of phosphaalkynes as alkyne-like building blocks in the formation of phosphorus containing unsaturated ring systems is of considerable synthetic use.[1,2] Despite several examples of controlled alkyne–alkyne coupling reactions at polynuclear carbonyl clusters,[3] in all our previous attempts to achieve an oligomerisation of phosphaalkynes in the coordination sphere of triruthenium and triosmium carbonyl clusters, we isolated products exclusively resulting from a carbonylation of the incoming $Bu^tC{\equiv}P$ to afford the phosphinidene ligand μ_3-PC(CO)Bu^t, *e.g.* in the complexes $[M_3(CO)_9\{\mu_3\text{-}PC(CO)Bu^t\}_2]$ (M = Ru, Os) and their derivatives.[4] The thermodynamic sink represented by the formation of these complexes is apparently efficient enough to prevent any phosphaalkyne oligomerisation. In an attempt to avoid this dominating pathway and also to facilitate alkyne-like reactions, we decided to modify the reaction system by introducing a precoordinated alkyne unit, a strategy that also proved to be successful in case of an Ir_4 carbonyl cluster system.[5] Here, we wish to present the results of the reaction between 2,2-dimethylpropylidynephosphine and the alkyne cluster $[Os_3(CO)_{10}(\mu_3\text{-}\eta^1,\eta^2,\eta^1\text{-}C_2Me_2)]$ **1**.

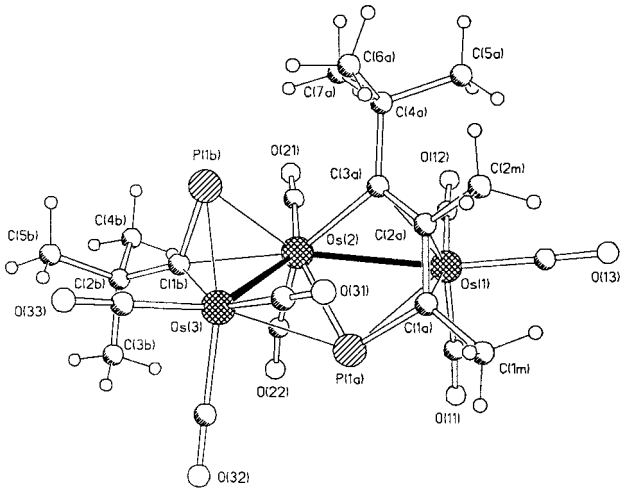

Fig. 1 Molecular structure of $[Os_3(CO)_8(\mu_2\text{-}PCBu^t)\{\mu_3\text{-}PC(Me)C(Me)C(Bu^t)\}]$ **2** with atom numbering scheme. The carbonyl carbon atoms bear the same numbers as the respective oxygen atoms. Selected bond lengths (Å) and angles (°): Os(1)–Os(2) 2.8130(8), Os(2)–Os(3) 2.8217(7), Os(1)–P(1A) 2.701(3), Os(2)–P(1A) 2.368(3), Os(3)–P(1A) 2.666(3), Os(1)–C(1A) 2.227(11), Os(1)–C(2A) 2.271(12), Os(1)–C(3A) 2.283(12), Os(2)–C(3A) 2.209(12), P(1A)–C(1A) 1.790(12), C(1A)–C(2A) 1.42(2), C(2A)–C(3A) 1.43(2), C(1A)–C(1M) 1.501(14), C(2A)–C(2M) 1.53(2), C(3A)–C(4A) 1.56(2), Os(2)–P(1B) 2.423(3), Os(2)–C(1B) 2.257(12), Os(3)–P(1B) 2.424(3), Os(3)–C(1B) 2.111(11), P(1B)–C(1B) 1.731(12), C(1B)–C(2B) 1.53(2), mean Os–C(CO) 1.929(25), mean C(CO)–O(CO) 1.141(18); Os(1)–Os(2)–Os(3) 117.09(2), P(1A)–Os(2)–Os(1) 62.14(8), P(1A)–Os(2)–Os(3) 61.08(8), C(3A)–Os(2)–P(1A) 83.8(3), C(3A)–Os(2)–Os(1) 52.4(3), C(1A)–P(1A)–Os(1) 55.1(4), C(1A)–P(1A)–Os(2) 99.8(4), C(1A)–P(1A)–Os(3) 108.8(4), P(1A)–C(1A)–C(2A) 118.4(8), P(1A)–C(1A)–C(1M) 116.8(8), C(2A)–C(1A)–C(1M) 123.6(11), C(1A)–C(2A)–C(3A) 120.8(11), C(1A)–C(2A)–C(2M) 114.0(10), C(3A)–C(2A)–C(2M) 125.2(10), C(2A)–C(3A)–C(4A) 119.6(11), C(1B)–Os(2)–Os(3) 47.5(3), C(1B)–Os(2)–P(1B) 43.2(3), P(1B)–Os(2)–Os(3) 54.41(7), C(2B)–C(1B)–P(1B) 132.3(9).

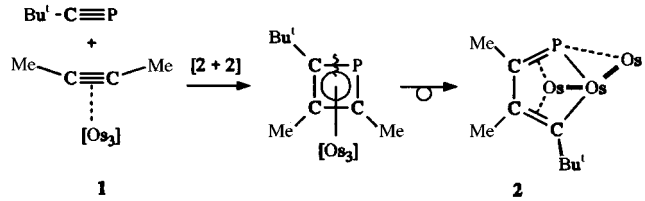
The reaction of cluster **1** with 1 equiv. of $Bu^tC{\equiv}P$ in refluxing CH_2Cl_2 resulted in the formation of cluster $[Os_3(CO)_8(\mu_2\text{-}PCBu^t)\{\mu_3\text{-}PC(Me)C(Me)C(Bu^t)\}]$ **2**, which was formulated on the basis of spectroscopic data† and the results of a single crystal structure analysis.‡

In addition to an edge-bridging $\mu_2\text{-}\eta^2:\eta^2$-coordinated phosphaalkyne moiety, this unusual complex bears an additional ligand formed by the coupling of the initial $\mu_3\text{-}\eta^1:\eta^2:\eta^1$-butyne ligand with a second phosphaalkyne molecule. The insertion of this ligand into the bond between Os(1) and Os(3) opens the metal triangle forming a bent three metal chain, with the phosphorus atom P(1a) bridging all three osmium atoms.

Together with the central osmium atom Os(2), this ligand forms a 1-osma-2-phosphacyclopentadiene ring which binds to the terminal osmium atom Os(1) in the η^5-coordination mode. This central five membered ring is essentially planar with the atoms deviating from the best plane by ±0.0579 Å.

It is of special significance, that it is not the ring carbon atom C(1a) vicinal to the phosphorus atom P(1a) which bears the Bu^t substituent of the former phosphaalkyne moiety but carbon atom C(3a). Therefore, the phosphorus carbon triple bond of this precursor is completely cleaved during the course of the reaction leading to the formation of **2**, and a plausible explanation for this finding is represented in Scheme 1. The insertion of the osmium atom Os(2) into a phosphorus carbon bond of an intermediate phosphacyclobutadiene ligand, formed in a [2 + 2]-cycloaddition of the but-2-yne and the phosphaalkyne, leads to the formation of the observed 1-osma-2-phospha-



Scheme 1 Hypothetical mechanism for the formation of the $\{\mu_3\text{-}PC(Me)C(Me)C(Bu^t)\}$-subunit in **2**

cyclopentadiene ring. There are relatively few examples of co-cyclodimerization reactions of alkynes and phosphaalkynes at transition metal centres resulting in phosphacyclobutadiene metal complexes that are comparable to the proposed intermediate.[6] Although no information regarding the detailed mechanism outlined in Scheme 1 is available, it is interesting to note that, since only one regioisomer is isolated, insertion into the proposed phosphacyclobutadiene intermediate occurs exclusively at the bond between the phosphorus and the carbon atom bearing the Bu^t substituent.

The fact that the basic open Os_3-triangle in the framework of **2** requires a total of 50 valence electrons with a contribution of four valence electrons from the second μ_2-η^2,η^2-coordinated phosphaalkyne ligand indicates that the central ligand formed by the coupling of butyne and Bu^{t}C≡P acts as a six electron donor. Therefore, it can be concluded that the lone pair centred on P(1a) does not contribute to the cluster framework. The coordination around phosphorus atom P(1a) can be described as a distorted square based pyramid with the three osmium atoms forming the base together with the carbon atom C(1a), while the lone pair of P(1a) points into the direction of the apex.

While the distances between Os(2) and either P(1a) or C(3a) are 2.368(3) and 2.209(12) Å, respectively, lying within the range of normal Os–P and Os–C single bonds,[7] the distances between P(1a) and either Os(1) or Os(3) are *ca.* 30 pm longer than the average [2.701(3) and 2.666(3) Å, respectively]. This indicates a very unusual bonding situation because steric reasons for the observed bond lengthening can be excluded at least in the case of the interaction between Os(3) and P(1a).

The second phosphaalkyne ligand in **2** bridges Os(2) and Os(3) in the μ_2-η^2,η^2-coordination mode with the participation of both P–C π-MOs. The P–C distance of the side on coordinated phosphaalkyne is 1.731(12) Å, which is too short for the expected single bond but easily fits the range of typical P–C double bonds.[7] The Bu^t substituent on the methylidyne carbon atom C(1b) bends away from the osmium atoms as a result of a rehybridisation caused by the coordination, thereby reducing the angle P(1b)–C(1b)–C(2b) from 180° in the free phosphaalkyne to 132.3(9)°. Similar features have been reported for the only other structurally characterized example of a side on-coordinated phosphaalkyne ligand, [$Mo_2Cp_2(CO)_4$(μ_2-η^2 : η^2-PCBu^t)],[8] where the P–C distance is 1.719(3) Å and the P–C–C angle 127.9(3)°.

We thank the Deutsche Forschungsgemeinschaft (Bonn, Bad Godesberg) for a postdoctoral fellowship (M. N.) and the EPSRC for support.

† *Synthesis of* **2**: A mixture of 37.9 mg (0.042 mmol) [$Os_3(CO)_{10}$(μ_3-η^1 : η^2 : η^1-C_2Me_2)] **1**[9] and 4.2 mg (0.042 mmol) 2,2-dimethyl-propylidyne-phosphine[10] in 50 ml of dry CH_2Cl_2 was heated under reflux for 24 h under an inert atmosphere. After filtration and concentration *in vacuo*, **2** was separated from unreacted starting material by thin layer chromatography [silica gel, CH_2Cl_2–hexane (3 : 7)] as the only major product (6%). Yellow crystals suitable for X-ray crystallography were grown by vapor diffusion of hexane into a CH_2Cl_2 solution. ^{1}H NMR [$(CD_3)_2CO$], δ 1.43 (s, 9H, Bu$^{t(b)}$), 1.60 (s, 9H, Bu$^{t(a)}$), 2.41 (s, 3H, Me^{2m}), 2.68 (s, 3H, Me^{1m}); ^{31}P NMR ($CDCl_3$), δ −118.0 (P^{1b}), 229.7 (P^{1a}); IR (CH_2Cl_2), ν_{CO} 2080s, 2050vs, 2023s, 2014s, 1993m, 1970m cm^{-1}; FABMS (MeCN/3-noba), *m/z* 1054 − 28*n*, 0 ≤ *n* ≤ 8, [M − *n* CO]$^+$.

‡ *Crystal data* for **2**·0.5 CH_2Cl_2: $C_{22}H_{24}O_8Os_3P_2$ + 0.5 CH_2Cl_2, M_w = 1091.41, monoclinic, space group *C*2/*c*, *a* = 31.052(4), *b* = 11.315(2), *c* = 17.258(2) Å, β = 108.394(10)°, *U* = 5753.9(13) Å^3, *Z* = 8, D_c = 2.520 Mg m^{-3}, *T* = 150 ± 2 K, *F*(000) = 3992, μ(Mo-Kα) = 13.463 mm^{-1}, yellow needle, 0.23 × 0.08 × 0.06 mm. Intensities of 5861 reflections were collected between 2.73 ≤ θ ≤ 25.06° on a STOE Stadi 4 diffractometer using Mo-Kα radiation (graphite monochromator, ω scan mode). Absorption corrections were applied using ψ-scan data: T_{min} = 0.136, T_{max} = 0.224. The structure was solved by direct methods[11] and refined by full-matrix least-squares on F^2. A molecule of CH_2Cl_2 lies disordered over four positions about the crystallographic two-fold axes (two unique orienations plus their symmetry equivalents; *Z* for the CH_2Cl_2 is thus 4, compared to 8 for the Os cluster and hence this is the hemidichloromethane solvate). The occupancy ratio of the unique molecules refined to 0.29 : 0.21(1), with two common isotropic displacement parameters being respectively refined for the C and Cl atoms. The positional parameters were refined subject to explicit geometry restraints [C–Cl 1.80(2), Cl–Cl 2.93(2) Å]. All other non-H atoms were refined freely with anisotropic displacement parameters.[12] Final *R* values: R_1 = 0.0418 and wR_2 = 0.0805 [based on F^2 and 5082 data with $I > 2\sigma(I)$ and 345 parameters]. The final Fourier difference map showed no residual density outside of −1.378 and 1.303 e Å^{-3}. CCDC 182/1010.

Synthesis and electrochemical properties of new star-shaped thiophene oligomers and their polymers

Frédéric Cherioux,*† Laurent Guyard and Pierre Audebert‡

Laboratoire de Chimie et Electrochimie Moléculaire, Université de Franche-Comté, UFR Sciences, 16, route de Gray, F-25030 BESANCON Cedex, France

The efficient synthesis of some 2,4,6-tris[5-(2,2′-bithienyl)]-1,3,5-triazines and 1,3,5-tris[5-(2,2′-bithienyl)]benzenes and their electrochemical properties are discussed.

Branched conducting polymers with electronically connected nodes are excellent candidates among the family of super-structured conducting polymers. In fact, with such polymers, there should be no need for interchain coupling or interchain electronic transfer in order to insure high electronic conductivity.[1] Moreover, this type of material possesses a three dimensional structure which could also assist the conductivity.

There are few previous reports of this type of conducting polymer because the starting precursors are difficult to synthesise. Previous approaches[2] were made to reticulated conducting polymers, but electronic conjugation was only weakly, or not at all, insured through the nodes. Also, star-shaped oligomers were used but in low proportions to prepare polythiophene gels which were no longer soluble in classical solvents and had high degrees of swelling.[3]

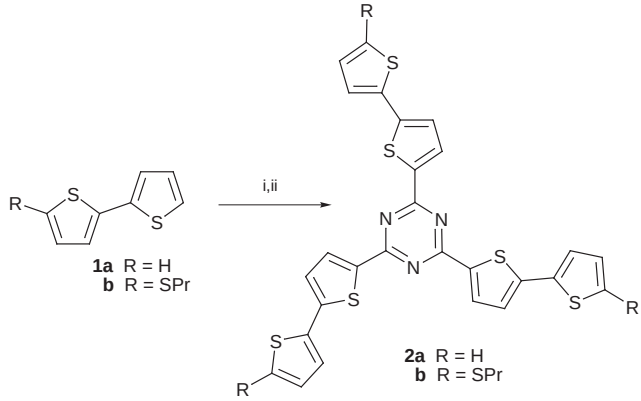
Here we present an efficient method for the synthesis of some 2,4,6-tris[5-(2,2′-bithienyl)]-1,3,5-triazine or 1,3,5-tris[5-(2,2′-bithienyl)]benzene derivatives which are precursor of two-dimensional conducting polymers. Their electrochemical properties have been investigated. A new polymer has been synthesised *via* chemical or electrochemical oxidation of 1,3,5-tris[5-(2,2′-bithienyl)]benzene and the charge transfer kinetics inside has been determined by chronoamperometry experiments.

The 2,4,6-tris[5-(2,2′-bithienyl)]-1,3,5-triazine derivatives **2** were obtained by a triple aromatic nucleophilic substitution of 2,2′-dithienyllithium salts on cyanuric chloride (see Scheme 1). This reaction is very efficient[4] because such substitutions are activated by the mesomer attractive power of the nitrogen atoms, which stabilises the intermediate species. So, 3 equiv. of 2,2′-dithienyllithium salt were added in one portion to 1 equiv. of cyanuric chloride in THF. The crude products were purified by column chromatography with light petroleum–CH_2Cl_2 (1 : 1) as eluent. Only the tri-substituted products **2**§ were formed with yields close to 90% (**2a**: 95%, **2b**: 90%).

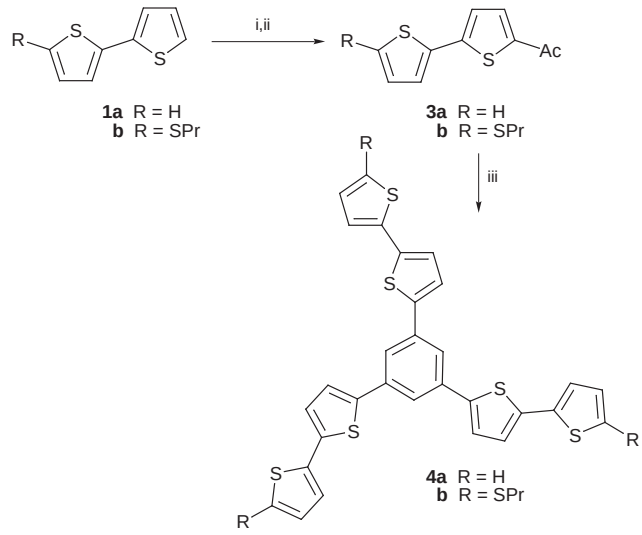
However, the tris(2,2′-bithienyl)benzene derivatives **4** were synthesised *via* an another route, as aromatic nucleophilic substitution on an inactivated benzene is very difficult. Moreover, there is only one report in the literature of 1,3,5-trisubstitution on a tri-substituted benzene.[5] Therefore, we adapted a recently described procedure based on a triple ketolisation and dehydration of an aromatic methyl ketone with tetrachlorosilane (TCS)–EtOH.[6] However, this method was developed to afford β-methylchalcone stereoselectively, without polymer formation. The authors obtained some 1,3,5-triarylbenzene derivatives as side products. We modified this reaction so that the major products were the 1,3,5-triarylbenzene derivatives. This was achieved using 5 rather than 1 equiv. of TCS, and increasing the reaction time from the 2–4 h given in the original paper to 18 h. Thus the more general character of this method is demonstrated.

The 5-(2,2′-bithienyl) methyl ketone **3** is made *via* the action of 2,2′-dithienyllithium salts on *N*,*N*-dimethylacetanilide (see Scheme 2). TCS–EtOH (5 equiv.) was added to 5-(2,2′-bithienyl) methyl ketone in anhydrous toluene under nitrogen atmosphere. The mixture was stirring of 18 h at room temperature (see Scheme 2). It was then poured in water, extracted with CH_2Cl_2, and the organic phase was separated, dried, and the solvent removed under reduced pressure. The residue was purified by column chromatography with light petroleum–CH_2Cl_2 (1:1) as eluent. The pure products **4**§ were obtained with good yield (**4a**: 65%, **4b**: 55%).

All the thiophene oligomers described are electrochemically oxidizable. In the cases of the oligomers **2a** and **4a** (with unblocked α-positions), entirely irreversible voltamograms are obtained whatever the scan rate up to 1000 V s^{-1} (peak



Scheme 1 *Reagents and conditions*: i, Bu^{n}Li; ii, 2,4,6-trichloro-1,3,5-triazine



Scheme 2 *Reagents and conditions*: i, Bu^{n}Li; ii, DMA; iii, TCS, EtOH, 18 h, room temp.

potentials at 1 V s^{-1} are 1.41 and 1.02 V *vs*. SCE for **2a** and **4a**, respectively). This demonstrates the very high reactivity of the electrogenerated cation radicals despite the presence of seven aromatic rings. On the other hand, as expected with oligomers **2b** (oxidation peak potential 1.27 V *vs*. SCE at 1 V s^{-1}) and **4b** [redox potentiel $E°$ (half sum of reversible peaks in CH_2Cl_2) of 1.00 V *vs*. SCE is obtained], a return peak is obtained in all cases. As a consequence of the presence of the propylthio group blocking the α-positions, the cation radicals cannot undergo either coupling nor nucleophilic attack due to the steric hindrance of the substituents. It is possible to obtain a standard reversible voltamogram with the benzenic derivative **4b** in CH_2Cl_2. However, in the case of the triazine **2b**, the return peak always features the oxidation of an adsorbed species whatever the solvent, showing that the propyl chains on sulfur are not sufficient in this case to insure sufficient solubility of the electrogenerated cation radical. Similarly in MeCN the cation radical of **4b** also precipitates. The irreversible dication formation is also observable at potentials of 2.13 and 1.97 V *vs*. SCE for **2b** and **4b**, respectively.

Upon oxidation of **2a**, no polymer formation was observed whatever the conditions, therefore probably the cation radicals favour nucleophilic attack on the s-triazine nitrogen atoms to coupling. Conversely the oxidation of **4a** gives an electrodeposited polymer, which displays electroactive characteristics analogous to polythiophene, with a broad reversible peak at an average potential of 0.9 V *vs*. SCE. Chronoamperometry was performed on average thickness films (300 nm) and the diffusion coefficient of the charge transfer is equal to 2×10^{-8} cm^2 s^{-1} (on the basis of one electron for every four thiophene units and a density of 1.5 g cm^{-3}) which is in accordance with values obtained with other conducting polymers.[7] Owing to the ease of the monomer synthesis, larger quantities of polymer can be made by chemical polymerisation with iron(III) chloride. The electrochemical behaviour of the blocked oligomers, especially π-dimer formation, is also being studied.

Diferrocenyl diselenides: excellent thiol peroxidase-like antioxidants

G. Mugesh,[a] Arunashree Panda,[a] Harkesh B. Singh,*[a] Narayan S. Punekar[b] and Ray J. Butcher[c]

[a] *Department of Chemistry, Indian Institute of Technology, Powai, Bombay 400 076, India. E-mail: chhbsia@chem.iitb.ernet.in*

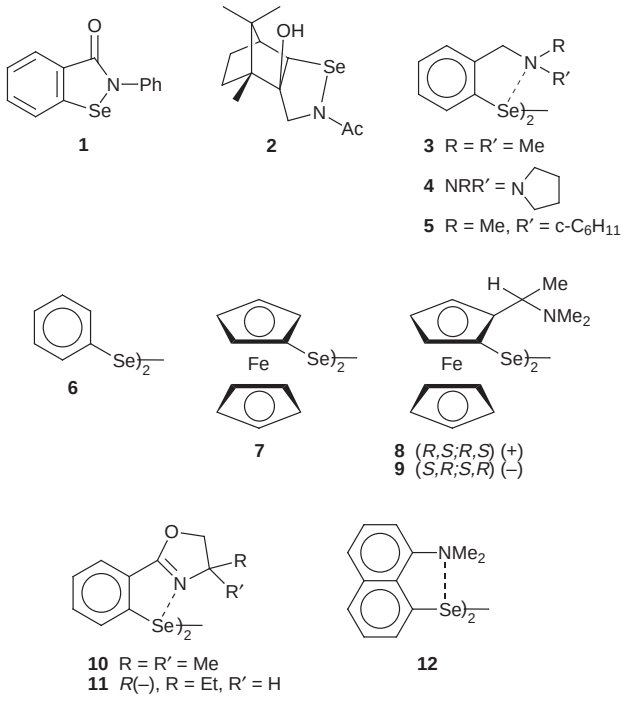
Synthesis, structure and thiol peroxidase-like antioxidant activity of several diaryl diselenides having intramolecularly coordinating amino groups are described; the diselenides having both tertiary amino groups and redox-active ferrocenyl units show excellent peroxidase activity.

Glutathione peroxidase (GPX) is a well known selenoenzyme which functions as an antioxidant.[1] This selenoprotein catalyses the reduction of harmful peroxides by glutathione and protects the cell membrane from oxidative damage. Recently, much attention has been devoted to the synthesis of simple organoselenium compounds that mimic the action of GPX. After the discovery of Ebselen **1**,[2] several other mimetics have been reported which include the Ebselen homologue,[3] benzoselenazolinones,[4] selenenamide **2**[5a] and related derivatives,[5b] diaryl diselenides,[6] various tellurides and ditellurides,[7] and the enzyme selenosubtilisin.[8]

Recently, diaryl diselenides **3**–**5** with basic amino groups have attracted much attention as GPX mimics because the Se···N intramolecular non-bonded interactions, (i) activate the Se–Se bond towards the oxidative cleavage and, (ii) stabilize the resulting selenenic acid intermediate against further oxidation.[6] In continuation of our work on intramolecularly coordinated organochalcogens,[9] we report here the synthesis, structure and thiol peroxidase activity of a series of closely related novel diselenides **7**–**12**.



Diselenides **3**,[9a] **7**,[10] **8**,[11] and **9**[11] used in the present study were prepared by the methods indicated. Novel diselenides **10**–**12** were prepared by the ortholithiation method.† The structures of **8**, **10**, **11** and **12** were determined by X-ray diffraction.‡ The catalytic activity was studied according to the method reported by Tomoda and coworkers[6b] using benzenethiol (PhSH) as a glutathione alternative. The initial rates (v_0) for the reduction of H_2O_2 (3.75 mM) by thiol (1 mM) in the presence of various catalysts (0.01 mM) [eqn. (1)] were determined in methanol medium by monitoring the UV absorption at 305 nm due to the formation of diphenyl disulfide (PhSSPh).

$$H_2O_2 + 2PhSH \xrightarrow{\text{Catalyst}} 2H_2O + PhSSPh \qquad (1)$$

Diselenide **6** showed a slight enhancement in the rate (v_0 = 0.55 ± 0.18 μmol dm^{-3} min^{-1}) as compared with the uncatalyzed rate (v_0 = 0.15 ± 0.04 μmol dm^{-3} min^{-1}). Ferrocene was inactive, however, *N*,*N*-dimethyl(ferrocenylethyl)amine, a ferrocene compound containing a basic amino group showed a much better activity (v_0 = 3.16 ± 0.52 μmol dm^{-3} min^{-1}). The rate (v_0 = 3.83 ± 0.32 μmol dm^{-3} min^{-1}) observed for **6** together with *N*,*N*-dimethyl(ferrocenylethyl)amine was equal to the sum of the rates observed for the individual cases (v_0 = 3.71 ± 0.70 μmol dm^{-3} min^{-1}). There was a significant improvement in the activity when the phenyl groups in **6** were replaced by redox active ferrocenyl groups, **7** (v_0 = 3.39 ± 0.37 μmol dm^{-3} min^{-1}). The activity of **7** could not be enhanced by the addition of *N*,*N*-dimethyl(ferrocenylethyl)amine as the rate of the mixed case (v_0 = 5.78 ± 0.79 μmol dm^{-3} min^{-1}) was almost equal to the sum of their rates in the individual cases (v_0 = 6.55 ± 0.45 μmol dm^{-3} min^{-1}). The initial rate in the presence of crystalline Wilson's catalyst (**3**), which has been previously used as liquid or HCl salt,[6a] was 28.38 ± 3.88 μmol dm^{-3} min^{-1}. Surprisingly, under similar conditions, the initial rates for the redox-active diselenides **8** and **9** were 574.01 ± 23.98 and 466.49 ± 28.26 μmol dm^{-3} min^{-1}, respectively. Diselenides **10**, **11** and **12** did not show any noticeable activity under identical conditions.

Almost 18 fold enhancement in the initial reduction rate of **8** and **9** compared with the Wilson's catalyst and *ca*. 900 fold enhancement compared with PhSeSePh under identical experimental conditions was observed. Although compounds **3**, **8** and **9** have similar amino groups, the large increase in the activities of **8** and **9** as compared with **3** indicates that the presence of redox-active group is crucial for high peroxidase activity of **8** and **9**. On the other hand, while compound **7** is much more reactive than **6**, the observation that **7**, whose redox potential§ is as low as those of **8** and **9**, is much less reactive than **8** or **9** clearly suggests that the nearby nitrogen moiety should be equally responsible for activity enhancement of **8** and **9**. In other words, these two functionalities (tertiary amino and redox-active) individually show moderate effects on the activity, however, when present together (**8** and **9**), the effect is synergistic.

The Se···N interaction of an intermediate strength (2.856 and 2.863 Å) in **3** shows moderate effect on the activity whereas, the most active compounds **8** and **9** do not have any such interactions in the solid state as the Se···N bond lengths (3.697 and 4.296 Å for **8**; 3.98 and 4.12 Å for **9**[11b]) are greater than the

sum of their van der Waals radii (3.54 Å). However, the activity of **8** and **9** cannot be regarded as evidence for unimportance of nearby nitrogen since the nitrogen atoms present in the compounds may come closer to the selenium in solution. The inactivity of **10**, **11** and **12** [in which the Se···N interactions are quite strong; **10** (2.705, 2.891 Å), **11** (2.778, 2.794 Å) and **12** (2.628, 2.652 Å)], may be ascribed not only to steric effect, but also to the nature of the nitrogen lone pairs which are either imine lone pair (**10**, **11**) or a lone pair in π-conjugation (**12**), suggesting that they are not basic enough to incorporate in the redox cycle.

In conclusion, we observe that the diselenides which have quite strong Se···N intramolecular interactions do not show any noticeable activity whereas the diselenides which have in-built coordinating basic amino group but do not have Se···N interaction show excellent activity. Secondly, the diselenides in which the selenium atom is directly bonded to a redox active group (ferrocenyl) show a dramatic increase in the peroxidase activity thus supports the supposition made by Back and Dyck.[5a]

We are grateful to the Royal Society of Chemistry, London for funding this work. R. J. B. wishes to acknowledge the DoD-ONR program for funds to upgrade the diffractometer.

A photocatalytic surface reaction—the decomposition of a submonolayer of stearic acid mediated by a rutile TiO_2 (110) single crystal—is examined by atomic force microscopy and the results reveal that the reaction occurs at substantially distinct rates at randomly distributed nanoscale surface sites.

The photocatalytic properties of TiO_2 are very interesting and are utilised in many situations. For example, ultraviolet irradiation of TiO_2 produces an amphiphilic surface with both antifogging and self-cleaning properties.[1–3] TiO_2 photocatalytic reactions, like many other surface reactions, have been studied for many years by macroscopic techniques such as vibrational spectroscopy. However, in the last decade, scanning probe techniques such as atomic force microscopy (AFM) have brought new insight on the morphology and molecular structure and periodicity of surfaces. In the present study, we examine the surface reactivity of rutile TiO_2 (110) during the photodecomposition of monolayer islands of stearic acid ($C_{17}H_{35}COOH$) using the AFM.

The submonolayer film of stearic acid was deposited onto a clean and polished rutile TiO_2 (110) single crystal substrate by way of the Langmuir–Blodgett (LB) technique. Film transfer was performed at 15 mN m^{-1} (area ≈ 0.201 nm^2 $molecule^{-1}$) at 20 °C in a clean room. The obtained film was imaged by contact-mode AFM (Seiko Instruments: SPA300 AFM system with a SPI3700 controller) under ambient conditions (T ≈ 20 °C, relative humidity = 40%) using a commercially available triangular Si_3N_4 sharpened cantilever. The force between the tip and sample was typically 1 nN. The UV light source was a Hypercure 200 UV lamp (Yamashita Denso, long wave UV λ_{max} ≈ 365 nm) equipped with a light guide. Incident UV light intensity (measured using a UV radiometer: Topcon UVR-1) at the sample surface was *ca*. 2.5 mW cm^{-2}. In a typical experiment, the tip was withdrawn from the sample before UV light irradiation. After irradiating for a predetermined period, the light was switched off and the tip reengaged for image recording. A representative AFM image before irradiation is shown in Fig. 1(a). A notable feature is the perfectly circular nature of the islands. In two-dimensional phase separated systems, circular domains are thermodynamically favourable and are formed as a result of the minimisation of surface energy through a reduction in interfacial length and curvature.[4,5]

The surface morphological changes upon UV light irradiation are depicted in Fig. 1(b)–(e). The reactivity pattern and reaction trends are very intriguing. Fig. 1(b) imaged at 5 min reaction shows the inhomogeneous pitting or etching of the island as stearic acid molecules photodecomposed. Typical hole diameters were in the range of 24 nm to 100 nm, with an average depth of *ca*. 0.9 nm (hole-depth range ≈0.0–2.25 nm, *cf.* a fully extended stearic acid molecule[6] has a chain length of ≈2.5 nm), corresponding to an estimated 2250 to 40000 stearic acid molecules having undergone photodecomposition, respectively. It should be noted that at this stage of the reaction the organic film comprises a mixture of adsorbed stearic acid as well as possible oxygenated alkyl intermediate molecules.[7] Likewise, we note that imaging of the island edges at higher resolutions revealed no clear trends in bulk island contraction. An island

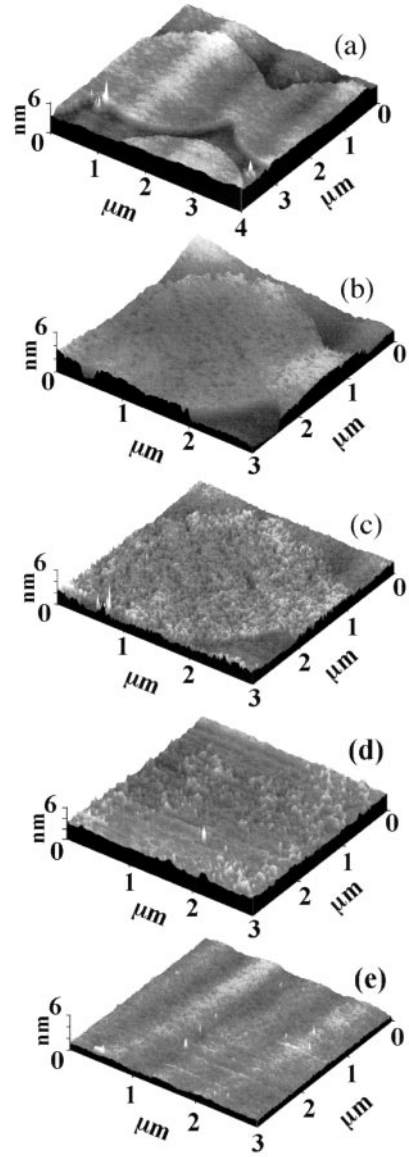

Fig. 1 Sequential 3-D AFM images of the rutile TiO_2 (110) mediated photodecomposition of stearic acid islands. Image (a) is 4 × 4 μm in size whereas all the other images are 3 × 3 μm. The images were obtained after: (a) 0, (b) 5, (c) 10, (d) 20, and (e) 60 min of UV light irradiation, respectively. Incident light intensity at the sample surface ≈2.5 mW cm^{-2}.

contraction scenario would arise if molecules at the edges photodecomposed at a faster rate than those in the interior. However, inhomogeneous decomposition at the edges as well as the interior suggests that the distribution of surface active sites governs surface reactivity. On analysing numerous other islands, we obtained the same randomisation phenomenon. With further irradiation, an even more peculiar reactivity pattern unfolds as depicted in Fig. 1(c) and (d). The surface morphology after irradiating for 10 min reveals a startling merging of holes to generate a mosaic, which eventually disappears with progress of reaction. At 20 min reaction [Fig. 1(d)], the island structure is no longer discernible. Prolonged irradiation resulted in the complete photodecomposition of the stearic acid molecules to CO_2 and H_2O.[8,9] That the reaction goes to completion was corroborated by parallel FT-IR experiments. Further control experiments in which monolayers of stearic acid were deposited onto CaF_2 substrates revealed that TiO_2 is essential for the photodecomposition of stearic acid.

The photodecomposition process is considered to proceed *via* two main oxidative routes, direct hole oxidation and $^{\cdot}OH$ oxidation.[10–12] The observed inhomogeneous reactivity pattern appears to mirror the momentary distribution of the surface active sites. Thus, the spatial localisation of the reaction appears to be largely influenced by the nature and composition of the photocatalyst. Spatially localised electrochemical reactions on TiO_2 surfaces have also been observed by scanning electrochemical microscopy.[13,14] In conclusion, this study reveals that a TiO_2 photocatalytic reaction is spatially localised and occurs at different rates at randomly distributed surface sites.

P. S. gratefully acknowledges financial support from the Science and Technology Agency. We thank Dr L. Jiang for assistance with the AFM measurements.

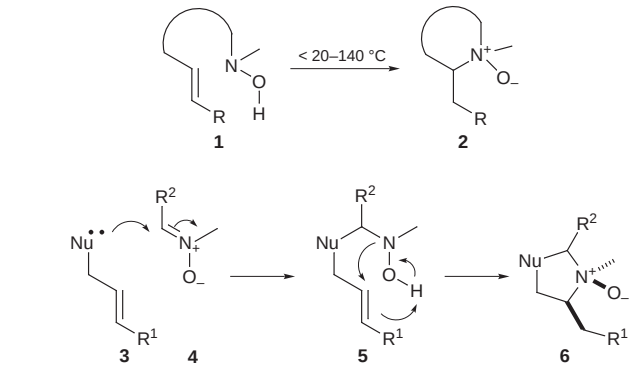
A new strategy for the elaboration of pyrrolidine *N*-oxides using the reverse-Cope elimination

Jane R. Hanrahan and David W. Knight*†

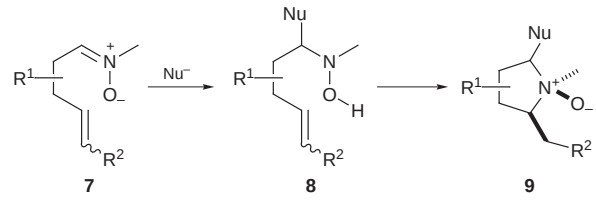
Chemistry Department, Cardiff University, PO Box 912, Cardiff, UK CF1 3TB

Condensations of the unsaturated nitrones 13 with lithiated methyl phenyl sulfone provide excellent yields of the unsaturated hydroxylamines 14 as single stereoisomers, which undergo rapid reverse-Cope elimination at ambient temperature, assisted by the constraint of the acetonide ring, leading to the pyrrolidine *N*-oxides 15 as single enantiomers.

As its name suggests, the reverse-Cope elimination is a reaction wherein a hydroxylamine and an alkene contained within the same molecule **1** undergo an addition reaction to give a cyclic *N*-oxide **2**. Originally discovered by the groups of House,[1] Black[2] and Oppolzer,[3] it is only relatively recently that the method has come to prominence, particularly due to the pioneering studies of Ciganek[4] who defined much of its scope and limitations as a useful approach to pyrrolidine *N*-oxides. Despite some earlier speculation,[1] results reported in a seminal paper by Oppolzer's group[5] provide excellent evidence that the transformation is a thermal pericyclic process related to the ene reaction. Subsequently, the latter group applied the reaction as a key step in a synthesis of the alkaloids lycorane and trianthine;[5] other neat applications by the Holmes group have further served to demonstrate the synthetic potential of the reverse-Cope process in the formation of pyrrolidines and also of cyclic nitrones, by related intramolecular additions of hydroxylamines to acetylene groups.[6] Our own contributions (Scheme 1) to this area have been centred around the use of condensation reactions between various unsaturated nucleophiles **3** and aldonitrones **4** to generate suitable hydroxylamines **5** which then undergo the reverse-Cope reaction to give a variety of five-membered heterocycles **6** [Nu = NMe, S, $PhSO_2CH$] and derivatives thereof.[7] With a view to extending the flexibility of the latter pyrrolidine *N*-oxide synthesis, we wondered whether suitable unsaturated hydroxylamines **8** could be generated by nucleophilic additions to molecules **7** containing both nitrone and alkene functions, with the idea of obtaining *N*-oxides **9** (Scheme 2). This idea also gave us an opportunity to test another speculation regarding the reverse-Cope elimination: would the rate of the reaction be increased if the two



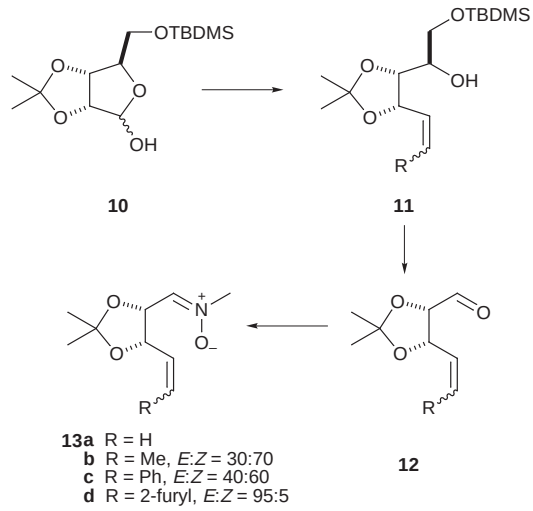
Scheme 1



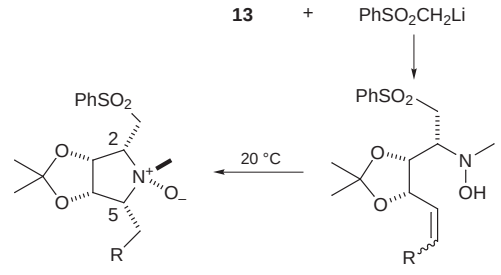
Scheme 2

reacting groups were held together by a second ring? In general, when a substituent is present on the terminus of the alkene group [*i.e.* **7**: $R^2 \neq H$], the rate of the reaction is slowed substantially, which can be a serious constraint when the sensitivity of the product precludes significant heating to induce cyclisation.[2,7] Ciganek in particular[4] has demonstrated the value of remote geminal substituents in aiding reverse-Cope cyclisations, presumably by a Thorp–Ingold effect, and we therefore felt that incorporation of a second ring would prove at least as effective. Herein, we report our first experiments in this area which have resulted in a new and highly stereoselective approach to pyrrolidine *N*-oxides and a somewhat unexpected stereochemical outcome.

We reasoned that an ideal starting material to test these ideas was D-ribose; protection of the primary hydroxy group as a silyl ether and acetonide formation[8] provided derivative **10** in which the acetonide ring provided the required constraint and the residual functionality the opportunity to incorporate the nitrone and alkene groups (Scheme 3). Subsequent Wittig homologation, crucially using potassium *tert*-butoxide as the base, led to good yields of the alkenes **11**, with the *E*/*Z* ratios shown. As the distal stereocentre would be removed if the reverse-Cope cyclisations were to be successful, we made no attempt to separate these isomers. Desilylation and diol cleavage then delivered the aldehydes **12** which were smoothly converted into the corresponding nitrones **13** under standard conditions.



Scheme 3



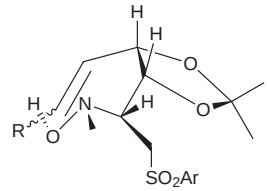
15a R = H, 1 h, 83%
b R = Me, 1 h, 83%
c R = Ph, 5 h, 65%
d R = 2-furyl, 2 h, 88%

Scheme 4

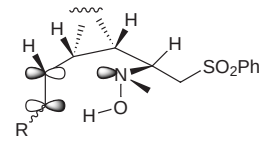
Addition of lithiated methyl phenyl sulfone (Scheme 4) to the nitrones **13** at −78 °C in THF, followed by warming to ambient temperature, quenching with aq. NH_4Cl and extractive work-up, delivered the expected[7] hydroxylamines **14**, essentially as single stereoisomers, according to ^1H and ^{13}C NMR analyses. At this stage, we did not know the configuration of the newly created stereocentre, although comparative spectroscopic data not unreasonably indicated that this was the same sense in each example. However, we suspected that the isomers shown (**14**) were formed, based on the work of the Dondoni group and the associated Houk model for such additions.[9] Further meaningful measurements was precluded when we were pleased to observe that the desired reverse-Cope elimination was already taking place as these analyses were being carried out. As indicated in Scheme 4, the cyclisations proceeded to completion remarkably quickly at ambient temperature in $CHCl_3$ solution, the slowest being the phenyl substituted analogue **14c** which, even so, only required 5 h. The final products **15** were purified by rapid column chromatography; following a brief elution with 5% MeOH–CH_2Cl_2, the rather polar *N*-oxides **15** were eluted as pure compounds using neat MeOH in the isolated yields shown (Scheme 4).

Each product was isolated as a single enantiomer, according to ^1H and ^{13}C NMR data. Detailed NMR analysis, in particular NOE measurements,[10] supported the all-*cis* structures **15** shown and was also consistent with the Dondoni–Houk conclusions concerning the initial carbanion addition.[9] This, perhaps at first, surprising result can be explained by the transition state conformation **16** wherein the alkene and hydroxylamine functions can line up in such a way as to allow for maximum orbital overlap, as indicated in the alternative view **17**. Molecular models indicate that such overlap is less favourable in the alternative chair-like conformation; attempts to quantify this argument are in progress. Such a transition state conformation is similar to one we have previously deduced to explain the stereochemical outcome of the reverse-Cope cyclisations summarized in Scheme 1.[7]

The remarkable ease with which the present cyclisations occur, presumably due to the additional ring constraint, together with the fact that this allows for the incorporation of additional functionality, suggests that this route should find many applications in the stereoselective synthesis of highly substituted pyrrolidines and derivatives thereof, in particular, the more difficult to obtain all-*cis* isomers. Studies aimed at exploiting this are in progress.



16



17

We are very grateful the EPSRC for generous support of this work (PDRA to J. R. H.) and to the EPSRC Mass Spectrometry service at Swansea University for the provision of high resolution mass spectral data..

$Li[Au(C_6F_5)_2]$ reacts with $TlNO_3$ in the presence of $OPPh_3$ affording a complex of stoichiometry $[AuTl(C_6F_5)_2(OPPh_3)_2]_n$, which presents different luminescence properties depending on the conditions and whose crystal structure reveals the existence of unsupported Au–Tl bonds forming a polymeric linear chain.

There is a renewed interest in mixed gold–transition metal compounds because of their fascinating and unique chemical and physical properties. A central issue in their chemistry is the study of closed-shell metal–metal interactions, which have been attributed to correlation effects that are strengthened by the relativistic effects for gold.[1] Structural and theoretical evidence has been accumulated for an entire family of cation–cation interactions between d^8–d^{10}–s^2 systems.[2] Particularly interesting are extended linear chain compounds, because the rationalization of the bonding of these structures still remains as a challenge.[3,4] For instance, $Tl_2Pt(CN)_4$,[5] with a Tl–Pt distance of 3.14 Å, was expected to be ionic with some covalent character[6] although correlation effects and the crystal-field contributions seem to be also important.[7] In contrast, $[AuTl\{Ph_2P(S)CH_2\}_2]$,[3,8] with a shorter Tl–Au distance (3.003 Å), displays mainly ionic bonds between Tl^+ and $[AuX_2]^-$ moieties.[2] This latter unit is also present in the polymeric species $[AgAuX_2L_2]$,[9,10] where X is a pentafluorophenyl group, thus avoiding any bridging effect. Mössbauer spectroscopic studies of such species indicate that $[Au(C_6F_5)_2]^-$ groups act as Lewis bases; the presence of perfluorophenyl groups seems to be the key for their donor properties,[11] which are similar to those postulated for dinuclear units of the form $[Au(ylide)]_2$.[12–14]

Despite the results previously reported, $[Au(C_6F_5)_2]^-$ has not hitherto been employed in the synthesis of other heterometallic compounds. We report here the synthesis and characterization of $[Tl(OPPh_3)_2][Au(C_6F_5)_2]$ (**1**), the first extended unsupported gold–thallium linear chain. This material is formed by reacting a mixture of triphenylphosphine oxide and a solution of $TlNO_3$ in MeOH with a freshly prepared solution of $Li[Au(C_6F_5)_2]$ in diethyl ether at −78 °C. The $LiNO_3$ formed is filtered off and the colourless solution is layered with pentane. Yellow-green crystals of complex **1** are collected after three days in a 40% yield. Compound **1** shows analytical and spectroscopic data in accordance with the proposed structure† and behaves as a 1 : 1 electrolyte in acetone. The absence of colour in ether or acetone solution implies that the interactions between the metal centres are restricted to the solid state.

In contrast, when the same reaction is carried out with the NBu_4^+ instead of the lithium salt, the complex is not formed and the gold(I) starting material is recovered unaltered. However, treatment of $[Au(C_6F_5)_2Cl(PPh_3)]$ with equimolecular amounts of thallium acetylacetonate surprisingly affords complex **1**. The mechanism of such a reaction is not clear, but it involves the reduction of the gold(III) centre and the oxidation of the triphenylphosphine.

The structure of **1** was determined by single-crystal X-ray diffraction[15]‡ (Fig. 1). The two independent gold atoms lie on inversion centres and thus display exact linear co-ordination by the C_6F_5 groups with Au–C distances of 2.058(5), 2.053(6) Å, whereas the thallium centre is bonded to two $OPPh_3$ ligands [O(1)–Tl–O(2) = 80.61(3)°] with typical Tl–O distances of 2.483(3) and 2.550(4) Å. The compound forms a one-dimensional polymer parallel to the crystallographic *x* axis. Including the metal–metal interactions, the geometry at gold is almost square planar and that at thallium is distorted trigonal bipyramidal with a vacant equatorial co-ordination site, presumably associated with the stereochemically active lone pair. The Tl–Au distances [Au(1)–Tl = 3.0358(8), Au(2)–Tl = 3.0862(8) Å] are nearly equal and similar to the sum of thallium and gold metallic radii (3.034 Å). They are similar to those found in $[AuTl(Ph_2P(S)CH_2)_2]_n$ [Tl–Au(intramolecular) = 2.959(2), Tl–Au(intermolecular) = 3.003(2) Å],[3,8] where two 'supporting', $Ph_2P(S)CH_2$ ligands are C-bonded to each gold centre and S-bonded to each thallium atom of a linear chain in which the metallic centres exhibit similar geometries as in **1**. Complex **1** may be considered as containing $[Au(C_6F_5)_2]^-$ and

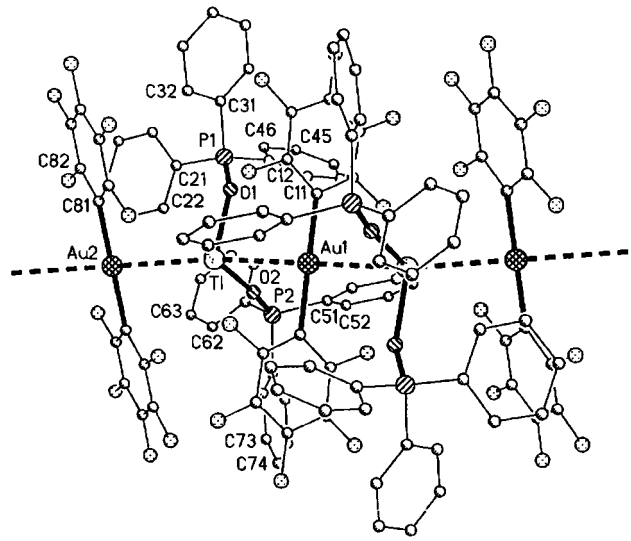

Fig. 1 Molecular structure of complex **1**. Selected distances (Å) and angles (°): Au(1)–C 2.058(5), Au(2)–C 2.053(6), Au(1)–Tl 3.0358(8), Au(2)–Tl 3.0862(8), Tl–O(1) 2.483(3), Tl–O(2) 2.550(4), C(11)–Au(1)–Tl 90.8(2), $C(11)^i$–Au(1)–Tl 89.2(2), C(81)–Au(2)–Tl^{ii} 88.0(2), C(81)–Au(2)–Tl 92.0(2), O–Tl–O 80.61(13), O(1)–Tl–Au(1) 94.73(11), O(2)–Tl–Au(1) 86.16(11), O(1)–Tl–Au(2) 99.04(11), O(2)–Tl–Au(2) 105.55(11), Au(1)–Tl–Au(2) 163.163(8). Symmetry operators: i $-x, -y+1, -z$; ii $-x+1, -y+1, -z$.

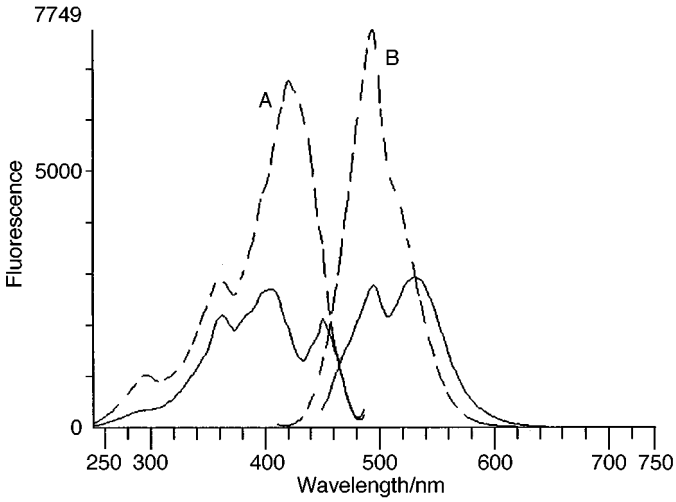

Fig. 2 Excitation and emission spectra of complex **1** in the solid state at 293 K (dashed line) and at 77 K (solid line) (excitation in curve **A**, emission in curve **B**)

$[Tl(OPPh_3)_2]^+$ ions, which are linked by weak M–M′ bonds thus forming the first unsupported Au–Tl linear chain. Four weak Tl···F contacts (3.313–3.488 Å) may also contribute to the stability of the system.

Furthermore, the heteronuclear complexes $[AuTl(Ph_2P(S)CH_2)_2]$ and $[Au_2Pb(Ph_2P(S)CH_2)_4]$[3,8] with d^{10} and s^2 electronic configurations are luminescent and also form linear Au–M linear chains. Similarly, complex **1** luminesces both at room temperature (293 K) (excitation at 421 nm, emission at 494 nm) and at 77 K (maximum excitation at 403 nm, emission at 494 and 530 nm) in the solid state (Fig. 2). The excitation and emission spectra for **1** are virtually mirror images of each other with only a small separation between excitation and emission peaks, suggesting that the dominant emission in this complex is perhaps fluorescence.

Previous Fenske–Hall molecular orbital calculations for a gold–thallium complex[3,8] indicated that although no formal metal–metal single bond is present, the HOMO is a σ* orbital mainly of Tl(I) and the LUMO is a σ orbital of both Au(I) and Tl(I) orbitals. Thus, a feature of this excited state is that the transfer of an electron from an antibonding orbital to a bonding orbital results in a net increase of intermetallic bonding in the excited state, but the luminescence spectrum suggests that there is no change in the Au–Tl distances in this linear chain species.

Neither the gold(I) nor Tl(I) precursor complexes are luminescent under similar conditions suggesting that the emission is a result of interactions between the metals. Moreover, when the product is dissolved in non-halogen solvents the green colour of the solid disappears and the resultant colourless solution is non-emissive. Evaporation of the solvents regenerates the colour and its optical properties. Another interesting feature is when **1** is saturated with halogenated solvents and irradiated with UV light, the emission is also quenched but, upon evaporation of the solvent, it does not regenerate the green product, but instead an uncharacterized grey solid appears which shows an emission at higher energy (476 nm). If the process of dissolution in CH_2Cl_2 is carried out in the dark, the green product is recovered without any change. This promising result seems to indicate that under UV radiation the excited state is able to react with halocarbons in an electron transfer reaction, perhaps making this product appropriate for practical applications.

We are grateful to Professor J. P. Fackler, Jr. for his helpful discussions and the facilities for using his laboratory material. This work was supported by the D.G.E.S. (PB97-1010-C02-02), the University of La Rioja (API-98/B09) and the Fonds der Chemischen Industrie.

A novel [2,3] intramolecular rearrangement of *N*-benzyl-*O*-allylhydroxylamines

Stephen G. Davies,*† Simon Jones, Miguel A. Sanz, Fátima C. Teixeira and John F. Fox

The Dyson Perrins Laboratory, University of Oxford, South Parks Road, Oxford, UK OX1 3QY

A novel [2,3]-sigmatropic rearrangement whereby *N*-benzyl-*O*-allylhydroxylamines undergo transformation to the corresponding *N*-allylhydroxylamines, which can subsequently be reduced to the corresponding allylamines, is described and evidence for the intramolecular nature of this process presented.

Intramolecular sigmatropic rearrangements have found widespread use in synthetic organic chemistry primarily due to the high selectivities observed in these transformations. In particular, effective use has been made of a variety of [2,3] processes, such as the Meisenheimer[1] and Stevens rearrangements[2] to control stereochemistry as they tend to proceed at significantly lower temperatures than [3,3] processes[3] and thus lead to better observed selectivities. For example, Anderson *et al.* have recently developed an aza-[2,3]-Wittig rearrangement which proceeds with excellent stereocontrol.[4]

During continuation of our lithium amide studies[5] we discovered that *N*-benzyl-*O*-allylhydroxylamine gives *N*-allyl-*N*-benzylhydroxylamine when treated with n-BuLi, a process which may be attributed to a novel [2,3] sigmatropic rearrangement analogous to the [2,3] Wittig rearrangement.[6] We now report our initial investigations into the nature of this rearrangement and demonstrate its synthetic use.

The substrates for all of the rearrangements were easily prepared in two steps and high yield starting from *syn*-benzaldehyde oxime **1** (Scheme 1). *O*-Allylation was achieved by formation of the potassium salt of the oxime and subsequent quenching by treatment with the appropriate allyl bromide.[7] The *O*-allyl oximes **2a**–**d** were reduced with pyridine–borane complex in EtOH–10% HCl to give the desired substrates **3a**–**d** in excellent overall yield.[8] In most cases purification of the intermediates and substrates was achieved by distillation.

The rearrangement was carried out by treatment of the simple *N*-benzyl-*O*-allylhydroxylamine **3a** in dry THF with 1 equiv. of n-BuLi at −78 °C for 1 h, followed by warming to room temperature for 30 min before quenching with water. This afforded the [2,3] rearrangement product **4a** in essentially quantitative yield by examination of the crude ^{1}H NMR spectrum. Purification of this compound proved to be difficult due to decomposition, although it was finally achieved by chromatography on previously deactivated silica gel (1% Et_3N). The hydroxylamine thus obtained as an oil was isolated in 61% yield and the structure confirmed by ^{1}H and ^{13}C NMR spectroscopy and HRMS. With conditions for the rearrangement identified,‡ it was repeated for the other substrates (Scheme 2). All gave the [2,3] rearrangement product, although in the case of the rearrangement to a trisubstituted centre (**3c** → **4c**), the reaction was found to be only 10% complete by ^{1}H NMR spectroscopy after 48 h. However, by heating the reaction mixture to reflux for 2 h after the initial addition of n-BuLi at −78 °C, the reaction proceeded to completion and the [2,3] product was obtained in 60% isolated yield. The hydroxylamines formed in all of these reactions were all very prone to decomposition during purification. Thus, isolated yields of the allylhydroxylamines were always considerably lower than the quantitative yields for the crude reaction observed by ^{1}H NMR spectroscopy. Attempted thermal rearrangement of **3a** by heating under reflux in xylene for 7 h led to only a trace amount of the desired rearrangement product in the ^{1}H NMR spectrum (< 5%).

The rearrangement of the crotylhydroxylamine **3b** rules out the possibility of a 1,2 anionic shift which would have given rise to the *N*-benzyl-*N*-crotylhydroxylamine instead of the observed product. However the possibility still existed that the reaction was intermolecular and not intramolecular. In order to demonstrate that the process was indeed intramolecular the rearrangement was carried out with two different substrates **3b** and **5** with 2 equiv. of n-BuLi (Scheme 3). If an intermolecular process was being observed then the mixed products **4a** and **7** from this rearrangement would be observed. All four of the possible products that could arise from this reaction were prepared in an analogous manner to the hydroxylamines prepared earlier. When the crude ^{1}H NMR spectrum of the mixed reaction was analysed, only peaks due to the respective intramolecular rearrangement products **4b** and **6** were present, and not the crossover products **4a** and **7** confirming that this reaction was indeed an intramolecular process.

Based on these results the reaction is comparable to a [2,3]-Wittig rearrangement, and thus reasonably proceeds *via* a transition state which is similar to that suggested for this process (Scheme 4).[6] Deprotonation of the N–H proton affords the

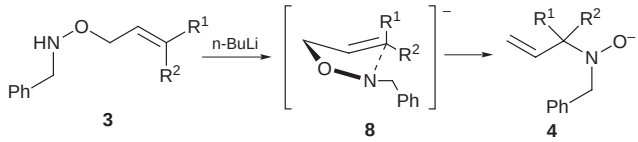
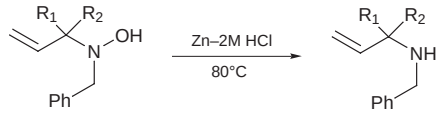


Scheme 4

lithium amide which rearranges through an envelope transition state **8**. The driving force for this reaction lies in the relative stability of the lithium oxy-anion **4** formed compared to the lithium amide precursor **8**, which is illustrated in the pK_a values of the corresponding alcohol and amine (pK_a EtOH = 15.9, pK_a $EtNH_2$ = 35). A similar [1,2] anionic process has been previously reported in which the anion derived from *N*,*O*-bis(trimethylsilyl)hydroxylamine rearranges to *N*,*N*-bis(trimethylsilyl)hydroxylamine.[9]

As already eluded to, the hydroxylamines produced were relatively unstable and were thus difficult to isolate or store for prolonged periods of time. However, the allylamines from which the hydroxylamines are derived are stable and are also useful synthons.[10] Thus, reduction of the hydroxylamines **4a**–**d** with Zn/2 M HCl at 80 °C for 1 h followed by neutralisation (NaOH) and extraction with Et_2O gave the respective amines **9a**–**d** in excellent yields (Scheme 5).

The versatility of this method for the synthesis of allylamines was demonstrated in the synthesis of *N*-allyl-*N*-benzylamine **9a**



Compound	Compound	Yield
4a $R^1 = R^2 = H$	**9a** $R^1 = R^2 = H$	90%
4b $R^1 = H, Me$; $R^2 = Me, H$	**9b** $R^1 = H, Me$; $R^2 = Me, H$	94%
4c $R^1 = R^2 = Me$	**9c** $R^1 = R^2 = Me$	92%
4d $R^1 = Ph$; $R^2 = H$	**9d** $R^1 = Ph$; $R^2 = H$	91%

Scheme 5

which was prepared in a two step process by rearrangement of the parent hydroxylamine **3a** and subsequent reduction of the crude material to afford the desired allylamine **9a** in excellent overall yield (91%).§ In a similar manner the crotyl- and cinnamyl-hydroxylamines **3b** and **3d** were rearranged then immediately reduced to give the allylic amines **9b** and **9d** in 93 and 92% overall yield respectively.

In conclusion we report a novel [2,3] rearrangement of *N*-benzyl-*O*-allylhydroxylamines to give the corresponding *N*-allyl-*N*-benzylhydroxylamines, which may be reduced to the *N*-benzylallylamines with Zn/HCl. This provides a novel approach to the synthesis of allyl substituted hydroxylamines and amines.

We would like to thank the Ministerio de Educación y Ciência (M. A. S.) and J.N.I.C.T. (Programa Ciência and Praxis XXI) (F. C. T.) for provision of funding and Oxford Asymmetry for technical and financial support.

‡ *Typical experimental procedure:* n-BuLi (1.66 M, 0.81 mL, 1.35 mmol) was added to a solution of **3a** (200 mg, 1.23 mmol) in anhydrous THF (15 mL) at −78 °C under N_2. After stirring for 1 h the reaction was allowed to warm to room temp. and stirred for a further 30 min. The reaction was quenched with distilled water (25 mL) and extracted with Et_2O (3 × 25 mL). The combined organic extracts were dried ($MgSO_4$) and concentrated *in vacuo*. The residue was purified by column chromatography on deactivated silica gel (1% Et_3N–petroleum ether) eluting with petroleum ether–Et_2O (6:1) to give the desired hydroxylamine **4a** as a clear yellow oil (122 mg, 61%).

§ *Typical proceedure for the reduction of the hydroxylamines*: **4a** (0.100 g, 0.61 mmol) was dissolved in 2 M HCl (5 mL) and zinc dust (0.200 g, 3.1 mmol) added cautiously. The reaction was heated at 80 °C for 1 h, cooled and neutralised with 2 M NaOH. The white suspension was extracted with Et_2O (3 × 15 mL) and dried ($MgSO_4$). Evaporation afforded **9a** (0.081 g, 90%).

Alternatively, the crude product **4a** obtained from rearrangement of **3a** was directly reduced by addition of 2 M HCl (3 mL) and zinc dust (0.200 g, 3.065 mmol) and heating at 80 °C. After 1 h the reaction was cooled, neutralised with 2 M NaOH, extracted with Et_2O (3 × 20 mL) and dried ($MgSO_4$). Evaporation afforded **9a** (0.082 g, 91% overall yield).

A library of more than 140 racemic 4-aryl-1,4-dihydropyrimidines has been synthesized using the single step Biginelli multicomponent condensation; the individual compounds were screened for enantiomer resolution, and the best candidate attached to a solid macroporous polymer support to afford a highly selective separation medium for chiral HPLC.

Combinatorial chemistry is a powerful tool for the rapid preparation of large numbers of different compounds that may be used in the development of new drug candidates and drugs,[1] metal complexing ligands,[2] polymers,[3] materials for electronics,[4] sensors,[5] peptidic ligands for affinity chromatography,[6] and in supramolecular chemistry.[7] The increasing awareness that individual enantiomers of drugs, agrochemicals, pheromones, flavors, fragrances and some other compounds have different interactions with biological systems drive both industry and academia to find means to replace racemates with their single enantiomers. Although the liquid chromatographic separation of enantiomers using chiral stationary phases (CSPs) has emerged only recently, a large number of chiral stationary phases (CSPs) are now commercially available.[8] Despite the variety of CSPs, none of these is universal and new chiral separation media must often be developed for the separation of specific compounds. The well-defined small molecule selectors pioneered by Pirkle[9] using chiral blocks derived from natural sources (amino acids) and porous silica as a support afford the most flexibility in the development of many different chiral stationary phases.

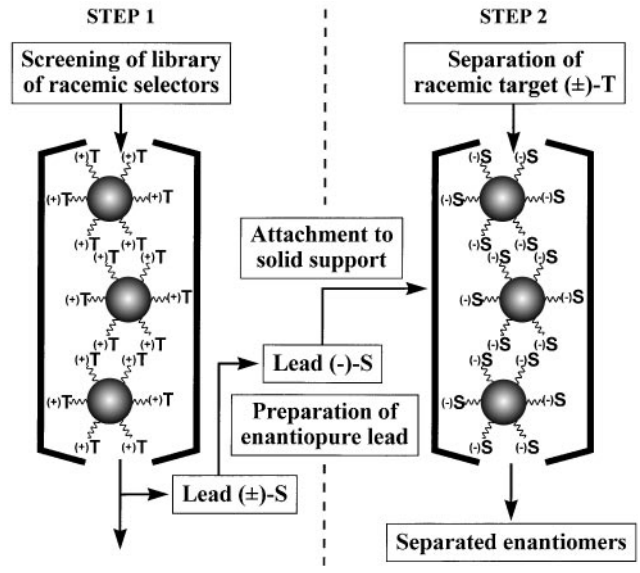
We have now designed an approach that uses combinatorial chemistry as a tool for the *rapid* development of novel, highly selective, chiral stationary phases for HPLC. Our approach applies the so-called principle of reciprocity, which has been introduced by Pirkle for the development of CSPs capable of separating important classes of pharmaceuticals. This principle states that if a single molecule of a chiral selector has different affinities for the enantiomers of another substance, then a single enantiomer of the latter will have different affinities for the enantiomers of the initial selector molecule.[10]

The reciprocal method is especially suitable for situations in which the target enantiomer is known and its separation from a racemate is required. Since chromatographic techniques are readily automated, a broad variety of novel chiral ligands may be considered. Scheme 1 illustrates the general concept of our approach. In the first step, a single enantiomer (+)-T of the target racemate is immobilized onto a suitable polymeric support[11] and the resulting CSP is used for the HPLC screening of a library of racemic compounds (potential selectors) that have been prepared using parallel combinatorial synthesis. The best separated member of this library (±)-S is then prepared as the single enantiomer [*e.g.* (−)-S], coupled to an optimized solid support,[11,12] and used in the second step for the required separation of the racemic target. While only two columns are required in this technique, the tradeoff for the simplicity of this approach is that the developed CSP is optimized for the enantioseparation of only one compound. In reality, this column may well separate other racemates as a result of cross selectivity, however, the α values may be lower.

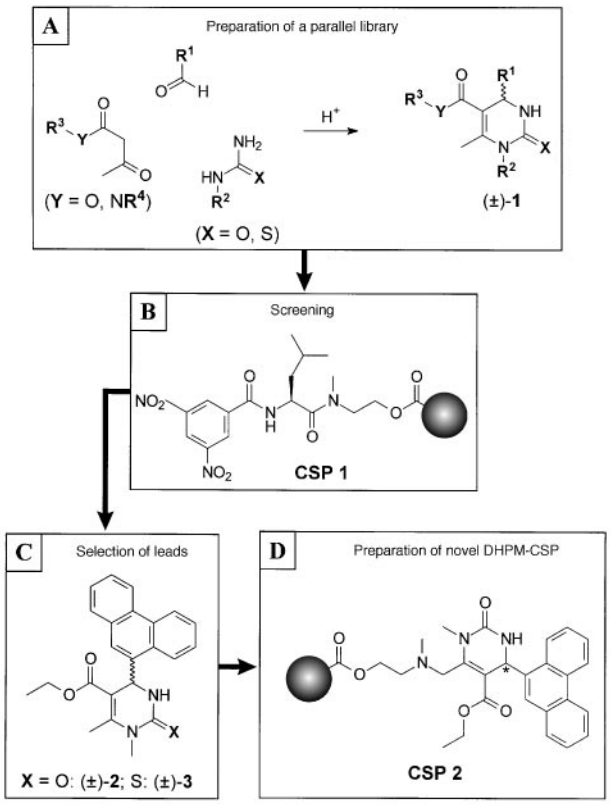
We have demonstrated the feasibility of this concept with a parallel library of racemic 4-aryl-1,4-dihydropyrimidines (DHPMs) (±)-**1** [Scheme 2(A)]. The DHPM scaffold resulted from our search for novel chiral selectors that do not rely on chiral starting materials from natural sources. DHPMs are easily accessible by the Biginelli multicomponent cyclocondensation developed more than 100 years ago.[13] This simple one-pot reaction combines a β-keto ester or β-keto amide, with an aldehyde and a urea or thiourea. Since a large number of components for the condensation are commercially available, over 140 various DHPMs have been prepared using combinations of 25 aldehydes with six ureas or thioureas, and seven acetoacetates or acetoamides and tested in this initial study.

The library was screened with a chiral stationary phase that contains (*S*)-(3,5-dinitrobenzoyl)leucine (model target) attached to poly[(*N*-methyl)aminoethyl methacrylate-*co*-methyl methacrylate-*co*-ethylene dimethacrylate] beads[12] [Scheme 2(B)] using normal-phase mode HPLC conditions. The separation factor $\alpha = (t_2 - t_0)/(t_1 - t_0)$, where t_0 is the retention time of an unretained compound or column void volume determined using 1,3,5-tri-*tert*-butylbenzene as a marker and t_1 and t_2 are the retention times of the individual enantiomers, was calculated to measure the selectivity of the separation.

While some racemic DHPMs in the library are not resolved at all ($\alpha = 1.0$), α values of 5.2 and 11.7 were achieved for the top candidates 4-(9-phenanthryl)-2-oxo-DHPM (±)-**2** and its thioxo analogue (±)-**3** [Scheme 2(C)], respectively. A single crystal X-ray structure analysis of the 2-oxo compound reveals a cleft-like conformation of the aromatic and heterocyclic ring systems



Scheme 1



Scheme 2

that appears particularly well suited for sterically controlled interactions.

For the next step, the preparation of the actual CSP requires the preparation of one of the lead compounds in enantiomerically pure form, followed by attachment to a support. Although different routes to the desired single enantiomer can be designed, we simply separated it from the racemate using a semi-preparative column packed with CSP 1 used previously for the screening process. Attachment of the enantiopure selector to the amino functionalized macroporous polymethacrylate support requires its modification to include a suitable coupling site. Although hydrolysis of the ester group to a free carboxy group seems to be attractive, rather harsh conditions have to be used resulting in decomposition of the DHPM. Therefore, a more convenient route—bromination of the methyl group at the C6 position—was applied instead. Since the bromination step is not well suited for the 2-thioxo-DHPM, we used the best 2-oxo-DHPM compound from the library: 4-(9-phenanthryl)-2-oxo-DHPM (−)-**2**. Coupling of the brominated DHPM to the amino functionalized support affords CSP 2 [Scheme 2(D)] which contains 0.20 mmol g^{-1} of the selector. A variety of racemates including amino acid and non-steroid anti-inflammatory drug (profens) derivatives, and dihydropyrimidines were separated on CSP 2 with α values up to 8. These α values are rather high, especially if one considers that the unoptimized methodology used in this demonstration leads to a CSP with a loading of only 0.20 mmol g^{-1}. Although the selectivity may not always be a linear function of loading, the specific selectivity of DHMP selectors is actually higher than that of amino acid based selectors. Since dihydropyrimidines possess well-established pharmacological potential,[8] the ability of CSPs with DHPM selectors to separate these drugs is a very promising tool for the development of these and similar drugs in their single enantiomeric form.

Funding of this research by the National Institute of General Medical Sciences, National Institutes of Health (GM-44885) is gratefully acknowledged. P. M. thanks the Swiss National Science Foundation for a postdoctoral fellowship.

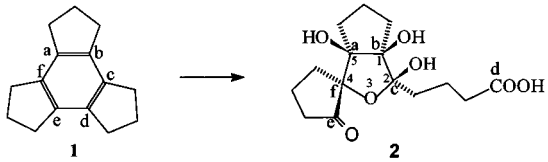
The complete, Ru(VIII) mediated oxidation of the benzene ring of trindane 1 is contained within the framework of peripheral methylenes to yield the unfragmented product 2.

This communication reports the formation of **2** on oxidation of trindane **1** with *in situ* generated Ru(VIII) species.



Trindane **1**, despite its ready availability,[1]‡ and being endowed with a three-fold symmetry, has hitherto attracted little synthetic interest.[2]§ In connection with the synthesis of benzene anchored three-fold symmetric systems, having pairs of donors and acceptors, that could lead to surfaces by self assembly, **1** was reacted with Ru(VIII) species, in anticipation of the oxidation of the six benzylic positions.§ The reaction gave no product from benzylic oxidation, but consistently afforded ~15% yields of a crystalline compound, mp 148–150 °C. The ^{13}C NMR spectrum coupled with DEPT studies suggested that the methylenes were intact and showed the presence of two types of carbonyls. The FAB (normal and negative ion) mass spectrum showed a molecular weight of 314. Elemental analysis was consistent with a molecular formula $C_{15}H_{22}O_7$ which when compared to the starting trindane ($C_{15}H_{18}$) amounts to the introduction of seven oxygens. The FTIR indicated the presence of hydroxy groups, cyclopentanone and another carbonyl peak at 1709 cm^{-1}.¶

Single crystal X-ray analysis‖ revealed the structure of the oxidation product as **2**. The crystal structure of **2** and selected interatomic parameters are presented in Fig. 1. All the bond distances and angles are within normal statistical bounds. The three five-membered rings are puckered.

A plausible reationalization of the **1** → **2** conversion, where oxidation is contained by the peripheral methylenes, is presented in Scheme 1.**

The basic framework of **2** is similar to that of ginkgolides,[3] a class of cytotoxic substances having therapeutic value. The one step transformation of hydrocarbon trindane to such condensed, highly oxygenated systems is noteworthy.

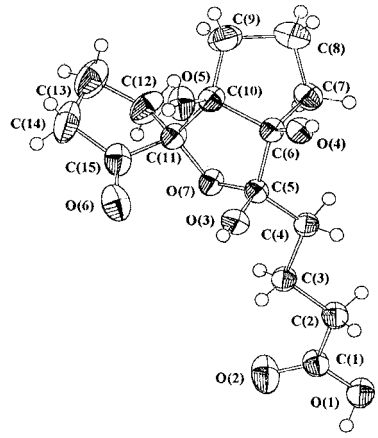


Fig. 1 The single-crystal X-ray structure of **2** with ellipsoids shown at 50% probability. For clarity the hydrogen atoms are not labelled. Selected bond lengths (Å) and angles (°): O(1)–C(1) 1.314(7), O(2)–C(1) 1.20(1), O(3)–C(5) 1.385(7), O(4)–C(6) 1.426(7), O(5)–C(10) 1.435(8), O(6)–C(15) 1.201(8), O(7)–C(5) 1.419(7), O(7)–C(11) 1.435(6); O(1)–C(1)–O(2) 122.6(6), O(1)–C(1)–C(2) 112.9(6), O(2)–C(1)–C(2) 124.5(5), O(3)–C(5)–O(7) 110.9(5), O(3)–C(5)–C(4) 108.1(4), O(3)–C(5)–C(6) 110.5(5), O(4)–C(6)–C(5) 110.0(4), O(4)–C(6)–C(7) 109.3(5), O(4)–C(6)–C(10) 112.7(5), O(5)–C(10)–C(6) 112.9(4), O(5)–C(10)–C(9) 112.9(5), O(5)–C(10)–C(11) 104.9(5), O(6)–C(15)–C(11) 124.6(5), O(6)–C(15)–C(14) 107.2(6), O(7)–C(11)–C(10) 106.3(4), O(7)–C(11)–C(12) 110.5(5), O(7)–C(11)–C(15) 110.2(5).

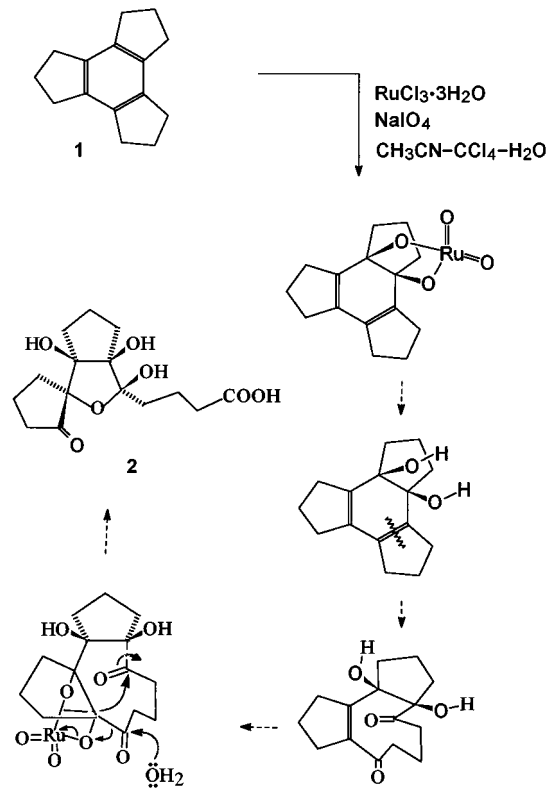
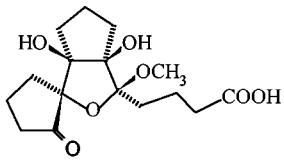


Scheme 1

The resemblance of **2** to sugars was highlighted by simultaneous isolation of **3**, by replacement of the anomeric hydroxy group during workup.††



3

The formation of highly functionalized complex condensed systems in one step, by the containment of aromatic ring oxidation within peripheral, methylene groups should be a general reaction. The unpredictable course of such reactions coupled with the delineation of their structures, largely by X-ray crystallography, should provide incentives for exploration along these lines, and which are currently being pursued.‡‡

We are grateful to Indian National Science Academy, New Delhi for support.

‡ A standardized procedure for **1** based on early reports (ref. 1) is given below:

Cyclopentanone (16 ml, 0.18 mol) in dry EtOH (18 ml) was mixed with conc. H_2SO_4 (8 ml dropwise), refluxed for 15 h, poured on to ice (~70 g), neutralised with sodium carbonate and extracted with CH_2Cl_2 (3 × 30 ml), washed with water, dried ($MgSO_4$), evaporated and chromatographed on a silica gel column using petroleum ether to get 4.0 g (33%) of **1** [mp 92 °C (lit.[1] 95–97 °C)].

§ To the best of our knowledge, the only report (ref. 2) pertains to benzylic hexabromination followed by zinc reduction to afford mixtures of dehydrogenated tricyclopentabenzenes.

¶ A mixture of trindane (0.495 g, 2.5 mmol), CH_3CN–CCl_4–H_2O (10 : 10 : 20 ml), $NaIO_4$ (9.63 g, 45 mmol), $RuCl_3{\cdot}3H_2O$ (2.2 mol%, ~0.015 g) was sealed, shaken for 3 h, cautiously opened, filtered, the residue washed with EtOAc (3 × 20 ml), the organic layers washed with water, dried, evaporated and chromatographed on a silica gel column. Elution with EtOAc–hexane (1 : 1) gave fractions containing **2** (TLC: R_f 0.25, $CHCl_3$–MeOH 9 : 1) which on concentration deposited crystals, mp 148–150 °C (0.120 g, ~15%), Anal. Found: C, 57.55; H, 7.33%. Calc. for $C_{15}H_{22}O_7$: C, 57.32; H, 7.00. ν(KBr, cm^{-1}) 3396, 2972, 1736, 1709, 1432, 1143; δ_H(300 MHz, $CDCl_3$–DMSO-d_6) 1.6–2.5 (m, CH_2), 4.4 (br, OH × 2), 5.9 (br, OH × 1), 7.7 (s, COOH); δ_C($CDCl_3$–DMSO-d_6) 16.19–34.66 (9 × CH_2), 85.99, 87.32, 93.04, 103.78 (4 × C-O), 174.40 (CO), 221.01 (CO); *m/z* (FAB) (neg) 313 (78%), *m/z* (FAB) (pos) + Na^+ 337 (77%).

Data were collected at 298(1) K, for a crystal of dimensions 0.20 × 0.20 × 0.30 mm, on an Enraf–Nonius CAD4-mach 2 diffractometer. A total of 2939 unique data were collected. The data were corrected for Lorentz polarisation and decay. The structure was solved by the direct method and refined on F using the full matrix least-squares technique using XTAL 3.2 program package and a total of 2195 reflections [$I \geqslant 3\,\sigma(I)$]. The final R,R_w indices were 0.061 and 0.067 for 205 parameters (non-hydrogen atoms, anisotropic hydrogen atoms in idealized positions, C–H 0.96 Å, O–H 0.87 Å with a fixed U_{iso} of 0.10. CCDC 182/1018.

** The nature of **2** would need the oxidation of each carbon centre of the aromatic ring. However, the sequence of events envisaged in Scheme 1 is largely notional. The step leading to *cis* hydroxylation, envisaged as the first step, is required to control the stereochemical outcome of the reaction. Preference, if any, of the reagent addition in the second step is obliterated since the process leads to oxidative C–C scission. Molecular models clearly show that the critical third step requires addition of the reagent from the side *anti* to the *cis* hydroxy grouping—which seem to be dictated by steric factors—to enable the generation of the oxabicyclooctane unit in **2** by transannular addition with correct stereochemical disposition at centres 2 and 4 (Scheme 1).

†† The formation of **3**, which was isolated as a gum, in ~7% yield has been traced to the use of small amounts of MeOH as the co-eluent. A spectral comparison of **2** with this compound indicated a simple replacement of a HO group by MeO, which was confirmed by analytical and detailed spectral studies. ν (neat)/cm^{-1} 3434, 1735, 1445, 1175; δ_H(300 MHz, $CDCl_3$) 1.4–2.4 (m, CH_2), 3.48, 4.21 (s, s, OH × 2, exchangeable), 6.42 (s, COOH, exchangeable), 3.66 (OMe); δ_C($CDCl_3$) 17.05–38.05 (9 × CH_2), 51.48 (CH_3O), 85.95, 88.35, 95.17, 105.00 (4 × C-O), 174.00, 222.90 (2 × CO) (DEPT studies showed 9 × CH_2 and 1 × CH_3]; *m/z* (FAB) (neg) 327.

‡‡ The immediate higher homologues of trindane can be readily prepared from the cyclanones (ref. 1). They would be the natural targets of further studies.

The first fluoroalkylation of amino acids and peptides in water utilizing the novel iodonium salt $(CF_3SO_2)_2NI(Ph)CH_2CF_3$

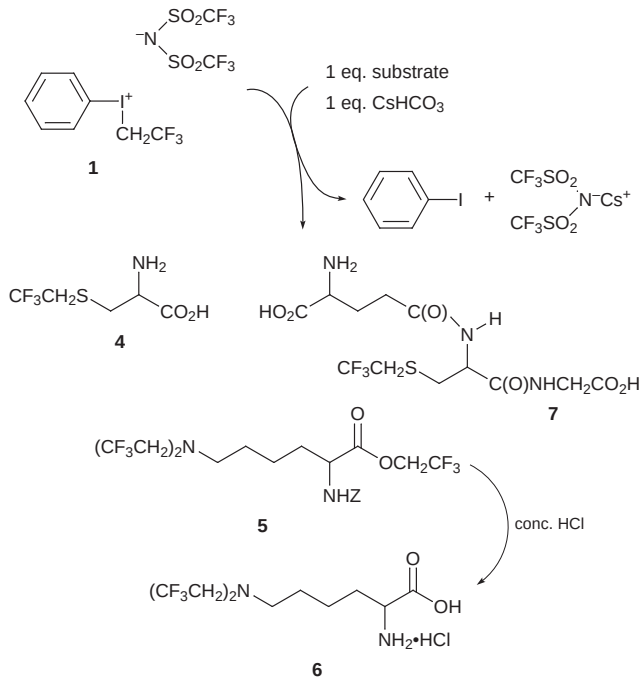
Darryl D. DesMarteau*† and Vittorio Montanari

Department of Chemistry, Box 341905, Clemson University, Clemson, SC 29634-1905, USA

The novel iodonium salt $(CF_3SO_2)_2NI(Ph)CH_2CF_3$ is a powerful alkylating reagent which can be utilized in water to trifluoroethylate amino acids and peptides.

Fluorine-containing amino acids have been actively investigated in view of their high potential for biological studies and medical applications.[1] In particular, the use of ^{19}F NMR as a sensitive mechanistic probe has been intensively studied.[2] Synthetic routes to fluorinated amino acids normally involve several steps using fluorinated building blocks, mostly obtained by the conversion of carbon–heteroatom bonds to C–F bonds. A more direct approach to the introduction of fluorine into biochemically significant substrates might involve fluoroalkylations.[3] Cysteine and related amino acids and peptides can be alkylated by alkyl halides or esters if both the substrate and alkylating reagent can be solubilized in mixed water–organic solvents or in liquid ammonia.[4] However, simple fluorine containing alkyl halides and esters are of low reactivity in analogous alkylations. Increasing the reactivity by incorporation of fluoroalkyl groups into iodonium salts such as $CF_3CH_2I(Ph)O_3SCF_3$ is successful[3] but until now such compounds could not be employed in aqueous media or basic solvents since they are instantly destroyed under these conditions.

In contrast the novel iodonium salt $(CF_3SO_2)_2NI(Ph)CH_2CF_3$ (**1**) is unexpectedly stable to water. Herein we report the first fluoroalkylations in aqueous media and the application of **1** to the alkylation of representative biochemically significant substrates (Scheme 1).



Scheme 1 Reaction of **1** with cysteine N^{α}-Z-lysine and glutathione and the trifluoroethylated products obtained

Bis(trifluoromethylsulfonyl)imide, $(CF_3SO_2)_2NH$ (**2**), originally devised for establishing the existence of Xe–N bonds,[5] is one of the strongest acids known in the gas phase.[6] Derivatives of the acid typically have unusual properties as exemplified by the *N*-fluoro compound which is a powerful fluorinating reagent.[7,8] Perfluoroionomers and ionene polymers made in this laboratory, containing the repeating $(R_fSO_2NXSO_2R'_f)$ unit (X = H or other cation) have high potential in solid polymer electrolyte fuel cells and polymer lithium batteries, and are promising superacid catalysts.[9] In connection with this research, it is useful to synthesize novel salts of **2** as model compounds for structure and reactivity studies. The first iodine(III) compound we prepared, $[Ph_2I]^+[N(SO_2CF_3)_2]^-$ (**3**), is a stable, low-melting compound (67 °C) and a strong arylating agent.[10] Encouraged by this result, a high-yield synthesis of **1** was developed.‡ We found that **1** immediately transfers the trifluoroethyl group to nucleophiles, such as aniline, in organic solvents. Surprisingly **1**, which is very slightly soluble in water, is hydrolyzed only slowly. This fact led us to investigate fluoroalkylation reactions in water as a solvent. Using simple amines as model compounds, we observed high yields of trifluoroethylamines from 1 equiv. each of **1**, substrate, and $NaHCO_3$.

Based on this novel result, our goal became the alkylation of amino acids. The reactive side-chain of cysteine and lysine were considered, anticipating that the products would be of interest for biochemical studies. *S*-Trifluoroethyl-L-cysteine (**4**) was readily obtained in 60–90% isolated yields.§ Fig. 1 shows the X-ray crystal structure of **4**.¶

Under the same conditions the commercially available N^{α}-Z-protected L-lysine unexpectedly reacted with 3 equiv. of **1** to give the ester $(CF_3CH_2)_2N(CH_2)_4CH(NH\text{-}Z)COOCH_2CF_3$ (**5**). Hydrolysis of **5** in 37% HCl gave N^{ε}-bis(trifluoroethyl)-L-lysine hydrochloride (**6**) in 60% overall yield.

Compounds **4** and **6** are modified in the side-chains but are otherwise normal amino acids: they can be converted into the Fmoc-protected acyl fluorides in good overall yield. This form of protection–activation is very useful in the assembly of peptides of any size according to many literature examples.[11] By means of these acyl fluorides the unlikely event of extensive racemization under our alkylation conditions could be easily ruled out: reaction with (*R*)- or (*S*)-phenethylamine gave

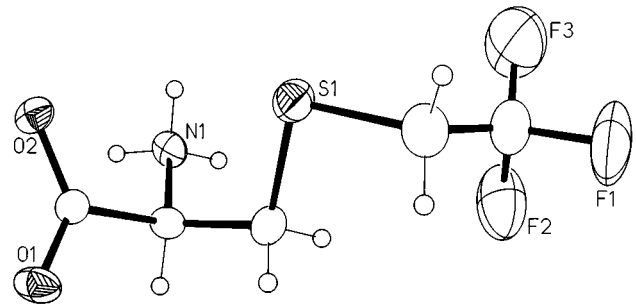


Fig. 1 Crystal structure of *S*-trifluoroethylcysteine **4** showing one of the two unique molecules in the unit cell

diastereoisomeric amides that are clearly distinguishable by ^{1}H and ^{19}F NMR.[12]

A different approach to the use of **1** is the direct reaction with a peptide having unprotected side-chains. We tested the reaction on glutathione (GSH, γ-Glu-Cys-Gly) because of its biochemical relevance and commercial availability in preparative amounts. Under the same conditions used for the preparation of **4**, we obtained complete conversion to a mixture of the desired *S*-trifluoroethylglutathione (**7**) and oxidized glutathione (**8**) in an 8:2 ratio. Compound **7** was separated from **8** by precipitation from water–ethanol.

In summary, we have reported that **1** reacts rapidly in water, under mildly alkaline conditions, with unprotected cysteine and glutathione, and with N^{α}-protected lysine, to give the novel amino acids **4** and **6**, and tripeptide **7**.

The covalent polar residue CF_3CH_2 can now be readily introduced into a variety of peptide building blocks or into suitable preassembled peptides. These results provide interesting potential for modifying the bioactivity of peptides and as probes for biochemical reactions.

The promise of **1** for the synthesis of other useful compounds, such as fluorine-tagged ligands for metal complexes,[13] is obvious, considering that the successful reactions described above were those with the greatest potential for failure, in our view. In fact, recent results show that the bis-fluoroalkylation observed with lysine is a general and facile reaction.[14]

Financial support of this research by the National Science Foundation is gratefully acknowledged. Crystallographic data were supplied by W. T. Pennington and G. Schimek.

‡ Bis(trifluoromethylsulfonyl)imide was obtained from its lithium salt (HQ-115™, 3M Co., St. Paul, MN) by vacuum sublimation from H_2SO_4 (see ref. 7). The other starting material $CF_3CH_2I(OCOCF_3)_2$, a hygroscopic solid that melts at 39–40 °C without decomposition, was prepared by oxidation of CF_3CH_2I with 50% H_2O_2 (available from Aldrich, Inc.) in TFAA under N_2 (3–5 d, RT). The preparation of **1** is simple, but anhydrous conditions must be maintained throughout the reaction. In a typical small-scale reaction, **2** (1.40 g, 5 mmol) was added under N_2, in one portion, into a solution of $CF_3CH_2(OCOCF_3)_2$ (2.16 g, 5 mmol) in CFC 113 (20 mL). This addition is endothermic. After 10 min, benzene (0.43 ml, 5 mmol) was rapidly added with ice–water cooling. The reaction mixture was allowed to return to 25 °C during 30 min and then stirred at 25 °C for 6 h. The volatiles were removed under vacuum and the residue was stirred with ice–water (50 ml) for 15 min. The precipitate was collected on a glass frit and freeze-dried to yield **1**, 1.28 g (46%) as a white powder, mp 77–79 °C. On a larger scale (up to 30 g of **1**) we have routinely obtained yields greater than 70%.

All other materials are commercially available and were used as received. The novel products **4–7** were fully characterized by ^{1}H, ^{19}F and ^{13}C NMR and elemental analysis.

§ Typical procedure. Cysteine (606 mg, 5 mmol), $CsHCO_3$ (968 mg, 5 mmol), and **1** (3.2 g, 5.6 mmol) were added into a degassed mixture of pH 10 buffer (Hydrion, Na_2CO_3–$NaHCO_3$, 20 mL) and CH_2Cl_2 (10 mL) at 5 °C under nitrogen with rapid stirring. The reaction mixture was allowed to return to 23 °C during 30 min. The aqueous phase was separated, neutralized and evaporated to a crystalline solid. This solid was refluxed twice in 30 mL CH_3CN to extract the Cs salt of **2**. The resulting powder was suspended in 10 mL water at pH 7, filtered through a syringe filter to remove insoluble cysteine and slowly evaporated to yield crystalline **4** (874 mg, 82%), $[\alpha]_D^{25}$ −15 (*c* 0.37, 4 M HCl).

¶ Crystal data of **4**: formula, $C_5H_8F_3NO_2S$; M = 203.2; monoclinic; $P2_1$(#4); T = 25 °C; a = 9.503(3), b = 5.166(3), c = 16.957(3) Å, β = 91.45(2)°; V = 832.2(6) Å^3; D_{calc} = 1.622 g cm^{-3}; Z = 4 (2 unique); μ = 0.40 mm^{-1}; empirical absorption correction (0.94–1.00); Mo-Kα radiation with graphite monochromator, λ = 0.71073 Å; Rigaku AFC7R diffractometer; 2119 measured reflections (R_{int} = 1.61%); 1676 reflections used with $F > 2\sigma(F)$; $2\theta_{max}$ = 55°; 217 parameters; non-H atoms refined anisotropically; H atoms fixed in calculated positions (C–H = 0.96 Å); full-matrix least-squares refinement; R = 4.68%/R_w = 5.93%. Stereochemical study on cyclic acetal formation during anodic oxidation of naphthalene derivatives by transformation of chiral alcohol to achiral acetal

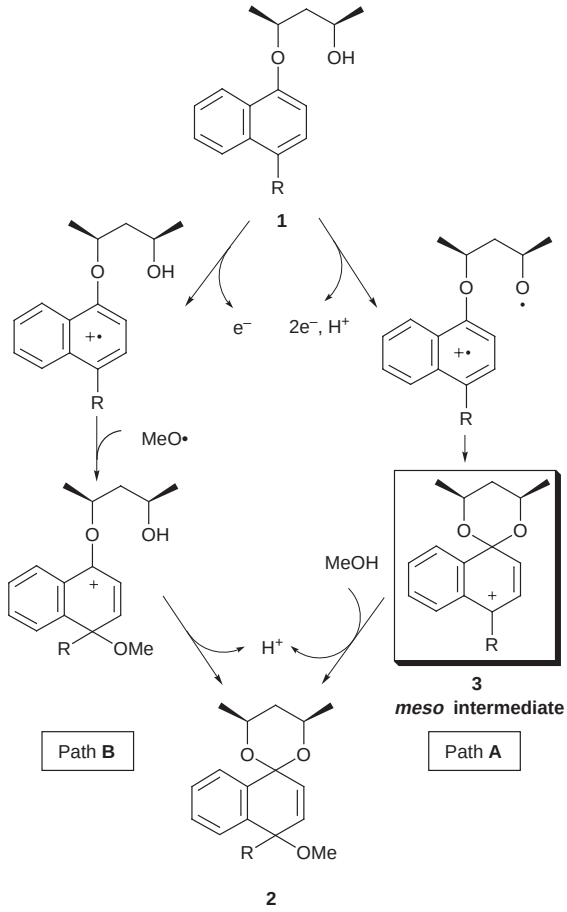
Morifumi Fujita,*† Masaki Ohshiba, Shohei Shioyama, Takashi Sugimura* and Akira Tai

Faculty of Science, Himeji Institute of Technology, Kanaji, Kamigori, Ako-gun, Hyogo 678-1297, Japan

A novel stereochemical approach is employed in anodic oxidation of naphthalene derivatives to discriminate the intramolecular radical addition *vs*. intermolecular radical addition paths; the contribution of the latter is revealed to be important, judging from the stereodifferentiating addition of MeOH at C-4 during the anodic oxidation of (1′*S*,3′*R*)-1-(3′-hydroxy-1′-methylbutoxy)-4-methylnaphthalene.

The anodic oxidation of arenes in alkaline MeOH provides oxidative 1,4-addition of the aromatic ring to give acetals or *p*-quinol ethers.[1,2] Swenton *et al*. have revealed that the anodic oxidation proceeds *via* coupling of the arene radical cation with the methoxyl radical (MeO·) generated by the one-electron oxidation of the methoxide anion, followed by nucleophilic addition of a second molecule of MeOH.[3] Introduction of an intramolecular alcoholic function in the substrate through a proper length of linker increases the product yield resulting in cyclic acetal formation on the oxidative product.[3] In this case, there are two possible modes for the coupling of the arene radical cation, *i.e*. with the intramolecular alkoxy radical (Path **A**) or the intermolecular one (Path **B**). Swenton *et al*. proposed that the intramolecular radical coupling is an important path for the anodic oxidation, based on the increase in product yield due to the effective trap of the arene radical cation by the intramolecular alkoxyl radical.[3] However, it is difficult to distinguish between the intramolecular radical coupling path and the intermolecular one using the usual product analyses because these paths give the same product. To discriminate the reaction pathways, we introduce a novel stereochemical approach,‡ named 'chiral eclipse' methodology. The essentials of this stereochemical analysis are as follows (Scheme 1). The intramolecular radical coupling path (Path **A**) gives a *meso* intermediate **3** from the chiral substrate. Therefore, no optically active product is expected in Path **A** because the chirality of the side chain has already disappeared at the time of the addition at C-4. In contrast, the intermolecular coupling path (Path **B**) maintains the chirality of the side chain in the C-4 addition, which is expected to give an optically active product. Here the importance of the intermolecular coupling path (Path **B**) is revealed during the anodic oxidation of naphthalene derivatives having a (1′*S*,3′*R*)-3′-hydroxy-1′-methyl butoxy moiety **1** judging from the result that the optically active alcohol moiety can act as a chiral auxiliary to give a stereodifferentiating product.

Stereochemically pure substrates **1** were prepared in 90–59% *via* the Mitsunobu reaction[4] with the corresponding naphthol and (2*R*,4*R*)-pentane-2,4-diol. The anodic oxidation of **1a** in 1% methanolic KF solution at constant current at a platinum anode§ afforded **2a** in 75% yield at room temperature and 69% yield at −78 °C as a single diastereomer. The two possible products, **2-*si*** or **2-*re***, shown in Fig. 1 are produced by *si*- or *re*-face attack in the intramolecular acetal formation, respectively. The exclusive *si*-face attack of the intramolecular alcohol (**2** = **2-*si***) was proven by the NOE signal between the olefin proton and the methine protons. The diastereoface differentiation may be due to the steric repulsion between the *peri*-proton of the naphthalene core and the cyclic acetal moiety. The chirality of the alcohol moiety of **2** disappears due to the cyclic acetal forming.



Scheme 1

In this case, the enantiomer ratio of the oxidative product shown in Table 1 directly gives the stereodifferentiation at the C-4 position.

During the anodic oxidation of **1a** at −78 °C, definite π-facial differentiation (67:33) at C-4 was observed, whereas the enantiomer ratio dropped to 53:47 at room temperature. The cyclic acetal **1a** was readily hydrolysed to give the corresponding dienone **4a** in 97% under acidic conditions. The enantiomer ratio of **4a** (67:33) is in good agreement with that of **2a** (67:33),

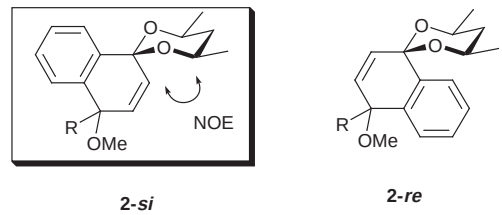


Fig. 1

indicating that the hydrolysis proceeds without epimerisation. The stereodifferentiation indicates the significant participation of Path **B** during the anodic oxidation of **1** because in Path **A** the chirality of the linker is eclipsed before the methanolic addition at C-4 resulting in a racemic product. A decrease in the stereodifferentiation was observed when bulky alkyl groups (Et, Pr^i) were introduced at C-4 (**1c**, **d**). The poor stereodifferentiation may be caused by a decrease in the contribution for path **B** due to steric hindrance for the intermolecular MeO· addition at C-4. In contrast, the enantiomer ratio slightly increased to 72:28 in the anodic oxidation of 1,8-dimethyl substituted naphthalene **1b** at −78 °C. The *peri* strain may partially inhibit the intramolecular alkoxyl radical coupling (Path **A**). Thus, the stereodifferentiating addition at C-4 is a general phenomenon during anodic oxidation of **1**, and reflects the contributions of Path **A** and Path **B** to the anodic oxidation mechanism.

As already mentioned, radical addition to the radical cation of the naphthalene derivatives is a key step for the stereodifferentiation during the anodic oxidation as well as the anodic oxidation itself. The regioselectivity for the radical attack at the arene radical cation is strongly influenced by the spin density of the arene radical cation. A high spin density (0.14) is observed at C-4 rather than at C-1 (0.04) in the 4-methylanisole radical cation by EPR measurements.[5,6a] This indicates that radical attack on C-4 is more favorable than on C-1 during the anodic oxidation and supports the importance of the intermolecular radical addition (Path **B**). The intramolecular solvation for arene radical cations has been reported using transient absorption spectra in low polarity media.[6b] The intramolecular alcohol solvates the arene radical cation without attacking it nucleophilically.[6b,7] Such intramolecular association by the chiral alcohol to the arene radical cation may contribute to the stereodifferentiating radical addition at C-4.

Regioselective alkylation in ionic liquids

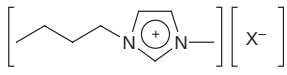
Martyn J. Earle,† Paul B. McCormac‡ and Kenneth R. Seddon§

The School of Chemistry, The Queen's University of Belfast, Stranmillis Road, Belfast, Northern Ireland, UK BT9 5AG

The room temperature ionic liquid 1-butyl-3-methylimidazolium hexafluorophosphate, [bmim][PF_6], is used as a 'green' recyclable alternative to dipolar aprotic solvents for the regioselective alkylation at the heteroatom of indole and 2-naphthol.

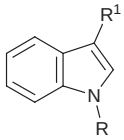
Efficient alkylation of the ambident nucleophiles indole **1** or 2-naphthol **4** is usually achieved by pre-formation of the ambident indolyl[1] or 2-naphtholate[2] anions and subsequent treatment with alkyl halide. Regioselective alkylation at the heteroatom for these anions is solvent dependant and can be achieved by use of a dipolar aprotic solvent such as DMF.[2,3] The procedure of Heaney and Ley for *N*-alkylation of indoles in DMSO with solid KOH is probably the most convenient method known and obviates the need for strong bases such as NaH or alkyllithiums.[4] However, despite the well known ability of solvents such as DMSO and DMF to accelerate nucleophilic displacements,[5] the relatively high boiling points of these solvents, their thermal instability, considerable odour problems and miscibility with both aqueous and organic phases can make product isolation difficult and solvent recovery almost impossible.

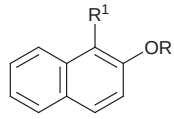
The introduction of air and moisture stable ambient temperature ionic liquids by Wilkes and Zaworotko[6] in 1992 considerably widened the possible applications of ionic liquid systems as solvents and reagents for organic synthesis. Recently room temperature ionic liquids have been reported as solvents for polymerisation,[7] hydrogenation[8] and as catalysts for the Diels–Alder reaction.[9] The ionic liquid [bmim][PF_6] is conveniently prepared,[10] fluid at room temperature, moisture stable and has no detectable vapour pressure. It is an excellent solvent for carbonyl compounds, alkyl halides, alcohols and amines, but is immiscible with saturated hydrocarbon solvents, dialkyl ethers and water. The unique solvating properties of this moisture stable ionic liquid makes it a strong candidate as a recyclable solvent.[11] Our recent interest has been in the area of clean synthesis[12] and as part of a programme to investigate the range of organic reactions possible in ionic liquids, we were interested in the reactions of **1** and **4** with alkyl halides in [bmim][PF_6].



[bmim][PF_6] X = PF_6

[bmim][BF_4] X = BF_4





1 R = R^1 = H
2 R = Et, Bu, Me or $PhCH_2$, R^1 = H
3 R = R^1 = Et, Bu, Me or $PhCH_2$

4 R = R^1 = H
5 R = Et, Bu, Me or $PhCH_2$, R^1 = H
6 R = R^1 = Et, Bu, Me or $PhCH_2$

The reaction of **1** with simple alkyl halides at room temperature was examined in [bmim][PF_6] using solid KOH as base; the products were conveniently extracted with Et_2O, and almost exclusive *N*-alkylation to form **2** was seen in all cases. The results for the alkylation of **1** with four typical alkyl halides in this solvent are outlined in Table 1. These reactions were carried out, typically as 10% w/v solutions of **1** in [bmim][PF_6] using 1.3 to 2 equiv. of alkyl halide and 2 equiv. of KOH. Reactions were complete in 2–3 h with almost quantitative extraction of products. The dialkylated products **3** were identified from the proton NMR spectra of the crude extracts and were only observed for the more reactive alkyl halides, $PhCH_2Br$ and MeI. Analogous results were seen for the alkylation of 2-naphthol, **4**, to give predominantly *O*-alkylated products **5** (Table 1). The solvent can be typically recovered by filtering to remove residual insoluble KOH and precipitated potassium halide followed by vacuum drying. The NMR spectra (^1H, ^{13}C, ^{19}F) of recovered solvent indicate no evidence of ionic liquid degradation during the course of the reactions and the recovered solvent has been recycled numerous times with no appreciable decrease in yield or regioselectivity, with only small mechanical losses. The ionic liquid [bmim][PF_6] can truly be compared with classical molecular solvents, with the added advantage of *in situ* generation of anion, and the non-nucleophilic hexafluorophosphate anion avoids problems associated with halide exchange which had been encountered by Brunet and co-workers in their study.[13] Further studies indicate that the related ionic liquid 1-butyl-3-methylimidazolium tetrafluoroborate [bmim][BF_4][14] is also an efficient solvent for alkylation of **1** and **4**.

In conclusion, room temperature ionic liquids are an attractive clean synthetic alternative to classical dipolar aprotic solvents for alkylation of ambident nucleophiles. There are many obvious advantages including simplicity of the methodology, the ease of product isolation, the lack of measurable solvent vapour pressure, the regioselectivity and the potential for recycling. Room temperature ionic liquids are neoteric solvents, and studies are underway to demonstrate their obvious potential as an alternative to classical molecular solvents for organic synthesis.

We are indebted to the EPSRC for funding this research, to the EPSRC and the Royal Academy of Engineering for the award of a Clean Technology Fellowship (to K. R. S.), and to

Enhancement of *Candida antarctica* lipase B enantioselectivity and activity in organic solvents

Marie-Claire Parker,*[a]† Stuart A. Brown,[b] Lindsey Robertson[b] and Nicholas J. Turner[b]

[a] *Department of Chemistry, Joseph Black Building, University of Glasgow, Glasgow, UK G12 8QQ*
[b] *Edinburgh Centre for Protein Technology, Department of Chemistry, University of Edinburgh, King's Buildings, West Mains Road, Edinburgh, UK EH9 3JJ*

The enantioselectivity and catalytic activity of Novozym 435® [*Candida antarctica* lipase B (CALB)] in organic solvents was found to dramatically increase upon the addition of a non-reactive organic base, such as Et_3N, to the reaction system.

It has been shown that the unusual microenvironment of enzymes in organic solvents can affect a number of parameters, including the degree of protein hydration,[1,2] secondary structure,[3] the susceptibility of the protein to inactivation and variations in the ionisation state[4] of side-chain residues. Frequently, these differences have been shown to result in interesting changes in the enzymes, including reversal of substrate specificity and changes in stereoselectivity, although the underlying reasons remain poorly understood.

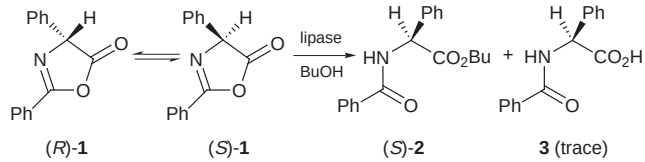
It is commonly accepted that the best predictor of enzyme catalytic activity in low water organic media is thermodynamic water activity (a_w).[1]‡ Over the past few years although much has been reported on enzyme enantioselectivity in organic media there are as yet no predictive rules available. Crude lipase preparations have proved to be simple and effective biocatalysts for kinetic resolutions, *e.g.* chiral carboxylic acids and alcohols. However, the low purity of these preparations (presence of other lipases and competing hydrolases) can, in specific reactions, lead to low and unpredictable enantioselective behaviour. This effect can be compounded when using organic solvents, due to the effect of different solvent properties on catalytic activity.

The starting point for the work described herein was the lipase (Lipozyme® *Mucor miehei*) catalysed dynamic resolution of 4-substituted oxazol-5(4*H*)-ones, a reaction we have previously employed for the synthesis of enantiomerically pure (*S*)-L-*tert*-leucine.[5] It was previously found that the modest enantioselectivity in toluene (*ca.* 68% ee) could be enhanced (*ca.* 97% ee) by the addition of a catalytic amount of Et_3N to the reaction; the role of Et_3N is not to facilitate racemisation of the substrate.

We decided to investigate this effect in more detail by using a commercially available immobilised lipase,§ Novozym 435 (*Candida antarctica* lipase B[6] (CALB), since a larger substrate range could be tested with this enzyme. The catalytic activity and enantioselectivity of the alcoholysis of (±)-2-phenyl-4-benzyloxazol-5(4*H*)-one **1** using butan-1-ol as the nucleophile (Scheme 1) was monitored¶ under a range of reaction conditions, including controlled water activity. Hydration was controlled by equilibrating‖ enzyme and solvent with the appropriate saturated salt solution[7] of known thermodynamic water activity a_w. Therefore a low a_w system will be one in which the solvent is poorly hydrated and the enzyme, similarly, has a low level of hydration, and at high a_w (*e.g.* 0.97) the solvent is near water saturation and the enzyme is fully hydrated (as would be found in an aqueous system). Table 1 shows the effect of hydration on the initial catalytic rate and enantioselectivity, in three different solvents, n-hexane, toluene and MeCN, either with or without Et_3N.**

It can immediately be seen that the lipase-catalysed reaction is very sensitive to water activity. The addition of a non-reactive organic base,†† Et_3N, to the reaction enhances significantly both the enantioselectivity and catalytic activity of the enzyme. Even low levels of hydration, present in the more nonpolar solvents such as n-hexane and toluene, are detrimental to the overall catalytic performance of CALB. We find that generally for optimum yield and enantioselectivity, both the enzyme and solvent should be rigorously dried prior to addition of Et_3N. We were interested to see if addition of Et_3N to a reaction already in progress and of poor enantioselectivity, could reverse this effect. As can be seen from Fig. 1, the addition of Et_3N after 140 min immediately results in enhanced catalytic rate and enantioselectivity.

In order to examine the generality of the effect of Et_3N we investigated a second reaction, namely the CALB-catalysed



Scheme 1

Table1 Effect of water activity on initial catalytic rate[a,b] and enantiospecificity as a function of hydration, with and without Et_3N

		No Et_3N		Et_3N	
Solvent[c]	a_w	Initial rate/nmol min^{-1} mg^{-1}	Ee (%)	Initial rate/nmol min^{-1} mg^{-1}	Ee (%)

[a] Initial rate for (*S*)-butyl ester enantiomer **2**. [b] Results reported are the average of three separate measurements. [c] Note ‖. [d] Ref. 8. [e] No reaction.

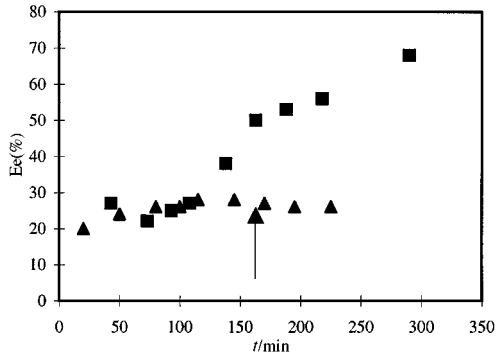

Fig. 1 Effect of Et_3N on ee. Reactions A (▲) and B (■) were carried out under identical conditions (a_w = 0.69). At t = 140 min, 14 mol% Et_3N was added to reaction B (arrow).

reaction between 1-phenylacetoxy-2-methylcyclohexene and butanol yielding 2-methylcyclohexanone and butyl phenylacetate.[9,15] Using n-hexane (a_w = 0) and MeCN (0.5% H_2O, a_w = 0.1) as the solvents, we observed that the addition of Et_3N to the solvent resulted in a dramatic increase in the catalytic activity. An approximate 200-fold increase in activity was observed in MeCN (a_w = 0.1) and a 700-fold one for that in n-hexane (a_w = 0.97). The higher activity found in n-hexane is presumably due to a more intimate contact between the enzyme and Et_3N in a more nonpolar environment. Similarly, the activation effect for (±)-2-phenyl-4-benzyloxazol-5(4*H*)-one ring-opening in MeCN is similar to that described above and is expected to be a result of less Et_3N adsorption to the enzyme in MeCN.

The ability of organic bases to increase the enantioselectivity of lipase-catalysed reactions in water-saturated organic solvents has previously been reported.[10–13] In some cases[11,12] this effect has been attributed to the formation of an ion-pair between the base and any by-product acid. Using electrospray ionisation mass spectrometry (ESI-MS)‡‡ we have detected the formation of carboxylic acid **3** during the course of the oxazolone reaction at intermediate to high water activities (*e.g.* a_w = 0.69–0.97). We have also found that addition of acid **3** to an already hydrated system results in loss of activity, which can be fully recovered upon addition of an organic base, presumably *via* formation of an ion pair. Ion pair formation is observed in both low and high dielectric non-hydrogen bonding solvents such as n-hexane and MeCN. In a high dielectric, non-hydrogen bonding solvent such as MeCN, where the acid was found to be more soluble, we find experimentally that dissolution of acid **3** in n-hexane and MeCN occurs upon addition of Et_3N, thus removing acid from the immediate microenvironment of the enzyme. However, the enhancement of catalytic performance and enantioselectivity for rigorously dried samples, and those of low water activity (a_w < 0.7) where we find no evidence for hydrolysis over the course of the initial rate measurement, cannot be explained in terms of hydrolysis products affecting enantioselectivity, since for an unrelated substrate, an activating effect on the catalytic activity has been demonstrated.

The addition of co-solvents, such as DMF and DMSO, was found to solubilise the acid and thus it was anticipated that they would perform a similar role to Et_3N in removing any acid from the immediate vicinity of the enzyme. Both DMF and DMSO were chosen as additives to the bulk organic solvent (toluene at a_w = 0.22). Although both DMF and DMSO increased the enantioselectivity of the reaction to 85% ee, there was no significant effect on the catalytic rate as found with Et_3N. Since the solvation of the carboxylic acid by these co-solvents occurs by a different mechanism to that of Et_3N, *i.e.* the additives are unable to form ion-pairs, they have limited use in reducing the overall effect.

The role of Et_3N therefore appears to be dual in nature, *i.e.* increasing both the enantioselectivity and catalytic activity of lipase-catalysed reactions. The addition of Et_3N therefore provides an additional strategy for improving the enantioselectivity of lipase-catalysed reactions. We are currently investigating this effect with other lipolytic enzymes.

We are grateful to Boehringer Mannheim, Germany, for the generous gift of lipase samples. The BBSRC is acknowledged for a David Phillips Fellowship (M. C. P.) and a studentship (S. A. B.).

Notes and References

† E-mail: m.parker@chem.gla.ac.uk

‡ The thermodynamic water activity (a_w) describes the mass action effect of water on hydrolytic equilibria and also describes the partitioning of various water phases that can compete for water binding (ref. 1).

§ Polyacrylamide gel electrophoresis of CALB desorbed from the solid support exhibited a single band corresponding to the reported molecular weight of CALB (33 KDa) (ref. 6).

¶ (±)-2-Phenyl-4-benzyloxazol-5(4*H*)-one **1** (0.16 mmol) was placed in a 4 ml screw top vial together with the solvent, (either anhydrous or hydrated), butan-1-ol (0.24 mmol, 1.5 equiv.) CALB (40 mg) and Et_3N (14 mol%). The reaction vial was shaken at 250 rpm on a rotary shaker at 37 °C and the progress and ee (%) of the reaction were monitored by chiral HPLC (Chiralcel-OD, 250 × 4.6 mm, Mallinckrodt Baker, n-hexane–Pr^iOH (90:10 v/v), UV detection λ = 254 nm).

‖ *Candida antarctica* lipase B (CALB) was received as an immobilised preparation (Novozym 435, Boehringer Mannheim, Germany) and was dehydrated over P_2O_5 (at room temp.) for 2–3 days. Rehydration of dried lipase to the desired water activity (a_w) was carried out using saturated salt solutions (equilibration period 48–72 h). (±)-2-Phenyl-4-benzyloxazol-5(4*H*)-one **1** was stored over P_2O_5 at 0 °C; anhydrous solvents were stored over freshly reactivated 3 Å or 4 Å molecular sieves. The water content of dried solvents was measured using Karl Fischer water titration (ref. 15) and found to be < 0.001 wt%. Solvents were hydrated separately from the enzyme using the same water equilibration procedure as described above, approximately 24 h before use.

** Control reactions showed that no detectable ester (as judged by HPLC) was formed in the absence of enzyme, either with or without Et_3N, over a 48 h analysis period.

†† Other organic bases give very similar results to Et_3N, *e.g.* DABCO and lutidine. Insoluble inorganic bases, *e.g.* $KHCO_3$ and K_2CO_3, had no effect and did not result in the high catalytic rate and enantioselectivity observed with the soluble organic bases.

‡‡ Electrospray ionisation mass spectrometry (ESI-MS) and atmospheric chemical ionisation (APCI) were performed on a Micromass Platform II spectrometer (cone voltage 20 V).

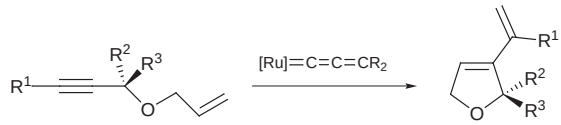
Catalytic synthesis of 3-vinyl-2,5-dihydrofurans from yne-enes promoted by photochemically activated metal–allenylidene $L_nRu{=}C{=}C{=}CR_2$ complex

Michel Picquet, Christian Bruneau, and Pierre H. Dixneuf†

UMR 6509 CNRS - Université de Rennes, Organométalliques et Catalyse, Campus de Beaulieu, F-35042 Rennes, France

The ruthenium(II)–allenylidene salt [(*p*-cymene)(PCy_3)ClRu=C=C=CPh_2]PF_6 acts as an olefin metathesis catalyst precursor for the yne-ene transformation of the mixed propargylic allyl ethers $HC{\equiv}C{-}CR_2OCH_2CH{=}CH_2$ into 3-vinyl-2,5-dihydrofurans; initial photochemical irradiation efficiently promotes the catalytic activity.

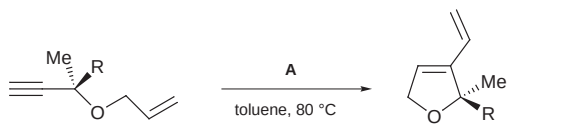
3-Vinyl-2,5-dihydrofurans have potential as Diels–Alder dienes and for access to optically active derivatives *via* asymmetric catalysis.[1] To the best of our knowledge, no direct preparation of these compounds has been reported, whereas a stereoselective route to 3-vinyltetrahydrofuran derivatives from cyclic allylsiloxanes has just been found.[2] However, it appears that the 3-vinyl-2,5-dihydrofuran structure **II** should be reached, in a straightforward way, from oxygenated yne-enes of type **I** *via* catalytic ring closing metathesis (RCM) reaction (Scheme 1). Indeed, since the pioneering work of Katz,[3] carbocycles have been made by RCM reactions using tungsten[3] or chromium[4] carbene catalysts. Recently, neutral 16-electron ruthenium carbenes $(PCy_3)_2Cl_2Ru{=}CHR$ (R = $CH{=}CPh_2$, Ph), which tolerate functional groups, have been shown to efficiently promote access to N- and O-containing heterocycles, *via* ring closing metathesis.[5,6] However, these Ru=CHR complexes appear to be less efficient for the ring closing metathesis of yne-ene derivatives containing a terminal C≡CH bond.[5,7]



I **II**

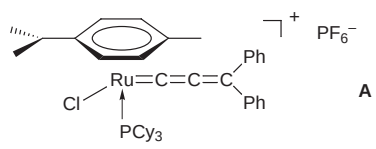
Scheme 1

We now report (i) a general method for the preparation of new 3-vinyl-2,5-dihydrofurans of type **II** directly from mixed propargylic allyl ether derivatives **I**, *via* a RCM reaction in the presence of a novel olefin metathesis catalyst, the 18-electron cationic ruthenium allenylidene complex [(arene)(PCy_3)Cl-Ru=C=C=CPh_2]PF_6, which has just been shown to perform the ring closing metathesis of 1,6- to 1,20-dienes,[8] and (ii) that the catalytic species formation is favoured by photochemical activation of the catalyst precursor.



1 R = Ph
2 R = CH_2CHMe_2

8 R = Ph (77%)
9 R = CH_2CHMe_2 (65%)



A

Scheme 2

The allyl prop-2-yn-1-yl ethers of type **I** were conveniently prepared from the corresponding prop-2-yn-1-ols on treatment by NaH and allyl bromide in DMF at room temperature (60–97%). The derivatives **1** and **2** were first reacted with 2.5 mol% of [(*p*-cymene)(PCy_3)ClRu=C=C=CPh_2]PF_6 (**A**) in toluene at 80 °C. The conversion was completed after 24 h and 6.5

Table 1 Catalytic synthesis of 3-vinyl-2,5-dihydrofurans **8–14** with photochemically activated ruthenium–allenylidene catalyst **A**[a]

Substrate	Product	Heating period at 80 °C[a]/h	Isolated yield (%)[b]
 **1**	 **8**	4	84
 **2**	 **9**	1	62
 **3**	 **10**	23	67
 **4**	 **11**	63[c]	41
 **5**	 **12**	1	74
 **6**	 **13**	1	63
 **7**	 **14**	24	83

[a] Initial UV irradiation (300 nm) at room temperature for 0.5 h in toluene followed by heating at 80 °C until complete conversion of **1–7**. [b] Yields were obtained after distillation under reduced pressure. [c] Reaction performed in refluxing CH_2Cl_2 after irradiation.

h, respectively, and derivatives **8** (77%) and **9** (65%) were obtained as the sole reaction products (Scheme 2).

The 18-electron catalyst precursor is expected to give an active catalytic species after partial decoordination or loss of the arene ligand to generate a highly coordinatively unsaturated ruthenium species. In order to check this hypothesis and in the search for better activity, the previous reaction was performed under UV irradiation [Hg lamp, 300 nm] in order to displace the *p*-cymene ligand, as was suggested for (*p*-cymene)$RuCl_2(PR_3)$.[9] After 0.5 h irradiation at room temperature in toluene followed by thermal reaction at 80 °C for 4 h, the conversion of **1** was completed (*vs*. 24 h at 80 °C previously without initial irradiation) and the 3-vinyl dihydrofuran **8** was obtained in 84% yield. Similarly, the complete conversion of **2** was achieved after only 1 h at 80 °C instead of 6.5 h without irradiation, and **9** was obtained in 62% yield (Table 1).

Preliminary UV irradiation tremendously favours the generation of the active catalytic species as the period of heating at 80 °C was significantly reduced. The allyl ethers **3**–**5** were reacted under the latter conditions and the 3-vinyldihydrofurans **10**–**12** were isolated in 62–84% (Table 1). It is noteworthy that these 3-vinyl-2,5-dihydrofurans are stable in solution at moderate temperature (80 °C) but decompose rapidly when isolated as pure compounds.

The increasing of the steric hindrance at the ether carbon atom C1 slows down the conversion of the ether (**2** > **1** >> **3**). The RCM reaction applied to derivative **6**, easily made from cyclohexanone, led after 1 h at 80 °C to the spirodihydrofuran **13** (63%), and showed reactivity similar to that of the disubstituted derivative **2**. The transformation of compound **7** into the 3-isopropenyldihydrofuran **14** in 83% yield, after irradiation and 24 h of reaction at 80 °C, compared with that of compound **1** (4 h, 84%), indicates that the ring closing metathesis reaction of enynes involving a disubstituted C≡C triple bond is disfavoured. This contrasts with the RCM of yne-enes containing amido or tosylamido functional groups.[5,7] It is noteworthy that the formation of the bis(dihydrofuran) was obtained previously from the disubstituted yne-ene CH_2=$CHCH_2OCH_2C$≡CCH_2OCH_2CH=CH_2 and the L_nRu=CHCH=CPh_2 catalyst.[6]

The above results show the second use of (arene)-Ru=C=C=CR_2 complexes in catalysis.[8] They are not only able to promote non-conjugated diene metathesis, they are also efficient catalysts for the ring closing metathesis of terminal yne-enes. These results bring evidence for the first time that the (arene)Ru=C=C=CR_2 complex **A** can be photochemically activated for improved generation of the active catalytic species and that this catalyst tolerates the presence of a terminal C≡CH bond.

The authors are very grateful to Dr A. Fürstner for creative discussions.

Asymmetric cycloadditions of dienes to chloronitroso compounds derived from carbohydrate ketones: syntheses of (−)-physoperuvine and (+)-epibatidine

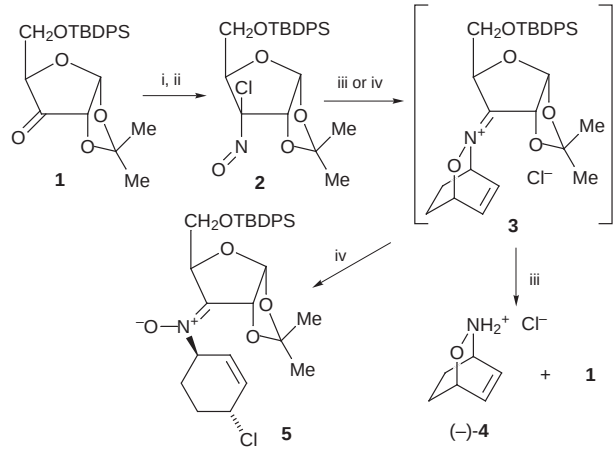
Adrian Hall,[a] Patrick D. Bailey,[a] David C. Rees[b] and Richard H. Wightman*[a]†

[a] *Department of Chemistry, Heriot-Watt University, UK EH14 4AS*
[b] *Organon Laboratories Ltd., Newhouse, Lanarkshire, UK ML1 5SH*

An α-chloronitroso compound derived from D-xylose undergoes cycloadditions with cyclic dienes to give bicyclic dihydrooxazines of high enantiomeric purity; such adducts were used in a synthesis of (−)-physoperuvine and a formal synthesis of (+)-epibatidine, whilst a pseudoenantiomeric chloronitroso compound is also available from L-sorbose.

There has been considerable interest in recent years in the development of asymmetric versions of the hetero-Diels–Alder cycloaddition[1] of dienes with *C*-nitrosocompounds to form 3,6-dihydro-1,2-oxazines, since the further manipulation of the initial cycloadducts can be used to prepare a wide range of nitrogen-containing organic compounds. Most work has been done using acylnitroso compounds bearing a chiral auxiliary,[2] although the removal of the auxiliary can involve conditions that are not compatible with sensitive functionality. Studies have also been carried out using chiral α-chloronitroso compounds, since in the presence of a nucleophilic solvent solvolysis of the initial cycloadduct occurs to liberate the dihydrooxazine directly. After initial work with steroidal chloronitroso compounds,[3] there has been emphasis on the use of chloronitroso compounds derived from carbohydrate hydroximino lactones.[4,5] We were attracted to the use of chloronitroso compounds derived from readily-available and sterically-rigid carbohydrate ketones; we now report that such systems can give very high degrees of enantioselectivity, whilst also regenerating the auxiliary in high yield and in a form in which it can be easily recycled. We also describe the use of one of our auxiliaries[6] in asymmetric syntheses of two natural products.

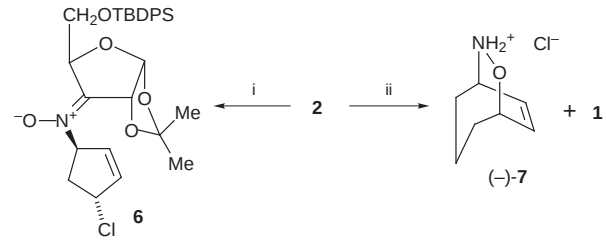
Thus, 1,2-*O*-isopropylidene-α-D-xylofuranose,[7] was selectively silylated and then oxidized (PCC, molecular sieves) to give ketone **1** (Scheme 1). Conversion of **1** to its oxime (mixed isomers) and subsequent treatment with *tert*-butyl hypochlorite gave the α-chloronitroso compound **2** (69% overall from D-xylose) as a blue crystalline solid. That chlorination had occurred from the *exo*-face was confirmed by X-ray crystallography, which also indicated the eclipsed nature of the chloronitroso unit[8] (dihedral angle Cl–C–N–O, 0.8°).



Scheme 1 *Reagents and conditions*: i, $NH_2OH·HCl$, $NaHCO_3$, EtOH–H_2O; ii, Bu^tOCl, CH_2Cl_2; iii, cyclohexa-1,3-diene, $CHCl_3$–Pr^iOH–H_2O (100:100:1), 0 °C; iv, cyclohexa-1,3-diene, $CHCl_3$, 0 °C

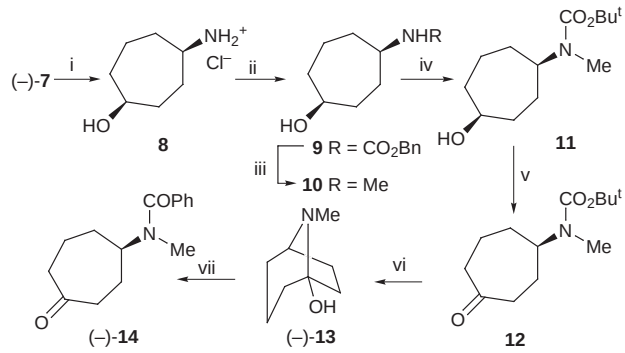
Treatment of **2** with cyclohexa-1,3-diene in $CHCl_3$–Pr^iOH containing water (1%) gave the cycloadduct (−)-**4** (94%), together with ketone **1** (95%), which could be recycled. The absolute configuration of (−)-**4** followed from the sign of its optical rotation,[4a,5] and the enantiomeric excess (ee) was shown to be 96% by reaction of (−)-**4** with (+)-camphor-10-sulfonyl chloride and integration of the two pairs of doublets for the diastereotopic protons at C-10 [major isomer from (−)-**4**, δ 2.91 and 3.37; minor isomer from (+)-**4**, δ 2.76 and 3.47].[4a] In contrast, when the reaction of **2** with cyclohexadiene was carried out in a non-nucleophilic and non-coordinating solvent ($CHCl_3$), only the nitrone **5** (69%) was obtained, a result that can be rationalized as occurring by attack of chloride ion on the intermediate iminium ion **3**.‡

Reaction of **2** with cyclopentadiene (Scheme 2) did not give any bicyclic dihydrooxazine under any conditions investigated. Instead, the only product isolated, even in the presence of nucleophilic solvents, was the nitrone **6** (93% in $CHCl_3$), and attempts to divert the course of reaction by addition of silver salts were unsuccessful. The structure of **6**, including the stereochemistry of the C=N double bond, was confirmed by X-ray crystallography. On the other hand, reaction of **2** with cyclohepta-1,3-diene in the presence of water gave only the bicyclic adduct (−)-**7** {$[\alpha]_D$ −11.0 (*c* 1.0, EtOH)} (93%) and ketone **1** (93%). Derivatization of **7** with camphor-10-sulfonyl chloride and analysis by ^1H NMR spectroscopy led to an estimated ee of ⩾96%. The pattern of reactivity shown by **2** as the diene is varied presumably reflects the degree of ring strain present in the intermediate iminium ions (**3** and the equivalent structures). The stereochemistries of (−)-**4** and (−)-**7**, and of **6**, can be rationalized in terms of cycloadditions occurring through *exo*-transition states on the less hindered *si*-face of the nitroso group, away from the isopropylidene unit.



Scheme 2 *Reagents and conditions*: i, cyclopentadiene, $CHCl_3$, room temp; ii, cyclohepta-1,3-diene, $CHCl_3$–Pr^iOH–H_2O (100:100:1), 4 °C

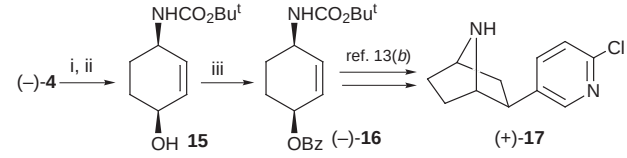
The cycloadduct (−)-**7** was used in an enantioselective synthesis of (−)-(*R*)-physoperuvine [(−)-**13**] (Scheme 3), the *S*-enantiomer of which is the major alkaloid of *Physalis peruviana* Linne.[9] Physoperuvine has been synthesized as a racemate,[10] and in one prior enantioselective synthesis.[11] Reduction of (−)-**7** gave the amino alcohol **8**, (95%) which was converted to the *N*-methyl compound **10** (69% overall) by reduction of the benzyloxycarbonyl derivative **9**. Direct oxida-



Scheme 3 *Reagents and conditions*: i, H_2, $Pd(OH)_2$/C, MeOH; ii, $ClCO_2Bn$, Na_2CO_3, acetone; iii, $LiAlH_4$, THF, reflux; iv, $(Bu^tOCO)_2O$, $EtNPr^i_2$, CH_2Cl_2; v, PCC, CH_2Cl_2; vi, TFA, then Na_2CO_3 aq; vii, BzCl, pyridine, CH_2Cl_2

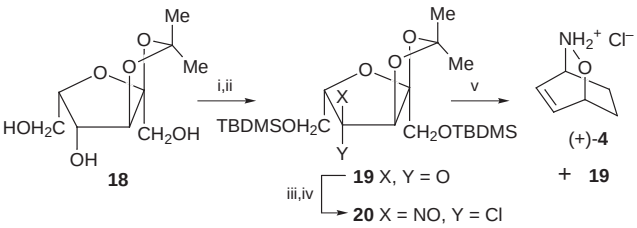
tion of **10** with Jones' reagent[10] gave (−)-**13**, but the isolation of the product in good yield was troublesome and the sequence shown in Scheme 3, involving protection of the basic nitrogen, gave (−)-**13** {$[\alpha]_D$ −50.0 (*c* 0.46, CH_2Cl_2)}§ in higher overall yield. Benzoylation of (−)-**13** gave the crystalline *N*-benzoyl derivative (−)-**14**, $[\alpha]_D$ −79.4 (*c* 0.97, CH_2Cl_2) {lit. for the enantiomer, $[\alpha]_D$ +78.0 (*c* 0.44, $CHCl_3$),[11] $[\alpha]_D$ +95.6 (*c* 1.3, $CHCl_3$)[9c]}.

The potent non-opioid analgesic activity shown by (−)-epibatidine [(−)-**17**], isolated from the poison frog *Epipedobates tricolor*, has led to many syntheses,[12] including some enantioselective approaches.[13] The availability of essentially enantiomerically pure cycloadduct (−)-**4** permitted a formal synthesis of (+)-epibatidine [(+)-**17**] (Scheme 4). Reductive cleavage of the N–O bond, and reaction with di-*tert*-butyl dicarbonate gave **15** (67%), and benzoylation of this gave (−)-**16**, mp 78–79 °C, $[\alpha]_D$ −87.6 (*c* 0.89, CH_2Cl_2), enantiomeric with an intermediate {mp 78–79 °C, $[\alpha]_D$ +86.6 (*c* 1.26, CH_2Cl_2)} used, *via ent*-**15**, in Trost and Cook's synthesis of (−)-epibatidine.[13b]



Scheme 4 *Reagents and conditions*: i, Zn, AcOH; ii, $(Bu^tOCO)_2O$, Na_2CO_3, acetone–MeOH; iii, BzCl, DMAP, pyridine, CH_2Cl_2

Although the use of a chiral auxiliary derived from D-xylose leads in both the above syntheses to the enantiomers of the natural products, the commercial availability of L-xylose makes it possible to employ identical chemistry in either enantiomeric series. However, L-xylose is relatively expensive, and so we have prepared (Scheme 5) a chloronitroso compound **20** pseudoenantiomeric with **2** from the cheap L-sorbose, *via* the



Scheme 5 *Reagents and conditions*: i, TBDMSCl, Et_3N, DMF; ii, PCC, mol. sieves, CH_2Cl_2; iii, $NH_2OH{\cdot}HCl$, $NaHCO_3$, EtOH–H_2O; iv, Bu^tOCl, CH_2Cl_2, 0 °C; v, cyclohexa-1,3-diene, $CHCl_3$–Pr^iOH–H_2O (100:100:1), 0 °C

monoisopropylidene compound **18**,[14] prepared using the same procedure as for the equivalent xylose derivative.[7]

When **20** was treated with cyclohexa-1,3-diene in the presence of water, the cycloadduct (+)-**4** was isolated in 76% yield, together with ketone **19** (86%). The ee of (+)-**4** was estimated as ⩾97% by derivatization with (+)-camphor-10-sulfonyl chloride.[4a] It thus appears that the two ketones **1** and **19** can be used to gain ready access to the two enantiomeric series through cycloadditions of the pseudoenantiomeric chloronitroso compounds **2** and **20**.

We thank the EPRSC for a studentship (A. H.) and for access to the National Mass Spectrometry Service Centre, Organon Laboratories Ltd for additional financial support, and Dr Georgina Rosair for X-ray crystallography.

‡ The analogous chloronitroso compound derived from di-*O*-isopropylidene-D-glucose behaved very similarly to **2** in the reactions of both Schemes 1 and 2.

§ The specific rotation of physoperuvine does not seem to have been previously reported. Small negative values have been reported for the *hydrochloride* of both natural {$[\alpha]_D$ −0.8 (*c* 1.0, MeOH)} [ref. 9(*b*)] and synthetic {$[\alpha]_D$ −0.98 (*c* 1.28, MeOH)} (ref. 11) *S*-physoperuvine, although a small positive value has also been quoted in a different solvent {$[\alpha]_D$ +1.2 (*c* 1.3, H_2O)} [ref. 9(*a*)]. Our results imply that natural (*S*)-physoperuvine, as the free base, is significantly dextrorotatory.

1,2-Asymmetric induction in the aldol addition reaction of malonate ester enolate to α-alkoxy aldehyde

Shinji Marumoto, Hiroshi Kogen*† and Shunji Naruto

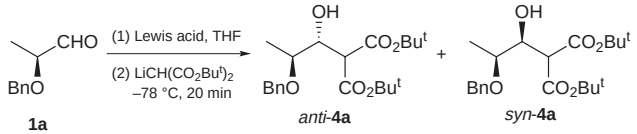
Exploratory Chemistry Research Laboratories, Sankyo Co., Ltd., 2-58, Hiromachi 1-chome, Shinagawa-ku Tokyo, 140-8710 Japan

Stereoselective aldol reactions between the lithium enolate of *tert*-butyl malonate and various α-alkoxy aldehydes in the presence of zinc chloride gave *anti*-1,2-diols in high yields; 2-trityloxypropanal yielded the *syn*-1,2-diol under the same conditions.

The stereoselective aldol reaction represents one of the major challenges of modern synthetic organic chemistry.[1] Many useful methodologies have been reported during the last few decades. For instance, 1,2-asymmetric induction in the aldol reaction of α-alkoxy aldehydes with silyl enol ethers or ketene silyl acetals is well-established.[2] The aldol reaction between α-alkoxy aldehydes and a malonate ester is especially useful for the synthesis of biologically active compounds.[3] For example, our recent synthesis of the neuritogenic agent epolactaene[4] relied exclusively on this operation for the formation of the 1,2-diol. However, Saba *et al*.[5] have been the only ones to report this type of aldol reaction, and the examples are limited. According to their report, when optically active dimenthyl malonate was added to chiral α-alkoxy aldehydes, the *anti* aldol adduct was obtained in ratios from 3:1 to 5:1, even in matched cases. Here we demonstrate simpler and more general methodologies for these aldol reactions which give higher *anti* product stereoselectively.

Initially, we attempted an 1,2-asymmetric aldol reaction between the lithium enolate of *tert*-butyl malonate and 2-benzyloxypropanal **1a**,[6] derived from methyl lactate, at −78 °C (Table 1). When this reaction was carried out without Lewis acid, aldol adduct **4a** was obtained with low diastereoselectivity (60:40, entry 1). However, when we added $MgBr_2$ to coordinate to the carbonyl group, the diastereoselectivity was slightly increased (68:32, entry 2). The reaction was further examined in the presence of various Lewis acids under various conditions.‡ The results are shown in Table 1. High *anti*-selectivity was observed using $ZnCl_2$ (82:18) or $BF_3{\cdot}OEt_2$ (91:9) (entries 4, 5). Moreover, when the reaction was carried out at −98 °C in the presence of $ZnCl_2$, the *anti* aldol adduct was obtained in excellent yield with high stereoselectivity (87:13).

Table 1 Aldol addition reaction of malonate ester enolate to 2-benzyloxypropanal



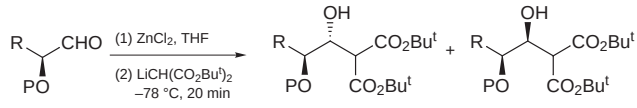
1a *anti*-**4a** *syn*-**4a**

Entry	Lewis acid	Yield (%)	*anti*:*syn*[a,b]
1	None	71[c]	60:40
2	$MgBr_2$	80	68:32
3	$ZnBr_2$	68	73:27
4	$ZnCl_2$	81	82:18
5	$ZnCl_2$	89[d]	87:13
6	$BF_3{\cdot}Et_2O$	52	91:9

[a] Ratios were determined by HPLC analysis of the crude mixture. [b] Stereochemical assignments were secured through deprotection to diol (see note §). [c] Reaction was carried out for 2 h. [d] Reaction was carried out at −98 °C.

In order to further evaluate the effect of the addition process on stereoselectivity, various α-alkoxy aldehydes were examined in this aldol reaction in the presence of $ZnCl_2$ at −78 °C. The results are summarized in Table 2. The stereoselectivity decreased somewhat when a bulky silyl group was used in place of the benzyl group as the protective group (entries 1–3). In contrast, when the alkyl group was changed from methyl to a more bulky isopropyl group (**2a**–**d**) high *anti*-selectivity was obtained using any aldehyde, although the chemical yield was affected by the size of the protective group (entries 4–7). The aldehyde **3a**, derived from mandelic acid, also gave a good result (entry 8).

Table 2 Influence of the substitution of the aldehyde in the aldol reaction in the presence of $ZnCl_2$

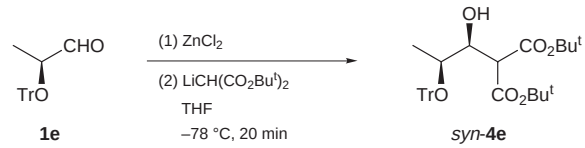


1 R = Me, **2** R = Pr^i, **3** R = Ph — **4** R = Me, **5** R = Pr^i, **6** R = Ph

Entry	Aldehyde	R	P	Yield (%)	*anti*:*syn*[a]
1	**1a**[b]	Me	Bn	81	82:18[c]
2	**1c**[d]	Me	Bu^{t}Ph$_2$Si	92	76:24[e]
3	**1d**[f]	Me	Ph$_3$Si	94	58:42[e]
4	**2a**[g]	Pr^i	Bn	75	97:3[c]
5	**2b**[f]	Pr^i	Bu^{t}Me$_2$Si	(90)[h]	98:2[e]
6	**2c**[i]	Pr^i	Bu^{t}Ph$_2$Si	(39)[h]	97:3[e]
7	**2d**[f]	Pr^i	Ph$_3$Si	(52)[h]	97:3[e]
8	**3a**[j]	Ph	Bn	83	94:6[c]

[a] Stereochemical assignments were secured through deprotection to the diol (see note §). [b] Ref. 6. [c] Ratios were determined by HPLC analysis of the crude mixture. [d] Ref. 7. [e] Ratios were determined by ^{1}H NMR analysis of the crude mixture. [f] Ref. 8. [g] Ref. 9. [h] Figures in parenthesis are the NMR yield. [i] Ref. 10. [j] Ref. 11.

To determine the extent to which the ratio of stereoisomers is affected by the protecting groups on the α-oxygen, we examined 2-trityloxypropanal **1e**[12] under the same conditions (Scheme 1). Surprisingly, the stereoselectivity was reversed and the *syn*-aldol product **4e** was preferred with high selectivity (90:10) in 53% yield (85% yield based on 62% conversion of the aldehyde **5** by ^{1}H NMR analysis). In this case, no aldol product was obtained in the absence of Lewis acid.



1e *syn*-**4e**

53% (85% conv. yield)

syn : *anti* = 90 : 10

Scheme 1

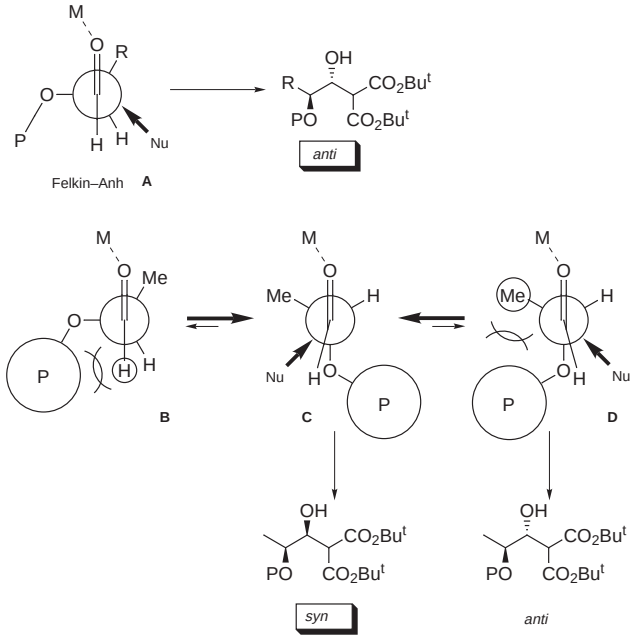


Fig. 1

To explain the reaction mechanism responsible for the observed stereoselectivity, we considered the following. The preferential formation of the *anti*- rather than *syn*-aldol product may be rationalized in terms of the normal Felkin–Anh transition state model[13] **A** described in Fig. 1. On the other hand, the remarkable *syn*-selectivity observed in Scheme 1 could not be explained by this Felkin–Anh transition state model. In this case, we postulate dipolar models **C** and **D**, avoiding steric interaction between the extremely bulky trityl group and aldehyde in model **B**. Because of the steric interaction between the trityl group and the methyl group in model **D**, model **C**, which provides a *syn*-aldol product, is favored over model **D**.

In conclusion, we have demonstrated 1,2-asymmetric induction in the aldol reaction between the lithium enolate of *tert*-butyl malonate and α-alkoxy aldehydes in the presence of a Lewis acid. *Anti*- or *syn*-aldol products were obtained in high yield with high stereoselectivity.

Dedicated to Professor Kenji Koga on the occasion of his 60th birthday.

‡ *General procedure*: To a solution of aldehyde (0.10 mmol) in THF (1 mL) was added zinc chloride (0.5 M in THF, 0.24 ml, 0.12 mmol) at room temperature. The reaction mixture was stirred for 1.5 h and then cooled to −78 °C. A solution of di-*tert*-butyl malonate (34 μl, 0.15 mmol) in THF (1 ml), which was treated with LHMDS (1.0 M in THF, 0.14 ml, 0.14 mmol) at −78 °C for 20 min, was added to the reaction mixture through a cannula. The stirring was continued for another 20 min at this temperature. To the mixture was added saturated aq. NH_4Cl, and the organic material was extracted with Et_2O. The combined organic extracts were dried over anhydrous $MgSO_4$ and concentrated *in vacuo* after filtration. Flash chromatography provided the aldol adduct. In the case of entry 7 in Table 2, the reaction was repeated on a 10 mmol scale. The same result was obtained.

§ The relative stereochemistry of the aldol adducts was determined by deprotection of the major and minor isomers of **1a**, **2a** and **3a** to give the diol and conversion to the corresponding acetonide followed by NOE observations.

Outstanding effect of SO_2 addition on the rate of carbon oxidation with a Pt catalyst

Junko Oi-Uchisawa,*† Akira Obuchi, Ryuji Enomoto, Atsushi Ogata and Satoshi Kushiyama

Atmospheric Environmental Protection Department, National Institute for Resources and Environment, 16-3 Onogawa, Tsukuba, Ibaraki 305-8569, Japan

Addition of trace SO_2 (*ca*. 8 ppm) to a reactant gas containing NO substantially enhanced the oxidation rate of carbon black mixed with a Pt/SiO_2 catalyst, which is attributed to SO_3 (or H_2SO_4) catalyzing the oxidation of carbon by NO_2.

The emission of soot from diesel engines is a serious environmental problem. Among the many catalysts for soot oxidation that have so far been reported, Pt exhibits high levels of catalytic activity.[1–5] Platinum is thought to promote soot oxidation indirectly, *i.e*. by oxidizing the NO normally coexisting in the exhaust gas into NO_2, which actually oxidizes soot to CO and CO_2. Here we report the effect of adding SO_2 to the reactant gas, which dramatically promoted the oxidation of carbon black.

Platinum (1 wt%) supported on silica gel (Pt/SiO_2) was prepared by impregnating SiO_2 (0.1 to 0.25 mm in diameter, 374 $m^2\ g^{-1}$) with a solution of $Pt(NH_3)_4(OH)_2$, followed by drying, reduction with H_2 at 400 °C and calcination in air at 600 °C. Commercially available carbon black (CB; Nippon Tokai carbon 7350F; primary particle size = 28 nm; specific surface area = 80 $m^2\ g^{-1}$; CHN analysis: C, 97.99; H, 1.12; N, 0.06%; H_2O = 0.58 wt%) was used as model soot. The Pt/SiO_2 catalyst (0.5 g) and CB powder (0.005 g) were simply mixed together with a spatula and placed in the reactor. Mixing in this way results in a 'loose' contact between the catalyst and carbon, which is thought to be close to that found in practical cases.[6] Temperature-programmed reactions (TPRs) were carried out in a tubular quartz reactor. Reactant gases—10% O_2, 7% H_2O, 0 or 1000 ppm NO, 0 to 100 ppm SO_2 and N_2, a composition which is typical of diesel exhaust gas, except for the absence of CO_2—were passed through the mixture of catalyst and CB at a flow rate of 0.5 dm^3 (STP) min^{-1}. The temperature of the reactor was raised from 80 to 700 °C by 10 °C min^{-1}. A non-dispersive IR gas analyzer was used to continuously measure the concentrations of CO and CO_2 emitted by the carbon oxidation. In addition, TPR measurements using an FTIR gas analyzer were separately conducted to measure the concentrations of NO, NO_2 and SO_2 in the product gas.

Fig. 1 shows the effect of the composition of the reactant gas on the CO_2 emission during the TPR. The CO concentration was almost zero in all cases (≤0.8 ppm). In the gas mixture N_2 + O_2 + H_2O [Fig. 1(○)], carbon was not oxidized at all below 500 °C, above which temperature the reaction rate increased abruptly and the oxidation was finished at 675 °C. Platinum had no accelerating effect on the carbon gasification under these conditions, since the TPR result using SiO_2 alone (not shown) was almost the same as that shown in Fig. 1(○). Fig. 1(●) shows the result when 100 ppm SO_2 was added to the reactant gas. Sulfur dioxide had no effect on the oxidation under these conditions. On the other hand, the addition of NO instead of SO_2 brought about an acceleration of carbon oxidation Fig. 1(△). The initial temperature, which we define as the point where the CO_2 concentration exceeds 100 ppm, was about 200 °C lower than that in N_2 + O_2 + H_2O. In the case of SiO_2 alone, such a promotional effect of NO was not observed, but when NO_2 was used instead of NO, the CO_2 emission curve shifted to nearly the same temperature region as Fig. 1(△). These results suggest that NO_2, which is formed by the oxidation of NO over Pt, oxidizes carbon black more strongly than O_2. The effect of NO_2 on soot oxidation has been already reported by several researchers.[4,5,7]

The striking effect of SO_2 was observed when it was further added to N_2 + O_2 + H_2O + NO over the Pt/SiO_2. By adding only 1 ppm of SO_2, the CO_2 emission level at 350 °C increased by 210 ppm [Fig. 1(▲)]. As the concentration of SO_2 was increased, a new peak appeared at around this temperature; when the SO_2 concentration exceeded 23 ppm, CO_2 emission was at its maximum at this temperature [Fig. 1(◇) and (◆)]. The temperature of maximum CO_2 emission was about 300 °C lower than that in the N_2 + O_2 + H_2O mixture and more than 200 °C lower than that in N_2 + O_2 + H_2O + NO. The initial temperature decreased to as low as 250 °C. The CO_2 concentrations at 350 °C in the experiments containing NO were plotted as a function of SO_2 content in the reactant gas (Fig. 2). The CO_2 concentration dramatically increases until the SO_2 content reaches 8 ppm and then almost levels off with further increases in SO_2 content. Such a promotional effect of SO_2 is not observed with SiO_2 alone, even when NO_2 is used instead of NO.

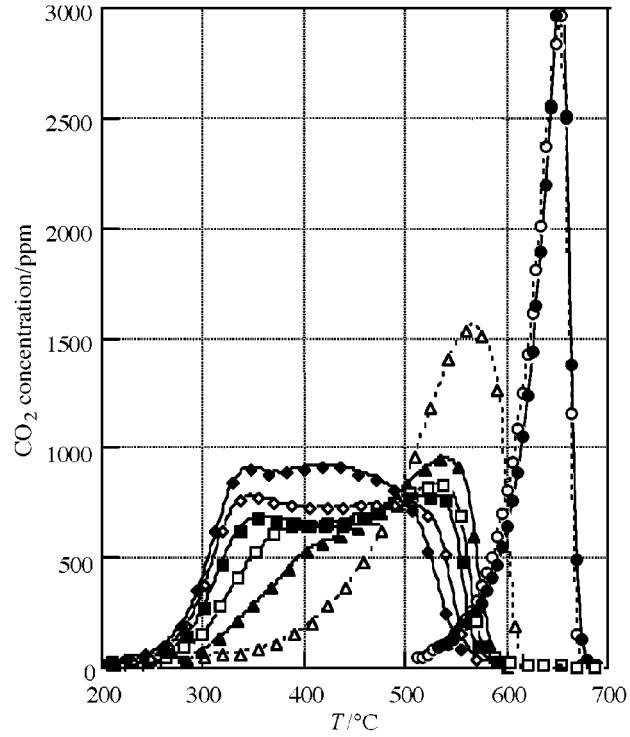

Fig. 1 TPR profiles of Pt/SiO_2 in carbon oxidation. Conditions; catalyst = 0.5 g, carbon = 0.005 g, flow rate = 0.5 $dm^3\ min^{-1}$ (0 °C, 1 atm) (**X** = 10% O_2 + 7% H_2O in N_2, **Y** = 10% O_2 + 7% H_2O + 1000 ppm NO in N_2): (○) **X**, (●) **X** + 100 ppm SO_2, (△) **Y**, (▲) **Y** + 1 ppm SO_2, (□) **Y** + 4 ppm SO_2, (■) **Y** + 8 ppm SO_2, (◇) **Y** + 23 ppm SO_2, (◆) **Y** + 100 ppm SO_2.

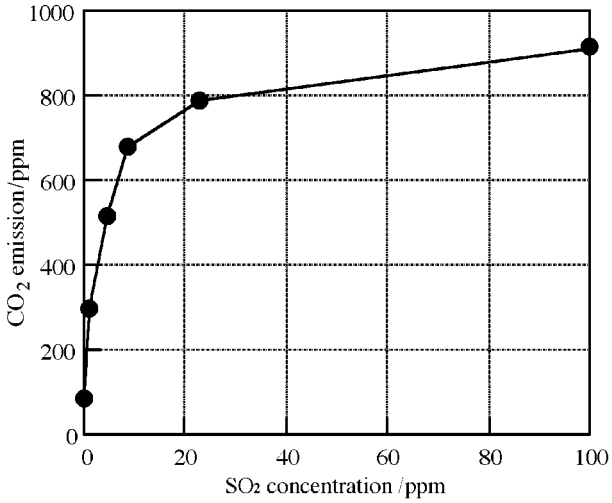

Fig. 2 Effect of the concentration of SO_2 on the activity of Pt/SiO_2 catalyst in carbon oxidation (T = 350 °C). Conditions are as in Fig. 1.

Separate TPR experiments using an FTIR gas analyzer were also carried out under the conditions of 10% O_2, 0.5% H_2O, 1000 ppm NO, 100 ppm SO_2 and N_2. Over Pt/SiO_2, NO starts to be oxidized to NO_2 at 160 °C. The concentration of NO_2 reached a maximum at 330 °C and then decreased in accordance with levels expected from the thermodynamic equilibrium between NO_2, NO and O_2. The concentration of SO_2 in the product gas started to decrease at 165 °C, reached a negligible level between 220 to 500 °C, and then gradually increased in accordance with levels expected from the thermodynamic equilibrium between SO_3, SO_2 and O_2. Evidently, the oxidation of NO into NO_2 and SO_2 into SO_3 (or H_2SO_4 below 300 °C) proceeded over Pt/SiO_2. Incidentally, the oxidation of SO_2 to SO_3 by gaseous NO_2 did not proceed to an observable extent over SiO_2 alone under the conditions of 10% O_2, 0.5% H_2O, 1000 ppm NO_2, 100 ppm SO_2 and N_2. Nitrogen dioxide is regarded as an oxidizer that directly attacks the carbon and turns into NO; the NO may be oxidized to NO_2 over Pt/SiO_2 and reused. On the other hand, the outstanding effect of SO_2 with Pt/SiO_2 only appeared in the presence of NO suggesting that SO_3, produced from SO_2 over Pt, plays a role as a catalyst that accelerates the oxidation of carbon by NO_2.

To confirm this possible role of SO_3 (or H_2SO_4), we tested the effect of NO_2 and H_2SO_4 addition on the carbon oxidation over SiO_2 alone. When 1000 ppm NO_2 and 100 ppm H_2SO_4 were added to the feed containing 10% O_2 + 7% H_2O in N_2, the oxidation was initiated at 280 °C and there were peaks in CO_2 concentration at 380 and 490 °C. By contrast the addition of 100 ppm H_2SO_4 alone did not have any effect on the CO_2 emission rate: the initial and peak temperatures were around 560 and 680 °C, respectively. These results strongly suggest that SO_3 (or H_2SO_4) formed over Pt surfaces catalyzes the oxidation of carbon by NO_2.

Lur'e *et al*.[7] reported that the process of CO_2 formation from the interaction of NO_2 with soot proceeds through the oxidation of active sites on the soot surface, *via* abstraction of oxygen atoms from NO_2, to produce partially oxidized surface species (> C=O) and NO. We suspect that the effect of SO_3 (or H_2SO_4) can be attributed to the enhancement of decomposition of the partially oxidized surface species. It is well known that H_2SO_4 promotes dehydration and decarboxylation of organic compounds.[8] The partially oxidized surface species created by NO_2 may be rather inactive against further oxidation, but can be readily decomposed by a strong acid such as SO_3 or H_2SO_4. After this secondary process, the ability of the carbon surface to be oxidized may be restored.

$^{19}F/^{23}Na$ Cross polarization NMR study of hydrofluorocarbon–zeolite binding on zeolite NaY

Kwang Hun Lim and Clare P. Grey*†

Department of Chemistry, SUNY Stony Brook, Stony Brook, NY 11794-3400, USA

$^{19}F/^{23}Na$ Cross polarization (CP) MAS NMR experiments of various asymmetric hydrofluorocarbons (HFCs) such as CF_3CFH_2 (HFC-134a) and CF_2HCFH_2 (HFC-143) adsorbed on zeolite NaY, demonstrate that the hydrogen-containing groups are bound more strongly to the zeolite framework, in the order $CF_3 << CF_2H < CFH_2$; the results help explain the preferential binding of CF_2HCF_2H (HFC-134) over HFC-134a, and hence the effectiveness of basic zeolites in the separation of HFC-134/134a gas mixtures.

The complete phase-out of chlorofluorocarbon (CFC) production in developed countries by the year 2000 has resulted in the development and production of a variety of environmentally-friendly alternatives (the HFCs) for different applications.[1] The syntheses of the HFCs are more complex than the syntheses of the CFCs and unwanted HFC and hydrochlorofluorocarbon isomers are often produced. For example, HFC-134 is a common byproduct in the synthesis of HFC-134a, the replacement for the refrigerant CFC-12 (CF_2Cl_2).[1] Basic molecular sieves have been proposed as a method for separating some of these isomer mixtures.[2] We have, therefore, been applying a variety of NMR and X-ray powder diffraction methods to determine the importance of different interactions in controlling the sorption properties of these gases on faujasite zeolites, and to rationalize trends in separations behavior and HFC reactivity.[3,4] Our previous work on the binding of HFC-134 on zeolite NaY demonstrated that Na-F interactions are very important in these systems, and are strong enough to cause migration of cations from the sodalite cages into the supercage where they can bind to both ends of the HFC molecule.[4]

The efficiency of ^{19}F magnetization transfer in a ^{19}F–^{23}Na CP experiment, from the different ends of the HFC molecule to the sodium cations present in the supercages of the zeolite, has been explored in research described here. The CP efficiency is very sensitive to the offset-frequency of the ^{19}F radio frequency (rf) field: as the offset frequency ($\Delta\nu$) of the rf field (ν_1) is increased, the polarization transfer rate is decreased by a factor $\nu_1^2/(\nu_1^2 + \Delta\nu^2)$.[5] Thus, if the CP experiment is performed with low rf power, the effect of offset-frequency on the transfer rate will be significant. Since the ^{19}F NMR spectra of the asymmetric HFCs show well separated resonances for the different $CF_{3-n}H_n$ groups (for example, the chemical shifts for the CF_3 and CFH_2 groups of HFC-134a are −81 and −246 ppm, respectively), it is possible to study the CP dynamics of the end-groups separately.

Methods used to prepare the samples are identical to those described elsewhere[4] and the samples are labeled *x*HFC/NaY, where *x* indicates the number of HFC molecules per unit cell. The ^{23}Na MAS NMR spectrum of the fully loaded HFC134a/NaY sample ($x \approx 44$–48) at −150 °C is shown in Fig. 1(*a*). The narrow resonance at −7 ppm is assigned to the site I cations of the faujasite structure (in the double six-rings), and the broader resonance centered at −40 ppm contains overlapping resonances from sodium nuclei originally in the site II and I′ positions, in the super and sodalite cages respectively.[4] The narrowing of this resonance, in comparison to that of bare NaY, suggests that some cation migration from site I′ to sites in the supercages may also be occurring on adsorption of HFC-134a.

Variable-temperature ^{19}F MAS NMR was initially performed to confirm that the isotropic motion of the HFCs was frozen out at −150 °C. Rf field strengths of 10–20 and 20–40 kHz were used for ^{23}Na and ^{19}F, respectively, in order to match the Hartmann–Hahn condition for quadrupolar nuclei with non-zero quadrupole coupling constants[5,6] and low rf field strengths and fast spinning speeds were used to help ensure effective ^{23}Na spin-locking.[7]

Fig. 1(*b*) and (*c*) show the $^{19}F \rightarrow ^{23}Na$ CP MAS spectra of the fully-loaded HFC134a/NaY at −150 °C, where the ^{19}F irradiation frequency is placed on the ^{19}F CFH_2 and CF_3 group resonances, respectively. Only one broad ^{23}Na resonance at approximately −40 ppm is observed and the site I resonance is absent, indicating that polarization is only transferred to cations in close proximity to the HFCs. Surprisingly, the CP intensity from the CFH_2 group is much higher than that from the CF_3 group which contains more fluorine spins. In order to investigate this behavior more fully, CP experiments were performed as a function of fluorine irradiation offset: A dramatic decrease in ^{23}Na CP intensity for 32HFC-134a/NaY was observed, as the fluorine irradiation offset $\Delta\nu_1$ is changed from on-resonance for the CFH_2 group (−58 kHz) to on-

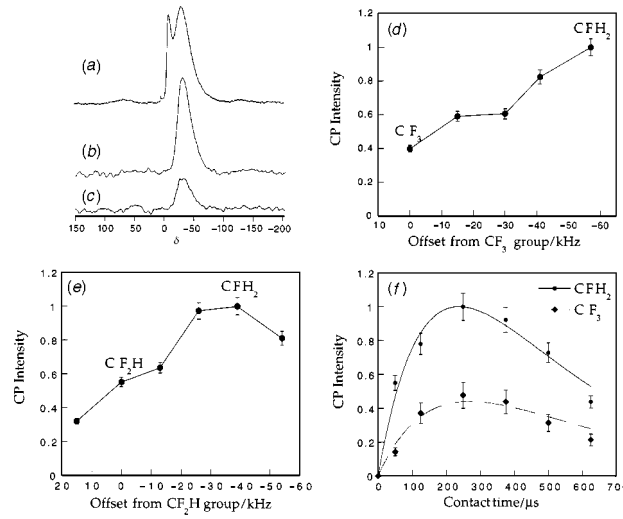

Fig. 1 (*a*) The ^{23}Na MAS NMR spectra of fully-loaded HFC-134a/NaY at −150 °C. Spinning speeds of 10 kHz were used; (*b*) and (*c*): The $^{19}F \rightarrow ^{23}Na$ CP MAS spectra of fully-loaded HFC-134a/NaY at −150 °C. The ^{19}F frequency was placed on resonance for the CFH_2 resonance and CF_3 resonance in (*b*) and (*c*), respectively. Spinning speeds of 9.5 kHz, a 400 μs CP contact time (ct) and an ^{19}F rf field strength, ν_1, of 40 kHz were used, and 1640 FIDs were recorded for each spectrum. $^{19}F \rightarrow ^{23}Na$ CP intensity as a function of fluorine irradiation offset of (*d*) 32HFC-134a/NaY at −150 °C (spinning speed = 9 kHz; ct = 333 μs; ν_1, = 40 kHz) and (*e*) 32HFC-143/NaY at −150 °C (spinning speed = 8 kHz; ct = 250 μs; ν_1 = 20 kHz). (f) 32HFC-134a/NaY at −150 °C, as a function of contact time (ν_1 = 20 kHz). The two curves drawn in (*f*) were obtained with equations for CP intensity given in refs. 11 and 13 (see text). Spectra were acquired with a double-tuned Chemagnetics probe, on a CMX-360 spectrometer with resonance frequencies for ^{19}F and ^{23}Na of 338.7 MHz and 95.2 MHz, respectively. The ^{23}Na chemical shifts reported were referenced to solid NaCl at 0.0 ppm.

resonance for the CF_3 group (0 kHz) [Fig. 1(*d*)]. The same experiment was performed for 32HFC-143/NaY and the CP intensity for on-resonance irradiation of the CFH_2 group was higher than that for the CF_2H group [Fig. (*e*)].

The $^{19}F \rightarrow {}^{23}Na$ CP intensity was studied as a function of the contact time for both samples and the CP curve for HFC-134a is shown in Fig 1(*f*). In order to fit these curves, $T_{1\rho}$ values for the ^{23}Na spins and the ^{19}F in the different groups were all independently measured. The ^{19}F $T_{1\rho}$s (150–300 μs) were much shorter than those for ^{23}Na (*ca.* 600 μs) and are responsible for the relatively rapid decrease in CP intensity for contact times of greater than *ca*. 250 μs. Fits to these curves using the measured $T_{1\rho}$s, using modified versions of expressions given in refs. 5 and 6, demonstrate that the polarization transfer rates ($1/T_{IS}$) are considerably larger for the more hydrogenated groups. For example, using the $T_{1\rho}$ values of 230 ± 5 and 205 ± 5 μs obtained for the CFH_2 and CF_3 and groups of HFC-134a, values of T_{1S} of 480 ± 20 and 1000 ± 50 μs were obtained assuming that each end group is close to only one sodium cation.

Partial charges for the hydrofluorocarbons, calculated with Hartree–Fock methods, are slightly higher for the CFH_2 fluorine in comparison to those found on the CF_3 fluorine atoms of HFC-134a,[8] which should result in an increased Na–F electrostatic interaction. Inelastic neutron scattering and Raman spectroscopy studies of HFC-134 and HFC-134a molecules adsorbed on zeolite NaX have shown that hydrogen bonding to the framework oxygen may also be important.[9] Our ^1H MAS NMR studies of HFC-143 (CFH_2CF_2H) and HFC-134a (CF_3CFH_2) adsorbed on NaY are consistent with this: the ^1H NMR resonance is shifted to higher frequency by 2 ppm on lowering the temperature to −150 °C, suggesting that the hydrogen-containing groups are hydrogen-bonded to the framework oxygens of the zeolite. These results imply that the hydrogen-bonding plays an important role in the binding of the asymmetric HFC molecules. Thus we propose that it is the combination of this hydrogen bonding, and the strong Na–F interaction, that tethers the CFH_2 group tightly to the framework at −150 °C, resulting in efficient fluorine-to-sodium magnetization transfer. The CFH_2 group is more strongly bound than the CF_2H group of HFC-143: again this may be a consequence of the higher partial charge for the CFH_2 group and the potential for more hydrogen bonding.

In conclusion, the double resonance experiments clearly show very different binding for the different end groups of asymmetric HFCs, and demonstrate that the hydrogen-containing groups are bound more strongly to the zeolite framework. The results are consistent with the higher heat of adsorption of CF_2HCF_2H (HFC-134) over HFC-134a,[2] the former containing two hydrogen-containing groups. These findings help provide a fundamental understanding of the role of basic zeolites in the separation of HFC-134/134a gas mixtures. Finally, the NMR results suggest new methods for probing interactions and gas binding in systems involving larger molecules with multiple gas–surface interactions. In these systems, while methods such as calorimetry and adsorption isotherm measurements will provide measures of the average heat of adsorption of the molecule, experiments sensitive to local structure and interactions will be extremely useful in helping to deconvolute the relative importance of the different, sometimes competing, interactions. The CP technique will be particularly applicable when one or more NMR nucleus has a large chemical shift range.

Support from the NSF through an interagency transfer to the US Department of Energy, Office of Basic Energy Sciences is gratefully acknowledged (DE FG02-96ER14681) and for funding to purchase the NMR spectrometer (CHE-9405436). Stimulating conversations with S. M. Auerbach are gratefully acknowledged.

Phosphorus monoxide as a quadruply bridging ligand: syntheses and X-ray crystal structures of $Ru_5(CO)_{15}(\mu_4\text{-PF})$ and $[H_2NCy_2][Ru_5(CO)_{15}(\mu_4\text{-PO})]$

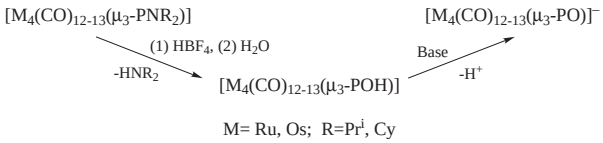
The reaction of $Ru_4(CO)_{13}(\mu_3\text{-PNCy}_2)$ 1 with $Ru(CO)_5$ in refluxing hexane yields $Ru_5(CO)_{15}(\mu_4\text{-PNCy}_2)$ 2 in high yield; treatment of 2 with $HBF_4{\cdot}Et_2O$ forms $Ru_5(CO)_{15}(\mu_4\text{-PF})$ 3 which is the first cluster complex to contain a μ_4-fluorophosphinidene ligand, while refluxing 2 with $HBF_4{\cdot}H_2O$ in CH_2Cl_2 yields 3 and the title compound $[Ru_5(CO)_{15}(\mu_4\text{-P=O})][H_2NCy_2]$ 4, an unprecedented example of a cluster complex containing a μ_4-PO ligand.

Phosphorus monoxide (PO) and diphosphorus monoxide (P_2O) are the simplest binary oxides of phosphorus. They have both been spectroscopically characterized in matrices and in molecular beams,[1] but they are not 'reagents in a bottle' since they are unstable with respect to the normal oxides P_4O_6 and P_4O_{10}.

In contrast to nitric oxide, the coordination and organometallic chemistry of PO and P_2O is poorly developed and only recently have methods of synthesizing complexes of these ligands been described.[2–6] To date only two types of coordination modes for phosphorus monoxide are known. Triply bridging μ_3-PO ligands have been trapped or generated in clusters by the direct oxidation of naked phosphide ligands[2,4,5] or by the hydrolytic cleavage of P–N bonds in aminophosphinidene (μ_3-PNR_2) clusters.[3] Examples of terminal, η^1-PO coordination, as in $Mo\{[NC(CD_3)_2Me](C_6H_3Me_2\text{-}3,5)\}_3(\eta^1\text{-P=O})$,[5] have also been described. Doubly and quadruply bonded PO ligands are as yet unknown. In this communication we report the synthesis and structural characterization of an anionic cluster $[Ru_5(CO)_{15}(\mu_4\text{-P=O})]^-$ containing a quadruply bridging phosphorus monoxide ligand. The designed synthesis of this molecule (Scheme 1) also affords the first example known to us of a μ_4-fluorophosphinidene ligand in the neutral cluster $Ru_5(CO)_{15}(\mu_4\text{-PF})$.

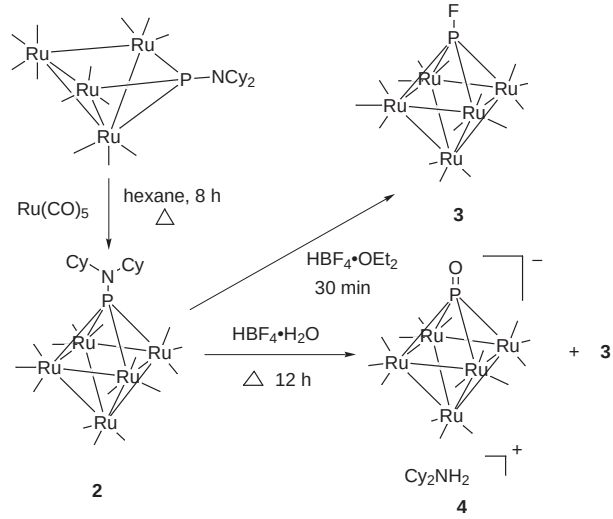
We recently described a rational, versatile route to PO ligands which essentially involves the acid promoted substitution of NR_2 groups in aminophosphinidene (μ-PNR_2) ligands by hydroxyl groups followed by deprotonation of the latter by base, as follows:[7]



To apply this strategy to the synthesis of a μ_4-PO ligand, we needed a reliable route to a cluster containing a μ_4-PNR_2 ligand. Treatment of $Ru_4(CO)_{13}(\mu_3\text{-PNCy}_2)$[8] **1** (770 mg, 0.78 mmol) in hexane for 8 h with an excess of $Ru(CO)_5$[9] forms $Ru_5(CO)_{15}(\mu_4\text{-PNCy}_2)$ **2**[10] (867 mg, 0.76 mmol) in greater than 95% yield. The cluster **2** consists of a square based pyramid of five ruthenium tricarbonyl groups, with the square face capped by the μ_4-aminophosphinidene ligand.

Reaction of a CH_2Cl_2 solution of **2** (503 mg, 0.51 mmol) with dry $HBF_4{\cdot}OEt_2$ (300 μl) at RT for 3 h afforded $Ru_5(CO)_{15}(\mu_4\text{-PF})$ **3**[11] (503 mg, 0.51 mmol) as green crystals in 96% yield. The ^{19}F and ^{31}P NMR spectra of **3** consist of doublets [$\delta(^{19}F)$ −20.49; $\delta(^{31}P)$ 548.6] with J_{P-F} = 1121 Hz. Since **3** appears to be the first μ_4-PF cluster a single crystal X-ray analysis was carried out.[12] Within the Ru_5 square pyramid (Fig. 1) there are two distinctively different sets of Ru–Ru distances with the bond lengths within the base (Ru–Ru av. 2.9196 Å) being distinctly longer than those to the apical atom Ru(5) (Ru–Ru av. 2.8252 Å). The stereochemistry at the phosphorus atom is that of a flattened square pyramid with a P–F distance of 1.595(2) Å which compares well with a value of 1.58 Å[13] for the axial P–F bonds in PF_5 where the phosphorus atom is also pentacoordinate.

In contrast to the reaction with anhydrous HBF_4, treatment of **2** (57 mg, 0.05 mmol) with an excess of $HBF_4{\cdot}H_2O$ for 6 h gave smaller amounts of **3** (15 mg, 0.01 mmol, 31%) and afforded as the major product $[H_2NCy_2][Ru_5(CO)_{15}(\mu_4\text{-PO})]$ **4** (37 mg, 0.03 mmol, 64%). Spectroscopically, **4**[14] is characterized by a medium strong ν(P=O) band in the infrared spectrum at 1060 cm^{-1} and by a ^{31}P resonance at low field (δ 515). The structure[15] of **4** (Fig. 2) consists of tetrahedral dicyclohexylamino cations packed in the crystal lattice with $[Ru_5(CO)_{15}(\mu_4\text{-PO})]$ cluster anions. In contradistinction with $[H_2N(^iPr_2)][Ru_4(CO)_{12}(\mu_3\text{-PO})]$ there are no significant hydrogen bond interactions between the PO oxygen atom and the cation (PO···HN = 1.75 Å). The geometry of the Ru_5P skeleton resembles that in **3** but the substitution of a PO ligand in **4** for μ_4-PF in **3** causes significant changes in P–X (X = O, F), Ru–P and basal Ru–Ru bond lengths. The P–O distance in **4** [1.516(4) Å] is 0.08 Å shorter than the P–F value [1.595(2) Å] in **3** and is consistent with P=O bond lengths of 1.48–1.52 Å in μ_3-PO clusters.[2–5] However the P–Ru bond lengths in **4** (av. 2.374 Å) are significantly elongated compared to **3** (av. 2.308 Å) and the basal Ru–Ru distances in **4** (av. 2.878 Å) are shorter than in **3**



Scheme 1

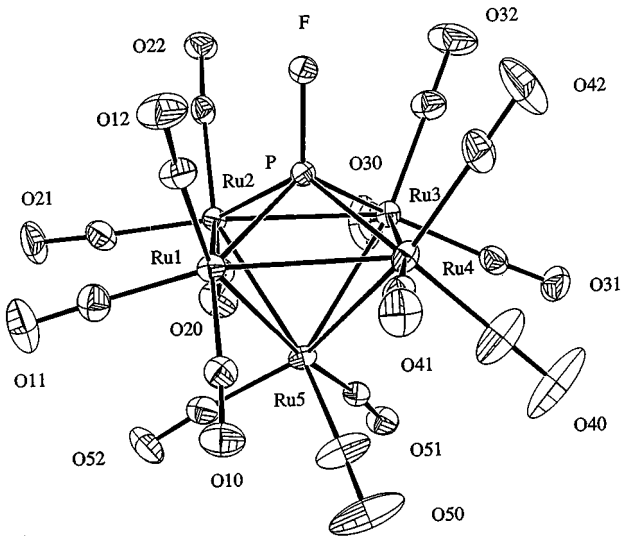


Fig. 1 An ORTEP diagram of $Ru_5(CO)_{15}(\mu_4\text{-PF})$ **3** showing 30% probability thermal ellipsoids. Hydrogen atoms are omitted for clarity. Selected bond lengths not mentioned in the text (Å): Ru(1)–Ru(2) = 2.9558(4), Ru(1)–Ru(4) = 2.9310(4), Ru(2)–Ru(3) = 2.8983(4), Ru(3)–Ru(4) = 2.8932(4), Ru(5)–Ru(3) = 2.8535(4), Ru(1)–Ru(5) = 2.7771(4), Ru(4)–Ru(5) = 2.8432(4), Ru(5)–Ru(2) = 2.8271(4).

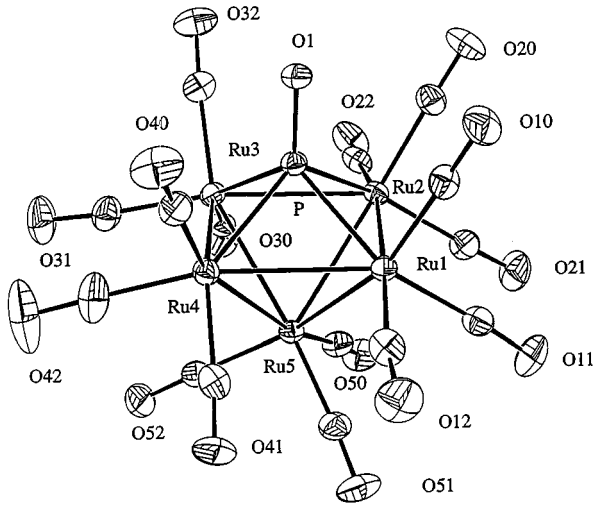

Fig. 2 An ORTEP diagram of $[Ru_5(CO)_{15}(\mu_4\text{-PO})][H_2NCy_2]$ **4** showing 30% probability thermal ellipsoids. Hydrogen atoms and the cation $[H_2N(Cy)_2]$ are omitted for clarity. Selected bond lengths not mentioned in the text (Å): Ru(1)–Ru(2) = 2.850(1), Ru(1)–Ru(4) = 2.876(1), Ru(2)–Ru(3) = 2.893(1), Ru(3)–Ru(4) = 2.908(1), Ru(5)–Ru(3) = 2.908(1), Ru(1)–Ru(5) = 2.836(1), Ru(4)–Ru(5) = 2.803(1), Ru(5)–Ru(2) = 2.843(1).

(av. 2.9196 Å). A simplistic explanation of these facts is that stronger phosphorus bonding to the *exo*-cage oxygen atom weakens cluster phosphorus bonding and strengthens metal–metal bonding.

Although **3** and **4** are obtained in the same reaction of **2** with $HBF_4{\cdot}H_2O$, attempts to directly convert **3** to **4** in the presence of H_2O and HO^- have not been successful.

The synthesis and characterization of a quadruply bridging P=O ligand in **4** adds to the terminal and triply bridging modes now known for this transient ligand. We are currently attempting to expand the range of μ_4-PO complexes and compare the chemistry of these coordinated ligands.

Unprecedented luminescence behaviour and structural characterization of a novel class of ruthenium(II) 2,2′-bipyridine complexes with orthometallated aminocarbene ligands

Vivian Wing-Wah Yam,* Ben Wai-Kin Chu and Kung-Kai Cheung

Department of Chemistry, The University of Hong Kong, Pokfulam Road, Hong Kong SAR, People's Republic of China.
E-mail: wwyam@hkucc.hku.hk

Novel luminescent ruthenium(II) bipyridine complexes with orthometallated aminocarbene ligands have been prepared and their photophysical properties studied.

The chemistry of metal σ-acetylide complexes has attracted considerable interest because of the unique properties of the delocalizable π systems. While most studies on ruthenium σ-acetylide complexes were focused on the use of phosphine ligands,[1] corresponding studies on nitrogen donor ligands are relatively rare.[2] In view of the rich photophysical and photochemical behaviour of ruthenium(II) polypyridyl complexes, we have started a program to design and synthesize luminescent organometallic ruthenium(II) σ-acetylide complexes containing polypyridyl ligands. In an attempt to prepare these complexes, we obtained the novel ruthenium(II) orthometallated aminocarbene complexes instead. Here we report the synthesis, characterization, electrochemistry, photophysical behaviour and X-ray crystal structure of this new class of ruthenium(II) orthometallated aminocarbene complexes with 2,2′-bipyridyl ligands, which represents the first of its kind.

Reaction of *cis*-$[Ru(bpy)_2(Me_2CO)_2](OTf)_2$ with phenylacetylene or 4-methoxyphenylacetylene in the presence of sodium ethoxide in ethanol, followed by metathesis reaction using NH_4PF_6 and subsequent recrystallization from MeCN–Et_2O, afforded *cis*-$[Ru(bpy)_2(CO)(\eta\text{-}CH_2Ph)]^+$ **1a**[3] or *cis*-$[Ru(bpy)_2(CO)(\eta\text{-}CH_2C_6H_4OMe)]^+$ **1b** as the PF_6^- salt in reasonable yield; the structure of **1b** was confirmed by X-ray diffraction studies.[4] On the other hand, treatment of *cis*-$[Ru(bpy)_2(Me_2CO)_2](OTf)_2$ with phenylacetylene in the presence of aniline in dry acetone under an inert atmosphere of nitrogen gave a stable orthometallated aminocarbene complex, $[Ru(bpy)_2{=}C(CH_2Ph)NHC_6H_4]^+$ **2a**. Similar reaction with *p*-anisidine in place of aniline gave $[Ru(bpy)_2{=}C(CH_2Ph)NHC_6H_3OMe]^+$ **2b** (Scheme 1).[5–7] The formulation of which were confirmed by satisfactory elemental analyses, FABMS, ^1H NMR and ^{13}C NMR spectroscopy† and the structure of **3b** was further established by X-ray crystallography (Fig. 1).‡

Complex **2b** shows a distorted octahedral structure. The N–Ru–N bond angles subtended by the chelating diimines are 77.0(2) and 77.6(2)°. A C(1)–Ru(1)–C(2) bond angle of 79.5(3)° subtended by the orthometallated *N*-arylcarbene has also been observed. The deviation from the ideal 90° for a regular octahedral geometry is a result of the steric requirement of the bidentate ligands. The bond angles around C(1) are 128.7(5), 116.9(5) and 114.3(6)°, consistent with the sp^2 hybridization of the carbene carbon. The bond distances of Ru(1)–N(1) [2.060(6) Å] and Ru(1)–N(4) [2.058(6) Å] are similar to those reported in other ruthenium(II) polypyridyl complexes (*ca*. 2.05 Å)[8] but those of Ru(1)–N(2) [2.141(5) Å] and Ru(1)–N(3) [2.120(5) Å] are longer than normal. This may be accounted for by the strong *trans* effect of the carbon atoms in the orthometallated *N*-arylcarbene ligand. The Ru(1)–C(2) bond distance [2.047(6) Å] is similar to that observed in other ruthenium(II) complexes with σ-bonded carbon ligands,[9] while the Ru(1)–C(1) bond distance [1.963(7) Å] is shorter than an average Ru–C bond [2.105(5) Å],[9e] which can be ascribed to the presence of Ru–C double bond character.[9f,10] A substantial double-bond character between the heteroatom and the carbene carbon is noticed as the C(1)–N(5) distance [1.318(9) Å] is reduced below that characteristic of a single bond between N and an sp^2 C, typical of Fischer type aminocarbenes (*ca*. 1.31 Å).[10]

The electronic absorption spectra of complexes **2a** and **2b** show moderately intense bands in the visible region which are tentatively assigned as MLCT transitions (Table 1). The intense absorptions in the UV region are assigned as intraligand

		Solid	77	701	
		Glass[b]	77	745	

[a] Excitation wavelength at 580 nm. Emission maxima are corrected values. [b] EtOH–MeOH (4 : 1, v/v).

transitions. Excitation of **2a** and **2b** at λ > 350 nm at room temperature produces red luminescence. It is likely that the origin of the emission is ^{3}MLCT in nature, arising from states derived from either a d_π(Ru) → π*(bpy) or a d_π(Ru) → π*(alkylidene) MLCT transition. The close similarity of the absorption and emission characteristics of complexes **2a** and **2b** suggests that the methoxy substituent on the *N*-aryl ring of the aminocarbene unit has relatively little influence on the charge-transfer transition in these complexes.

The redox properties of the complexes **2a** and **2b** are investigated by cyclic voltammetry in acetonitrile using 0.1 mol dm^{-3} NBu_4PF_6 as the supporting electrolyte. Reversible to quasi-reversible reduction couples are observed at −1.66 and −1.89 V *vs*. SCE for **2a** and −1.65 and −1.88 V *vs*. SCE for **2b**; the potentials of which are relatively independent of the scan rate with $\Delta(E_{pa} - E_{pc})$ values of *ca*. 60–90 mV, assigned to the successive reduction of the bipyridine ligand. The relative insensitivity of the reduction potentials to the substituent effect on the aminocarbene unit in **2a** and **2b** further confirms its assignment as bpy-centered reduction. A quasi-reversible oxidation couple is observed at +1.42 V *vs*. SCE for **2b** and an irreversible oxidation wave is noted at E_{pa} = +1.67 V *vs*. SCE for **2a**, which are assigned as metal-centered oxidation. The irreversible nature of the oxidation in **2a** is indicative of the instability of the Ru(III) aminocarbene complex in which the electron-rich methoxy substituent capable of stabilizing the electron-deficient Ru(III) metal center is absent, which may lead to its decomposition.

Further spectroscopic studies to elucidate the nature of the lowest lying excited state are in progress.

Synthesis and structural characterization of novel silver(I) complexes of tetradehydro[16]annulene annelated with bicyclo[2.2.2]octene units

Tohru Nishinaga, Tetsu Kawamura and Koichi Komatsu*

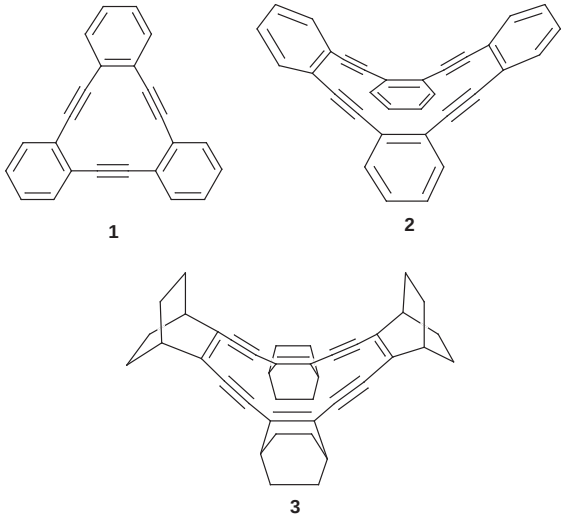
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611-0011, Japan. E-mail: komatsu@scl.kyoto-u.ac.jp

The first silver(I) complexes of tetradehydro[16]annulene annelated with bicyclo[2.2.2]octene units were prepared and the incorporation of a silver atom into the cavity center was shown by X-ray crystallography.

The versatility of tribenzotridehydro[12]annulene (**1**) as a ligand in metal complexes was demonstrated by Youngs *et al*.[1] The cavity size of ligand **1** was shown to be suitable for the incorporation of first row transition metals into the cavity center, while the size is too small for a second row transition metal. For example, silver gave only a sandwich complex.[1] Even for a higher homologue, tetrabenzotetradehydro[16]annulene (**2**), there has been no example of incorporation of a second or third row transition metal within its cavity. Only a dicobalt complex has been reported, in which two of the triple bonds are coordinated from the outer side.[2]

Recently we synthesized a series of dehydroannulenes annelated with bicyclo[2.2.2]octene (abbreviated as BCO) including tetradehydro[16]annulene (**3**),[3] which are characterized by a rather low oxidation potential indicative of a raised HOMO level by the annelation of the BCO units.[3] The raised HOMO level should be effective for an interaction between the occupied 2p orbital of the ligand and empty 5s orbital of the silver,[4] which would strengthen the coordination bond by donation from the ligand to the metal.[5] Here we report the synthesis of novel silver-dehydro[16]annulene **3** complexes prepared based on such a rationale.

Annulene **3** was stirred with 1 equiv. of silver(I) triflate (AgOTf) or silver(I) hexafluoroantimonate ($AgSbF_6$) in THF at room temperature for a few days. After concentration of the solution, hexane was added to give precipitates of silver complex **4** (**3**·AgOTf) or **5** (**3**·$AgSbF_6$) both as red powders in 84% or 92% yield respectively. These complexes are stable to air, moisture, and light, in contrast to many silver-alkene, -alkyne, and -arene complexes which are essentially light- or air-sensitive.[6,7]



1 **2** **3**

Single crystals of **4** containing 0.5 equiv. hexane and of **5** containing 1 equiv. dichloromethane were obtained and examined by X-ray crystallography.† As shown in Fig. 1, the silver atom is present in the center of the cavity for both complexes and the counter anions are located above the silver atom. The structure of the central ring of the ligand is still tub-like but the folding angles are smaller compared with the X-ray structure of **3**.[3] The shortest distances between the silver and the counter anions, *i.e.* Ag–O in **4** and Ag–F in **5**, were 2.31(1) and 2.67(1) Å respectively. The Ag–O distance is shorter than those (2.36–2.53 Å) in nine reported complexes of AgOTf with arenyl or alkynyl ligands,[7–10] whereas the Ag–F distance is longer than

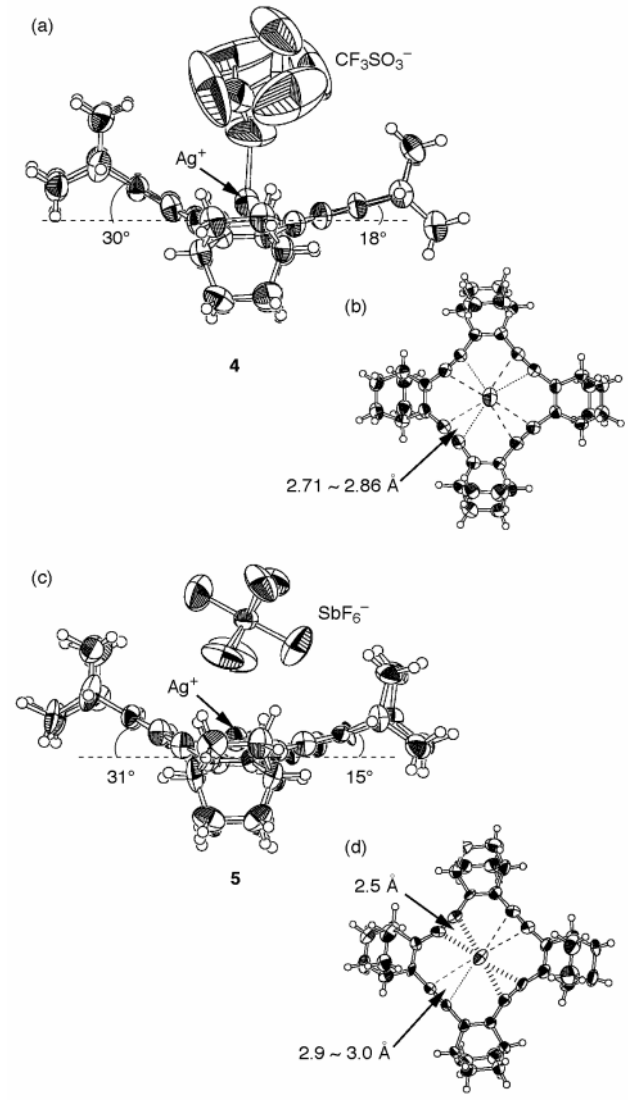


Fig. 1 ORTEP drawing showing (a), (c) side views and (b), (d) top views of **4** and **5**. The counter anions are omitted in the top views for clarity.

Table 1 ^{1}H and ^{13}C NMR spectra for **3–5**

	^{1}H NMR, δ		^{13}C NMR, δ			
Compd.	CH	CH_2	C=C	C≡C	CH	CH_2
3[a]	2.47	1.47 (32H)	132.8	95.4	37.2	25.3
3[b]	2.49	1.54 (16H)	132.5	95.0	36.9	24.9
		1.44 (16H)				
4[a]	2.61	1.55 (32H)	133.4	97.4	36.7	25.1
5[b]	2.64	1.65 (16H)	133.4	98.3	36.5	24.7
		1.44 (16H)				

[a] In $CDCl_3$. [b] In CD_2Cl_2.

the average (2.63 Å) of those (2.54–2.71 Å) in three reported complexes of $AgSbF_6$ with arenyl ligands.[11]

These Ag–anion distances are reflected in the modes of coordination with ligands. The Ag–C(alkyne) distance of complex **4** varies only from 2.714(7) Å to 2.863(7) Å, indicating almost equal coordination with the four acetylene units. On the other hand, the ligand of complex **5** is deformed due to the stronger coordination with a pair of acetylene units which are opposite to each other. The Ag–C distance at the stronger coordination site is 2.52(1)–2.54(1) Å whereas that at the other site is 2.85(2)–3.05(2) Å. Accordingly, the C≡C–C angle for **4** varies only from 170.0(8)° to 174.1(8)°, whereas for **5** the C≡C–C angle is 164(1)–170(1)° at the more strongly coordinated site and 174(1)–178(1)° at the other site.

In order to compare the degree of coordination in **4** and **5**, the Mulliken charge was calculated at the HF/STO-3G level for the silver atoms of AgOTf and $AgSbF_6$ using the X-ray structures with and without the ligand. The charge of silver in the structure with the ligand was calculated to be +0.20 for AgOTf and +0.29 for $AgSbF_6$, while that for the structure without the ligand was +0.50 for AgOTf and +0.77 for $AgSbF_6$. These results indicate that this annulene-type ligand reduces the positive charge on the silver atom and the extent of this reduction is larger for the case of $AgSbF_6$. This type of coordination is presumed to be principally due to the electron donation from the HOMO of the ligand to the LUMO of the metal, and the annelation of the BCO units which raises the HOMO level of the π-system would strengthen this coordination.

The IR spectrum of complex **4** showed that the energy of the C≡C stretching band became weak [2155 cm^{-1} (br)] compared with the free ligand **3** (2251, 2173 cm^{-1}), while the absorption for **5** was too weak to observe. As shown in Table 1, both the ^{1}H and ^{13}C NMR spectra for **4** and **5** also showed slight changes from those of the free ligand. Particularly noteworthy is the downfield shift for the NMR signal for the acetylenic carbon. For the methylene carbon of complexes **4** and **5**, only one NMR signal was observed, indicating that the central ring of the ligand was inverting rapidly on the NMR time scale, like the free ligand **3**.

In summary, we prepared a novel silver complex of tetradehydro[16]annulene annelated with BCO units. This [16]annulene-type ligand was found to have a cavity size suitable for the incorporation of second-row metals, *i.e.* silver, into the center of the ring. Calculated Mulliken charges for the complexes of **4** and **5** indicated that there is considerable electron donation from the ligand to the silver atom.

The present work is supported by Grant-in-Aid from the Ministry of Education, Science, Sports and Culture, Japan. Computation time was provided by the Super Computer Laboratory, Institute for Chemical Research, Kyoto University.

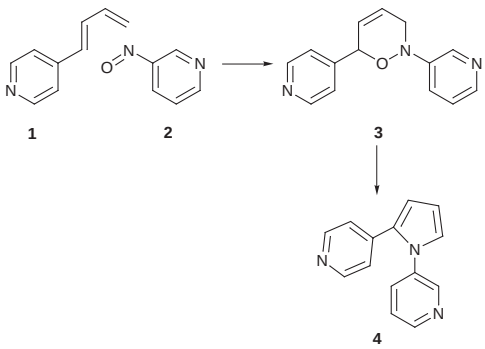
The hetero-Diels–Alder reaction between a pyridylbutadiene and 3-nitrosopyridine is accelerated by a variety of metalloporphyrin trimers; there is a weak correlation between rate acceleration and product binding strength.

The acceleration of Diels–Alder reactions by artificial receptor molecules is well documented,[1] but there are few systematic studies of how the rate of an intra-cavity reaction can be influenced by fine-tuning the size and flexibility of the host.[2] The examples described so far are special cases of Diels–Alder reactions that have been carefully chosen to match the available hosts, in part because of the synthetic difficulties associated with producing a range of hosts. We now show that the regiospecific hetero-Diels–Alder reaction[3,4] of pyridyl diene **1** with 3-nitrosopyridine **2** to give oxazine **3** (Scheme 1) is a second pericyclic reaction that can be influenced by porphyrin trimer systems such as **5–8**. This cycloaddition is more readily monitored kinetically than our original Diels–Alder reaction as the process is essentially irreversible‡ and forms only a single, fairly robust product. The product has been rearranged to the 1,2-disubstituted pyrrole **4**;[5] if this rearrangement could be induced to occur under conditions compatible with the porphyrin trimers then the possibility of catalytic turnover arises.§

Trimers **5**[6]¶ and **6**[7] each contain three conventional porphyrins while the new[8] heterotrimers **7** and **8** contain one or two dioxoporphyrins respectively. The control (host-free) Diels–Alder reaction between diene **1** and dienophile **2** was monitored by ^{1}H NMR spectroscopy in $CDCl_3$ and in [$^2H_8$]toluene, and showed clean transformation of the starting substrates to the oxazine without significant formation of side products. However, HPLC was the preferred analytical technique for host-accelerated kinetic investigations. In a typical reaction, diene **1**, dienophile **2** and host were mixed in equimolar amounts, each at a concentration of 0.333 mM. The reaction was carried out at 25 °C in CH_2Cl_2 (and also in toluene for trimer **5**) and monitored by HPLC.‖ It proved to be first order with respect to both the diene and dienophile with a rate constant of 3.9×10^{-3} M^{-1}s^{-1} (Table 1). The host-induced rate accelerations (calculated relative to the host-free reaction) for the different hosts are summarised in Table 1.



Scheme 1

In order to gauge the affinity of the substrates and product to the various hosts, a series of UV–visible titrations were performed using the established procedure;[9] results for the oxazine product **3** are also summarised in Table 1, together with the effective molarity for binding **3** relative to the two substrates.** For trimer **6**, the values represent an average of all the possible binding interactions to that host (inside/outside for the monodentate substrates, or across acetylene/butadiyne for the bidentate oxazine). Complications arise for the mixed dioxo hosts because pyridine-binding gives no noticeable shift in the Soret band:[8] monitoring the shift of the porphyrin Soret band in these species can thus only yield information about binding interactions at the porphyrin sites and not at the dioxo sites.

In CH_2Cl_2 an acceleration of 1030-fold (relative to the control reaction) was observed for the unsymmetrical host **6**. This is coupled with a particularly high binding affinity of oxazine **3** to **6**, suggesting that the 'product-like' transition state

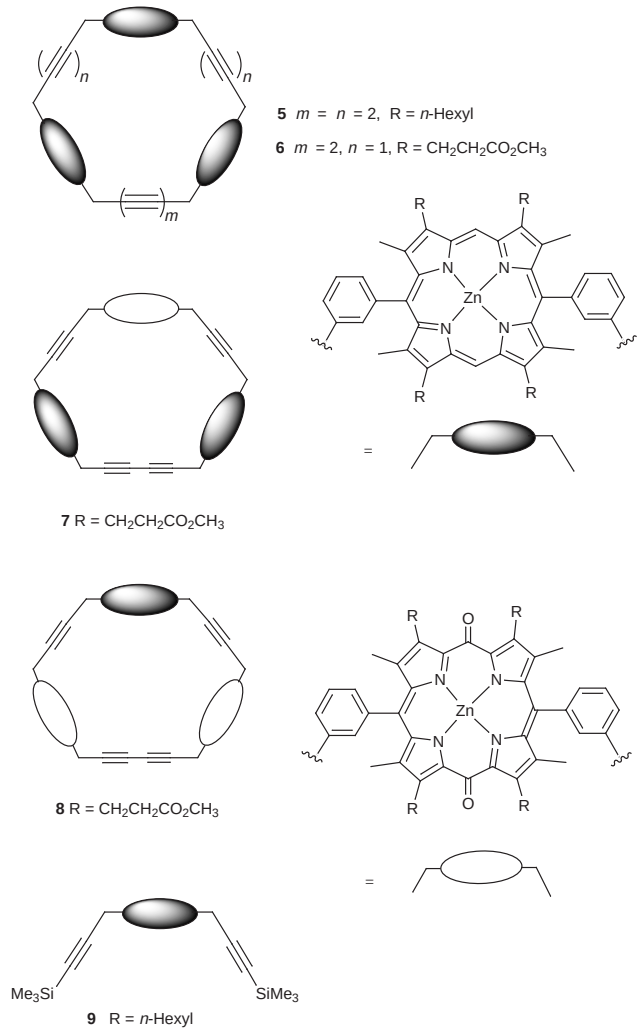


Table 1 Kinetic and equilibrium constant data for formation and binding of **3** with various hosts

Host	Solvent	k/M^{-1} s^{-1}	Rate acceleration (approx.)	Binding constant/M^{-1}	E.M.[a]
Control	CH_2Cl_2	0.0039	—		
Control	PhMe	0.0023	—		
9	CH_2Cl_2	0.0064	2	6.9×10^3	0.0035
9	PhMe	0.0025	1	8.2×10^3	0.0012
5	CH_2Cl_2	1.1	280	7.3×10^6	3
5	PhMe	1.9	830	5.6×10^7	3
6	CH_2Cl_2	4.0	1030	2.3×10^8	13
7	CH_2Cl_2	3.2	820	2.4×10^8	23
8	CH_2Cl_2	2.2	560	1.2×10^8	2

[a] See note **.

for the reaction prefers to bridge the shorter acetylene linker present in this host, rather than the butadiyne link in **5**. Further evidence to support this is obtained from molecular modelling of the oxazine using CERIUS[2] which confirms that the geometry is more complementary to the smaller porphyrin–porphyrin distance. A similar rate acceleration (820-fold) was observed for the mono-dioxo host **7**.

As the magnitude of binding constants and reaction rate constants are likely to display solvent dependence, and as this may subsequently lead to a different rate acceleration, the control reaction and the **5**-host accelerated reaction were also studied in toluene: the 830-fold rate acceleration is significantly higher in toluene than the 280-fold in CH_2Cl_2 (Table 1). The control reaction is 1.7 times faster in CH_2Cl_2 than in toluene, while the host-accelerated reaction is 1.7 times faster in toluene than in CH_2Cl_2 (Table 1). It is possible that in the control reaction the solvent stabilises the Diels–Alder transition state better than the reactants, and that this stabilisation is more significant in CH_2Cl_2 than in toluene, leading to a higher reaction rate in CH_2Cl_2. This is consistent with the observed binding constants being larger in toluene than in CH_2Cl_2.** This stronger binding in toluene will also lead to an increased concentration of the host–substrate reactive complex and to a larger rate enhancement. In addition, it is also possible that the reactants and transition state are not well solvated inside the trimer cavity. In this case, therefore, solvent stabilisation is not as significant as in the control reaction, where the reactive species are not shielded by the host and are easily solvated.

In order to prove that the cycloaddition reaction occurs inside the cavity of the trimeric porphyrin hosts, an inhibition experiment was carried out in which 1 equiv. of oxazine **3** was added to the reaction mixture in the presence of **5**. The resulting rate acceleration is reduced by roughly 20-fold in CH_2Cl_2 and 270-fold in toluene, giving a reaction rate similar to that observed in the presence of porphyrin monomer. Pyrrole **4** is a less effective inhibitor when added to the CH_2Cl_2 or toluene reaction mixture in the presence of **5**: although the initial reaction rate drops to one third of that observed for the **5**-accelerated reaction, complete inhibition does not occur and catalytic turnover is still feasible. The observed decrease is readily explained: if the pyrrole occupies one site inside the cavity, this leaves only two sites to bind the diene and dienophile, decreasing the number of constructive binding possibilities from six to two.

Preliminary results indicate that the hetero-Diels–Alder reaction described is well suited for intra-cavity kinetic studies. Future investigations will focus on initiating the pyrrole formation under conditions compatible with the Diels–Alder cycloaddition, exploring solvent effects, and exploring the influence of changes to the host geometry.

We thank the EPSRC, CIBA Jubiläumsstiftung, British Council, Israel Academy and Ministry of Science, and B'nai B'rith for financial support.

‡ If the reverse hetero-Diels–Alder reaction were to proceed at a significant rate, a solution of the oxazine would always contain some dienophile **2** which could be trapped by the use of a scavenger. In a control experiment, 10 equiv. of cyclopentadiene were added to a solution of the oxazine in CH_2Cl_2 at 25 °C; after 48 h, ^{1}H NMR analysis showed no evidence for a new adduct.

§ Model building suggests that the intracavity cycloaddition and rearrangement would be even more favourable for 4-nitrosopyridine, but this potential substrate proved too unstable to isolate.

¶ Porphyrins with solubilising *n*-hexyl side chains in place of esters are prepared by the procedure published previously (ref. 6) using the appropriate hexyl-substituted dipyrrole.

‖ Accelerated reactions were initiated by addition of the host and reaction progress was monitored by HPLC (normal phase 8 × 225 mm Spheris S5W column on a HP Series 1050 instrument) or GC (5% dimethyldiphenyl siloxane 25 m × 0.32 mm × 0.25 μm column on a HP GC 5890 Series II instrument). For all the reactions the decrease in concentration of diene and dienophile was monitored. After completion of the host-accelerated reactions a few drops of TFA were added to the reaction mixture to demetallate the porphyrin hosts. The oxazine product is thus released from the cavity and may then be detected by HPLC, confirming that the disappearance of the starting substrates correlates directly with oxazine formation.

** Thermodynamic effective molarity (E.M.) for binding = K(**3**)/[K(**1**)K(**2**)]. In CH_2Cl_2 K(**1**) and K(**2**) are generally *ca* 5×10^3 and 1×10^3 M^{-1} respectively, while in toluene they are around 2–3 times larger.

Gel phase MAS ^{1}H NMR as a probe for supramolecular interactions at the solid–liquid interface

Yolanda R. de Miguel,[a] Nick Bampos,[a] K. M. Nalin de Silva,[a] Stephen A. Richards[b] and Jeremy K. M. Sanders*[a]†

ArgoGel beads functionalised with mono- and bi-dentate pyridyl ligands give excellent gel phase (MAS) ^{1}H NMR spectra that allow detailed structural characterisation of their non-covalent complexes with metalloporphyrins.

We show here that, in favourable circumstances, gel phase magic angle spinning (MAS) ^{1}H NMR spectroscopy can provide a powerful new tool for probing non-covalent interactions at the solid–liquid interface: such interactions lie at the heart of much of separation science, especially affinity chromatography, and of solid-phase organic synthesis. The recent explosion of polymer-supported chemistry has been accompanied by the development of techniques for coding, tagging and releasing the resulting resin-bound molecules, but there have been few rapid or non-destructive techniques that provide subtle analytical or spatial information for the resin-bound species themselves.[1] Gel phase MAS NMR[2] has recently been applied to structure analysis of molecules attached onto solid supports, and we now demonstrate the potential of this new analytical tool for investigating molecular recognition at interfaces by probing events that occur between polymer-bound pyridyl ligands and a range of porphyrins.

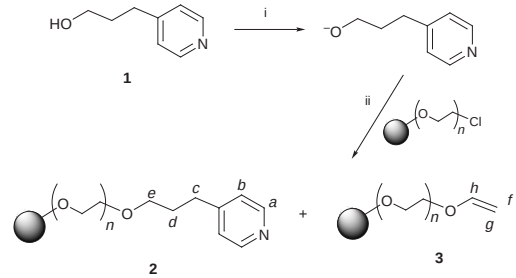
In a conventional solution-state spectrometer, organic solids generally give ^{1}H and ^{13}C NMR resonances with linewidths of 10^4–10^5 Hz due to a combination of strong dipolar interactions and spatial inhomogeneities.[3] If the species of interest is a small molecule attached to a solvent-swollen polystyrene bead *via* a flexible tether, then its molecular mobility can approach that of the solution state. In such circumstances, dipolar interactions are dramatically reduced by averaging and the major line broadening mechanism that remains is the spread of chemical shifts due to spatial inhomogeneities, *i.e.* different effective magnetic fields are experienced by molecules on the inside and outside of a bead or by beads in different parts of the sample tube.[4] This spread of chemical shifts (*ca* 10^3 Hz) can be eliminated by magic angle spinning at relatively low speeds (*ca* 10^3 Hz) in a solution-state spectrometer to give spectra with linewidths that are comparable with small molecules in free solution.

Given our interests in porphyrin-accelerated reactions[5] and in approaches to catalyst discovery that involve selecting potential catalysts *via* strong binding of transition state analogues (TSAs),[6] we wished to investigate the molecular recognition properties of pyridines and TSAs that were covalently bound to polymer beads. Both for the spectroscopic reasons outlined above, and to give maximum molecular accessibility, we chose to attach these ligands to ArgoGel beads: these contain highly flexible PEG chains, grafted to lightly cross-linked polystyrene beads *via* a stable bifurcated linkage, thereby allowing bound molecules to experience a solution-like environment. The attachment of pyridyl ligand **1** onto the beads was performed by deprotonation of the alcohol (Scheme 1) followed by treatment with ArgoGel chloride beads. After reaction, microanalysis suggested complete displacement of chlorine but the nitrogen content was 0.39% instead of the expected 0.59%, highlighting the danger of relying on microanalysis to monitor solid-phase organic reactions. However, after removal of residual broad polymer signals using a CPMG spin-echo sequence,[3] the gel phase MAS ^{1}H NMR spectrum of the beads gave *ca* 1 Hz resolution and allowed direct structural determination of the bound molecules without the need for cleavage [Fig. 1(*a*)].‡ As well as the signals *a*–*e* for **2**, three unexpected signals (*f*, *g* and *h*) were observed. These were assigned to the terminal enol ether by-product **3** resulting from HCl elimination from the resin. Although this is an inconvenient side-product, it proved to be a useful internal standard for binding studies.

Ruthenium porphyrins bind very strongly to pyridine ligands (K *ca* 10^5 M^{-1}),[7] so the pyridyl beads were treated with an excess of ruthenium porphyrin **4**. The dark orange colour of the porphyrin present in the resulting beads did not leach out on washing with a non-coordinating solvent (*e.g.* CH_2Cl_2). After displacement of the solvent molecule in the starting porphyrin, a 1:1 complex had formed on the beads. The CPMG ^{1}H NMR spectrum [Fig. 1(*b*)] showed the characteristic large chemical shift changes experienced by the bound pyridyl ligand due to the porphyrin ring current (Scheme 2); a COSY spectrum confirmed the assignments shown. The CO ligand in the bound complex was evident in a new sharp peak at 1945 cm^{-1} in a spectrum obtained by single bead FT-IR microspectroscopy.[7]

The analogous complex with zinc porphyrin **5** was also prepared. In this case, dark purple beads were obtained which leached porphyrin on washing with CH_2Cl_2. This is not surprising as zinc porphyrins bind relatively weakly (K *ca* 10^3 M^{-1}) to pyridine ligands in solution. The non-spin echo ^{1}H NMR spectrum [Fig. 1(*c*)] of the complex exhibited (superimposed on a broad polymer background) sharp enol ether peaks and two sets of aryl and β signals for the porphyrin itself; these appear to correspond to bound porphyrin within the bead and free porphyrin exchanging with surface-accessible bound porphyrin. The set of inner bound porphyrin signals was assigned by its greater attenuation in a CPMG spectrum [Fig. 1(*d*)]. All the resonances belonging to ligand **2** were broadened beyond detection in this spectrum, presumably due to an exchange process, the details of which are still unclear.

A bipyridyl ligand (which is a TSA for a hetero-Diels–Alder reaction[8] was attached to the resin by the same method as in



Scheme 1 *Reagents and conditions*: i, NaH, THF, 5 h, room temp.; ii, THF, 45 h, 60 °C

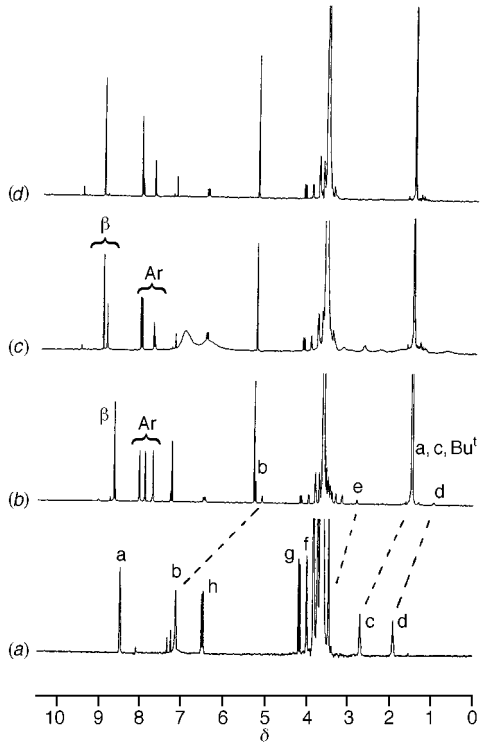


Fig. 1 400 MHz gel phase MAS ^{1}H NMR spectra: (*a*) CPMG spectrum of functionalised beads showing resonances due to **2** and **3**; (*b*) the same beads complexed to porphyrin **4**; (c) non-CPMG spectrum of the beads in (*a*) in the presence of excess porphyrin **5**; (*d*) CPMG spectrum of same sample as in (*c*)

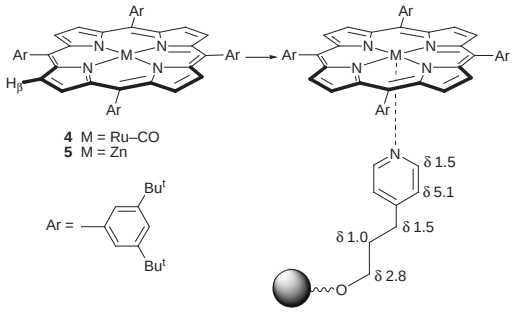
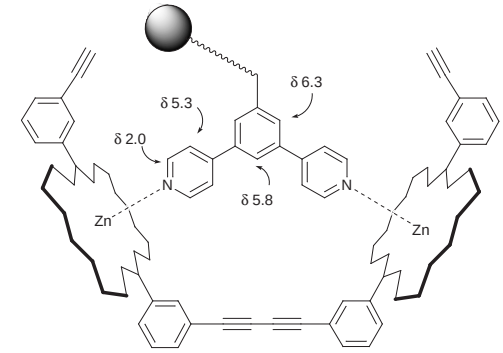


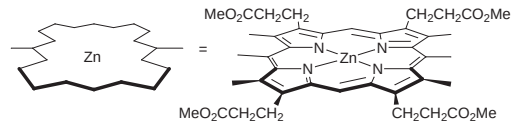
Scheme 2

Scheme 1. The gel phase NMR spectrum of the beads allowed characterisation of the supported bidentate ligand, and again demonstrated formation of enol ether **3**. Treatment of these beads with a flexible porphyrin dimer in CH_2Cl_2 gave the corresponding complex **6** as dark purple beads that did not leach colour on washing, which is consistent with an expected binding constant of more than 10^6 M^{-1}. The one-dimensional and NOESY spectra of these beads allowed assignment of all the bound aromatic resonances of **6** and confirmed that the chemical shifts of ligand and host were essentially identical to the corresponding solution-state complex.

Finally, the bipyridyl beads were treated with our symmetrical Zn_3-butadiyne-linked cyclic porphyrin trimer.[5] Again the bound chemical shifts were as expected, but now all resonances including the enol ether were somewhat broadened. The implication of this result is that overall polymer mobility is reduced, even in chains that are not directly bound to host. We tentatively assign this observation to cross-linking of separate



6



ligand chains *via* binding to the same trimer molecule within bead cavities. As expected, this is reversible: virtually all colour is removed from the beads by addition of the strongly-binding tri-functional ligand tripyridyltriazine.

We have shown that gel phase MAS ^{1}H NMR spectroscopy allows the study of non-covalent interactions between hosts and tethered guests. A wide range of two-dimensional techniques is available, and use of CPMG sequences of variable length should give access to subtle molecular mobility information. Furthermore this powerful technique holds out the prospect of studying the kinetics of molecular penetration into, and exit from, the interior of beads, and of characterising non-covalent cross-linking of ligand chains.

We thank Argonaut Technologies for providing ArgoGel resins and the EPSRC for financial support.

Crystal structure of β-MNX (M = Zr, Hf; X = Cl, Br)

Andrew M. Fogg, John S. O. Evans and Dermot O'Hare*

Inorganic Chemistry Laboratory, University of Oxford, South Parks Road, Oxford, UK OX1 3QR. E-mail: dermot.ohare@chem.ox.ac.uk

Superconductivity with critical temperatures of up to 25.5 K has recently been reported for alkali metal intercalates of β-MNX (M = Zr, Hf; X = Cl, Br); we have investigated the structures of these host lattices and found that they are not as reported in the literature but are isostructural with rhombohedral SmSI.

β-ZrNX (X = Cl, Br) was first prepared by Juza and Heners.[1] The crystal structures were reported by Juza and Friedrichsen to consist of a random stacking sequence of hexagonal XZrNNZrX layers leading to cell parameters of $a = b = 2.08$ Å, $c = 9.22$ Å ($a = 3.60$ Å using conventional axes).[2] A second synthetic route to β-ZrNCl *via* chemical vapour transport was reported by Ohashi *et al.* who demonstrated that a supercell with $\sqrt{3}a$ and $3c$ relative to the previous study was required to index their diffraction data though no further structural details were reported.[3]

The intercalation of lithium into β-ZrNCl was first reported by Yamanaka *et al.* in 1984.[4,5] It was subsequently shown that these and other alkali metal intercalates become superconducting below 15 K for doping levels of up to 0.4 mol alkali metal per ZrNCl.[6,7] These compounds represent the first examples of superconducting layered metal nitrides. More recently, β-$Li_{0.48}(THF)_y$HfNCl was shown to undergo a superconducting transition at 25.5 K, the highest of any nitride.[8] Any understanding of these materials will require a correct structural model of both the host lattice and its intercalation compounds. We have thus redetermined the structure of the β-MNX (M = Zr, Hf; X = Cl, Br) host lattices and find the true structure to be different from that generally accepted.

β-MNX (M = Zr, Hf; X = Cl, Br) were synthesised by the reaction of ZrH_2 or Hf with NH_4X followed by crystal growth *via* vapour transport under conditions reported previously.[3,9] Powder X-ray diffraction data for β-ZrNCl, β-ZrNBr and β-HfNCl indicated that in each case the three layer supercell proposed previously was necessary to index the diffraction patterns. Structural studies on β-ZrNCl are complicated by a number of factors relating to its crystal morphology. Firstly, the prevalence of stacking faults along the *c*-axis makes single crystal analysis extremely difficult. These stacking faults are presumably related to the disordered hexagonal cell reported previously.[2] Secondly, the plate-like morphology of the crystals causes preferred orientation to be extreme in microcrystalline samples. Indeed in conventional Bragg–Brentano geometry the preferred orientation is so great that the 00*l* class of reflections are frequently the only ones observed. Attempts to alleviate this problem by grinding and subsequent annealing of the sample resulted in significant loss of crystallinity. In order to obtain suitable data for structural analysis diffraction data were collected in two distinct geometries. The microcrystalline samples were sieved to less than 90 μm and either loaded into a 0.3 mm glass capillary or sprinkled onto a thin Mylar sheet and recorded in transmission geometry on a Siemens D5000 diffractometer using Cu-Kα radiation and a Braun linear position sensitive detector. In this manner data sets were obtained showing either artificially enhanced or diminished 00*l* intensity. The capillary data together with a calculated diffraction pattern based on the reported structural coordinates of the original structure are shown in Fig. 1. The calculated diffraction pattern was produced for a rhombohedral stacking sequence of layers with the layer structure suggested by Juza *et al.* The poor agreement is apparent.

The structure was solved by constructing trial solutions based on ClZrNNZrCl layers with differing stacking sequences and calculating their diffraction patterns within the InsightII software package.[10] The structure showing the closest agreement between the observed and calculated diffraction patterns was found to have rhombohedral symmetry (space group $R\bar{3}m$) and was used as the starting point for a combined Rietveld refinement of both sets of data within the GSAS software suite.[11] The final refinement consisted of 52 parameters (7 structural and 45 instrumental and background) with 3549 data points (9–80° 2θ, step = 0.02°,46 reflections) for the capillary data and 4098 data points (8–90° 2θ, step = 0.02°, 59 reflections) for the flat plate data. Isotropic temperature factors for the Zr and N atoms were constrained to be equal. A refinement in which all the temperature factors were allowed to refine freely led to no improvement in the agreement factors. Convergence was achieved at $\chi^2 = 2.07$, $R_{wp} = 2.40\%$ (capillary), $R_{wp} = 6.40\%$ (flat plate), $R_{wp} = 3.81$ (combined), $R_{F^2} = 16.4$ (capillary) and $R_{F^2} = 16.3\%$ (flat plate) for a rhombohedral cell with $a = 3.6052(1)$, $c = 27.6716(7)$ Å. Whilst these agreement factors are higher than those normally reported, we believe our model to be essentially correct. The diffraction data shown in Fig. 2 illustrate the dramatic effect which preferred orientation can have on the intensities of Bragg reflections of this phase. The structural model reported simultaneously provides a satisfactory fit to both data sets with only a simple March–Dollase type preferred orientation correction.[12,13] For the capillary data, the preferred orientation parameter for the 001 direction is 0.72 and for the flat plate data is 2.14. The atomic coordinates of β-ZrNCl are given in Table 1 and the final Rietveld fits of both sets of data are shown in Fig. 2. Bond valence calculations gave values of 4.51 for Zr, 3.56 for N and 0.96 for Cl.[14,15]

The structure of β-ZrNCl is shown in Fig. 3(a) and it is isostructural with SmSI.[16,17] This structure is known to support intercalation as shown, for example, by the insertion of pyridine into YbOCl.[18] In this structure each Zr atom is seven coordinate in a distorted monocapped octahedral arrangement with three Cl

Cl	2/3	1/3	0.4460(2)	0.0117(11)

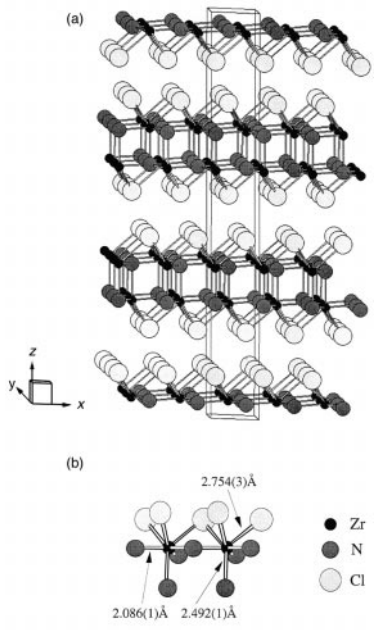

Fig. 3 (a) Structure of β-ZrNCl and (b) local coordination geometry of Zr in β-ZrNCl

atoms at 2.754(3) Å and three N atoms at 2.086(1) Å in a *fac*-arrangement with a fourth capping nitrogen at 2.492(1) Å as shown in Fig. 3(b). The octahedra are distorted by the displacement of the Zr atom from the centre towards the capped N_3 face to such an extent that the Zr and N atoms become essentially coplanar. These monocapped octahedral units are arranged in an edge sharing manner forming the ClZrNNZrCl layer structure. The ClZrNNZrCl layers are held together by van der Waals interactions. Alternatively the structure can be viewed as originating from the NaCl structure in a rhombohedral setting. Removal of alternate layers of cations and replacement of one half of the chloride layers in the sequence ClNNCl gives the β-ZrNCl structure. The vacant Zr layers can then collapse down so that one face of the *fac*-ZrN_3Cl_3 octahedron is capped by an additional N atom. The close relationship between the ZrN slabs in β-ZrNCl and the rock salt structure adopted by ZrN is perhaps of relevance to the superconductivity in the intercalates of β-MNX as the binary nitrides themselves undergo superconducting transitions at 9.05 K (ZrN) and 8.3 K (HfN).[19,20] Perhaps the most significant difference between this structure and the one originally reported is the absence of a short Zr–Zr distance which is instead replaced by the fourth capping N atom.[2,21,22] This Zr–Zr interaction had been thought to play an important role in the superconducting intercalates.

Further confirmation that this is the correct structure can be sought by simulating a structure in DIFFaX in which there is random stacking of the layers.[23] If this model is correct then it should be able to reproduce the data reported by Juza *et al.* This is found to be the case, suggesting that the chemical transport synthesis of Ohashi *et al.* produces a material with the same constituent layers as that produced by Juza, but with significantly enhanced ordering of layer stacking.

Refinement of the structures of β-ZrNBr and β-HfNCl using the same structural model showed that these compounds are indeed isostructural with β-ZrNCl as reported here. Full details of these refinements, the metallocene intercalation chemistry of β-ZrNCl and intercalation of β-ZrNBr will be published elsewhere.

Synthesis of carbyne nano-particles by dehydrochlorination of 1,1,1-trichloroethane

Gaoquan Shi†

Department of Chemistry and State Key Laboratory of Coordination Chemistry, Nanjing University, Nanjing 210093, People's Republic of China

Chemical dehydrochlorination of 1,1,1-trichloroethane with anhydrous KOH in the presence of a poly(ethylene glycol) oligomer as phase transfer catalyst leads to the formation of carbyne particles with diameters in the range of 30–50 nm.

Synthesis of carbynes or cumulenic carbons has attracted the attention of many researchers,[1] as we still know much less about this material than about the other carbon polymorphs such as graphite, fullerenes and diamond.[2] Several synthetic routes to carbynes have been developed,[3–5] however, none of them concerned dehydrochlorination of low molecular weight carbon halides. Presented here is a novel chemical approach for synthesizing a carbyne analogue from 1,1,1-trichloroethane.

Carbyne can be prepared by reaction of 1,1,1-trichloroethane with a large amount of anhydrous KOH powder (the molar ratio of the base and the halide should be greater than 5 : 1) in the presence of a poly(ethylene glycol) with molar mass greater than 200 g mol^{-1} as phase transfer catalyst. The reaction can be represented by eqn. (1).

$$n\ CH_3CCl_3 + 3n\ KOH \xrightarrow[20\text{–}30\ ^\circ C,\ 4\ h]{HO(CH_2CH_2O)_mH\ (m\ >\ 3)} \underset{42\%}{-(C\equiv C)_n-} + 3n\ KCl + 3n\ H_2O \quad (1)$$

KOH in excess acts as a water absorbent and removing of water forces the reaction to the right hand. Otherwise, as a large amount of water exist in the system, the reaction produces only 1-chloroacetylene or 1,1-dichloroethylene and no carbon is obtained.

The black powdery carbon obtained by this technique had a particle size of 30–50 nm as shown by its transmission electron micrograph (Fig. 1). Powder X-ray diffraction analysis showed a broad peak at 2θ = 21°, showing the product to be amorphous.

The FT-IR spectrum of the product (Fig. 2) shows no C–Cl bands in the region 520–700 cm^{-1}, indicating extensive dehydrochlorination of the halide. New absorption bands appear in 1600 and 2130 cm^{-1}. They are typical of valence vibrations of carbon–carbon double and triple bonds, respectively.[6,7] The band in the region of 1700 cm^{-1} may be attributed to cumulative double bonds.[8] The very strong band at 1100 cm^{-1} is assigned to the stretching vibration of the C–C bond.[6] Absorption bands typical of valence vibrations of CH_2 were found in the region of 2800–2990 cm^{-1}. No band was observed above 3000 cm^{-1}, which demonstrated that no substitution side reaction was present during the carbonization process.

In the FT-Raman spectrum (Fig. 2) there appears a broad band centered at *ca.* 1900 cm^{-1}, which is attributed to conjugated carbon–carbon triple bonds. A much weaker band centered at *ca.* 1600 cm^{-1} is of 'inner layer' graphite bound by two adjacent graphite planes and the band centered at *ca.* 1400 cm^{-1} is the A_{1g} mode of $D_{6h}{}^4$ symmetry for small graphitic crystallites.[9] The intensity ratio of the 1900 cm^{-1} ($I_{C\equiv C}$) band and 1600 cm^{-1} band (I_{g-C}) is calculated to be 4.0 ± 0.5. There exists no other solid carbon material showing such intense Raman signals for triple-bonded carbon (the $I_{C\equiv C}/I_{g-C}$ of carbynes made *via* other systems was found to be lower than 2.2).[2] The conjugation length of carbyne estimated by the equation developed by Kuzmany *et al.* is *ca.* 15. This value is higher than those of the carbynes reported previously (6–10).[2,4]

While the existence of carbyne has been repeatedly doubted, all the criticisms are not convincing enough to reject the concept of linear carbon allotropes.[10] On the other hand, the FT-IR and FT-Raman spectra results described above provide strong evidence of carbon particles made from 1,1,1-trichloroethane having a polyyne structure with high concentrations of relatively long conjugated triple-bonded carbon sequences.

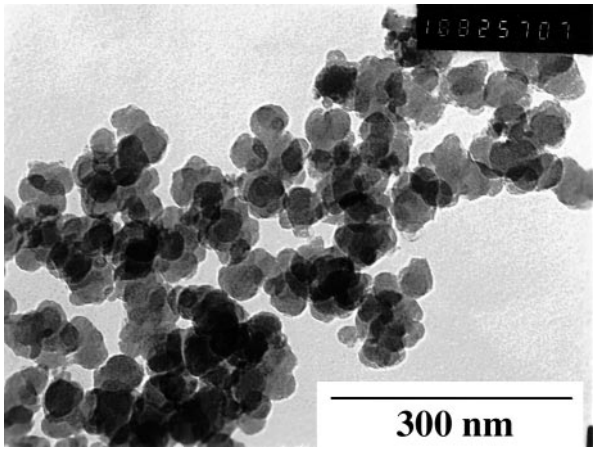

Fig. 1 Transmission electron micrograph of the carbon made from 1,1,1-trichloroethane.

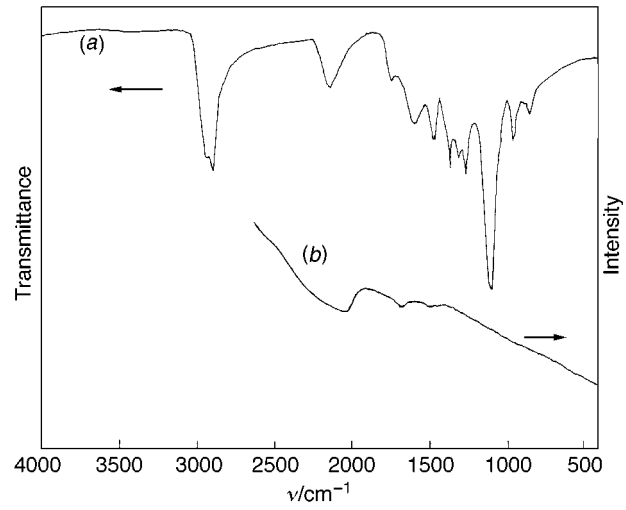

Fig. 2 (*a*) FT-IR and (*b*) FT-Raman spectra of the carbon made from 1,1,1-trichloroethane.

In conclusion, 1,1,1-trichloroethane can be carbonized by anhydrous KOH powder into amorphous carbyne nano-particles. This is the first example of dehydrochlorination of low molecule weight carbon halides into carbynes.

I thank the Natural Science Foundation of China for support of this work (No: 29773019).

A stereoselective and novel approach to the synthesis of 1,3-diols: simple control of diastereoselectivity

Rainer Mahrwald*† and Bilgi Gündogan

Institut für Organische und Bioorganische Chemie der Humboldt-Universität Berlin, Hessische Str. 1-2, D-10115 Berlin, Germany

Complete control of simple diastereoselectivity in the synthesis of 1,3-diols was realized through the use of a one-pot aldol addition and reduction process.

The diastereoselective synthesis of *syn* and *anti* 1,3-diols is currently of considerable interest, as these synthons are frequently found in a variety of polyketide natural products. Those diols with two chemically distinct hydroxy groups are of particular interest, as they are suitable building blocks for further stereoselective transformations. Multistep and more particular syntheses were found in the literature (hydrosilylation[1] or alkylmagnesation[2] of suitable alkenes, oxidative cleavage of double bonds,[3] reductive rearrangement of alkenyl acetals[4]). Moreover there are only a few examples of procedures for synthesising *anti* diols.[5]

Herein, we describe a simple and more general one-pot procedure for the synthesis of both *syn* and *anti* 1,3-diols by the utilization of titanium Lewis acids. Our studies on diastereoselective aldol additions in the presence of titanium Lewis acids have outlined a new series of highly regio-[6] and stereoselective reactions.[6,7] Very recently, we described the stereoselective aldol addition of aldehydes with enolizable aldehydes in the presence of titanium(IV) chloride.[7] The reactions were accomplished with the aid of an amine base. Surprisingly, substituting a titanium(IV) alkoxide as a base resulted in complete reduction of the intermediate β-hydroxy aldehydes when used in a one-pot procedure (Scheme 1).

Importantly, equimolar amounts of titanium(IV) alkoxides were added to a mixture of each starting aldehyde and 1 equiv. titanium(IV) chloride. When using a chloroisopropoxytitanium agent [*i.e.* $ClTi(OPr^i)_3$, $Cl_2Ti(OPr^i)_2$ or $Cl_3Ti(OPr^i)$] in place of both titanium(IV) chloride and the titanium(IV) alkoxide no reactions occurs; neither aldol additions nor reduction processes are observed.‡

Reactions were carried out in toluene or CH_2Cl_2; when using oxygen-containing solvents (Et_2O, THF) this described aldol addition-reduction sequence failed to occur.

The reaction mechanism is thus likely to be very similiar to a Meerwein–Ponndorf reduction. No reduction was observed by using tertiary titanium(IV) alkoxides [*e.g.* titanium(IV) alkoxides derived from from Bu^tOH or BINOL]. Thermodynamic equilibration occurs during the reduction process. The isolated 1,3-diols were formed with a high degree of *anti* selectivity (entries 1–4, Table 1). Similar observations were made in catalytic equilibration processes of hydroxy aldehydes.[7]

Utilizating the $TiCl_4/Ti(OPr^i)_4$ system at low temperature (−78 °C) only equilibration of the formed 3-hydroxy aldehydes is observed, whereas at higher temperatures (0–10 °C) an additional reduction process to the corresponding diols takes place.

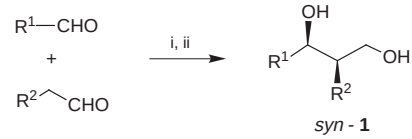
[a] Isolated yields. [b] Determined for the crude products by ^1H and ^{13}C NMR spectroscopy. Method A: $Ti(OPr^i)_4$ was added to a mixture of 1 equiv. of $TiCl_4$ and 1 equiv. of the corresponding starting aldehyde (ref. 5). (Scheme 1). Method B: the β-hydroxy aldehydes were synthesized by a literature procedure (ref. 7). After 16 h, 1 equiv. of $LiAlH_4$ was added to the crude reaction mixture (Scheme 2). [c] Ref. 8. [d] Ref. 2. [e] Ref. 1 and 12. [f] Ref. 11. [g] Ref. 1 and 9. [h] Ref. 10.



Scheme 2 *Reagents and conditions*: i, $TiCl_4$, base, −78 °C; ii, $LiAlH_4$

Reversal and thus complete control of the simple diastereoselectivity using this one-pot aldol addition-reduction sequence was realized through the synthesis of the corresponding *syn* 1,3-diols. This was achieved by reduction of the crude aldol reaction mixture[7] with $LiAlH_4$. The 1,3-diols thus obtained were isolated with a high degree of *syn* selectivity (see entries 5–8, Table 1 and Scheme 2).

Preparation, structure and morphology of polymer supports

David C. Sherrington†

Department of Pure and Applied Chemistry, University of Strathclyde, 295 Cathedral Street, Glasgow, UK G1 1XL

Received (in Cambridge, UK) 19th May 1998, Accepted 18th June 1998

The use of polymer resin beads as an aid to synthesis is becoming an increasingly common feature in both academic and industrial synthesis laboratories. The large majority of users employ materials sourced commercially and adopt or adapt procedures already described in the literature without thinking too deeply about the physico-chemical aspects of the support. Success can be immediate, but more often a learning curve needs to be traversed. The present article seeks to describe the chemistry of synthesising supports and to present a user-friendly description of their key physico-chemical properties. A qualitative and pictorial view of how specific morphologies can be generated, and the relevance of these, is also presented. It is hoped that this insight will be of advantage to users in planning and pursuing their chemistry using polymer supports.

Background

Following the discovery and exploitation of ion exchange resins based on suspension polymerised styrene–divinylbenzene (DVB) beads during the 1950s, an enormous amount of effort was directed towards investigating styrene–DVB sulfonic acid resins as potential heterogeneous catalysts. Patenting activity was extensive and throughout the following decades many key large-scale chemical processes have been established employing sulfonic acid resins as the catalyst.[1,2] These include the manufacture of bisphenol A, isopropyl alcohol, alkylated phenols, branched ethers (petrol organic 'anti-knocks') such as methyl *tert*-butyl ether (MTBE), and a variety of alkyl esters including important (meth)acrylate esters. Despite this, there remains a dearth of knowledge amongst synthetic chemists regarding the usefulness of these polymer-based catalysts.

In 1963 Merrifield took the first step towards introducing polymer-supported chemistry to the wider world of synthesis with the publication of his 'solid phase' peptide synthesis methodology.[3] Notwithstanding this however a more widespread appreciation of the advantages that polymer (and other) supports have to offer to synthesis has only really occurred in the last five years or so, with the explosion in the use of solid phase combinatorial synthetic methodologies,[4,5] spurred on by the need for rapid synthesis and screening of potential lead compounds in drug discovery programmes within the pharmaceutical industry. Increasing familiarity with, and confidence in, the use of polymer resins in solid phase synthesis has stimulated even mainstream organic synthetic groups[6,7] to investigate the prospects of employing polymers as catalyst supports for use, for example, in solution phase combinatorial synthesis. Thus those of us who have been struggling with these systems for many years now find ourselves joined by more illustrious and no doubt more imaginative and skilful colleagues.

Recently the areas of polymer-supported organic reactions[4,8] and polymer-supported catalysts[9,10] have been reviewed from the point of view of the solid phase synthetic chemistry which can be carried out on resins and the reactions that have been catalysed by polymer-supported metal complexes *etc*. The main objective of the present article is to focus on the polymer support itself, and to bring a more informed picture of the molecular structure, porous morphology and physico-chemical nature of the support to hard-pressed users and would-be users of these polymers. The hope is that this insight might explain some of the advantages already experienced in the use of supports and, perhaps more importantly, might help overcome some of the disadvantages or downright failures experienced with attempts to use polymer supports.

Linear polymers

Most polymer supports are based on addition polymers typified by polystyrene, the latter conveniently synthesised from styrene *via* a free radical chain propagation reaction (Fig. 1). Since

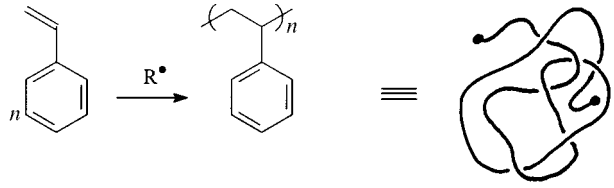

Fig. 1 Polymerisation of styrene to form linear polystyrene, which is a random coil macromolecule.

polystyrene-based supports are particularly widely employed, this is a very convenient model upon which to base a description of the relevant polymer physical chemistry. The principles to be described, however, are widely applicable to other polymer types. Synthetic polymers are generally devoid of any significant secondary or tertiary structure, such as commonly occurs with natural polymers (*e.g.* proteins, DNA), and so individual isolated polymer molecules exist as a random coil typically ~10–20 nm in size, depending upon the molecular weight.[11]

A collection of chemically similar polymer molecules exist as a mass of interpenetrating random coils—not unlike a bowl of spaghetti. In the case of polystyrene in the solid state, at room temperature, individual polymer chains cannot migrate relative to each other, and indeed even rotation about the bonds in the polymer backbone is very inhibited. Only rotation A (Fig. 2) of

Professor D. C. Sherrington graduated from the University of Liverpool with a B.Sc. (Hons) in Chemistry in 1966 and with a Ph.D. in 1969. He was appointed Lecturer at the University of Strathclyde, Department of Pure and Applied Chemistry, in 1971, then Senior Lecturer and Reader, and finally Professor of Polymer Chemistry in 1987. Professor Sherrington has broad interests covering many aspects of polymer chemistry but, in particular, has pioneered the use of polymers as supports for reagents and catalysts in organic chemistry. He has published 220 papers and reviews, and is co-editor of two seminal research texts on polymer-supported species (1981 and 1988). He was international editor of the journal Reactive Polymers *(1987–1996), was elected Fellow of The Royal Society of Edinburgh (1990) and was awarded his D.Sc. (1992) from the University of Liverpool. Finally, he was awarded the RSC/SCI Beilby Medal (1993) for the 'Advancement of Chemistry and its Practice'.*

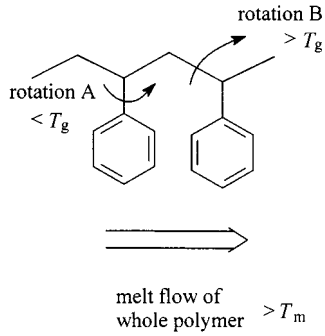

Fig. 2 Molecular motions in polystyrene: T_g = glass transition temperature; T_m = melting point.

the phenyl sidechains occurs freely at room temperature. Overall therefore the polystyrene 'bowl of spaghetti' is essentially frozen at room temperature. Technically the material is said to be below its glass transition temperature, T_g, and the material is amorphous and very glass-like in its general physical nature. The T_g for polystyrene is ~100 °C.[12] Above this temperature free rotation B (Fig. 2) about the bonds of the main chain occurs and the polymer becomes pliable or 'plastic'. The analogy now would be a bowl of 'rubbery spaghetti'. *Complete* movement (translation) of individual polymer chains relative to each is still inhibited until ~250 °C. This is the melting point,[12] T_m, above which polymer chains can flow over and through each other and the polymer becomes a viscous liquid or 'melt' (*i.e.* the 'spaghetti' is now hot and mobile and ready to eat). In the glass-like solid state diffusion of even small non-interacting molecules through solid polystyrene is extremely slow.

Solvation behaviour of polymers

The changes described above brought about by an increase in temperature can also be induced at ambient temperatures by the introduction of small interacting organic solvent molecules. Depending upon the relative strength of the interactions of the solvent–solvent, polymer–polymer, and polymer–solvent molecules, an organic solvent may sorb into polystyrene and allow backbone rotation to occur. This is termed 'plasticisation' and the polymer changes from a glass-like solid material into a soft plastic material. A sorbed solvent may interact even more favourably with the polymer chains, heavily solvate them, and allow them to move apart. Such solvents are called thermodynamically 'good' solvents or 'swelling' solvents (see later). This is the onset of the process of dissolution and if enough of such a solvent is added the individual polymer coils will move completely apart to form an isotropic (uniform) solution in the solvent (Fig. 3). Some solvents interact hardly at all with a given

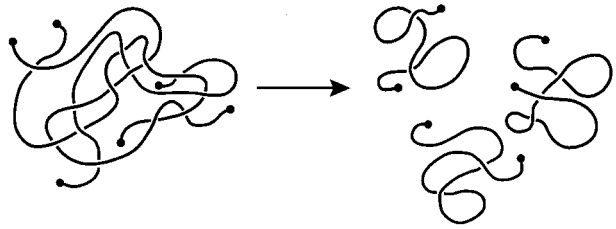

Fig. 3 Dissolution of interpenetrating polymer coils to form independent solvated coils.

polymer and are termed thermodynamically 'bad' solvents, *i.e.* non-solvents, or precipitants. If a polymer is dissolved in a 'good' solvent, and an excess of a 'bad' solvent is added, then the polymer can be precipitated as a solid material. Some typical 'good' solvents and 'bad' solvents for polystyrene are shown in Table 1.

In discussing the compatibility or otherwise of different materials a useful thermodynamic parameter is the solubility parameter δ. This is a measure of the attractive strength between molecules in a material. A solvent and a polymer are likely to be compatible, *i.e.* the solvent is likely to be a 'good' solvent for the polymer, if they have very similar solubility parameters. If the solubility parameters differ, the solvent is likely to be a 'bad' solvent or precipitant for the polymer. The solubility parameter for polystyrene (and copolymers of styrene and divinylbenzene, see later) is ~17–18 $(MPa)^{0.5}$. The corresponding values for a number of 'good' and 'bad' solvents are shown in Table 1.[13] Note that one group of 'bad' solvents has solubility parameters below that of polystyrene, while the other group has values above that of polystyrene.

Soluble polymer supports

In principle therefore soluble linear polymers seem excellent candidates as reaction and catalyst supports, and indeed they have been well-researched in this context.[14] Dilute solutions of linear polymers should allow rapid unimpeded access of reactants and reagents to functional groups on the support, and the recovery and separation of the polymer might be achieved by addition of a suitable precipitant, by micro- or ultra-filtration, and in some cases by thermal cycling. A major disadvantage of linear polymers as supports is that in general they are useful only with solvents in which they will dissolve. If a solvent is used or required, which will not dissolve the polymer, essentially all the advantages of using a linear polymer as a support are lost. In many instances therefore reagents and catalysts are excluded from use, or possible reaction conditions eliminated, simply because a suitable solvent for the polymer and the reaction cannot be found. Furthermore, in practice micro- and ultra-filtration processes are relatively costly and are not convenient, especially for the hard-pressed laboratory organic synthetic chemist, for laboratory automation, or an industrial chemical manufacturer. While precipitation of many polymers by addition of a suitable non-solvent yields a hard granular product which is readily filtered, linear polymers can selectively sorb a 'good' solvent and be precipitated as a sticky mass, impossible to filter. It is also important to realise that linear polymer coils in solution remain isolated from each other only at concentrations below ~1–2 wt%. Above this threshold, polymer coils interact and start to interpenetrate, and at more practical synthetic organic chemical concentrations, say >5 wt%, solutions can become impractically viscous. Bearing in mind that lightly crosslinked polymer networks can be prepared such that they can swell to imbibe >5 times their own mass of solvent (see shortly) and yet remain in a physical form useful for manipulation, the attractiveness of linear polymers as supports is rather limited.

Nevertheless there are situations where linear soluble polymers can be extremely useful and a key factor in this is that chemical reactions performed on such polymers can be

Table 1 Polystyrene solvents and non-solvents solubility parameters δ^a

monitored by, for example, high resolution solution phase ^{1}H and ^{13}C NMR spectroscopy.[15] Though the resonances due to backbone protons are usually broadened, signals arising from mobile groups in the sidechain are often as sharp as resonances from analogous low molecular weight groups in isotropic solution. Recently, however, considerable advances have also been made in ^{1}H and ^{13}C NMR analysis of crosslinked polymers[16] (see later).

Copolymers and copolymerisation

The introduction of functionality onto a polymer support can often be readily achieved simply by treating the polymer as a structural analogue of a low molecular weight species and then utilising identical chemistry to achieve a desired derivatisation or structural elaboration. Thus polystyrene can be treated as isopropyl benzene and, for example, subjected to electrophilic substitution. An enormous amount of chemistry has been developed using this approach.[1,4,5,17,18] An alternative or complementary approach is to introduce a specific functionality during free radical polymerisation, by utilising a comonomer which already carries the required function, or some precursor group which can subsequently be readily transformed. For example, copolymerisation of styrene and 4-vinylphenyl(diphenyl)phosphine yields polystyrene with pendant triphenylphosphine residues. This approach can be useful in producing a structurally well-defined polymer, for controlling the proportion of functional groups introduced and for providing some information on the distribution of the groups along the polymer chain.

It is important in this context to appreciate that all monomers are not incorporated at the same rate. In a free radical copolymerisation of two vinyl monomers, A and B, the rate at which a given monomer is copolymerised depends on the reactivity of the monomer, the reactivity of the free radical derived from the monomer, and how these two reactivities compare with the corresponding reactivities of the other monomer and its derived radical. These factors are all incorporated in so-called pairs of reactivity ratios, r_A and r_B. Reactivity ratios are determined experimentally and are extensively tabulated[19] for pairs of most common monomers. The values generally fall in the range 0 to 1, but can be much higher in special cases. A low value indicates low reactivity, a high value high reactivity. If two monomers each have a moderate value ($\sim$0.5) then the copolymer they form will have similar composition to that of the comonomer solution. If both monomers have a low value ($\sim$0) then copolymerisation will be slow and a rather regular alternating 1 : 1 copolymer will form, with alternate segments comprised of the different monomer residues. If one reactivity is low ($\sim$0) and the other high ($\sim$1), then the initially formed polymer will be essentially a homopolymer of the most reactive monomer, with extremely low incorporation of the less reactive monomer. In all cases the processes are subject to some statistical distribution and, in addition, in a batch copolymerisation, if the monomers are initially incorporated at different rates the more reactive monomer will be depleted from solution more quickly, and this in turn will start to slow its incorporation. The composition of the copolymer formed will therefore alter with time as polymerisation proceeds (composition drift).

A simple kinetic treatment[20] shows that the copolymer composition, A_{pol}/B_{pol}, is given by eqn. (1),

$$A_{pol}/B_{pol} = \frac{[A](r_A[A]+[B])}{[B](r_B[B]+[A])} \quad (1)$$

where [A] and [B] are the concentrations of the respective comonomers. Knowledge of the r_A and r_B values also allows computation of the mean sequence lengths, S_A and S_B, of A monomer and B monomer segments respectively in the copolymer from eqn. (2).

$$\bar{S}_A = \frac{r_A[A]}{[B]} + 1 \text{ and } \bar{S}_B = \frac{r_B[B]}{[A]} + 1 \quad (2)$$

Thus the reactivity ratios for 4-vinylphenyl(diphenyl)phosphine and styrene are 1.43 and 0.52 respectively, so that the phosphine monomer is considerably the more reactive. For a comonomer mixture of 1:1 therefore the corresponding copolymer composition A_{pol}/B_{pol} will be 1.6, and the values of S_A and S_B, 2.4 and 1.5 respectively. Hence the copolymer formed initially is enriched in phosphine monomer residues and these occur on average in blocks of 2–3 segments. In contrast the reactivity ratios for 4-vinylpyridine and styrene are very similar ($\sim$0.55), so that these comonomers polymerise more or less in a random fashion, with the copolymer backbone composition being controlled essentially by the initial composition of the comonomer mixture. These effects are extremely important, for example, in designing functional copolymers where it is desired to ensure that functional groups are remote from each, and essentially 'site isolated'.[21]

Crosslinked polymers

If styrene is polymerised in a mixture with divinylbenzene (DVB) then the latter becomes a constituent of two polymer chains, effectively linking (crosslinking) the chains together. When all the polymer chains are mutually connected an 'infinite network' is formed (Fig. 4). In our 'bowl of spaghetti' analogy,

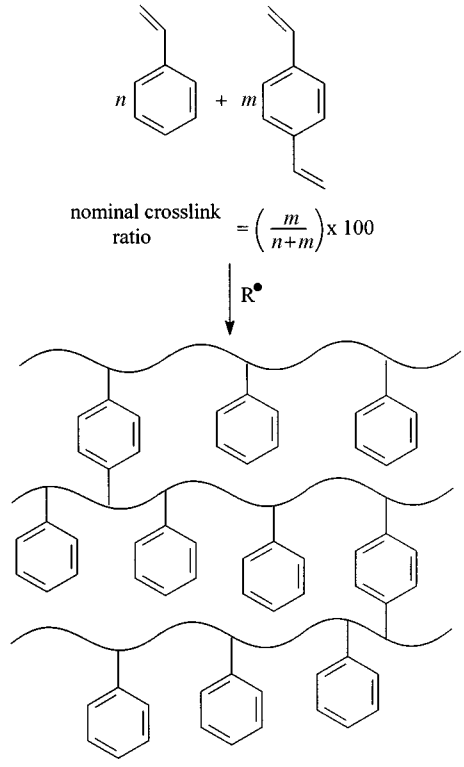

Fig. 4 Polymerisation of styrene and divinylbenzene to form an infinite polymer network.

all the spaghetti strands have been interconnected. Other useful crosslinking monomers are ethylene glycol dimethacrylate (EGDMA) (ethane-1,2-diyl dimethacrylate), trimethylolpropane trimethacrylate (TRIM) [1,1,1-tris(methacryloyloxymethyl)propane] and *N*,*N*-methylenebisacrylamide (MBA). Note that each TRIM residue effectively links three polymer chains together. DVB has three positional isomers (*o*-, *m*- and *p*-) and there are two routinely available commercial grades of DVB, each of which is a complex mixture. There are four major components, *m*- and *p*-DVB, typically in a ratio of $\sim$2 : 1, and *m*- and *p*-ethylstyrene in a similar ratio. In one commercial grade the DVB isomer content is $\sim$50%, and in the other

~80%. Care is therefore required in defining or interpreting the DVB content of crosslinked polymers since this might be quoted as a percentage of technical DVB used to make the polymer, or the figure can be adjusted to reflect only the content of *actual* DVB isomers present. Since for convenience the nominal crosslink ratio or degree of crosslinking of a polymer network is often quoted as the mol% of crosslinker used to prepare the network, defining the actual percentage of DVB isomers employed is more informative since this equates with the nominal crosslink ratio (Fig. 4). Bearing in mind that there is no unambiguous method, and certainly no simple and rapid method, for determining the real crosslink ratio in a polymer network, the nominal figure based on the actual DVB feed is a very useful parameter.

Other structural complications also arise which make defining and measuring the real crosslink ratio even more problematical. Although a defined level of crosslinker can be used to synthesise a polymer matrix there is no guarantee that both vinyl groups of *all* crosslinker molecules will react. Indeed, it is well-known that, particularly when higher levels of DVB are used, a significant number of vinyl groups remain unreacted; indeed these can be exploited as sites for further chemical modification. Much effort has been expended in trying to quantify accurately the levels of residual pendant double bonds, and single pulse excitation (SPE) ^{13}C solid state NMR analysis has recently allowed this.[22] Rather remarkably a crosslinked resin prepared from 100% *p*-divinylbenzene has ~45% of vinyl groups unreacted, *i.e.* the effective crosslink ratio is ~55%. For a resin prepared with the 80% grade of technical DVB, 45% of initial vinyl groups remain, *i.e.* the effective crosslink ratio is ~45%, while for a resin prepared with the 50% grade of technical DVB, ~32% of initial vinyl groups remain, *i.e.* the effective crosslink ratio is ~35%.

During formation of a crosslinked network it is also possible to produce additional (mobile) crosslinks by virtue of spurious entanglements which cannot disassemble (Fig. 5). Generally

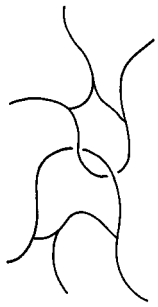

Fig. 5 Permanent entanglement crosslink.

'entanglement crosslinks' increase when the rate or speed of polymerisation is increased. This in turn can be induced by increasing the free radical flux in the polymerisation by increasing the temperature of the reaction and/or the quantity of free radical initiator used. Entanglement crosslinking is also high in a non-agitated polymerisation system, whereas vigorous agitation tends to minimise entanglements. Detecting and quantifying the level of entanglement crosslinking is very difficult.

Further uncertainty in the real level of crosslinking can arise following chemical modification of a polymer network. Some reactions, for example, chloromethylation and sulfonation of polystyrenes, are well known to be accompanied by intramolecular side-reactions which introduce additional crosslinks (Fig. 6) depending upon the conditions used. Again much investigative work has been carried out to try and quantify these reactions and SPE ^{13}C solid state NMR has proved very valuable in the case of the methylene bridging which accompanies chloromethylation.[23] Using the typical conditions to secure essentially quantitative chloromethylation of aromatic

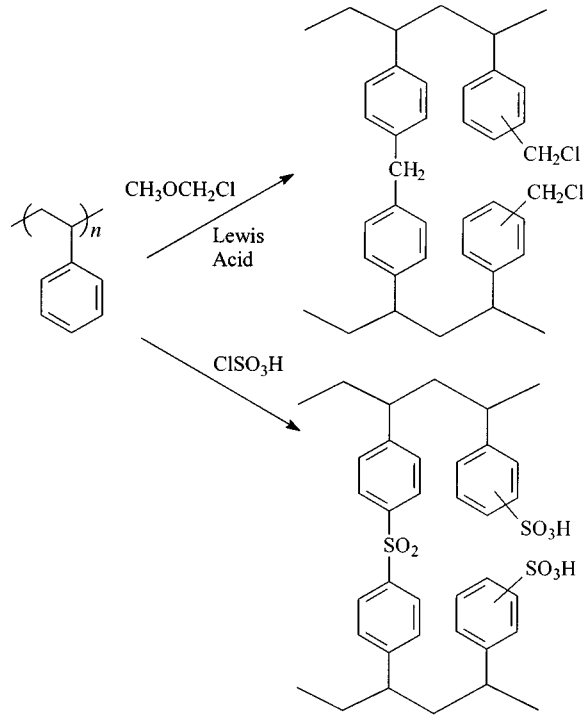

Fig. 6 Secondary crosslinking reactions.

groups in polystyrene resins simultaneously induces ~50% of the aromatic groups to become methylene bridged. While industrial manufacturers of anion exchange resins have learnt to live with, indeed exploit, the methylene bridging side reaction, the discovery of such high levels of these structural units came as a surprise.

Returning to the styrene–DVB copolymerisation, the r_A, r_B values quoted[19] for styrene and *m*-DVB are 0.58 and 0.58, and for styrene and *p*-DVB are 0.26 and 1.2, where the DVB figure refers to the first double bond in the molecule. After this first vinyl group is reacted the now pendant second double bond will assume a reactivity close to that of styrene. In the case of styrene–DVB mixtures these data predict (or imply) that initially the *p*-DVB isomer is incorporated into the copolymer significantly more quickly than styrene (and the *m*-DVB isomer) and that the initially so-formed copolymer is enriched in *p*-DVB residues relative to the composition of the solution phase. The latter becomes progressively more depleted in *p*-DVB and hence its rate of incorporation into the copolymer also falls. These reactivity data therefore predict a copolymer primary structure relatively rich in DVB residues at the start of a chain and somewhat depleted at high chain lengths. The situation however is complex and extensive unpublished data from industrial sources[24] suggest that overall there seems to be a strong tendency for styrene and DVB residues to be incorporated more or less evenly initially to produce a rather regular structure along the backbone tending towards a 1:1 alternating relationship; to some extent this occurs irrespective of the initial styrene–DVB composition of the comonomer solution.

As pointed out earlier, with a divinyl comonomer the polymer formed becomes crosslinked as the second pendant double bond is reacted. Initially this is a local phenomenon with the formation of small volumes of microgel (microgelation) (Fig. 7). Eventually however the mass of growing polymer molecules dissolved in solution becomes crosslinked into one infinite network; the system reaches its 'gel-point'. At the point of macrogelation the comonomer swollen crosslinked polymer mass becomes a monolith soft gel filling the containing vessel (Fig. 7). At this point macroscopic diffusion of molecular compounds in the gel starts to become impaired, with the problem growing more acute as crosslinking increases. Further

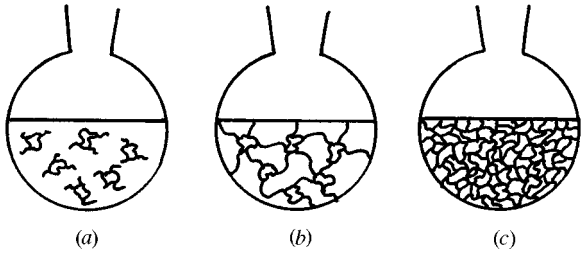

Fig. 7 Polymerisation of a monomer and crosslinker to undergo initially (*a*) microgelation, then (*b*) macrogelation, and finally (*c*) forming a solid glass.

incorporation of comonomers into the crosslinked copolymer becomes less controlled by solution reactivity parameters and more controlled by the composition of the comonomers in the swollen gel, *i.e*. the composition of the copolymer formed tends towards the composition of the comonomers in solution at the gel-point, with formation of a structurally fairly uniform copolymer. If polymerisation is allowed to continue, the liquid comonomers are gradually consumed, the polymer mass becomes increasingly desolvated and finally an amorphous crosslinked glassy monolith is formed in the shape of the containing vessel (Fig. 7). The monolith can be recovered, crushed, solvent extracted and dried to form crosslinked polymer particles or powder with irregular size and shape.

Suspension polymerisation

In practice the size, shape, and often the uniformity of crosslinked polymer particles is vital in most applications. For example, irregularly shaped particles are much more susceptible to mechanical attrition and breakdown to 'fines'. One of the major advantages in using crosslinked polymers as supports is the ease of handling, and robust spherical particles of an appropriate size and size distribution are essential in most applications. The technique of suspension polymerisation allows such particles to be produced fairly readily and highly reproducibly. The methodology is used widely on a laboratory scale but it is also a major large-scale industrial technology as well. Typically a styrene and DVB liquid mixture is dispersed as spherical liquid droplets (the dispersed or non-continuous phase) in a excess of an immiscible water phase (the continuous phase). The styrene–DVB mixture also contains a source of free radicals, the polymerisation initiator, and the aqueous phase generally contains a low level of some dissolved 'suspension stabiliser', a surface active species, often a water-soluble polymer, which helps to maintain the organic monomer droplets separate from each other. The suspension is maintained stable by continuous stirring and the reaction typically heated to ~80 °C for 12 h. During this period the spherical liquid monomer droplets are converted into hard glassy polymer particles, still retaining the spherical symmetry of the original liquid droplets (Fig. 8). The rather attractive 'beads' or 'pearls'

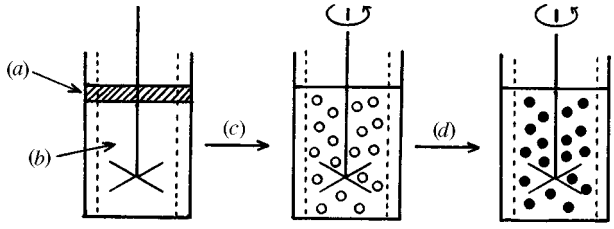

Fig. 8 Schematic representation of suspension polymerisation: (*a*) organic comonomer mixture (with porogen) containing dissolved initiator; (*b*) aqueous continuous phase containing dissolved polymeric suspension stabiliser; (*c*) shearing to form comonomer liquid droplets; (*d*) thermal polymerisation to form solid polymer resin beads.

are referred to as 'resins' (Fig. 9). In the laboratory, when the reaction is complete the resin particles can be collected by

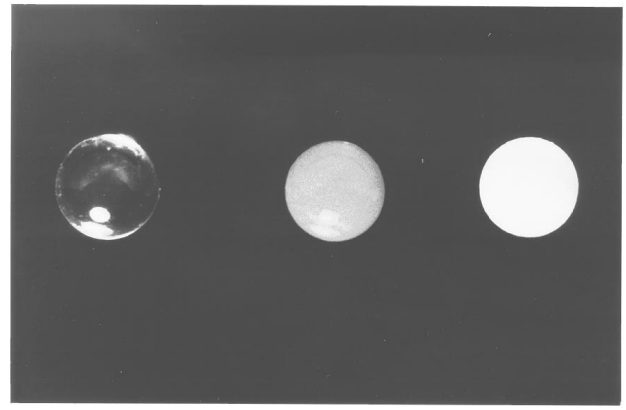

Fig. 9 Optical photograph of (left) gel-type bead, (right) macroporous bead, and (centre) mixed morphology.

filtration and traces of unreacted monomer, initiator and other organic fragments removed by solvent extraction in a Soxhlet, and finally the particles are vacuum dried. Fig. 10 shows the

type of suspension polymerisation reactor used in the author's laboratory. Further extensive details of suspension polymerisations are available in the literature.[25,26]

Resin morphology

Gel-type resins

When the comonomer mixture in a suspension polymerisation consists only of styrene and DVB (plus the polymerisation initiator) the product generally consists of hard glassy transparent resin beads (see left-hand sample Fig. 9). The percentage

of DVB can be varied in principle from 0–100% but typically for most resin applications the range 0.5–20% is more usual and for combinatorial synthesis resins, 0.5–2%. As described earlier such materials are composed of an amorphous crosslinked infinite network of interpenetrating polymer chains without any fine structure. The polymer chains are in molecular contact with each other, and the resins have very low surface area in the dry state when measured by, for example, N_2 sorption and application of the BET theory, typically less than 10 $m^2\ g^{-1}$ of dry resin. The diffusion of even small molecules through this polymeric glass is very slow indeed. These materials will, however, swell in a 'good' solvent, *e.g.* toluene (*i.e.* a solvent with a solubility parameter similar to that of the polymer), with the percentage swelling typically being inversely related to the DVB content or nominal crosslink ratio. Swelling creates space or 'solvent porosity' within the resin and allows ready access by small molecules to the polymer network. The swelling process itself occurs largely 'from the outside to the interior' and this behaviour has been treated quantitatively using the so-called 'shrinking core' model. In this the polymer network on the geometric exterior of resin beads becomes swollen first, forming an expanded pellicular layer and leaving a central unswollen glassy core. As time goes on the thickness of the swollen layer increases and the central core gradually shrinks and finally disappears (Fig. 11).

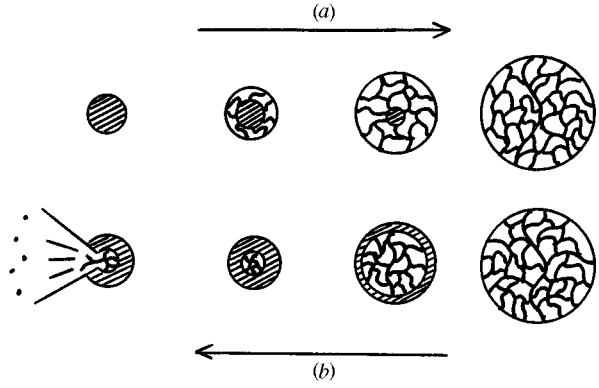

Fig. 11 Solvent response of gel-type resins: (*a*) shrinking glassy core to form an expanded gel in a good solvent; (*b*) contraction of swollen gel on addition to a bad solvent with bursting of resin due to osmotic shock.

Unlike linear polymers (see earlier) even a very 'good' solvent cannot make the individual polymer chains migrate apart because each chain is connected to at least one other by a crosslink—the polymer chains are part of a continuous infinite network. With a very 'good' solvent, the network will swell to its elastic limit, where further expansion is limited by the crosslinks. Note that no swelling occurs with 'bad' solvents for the network, and gel-type resins cannot be exploited in such solvents.

Providing the degree of crosslinking is low, sufficient swelling occurs in appropriate solvents to allow all the network to be penetrated and exploited in chemical reactions. The resultant resin particles, typically ~0.1-1 mm in diameter, have a molecular structure analogous to a ball of rubbery spaghetti, with all spaghetti strands interconnected and the network saturated with free flowing 'sauce'. Very low levels of crosslinker (< 1%) however yield mechanically weak swollen resin networks, easily damaged by shear. On the other hand, highly crosslinked gel-type resin networks, although mechanically stronger, may swell too little even in a very 'good' solvent to allow all the network to be penetrated and exploited.

If a gel-type resin is fully swollen in a 'good' solvent and then introduced into an excess of 'bad' solvent, the solvent types will exchange and the resin starts to shrink. This is the reverse of the swelling process, but again shrinking takes place 'from the outside to the interior'. This can cause very high levels of stress in the resin and if there are any microscopic flaws, *e.g.* cracks, the resin particles can fracture or burst (Fig. 11). The effect is known as osmotic shock, and gel-type resins are only useful if the matrix is able to undergo many cycles of swelling and deswelling without mechanical damage.

With regard to the stepwise synthesis of a complex structure on a gel-type resin, especially when the synthesis is performed under high load conditions (*i.e.* a large proportion of polymer segments are derivatised) it is important to realise that the swelling behaviour of the resin can change enormously as each modification to the resin is made. A very simple example is a chloromethylated polystyrene resin which is highly swollen in toluene and completely collapsed in water. On reaction with trimethylamine to form benzyltrimethylammonium chloride residues the resultant resin is collapsed in toluene yet swollen in water. Such dramatic changes can, for example, give rise to sudden attenuation of reaction and hence low conversion, or can result in the trapping of reagents or by-products. Careful assessment of such possibilities before reaction and an appropriate choice of a (compromise?) solvent or solvent mixtures can be invaluable.

Generally highly swollen gel-type resins are soft and compressible and this can restrict their use in packed columns, particularly on a large scale, when large back pressures can build-up as the resins particles compress into the restricted geometric shape available to them. Many of the above shortcomings can be overcome by the use of macroporous resins.

Macroporous resins

The term 'macroporous' resin is somewhat misleading because its use is not intended to convey anything about the size of pores in a resin. Instead the expression is used simply to indicate a class of resins which have a permanent well-developed porous structure even in the dry state.

If a suspension polymerisation of a styrene–DVB mixture is carried out with the comonomer mixture also containing an appropriate organic solvent (diluent or porogen) at some appropriate level then the internal structure (morphology) of the product resin beads can be very different to that of a gel-type resin. In particular, removal of the solvent or porogen at the end of the polymerisation can leave resin beads which are hard but opaque and with a rough surface which might be visible even with a good optical microscope (see right hand sample, Fig. 9). The polymer matrix is rather heterogeneous or non-uniform. Some areas consist of impenetrable crosslinked and entangled polymer chains, other areas are devoid of polymer. Most importantly, these materials can have much higher surface areas in the dry state (again measured by N_2 BET) than gel-type resins, typically ranging from ~50 to ~1000 $m^2\ g^{-1}$. Unlike gel-type resins these materials do not need to swell in a solvent to allow access to the interior because they possess a permanent porous structure, *i.e.* a permanent network of pores whose dimensions can be manipulated by the precise conditions used in polymerisation. Such materials are called 'macroporous' resins. Providing the surface of the pores is wetted with a compatible solvent, the pore structure can be accessed by essentially all solvents whether categorised as 'good' or 'bad', *e.g.* even water can penetrate macroporous styrene–DVB resins. When a 'good' solvent is contacted with a macroporous resin then as well as filling the pore volume, the solvent may also swell the polymer matrix (*i.e.* the microgel particles—see next section) to some extent. This swelling often occurs rather rapidly because the permanent pore structure gives rapid access to the solvent throughout the whole resin. The swelling (and deswelling) is not restricted in direction 'from the outside to the interior' as with gel-type resins, and no 'shrinking core' effect is manifest. Consequently macroporous resins show much better resistance to osmotic shock.

There is no universally accepted definition of a macroporous resin but in the case of styrene–DVB resins Millar *et al.*[27] suggested that 'The criterion of macroporosity … is that the uptake of cyclohexane in 16 h should not be less than 0.1 $m^2\ g^{-1}$ dry polymer' with cyclohexane falling into the category of a 'bad' solvent for this resin. Recently[28] Millar has suggested the use of *n*-heptane in place of cyclohexane since the latter has a low but finite tendency to sorb into styrene–DVB glassy matrices.

For many years there has been confusion in the literature over the terms 'macroreticular' resins and 'macroporous' resins. A recent patent settlement now allows a clearer definition: a macroreticular resin being one produced in a suspension copolymerisation in which the presence of an appropriate porogen or inert diluent at an appropriate level in the comonomer phase gives rise to phase separation or precipitation of the crosslinked polymer. The resultant isolated dried resin is permanently porous, *i.e.* macroporous, having been produced in this 'macroreticulation process'. The description therefore distinguishes these macroporous species from others where the porosity is created by a different mechanism, *e.g.* gas blowing. The term 'macroreticular' was coined by scientists from Rohm and Haas Co.,[29] although other groups were reporting similar resins around the same time.[27,28,30] In principle, in a suspension polymerisation it is possible to employ a porogen or inert diluent with an appropriate solubility parameter with a particular comonomer composition which does not induce phase separation, or to employ sufficiently low levels of porogen that phase separation does not occur.

Macroporous resins are therefore formed when a porogen is present in the comonomer mixture which causes phase separation of the polymer matrix. At full conversion each polymer bead is composed of a crosslinked polymer phase and a discrete porogen phase, the latter acting as a template for the permanent porous structure of the resin (Fig. 12). Removal of the porogen and drying yields rigid opaque permanently porous beads (see right hand sample, Fig. 9). The point at which phase separation occurs depends upon the nature of the porogen, its compatibility with the incipient polymer matrix and the level at which it is used. These are the key factors that control the fine detail of the resin porous morphology and are discussed in detail in the next section.

In practice the level of crosslinker employed also influences the onset of phase separation and for some commercially produced styrene–DVB resins, the DVB level is adjusted upwards such that even with toluene, a thermodynamically good solvent (for polystyrene) as a porogen, phase separation occurs eventually, since pure poly(DVB) is less compatible with toluene than is polystyrene itself. Thus a matrix prepared from ~25% DVB and ~75% styrene requires ~70% phase volume toluene for phase separation, whereas a mixture with ~80% DVB and ~20% styrene requires only ~30% phase volume of toluene for phase separation as a result of the reduced compatibility arising from the higher DVB level.[24]

It is also worth emphasising that gel-type resins can be made in the presence of a porogen providing the latter is present at a level which does not cause precipitation of the growing polymer. Generally this also requires a low level of crosslinking and the network is formed in a solvent expanded form relative to a normal gel-type species. Hence, for example, a resin prepared with ~5% DVB and ~95% styrene with ~65% phase volume of toluene shows very similar physical characteristics to a normal gel-type resin prepared with ~2% DVB and no toluene present.[31] To some extent therefore the presence of the solvating toluene compensates for the higher level of DVB.

Morphology generation and control

Within each comonomer droplet many polymer molecules begin to grow *via* free radical chain propagation, and indeed with a styrene–DVB mixture these start to crosslink. Initially microgelation occurs but eventually macrogelation of each droplet ensues. In the presence of a porogen sooner or later precipitation of the polymer occurs and this can be before or after macrogelation. Irrespective of this, eventually a well-developed system of microgel particles or microspheres can be detected within each resin bead. These are of approximate spherical symmetry since this represents the form of lowest surface energy. Thus macroporous resin beads (~50–500 μm diameter) are composed of a mass of microgel particles (typically ~1000 Å in diameter) and the molecular structure of an individual microgel particle is very similar to that of a whole gel-type resin bead. To a good approximation therefore a macroporous resin particle can be regarded as comprised of a mass of tiny gel-type particles between which is a complex pore structure or labyrinth of channels (Figs. 13 and 14). The microgel particles are referred to as the 'gel-phase' and the pore structure as the 'pore-phase'. In reality the manner in which the porous morphology develops is very complex, and indeed difficult to study. Further details are available in references 32 and 33, and the references cited therein.

From a practical point of view macroporous resins can be prepared with a wide range of porous structures. These can vary from species with rather low surface area (~50 $m^2\ g^{-1}$ determined by N_2 sorption and application of the BET theory) and a large proportion of macropores (IUPAC definition: micropores < 20 Å; mesopores 20–500 Å; macropores > 500 Å) to species with a very high surface area (~800 $m^2\ g^{-1}$) with a large proportion of micropores. Control of the fine detail of this morphology is exercised by choice of the nature and proportion of the porogen, and the level of crosslinker employed. In particular, controlling the point during polymerisation when phase separation of the polymer network occurs is crucial.

Thus, when a porogen with good compatibility with the polymer network is utilised the network remains fully solvated up to high conversion of monomers into polymer. When phase separation finally occurs the microgel particles are small and discrete, and are swollen with residual monomer and crosslinker. Likewise the separate porogen phase contains unreacted monomer and crosslinker. Further polymerisation in the porogen phase creates additional polymer which acts to fuse microgel particles together; however, relatively low levels of polymer are formed in this way since the conversion of monomer to polymer at the point of phase separation is already rather high. The microgel particles therefore tend to retain their

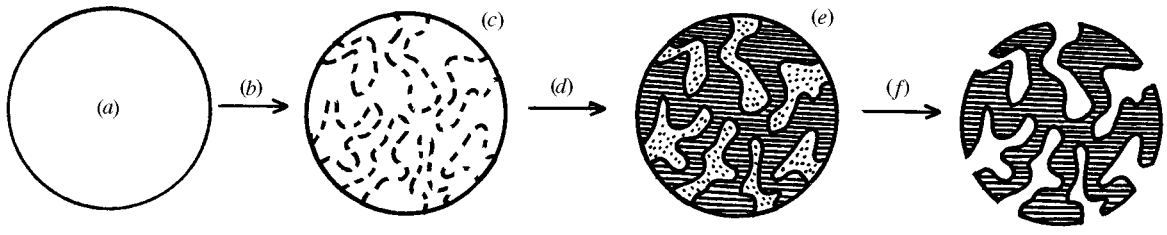

Fig. 12 Action of porogen in forming porous morphology in a macroporous resin: (*a*) monomer, crosslinker and porogen isotropic solution; (*b*) polymerisation; (*c*) polymer network forming; (*d*) porogen and network start to phase separate; (*e*) porogen phase acts as pore template; (*f*) porogen phase removed to yield pores (hatched area = crosslinked polymer; dots = porogen phase).

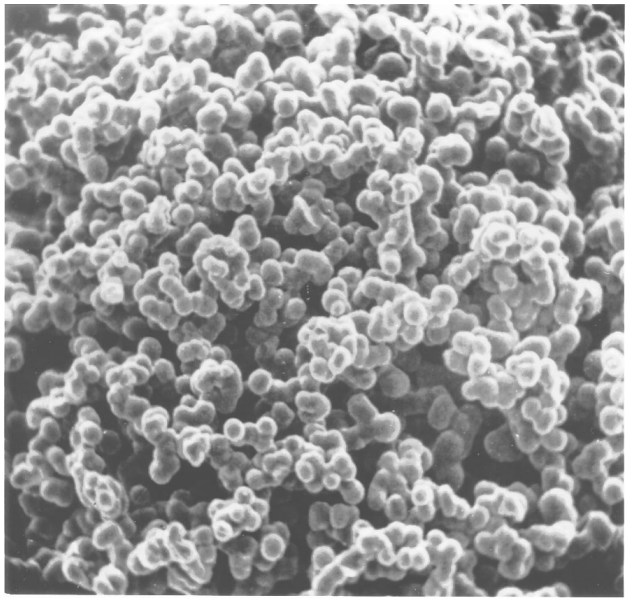

Fig. 14 Scanning electron micrograph of a macroporous resin fracture section (magnification = 5000×).

individual identity and the network of micro- and meso-pores, generated between the microgel particles when first formed, is essentially retained [Fig. 15(*a*)]. Such resins therefore have high

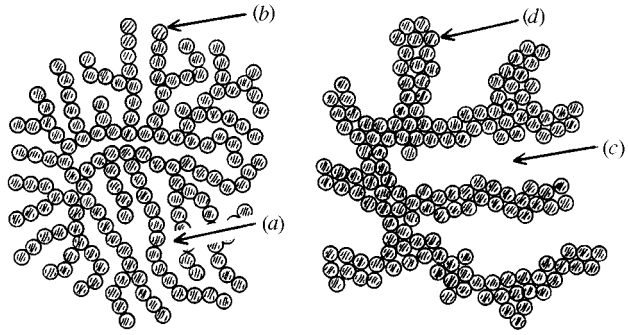

Fig. 15 Connectivity of microgel particles showing formation of small pores (*a*) from a network of interconnecting individual microgel particles (*b*) and large pores (*c*) from a network of fused or aggregated microgel particles (*d*).

surface area and a pore size distribution with a maximum in the micropore/mesopore region. Typically, for styrene–DVB mixtures, porogens such as toluene and xylene are useful in this respect but they must be used with relatively high levels of DVB (> 50%) in order to achieve satisfactory phase separation.

When a porogen is used which induces polymer network phase separation at much lower conversion, then again microgel particles are formed, now swollen with a high level of monomer and crosslinker, and likewise the separate porogen phase contains significant levels of monomer and crosslinker. A great deal more copolymer is therefore formed in the porogen phase after the phase separation process, and this has the effect not only of fusing the microgel particles together, but also causing significant in-filling of small pores between the microgel particles. In an extreme case the individual microgel particles can lose their identity and in scanning electron micrographs large fused *aggregates* of microgel particles can be seen interconnecting to form a labyrinth mainly of macropores, all the micropores having long since been in-filled [Fig. 15(*b*)]. Typically, for styrene–DVB mixtures porogens such as aliphatic hydrocarbons or higher alcohols (*e.g.* 2-ethylhexanol) are useful in this context. Phase separation of styrene-based networks with formation of stable microgel particles occurs readily even with DVB levels down to ~12% and resins are formed with a surface area typically ~50 $m^2 g^{-1}$ and a pore size distribution skewed towards the macropore region. Note that generally the total pore volume is controlled largely by the amount of porogen employed and is less influenced by the nature of the porogen.

Appearance of resin beads

Dry gel-type resin beads appear clear and transparent (or translucent) because the system is an amorphous glassy solid with no discontinuities to allow interaction with visible light and hence scattering and opacity. Various mechanisms can arise giving rise to light scattering. However, for strong scattering some particulate or porous structure is required where the discontinuous features of differing refractive indices have dimensions similar to the dimensions of the wavelength of visible light. The arrays of aggregated microgel particles described above generally are of this size and so macroporous resins prepared with thermodynamically bad porogens are particularly opaque. The microgel particles themselves are usually individually much smaller than the wavelength of light, and so cannot scatter strongly by this mechanism. They can scatter by a less efficient process and so those macroporous species with microgel particles which retain substantially their individual identify (*i.e.* those formed with good porogens and not aggregated) are often less opaque and can even be quite translucent. Depending on the refractive index of the solvent employed all macroporous resins tend to become much less opaque when imbibed with solvent.

Morphology diagram

Putting all the available experimental data together it is possible to generate an idealised morphology or pseudo-phase diagram[27,28,33] defining resin systems in terms of the morphology anticipated from a given type and level of porogen, coupled with the level of crosslinker (Fig. 16). This has been developed for styrene–DVB resins but extensive data now exists for methacrylate resins crosslinked with trimethylolpropane trimethacrylate, and a similar treatment seems possible for this system as well.[34,35] In any event the principles embodied here are more widely applicable. Compositions of polymerising mixtures falling within the macroporous domain yield porous resins whereas those compositions outside this domain yield essentially gel-type or related resins. Thus, for a DVB content of X%, porogen levels below A% do not cause phase separation of the polymer matrix and the network formed is a lightly solvated gel-type which collapses to form a glassy amorphous gel-type resin on drying. For porogen levels between A and B%, phase separation of the polymer network does occur and the dried resins are macroporous types. The total pore volume of the resins increase in going from A to B% and phase separation occurs more quickly as the porogen content increases from A%. The surface area of the so-formed resin therefore falls while the

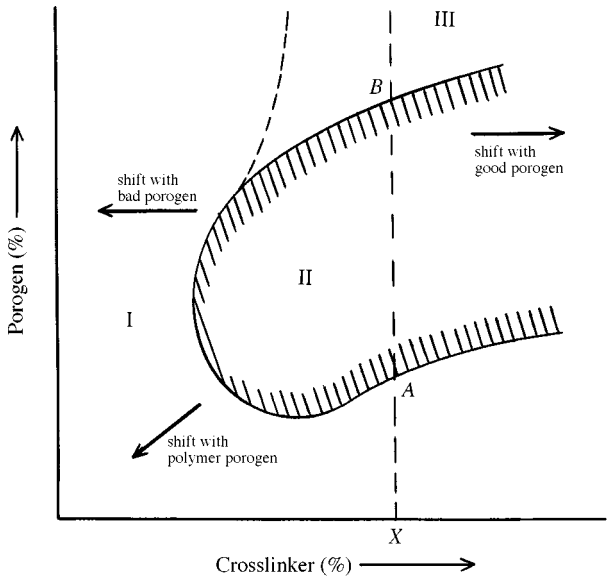

Fig. 16 Resin pseudo-phase diagram: I = gel-type resins; II = macroporous resins; III = microgel powder.

average pore diameter rises. On approaching *B*% porogen the total concentration of polymer formed can become too low for stable beads to be formed (*i.e.* the microgel particles are not well-fused) and above *B*% porogen the microgel particles appear as a fine powder.

Those porogens falling into the category of thermodynamically good solvents push the macroporous domain towards higher crosslink ratios, whereas thermodynamically poor porogens shift the macroporous domain to lower crosslink ratios. A rather interesting and much less studied class of porogens are oligomers or polymers.[28,33] Different polymer types tend to be very incompatible and so rather low levels of a polymer can be employed as a porogen to induce phase separation in polymerisation, with or without a solvent coporogen. The overall trend is to cause phase separation at much lower levels of porogen and at much lower levels of crosslinker. In addition, polymeric porogens tend to create large pores in keeping with the idea that earlier phase separation allows more aggregation of microgel particles and in-filling of small pores.

Bearing in mind that the quantity of initiator, polymerisation temperature and degree of agitation are additional variables that can influence morphology generation, albeit in a less dramatic manner, it is quite clear that these systems are very complex in physico-chemical terms. Not surprisingly therefore the boundary between the formation of a macroporous and an essentially gel-type resin is by no means as sharp as that indicated in Fig. 16. A particularly intriguing regime for styrene–DVB resins is that ~7–12% DVB. Within this range there are polymerisation compositions that can be employed which generate a well-defined macroporous morphology, but the latter is apparently lost on removal of the porogen phase, *i.e.* the pore structure collapses (reversibly) resulting in the formation of a clear glassy amorphous bead.[26,36–38] However, these species are not conventional gel-types since on addition of a suitable solvent the resin re-swells *and* reforms its macroporous morphology. The transparent glassy beads can indeed swell and become opaque, depending on the refractive index of the solvent used. Whether such resins fold and collapse on drying, and the extent to which the pore structure is lost, depends also on the solvent from which drying is undertaken. Though superficially such resins seem to embody the weaknesses of both gel-types and macroporous species, they do offer macroporous morphologies in the swollen state with rather low levels of crosslinker in the microgel particles, and there are applications where this might be a significant advantage.

Composite resin supports

With regard to performing stepwise synthesis of oligopeptides on a support, Merrifield[39] and others settled for very simple gel-type lightly crosslinked polystyrene–DVB beads as optimum. Later, Atherton and Sheppard[40] introduced a more polar *N*,*N*-dimethylacrylamide-based resin, together with an orthogonal protecting group strategy, but again the resin was a gel-type. Rigid macroporous resin beads more suitable for automated use in packed columns, and having greater versatility in terms of use of solvents, gave problems associated with omission of peptide residues, and truncation of peptide growth, probably arising from chemistry taking place in the heavily crosslinked microgel particles. In an attempt to overcome these difficulties two composite supports were developed and commercialised. One employs Kieselguhr as a rigid inorganic primary support, within which is deposited a soft highly swollen polyamide gel and upon which peptide synthesis is performed.[41] The other employs rigid particles of polystyrene in the form of a PolyHIPE®.[42] The latter is a low density (~0.1 g ml^{-1}) macrocellular (~5–10 μm cell diameter) material which allows incorporation of a high level of a soft highly swollen polyamide gel, again the locus for the assembly of peptides. The latter composite functions well in a packed column and offers loading capacities up to ~5 mmol g^{-1}.

More recently those involved in solid phase combinatorial synthesis[5] initiated their work using lightly crosslinked (0.5–2%) gel-type resins developed typically for use with peptide chemistry. These however have been quickly shown to have considerable limitations in terms of both the organic synthetic chemistry that can be carried out on them, and the maximum capacity available. A major limitation in terms of the chemistry is the range of solvents which are capable of swelling styrene–DVB gel-type resins, to the extent that reactions in aliphatic hydrocarbons, alcohols and water are not applicable. A major step forward in this context has been the polystyrene–poly(ethylene glycol) (PEG) composite resin beads developed by Bayer and Rapp[43,44] which form the basis of the TentaGel® range of supports available from Rapp Polymere (Tübingen, Germany) and known also as the 'Rapp resin'. These have a 1–2% crosslinked styrene–DVB resin as their basis, but grafted onto this are long PEG sidechains or 'tentacles' (Fig. 17), the

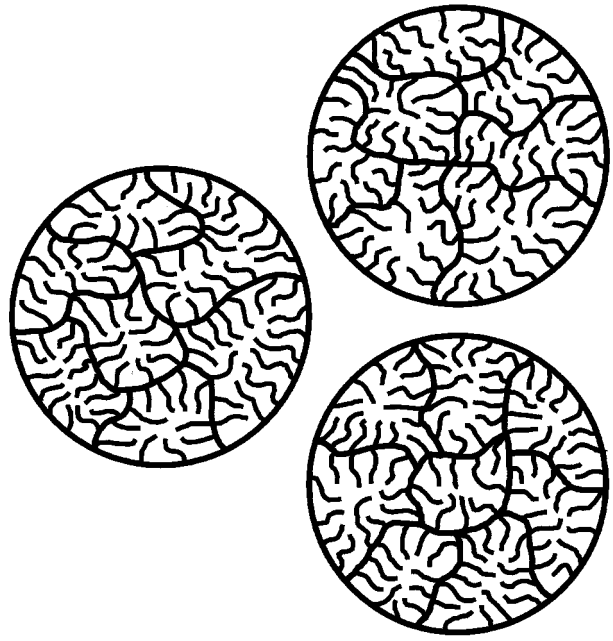

Fig. 17 Tentagel® or Rapp resin showing PEG chains grafted onto gel-type polystyrene–DVB resin; the PEG chains form separate microdomains.

free termini of which are the sites for solid phase synthesis.[45] The materials are unusual and very versatile because of the

broad solvent compatibility range they offer, and also for the high flexibility and accessibility of the functional endgroups. Typically these composites swell 2–4 times in water, alcohols and ether, and 5 times in CH_2Cl_2 and toluene. The PEG chains have a molecular weight of ~3000, and typically the composite comprises ~70 wt% PEG and ~30 wt% crosslinked poly(styrene–DVB).[43] Such high levels of PEG are needed to generate the advantageous broad solvation properties, and unfortunately brings with it some limitations. The composite can therefore be very sticky and difficult to dry; the capacity of the endgroups is necessarily low and so the synthetic capacity of the resin is likewise low. A specific chemical limitation is the benzyl ether linkage between the PEG chains and the polystyrene backbone which can be readily cleaved yielding PEG contamination of products. Some of these problems have been addressed by second generation analogues produced in the USA;[46] in particular it is claimed that the capacity has been improved, and the cleavage problem much reduced. The simple model that synthesis occurs on a long PEG spacer arm from polystyrene is too naive. Undoubtedly in polymer physical chemistry terms these composites represent microphase-separated systems (Fig. 17) in which solid phase synthesis occurs in the microdomains of PEG rather than polystyrene, and both the solvation effects in synthesis and the gel-phase ^{13}C NMR spectroscopy of bound species tend to confirm this.[47]

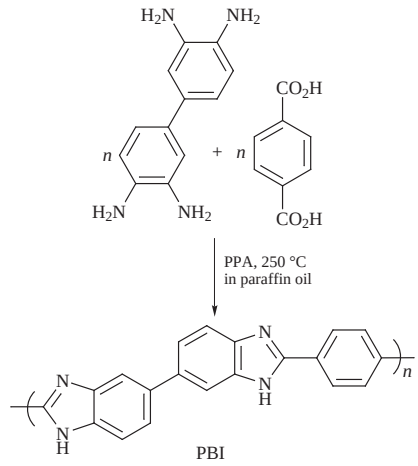
Thermo-oxidatively stable supports

Polymer supports based on vinyl-type monomers (styrene, methacrylates and acrylamides) have found wide applicability, but a serious limitation is their restricted thermo-oxidative stability. Typically the maximum temperature at which these supports can be operated continuously is currently ~120 °C, although under highly reductive conditions more extreme regimes may be tolerable. Many potentially useful hydrocarbon oxidation catalysts function optimally at higher temperatures under highly oxidative conditions, and there is therefore an opportunity for the development and exploitation of much more thermally stable polymer supports than those routinely available. In this context the use of polyacrylonitrile, polyamides, polysulfones, polyaniline and polysiloxanes has been reported, but these materials have not been produced in the spherical porous particulate form so useful for application in both batch and continuous catalytic processes.

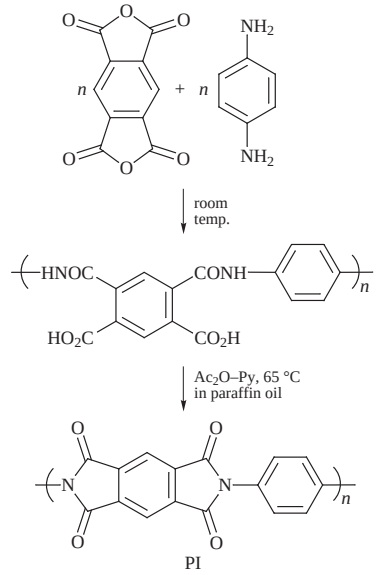
Recently the preparation of spherical particulate forms of polybenzimidazoles,[48] polyimides[49] and polysiloxanes[50] have been reported, and their successful exploitation as supports for alkene transition metal complex oxidation catalysts demonstrated.[51,52] In each case paraffin oil is used as the continuous medium within which droplets of the appropriate polymerisation phase are dispersed using the principles of suspension polymerisation.

For polybenzimidazole (PBI) it is necessary to condense an aromatic tetraamine with an aromatic dicarboxylic acid (Scheme 1) usually in the presence of polyphosphoric acid at ~250 °C.[48] The reaction is difficult to control and reproduce in the laboratory, but samples are now available from a commercial source.[53] Typically the surface area of the dry beads is rather low (~10 $m^2\ g^{-1}$) but remarkably they will sorb ~1 ml of toluene per gram of resin to allow catalyst preparation and exploitation.

The polyimide (PI) species are prepared by condensation of an aromatic dianhydride and an aromatic diamine in a two step process (Scheme 2). Initially polyamide formation occurs at ambient temperature in a solvent such as dimethylacetamide, then imidisation can be induced very conveniently by treatment with acetic anhydride and pyridine at ~65 °C. This dispersion polycondensation *is* conveniently carried out in the laboratory, and functional groups can be introduced by utilising appropriately derivatised diamines into the polymerisation. Using



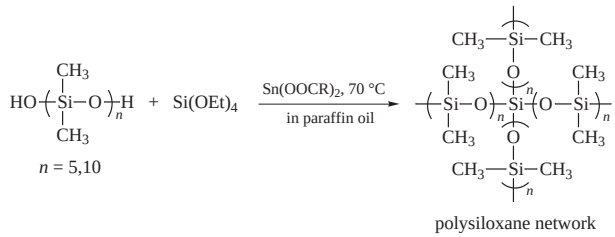
Scheme 1



Scheme 2

also a tetraamine as a crosslinker some of the methodology of macroporous resin preparation has been exploited to prepare species with surface area up to ~80 $m^2\ g^{-1}$.[49]

Most recently a similar dispersion methodology has been exploited in producing spherical particulate polysiloxanes.[50] Typically an oligomeric silanol is dispersed with a tetraalkoxysilane and a Sn^{II} catalyst (Scheme 3) in paraffin oil, and the



Scheme 3

polycondensation performed at ~70 °C. The highly elastomeric spherical particulate products are most unusual, have essentially no surface area in the dry state, but swell readily in non-polar solvents. While their potential for exploitation is still being explored, the value of PBI and PI particulates as metal complex catalyst supports has already been well-demonstrated. In particular, PBI has been shown to offer highly active, long-lived

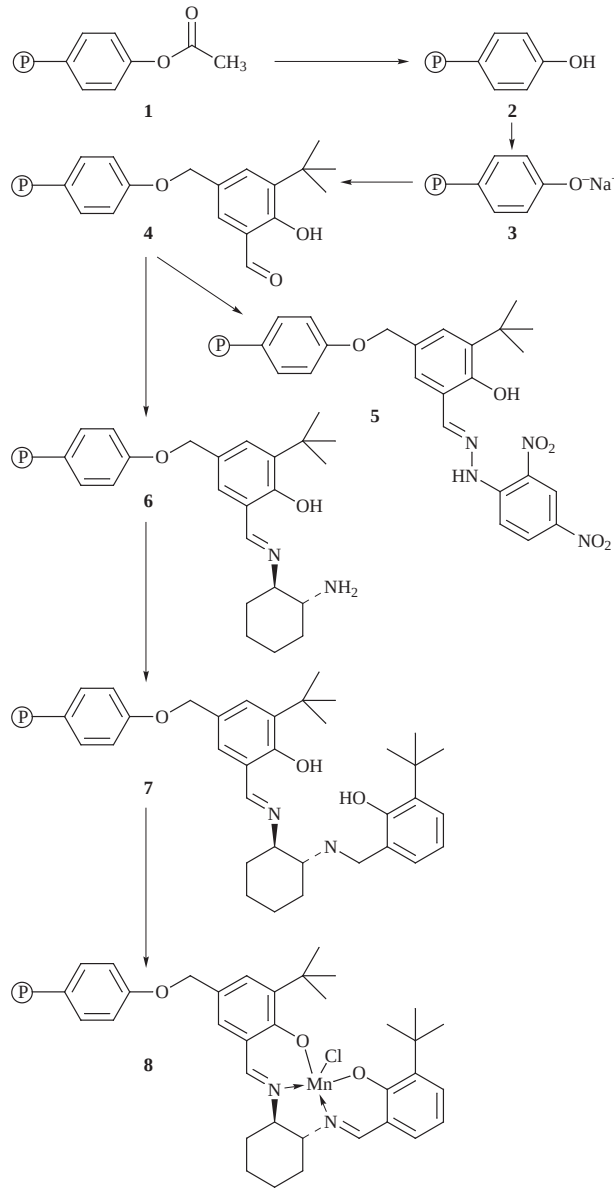
and thermo-oxidatively stable Mo-based alkene epoxidation catalysts, perhaps limited only by cost factors. Overall however all of these support species live up to expectation in terms of their thermo-oxidative stability, with thermogravimetric analytical data typically showing little evidence for decomposition in these resins in air below 400 °C.

Technological prospects for polymer supports in synthesis

The two main areas where technological application already exists, and further growth will undoubtedly occur, are polymer-supported catalysts and solid phase combinatorial synthesis and related methodologies. Polystyrene sulfonic acid resins are important industrial catalysts,[1,2] and polymer-supported transition metal complex catalysts are poised to make an important contribution in both the commodity chemicals and speciality fields. A partially Pd^{2+}-exchanged sulfonic acid resin is already used in the B.P. Chemicals Etherol Process[54] in which a mixed C_4 alkane/alkene/diene feedstream is converted in the presence of H_2 and methanol into a mixture of alkanes and branched ethers for direct use in the blending of unleaded petrol. A recently announced methanol carbonylation technology for the production of acetic acid utilises a poly(4-vinylpyridine) resin to immobilise the active Rh catalyst.[55] If ultimately commercialised this will add considerable impetus to the further use of polymer-supported metal complex catalysts. Until recently most polymer-heterogenised versions of asymmetric catalysts have performed rather poorly and, in particular, have given levels of asymmetric induction significantly lower than their homogeneous counterparts.[9,10] We have, however, developed an insoluble branched poly(tartrate ester)[56] with technological potential, since this acts as a very efficient heterogeneous asymmetric ligand in the Sharpless epoxidation of allylic alcohols using $Ti(OR)_4$–*tert*-butylhydroperoxide. Seebach *et al.*[6] have also reported the synthesis of a number of polymer-supported TADDOL ligands and use of these to generate, for example, asymmetric Ti-based Lewis acids. The latter have been shown to function as enantioselective reagents and catalysts in a number of reactions with, in many instances, activity and selectivity very comparable to their homogeneous analogues. Recently also we have developed a number of polymer-supported analogues of Jacobsen's asymmetric alkene epoxidation catalyst with emphasis on ensuring site isolation of the catalyst and pendant attachment of the chiral salen ligand.[57] Scheme 4 shows a typical route we have adopted and in this case the steps in the synthesis can be monitored qualitatively by the obvious colour changes that occur in the resin at each stage (**1**, white; **2**, cream; **3**, pale pink; **4**, sandy yellow; **5** orange; **6**, yellow; **7**, yellow; **8** dark red-brown).‡ The resin catalyst performance compares favourably with the soluble catalyst but is very substrate dependent.

In solid phase combinatorial chemistry primarily gel-type resins have been used as the support, based on experience from solid phase peptide synthesis. However, the more diverse chemistry that must be achieved on supports nowadays is encouraging the use of a broader range of resin morphological variants, and commercial sources of these are becoming available.[46,58]

Automation is also a key factor in combinatorial synthetic methodology, and so scope exists for ingenious development of supports with novel formats to facilitate automation. In this context there is the important concept of inverting the whole solid phase strategy, and carrying out all the combinatorial assembly in solution, by employing an array of supported reagents, catalysts and protecting groups (inverse solid phase combinatorial synthesis). This approach overcomes the major weakness of the normal solid phase method, *i.e.* the limitation in achieving precise molecular structural characterisation at each step of a synthesis. Though magic angle spinning ^{13}C and ^{1}H



Scheme 4

gel-phase NMR[16] and single bead FTIR, Raman and mass spectral techniques have impinged significantly on this problem, very often the analytical capability still falls far short of that which is achievable with soluble molecules. Interestingly therefore the areas of (inverse) solid phase combinatorial synthesis and polymer-supported catalysts and reagents seem destined to converge and there may be much to be gained by practitioners combing the early literature in this area.[59,60]

Whenever separation problems arise in synthesis, polymer-supported species may have something very positive to offer. These need not involve complex species, *e.g.* poly(4-vinylpyridine)-based resins are useful scavengers of HCl and can avoid the need for aqueous/organic liquid-liquid extractions. The resin is also readily regenerated with aqueous NaOH. At the other extreme, if there is a requirement to trap a particular metal ion from a mixture of ions, then synthesis of a selective chelating ion exchange resin may provide the way forward. A number of groups are also synthesising small libraries of compounds for various applications, and then using a resin-bound specific binding group to 'fish-out' any compound showing a particularly high binding constant.

Not always obvious to the bench/batch chemist are the processing and operational advantages that supported systems can offer. Indeed the option to operate a process under particularly favourably physico-chemical conditions, not acces-

sible when using soluble catalysts, may prove an important driver in the successful application of supported systems. Interestingly, detecting such advantages is not always readily possible until industrial process conditions are probed. So, for those of us committed to this area, a further period of patience and dedication may be required but there is no doubt that the future for polymer-supported synthesis has never been so optimistic.

Nanoporous silica from amphiphilic block copolymer (ABC) aggregates: control over correlation and architecture of cylindrical pores

Christine G. Göltner,* Beate Berton, Eckart Krämer and Markus Antonietti

Max-Planck-Institute of Colloids and Interfaces, Kantstr. 55, 14513 Teltow/Seehof, Germany.
E-mail: goeltner@mpikg-teltow.mpg.de

Received (in Bath, UK) 20th August 1998, Accepted 9th September 1998

Novel nonionic ABCs are shown to be versatile templates for the sol–gel synthesis of nanoporous silicas, the structure can be fine-tuned by varying the template concentration.

Amphiphilic block copolymers (ABCs), consisting of one hydrophilic and one hydrophobic block, are gaining increasing importance as structure-directing agents in the synthesis of nanoporous ceramic oxides.[1,2] When mixed with water, these polymers undergo aggregation into lyotropic liquid crystalline phases, which are stable over a wide range of composition and temperature. These self-organizing systems, although not mechanically robust in their own right, are well suited as nanotemplates to imprint structure and porosity onto an otherwise dense and amorphous material, such as sol–gel-derived silica.[3–6] ABC templates help to extend the boundaries for pore size, wall thickness and mechanical strength beyond those of previously known nanoporous ceramic oxides.[7,8]

Cylindrical pores represent the closest approximation of one-dimensional cavities, which are of growing importance for a number of topochemical or spectroscopic applications and the generation of anisotropic nanostructured materials. The latter has been elegantly demonstrated by preparing monodisperse carbon nanotubules within nanopores of alumina.[9] Ordered nanoporous arrays were also utilized as tubular membrane separation devices.[10] There is a demand to increase the density of cylindrical pores to a filling factor (*i.e.* volume fraction of the voids) of 0.7 in hexagonally ordered silica to make similar 'nanocapillary' reactors very efficient.

Existing templating routes towards hexagonal porous silica, however versatile they may be, produce defect sites, which are reflected in the physical properties or even reproduced in the secondary cast of the porous material. For example, ABC templates of the poly(butadiene-b-ethylene oxide) (PB–PEO) type were shown recently to be suitable templates for the generation of a rich variety of pore structures in silica.[11] Although these polymers show good solubility in water, their structural polymorphism in these mixtures is such that often wide biphasic ranges occur. This phenomenon increases the number of defect sites over the statistically determined measure.

Therefore, there is a demand for self-organizing templates with a more pronounced tendency to form well ordered phases, which possess a smaller number of defect sites. In this contribution, we present new low-cost, nonionic polymer templates which form superbly stable, homogeneous lyotropic liquid crystalline phases. Such nanocasting media facilitate the control over correlation and architecture by simply varying synthetic parameters during the templating procedure, as opposed to selecting from a library of ABCs.

The results demonstrate the great potential inherent in ABC nanocasting as the method of choice for pore design in ceramic oxides. Poly[(ethylene-co-butylene)-b-(ethylene oxide)] (KLE-3729 and KLE-3736, see Table 1) were obtained from Th. Goldschmidt AG, Essen, Germany, and freeze-dried prior to use.

TMOS was obtained from Aldrich and used as received. HCl (1 M solution from Aldrich) was diluted using distilled water. Sol–gel synthesis of silica in the presence of ABC templates has been described in detail elsewhere.[1] Typically, the ABC (30, 50 or 70 mass% with respect to water) was dissolved in 2 g TMOS before adding 1 g of hydrochloric acid (pH 2). After the hydrolysis had abated, the flask was evacuated for 5–10 min in order to remove methanol, formed during the hydrolysis of TMOS. The birefringent, viscous mixture was then left to polycondense in an open container at 60 °C. The resulting inorganic–organic hybrid materials were calcined at 500 °C (12 h under nitrogen, 16 h under oxygen).

The birefringence of the lyotropic phases was studied between crossed polarizers of an Orthoplan-Pol microscope (Leitz) equipped with a hotstage. Nitrogen sorption measurements were recorded on a Micromeritics Gemini surface analyzer. The sample morphologies were studied with a Zeiss DSM 940 scanning electron microscope operating at an acceleration voltage of 20 kV. Standard TEM investigations were carried out on ground samples. TEM pictures were recorded with a Zeiss EM 912 Omega TEM operating at an acceleration voltage of 120 kV. Optical textures of the ABCs in water revealed that both polymers presented here form lyotropic liquid crystalline phases between 15 and 85% (m/m). Both ABCs show lyotropic phases of normal topology only, as expected from the length ratios of the blocks. This was confirmed by the water-miscibility of the polymer–water phases at all compositions within the phase diagrams.

Sol–gel synthesis of silica in the lyotropic phases of KLEs resulted in homogeneous hybrid materials, which showed no indication of phase separation, as estabished by SEM analysis. The silica monoliths were calcined to completely remove the template.

At low polymer concentrations, casts of spatially non-correlated, cylindrical micelles with low degree of intermicellar order are observed [Fig. 1(a)]. At higher concentrations (50%), these cylinders are closely packed into hexagonal arrays [Fig. 1(b)]. Further increasing the template concentration causes the formation of a lamellar/vesicular structure [Fig. 1(c)], which collapses upon calcination. The deterioration of the lamellar/vesicular structure is expected, as calcination removes the 'scaffolding' ABC template, which keeps individual lamellae apart.

The nitrogen adsorption–desorption isotherms show pronounced hysteresis, making the determination of the pore size distribution by non-imaging methods unreliable. However, the transition from the cylindrical morphologies into a lamellar structure is manifested in the different shape of the nitrogen adsorption-desorption isotherm, with the lamellar sample

Table 1 Physical data of the amphiphilic block copolymers used as templates

ABC	M_n	M_w/M_n	N_A[a]	N_B[a]	Block ratio
KLE-3729	6.6	1.069	68	66	1 : 1
KLE-3736	7.3	1.103	68	82	1 : 1.2

[a] Number of repeat units.

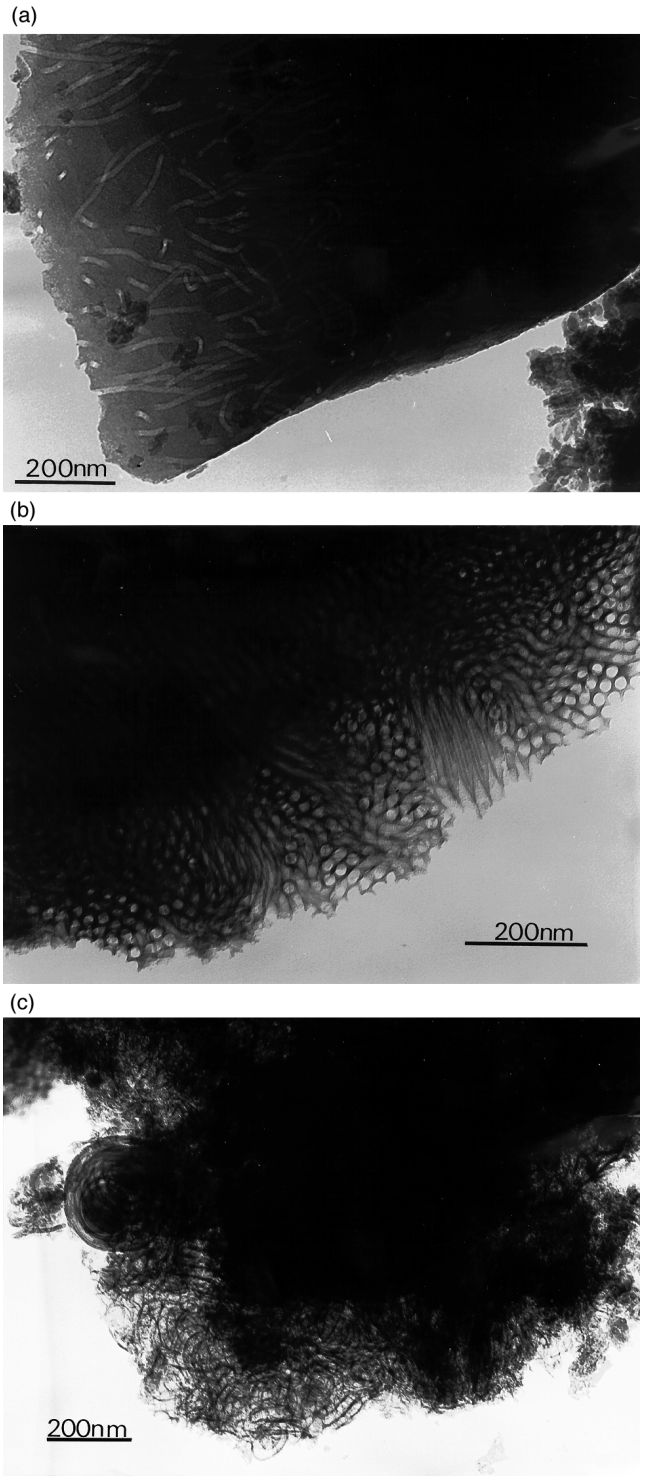

Fig. 1 TEM micrographs of KLE-3729-templated silicas: (a) 30% template (m/m with respect to water): isolated cylinders (diameter 14 nm) display no spatial order with respect to each other and are separated by up to 50 nm thick walls; (b) 50% template: hexagonally packed cylinders (diameter 16 nm, wall thickness 7 nm), (c) 70% template collapsed lamellae and multilamellar vesicles.

lacking distinctive pore condensation. For the cylindrical systems, the specific surface area increases with increasing

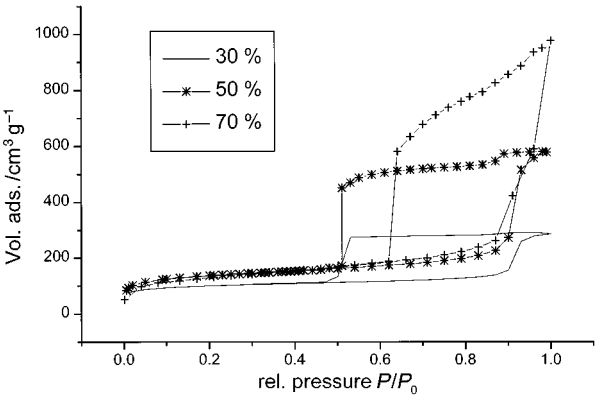

Fig. 2 Nitrogen adsorption–desorption isotherms of KLE-3729-templated silicas depending on the template content: 30% and 50%: typical isotherms showing pore condensation with pronounced hysteresis; 70%: the lamellar/vesicular structure, which is partially collapsed, expectedly does not show distinct pore condensation in the mesopore regime.

template content, demonstrating the contribution of each individual ABC molecule to the overall interface area (Fig. 2).

Amphiphilic block copolymers of the KLE type have proven to be exceptionally well suited for the synthesis of nanoporous silica with cylindrical pore shape. The pore density can be controlled *via* the template content between 30 and 50%. Traversing this concentration regime, isolated cylindrical pores with low spatial correlation evolve into correlated ones with high degree of packing order. Adjusting the pore density and thus the packing order of the cylindrical pores allows control over the pore curvature, as the packing into an hexagonal array automatically goes along with a considerable straightening. Future work will focus on the synthesis of curved and straight nanowires with high aspect ratios. For this purpose, KLE-templated silicas appear to be the most promising candidates presently available.

The authors would like to thank R. Pitschke for graphical work, Th. Goldschmidt AG for generously providing the KLE-type ABCs, the Max-Planck Society and the Deutsche Forschungsgesellschaft (Sfb 1623) for financial support.

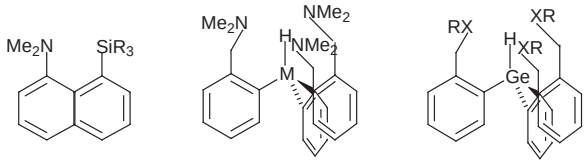
Received (in Cambridge, UK) 21st July 1998, Accepted 10th September 1998

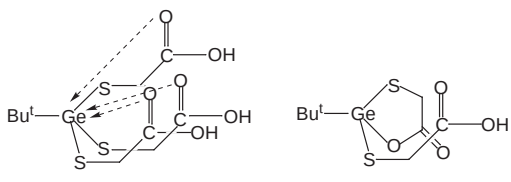
Reaction between Bu^tGeCl_3 and mercaptoacetic acid afforded a novel type of pentacoordinate germanium compound *via* $Bu^tGe(SCH_2CO_2H)_3$ which loses one mole of SCH_2CO_2H to afford the pentacoordinate species.

Hypercoordination of organosilicon compounds has been extensively investigated by Corriu and coworkers.[1] Thus, they described a variety of penta-, hexa- or hepta-coordinate silicon compounds where in most cases the donor is a nitrogen moiety (*e.g.* dimethylamino), and the geometrical relation between the silicon and the donor is more or less sterically congested as is the case with 1,8-disubstituted naphthalenes **1**[2] or *o*-substituted tribenzylsilanes **2**.[3,4] They have shown that hypercoordination was also observed for *o*-substituted tribenzylgermanes **3**. We recently reported that, in the related compounds **4** and **5**, the germanium atom is either hexa- or hepta-coordinate although the incipient bonding between germanium and oxygen or sulfur is not very strong.[5]



1 **2** M = Si, **3** M = Ge, **4** X = O, **5** X = S

These findings prompted us to examine a further possibility; *i.e.* to observe hypercoordination of germanium atom where the geometrical relation between germanium and the donor atoms is more flexible. Initially we expected that the reaction of *tert*-butyltrichlorgermane (Bu^tGeCl_3) with mercaptoactetic acid ($HSCH_2CO_2H$) (molar ratio 1 : 3) under basic conditions would afford 2,2′,2″-[*tert*-butylgermanetriyltris(thio)]trisacetic acid, $Bu^tGe(SCH_2CO_2H)_3$ which would form heptacoordinate germanium species **6**.



6 **7**

The product, (colorless crystals, mp 152–154 °C from ethyl acetate) corresponds, however, to the molecular formula $C_8H_{14}GeO_4S_2$ [mass spectrum (FBMS): *m*/*z* = 310.9630 $(M + H)^+$; calc. for $C_8H_{14}{}^{72}GeO_4S_2$ = 310.9633], indicating the loss of one mole of $HSCH_2CO_2H$. The product was confirmed by X-ray analysis† as 2-(2-*tert*-butyl-5-oxo-1,3,2-oxathiagermolan-2-ylthio)acetic acid **7**. It is likely that **6** was indeed formed since its yield was substantially decreased when lower amounts (*e.g.* 1 : 2) of mercaptoacetic acid were used. Subsequently an intramolecular nucleophilic substitution takes place on germanium, where one of the $-SCH_2CO_2H$ moieties of **6** acts as a nucleophile while the other is the leaving group to give **7**.

The ORTEP drawing of **7** is shown in Fig. 1, while the molecular packing in crystal is depicted in Fig. 2. The question

of whether the carbonyl oxygen or the hydroxyl oxygen is coordinated to Ge was resolved by the location of the hydrogen atom which was achieved by refining the analysis.‡ The result shown in Fig. 2 is very conclusive; there is a hydrogen atom between O4 of one molecule and O2 of the adjacent molecule (O2′) to indicate hydrogen bonding in **7** between the CO_2H of one molecule and the lactone carbonyl oxygen of an adjacent molecule. Thus it is the carbonyl oxygen which was coordinated to Ge.

Characteristic points observed for **7** are as follows: (1) The germanium atom is pentacoordinate with trigonal bipyramidal structure. (2) The Ge1–S1, Ge1–S2 and Ge1–C1 bonds are equatorial while the Ge1–O1 and Ge1–O3 bonds are apical with equal length (*ca*. 2.04 Å, a little longer than the standard Ge–O covalent bond length (*ca*. 1.7–1.8 Å). (3) Four atoms, Ge1, S1, S2 and C1 are coplanar with S1, S2 and C1 in a trigonal planar arrangement around Ge. (4) The O1–Ge1–O3 hypercoordinate bond is nearly perpendicular to the S1–S2–C1 plane though the angle (166.7°) slightly deviates from the ideal trigonal bipyramidal structure.

In the case of pentacoordination of group 14 elements, deviation from the ideal trigonal bipyramidal structure is often observed. Thus, Corriu and coworkers[6] reported that the C–Si···N angle of a pentacoordinate compound, 1-(8-dimethylamino)naphthylphenylsilane, is 166.9°.

Altogether it is clear that we obtained a pentacoordinate organogermanium compound where no steric enforcement is involved to enhance the hypercoordination. It should be noted that rotation about the S–CH_2 bond, which should be feasible, would move the CO_2H group far apart from germanium. This in turn appears to suggest that the Ge–O interaction is strong enough to lead to hypercoordination. It should be noted that the solid state, trigonal bipyramidal structure of **7** can be regarded as a model for the intermediate of the S_N2 type reaction on germanium.

The ^1H and ^{13}C NMR spectra of **7** exhibit only one signal for both CH_2 protons and carbonyl carbon nuclei. This can be interpreted only if we assume a rapid equilibrium between two identical pentacoordinate species in solution as indicated below.

A long-lived ^{2}E state for a Cr(III)N_6 amine chromophore at 298 K: [Cr(*fac*-Me_5-D_{3h}tricosaneN_6)]Cl_3†

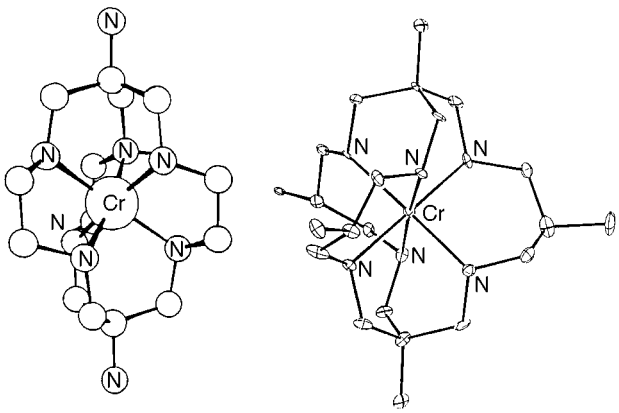
Received (in Cambridge, UK) 11th August 1998, Accepted 15th September 1998

The ^{2}E state lifetime of the C_3 ion [Cr(*fac*-Me_5-D_{3h}tricosaneN_6)]$^{3+}$ is 235 μs in H_2O and 1.5 ms in D_2O at 298 K, the longest lifetimes yet reported for a saturated Cr(III)N_6 chromophore at room temperature.

The Cr(III) sarN_6 cage complexes (example shown in **I**) feature surprisingly short ^{2}E lifetimes at 298 K (< 10 ns)[1,2] in comparison with that of the parent [Cr$(NH_3)_6$]$^{3+}$ ion (2.2 μs at 293 K).[3] In contrast, the larger [Cr(*fac*-Me_5-D_{3h}tricosaneN_6)]$^{3+}$ complex (**II**) has a considerably longer ^{2}E lifetime of 235 μs in aqueous solution at the same temperature. This latter complex was obtained recently from the reaction of [Cr$(py)_3Cl_3$] and the free Me_5-tricosaneN_6 ligand in the presence of zinc dust under anaerobic conditions and was characterised by microanalysis, X-ray crystallography, electrochemistry and electronic spectroscopy.[4–6]



I **II**

Cooling the [Cr(*fac*-Me_5-D_{3h}tricosaneN_6)]$^{3+}$ ion to 77 K merely doubles the ^{2}E lifetime (to 440 μs) and deuteration of the secondary amines extends it to 1.5 ms at 298 K. In contrast, the ^{2}E lifetime for the [Cr(sar)]$^{3+}$ ion increases by ⩾ 10^4-fold upon cooling to 77 K (Fig. 1), to 60 μs, a value consistent with those for a range of related Cr(III) hexaamine complexes.[1,2] Why these apparently similar cage complexes have markedly different photophysical properties needs to be explored.

The rate of excited state relaxation is determined by radiative and non-radiative processes. In the latter instance, electronic energy is dissipated into vibrational energy of the chromophore or the solvent molecules. Photochemical processes such as bond dissociation and redox processes can also contribute to the decay. The Cr(III) cage complexes **I** and **II** have no discernible photochemical ligand dissociation from either the ^{2}E or $^4T_2$ states, unlike the parent [Cr$(NH_3)_6$]$^{3+}$ ion and related di-, tri- and multi-dentate Cr(III)N_6 complexes.[1–4,6–9] It should also be noted that a proposed associative pathway[9–11] is unlikely since the steric constraints of the cage complexes hinder the coordination of a seventh donor group.[1,2] There is also no redox quenching in the presence of a reductant,[4] so it is unlikely that such a process contributes significantly to the ^{2}E decay rate. Back intersystem crossing ($^2E \rightarrow {}^4T_2$) can sometimes provide a deactivation route for Cr(III) complexes; however, the $^4T_2$ state is *ca.* 7000 cm^{-1} higher in energy than the ^{2}E state for both cage complexes. This energy gap is similar to that of other Cr(III) hexaamine complexes where back intersystem crossing has been considered negligible.[8,12–15]

The ^{2}E lifetimes of most saturated amine Cr(III)N_6 complexes lie in the range 60–440 μs in the temperature-independent regime[1,2,8,9,13,15–18] and quantum efficiencies for the luminescence are *ca.* 1%.[1,13,15–17,19] The relaxation rate is thus dominated by non-radiative deactivation, a multiphonon process and as such, strongly dependent on the energy of vibrations accessible in ground and excited states (accepting and promoting modes, respectively). High energy acceptors include N–H stretching modes in this instance and the ^{2}E lifetime dependence on the number of N–H modes in the first coordination sphere has been addressed for a range of Cr(III)N_6 complexes.[17,20] Although deuteration of the coordinated amines increases the lifetime for both cage complexes roughly tenfold at 77 K, the N–H acceptors alone do not account for their very different temperature dependences.

The promoting modes couple the excited state and the ground state and modify the electronic gap by their frequency.[13,21] The population of promoting modes can lead to a strong temperature dependence of the ^{2}E lifetime. In particular, the rapid decrease in the ^{2}E lifetimes from 150 to 200 K for the Cr(III) sar complexes[2] indicates the existence of such an efficient

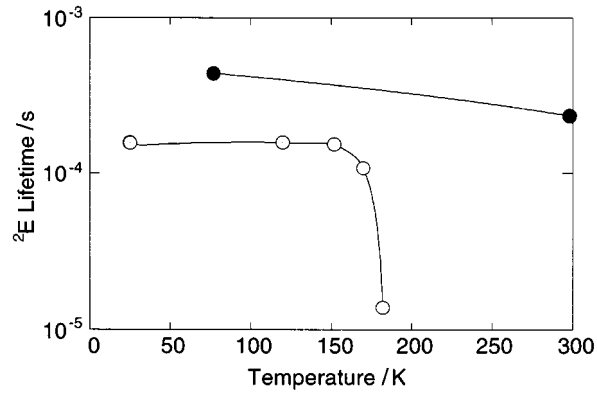


Fig. 1 Temperature dependences of the ^{2}E lifetimes for [Cr(*fac*-Me_5-D_{3h}tricosaneN_6)]Cl_3 (●) and [Cr(sar)]Cl_3 (⊙) in ethylene glycol–water (2 : 1 and 1 : 1, respectively).

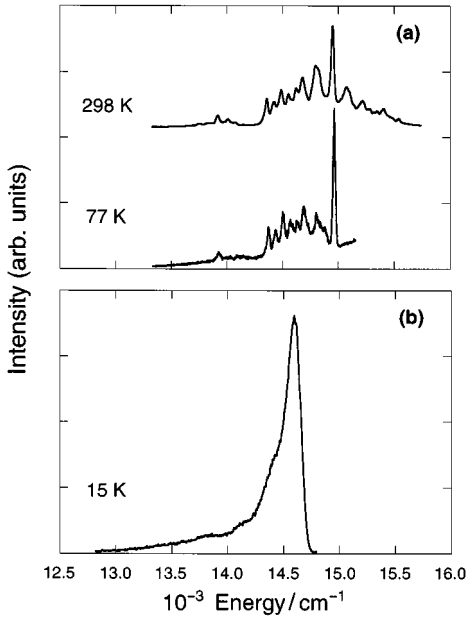

Fig. 2 Emission spectra of (a) [Cr(*fac*-Me_5-D_{3h}tricosaneN_6)]Cl_3 at 298 and 77 K (2 : 1 ethylene glycol–water) and (b) [Cr(sar)]$(CF_3SO_3)_3$ at 15 K (2 : 1 ethylene glycol–water).

promoting mode which becomes thermally activated. In contrast, the lifetime of the [Cr(*fac*-Me_5-D_{3h}tricosaneN_6)]$^{3+}$ ion is decreased only slightly at 298 K, inferring that there is no corresponding and effective promoting mode for this complex.

The 0–0 transition is accompanied by relatively intense vibrational sidelines in the [Cr(*fac*-Me_5-D_{3h}tricosaneN_6)]$^{3+}$ spectrum, characteristic of magnetic dipole-allowed transitions [Fig. 2(a)]. In contrast, the 0–0 transition dominates the emission spectrum of the [Cr(sar)]$^{3+}$ ions [Fig. 2(b)] and the vibrational fine-structure is poorly resolved due to more pronounced inhomogeneous broadening.[22,23] As the N–H interactions for the two types of complexes with the surrounding matrix are likely to be similar, the magnitude of this broadening can be ascribed to the [Cr(sar)]$^{3+}$ ion existing in different conformations. The sar complexes are able to undergo conformational changes such as twisting the ligand caps to change the symmetry from C_3 to D_3. This movement is coupled to other conformational changes involving the alignment of the C–C bond of the ethylenediamine chelate strap with the C_3 axis. The C–C bond may be oblique (*ob*) or parallel (*lel*) to the C_3 axis, giving rise to ob_3, ob_2lel, $oblel_2$ or lel_3 conformations. The same conformational lability is anticipated in the ^{2}E state, since its electronic configuration and thus equilibrium geometry are similar to that of the ground state. The number of effective accepting modes is governed by symmetry and interconversion results in variations in microsymmetry about the Cr(III)N_6 chromophore which induces more accepting modes. It follows that the conformational changes may result in a promoting mode which can be thermally activated.

Conformer interconversion is rather more difficult for the [Cr(*fac*-Me_5-D_{3h}tricosaneN_6)]$^{3+}$ ion. Topological constraints require that cap twisting converts the six-membered chelate rings forming the straps from the stable chair to the less stable skew-boat conformations. The equatorial methyl groups are thereby driven to more axial and less stable positions. Both factors restrict the conformational changes. It is anticipated that the excited state complex also has the same conformational preference and conformational interconversion therefore would not act as a promoting mode in this case. This rigidity may account for the remarkably long ^{2}E state lifetime at 298 K, in contrast to those of the Cr(III) sar complexes. The greater inhomogeneous broadening in the emission spectra of the smaller cage complexes independently supports this argument.

$[Mo_9S_8O_{12}(OH)_8(H_2O)_2]^{2-}$: a novel polyoxothiomolybdate with a Mo^{VI} octahedron encapsulated in a reduced Mo^{V} cyclic octanuclear core

Anne Dolbecq, Emmanuel Cadot and Francis Sécheresse*

Institut Lavoisier, UMR C 173 du CNRS, Université de Versailles Saint Quentin, 45 Avenue des Etats Unis, 78035 Versailles, France. E-mail: secheres@chimie.uvsq.fr

Received (in Basel, Switzerland) 13th July 1998, Accepted 8th September 1998

The novel polyoxothioanion $[Mo_9S_8O_{12}(OH)_8(H_2O)_2]^{2-}$ was prepared from the acido-basic condensation of four $\{Mo^{V}_2S_2O_2\}$ building units around a central $\{Mo^{VI}O_6\}$ octahedron, the anion was characterized by X-ray diffraction as a tetramethylammonium salt.

The field of polyoxometalates, although explored for several years, still attracts significant attention,[1] because of its large number of potential applications, especially in the domain of heterogeneous catalysis.[2] We are currently interested in the synthesis of sulfur-containing polyoxoanions, a first step towards the design of sulfur-containing (possibly microporous) three dimensional frameworks. We thus developed a strategy based on the acido-basic condensation of the oxothio building block $\{Mo_2S_2O_2\}$. The efficiency of this method was recently[3] evidenced by the preparation of $[Mo_{12}S_{12}O_{12}(OH)_{12}(H_2O)_6]$, a cyclic oxothio compound prepared from the one-step self-condensation of $[Mo_2S_2O_2]^{2+}$. The condensation reaction was performed by controlled addition of potassium hydroxide to an acidic aqueous solution of the thiocation.† $[Mo_{12}S_{12}O_{12}(OH)_{12}(H_2O)_6]$ appeared to be a convenient starting material for further syntheses because of its ability to regenerate straightforwardly the $\{Mo_2S_2O_2\}$ unit either in acidic solution, as the $[Mo_2S_2O_2(H_2O)_6]^{2+}$ dithiocation,[3] or in basic solution. Indeed, there is strong evidence that $[Mo_{12}S_{12}O_{12}(OH)_{12}(H_2O)_6]$ hydrolyses, at pH > 11, into the dark red, air sensitive, $[Mo_2S_2O_2(OH)_4(H_2O)_2]^{2-}$ dianion.‡ In this way, the condensation of the $\{Mo_2S_2O_2\}$ building blocks occurs when the pH of the solution is lowered. Accordingly, in the absence of any other reactants, the cyclic compound $[Mo_{12}S_{12}O_{12}(OH)_{12}(H_2O)_6]$ is reformed, around pH = 1.5. This procedure is convenient when the reactants are unstable in acidic media; this is the case, for example, for MoO_4^{2-}, which can self condense to give various types of oxoanions.[4]

We thus report here the results of the reaction of MoO_4^{2-} with $[Mo_2S_2O_2(OH)_4(H_2O)_2]^{2-}$, at pH about 5. The synthesis§ is quite straightforward, starting from MoO_4^{2-} and a solution of the dianion. Four building units condense around the central $[MoO_4(H_2O)_2]^{2-}$ anion, which serves as a template, to form the novel polyoxothio anion $[Mo_9S_8O_{12}(OH)_8(H_2O)_2]^{2-}$. This compound has been fully characterized by IR spectroscopy, microanalysis and single crystal X-ray diffraction.¶

The molecular structure of the compound is shown in Fig. 1. The anion has crystallographically imposed inversion symmetry. It can be described as an eight-membered ring encapsulating an $Mo^{VI}O_6$ octahedron. As already observed[3] the $\{Mo_2S_2O_2\}$ unit has a strong tendency to form cyclic arrangements. This eight-membered ring compares well with the one obtained by the condensation of the oxo analog $[Mo_2O_4]^{2+}$ in the presence of oxalic acid.[5] The Mo^{V} atoms have a slightly distorted octahedral coordination: they are connected to a terminal oxygen atom, two hydroxo and two sulfido bridging ligands; the coordination sphere of the Mo centers is completed by a bridging oxygen bound to the central Mo^{VI} atom. The octahedra within the $\{Mo_2S_2O_2\}$ building blocks share edges but they are connected by faces as shown in Fig. 1. Short (*ca.* 2.8 Å) Mo–Mo distances characteristic of a single Mo^{V}–Mo^{V} bond alternate with longer (*ca.* 3.2 Å) Mo–Mo distances within the ring. The inner Mo^{VI} atom is disordered over four positions around the inversion centre, with a 25% occupancy,[6] this disordered Mo atom exhibits a distorted octahedral coordination [Mo–O distances from 1.745(7) to 2.391(7) Å]. In this mixed-valence compound, the electrons are thus strictly localized, as demonstrated by the absence of the blue colour characteristic of electron delocalization in the so-called 'molybdenum blue' species.[4,7]

In conclusion, the synthesis and isolation of the tetramethylammonium salt of the novel polyoxo anion $[Mo_9S_8O_{12}(OH)_8(H_2O)_2]^{2-}$ is straightforward, with a good yield, by simply mixing starting materials which are readily available. The complexity of the anions can be increased by replacing the central MoO_6^{2-} octahedron with a more sophisticated anionic template. The synthesis of $[Mo_9S_8O_{12}(OH)_8(H_2O)_2]^{2-}$ there-

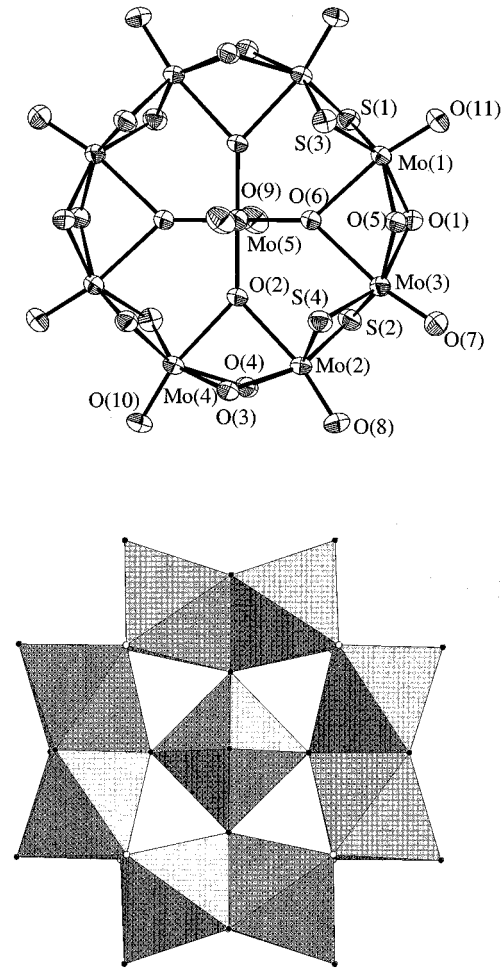

Fig. 1 Molecular structure of the polyoxothioanion $[Mo_9S_8O_{12}(OH)_8(H_2O)_2]^{2-}$. Top: ball-and stick model showing the eight-membered ring and the central $\{MoO_6\}$ octahedra. Thermal ellipsoids are drawn at the 50% probability level. For clarity, the disordered Mo(5) atom has been located at its mean position on the inversion centre, with a mean isotropic factor. Bottom: polyhedral representation showing the connectivity of the building blocks.

fore demonstrates that the acido-basic condensation of the $\{Mo_2S_2O_2\}$ fragments, either starting from an acidic solution or a basic solution, is a promising approach for the preparation of a variety of polyoxothio compounds.

Notes and references

† It should be noted that the crude product, obtained by the synthetic procedure described in ref. 3, before recrystallization has the composition $K_{2.6}(NMe_4)_{0.4}I_3[Mo_{12}S_{12}O_{12}(OH)_{12}(H_2O)_6]\cdot 30H_2O$ as shown by elemental microanalysis: Calc. (Found) C 0.62(1.23); I 12.31(12.13); K 3.29(3.27); Mo 37.23(36.71); N 0.18(0.40); S 12.42(12.72)%.

‡ $[Mo_2S_2O_2(OH)_4(H_2O)_2]^{2-}$ was precipitated as a potassium salt from a 1 M KOH solution, and isolated as a dark red powder. Elemental microanalysis confirmed the molecular formula $K_2[Mo_2S_2O_2(OH)_4(H_2O)_2]\cdot 13H_2O$: Calc. (Found) K 15.85(15.34); Mo 38.88(38.75); S 12.97(13.45)%.

§ As the intermediate $[Mo_2S_2O_2(OH)_4(H_2O)_2]^{2-}$ dianion is sensitive to air oxidation, the synthesis has to be carried out under a constant flow of N_2 gas. 20 ml of 1 M NaOH was first degassed for 10 min and 1 g (0.33 mmol) of $K_{2.6}(NMe_4)_{0.4}I_3[Mo_{12}S_{12}O_{12}(OH)_{12}(H_2O)_6]\cdot 30H_2O$ was added. The solution was stirred vigorously until the yellow powder dissolved to give a dark red solution of the $[Mo_2S_2O_2(OH)_4(H_2O)_2]^{2-}$ dianion. 0.16 g (0.66 mmol) of $Na_2MoO_4\cdot 2H_2O$ was then rapidly added and the pH was adjusted to 4.5 with a solution of 4 M HCl. The precipitation of the polyoxothio anion was achieved by the addition of 0.44 g (4.4 mmol) of $[NMe_4]Cl$ and gave 0.76 g of a thin yellow powder [yield = 86% (based on Mo)]. This powder was collected by filtration, washed with water and ethanol and dried with diethyl ether. IR spectra (KBr pellet, ν/cm^{-1}) gave absorptions at *ca.* 1480s, 1446w, 948s, 830m, 745m, 512s, 415w, 348w. Elemental microanalysis confirmed the molecular formula $[N(CH_3)_4]_2[Mo_9S_8O_{12}(OH)_8(H_2O)_2]\cdot 8H_2O$: Calc. (Found) C 5.46 (5.94); H 2.96 (2.79); Mo 49.09 (48.61); N 1.59 (1.61); S 14.55 (14.26)%. A few single crystals, suitable for X-ray diffraction, were grown in a solution containing only a small amount of tetramethylammonium cations.

¶ *X-Ray crystal structure analysis* for $[N(CH_3)_4]_2[Mo_9S_8O_{12}(OH)_8(H_2O)_2]\cdot 5H_2O$: Intensity data collection was carried out on a yellow crystal of 0.28 × 0.18 × 0.02 mm, with a Siemens SMART three-circle diffractometer equipped with a CCD bidimensional detector, using monochromatized λ(Mo-Kα) = 0.71073 Å. T = 293 K. The absorption correction was based on multiple and symmetry-equivalent reflections in the data set using the SADABS program[8] based on the method of Blessing.[9] *Crystal data* for $C_8H_{24}Mo_9N_2O_{27}S_8$: a = 15.0752(2), b = 12.9951(2), c = 12.6676(1) Å, β = 113.530(1)°, U = 2275.3(5) Å^3, Z = 2, M = 1700.22, D_c = 2.505 g cm^{-3}, monoclinic, space group $P2_1/c$ (no. 14), μ = 28.40 cm^{-1}, index ranges $-12 \leqslant h \leqslant 20$, $-17 \leqslant k \leqslant 17$, $-17 \leqslant l \leqslant 13$; total data 15389; unique data 5817 (R_{int} = 0.037), data with $I_o > 2\sigma(I_o)$ 4419. The structure was solved by direct methods and refined by full matrix least-squares, based on F^2, using the SHELX-TL software package.[10] All non-hydrogen atoms were refined anisotropically except for the disordered molybdenum atom and the water oxygen atoms. No. of variables, 242; final $R(F)$ = 0.040, $wR(F^2)$ = 0.098; GOF 1.08; minimum and maximum peak in difference electron density map −0.96 and 1.57 e Å^{-3}. CCDC 182/1006.

Phosphinocarboxylic acids as building blocks in organometallic crystal engineering. Self-organisation of one-dimensional photoluminescent cyclometallated platinum(II) polymeric structures

Man-Chung Tse, Kung-Kai Cheung, Michael C.-W. Chan and Chi-Ming Che*

Department of Chemistry, The University of Hong Kong, Pokfulam Road, Hong Kong. E-mail: cmche@hkucc.hku.hk

Received (in Cambridge, UK) 20th July 1998, Accepted 15th August 1998

Diphenylphosphinopropanoic acid (Ppa) is utilised for the self-organisation of a luminescent organoplatinum polymeric material, the crystal structure of which features intermolecular hydrogen bonding and π-stacking interactions.

Tertiary phosphines are versatile ligands in coordination and organometallic chemistry, but functional groups which are capable of complementary hydrogen bonding, such as carboxylic acids,[1] are rarely incorporated.[2] Molecular self-assembly employing hydrogen bonding has generated considerable interest in the domain of supramolecular chemistry and molecular recognition.[3] From an organometallic perspective,[4,5] the resultant materials have potential applications in non-linear optics, conductivity and ferromagnetism. The use of π–π stacking interactions in crystal engineering has also been prominent.[6] Their importance is further emphasised by their manifestation, in tandem with hydrogen bonding, in the structures of biological molecules such as DNA and proteins. Our earlier work on cyclometallated-(6-phenyl-2,2′-bipyridine) platinum(II) complexes revealed favourable π–π interactions in solid and solution states.[7] Herein, we describe the employment of diphenylphosphinopropanoic acid[8] (Ppa) as a building block in the supramolecular assembly of an organometallic polymer directed by π-stacking and hydrogen-bonding interactions.

Treatment of Pt(L)Cl [HL = 4-(*p*-tolyl)-6-phenyl-2,2′-bipyridine][7] with Ppa in CH_3CN–H_2O (1 : 1 v/v) at room temperature in the presence of excess NH_4PF_6 yielded [Pt(L)(Ppa)]PF_6 **1** as an orange crystalline solid in 75% yield.† Absorption bands at 1709 and 3448 cm^{-1} in the IR spectrum are assigned to ν(CO) and ν(OH) respectively of the Ppa ligand, while ^{195}Pt satellites (J_{PtP} 3943 Hz) are observed in the ^{31}P NMR spectrum.

The structure of **1** has been determined by X-ray crystallography (Fig. 1).‡ The tridentate cyclometallated ligand L and the phosphine are arranged in a distorted square-planar geometry about the platinum atom. The platinum–nitrogen bond length *trans* to the phenyl group [Pt(1)–N(1) 2.128(8) Å] is noticeably longer than that *trans* to the phosphine ligand [Pt(1)–N(2) 2.018(8) Å]; this is consistent with the greater *trans* influence exerted by the phenyl substituent. The crystal packing in **1** [Fig. 1(b)] reveals hydrogen bonding between two carboxylic acids in adjacent molecules, with clear directionality and short intermolecular contacts [2.65(1) Å] between successive oxygen atoms (O–H···O=C). π-Stacking between the aromatic planes of L (mean 3.68 Å) is more distant than that in [Pt(6-phenyl-2,2′-bipyridine)(PPh_3)]ClO_4 (mean 3.35 Å), although an identical 'head–tail' orientation of the overlapping ligands is evident in both structures.[7] Infinite one-dimensional polymeric zig-zag chains linked by alternating hydrogen-bonding and π–π

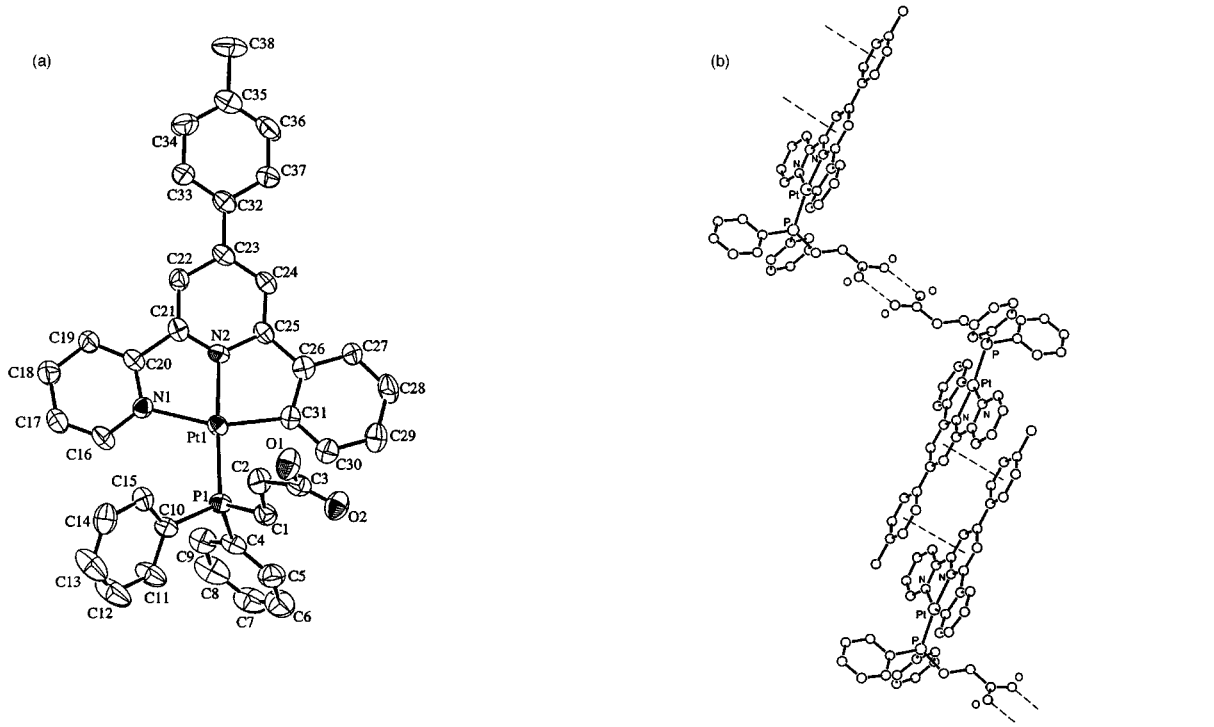

Fig. 1 (a) Perspective view of cation in **1** [40% thermal ellipsoids, all hydrogens are omitted including H(1) attached to O(1)]. Selected bond distances (Å) and angles (°): Pt(1)–P(1) 2.249(3), Pt(1)–N(1) 2.128(8), Pt(1)–N(2) 2.018(8), Pt(1)–C(31) 2.03(1), O(1)–C(3) 1.31(1), O(2)–C(3) 1.21(1), N(1)–Pt(1)–N(2) 76.7(3), N(1)–Pt(1)–C(31) 158.0(4), N(2)–Pt(1)–C(31) 82.1(4), P(1)–Pt(1)–N(2) 172.7(2), O(1)–C(3)–O(2) 124(1). (b) Crystal packing in **1**, showing infinite polymeric zig-zag chains linked by alternating hydrogen-bonding and π–π interactions (anion and all hydrogens are omitted for clarity).

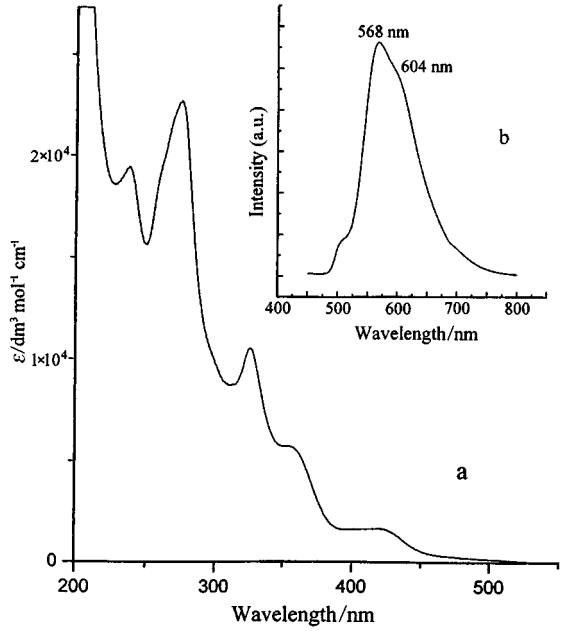

Fig. 2 UV–VIS absorption (a, in CH_3CN) and solid-state emission (b, E_{ex} 350 nm) spectra of **1** at room temperature.

interactions are therefore created. This combination of supramolecular synthons is rarely encountered in coordination compounds.[9]

The absorption spectrum of **1** [Fig. 2(a)] contains a broad low-energy absorption at 430 nm (ε_{max} 1560 dm^3 mol^{-1} cm^{-1}) which is tentatively assigned, like analogous cyclometallated platinum(II) derivatives,[10] to a metal-to-ligand charge transfer (MLCT) transition, namely (5d)Pt→π*(L). Complex **1** exhibits luminescence in solution and in the solid state. Emission at 542 nm in CH_3CN solution at room temperature is similarly ascribed to ^{3}MLCT. The solid-state emission is red-shifted to 568 nm with a shoulder at 604 nm [Fig. 2(b)] and is at a higher energy than the metal–metal-to-ligand charge transfer (MMLCT) emission (630 nm) of $[Pt_2(6\text{-phenyl-2,2′-bipyridine})_2(\mu\text{-dppm})]^{2+}$ which exhibits close intramolecular Pt–Pt contacts [3.270(1) Å].[7] The emission is therefore proposed to originate from ^{3}MLCT accompanied by partial excimeric character. Similar shifts in emission energy have recently been found for transmetallated gold(III) complexes.[11] A blue shift to 528 nm with well-resolved vibronic structure is observed in the frozen state, where the vibrational spacing of 1240 cm^{-1} is comparable to the skeletal stretching of the free ligand L.

Finally, it is pertinent to note that ligation of diphenylphosphinopropanoic acid does not necessitate the formation of complexes with complementary hydrogen bonding in the solid state. The molecular structure of the silver(I) dimer $[(PPh_3)(Ppa)Ag]_2(\mu\text{-Cl})_2$ **2**, synthesised from the reaction of $[AgCl(PPh_3)]_4$ with Ppa, is comprised of bulky peripheral phenyl groups and no hydrogen bonding is apparent.[12] This situation is expected for complexes with congested geometry where possible hydrogen-bonding motifs are segregated and such interactions are precluded. Our future work will exploit phosphinocarboxylic acids as versatile building blocks in transition metal-based crystal engineering.

An artificial receptor for the intermolecular and enantioselective formation of peptide sheets

Frank Eblinger and Hans-Jörg Schneider*†

FR Organische Chemie, Universität des Saarlandes, D 66041 Saarbrücken, Germany

Received (in Cambridge, UK) 22nd July 1998, Accepted 7th September 1998

Peptide strands coupled at the C terminus to bis[*p*-(aminomethyl)phenyl] ether allow in $CHCl_3$ solution association of lipophilic N-protected peptides with hydrogen bonds in the mode of antiparallel β-sheets; the enantioselectivity observed with a phenylalanine derivative is characterized by a binding constant ratio of around 15.

The formation of β-sheets in peptide strands is an important part of protein folding and is of general interest with respect to peptide recognition. Models showing typical β-sheet patterns have until now invariably been formed between *covalently* bound peptide strands with *intramolecular* hydrogen bonds. For the construction of β-sheet patterns Feigel *et al*. used amino acid fragments within macrocycles,[1] whereas in the models of Kemp *et al*.,[2] Kelly *et al*.,[3] Nowick *et al*.,[4] Gellman *et al*.[5] and Ogawa *et al*.,[6] special scaffolds between peptide chains secure a possible intramolecular binding in such hairpin-type structures. In line with our earlier analyses of energetic contributions of hydrogen bonds in such amide-type structures[7] we wanted to measure association constants between separate peptide strands; at the same time we were looking for biomimetic receptors which could distinguish enantiomers on the basis of hydrogen bonds between peptide strands.

Computer aided molecular modelling suggested two peptide strands coupled *via* the *para* positions to a diphenyl ether spacer (or diphenylamine, or diphenylmethane) as suitable host. Such an entity could bind a single strand peptide in the fashion of an antiparallel β-sheet, *e.g*. with two hydrogen bonds per amino acid at each side of the guest molecule (see Fig. 1). In order to avoid steric interference with the spacer the N-terminus of the guest peptide had to bear a formyl group, whereas the C-terminus can in principle take up any amine (or amino acid sequence). The semi-open structure makes this type of receptor a promising starting point for the building-up of longer β-sheets.

As in most other studies[8] relying on hydrogen bonds for complex formation, both host and guest compounds had to be soluble in hydrophobic media such as $CHCl_3$. We tried to achieve this first by introduction of long alkyl chains at the end of the peptide strands. The corresponding derivatives (*e.g*. with R = $C_{15}H_{31}$), however, turned out to be sparingly soluble in $CDCl_3$. Only introduction of the more bulky and spherical adamantyl groups avoid lattice stabilization in the solid state *via* parallel aligned n-alkane chains, and provided materials soluble in $CHCl_3$. Scheme 1 shows the synthesis of the host and guest derivatives; the cleft compound **1** was obtained in 10% overall yield, with $[\alpha]_D^{25}$ = −67.3 (*c* 0.2 M in EtOH) and only one set of ^1H and ^{13}C NMR signals at 400 and 100 MHz, respectively, indicating the absence of racemization. The enantiomers D-**2** and L-**2**, synthesized from commercially available amino acids, show $[\alpha]_D^{25}$ values of −14.7 and +15.2, respectively (*c* 0.2 M in EtOH).

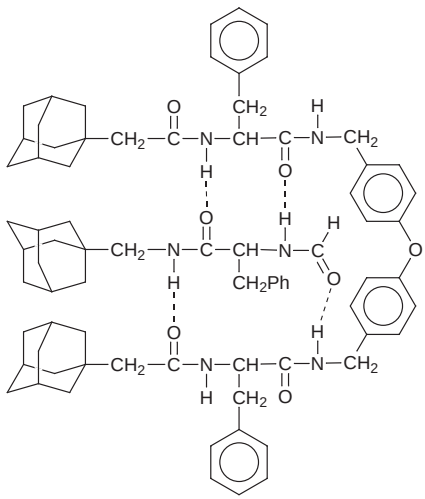

Fig. 1 Antiparallel β-sheet structure of host **1** and guest **2**.

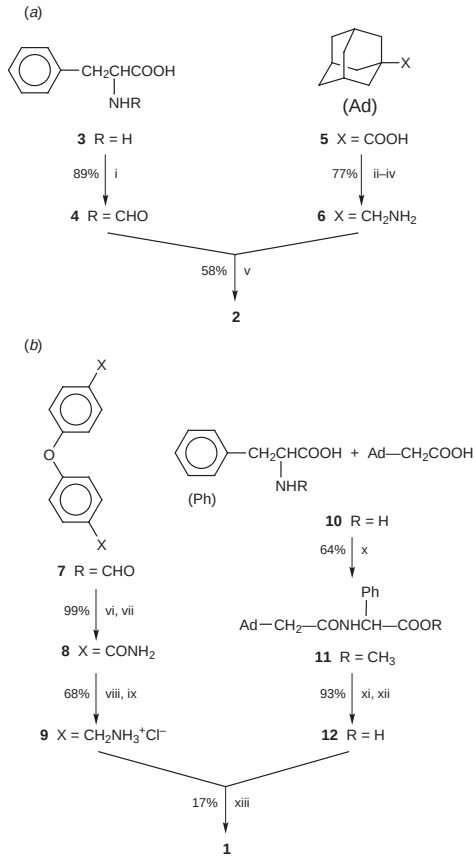

Scheme 1 *Reagents and conditions*: i, HCO_2H, Ac_2O, 278 K; ii, PCl_5; iii, NH_3; iv, BH_3·THF; v, DCC, room temp.; vi, $SOCl_2$; vii, aq, NH_3; viii, BH_3·THF; ix, MeOH, HCl; x, carbonyldiimidazole; xi, NaOH; xii, HCl; xiii, carbonyldiimidazole.

Fig. 2 shows titration curves with host **1** and the enantiomeric guest compounds D-**2** and L-**2**. Whereas the complex with the L-isomer is strong enough to be evaluated *via* non-linear least-squares fitting of the N–H NMR shift change, the complexation constant for the D-isomer can only be obtained from the

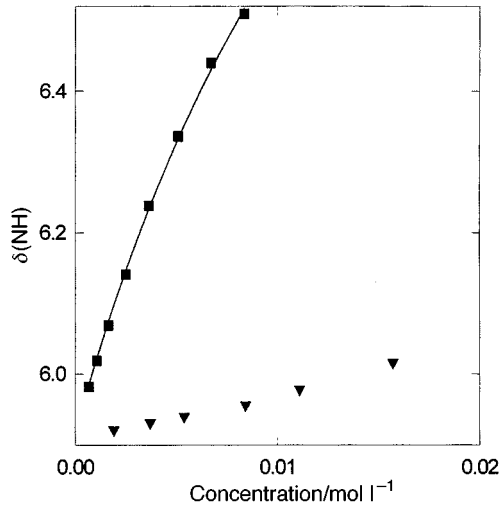

Fig. 2 Titration curves of host **1** with guests (■) L-**2** and (▼) D-**2** in $CDCl_3$ at 298 K. The line represents the best fit.

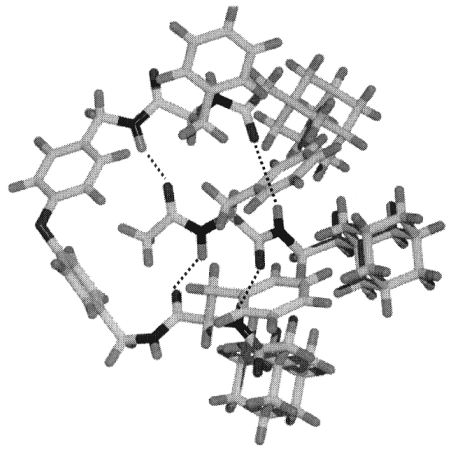

Fig. 3 Quanta/CHARMm minimized structures of the complex of host **1** and guest L-**2**. Hydrogen bonds are marked as dashed bonds.

Table 1 NMR titration results of host **1** and guests D-**2** and L-**2** in $CDCl_3$ at 298 K (The data represent the mean values of two observed N–H signals)

Complex	K/M^{-1}	ΔG/kJ mol^{-1}	CIS (ppm)
1·L-**2**	80 ± 6%	−10.8	1.79
1·D-**2 D**	5 ± 10%	−4.1	(1.79)

observed two N–H shifts of host compound **1** in comparison to the CIS value of 1.8 ppm which is expected for a 100% complex formation. The corresponding CIS for the L-enantiomer complex calculated from the least-squares fit is close to the N–H shielding effects observed in related amide-type associations,[7b] in line with the structure proposed in Fig. 1. The expected downfield shifts of the CH(α) protons could not be evaluated due to small shift changes and/or overlapping with other signals during the titration. Control experiments with related peptide derivatives, also bearing adamantyl groups for solubility reason, showed no self-association in $CHCl_3$; this supports the suggestion that an effective recognition requires hydrogen bonds from *two* sides of the guest as depictet in Fig. 1.

The total binding free energy ΔG (Table 1) for the 'best' isomer L-**2** (11 kJ mol^{-1}) is relatively small in comparison with values observed with related systems, which for $CHCl_3$ as solvent predict up to 5 kJ mol^{-1} per hydrogen bond.[7] The reason for the relatively weak binding might be due to some geometric mismatch, but must be seen primarily as a consequence of unfavourable secondary interactions between donor and acceptor groups. These have been elucidated by Jorgensen *et al*.,[9] and were found to be as large as *e.g*. 2.8 kJ mol^{-1} by systematic analysis of many amide-type associations in $CHCl_3$.[7b]

The degree of chiral discrimination ($\Delta\Delta G \approx 7$ kJ mol^{-1}) compares favourably with the few enantioselective peptide receptors hitherto available.[8a,10] Molecular mechanics calculations (gas phase, $\varepsilon = 3$) using CHARMm[11] shed light on the origin of the observed stereoselectivity: only with the L-isomer does one obtain after energy minimization a structure with the four hydrogen bonds, as depicted in Fig. 3. Minimizations with the D-isomer invariably lead to structures without hydrogen bonds: Unfavourable interactions of the guest (D-**2**) and host benzyl groups lead to deformation of the backbone, preventing the formation of hydrogen bonds. As is often the case, the observed stereoselectivity of association is a consequence of repulsion between groups which are not involved in the formation of non-covalent bonds, and which are remote from the actual binding sites.

High performance conducting polymer supported oxygen reduction catalysts

Zhigang Qi and Peter G. Pickup*

Department of Chemistry, Memorial University of Newfoundland, St. John's, Newfoundland, Canada A1B 3X7. E-mail: ppickup@morgan.ucs.mun.ca

Received (in Columbia, MO, USA) 6th July 1998, Accepted 23rd September 1998

Conducting poly(3,4-ethylenedioxythiophene)/poly(styrene-4-sulfonate) composites containing Pt catalyst nanoparticles produce currents as high as 0.4 A cm^{-2} at 0.5 V *vs.* NHE for oxygen reduction in gas diffusion electrodes.

Composites consisting of a conducting polymer and a polyanion could be the ideal catalyst supports for proton exchange membrane fuel cells (PEMFC) because they possess both high electronic and proton conductivities as well as being permeable to gases and water. We have reported the chemical deposition of Pt and platinum oxide nanoparticles on a polypyrrole/poly(styrene-4-sulfonate) (PSS) composite, and demonstrated oxygen reduction performances superior to those previously obtained with conducting polymer supported catalysts.[1,2] However, one of the biggest challenges we faced was that the electronic conductivity of the polypyrrole was seriously degraded by the deposition of the catalyst particles under both reducing (formaldehyde, hydrogen, or citrate) and oxidizing conditions (H_2O_2).[1] We found that polyaniline also suffered irreversible conductivity losses when catalysed under similar conditions, and so we turned our attention to poly(3,4-ethylenedioxythiophene) (PEDOT) which is reported to be more stable than polypyrrole under oxidizing conditions[3] and at elevated temperatures.[4] Preliminary results on the chemical synthesis of PEDOT/PSS particles and their use as a catalyst support are reported here. PSS was used as the counter anion during synthesis so that the resulting polymer composite would be a cation (proton) conductor.[5]

Since the EDOT monomer has a low solubility in water (2.1 g l^{-1} at 20 °C) and NaPSS is not soluble in suitable organic solvents, polymerization from solution can only be done under dilute conditions. This is known to lead to conducting polymers with inferior conductivities[6] and this was confirmed in our preliminary experiments. A better approach was to polymerize EDOT from a suspension in NaPSS(aq). In a typical procedure, 0.8 ml of EDOT (7.5 mmol; Bayer) was added to 15 ml of 0.1 M NaPSS (1.5 mmol; Aldrich), and the mixture was stirred vigorously for 30 min. EDOT dispersed much better in 0.1 M NaPSS than in pure water, and this is a key factor in the formation of highly conducting PEDOT/PSS. Upon addition of 15.3 g $Fe(NO_3)_3{\cdot}9H_2O$ (38 mmol) in 5 ml of water, EDOT polymerized immediately leading to a dark blue mixture. A deep blue powder was collected by filtration after 2 h and dried overnight at 50 °C under vaccum. The electronic conductivity of this composite measured with a four-point probe assembly described elsewhere[7] was 9.9 S cm^{-1}. For comparison, the conductivity of carbon black (Vulcan XC-72R) measured similarly was 3.0 S cm^{-1}. After 11 months storage in air, the conductivity of the PEDOT/PSS sample had dropped to 2.2 S cm^{-1}.

Pt deposition (20% by mass) on this PEDOT/PSS composite was then performed in the following way. 0.2010 g PEDOT/PSS and 0.1330 g $H_2PtCl_6{\cdot}xH_2O$ were stirred in 50 ml of aqueous formaldehyde (18%) for 1 h at room temperature. The mixture was then heated to reflux for 1 h, followed by filtration and vacuum drying. A 95% yield of Pt/PEDOT/PSS was obtained. Transmission electron microscopy and X-ray diffraction revealed that this deposition method produces Pt particles on the polymer composite with an average diameter of *ca.* 4 nm.

The electronic conductivity of the catalyzed material was 4.0 S cm^{-1} (Vulcan XC-72R catalyzed with 20% Pt (Electrosynthesis) gave a conductivity of 3.3 S cm^{-1} under the same conditions). Thus PEDOT/PSS is relatively stable to the reducing conditions (formaldehyde) required for Pt decomposition. This is in dramatic contrast to other conducting polymers such as polypyrrole and polyaniline whose conductivities decreased by 3–4 orders of magnitude when refluxed in formaldehyde for 15 min.

After 11 months storage in air, the conductivity of the Pt catalysed PEDOT/PSS sample had dropped to 5 mS cm^{-1}. Other Pt/PEDOT/PSS samples were found to be stable over extended periods when stored in methanol, suggesting that the instability in air is due to overoxidation[8] by O_2 which is activated by the Pt particles. This instability must clearly be overcome before conducting polymer supported catalysts can be considered as viable materials for commercial applications.

Since it has been reported that PEDOT has good stability under oxidizing conditions, we attempted to deposit platinum oxide on PEDOT/PSS *via* the oxidation of $Na_6Pt(SO_3)_4$ by 0.35% H_2O_2.[9] However, we found that the polymer composite was destroyed by the H_2O_2, and only a *ca.* 3% yield of a poorly conducting material was obtained.

A number of Pt catalysed (formaldehyde reduction of H_2PtCl_6) polymer composites were tested for oxygen reduction in a cell[2,7] designed to approximate the conditions in an ambient temperature PEMFC. For comparison, a commercial catalyst (Electrosynthesis; 20% Pt on Vulcan XC-72R carbon black) was tested in the same way. Polarization curves for the catalysed polymers and Pt on XC-72R are shown in Fig. 1. The best Pt/PEDOT/PSS electrode achieved a current density of 0.47 Å cm^{-2} at 0.45 V (*vs.* NHE), which is much better than any previously reported conducting polymer supported system.[2] This electrode gave comparable performance to one with the commercial carbon supported catalyst although a higher Pt

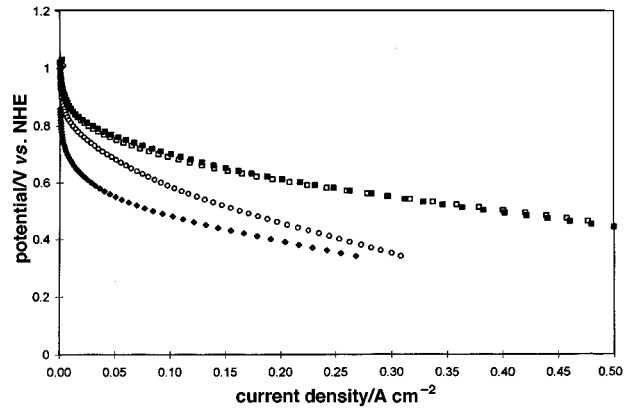

Fig. 1 Polarization curves for oxygen reduction in gas diffusion electrodes at ambient temperature (*ca.* 25 °C). The catalyst was mixed with a PTFE binder and sandwiched between carbon fibre paper exposed to O_2 (1 atm) and a Nafion membrane in contact with 1 M H_2SO_4(aq) containing a reference and counter electrode. (■) Commercial 20% Pt on carbon (0.31 mg Pt cm^{-2}), (□) 37% Pt on PEDOT/PSS prepared at high dilution (0.89 mg Pt cm^{-2}), (○) 19% Pt on PEDOT/PSS prepared at high dilution (0.29 mg Pt cm^{-2}), (◆) 20% Pt on emulsion polymerized PEDOT/PSS (0.40 mg Pt cm^{-2}). Data collected after 2 s at each potential.

loading was required (there was no significant dependence on Pt loading for the commercial catalyst for loadings from 0.2 to 1.0 mg cm^{-1}). Surprisingly, the catalysts prepared with PEDOT/PSS synthesized under dilute conditions performed significantly better than that prepared with the PEDOT/PSS synthesized from an EDOT suspension, despite their lower electronic conductivities (*ca.* 0.3 S cm^{-1}). The active Pt areas and proton conductivities of the two catalysts were similar, suggesting that the different performances are due to different oxygen permeabilities. The factors that determine the activities of Pt/PEDOT/PSS catalysts are under current investigation and will be discussed in detail elsewhere.

The results presented here show that high performance fuel cell catalysts can be prepared with conducting polymer supports. Further optimization can be expected to lead to catalysts that are competitive with the current state of the art in PEMFC catalysts. However, a significant problem that must be overcome is the long term stability of the conducting polymer support in the presence of oxygen and catalytic Pt particles.

This work was supported by the Natural Sciences and Engineering Research Council of Canada and Memorial University. We would also like to thank Mark Lefebvre for making the long term conductivity measurements.

Received (in Liverpool, UK) 30th June 1998, Accepted 4th September 1998

Natural abundance deuterium auto-correlation 2D NMR experiments of enantiomers orientated in a chiral polypeptide liquid crystalline solvent (PBLG) are used as a novel analytical tool for the study of chiral solutes.

Enantiomeric analysis *via* NMR spectroscopy is a real challenge for organic chemists.[1–3] In a recent study we have shown the feasibility of visualisation of chiral molecules orientated in the poly(γ-benzyl L-glutamate) (PBLG) liquid crystalline system using proton-decoupled natural abundance deuterium NMR spectroscopy.[4] The proton-decoupled deuterium (^{2}H-{^{1}H}) NMR spectrum of an oriented molecule containing a single deuterium nucleus ($I = 1$) consists of a quadrupolar doublet separated by $\Delta\nu_Q = 3/2(e^2qQ/h)S_{C-D}$, where (e^2qQ/h) is the quadrupole coupling constant and S_{C-D} is the order parameter along the C–D bond.[2,4,5] In a chiral medium the enantiomeric discrimination is observed *via* the measurement of the quadrupolar splitting differences ($\Delta\nu_Q^R - \Delta\nu_Q^S$) and we have shown that the sensitivity of natural abundance deuterium NMR is sufficient to measure the 'Differential Ordering Effects' (DOE) without isotopic enrichment.[4]

In natural abundance deuterium NMR spectroscopy the spectral analysis in an anisotropic medium is simplified due to the absence of residual dipolar couplings between two rare atoms. However, since all deuterons of the chiral solute are simultaneously probed, the spectrum may appear extremely complex for large molecules, due to the excessive overlapping of peaks. In order to illustrate this, the natural abundance ^{2}H-{^{1}H} NMR spectrum of (±)-but-3-en-2-ol dissolved in the PBLG–$CHCl_3$ phase at 301 K is shown in Fig. 1(*a*).‡ The spectrum was recorded at 38.4 MHz using a Bruker AM 250 spectrometer equipped with a 5 mm diameter inverse broadband probe in the unlocked mode.§

In the racemic mixture of but-3-en-2-ol, twelve different chiral isotopomers exist. Consequently, a maximum of 24 peaks (12 doublets), disregarding the solvent doublet, are expected in the natural abundance ^{2}H spectrum, assuming that all deuteron sites are discriminated in a chiral medium. In the experimental 1D spectrum 14 lines of various intensities are clearly observed [Fig. 1(*a*)]. A first analysis of the spectrum based on the chemical shifts allowed us to attribute some of the signals, such as the two quadrupolar doublets for the methyl group (δ 1.19) [Fig. 1(*a*),(*b*)] and the doublet of solvent, which is used as internal reference (δ 7.30) [Fig. 1(*a*),(*g*)]. But we were enable to assign easily the other signals visible in the spectrum. When the assignment problem becomes acute, the use of 2D auto-correlation deuterium NMR experiments is needed in order to attribute the two components of each quadrupolar doublet. A method for the assignment of quadrupolar doublets in perdeuterated liquid crystal molecules was developed many years ago by Emsley and Turner using the pulse sequence $\pi/2 - t_1/2 - \pi/2 - t_1/2 -$ acq.(t_2).[6] However, the analysis of the 2D spectrum is only possible when the deuterons are dipolar coupled, which is not the case in natural abundance ^{2}H-{^{1}H} NMR. In order to resolve specifically the analysis of overcrowded natural abundance deuterium spectra, we propose applying a new 2D pulse sequence developed using the product-operator formalism for spin $I = 1$ nuclei. The basic idea of this sequence is to maximise the intensity of cross peaks which auto-correlate the components of each quadrupolar doublet in the 2D contour plot. This 2D experiment is then complemented by a composite pulse decoupling using the WALTZ-16 sequence to remove the proton–deuterium scalar and dipolar couplings.

The sequence proposed is derived from a COSY experiment in which a π read pulse must be used to transfer coherences in the proper way. In this experiment the diagonal peaks cancel out and only the '*N*-type' cross peaks[7] are observed in the 2D spectrum with a single scan. Disregarding all relaxation terms and phase factors, the expression of the signal during the acquisition period (t_2) is given by eqn. (1).

$$S(t_1,t_2) = e^{[-i(\omega + \pi\Delta\nu_Q)t_1]}.e^{[i(\omega - \pi\Delta\nu_Q)t_2]} + e^{[-i(\omega - \pi\Delta\nu_Q)t_1]}.e^{[i(\omega + \pi\Delta\nu_Q)t_2]} \quad (1)$$

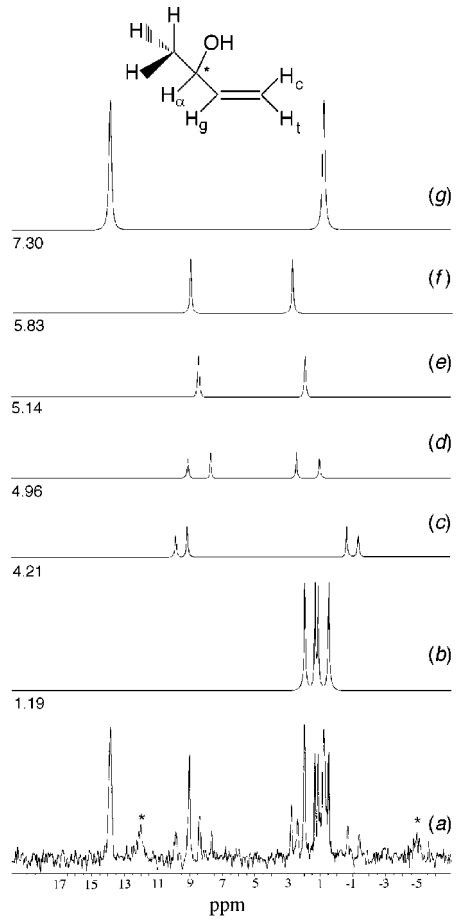

Fig. 1 (*a*) Natural abundance ^{2}H-{^{1}H} NMR spectrum of (±)-but-3-en-2-ol. (*b*)–(*g*) Fitted subspectra of all deuterated isotopomers in the mixture: (*b*) CDH_2, (*c*) D_α, (*d*) D_t, (*e*) D_c, (*f*) D_g and (*g*) $CDCl_3$. The signals of the hydroxy group (*) could not be clearly separated from noise and were not fitted.

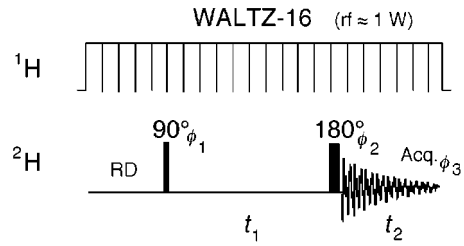

Fig. 2 Schematic diagram of the 2D Q-COSY pulse sequence.

Table 1 Phase cycling[a] of the Q-COSY sequence

ϕ_1	ϕ_2	ϕ_3
x	x	x
x	y	$-x$
x	$-x$	x
x	$-y$	$-x$

[a] The total phase cycling (16 steps) is obtained by applying the CYCLOPS procedure.

The pulse scheme and the phase cycling of the sequence denoted 'Quadrupole-COSY' (Q-COSY) are shown in Fig. 2 and Table 1, respectively. The phase cycling is identical to that used in a classical COSY experiment. As the pulse sequence basically produces a 'pseudo-quadrature' in the F_1 dimension, the 2D spectrum should be displayed in the magnitude mode to avoid the so-called 'phase-twist' lineshape.[7] The analysis of the Q-COSY sequence using the product operator-formalism shows that during the t_2 period only single quantum coherences are different from zero. Thus, this sequence is more sensitive, by a factor of 2, than the sequence of Emsley and Turner.[6] In other words it means that the Q-COSY sequence drives to maximum sensitivity, which is a major advantage for the observation of molecules *via* natural abundance deuterium NMR spectroscopy.

In order to explore the potentialities of the sequence, the natural abundance ^{2}H Q-COSY 2D spectrum of (±)-but-3-en-2-ol dissolved in the PBLG–$CHCl_3$ phase at 301 K was recorded (Fig. 3). The 2D spectrum was obtained using a spectral digitisation of 256 (t_1) × 1024 (t_2) data points, 848 transients per FID were added, leading to a total number of 217088 scans and a total experiment time of around 53 h.¶

As expected, the observation of the cross peaks in the 2D surface enable us to separate all sets of quadrupolar doublets. The comparison with the 1D spectrum recorded under the same conditions then allows us to attribute unambiguously each doublet. Thus, from the 2D contour plot, we can clearly deduce that the peak located at δ9.05 on the 1D spectrum is fortuitously made of three different lines corresponding to three different isotopomers. The same situation arises for the NMR line at δ1.95. These two examples illustrate the usefulness of 2D auto-correlation experiments in enantiomeric analysis *via* natural abundance ^{2}H-{^{1}H} NMR.

From the spectral analysis of the 2D spectrum all the clearly observable quadrupolar doublets in the 1D spectrum could be independently fitted for each isotopomer of mixture as presented in Fig. 1(b)–(g). The analysis shows that only three out of the six possible couples of chiral isotopomers are discriminated, *i.e.* the methyl group, the chiral centre (D_α) and *trans*-position (D_t) in the vinyl group. In addition, because the C–D bonds for the *cis*- and *gem*-deuterons (D_c and D_g) in the vinyl group are more or less parallel, they show a very similar orientation relative to the magnetic field and they must then exhibit the same behaviour relative to the chiral discrimination. In our case the quadrupolar splitting difference between the *cis*- and *gem*-positions is < 3%, and both are not discriminated, thus confirming our spectral assignment.

In conclusion we have demonstrated that natural abundance deuterium 2D auto-correlation experiments with routine magnetic field strengths (5.87 T) and standard NMR instrumentation are feasible and provide crucial information for enantiomeric analysis in chiral liquid crystals. The total experimental time needed to obtain a reasonable signal-to-noise ratio for each deuterium signal on a 250 MHz spectrometer may appear as an important limitation of this technique. However the use of higher magnetic fields will greatly reduce the experimental time.[4] Thus, operating on a 400 MHz spectrometer, only *ca*. 15 h would be needed to reach the same signal-to-noise ratio for (±)-but-3-en-2-ol. Finally, we note that natural abundance deuterium 2D experiments have sensitivities comparable with those of the carbon-13 2D INADEQUATE experiments which are commonly used.[7] Additional studies of the scope of the Q-COSY sequence (sensitivity, resolution improvement and phase sensitive mode) are currently underway. The sequence reported in this study belongs to a new class of 2D auto-correlation experiments for the NMR analysis of spins $I = 1$ in oriented media that we denote 'QUadrupole Ordered SpectroscopY' (QUOSY). Other 2D auto-correlation experiments are currently under development to assess their analytical potential in natural abundance deuterium NMR spectroscopy.

‡ *Sample composition* : The NMR sample was made from racemic substrate (100 mg), PBLG (100 mg) with a DP = 854, MW ≈ 188000 (Sigma), and $CHCl_3$ (350 mg). The sample preparation is described in refs. 2–4.

§ *1D Experiment*: The sample was not spun in the field and the temperature was controlled by a BVT 1000 system. The spectrum was recorded using 60° pulses, a 0.5 s recycling delay and 150 000 scans with 1 K data points (around 20 h of experiment time) (see ref. 4). Zero filling to 4 K data points without apodisation was applied. The linewidths of the solute are 3–7 Hz.

¶ *2D experiment*: The recycling delay of the sequence is of 0.75 s. The spectral width in the F_1 and F_2 dimensions is 1500 Hz. A Gaussian filtering in both dimensions ($LB_1 = -4$ Hz, $GB_1 = 20\%$ and $LB_2 = -3$ Hz, $GB_2 = 15\%$) and a symmetrisation procedure were applied.

Formation and *in situ* characterization of the first dihydrogen aqua complex: $[Ru(H_2O)_5(H_2)]^{2+}$

Nicolas Aebischer, Urban Frey and André E. Merbach*

Institut de Chimie Minérale et Analytique, Université de Lausanne, BCH-Dorigny, CH-1015 Lausanne, Switzerland. E-mail: andre.merbach@icma.unil.ch

Received (in Basel, Switzerland) 17th July 1998, Accepted 17th September 1998

The product of the reaction between $[Ru(H_2O)_6]^{2+}$ and pressurized H_2 in water is $[Ru(H_2O)_5(H_2)]^{2+}$ whose nature was unambiguously demonstrated by ^1H and ^{17}O NMR and which is the first characterized dihydrogen aqua complex.

$[Ru(H_2O)_6]^{2+}$ **1** is an ideal starting material for the preparation of a great variety of new Ru(II) aqua complexes. For example, the easy reaction of **1** with dissolved gases (CO,[1] N_2[2] and C_2H_4[3]) to form the corresponding $[Ru(H_2O)_5L]^{2+}$ complex is of particular interest for its simplicity and its cleanliness. More interestingly, the dimerization of ethylene catalyzed by **1** in water and under very soft conditions was described.[3] The products of the reaction were identified as different butene isomers, but no indication about the mechanism was given. The existence of a hydride complex may be an intermediate in the reaction pathway. However, no ruthenium(II) aquacomplex containing either a hydride or a dihydrogen ligand has ever been described.

Morris *et al.* proposed a way to predict the stability of a H_2 complex.[4] If a N_2 complex exhibits a stretching frequency, ν_{NN}, in the range 2060–2150 cm^{-1}, the corresponding H_2 complex will be stable *vs.* thermally unstable complexes for $\nu > 2150$ cm^{-1} and hydrides for $\nu < 2060$ cm^{-1}. In the case of $[Ru(H_2O)_5(N_2)]^{2+}$, a ν_{NN} of 2156 cm^{-1} was reported for the solid compound (Nujol mull), and of 2141 cm^{-1} in aqueous solution.[2] These values indicate thus that a dihydrogen complex of limited stability could be prepared but not the hydride complex.

To a 0.1 mol kg^{-1} aqueous solution of $[Ru(H_2O)_6]^{2+}$, prepared in a home-made 10 mm sapphire tube,[5] we applied 4.0 MPa of dihydrogen pressure.† The appearance of only one new peak at −7.68 ppm (beside the peaks of the starting materials) was detected in the ^1H NMR spectra. After 1.5 h, Ru(0) started to deposit on the wall of the tube, probably due to the reduction of the metal by dihydrogen. A new solution was prepared containing $[Ru(H_2O)_6]^{2+}$ (0.110 mol kg^{-1}), toluene-*p*-sulfonic acid (Htos, 0.130 mol kg^{-1}) in 99.95 % D_2O. Subsequently, 3.9 MPa of dihydrogen was applied. After 20 min, beside the signals of the solvent and of the tosylate anion, two singlets at −7.65 and at 4.62 ppm (bound and free dihydrogen) could be observed in the ^1H NMR spectrum. The solution was kept under H_2 pressure for 19 h and shaken from time to time. Then, two 1 : 1 : 1 triplets could be observed [Fig. 1(a)] in addition to the previously mentioned singlets. The first triplet at 4.59 ppm exhibits a coupling constant, $^1J_{HD}$, of 42.8 Hz and is typical of free HD dissolved in bulk water. The second triplet at −7.68 ppm exhibits a $^1J_{HD}$ value of 31.2 Hz and an isotopic shift, $\delta_{HH} - \delta_{HD}$, of +0.023 ppm compared to the signal of bound H–H. The chemical shift as well as the coupling constant of this latter signal are characteristic of a dihydrogen ligand bound to a metal center.[6] No reduction was observed after keeping the solution for three days under H_2 pressure, showing the increased stability of the complex in more acidic medium.

The simplest conceivable dihydrogen complex has the formula $[Ru(H_2O)_5(H_2)]^{2+}$. To verify the formation of such a complex, a new solution was prepared containing $[Ru(H_2O)_6]^{2+}$ (0.0994 mol kg^{-1}) and Htos (0.562 mol kg^{-1}) in 10% oxygen−17 enriched water.‡ Then, 54.0 MPa of dihydrogen pressure was applied to this solution at 297.0 K in a home made high gas-pressure NMR microreactor which assured a constant mixing between the solution and the gas.[7] After 35 min, a singlet at −7.54 ppm was the only new peak in the ^1H NMR spectrum. Simultaneously, the ^{17}O NMR spectrum revealed the appearance of two new peaks at −80.4 and −177.4 ppm beside the signal of bulk water (at 0 ppm) concomitant to the decrease of the Ru(II) hexaqua complex signal at −191.0 ppm [Fig. 1(b)]. The ratio of the integral of the two new peaks is 4.1, with is in very good agreement with the theoretical value of 4 expected for a complex of the formula $[Ru(H_2O_{ax})(H_2O_{eq})_4(H_2)]^{2+}$. The formation reaction of the dihydrogen complex is summarized in eqn. (1), where an estimated value of the equilibrium constant, calculated from the integrals of the ^{17}O NMR signal, is also given.

$$[Ru(H_2O)_6]^{2+} + H_2 \underset{}{\overset{K_{eq} \approx 4 \text{ kg mol}^{-1}}{\rightleftharpoons}} [Ru(H_2O)_5(H_2)]^{2+} \quad (1)$$

An empirical equation has been proposed to calculate the H–D bond distance (in Å) from the $^1J_{HD}$ coupling constant [in Hz, eqn. (2)].[8] With a $^1J_{HD}$ value of 31.2 Hz (*vide supra*), we can

$$d_{H-D} \cong -0.0167\, J_{HD} + 1.42 \quad (2)$$

calculate a H–H bond length of 0.899 Å, only slightly longer than the experimental bond length of free dihydrogen (0.740 Å). This indicates little electron back donation from the metal to the σ* antibonding orbital of the dihydrogen ligand. The main contribution to the Ru–H_2 bond is thus probably an electron donation from the σ orbital of H_2 to the metal. This should cause

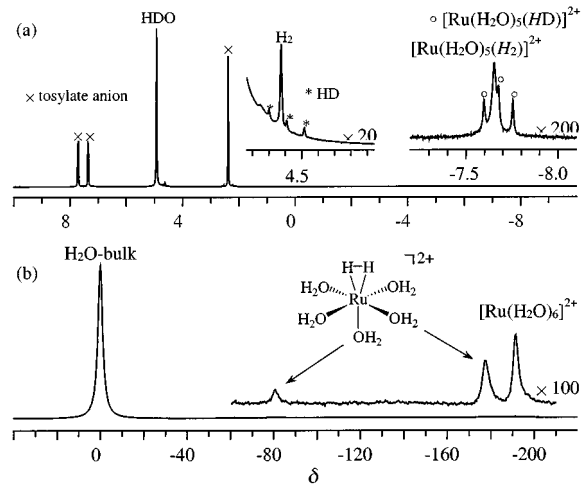

Fig. 1 (a) 400 MHz ^1H NMR spectrum, recorded at 298.4 K, of a solution containing initially $[Ru(H_2O)_6]^{2+}$ (0.110 mol kg^{-1}), toluene-*p*-sulfonic acid (0.130 mol kg^{-1}) in 99.95 % D_2O and kept for 19 h at ambient temperature and under 3.9 MPa of dihydrogen pressure in a 10 mm sapphire tube; (b) 54 MHz ^{17}O NMR spectrum, recorded at 297.0 K, of a solution containing initially $[Ru(H_2O)_6]^{2+}$ (0.099 mol kg^{-1}) and toluene-*p*-sulfonic acid (0.562 mol kg^{-1}) in 10% $H_2{}^{17}O$ and kept for 40 min under 54.0 MPa of dihydrogen pressure at 297.0 K.

an electron depletion of the H–H bond and thus gives an acidic character to the dihydrogen ligand. This may explain the enhanced stability of the dihydrogen complex with the decrease of the pH, possibly by displacing an equilibrium between dihydrogen–hydride complexes [eqn. (3)]. The increase of the

$$[Ru(H_2O)_5(H_2)]^{2+} \underset{+\,H^+}{\overset{-\,H^+}{\rightleftharpoons}} \underset{\text{(intermediate)}}{\{Ru(H_2O)_5(H)^+\}} \underset{-\,D^+}{\overset{+\,D^+}{\rightleftharpoons}} [Ru(H_2O)_5(HD)]^{2+} \qquad (3)$$

acidic character of η^2-coordinated H_2 is in accord with the formation of both bound and free HD molecules observed in the ^{1}H NMR spectra, resulting from an activation of the H–H bound by the metal center.

The longitudinal relaxation time of the ^{1}H NMR signal of bound dihydrogen was also determined at different temperatures by inversion–recovery experiments.§ The T_1 values decreased as a function of the temperature, yet the minimum of the T_1 values was not reached. Nevertheless, all the measured values, < 100 ms, confirm the dihydrogen nature of the ligand. It was shown that dihydrogen ligand has T_1 values < 100 ms but for hydride ligand the value is usually > 350 ms.[6]

The $[Ru(H_2O)_5(H_2)]^{2+}$ complex is the first example of an η^2-dihydrogen complex containing only water as other ligand in the first coordination sphere. There is thus no π-acid ligands to discharge the ruthenium center from some of its electronic density. This situation is similar to the previously reported $[Os(NH_3)_5(H_2)]^{2+}$,[9] and $[Os(NH_3)_4(H_2O)(H_2)]^{2+}$,[10] complexes where, similarly, no π-acid ligands are present in the first shell. However, for these two latter examples, very long relaxation times determined at 20 °C and 400 MHz (T_1 = 345 and 346 ms, respectively) and very small coupling constants ($^1J_{HD}$ = 15.2 and 8.1 Hz, respectively) were reported, indicating long H–H distances. This is due to electron back−donation from the osmium center to the σ* orbital of H_2 causing the elongation of the H–H bond. A similar trend was reported for the complex $[Os(en)_2(H_2)H_2O]^{2+}$, where a dissociative mechanism for the substitution of the water molecule was assigned, with a stabilization of the penta−coordinate intermediate by rearrangement to the dihydride of Os(IV) complex, $[Os(en)_2(H)_2]^{2+}$.[11] In $[Ru(H_2O)_5(H_2)]^{2+}$, the situation is completely different as short relaxation times and large coupling constants were determined. This indicates little π-back-donation to the σ* orbital of H_2. This is a surprising result, as it is well known that Ru(II) aqua complexes bind strongly to π−acid ligands with efficient back-donation from the metal to the ligand which stabilizes the metal center towards oxidation.[12] A similar behavior was reported for $[Ru(H_2O)_5(N_2)]^{2+}$ where it was shown using density functional calculation results that there was no π back-bonding from Ru to N_2, resulting in a weak Ru–N_2 binding energy.[12]

We report here the characterization of the first dihydrogen aquacomplex containing water as the only other ligand. The dihydrogen nature of the ligand was demonstrated by the value of the ^{1}H NMR chemical shift of the bound H_2 signal, by the longitudinal relaxation time, T_1, of this signal and by the characteristic $^1J_{HD}$ value of the coordinated H–D ligand. Moreover, the $[Ru(H_2O_{ax})(H_2O_{eq})_4(H_2)]^{2+}$ structure of the complex was demonstrated by ^{17}O NMR. The activation of the H–H bond was also demonstrated by the appearance in D_2O of the ^{1}H NMR signals of coordinated and free HD molecules. These observations may be of primary importance in understanding the catalytic activity of $[Ru(H_2O)_6]^{2+}$ in the ring opening metathesis polymerisation reaction or in the dimerisation of ethylene. It may also open a new perspective in designing new H_2 activators with very simple chemical structure and efficient catalytic activity in water.

Notes and references

† All the solutions were prepared in a glove box, the solvent was previously degassed using a 20 min argon stream before use and all the observations were carried out under inert atmosphere. For the ^{1}H NMR spectra, the methyl of the toluene-*p*-sulfonic anion signal was taken as a reference at 2.38 ppm.

‡ The solution was kept for half an hour in the glove box to enrich the Ru(II) aquacomplex and reach the isotopic equilibrium. Under these conditions, the half life of the water exchange < 1 min ($k_{ex}^{H_2O}$ = 0.018 s^{-1} at 298 K).[13]

§ The variation as a function of the temperature of the longitudinal relaxation time, T_1, of the signal of H_2 bound in $[Ru(H_2O)_5(H_2)]^{2+}$ were determined on a 400 MHz NMR spectrometer for a solution containing initially $[Ru(H_2O)_6]^{2+}$ (0.101 mol kg^{-1}), toluene-*p*-sulfonic acid (0.598 mol kg^{-1}) and under 5.0 MPa of dihydrogen pressure. The following values were obtained: T_1 (400 MHz) = 55.7 ms (at 296.4 K), 67.1 ms (305.9) and 99.7 ms (321.7).

An illustration of the expression of cooperative binding energy in arrays of non-covalent interactions

Ben Bardsley and Dudley H. Williams*

Cambridge Centre for Molecular Recognition, University Chemical Laboratory, Lensfield Road, Cambridge, UK CB2 1EW. E-mail: dhw1@cam.ac.uk

Received (in Cambridge, UK) 1st September 1998, Accepted 18th September 1998

An analysis of a thermodynamic cycle for the formation of ligand-bound dimers gives a simple illustration as to how a cooperative binding energy ($\Delta G°_{coop}$) can be expressed over a range of interfaces, rather than at just one of the interfaces within the array.

The phenomenon of cooperativity has been shown to be important in a variety of molecular recognition processes throughout Nature.[1] In such systems, cooperative enhancements to binding are important in conferring relatively large Gibbs free energies of association and also high specificities on binding processes. Different mechanisms for the operation of cooperative binding exist, including conformational changes in the receptors involved, or more subtle structure tightening which may occur without a significant change in receptor conformation.[2–7] This paper gives a simple illustration as to how cooperativity occurring without a significant conformational change can potentially result in large Gibbs free energies of binding and how binding to one part of a receptor can result in the strengthening of binding at other interfaces within that receptor.

In previous work, we have shown that the dimerisation of vancomycin group of antibiotics is cooperative with the binding of ligands (peptides terminating in the sequence –Lys-D-Ala-D-Ala).[8] That is, dimerisation constants are typically greater in the presence of cell wall precursor analogues than in their absence, and ligand binding constants to antibiotic dimers are greater than those to monomers. As a result, dimerisation, with the resultant formation of a tetrameric cooperative array (two ligands binding to an antibiotic dimer), is beneficial to antibacterial activity.[8,9]

Recently, we have identified correlations between the chemical shifts of particular antibiotic protons and the Gibbs free energies of ligand binding ($\Delta G°_{lig}$) and dimerisation ($\Delta G°_{dim}$).[10–12] In both cases, the parameters under consideration (chemical shift) were determined under limiting conditions, *i.e.* antibiotic fully bound by ligand or antibiotic fully dimerised. We have used these monitored proton resonances as microscopic probes of the local tightness of the ligand binding and dimerisation interfaces; when the association constant is large, the resonance related to that interface shows a greater chemical shift change relative to the unassociated state.[11] Using these microscopic probes, we have been able to analyse the interfacial origins of the cooperative binding energy expressed upon formation of a ligand-bound dimer for a number of vancomycin group antibiotics.[12] We describe here a new analysis of this extended cooperative array, based on a thermodynamic cycle, from which it is possible to illustrate in a simple way useful conclusions regarding the expression of cooperative binding energy.

The enhancements to dimerisation and ligand binding resulting from cooperativity can be represented in a thermodynamic cycle showing the formation of a fully ligand-bound dimer from the constituent elements of two antibiotic monomers and two ligand molecules (Fig. 1).[8] There are four binding events occurring in this cycle. The left-hand half of Fig. 1 shows the formation of a fully ligand-bound dimer through the formation of a ligand-free antibiotic dimer followed by the binding of two ligand molecules to that dimer (**A** → **B** → **D**/**E**). The right-hand half of Fig. 1 shows the formation of the same fully ligand-bound dimer, but through the formation of two ligand-bound antibiotic monomers followed by dimerisation of these two monomers (**A** → **C** → **D**/**E**). Two possible scenarios (**D** and **E**) are considered for the formation of the fully ligand-bound dimer. **D** is the hypothetical situation where there is no cooperativity between dimerisation and ligand binding. In this case, there are no net influences on ligand binding due to dimerisation, and *vice versa*, *i.e.* no net influences on dimerisation due to ligand binding. **E** is the situation for the majority of vancomycin group members where dimerisation and ligand binding are cooperative processes, and the resultant Gibbs free energy benefit due to cooperativity is defined as $\Delta G°_{coop}$. We can use this thermodynamic cycle to illustrate the means by which a measured cooperative binding energy can, in theory, be expressed at any of the interfaces within an extended array.

In Fig. 1, the local tightness of the respective ligand binding and dimerisation interfaces (as evidenced from NMR data[11,12]) is represented schematically simply by greater distances between associating entities when the association at that interface is looser. The experimental data show that locally looser interfaces correlate with smaller K_{dim} and K_{lig} (*i.e.* less negative $\Delta G°_{dim}$ and $\Delta G°_{lig}$) values.[11,12] If there is no cooperativity between ligand binding and dimerisation (**D**), then the dimerisation and ligand binding interfaces are antici-

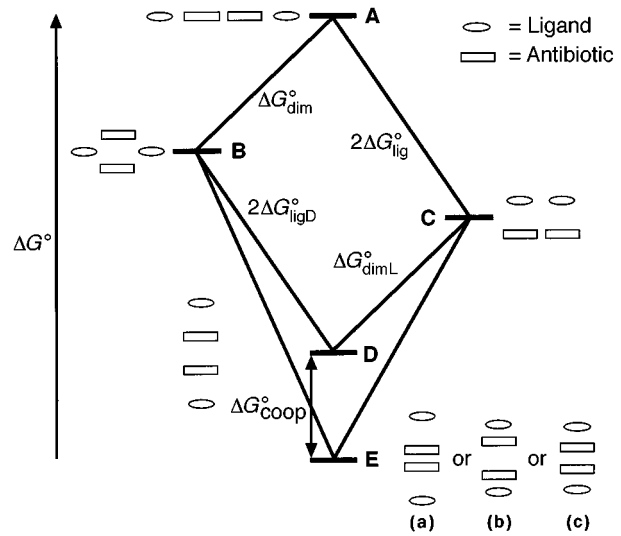

Fig. 1 Schematic thermodynamic cycle showing the formation of a fully ligand-bound antibiotic dimer from the constituent elements of two ligand molecules and two antibiotic monomers (**A**) *via* either a ligand-free antibiotic dimer (**B**) or two ligand-bound antibiotic monomers (**C**). The ligand-bound dimer at (**D**), is formed with no cooperativity between dimerisation and ligand binding. The ligand-bound dimers at (**E**) are formed with a cooperative Gibbs free energy ($\Delta G°_{coop}$) between dimerisation and ligand binding. For the two ligand binding events (**A** → **C** and **B** → **D**/**E**), the Gibbs free energies of binding are multiplied by 2 since each event involves the binding of two ligand molecules. See text for further analysis.

pated to be unchanged from those in **B** and **C**, respectively. If dimerisation and ligand binding are cooperative (**E**), however, then the cooperative binding energy ($\Delta G°_{coop}$) can, in theory, be expressed by tighter binding at either of the two interfaces, *i.e.* at the dimerisation interface and/or at the ligand binding interface.

There are two extreme states to consider for the expression of the cooperative binding energy, $\Delta G°_{coop}$. In **E(a)**, $\Delta G°_{coop}$ is expressed solely at the dimerisation interface and the tightness of the ligand binding interface remains the same as that in **C**. In **E(b)**, $\Delta G°_{coop}$ is expressed solely at the ligand binding interface and the tightness of the dimerisation interface remains the same as that in **B**. In practice, ligand-bound dimers are likely to express cooperative binding energy across both ligand binding and dimerisation interfaces as shown in **E(c)**. However, if we consider one of the extreme cases, *e.g.* **E(a)**, where all the cooperative binding energy is expressed at the dimerisation interface, then $\Delta G°_{coop}$ can still potentially be determined *via* measurement of either of two quantities: the ligand binding constant to dimer (**B** → **E**), or the dimerisation constant of ligand-bound antibiotic (**C** → **E**). For both measurements, $\Delta G°_{coop}$ is the same (**D** → **E**) and can be calculated from the increase in $\Delta G°_{dimL}$ over $\Delta G°_{dim}$, or from the increase in $2\Delta G°_{ligD}$ over $2\Delta G°_{lig}$. It is clear from this that in **E**(**a**), although $\Delta G°_{coop}$ is being expressed solely at the dimerisation interface and there is no increase in the tightness of the ligand binding interface, $2\Delta G°_{ligD}$ will show the same cooperative enhancement over $2\Delta G°_{lig}$ as will $\Delta G°_{dimL}$ over $\Delta G°_{dim}$. The same situation will exist even if $\Delta G°_{coop}$ is expressed solely at the ligand binding interface [**E(b)**]. In this case, although there will be no tightening of the dimer interface, $\Delta G°_{dimL}$ will still show an enhancement of $\Delta G°_{coop}$ over $\Delta G°_{dim}$. Thus, when $\Delta G°_{coop}$ is actually measured, *e.g.* by an increase in $\Delta G°_{dimL}$ over $\Delta G°_{dim}$, it is not possible to say, without further analysis of the complexes formed, at which interface the cooperative binding energy is expressed. (We have recently performed such an analysis of the partitioning of the cooperative Gibbs free energy between the dimerisation and ligand binding interfaces using the chemical shift of a proton at the dimer interface as a probe of interface tightness.[12])

Analogous diagrams would simply illustrate that in any system of weak interactions where there is a cooperative binding energy ($\Delta G°_{coop}$) expressed through the formation of an extended aggregate, then $\Delta G°_{coop}$ can potentially occur at *any* of the interfaces which go to make up that extended array. Also, if cooperativity is observed for a particular binding event in such an extended array, it does not necessarily follow that the bonding at the interface for that particular binding event has been improved.

One consequence of the above discussion is that the size of an extended array (number of non-covalent interactions making up the array) will affect the amount of cooperative binding energy ($\Delta G°_{coop}$) which can potentially be expressed. In the case of a fully ligand-bound antibiotic dimer, $\Delta G°_{coop}$ can be expressed over three binding interfaces whereas, if only one ligand was bound to the dimer, the cooperative binding energy could only be expressed over two binding interfaces. More generally, the greater the number of cooperatively-linked binding interfaces, the greater the scope for cooperative enhancements to binding. It thus follows that the greatest potential for expressing cooperative binding energies that would be expected in Nature are those involving the associations of large arrays of weak interactions, *e.g.* DNA duplexes, ligands binding to proteins.

Bis(diphenylphosphino)methane and related ligands as hydrogen bond donors†

Peter G. Jones and Birte Ahrens

Institut für Anorganische und Analytische Chemie, Technical University of Braunschweig, Postfach 3329, 38023 Braunschweig, Germany. E-mail: jones@xray36.anchem.nat.tu-bs.de

Received (in Basel, Switzerland) 26th May 1998, Accepted 15th September 1998

A search of the Cambridge Structural Database reveals that the methylene group of coordinated bis(diphenylphosphino)methane and related ligands can act as a hydrogen bond donor, with H···O distances as short as 2.20 Å; analogous C–H···Cl⁻ interactions are a feature of the packing of dppmSe complexes of silver(I) and gold(I).

Secondary bonding interactions have been the focus of increased interest for several years. The classical hydrogen bond is a well known structural phenomenon; the C–H···O hydrogen bond, at first a controversial postulate, is now accepted as an important factor in determining the nature and stability of solid-state structures.[1] It has been recognised that more acidic C–H groups are likely to provide stronger (shorter) hydrogen bonds, although the inverse correlation between length and strength may not be totally reliable.[1]

It is normal practice in X-ray structure determination to check newly determined structures for possible hydrogen bonds, and indeed this process can now be performed automatically for classical hydrogen bonds.[2] The search for C–H···X interactions is less well integrated into common program systems; correspondingly, it may be assumed that many such interactions fail to be reported. In this Institute, such searches have only recently become routine;[3] we use a default cutoff of 2.6 Å for the H···O distance, although appreciably longer interactions (up to 3 Å) have often been considered genuine hydrogen bonds.

In a recent study of six-membered heterocycles involving the P–CH_2–P unit, we observed some strikingly short intermolecular C–H···O interactions (H···O 2.25, C···O 3.24 Å) involving the methylene group between the phosphorus atoms.[4] This prompted us to re-inspect some of our older structures involving organic phosphorus heterocycles, and we discovered two cases where we had overlooked short intermolecular contacts between the H atoms of a P–CH_2–P unit and keto oxygens (H···O 2.38, 2.29 Å)[5]

Another molecule involving the P–CH_2–P group is the common ligand bis(diphenylphosphino)methane (dppm), $Ph_2PCH_2PPh_2$. The methylene hydrogens of dppm are known to be acidic, particularly in metal complexes; the deprotonated form of the ligand contains an additional donor, the methanide group.[6] It thus seemed likely that dppm complexes might display C–H···O hydrogen bonds.

A search of the Cambridge Structural Database[7] (Oct. 1997 version) was conducted for the fragment P–CH_2–P with an intermolecular H···O contact of < 2.5 Å to any O–C bond. The search was restricted to error-free, ordered structures. Apart from the two structures previously mentioned, a total of 23 structures (all of them complexes or clusters involving dppm or related ligands) with 28 C–H···O substructures were found. The geometry was in all cases acceptably linear (one C–H···O angle of 133°, all others > 143°). The shortest H···O contact was 2.20 Å.

The hydrogen bonds can be classified as follows: M–$CO_{terminal}$···H, 10 cases; M–$CO_{bridging}$···H, 2; $O_{solvent}$···H, 8; O_{anion}···H, 3; ligand C=O···H, 5. In no case were the C–H···O hydrogen bonds mentioned in the original publication; in several cases it was explicitly stated that *no* unusual intermolecular contacts were observed. It should be noted that these relatively few examples represent the shortest such interactions; there are presumably many more with somewhat longer H···O distances.

Although this initial search was restricted to oxygen acceptors, it is clear that other electronegative elements should accept hydrogen bonds from dppm. In view of our interest in coinage metal complexes with selenium ligands,[8] we therefore determined structures of the type $[(dppmSe)_2M]^+Cl^-$ (**1a**, M = Ag, dichloromethane solvate; **1b**, M = Ag, ethanol solvate; **2a**, M = Au, chloroform solvate; **2b**, M = Au, ethanol solvate).‡§ These are the first complexes involving P_2Se_2 coordination at silver(I) and gold(I). The coordination at the metal atoms is distorted tetrahedral; angular distortions arise from the restricted bite of the ligands, but the gold complexes additionally display a major difference in Au–Se bond lengths (0.16 Å in **2b** and 0.30 Å in **2a**; values are given in Figs. 1 and 2). The structure of a two-coordinate gold(I) complex of the same ligand has been reported by Schmidbaur, *et al.*[9] and by chance belongs to the set of 23 compounds discussed above; it displays two C–H···$O_{acetone}$ hydrogen bonds.

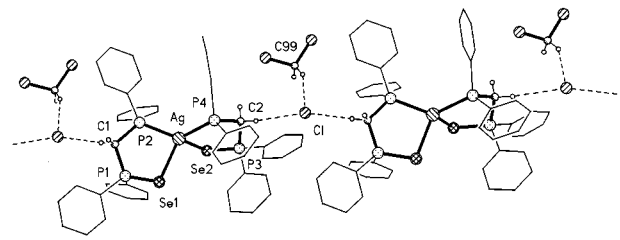

Fig. 1 The structure of **1a** in the crystal. Hydrogen atoms of the phenyl groups are omitted for clarity, radii are arbitrary. Dashed lines represent H bonds. Selected bond lengths (Å) and angles (°): Ag–Se1 2.7086(12), Ag–Se2 2.7749(13), Ag–P2 2.453(3), Ag–P4 2.439(2); bite angles P2–Ag–Se1 92.49(6), P4–Ag–Se2 91.40(6); H···Cl⁻···H 164. The structures of **1b** (isostructural) and **2b** (equivalent packing) are similar to **1a**: **1b** Ag–Se1 2.7179(10), Ag–Se2 2.7643(10), Ag–P2 2.454(2), Ag–P4 2.440(2); P2–Ag–Se1 92.69(5), P4–Ag–Se2 91.64(5); H···Cl⁻···H 159. **2b** Au–Se1 2.9459(12), Au–Se2 2.7891(12), Au–P2 2.306(3), Au–P4 2.319(2); P2–Au–Se1 89.64(7), P4–Au–Se2 91.61(7); H···Cl⁻···H 160.

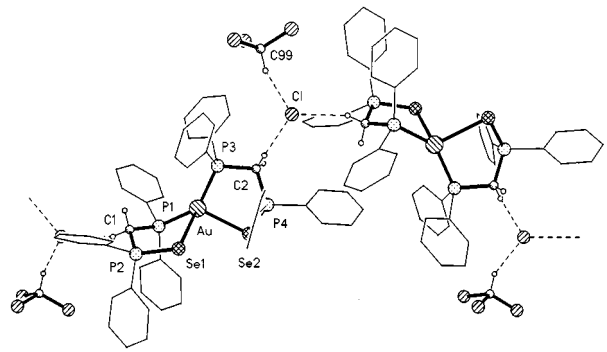

Fig. 2 The structure of **2a** in the crystal. Hydrogen atoms of the phenyl groups are omitted for clarity, radii are arbitrary. Dashed lines represent H bonds. Selected bond lengths (Å) and angles (°): Au–Se1 3.0571(10), Au–Se2 2.7535(9), Au–P1 2.298(2), Au–P3 2.329(2); P1–Au–Se1 83.46(5), P3–Au–Se2 92.65(5), H···Cl⁻···H 112.

Table 1 Hydrogen bond geometry in compounds **1a**,**b**, **2a**,**b**

Compound, H bond	H···Cl⁻/Å	C···Cl⁻/Å	C–H···Cl⁻/°
1a, C–H_{dppm}···Cl⁻	2.87	3.839(9)	168
1a, C–H_{dppm}···Cl⁻	2.61	3.556(9)	160
1a, C–H_{solv}···Cl⁻	2.58	3.467(14)	149
1b, C–H_{dppm}···Cl⁻	2.82	3.779(6)	164
1b, C–H_{dppm}···Cl⁻	2.75	3.705(7)	163
2a, C–H_{dppm}···Cl⁻	2.64	3.576(7)	157
2a, C–H_{dppm}···Cl⁻	2.57	3.535(7)	166
2a, C–H_{solv}···Cl⁻	2.70	3.554(12)	144
2b, C–H_{dppm}···Cl⁻	2.68	3.616(9)	157
2b, C–H_{dppm}···Cl⁻	2.61	3.567(10)	163
2b, O–H_{solv}···Cl⁻		3.042(10)	

All four structures **1a**,**b**, **2a**,**b** display C–H···Cl hydrogen bonds (Table 1), which play a central role in determining the crystal packing. In each structure, the ions are connected into chains (Figs. 1 and 2) by hydrogen bonds C–H_{dppm}···Cl⁻, whereby the chloride accepts two hydrogen bonds. Additionally, there is a C–H_{solv}···Cl⁻ contact from a solvent molecule in **1a** and **2a**, an O···Cl contact involving the ethanol of **2b**, and a similar contact in **1b**, in which however the ethanol is poorly resolved.

A second database search,[7] this time for C–H···Cl contacts, also proved fruitful; a total of 28 hydrogen bonds in 21 structures were found with H···Cl < 2.8 Å and C–H···Cl > 130°. These contacts can be classified as: 14 C–H_{dppm}···Cl_{coord}; 12 C–H_{dppm}···Cl⁻, 2 C–H_{dppm}···$Cl_{(other\ anions)}$. Only one of these contacts was mentioned explicitly as an interaction with dppm in the original publications;[10] it should however be stressed that it was until recently not usual to look for hydrogen bonds involving C–H units. As an example of an unrecognised hydrogen bond, we can again cite our own work; the structure of $[(dppm)_2Au_3Cl_2]^+[(C_6F_5)_3AuCl]^-$ [11] involves a contact C–H_{dppm}···Cl_{anion} with H···Cl 2.70 Å, C–H···Cl 139°.

It may be concluded that coordinated dppm is capable of acting as a C–H···X hydrogen bond donor; in such cases it presumably exerts a significant influence on structure and stability, although to the best of our knowledge this possibility has not previously been discussed in detail. An obvious corollary is that structures of complexes of dppm and related ligands should be routinely screened for such hydrogen bonds.

We thank the Fonds der Chemischen Industrie (Frankfurt) for financial support and Dr C. Thöne for helpful discussions.

Notes and references

† Dedicated to Professor Armand Blaschette on the occasion of his 65th birthday.

‡ Bis[(diphenylphosphino)(diphenylphosphineselenido)methane]silver(I) chloride **1** was obtained from dppmSe and AgCl in 2:1 molar ratio in acetone; after filtration, the product was precipitated in 67% yield with light petroleum. Crystals were grown by diffusion of light petroleum into a solution of **1** in dichloromethane (**1a**) or by diffusion of diethyl ether into a solution of **1** in ethanol (**1b**).

Bis[(diphenylphosphino)(diphenylphosphineselenido)methane]gold(I) chloride **2** was obtained from the reaction of dppmSe with a suspension of (tht)AuCl (tht = tetrahydrothiophene) in 2:1 molar ratio in toluene, followed by precipitation with diethyl ether (yield 66%). Crystals were grown by diffusion of diethyl ether into a solution of **2** in chloroform (**2a**) or ethanol (**2b**).

Satisfactory elemental analyses and consistent NMR spectra (^1H, ^{13}C, ^{31}P, ^{77}Se) were obtained.

§ *X-Ray structure determinations*: data were measured at −100 °C on a Siemens P4 diffractometer using Mo-Kα radiation. Absorption corrections using psi-scans (**2b**: SHELXA[2]). Structures were refined on F^2 using all reflections (program SHELXL-93[2]). Hydrogen atoms were included using a riding model; C–H bond lengths (and H···X contacts) are thus systematically shortened with respect to the true values.

New sodium organobis(silantriolates)

Bruno Boury,* Francis Carré, Robert J. P. Corriu* and Rosario Nuñez

UMR 5637, CC 007, Université Montpellier II, Sciences et Techniques du Languedoc, 34095 Montpellier Cedex 05, France. E-mail: boury@crit.univ-montp2.fr

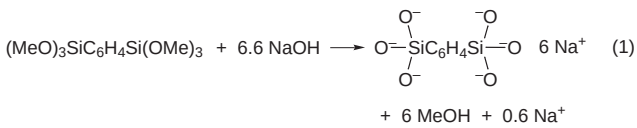
Received (in Basel, Switzerland) 3rd June 1998, Accepted 16th September 1998

The sodium salt $(NaO)_3SiC_6H_4Si(ONa)_3$ has been prepared by reaction of the corresponding methoxysilane with an aqueous solution of NaOH and was fully characterized by X-ray crystallographic studies, which indicates the presence of 13 water molecules and one hydroxide group in the crystal structure.

An enormous variety of silicates of general formula SiO_4M_4 is known, based on the different possibilities to associating the basic tetrahedral unit SiO_4 forming linear or cyclic, infinite chains and sheets.[1] By comparison, organosilanolates of general formula $R_xSi(OM)_{4-x}$ (M = group 1 or 2) metal cation are less well known. The preparation of such organosilanolates was first reported by reacting chlorosilane[2] with strong bases, and later, using siloxanes[3] and silanols[4] treated directly with metallic alkali or alkali metal hydroxides. These reaction conditions do not lead to cleavage of the Si–C bond and the organic part remains intact in the silicate. Compounds R_3SiOM (M = Na,[5] K,[6] Cs and Rb[7]) and $R_2SiO_2M_2$ (M = Li and Na[8]) were isolated and fully characterized by crystal X-ray diffraction. More recently, the possibility to prepare siloxanes and silsesquioxanes with silanolate functionalities was demonstrated.[9] Here, we report the synthesis and structural characterization of the first organosilanolate isolated from the reaction of a 1,4-bis-(trialkoxysilyl)benzene with NaOH in aqueous solution.

The growing interest for the elaboration of hybrid materials from molecular precursors led us to investigate the formation of such organosilanolates from precursors of the general formula $(MeO)_3Si–R–Si(OMe)_3$, this type of compound is currently under investigation for the preparation of hybrid materials by sol–gel polycondensation.[10] We were particularly attracted by the possibility to form lamellar or pillared materials and to consider the possibility to organize the organosilanolate molecules through the interaction of ionic Si–O^- groups with the associated cation. We first looked at $(MeO)_3SiC_6H_4Si(OMe)_3$ since the regidity of the phenylene group will favor construction of the corresponding organosilanolate.

The preparation of the sodium salt of $^-O_3SiC_6H_4SiO^-_3$ was carried out in water by treatment of **1** with a slight excess of NaOH (1 : 6.6) [eq. (1)].† The compound obtained after



(1)

evaporation of water is a hygroscopic crystalline white powder **2**.‡ Colorless crystals of **3** were isolated from a solution of **2** at 4 °C.† They were poorly stable to air at 25 °C due to loss of water, however, they could be stored for several weeks at −20 °C in a atmosphere saturated in water and this allowed a full characterization by X-ray diffraction crystal structure analysis.§ Fig. 1 shows the ORTEP drawing and important bond lengths and bond angles for **3**.¶ This crystal structure is triclinic and an inversion center is present. In this structure, 13 molecules of water and one hydroxide group are involved in coordination to the sodium cations. The presence of ligated water also results in a high number of strong hydrogen bonds (only some of these are shown is Fig. 1 for clarity, and because the lack of accuracy in the position of some of the hydrogen atoms, prevented location of all of them). The presence of an extended network of strong hydrogen bonds is similar to layered sodium polysilicate hydrates.[11] Another general feature of the sodium phenyl-1,4-bis(silantriolate) packing is the organisation of the phenylene groups which are all parallel to each other and oriented in the same direction, however the interaction between the organic moieties (C_6H_4) are limited since they are surrounded by coordinated Na^+ cations.

In the crystal structure, each silicon atom is bonded to three oxygen atoms and to a carbon atom of the phenyl group. The Si–C bond length of 1.89(8), is typical for such arylsilicon compounds [Si–C_{aryl} (average) 1.88(1) Å]. The geometry around the silicon atom is slightly distorted tetrahedral, one of the three Si-O^- bonds being longer than the other two: Si1–O1 1.679(5) Å, Si1–O2 and Si1–O3 1.605(6)– and 1.609(5) Å, respectively. All these values are typical of Si–O^- bond lengths [≈1.63(4) Å] found in silicates.[12] This distortion is also reflected in the differences between angles O2–Si1–O3 [115.8(3)°] and O3–Si1–O1 [106.6(3)°], both being close to those reported for the sodium trimethylsilanolate trihydrate[5] and sodium silicates.[12] These distortions can be related to the different environment involving the oxygen atoms of the

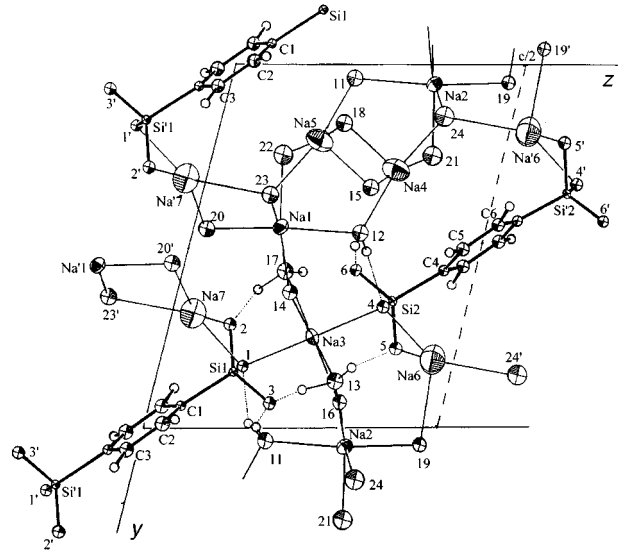


Fig. 1 ORTEP drawing of compound **3**. Select bond distances (Å) and angles (°): Si1–O1 1.679(5), Si1–O2 1.605(6), Si1–O3 1.609(5), Si1–C1 1.887(8), C1–C2 1.389(11), C2–C3 1.396(12), C1–C3 1.402(11), Si2–O4 1.679(5), Si2–O5 1.603(6), Si2–O6 1.601(5), Si2–C4 1.890 C4–C5 1.387(11), C5–C6 1.384(12),. C4–C6 1.397(11), Na1···O17 2.347(6), Na1···O14 2.367(6), Na1···O20 2.399(7), Na1···O22 2.428(7), Na1···O23 2.496(7), Na1···O12 2.582(7), Na3···O14 2.344(6), Na3···O13 2.344(6), Na3···O1 2.491(6), Na3···O4 2.500(6), Na3···O17 2.573(6), Na3···O16 2.576(6), Na4···O12 2.329(7), Na4···O18 2.334(8), Na4···O24 2.363(8), Na4···O15 2.495 Na4···O21 2.603(8), Na6···O5 2.655(8), Na6···O4 2.765(7), Na6···O19 2.774(8), Na6···O24 2.781(8), C1–S1–O1 107.2(3), C1–S1–O1 111.1(3), C1–S1–O3 107.2(3), O1–Si1–O2 108.5(3), O2–Si1–O3 115.8(3), O3–Si1–O1 106.6(3), Si1–C1–C2 123.2(6), Si1–C1–C3 120.8(6), C2–C3–C1 122.1(7).

–SiO_3^{3-} group, especially through their interaction with the sodium atoms.

In the crystal structure of **3**, four kinds of sodium atoms are present, with deficiency coordination number and nature of ligating atoms. Hexacoordination is typical for Na^+ cations in ionic organic structures.[13] In compound **3** some of the sodium atoms are coordinated only to oxygen atoms of water or hydroxide ligands: atoms Na1 and Na2 are hexacoordinated (octahedral geometry) while atoms Na4 and Na5 are pentacoordinated (square pyramidal geometry). For the other Na atoms, interaction with oxygen atoms of the Si-O^- group is observed: Na6 and Na7 are tetracoordinated to two water molecules and to two Si–O^- from the same –SiO_3^{3-} group (tetrahedral geometry) while Na3 is hexacoordinated by water molecules, O13, O14, O16, O17, and by the oxygen atoms O1 and O4 of two Si–O^- of two different phenylene-1,4-bis(silantriolate) anions (octahedral geometry). In addition, some of the ligands are shared between two sodium atom, *e.g.* Na7 shares atom O1 with Na3, as well as Na6 shares O4 and O19 with respectively Na3 and Na2. Similarly, O13 of a water molecule is coordinated to Na3 and Na2.

For the hexa- and penta-coordinated sodium cations, the Na···O interatomic distances are in the range of the Si-O···Na bond lengths (2.303 < d/Å < 2.549 Å) typical of sodium silicates[12] or ionic organosilicate hydrates,[5] and are characteristic of a strong ion-dipole interaction. For sodium atoms in tetrahedral geometry, longer Na···O distances are observed [2.645(8)–2.781(8) Å]. In addition, a distorted tetrahedral arrangement is seen for atoms Na6 and Na7, the O4-Na6-O24 [137.1(3)°] and O1–Na7–O23 [138.0(3)°] angles being much larger than O19–Na6–O24 [92.1(2)°] and O4–Na6–O24 [91.9(2)°]. This distortion can be explained by the participation of the oxygen atoms in ionic interactions and to H bonding.

In conclusion, this type of organobis(silantriolate) species can be easily prepared by treatment of the corresponding organoalkoxysilane with a strong base. Their structure and their crystallization with water present some similarities with mineral and synthetic silicates. Our current investigations of this types of organosilantriolate in our laboratory are mainly directed to the preparation of organized organomineral materials, especially on the role of the cation and the elimination or replacement of water ligands.

Notes and references

† *Typical experimental procedure*: **1**: The synthesis of 1,4-bis(trimethoxysilyl)benzene **1** has been described previously.[14] **2**: To a Schlenk tube containing 1,4-bis(trimethoxysilyl)benzene **1** (2.95 g, $9.28\cdot10^{-3}$ mol) were added 6.6 equiv. of NaOH (2.45 g, $6.12\cdot10^{-2}$ mol.) dissolved in 30 ml of deionized water (pH = 6). The mixture was stirred at room temperature for several hours to obtain a transparent and homogeneous solution. The water was evaporated under reduced pressure at 25 °C to give a crystalline white solid, which was dried *in vacuo* (1 mm Hg) at 25 °C for 16 h to give 6.52 g of compound **2**. **3**: Colorless crystals of **3** (0.51 g) were obtained from a solution of 5 g of **2** in 100 ml of deionized water cooled to 4 °C, at pH = 12.3.

‡ *Selected spectroscopic and analytical data for* **2**: ^{1}H NMR (200 MHz, D_2O, 20 °C): δ7.55 (s, 4H, C_6H_4). FTIR (KBr, cm^{-1}): 3384 ν(H–OH), 3030 ν (C_{ar}-H), 1448, 1131, 1008 ν(Si–O), 880 ν(Si–OH), 778 ν(Si–C).

§ *Crystal data for* **3**: Nonius CAD 4 automated diffractometer, crystal fixed in oil under nitrogen, $C_6H_{31}Na_7O_{20}Si_2$, M_r = 640.4, triclinic, space group $P\bar{1}$ crystal dimensions 0.05 × 0.07 × 0.11 mm, a = 6.265(2), b = 11.949(1), c = 18.844(2) Å, α = 101.594(8), β = 99.56(1), γ = 105.23(1)°, U = 1297.0(4) Å^3, D_c = 1.640 g cm^{-3}, T = 193 K, Z = 2, F = 664, μ(Mo-Kα) = 3.22 cm^{-1}, A^* = 0.55, $2\theta_{max}$ = 44° , R,R_w = 0.0554,0.0586 (statistical weights), N_0 = 1912 observed [$I > 2\sigma(I)$] reflections out of N = 2686 unique, λ(Mo-Kα) = 0.71069 Å The hydrogen atoms of the phenyl groups were placed calculated positions (SHELX-76). After four least-squares refinement cycles with anisotropic thermal parameters for all non-hydrogen atoms some water hydrogen atoms were positioned in a difference Fourier map. These hydrogen atoms were taken in account in the next refinement and Fourier calculations, but their positional parameters were then kept fixed. After six such refinements and difference Fourier maps, the refinement converged to a final R value of 0.0554 (R_w = 0.0586). One of the last peaks searched as a possible hydrogen atom. (on O23) was rejected in view of the unacceptable resulting H–O–H angle value (88°). In the same way, no more than one relevant peak was observed on oxygen atom O22. The list of hydrogen atoms coordinates is available in the supplementary data. Absorption corrections were neglected. Direct methods (SHELXS-86) succeeded in locating the bis-silanolate anion. The other non-hydrogen atoms were located in a Fourier map and two subsequent difference Fourier maps. CCDC 182/1022

¶ Studies have been undertaken to demonstrate if the crystal structure of **3** is representative of the bulk white solid **2**.

Convenient synthetic approach towards regioselectively sulfated sugars using limpet and abalone sulfatase-catalyzed desulfation

Hirotaka Uzawa,[a]† Tadashi Toba,[b] Yoshihiro Nishida,[b]‡ Kazukiyo Kobayashi,[b] Norihiko Minoura[a] and Kazuhisa Hiratani[c]

[c] *National Institute for Advanced Interdisciplinary Research, 1-1-4 Higashi, Tsukuba 305-8562, Japan*

Received (in Cambridge, UK) 27th July 1998, Accepted 1st September 1998

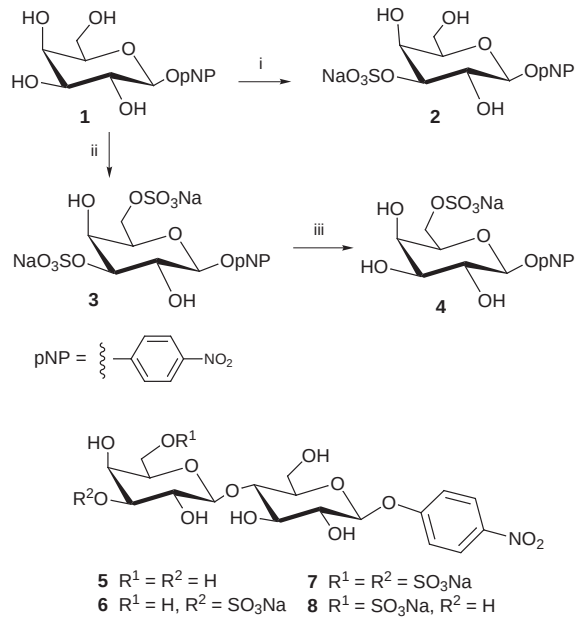
3,6-Disulfated *p*-nitrophenyl β-D-galactopyranoside 3 and 3′,6′-disulfated *p*-nitrophenyl β-lactoside 7, which were regioselectively obtained *via* organotin methodology, were subjected to enzymatic desulfation: limpet and abalone sulfatases (EC 3.1.6.1) hydrolyzed regioselectively the 3- and 3′-sulfate moieties of 3 and 7 to afford 6-monosulfated galactopyranoside 4 and 6′-monosulfated lactoside 8, respectively.

Various sulfated analogues of sialyl Le[a] and Le[x] have been prepared by different groups[1–9] as artificial ligands of the selectin families, which include artificial glycoconjugate polymers and dendrimers carrying sulfated carbohydrates.[10–13] As part of our project to develop biofunctional glycoconjugate polymers able to adsorb certain pathogenic bacteria and their toxins,[14,15] our interests have been directed to regioselectively sulfated sugars as substitutes for natural sialyl oligosaccharides and sulfatides known to bind with various viruses and pathogenic bacteria.[16] Here we report a new chemoenzymatic synthetic approach towards regioselectively sulfated *p*-nitrophenyl (pNP) β-D-galactopyranosides and lactosides.

Regioselective sulfations of carbohydrate molecules reported in recent years may be divided into the following types; chemical methods using stannylated sugars[17] and enzymatic approaches using sulfotransferase for non-sulfated sugar acceptors[18] or glycosyltransferases for sulfated acceptors.[19] Here we describe a convenient synthetic approach using *sulfatases*. Although various types of sulfatases are commercially available at low cost, their utility for chemoenzymatic syntheses has not yet been fully explored. Now we propose a new practical approach which involves introduction of plural sulfates into sugars *via* organotin methodology and then regioselective desulfation with sulfatases. pNP β-D-Galactopyranoside **1** and pNP β-lactoside **5** (Scheme 1) were employed as model compounds to demonstrate our approach. The pNP group is used due to its ready conversion to a *p*-*N*-acryloylaminophenyl group ready for subsequent polymerization.[20,21] Moreover, sulfated galactoses and lactoses are promising ligand candidates for influenza viruses and the other microbes.

The initial chemical approach to **1** and **5** was as follows. Reaction of **1** with Bu_2SnO (1 equiv.) and then SO_3NMe_3 (1 equiv.) gave 3-monosulfated galactoside **2** in 77% yield, while the use of $(Bu_3Sn)_2O$ (0.75 equiv.) and an excess of SO_3NMe_3 (5 equiv.) gave 3,6-disulfated derivative **3** in 97% yield.§ Thus, these chemical methods afforded 3-mono- and 3,6-di-sulfated galactosides in a regioselective manner, while not affording directly the 6-monosulfated galactose **4**. A similar process for **5** using Bu_2SnO (1 equiv.) and then SO_3NMe_3 (1 equiv.) gave selectively 3′-monosulfated pNP β-lactoside **6** (57% isolated yield).¶ Use of Bu_2SnO (3 equiv.) and SO_3NMe_3 (3 equiv.) afforded 3′,6′-disulfated lactoside **7** as the main product (40% yield).‖ Similar reaction of **5** using $(Bu_3Sn)_2O$ instead of Bu_2SnO gave a complex mixture of sulfated products.

The location of sulfate groups in sulfated lactosides **6** and **7** was determined by 2D NMR experiments (^{1}H-^{1}H COSY). The



Scheme 1 *Reagents and conditions*: i, Bu_2SnO (azeotropic), SO_3NMe_3, then Dowex Na^+; ii, $(Bu_3Sn)_2O$, (azeotropic), SO_3NMe_3, then Dowex Na^+, 97%; iii, sulfatase, 0.25 M NaOAc–AcOH buffer (pH 6.8), 37 °C, 80%.

signal of H-3′ of a galactose residue (δ 4.32–4.38, dd, *J* 3.0–3.3 and 9.5–9.8 Hz) of **6** and **7** showed downfield shift due to the sulfation at the geminal O-3′, while the H-3 of glucose (δ 3.796 and 3.805, br t, *J* 9.5–9.9 Hz) did not show the corresponding downfield shift. These results showed that the sulfate group was located at O-3′ in the galactosyl residues for both **6** and **7**.

3,6-Disulfated galactoside **3** and 3′,6′-disulfated lactoside **7** were subjected to enzyme-catalyzed desulfation with sulfatases (EC 3.1.6.1) (Table 1).** Three types of commercially available sulfatases were tested, and each of the desulfated products was analyzed by ^{1}H NMR spectroscopy. The enzyme reaction of **3** with snail sulfatase in NaOAc–AcOH buffer (pH 6.8, 37 °C) was completed in 2 days to afford a less polar product. The

Table 1 Regioselectivity of sulfatase-catalyzed desulfation

Substrates	Sulfatases origins[a]	*t*/days[b]	Conversion (%)	Product
3	snail	2	94[c]	**4**
3	abalone	2	> 95[d]	**4**
3	limpet	2	> 95[d]	**4**
7	snail	3	0	—
7	abalone	3	40[c]	**8**
7	limpet	3	> 95[d]	**8**

[a] Commercially available sulfatases from snail (*Helix pomatia*), abalone and limpet (*Patella vulgata*) were used. [b] Typical procedure is shown in footnote ††. [c] Isolated yield. [d] Determined by ^{1}H NMR analysis or TLC.

product was isolated in >90% yield and identified as 6-monosulfated galactoside **4**.†† The 6-sulfated structure could be determined by ^{1}H NMR analysis, *via* comparison of the spectral data with those of **3** and pNP β-D-galactopyranoside **1**. The downfield shift of H-3 (δ 4.484, dd, J = 3.3 and 9.6 Hz for **3**) due to the 3-sulfate could not be observed for **4**, while the downfield shift of the H-6 signals remained. The structure of **4** was further confirmed by an alternative synthesis *via* multiple protections and deprotections. A reference reaction of **3** without the enzyme gave no product. This eliminated the possibility of non-enzymatic hydrolysis. The other two sulfatases (abalone and limpet) showed similar reactivity and regioselectivity. This is the first regioselective desulfation by sulfatases of sulfated sugars bearing more than two sulfate groups in one molecule. 3′,6′-Disulfated lactose **7** showed characteristic behavior towards each of the three enzymes as shown in Table 1; this compound is not a substrate for the snail enzyme, but is an excellent substarte for the limpet enzyme and an acceptable one for the abalone enzyme. The desulfated product of both enzymes could be identified as the 6′-monosulfated lactoside **8**.‡‡ Thus, the sulfatases studied here showed a clear tendency to hydrolyze the 3-sulfate group of galactose and the 3′-sulfate of lactose. This activity can be ascribed to the ability of arylsulfatase A to catalyze desulfation for sulfatides.[22]

In conclusion, we have presented a convenient, regioselective, chemoenzymatic method of sulfating pNP-β-D-galactosides **2**–**4** and pNP-lactosides **6**–**8**. Synthesis and application of glycoconjugate polymers carrying each of these sulfated sugars are in progress and will be reported in due courses.

A new class of photochromic 1,2-diarylethenes; synthesis and switching properties of bis(3-thienyl)cyclopentenes

Linda N. Lucas, Jan van Esch, Richard M. Kellogg* and Ben L. Feringa*

Department of Organic and Molecular Inorganic Chemistry, University of Groningen, Nijenborgh 4, 9747 AG Groningen, The Netherlands. E-mail: r.m.kellogg@chem.rug.nl; b.l.feringa@chem.rug.nl

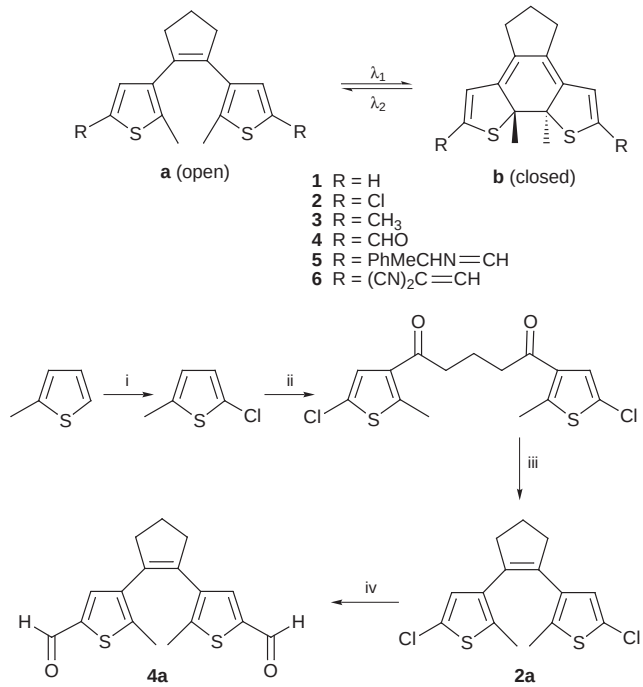
Received (in Cambridge, UK) 8th September 1998, Accepted 17th September 1998

A novel synthetic route to diarylethenes fixed in a cyclopentene based on titanium-mediated carbonyl coupling leads to bis(3-thienyl)cyclopentenes that show photochromic behaviour similar to that of known diarylethenes.

Diarylethenes constitute an important class of photochromic molecules, as they are thermally irreversible and show high fatigue resistance,[1] which are promising features for application in optical data storage[2] and as molecular switches.[3,4] The aryl groups are bound to a cycloalkene to prevent *cis–trans* isomerization, which might compete with photocyclization. 1,2-Bisaryl-substituted maleic anhydride,[5] maleimide[6] and perfluorocyclopentene[7] moieties have been employed so far. Each bridging unit has its advantages and disadvantages. Diarylmaleic anhydrides are readily accessible, but are sensitive to acidic conditions and need certain types of aryl derivatives to maintain their photofatigue resistance in the presence of air.[8] Diarylmaleimides are also sensitive to acidic conditions and furthermore show some degradation in the presence of oxygen.[9] Diarylperfluorocyclopentenes exhibit excellent photochromic behaviour, since up to 80 °C they are stable in the presence of air during cyclization, unless strong electron-donating and −withdrawing substituents are introduced at the 5-position of the thiophene ring.[10] Despite these highly attractive properties the expensive and rather volatile starting material octafluorocyclopentene and the low yields commonly found in double substitution reactions of octafluorocyclopentene with lithiated thiophenes are major disadvantages.

Herewith we present a new class of diarylethenes, the dithienylcyclopentenes, and a novel synthetic route to diarylethenes based on titanium-mediated carbonyl coupling. The synthesis can be performed on a large scale from rather cheap starting materials (Scheme 1). We envisioned that an intramolecular McMurry coupling of a bisthienyl substituted 1,3-dicarbonyl compound would be a feasible route to 1,2-dithienylcyclopentenes. Compounds **1–6**† were synthesized starting from 2-methylthiophene, which was chlorinated at the 5-position with NCS in AcOH and benzene, followed by a Friedel–Crafts reaction with $AlCl_3$ and glutaryl chloride at 0 °C. The resulting 1,5-bis(5-chloro-2-methyl-3-thienyl)pentadione was used in a McMurry reaction[11] with $TiCl_3(THF)_3$ and Zn in THF at 40 °C to provide **2a**. Starting from 2,5-dimethylthiophene, **3a** was obtained *via* the same procedure as described above. By using Mg instead of Zn in the McMurry reaction with 1,5-bis(5-chloro-2-methyl-3-thienyl)pentane-1,5-dione, **1a** was obtained.‡ Dialdehyde **4a** was synthesized by double lithiation of **1a** or **2a** followed by quenching with DMF. The conversion of **4a** to **5a** and **6a** was performed according to published procedures.[10,12] Enantiomerically pure (+)-(*R*)-1-phenylethylamine was used in the synthesis of compound **5**.[12] Although the yields in the low-valent titanium coupling step are still modest, this new route provides ready access to a variety of dithienylcyclopentenes.

The photochromic behaviour was followed by both ^1H NMR and UV spectroscopy. Fig. 1 illustrates the change in absorption of a solution of **4a** in benzene upon irradiation at 313 nm. A new absorption band appeared at 583 nm due to formation of the closed form, which has an extended conjugated structure. Table 1 shows the UV–VIS data for the open and closed forms of the new photochromic compounds. Compared to the known diarylethene derivatives the wavelengths at the absorption maxima of the closed forms show a blue shift; only **6b** measured in benzene showed the same absorption maximum in the closed form as was reported earlier for the perfluorocyclopentene analog.[10] The diarylethenes **1a**, **2a** and **3a** turn yellow upon UV irradiation, which is unusual; no diarylethene compounds showing this behaviour have been described in literature. The



Scheme 1 *Reagents and conditions*: i, NCS, AcOH, benzene, reflux, 80%; ii, $AlCl_3$, glutaryl chloride, CS_2, 0 °C, 94%; iii, $TiCl_3(THF)_3$, Zn, THF, 40 °C, 44%; iv, Bu^nLi, DMF, 39%.

4b	CH_2Cl_2	580	6.9
5a	hexane	305[a]	23.5
5b	hexane	557	13.1
6a	benzene	391	41.6
6b	benzene	726	29.8
6a	CH_2Cl_2	395	27.6
6b	CH_2Cl_2	734	20.1

[a] Shoulder.

absorption spectra of compounds **1b** and **3b** show no maxima in the visible region. Therefore diarylethenes **1**–**3** are not suitable for optical switching. Upon photochemical ring closure of **4a**, **5a** (λ = 313 nm) and **6a** (λ = 405 nm), only one methyl signal appeared at high field in their ^{1}H NMR spectra.§ In accordance with the Woodward–Hoffmann rules,[13] we anticipate conrotatory ring closure and a *trans* disposition of the methyl groups.

The half life of the thermal ring opening in benzene at 60 °C of compound **6b** is 4.27 min. Compared to the perfluorocyclopentene analog[10] it shows slower thermal ring opening. Preliminary investigations show that compounds **4b**, **5b** and **6b** are thermally stable under ambient conditions. Finally a number of photochemical bleaching and colouring experiments were performed with compounds **4** and **5**. Dialdehyde **4** showed a ±8% decrease in absorption (UV–VIS) after one cycle, but bisimine derivative **5** performed very well and after ten cycles no degradation was detected. For compounds **1**–**3** it was not possible to perform such switching cycles, because it was impossible to bleach the molecules completely due to a minor difference between the absorption maxima of the open and closed forms of the compounds.

In conclusion a facile synthetic route to a new class of diarylethenes, bis(3-thienyl)cyclopentenes, has been developed. It appears that these bis(3-thienyl)cyclopentenes, which are now readily accessible, show photochromic behaviour, similar to known diarylethenes. Provided the proper substituents are present thermal irreversibility and fatigue resistance are observed. Assessment of the scope of this new methodology and study of applications of these new photochromic compounds is in progress.

Notes and references

† All compounds were fully characterized showing spectroscopic and analytical data in accordance with the structures shown.

‡ Dechlorination occurs during McMurry coupling with low valent titanium prepared using Mg.

[b] *Chemical Analysis Center, Chiba University, Yayoi-cho, Inage-ku, Chiba 263-8522, Japan*

Received (in Cambridge, UK) 16th July 1998, Accepted 21st September 1998

_O_-Methyl _N_-(2,2-dimethylbut-3-enoyl)-_N_-phenylthiocarbamate crystallized in the chiral space group $P2_1$, and the solid state photoreaction initiated intramolecular [2+2] thietane formation followed by rearrangement, leading to optically active γ-thiolactone.

Solid state photoreaction provides product selectivity and stereoselectivity compared to reactions that occur in solution due to restriction of molecular movement imposed by the crystal lattice.[1–5] Stereospecific solid state chemical reactions of chiral crystals formed by achiral materials are defined as 'absolute' asymmetric syntheses.[6–11] This asymmetric synthesis must involve two aspects: generating chiral crystals and performing topochemically controlled solid state reactions which yield chiral products. Now we have found a new example of 'absolute' asymmetric synthesis involving the photochemical reaction of an achiral *N*-(β,γ-unsaturated carbonyl)thiocarbamate leading to optically active thiolactone and a unique structure in the crystalline state.

O-Methyl *N*-(β,γ-unsaturated carbonyl)-*N*-phenylthionocarbamates **1a**,**b** were synthesized by acylation of *O*-methyl *N*-phenylthiocarbamate with the corresponding acid chloride in the presence of Et_3N. Recrystallization of **1a** from a hexane yielded colorless crystals; however, single crystals suitable for X-ray crystallographic analysis could not be obtained. On the other hand, thiocarbamate **1b** afforded prismatic single crystals, which were analysed by X-ray crystallography.† It is notable that the conformation of the imide chromophore is *E*,*E*, and remarkably twisted from the ideal imide plane. (Fig. 1) The twist angle of the C(=O)–N moiety is 47.4° and is much greater than that of the C(=S)–N moiety (19.4°).[12] This structure is consistent with the lone pair electrons of the nitrogen atom being conjugated through the thiocarbonyl rather than through a carbonyl group. The phenyl ring is almost orthogonally twisted to the sp^2 nitrogen atom (67°).

Irradiation of a benzene solution of **1a** gave tricyclic thietane, 2,2-dimethyl-5-methoxy-4-phenyl-6-thia-4-azatricyclo-[5.4.$0^{1,7}$.$0^{1,5}$]nonan-3-one **2a**, in 83% yield (Table 1, entry 1). The solid state photolysis also gave racemic **2a** (81%, 80% conversion) (entry 2). The solid state reaction proceeded even at −78 °C (entry 3). The structure of **2a** was determined on the basis of spectroscopic data.

When thiocarbamate **1b** was irradiated in benzene solution, thiolactone **3b** was isolated in 90% yield (entry 4). The solid state photolysis also gave thiolactone **3b** in 85% yield when the reaction conversion was 78% as shown in Table 1, entry 4. The IR spectrum of **3b** showed characteristic absorption due to the thiolactone carbonyl at 1697 cm^{-1} and the C=N bond at 1666 cm^{-1}. The ^1H NMR spectrum showed the absence of an alkenyl group. The ^{13}C NMR spectrum displayed the absence of the signal due to the thiocarbonyl carbon at δ_C 190.8 and exhibited new a sp^3 triplet peaks at δ 30.7 and a doublet at δ 47.7. New singlet peaks derived from the thioester and imino carbons were exhibited at δ 210.7 and 160.7, respectively.

The stereoselective generation of the chiral center is exemplified by the formation of **3b** at the C-4 position {$[\alpha]_D^{20}$ = +8 (*c* 1.0 in $CHCl_3$, 10% ee)} (entry 5). The enantiomeric purity of **3b** was determined by HPLC employing a chiral cell OJ (Daicel Chemical Industry). The solid state photoreaction also proceeded at −78 °C and an optically active compound which showed a better ee value was formed; 20% ee at 84% conversion (entry 6) and 31%ee at 15% conversion (entry 7). The space group of the crystal of **1a** could not be determined because **1a** did not afford single crystals suitable for X-ray crystallography; however, the production of racemic **2a** shows that the crystals are achiral (entries 2 and 3).

A plausible mechanism for the formation of **3** is rationalized on the basis that photolysis of **1** undergoes [2+2] cyclization to thietane **2** and subsequently rearranges to thiolactone **3** (Scheme 1). Ring opening of the initially formed thietane **2** leading to zwitterion **5**, which is facilitated by the lone pair electrons of the nitrogen and oxygen atoms, and subsequent nucleophilic reaction between the thiolate anion and the carbonyl carbon to give **3**.[13] For the tricyclic thietane **2a**, nucleophilic addition of thiolate anion is difficult, because of the conjunction of the

cyclohexane ring, which results in the formation of stable thietane **2a**.

It is generally accepted that a solid state reaction proceeds with minimum atomic and molecular motion. Therefore, the reactivity is determined the by atomic arrangement, represented by the distances and angles between the reaction sites. From the X-ray structural analysis of the starting thiocarbamate **1b**, the distances between the thiocarbonyl sulfur atom S(1) and the alkenyl carbon C(14) and between the thiocarbonyl carbon C(1) and the alkenyl carbon C(13) are 4.69 and 3.00 Å, respectively (Fig. 1). The fact that the reaction proceeded under these restricted conditions, in which the S(1)···C(14) distance is significantly longer than the sum of the van der Waals radii (3.23 Å), is accounted for by the fact that the initial reactions occurred in a defect in the crystalline lattice, and later reactions occurred in the increasing number of defective regions formed during reaction. Furthermore, two plausible factors are responsible for the relatively low enantiomeric excess of **3b**. One is that the process of cyclization results in increasing numbers of defective regions in the surrounding crystal lattice, in which racemization of the reactant easily takes place. The other is the structural interconversion of the biradical intermediate. If the interconversion of the intermediate seven-membered 1,4-diradical **4** is possible in the space in the crystal lattice or in the increasing number of defective regions where the C–S bond formation took place, it would result in lowering of optical purity.

In conclusion, photoreaction *O*-methyl *N*-(β,γ-unsaturated carbonyl)-*N*-phenylthiocarbamate provides a new example of absolute asymmetric synthesis using a chiral crystalline environment.

Impurity annihilation; a strategy for solution phase combinatorial chemistry with minimal purification

Anthony G. M. Barrett,*† Marie L. Smith* and Frederic J. Zecri

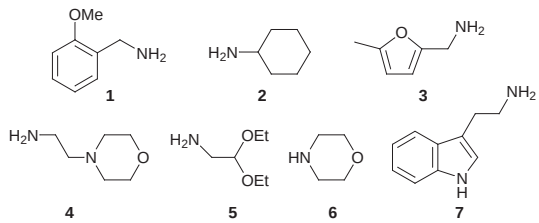
Received (in Cambridge, UK) 26th August 1998, Accepted 7th September 1998

The selective annihilation of all contaminants in the solution phase formation of amides or sulfonamides is accomplished by their incorporation into a polyurea and removal by filtration.

Combinatorial chemistry has received much attention of late as an engine for the discovery of new pharmaceuticals, catalysts and materials. Library generation may be accomplished using solid phase organic synthesis or by using conventional solution phase chemistry.[1] There is, however, an unending controversy as to which of the major synthetic strategies for library synthesis is superior. Polymer supported synthesis has the clear advantages of ease of manipulation, the ability to drive reactions to completion by use of excess reagent and isolation of the product by filtration alone. However, many synthetic transformations on solid phase encounter difficulties of analysis and reaction tracking. The development of new reactions on a solid phase is frequently time consuming although once developed they may be used in rapid automated production of libraries. In contrast, the primary advantage of solution phase chemistry is its familiarity to the synthetic chemist. Additionally reactions are generally amenable to easy tracking and analysis. Nonetheless the complicated work-up procedures usually associated with such reactions in solution have been a major hurdle to automation and the use of multi-step sequences. Recently the use of polymer supported scavengers has been described as a method to overcome these problems.[2] Disadvantages include the often slow removal of contaminants and variable quality of the libraries produced. Other strategies include the use of fluorous phase chemistry. Disadvantages here include the lack of fluorinated reagents which often need to be prepared by highly specialised syntheses.[3]



Herein we report a novel method which readily addresses the problem of solution phase library clean-up discussed above. Our approach is based upon the selective annihilation of all contaminants which are then removed by simple filtration as an insoluble product. The procedure is exemplified by the synthesis of amides from the condensation reaction of acid chlorides with amines. Reaction of an acid chloride with excess amine may be used to prepare pure amides in the solution phase without chromatography simply by the polymerisation of the excess amine and filtration (Scheme 1). Co-polymerisation of 1,4-phenylene diisocyanate and pentaethylenehexamine was used to effectively remove the excess amine as a highly insoluble easily filtered polyurea (Table 1).‡ The procedure appears widely applicable with both primary and secondary amines affording the corresponding amides in excellent yield and purity. One caveat is the presence of a second unprotected indole NH function (entry 7, Table 1) which affords none of the desired amide due to its propensity to undergo reaction with 1,4-phenylene diisocyanate and thence to polymer. Sulfonamides may be prepared by the reaction of a sulfonyl chloride with excess amine (Scheme 2 and Table 2).‡ The use of an arenesulfonyl chloride generally gave superior results, both in terms of yield and purity, compared with an alkanesulfonyl chloride.

Amide and sulfonamide formation may also be accomplished by the reaction of amine with an excess of acyl or sulfonyl chloride, respectively (Scheme 3). Under these circumstances it is necessary to add an excess of poly(vinylpyridine) to capture liberated hydrogen chloride and enable amide or sulfonamide formation to proceed to completion. The excess acyl or sulfonyl chloride is then scavenged by the addition of the polyamine (3

equiv.) followed by the addition of the diisocyanate (3 equiv.) to induce polymerisation to the polyurea. Both the polyurea and poly(vinylpyridine) are then simply removed by filtration. Once again excellent yields and purities are obtained (results for various chlorides are listed in Table 3).§ Thus component annihilation is suitable for the removal of either excess electrophilic or nucleophilic components.

In summary, we have developed a method for the efficient 'clean-up' of a number of solution phase reactions that affords the desired products in excellent yields and purities in a reasonable time frame. This methodology has been successfully carried out manually and with the use of automation.¶ Extension of this methodology to the synthesis of esters and for the annihilation of other common reagents‖ will be reported in due course.

‡ Typical procedure for the formation of amides or sulfonamides using an acid chloride or sulfonylchloride respectively with excess amine: To a solution of the acid chloride or sulfonamide (0.1 mmol) in CH_2Cl_2 (1 ml) was added a solution of the amine (3 equiv.) in CH_2Cl_2 (1 ml). The mixture was stirred at room temperature for 30 min and a solution of 1,4-phenylene diisocyanate (6 equiv.) in CH_2Cl_2 (4 ml) was added. The mixture was stirred at room temperature for 40 min and a solution of pentaethylenehexamine (2.5 equiv.) in CH_2Cl_2 (4 ml) was added. After stirring for 1 h, the heterogeneous mixture was filtered. Evaporation of the solvent under reduced pressure afforded the expected amide in high yield and purity (see Tables 1 and 2 respectively).

§ Typical procedure for the formation of amides or sulfonamides using an amine with excess acid chloride or sulfonyl chloride respectively: To a solution of the amine (0.1 mmol) in CH_2Cl_2 (1 ml) was added a solution of the acid chloride or sulfonyl chloride (3 equiv.) in CH_2Cl_2 (1 ml) and poly(vinylpyridine) (100 mg). The mixture was stirred at room temperature for 30 min when a solution of pentaethylenehexamine (3 equiv.) in CH_2Cl_2 (4 ml) was added. The mixture was stirred at room temperature for 40 min. and a solution of 1,4-phenylene diisocyanate (3 equiv.) in CH_2Cl_2 (4 ml) was added. After stirring for 1 h, the heterogeneous mixture was filtered. Evaporation of the solvent under reduced pressure afforded the expected amide or sulfonamide in high yield and purity (see Table 3).

¶ Automated synthesis was carried out using a Nautilus™ 2400 Organic Synthesizer (Argonaut Technologies, Inc.).

‖ Kurth has recently reported the use of 1,4-phenylene diisocyanate as a convenient reagent for the generation of nitrile oxides from nitroalkanes since the by product urea readily polymerises (see ref. 4).

Thermal decomposition of 1-(aminophenyl)-5-*tert*-butyl-4,4-dimethyl-2,6,7-trioxabicyclo[3.2.0]heptanes: unusual O–O bond cleavage competing with normal fragmentation of 1,2-dioxetanes

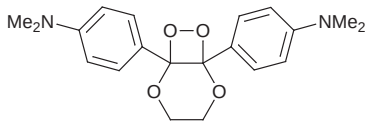
Masakatsu Matsumoto,* Hiroyuki Murakami and Nobuko Watanabe

Department of Materials Science, Kanagawa University, Tsuchiya, Hiratsuka, Kanagawa 259-12, Japan.
E-mail: matsumo@info.kanagawa-u.ac.jp

Received (in Cambridge, UK) 2nd September 1998, Accepted 21st September 1998

A dioxetane (*ortho*-3a) decomposes thermally to give the normal carbonyl product while dioxetanes (*ortho*-3b–c) decompose at low temperature to afford heterocycles 6 and 7 in high yields.

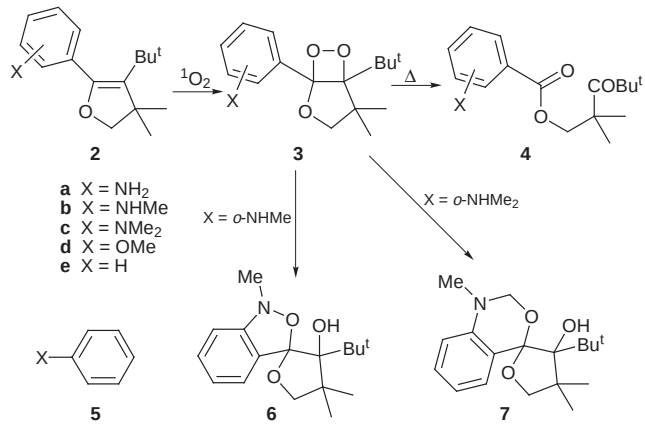
Thermal decomposition of rather simple 1,2-dioxetanes gives in general two carbonyl products.[1] Charge transfer (CT)-induced decomposition of dioxetanes bearing an electron donor also affords two carbonyl fragments, although its mechanistic aspects and accompanying luminescence should be differentiated from those of simple thermolysis.[2–4] A dioxetane



1

bearing *p*-(*N*,*N*-dimethylamino)phenyl groups (**1**) is a typical example of species that undergo CT-induced decomposition.[5] In the course of our investigations on highly efficient chemiluminescent substrates, we found that dioxetanes (*ortho*-**3b–c**) bearing a phenyl substituted with an *N*-methylamino or *N*,*N*-dimethylamino group at the *ortho* position suffer unusual decomposition competing with normal fragmentation, although their unsubstituted *o*-amino (*ortho*-**3a**), *p*-amino (*para*-**3**), and *m*-amino analogues (*meta*-**3**) undergo thermal decomposition to afford normal carbonyl products.

When a dihydrofuran (*para*-**2a**) (100 mg) was irradiated in the presence of catalytic amount of tetraphenylporphin (TPP) in CH_2Cl_2 (10 ml) with a 940 W Na lamp under O_2 atmosphere at 0 °C for 1 h, a dioxetane (*para*-**3a**) bearing a *p*-aminophenyl group† was selectively produced (Scheme 1), although it decomposed considerably during isolation by chromatography (SiO_2) (colorless crystals melted at 83.0 °C, 23% yield). Similar singlet oxygenation of dihydrofurans *para*-**2b** and *para*-**2c** gave dioxetanes *para*-**3b** (*N*-methylamino) and *para*-**3c** (*N*,*N*-dimethylamino),‡ respectively. These dioxetanes (*para*-**3a–c**) decomposed *via* a first-order process to afford the corresponding keto esters (*para*-**4a–c**) exclusively in hot toluene-d_8. The decomposition rates were measured at various temperatures (70–110 °C) in toluene-d_8 and activation parameters for thermolysis of *para*-**3a–c** were estimated as shown in Table 1, where those for dioxetanes bearing a *p*-methoxyphenyl (*para*-**3d**) and a phenyl moiety (**3e**), which were synthesized similarly, are also cited. Table 1 discloses that (i) the thermal susceptibility of *p*-amino derivatives (*para*-**3a–c**) is prominent, (ii) the order of half-life ($t_{1/2}$) (at 25 °C) is *para*-**3c** < *para*-**3b** < *para*-**3a** << *para*-**3d** < **3e**, and (iii) this order is in good agreement with the order of formal oxidation potential of the parent arenes (**5**) corresponding to dioxetanes (*para*-**3a–e**): **5c** < **5b** < **5a** << **5d** < **5e**.[6] These results are consistent with a report on **1** by Schaap[5] and show that CT-induced decomposition takes place most likely for a dioxetane bearing an aryl moiety with low oxidation potential. However, it should be noted that these marked differences in rates of thermal decomposition of *para*-**3** were not observed for *meta*-analogues (*meta*-**3a**, *meta*-**3d**,[7] **3e**): even *meta*-**3a** is very persistent thermally, as shown in Table 1.



Scheme 1

These facts prompted us to next examine thermolysis of *ortho*-analogues of **3a–c**.

An *o*-aminophenyl moiety was first expected to induce decomposition of dioxetanes (*ortho*-**3a–c**) into **4** similarly to *para*-**3a–c**. A dioxetane bearing an *o*-aminophenyl moiety (*ortho*-**3a**) was synthesized from a dihydrofuran (*ortho*-**2a**) similarly to the case of *para*-**3a** (62% isolated yield). Dioxetane (*ortho*-**3a**) was as unexpectedly stable as its *meta*-analogue (*meta*-**3a**), although it decomposed into the normal product (*ortho*-**4a**) exclusively on heating (see Table 1). The result suggests that the CT from an *o*-aminophenyl moiety most likely occurs far less easily than from a *p*-aminophenyl moiety. The significant difference in ease of CT may be attributed mainly not to electronic factors but to the steric characteristics of the aromatic electron donor: the aryl group for *ortho*-**3a** does not rotate around the C–C bond to the dioxetane ring as freely as that for *para*-**3a** because of steric hindrance by the *o*-amino group.§ This tendency was also observed for the *o*-methoxy derivative (*ortho*-**3d**) which is far more persistent than *para*-**3d**, *meta*-**3d** and the parent dioxetane **3e**.

Singlet oxygenation (−78 °C) of an olefin (*ortho*-**2b**) substituted with an *o*-(*N*-methylamino)phenyl group also gave

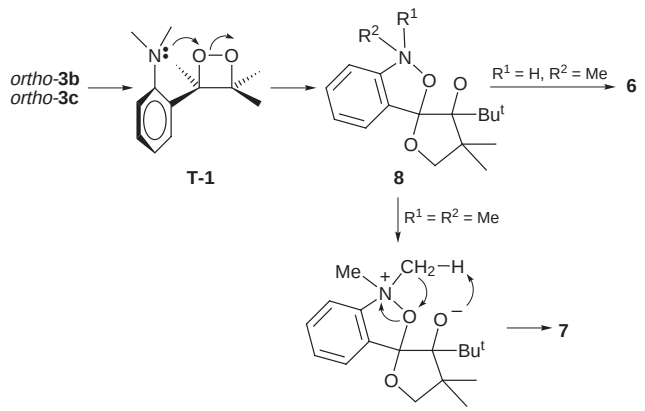
ortho-**3a**	30.1	12.9	28	
ortho-**3d**	30.7	12.0	660	

[a] Thermolysis was carried out in toluene-d_8 or in *p*-xylene-d_{10}. [b] Oxidation half-wave potential (ref. 6); solvent system: $R_4N^+ClO_4^-$. (R = Bu or Pr)/MeCN, reference electrode = SCE, working electrode = Pt.

the corresponding dioxetane (*ortho*-**3b**). The thermal decomposition of *ortho*-**3b** exhibited features completely different from those for the dioxetanes described above. On standing for several hours at room temperature in toluene or $CDCl_3$, *ortho*-**3b** changed into an unusual product (**6**) (pale yellow granules melted at 59.0 °C)† without any detectable amount of the normal product (*ortho*-**4b**) expected initially. Dioxetane *ortho*-**3b** decomposed, however, into *ortho*-**4b** in high yield on heating in refluxing toluene. It should be noted that both products **6** and *ortho*-**4b** are thermally stable and do not change into each other upon heating. Thus, we carried out thermolysis of *ortho*-**3b** at various temperatures in toluene-d_8 and measured the product ratio of **6**:*ortho*-**4b**) by 1H NMR spectroscopy: **6**:*ortho*-**4b** = 93:7 at 50 °C, 72:28 at 70 °C, 35:65 at 90 °C, 11:89 at 110 °C. These results suggest that decomposition to *ortho*-**4b** (mode **A**) and unusual decomposition to **6** (mode **B**) take place concurrently in a temperature-dependant manner for dioxetane *ortho*-**3b**.

The decomposition of mode **B** is most likely rationalized by a mechanism similar to the Adam reaction,[9]¶ comprising the intramolecular nucleophilic attack of an *N*-methylamino group at the O–O moiety of the dioxetane and successive O–O bond fission accompanying a proton exchange in an intermediary twitterion (**8**, R^1 = H, R^2 = Me), as illustrated in Scheme 2. Although the proposed mechanism includes multi-step reactions, the decomposition of *ortho*-**3b** to **6** should be essentially a unimolecular reaction as in the pathway to *ortho*-**4b** (mode **A**). Consequently, the product ratio (**6**/*ortho*-**4b**) described above should be equal to the ratio of rate constants (k**B**/k**A**) for the corresponding modes at a given temperature. By plotting log(**6**/*ortho*-**4b**) *vs*. 1/T, we estimated differences in activation energy E_a and log A between modes **A** and **B** as $\Delta E_a = E_a$ (**A**) − E_a (**B**) = 18.9 kcal mol^{-1} and $\Delta \log A = \log A$ (**A**) − $\log A$ (**B**) = 11.7. The result suggests that the mode **B** requires far a lower activation energy and proceeds through a transition state far more highly ordered than mode **A**. As such in the transition state, one can image a structure where the *o*-aminophenyl moiety lies in or near the plane comprising O–C–C shown as **T-1**.

Finally, we attempted to synthesize a dioxetane (*ortho*-**3c**) bearing an *o*-(*N*,*N*-dimethylamino)phenyl moiety. When singlet oxygenation of a dihydrofuran (*ortho*-**2c**) was carried out similarly to the case of *ortho*-**2a** in CH_2Cl_2 at 0 °C, *ortho*-**2c** gave none of the expected dioxetane (*ortho*-**3c**) but gave instead an unprecedented oxygenation product **7** (colorless granules, mp 140.0 °C, 93%)† and a small amount of a keto ester (*ortho*-**4c**) (7%). The low-temperature singlet oxygenation of *ortho*-**2c** gave similar results, so that we could obtain little direct evidence for formation of a dioxetane (*ortho*-**3c**). However, the reaction is reasonably thought to proceed through an unstable dioxetane (*ortho*-**3c**), because both **7** and *ortho*-**4c** are products in which both carbons in the C=C moiety of the starting dihydrofuran (*ortho*-**2c**) are oxygenated. Formation of the unique cyclic aminal **7** is probably attributed to an intramolecular nucleophilic reaction of a dimethylamino group with O–O as in the case of *ortho*-**3b** to **6**; the initially formed zwitterionic intermediate (**8**, R^1, R^2 = Me) may undergo Stevens-like rearrangement[10] to afford **7** as shown in Scheme 2.¶‖



Scheme 2

In conclusion, the present results show that, for dioxetanes bearing a substituted phenyl moiety, a *p*-amino group accelerates significantly decomposition of the dioxetane in the order of H < OMe << NH_2 < NHMe < NMe_2, while *meta*-analogues are insensitive to this substituent effect. On the other hand, *o*-methylamino and *o*-dimethylamino groups cause preferentially unusual decomposition of dioxetane by their intramolecular nucleophilic attack at O–O of the dioxetane, though their unsubstituted amino analogue decomposes to give the normal carbonyl product.

Notes and references

† Structures of all products obtained here were characterized by ^{1}H NMR , ^{13}C NMR, IR, and mass spectral analysis. *Selected data* for **6**: δ_H(400 MHz, $CDCl_3$) 0.92 (s, 9H), 1.22 (s, 3H), 1.54 (s, 3H), 3.14 (s, 3H), 3.72 (qAB, J 7.3, 2H), 4.01 (s, 1H), 6.78 (d, J 7.8, 1H), 7.05 (ddd, J 7.8, 7.3, 1.0, 1H), 7.33 (ddd, J 7.8, 7.3, 1.0, 1H), 7.54 (d, J 7.8, 1H); δ_C(100 MHz, $CDCl_3$) 21.4, 25.7, 28.2, 39.4, 46.7, 47.6, 80.7, 88.4, 110.8, 119.5, 122.3, 127.5, 127.5, 129.8, 151.8. For **7**: δ_H(400 MHz, $CDCl_3$) 0.70 (br s, 9H), 1.19 (s, 3H), 1.50 (s, 3H), 2.86 (s, 3H), 3.73 (qAB, J 7.8, 2H), 4.40 (s, 1H), 4.42 (qAB, J 7.3, 2H), 6.76 (d, J 8.3, 1H), 6.86 (m, 1H), 7.26 (m, 1H), 7.75 (dd, J 7.8, 1.5, 1H); δ_C(100 MHz, $CDCl_3$) 22.7, 26.2, 28.2, 35.1, 40.2, 48.0, 78.5, 79.5, 90.6, 108.0, 112.7, 118.6, 125.2, 129.3, 132.0, 148.9.

‡ Dioxetanes *para*-**3b**,**c** were unstable under the chromatographic conditions, so that the crude *para*-**3b**,**c** including little other than a trace amount of keto ester (*para*-**4b**,**c**) was used without purification for thermolysis.

§ The rate of the CT-induced decomposition of a dioxetane bearing a phenoxide anion as an electron donor has been reported to decrease *via* restriction of rotation of the aromatic ring (ref. 8).

¶ Nucleophilic cleavage of a dioxetane with an aromatic amine is unprecedented, although a *sec*-alkylamine has been reported to cause decomposition of a dioxetane to yield *N*,*N*-dialkyl-*O*-(2-hydroxyethyl)hydroxylamine (Adam reaction) (ref. 9). The possibility cannot be ruled out that the reaction of *ortho*-**3b** to give **6** proceeds by a mechanism including attack of a diradical formed initially by homolytic O–O bond cleavage on an amino group, although *ortho*-**3a** should also give an analogue of **6** by this mechanism. The marked difference in decomposition mode between *ortho*-**3a** and *ortho*-**3b** is most likely attributed to a difference in nucleophilicity between NH_2 and NHMe: the order of nucleophilicity would be NH_2 < NHMe < NMe_2. The thermal instability of *ortho*-**3c** might be also rationalized by the high nucleophilicity of the NMe_2 group.

‖ Nucleophilic attack of a *tert*-alkylamine on a dioxetane has been reported to lead only to normal carbonyl products through Grob fragmentation (ref. 11) of an intermediary zwitterion (ref. 9). For an intramolecular reaction as presented here, a zwitterion such as **8** might, however, cause predominantly Stevens-like rearrangement, because an oxy anion would lie so close to a methyl of the ammonium ion (ON^+Me_2) that the oxy anion is able to easily abstract a methyl proton. The formation of a minor product (*ortho*-**4c**) may be due to Grob fragmentation of **8** and/or direct decomposition of *ortho*-**3c** as in the case of *para*- and *meta*-**3**.

Chloride ion effects on kinetic resolution in Pd-catalysed allylic alkylation

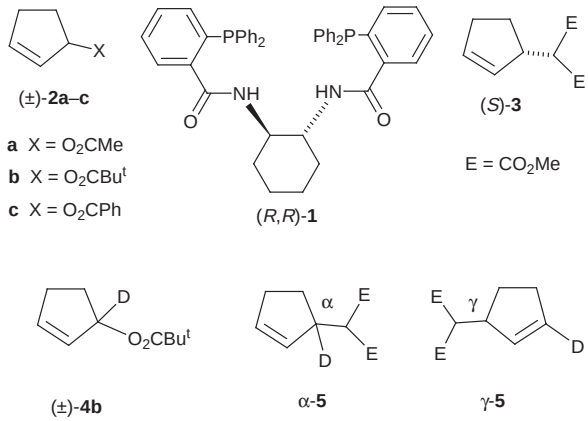
Guy C. Lloyd-Jones* and Susanna C. Stephen

School of Chemistry, Cantock's Close, Bristol, UK BS8 1TS. E-mail: guy.lloyd-jones@bris.ac.uk

Received (in Cambridge, UK) 7th August 1998, Accepted 22nd September 1998

Chloride ion (5 mol%) accelerates and stabilises the oxidative addition of the slow-reacting enantiomer of cyclopentenyl pivaloate to Pd⁰ complexes bearing the Trost modular ligand.

Astute chemical design and serendipity have led to a range of very effective ligands for enantioselective Pd-catalysed allylic alkylation.[1] Cyclic substrates have proven the hardest systems to substitute with high enantiomeric excess (ee) and the modular



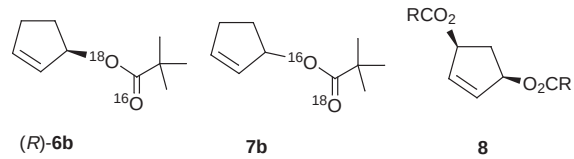
ligand systems of Trost,[2] *e.g.* (*R*,*R*)-**1**, have been almost[3] uniquely successful for this reaction type.

We recently reported a mechanistic study[4] of the 'memory effect'[5] in the '[Pd(*R*,*R*)-**1**]'-catalysed reaction of **2a** with sodio dimethyl malonate ($NaCHE_2$; E = CO_2CH_3) in THF to give (*S*)-**3**. Herein we report on the effect of catalytic chloride ion on the kinetic resolution[6] of **2** and **4** by '[Pd(*R*,*R*)-**1**]'.

Pro-catalysts generated *in situ* from a bidentate ligand (L_2) and $[Pd(allyl)Cl]_2$ are often employed in Pd-catalysed allylic alkylation with $NaCHE_2$. Entry into the catalytic cycle is assumed to proceed *via* alkylation–reduction of $[(L_2)Pd^{II}$-π-allyl][Cl] to generate NaCl, allyl-CHE_2 and '$[Pd(L_2)]$'.[7] Using 2.25 equiv. $NaCHE_2$ and 5 mol% of '[Pd(*R*,*R*)-**1**]' generated *in situ* from (*R*,*R*)-**1** and $[Pd(allyl)Cl]_2$ (**1**/Pd = 3/2) complete conversion of both enantiomers of deuterium labelled pivaloate (±)-**4b** to a mixture of isotopomeric α- and γ-**5** occurs, in THF, within 10 min at room temp. (Table 1, entry 1).

When the reaction was quenched after 5 s, there was evidence of a moderate kinetic resolution ($k_S/k_R \approx 9$): recovered **4b** (25%) was 88% ee (*R*) and α/γ-**5** were obtained in 38% yield.† However, when the '[Pd(*R*,*R*)-**1**]' was generated under chloride-free conditions[8] from $[Pd_2dba_3.CHCl_3]$ (dba = dibenzylideneacetone) or $[Pd(allyl)(MeCN)_2][OTf]$ (**1**/Pd = 3/2) the rate of reaction was reduced and kinetic resolution enhanced. After 10 min, α-**5** and γ-**5** arising exclusively (≥97%) from matched (*S*)-**4b** were obtained in 38–43% yield and mismatched (*R*)-**4b** had been partially resolved (47–51% ee) (Table 1, entry 2). After a further 2 h (*R*)-**4b** was recovered in 28–32% yield and ≥90% ee.‡ There was no racemisation or further conversion[9] of (*R*)-**4b** (despite a large excess of $NaCHE_2$) over a period of 48 h. However, with substoichiometric (0.5 equiv.) $NaCHE_2$ rapid (≤60 s) partial resolution of (±)-**2c** was followed by Pd-catalysed racemisation of remaining (*R*)-**2c** (Fig. 1).

With excess nucleophile, labelled substrates were recovered unscrambled—there was no evidence of the γ-^{2}H isotopomer of (*R*)-**4b** and reaction of (±)-**6b** (95% ^{18}O) afforded (*R*)-**6b** (≥90% ee) and no acyl-^{18}O isotopomer **7b**. These results suggest non-reversible Pd-allyl formation from (*R*)-**4** and (*R*)-**6** under turn-over conditions[10]§ and implicate the nucleophile in the catalyst deactivation process.



The efficient kinetic resolution of (±)-**4b** by '[Pd-(*R*,*R*)-**1**]' is not in itself surprising—the tight 'chiral pocket'[11] of (*R*,*R*)-**1** is known to effect highly enantioselective (*matched)* ionisation of *meso*-diesters **8**.[2b] More remarkable however, is that 5 mol% chloride ion increases the conversion (not *via* racemisation) of mismatched[12] (*R*)-**4b** (Table 1, compare entries 1 and 2) and inhibits catalyst deactivation. The importance of halide ions, at

Table 1 The effect of chloride on kinetic resolution with Pd^{II} *vs.* Pd^0 catalyst pre-cursors, in THF and CH_2Cl_2

3	Pd^{II} [a] + dba[b] + LiCl[c] or Pd^0 [a] + LiCl[c]	33 (< 5:95)	14 (> 95:5)	17–28 (> 95:5)
4	Pd^{II} [a] + LiCl[c]	46 (43:57)	31 (39:61)	0 (—)
5[d]	Pd^{II} [a]	20 (11:89)	5 (66:34)	74 (64:36)
6[d]	$[Pd(allyl)Cl]_2$	60 (33:67)	27 (19:81)	0 (—)

[a] Pd^{II} = $[Pd(allyl)(MeCN)_2][OTf]$; Pd^0 = Pd_2dba_3·$CHCl_3$. [b] 7.5 mol% dba. [c] 5 mol% LiCl. [d] In CH_2Cl_2, 145 min.

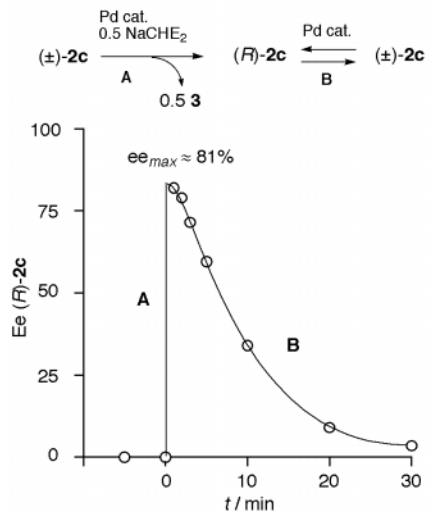

Fig. 1 Kinetic resolution (**A**) then racemisation (**B**) of (±)-**2c** on reaction with 0.5 equiv. $NaCHE_2$, catalysed by chloride-free pro-catalyst generated from 7.5 mol% (*R*,*R*)-**1** and 5 mol% [Pd(allyl)$(MeCN)_2$][OTf].

both the Pd^0 and Pd^{II} oxidation state in cross-coupling and Heck reactions is well documented.[13] However, although a variety of halide effects have been reported in Pd-catalysed allylic substitution[14] these are all mechanistically implicated at the Pd^{II}-π-allyl stage.

To gain further information, we compared the effect of chloride on the selectivity with different pro-catalyst systems in THF. Use of 5 mol% of the Pd^0 pro-catalyst derived from (*R*,*R*)-**1**, [Pd_2dba_3·$CHCl_3$] and LiCl (**1**/Pd/Cl = 3/2/2) resulted in even more effective kinetic resolution giving (*R*)-**4b** (28% yield) in ⩾95% ee in under 10 min (Table 1, entry 3). At this point (*S*)-α-**5** (⩾95% ee) and (*R*)-γ-**5** (⩾90% ee) were derived almost exclusively (> 97%) from matched (*S*)-**4b** and this suggests $k_S/k_R \geqslant 100$.¶ However, complete conversion of residual (*R*)-**4b** to α/γ-**5** occurred in less than 12 h to give α/γ-**5** in 74% yield. Hence the LiCl retarded catalyst deactivation but not kinetic resolution.

With 5 mol% of the Pd^{II} pro-catalyst derived from (*R*,*R*)-**1**, [Pd(allyl)$(MeCN)_2$][OTf] and LiCl (**1**/Pd/Cl = 3/2/2), complete conversion of (±)-**4b** to **5** occurred within 10 min (Table 1, entry 4). When dba (7.5 mol%) was also added to the pro-catalyst mixture, catalysis slowed dramatically and the system behaved similarly to that derived from a Pd^0 source (Table 1, entry 3). When the LiCl was omitted initially but added after 10 min of catalysis, powerful kinetic resolution of (±)-**4b** and catalyst deactivation occurred in the first 10 min and, on addition, the LiCl did not reactivate the catalyst.

The effect of solvent was also briefly studied. In CH_2Cl_2 reactions were slower. There was moderate kinetic resolution (k_S/k_R *ca.* 9) under chloride-(ion)-free conditions (Table 1, entry 5) and a greater 'memory effect' in the presence of 5 mol% chloride (Table 1, entry 6).

Taken together, the results suggest the following: (i) chloride coordination to Pd^0 results in a more reactive and less selective palladate-type catalyst, (ii) palladate formation is disrupted by dba, and (iii) in the absence of chloride and in the presence of $NaCHE_2$, mismatched ionisation of slower reacting (*R*)-**4b** tends to lead to catalyst decomposition.

Generous donations from the Zeneca Strategic Research Fund are gratefully acknowledged. S. C. S thanks the University of Bristol for a Postgraduate Scholarship.

Notes and references

† The deuterium label and stereospecific mechanism allows the distinction of **5** arising from (*R*)- and (*S*)-**4**. Ratios were determined by NMR analysis in C_6D_6 with (+)-Eu(hfc)$_3$: (*S*)-**4b**/(*R*)-**4b** by ^{1}H NMR analysis and (*S*)-α-**5**/(*R*)-γ-**5**/(*R*)-α-**5**/(*S*)-γ-**5** by ^{13}C NMR analysis (see ref. 4).

‡ Analogous results were obtained with (±)-**4a** and (±)-**4c**. Pd-catalysed reaction (5 mol% [(dppf)Pd(allyl)][OTf], THF, 25 °C, 60 s) of the resultant (*R*)-**4a** with 2.25 equiv. $NaCHE_2$ afforded (*R*)-α-**5** and (*S*)-γ-**5** exclusively (> 96%).

§ Reversible ionisation cannot be completely ruled out if a very tight ion-pair {[(**1**)-Pd-(η^x-*c*-C_5H_7)]$^+$[O_2CCMe_3]$^-$} is formed and there is slow relaxation of nucleofuge orientation (*i.e.* equilibration of $^{18}O/^{16}O$) relative to exclusive internal return at the *mismatched* (α) carbon.

¶ For 98% selective conversion of (*S*)-**4b** over (*R*)-**4b** to α/γ-**5** at 43% conversion, $(k_S/k_R)_{calc}$ = 107. This calculation assumes that the slow mismatched ionisation of (*R*)-**4** gives no side products. Thus (k_S/k_R) may be much lower.

Anion-templated formation of a unique inorganic 'super-adamantoid' cage $[Ag_6(triphos)_4(O_3SCF_3)_4]^{2+}$ [triphos = $(PPh_2CH_2)_3CMe$]

Stuart L. James,* D. Michael P. Mingos,* Andrew J. P. White and David J. Williams

Department of Chemistry, Imperial College of Science Technology and Medicine, South Kensington, London, UK SW7 2AY. E-mail: s.l.james@ic.ac.uk; d.mingos@ic.ac.uk

Received (in Basel, Switzerland) 12th August 1998, Accepted 23rd September 1998

In the presence of templating anions, 2 : 3 molar mixtures of triphos and silver(I) cations unexpectedly give novel hexanuclear cages, which result from an unusual '*endo*-methyl' geometry of the triphos ligands.

Multidentate ligands in general tend to promote the formation of metal clusters or aggregates by forming radial metal–ligand bonds which place the metal atoms at the centre of the molecule. For example, 2 : 2 (ligand : metal) diphosphine complexes of silver(I) or copper(I) generally form dinuclear rings shown in Fig. 1(a) and (b), with terminal or bridging anions.[1] Metallocage assembly is receiving increasing attention,[2] and the use of appropriate tripodal phosphines in a 2 : 3 ratio might be expected to give trinuclear cages of the type shown in Fig. 1(c). The only triphos $[MeC(CH_2PPh_2)_3]$ silver(I) complex to be structurally characterised so far is the mononuclear 1 : 1 complex [Ag(triphos)I].[3] Here we report our unexpected observation that a 2 : 3 molar mixture of triphos and silver(I) ions in fact gives a novel hexanuclear cage of formula $[Ag_6(triphos)_4X_4]^{2+}$. The triphosphine ligands assemble with their methyl groups concentrating in the central region of the molecule, and the dative bonds to the complexed phosphino substituents lead to an aggregate of silver ions on the surface. Anions are further complexed to the outside of the cage and appear to play an important templating role.

When solutions of triphos are titrated against a silver(I) salt of an oxo anion [AgX] (X = SO_3CF_3, ClO_4, NO_3) and monitored by $^{31}P\{^1H\}$ NMR spectroscopy, broad featureless signals are seen until a molar ratio of 2 : 3 (triphos : silver) is reached, when only a very sharp pattern with well defined ^{109}Ag–^{31}P and ^{107}Ag–^{31}P coupling is observed. Crystals of the 2 : 3 adduct **1** (X = SO_3CF_3 **1a**, ClO_4 **1b**, NO_3 **1c**)† suitable for X-ray analysis were grown by diffusion of hexane into a tetrachloroethane–acetonitrile solution of the complex.‡ The molecular structure (Fig. 2) is based on a cage of stoichiometry $[Ag_6(triphos)_4(O_3SCF_3)_4]^{2+}$ with approximate *T* symmetry.§ It may be simply represented as a truncated tetrahedron in which the four triphos ligands define the truncated apices and the six silver ions occupy the edges (Fig. 3). The four faces of the cage correspond to fused 18-membered rings each having local C_3 symmetry, containing six phosphorus atoms and three silver(I) centres. Approaching each facial trio of silver(I) atoms is a triflate ion with its oxygen atoms directed inwards. A novel feature is the

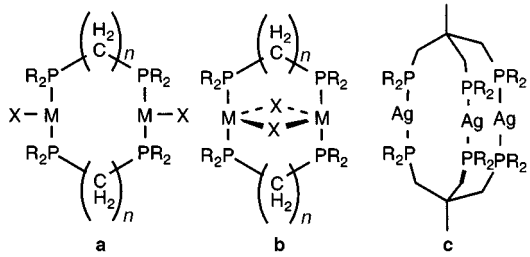

Fig. 1 Macrocyclic diphosphine silver(I) and copper(I) complexes with terminal (a) or bridging (b) anions and postulated trinuclear cages based on triphos ligands (c).

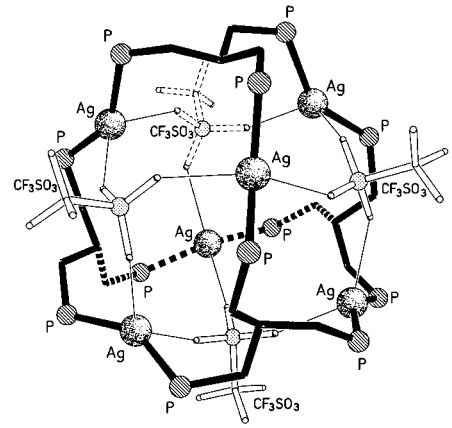

Fig. 2 The central core of complex **1a**. The phenyl and methyl groups on the triphos ligands have been omitted for clarity.

'*endo*-methyl' conformation of the triphos ligands, in which their methyl groups point toward the centre of the cage, leaving only a small cavity of van der Waals radius *ca.* 2.4 Å at the centre. This arrangement differs markedly from the '*exo*-methyl' conformation observed when triphos acts as a face capping ligand.[4] As a consequence, the in-pointing methyls generate an ordered hydrophobic interior and the Ag^+ and $O_3SCF_3^-$ ions form a polar spherical surface.

The average Ag–O distance is 2.66 Å indicating a significant degree of interaction [*cf.* 2.639(4), 2.712(6) and 2.74(2) in $[Ag_2\{\mu\text{-}Ph_2P(CH_2)_6PPh_2\}_2(\mu\text{-}ClO_4)_2]$[1a]]. The resulting geometry at each Ag(I) centre can best be described as distorted tetrahedral, the angles subtended at the two independent metal centres by the phosphorus atoms being 144.6(1) and 147.9(1)°, and by the oxygen atoms 128.2(5) and 126.8(5)° respectively. The O–Ag–O and P–Ag–P planes at each silver ion are essentially orthogonal (between 88 and 90°). The Ag–P

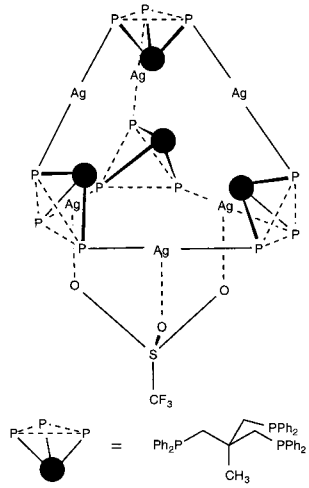

Fig. 3 Truncated tetrahedral representation of complex **1a**.

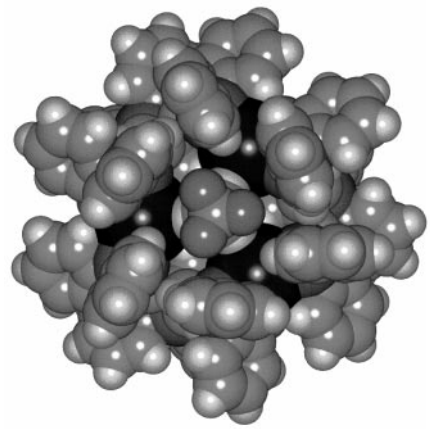

Fig. 4 Space-filling representation of the solid state structure of **1a** viewed along the crystallographic C_3 axis.

distances are in the range 2.405(4)–2.416(4) Å. The ability of triflate to coordinate to the cage is perhaps surprising given the steric bulk of the triphos phenyl substituents. However, the space filling representation of **1a** (Fig. 4) reveals how the phenyl groups are arranged in such a way as to provide channels through which the triflate anions can approach the silver ions. These channels are chiral and could potentially discriminate between enantiomeric anions.

The presence of four faces which are tetrahedrally disposed, each with approximate C_3 symmetry (as in adamantane) but composed of 18-membered rings (*cf.* six-membered as in adamantane) suggests the description 'super-adamantoid' for the cage. In the super-adamantoid cage, bridgehead atoms are replaced by tridentate triphos ligands, and the bridging atoms are replaced by silver ions.

As mentioned above, in solution, sharp ^{31}P NMR spectra are observed at room temperature which indicate chemically equivalent phosphorus atoms. The silver–phosphorus coupling constants $^1J_{^{109}Ag-^{31}P}$ for **1a**–**c** lie in the range 588–561 Hz which is consistent with the silver(I) centres being coordinated to two phosphine groups.[5,6] In addition the, albeit small, variations in chemical shift and silver–phosphorus coupling constants between **1a**, **1b** and **1c** imply that some degree of anion coordination occurs at the silver(I) centres in solution. This is further supported by the ^{19}F NMR spectrum of the triflate complex **1a**, which consists of two singlets at δ −77.9 and −78.6 in a 4 : 2 intensity ratio, as expected for four coordinated and two free triflate anions. On the basis of the closely related NMR spectra of complexes **1a**–**c**, we assume that similar cage structures are formed, at least in solution, for complexes **1b** (X = ClO_4) and **1c** (X = NO_3). By contrast, under similar conditions, a mixture of triphos and $AgBF_4$ gave a solution whose ^{31}P NMR spectrum consisted for the main part (98% of the total intensity) of a broad signal lacking any evidence of ^{109}Ag–^{31}P couplings. The remaining 2% consisted of sharp signals indicative of cage formation. With $AgSbF_6$, only the broad featureless signal was observed. It therefore seems that the less nucleophilic BF_4 and SbF_6 anions are unable to promote the selective formation of the cage structure in solution.

The anion-specific behaviour noted above, *i.e.* selective formation of a rigid cage when X = SO_3CF_3, ClO_4 or NO_3 *vs.* more labile species in which phosphine dissociation occurs on the NMR timescale at room temperature when X = BF_4 or SbF_6, may be related to the μ_3-face-capping coordination mode of the anion in the structure. The anion is required to be tridentate and reasonably nucleophilic. These criteria are satisfied by the O_3SCF_3, ClO_4 and NO_3 anions, but not BF_4^- and SbF_6^-.

In conclusion, complexes **1** have a unique super-adamantoid structure which results from the phosphines adopting a novel tetramer at the centre of the molecule, providing an outer surface which enables the coordination of six silver ions in an octahedral aggregate. This unusual geometry is stabilised by tridentate anions capable of capping the faces of the octahedron.

We would like to thank Dr J. S. Fleming and Mr C.-A. Carraz for obtaining ^{19}F NMR spectra.

Notes and references

† *Experimental*: in a typical preparation, a solution of triphos (70 mg, 0.122 mmol) in tetrachloroethane (4 cm^3) was added to a solution of [AgX] (0.183 mmol) in MeCN (1 cm^3) and the resulting solution layered with hexane to give the product as colourless crystals. ^{31}P NMR (110 MHz, CD_3CN–$CDCl_3$, 4 : 1, 25 °C, 85% H_3PO_4) δ −5.95 ($^1J_{^{109}Ag-^{31}P}$ 588 Hz) **1a**; −4.49 ($^1J_{^{109}Ag-^{31}P}$ 587 Hz) **1b**; −4.75 ($^1J_{^{109}Ag-^{31}P}$ 561 Hz) **1c**. Reactions between triphos and $AgBF_4$ or $AgSbF_6$ were conducted similarly. ^{31}P NMR (110 MHz, CD_3CN–$CDCl_3$, 4 : 1, 25 °C, 85% H_3PO_4); $AgBF_4$: 98% of total intensity is a broad signal from δ −5 to −12, 2% is sharp, with δ −3.67 ($^1J_{^{109}Ag-^{31}P}$ 588 Hz); $AgSbF_6$: broad signal from δ −5 to −12.

‡ *Crystal data* for **1a**: $[(C_{164}H_{156}P_{12}Ag_6)(CF_3SO_3)_4](CF_3SO_3)_2\cdot 6(C_2H_2Cl_4)$, M = 5047.2, rhombohedral, space group $R\bar{3}$ (no. 148), a = 24.454(2), c = 70.832(6) Å, V = 36684(5) Å^3, Z = 6 (the complex has crystallographic C_3 symmetry), D_c = 1.371 g cm^{-3}, μ(Cu-Kα) = 79.5 cm^{-1}, F(000) = 15 192, T = 183 K, clear prisms, 0.53 × 0.53 × 0.37 mm, Siemens P4 rotating anode diffractometer, ω-scans, 11 915 independent reflections. The structure was solved by direct methods and all of the non-hydrogen atoms of the complex and its associated counter-ions were refined anisotropically. The solvent molecules and the remaining counter-ions were found to be highly disordered and could not be resolved. They were thus modelled by the assignment of appropriate partial occupancy atoms to fit the electron density throughout the diffuse area. Refinements were by full matrix least-squares based on F^2 to give R_1 = 0.109, wR_2 = 0.283 for 5962 independent observed absorption corrected [semiempirical based on ψ-scans, max. and min. transmission factors 0.23 and 0.08 respectively] reflections [$|F_o| > 4\sigma(|F_o|)$, $2\theta \leqslant 120°$] and 720 parameters. CCDC 182/1030.

§ The crystallograpic symmetry is C_3 only about an axis passing through one of the triflate anions, though the departures from this symmetry about the other three anions are only slight.

6 Camalli *et al.* (ref. 3), in broad agreement with our observations, report that reaction between triphos and [AgX] (X = ClO_4 or NO_3) was found to give complexes with silver–phosphorus coupling constants 'higher than expected for complexes of the type AgP_3' (P = phosphine). While noting that definitive structure assignments could not be made, it was postulated that these complexes were two-coordinate with one arm of the triphos ligand non-coordinate. We suggest that they were in fact observing the cages **1b** and **1c** respectively.

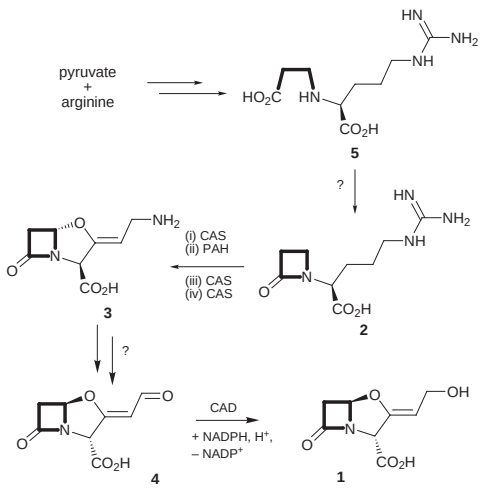
Received (in Cambridge, UK) 27th August 1998, Accepted 15th September 1998

A synthetase enzyme catalyses formation of the monocyclic β-lactam ring during clavulanic acid biosynthesis.

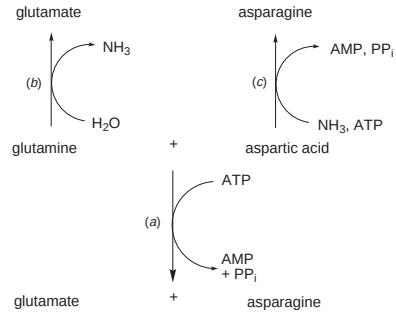
The most important inhibitor of serine β-lactamases is clavulanic acid **1**,[1] which is produced by some *Streptomyces spp*.[2] Whilst the central portion (*i.e*. **2** to **3**) of the clavulanic acid **1** biosynthesis pathway is established, significant gaps remain (Scheme 1). Nearing the end of the pathway the process by which the stereochemistry of the ring junction and C-3 positions of clavulanic acid are inverted to give the aldehyde **4** is unknown. At the beginning of the pathway, the intermediates leading to monocyclic β-lactam **2** are unclear. Labelling experiments have demonstrated that likely direct primary metabolic precursors of the 3 and 5-carbon portions of the clavulanic acid skeleton are pyruvate[3,4] and arginine.[5] Further studies have indicated that **5** is an intermediate in the pathway.[6]

Our sequencing studies demonstrated that within the biosynthesis gene cluster[7] of **1** an open reading frame (ORF3) displays a *ca*. 25% sequence identity over 434 of its 513 residues with Asn synthetase B (AS-B), the first 50 amino acids showing no homology. AS-B catalyses the ATP dependent synthesis of Asn from Asp and Gln; *in vitro* Gln can be replaced with NH_3 (Scheme 2).[8] We speculated that the ORF3 gene encoded the enzyme responsible for the conversion of **5** to **2**. Instead of catalysing the intermolecular formation of an amide bond as for AS-B, we envisaged that a synthetase catalysed the cyclisation of **5** to **2**, which in one sense may be viewed as a 'reverse' β-lactamase.

The ORF3 gene was PCR amplified from a cosmid containing the genetic information for the biosynthesis of **1** and sub-cloned into the pET-24a(+) vector,‡ which expressed



Scheme 1 Outline of the biosynthetic pathway leading to clavulanic acid. CAS = clavaminate acid synthase, PAH = proclavaminate amidinohydrolase, CAD = clavulanic acid dehydrogenase. Each CAS catalysed step is coupled to the conversion of 2-oxoglutarate and dioxygen to succinate.

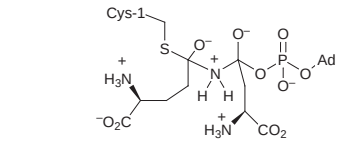


Scheme 2 Reactions catalysed by *E. coli* asparagine synthetase B (AS-B): (*a*) *in vivo* reaction, and (*b*) and (*c*) reactions also catalysed *in vitro*.

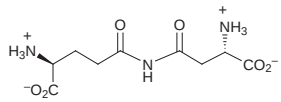
native recombinant enzyme in *Escherichia coli* BL21(DE3) at *ca*. 10% of total soluble cell protein. The recombinant ORF3 protein was purified by standard methodologies. N-Terminal sequencing, Western blot, and SDS-PAGE analyses demonstrated the expression and purification of the desired 56 kDa protein.§ Synthetic standards of **5** and **2** were prepared by published methods[9] and used to devise HPLC assays for these compounds. Crude extracts of the recombinant *E. coli* containing the ORF3 gene product and purified protein product were tested for the ability to catalyse the conversion of synthetic **5** to β-lactam **2**. The most sensitive assay involving the derivatisation of guanidino side chains based on the work of Kai *et al*.[10] showed clear conversion of **5** to **2**, when using either crude or purified recombinant protein, but only in the presence of Mg^{2+}, enzyme and ATP. The production of **2** was confirmed by preparative HPLC leading to its isolation. Spectroscopic characterisation of **2** showed it to be identical to the authentic synthetic material [δ_H(500MHz; D_2O) 1.48–1.55 (2H, m, $CH_2CH_2CH_2N$), 1.65–1.73 and 1.76–1.80 (2 × 1H, 2 × m, CH_2CH_2CHN), 2.82–2.89 (2H, m, NCH_2CH_2CO), 3.13 (2H, t, *J* 5, $CH_2CH_2CH_2N$), 3.29–3.31 and 3.35–3.38 (2 × 1H, 2 × m, NCH_2CH_2CO), 3.99 (1H, dd, *J* 5 and 10, $CHCO_2H$); *m/z* (ESI) 229 (MH^+)]. The ORF3 product catalysing the conversion of **5** to **2** was named β-lactam synthetase 1 [BLS (1)].

AS-B possesses an N-terminal cysteine residue and is a member of the family of Ntn (N-terminal nucleophilic) amidotransferases.[11] Studies on AS-B suggest that the N-terminal cysteine attacks the carbonyl of the amide of Gln, in order to increase the nucleophilicity of the amide nitrogen for reaction with the acceptor carbonyl.[12] The β-carboxylate of Asp is activated by reaction with ATP to form β-Asp-AMP and pyrophosphate (PP_i). The timing of nitrogen transfer from the activated glutamine is uncertain, but may proceed *via* a complex to which AMP is still bound **6** or an imide intermediate **7**.[13]

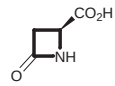
Amongst Ntn enzymes, BLS has an unusual N-terminus lacking an N-terminal cysteine (or serine/threonine), and is probably incapable of activating the nitrogen of the Gln amide for nucleophilic attack. We propose BLS activates the β-amino acid **5** by reaction with ATP to form an acyl adenylate **9** (Scheme 3). Instead of being attacked by Gln this intermediate undergoes cyclisation to **2** and AMP. The N-terminal residue of



6



7



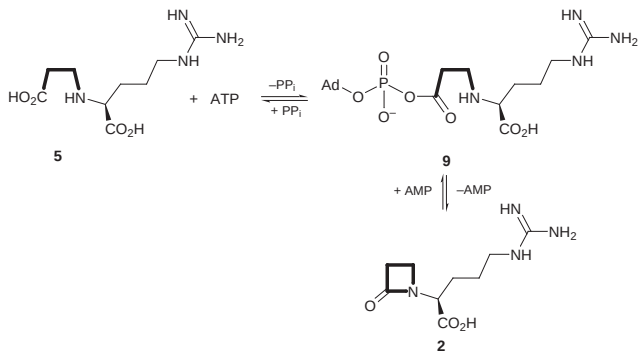
8

BLS is Gly, implying an Ntn type mechanism is not operating in BLS catalysis, unless the N-terminal amino group acts as the general base presumably required to deprotonate the β-amino group of **5**. The proposed BLS mechanism leads to the possibility that the transfer of NH_3 from Gln to Asp during AS-B catalysis also proceeds *via* a β-lactam, **8**. Whatever, the structural and mechanistic relationships between AS-B enzymes and BLS suggest a close evolutionary relationship. Studies aimed at converting AS-B into a β-lactam synthetase and *vice versa* have been initiated.

An open reading frame (*car*A) encoding for an enzyme with sequence similarities to AS-B/BLS has also been found within the biosynthetic gene cluster encoding for enzymes making 1-carbapenem-3-carboxylic acid.[14,15] The particular step catalysed by the CarA enzyme is unknown, but it has been proposed that it catalyses the formation of the β-lactam ring.[15,16] Our results support this proposal, but suggest the CarA enzyme catalyses an ATP/synthetase type reaction rather than a β-lactam cyclisation reaction proceeding *via* a thiol ester intermediate.[17,18]

The only other β-lactam forming enzyme to be so far described is isopenicillin N synthase,[19] which catalyses the oxidation of the peptide L-δ-(α-aminoadipoyl)-L-Cys-D-Val to give isopenicillin N, the first β-lactam formed in the biosynthesis of penicillins. Thus, β-lactam formation during the biosynthesis of clavams, which is driven by the hydrolysis of ATP, occurs *via* a very different mechanism to that during penicillin formation, which is driven by the reduction of dioxygen.

Since AS-B and related enzymes are widespread, and relatively minor modifications of them might lead to BLS type enzymes, BLS activity may have evolved before the less common and seemingly more complex secondary metabolic machinery required for penicillin and cephalosporin biosynthesis. Simple β-lactams such as **8** might have been (and may still be?) present in metabolism before other β-lactams which are more well known because of their antibacterial activity. β-Lactamases may have initially evolved to hydrolyse these monocyclic β-lactams, suggesting they may be ancient enzymes, and it is possible the chromosomal location of some β-lactamase genes reflects this.



Scheme 3

Analogous modifications of other Ntn enzymes may result in the formation of enzymes catalysing intramolecular cyclisation rather than intermolecular reactions. Thus, for example, modification of Ntn glutamine synthetases would lead to enzymes catalysing the formation of pyroglutamate from glutamate or other γ-lactams from appropriate γ-amino acid precursors.

Note: After acceptance of our manuscript we became aware of the work of Bachmann *et al*.,[20] which also demonstrates that ORF3 encodes for a BLS involved in clavam biosynthesis.

Dedicated to Professor Jack E. Baldwin on the occasion of his 60th birthday.

Germanium(II) azides: synthesis and crystal structure of Tp′GeN_3 [Tp′ = hydrotris(3,5-dimethylpyrazol-1-yl)borato]

Alexander C. Filippou,* Peter Portius and Gabriele Kociok-Köhn

Fachinstitut für Anorganische und Allgemeine Chemie, Humboldt-Universität zu Berlin, Hessische Str. 1-2, D-10115 Berlin, Germany. E-mail: filippou@chemie.hu-berlin.de

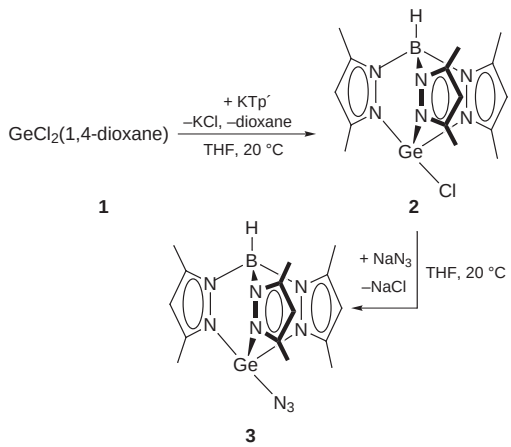
Received (in Basel, Switzerland) 8th June 1998

The synthesis of the germanium(II) azide Tp′GeN_3 (3) from Tp′GeCl (2) [Tp′ = $HB(3,5\text{-}Me_2pz)_3$] and NaN_3 is reported and the crystal structures of 2 and 3 are compared.

Silicon(IV) and tin(IV) azides have been reported to be versatile reagents in main-group element chemistry[1] and in organic synthesis.[2] In comparison, studies on germanium(IV) azides are still limited[3] and germanium(II) azides are to our knowledge not known, probably due to their propensity to decompose to germanium(IV) nitrides. This has prompted us to carry out the following work describing the synthesis and characterization of the germanium(II) azide Tp′GeN_3 (**3**). **3** was obtained from $GeCl_2$(1,4-dioxane) (**1**)[4] in two steps. In the first step **1** was converted with KTp′ to Tp′GeCl (**2**), which then was treated with NaN_3 to afford selectively **3** (Scheme 1).

Compounds **2** and **3** were isolated as white, slightly air sensitive solids, which are soluble in CH_2Cl_2, moderately soluble in THF and insoluble in pentane, and were fully characterized.† Thus, the IR spectra of **2** and **3** in KBr display the expected absorption bands for the Tp′ ligand. In addition, the azide group in **3** gives rise to two absorptions at 2043 cm^{-1} and 1272 cm^{-1}, which are assigned to the N_3 asymmetric and symmetric stretching vibrations, respectively. The $\nu_{asym}(N_3)$ absorption of **3** appears at lower frequency than that of the germanium(IV) azide Me_3GeN_3 [$\nu_{asym}(N_3)$ = 2103 cm^{-1}][3b] and higher than that of the azide anion [$\nu_{asym}(N_3)$ of $[N(PPh_3)_2]N_3$ in CH_2Cl_2 = 2005 cm^{-1}]. The ^1H and $^{13}C\{^1H\}$ NMR spectra of **2** and **3** display resonances for three equivalent pyrazolyl rings and indicate, taking into consideration the crystal structures of **2** and **3**, that these compounds are fluxional at room temperature.† The activation barrier to the process which equilibrates the pyrazolyl rings is low, since the static structures of **2** and **3** were not observed in CD_2Cl_2 solution even at −83 °C (300 MHz spectrometer).

Compounds **2** and **3** were characterized by X-ray diffraction as shown in Figs. 1 and 2.‡ Single crystals of **2** and **3** were obtained upon diffusion of pentane into a CH_2Cl_2 solution of **2** at ambient temperature and diffusion of an Et_2O–pentane mixture into a THF solution of **3** at −30 °C respectively. Both compounds show a distorted pseudo trigonal bipyramidal coordination geometry around the germanium atom, which is similar to that of related tin(II) compounds.[5] The halogen atom (pseudohalogen) occupies one axial site and the tridentate Tp′ ligand spans the other axial and two equatorial sites. The stereochemically active lone pair at germanium presumably is oriented towards the remaining equatorial vertex. Consequently, the N_{ax}(pz)–Ge–Cl bond angle in **2** [163.15(9)°] and the N_{ax}(pz)–Ge–N_{azide} bond angle in **3** [162.8(2)°] deviate from



Scheme 1

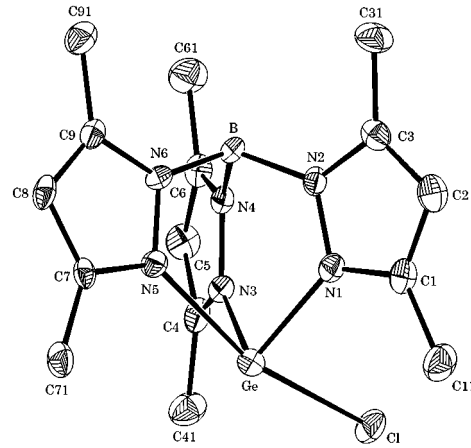


Fig. 1 ZORTEP plot of the molecular structure of **2** with thermal ellipsoids drawn at the 50% probability level. Hydrogen atoms are omitted for clarity. Selected bond lengths (Å) and angles (°): Ge–N(1) 2.023(3), Ge–N(3) 2.013(4), Ge–N(5) 2.379(3), Ge–Cl 2.536(1), N(1)–Ge–N(3) 88.7(1), N(1)–Ge–N(5) 79.9(1), N(3)–Ge–N(5) 79.9(1), Cl–Ge–N(1) 88.4(1), Cl–Ge–N(3) 87.8(1), Cl–Ge–N(5) 163.15(9).

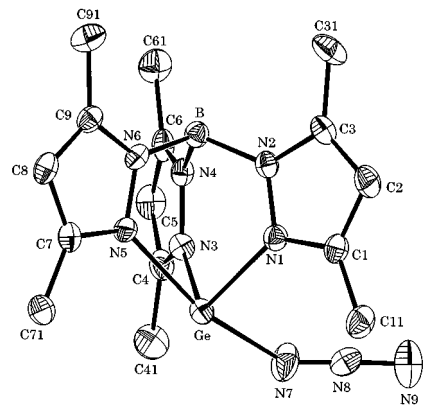

Fig. 2 ZORTEP plot of the molecular structure of **3** with thermal ellipsoids drawn at the 50% probability level. Hydrogen atoms are omitted for clarity. Selected bond lengths (Å) and angles (°): Ge–N(1) 2.034(3), Ge–N(3) 2.013(3), Ge–N(5) 2.297(3), Ge–N(7) 2.262(4), N(7)–N(8) 1.136(5), N(8)–N(9) 1.179(6), N(1)–Ge–N(3) 88.5(1), N(1)–Ge–N(5) 81.9(1), N(3)–Ge–N(5) 80.2(1), N(1)–Ge–N(7) 89.4(1), N(3)–Ge–N(7) 84.8(1), N(5)–Ge–N(7) 162.8(2), Ge–N(7)–N(8) 136.8(3), N(7)–N(8)–N(9) 176.9(5).

180°, the N_{ax}(pz)–Ge–N_{eq}(pz) bond angles are smaller than 90°, and the Ge–N_{ax}(pz) bond [**2**: 2.379(3) Å; **3**: 2.297(3) Å] is considerably longer than the Ge–N_{eq}(pz) bonds [**2**: 2.013(4) and 2.023(3) Å; **3**: 2.013(3) and 2.034(3) Å].[5,6] Striking features of the structures of **2** and **3** are the bonding parameters of the Ge–X groups (X = Cl, N_3). Thus, the Ge–Cl bond of **2** [2.536(1) Å] is considerably longer than those of other germanium(II) chlorides [*e.g.* (C_5Me_5)GeCl: 2.3841(8) Å; $GeCl_2$(1,4-dioxane): 2.265 Å; $GeCl_2$ (g): 2.186(4) Å],[7] and the Ge–N_{azide} bond of **3** [2.262(4) Å] is considerably longer than that of H_3GeN_3 (g) [1.845(6) Å].[3e] Furthermore, the angle at the germanium-bonded nitrogen atom of the azide group is, at 136.8(3)°, larger than those found in covalent main-group element azides, the azide group is almost linear as shown by the angle N(7)–N(8)–N(9) of 176.9(5)°, and the N(7)–N(8) bond is, at 1.136(5) Å, shorter than the N(8)–N(9) bond [1.179(6) Å]. These bonds have lengths between those of a N–N double [1.24 Å] and a N–N triple bond [1.10 Å].[8] All these data let us suggest in valence bond terms a certain contribution of the ionic resonance form [Tp′Ge]$^+$X$^-$ to the Ge–X bond in **2** and **3**.

In conclusion, we have shown that germanium(II) azides can be stabilized using a combination of electronic and steric properties as found in the Tp′ ligand.[9] Preliminary studies show that this concept can be extended also to other ligands providing a valuable access to this interesting class of compounds.

We thank the Deutsche Forschungsgemeinschaft for financial support.

Synthesis and structure of ITQ-9: a new microporous SiO_2 polymorph

Luis A. Villaescusa, Philip A. Barrett and Miguel A. Camblor*

Instituto de Tecnología Química, Avda. Los Naranjos s/n, 46071 Valencia, Spain. E-mail: macamblo@itq.pv.es

Received (in Bath, UK) 20th August 1998, Accepted 22nd September 1998

The new pure silica polymorph ITQ-9 has been synthesised and its structure, comprising medium pore channels and cages, has been solved by direct methods using low resolution powder X ray diffraction data.

Crystalline silica occurs in nature in a small variety of non-porous structural forms. However, it is also possible to synthesise SiO_2 as microporous solids by hydrothermal crystallisation in the presence of organic additives. These additives, which typically remain occluded within the porous silica framework, are called structure directing agents (SDA) and may generally be removed by calcination giving stable, crystalline pure silica polymorphs. A recent viewpoint considers that the role of SDA molecules is to select between different possible silica structures[1] with similar enthalpies of formation.[2] In our opinion, the SDA either kinetically or thermodynamically directs the crystallisation toward a specific phase. When the crystallisation is carried out at near to neutral pH (7–9.5) in the presence of fluoride anions which act as mineralisers, the crystalline silica obtained after calcination generally shows a very high degree of perfection. More specifically, those phases present essentially no Si–O–Si connectivity defects, which are by contrast frequent if the synthesis is carried out in basic medium (with OH^- acting as mineraliser). Owing to the lack of defects the final materials prepared in fluoride aqueous media are very attractive since they show strict hydrophobic properties[3] and a high degree of both short and long range order.[4] We describe here the synthesis of a new crystalline form of SiO_2, denoted ITQ-9 (Instituto de Tecnología Química, no. 9), which possesses a large micropore volume. In addition, we also show that the high degree of crystallographic order presented by this material afforded the resolution of its low symmetry structure by direct methods using low resolution powder X ray diffraction data (PXRD).

Pure silica ITQ-9 has been synthesised using *N*,*N*-dimethyl-6-azonium-1,3,3-trimethylbicyclo(3.2.1)octane (**I**) as SDA. 24.89 g of tetraethylorthosilicate were hydrolysed in 36.65 g of an aqueous solution of this cation in hydroxide form (1.63 moles per 1000 g of solution) under stirring and allowing evaporation of all the ethanol produced plus 16.7 g water. Then, 2.48 g of HF (48% aq.) were added and the thick paste obtained was homogenised by hand stirring before pouring into Teflon lined stainless steel autoclaves. These were heated at 150 °C under slow rotation (60 rpm). After 16 days of heating the contents were filtered, washed and dried. A highly crystalline solid was obtained and its PXRD pattern was indexed as monoclinic, space group *I*2/*m*, *I*2 or *Im*, a = 14.7906, b = 18.1528, c = 7.4547 Å, β = 110.76°. Chemical analysis suggests the chemical formula for as-made ITQ-9 is $[C_{12}H_{24}NF]_2[SiO_2]_{32}$ (based on the unit cell of the calcined material determined in this work, see below) and that the organic SDA is intact within the zeolite.

Calcination in air at 800 °C for 3 hours allows complete removal of the guest species yielding a pure SiO_2 framework with a large micropore volume of 0.21 $cm^3\ g^{-1}$ (determined by the t-plot method from the N_2 adsorption isotherm at 77 K). This framework is essentially free of connectivity defects, as demonstrated by the lack of significant Si(3Si,1OH) resonances near −101 ppm in the ^{29}Si MAS NMR spectrum (Fig. 1, top). The spectrum shows only Si(4Si) resonances in the −107 to −116 ppm chemical shift range. As a consequence of the absence of defects and high short range order there is a high resolution of Si(4Si) sites corresponding to framework Si in at least 6 different crystallographic sites.

After calcination splitting of a number of peaks in the PXRD pattern of ITQ-9 was observed. All the peaks could be indexed as a triclinic cell close to that for the as-prepared material, whilst maintaining the I centering (space group *I*-1). Direct methods using the Sirpow[5] program with Le Bail[6] extracted intensities from the Mprofil[7] program gave no satisfactory solution (a cell content of 32 SiO_2 derived from the density of 1.662 g cm^{-3} determined by pycnometry was used). We thus decided to use the PXRD data of the as-made sample due to its higher monoclinic symmetry. Le Bail extraction and direct methods were repeated as before using space group *I*2/*m* for which a good solution for the framework lacking no Si or O atoms and consisting of a 3D 4-connected net was obtained. Small fragments of organic matter were also found. Hence, the SiO_2 framework obtained for the as-made sample was used, after generation of the additional atomic positions in space group *I*-1, as a starting model for the Rietveld[8] refinement of the calcined triclinic phase, using conventional laboratory PXRD data in the program GSAS[9] with a manually interpolated background together with a pseudo Voigt[10] function to describe the peak shape. Constraints on the Si–O distances were used in the first stages of the refinement and finally removed before the model was refined to convergence. The crystallographic data are summarised in Table 1 and the final atomic positions are

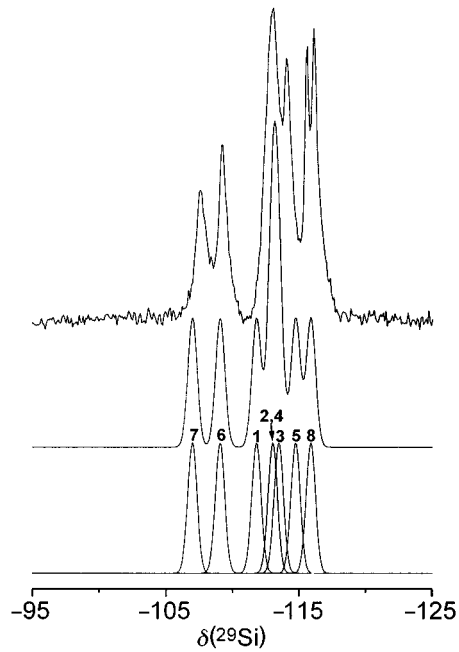

Fig. 1 ^{29}Si MAS NMR (*vs.* TMS) spectrum of calcined pure silica ITQ-9 (top) together with a simulation (middle) obtained by applying the equation of Thomas *et al.*[11] to the average Si–O–Si angles of each Si site in the refined structure (calculated resonances for each individual site are shown at the bottom). Note the absence of Si(3Si,1OH) resonances near −101 ppm and the high resolution of crystallographic sites in the experimental spectrum.

Table 1 Data collection and crystallographic parameters for calcined ITQ-9

Wavelength		Cu-Kα
Temperature/K		298
2θ range/°		5–85 (Range used 15–85)
Step size, 2θ/°		0.01
Count time/s step^{-1}		10 (5–50° 2θ); 40 (50–90° 2θ)
Number of data points		6910
Number of reflections		2527
Number of profile parameters		11
Number of structural parameters		81
Number of constraints		32
Unit cell	*a*/Å	14.7685(13)
	b/Å	18.1793(17)
	c/Å	7.3823(7)
	α/°	89.1402(21)
	β/°	110.6790(26)
	γ/°	90.945(4)
Space group		*I*-1
Residuals	R_{exp}	7.45
	R_{wp}	9.57
	R_p	7.72
	R_b	9.16
	χ^2	1.719

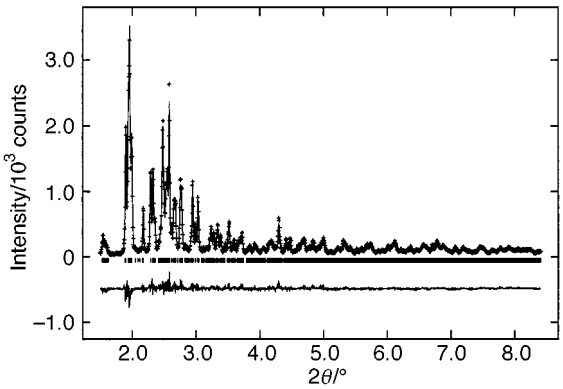

Fig. 2 Rietveld plot for calcined pure SiO_2 ITQ-9: observed data (+), calculated profile (solid line) and difference (lower trace). The tick marks represent the positions of allowed reflections.

available as Electronic Supplementary Information (http://www.rsc.org/suppdata/cc/1998/xxxx), with the final Rietveld plot depicted in Fig. 2. The average Si–O bond length (1.596 Å) and average O–Si–O and Si–O–Si angles (109.4 and 149.9° respectively) are in excellent accord with those expected for zeolite materials. Moreover, simulation of the ^{29}Si MAS NMR spectrum using the average Si–O–Si angles determined by Rietveld refinement for each Si site and the empirical equation of Thomas *et al.*[11] is in excellent agreement with the experimental spectrum (Fig. 1). Energy minimisation calculations using the GULP code[12] together with the potential model of Saunders *et al.*[13] reveal the symmetry lowering to be favourable by *ca.* 5 kJ mol^{-1}.

A projection of the structure of ITQ-9 is presented in Fig. 3. ITQ-9 is a new pure silica polymorph containing one dimensional sinusoidal pores running along [001] with access through ten membered ring windows (10MR windows). The windows are nearly circular in shape and have an average free diameter of around 5.7 Å (assuming the van der Waals radius of O to be 1.35 Å). The maximum and minimum diameters are 6.0 and 5.4 Å, respectively. Between two adjacent 10MR windows there are wider spaces with approximate free dimensions 10.9 Å × 7.4 Å × 4.7 Å. Thus, the pores in essence may be regarded as a one-dimensional arrangement of cages joined through single 10MR windows. In some directions the separation between adjacent pores is a wall with a single O atom (Fig. 3). This and the presence of cages explains the sizeable micropore volume of ITQ-9 (0.21 cm^3 g^{-1}) which is exceedingly large compared to other one-dimensional 10MR (ZSM-23, 0.04 cm^3 g^{-1}), 12MR

Fig. 3 A perspective view of the framework structure of ITQ-9 down [001], showing the nearly circular one-dimensional 10MR pores (average free diameter ≅ 5.7 Å). Large spheres represent tetrahedral Si, while small spheres are two-coordinated O.

(SSZ-24, 0.12 cm^3 g^{-1}) or even 14MR (CIT-5, 0.13 cm^3 g^{-1})[14] zeolites.

Finally, Al can be introduced by direct synthesis into the structure of ITQ-9. The aluminosilicate ITQ-9 presents strong Brønsted acid sites attributed to $[Al(OSi)_4]^-$ framework groups, as revealed by pyridine adsorption and desorption at increasing temperatures monitored by IR spectroscopy. This, together with the large micropore volume of the zeolite, renders ITQ-9 an attractive material for the catalytic transformation of hydrocarbons. Its activity and shape selectivity properties (due to the peculiar pore system encompassing medium sized windows and large cages) are currently under investigation.

Received (in Cambridge, UK) 1st September 1998, Accepted 21st September 1998

***meso*-η¹-Palladio- and platinioporphyrins have been isolated for the first time by means of oxidative addition of bromoporphyrins to Pd(0) and Pt(0) complexes; the X-ray crystal structure of the title complex was determined.**

Palladium-catalysed coupling reactions have been employed by a number of research groups to prepare novel porphyrins. Mercuration/palladation was used by Smith and co-workers to introduce unsaturated substituents into mono-porphyrins,[1] and one of us first applied palladium/phosphine catalysis to the formation of bis(porphyrins).[2] Numerous coupling reactions of the Heck, Suzuki, Sonogashira, and Stille types have since been used to prepare substituted porphyrins and multi-porphyrin arrays linked by alkenes and alkynes, with or without accompanying aryl linkers.[3,4] The most direct entry to this chemistry is *via meso*-haloporphyrins,[4] which are readily prepared in the case of β-unsubstituted porphyrins of the 5,15-diaryl type, such as 5,15-diphenylporphyrin, DPP.[5] For example, 5-bromoDPP and 5-iodoDPP [as the nickel(II) or zinc(II) complexes], couple easily with terminal alkynes, organotin or organozinc compounds, in the presence of Pd(II) or Pd(0) phosphine complexes.[4,6] An essential process in these catalytic cycles appears to be the oxidative addition of the *meso*-carbon-to-halogen bond to a zerovalent palladium precursor. However, until now there were no examples of isolated and characterised *meso*-η¹-palladioporphyrins. Here we report the stoichiometric (rather than catalytic) preparations of a number of such novel organometallic porphyrins, and the single crystal X-ray structure of one example.

	M	X	Y
1	Ni	H	$Pd(PPh_3)_2Br$
2	H_2	H	$Pd(PPh_3)_2Br$
3	H_2	H	$Pd(AsPh_3)_2Br$
4	Ni	$Pd(PPh_3)_2Br$	$Pd(PPh_3)_2Br$
5	H_2	H	Pd(dppe)Br
6	Ni	H	*cis*-$Pt(PPh_3)_2Br$
7	Ni	H	*trans*-$Pt(PPh_3)_2Br$
8	H_2	H	*cis*-$Pt(PPh_3)_2Br$
9	H_2	H	*trans*-$Pt(PPh_3)_2Br$
10	Ni	$Pd(PPh_3)_2Br$	*trans*-$Pt(PPh_3)_2Br$

The palladioporphyrins **1–5** were prepared by addition of the appropriate stoichiometric amount of palladium(0) precursor [$Pd(PPh_3)_4$ or Pd_2dba_3† + PPh_3, $AsPh_3$, or dppe] to 5-bromoDPP or 5,15-dibromoDPP or the corresponding nickel(II) complexes, in argon-purged toluene at 105 °C. The mono-adducts with the monodentate Group 15 ligands were formed quantitatively within a few minutes, while the double addition to form **4** required 40 minutes heating, and the dppe complex **5** required 8 hours heating. The complexes were readily isolated in high yield by evaporation of the toluene and trituration with ether. The palladioporphyrins are air-stable solids which undergo some Br/Cl exchange when dissolved in chlorinated solvents. We have also extended this chemistry to the analogous *meso*-platinioporphyrins. The addition of $Pt(PPh_3)_3$ to either 5-bromoDPPNi or 5-bromoDPP free-base in refluxing toluene initially leads within about 20 minutes to the *cis* adducts **6** and **8**, respectively, as shown by the characteristic ^1J(PtP) coupling constants in the ^{31}P NMR spectra [*e.g.* for **6**, *J trans* to porphyrin = 1790 Hz, *J trans* to Br = 4250 Hz, ^2J(PP) = 17 Hz]. These initial adducts isomerise over a period of 6 hours to the respective *trans* isomers **7** and **9**. The complexes were characterised by ^{1}H and ^{31}P NMR, electronic absorption, and FAB-mass spectra,‡ and in the case of the diphosphine derivative **5**, by X-ray crystallography.§ For all the Pd complexes except **5**, the ^{31}P NMR spectra showed that the Pd(II) centres have the *trans* geometry.

The crystal structure of **5** comprises two independent molecules in the asymmetric unit. Molecules A and B both display slightly distorted square-planar coordination about the Pd(II) atom, which is η¹-bonded to the *meso*-carbon of a weakly-ruffled porphyrin core (maximum deviation from the 24-atom mean plane = 0.28 Å in molecule A). Molecules A and B differ most markedly in the dihedral angles between the mean planes of the porphyrin and the 10,20-phenyl groups. In molecule A, these angles are 88 and 58°, and in molecule B, 56 and 59°. There is no obvious reason for the unique orthogonality of the phenyl ring in molecule A. Fig. 1 shows the coordination plane of the Pd atom for molecule A. The view from above the porphyrin ring, shown in space-filling form in Fig. 2, indicates how the phenyl groups of the diphosphine ligand shield the face of the porphyrin. This suggests immediately a use for this methodology in the engineering of cavities with tailored shape and hydrophobicity above and below a porphyrin ring, without the typically difficult and tedious synthetic work associated with 'capping' and 'strapping' opposite sides of a porphyrin. Moreover, the use of a chiral diphosphine may offer the intriguing possibility of generating chiral catalytic metalloporphyrins based on the present structural class.

The second insertion of the Pt(0) fragment into 5,15-dibromoDPPNi is so slow that the interesting compound **10** (containing all three members of the nickel triad) could be prepared by addition of $Pt(PPh_3)_3$, heating for 3 hours, followed by addition of Pd_2dba_3/PPh_3, and a further 3 hours heating. A similar but weaker deactivating effect of the Pt(II) fragment was noted by Stang and co-workers in their work on simpler arylene-bridged dipalladium and diplatinum organometallics, examples of which have also recently been reported by Kim *et al.*[7]

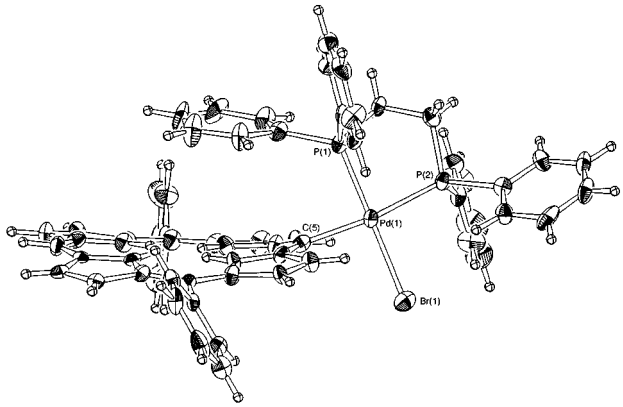

Fig. 1 Molecular structure of **5** (molecule A), showing the Pd coordination plane. Selected bond lengths and angles: Pd(1)–Br(1) 2.469(3), Pd(1)–P(1) 2.240(6), Pd(1)–P(2) 2.327(6), Pd(1)–C(5) 2.05(2) Å; P(1)–Pd(1)–P(2) 85.2(2), Br(1)–Pd(1)–P(2) 96.2(2), Br(1)–Pd(1)–C(5) 91.9(5), P(1)–Pd(1)–C(5) 87.2(6)°.

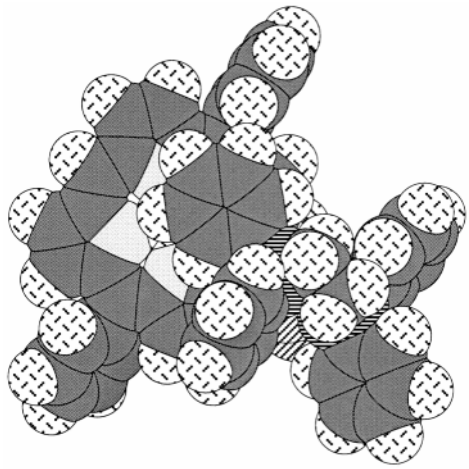

Fig. 2 Space-filling version of the molecular structure of **5**, viewed from normal to the porphyrin plane.

The electronic absorption spectra of our compounds are unexceptional, and the bromobis(phosphine/arsine)metallo moiety exerts a bathochromic effect of similar magnitude to that of a simple bromo substituent. The high polarizability of the heavy metal atoms(s) in direct communication with the porphyrin π-electrons may confer interesting third-order non-linear optical properties on this new class of organometallic compound. We will be exploring their potential applications in this field, as well as in catalysis and for the construction of multi-porphyrin supramolecular arrays.[8]

We thank Q.U.T. for a Special Small Grant, and the Centre for Instrumental and Developmental Chemistry for financial support.

A functionalized ruthenium(II)-bis-terpyridine complex as a rod-like luminescent sensor of zinc(II)

Received (in Basel, Switzerland) 12th August 1998, Accepted 23rd September 1998

The nearly non-luminescent ruthenium(II)-terpyridine chromophore, functionalized with an uncoordinated terpyridine fragment, 2, undergoes Zn(II)-induced association leading to a luminescent rod-like 2 : Zn^{2+} : 2 species with a luminescence enhancement factor, EF ⩾ 10.

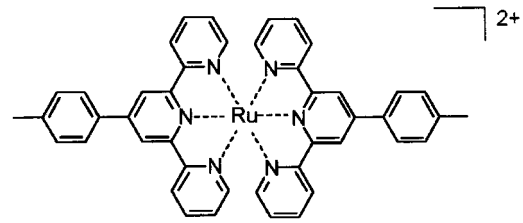
In the field of transition metal chemistry the assembly of Ru(II), Os(II), and Re(I) complexes to yield polymetallic species is being pursued both for fundamental and practical reasons.[1–4] Examples include (i) the investigation of energy and electron transfer processes in geometrically well defined systems where the metal-based components are held together by covalent bonds,[5–7] (ii) the exploitation of spectroscopic properties (particularly luminescence) for testing the sensing ability of appended groups towards protons, cations, and anions,[1–3] and (iii) the building up of dendritic species comprising tens of metal centres for light-harvesting and energy-collection purposes.[8,9]

An interesting Ru-based chromophore to be employed in such type of assemblies is $[Ru(tpy)_2]^{2+}$ {tpy is 2,2′:6′,2″-terpyridine; Scheme 1 shows the related complex $[(ttp)Ru(ttp)]^{2+}$ **1**, containing the 4′-tolyl-tpy ligand, ttp}.[10] This is because substitution at the 4′ position of tpy allows the construction of geometrically well-defined rod-like rigid species.[11] The luminescence properties of both $[Ru(tpy)_2]^{2+}$ and **1** are rather poor (their room temperature luminescence quantum yield and lifetime in acetonitrile solvent are $\Phi \approx 10^{-5}$ and $\tau < 1 \times 10^{-9}$ s, respectively[10]) but the incorporation of these or related complexes in polynuclear species may result in significant luminescence improvements.[7,12]

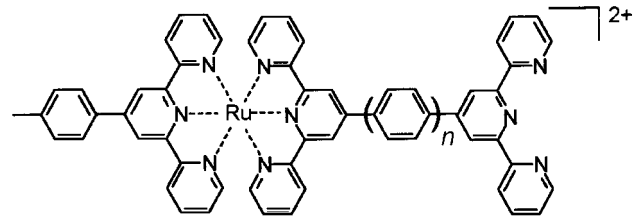
By using luminescence spectroscopy we have investigated the properties of acetonitrile–water solutions of the complexes $[(ttp)Ru(tpy\text{-}tpy)]^{2+}$ **2** and $[(ttp)Ru(tpy\text{-}ph\text{-}tpy)]^{2+}$ **3**, Scheme 1,† in the presence of Zn^{2+} [ph = 1,4-phenylene]. We found that Zn^{2+} coordination of the free tpy fragments of **2**[13] is accompanied by a substantial enhancement of luminescence intensity; by contrast no such effect is observable for **3**. Luminescence results are collected in Table 1. In addition we could use luminescence spectroscopy to monitor the formation of the tripartite species, **2** : Zn^{2+} : **2**.

The absorption spectra of **2** and **3** in acetonitrile–water (1 : 1 v/v) display intense absorption bands in the UV region (250–350 nm, $\varepsilon \approx 10^5$ M^{-1} cm^{-1}) and moderately intense bands in the visible region (450–550 nm, $\varepsilon \approx 10^4$ M^{-1} cm^{-1}). The former bands are due to ligand centered (^{1}LC) transitions and those occurring in the visible are due to metal-to-ligand charge-transfer (^{1}MLCT) transitions, of Ru→L electronic configuration.[6,11] Owing to the presence of the uncoordinated tpy fragment in **2** and **3,** addition of Zn^{2+} causes[13] some changes in the absorption features. These changes are only modest in the region of the ligand-centred transitions of both complexes; however, for **2** the longest-wavelength band maximum (MLCT region) undergoes a bathochromic shift from 491 to 498 nm (for **3** the corresponding absorption maximum at 491 nm is not affected by the presence of Zn^{2+}). This indicates that for **2**, the Zn^{2+} ion causes stabilization of the lowest-lying Ru→L CT energy level, which involves the tpy-tpy fragment, Scheme 1. For **3** no such effect is apparent.

The excited states responsible for the luminescence, Table 1, are formally triplet levels of Ru→L CT nature, and involve in



$[(ttp)Ru(ttp)]^{2+}$ **1**



$n = 0$; **2**
$n = 1$; **3**

Scheme 2

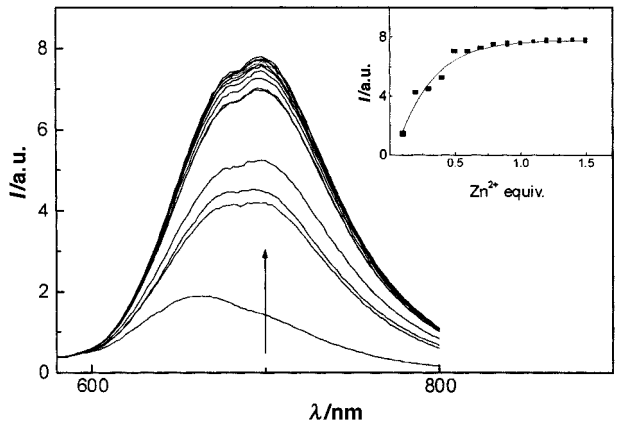

Fig. 1 Luminescence spectrum of complex **2** after Zn^{2+} addition. Excitation wavelength is at 494 nm, where the changes in absorbance intensity are within 5%. The inset shows the luminescence intensity taken at 700 nm *vs.* the added Zn^{2+} equivalents.

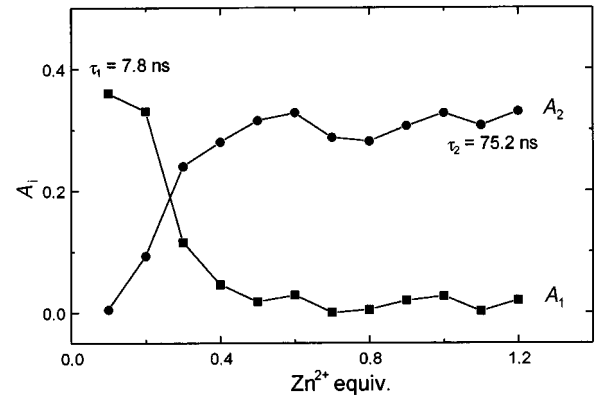

Fig. 2 Changes in the relative amplitudes A_1 and A_2 for the dual luminescence decay of complex **2** (concentration 1×10^{-5} M) upon Zn^{2+} addition. The decays are monitored over the full emission range.

each case the larger size ligand present on either side of the Ru(II) centre, *i.e.* tpy-tpy and tpy-ph-tpy for **2** and **3,** respectively.[10] The luminescence properties gathered in Table 1 indicate that Zn^{2+} remarkably affects the luminescence band maximum, intensity and lifetime for the case of **2**. In contrast, for **3** no substantial changes can be registered. This different behaviour may be understood in terms of the role of the phenylene group in decoupling the Ru-based chromophore and the tpy appended site.[14]

The results of a titration experiment on the luminescence intensity of **2** are illustrated in Fig. 1. For this complex, subsequent additions of Zn^{2+} cause gradual shifts of the band maximum from 660 to 700 nm, with a concomitant increase of the luminescence intensity. The inset of Fig. 1 shows that the change in luminescence intensity at 700 nm *vs.* the Zn^{2+} concentration is consistent with formation of a **2 :** Zn^{2+} **: 2** species.

The same conclusion is supported by the time resolved luminescence properties exhibited upon titration of complex **2** with Zn^{2+}. The luminescence decayed according to a dual exponential law, $I(t) = A_1\exp(-t/\tau_1) + A_2\exp(-t/\tau_2)$, and a global analysis as performed on 12 decay profiles gave τ_1 = 7.8 ns and τ_2 = 75.2 ns, with varying amplitudes (A) depending on the added equivalents of Zn^{2+}, see Fig. 2. Comparison of the results depicted in Fig. 2 with the luminescence properties reported in Table 1 suggests that the two species responsible for the dual exponential behavior are **2** and **2** : Zn^{2+} : **2**. Based on the coordination number of 6 for the Zn(II) centre and on the geometry of the tpy coordination site,[7,13] the **2 :** Zn^{2+} **: 2** complex is most likely linearly arranged with an estimated Ru–Ru distance of 2.2 nm, Scheme 2.

With respect to the starting complex **2**, it is noteworthy that the **2** : Zn^{2+} : **2** complex exhibits improved luminescence properties, EF = 10 (with respect to **2** in neat acetonitrile, EF ≈ 50). This is due to the delocalizing ability of the tpy-tpy ligand[12] combined with the stabilizing effect of the Zn^{2+} centre. Our results, which are in line with those of a recent report on polynuclear complexes where the bridging ligands contain the highly delocalizing ethynyl group,[7] suggest that it is possible to use Ru(II)-terpyridine derivatives both to develop Zn^{2+} luminescent sensors and to construct nanometric rod-like assemblies with tuneable luminescence properties.

Notes and references

† The synthesis and characterization of complexes **1**, **2**, and **3** were described previously.[11] Absorption and luminescence spectra of dilute solutions (≈ 10^{-5} M) in acetonitrile–water (1 : 1 v/v) were recorded with a Perkin Elmer Lambda 5 spectrophotometer and with a Spex Fluorolog II spectrofluorimeter, respectively. Uncorrected luminescence band maxima are used throughout the text. In order to determine corrected band maxima and luminescence quantum yields we followed a procedure described in ref. 12. Luminescence lifetimes were obtained with an IBH single-photon-counting apparatus. The titration experiments were conducted with Gilson P20 Pipetman microburettes by using concentrated solutions (10^{-3} M) of $ZnCl_2$.

Macrocyclic polyamine lactam synthesis by diphenyl ether closure of 23-, 24- and 28-membered rings

Simon Carrington,[a] Alan H. Fairlamb[b] and Ian S. Blagbrough*[a]†

[a] *Department of Pharmacy and Pharmacology, University of Bath, Bath, UK BA2 7AY*
[b] *Department of Biochemistry, University of Dundee, Dundee, UK DD1 5EH*

Received (in Cambridge, UK) 26th August 1998, Accepted 10th September 1998

Novel 23-, 24- and 28-membered cyclic polyamine amides (cinnamamides) have been prepared by closure of diphenyl ethers; functionalized conjugates of spermidine and spermine underwent intramolecular aromatic nucleophilic substitution to afford nitro-substituted analogues of cadabicine class (24-membered polyamine lactam) alkaloids.

Polyamines such as triamine spermidine **1** and tetraamine spermine **2** are widely distributed in nature and display a variety of biological activities.[1] Cinnamic acid (3-phenylpropenoic acid) conjugates are commonly isolated as the corresponding *N*-substituted amides from plant sources.[2] Ferulic acid (4-hydroxy-3-methoxycinnamic acid) **3** is found as feruloylputrescine, a conjugate of 1,4-diaminobutane.[3] N^1,N^3-Di-(*E*)-feruloylspermidine **4** has been isolated from *Corylus avellana* L.[3,4] Spermidine conjugates have also been found asymmetrically substituted with both ferulic and caffeic (3,4-dihydroxycinnamic) acids **5**.[3] Maytenine,[5] from *Maytenus chuchuhuasha*, is the unsubstituted dicinnamamide of spermidine **1**. Dicinnamamides of spermine **2** include kukoamine A, a biologically active bis(dihydrocaffeoyl) conjugate.[6,7]

Cyclic polyamine amide containing cinnamamides are less common natural products whose biological activities are largely unknown.[2,8] Spermine **2** containing macrocyclic polyamine lactams include *inter alia* chaenorhine and ephedradine A.[8] Spermidine **1** containing polyamine lactams include codonocarpine **6**, from *Codonocarpus australis*,[9] and capparisinine **7**.[10] Cadabicine **8** is a diphenyl ether 24-membered ring containing spermidine **1**, from *Cadaba farinosa* Forsk. The regiochemical substitution of the diphenyl ether moiety is reversed with respect to the unsymmetrical spermidine moiety in **6** and **7**.[11] We are unaware of a synthesis[2,8] of a cadabicine **8** class alkaloid, although a regiocontrolled synthesis of the *Lunaria* diphenyl ether alkaloid codonocarpine **6** has been reported.[12]

Macrocycles containing diphenyl ethers are of chemical and biological interest as they occur in vancomycin and ristocetin antibiotic families.[13–15] Also, these substitution patterns are found in anti-cancer peptide conjugate RA-VII and ACE inhibitor K-13.[15,16] Macrocyclic polyamine lactams incorporating a diphenyl ether have been prepared using intermolecular Ullmann diaryl ether synthesis followed by lactam formation.[8,12] Herein we report the first design and synthesis of 23-, 24- and 28-membered ring polyamine lactam conjugates that are nitro-substituted analogues of cadabicine **8** class alkaloids.

The required substituted cinnamic acids were prepared from the corresponding benzaldehydes by Knoevenagel condensation.[17,18] Isoferulic acid (3-hydroxy-4-methoxycinnamic acid) **9** was prepared in good yield (92%) under standard conditions starting with malonic acid (EtOH, piperidine, pyridine, 3 h, reflux).[17] 4-Fluorobenzaldehyde was similarly converted into 4-fluorocinnamic acid **10** (85%). Nitration *ortho* to fluorine, in order to activate the final intramolecular nucleophilic substitution (S_NiAr) reaction, achieved with conc. nitric acid, afforded 4-fluoro-3-nitrocinnamic acid **11** (1 h, 0 °C, 72%).

For the 23-membered ring **12**, *N*-(3-aminopropyl)-1,3-diaminopropane was protected with trifluoroacetyl groups on the

primary amino groups (2 equiv. CF_3CO_2Et, THF, 10 min, 25 °C).[19–21] This was followed by immediate Boc protection of the central, secondary amine (Boc_2O, THF, 18 h, 25 °C). Conc. aq. ammonia was added to the solution of tri-protected triamine until the pH was greater than 11 to remove the trifluoroacetyl protecting groups (24 h). Mono-Boc protected amine was isolated and purified by flash column chromatography (15 : 5 : 1, CH_2Cl_2–MeOH–conc. aq. NH_3, v/v/v, R_f 0.13). The cinnamic acid moieties[17,18] were coupled sequentially (first the isoferuloyl **9** then the 4-fluoro-3-nitro **11**) to the primary amines by pre-activation with 2-mercaptothiazoline (2-thiazoline-2-thiol, thiazolidine-2-thione)[5] (DCC, 0.01 equiv. DMAP, CH_2Cl_2, 1 h, 25 °C, followed by filtration to remove the urea). Mono-Boc protected triamine was added to the yellow CH_2Cl_2 solution of the *N*-acylated 2-mercaptothiazoline and the coupling was typically complete after 3 h (*ca*. 50% each acylation). Cyclisation was brought about by stirring with 5 equiv. CsF in anhydrous DMF (18 h) to give 23-membered ring polyamine lactam **12** (79% isolated yield). *O*-Arylation has occurred by intramolecular aromatic nucleophilic substitution (S_NiAr) reaction of *o*-nitro-activated fluoride by the remote phenol.

For the 24-membered ring **14**, spermidine **1** was reacted with formalin to give a hexahydropyrimidine adduct (0.95 equiv. 37% w/w aq. formaldehyde, H_2O, 1 h, 91%) as developed independently by Ganem and Hesse and their co-workers.[22,23] Isoferulic acid **9**[17,18] was coupled to the primary amine of this regioselectively protected spermidine through the 2-mercaptothiazoline activated intermediate (−78 to 25 °C, 55%). After chromatography, this hexahydropyrimidine was deprotected by heating with malonic acid and pyridine (EtOH, reflux, 2 h, 79%).[22] 4-Fluoro-3-nitrocinnamic acid **11** was coupled to the uncovered primary amine and then the secondary amine was protected by a Boc group (1.1 equiv. Boc_2O, MeOH, 18 h, 25 °C, 89%) to afford a linear precursor of cadabicine analogue **13**. Cyclisation was carried out by stirring with 3 equiv. CsF in anhydrous DMF (18 h, 71% isolated yield), final purification by RP-HPLC (5 μm C8 inertpak column eluting with 1:4 aq. TFA (0.1%)–MeOH, v/v, λ = 250 nm). TFA catalysed deprotection (1:1 TFA–CH_2Cl_2, v/v, 45 min, 0 °C, 90%) of the Boc group in diaryl ether **15** was followed by *O*-demethylation with BBr_3 (1.2 equiv., CH_2Cl_2, 3 h, −78 °C) to give 2′-nitrocadabicine **14** in 60% isolated yield.

For the 28-membered ring **15**, spermine **2** was protected in a similar fashion to *N*-(3-aminopropyl)-1,3-diaminopropane *vide supra*. Trifluoroacetyl groups were used to block the two primary amines then two Boc groups were introduced at the secondary amines. Conc. aq. ammonia was used to remove the trifluoroacetyl protecting groups and the N^2,N^3-diBoc spermine was then purified by chromatography. The two cinnamic acid moieties[17,18] were introduced in a stepwise fashion using 2-mercaptothiazoline activation to yield the cyclisation precursor. Cyclisation was carried out in anhydrous DMSO with 3 equiv. K_2CO_3 and 10 equiv. 18-crown-6, the oxygen nucleophilicity was found to be too low without the crown ether. The cyclisation reaction did not proceed to completion at 25 °C (starting material still present after 24 h). However, heating the mixture to 50 °C, in the presence of 18-crown-6, led to complete reaction after 5 h, yielding the desired macrocycle **15** (66%).

The previously proposed mechanism of cyclisation involved bringing the two sites of reaction into proximity by π-orbital stacking interactions between the electron rich guaiacol (2-methoxyphenol) ring and the electron deficient *o*-fluoronitrophenyl ring.[15] However, macrocycle formations of this type have recently been demonstrated to proceed in good yield when the aryl hydroxy group is replaced by an alkyl hydroxy group, proving that such π–π interactions are not necessary for successful cyclisation.[24] As the isolated yields are high, this practical approach by aromatic nucleophilic substitution (intramolecular S_NiAr reaction) should find ready application in the synthesis of natural products and their analogues with particular reference to cyclic spermidine and spermine alkaloids of the codonocarpine **6** and cadabicine **8** classes.

We thank the Department of Pharmacy and Pharmacology, University of Bath, for a studentship (to S. C.). We acknowledge useful discussions with Dr William N. Hunter (University of Dundee), Professor Manfred Hesse (University of Zürich) and Dr Ian S. Haworth (University of Southern California). I. S. B. and I. S. H. are recipients of a NATO grant (CRG 970290). A. H. F. is funded by the Wellcome Trust.

Strong intramolecular exchange interactions between nitronyl nitroxide radicals bridged by olefinic spacers

Christophe Stroh,[a] Philippe Turek[b] and Raymond Ziessel*[a]

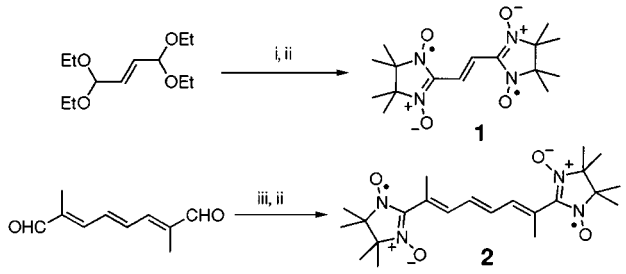
Received (in Cambridge, UK) 3rd August 1998, Accepted 25th September 1998

Nitronyl nitroxide radicals bridged by olefinic spacers display strong intramolecular and antiferromagnetic exchange interactions, the magnitude of which depends on the length of the spacer and on steric crowding around the radicaloid subunits.

An essential concern for the development of organic molecular magnetic materials involves minimizing undesired radical–radical interactions whilst promoting efficient exchange coupling along the molecular axis. Because of the inherent difficulty in coupling organic radicals through a bridging framework the use of bis-radicaloid systems has proved less popular than the alternative approach of using transition metals to separate monoradicals.[1] For example, nitronyl nitroxide (NIT) radicals interact only weakly through the π orbitals of an interspersed aromatic spacer because of stereoelectronic inhibition of cross-conjugation[2,3] while directly-linked NIT diradicals exhibit through-space antiferromagnetic coupling.[4] We now report that olefinic spacers promote strong through-bond (TB) interaction between terminal NIT radicals in such a way that complexation to paramagnetic cations might provide novel ferrimagnetic materials.

The deep green diradicals **1**[5] and **2** were synthesised as outlined in Scheme 1.† The all-*trans* conformation of the polyenic skeleton of each diradical was confirmed by X-ray crystallography (Fig. 1).‡ In **1**, the two radicals lie coplanar with the olefinic moiety while the crystal packing shows that the molecules are quasi-isolated with the shortest intermolecular NO···ON distances being > 5 Å. In contrast, the two radical centres in **2** are tilted from coplanarity by 24.9°, due to steric crowding with the neighbouring methyl groups. The crystal packing of **2** reveals relatively short contacts [NO···ON at 3.70 and 3.65 Å, respectively, for OO′ and ON′] between neighbouring molecules within a crystallographic chain [$x + 1$, y, $z + 1$]. Here, the head-to-tail arrangement of the NO subunits, and their relative orientation, are favourable for intermolecular antiferromagnetic interactions. This is indicated by an α angle of 82° for the ON···ƆN and by a β angle of 90° formed between a vector normal to the π* orbitals of the NIT radicals and the N_2O_2 plane.[6]



Scheme 1 *Reagents and conditions*: i, MeOH, H_2O, *N*,*N*′-dihydroxy-2,3-diamino-2,3-dimethylbutane sulfate salt, 20 h; ii, $NaIO_4$, H_2O, CH_2Cl_2, 1 h; iii, Benzene, *N*,*N*′-dihydroxy-2,3-diamino-2,3-dimethylbutane, azeotropic distillation, 0.5 h.

The magnetic properties of these two diradicals were studied with a SQUID susceptometer. At 300 K, the product of molar susceptibility and temperature (χT) for both **1** (0.373 emu K mol^{-1}) and **2** (0.613 emu K mol^{-1}) is lower than that expected for two independent spins [0.75 emu K mol^{-1}]. This indicates the predominance of antiferromagnetic interactions. With decreasing temperature, χT for **1** shows a monotonous decrease to zero while a maximum in the susceptibility curve is seen at 75 K for **2** (Fig. 2). The Curie tail observed at low temperature is due to a weak amount (*ca*. 0.1%) of paramagnetic impurities.

In order to avoid intermolecular interactions, compounds **1** and **2** were dispersed in a polystyrene matrix and studied over the 200–300 K temperature range. The χT *vs*. T and the χ *vs*. T plots, respectively, for **1** and **2** display features similar to those found for microcrystalline samples. For **2**, maximal susceptibility is again found around 75 K [inset in Fig. 2(*b*)]. No relevant intermolecular contacts are seen for **1**, such that a good fit of the experimental data was obtained using the Bleaney–Bowers law for an isolated two-spin 1/2 model[7] where the magnetic exchange coupling constant J corresponds to a Hamiltonian of the form $H = -2JS_1S_2$. Here, a large singlet–triplet splitting of $2J/k_B = -469$ K was found, indicating strong TB antiferromagnetic interaction.

In order to fit the susceptibility data for **2**, the Bleaney–Bowers expression for the magnetic susceptibility of a dimer had to be modified by including a mean-field approximation, estimated by a Weiss temperature θ. This describes the average intermolecular interactions throughout the crystal. With respect to **1**, a much weaker TB antiferromagnetic coupling ($2J/k_B = -90$ K) was found, after correction for a mean field temperature of $\theta = -32$ K.

EPR spectra of **1** and **2** were recorded at room temperature in deoxygenated CH_2Cl_2 solutions (*ca*. 5×10^{-5} mol dm^{-3}) and in polystyrene matrices (*ca*. 3.6% w/w). In solution, the EPR

signal obtained from **2** consists of nine well-separated lines centred at g_{iso} = 2.0065, corresponding to an isotropic hyperfine coupling constant a_N = 3.76 G. This pattern is consistent with strong exchange interaction between a pair of NIT radicals. The solution EPR spectrum of **1** is distorted and centred at g_{iso} = 2.0067, with the observable peaks being separated by *ca*. 3.75 G and lying within the strong exchange limit. In frozen solution, each compound exhibits fine structure (dipolar) lines and a half-field signal (g = *ca*. 4) due to the so-called forbidden (ΔM_S = 2) transitions (Fig. 3).[8] The zero field splitting (ZFS) parameters are estimated as D = 168 G for **1** and D = *ca*. 31 G for **2**, in rough agreement with the values calculated from the crystal structure on the basis of the point dipole approximation (146 < D < 302 G for **1**, and 34 < D < 41 G for **2**).

The experimental data can be well explained by taking into account strong TB antiferromagnetic interaction between the NIT radicals. The geometry and availability of a conductive pathway combine to favour TB interaction rather than through-space exchange. Indeed, the bridging polyenic spacer shows a high propensity for exchange interactions between remote NIT radicals. This is presumably due to efficient orbital overlap between the radicals and the conjugated framework. In this respect, the olefinic spacer is much more effective than aromatic

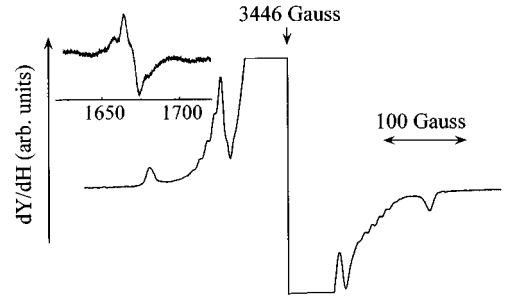

Fig. 3 Fine structured lines observed in the first derivative EPR absorption spectrum (X-band; ν = 9.73 GHz) of **1** dispersed in a polymer matrix and recorded at room temperature. The inset shows the half-field signal.

groups. However, a marked stereoelectronic effect is present in **2**, owing to the presence of methyl substituents at the α position relative to the radicals, which curtails exchange interaction.

In summary, in the absence of steric crowding an olefinic bridge favors a planar diradical in the solid state whose conformation is ideal for TB exchange interaction. This is in marked contrast to bis-NIT coupled directly[4] or *via* aryl spacers. Moreover, the magnetic and electronic properties observed in the crystals are conserved in a diluted polymeric matrix. The pronounced TB interaction inherent in these simple systems might provide access to ferrimagnetic scaffolds by judicious coordination to magnetic metal ions.

Stereochemical evidence for elimination–addition and a methylenethioxophosphorane (thiophosphene) intermediate in nucleophilic substitution at the P=S centre of a benzylic phosphonamidothioic chloride

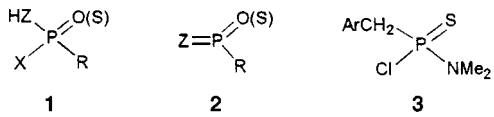
Martin J. P. Harger

Department of Chemistry, The University, Leicester, UK LE1 7RH

Received (in Liverpool, UK) 4th September 1998, Accepted 22nd September 1998

The two diastereoisomers of $ArCH_2P(S)(NMeR^*)Cl$ (Ar = 4-$NO_2C_6H_4$, R* = CHMePh) react with Et_2NH (0.2 mol dm^{-3}) in CH_2Cl_2 to give mixtures of the diastereoisomers of $ArCH_2P(S)(NMeR^*)NEt_2$ in practically the same ratio (54.5 : 45.5 or 53 : 47); such non-stereospecificity points to a thiophosphene intermediate ArCH=P(S)NMeR* as the product-forming species.

Nucleophilic substitution at a phosphoryl (P=O) or thiophosphoryl (P=S) centre generally proceeds by an associative $S_N2(P)$ mechanism with a five-coordinate intermediate or transition-state.[1] An alternative dissociative mechanism, involving elimination–addition (EA) and a transient three coordinate P^V intermediate **2**, is sometimes favoured when the substrate **1**

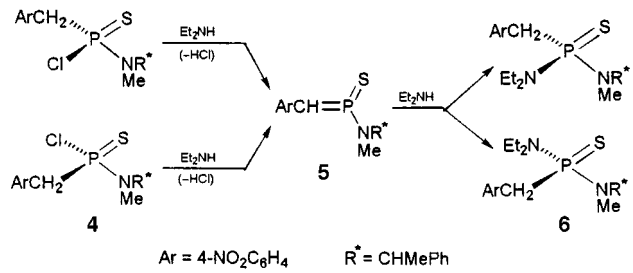


1 **2** **3**

(X = leaving group) has an acidic ligand HZ,[1,2] *i.e.* when Z is an oxygen,[3] sulfur[4] or nitrogen[5] atom. When Z is just a saturated carbon atom however, elimination–addition seems unable to compete with the normal $S_N2(P)$ reaction.[6] An exception may be the benzylic phosphonamidothioic chloride **3**, at least when it is substituted with a nitro group (Ar = 4-$NO_2C_6H_4$).[7] Then it displays remarkably high reactivity towards basic nucleophiles such as Et_2NH, perhaps because the C_α–H bonds are sufficiently acidic for reaction to proceed rapidly by an EA mechanism. To substantiate such a mechanism, and in particular the intermediacy of a three-coordinate methylenethioxophosphorane (thiophosphene) intermediate $[ArCH{=}P(S)NMe_2]$, there is a need of stereochemical information. Working with the individual enantiomers of **3** (Ar = 4-$NO_2C_6H_4$) would present problems, both preparative and analytical, so our attention turned to the related compound **4** (Ar = 4-$NO_2C_6H_4$) (Scheme 1). This is chiral at carbon as well as phosphorus so both substrate and substitution product will exist as diastereoisomers.

The phosphonamidothioic chloride **4** was prepared using 4-nitrobenzylphosphonothioic dichloride $[ArCH_2P(S)Cl_2]$[7] and (*S*)-(−)-PhMeCHNHMe. It is known that benzylic phosphonothioic dichlorides tend to go directly to the diamide when they react with secondary amines,[8] but by keeping the amine concentration low [addition over 5–6 h to a dilute CH_2Cl_2 solution of $ArCH_2P(S)Cl_2$], and having some of the amine hydrochloride (the byproduct of the reaction) present in solution from the outset, the amidic chloride **4** was the major product. Chromatography (silica gel; 15% EtOAc in light petroleum) followed by crystallisation of appropriate fractions afforded pure samples of the two diastereoisomers (**A** and **B**) of **4** [*m*/*z* 370, 368 (M^+, 6%): **A**, mp 108–109 °C, $\delta_P(CDCl_3)$ 90.00; $\delta_H(CDCl_3)$ 3.92 (2H, m, C*H*$_2$Ar), 2.575 (3H, d, J_{PH} 15, N*Me*) and 1.525 (3H, d, J_{HH} 7, CH*Me*Ph); **B**, mp 87–88 °C, $\delta_P(CDCl_3)$ 90.57; $\delta_H(CDCl_3)$ 3.91 (2H, m, C*H*$_2$Ar), 2.61 (3H, d, J_{PH} 15, N*Me*) and 1.30 (3H, d, J_{HH} 7, CH*Me*Ph)].†

The amidic chloride **4** reacted readily with Et_2NH as a dilute solution in CH_2Cl_2, giving the expected diamide product **6** as a mixture of diastereoisomers [$\delta_P(CDCl_3)$ 81.24 and 81.20; $\delta_H(CDCl_3)$ 2.475 and 2.435 (d, J_{PH} 10.5, N*Me*), 1.48 and 0.97 (d, J_{HH} 7, CH*Me*Ph) and 1.135 and 1.015 (t, J_{HH} 7, CH_2*Me*), *m*/*z* 405 (M^+, 15%)]. Whichever diastereoisomer of the substrate was used, the product **6** was obtained as practically the same 54 : 46 mixture having the low-field diastereoisomer (δ_P 81.24; δ_H 2.475, 1.48 and 1.135) in slight excess. As long as the diastereoisomers are configurationally stable under the conditions of reaction, it follows that substitution is non-stereospecific but slightly stereoselective. Such behaviour is not compatible with the normal $S_N2(P)$ mechanism of nucleophilic substitution,[9] but it is entirely reasonable for an EA mechanism in which both diastereoisomers of substrate form the thiophosphene intermediate **5** (Scheme 1). This is planar (trigonal) at phosphorus and can be attacked by Et_2NH at either face (non-stereospecificity), but the two faces are diastereotopic (chirality in NMeR*) so they will not necessarily be attacked with equal ease (diastereoselectivity).



Scheme 1

To assess the stability of the configuration at phosphorus the reactions of the two diastereoisomers of **4** were monitored by ^{31}P NMR spectroscopy, using a 0.2 mol dm^{-3} solution of Et_2NH (large excess) in CH_2Cl_2. In both cases the diastereoisomer composition of the product **6** (*ca.* 54 : 46) remained constant throughout the reaction ($t_{\frac{1}{2}}$ = 35–40 min at 19 °C) and the stereochemical integrity of the substrate was retained (≥95% one diastereoisomer at ≥90% completion).‡ It is therefore certain that non-stereospecificity is an integral part of the process of substitution.

In the course of the NMR experiments it became apparent that the products from the two diastereoisomers of the substrate were in fact not quite identical, the diastereoisomer ratios being 54.5 : 45.5 for **A** and 53 : 47 for **B**. The most obvious explanation is that elimination–addition is not completely dominant, so that a small proportion (1.5%) of the substrate is able to react stereospecifically by the normal $S_N2(P)$ mechanism. This, however, is difficult to reconcile with the behaviour observed using an amine less bulky than Et_2NH. As a base there is not much difference between Et_2NH and Me_2NH but as a nucleophile at a tetrahedral phosphorus centre there is;[10] with $PhP(S)(NMe_2)Cl$, for example, Me_2NH reacts at least a hundred times faster than Et_2NH.[7] If $S_N2(P)$ does compete with the EA

mechanism, it will surely do so much more effectively in the case of Me_2NH. In fact the reaction of **4** with Me_2NH is hardly more stereospecific at all. Using 0.2 mol dm^{-3} Me_2NH in CH_2Cl_2 the diamide product (**6** with Me_2N in place of Et_2N) [*m*/*z* 377 (M^+, 15%)] was formed ($t_{\frac{1}{2}}$ = *ca.* 15 min at 19 °C) with diastereoisomer ratios of 52.5 : 47.5 and 50.5 : 49.5 from **A** and **B** respectively, and again the low-field diastereoisomer [$\delta_P(CDCl_3)$ 85.04; $\delta_H(CDCl_3)$ 2.58 (d, J_{PH} 13, NMe_2), 2.46 (d, J_{PH} 10.5, NMe) and 1.45 (d, J_{HH} 7, CH*Me*Ph)] was formed in slight excess of the other (δ_P 84.97; δ_H 2.41, 2.41 and 0.88).‡ Here too, then, substitution is almost completely non-stereospecific. Any contribution from $S_N2(P)$ must be slight (2%) even with Me_2NH, and with Et_2NH it will surely be negligible. That being so, it seems likely that the reaction of **4** with Et_2NH proceeds entirely by an EA mechanism, with a thiophosphene intermediate, and that slight differences in the composition of the product from the two diastereoisomers are a consequence of the structure of the thiophosphene and/or the environment in which it is formed.§

Notes and references

† The substrate **4** and the products derived from it were fully characterised by NMR (^1H and ^{31}P) and IR spectroscopy, mass spectrometry (EI), and elemental analysis and/or accurate mass measurement.

‡ In CH_2Cl_2 the relative ^{31}P NMR chemical shifts of the two diastereoisomers of the diamide product are reversed (relative to $CDCl_3$) so the product formed in excess appeared at high field [$\delta_P(CH_2Cl_2)$ 80.96 and 81.02 with Et_2NH; 84.71 and 84.82 with Me_2NH].

§ The thiophosphene **5** has a (formal) C–P double bond so (in principle) it exists as *E* and *Z* isomers; these may be formed in differing proportions from the two diastereoisomers of the substrate and react with the nucleophile with differing stereoselectivities. Also, the thiophosphene may be so short-lived that some of it is trapped by the nucleophile before it is able to diffuse away from the chloride ion (or amine hydrochloride) released in the elimination step of the EA mechanism. In these ways the stereochemistry of the product could be influenced by the configuration of the substrate, notwithstanding the planarity at the phosphorus atom of the thiophosphene intermediate.

Clean catalysis with ionic solvents—phosphonium tosylates for hydroformylation

Nazira Karodia, Steven Guise, Craig Newlands and Jo-Ann Andersen*

School of Chemistry, University of St Andrews, St Andrews, Fife, UK KY16 9ST. E-mail: jma2@st-andrews.ac.uk

Received (in Basel, Switzerland) 10th July 1998, Accepted 7th September 1998

High-melting phosphonium tosylates are synthesised and applied for the first time as solvents in catalytic hydroformylation reactions; variation in the substituents attached to phosphorus can lead to markedly different results; the catalyst systems are non-corrosive, easily manipulated and can readily be recovered and reused.

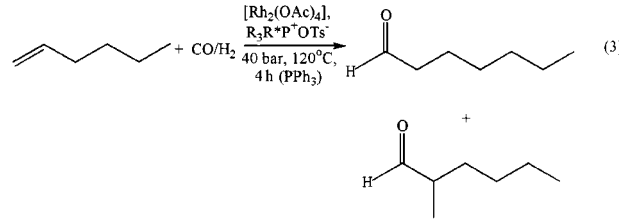
One of the major problems associated with homogeneous catalysts is that they are difficult to recover at the end of the reaction. Frequently distillation is used as a separation technique, but this is a very energy-intensive process. High-boiling products can remain with the catalyst and lead to catalyst deactivation or product contamination. This problem, especially for expensive and/or toxic precious metal catalyst systems, has precluded their more widespread application in the catalysis industry.

In today's environmentally conscious world, another problem with homogeneous catalysts has emerged, *viz.* many of the solvents traditionally used in transition metal catalysis, such as chlorinated hydrocarbons, acetonitrile, DMF to name but a few, are currently on the 'environmental blacklist'. It is rapidly becoming apparent that the way in which solvents are used in organic synthesis needs rethinking. The way forward may thus be to choose the solvent on environmental grounds and then optimise the reaction in that solvent.[1] In this respect, the use of high-melting ionic solvents (molten salts/ionic liquids) will be highly advantageous if the product(s) can readily be decanted off the stable catalyst system. The advantages of these systems will be manifold: in addition to facilitated catalyst recovery, they may exhibit low viscosity, high thermal and air stability, good electrical conductivity, low vapour pressure and they will readily solubilise the reagents and catalyst. They also exhibit a large 'liquid range', allowing for extensive kinetic control.[2] Room temperature ionic liquids such as alkylimidazolium chloride/$AlCl_3$ have been developed by Seddon and others[2,3] and have been found to function as highly efficient catalytic systems for reactions such as dimerisation and alkylation. However, much less attention has been paid to higher melting ionic solvents such as tetraalkyl ammonium and phosphonium salts. These offer advantages over the room temperature systems in that (i) they are not corrosive and (ii) being solid at room temperature, they are more easily manipulated and product separation is simple, being accomplished by decantation rather than by biphasic extraction. They are also stable to much higher temperatures, thereby enabling more forcing reaction conditions to be applied. We now report our results on the synthesis of tetraalkyl/aryl phosphonium tosylates and their application as solvents in hydroformylation reactions.

Salts **1–4** were synthesised by reaction of the tosylate esters [eqn. (1)] with the appropriate tertiary phosphine [eqn. (2)].

	R	R*
1	Ph	Et
2	Ph	Bu
3	Ph	Octyl
4	Bu	Et

All four salts were fully characterised; selected data are shown in Table 1. They were then applied as solvents in the hydroformylation of hex-1-ene to heptanal (**A**) and 2-methylhexanal (**B**) [eqn. (3)] in the presence of $[Rh_2(OAc)_4]$, both



with and without added phosphine ligand. Selected results are shown in Table 2.

In some instances, trace amounts (*ca.* 1–2%) of additional reaction products were observed. The isomerisation products 2-methylhexanal (**B**) and 2-ethylpentanal (**C**) (derived from the isomerisation of hex-1-ene to hex-2-ene and subsequent hydroformylation) were typically present in small amounts. In the case of $Ph_3PBu^+OTs^-$ and $Ph_3POc^+OTs^-$, the corresponding C_5 aldehyde and C_9 aldehyde were observed, respectively. These are most likely to derive from elimination of the bulky alkyl moiety (butyl or octyl) to form the corresponding alkene, analogous to Hoffmann eliminations in ammonium salts. The alkene is then hydroformylated to the corresponding aldehydes (**F**–**J**; see Scheme 1). This elimination process does not occur with $Bu_3PEt^+OTs^-$ or with $Ph_3PEt^+OTs^-$; presumably, in these cases, the ethyl group is small enough to remain bound to the P atom and does not eliminate.

Table 1 Characterisation of phosphonium salts

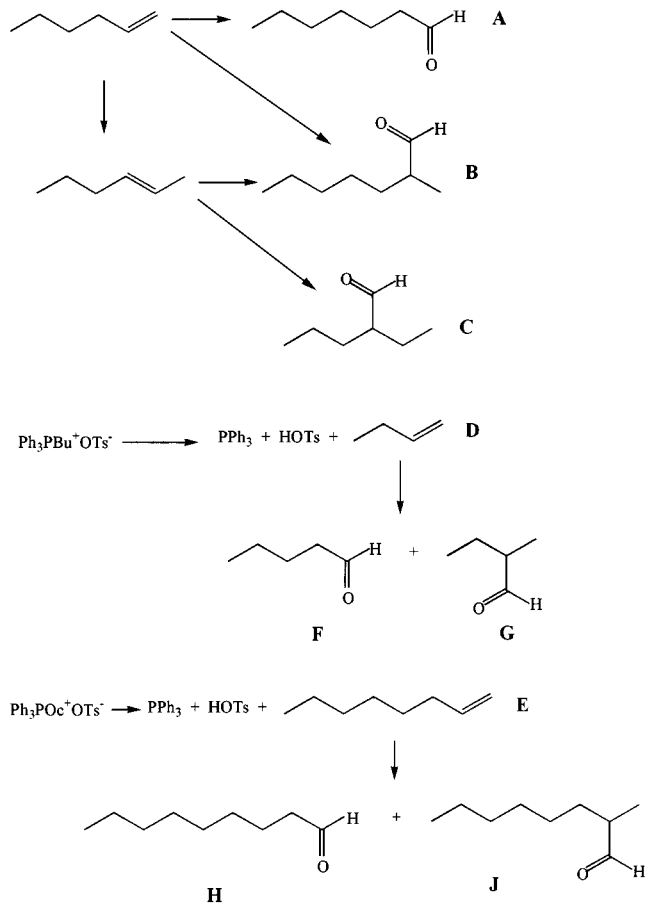

Scheme 1 Hydroformylation of hex-1-ene.

The results in Table 2 indicate that the substituents attached to the central phosphorus atom of the phoshonium salt exert a significant effect on the catalyst performance. With no added phosphine ligand, the conversions range from 66% (for $Ph_3POc^+OTs^-$) to 100% (for $Bu_3PEt^+OTs^-$) and the n : iso ratios range from 2.5 : 1 (for $Bu_3PEt^+OTs^-$) to 1 : 4 (for $Ph_3POc^+OTs^-$). This solvent effect is remarkable and is almost unparalleled in conventional homogeneous catalysis. In addition, our catalyst systems offer the advantage of extremely facile catalyst recovery post-reaction. Upon the addition of excess PPh_3, the catalytic results are very similar to each other (conversions range from 95 to 100% and n : iso ratios range from 1.5 : 1 to 2.2 : 1). We propose that in this case $(Ph_3P)_3Rh(CO)(H)$ forms initially (from $[Rh_2(OAc)_4]$, PPh_3, CO and H_2) and is then the catalytically active species in every reaction. Thus, one would expect very similar results, with only small influences being exerted by the phosphonium solvent.

At the end of the reaction, the reaction mixture was cooled and the liquid organic product was decanted and analysed by GC, GC-MS and NMR. This facile product recovery is the most significant advantage of these systems. The recovered solid was characterised in order to determine that the phosphonium salt had not changed during the course of the reaction, which was indeed the case. The organic products were analysed for rhodium content (by atomic absorption); in all cases, negligible amounts (if any) were observed, indicating that the rhodium catalyst remains within the (crystalline) structure of the solid solvent. These catalyst systems have been re-used several times and gave reproducible results.

Studies are now under way with a larger range of salts, substrates and reaction types to investigate the general applicability of these novel solvents which are analogous to conventional dipolar aprotic solvents but also offer the considerable advantage of facile catalyst recovery and cleaner, efficient catalytic reactions.

We thank the Royal Society of Edinburgh (J. A.), the EPSRC (N. K.) and the Carnegie Trust, University of St Andrews (C. N.).

Stable bis(silyl)nickel complexes with *o*-carboranyl unit: a facile double silylation of alkynes and alkenes

Youngjin Kang,[a] Junghyun Lee,[b] Young Kun Kong,[b] Sang Ook Kang,*[a] and Jaejung Ko*[a]

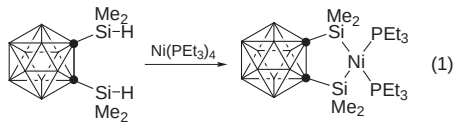
[a] *Department of Chemistry, Korea University, Chochiwon, Chungnam 339-700, Korea. E-mail: jko@tiger.korea.ac.kr*
[b] *Department of Chemistry, Kyunggi University, Suwon, Kyunggido 440-760, Korea*

Received (in Cambridge, UK) 17th August 1998, Accepted 15th September 1998

The reaction of *o*-bis(dimethylsilyl)carborane with $Ni(PEt_3)_4$ in pentane affords the reactive intermediate, $[o\text{-}(SiMe_2)_2C_2B_{10}H_{10}]Ni(PEt_3)_2$ 2; the facile double silylation of alkynes catalyzed by 2 is reported.

The double silylation of unsaturated organic substrates catalyzed by group 10 metals has been well documented for two decades.[1] Nickel complexes, in particular, provide excellent catalysts for the transformation of silicon-containing linear compounds. Cyclic bis(silyl)nickel complexes have been implicated as important intermediates in the nickel-catalyzed double silylation of arenes,[3] alkynes,[4] alkenes[5] and aldehydes.[6] However, the intermediates have not been isolated due to their instability. We now describe (i) the isolation of the reactive intermediate cyclic bis(silyl)nickel compound with a bulky *o*-carborane unit; (ii) the facile double silylation of alkynes catalyzed by the intermediate under mild conditions; and (iii) the double silylation of alkenes by the stoichiometric reaction with the intermediate.

Addition of 1.2 equiv. of *o*-bis(dimethylsilyl)carborane, prepared from 1,2-$Li_2C_2B_{10}H_{10}$ and 2 equiv. of $SiMe_2ClH$, to $Ni(PEt_3)_4$ in pentane at 25 °C gave a dark red solution, concomitant with the evolution of gas. Standard workup and crystallization from toluene–pentane gave $[o\text{-}(SiMe_2)_2C_2B_{10}H_{10}]Ni(PEt_3)_2$ **2** as a spectroscopically pure, dark red crystalline solid sensitive to air and stable during brief heating to 100–110 °C in 86% yield [eqn. (1)].† The unusual thermal



1 **2**

stability of the nickel bis(silyl) compound is attributed to the advantageous properties of the carboranyl unit, including electronic and steric effect.

The ^1H, ^{13}C, ^{31}P and ^{29}Si NMR spectra for **2** support the proposed structure. In particular, the ^{29}Si NMR chemical shift of δ 43.19 as a triplet ($J_{Si-P(cis)}$ 40.11 Hz) resembles the literature value reported for the *cis*-$NiSi_2PC$ complex.[7] The structure of **2** was unambiguously established by a single-crystal X-ray analysis (Fig. 1).‡ Complex **2** has a distorted tetrahedral geometry with the dihedral angle between P(1)–Ni–P(2) and Si(1)–Ni–Si(2) being 86.03°. Such bis(silyl)nickel complexes are rare as indicated by a search of the Cambridge Data Base which revealed only a few previous examples.[8] As expected, the average Ni–Si bond length [2.2424(9) Å] is slightly longer than that of 2.171(3) Å in $[(\mu\text{-}Cl)_2Ni_2(SiCl_3)_4][(CMe_3)_2C_5H_3NH]_2$.[8] The Ni–P bond distance [2.2305(8) Å] is consistent with those observed in other phosphine nickel compounds.[9]

Compound **2** was found to be a good reactive intermediate for the double silylation reaction. The reaction of *o*-bis(dimethylsilyl)carborane **1** with 1-phenylprop-1-yne (1 equiv.) in the presence of a catalytic amount of **2** (0.03 equiv.) for 6 h afforded the double-silylated product **3** in 94% (GC) yield. The reaction was quite sensitive to the reaction conditions. When the same reaction was carried out at higher temperature (70–75 °C), the major component was identified as the acetylene cyclotrimerization product **4** (Scheme 1), which has been characterized by spectroscopic techniques.

When hex-1-yne is employed as a terminal alkyne in the reaction with **1** under the same conditions, the five-membered disilyl ring compound **5** is isolated as a colorless liquid in 71% yield. All the spectral data of **5** was consistent with the proposed formulation.

The reaction of **2** with 1 equiv. of styrene takes place at a higher temperature (80 °C) and affords a moderate yield of the five-membered disilyl ring compound **6** (Scheme 2). A key feature in the ^1H NMR spectrum of **6** includes a singlet at δ 7.71 assigned to the vinyl proton. A characteristic low frequency ^{13}C NMR resonance at δ 139.75 provides evidence for a tethered carbon atom of the two silicon moieties. The structure of **6** has been determined by X-ray crystallography.‡ Such formation of the disilyl ring compound has been observed during the nickel-catalyzed reaction of benzo-disilacyclobutene with styrene.[5] Treatment of **2** with 1 equiv. of 1,1-diphenyl-ethylene in toluene at 80 °C resulted in a brown solution from which the five-membered disilyl ring compound **7** was isolated in a yield of

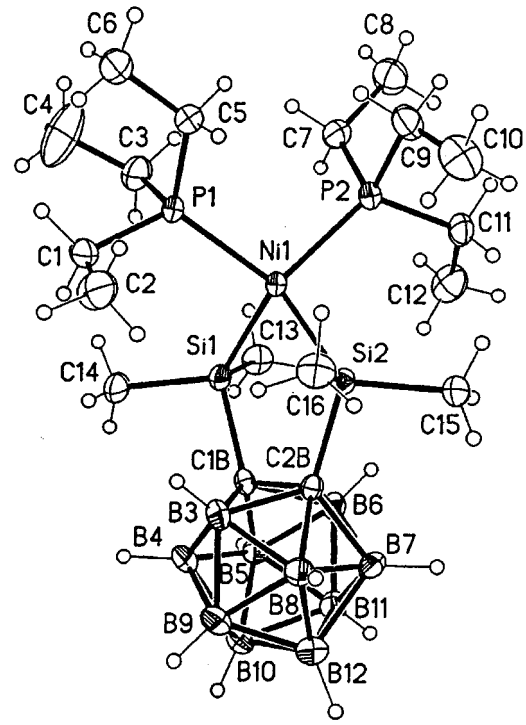


Fig. 1 Molecular structure of **2** showing the atom numbering scheme. Selected distances (Å) and angles (°): Ni(1)–P(1) 2.2265(8), Ni(1)–P(2) 2.2346(8), Ni(1)–Si(1) 2.2371(9), Ni(1)–Si(2) 2.2477(9), Si(1)–C(1B) 1.941(3), Si(2)–C(2B) 1.940(3), C(1B)–C(2B) 1.669(4); P(1)–Ni(1)–P(2) 101.95(3), Si(1)–Ni(1)–Si(2) 83.69(3), P(1)–Ni(1)–Si(1) 96.06(3), P(2)–Ni(1)–Si(1) 140.35(4).

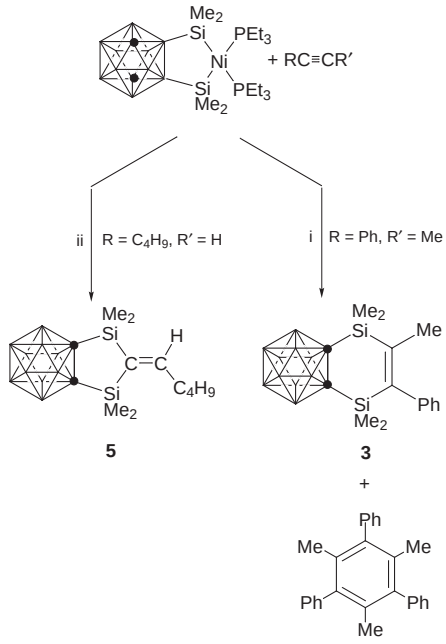
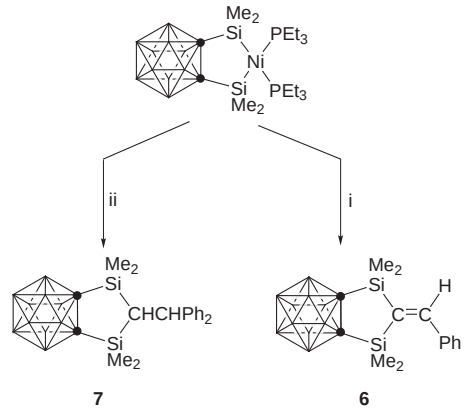


Scheme 1 *Reagents and conditions*: i, PhCCMe (1 equiv.), **1** (1 equiv.), **2** (0.03 equiv.), toluene, 25 °C, 94%; ii, $HCCC_4H_9$ (1 equiv.), **1** (1 equiv.), **2** (0.03 equiv.), toluene, 25 °C, 71%.



Scheme 2 *Reagents and conditions*: i, $PhCHCH_2$ (1 equiv.), **2** (1 equiv.), toluene, 80 °C, 84%; ii, Ph_2CCH_2 (1 equiv.), **2** (1 equiv.), toluene, 80 °C, 74%.

74%. The formulation of **7** was confirmed by a spectrometric analysis. The mass spectrum of the product showed a molecular ion at *m/z* 440.

Two doublets (δ 3.93, 1.81) in the ^{1}H NMR spectrum of **7** are assigned to the methine protons. A low-frequency ^{13}C NMR resonance at δ 49.87 provides evidence for the tethered carbon atom of the two silicon moieties.

In summary, we have isolated the reactive intermediate, the cyclic bis(silyl) nickel complex, which reacts with unsaturated organic substrates such as an alkyne and alkene, generating a new class of heterocyclic compounds. The intermediate **2** is quite reactive and readily attacked by a variety of organic substrates. This potential has been further exploited in a series of novel chemical transformations with this system.

We are grateful to KOSEF for the generous financial support.

TiO_2 photocatalytic reduction of bis(2-dipyridyl)disulfide to 2-mercaptopyridine by H_2O: incorporation effect of nanometer-sized Ag particles

Hiroaki Tada,*[a] Kazuaki Teranishi,[b] Yo-ichi Inubushi[b] and Seishiro Ito[b]

[b] *Department of Applied Chemistry, Faculty of Science and Engineering, Kinki University, 3-4-1, Kowakae, Higashi-Osaka, 577-8502, Japan.*

Received (in Exeter, UK) 27th July 1998, Accepted 25th September 1998

A highly endothermic reduction of bis(2-dipyridyl)disulfide to 2-mercaptopyridine by H_2O selectively proceeds using TiO_2 as a photocatalyst, being significantly enhanced upon incorporation of nanometer-sized Ag particles on TiO_2.

Thiols are the most important of the sulfur containing molecules, owing to their usefulness as starting materials for the syntheses of agrochemicals, pharmaceutical products, petrochemicals, *etc.* Several methods for reducing disulfides to the corresponding thiols use reducing agents, including lithium aluminium hydride, sodium hydride, chromium(II), and triphenylphosphine–H_2O.[1] On the other hand, sulfur compounds frequently have a poisoning effect on transition metal catalysts, which was also observed in the reduction of disulfides to thiols by Pd/charcoal catalyst.[2] Poisoning is generally caused by the high adsorption strength of sulfur compounds for the surface active sites of transition metals. This is the first report on TiO_2 photocatalytic reduction of bis(2-dipyridyl)disulfide (RSSR) to 2-mercaptopyridine (RSH) by H_2O. Particular emphasis was placed on the promoting effect with loading of nanometer-sized Ag particles on TiO_2 (Ag/TiO_2).

TiO_2 and Ag/TiO_2[3] absorb light intensely below 385 nm due to the band gap transition. Nanometer-sized Ag particles have a surface plasmon absorption in the wavelength range $300 < \lambda < 500$ nm.[4] In the spectrum of RSSR, there are two absorption bands above 220 nm, at 233 and 281 nm. Light with $\lambda < 300$ nm was cut off by a Pyrex glass filter and both TiO_2 and Ag were excited by irradiation. When the TiO_2 or Ag/TiO_2 suspension containing RSSR [solvent : H_2O–acetonitrile (99 : 1 v/v)] is irradiated under deaerated conditions, the peak intensities of RSSR weaken concurrently with the appearance of new two bands at 272 and 342 nm, which are in complete agreement with the peak positions of authentic RSH. The production of RSH was also confirmed by HPLC and negligible amounts of by-products were detected. A stoichiometric relation with a ratio of [RSH]/[RSSR] of *ca.* 2 was obtained in the conversion of RSSR to RSH, indicating the selective reduction of RSSR to RSH.

Photoillumination of either Ag/TiO_2 or TiO_2 was required to reduce RSSR. This reaction is thus induced not by Ag photoexcitation but by the band gap transition of TiO_2. During the reaction, a gradual decrease in pH of the solution from 5.8 to 4.8 was observed. A small amount of O_2 was detected in a closed reaction system by gas chromatography. This is probably due to its consumption through the successive reduction by the excited electron and/or the reaction with RSSR. The possibility of the oxidation of acetonitrile, which was added to H_2O in order to dissolve RSSR, was excluded, since no reduction occurred upon using dehydrated acetonitrile as the solvent. From these results above, the overall reaction can be written as eqn. (1).

$$\mathrm{RSSR} + \mathrm{H_2O} \xrightarrow[\mathrm{TiO_2\ or\ Ag/TiO_2}]{h\nu(\lambda > 300\ \mathrm{nm})} 2\mathrm{RSH} + 1/2\mathrm{O_2} \quad \Delta H = +207.9\ \mathrm{kJ\,mol^{-1}} \qquad (1)$$

This highly endothermic reaction may also be attractive from the viewpoint of converting light energy to chemical energy.

Fig. 1 shows time course of the RSH production in the presence of TiO_2 (a) and Ag/TiO_2 (b). The rate of the reaction calculated from the concentration of RSH formed after 100 min illumination (v) is increased by a factor of 5.2 with Ag loading. The continuous formation of RSH for more than 150 min suggests high chemical stability of the Ag deposits under the present conditions. The dependence of v on the amount of Ag loaded ($0 < x < 1$ wt.%) was examined. It was shown that v goes through a maximum near $x = 0.24$ wt.%. A possible explanation for the decrease in v at $x > 0.24$ wt.% is light shielding by Ag. This fact again precludes the possibility of Ag photoinduced reduction of RSSR.

Adsorption isotherms of RSSR on TiO_2 (a) and Ag/TiO_2 (b) were measured at 28.5 ± 0.5 °C. From the analyses of the Langmuir plots, the saturated adsorption amount (Γ_s) and the constant indicative of adsorption strength (β) were calculated to be 1.07×10^{-6} mol g^{-1} and 1.27×10^5 dm^3 mol^{-1} for TiO_2, and 1.92×10^{-5} mol g^{-1} and 1.56×10^6 dm^3 mol^{-1} for Ag/TiO_2. Various self-assembled monolayers (SAMs) of surface active organosulfur compounds such as thiols (R′SH), sulfides (R′SR′) and disulfides (R′SSR′) that adsorb on Ag or Au, owing to the specific interaction of R′S–Ag or R′S–Au, have been a topic in the field of surface science.[5] It has been revealed that R′SSR′ chemisorbs on the surface of Ag(111) or Au(111) *via* S–S bond cleavage.[5] The RS group was previously confirmed by other workers to adsorb on Ag stably without S–C bond fission.[6] The areas occupied by one RS group in the Ag/TiO_2 were calculated to be 6.4 nm^2 group^{-1} for TiO_2 and 0.1 nm^2 group^{-1} for Ag. The corresponding areas for the RS group adsorbed in

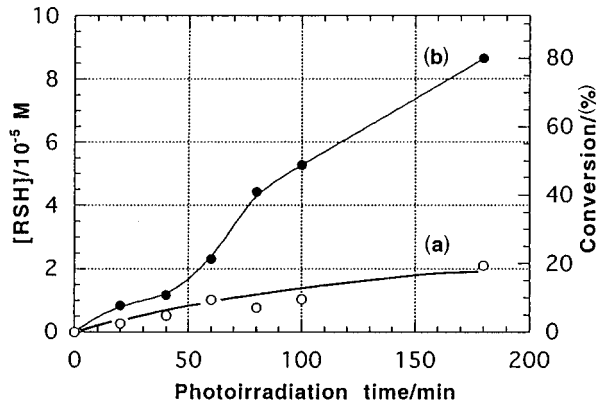

Fig. 1 Time courses of the RSH production in the presence of TiO_2 (a) and Ag/TiO_2 (b). A 5.41×10^{-5} M RSSR solution (50 ml of H_2O–acetonitrile (99 : 1 v/v) was irradiated in the presence of 50 mg TiO_2 or Ag/TiO_2 at 22 ± 1 °C. The light intensity integrated from 320 to 400 nm was 4.62 mW cm^{-2}. Irradiation was commenced after removal of dissolved O_2 by 15 min N_2 bubbling and attainment of adsorption equilibrium by stirring for 1 h in the dark; N_2 bubbling was continued throughout the reaction.

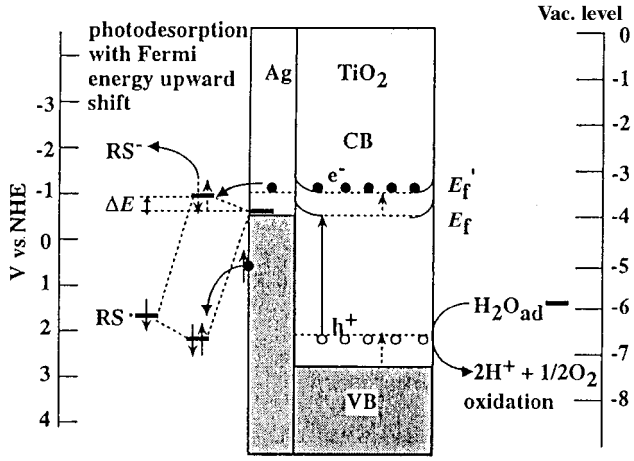

Fig. 2 Energy diagram of the reaction system. The following values were used for its construction: work function of Ag = 4.0 eV;[8] electron energy for the standard hydrogen electrode (SHE) = −4.5 eV *vs.* SHE;[9] flat band potential of TiO_2 at pH 5.5 = −0.45 V from the vacuum level;[10] band gap energy of TiO_2 = 3.2 eV;[10] oxidation potential of H_2O at pH 0 = 1.23 V *vs.* SHE;[10] HOMO of RS· radical = −6.4 eV (this value was obtained from PM3 MO calculations).

the closest packing states were estimated to be *ca.* 0.16 nm^2 $group^{-1}$ for the flat lying orientation and 0.1 nm^2 $group^{-1}$ for the vertical orientation using the PM3 optimized molecular structure. Clearly, the RS groups adsorb on the surface of nanometer-sized Ag particles in a close packed state analogous to those in SAMs, while most of the TiO_2 surface is directly in contact with H_2O.

A plausible reaction mechanism is summarized as follows. In the initial stage of the reaction, selective RSSR adsorption on the surface of Ag accompanied by S–S bond cleavage takes place. Electron–hole pairs are generated by the band gap excitation of TiO_2. Most of the pairs are lost by recombination but a portion of the electrons excited to the conduction band (CB) flow into Ag, while the holes are left in the valence band (VB) of TiO_2. The Schottky barrier at the Ag/TiO_2 interface would assist the charge separation. The hole has enough potential to oxidize H_2O to yield H^+ and O_2. The coupling of H^+ and RS^-, driven to desorb reductively by the excited electron, forms RSH. A similar reductive desorption of *n*-alkanethiols from an Au electrode has been reported by Widrig *et al.*[7] In the TiO_2 system, the reduction of RSSR is thought to proceed in a similar manner as in the Ag/TiO_2 system; however, the alternative reduction site would be surface Ti^{3+} ions. Three factors for reaction enhancement effect of the Ag loading can be proposed. The first is enhanced adsorption of RSSR, the second is the separation of reduction (Ag) and oxidation sites (TiO_2) and the third is that the oxidant (RSSR) and the reductant (H_2O) selectively adsorb on the reduction and oxidation sites, respectively, resulting in a highly selective reaction.

Since the turnover number is calculated to be *ca.* 6.7×10^{14} molecules cm^{-2}, this reaction is qualified to be catalytic. The strangest and most intriguing question raised by this reaction is why RS adsorbed on Ag desorbs from the surface upon irradiation despite its strong adsorption strength as evidenced by the large β value of 1.56×10^6 dm^3 mol^{-1} for Ag/TiO_2. Fig. 2 depicts the energy diagram of the reaction system. A couple of bonding and antibonding orbitals are formed as the result of the interaction between the highest occupied molecular orbital (HOMO) of RS·[11] and an unoccupied molecular orbital (UMO) above the Fermi energy (E_f) of Ag.[12] In the ground state, the bonding orbital is occupied by two electrons, each of which originally belongs to RS· and Ag, respectively, leading to a strong interfacial RS–Ag bond. The contribution of the HOMO of RS· to the bonding orbital is much greater than that of the UMO of Ag. Thus the interfacial bond can approximately be described as RS^-–Ag^+, which is confirmed by XPS measurements of SAMs.[13] On the other hand, in the photoexcitation state, E_f is raised by several hundreds of meV (E_f'),[14] which corresponds to the bonding energy of R′SSR′ on Au (*ca.* 0.5 eV per R′S group).[15] If E_f' exceeds the energy of the interfacial antibonding orbital, it would be occupied by the two electrons from Ag. The destabilizing energy will enable the desorption of RS^- upon illumination, and further the photocatalytic cycle in this reaction. We refer to this as photodesorption with an upward shift of the Fermi energy. Essentially, the electrochemical reductive desorption of *n*-alkanethiol monolayers from Ag and Au electrodes can be interpreted as desorption with an upward shift of the Fermi energy induced by the application of external electric voltage. Widrig *et al.* explained the fact that the reductive desorption from Ag as compared to Au occurs at 0.30 V more negative potential due to the differences in the point of zero charge for the two metals.[7] According to our theory, this can alternatively be attributed to the differences in the work function (Ag = 4.0 ± 0.15 eV, Au = 5.1 ± 0.1 eV),[8] assuming comparable interaction energy (ΔE in Fig. 2).

In conclusion, it has been demonstrated that a highly endothermic reduction of RSSR to RSH by H_2O proceeds selectively and efficiently using Ag/TiO_2 as a photocatalyst. The essential reaction mechanism is presented on the basis of the adsorption and kinetic data. Photodesorption with an upward shift of the Fermi energy is proposed as a key process in the catalytic cycle. This action of Ag/TiO_2 may open up a new field of photocatalytic reactions of heterocompounds, whose thermal catalytic reactions using transition metal catalysts are usually not straightforward due to their poisoning effect.

Support of this work by the ESRI (Kinki University) under the artificial photosynthesis program is gratefully acknowledged.

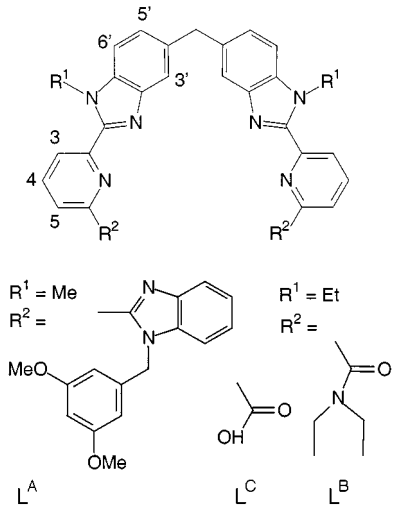
Received (in Cambridge, UK) 28th August 1998, Accepted 25th September 1998

Triple-stranded bimetallic helicates $[Ln_2(L^C - 2H)_3]$ form in water by a strict self-assembly process and are shown to be thermodynamically very stable (log β_{23} > 26) and luminescent (Ln = Eu).

To cope with the demand for efficient light-converting devices arising from the development of time-resolved fluoroimmunoassays, signalling and luminescent labelling technologies,[1–4] including bimetallic probes which provide two probe signals in one stain, co-ordination chemists have developed several strategies. Among these, self-assembly processes[5] based on the induced fit concept[6] have proved efficient in designing lanthanide building blocks with predetermined structural and physicochemical properties.[7] The ditopic ligand L^A was



L^A L^C L^B

designed to produce the cationic triple-stranded helicate $[Ln_2(L^A)_3]^{6+}$ by strict self-assembly and the resulting complexes exhibit a large stability in MeCN.[8] The $[Eu_2(L^A)_3]^{6+}$ helicate is, however, only weakly luminescent and is water sensitive, two severe handicaps for its use as a probe. A substantial improvement was achieved upon replacing the terminal benzimidazole groups in L^A by carboxamide binding units in L^B, with a large increase in the Eu-centred luminescence and a good resistance of the triple-stranded helicate $[Eu_2(L^B)_3]^{6+}$ toward hydrolysis in MeCN containing up to 2.5 M water.[9] However, biomedical applications require water soluble probes and, to our knowledge, self-assembly of bimetallic lanthanide-containing edifices in water have only been reported for $[Ln_2L_2]$ supramolecular boxes where L is 2,6-bis[*N*,*N*-bis(carboxymethyl)aminomethyl]-4-benzoylphenol and in which the Ln^{III} cations are linked to each other by an aqua bridge inside the cage.[10] In order to test whether the energetic drive leading to the formation of bimetallic helicates in water is able to compensate the large dehydration enthalpy of the lanthanide aquo-ions, we have introduced two carboxylic acid functions in L^C, which led to the quantitative formation of neutral $[Ln_2(L^C - 2H)_3]$ triple-stranded helicates. These new compounds are thermodynamically highly stable and luminescent (Ln = Eu) and they are the first examples of such structures self-assembled in water.

Ligand L^C was obtained from the hydrolysis of L^B† and the pK_a of the carboxylic groups were determined by potentiometry to be 4.15 ± 0.05 and 7.05 ± 0.05 (0.1 M Et_4NClO_4). ^1H NMR titration of L^C with $Eu(ClO_4)_3 \cdot xH_2O$, in D_2O at pD = 12.74, points to the exclusive formation of a 2 : 3 species (break at $[Eu]/[L^C]$ = 0.64, no hydroxide precipitation before the break point). This speciation is confirmed by spectrophotometric data obtained at pH 7.2 and 298 K in H_2O ($[L^C] = 1.05 \times 10^{-5}$ M, $0 < [Ln] < 1.6 \times 10^{-5}$ M), which can be fitted to eqn. (1) for Ln = La (log β_{23} = 30 ± 1), Eu (26.1 ± 0.4) and Lu (27.3 ± 0.6).‡ Titrations with solutions in MeOH–H_2O 98 : 2 (v/v) yield similar log β_{23} values, 29.6 ± 0.8 (La), 27.8 ± 0.6 (Eu) and 25.9 ± 0.3 (Lu), but data for Eu and Lu have to be fitted to eqns. (1) and (2) with log β_{22} = 21 ± 0.6 (Eu) and 19.1 ± 0.5 (Lu). As a

$$2\ Ln^{3+} + 3\ (L^C - 2H)^{2-} \rightleftharpoons [Ln_2(L^C - 2H)_3] \quad \log \beta_{23} \qquad (1)$$

$$2\ Ln^{3+} + 2\ (L^C - 2H)^{2-} \rightleftharpoons [Ln_2(L^C - 2H)_2]^{2+} \quad \log \beta_{22} \qquad (2)$$

comparison, helicates formed by L^B in aprotic MeCN display log β_{23} values in the range 24–25 and log β_{22} values in the range 19–20.[9] The large thermodynamic stability of the $[Ln_2(L^C - 2H)_3]$ helicates in water is further demonstrated by the partial decomplexation observed in the ^1H NMR spectrum of $[Eu_2(L^C - 2H)_3]$ 3.2×10^{-3} M in D_2O upon adding a 20-fold excess of H_2EDTA^{2-}.

Solid complexes have been isolated for Ln = La, Pr, Nd, Eu, Gd, Tb, Tm, Yb, Lu and crystals suitable for crystallographic investigation were obtained for Eu, Tb and Yb.§ The structure of the Eu-helicate is presented in Fig. 1.¶ The asymmetric unit contains two slightly different neutral bimetallic helicates without imposed crystallographic symmetry but with pseudo-D_3 symmetry, as well as 41 water molecules. Molecule A has an Eu···Eu separation of 8.807(3) Å and features two nine-coordinate Eu^{III} ions with marginally different environments [mean Eu–N distances 2.59(3)/2.62(4) Å, mean Eu–O distances 2.40(2)/2.39(2) Å, ionic radius 1.12(3)/1.13(5) Å]. Molecule B displays a larger Eu···Eu separation, 9.044(3) Å, and co-ordination to carboxylic groups is less symmetrical [mean Eu–N distances 2.60(3)/2.59(5) Å, mean Eu–O distances

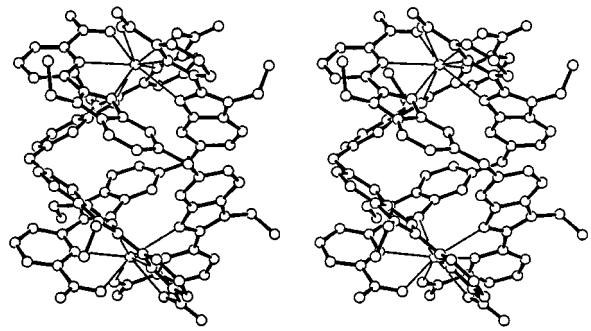


Fig. 1 ORTEP III stereoview of molecule A $[Eu_2(L^C - 2H)_3] \cdot 20.5H_2O$, perpendicular to the pseudo-C_3 axis (upper ion: Eu1A, lower ion: Eu2A).

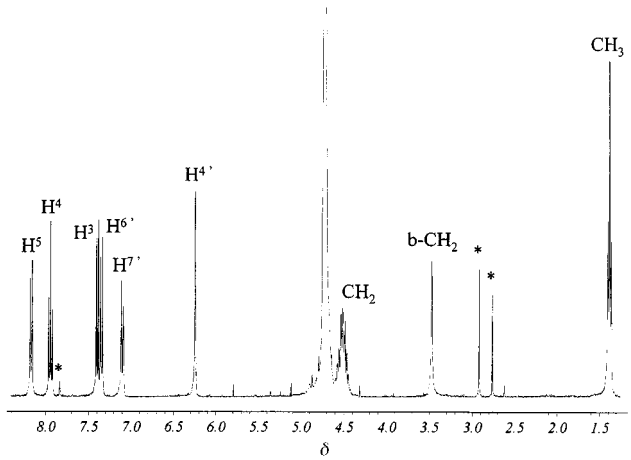

Fig. 2 ^{1}H NMR spectrum of 10^{-4} M $[La_2)L^C - 2H)_3]$ in D_2O at pD = 7 and 303 K, with assignment (b-CH_2: bridging methylene; DMF as internal reference*).

2.40(6)/2.41(4) Å, ionic radius 1.12(5)/1.12(4) Å]. As the pH of the mother liquor is *ca.* 7.5–8.2, a partial protonation of the carboxylic groups associated with the presence of hydroxide counter-anions in the asymmetric unit[11] is not likely especially that the mean C–O distances for coordinated (1.27 Å, A and B) and non-coordinated (1.23 Å, A and 1.24 Å, B) O atoms closely match those found in the tris(dipicolinate)anion.[12] Analysis of the coordination polyhedra[13] of the four different metal ions reveals slightly distorted tricapped trigonal prisms. The facial planes of the two distal tripods defined by the three coordinated O atoms from the carboxylates and the three N atoms from the benzimidazole moieties are almost parallel with mean dihedral angles of 3.4° (A) and 6.8° (B) and the interligand ω_i angles[13,14] are in the ranges 11.1–13.6° (A) and 8.1–14.9° (B) (ideal trigonal prism: 0°). The distances between these facial planes, 3.16 Å (A) and 3.23 Å (B), are substantially shorter than that found in the monometallic tris(dipicolinate) Eu-complex (3.44 Å),[12] pointing to a significant compression along the pseudo C_3 axis. The helical twist of the ligand strands (pitch: 23.7 Å, A and 24.4 Å, B) is achieved through rotation about the methylene C–C bond with interplanar angles between the benzimidazole units in the range 66.5–74.6° (A) and 62.4–72.7° (B). The entire structure is held together by an extensive network of water molecules. Preliminary results on the structure of the Tb and Yb helicates reveal an isotypic series of complexes with Ln^{III} environments comparable to those found for Eu^{III}.

The triple helicate structure is maintained in solution, as demonstrated by the observed ^{1}H NMR spectra in D_2O, which imply the formation of a single, inert and compact complex with D_3 symmetry (Fig. 2).[8,9] A preliminary analysis for the complete Ln series, including separation of the contact and dipolar contributions to the chemical shifts points to an isostructural set of helicates. The $[Ln_2(L^C - 2H)_3]$ complexes display interesting photophysical properties. The quantum yield of the ligand-centred luminescence with respect to quinine sulfate (0.044–0.047 at pH 6.8–12.1 in H_2O) increases 10-fold in the La^{III} and Lu^{III} helicates (0.52 at pH 6.8), while it decreases by a factor 2.5 in the Gd^{III} helicate (0.017 at pH 6.7). The $^1\pi\pi^*$ luminescence disappears in the Eu^{III} and Tb^{III} helicates and the characteristic f–f emission bands are observed. The emission spectrum of the $[Eu_2(L^C - 2H)_3](aq)$ is similar to the solid state spectrum, and the $Eu(^5D_0)$ lifetime of 10^{-8} M solutions amounts to 2.5 ms (H_2O) and 4.6 ms (D_2O). This substantiates the conclusion based on the NMR spectra regarding the solution structure of the helicates and proves that no OH oscillator is interacting directly with the metal ion, the lengthening of the lifetime in D_2O, formally corresponding to an inner-sphere interaction with 0.2 water molecule,[4] can be assigned to second sphere effects.[15] The quantum yield Q^{Eu}_{rel} of the metal-centred luminescence has been measured for solutions in H_2O (pH 7.0) with respect to 10^{-3} M $[Eu(tpy)_3](ClO_4)_3$ in MeCN[9] and is equal to 1.00 (absolute yield: 1.3%), leading to a detection limit of 10^{-9}–10^{-10} M in H_2O and 10^{-10}–10^{-11} M in D_2O. Although Tb^{III} appears to be effectively sensitized by L^C, Q^{Tb}_{rel} is low (0.038) due to an efficient back transfer process which was evidenced by measuring the $Tb(^5D_4)$ lifetime of the helicate between 77 K (2.1 ms) and 270 K (0.05 ms), and which arises from a too close proximity of the $L^C(^3\pi\pi^*)$ and $Tb(^5D_4)$ levels.

In conclusion, strict self-assembly of L^C with Ln^{III} ions in water leads to the formation of a new class of lanthanide carboxylates. The resulting triple-stranded helicates are thermodynamically highly stable and luminescent (Ln = Eu) and the structural control achieved for these architectures is similar to the one provided by pre-organized receptors.

We thank the Swiss National Science Foundation for supporting grants, the Werner Foundation for a grant to C. P. and the Herbette Foundation (Lausanne) for spectroscopic equipment.

Efficient copper (II)-mediated nuclease activity of *ortho*-quinacridines

Olivier Baudoin, Marie-Paule Teulade-Fichou, Jean-Pierre Vigneron and Jean-Marie Lehn*

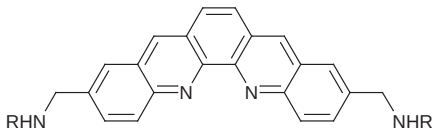
Laboratoire de Chimie des Interactions Moléculaires (CNRS UPR 285), Collège de France, 11 place Marcelin Berthelot, 75005 Paris, France. E-mail: lehn@cdf.in2p3.fr

Received (in Basel, Switzerland) 3rd August 1998, Accepted 25th September 1998

The *ortho*-quinacridine compounds OQ_1 and OQ_2 bind strongly to double stranded DNA and effect efficient cleavage in the presence of Cu^{2+} and in the absence of reducing agent; their activity increases further in the presence of hydrogen peroxide.

Artificial metallonucleases have proven to be efficient tools for the footprinting and sequence-specific targeting of nucleic acids.[1] They are composed of a transition or lanthanide metal ion and of a ligand which plays two major roles: it modulates the reactivity of the metal and interacts with the nucleic acid, delivering the reactive metallic species in the vicinity of the sensitive functionnalities of the biopolymer. Among these compounds, copper(II) complexes were found to cleave DNA, most of them in an oxidative manner.[1–3] They usually require high concentrations of the complex and of an external reducing agent (such as dithiothreitol, DTT) to form *in situ* a reactive copper(I) species, two features which may limit their scope for biological applications at the cellular level. A recent article reports the cleavage of double stranded (ds) plasmid DNA by low concentrations of a tambjamine–copper complex; in this case the ligand is acting as an internal reducing agent.[4]

These considerations prompt us to report on results obtained with water-soluble dibenzo[*b*,*j*]phenanthroline (*i.e.* quinacridine) ligands, fused heteroaromatic pentacycles that display a crescent-shaped structure and were designed to present a large overlap area with pairs or triplets of nucleobases. We recently described their synthesis[5] and their ability to stabilise DNA triple helices through putative intercalation.[6] Among them, the *ortho*-quinacridines (OQ) OQ_1 and OQ_2 possess the *ortho*-phenanthroline (OP) substructure, which forms stable copper complexes. Indeed $Cu(OP)_2^{2+}$ is well known for its ability to cleave nucleic acids oxidatively in the presence of a reducing agent, *via* the formation of Cu(I) and subsequently of copper–oxo species.[1,7] At pH 6, OQ_1 and OQ_2 bear respectively two and



OQ_1, R = $CH_2CH_2CH_3$
OQ_2, R = $(CH_2)_3N(CH_3)_2$

four positive charges located on the ammonium groups of the two side chains.† The ability of OQ to bind to ds DNA was monitored by thermal denaturation experiments and by fluorescence quenching assay[8] (Table 1).

Significant stabilisation of poly(dA.dT)–poly(dA.dT) and efficient displacement of ethidium bromide were observed, indicating that OQ_1 and OQ_2 bind strongly to DNA. OQ_2 was found to be a better DNA ligand than OQ_1 due to its additional positive charges; in addition it seems to have an affinity for DNA comparable to that of the reference compound Hoechst 33258 (stability constant *ca.* 10^7 dm^3 mol^{-1}).[9] Furthermore, the observation of fluorescence contact energy transfer[10] from DNA nucleobases to both dyes gave evidence that intercalation is occurring (data not shown).

Table 1 Interaction of OQ_1 and OQ_2 with Poly(dA.dT)–Poly(dA.dT)

	Ethidium	H33258	OQ_1	OQ_2
ΔT_m[a]/°C	+12	+27	+15	+25.5
C_{50}[b]/μM	—	0.082	0.65	0.081

[a] Variation of the melting temperature of DNA (40 μM in phosphate units) upon addition of the various ligands (6 μM), accuracy ± 1 °C, determined in 30 mM cacodylate buffer (pH 6.0)–10 mM NaCl; the T_m of DNA alone in these conditions was 53.5 °C. [b] Concentration of drug necessary to displace 50% of the DNA-bound ethidium bromide; concentration of DNA 1 μM (in phosphate units) and ethidium 1.26 μM in 30 mM cacodylate buffer (pH 6.0)–10 mM NaCl; the fluorescence emission of ethidium at 595 nm (λ_{exc} = 546 nm) was used to follow this titration.[8]

The ability of OQ to cleave ds plasmid DNA in the presence of Cu^{2+} was then examined (Fig. 1). A slow cleavage was observed (lanes 4–8), with conversion of supercoiled form I to nicked form II at 37 °C over 4 h, in the absence of any reducing agent. In the presence of 100 μM H_2O_2, the nuclease activity of OQ_1–Cu^{2+} and OQ_2–Cu^{2+} was greatly enhanced: Fig. 2 shows a comparison of the cleavage of plasmid DNA (0.4 μg) with low concentrations of OQ or OP (12 μM, [DNA]/[drug] = 10)§ and Cu^{2+} (12 μM), after 5 min incubation at 37 °C, in the absence or presence of 1 mM DTT. In these conditions, all controls were negative including OQ/Cu^{2+} (not shown) and Cu^{2+}/H_2O_2 (lanes 2–3). In the absence of DTT, OQ_1–Cu^{2+} (lane 4) and OQ_2–Cu^{2+} (lane 6) convert effectively form I to forms II (nicked) and III

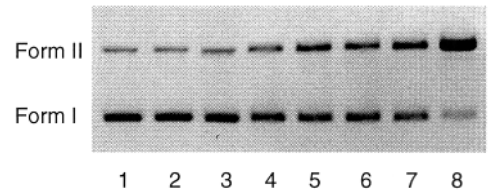


Fig. 1 Cleavage of pUC18 plasmid DNA by OQ_2 in the presence of Cu^{2+}. DNA (0.4 μg) was incubated with OQ_2 in the presence of $CuSO_4$ in 50 mM cacodylate buffer (pH 6.0, total volume 10 μl) at 37 °C and different time. Lane 1, DNA control, 4 h; lane 2, Cu^{2+} 160 μM, 4 h; lane 3, OQ_2 24 μM, 4 h; lanes 4–8, OQ_2 24 μM + Cu^{2+} 160 μM, 15-30-60-120-240 min. OQ_1 exhibited a similar cleavage pattern (data not shown).‡

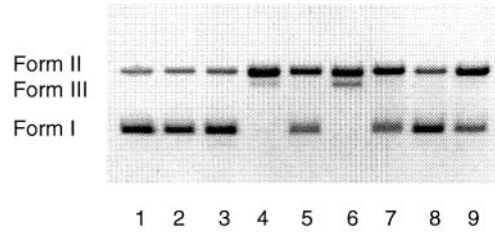

Fig. 2 Cleavage of pUC18 DNA by OQ and OP in the presence of Cu^{2+} and H_2O_2. DNA (0.4 μg) was incubated with the dye in the presence of $CuSO_4$ and H_2O_2 for 5 min at 37 °C in the same buffer as in Fig. 1. Lane 1, DNA control; lane 2, Cu^{2+} 12 μM + H_2O_2 100 μM; lane 3, lane 2 + DTT 1 mM; lane 4, lane 2 + OQ_1 12 μM; lane 5, lane 3 + OQ_1 12 μM; lane 6, lane 2 + OQ_2 12 μM; lane 7, lane 3 + OQ_2 12 μM; lane 8, lane 2 + OP 12 μM; lane 9, lane 3 + OP 12 μM.‡

Table 2 Variation of the absorption maxima of OQ_2 upon addition of Cu^{2+} and H_2O_2[a]

	λ_1	ε_1	λ_2	ε_2	λ_3	ε_3
OQ_2	317	36700	325	34800	—	—
$(OQ_2)Cu^{2+}$	317[b]	29700	328	35400	576	200
$(OQ_2)Cu^{2+}$ + H_2O_2	317[b]	26900	326	29600	577	1400

[a] Wavelength (λ) in nm and molar absorption coefficients (ε) in $dm^3\ mol^{-1}\ cm^{-1}$. Concentration of OQ_2 12 μM in 50 mM cacodylate buffer (pH 6.0); added $CuSO_4$ and H_2O_2 120 μM and 100 μM, respectively. Controls with Cu^{2+} alone (120 μM) and in the presence of H_2O_2 (100 μM) did not show any significant absorption. [b] Present as a shoulder in the major band.

(linear) whereas, as expected, the $(OP)_2Cu^{2+}$ complex (lane 8) does not do so. OQ_2–Cu^{2+} seems more efficient than OQ_1–Cu^{2+} in accordance with the binding affinity of the ligands alone. In presence of DTT, which reduces *in situ* Cu^{2+} to Cu^+, the OP complex becomes active (compare lanes 8 and 9) whereas the activity of the OQ complexes is decreased (lanes 4 to 5 and 6 to 7) though remaining comparable to that of the OP complex. Increasing the time of incubation with OQ_1–Cu^{2+} and OQ_2–Cu^{2+} leads to additional scissions, with increasing percentage of linear form III and appearance of smearing bands.

The efficiency of the DNA cleavage by OQ_2 is dependent on the concentration of copper, with a maximum around 5 equiv. of metal per ligand. A UV titration of OQ_2 by Cu^{2+} indicated the formation of a 1 : 1 complex with a stability constant of 4.7 (in log units). The plateau of the titration is reached at 5 equiv. of Cu^{2+}, in accordance with the copper dependence of the DNA cleavage. The steric hindrance in the vicinity of the two heterocyclic nitrogens prevents a square-planar 1 : 2 Cu^{2+} coordination with OQ_2. Thus a 1 : 1 complex is observed, $(OQ_2)Cu^{2+}$, which is likely the active species responsible for the DNA cleavage. Its relatively weak stability might be ascribed to the effect of the positively charged ammonium linkers of the ligand, which also decreases the basicity of the lone pairs of the heterocyclic nitrogens.[5] By contrast, OP forms a stable square-planar $(OP)_2Cu^{2+}$ complex[11] that is itself unable to cleave DNA. These differences in metal coordination in the $(OQ_2)Cu^{2+}$ and $(OP)_2Cu^{2+}$ complexes might explain the unusual reactivity observed for the former toward DNA. Upon addition of a reducing agent like DTT, the reactive tetrahedral $(OP)_2Cu^+$ is formed *in situ* with subsequent oxidative scission of DNA. The reduced cleavage observed with OQ in these same conditions might be ascribed to the formation of the tetrahedral $(OQ_2)_2Cu^+$ species, which nevertheless retains an activity comparable to that of $(OP)_2Cu^+$ itself.

Table 2 displays the features of the UV spectra of OQ_2 alone and of $(OQ_2)Cu^{2+}$ in the absence and presence of H_2O_2. Upon addition of Cu^{2+} to a solution of OQ_2, a modification of the spectrum is observed with a decrease of the band at 317 nm concomitant to the increase of the band at 325 nm (slightly red-shifted), both bands corresponding to π–π* transitions of the quinacridine moiety; a new band ascribable to d–d transitions of the copper is also emerging at 576 nm. When H_2O_2 is added, a hypochromism of the major band of the ligand (325 nm) is noted along with a hyperchromism of the band at 576 nm, which indicates a strong modification of the metal coordination.

The cleavage of DNA by $(OQ)Cu^{2+}$ complexes and H_2O_2 was inhibited by various radical scavengers: ethanol, thiourea ($HO^\bullet$ scavengers), Tiron ($O_2^{\bullet-}$ scavenger), KI and catalase (H_2O_2 scavengers). These results suggest that the scission mechanism involves the formation of a coordinated peroxide species, with subsequent production of reactive oxygen species that induce oxidative DNA strand scissions. The cleavage in the absence of H_2O_2 (*i.e.* Fig. 1) was not inhibited by reasonable amounts of such scavengers, which does not allow to rule out the intervention of reactive oxygen species.

In conclusion, the $(OQ)Cu^{2+}$ complexes are able to perform an efficient oxidative cleavage of DNA in absence of reducing agent. These new artificial metallonucleases might be interesting lead compounds for the scission of various DNA targets. Further investigations on the reaction mechanism as well as on the structure and sequence selectivity of these reagents are currently underway.

We would like to thank Dr Mireille Fauquet for providing us with generous amounts of pUC18 plasmid and Dr David M. Perrin for helpful discussions.

Notes and references

† All experiments were conducted at pH 6 (cacodylate buffer) where OQ_1 and OQ_2 exist respectively as biprotonated and tetraprotonated species.[5]
‡ All experiments were conducted in the dark in order to avoid photocleavage of DNA by the dyes. Reactions were quenched by adding 1 M KCN and analysed by electrophoresis on 1% agarose gels in 1 M Tris-acetate buffer (80 V, 1 h). The gels were photographed on a UV transilluminator after staining with ethidium bromide.

Received (in Basel, Switzerland) 4th August 1998, Accepted 25th September 1998

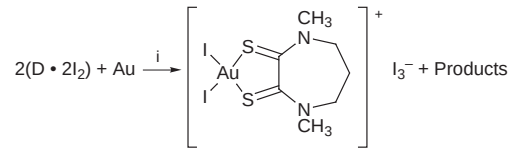
The oxidation of gold powder by a new safe and powerful oxidising reagent, the bis-diiodine adduct of *N,N′*-dimethylperhydrodiazepine-2,3-dithione (D), to produce $[AuI_2D]I_3$ under ambient conditions is described.

The potential of dihalogen or interhalogen adducts as new oxidising reagents towards elemental metals has been pointed out in recent years by the pioneering work of the McAuliffe group.[1] The used adducts were mainly halogeno-phosphoranes and -thioethers and a variety of complexes with unusual features (for stoichiometries, oxidation numbers and geometries) have been obtained. In particular in the reaction of $Me_3As{\cdot}I_2$ with the noble metal gold, the square-planar $[AuI_3(Me_3As)]$ complex was obtained, while $[AuI_3(Me_3P)_2]$, where gold(III) shows a trigonal-bipyramidal geometry, was produced using $Me_3P{\cdot}I_2$.[2] The importance of these results, apart from their intrinsic interest in the field of inorganic chemistry, lies in the new perspectives opened by these reaction routes in many applications, such as in the recovery of noble metals from exhausted catalysts or in the metal refining industry. In the case of gold, treatments with cyanide are still in use.† The desirable reagents should fulfill the following requirements: they should be inexpensive, easy to handle, non polluting and hopefully also selective. Moreover, it is preferable that they react rapidly.

Based on our extensive past experience in the area of the dihalogen adducts of sulfur and selenium-rich donors, we are now investigating the above mentioned metal activation reaction using the adducts of polyfunctional thione donors.[3] Our working hypothesis is that the proper choice of polyfunctional donors, which can favour the preferred geometry required by the metal undergoing oxidation and give chelation, will add a favourable condition to the spontaneity and selectivity of the oxidation reaction.

Here we present the results obtained using the bis-diiodine adduct of *N,N′*-dimethylperhydrodiazepine-2,3-dithione[4] towards gold. This ligand is a cyclic dithio-oxamide where the two vicinal thioamido groups are suitable to accommodate the square-planar geometry demanded by Au^{III}. The adduct was prepared by mixing the donor and diiodine in a 1 : 2 molar ratio in $CHCl_3$ at room temperature. The orange-brown shiny crystals obtained by slow evaporation were characterized as $D{\cdot}2I_2$. The presence of a strong Raman peak at 146 cm^{-1} assignable to ν(I–I) suggests that the interaction strength in the adduct is medium–strong.[5,6]

The reaction of $D{\cdot}2I_2$ with gold powder is given in Scheme 1. The reaction is performed under mild conditions and without any protection from the air and/or moisture. The solution of the adduct turns from red-orange to red-brown on addition of the metal and after a relatively short time the gold powder disappears. This solution is allowed to stand and the obtained solid is recrystallized from THF–Et_2O giving well-shaped crystals of $[AuDI_2]I_3$. The molecular structure of the cation of



Scheme 1 i, THF, room temperature, 30 min to dissolve 14 mg of gold.

$[AuDI_2]I_3$[7] is shown in Fig. 1. The gold atom has an approximately square-planar configuration [max. dev. −0.037(4) Å for S(1)]. *N,N′*-Dimethylperhydrodiazepine-2,3-dithione acts as an *S,S*-chelating ligand, and bond distances show that electron delocalization does not involve C(1)–C(2).

One of the iodides coordinated to the metal strongly interacts with the anion [I(1)···I(5) (*x*, *y* − 1, *z*) 3.582(2) Å], while the other participates in the formation of chains of monocationic complexes running parallel to *c* by interacting with a sulfur atom of another cation [I(2)···S(1) (*x*, *y*, *z* − 1) 3.790(5) Å].

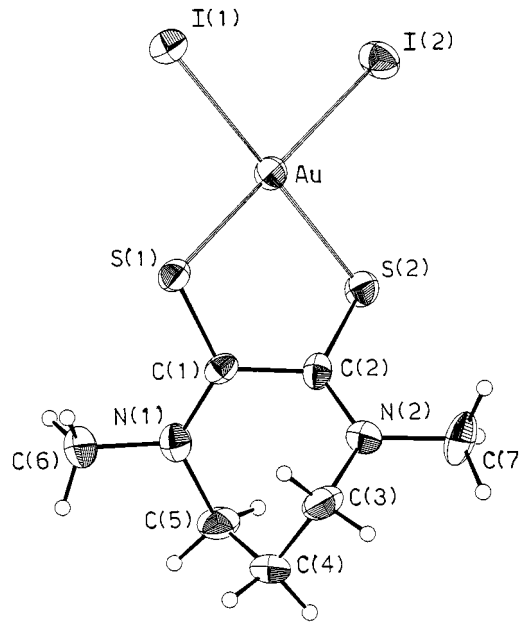


Fig. 1 Molecular structure of $[AuI_2(C_7H_{12}N_2S_2)]^+$. Thermal ellipsoids are drawn at the 30% probability level. Selected bond lengths [Å] and angles [°]: Au–I(1) 2.609(1), Au–I(2) 2.593(2), Au–S(1) 2.351(4), Au–S(2) 2.371(3), S(1)–C(1) 1.672(12), S(2)–C(2) 1.697(13), N(1)–C(1) 1.332(16), N(1)–C(5) 1.484(17), N(1)–C(6) 1.475(17), N(2)–C(2) 1.324(16), N(2)–C(3) 1.455(18), N(2)–C(7) 1.449(17), C(1)–C(2) 1.488(16), C(3)–C(4) 1.51(2), C(4)–C(5) 1.53(2). I(1)–Au–I(2) 92.24(4), I(1)–Au–S(1) 88.07(8), I(2)–Au–S(2) 88.71(9), S(1)–Au–S(2) 90.98(12), C(1)–S(1)–Au 98.3(4), C(2)–S(2)–Au 96.9(4).

The triiodide counterion is asymmetric and essentially linear: I(3)–I(4) 2.863(2), I(4)–I(5) 2.987(2) Å, I(3)–I(4)–I(5) 177.73(5)°. The Raman spectrum in the low frequency range shows peaks at 106s and 138m cm^{-1}, which are assigned to the symmetrical and antisymmetrical stretching of the triiodide units,[5a,b] and peaks at 153s, 166sh cm^{-1} which are likely to be related to the Au–I vibrations.

In conclusion a new oxidation reagent towards the noble metal gold has been synthesized. Since it reacts rapidly under ambient conditions in a one-step reaction and is scarcely polluting, inexpensive and easy to handle, this reagent can be used in practical applications. For the oxidation of noble metals, it represents a significant improvement over the previously reported reagents, $Me_3E{\cdot}I_2$ (E = P, As), which use polluting materials and are impractical since they require strictly anhydrous, anaerobic conditions and long reaction times.

This research was carried out as part of the project 'Materiali Speciali per Tecnologie Avanzate II' supported by the Consiglio Nazionale delle Ricerche (CNR).

Asymmetric synthesis and electrochemical behaviour of a C_2 chiral bisferrocenyl orthoquinone

Ana Gomez Neo, Aurore Gref and Olivier Riant*

Laboratoire des Réactions Organiques Sélectives, ICMO, Université Paris-Sud, 91405 Orsay, France.
E-mail: oliriant@icmo.u-psud.fr

Received (in Cambridge, UK) 4th August 1998, Accepted 25th September 1998

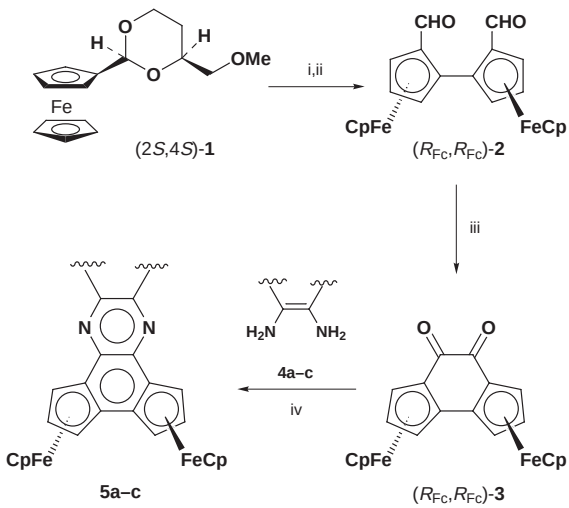
A new chiral bisferrocenyl quinone with C_2 symmetry was prepared by asymmetric synthesis; further condensation with 1,2-diamines led to enantiopure polyaromatic heterocycles into which two ferrocene units are fused.

Due to their unique structural and electronic properties, *o*-benzoquinones[1] and their diimine derivatives have received a great deal of attention as transition metal ligands in coordination chemistry and catalysis.[2] Their 1,2-diketone structure allows the construction of polyaromatic systems *via* various types of condensation reactions. This has led to numerous applications in material sciences[3] and supramolecular chemistry.[4]

We report here the asymmetric synthesis of a new chiral orthoquinone in which two electron-rich ferrocene units are fused. Diastereoselective ortholithiation of enantiopure ferrocenyl acetal (2*S*,4*S*)-**1** by the reported method[5] and further oxidation of the lithio intermediate by iron(III) acetylacetonate led, after removal of the acetal protecting groups, to the chiral bisferrocene bisaldehyde (R_{Fc},R_{Fc})-**2**† in a 70% yield (Scheme 1). Due to the high diastereoselectivity of the deprotonation (98%), only the C_2 symmetric isomer was formed and no *meso* isomer was detected. Pinacolisation of (R_{Fc},R_{Fc})-**2** was efficiently realised by reaction of an excess of SmI_2 in THF and gave a mixture of air sensitive diols which were directly oxidised by MnO_2 in dry $CHCl_3$. After chromatographic purification, the new C_2 symmetric *o*-quinone (R_{Fc},R_{Fc})-**3**‡ was isolated in 55% yield (starting from **2**) and was fully characterised. This deep blue complex proved to be air stable and could be easily prepared on a multigram scale using this procedure.

As a first application, we turned to the condensation of (R_{Fc},R_{Fc})-**3** with various aromatic 1,2-diamines. After optimisation, it was found that condensation of quinone **3** with an excess of 1,2-diaminobenzene in refluxing toluene gave a quantitative yield of the quinoxaline derivative **5a** when freshly activated 4 Å molecular sieves or alumina[6] were used as a dehydrating agent. In the case of adducts **5b**,**c**, longer reaction time were required and optimised yields reached 70% after purification. We found as well that *N*-alkylation of the pyridine nitrogen of adduct **5b** by iodomethane gave a quantitative yield of the stable green pyridinium salt **6**. The structure of the quinoxaline adducts as well as the starting quinone could be unambiguously confirmed by standard ^{1}H and ^{13}C NMR methods as well as HRMS. The electrochemical behaviour of bisferrocene (Fe^{II}, Fe^{II}) complexes such as **3** and **5a** was studied by cyclic voltammetry[7] (Fig. 1). This allowed us to study the stability in solution of the higher oxidation states (Fe^{II}, Fe^{III}) and (Fe^{III}, Fe^{III}). Recording the CV at low sweep rate for **5a** gave two reversible one electron oxidation waves at low potential. In the time scale of the analysis, the mixed valence complex (Fe^{II}, Fe^{III}) is completely stable as well as the corresponding bisferricinium (Fe^{III}, Fe^{III}). As expected, quinone **3** proved to be more difficult to oxidize, showing an increase of +0.34 V for the first oxidation compared to **5a**. The first oxidation wave giving the mixed valence state is reversible at all sweep rates, but the second oxidation wave remains irreversible for sweep rates up to 1000 V s^{-1}, thus showing chemical evolution of the bisferricinium complex. Increasing the sweep rate up to 2000–3000 V s^{-1} shows that this evolution is slow and a life time for the bisferricinum (Fe^{III},Fe^{III}) was evaluated at 3×10^{-2} s. It was also noted that **3** didn't display any reduction wave, in agreement with the electron-rich nature of the carbonyl groups.

We are currently studying the chemistry and the electrochemical behaviour of those enantiopure bimetallic complexes as well as the isolation of the mixed valence complexes.



Scheme 1 *Reagents and conditions*: i, Bu^{t}Li (1.1 equiv.), Et_2O, −78 to 25 °C, 1 h, then $Fe(acac)_3$ (1.4 equiv.), 25 °C, 15 h; ii, TsOH, CH_2Cl_2, H_2O, 25 °C, 3 h (70% from **1**); iii, SmI_2 (2.4 equiv.), THF, 25 °C, 15 min, then MnO_2, $CHCl_3$, 25 °C, 30 min (55–60% from **2**); iv, 1,2-diamine (2–3 equiv.), PhMe, 4 Å MS or Al_2O_3, reflux.

Cruciform porphyrin pentamers

M. Graça H. Vicente,* Mark T. Cancilla, Carlito B. Lebrilla and Kevin M. Smith*

Department of Chemistry, University of California, Davis, CA 95616, USA. E-mail: kmsmith@ucdavis.edu

Received (in Corvallis, OR, USA) 14th August 1998, Accepted 25th September 1998

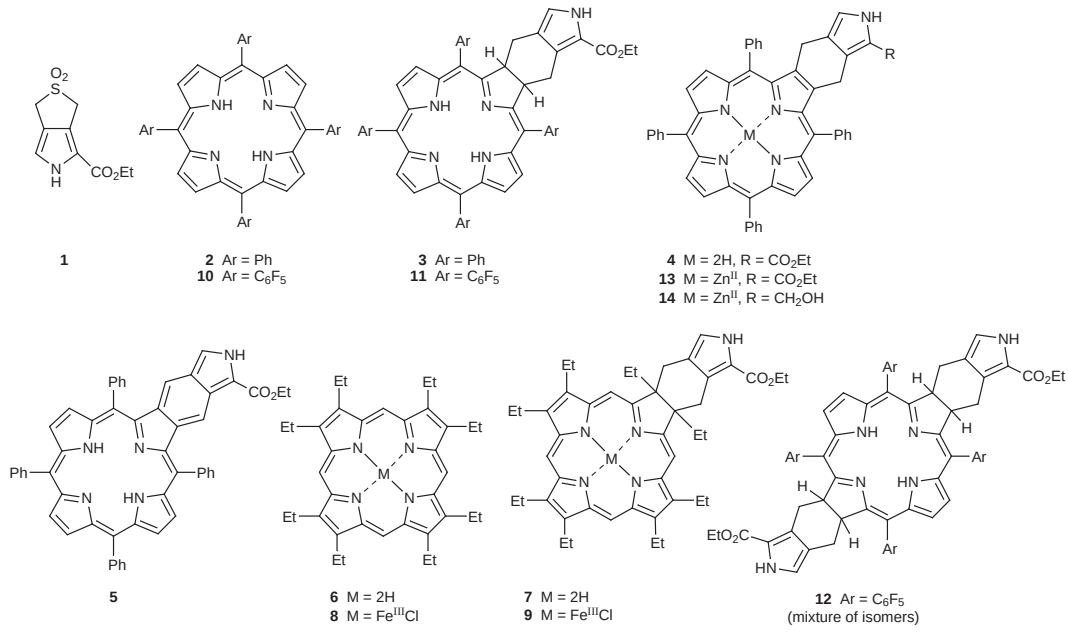
Cruciform porphyrin pentamers 15 and 16 are obtained in good yield by acid-catalyzed tetramerization of Zn^{II}–pyrroloporphyrin 14, followed by oxidation with DDQ; pyrroloporphyrins are in turn obtained from the corresponding pyrrolochlorins by Diels–Alder type reactions of porphyrins involving thermal extrusion of sulfur dioxide from a pyrrole-fused 3-sulfolene.

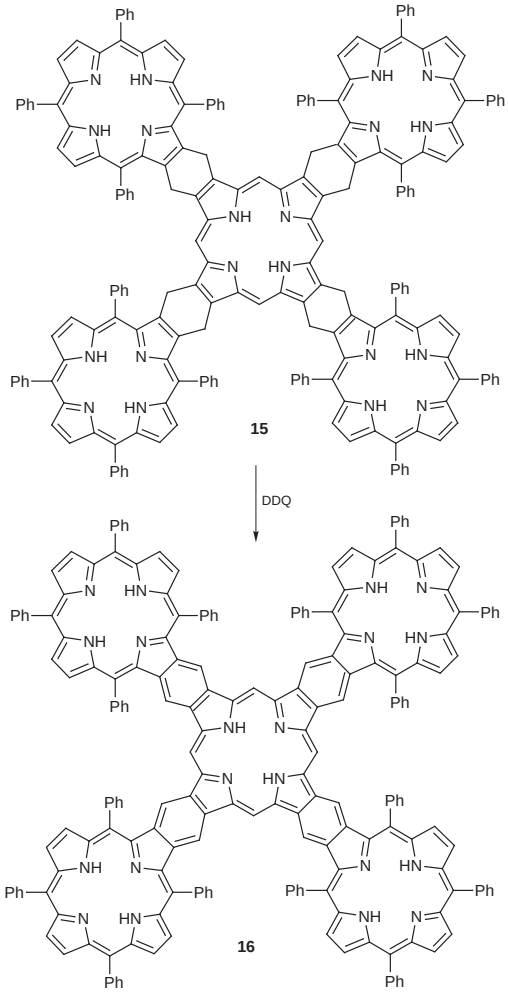
Syntheses of covalently-linked porphyrin arrays have recently attracted much attention due to their unique photoelectronic properties and potential applications as mimics of light-harvesting in photosynthesis, and as electron/energy transfer moieties in molecular wires.[1–4] A variety of model structures have been reported, mostly containing two or three porphyrin units, either directly coupled,[2] bridged by coplanar aromatic systems,[3] or beta-fused.[4] Coplanar-linked porphyrin arrays are believed to lead to more efficient energy- and electron-transfer superstructures. Recently, a linear beta-fused trimer[4] was prepared from a fused pyrroloporphyrin.[5] Herein we describe the first synthetic route to covalently-linked cruciform pentamer porphyrins, one of which is planar and fully conjugated.

One of our long term objectives is to modify porphyrin macrocycles for use both as dienes and dienophiles. The synthesis and cycloaddition reactions of a pyrrole-fused 3-sulfolene **1** with standard dienophiles were recently reported,[6] and porphyrins have also been shown to react with electron-rich dienes.[7] Thus, when TPP **2** was heated at 240 °C in the presence of an excess of pyrrole **1** and 4 Å molecular sieves, the pyrrolochlorin **3** was produced as a mixture of enantiomers in 20–22% yield. Two minor products are also obtained from this reaction: pyrroloporphyrin **4** (6–10% yield) and isoindoloporphyrin **5** (usually $< 1\%$ due to its ready transformation into further products). Trace amounts of bacteriochlorin were also detected by spectrophotometry. Based on recovered starting material **2**, the yield of products **3–5** was quantitative. Products obtained simply from the dimerization and polymerization of the reactive pyrrolodiene, generated *in situ* from **1**, were also identified by ^{1}H NMR and mass spectrometry. Products **4** and **5** were obtained from pyrrolochlorin **3** by oxidation with *p*-chloranil or DDQ. The Ni^{II} and Zn^{II} complexes of TPP reacted under similar conditions to afford the same products in lower yields due to increased susceptibility toward unwanted oxidation reactions. When the same reaction conditions were applied to octaethylporphyrin **6**, the pyrrolochlorin **7** was obtained in low yield (2–5%). Under the same conditions the iron(III) complex **8** afforded pyrrolochlorin **9** in 6% yield (unoptimized). In contrast, the electron-deficient *meso*-tetra(pentafluorophenyl)porphyrin **10** readily reacted to afford only two products, the pyrrolochlorin **11** (32–39% yield) and the bacteriochlorin **12** (5–10%). When the same reaction was applied to a porphyrin or chlorin bearing a β-vinyl substituent the cycloaddition reaction took place predominantly at the vinyl group. Reactions of pyrrole **1** with functionalized chlorins led to mixtures of products which include bacteriochlorins, isoindolochlorins, and products resulting from addition of another pyrrole to the isoindolochlorin.

All new compounds possessed spectroscopic data in accord with the assigned structures. Pyrrolochlorins **3**, **7**, **9** and **11** possess typical chlorin absorption spectra, with a strong band at λ_{max} 652 nm; pyrroloporphyrin **4** shows an electronic absorption spectrum similar to that of TPP **2**, and isoindoloporphyrin **5** shows a type of rhodo-visible spectrum characteristic of monobenzoporphyrins. Compound **12** (λ_{max} 746 nm) displayed an optical spectrum characteristic of a bacteriochlorin.

Insertion of zinc into pyrroloporphyrin **4** yielded complex **13** in 85–90% yield. The ester function of compound **13** was reduced with $LiAlH_4$ to give alcohol **14** which afforded the crude pentamer **15** after treatment (*e.g.* ref. 8) with acid and





Scheme 1

oxidation with *p*-chloranil. Filtration through Sephadex G-25 resulted in isolation of **15** in 65–75% yield. Mass spectrometry was performed on **15** using matrix-assisted laser desorption ionization (MALDI) with a Fourier transform mass spectrometry (FTMS) analyzer.† This technique has been shown to be highly effective for high resolution MS determinations of large porphyrin compounds.[9] The ^{1}H NMR spectrum of **15** showed only broad bands, even upon addition of TFA, possibly due to aggregation effects of these high molecular-weight molecules. Treatment of pentamer **15** with an excess of DDQ gave the fully conjugated pentamer **16** in quantitative yield (Scheme 1). Compound **16** was also characterized by MALDI-FTMS;† its absorption spectrum showed a long-wavelength band at λ_{max} 774 nm (838 nm in acid). Pentamers **15** and **16** display good solubilities in most organic solvents. The methodology described above offers the opportunity for synthesis of novel heterobimetallic cruciform porphyrin pentamers, and this work is in progress.

This research was supported initially by a grant from JNICT-Portugal (PBIC/C/QUI/2156/95 to MGHV), and subsequently by the National Institutes of Health (HL 22252).

Enantioselective intramolecular cyclizations of prochiral cyclohexanones using chiral lithium amide bases

Jeffrey E. Kropf and Steven M. Weinreb*

Department of Chemistry, The Pennsylvania State University, University Park, Pennsylvania 16802, USA. E-mail: smw@chem.psu.edu

Received (in Corvallis, OR, USA) 31st August 1998, Accepted 25th September 1998

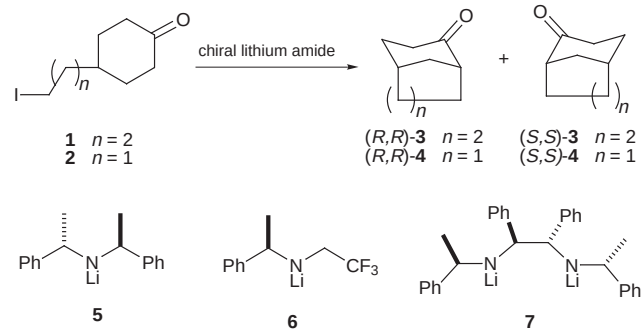
The first examples of intramolecular cyclizations of prochiral cyclohexanones with chiral lithium amide bases have been effected in good yields and enantiomeric ratios.

The use of an amide base and an electrophile to form a carbon–carbon bond at the α-position of a ketone is a fundamental method in organic chemistry. The enantioselective intermolecular version of this reaction, in which a chiral lithium amide base is used with a prochiral ketone, is becoming increasingly widespread.[1–3] As part of an ongoing project in natural product total synthesis, we were interested in applying an intramolecular variation of this chiral alkylation methodology to the preparation of a scalemic intermediate. To the best of our knowledge, this type of enantioselective cyclization has not been previously reported. Here we describe the first examples of the use of chiral lithium amide bases in the enantioselective *intramolecular* deprotonation–alkylation of two prochiral cyclohexanones.

The readily available iodo ketones **1**[7] and **2**[8] which were examined in this methodological study are shown in Scheme 1. The chiral lithium amides used are represented by structures **5**,[9] **6**[10] and **7**.[11] Using published work on intermolecular enantioselective deprotonations of cyclohexanones as a guide, experiments were conducted on cyclization of ketones **1** and **2** to bicyclic systems **3** and **4**, respectively, with amide bases **5**–**7**. Representative results are listed in Table 1.

Initial exploratory experiments were conducted with iodo ketone **1** and amide base **5**. This system leads preferentially to the (*R*,*R*)-enantiomer of **3**.[12,13] This absolute configuration is in accord with published results on deprotonation of simple 4-substituted cyclohexanones with base **5**.[14] Using HMPA as an additive in the intramolecular deprotonation–alkylation of **1** led to bridged ketone **3** in poor to moderate ers (enantiomeric ratios) (entries 1 and 2). These results are in accord with previously reported observations which suggest that HMPA is most effective in inducing high ers with a base that contains one or more internal ligation sites.[1b] However, LiCl has been shown to be a beneficial additive when employing bases either with or without internal ligation sites.[1f] In fact, the best yield and er of (*R*,*R*)-**3** (62% and 87:13, respectively) were achieved using amide **5** along with 2.5 equiv. of LiCl (entry 4).

Cyclization of ketone **1** with amide base **6** led preferentially to the (*S*,*S*)-enantiomer of **3**, whereas base **7** afforded the (*R*,*R*)-enantiomer, although ers were only moderate with both systems (73:27–80:20, entries 5–9). Unlike base **5**, amide base **6** gave



Scheme 1

Table 1 Enantioselective intramolecular cyclization of prochiral cyclohexanones with chiral lithium amides[a]

Entry	Ketone	Lithium amide (equiv.)	Additive (equiv.)	*T*/°C	Product	Yield (%)	Er[b] (*RR*:*SS*)
1	**1**	5 (1.3)	HMPA (2.4) + LiCl (1.3)[c]	−40→room temp.	(*R*,*R*)-**3**	58	59:41
2	**1**	5 (1.3)	HMPA (2.5) + LiCl (1.3)[c]	−50→−10	(*R*,*R*)-**3**	29	82:18
3	**1**	5 (1.3)	LiCl (1.3)[c]	−50→−10	(*R*,*R*)-**3**	44	87:13
4	**1**	5 (1.5)	LiCl (1.0) + LiCl (1.5)[c]	−60→−20	(*R*,*R*)-**3**	62	87:13

10	**2**	5 (1.5)	LiCl (1.0) + LiCl (1.5)[c]	−60→−20	(*R*,*R*)-**4**	53	79:21
11	**2**	5 (1.05)	LiCl (1.0) + LiCl (1.05)[c]	−80→−40	(*R*,*R*)-**4**	58	90:10
12	**2**	6 (1.5)	LiCl (1.0)	−60→−20	(*S*,*S*)-**4**	61	20:80
13	**2**	6 (1.05)	LiCl (1.0)	−80→−40	(*S*,*S*)-**4**	45	11:89
14	**2**	6 (1.5)	LiCl (1.0)	−80→−40	(*S*,*S*)-**4**	70	10:90
15	**2**	7 (1.1)	LiCl (1.0)	−60→−20	(*R*,*R*)-**4**	57	68:32
16	**2**	7 (1.05)	LiCl (1.0)	−80→−40	(*R*,*R*)-**4**	79	73:27

[a] The experimental procedure for entry 14 is typical: Under an argon atmosphere, a solution of BuLi in hexane (0.30 ml, 1.67 M, 0.502 mmol) was added to a solution of chiral amine (0.102 g, 0.502 mmol) and LiCl (0.014 g, 0.335 mol) in THF (13 ml) at −80 °C affording amide base **6**. The mixture was stirred for 30 min and ketone **2** in THF (0.5 ml) was then added *via* cannula. The solution was allowed to warm to −40 °C and was stirred for 18 h. The reaction mixture was quenched with saturated NH_4Cl (5 ml) and extracted with Et_2O (3 × 15 ml). The organic extracts were sequentially washed with brine (1 × 20 ml), 10% $Na_2S_2O_3$ (1 × 20 ml), 5% HCl (2 × 20 ml) and brine (1 × 20 ml). After drying with Na_2SO_4, and evaporation *in vacuo*, flash chromatography (SiO_2; pentane–Et_2O, 10:1) of the residue gave ketone **4** (0.029 g; 70%). [b] Ers (enantiomeric ratios) were determined by GLC using a chiral Supelco β-DEX 390 column. [c] Formed *in situ* from the hydrochloride salt.

the best results (39% yield and a 78:22 er) when using only 1.0 equiv. of LiCl (entry 6). These results could be improved slightly by substitution of LiBr as the additive in place of LiCl (entry 7). Amide base **7** gave a slightly higher chemical yield of **3** (61%, entry 8) than did amide **6**, but the er was not improved significantly. Thus, of the three bases tested, amide **5** provided the best overall results in cyclization of iodo ketone **1** (entry 4).

As was the case for cyclization of ketone **1**, iodo ketone **2** gave predominantly the (*R*,*R*)-enantiomer of bicyclic ketone **4** with bases **5** and **7**, and the (*S*,*S*)-enantiomer with **6**.[12] Interestingly, the results of the cyclization of ketone **2** were not optimal under the best reaction conditions determined for ketone **1** (*cf*. entries 10, 12 and 15). It was eventually found that of the three bases, lithium amide **6** gave the best results in cyclization of **2** with a 70% yield and a 90:10 er of (*S*,*S*)-**4** using the experimental conditions outlined in entry 14.

In conclusion, we have demonstrated that intramolecular enantioselective cyclizations of prochiral ketones using chiral lithium amide bases are feasible, and can be effected with good ers. The cyclization of ketone **1** was best accomplished to give (*R*,*R*)-**3** in 62% yield and an 87:13 er using lithium amide base **5**, while the cyclization of homologous ketone **2** was effected to afford (*S*,*S*)-**4** in 70% yield and a 90:10 er with amide base **6**. It appears that the chemical yields and ers in these intramolecular cyclizations are highly dependent upon the reaction conditions, base, additive and substrate used, and no obvious trends are evident at this very early stage of development. We are hopeful, however, that with additional work some empirical rules can be devised for this type of enantioselective cyclization.

We are grateful to the National Institutes of Health (CA-34303) for generous financial support. We also thank Professor Xumu Zhang and his research group for help with GLC analyses.

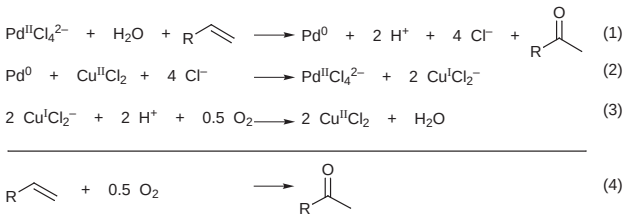
Received (in Cambridge, UK) 19th August 1998, Accepted 21st September 1998

Water soluble palladium(II) complexes of bidentate diamine ligands, such as bathophenanthroline disulfonate, are stable, recyclable catalysts for the selective aerobic oxidation of terminal olefins to the corresponding alkan-2-ones in a biphasic liquid–liquid system.

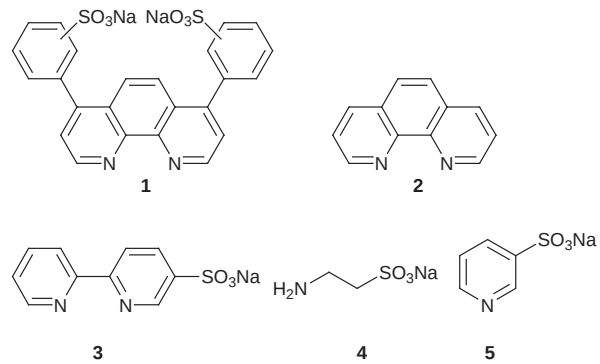
The aerobic oxidation of ethylene to acetaldehyde and terminal olefins to the corresponding alkan-2-ones [eqn. (1)–(4)] catalysed by an aqueous solution of palladium(II) and copper(II) salts are collectively known as Wacker oxidations.[1] The function of the copper co-catalyst is to mediate the reoxidation of palladium(0).



Although commercially successful, this process has several drawbacks. Substantial concentrations of copper salts (*ca.* 1 M) and chlorides (*ca.* 2 M) are added to achieve favourable redox potentials of the Pd^{II}/Pd^0) and Cu^{II}/Cu^{I} couples and to solubilise Cu^{I} as $Cu^{I}Cl_2^-$. Acid (HCl) is required to circumvent clustering of transient atomic palladium. This not only renders the system highly corrosive, but also reduces the catalyst activity, since the rate[2] is inversely proportional to $[H^+]$ and $[Cl^-]^2$. Furthermore, the presence of large amounts of chloride leads to the formation of chlorinated by-products. Hence, much effort has been devoted[1] to the development of alternative co-catalysts, notably the heteropolyacid, $H_3PMo_6V_6O_{40}$, which still requires chloride, albeit in much lower amounts than the conventional Wacker process,[3] and two-component systems involving benzoquinone in combination with iron(II) phthalocyanine[4] or heteropolyacid.[5]

The oxidation of higher olefins introduces additional complications. Rates are much lower owing to their low solubilities in water and raising the temperature results in palladium black formation. Moreover, the products are contaminated with chlorinated by-products and isomerised olefins. Rates can be improved by using water-miscible cosolvents, *e.g.* DMF,[6] or phase transfer catalysis with tetraalkylammonium salts[7] or polyethylene glycols[8] or modified cyclodextrins[9] as inverse phase transfer catalysts. Immobilised catalysts have also been described, *e.g.* palladium-on-vanadium pentoxide,[10] organic polymer-anchored palladium[11] and supported aqueous phase catalysts.[12] However, these systems employ copper/chloride combinations and/or exhibit poor activities and selectivities. There still remains a definite need, therefore, for a system which avoids the use of copper ions, chloride ions and polar organic solvents and which is active, selective and recyclable. We report here a new catalytic system, based on water soluble palladium diamine complexes, which appears to meet these criteria.

Our approach was to stabilise Pd^0 *via* complexation with oxidatively stable (di)amine ligands. In an initial screening we tested ligands **1**–**5** in the oxidation of hex-1-ene at 100 °C.



Promising results were observed with the chelating diamines **1**–**3**, while the monodentate ligands **4** and **5** were less effective (Table 1). The best results were observed with bathophenanthroline disulfonate **1**. The catalyst solution was prepared by stirring $Pd(OAc)_2$ (0.0224 g; 0.1 mmol) and **1** (0.0546 g; 0.1 mmol) overnight with 42.5 g of water to afford a clear orange solution. In a typical procedure a 175 ml autoclave was cooled to 0 °C and charged with the catalyst solution, olefin (10 mmol) and internal standard (n-alkane). The autoclave was pressurised with air, heated to 100 °C (30 bar) and kept at this temperature for 10 h. After reaction the autoclave was cooled to 0 °C and depressurised, collecting any volatile material in a liquid nitrogen trap. The mixture was extracted with Et_2O, the extract

Table 1 The palladium catalysed oxidation of olefins[a]

Olefin	Ligand	Olefin conversion (%)	Selectivity to alkanone (%)
Hex-1-ene	**1**	48	99
Hex-1-ene	**2**	42	99
Hex-1-ene	**3**	36	97
Hex-1-ene	**4**	12	40[b]
Hex-1-ene	**5**	2	50[b]
Pent-1-ene	**1**	50	99
Oct-1-ene	**1**	25	99
Cyclopentene	**1**	2	47[c]
Cyclohexene	**1**	2	50[d]
Cyclooctene	**1**	30	100

[a] Conditions: 0.1 mmol $Pd(OAc)_2$, 0.1 mmol ligand, 10 mmol olefin, 10 mmol NaOAc, 10 h at 100 °C and 30 bar in 42.5 g H_2O. [b] Main by-products were hex-2-ene and hex-3-ene. [c] Main by-products were cyclopent-2-en-1-ol and cyclopent-2-en-1-one. [d] Cyclohex-2-en-1-ol, cyclohex-2-en-1-one, benzene and cyclohexane were detected as by-products.

Table 2 Recycling of the catalyst[a]

Cycle	Hex-1-ene conversion (%) with NaOAc	Hex-1-ene conversion (%) without NaOAc
1st	48 (99%)	47 (99%)
2nd	44 (96%)	28 (97%)
3rd	40 (95%)	15 (96%)

[a] Conditions as in Table 1, with and without NaOAc (10 mmol).

dried over $MgSO_4$ and analysed by GC using a Varian Star 3400 instrument equipped with a CP Sil 5-CB column (50 m × 0.53 mm).

Under these conditions hex-1-ene underwent 48% conversion to give hexan-2-one in > 99% selectivity. No isomerisation of hex-1-ene and no palladium black formation was observed. Up to 50% conversion (50 turnovers) the rate was independent of [hex-1-ene], indicative of saturation kinetics. Thereafter, the reaction became first order in [hex-1-ene]. When the substrate/catalyst ratio was increased from 100 to 200 the reaction was zero order in hex-1-ene up to 100 turnovers.

Similarly, various terminal and cyclic olefins were oxidised using $Pd(OAc)_2$–**1** under the same conditions (Table 1). Terminal olefins were oxidised selectively, whereas oxidation of cyclopentene and cyclohexene underwent competing allylic oxidation and tended to stop after a few turnovers. At higher temperatures (150 °C) cyclohexene was dehydrogenated into benzene in *ca*. 90% selectivity, in the presence of ionol, as a radical scavenger.

The catalyst could be recycled as is shown in Table 2. The addition of sodium acetate was necessary to stabilise the catalyst. Without NaOAc, formation of palladium black was observed after the second and third cycles. The beneficial effect may be due to preventing the formation of inactive dimers,[13] giant palladium clusters,[14] or even colloidal palladium.[15] Thus, when a solution of the orange complex was heated at 120 °C in the absence of NaOAc the solution became brown–black, indicative of giant cluster or colloidal palladium formation.

In the experiments described in Table 1 stoichiometric amounts of NaOAc were added, but in separate experiments with hex-1-ene it was shown that several equivalents with respect to palladium were sufficient for maintaining stability. The turnover frequency of hex-1-ene was measured as a function of the temperature in the range 70–120 °C. From these data the activation energy was calculated to be 90.2 kJ mol^{-1}. In the presence of sodium acetate the selectivity to hexan-2-one was *ca*. 99% even at 120 °C.

In conclusion, the water soluble bathophenanthroline palladium complex is an effective catalyst for the aerobic oxidation of terminal olefins to the corresponding alkan-2-ones. Catalyst recycling is simple, and due to the absence of $CuCl_2$ and acid, chlorinated and isomerised side products are completely avoided. We are currently investigating the scope of this system, *e.g*. in intramolecular oxypalladation reactions.[16]

Investigation of glycerol incorporation into soraphen A

Alison M. Hill,* Jonathan P. Harris and Alexandros P. Siskos

Department of Chemistry, King's College London, Strand, London, UK WC2R 2LS. E-mail: alison.hill@kcl.ac.uk

Received (in Cambridge, UK) 3rd August 1998, Accepted 25th September 1998

Glycerol has been incorporated mid-chain into the polyketide soraphen A 1 at C-3,4 and C-11,12; the *pro*-(*S*)-hydroxymethyl group of glycerol is lost and one of the hydrogens in the *pro*-(*R*)-hydroxymethyl group is retained at C-11 which excludes hydroxymalonate as the immediate precursor to the vicinal methoxy groups at C-11,12.

In polyketide biosynthesis, both the chain starter and extension units are bound *via* thioester linkages to the polyketide synthase (PKS) where condensation takes place. Subsequent condensations occur with the growing acyl chain remaining enzyme bound, until a chain of the correct length is formed. This is released to give the first enzyme free intermediate which can undergo further enzymically catalysed modifications to yield the final product. Acetate and propionate *per se* are not used as the chain extension units, but are activated by carboxylase enzymes to generate malonyl CoA and methylmalonyl CoA, respectively, which undergo a decarboxylative condensation with the enzyme bound acyl chain to add a C_2 or C_3 unit.[1]

The carbon skeleton of the potent antifungal polyketide metabolite, soraphen A **1**, is derived from a benzoyl CoA starter unit, three acetate and three propionate chain extender units and three methionines (Fig. 1);[2] the vicinal hydroxy groups at carbons 3,4 and 11,12 were not labelled by acetate. Unpublished work from Höfle's laboratory has shown that [2-^{13}C]glycerol was incorporated into **1** at carbons 4 and 12.[3] The incorporation of glycerol mid-chain into polyketide metabolites is highly unusual and has been observed in only two other metabolites: leucomycin[4] and concanomycin.[5] It has been postulated in both cases that glycerol is converted to glycolate (or an activated form such as 2-phosphoglycolate) prior to incorporation into the final metabolite. The incorporation of glycolate into geldanamycin[6] has also been observed and it is postulated to be an intermediate in niddamycin biosynthesis,[7] however, it is possible that for all four polyketides, activation of this C_2 unit by a carboxylase enzyme to generate hydroxymalonyl CoA or methoxymalonyl CoA occurs. Here we report the results of preliminary labelling experiments which establishes that the incorporation of glycerol mid-chain into soraphen A is stereospecific and that hydroxymalonate cannot be the immediate precursor for the C_2 unit incorporated at C-11,12.

When [1,3-$^{13}C_2$]glycerol **2a** was administered to the organism,† enhanced signals in the ^{13}C NMR spectrum were observed in the resulting **1** compared with an unlabelled control sample. The feeding experiment resulted in a complex labelling pattern as glycerol had been extensively metabolised through glycolysis, the Krebs cycle and the shikimate pathway. Consequently, enrichments were observed for all the β-positions of acetate-derived carbons, for all positions which originate from propionate, and the phenylalanine-derived carbons C-17, 2′/6′, and 4′ (Fig. 2). Enrichment of the methionine-derived carbon atoms was also observed due to the metabolism of glycerol to *S*-adenosylmethionine *via* serine. The highest level of incorporation of ^{13}C label into **1**, however, was observed at C-3 and 11 (11–15-fold). The feeding experiment with [2-^{13}C]glycerol also gave rise to a complex labelling pattern which was similar but not identical to that obtained by Höfle.[3] The ^{13}C label was incorporated into C-4 and 12 as well as the carboxylate-derived positions of acetate and the phenylalanine-derived carbons 3′/5′ (data not shown). However, the enrichment levels we observed were much higher (*e.g.* 8–13-fold for C-4 and 12, *cf.* 3-fold) and we also observed enrichments of the carboxylate-derived positions of propionate and the phenylalanine-derived carbon 1′ (data not shown).

The above results demonstrated that glycerol was being metabolised *via* glycerate to acetate. Glycerate can also be oxidised to give serine, and subsequently glycine, which is a source of glycolate.[4] Hence, we decided to investigate the possible involvement of glycolate as the C_2 source for the vicinal hydroxy groups at carbons 3,4 and 11,12 by feeding [2-^{13}C]glycine. When [2-^{13}C]glycine was fed to *Sorangium cellulosum*, however, no enhanced signals in the ^{13}C NMR spectrum were observed in the resulting **1** compared with an unlabelled control sample. Labelling studies with [1-^{13}C]glycine and [1-^{13}C]glycolate to investigate leucomycin A biosynthesis resulted in the incorporation of neither precursor into the metabolite, which the authors explained was due to a cell-membrane permeability problem.[4] Hence, it is possible that we have the same problem and that glycolate is still a possible precursor in soraphen A biosynthesis.

To investigate the mechanism of glycerol incorporation into soraphen A further, [$^2H_8$]- and *rac*-, (*R*)- and (*S*)-[1-$^2H_2$]-glycerol‡ were administered to *S. cellulosum* and the resulting **1** analysed by ^{2}H NMR spectroscopy. Deuterium was observed at D-11 and D-14a but it was not incorporated at the same level in all cases (Table 1): the highest percentage incorporation was observed for [$^2H_8$]glycerol and (*R*)-[1-$^2H_2$]glycerol **2b**. The C-3 propionate-derived positions (*i.e.* H-18, 20 and 21) and methionine-derived positions (*i.e.* H-19, 22 and 23) were labelled for the racemic glycerol samples (data not shown) indicating that extensive metabolism had once again occurred.

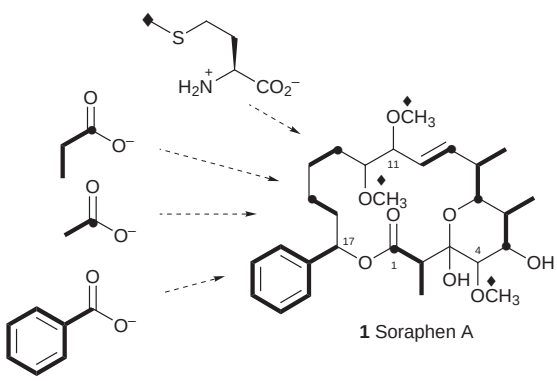

Fig. 1 Biosynthetic origin of soraphen A **1** (ref. 2).

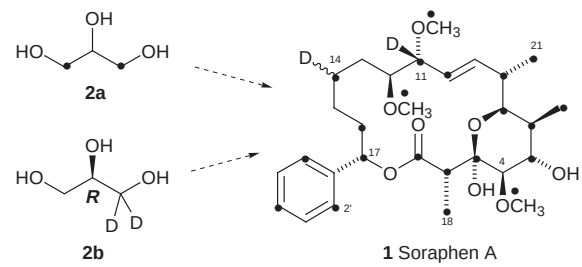

Fig. 2 Incorporation of [1,3-$^{13}C_2$]- and (*R*)-[1-$^2H_2$]-glycerol (**2a** and **2b**) into soraphen A **1**.

Table 1 Incorporation of [$^2H_8$]- and *rac*-, (*R*)- and (*S*)-[1-$^2H_2$]-glycerol into soraphen A **1**

Glycerol	^{2}H Enrichment (%)[a] D-11	D-14
[$^2H_8$]	6.6	2.3
rac-[1-$^2H_2$]	1.5	2.0
(*R*)-[1-$^2H_2$]	5.4	4.3
(*S*)-[1-$^2H_2$]	1.1	0.5

[a] Expressed as % deuterium calculated from natural abundance chloroform signal.

No deuterium was observed at H-4 in **1** from the [$^2H_8$]glycerol feeding experiment, indicating that oxidation at C-2 had taken place before incorporation into H-4. It was not possible to say with certainty that H-12 was not labelled as its signal overlaps with those of H-19 and 23. The incorporation of deuterium at H-11 was 5-fold higher for (*R*)-glycerol compared to its antipode; moreover, incorporation into H-14 was also higher for the (*R*)-enantiomer, demonstrating that this enantiomer was metabolised by the organism in preference to (*S*)-glycerol. Recent experiments conducted with chiral glycerols have shown that (*R*)-glycerol is metabolised in preference to its enantiomer in the biosynthesis of fluoroacetate and 4-fluorothreonine in *Streptomyces cattleya*,[8] and in the biosynthesis of macrophomic acid by the fungus *Macrophoma commelinae*.[9] It is notable that the three different organisms, producing structurally diverse compounds, all metabolise glycerol such that the *pro*-(*R*)-hydroxymethyl group is retained in the metabolite and the *pro*-(*S*)-hydroxymethyl group is lost.

The results from these experiments are consistent with the following observations: the *pro*-(*R*)-hydroxymethyl group is retained and incorporated into **1** at C-3 and 11 [consequently the *pro*-(*S*)-hydroxymethyl group is lost] and C-2 of glycerol is incorporated into C-4 and 12 of **1**. Oxidation of C-2 takes place prior to incorporation into C-4 and possibly also for C-12.

These results raise some interesting questions on how the C_2 unit is incorporated by the soraphen A PKS. Chain extender units, such as malonyl CoA, are attached to the PKS *via* thioester linkages. Clearly, glycerol itself cannot be the immediate precursor in soraphen A biosynthesis. Oxidation of the *pro*-(*S*)-hydroxymethyl group would provide a carboxy group which could be used in the decarboxylative condensation step with the enzyme bound tri- and hepta-ketide intermediates. However, how the *pro*-(*R*)-hydroxymethyl group attaches itself to the PKS is a much more difficult problem. It is possible that glycerol is metabolised to glycolate and then hydroxymalonate (or even methoxymalonate). This mechanism would require oxidation of the *pro*-(*R*)-hydroxymethyl group to a carboxylic acid or coenzyme A thioester, which could then attach to the PKS *via* a thioester linkage. This mechanism is consistent with the ^{13}C labelling experiments, but it would result in complete loss of the deuterium label on the *pro*-(*R*)-hydroxymethyl group, which is inconsistent with the ^{2}H labelling experiments. Hence, while it is possible for the C_2 unit incorporated into C-3,4 of **1** to derive from hydroxy- or methoxy-malonate, retention of the deuterium label at H-11 excludes these precursors as the source for the C_2 unit incorporated at C-11,12. The *pro*-(*R*)-hydroxymethyl group of glycerol must remain as an alcohol (or phosphorylated derivative) or be oxidised to an aldehyde before incorporation into C-11,12; *it cannot be oxidised to a carboxylic acid or coenzyme A thioester*. An alternative, but less likely, explanation is that the *pro*-(*R*)-hydroxymethyl group of glycerol is oxidised to a carbonyl moiety and subsequent reduction, with redelivery of deuterium from a co-factor, results in deuterium enrichment at H-11. Experiments are in progress to further probe the mechanism of glycerol incorporation into soraphen A and to identify a more immediate precursor than glycerol in its biosynthesis. Possible candidates include hydroxypyruvate and glycerate.

Sorangium cellulosum kanamycin resistant wild-type strain M15 was provided by Novartis, Research Triangle Park, North Carolina, USA. We thank Dr T. Schupp (Novartis, Switzerland) for providing Probion S and Mrs J. Hawkes and Mr J. Cobb for NMR support. Deuterium NMR spectra were obtained using the Bruker AMX 400 University of London Intercollegiate Research Service for NMR at King's College. This work was financially supported by funding from King's College, London, The Royal Society, The University of London Central Research Fund and the State Scholarships Foundation (Republic of Greece) (A. P. S.). We thank Dr H. C. Hailes (University College London) for helpful discussions.

Notes and references

† Cultures of a kanamycin resistant strain of *S. cellulosum* (wild-type strain M15) were used in the incorporation experiments. In a typical experiment, production medium G55 (ref. 11) containing 50 g l^{-1} XAD-1180 resin was inoculated with a 9 day old growth medium G51t (ref. 12) culture and isotopically labelled compounds were pulse-fed in duplicate every 48 h between 10 and 16 days post inoculation. [1,3-$^{13}C_2$]-, [2-^{13}C]- and [$^2H_8$]-glycerol (1 g each) and [1-$^2H_2$]-, (*R*)-[1-$^2H_2$]- and (*S*)-[1-$^2H_2$]-glycerol (0.4–0.58 g each) were added as sterile aqueous solutions. The cultures were harvested on day 19 and the resin extracted with Pr^{i}OH. The crude soraphen A was purified by flash chromatography and preparative reverse phase HPLC (C-18) prior to NMR analysis. Typically 30 mg l^{-1} of soraphen A was obtained.

‡ [1-$^2H_2$]Glycerol was made in four steps from solketal: (i) solketal, $KMnO_4$, NaOH; (ii) CH_2N_2 (60% over 2 steps); (iii) $LiAlD_4$ (95%); (iv) AcOH, H_2O, room temp., 16 h (97%). (*R*)- and (*S*)-[1-$^2H_2$]glycerol were made in two steps from methyl isopropylidine-L-glycerate and methyl isopropylidine-D-glycerate, respectively, in 92% yield as above using a modified version of the protocol previously reported (ref. 8); (*R*)-[1-$^2H_2$]solketal, $[\alpha]_D$ +11.2 (*c* 9.4, MeOH) [lit. +15.3 (neat) (ref. 9)] and (*S*)-[1-$^2H_2$]solketal $[\alpha]_D$ −12.4 (*c* 8.7, MeOH) [lit. −14.9 (neat) (ref. 9)]. All three compounds contained 94% deuterium at C-1.

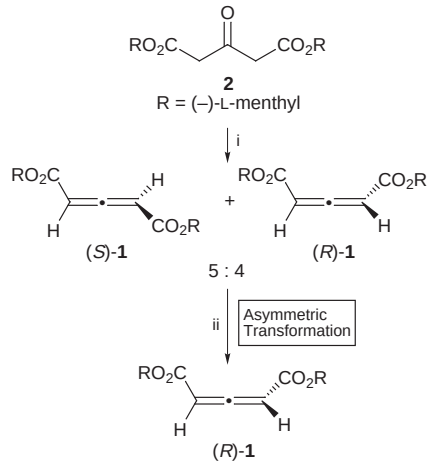
A new efficient synthesis of di-(−)-L-menthyl (*R*)-allene-1,3-dicarboxylate [(*R*)-1] involving asymmetric transformation through *epimerization–crystallization* with the assistance of a catalytic amount of Et_3N was developed; the highly *endo*-selective asymmetric Diels–Alder reaction of (*R*)-1 with *N*-Boc-pyrrole for the asymmetric synthesis of 7-*tert*-butoxycarbonyl-7-azabicyclo[2.2.1]heptan-2-one [(−)-6], a synthetic intermediate of (−)-epibatidine, is described.

Allene-1,3-dicarboxylates are useful for [4 + 2] cycloaddition as dienophiles.[1] Kanematsu and his colleagues have reported the highly diastereoselective Diels–Alder reaction of cyclopentadiene with optically active dimenthyl allene-1,3-dicarboxylate **1**, which was prepared by optical resolution using crystallization from a diastereomeric mixture of di-(−)-L-menthyl allene-1,3-dicarboxylates.[2] Naruse and his colleagues recently reported the enantiomeric enrichment of allene-1,3-dicarboxylates by a chiral organoeuropium reagent.[3] For the synthesis of optically active allene, the former method using optical resolution provides a low yield (< 25%), and the latter method has major drawbacks, *i.e*. the need for an equimolar amount of expensive $Eu(hfc)_3$, and the partial decomposition of the substrate due to the long reaction times needed. Therefore, a more efficient method for the preparation of optically active allene-1,3-dicarboxylate is required. Although several crystallization-induced asymmetric transformations by racemization have been reported,[4] the asymmetric transformation of dissymmetric compounds such as allenes has not been examined. We report here a new efficient synthesis of optically active allene-1,3-dicarboxylate by asymmetric transformation through *epimerization–crystallization* with the assistance of a catalytic amount of Et_3N, and its application to the formal total synthesis of (−)-epibatidine using the Diels–Alder reaction as a key step.

Since allene-1,3-dicarboxylate is an excellent Michael acceptor,[5] the epimerization of optically active allene-1,3-dicarboxylate, which was prepared from di-L- or -D-menthyl acetone-1,3-dicarboxylate by a new method[6] using 2-chloro-1,3-dimethylimidazolinium chloride (DMC), as shown in Scheme 1, was examined in the presence of a catalytic amount of Et_3N.

Thus, an optically pure di-(−)-L-menthyl (*R*)-allene-1,3-dicarboxylate [(*R*)-**1**][2] was treated with Et_3N (0.1 equiv.) in an NMR tube to give a diastereomeric mixture of **1** (*R*:*S* = 4:5) within 30 min. This experiment shows that these diastereomers are in equilibrium in the presence of a catalytic amount of Et_3N, as shown in Scheme 2. This result suggests that crystallization-induced asymmetric transformation of **1** would be possible, since the *R* diastereomer formed good crystals.[2a]

To crystallize the *R* diastereomer, a pentane solution of a diastereomeric mixture (*R*:*S* = 4:5) of di-(−)-L-menthyl allene-1,3-dicarboxylate **1** and 0.01 equiv. of Et_3N was kept below −20 °C for 2 days. After removal of the mother liquid, the precipitated crystals were washed with cooled pentane. This crystallization procedure of the mother liquid was repeated twice. Colorless crystalline (*R*)-**1** was obtained in 90% yield (> 98% de). Similarly, the enantiomer (*S*)-**1** was also obtained

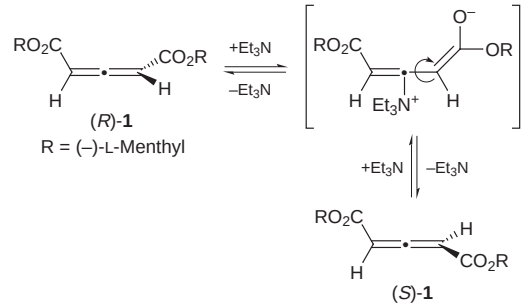


Scheme 1 *Reagents and conditions*: i, DMC, Et_3N, CH_2Cl_2, room temp., 86%; ii, Et_3N (0.01 equiv.), pentane, crystallization (×3), 90%.

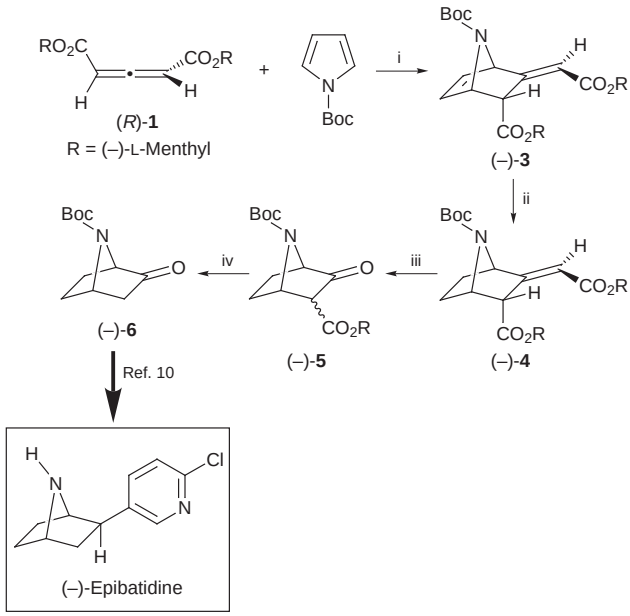
by the above asymmetric transformation using (+)-D-menthol as a chiral auxiliary.

Next, we applied di-(−)-L-menthyl (*R*)-allene-1,3-dicarboxylate (*R*)-**1** to an asymmetric synthesis of (−)-epibatidine, which was isolated from the skin of the Ecuadorian poison frog *Epipedobates tricolor*, and possesses a unique 7-azabicyclo-[2.2.1]heptane skeleton and a potent non-opioid analgesic effect.[7] There have been only a few reports[8] on the asymmetric synthesis of (−)-epibatidine, although there have been many reports on its total synthesis.[9,10] We planned the asymmetric synthesis of a synthetic intermediate for (−)-epibatidine using the Diels–Alder reaction of **1** according to Kanematsu *et al*.,[2a] as shown in Scheme 3.

The Diels–Alder reaction of (±)-dimethyl allene-1,3-dicarboxylate with *N*-Boc-pyrrole (10 equiv.) gave almost equimolar amounts of the *endo* and *exo* adducts, both at a low temperature with the assistance of a Lewis acid [$AlCl_3$ (1.2 equiv.), CH_2Cl_2, −78 °C, 12 h, 73%], and at a high temperature[9d] [toluene, 90 °C, 12 h, 89%]. On the other hand, we found that the same reaction of di-L-(−)-menthyl allene-1,3-dicarboxylate (*R*)-**1** with *N*-Boc-pyrrole and $AlCl_3$ in CH_2Cl_2 at −78 °C for 13 h gave the endo adduct (−)-**3** as a sole product in 86% yield. The absolute stereochemistry of the *endo*



Scheme 2



Scheme 3 *Reagents and conditions*: i, $AlCl_3$, CH_2Cl_2, −78 °C, 13 h, 86%; ii, 10% Pd/C, H_2, EtOAc, room temp., 99%; iii, O_3, PPh_3, CH_2Cl_2, −78 °C, 52%; iv, 10% HCl, heat, then Boc_2O, Et_3N, CH_2Cl_2, room temp., 55%.

adduct (−)-**3** was elucidated by an X-ray crystallographic analysis.

The observed significant difference in *endo*/*exo* selectivity between the dimethyl ester and the di-L-(−)-menthyl ester could be explained on the basis of steric repulsion between the *N*-Boc group of the diene and the methyl or menthyl group in the dienophile **1**, based on an X-ray crystallographic analysis.[2a]

The *endo* adduct (−)-**3** was subsequently converted into a synthetic intermediate (−)-**6**[10] for (−)-epibatidine. Thus, regioselective hydrogenation of non-conjugated olefin on (−)-**3** with 10% Pd/C gave the dihydro derivative (−)-**4** quantitatively. After ozonolysis of the remaining double bond, the obtained β-keto ester **5** was subjected to hydrolysis, decarboxylation, and *N*-*tert*-butoxycarbonylation (reprotection of the deprotected secondary amine) to give (−)-**6** in moderate yield; its specific rotation {$[\alpha]_D^{17}$ −74.5 (*c* 1.02, $CHCl_3$), lit.[10a] $[\alpha]_D^{26}$ −75.1 (*c* 1.56, $CHCl_3$)} and spectroscopic data were identical to those in the literature.[10] This transformation constitutes a formal asymmetric synthesis of (−)-epibatidine.

In conclusion, we have developed the first asymmetric transformation of dissymmetric allene-1,3-dicarboxylate through *epimerization* based on addition–elimination with a tertiary amine, and a quite efficient synthesis of (−)-**6** from di-(−)-L-menthyl acetone-1,3-dicarboxylate.

Received (in Bloomington, IN, USA) 24th July 1998, Accepted 25th September 1998

The complex $[Ru_2(\mu\text{-}CO)(CO)_4(\mu\text{-}dppm)_2]$ is more active than mononuclear ruthenium complexes as a catalyst for decomposition of formic acid to CO_2 and H_2; under conditions of highest activity, a coordinatively unsaturated diruthenium dihydride $[Ru_2H(\mu\text{-}H)(\mu\text{-}CO)(CO)_2(\mu\text{-}dppm)_2]$ is present and can be isolated from solution.

This paper reports the first study of the decomposition of formic acid to hydrogen and carbon dioxide using a locked binuclear catalyst and presents evidence that this is an unusual catalytic reaction in which two metals can act cooperatively to give enhanced activity.† The reversible reaction between HCO_2H and $H_2 + CO_2$ has been the subject of considerable interest, either for catalytic transfer hydrogenation using formic acid or for utilization of CO_2 as a reagent in organic synthesis.[1,2]

The reaction of $[Ru_2(\mu\text{-}CO)(CO)_4(\mu\text{-}dppm)_2]$ **1**,[3] dppm = $Ph_2PCH_2PPh_2$, in acetone (5×10^{-3} M) with formic acid (10^{-1} M) in a closed tube at 20 °C was monitored by NMR. The products were H_2 [$\delta(^1H)$ 4.5] and CO_2 [$\delta(^{13}C)$ 125.8] only and the reaction was complete in 0.3 h, corresponding to a mean turnover rate of *ca.* 70 h^{-1}, and considerably higher activity was observed when the reaction was carried out in an unsealed vessel, for reasons discussed below. The activity is significantly higher than for comparable mononuclear ruthenium complex catalysts: for example, $[RuHBr(CO)(PEt_2Ph)_3]$ gives a turnover rate of *ca.* 4 h^{-1} in refluxing acetic acid (117 °C).[1a]

The high catalytic activity of **1** prompted a more detailed study and some important features of the binuclear catalysis have been elucidated. The catalysis is more efficient in the dipolar aprotic solvent acetone than in solvents such as toluene or dichloromethane. The catalytic reaction is strongly or completely inhibited by the presence of excess CO; in a sealed vessel, CO dissociates from **1** at intermediate stages of reaction and then acts as inhibitor, whereas, in a vessel in which evolved gases sweep CO from the system, this effect cannot occur and so the catalysis is faster. The reaction appears not to be wholly intramolecular since decomposition of either HCO_2D or DCO_2H leads to formation of a mixture of H_2, HD and D_2 rather than HD alone, but the conclusion is weakened by the observation that decomposition of HCO_2H in the presence of D_2 gives both H_2 and HD. The final product mixture from decomposition of HCO_2D or DCO_2H is approximately that expected from statistical considerations ($H_2 : HD : D_2 = 1 : 2 : 1$, determined by MS) but in the very early stages of reaction H_2 is predominant. Under these reaction conditions, there was no evidence for reversibility which would lead to isomerization between HCO_2D and DCO_2H. Decomposition of $H^{13}CO_2H$ gave only H_2 and $^{13}CO_2$, with no free or coordinated ^{13}CO detectable by either IR or ^{13}C NMR.

There were interesting changes in the ruthenium complexes present at various stages of the catalytic reaction and several of these could be isolated or identified spectroscopically. When the reaction was carried out in a sealed tube, the only ruthenium complex present when reaction was complete was unchanged **1** but other complexes were present during catalysis (Scheme 1). The first complex formed at −30 °C was $[Ru_2(\mu\text{-}H)(\mu\text{-}CO)(CO)_4(\mu\text{-}dppm)_2]^+$ **2**, as the formate salt.‡ This complex is formed by protonation of the Ru–Ru bond of **1** and the same cation is formed by protonation with other acids such as $H[BF_4]$.[4] Next to be formed was the cation $[Ru_2(\mu\text{-}HCO_2)(CO)_4(\mu\text{-}dppm)_2]^+$ **3** (also as the formate salt), whose spectroscopic properties‡ are very similar to the known μ-acetate analogue;[4,5] the first formation of H_2 could be detected at this stage. When most formic acid was consumed, two more complexes were formed transiently. The major complex was characterized as $[Ru_2H_2(CO)_4(\mu\text{-}dppm)_2]$ **5**, by the following spectroscopic data.‡[6] In the ^1H NMR spectrum, a hydride resonance at $\delta(^1H)$ −9.25 [qnt, J(PH) 9 Hz] integrated for two protons and a single resonance at $\delta(CH_2P_2)$ 4.6 were observed, in the ^{13}C NMR spectrum a single terminal carbonyl resonance was observed at δ(CO) 196.8, and in the ^{31}P NMR spectrum a singlet was observed at δ(P) 34.3. These data indicate structure **5**, having D_{2h} symmetry; a less symmetrical but fluxional structure is also possible[6] though no change in the NMR spectra was observed at −70 °C. The second transient complex was tentatively identified as $[Ru_2H(HCO_2)(CO)_4(\mu\text{-}dppm)_2]$ **4**.‡ It is characterized in the ^1H NMR by resonances at δ −6.7 (br s, 1H, RuH) and at δ 8.5 (s, 1H, HCO_2), in the ^{13}C NMR (in a reaction using $H^{13}CO_2H$) by δ 165 (s, CH, HCO_2) (the concentration of **4** was never great enough to allow identification of the metal carbonyl resonances even using ^{13}C enriched starting material **1**) and in the ^{31}P NMR by a single resonance at δ 39.8.[5] If structure **4** is correct, it is required to be fluxional in order to give a single resonance in the ^{31}P NMR spectrum.[4] Further

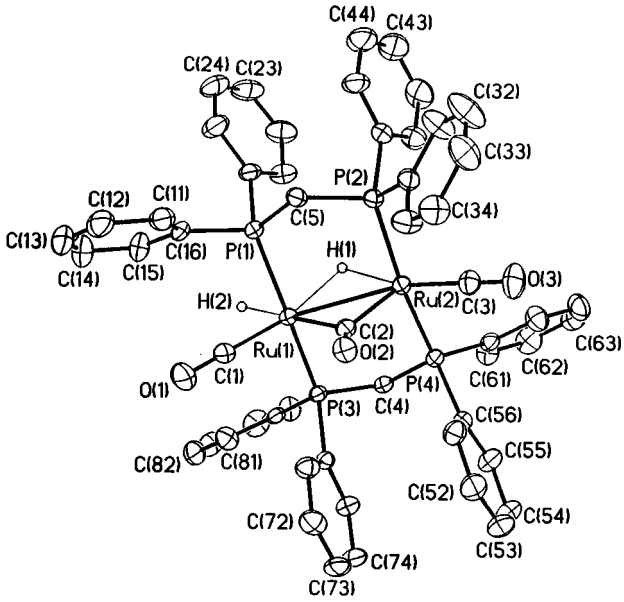

Fig. 1 A view of the structure of $[Ru_2H(\mu\text{-}H)(\mu\text{-}CO)(CO)_2(\mu\text{-}dppm)_2]$. Distances (Å): Ru(1)–Ru(2) 2.8769(5), Ru(1)–C(1) 1.857(5), Ru(1)–C(2) 2.198(5), Ru(2)–C(2) 2.006(4), Ru(2)–C(3) 1.841(5). The hydride H-atoms were located but not refined; approximate distances Ru(1)–H(1) 2.16, Ru(2)–H(1) 2.16, Ru(1)–H(2) 1.66.

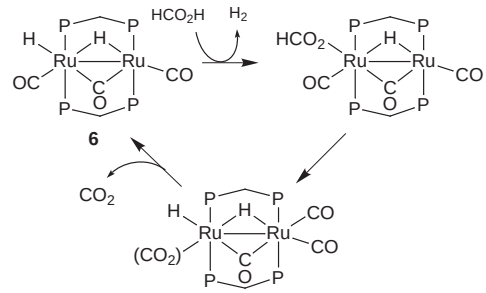
study indicated that the concentration of **5** with respect to **2** was pH dependent, since addition of Et_3N led to an increase in the relative concentration of **5**. Overall then, at high $[HCO_2H]$, complex **1** reacted to give **2** and **3** and, as HCO_2H was consumed, the concentrations of these complexes decreased and the transient complexes **4** and **5** appeared, quickly followed by reformation of **1**. These observations are readily rationalized since **5** is expected to be very reactive towards formic acid, and formate probably dissociates easily from **4** in the presence of formic acid to give the less nucleophilic anion $[H(O_2CH)_2]^-$; hence the concentration of these complexes **4** and **5** only builds up to detectable levels when the concentration of formic acid is low.

When the reaction was carried out in an unsealed vessel, the initial reactions were similar but a new complex $[Ru_2H(\mu\text{-}H)(\mu\text{-}CO)(CO)_2(\mu\text{-}dppm)_2]$, **6**, was formed in the later stages rather than **4** or **5**. Complex **6** is a unique example of a coordinatively unsaturated binuclear ruthenium dihydride;[4,6] it could be crystallized from the reaction mixture and was fully characterized by an X-ray structure determination (Fig. 1) as well as by spectroscopic methods.‡ Complex **6** was stable in the solid state but in solution it was stable only in the presence of hydrogen and in the complete absence of oxygen; it reacted rapidly with CO to give **1** with loss of H_2. Clearly, this high reactivity of **6** with CO explains why no **6** is formed when the reaction is carried out in a sealed tube; **6** reacts with one equivalent of CO to give **5** and then with a second equivalent of CO to give **1** and H_2. Solutions containing the coordinatively unsaturated complex **6** were particularly active for further catalytic decomposition of formic acid.

It is interesting to speculate on why the binuclear system described above is so reactive for decomposition of formic acid. The key steps in the initial catalytic reaction are likely to be the overall oxidative addition of formic acid to ruthenium(0) to give a hydrido(formato) complex and then probably a ß-elimination from the formate to give a transient dihydrido(CO_2) complex which ultimately yields H_2 and CO_2. Both of these proposed steps require a vacant coordination site, and the necessary dissociation of two CO ligands is probably easier to accomplish in the binuclear system. There is some independent evidence for CO labilization *cis* to the bridging hydride ligand in complex **2**. Thus, exposure of **2** to ^{13}CO led to carbonyl exchange but the substitution in the terminal carbonyl sites *cis* to the μ-H ligand [$\delta(^{13}C)$ 198.6] was much faster (exchange detected in < 1 h)



Scheme 2 A possible mechanism of catalysis.

than in the *trans* terminal [$\delta(^{13}C)$ 200.8] or bridging [$\delta(^{13}C)$ 278.6] carbonyl sites (exchange detected after one day).§ While the reactions of Scheme 1 provide a viable route for the catalytic reaction in the presence of CO, the data suggest that CO-deficient complexes, such as **6**, are most active and it is likely that other key intermediates are too short-lived to be detected. A reasonable catalytic cycle involving **6** is shown in Scheme 2.

In summary, this article describes a novel binuclear catalytic system for formic acid decomposition, in which the major ruthenium complexes in solution are dependent on both reaction conditions and the stage of the catalytic reaction. It suggests that binuclear and cluster complexes, especially those that can easily achieve coordinative unsaturation, may have distinct advantages over mononuclear transition metal catalysts for this and related catalytic reactions.[7]

We thank the NSERC (Canada) for financial support.

Notes and references

† Binuclear complexes have been identified in formic acid decomposition previously but were not thought to be involved in the catalytic cycle.[1c]

_N_-Methylimidazole and acetonitrile are suitable solvents for the direct reactions of europium metal with 2,6-$Me_2C_6H_3OH$ and 2,6-$Pr^i_2C_6H_3OH$, which lead to crystallographically characterizable (*N*-methylimidazole)$_3$Eu(μ-$OC_6H_3Me_2$-2,6)$_3$Eu(*N*-methylimidazole)$_2$($OC_6H_3Me_2$-2,6) 1 and [(MeCN)$_2$(2,6-$Pr^i_2C_6H_3O$)Eu]$_2$(μ-$OC_6H_3Me_2$-2,6)$_2$(μ-NCMe) 2, a complex which contains a μ-η¹-acetonitrile ligand.

Owing to the special fluorescent properties of europium,[1] it is desirable to be able to synthetically manipulate this element in a variety of ways in order to optimize its incorporation into devices of practical utility.[2] Syntheses starting from the metal are best since they avoid the preparation of starting materials, such as chlorides or nitrates, require no drying of these materials, and eliminate the possibility of incorporating some of the starting material ligands into the final product. Europium alkoxide and aryloxide complexes, potentially useful in sol-gel processing,[3] can be made by direct reaction of europium with alcohols and phenols in liquid ammonia,[4–6] by reaction of europium with $Hg(C_6F_5)_2$ in phenols,[7] by reaction of europium with Tl(OAr) in THF,[7] and by reaction of europium with Pr^iOH in the presence of Hg^{II} catalysts,[8] but more convenient are the direct reactions of europium solely with liquid alcohols.[9,10] However, the latter route is not as suitable for solid 2,6-dialkylphenols, which provide good ligands for stabilizing and solubilizing europium ions and for making polyeuropium complexes.[4–6,9] We report here that by using *N*-methylimidazole and acetonitrile as solvents, direct reactions of europium with 2,6-dialkylphenols can be achieved to form fully characterizable europium aryloxide complexes. In addition, we report a new type of bonding mode for acetonitrile.

Europium reacts slowly with 2,6-$Me_2C_6H_3OH$ and 2,6-$Pr^i_2C_6H_3OH$ at room temperature in *N*-methylimidazole or acetonitrile to form yellow solutions of paramagnetic divalent europium complexes.† Each 2,6-$R_2C_6H_3OH$ reacts in each solvent, but the R = Me/*N*-methylimidazole and R = Pr^i/MeCN combinations readily provide crystallographically characterizable complexes.‡ (*N*-methylimidazole)$_3$Eu(μ-$OC_6H_3Me_2$-2,6)$_3$Eu(*N*-methylimidazole)$_2$($OC_6H_3Me_2$-2,6) **1** (Fig. 1) and [(MeCN)$_2$(2,6-$Pr^i_2C_6H_3O$)Eu]$_2$(μ-$OC_6H_3Me_2$-2,6)$_2$(μ-NCMe) **2** (Fig. 2).

The bimetallic nature of **1** and the arrangement of the anionic ligands are identical to those reported for (DME)$_2$Eu(μ-$OC_6H_3Me_2$-2,6)$_3$Eu($OC_6H_3Me_2$-2,6)(DME) **3** (DME = 1,2-dimethoxyethane), isolated from a Eu/$HOC_6H_3Me_2$-2,6 liquid ammonia reaction.[4] This unsymmetrical arrangement has also been observed in some calcium and barium alkoxide and siloxide complexes.[11] The structures of **1** and **3** differ in that three *N*-methylimidazole ligands in **1** take the place of two bidentate DME ligands in **3** and hence both europium atoms in **1** are six coordinate, whereas **3** contains one six- and one seven-coordinate europium atom.

Each europium atom in **1** is surrounded by a distorted face sharing bioctahedral arrangement of oxygen and nitrogen donor atoms with the shared face consisting of anionic oxygen atoms. The 2.365(3) Å Eu–O(terminal) and 2.479(3)–2.632(3) Å Eu–O(bridging) bond lengths in **1** are in the range of analogous bond lengths in the literature.[4,12]

Complex **2**, like **1**, is also bimetallic and has a face sharing bioctahedral arrangement of ligand donor atoms. However, its structure differs in that each metal atom has the same set of ligands. Although reactions in liquid ammonia and coordinating solvent yielded structurally similar complexes **1** and **3**, complex **2** is substantially different from the product obtained from europium and $HOC_6H_3Pr^i_2$-2,6 in liquid ammonia, Eu_4(μ-$OC_6H_3Pr^i_2$-2,6)$_4$($OC_6H_3Pr^i_2$-2,6)$_2$(μ_3-OH)$_2$($NCMe_3$)$_6$ **4**.[5] The 2.286(6) and 2.289(5) Eu–O(terminal), 2.438(6), 2.463(5), 2.487(5) and 2.494(6) Eu–O(bridging), and the 2.625(9)–2.667(9) Å Eu–N(terminal) bond lengths in **2** are not unusual for europium(II) aryloxide complexes.[5,12]

The most remarkable feature in **2** is that it contains a μ-η¹ : η¹-acetonitrile ligand, which, to our knowledge, is the first observation of this binding mode for acetonitrile. The 2.847(8) and 2.913(9) Å Eu–N bond lengths of the bridging acetonitrile are longer than the Eu–N(terminal) distances in **2**, as expected.

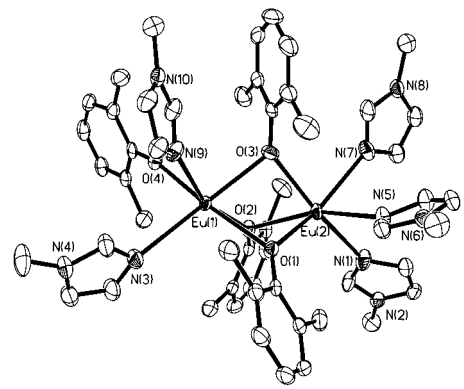

Fig. 1 Plot of $Eu_2(OC_6H_3Me_2$-2,6)$_4$(*N*-methylimidizole)$_5$ **1** with thermal ellipsoids drawn at the 50% probability level and hydrogen atoms omitted for clarity.

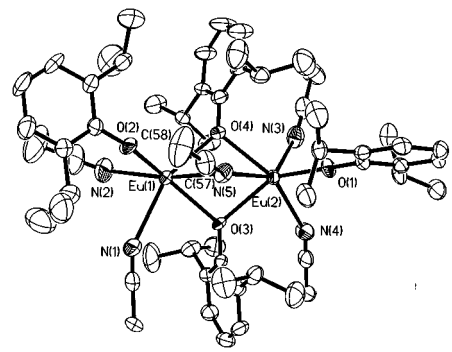

Fig. 2 Thermal ellipsoid plot of $Eu_2(OC_6H_3Pr^i_2$-2,6)$_4$($NCCH_3$)$_5$ **2** with thermal ellipsoids drawn at the 50% probability level and hydrogen atoms omitted for clarity.

The bridging is unsymmetrical with 164.5(8) and 105.0(7)° Eu–N(5)–C(57) angles. This places C(57) closer to Eu(1) than Eu(2), but the 3.391 Å Eu(1)–C(57) distance is too long to constitute a Eu–C bond. Structurally characterized by μ-η^2-acetonitrile ligands have M–C(nitrile) interactions in the range of 1.876(9) to 2.114(7) Å.[13] The Eu(1)–N(5)–Eu(2) angle is 79.9(2)° and the Eu(1)–C(57)–Eu(2) angle is 59.9°. A space filling model of **2** suggests that the μ-η^1 : η^1-nature of this ligand and the inequivalence of the Eu–N(5)–C(57) angles arise because there is only a limited space available for the acetonitrile to fit between the bulky 2,6-diisopropylphenoxide ligands.

The results to date on divalent europium aryloxide chemistry suggest that isolable, crystalline complexes more readily form with either a combination of larger 2,6-dialkyl substituents, such as isopropyl groups, and relatively small ligands, such as acetonitrile, or with a combination of smaller 2,6-dialkyl substituents, such as methyl groups, and larger ligands, such as *N*-methylimidazole or 1,2-dimethoxyethane. Variable binding modes are undoubtedly helpful in accommodating crowded ligand environments and the structure of **2** demonstrates another variation in the binding capacity of acetonitrile.

For support of this research, we thank the Division of Chemical Sciences of the Office of Basic Energy Sciences of the Department of Energy.

Notes and references

† Compounds **1** and **2** are obtained by reaction of europium ingots (typically 5–10 mm in diameter) with $HOC_6H_3Me_2$-2,6 in *N*-methylimidazole or $HOC_6H_3Pr^i_2$-2,6 in acetonitrile, respectively, over 2 days at room temperature followed by centrifugation and recrystallization from the supernatant. Single crystals of complex **2** were isolated in 40% yield from the concentrated acetonitrile solution after several days. Single crystals of complex **1** was isolated from the *N*-methylimidazole solution. However, since the yield was low and the high boiling point of *N*-methylimidazole made solvent removal tedious, an alternate procedure was developed. The direct reaction of europium metal with $HOC_6H_3Me_2$-2,6 in a dilute solution of *N*-methylimidazole (0.5 ml) in toluene (7.0 ml), followed by centrifugation and removal of the toluene under vacuum, forms crystalline **1** in 20% yield, based on reacted Eu. Both **1** and **2** give satisfactory elemental analyses and the effective magnetic moments of 7.5 and 8.0 μ_B for **1** and **2**, respectively, are consistent with Eu^{II}.

‡ *Crystal data* for **1**: $C_{52}H_{66}Eu_2N_{10}O_4$, M = 1199, triclinic, space group $P\bar{1}$, a = 12.142(2), b = 12.763(9), c = 18.906(5) Å, α = 71.60(4), β = 73.718(10), γ = 76.48(3)°, V = 2634.3(20) Å, Z = 2, T = 158 K, μ = 2.412 mm^{-1}, Mo-Kα radiation, graphite monochromator. The raw data were processed with a local version of CARESS. All 9678 data points were corrected for Lorentz and polarization effects and were placed on an approximately absolute scale. All calculations were carried out using the SHELXL program. The structure was solved by direct methods and refined on F^2 by full-matrix least-squares techniques. Hydrogen atoms were included using a riding model. At convergence, $wR2$ = 0.0787 and GOF = 1.036 for 613 variables refined against all 9199 unique data [in comparison, for refinement on F, $R1$ = 0.0282 for those 7984 data with $F > 4.0\sigma(F)$]. For **2**: $C_{58}H_{83}Eu_2N_5O_4$, M = 1218, monoclinic, space group Pn, a = 11.8317(12), b = 21.6202(16), c = 12.9773(13) Å, β = 112.917(7)°, V = 3057.6(5) Å, Z = 2, T = 158 K, μ = 2.077 mm^{-1}, Mo-Kα radiation, graphite monochromator. All 7348 data were collected using a Siemens P4 diffractometer, and handled as described for **1**. All calculations were carried out as described for **1** above and hydrogen atoms were included using a riding model. At convergence, $wR2$ = 0.1141 and GOF = 0.766 for 627 variables refined against all 7348 unique data [in comparison, for refinement on F, $R1$ = 0.0382 for those 6939 data with $F > 4.0\sigma(F)$]. Novelties of eclectically engineered sulfated zirconia and carbon molecular sieve catalysts in cyclisation of citronellal to isopulegol

G. D. Yadav* and J. J. Nair

Chemical Engineering Division, University Department of Chemical Technology, University of Mumbai (formerly Bombay), Matunga, Mumbai - 400 019, India. E-mail: gdy@udct.ernet.in

Received (in Cambridge, UK), 2nd September 1998, Accepted 28th September 1998

Sulfated zirconia (S-ZrO_2) is a well-known solid superacid catalyst used in various reactions of commercial importance such as isomerisation, alkylation and acylation, nitration, *etc.* The selectivity towards the formation of isopulegol, a potential intermediate in the synthesis of menthol, can be drastically increased by using carbon molecular sieve (CMS) with S-ZrO_2.

Isopulegol is an important intermediate for the manufacture of menthol, used extensively in pharmaceuticals, cosmetics, toothpastes, chewing gum, and other toilet goods as well as in cigarettes.[1] Isopulegol is manufactured from the cyclisation of citronellal. Bogert and Hasselstrom[2] have reported the use of UV in the cyclisation reaction. Activities and selectivities of acid clinoptilolite, mordenite, and faujasite zeolites in the isomerisation of citronellal in n-hexane, chloroform and dichloromethane as solvents have been investigated.[3] The activities of the acidic zeolites for the isomerisation of citronellal were found to be in the following order: HY(max.) > HCC > (clinoptilolite) > HMCP (clinoptilolite + mordenite) > HX at 84 °C in dichloroethane, and the selectivities to isopulegol were HCC (90%) > HMCP (85%) > HY (80%) > HMP (72%) at 80% conversion level. The activity in these studies is related to the total amount of Brønsted acid sites of the catalysts and only a fraction of these sites, located mainly on the external surface of the crystal, were accessible to the reactants due to the diffusional resistance. It was found that the selectivity increases to the isopulegol ether as the accessibility to the acidic centres increases. There are several reports whereby Cu–Cr and Cu–Cr–Mn,[4] tris(triphenylphosphine)rhodium chloride[5] and micellar[6] catalysts have been employed to catalyse the cyclisation reaction. Several Lewis acids as catalyst for the preparation of L-isopulegol from D-citronellal have been used.[7] Dean and Whittaker[8] have studied this reaction with superacids (*e.g.* FSO_3H/SO_2) to observe that the cyclisation follows the same path as the normal acids, yielding isopulegol and neoisopulegol.

We present here the efficacy of a novel shape selective catalyst synergistically produced from sulfated zirconia (S-ZrO_2) and carbon molecular sieve (CMS) in the cyclisation of citronellal to isopulegol. S-ZrO_2 is a very well-known solid superacidic catalyst used in various reactions. The activity of this catalyst is superior to many other solid acid catalysts. But one of the major drawbacks of S-ZrO_2 is that it is not a shape selective catalyst. Hence it cannot be employed in reactions where selectivity is of utmost importance. However, S-ZrO_2 when combined with other materials can produce the desired shape selective catalyst. In this respect, carbon molecular sieve (CMS) can be used in combination with S-ZrO_2 to get a composite shape selective catalyst. The selectivity engineering aspects of catalysts are embodied in this CMS–S-ZrO_2 composite media where one acts as a siever and the inside core as the true catalyst. The isomerisation of citronellal was considered to be interesting in view of the fact that the reaction has been studied by others using zeolites and there are several products generated depending on the type of carbocation and hence on the type and strength of acidic sites.

Zirconium oxychloride, 25% ammonia solution, polyvinyl alcohol, toluene and 98% sulfuric acid were obtained from S.D. Fine Chemicals Ltd. Citronellal containing about 14% isopulegol was obtained from Arofine Industries Ltd.

The catalyst was prepared using the conventional precipitation method.[9] 100 g of zirconium oxychloride were dissolved in distilled water. The solution was then filtered. This solution and 25% aqueous ammonia were added dropwise simultaneously in a beaker with constant stirring while a white precipitate of zirconium hydroxide was obtained at pH 9–10. After complete precipitation it was digested in the vessel for 6 h. The precipitate was filtered through a Buchner funnel and washed thoroughly with distilled water until free of ammonia and chloride ions. The filtered precipitate was dried in an oven at 120 °C for 24 h. The dried catalyst was then crushed to make a fine powder, which was treated with 0.5 M H_2SO_4. 15 ml of 0.5 M H_2SO_4 was required for 1 g of the catalyst. The catalyst so prepared was dried in an oven at 120 °C for 24 h followed by calcination at 230 to 650 °C.

To 10 g of the above prepared catalyst 7.2 ml polyvinyl alcohol (PVA) solution (2 g PVA dissolved in 25 ml distilled water) was added dropwise until it was just wet. It was mixed well to get a uniform coating. It was dried at 100 °C for 1 h and calcined at different temperatures. This catalyst is referred to as S-ZrO_2/CMS catalyst.

In another method, S-ZrO_2 was initially soaked with different solvents such as benzene, cyclohexane, carbon tetrachloride, hexane till wetness. This was coated with the same amount of PVA solution as was done without wetting the catalyst with solvent. These were calcined at different temperatures. Eight different catalysts were prepared as shown in Table 1 where the nomenclature S-ZrO_2/Benzene/CMS refers to S-ZrO_2 soaked with benzene followed by coating with CMS.

All experiments were conducted in a 100 ml fully baffled glass reactor of 5 cm internal diameter. The reactant and solvent were charged to the reactor and the temperature was raised to 95 °C. 0.5 g (2.13×10^{-2} g cm^{-3}) of the desired catalyst was then added to the reactor under constant stirring.

Table 1 Activities of catalysts for cyclisation of citronellal

Catalyst	Time/min	Conversion of citronellal (%)	Selectivity for isopulegol (%)
ZrO_2[230–350]	90	0	—
S-ZrO_2[230–350]	10	96	46
S-ZrO_2[650]	05	95	35
S-ZrO_2[230–350]/CMS	30	91	65
S-ZrO_2[230–350]/Benzene/CMS	20	95	52
S-ZrO_2[230–350]/Cyclohexane/CMS	20	96	61
S-ZrO_2[230–350]/CCl_4/CMS	30	88	53
S-ZrO_2[230–350]/Hexane/CMS	20	95	58

Solvent: toluene = 15 g, reactant: citronellal = 5 g, temperature: 95 °C. Values inside square brackets indicate the calcination temperature.

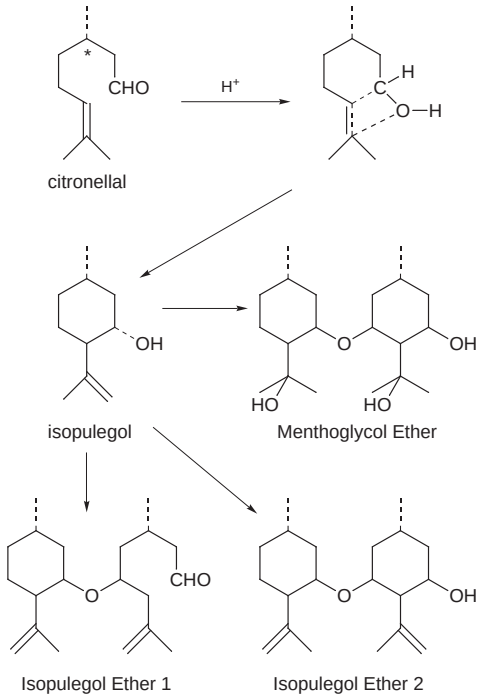

Fig. 1 *trans* addition and cyclisation mechanism.

An initial sample was drawn and the progress of the reaction was monitored on a Perkin Elmer (Model 8500) Gas Chromatograph using an FID detector and coupled with an integrator/plotter. A 2 m × 1/8′ S.S. column of Carbowax with Chromosorb W and 10% C-20M + 2% KOH washed, 80–100 mesh was used. The by-products obtained were predicted, from GC-MS, to be an ether of citronellal–isopulegol (isopulegol ether 1), diisopulegol (isopulegol ether 2) and dimenthoglycol ether (Fig. 1). The mechanism given in Fig. 1 shows the cyclisation of citronellal to isopulegol and the different ethers obtained from isopulegol.[10] There are different stereoisomers of isopulegol.

Table 1 lists the results of the experiments conducted under otherwise similar conditions of mole ratio of reactant and solvent, catalyst loading, speed of agitation and temperature.

It is well established that the formation of isopulegol ether takes place if citronellal is easily accessible to the Brønsted acid sites of the catalyst. Hence, in the case of S-ZrO_2[650] as catalyst, where the calcination temperature is high, the average pore size was found to be 41 Å by nitrogen adsorption isotherm using a Micromeritics surface area analyser (ASAP 2010 Model). When S-ZrO_2[650] was compared with S-ZrO_2[230–350] the selectivity towards the formation of isopulegol was found to increase in the latter. The pore size of S-ZrO_2[230–350] was found to be 28 Å. Hence, even though the Brønsted acidity is expected to be more in case of S-ZrO_2[230–350] as compared to S-ZrO_2[650], which is a Lewis acid catalyst, the pore size is smaller than the latter. This leads to the diffusion controlled formation of isopulegol ether which is kinetically much bulkier than isopulegol and hence the subsequent increase in the formation of the latter. The same reason is true for the decrease in the rate of the reaction. Further, when S-ZrO_2[230–350] is coated with CMS a uniform barrier of pore size 27 Å is obtained. This marginal drop in pore size provides further resistance to the formation of isopulegol ether and hence favour the formation of isopulegol. Also, the external surface of the catalyst which may consist of Brønsted acid sites becomes inaccessible to citronellal which further decreases the formation of isopulegol ether.

In other catalysts used S-ZrO_2[230–350] was initially soaked with different solvents which were immiscible with polyvinyl alcohol solution, before coating with CMS, to prevent the diffusion of polymers into the pores of the catalyst, if any. The initial soaking was not found to be very effective though there was a slight increase in the formation of isopulegol.

S-ZrO_2 modified carbon molecular sieve can be prepared using different polymers as precursors and hence the catalysts can be tailor-made by fine-tuning the pore size according to the requirements. Thus eclectically engineered S-ZrO_2/CMS catalysts lead to much greater selectivity to isopulegol in the cyclisation of citronellal.

An osmium nitrido complex as a π-acid ligand for late transition metals

Thomas J. Crevier, Scott Lovell and James M. Mayer*

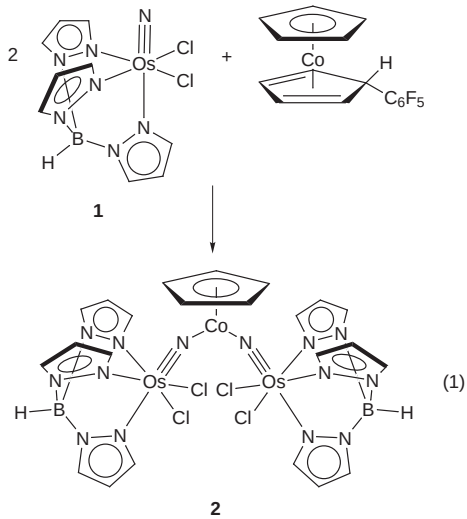
Department of Chemistry, Box 351700, University of Washington Seattle, Washington 98195-1700, USA

Received (in Bloomington, IN, USA) 7th July 1998, Accepted 22nd September 1998

The Os(VI) nitrido complex, $TpOs(N)Cl_2$ (1), acts as a π-acid ligand in the cobalt and platinum complexes $CpCo[NOs(Tp)Cl_2]_2$ (2) and $(Me_2S)Cl_2Pt–N{\equiv}Os(Tp)Cl_2$ (3).

Transition metal nitrido complexes $L_nM{\equiv}N$ typically act as nucleophiles, being alkylated or binding to other metals.[1] The two dozen or so known hetero-bimetallic μ-nitrido complexes all involve nucleophilic nitrido complexes and are described as dative adducts $L_nM{\equiv}N{\rightarrow}M'L_m$ (**A**) or metalloimido complexes $L_nM{\overset{\equiv}{=}}N–M'L_m$ (**B**).[2] We have recently prepared an Os(VI) nitrido complex, $TpOs(N)Cl_2$ [**1;** Tp = hydrotris(1-pyrazolyl)borate],[3] that acts as an electrophile. Electrophilic multiply-bonded ligands are less common but such ligands are important in various processes, including atom and group transfers, and dihydroxylation and aminohydroxylation of olefins.[4] Complex **1** is unreactive with protic acids, methyl triflate (MeOTf), $BF_3{\cdot}Et_2O$, and $[Ph_3C][BF_4]$, but it reacts with PPh_3 and carbanions at nitrogen.[3] Despite its lack of reaction with simple electrophiles, we report here that **1** is a good ligand for Co(I) and Pt(II) centers. We propose that the complexes reported herein are a new type of μ-nitrido compound, in which the multiply bonded nitrido fragment is best described as a π acid ligand for the heterometal.

$CpCo(\eta^4\text{-}C_5H_5C_6F_5)$[5] was chosen as a source of the electron-rich CpCo(I) fragment since the η^4-diene should be easily displaced. Indeed, addition of **1** to a benzene solution of $CpCo(\eta^4\text{-}C_5H_5C_6F_5)$ causes an immediate darkening of the solution and precipitation of purple $CpCo[NOs(Tp)Cl_2]_2$ (**2**)† in good yield [eqn. (1)]. NMR data are consistent with a



(1)

2

diamagnetic compound with two TpOs fragments per CpCo unit. Slow evaporation of a chloroform solution of **2** forms single crystals suitable for X-ray diffraction.‡ The structure (Fig. 1) shows a two-legged piano stool geometry about the cobalt atom with the two legs being octahedral osmium centers, connected to the cobalt by μ-nitrido ligands. The structure is quite similar to other $CpCoL_2$ complexes, such as $Cp^*Co(CO)_2$.[6] The Co–N–Os angles are essentially linear [171.6(6), 171.8(7)°], which is typical of such μ-nitrido linkages[1a] and indicates sp hybridization at nitrogen. The Os–N

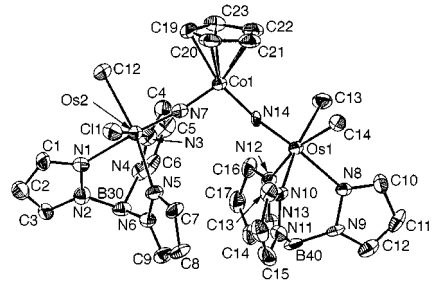


Fig. 1 ORTEP drawing of $CpCo[NOs(Tp)Cl_2]_2$ (**2**), with hydrogen atoms and two $CHCl_3$ of crystallization omitted for clarity. Selected bond lengths (Å) and angles (°): Os(1)–N(14) 1.704(9), Os(2)–N(7) 1.741(10), Co(1)–N(7) 1.696(11), Co(1)–N(14) 1.737(9), Os(2)–N(1) 2.189(11), Os(2)–N(3) 2.054(12), Os(2)–N(5) 2.086(10), Os(1)–N(8) 2.198(10), Os(1)–N(10) 2.070(10), Os(1)–N(12) 2.060(11), Os(1)–N(14)–Co(1) 171.6(6), Os(2)–N(7)–Co(1) 171.8(7), N(7)–Co(1)–N(14) 101.3(5).

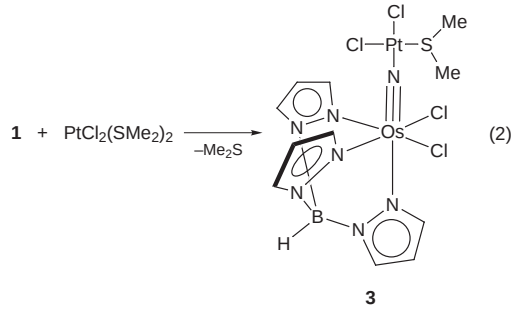
distances of 1.704(9) and 1.741(10) Å are indicative of substantial multiple bonding (as is the significant *trans* influence of the nitrido ligand), but these distances are longer than all crystallographically characterized terminal osmium–nitrido bonds (1.525–1.703, av. 1.629 Å).[7] The Co–N bonds are very short [1.696(11) and 1.737(9) Å], much shorter than would be expected for a simple dative interaction. For instance, they are substantially shorter than all reported cobalt–nitrile bonds, which also involve an sp hybridized nitrogen (Co–N 1.883–2.179, av. 1.997 Å).[7] The Co–N bonds in **2** are most similar to those in linear nitrosyl complexes (1.590–1.720, av. 1.658 Å) and are close to cobalt–carbonyl bond lengths (CpCo–CO 1.615–1.782, av. 1.721 Å).[7]

Complex **2** is thermally robust, showing only minor decomposition over two weeks at 75 °C in chloroform solution by ^{1}H NMR. There is no reaction under these conditions with 1 equiv. of PPh_3. Since **1** reacts rapidly with PPh_3, this shows that **2** does not dissociate to **1** at 75 °C. There is also no reaction when a chloroform solution of **2** is heated under 100 Torr of CO at 75 °C for several days.

Complex **1** reacts slowly with $PtCl_2(SMe_2)_2$ in benzene with with loss of Me_2S to give $(Me_2S)Cl_2Pt–N{\equiv}Os(Tp)Cl_2$ (**3**) in good yield [eqn. (2)].† Single crystals of **3** were obtained by



(2)

3

slow evaporation of a benzene solution. The X-ray structure (Fig. 2)‡ shows a molecule of **1** bound to a square planar platinum center. The Pt–N bond of 1.868(8) Å is at the short end of the range of Pt–N bonds in *cis*-dichloroplatinum complexes (1.848–2.371 Å),[7] again closer to those in nitrosyl rather than nitrile complexes. The Os–N bond [1.687(8) Å] is apparently

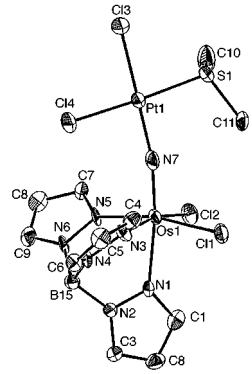


Fig. 2 ORTEP drawing of $(Me_2S)Cl_2Pt{-}N{\equiv}Os(Tp)Cl_2$ (**3**), with hydrogen atoms omitted for clarity. Selected bond lengths (Å) and angles (°): Os(1)–N(7) 1.687(8), Pt(1)–N(7) 1.868(8), Os(1)–N(1) 2.178(7), Os(1)–N(3) 2.071(7), Os(1)–N(5) 2.068(7), Pt(1)–S(1) 2.286(2), Pt(1)–Cl(3) 2.297(2), Pt(1)–Cl(4) 2.317(2), Os(1)–N(7)–Pt(1) 169.2(5).

shorter than those in **2**, although it is presumably slightly longer than in **1**.

The data are most consistent with **1** acting as a π acid ligand in **2** and **3**, as opposed to simply a dative (**A**) or σ only (**B**) ligand. The CpCo(I) fragment forms two legged piano stool structures only with soft and/or π-acid ligands; related CpCo(III) complexes adopt three-legged stool geometries.[8,9] The short Co–N and Pt–N distances and the kinetic inertness of the Co–N bonds are indicative of multiple bond character. The other known platinum μ-nitrido complexes are $(Et_2PhP)_3Cl_2Re{\equiv}N{-}PtCl_2(PEt_3)$,[2d] $(Me_3SiO)_3V{\equiv}N{-}Pt(Me)(PEt_3)_2$,[2a] and three complexes with $[Os(N)O_3]^-$.[10] The first is a labile adduct with dative bonding (resonance form **A**), while the others have N–Pt bond distances [VN–Pt, 2.030(7); O_3OsN–Pt, 2.03(4), 2.040(7), 1.958(7), 2.05(1) Å] which are indicative of single bonding (form **B**) and significantly longer than that in **3**. *Ab initio* DFT calculations on **1** show that the LUMO and LUMO+1 are low-lying Os–N π* orbitals, with significant density at nitrogen.[11] These empty orbitals are quite similar to the π* orbital of CO, the prototypical π acid (Fig. 3).§ The small apparent lengthening of the Os≡N bond in **2** is reminiscent of the small change in the C≡O distance on coordination. This lengthening is smaller if present in **3**, consistent with Pt(II) being a poorer π-donor than Co(I). The bonding in **2** and **3** could alternatively be described as a resonance hybrid of **A** or **B** with a multiple bond form Os=N⇐M′ or Os=N=M′, the latter well known for homonuclear μ-nitrido complexes.[1a]

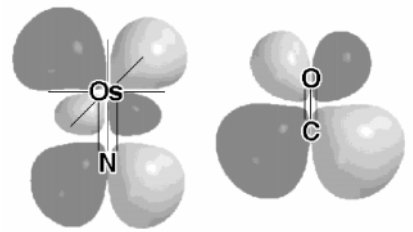

Fig. 3 Calculated LUMOs for **1** and CO.§

The ability of **1** to act as a strong ligand to late transition metals is perhaps surprising in light of its lack of reaction with main group Lewis acids such as $BF_3{\cdot}Et_2O$ and $[Ph_3C][BF_4]$. Complex **1** should be contrasted with the more nucleophilic hydrocarbyl derivatives $TpOs(N)Ph_2$[3a,12] and $CpOs(N)(CH_2SiMe_3)_2$.[2c] The latter forms a BF_3 adduct with $BF_3{\cdot}Et_2O$, is alkylated by MeOTf, and binds to Ag^+ giving a μ-nitrido complex $[Cp(R)_2OsN]_2Ag^+$.[2c] The Ag–N distances [2.15(1), 2.12(2) Å] are 0.27 Å longer than the Pt–N distances in **3**, much larger than the differences in ionic radii (2-coordinate Ag^+, 0.81 Å; 4-coordinate Pt^{2+}, 0.74 Å[13]). $TpOs(N)Ph_2$ does not react with $CpCo(\eta^4\text{-}C_5H_5C_6F_5)$ and an analog of **2** is not observed. The observation that the more nucleophilic osmium nitrides bind more poorly and form longer M–N bonds is not consistent with **1** acting as a simple σ donor ligand (type **A** or **B** bonding). We propose that the osmium nitrido unit in **1** acts as a π-acid ligand as a result of the low lying empty Os–N π* orbitals (Fig. 3). Further studies of **2** and **3**, and preparations of other compounds containing **1** as a ligand, are in progress.

We thank the National Science Foundation for financial support of this research. We also thank Dr B. Bennett for providing results prior to publication, Dr D. Hrovat for assistance in preparing Fig. 3 and Dr K. Goldberg and D. Wick for $PtCl_2(SMe_2)_2$.

Notes and references

† Full preparative, spectroscopic, and calculational details for **1**, **2**, **3**, and $TpOs(NPPh_3)Cl_2$ will be reported in an upcoming full paper. *Selected NMR data*: for **2,** ^{1}H NMR ($CDCl_3$) 5.96 (2H, t), 7.32 (2H, d), 7.49 (2H, d), 6.17 (4H, t), 7.51 (4H, d), 7.55 (4H, d), 5.40 (5H, s); ^{13}C NMR ($CDCl_3$) 107.8, 136.0, 146.0 (pz *trans* to μ-N), 108.5, 137.8, 144.4 (pz *trans* to Cl), 91.2 (Cp). For **3**, ^{1}H NMR ($CDCl_3$) 6.03 (1H, t), 7.42 (1H, d), 7.54 (1H, d), 6.47 (2H, t), 7.75 (2H, d), 8.12 (2H, d), 2.85(6H, s).

‡ Data for both structures were collected on a Nonius KappaCCD with Mo-Kα (λ = 0.71070 Å). *Crystal data*: for **2**·2CH$\underline{C}$l$_3$ at 161 K, $C_{25}H_{27}B_2Cl_{10}Co_1N_{14}Os_2$, M = 1339.06, triclinic, $P\bar{1}$ (no. 2), a = 11.3261(8), b = 14.2844(10), c = 15.3497(10) Å, α = 64.666(5), β = 75.612(5), γ = 68.010(5)°, V = 2069.7(2) Å^3, D_c = 2.149 g cm^{-3}, Z = 2, μ = 72.07 cm^{-1}. Of the 70903 reflections, 7908 unique reflections were used in the final least-squares refinement to yield R = 0.0651 and R_w = 0.1821. For **3** at 161 K, $C_{11}H_{16}B_1Cl_4S_1N_7Pt_1Os_1$, M = 815.26, triclinic, $P\bar{1}$ (no. 2), a = 8.5517(3), b = 10.9693(3), c = 13.2976(3) Å, α = 95.4985(19), β = 92.2917(19), γ = 104.4479(12)°, V = 1199.74(6) Å^3, D_c = 2.257 g cm^{-3}, Z = 2, μ = 116.56 cm^{-1}. Of the 17880 reflections, 4459 unique reflections were used in the final least-squares refinement to yield R = 0.0364 and R_w = 0.1283. CCDC 182/1026.

§ Minor contributions of other atoms to the LUMO in **1** are omitted for the sake of clarity. Full details of the calculations will be published in a forthcoming report.[11]

NaB_5C: carbon insertion into a three-dimensional framework of boron octahedra leads to electron-precise cubic carbaborides

Barbara Albert* and Konny Schmitt

Institut für Anorganische Chemie der Rheinischen Friedrich-Wilhelms-Universität, Gerhard-Domagk-Str. 1, 53121 Bonn, Germany. E-mail: albert@snchemie2.chemie.uni-bonn.de

Received (in Cambridge, UK), 8th September 1998, Accepted 29th September 1998

The discussion of whether hexaborides need a minimum electronic stabilisation to exist or not, has now been enriched by the synthesis of NaB_5C, crystallising with the cubic CaB_6 structure.

Carbaborides are solids with an anionic framework consisting of linked boron polyhedra, which are electronically stabilised by the insertion of carbon. The name already indicates a similarity to polyhedral molecules, which are called carbaboranes: substitution of boron by carbon provides electrons which stabilise a certain polyhedral arrangement. Recently, we were able to synthesise a new ternary boron-rich compound, which crystallises in the cubic CaB_6[1] structure type, NaB_5C.

The existence of cubic alkali metal hexaborides has been discussed controversially for a long time. Two compounds, NaB_6[2] and KB_6,[3] have been reported. In an earlier work, we were able to show that 'NaB_6' should actually be described as Na_3B_{20},[4] which does not crystallise in the hexaboride structure type. According to Longuet-Higgins and de V. Roberts,[5] the reason for the instability of cubic hexaborides with monovalent cations is the electronic deficiency of their framework. Following traditional bonding concepts, derived analogous to Lipscomb's model for boron molecules, each B_6 octahedron needs twenty electrons: fourteen intramolecular, to fill the bonding molecular orbitals within the octahedra, plus six intermolecular to satisfy the 2 electron–2 center bond between neighbouring octahedra. This requirement of course is fulfilled for the electron-precise mother compound of the structure type CaB_6, but not for the alkali metal hexaborides, which are low in electrons. On the other hand, similar compounds with excess electrons, like LaB_6, are well known, the extra electron causing their metallic behaviour.

Looking for additional experimental evidence to illuminate the question of bonding and stability of hexaborides, we succeeded in synthesising a new compound. The reaction of a mixture of sodium, boron, and carbon at high temperatures[6] yields a crystalline powder, which contains carbon and shows the typical powder diffraction pattern of cubic hexaborides. The unprecedented combination of these two findings led to the assumption that carbon atoms are statistically distributed at the boron positions in NaB_5C. The substance is black and consists of crystallites similar to cubes and with edge lengths between 0.5 and 1 μm (Fig. 1). Electron energy loss spectroscopy (EELS) at several crystallite fragments proved a boron : carbon ratio of 5 : 1.

The crystal structure of NaB_5C was refined using X-ray powder data and the CaB_6 structure as starting model, boron and carbon sharing the 'framework positions' (Wyckhoff symbol 6f).[7,8] In Fig. 2, the fit between the observed data and the calculated diffraction pattern is shown. As was expected, the

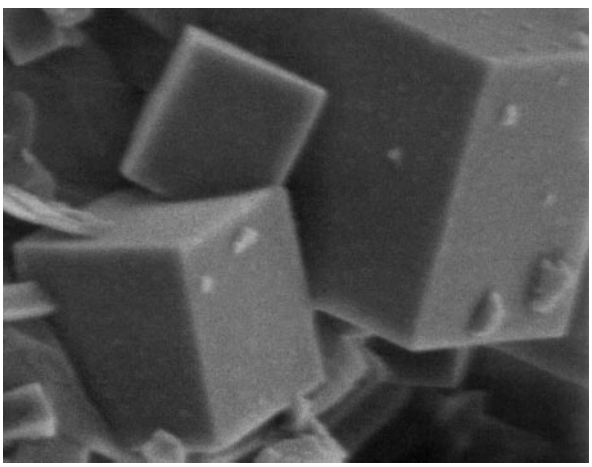

Fig. 1 Scanning electron micrograph of NaB_5C. The length of the edge of the crystallite in the front is 1 μm.

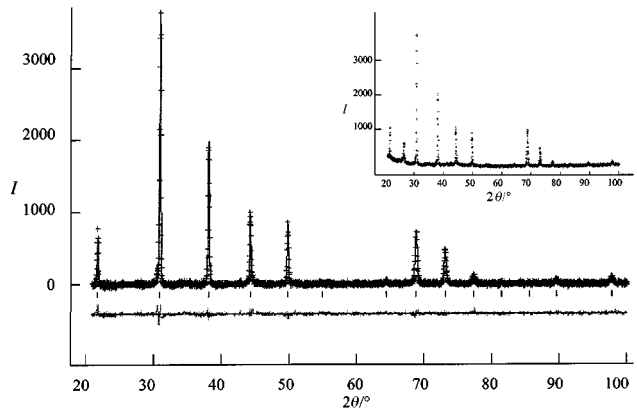

Fig. 2 Observed (+) and calculated (solid line) powder diffraction pattern (corrected for the background) with the difference curve (bottom). The vertical dashes indicate the positions of reflections. The uncorrected data are shown in the insert.

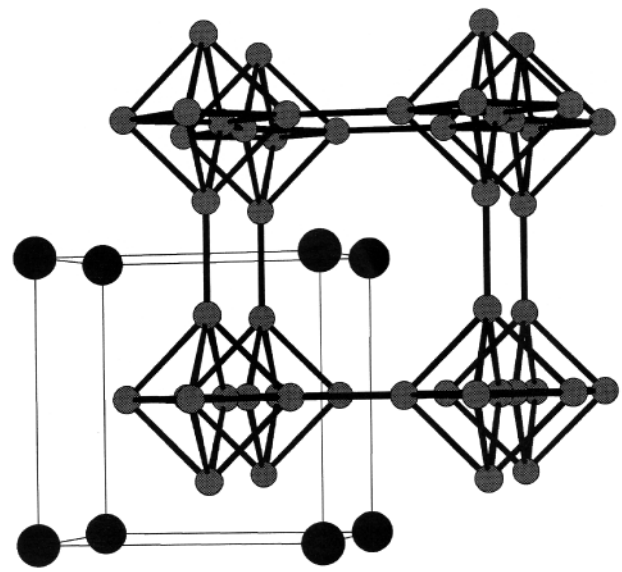

Fig. 3 Section of the structure of NaB_5C (Na: black, B/C: grey).

lattice constant of NaB_5C is smaller (4.09 Å) than the lattice constant which has been predicted for 'NaB_6'[9] (4.16 Å). In addition, we proved the mean B/C–B/C distance to be shorter than the mean B–B distance in hexaborides (1.706 Å in NaB_5C *versus* 1.736 Å in CaB_6[10]). Similar to other boron-rich compounds, the intramolecular bond distances within the octahedra are longer than the distances between them (1.716 Å *versus* 1.665 Å).

In conclusion, the new compound sodium hexa(carbaboride) exhibiting a cubic crystal structure (Fig. 3[11]) contains exactly the amount of carbon atoms in the anionic framework necessary to balance the electron deficiency of a hypothetical binary Na/B compound with a three-dimensional octahedral framework—one carbon atom per octahedron.

We thank Prof. Dr. Johannes Beck, Gieβen, Prof. Dr. Martin Jansen, Stuttgart, Dr. Ulrike Ciesla, Santa Barbara, and Lars-Peter Zenser, Gieβen, for their help. This work was supported by the Land Nordrhein-Westfalen (Lise-Meitner grant for B. A., and Bennigsen-Foerder program) and the Fonds der Chemischen Industrie.

2,3-Methanoamino acid analogs of Arg stabilize secondary structures of a 13 amino acid peptide in aqueous solution

Dongyeol Lim,[a] Destardi Moye-Sherman,[a] Inhye Ham,[a] Song Jin,[a] J. Martin Scholtz[b] and Kevin Burgess*[a]

[a] *Department of Chemistry, Texas A & M University, PO Box 300012, College Station, TX 77842-3012, USA. E-mail: burgess@mail.chem.tamu.edu*

[b] *Department of Medical Biochemistry and Genetics, 440 Reynolds Building, College Station, TX 77843-1114, USA*

Received (in Corvallis, OR, USA) 9th July 1998, Accepted 28th September 1998

Peptidomimetics 1 and 2 of RN24 (an RNase A *C*-peptide analog) in which the Arg$^+$-10 residue is replaced by 2*R*,3*S*-cyclo-Arg′ and by 2*S*,3*S*-cyclo-Arg′, respectively, show less temperature dependence in CD studies than the parent peptide.

The *N*-terminal fragment of RNase A has been adopted as a paradigm for conformational studies of short helical peptides. For instance, CD and NMR studies of a succinimidyl-capped analog of the *C*-peptide, RN24, indicate this 13-mer is *ca*. 50% helical in aqueous buffer at around 3 °C.[1,2] One of the key intramolecular interactions that is thought to stabilize this helical ensemble of conformations is a salt bridge between Glu$^-$-2 and Arg$^+$-10.[3,4] Syntheses of two 2,3-methanoarginine stereoisomers, 2*R*,3*S*-cyclo-Arg′ and 2*S*,3*S*-cyclo-Arg′,[5] gave us a unique opportunity to manipulate the Glu$^-$-2/Arg$^+$-10 interaction by constraining the guanidine functionality to point towards the *C*- and *N*-termini, respectively. Here we report the syntheses of these RN24 peptidomimetics, and CD studies to elucidate their conformational stabilities.

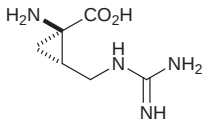
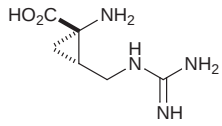
succ-A^{1}E^{2}T^{3}A^{4}A^{5}A^{6}K^{7}F^{8}L^9(*2S,3S*-cyclo-R)^{10}A^{11}H^{12}A^{13}-amide **2**



2*R*, 3*S*-cyclo-Arg'
or 2*R*, 3*S*-cyclo-R'



2*S*, 3*S*-cyclo-Arg'
or 2*S*, 3*S*-cyclo-R'

Peptidomimetics **1** and **2** were prepared *via* stepwise couplings of Fmoc-amino acid derivatives[6] on Rink's amide resin[7] using a manual shaker system.[8] Typical conditions and side-chain protecting groups were used. Couplings of natural amino acids were performed by premixing the amino acid with *N*-methylmorpholine, HOBt and PyBOP[9] in DMF. This coupling protocol was modified to incorporate the hindered cyclo-Arg′ residues and the amino acid immediately following (Leu-9). For these couplings, acid fluorides were produced *in situ via* the reagent TFFH (*i.e.* tetramethylfluoroformadinium hexafluorophosphate)[10] with HOAt (1-hydroxy-7-azabenzotriazole)[11] as an activating agent. The coupling to incorporate the cyclo-Arg moieties required only 1 h, whereas the subsequent coupling was more difficult and was run for 12 h. Deprotection of the side chains and cleavage from the resin was performed using TFA and a mixture of scavengers (phenol, ethane-1,2-dithiol and thioanisole). The crude peptide was further purified by preparative RP-HPLC.† Overall yields of isolated materials were in the 10% range giving enough sample for CD studies but not for NMR analysis.

Fig. 1(*a*) compares the CD spectra obtained for RN24, and the peptidomimetics at 3 °C (pH 5.1 buffer, 1 mM in each of sodium citrate, sodium phosphate and sodium borate, was used throughout this study). Peptide/peptidomimetic concentrations were accessed by calibration of the UV absorbance at 212 nm. These data show that the two peptidomimetics adopt helical conformations, but these are less populated than for RN24. With regards to the shape of the spectra, the 2*R*,3*S*-cyclo-Arg′ derivative **1** had an accentuated negative ellipticity at 222 nm relative to a classical α-helix. The other peptidomimetic, **2**, had a CD spectrum with a shape like that of RN24.

Variable temperature CD spectra of the peptidomimetics were particularly informative. The stability of the helical ensemble can be related directly to the change in the helical CD signal with temperature. Relative changes in $[\theta]_{222}$ requires the use of only one peptide solution, thus eliminating the error in the absolute peptide concentration and the variability between peptides. Fig. 1(*b*) is an overlay of five CD spectra for RN24 recorded at 5 °C intervals.‡ The molar ellipticity at 222 nm steadily decreased as the temperature was raised, ultimately corresponding to a *ca*. 40% reduction of the helical character. However, for peptidomimetics **1** and **2** the loss was significantly less over the same temperature range. Estimates for the loss of helical character for these two compounds were 30 and 23%, respectively.

Molecular dynamics simulations of RN24 and the two peptidomimetics was performed. Briefly, CHARMm parameters and coordinates for an ideal α-helix were modified using data sets already developed for the 2,3-methanoarginine analogs.[12] A medium of relative permittivity (ε = 80), and a simulated temperature of 276 K was used throughout. Trajecto-

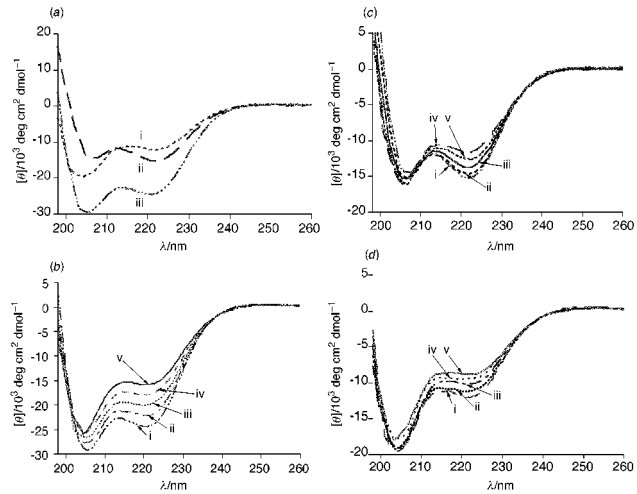


Fig. 1 (*a*) CD of (i) 2*S*,3*S*-cyclo-Arg′ **2**, (ii) 2*R*,3*S*-cyclo-Arg′ **1** and (iii) RN-24. Variable temperature CD of (*b*) RN-24, (*c*) **1** and (*d*) **2** at (i) 3, (ii) 8, (iii) 13, (iv) 18 and (v) 23 °C.

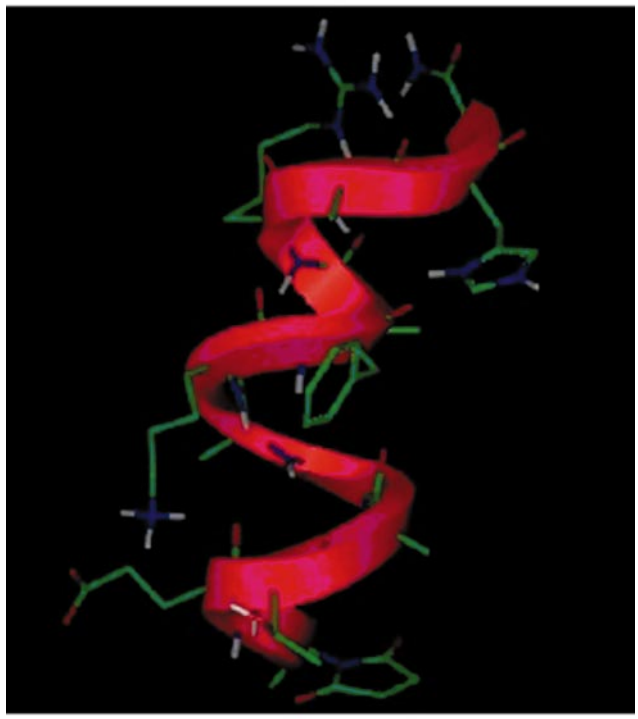
(*a*)



(*b*)

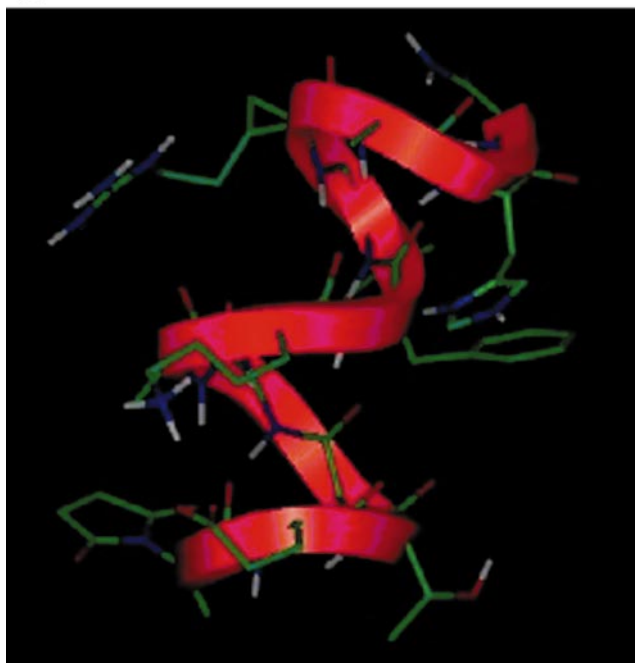


Fig. 2 Illustrative conformers after 200 ps of molecular dynamics for peptidomimetics (*a*) **1** and (*b*) **2**.

ries for the three starting structures sampled over a 200 ps interval showed that helical conformations were maintained for all three compounds throughout the dynamics run; Fig. 2 shows representative snap-shots of peptidomimetics **1** and **2**, respectively. These demonstrate a general trend observed in the molecular simulations, *i.e.* that peptidomimetic **1** tended to favor more tightly wound helical conformers than the 2*S*,3*S*-cyclo-Arg′-containing peptidomimetic **2**.§

In conclusion, we propose that the rigidity of the 2,3-methano analogs of arginine in peptidomimetics **1** and **2** can be used to impart conformational constraints. In this study, CD spectra of peptidomimetics containing these protein amino acids surrogates showed less temperature variations than that of RN24, indicative of a more stable helical structure. We also suggest that these same constraints distort the helical conformations such that atypical CD spectra were observed. The 2*R*,3*S*-cyclo-Arg′-containing peptidomimetic **1** has the Arg-side chain oriented towards the *C*-terminus where it cannot interact with the Glu-2 side-chain [Fig. 2(*a*)]. However, the guanidinium group locked in this orientation reinforces the helix dipole.[13] Conversely, 2*S*,3*S*-cyclo-Arg′ in peptidomimetic **2** presents the same side-chain in such a way that its charge opposes the helix dipole. The guanidinium moiety in this compound is oriented towards the Glu-2 residue, but the salt bridge is disrupted relative to RN24 because the cyclo-Arg′ has one less side chain methylene than natural arginine. The latter two effects result in less perfect helical conformations for peptidomimetic **2** than for **1** [Fig. 2(*b*)]. Other substitutions of 2,3-methanoamino acids into the RNase A *C*-peptide sequence are being investigated in these laboratories.[14]

Asymmetric synthesis of 3-phenyl-2,3-methanophenylalanine developed by panning catalysts in a library format

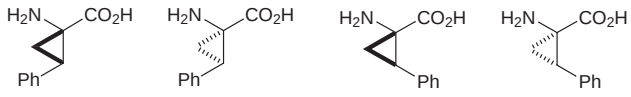
Destardi Moye-Sherman, Mike B. Welch, Joe Reibenspies and Kevin Burgess*

Department of Chemistry, Texas A & M University, PO Box 300012, College Station, TX 77842-3012, USA. E-mail: burgess@mail.chem.tamu.edu

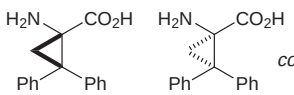
Received (in Corvallis, OR, USA) 10th July 1998, Accepted 28th September 1998

Optimal catalysts for the key cyclopropanation step in a synthesis of the title compound were identified by screening libraries of metal complex–ligand combinations; the synthesis was completed, and a derivative of the final product was crystallized to establish its solid state conformation.

Stereoisomers of 2,3-methanophenylalanine, 'cyclo-Phe', are useful phenylalanine surrogates for syntheses of conformationally constrained peptidomimetics.[1] They impart very specific steric perturbations at the *C*-terminal side or at the *N*-terminal side, depending on the cyclo-Phe isomer selected.[2] For some applications, however, it would be desirable to introduce this type of constraint at the *N*- and *C*-termini *simultaneously*. Consequently, we set about an asymmetric synthesis of 3-phenyl-2,3-methanophenylalanine, '3-Ph-cyclo-Phe'.



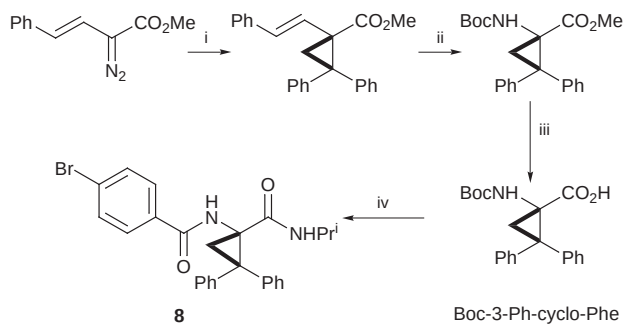
stereoisomers of cyclo-Phe



stereoisomers of 3-Ph-cyclo-Phe
constrain N- and C-termini simultaneously

Davies and co-workers have developed remarkably direct and effective syntheses of cyclo-Phe stereoisomers that involve enantio- and regio-selective cyclopropanations of phenylethene.[3] Doyle and co-workers have also shown 1,2-diphenylethene is a good substrate for asymmetric cyclopropanations using phenyl diazoacetate.[4] While it was apparent that the target compound identified above could be obtained using a modification of this approach (Scheme 1), the ideal catalyst for the cyclopropanation step was unknown. We therefore decided to screen some options in a library format.[5–9] This was done by manually weighing and pipetting catalysts and reagents into 24 glass vials set in wells drilled in a cooled aluminium block. Other papers from this laboratory describe the procedure used,[10] but some critical points are given here. All manipulations prior to the analysis were done in a glove box to maintain an inert atmosphere. After the reactions were mostly complete (TLC), the contents of each vial was manually filtered through a silica plug, an internal standard was introduced, and the sample was made up to a standard volume. The analysis was performed using an HPLC instrument equipped with an autosampler and a chiral column (Whelk-O *SS* , Regis Technologies). We estimate this protocol is one or two orders of magnitude faster than a conventional approach wherein a researcher would screen 2–3 reactions at a time.

Several generalities became apparent early in these investigations. First, the weighing errors with respect to the catalyst precursors became significant if the reactions were performed on 10 mg of diazo compound. The test reactions on a plate format were therefore performed on a 50 mg scale, and the important ones were checked on a larger scale. Second, pentane appeared to be the best solvent so this medium was used for all the latter screens. However, this provided a stringent test of reproducibility in these experiments because the data obtained using relatively insoluble catalyst precursors in this very apolar medium were related to the degree of agitation. Small stirrers were used in each well, but we were unable to arrange it so that they all spun smoothly; consequently, some reproducibility issues arose.† Nevertheless, the data obtained from the library screens did indicate promising catalysts for further development.



Scheme 1 *Reagents and conditions*: i, 1,1-diphenylethene (5 equiv.), Rh_2(*S*-TBSP)$_4$ (1 mol%), 0 °C, 24 h (86%, 97% ee); ii, cat $RuCl_3$, $NaIO_4$, MeCN–H_2O, CCl_4, 25 °C, 5 h then $(PhO)_2P(O)N_3$, NEt_3, Bu^tOH, reflux, 17 h (90% for 2 steps); iii, LiOH, aq. Table 1 Data for catalyst systems tested in conventional way[a]

Entry	Catalyst system	Metal/mol%	Ee (%)[b]	Yield (%)[c]
1[d]	**1B**	5.0	65[e]	62
2[d]	**2A**	5.0	24	2
3	**2B**	5.0	3 (9)	23 (4)[f]
4	**2C**	5.0	> 98 (75)	6 (14)[f]
5	**2D**	5.0	> 98 (69 and 78)	10 (6 and 24)[f]
6[d]	**2D**	5.0	> 98	1
7	**4D**	5.0	86 (75)	9 (16)[f]
8	**6**	10	94	85
9	**6**	5.0	97	88
10	**6**	1.0	97	86
11	**6**	0.1	89	63
12	**7**	1.0	> 98	50

[a] 50 mg scale, pentane, 0 °C, 1,2-diphenylethene (5 equiv.), ligand:metal = 1.5:1.0 for catalysts formed *in situ*. [b] Values in parentheses indicate data obtained in library screen. [c] Isolated yields unless otherwise indicated. [d] Reaction run at 25 °C. [e] > 95% ee after one recrystallization. [f] Measured *vs*. internal standard.

Data given in Fig. 1 and Table 1 indicate that the Davies/McKervey catalysts **6** and **7** were the most useful for the desired transformation. Other combinations gave poor yields and/or enantioselectivities except for the combination of copper triflate with ligand **1**. This gave product with a moderate enantioselectivity and yield, and the product could be crystallized to optical purity. This could be useful in some situations because the latter system, and the Davies/McKervey catalysts **6** and **7**, gave opposite enantiomers of the product.§

The synthesis of Boc-protected 3-Ph-cyclo-Phe was completed as indicated in Scheme 1. Absolute configurations here are assigned by extrapolation of Davies' model for enantioselective cyclopropanations with catalysts like **6** and **7**,[3,11] hence this must be regarded as a prediction rather than an established fact. Finally, a sample of this product was converted into diamide **8**, and single crystals of this material were formed for X-ray diffraction; a Chem3D diagram of the molecular structure is given in Fig. 2.¶ The observed φ,ψ angles (87.7, −152°) do not correspond closely with any idealized turn structure. The conformation seems to be governed by the phenyl rings adopting orientations with their faces beneath the *N*- and *C*-termini, with the *N*- and *C*-amide bonds in pseudo-parallel arrangements below these. Further studies are planned to elucidate less localized effects of 3-phenyl-cyclo-Phe on secondary structures.

Notes and references

† Four experiments were repeated on the same plate to check reproducibility in the same library; the worst correspondence of ee values was 26 *vs*. 6%, and the best was 19 *vs*. 18%. Table 1 shows the data obtained from experiments repeated on a larger scale, run in the conventional way. Five data points correspond to experiments that were performed in the plate format. The worst correspondence observed was for entry 5 (98 *vs*. 69% ee). In all five cases the ees obtained when the reactions were repeated on a large scale with efficient stirring were higher than those corresponding to the plate format.

‡ Percent yield for each well measured *vs*. an internal standard (1-acenaphthone): **1A** = 12%; **1B** = 23%; **1C** = 8%; **2A** = 18%; **2B** = 4%; **2C** = 14%; **2D** = 6%; **3A** = 12%; **3B** = 27%; **3C** = 2%; **3D** = 24%; **4A** = 41%; **4B** = 13%; **4C** = 1%; **4D** = 16%; **5A** = 29%; **5B** = 66%; **5C** = 1%; **5E** = 2%; catalyst **7** = 40%.

§ Both enantiomers of $Rh_2(TBSP)_4$ and of $Rh_2(DOSP)_4$ are commercially available from Aldrich, but in each case one is more expensive than the other.

Crystal structure of an azo dye rotaxane

Sally Anderson,[a] William Clegg[b] and Harry L. Anderson[a]

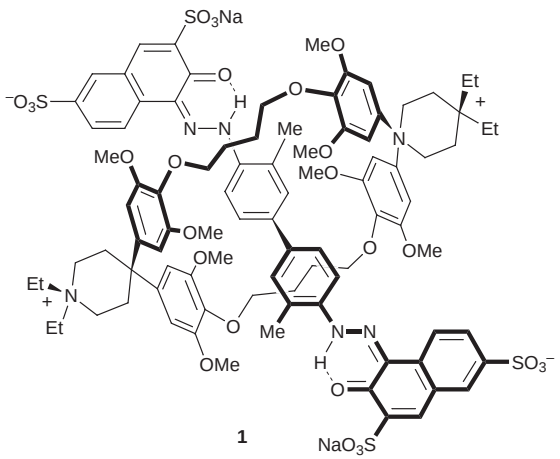
[a] *Department of Chemistry, University of Oxford, Dyson Perrins Laboratory, South Parks Road, Oxford, UK OX1 3QY. E-mail: harry.anderson@chem.ox.ac.uk*

[b] *Department of Chemistry, University of Newcastle, Newcastle-upon-Tyne, UK NE1 7RU and CCLRC Daresbury Laboratory, Warrington, UK WA4 4AD*

Received (in Liverpool, UK) 20th July 1998, Accepted 28th September 1998

The crystal structure of an anionic azo dye rotaxane shows that the cyclophane embraces the centre of the dye; sodium coordinates to both the dye and the cyclophane, as well as DMSO solvent molecules, resulting in an infinite poly-rotaxane network.

Recently we prepared the first azo dye rotaxanes, by an azo-coupling reaction in water, using hydrophobic binding to ensure that the dye was formed threaded through the cyclophane.[1]



1

Formation of rotaxane encapsulated dyes, such as **1**, allows the environment of the chromophore to be precisely controlled, which may lead to dyes with enhanced chemical and photochemical stability. Here we present the first crystal structure of a rotaxane of this type. Despite the industrial importance of anionic sulfonated naphthalene azo dyes, few crystal structure determinations of these dyes have been reported, which reflects their reluctance to form suitable crystals.[2] The crystal structure of **1** provides valuable insights into the conformational behaviour of both the azo dye and cyclophane components, and shows how these units interact.

Slow diffusion of butanone into a saturated solution of **1** in DMSO and *n*-butanol gave small single crystals suitable for analysis by synchrotron X-ray diffraction at 160 K.† The crystals were highly solvated; six water and five DMSO molecules were located in the asymmetric unit, which contains one rotaxane molecule. **1** crystallises in a centrosymmetric space group P1. The unit cell contains both enantiomeric conformations of the rotaxane. The cyclophane embraces the centre of the dye as shown in Fig. 1. There are no face-to-face stacking π–π interactions between the biphenyl and the cyclophane, but there may be edge-to-face interactions between the four central hydrogens of the biphenyl and the cyclophane aromatic rings (H–centroid distances are 2.87, 3.17, 3.20 and 3.27 Å).[3]

The two ends of the azo dye dumbbell have essentially the same geometry; average bond lengths are shown on Fig. 2. A sodium cation chelates between the β-naphthol oxygen and the

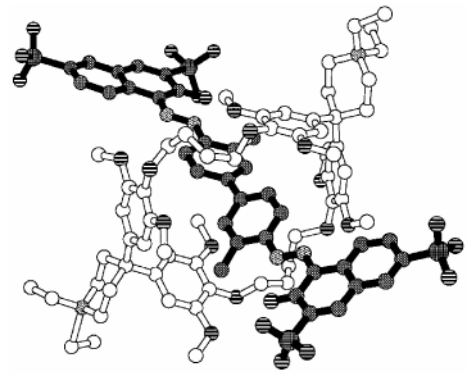


Fig. 1 Molecular structure of rotaxane **1**, not showing solvent molecules, hydrogen atoms and sodium cations.

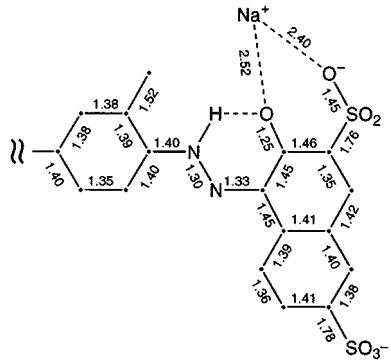

Fig. 2 Average bond lengths (Å) in the azo dye dumbbell componentof **1**.

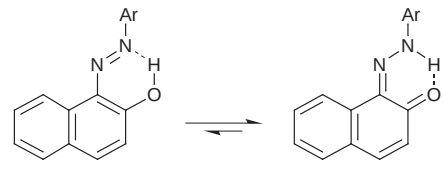
sulfonate, yet, like most β-naphthol azo dyes,[2a,b,4] this dye is predominantly the hydrogen-bonded hydrazone, rather than azo, tautomer (Scheme 1). This is evident from the short C–O bond (1.25 Å; *cf.* 1.36 Å in PhOH and 1.21 Å in cyclohexanone),[5] short C_α–N bond (1.33 Å; *cf.* 1.24 Å in *E*-azobenzene[6] and 1.39 Å in 1,2-diphenylhydrazine[7]) and long C_α–C_β bond (1.45 Å; *cf.* 1.37 Å in naphthalene[8] and 1.52 Å in cyclohexane[9]).‡ Each half of the dye is approximately planar, with twists of 8.6 and 6.7° about the N–N linkages; the twist about the biphenyl link is 39.8°. The methyl of the tolidine resides near the β-naphthol oxygen, as observed in solution by NMR spectroscopy.[1]



Scheme 1

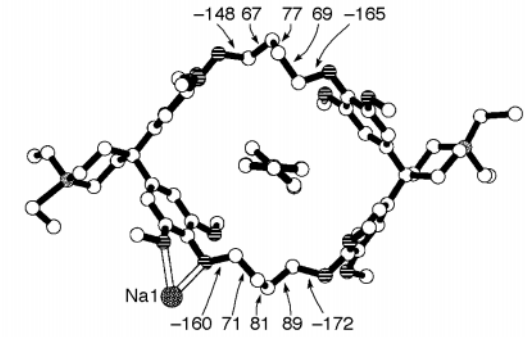


Fig. 3 Structure of the cyclophane component of **1**, showing selected torsion angles (°), viewed down the axis of the biphenyl unit of the dye, which is shown at the centre.

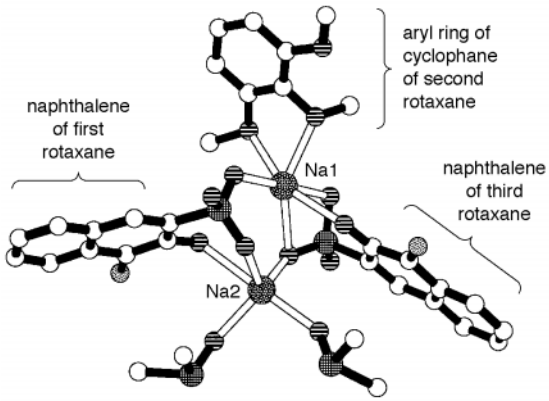

Fig. 4 Two sodium cations coordinate to two anionic dyes; Na1 also binds to the oxygens of the cyclophane of another rotaxane unit, while Na2 binds two DMSO molecules, giving irregular six- and five-coordination geometries.

The conformation of the cyclophane is remarkably convoluted. Both $O(CH_2)_4O$ links are in helical $ag^+g^+g^+a$ conformations, as shown by the torsion angles in Fig. 3. This allows the cyclophane to contract round its guest, which explains how it binds strongly to guests which seem too small to fill the cavity. Three previous crystal structures of cyclophanes of this type have $O(CH_2)_4O$ links with three *anti* and two *gauche* bonds.[10] A sodium cation (Na1) chelates to two *ortho* oxygens on one ring of the cyclophane, twisting it away from the cavity.

Pairs of sodium cations act as a 'glue', binding together the naphthalenes of two separate dyes and a cyclophane of a third rotaxane, as shown in Fig. 4. One sodium cation (Na2) is also coordinated by two DMSO solvent molecules. The Na–O interactions marked in Fig. 4 are in the range 2.24–2.60 Å (mean 2.39 Å); the next shortest Na–O distance is 3.25 Å. Thus the dyes are linked together, generating one-dimensional polymeric strands in the direction of the *a*-axis. Sodium coordination to the cyclophane links these strands together in the *b*-direction, to form double strand ladders. Electrostatic attraction between sulfonates and diethylammonium groups locks these ladders together in the *c*-direction (Fig. 5). Many features of the polyrotaxane network may be unique to this crystal structure, but the conformations of the azo dye and the cyclophane, and the coordination of both components with sodium, are relevant to the behaviour of molecules of this type in solution.

We gratefully acknowledge EPSRC and CCLR for financial support and Dr M. G. Hutchings (BASF, Manchester) for helpful discussion.

Novel tellurium halides Te_2Cl_2 and Te_2Br_2

Jarkko Pietikäinen and Risto S. Laitinen

Department of Chemistry, University of Oulu, Linnanmaa, FIN-90570 Oulu, Finland. E-mail: risto.laitinen@oulu.fi

Received (in Basel, Switzerland) 26th May 1998, Accepted 23rd September 1998

Novel Te_2Cl_2 and Te_2Br_2 were prepared by the reaction of Li_2Te and TeX_4 and characterized by mass spectroscopy and ^{125}Te NMR spectroscopy, and by successful syntheses of 1,2-Te_2S_5 and 1,2-Te_2Se_5.

Disulfur and diselenium dihalides are relatively stable[1] and form a useful class of reagents for many synthetic applications. The existence of mixed selenium–sulfur dihalides has also been reported.[1l,2] Here we describe a facile synthesis of Te_2Cl_2 and Te_2Br_2 that have turned out to be surprisingly stable,† though the phase diagrams of the Te–$TeCl_4$ and Te–$TeBr_4$ systems do not give any indications about the existence of Te_2Cl_2 and Te_2Br_2.[4] The closest known tellurium halides of this type are polymeric $(Te_2Cl)_x$, $(Te_3Cl_2)_x$ $(Te_2Br)_x$ and $(Te_2I)_x$.[5]

Te_2Cl_2 and Te_2Br_2 were prepared by reducing elemental tellurium with superhydride and treating the resulting telluride with appropriate tellurium tetrahalogenide [eqn. (1)].‡

$$\mathrm{Te} \xrightarrow{\mathrm{LiBHEt_3}} 1/x\,\mathrm{Te}_x^{2-}$$

$$\mathrm{Te}_x^{2-} + x\mathrm{TeX}_4 \rightarrow x\mathrm{Te}_2\mathrm{X}_2 + 2x\mathrm{X}^- \ (\mathrm{X} = \mathrm{Cl},\ \mathrm{Br}) \quad (1)$$

Ditellurium dichloride was obtained as a yellow liquid, and ditellurium dibromide as an orange–red liquid. Both Te_2Cl_2 and Te_2Br_2 should be stored under an inert atmosphere. Te_2Br_2 however, is stable for hours at room temperature. Te_2Cl_2 is not as stable as Te_2Br_2, but it can also be stored for hours, especially in organic solutions. Chlorinated solvents, however, should be avoided.

Both Te_2Cl_2 and Te_2Br_2 exhibit one major ^{125}Te resonance in their respective NMR spectra (Fig. 1).§ The ^{125}Te chemical shift of Te_2Cl_2 in CS_2 is at 1336 ppm and that of Te_2Br_2 at 1253 ppm. The chemical shift of Te_2Cl_2 in toluene is 1297 ppm.[3] The ^{125}Te chemical shifts of the two species bear a relationship that is expected from the comparison with the ^{77}Se chemical shifts of Se_2Cl_2 and Se_2Br_2.¶ The appearance of only one resonance in the spectra of both compounds indicate an open-chain X–Te–Te–X structure rather than a branched $X_2Te{=}Te$ structure. One minor signal was observed in both spectra (Fig. 1). The chemical shift of this resonance varies (820–880 ppm) and its intensity relative to that of the main resonance increases as a function of time and implies the decomposition of Te_2Cl_2 and Te_2Br_2. We have previously made a tentative assignment of a weak resonance observed at 849 ppm in the S–Se–Te melt at 145 °C to Te_8.[6] It is possible that the decomposition of Te_2X_2 (X = Cl, Br) produces Te_8.‖

The mass spectra of Te_2Cl_2 and Te_2Br_2 are shown in Fig. 2.** The observed isotopic distribution for the molecular ion of Te_2Cl_2 as well as those for its fragments are in a good agreement with the calculated distributions. A reasonable fragmentation that exhibits the expected isotopic distributions could also be deduced in the mass spectrum of Te_2Br_2, though we did not observe the molecular ion.

It is well established that $[Ti(C_5H_5)_2S_5]$ and $[Ti(C_5H_5)_2Se_5]$ react with S_2Cl_2 or Se_2Cl_2 to produce cyclic seven-membered chalcogen compounds (S_7, 1,2-Se_2S_5 and 1,2,3,4,5-Se_5S_2, Se_7, respectively).[7] These titanocene reagents can be used to further verify the identities of Te_2Cl_2 and Te_2Br_2. We present here the preparation of 1,2-Te_2S_5 and 1,2-Te_2Se_5 [eqn. (2)] by treating Te_2Cl_2 with $[Ti(C_5H_5)_2E_5]$ (E = S, Se) in CS_2 in an analogous manner as described previously for 1,2,3,4,5-Se_5S_2.[8]††

$$[\mathrm{Ti}(\mathrm{C_5H_5})_2\mathrm{E_5}] + \mathrm{Te_2X_2} \rightarrow 1,2\text{-}\mathrm{Te_2E_5} + [\mathrm{Ti}(\mathrm{C_5H_5})_2\mathrm{X_2}] \quad (2)$$

Only one ^{125}Te NMR resonance is observed in spectra of both compounds. The signal at 1732 ppm is assigned to 1,2-Te_2S_5 and that at 1724 ppm to 1,2-Te_2Se_5. The latter resonance is

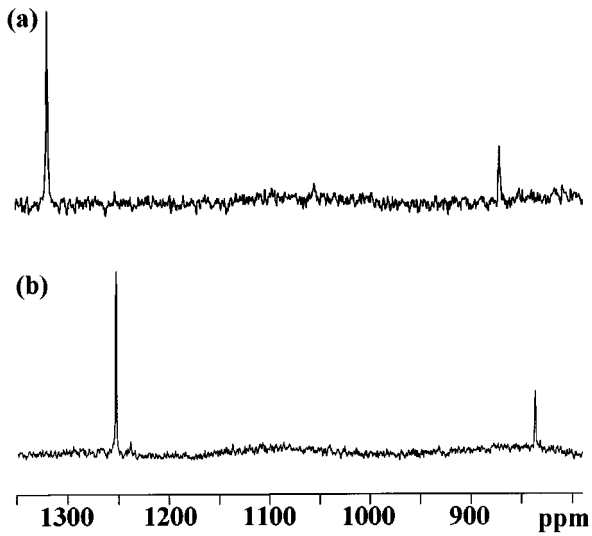

Fig. 1 ^{125}Te NMR spectra of (a) Te_2Cl_2 and (b) Te_2Br_2 in CS_2.

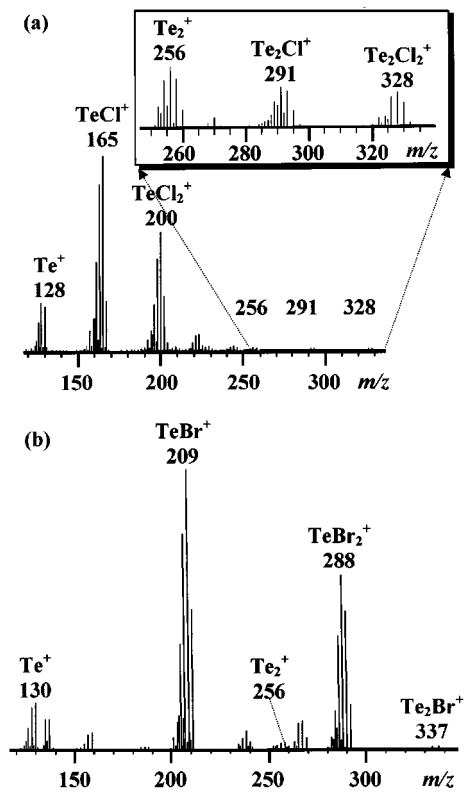

Fig. 2 12 eV mass spectra of (a) Te_2Cl_2 and (b) Te_2Br_2.

expectedly upfield, since selenium is less electronegative than sulfur.[11] The ^{77}Se NMR resonances of 1,2-Te_2Se_5 are 1040, 1019 and 982 ppm (intensity ratio 2 : 1 : 2). These signals are consistent with the ^{77}Se chemical shifts of 1,2,3,4,5-Se_5S_2[12] and imply that 1,2-Te_2Se_5 is also fluxional. It should be noted that Te_2Br_2 is less reactive than Te_2Cl_2.

Financial support from Academy of Finland is gratefully acknowledged.

Notes and references

† Preliminary information on Te_2Cl_2 has been reported previously.[3]

‡ All reactions were carried out under a dry argon atmosphere. $LiBHEt_3$ (15.7 cm^3, 15.7 mmol, 'Super-Hydride' 1 M in THF) and elemental tellurium (1.00 g, 7.84 mmol) were stirred for 15 min under slight warming. The solution was cooled to room temperature and the solution of $TeCl_4$ (2.11 g, 7.84 mmol) or $TeBr_4$ (3.51 g, 7.84 mmol) in 50 cm^3 of THF was added dropwise. The solution was filtered and solvent removed under a dynamic vacuum. The product was dissolved in CS_2 to remove LiX, elemental tellurium, and the unreacted TeX_4 (yields in both cases *ca.* 40% based on the initial amount of TeX_4).

§ The ^{77}Se and ^{125}Te NMR spectra were recorded at 300 K on a Bruker DPX 400 spectrometer (76.311 and 126.241 MHz for ^{77}Se and ^{125}Te, respectively). D_2O was used as an external ^{2}H lock and saturated D_2O solutions of SeO_2 and H_6TeO_6 as external references. The ^{77}Se and ^{125}Te chemical shifts were reported relative to neat Me_2Se and Me_2Te, respectively [$\delta(Me_2Se) = \delta(SeO_2) + 1302.6$; $\delta(Me_2Te) = \delta(H_6TeO_6) + 712$].

¶ The ^{77}Se chemical shift in Se_2Cl_2 is 1271 ppm and that in Se_2Br_2 1171 ppm.[2b]

‖ To test this assignment Te_2Cl_2 was reacted with [$Ti(MeC_5H_4)_2(\mu$-$Te_2)_2Ti(MeC_5H_4)$] (molar ratio 2 : 1) in CS_2. This reaction is expected to form Te_8. We observed a single ^{125}Te resonance at 868 ppm.

** EI-MS mass spectra of Te_2Cl_2 and Te_2Br_2 were recorded using a Kratos MS 80 spectrometer at 12 eV electron energy.

†† 0.26 g of [$Ti(C_5H_5)_2S_5$][9] or 0.44 g of [$Ti(C_5H_5)_2Se_5$][10] (0.77 mmol) was dissolved in 50 cm^3 of CS_2. Te_2Cl_2 (0.25 g; 0.77 mmol) in 10 cm^3 of CS_2 was added into this solution that was subsequently cooled down to −78 °C to precipitate 1,2-Te_2E_5 and [$Ti(C_5H_5)_2Cl_2$]. After filtration and redissolving of [$Ti(C_5H_5)_2Cl_2$] in $CHCl_3$, the remaining product was dried *in vacuo* [yields 0.11 g (34.2%) and 0.31 g (47.6%) for Te_2S_5 and Te_2Se_5, respectively].

A novel route to the preparation of aldehyde end-functionalised oligomers *via* catalytic chain transfer polymerisation

Thomas P. Davis,*[a] Michael D. Zammit,†[a] Johan P.A. Heuts[a] and Keith Moody[b]

[a] *School of Chemical Engineering and Industrial Chemistry, University of New South Wales, Sydney, NSW 2052, Australia. E-mail: t.davis@unsw.edu.au*

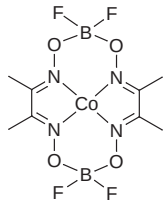
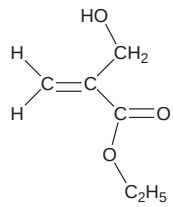
Received (in Cambridge, UK) 15th September 1998, Accepted 30th September 1998

Catalytic chain transfer polymerisation of ethyl α-hydroxymethacrylate with cobaloxime boron fluoride is shown to be an effective route for the production of oligomers with an aldehyde end-functionality.

Catalytic chain transfer polymerisation has proven to be a very efficient technique for molecular weight control in free-radical polymerisation.[1] The catalytic nature of this process and the very high chain transfer constants associated with the used chain transfer agents (*i.e.* certain low spin Co^{II} complexes such as cobaloximes and porphyrins) require only parts per million quantities for a molecular weight reduction by orders of magnitude. Numerous experimental investigations have shown this process to be most efficient for monomers containing an α-methyl group, such as the methacrylate series of monomers.[1,2] Chain transfer constants (*i.e.* the ratio of the chain transfer and the propagation rate coefficients) for cobaloxime boron fluoride



1

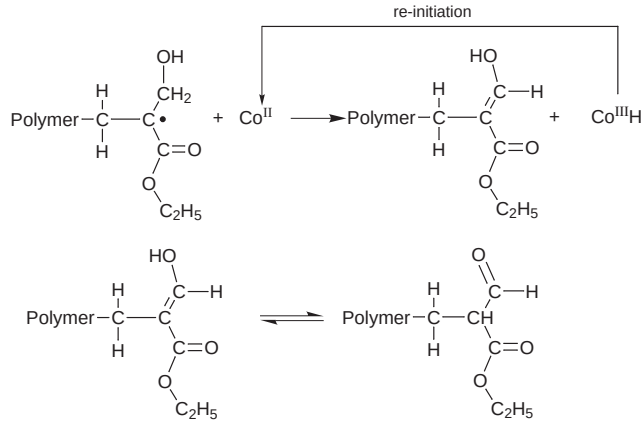


2

1 in methyl methacrylate polymerisation are typically of the order 10^4, whereas they are typically an order of magnitude smaller for styrene (*i.e.* a monomer without an α-methyl group).[2]

The use of catalytic chain transfer agents instead of conventional chain transfer agents such as mercaptans has a further advantage in that it introduces an end-functionality in the form of a terminal double bond, which can subsequently be modified. In the present investigations, our main aim is to introduce a different end-functionality without the need for a post-polymerisation modification. Our target is the acetoacetyl functionality, which has found interesting uses in the field of thermoset coatings chemistry.[3] This functionality can be used for a whole series of crosslinking reactions and Michael additions. Here, we show that this functionality can be introduced by the catalytic chain transfer polymerisation of ethyl α-hydroxymethacrylate **2**, a monomer which belongs to the methacrylate series (and hence should readily undergo the catalytic chain transfer reaction), and whose derived polymeric radical should give the acetoxyacetal functionality *via* a tautomeric rearrangement of the formed enol after the abstraction of a hydrogen atom of the α-hydroxymethyl group (see Scheme 1).

Ethyl α-hydroxymethacrylate **2** was prepared according to the method described by Villieras and Rambaud.[4]‡ It was found that the monomer readily undergoes free-radical polymerisation yielding polymers consisting of approximately 700 monomer units (at 60 °C, [AIBN] = 10^{-2} M) as determined by gel



Scheme 1

permeation chromatography using a poly(methyl methacrylate) calibration curve. In order to investigate the catalytic chain transfer behaviour of ethyl α-hydroxymethacrylate with COBF, we estimated its chain transfer constant [with respect to a poly(methyl methacrylate) calibration curve] using the conventional Mayo procedure.[5] In this procedure, the chain transfer constant is determined from the slope of a plot of the reciprocal degree of polymerisation (1/DP) *vs.* the ratio of [chain transfer agent] to [monomer]. In Fig. 1, such a plot is shown for the current system at 60 °C and a chain transfer constant of 700 is found.§ This value, which we expect to be higher once we can use the true Mark–Houwink constants in our molecular weight analysis, clearly indicates that the current monomer is suitable for catalytic chain transfer polymerisation.

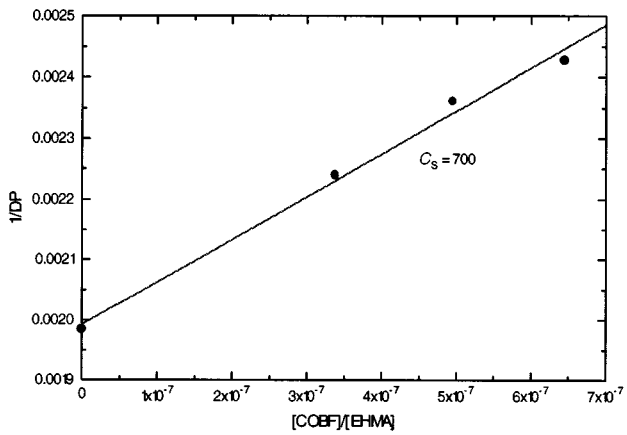


Fig. 1 Mayo plot for the determination of the chain transfer constant (C_S) for COBF in a free-radical polymerisation of ethyl α-hydroxymethacrylate at 60 °C.

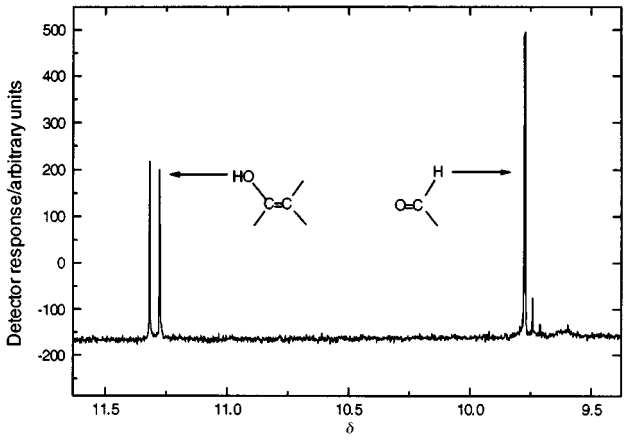

Fig. 2 Expansion of the 300 MHz ^{1}H NMR spectrum of poly(ethyl α-hydroxymethacrylate) in the region between δ 9.5 and 11.5, clearly indicating the presence of aldehyde (δ 9.77) and enol (δ 11.29) endgroups.

The homopolymers obtained *via* catalytic chain transfer polymerisation were analysed using 300 MHz ^{1}H NMR spectroscopy (Bruker ACF 300), and the most interesting region of the obtained NMR spectrum is shown in Fig. 2. The signals that are shown in this figure do not appear in the spectrum of the monomer and can be attributed to the formyl proton (δ9.77) and to enolic hydroxyl protons (δ 11.29). Both signals are characteristic for diketonic systems displaying a keto–enol tautomeric equilibrium.[6] Although further and more detailed NMR studies are required for a more detailed assignment of the signals (*e.g.* whether intramolecular hydrogen bonding occurs),[7] the current results are sufficient proof that the aldehyde end-functionality is indeed formed in significant quantities.

In summary, we have clearly shown that ethyl α-hydroxymethacrylate readily undergoes an effective catalytic chain transfer polymerisation with COBF, and that using this procedure the very useful aldehyde end-functionality is introduced.

We gratefully acknowledge financial support by the Australian Research Council, ICI and Orica, as well as helpful discussions with Professor Mike Gallagher.

‡ *Monomer synthesis*. The synthesis route of Villieras and Rambaud was followed exactly, with the only difference that the addition step of the potassium carbonate solution was carried out at 0 °C instead of room termperature. Yield: 75%. δ_H($CDCl_3$, 298 K, 300 MHz) 5.8 and 6.2 (=CH_2), 1.28 (–CH_3), 2.63 (–OH), 4.23 (–CH_2–); ν_{max}(NaCl)/cm^{-1} 1630 (C=C), 1710 (C=O).

§ *Chain transfer constant measurements*. The monomer was purged with high purity nitrogen gas for 1 h prior to use. Two stock solutions were prepared: (i) an initiator stock solution, and (ii) a catalyst stock solution. (i) The initiator solution was prepared by dissolution of approximately 220 mg of AIBN in 45 ml of monomer. (ii) The catalyst stock solution was prepared by dissolution of approximately 3 mg of catalyst into 10 ml of solution (i) and a subsequent 10-fold dilution with solution (i). Four reaction mixtures were then prepared, each containing 4.0 ml of initiator solution and 0, 0.2, 0.3 and 0.4 ml of catalyst stock solution, respectively. At all stages of these preparations, care was taken to exclude oxygen from the reaction mixtures. The reaction ampoules, specially modified for use with standard Schlenck equipment, were further deoxygenated by two freeze-pump-thaw cycles and subsequently placed in a waterbath (thermostatted at 60 °C) for 15 min. Finally the obtained polymer was isolated and molecular weight analysis performed with gel permeation chromatography.

Stable vesicles made from new triple-chain amphiphiles: long-term stability toward leakage of the trapped substances

Yasushi Sumida,[a] Araki Masuyama,[b] Hiroshi Maekawa,[b] Mayuko Takasu,[b] Toshiyuki Kida,[b] Yohji Nakatsuji,[b] Isao Ikeda*[b] and Masatomo Nojima[b]

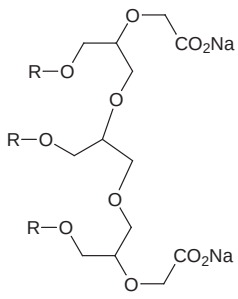
Received (in Cambridge, UK) 4th September 1998, Accepted 29th September 1998

Very stable vesicles, which can keep 5(6)-carboxyfluorescein trapped inside for months, are obtained from triple-chain amphiphiles bearing two carboxylate groups derived from 1-*O*-alkylglycerols.

Numerous endeavours to construct stable liposomes or vesicles have been made. There are two classical approaches to suppressing the leakage of trapped substances: one is the addition of other molecules, such as cholesterol[1] or cholesterol polysaccharides,[2] to bilayer systems, and the other is the introduction of special group(s) or structures into the hydrophobic moiety of the amphiphiles. As examples of the latter, unique amphiphiles bearing polymerisable functional groups[3] or phytanyl moieties[4] in the hydrophobic chains have been reported. It should be noted that most of these specially designed amphiphiles are based on the conventional 'double-chain' structure, like phospholipids.

A series of novel amphiphiles bearing three hydrophobic alkyl chains and two hydrophilic head groups has been designed and prepared previously by the authors' group.[5] It was found that these 'triple-chain' compounds showed a greater ability to lower surface tension and to form micelles at lower concentrations than the corresponding 'double-chain' surfactants bearing two ionic head groups. These results suggest that the three alkyl chains in the molecule can make a positive contribution to the surface-active properties because both the inter- and intramolecular hydrophobic interactions are strengthened compared to those of the corresponding double-chain surfactants.[6] This speculation prompted us to prepare vesicles made from the triple-chain amphiphiles and to compare their ability to suppress the leakage of substances trapped inside with that of vesicles made from conventional phosphatidylcholines.



1 R = *n*-$C_{16}H_{33}$

2 R = *n*-$C_{18}H_{37}$

The triple-chain amphiphiles used in this work (**1** and **2**) were bis(carboxylate)s prepared from 1-*O*-alkylglycerols.[5]† Dipalmitoyl- and distearoyl-phosphatidylcholines (DPPC and DSPC, respectively; Nippon Fine Chemical Co., 99.8%) were also used as the reference lipids because these phosphatidylcholines (PCs) bearing saturated acyl chains are known to form relatively stable bilayer membranes at room temperature.[7] Small unilamellar vesicles containing concentrated 5(6)-carboxyfluorescein (CF) in an aqueous buffer solution were prepared by the conventional hydration–sonication method.‡ Fig. 1 shows the released percentage of CF from vesicles made from phospholipids or triple-chain amphiphiles during storage at 40 °C.

Upon comparing the results for the triple-chain amphiphiles with those for the corresponding phospholipids bearing the same number of carbon atoms in one hydrophobic chain (**1** *vs.* DPPC, **2** *vs.* DSPC, respectively), we found that the vesicles made from the triple-chain amphiphiles were much more stable toward the leakage of trapped CF. In particular, vesicles made from **2** released less than 10% of the CF after 12 months under the experimental conditions used in this work. The transition temperatures from the gel state to the liquid crystal state (T_c), measured *via* DSC, of aqueous dispersions of these lipids or amphiphiles are as follows: 45.3 °C (for **1**), 59.3 °C (**2**), 41.1 °C (DPPC) and 56.3 °C (DSPC). In the case of vesicles made from **1** or DPPC, the relatively fast release of trapped CF may be attributed to the high fluidity of the membrane because the T_c of these two compounds is only a little higher than the storage temperature. The large difference in the ability to suppress the leakage between **2** and DSPC, however, cannot be explained by the T_c value.

The microfluidity of the bilayer membrane was estimated by the established method using pyrene as a fluorescent probe.[8] The I_e/I_m ratio (I_e and I_m are fluorescence intensities of the pyrene eximer at 468 nm and the pyrene monomer at 394 nm, respectively) increases as the microfluidity of the hydrophobic phase in the membrane increases. The relation between the I_e/I_m ratio and the measured temperature is shown in Fig. 2. [conditions: amphiphile or lipid (10 mM), pyrene (0.15 mM), 100 mM NaCl, 20 mM Tris-HCl (pH 7.5), excitation at 335 nm]

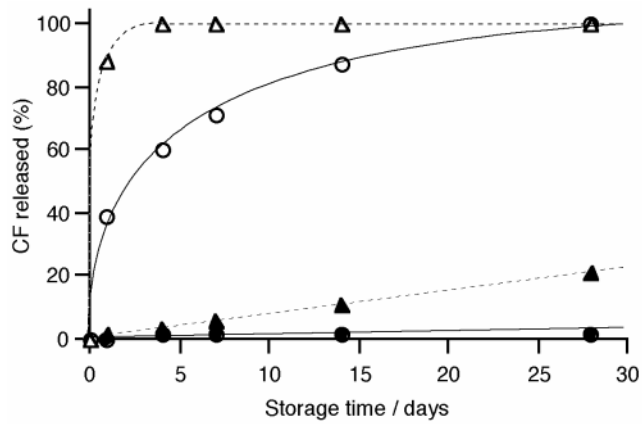


Fig. 1 Release (%) of 5(6)-carboxyfluorescein (CF) trapped inside vesicles of (△) DPPC, (▲) DSPC, (○) **1** and (●) **2** as a function of storage time (days) at 40 °C.

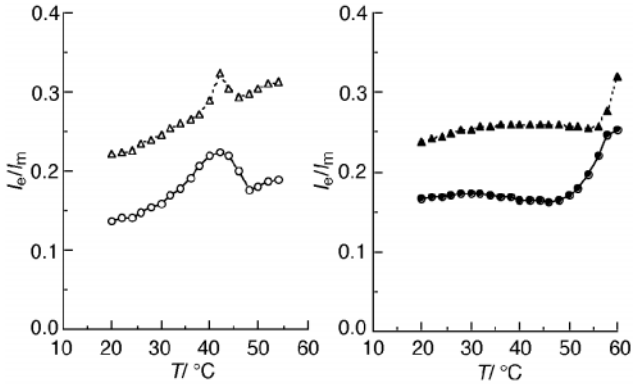

Fig. 2 Effect of temperature on the I_e/I_m ratio of pyrene buried in the membrane of (△) DPPC, (▲) DSPC, (○) **1** and (●) **2** vesicles. Conditions: amphiphile or lipid (10 mM), pyrene (0.15 mM), 100 mM NaCl, 20 mM Tris-HCl (pH 7.5), excitation at 335 nm.

Although the I_e/I_m ratios for **1** and DPPC increased gradually from 30 °C up to about 45 °C, there was very little change in the ratios for **2** and DSPC until 50 °C. These results agree well with the T_c of each compound. It is noteworthy that the I_e/I_m ratio of the triple-chain amphiphile is much lower than that of the corresponding phospholipids bearing the same number of carbons in a hydrophobic chain, meaning lower microfluidity of the membrane made from the triple-chain amphiphiles than that of the phospholipids. In summary, it is possible to say that the long-term stability of vesicles made from **2** toward the leakage of trapped CF may result from the three much more closely packed octadecyl chains in the bilayer of **2**, as compared to other lipids.

Because the triple-chain compounds in this work have two carboxylate groups, vesicles made from these amphiphiles are expected to have some pH-sensitive functions. Detailed investigation of their vesicles under various pH conditions is now in progress.

Notes and references

† The structure and purity of new compounds **1** and **2** were confirmed using the corresponding dimethyl esters because bis(carboxylate) compounds **1** and **2** were hygroscopic. *Selected data* for the dimethyl ester of **1** (R = *n*-$C_{16}H_{33}$), mp 78–79.5 °C (from EtOH); δ_H(400 MHz; $CDCl_3$) 0.88 (t, 9 H), 1.25–1.77 (m, 84 H), 3.40–3.60 (m, 21 H), 3.75 (s, 6 H), 4.35 (m, 4 H); *m/z* (FAB) 1095 [(M+K)$^+$, 100%], 1057 [(M+1)$^+$, 4] (Calc. for $C_{63}H_{124}O_{11}$: C, 71.54; H, 11.81. Found: C, 71.52; H, 11.92%). For the corresponding dimethyl ester of **2** (R = *n*-$C_{18}H_{37}$), mp 80–81 °C (from EtOH); δ_H(400 MHz; $CDCl_3$) 0.88 (t, 9 H), 1.17–1.60 (m, 96 H), 3.34–3.62 (m, 21 H), 3.73 (s, 6 H), 4.33 (m, 4 H); *m/z* (FAB) 1095 [(M+K)$^+$, 100%], 1057 [(M+1)$^+$, 4] (Calc. for $C_{69}H_{136}O_{11}\cdot H_2O$: C, 71.45; H, 11.99. Found: C, 71.55; H, 11.95%).

‡ A film of lipid or amphiphile (40 μmol) was prepared on the inside wall of a test tube by evaporation of its $CHCl_3$ solution and stored in a desiccator overnight under reduced pressure. After addition of 4 ml of a Tris-HCl buffer (20 mM, pH 7.5) containing 100 mM of CF to the test tube, the mixture was vortex-mixed for 10 min and successively sonicated for 5 min at about 10 °C higher than its T_c using a probe-type sonicator under a stream of nitrogen. Small unilamellar vesicles containing trapped CF were separated from untrapped CF by eluting the vesicle dispersion through a Sephadex G-50 gel column with 20 mM Tris-HCl buffer containing 100 mM of NaCl (pH 7.5). The formation of vesicles from compounds **1** and **2** was confirmed by a well-established gel-filtration method (ref. 9). Thus two fractions containing CF were observed in a series of eluates. The first fraction, which was eluted with an excluded volume of the column, indicated the presence of particles including a water phase separated from the outside phase. The second fraction contained a large quantity of untrapped CF only. This was also the case for DPPC and DSPC experiments in this work. The amount of CF released (%) from the vesicles was calculated by means eqn. (1),

$$\text{CF released } \% = (I_x - I_0)/(I_t - I_0) \times 100 \quad (1)$$

where I_0 is the fluorescence intensity of the vesicle suspension containing CF at initial time, I_x is the intensity of the suspension after a definite period of storage, and I_t is the fluorescence intensity after addition of an aqueous solution of Triton X-100 (100 g l^{-1}) to the suspension. The fluorescence intensity at 530 nm was measured at 25 °C using an excitation wavelength at 490 nm.

Received (in Liverpool, UK) 15th September 1998, Accepted 29th September 1998

Prepared in a three-step sequence including acid-catalysed cycloaddition of cyclopentadiene to 6-oxo-6*H*-1,3,4-oxadiazines, dehydrogenation with DDQ of the dihydro-α-pyrones formed and reduction of the resulting α-pyrones with DIBAL-H, 1,4-disubstituted cyclopenta[*c*]pyrans are shown to undergo electrophilic substitution; the molecular structures of 1-(4-anisyl)-4-phenylcyclopenta[*c*]pyran and 4-isopropyl-1-phenylcyclopenta[*c*]pyran-7-carbaldehyde have been determined by single crystal X-ray diffraction studies.

Iridoids with a cyclopenta[*c*]pyran skeleton occur widely.[2] For example, plagiolactone **1** is a constituent of the defence secretion produced by the larvae of *Plagiodera versicolora*[3a] and viburtinal **2** was obtained by hydrolysis of the esters

4 X = Bu^t, Y = H
5 X = Bu^t, Y = Ph

extracted from the leaves of *Viburnum tinus*.[4a] One synthesis for each of these compounds is known.[3b,4b]

We report here on a simple route to compounds having the bicyclic systems of **1** and **2** as well as to aldehydes that differ from **2** only by the substituents in the six-membered ring. Hitherto, only three cyclopenta[*c*]pyrans without an acceptor substituent have been described: the parent heterocycle **3**, its *tert*-butyl derivative **4**[5] and its *tert*-butyldiphenyl derivative **5**.[6] No reactions were performed with **3**–**5**. Being 10π-electron systems, they should be aromatic[7] and thus amenable to electrophilic substitution.

The non-catalysed reaction of diphenyl-1,3,4-oxadiazin-6-one **6a** with cyclopentadiene proceeded unsatisfactorily. However, as in the case of norbornene,[8] the presence of TFA led to a strong acceleration of the desired cycloaddition with subsequent formation of the regioisomeric dihydro-α-pyrones **7a** and **8a**. Eleven further oxadiazinones[9] were utilised. Scheme 1 summarises the best results. We had shown previously that the methyl oxooxadiazinecarboxylate **6c** reacts rapidly with cyclopentadiene in the absence of a catalyst.[10] On treatment with triflic acid, the resulting γ-oxoketene now cyclised smoothly to give pure *exo*-**8c**.

The next step was the conversion of **7** and **8** into the α-pyrones **9** and **10**, respectively, with DDQ with yields ranging from 27 (**10c**) to 76% (**9b**/**10b**). In order to improve the yield of

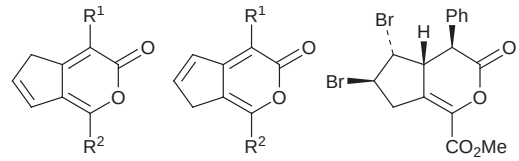
d	Pr^i	Ph	5:1	84
e	Pr^i	4-ClC_6H_4	>5:<1	85
f	Pr^i	4-$MeOC_6H_4$	>5:<1	80

Scheme 1



9a–f **10a–d** **11**

10c, we added bromine to **8c** and treated the resulting dibromide **11** with DBU, giving rise to a 1:8 mixture of **9c** and **10c** in 81% overall yield.

To our surprise, the α-pyrones **9** and **10** were directly transformed to the target compounds **12** by DIBAL-H (Scheme 2). The low yield of **12c** has its origin in the attack of the reagent at the ester group. Applying 4 equiv. of DIBAL-H afforded the alcohol **12g** (36% yield). An effect analogous to that of DIBAL-H could be achieved by $AlMe_3$, which converted **9a**/**10a** into the methyldiphenylcyclopenta[*c*]pyran **13** (50%).

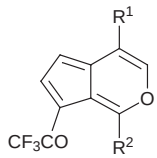
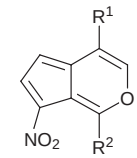
15



16a,**d**,**g**



17a,**g**

The availability of compounds **12** and **13** made us try electrophilic substitutions. Formylation with DMF/$POCl_3$ at 0 °C furnished mainly the aldehydes **14** and **15** (61–84%). TFAA/NEt_3 at 20 °C produced the trifluoromethyl ketones **16a**,**d**,**g** (74, 46, 11%). In the case of **16g**, the alcohol **12g** had to be transformed to the TMS ether **12h** prior to trifluoroacetylation. Nitration was achieved with tetranitromethane/Py at 0 °C giving rise to the products **17a**,**g** (56, 38%).

The cyclopenta[*c*]pyrans **12** and **13** are orange to deep red, rather sensitive compounds, which could be purified by chromatography on basic alumina of activity IV. Only the crystalline products (**12a**,**b**,**c**, **13**) were persistent at room temperature, whereas the oils and solutions could only be stored at −30 °C for a short time.

Detailed information on the structures of **12b** and **14d** is provided by X-ray analyses (Fig. 1).‡ The formyl group of **14d** is almost coplanar with the five-membered ring (angle between their best least-squares planes 172°). Astoundingly, the CC bond lengths in the five-membered ring of **14d** hardly differ from those of **12b**. Thus, the distances C(4a)–C(5), C(5)–C(6) and C(6)–C(7) are nearly the same (138.2–139.3 pm) and similar to those of benzene and the corresponding ones of azulene.[11] Also C(4a)–C(7a) and C(7)–C(7a) resemble each other closely (144.5–145.1 pm), but are significantly shorter and longer than the respective bonds of azulene (*ca*. 150 and 140 pm). Unlike its effect in the five-membered ring, the formyl group causes remarkable changes of several bond lengths in the pyran subunit.

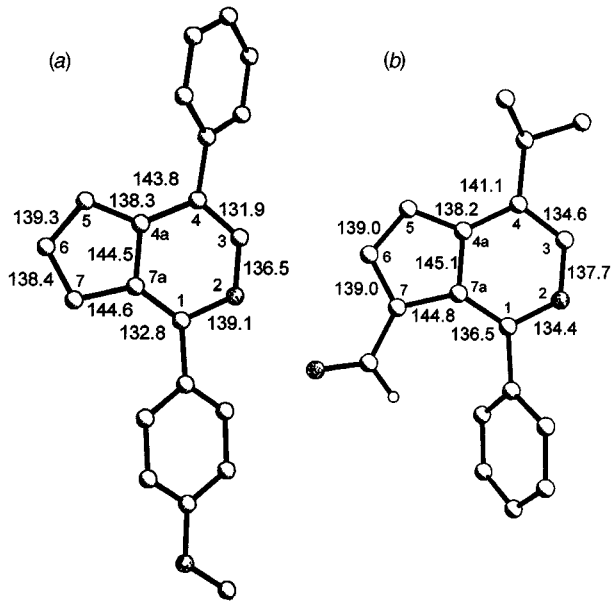


Fig. 1 Molecular structures of (*a*) 1-(4-anisyl)-4-phenylcyclopenta[*c*]pyran **12b** and (*b*) 4-isopropyl-1- phenylcyclopenta[*c*]pyran-7-carbaldehyde **14d**, together with the atomic numbering scheme and some selected bond lengths (pm).

In the UV–VIS spectra (MeCN) of **12a**,**b** and **13** the absorption maxima at longest wavelengths are found at 437–450 nm (log ε 3.13–3.20). As compared to those of **12a** and **13**, the absorptions of the aldehydes **14a** and **15** show hardly any shift in the wavelengths, but an increase of the molar extinction coefficient (log ε 3.73, 3.82). The methyl carboxylate **12c** absorbs at the longest wavelength (490 nm, log ε 2.95).

We thank the Deutsche Forschungsgemeinschaft as well as the Fonds der Chemischen Industrie for financial support, and Degussa AG for gifts of chemicals.

Photoinduced non-oxidative coupling of methane over silica-alumina and alumina around room temperature

Yuko Kato,[a] Hisao Yoshida*[a] and Tadashi Hattori[b]

[a] *Department of Applied Chemistry, Graduate School of Engineering, Nagoya University, Nagoya 464-8603, Japan. E-mail: yoshida@apchem.nagoya-u.ac.jp*

Received (in Cambridge, UK) 2nd September 1998, Accepted 18th September 1998

Around room temperature, photoinduced coupling of methane proceeds without any oxidant molecules on silica-alumina and alumina evacuated at 1073 K; many coupling products in the gaseous phase are obtained from silica-alumina, while most of products on alumina are obtained only through thermal desorption.

The oxidative coupling of methane is an expedient reaction to convert natural gas into useful chemicals. However, it is very difficult to obtain the coupling products in high yield, because oxidation of the coupling products to CO_x proceeds more selectively than the coupling reaction. If the oxidant molecules are removed to avoid complete oxidation, the reaction requires very high temperature[1] and has no practical use. Photoinduced reactions are one of the most available reactions taking place at low temperature where complete oxidation could be minimized. Recently, it was reported that photo-induced coupling of methane proceeded at 373–473 K in the presence of oxygen over TiO_2[2] which is the most widely used photocatalyst. However the selectivity of CO_x was very high and the yield of coupling products was only *ca.* 0.5%. Use of N_2O as oxidant improved the selectivity of coupling products on MgO, but the yield was $< 0.2\%$.[3,4] The possibility of the photoinduced non-oxidative coupling, where no oxidant molecules are employed, was suggested by using transition metal oxides, such as V/SiO_2,[5] TiO_2[6] and Mo/SiO_2.[7] However, the highest yield was only *ca.* 0.007% in the gaseous phase and $< 0.4\%$ even after forced desorption by heating or by admission of water vapor.[7]

Here, we describe that the coupling products are obtained in yields as high as 5% without formation of CO and CO_2 in the non-oxidative coupling of methane over silica-alumina and alumina under photoirradiation. Silica-alumina, which is a member of silica-based materials recently attracting a great deal of attention as a new photocatalyst family,[8–13] was found to be photoactive; it exhibited a characteristic phosphorescence emission spectrum.[9] The photoreactivity of silica-alumina toward gaseous molecules, however, has not been investigated, and the present report is the first in this area.

The silica sample was prepared from $Si(OEt)_4$ by the sol–gel method followed by calcination in dry air at 773 K[14] and its specific surface area was 679 $m^2\ g^{-1}$. The silica-alumina samples, SiO_2–Al_2O_3(L) and SiO_2–Al_2O_3(H), employed were reference catalysts of the Catalysis Society of Japan, JRC-SAL-2 and JRC-SAH-1, respectively.[15,16] The alumina contents were 13.75 and 28.61 mass% and the specific surface areas were 560 and 511 $m^2\ g^{-1}$, respectively.[15,16] The alumina sample was also the JRC sample, JRC-ALO-4 (surface area; 174 $m^2\ g^{-1}$).[15,16]

The reaction tests were carried out in a closed quartz reaction vessel (82 cm^3). The sample (1.0 g) was spread on the flat bottom of vessel (19.6 cm^2), and was treated with 60 Torr (1 Torr = 133 Pa) O_2 for 1 h at 1073 K, followed by evacuation for 1 h at 1073 K. Methane (99.95%) was purified by a vacuum evaporation before use and introduced into the reactor. The initial pressure of methane (100 μmol) in the reactor was 21 Torr and no oxidant molecules were introduced. The sample was irradiated with a 250 W Xe lamp for 18 h. Under photoirradiation, the temperature of the sample bed was measured to be *ca.* 310 K. Products in the gaseous phase were collected with a liquid-N_2 trap and analysed by GC. Then adsorbed products were thermally desorbed by heating (573 K, 15 min), collected, and analysed by GC.

Table 1 shows the product yields in photoinduced non-oxidative coupling of methane, in the absence of gaseous oxidants, over silica, silica-alumina and alumina. Note that in all cases no oxygenates (MeOH, HCHO, CO_2, CO) were detected.

For the empty reactor (run 1), only a trace amount of C_2H_6 was formed upon photoirradiation. On the silica sample (run 2), a small amount of C_2H_6 and C_3H_8 were obtained in the gaseous phase, and a trace amount of C_2H_4 and C_3H_6 were observed as the thermally desorbed products.

Over the silica-alumina samples (runs 3 and 4), the conversions were obviously much higher than that over silica. In the gaseous phase, a large amount of C_2–C_4 alkanes was obtained while smaller amounts of C_2–C_6 alkanes and alkenes were desorbed upon heating. Among the thermally desorbed products, alkenes were the major products. In the dark (in an electric furnace, run 6) at 473 K, no products were detected, clearly indicating that photoirradiation is necessary for the above reaction. On SiO_2–Al_2O_3(L), the total yield reached

Table 1 Results of photoinduced non-oxidative coupling of methane[a]

		Yield of gaseous phase product (C%)[b]				Yield of thermal desorption product at 573 K (C%)[b]								Total

4	SiO_2–Al_2O_3(H)	1.82	0.27	0.03	2.12	0.29	0.02	0.24	0.01	0.12	tr.	0.22	0.90	3.02
5	Al_2O_3	0.48	0.02	0	0.50	0.33	2.64	0.03	1.18	0	0.49	0.16	4.83	5.33
6[d]	SiO_2–Al_2O_3(L)	0	0	0	0	0	0	0	0	0	0	0	0	0
7[d]	Al_2O_3	0	0	0	0	0	0	0	0	0	0	0	0	0

[a] Reaction temperature = *ca.* 310 K, reaction time = 18 h, CH_4 = 100 μmol. [b] Based on the initial amount of CH_4. [c] A blank test. [d] Reaction at 473 K without UV-irradiation. tr. = trace.

5.90% and the yield of gaseous phase products reached 4.53%, much higher than those in any other reports on photoinduced coupling of methane.[2–7] It should be noted that no oxidant molecules were introduced in the reaction system and that the temperature of the sample bed, measured by a thermocouple, was only 310 K. The total yield on SiO_2–Al_2O_3(L) was higher than that on SiO_2–Al_2O_3(H). It is reported that SiO_2–Al_2O_3(L) has a larger phosphorescent emission spectrum with fine structure and a clearer peak in its excitation spectrum than SiO_2–Al_2O_3(H). From this result, it is proposed that highly dispersed aluminum species in the silica tetrahedral matrix are responsible for the photoactivity of silica-alumina. In the present case, such species would also play an important role in the photoinduced reaction.

On the alumina sample (run 5), the total yield (5.33%) was as high as that on the silica-alumina sample [SiO_2–Al_2O_3(L)]. Alumina exhibited no activity in the dark (run 7), indicating that photoirradiation is also necessary for the reaction over alumina. However, the feature of reaction on alumina was different from that on silica-alumina; on alumina, the yields of gaseous phase products (C_2H_6 and C_3H_8) were much lower and the most of products were obtained on heating. Among the thermal desorption products, alkanes were dominant on alumina, while they were minor products on silica-alumina.

In conclusion, it was found that the coupling of methane proceeded under photoirradiation on silica-alumina and alumina in the absence of any oxidant molecules. A meaningful amount of coupling products was obtained without the formation of CO and CO_2. Specially, silica-alumina, whose alumina content is lower, exhibited the highest activity without any thermal desorption.

Received (in Cambridge, UK) 10th September 1998, Accepted 30th September 1998

Made by a metal–metal partial exchange reaction involving lithium *tert*-butylamide, rubidium *tert*-butoxide and TMEDA, the title compound represents the first mixed lithium–rubidium organoelement species of its type.

Recent times have witnessed a revival of interest in metal alkoxides. Considerable attention has been paid to them as precursors for the deposition of metal oxides used in the electronics and ceramics industries.[1] Within preparative chemistry, they are best known for their role in two-component superbasic mixtures, typified by 'BuLi·KOBu^t', which often succeed where orthodox alkyllithium reagents fail in difficult proton abstraction applications.[2] Also, the stereochemical rigidity of the Bu^tO^- ligand frequently aids the crystallisation process, thus permitting the gathering of valuable structural information from X-ray crystallographic studies. Recent important crystal structures in this category of $[(C_6H_{11}O^-)_4(Bu^tO^-)_4(Li^+)_4(K^+)_4(KOH)\cdot 5THF]$,[3] $[(Bu^tOLi)_{10}(LiOH)_6]$,[4] $[\{[PhN(H)]_2(Bu^tO)LiNaK\cdot 2TMEDA\}_2]$,[5] and $[\{(cyNLi)_3Sb\}(Bu^tOK)_3\cdot x PhMe]$,[6] respectively give insight into the nature of alkoxide–enolate interactions, the intermediates involved in the hydrolytic degradation of lithium alkoxides, the architecture of an amide–alkoxide model superbase, and the assembling of large polyamidoantimony anionic cage complexes. In earlier work we reported the crystal structure of an octalithium dipotassium mixed oxide alkoxide, which can be formally represented as $[(Bu^tOLi)_6(Bu^tOK)_2(Li_2O)\cdot 2TMEDA]$ **1**.[7] This was prepared by a permutational metal–metal exchange reaction [eqn. (1)], which was incomplete in the sense that a proportion of the potassium *tert*-butoxide reactant molecules remains in the product as part of **1**. We pondered whether this same synthetic strategy applied to rubidium *tert*-butoxide could generate a mixed lithium–rubidium compound, in the knowledge that hitherto no such compound exists in the Cambridge Crystallographic Database.[8] The dearth of studies in organorubidium chemistry generally, flagged in a recent review,[9] provided another incentive for pursuing this topic. As revealed herein, our goal has been realised through the synthesis and crystallographic characterisation of the heptalithiumtetrarubidium mixed alkoxide peroxide $[\{(Bu^tOLi)_5(Bu^tORb)_4(Li_2O_2)\cdot 2TMEDA\}_\infty]$ **2**, the composition, structure, and bonding of which are unprecedented.

$$Bu^tN(H)Li + Bu^tOK \xrightarrow{TMEDA} 1/x[(Bu^tOLi)_6(Bu^tOK)_2(Li_2O)\bullet 2TMEDA] + \text{other products} \quad (1)$$

Standard inert-atmospheric (argon) Schlenk techniques were employed throughout the preparative procedure. Rubidium *tert*-butoxide was pre-prepared as a white powder by a literature method,[10] and subsequently suspended in hexane. To this was added an equimolar amount of $Bu^tN(H)Li$ (in hexane), prepared *in situ* beforehand by lithiation of *tert*-butylamine. The resulting mixture was heated to reflux for 1.5 h, then filtered to remove fine solids leaving a transparent brown solution. Addition of TMEDA (1 mol equivalent) caused the solution to darken. Refrigerating the solution at *ca.* 4 °C for 48 h afforded colourless crystals of **2** [eqn. (2)]. Based on consumption of butoxide molecules the yield obtained was 51%. Satisfactory C, H, Li, N, Rb analyses were obtained. No other product could be crystallised despite prolonged cooling of the solution remaining following removal of **2** (analogous to the situation found with **1**). This is perhaps not surprising since the leftover solutions in containing a mixture of amide (mainly) and butoxide molecules can be likened to a type of superbase, which is a class of compound notoriously difficult to crystallise.

$$Bu^tN(H)Li + Bu^tORb \xrightarrow{TMEDA} 1/x[\{(Bu^tOLi)_5(Bu^tORb)_4(Li_2O_2)\bullet 2TMEDA\}_\infty] + \text{other products} \quad (2)$$

The structure of **2** (Fig. 1)† consists of polynuclear $(Bu^tO)_9(O_2)Li_7Rb_4$ cages (Fig. 2) which link together *via* Rb–TMEDA–Rb bridges. As Fig. 3 shows, this produces polymeric sheets, arranged in layers such that the cages in one sheet run orthogonal to those in the next sheet. The cage possesses exact twofold rotation symmetry about the O(5)···Li(2) axis which bisects the peroxide O(6)–O(6A) bond; the Bu^t group on O(5) is disordered over two orientations. Thus there are three pairs of Li

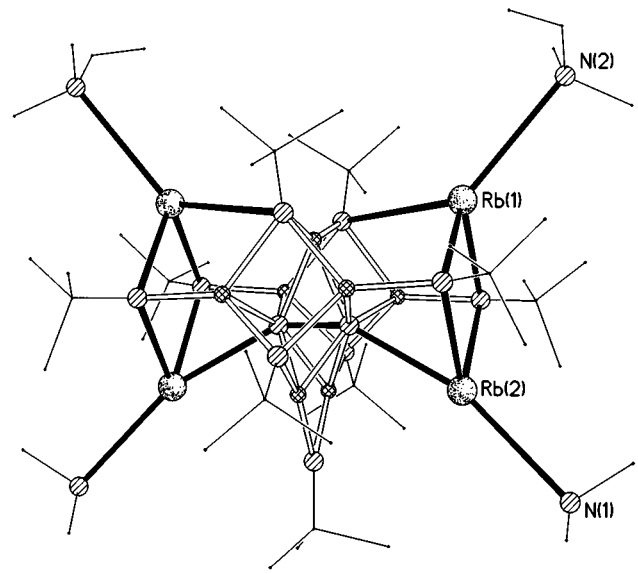

Fig. 1 Double asymmetric unit of **2**. Hydrogen atoms have been omitted for clarity. Selected bond lengths (Å): Rb(1)–N(2) 3.267(7), Rb(2)–N(1) 3.126(7), Rb(1)–O(1) 2.743(5), Rb(1)–O(2) 2.748(5), Rb(1)–O(4) 3.393(5), Rb(2)–O(6) 2.749(4), Rb(2)–O(1) 2.841(5), Rb(2)–O(2) 2.851(5), Li(1)–O(1) 1.873(12), Li(1)–O(3A) 1.944(12), Li(1)–O(4) 2.038(13), Li(1)–O(6) 2.333(11), Li(2)–O(4) 1.844(6), Li(2)–O(6) 1.937(17), Li(3)–O(2) 1.907(13), Li(3)–O(3) 1.934(13), Li(3)–O(4A) 2.101(14), Li(3)–O(6) 2.278(13), Li(4)–O(5) 1.830(14), Li(4)–O(3) 1.876(13), Li(4)–O(6) 1.968(12), Li(4)–O(6A) 1.971(13).

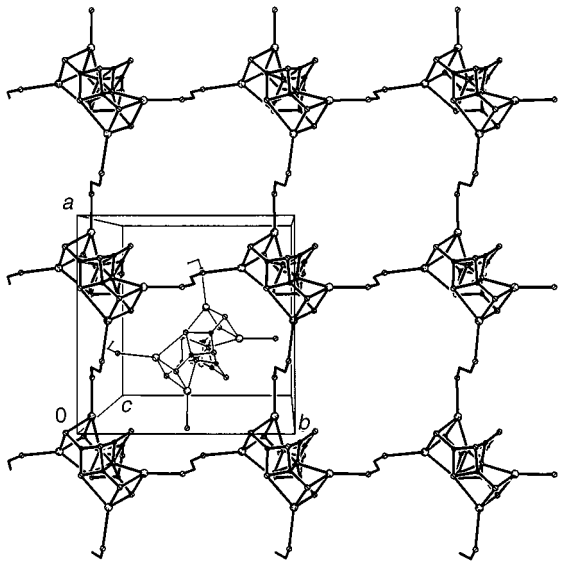

Fig. 3 View showing layer arrangement of polymeric **2**, without Bu^t and TMEDA methyl groups. For clarity, only one cage unit is shown in the further layer.

centres [Li(1), Li(3), Li(4) and their symmetry equivalents] and a unique Li(2), each in a distorted tetrahedral environment; two pairs of distorted tetrahedral Rb centres [Rb(1), Rb(2) with their equivalents]; three pairs of four-coordinate [O(1), O(2), O(3)] and one pair of five-coordinate [O(4)] butoxide O centres and a unique three-coordinate O(5); and a single peroxo unit [O(6)–O(6A)]. The (butoxide) O–Li bond lengths span a wide range [1.830–2.101 Å] reflecting the various coordination numbers involved. This compares with a range of 1.856–2.063 in **1**. Excluding the long O(4)–Rb(1) contact [length 3.393(Å)], the (butoxide) O–Rb bond lengths in **2** have a mean value (2.796 Å) close to that in the $[(Bu^tORb)_4]$ cubane (2.757 Å).[10] To the best of our knowledge, **2** provides the first example of Rb–TMEDA–Rb bridging (mean N–Rb bond length, 3.197 Å), though bridges of this type have long been known for lithium, *e.g.* in $[\{(MeLi)_4{\cdot}2TMEDA\}_\infty]$[11] and $[\{(Bu^nLi)_4{\cdot}TMEDA\}_\infty]$.[12] The peroxo O(6)–O(6A) molecule in **2** is side-on coordinated by Li(2), Li(4) and Li(4A) (mean length, 1.958 Å) forming three OOLi triangles. A similar arrangement exists within the peroxide fragment of the triple-anion structure of $[\{(Me_3SiOLi)_4{\cdot}Li_2O_2{\cdot}(Me_3Si)_2NLi\}{\cdot}2THF]$ [mean peroxo O–Li bond length, 2.002 Å],[13] which coincidentally also contains seven Li centres. Additional end-on coordinations of O(6) and O(6A) in **2** occurs *via* Li(1), Li(3) and Rb(2) (mean lengths: O–Li 2.306 Å, O–Rb 2.749 Å). The O–O bond itself measures 1.541(9) Å, in good agreement with that (1.557 Å) in the aforementioned triple-anion structure. Here the presence of the peroxide molecule demonstrates again the strong oxophilic nature of metal alkoxides, which in **1** manifests itself in the form of oxo (O^{2-}) ions. Peroxide incorporation has also been reported in the barium diketonate $[(thd)_{10}(O_2)(H_2O)_6Ba_6]$ (thd = 2,2,6,6-tetramethylheptane-3,5-dionate),[14] while both peroxo and oxo ions appear in the mixed lithium–magnesium amide $[\{(Me_3Si)_2N\}_4Li_2Mg_2(O_2)_x(O)_y]$.[15] Obviously the mode of formation of such anions is complex and as such, is not yet understood.

Recorded in $[^2H_8]$toluene solution at 300 K, the ^1H NMR (400 MHz) spectrum of **2** exhibits two broad Bu^{t}O resonances centred at 1.25 and 1.44 ppm in an approximate ratio of 5 : 4. The former resonance can be tentatively assigned to the five cage Bu^{t}O$^-$ ligands bound only to Li centres (provided the long O–Rb contacts are disregarded). Significantly, pure Bu^{t}OLi comes at a near-identical chemical shift (1.26 ppm). Likewise, the latter resonance can be assigned to the four cage Bu^{t}O$^-$ ligands bound to mixed Li/Rb centres. Interestingly, the order and chemical shifts of the TMEDA resonances (CH_2, 2.32 ppm; Me, 2.11 ppm) are characteristic of uncoordinated molecules. Hence the implication is that the Li_7Rb_4 cage remains intact, but that the Rb–TMEDA–Rb bridges linking them together in the solid state, cleave in solution. This could explain why **2** is soluble in arene solvents.

In conclusion, we have demonstrated that a metal–metal partial exchange methodology between a rubidium alkoxide and a lithium amide can successfully yield a mixed lithium–rubidium crystalline product, the first of its type. Future work will examine whether the presence of amide ligands is essential for the crystallisation of such novel compositions; or are they accessible by simply mixing together the appropriate homometallic alkoxides?

We thank the EPSRC (for equipment to W. C.) and the University of Strathclyde (for studentship to A. M. D.).

Received (in Bloomington, IN, USA) 21st May 1998, Accepted 25th September 1998

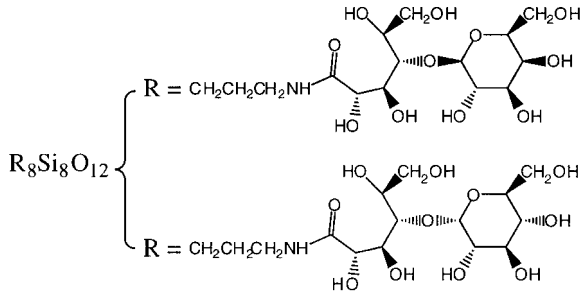
Two carbohydrate-functionalized silsesquioxanes 2 and 3 have been prepared by the reactions of $(H_2NCH_2CH_2CH_2)_8Si_8O_{12}$ 1 with *O*-β-D-galactopyranosyl-(1→4)-D-gluco-1,5-lactone and *O*-α-D-glucopyranosyl-(1→4)-D-gluco-1,5-lactone; the latter (*i.e.* 3) possesses eight maltose-derived substituents and binds with *Concanavalin A*, while the former possesses eight lactose-derived substituents that demonstrates selective binding to the hepatic asialoglycoprotein receptor.

Cell surface carbohydrates play an important role in cell recognition processes and have been implicated in a variety of pathological disorders.[1] In many instances the mechanisms by which these carbohydrates function as signals for cell recognition and subsequent biochemical transformations are not well understood, but the development of new drugs to block undesirable interactions could provide powerful tools for treating or preventing a variety of diseases.[2] One interesting approach for elucidating molecular-level details of recognition phenomena and developing new chemotherapeutics involves the use of polyfunctional molecules as 'scaffolds' to organize structurally well defined assemblies of oligosaccharide units.[3]

Here, we report the first use of polyhedral oligosilsesquioxanes (POSS) as scaffolds for the presentation of multiple carbohydrate units.

We recently introduced the use of $(H_2NCH_2CH_2CH_2)_8Si_8O_{12}$ **1** as a core for dendrimer synthesis[4a] and as a scaffold for the presentation of polypeptide chains.[4b] This water-soluble framework can be prepared *via* neutralization of its octahydrochloride salt, which is obtained in one step (> 35% yield) by the hydrolytic condensation of readily available $H_2NCH_2CH_2CH_2Si(OEt)_3$. Carbohydrate substituents can be attached to the eight amine groups of **1** *via* standard coupling protocols with carbohydrate-derived lactones.[3a–e] For example, the reaction of **1** with *O*-β-D-galactopyranosyl-(1→4)-D-gluco-1,5-lactone affords octagalactose-substituted framework **2**, which is obtained in high yield as a white powder after dialysis against water and precipitation by methanol.† Similarly, the reaction of **1** with *O*-α-D-glucopyranosyl-(1→4)-D-gluco-1,5-lactone produces an excellent yield of **3**, which possesses eight equivalent maltose-derived substituents. The course of these lactone coupling reactions can be conveniently monitored by ^{1}H NMR spectroscopy [$(CD_3)_2SO$] because the chemical shift for the CH_2N group of **1** (δ 2.8) shifts downfield by *ca.* 0.2 ppm upon acylation. The prominent product amide NH resonance at δ 7.7 can also be integrated and used to determine the extent of reaction. Both carbohydrate-functionalized frameworks are stable in solution (water or Me_2SO, 25 °C, 7 days) and elevated temperatures (100 °C) for short durations; both frameworks are also stable in the presence of acids (*e.g.* 1 M HCl or conc. HOAc) and non-nucleophilic bases (*e.g.* DIEA in DMSO).

Both **2** and **3** were characterized by a variety of techniques, including combustion analysis, MALDI-TOF mass spectrometry and multinuclear (^{1}H, ^{13}C, ^{29}Si) NMR spectroscopy [D_2O or $(CD_3)_2SO$]. Assignment of all ^{1}H and ^{13}C resonances



for **2** and **3** could be made on the basis of COSY, HMQC and DEPT experiments, but at concentrations normally required to obtain good signal-to-noise, aggregation of these highly polar frameworks causes marked broadening of many resonances. Dynamic light scattering measurements indicate that aggregation occurs at *ca.* 0.4 mM in water and that aggregates with an effective radius of 100 nm are present at 1.0 mM. The nature of this aggregation is not known, but at 3 mM the ^{29}Si, ^{1}H and ^{13}C spectra [D_2O and $(CD_3)_2SO$] are consistent with two distinct environments (*ca.* 4 : 1) for the pendant groups. The integrated intensities of the featureless resonances attributable to each environment do not appear to change over a concentration range of 1–8 mM and a temperature range of 25–60 °C, but the ratio abruptly changes below 1 mM and is *ca.* 1 : 1 over the concentration range of 0.05–0.5 mM. ^{1}H NMR spectra (D_2O) recorded below 1 mM also exhibit dramatically better resolution with well defined first-order multiplets for the aminopropyl spacers. We suspect that the two different environments are due to restricted rotation about the amide C–N bonds, which can create distinct *cis* and *trans* conformations for the pendant groups. If this is indeed the case, our results are consistent with strong inter- and intra-molecular interactions between pendant carbohydrate groups because *cis–trans* isomerization is slow on the NMR timescale at 25 °C and the *cis*/*trans* ratio changes upon the onset of intermolecular aggregation.

We have explored biological binding affinities of **2** and **3** using the asialoglycoprotein receptor (ASGPR) and *Concanavalin A* (Con A). The ASGPR is an integral mammalian hepatocyte membrane receptor which has selective binding to terminal non-reducing β-D-galactopyranosyl residues and demonstrates increased binding with an increased number of antennary β-D-galactopyranosyl groups.[2,5,6] Early suggestions that enhanced binding to the ASGPR occurs when three galactosyl residues are situated 15, 22, and 25 Å apart and separated by flexible organic spacers (*e.g.* PEG)[7] were supported by observations that three galactose residues tethered to glycerol[6c] or TRIS[2,6a,8] with this approximate spacial relationship exhibit enhanced binding to the ASGPR over mono- or di-valent analogs. Stochastic dynamics calculations[3h] (Macromodel v. 5.5) on **2** show inter-galactose separations comparable to the distances required for enhanced-binding to the ASGPR.

The results from a competitive inhibition study of binding to ASGPR of HepG2 cells are shown in Fig. 1. As illustrated in

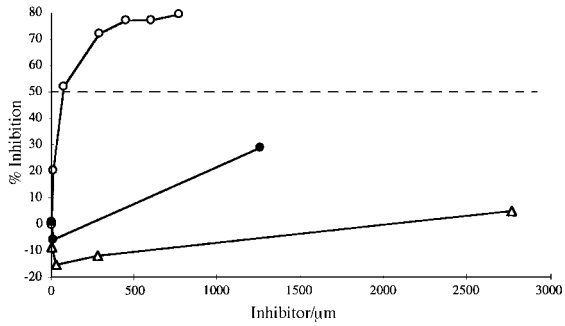


Fig. 1 Competitive inhibition of HepG2-ASGPR mediated uptake of ^{125}I-ASOM (1 μM, 0.5 ml/well) by the hydrochloride salt of **1** (△), **2** (○) and **3** (●) as measured by scintillation counting of the ^{125}I label. The reaction was performed in binding media (0.5 ml/well, pH = 7.4), incubated at 37 °C for 2 h before lysis with 10% SDS (0.5 ml/well). The inhibitory potency (IC_{50}) for unlabelled ASOM was determined to be 0.65 μM from a separate control experiment.

Fig. 1, neither the octahydrochloride of **1** nor the octa-glucose-terminated framework (*i.e.* **3**) substantially inhibit ASGPR-mediated uptake of ^{125}I-labeled Asialoorosomucoid (^{125}I–ASOM) into HepG2 cells (37 °C). In contrast, the octa-β-D-galactose substituted framework (*i.e.* **2**) strongly inhibits uptake of ^{125}I–ASOM. These results are consistent with selective recognition and binding of ASGPR to the β-galactose residues of **2** and no binding to the glucosyl residues of **3** or the ammonium groups of **1**.

It is interesting that the IC_{50} of **2** (57 μM at 37 °C) is comparable to the inhibition potency observed in a similar experiment for a glycerol molecule possessing three pendant lactose residues (IC_{50} = 9.83 μM at 4 °C).[6c] This clearly indicates that the rigid Si_8O_{12} core of **2** does not hinder binding of the galactosyl residues to the ASGPR, and it suggests that each ASGPR is interacting with three of the eight pendant groups from a single molecule of **2**.

The specific binding affinities of **2** and **3** were also assessed using *Concanavalin A* (Con A), which has four domains available for the binding of non-reducing D-glucosyl and D-mannosyl residues. As shown in Fig. 2, mixtures of Con A (35 μM) and **3** at concentrations as low as 7 μM display immediate turbidity and precipitation of a Con A-crosslinked aggregate while there is no significant turbidity when Con A (35 μM) is added to **2** at concentrations as high as 420 μM. These results are consistent with selective recognition and binding of Con A to the D-glucosyl residues of **3** and no binding to the galactosyl residues of **2**. Precipitation of the Con A/**3** aggregate can be reversed by adding D-maltose. The addition of 1.5 mol equiv. of D-maltose leads to a slight decrease in turbidity (*ca.* 25%), but the effect is minor and comparable to the decrease observed upon addition of 75 mol equiv.; complete loss of turbidity occurs upon addition of 750 mol equiv. of D-maltose. These results are similar to results for Con A binding to glycosylated PAMAM dendrimers,[3c,g] a macrocyclic sugar cluster[3a,b] and polystyrene derivatives having pendant oligosaccharides.[3h]

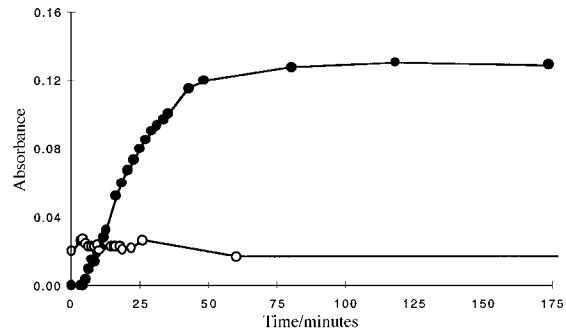

Fig. 2 Interaction of Con A (35 μM) with **2** (420 μM, ○) and **3** (7 μM, ●) as measured by absorbance at 450 nm. The reaction was performed at 25 °C and pH = 7 (0.01 M PBS).

In summary, we have synthesized carbohydrate-functionalized silsesquioxanes that exhibit highly selective and reversible complexation to carbohydrate-binding proteins. In light of the fact that $R_8Si_8O_{12}$ frameworks can be selectively monofunctionalized and subsequently modified to create new $R^1{}_7R^2Si_8O_{12}$ frameworks,[9] these observations have exciting implications for molecular recognition and the design of new site-specific drugs.

These studies were supported by the National Science Foundation (F. J. F.) and the National Institute of Health (D. J. K.). The authors gratefully acknowledge the advice and technical assistance provided by Professors David A. Brant and Charles G. Glabe (UCI), as well as the enthusiastic advice and encouragement provided by Professor A. Richard Chamberlin (UCI) and Dr Mark A. Scialdone (E. I. du Pont de Nemours).

† *Synthesis* of **2**: a solution of **1** (216 mg, 0.245 mmol) in MeOH (3.3 ml) was added to a solution of *O*-β-D-galactopyranosyl-(1→4)-D-glucono-1,5-lactone lactone[3e,5] (1.16 g, 3.41 mmol) in dry Me_2SO (*ca.* 3 ml); the MeOH was immediately removed by stirring under vacuum (25 °C, 0.001 Torr). The solution was stirred under nitrogen (25 °C, 24 h), filtered, and then evaporated (30 °C, 0.01 Torr) to afford a colorless resin, which was dialyzed against H_2O (25 °C, 3 × 4 l) over a period of 24 h. Evaporation (30 °C, 0.01 Torr) of the resulting solution afforded **2** as a spectroscopically pure white powder (472 mg, 53%), which was further purified by reprecipitation from H_2O–MeOH at −30 °C. Yield: 340 mg (40%). ^{1}H NMR [500.0 MHz, 5 mM in $(CD_2)_2SO$, 25 °C]: δ 7.66 (br, NH, 8H), 5.17–3.38 (m, carbohydrate, 168H), 3.10, 3.04 (br, CH_2N, 16H), 1.47 (br, $SiCH_2CH_2$, 16H), 0.56 (br, $SiCH_2$, 16 H). ^{13}C{^{1}H} NMR [125.7 MHz, 5 mM in $(CD_3)_2SO$, 25 °C]: δ 172.36 (s, CO), 104.66 (s, 1′-C), 83.16 (s, 4-C), 75.69, 73.22, 72.00, 71.70, 71.43, 71.17, 70.55, 68.23 (4′-C), 62.34 (s, 6-C), 60.72 (6′-C), 40.89 (br, CH_2N), 22.57 (br, $SiCH_2CH_2$), 8.77 (br, $SiCH_2$). ^{29}Si{^{1}H} NMR (99.38 MHz, 5 mM in D_2O, 25 °C): δ −65.9 (80%), −66.9 (20%). Received (in Bloomington, IN, USA) 24th July 1998, Accepted 17th September 1998

Metal-catalysed addition of $B_2cat'_2$ (cat′ = 4-Bu^t-1,2-$O_2C_6H_3$) to ketimines affords *N*-borylenamines and HBcat′. Analogous catalysed reactions of ketimines with HBcat′ in tetrahydrofuran afford multiply borated products, providing the first examples of metal-catalysed hydroboration of enamines.

Transition metal catalysed diboration of alkenes and alkynes is receiving considerable attention as a convenient and efficient method of generating alkyl- and alkenyl-boronic esters with well defined selectivities.[1] These compounds are valuable substrates for Suzuki coupling,[2] and new developments in this field include the direct synthesis of arylboronic esters from the corresponding aryl halides using diboron compounds[3] or dialkoxyboranes.[4] To date, catalysed diborations have been restricted to functionalizing unsaturated hydrocarbons, with the exception of a recent report by Marder and coworkers describing the 1,4-diboration of α,β-unsaturated ketones.[5] Our interest in aminoboron chemistry prompted us to investigate the diboration of imines. Transition metals can be used to catalyse the hydroboration of imines[6] and we recently found that the corresponding diboration of aldimines provides a direct route to the potent enzyme inhibitors, α-aminoboronic acids.[7,8] In this report we describe the versatility of metal-catalysed boron additions to ketimines which give a variety of novel aminoboronate esters and provide the first examples of metal-catalysed enamine hydroboration.

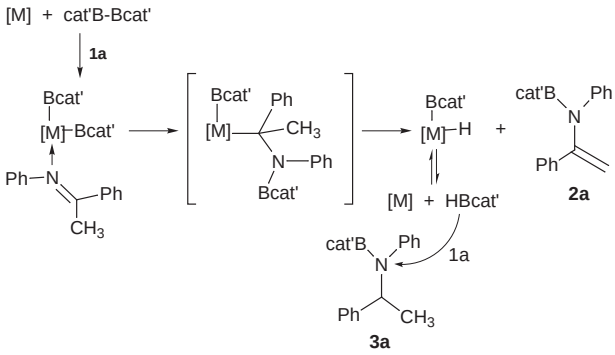
Reaction of acetophenone-derived imine, PhN=C(CH_3)Ph **1a**, with $B_2cat'_2$ (cat′ = 4-Bu^t-1,2-$O_2C_6H_3$) did not proceed without a catalyst, even at elevated temperatures (90 °C for 1 week).[9] Using 2 mol% $RhCl(PPh_3)_3$ at 25 °C, the reaction produced equal amounts of *N*-borylenamine **2a** and *N*-borylamine **3a**, as ascertained by NMR spectroscopy.[10] These products arise presumably from initial oxidative addition of the diboron compound to the metal center, followed by coordination of the ketimine with subsequent regioselective insertion into the M–B bond. Finally, β-H elimination generates *N*-borylenamine **2a** and 1 equiv. of HBcat′ which can subsequently add to unreacted **1a** to give **3a** (Scheme 1). Similar boration reactions have been observed previously in analogous diboration[1c] and hydroboration[11] reactions of alkenes. Ketimine diborations carried out using a catalytic amount of $Pt(dba)_2$ (dba = dibenzylidene acetone) gave primarily **2a** and HBcat′, as the resulting Pt complex is less effective in catalysing the competitive hydroboration of **1a**. Variation of the steric and electronic properties of the ketimine had a nominal effect on the product distribution as analogous reactions with a variety of ketimines **1b**–**e** gave similar results, as determined by NMR spectroscopy.‡

	R	Ar
1a	H	Ph
1b	H	$C_6H_4CF_3$-*p*
1c	H	C_6H_4OMe-*o*
1d	Ph	C_6H_4OMe-*p*
1e	Me	$C_6H_4CF_3$-*p*

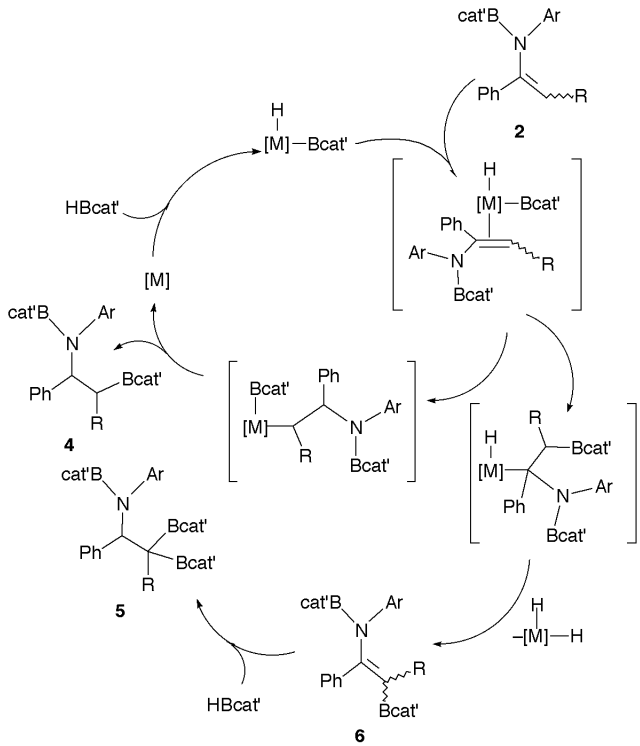
In order to obtain evidence for the mechanistic pathway discussed above, we examined the stoichiometric reaction of the unsaturated bis(boryl) complex $RhCl(Bcat')_2(PPh_3)_2$ (generated *in situ* from $RhCl(PPh_3)_3$ and $B_2cat'_2$) with ketimine **1a** and observed quantitative formation of dihydride $RhH_2Cl(PPh_3)_3$[11a,12] along with 2 equiv. of *N*-borylenamine **2a**. This surprising result suggests that intermediate RhHCl(Bcat′)$(PPh_3)_2$,[13] arising from the boration step, reacts with **1a** to give **2a** at a comparable rate to that of the bis(boryl) complex. Previous theoretical studies of metal-catalysed hydroboration indicated that alkene insertion into both M–H and M–B bonds is energetically feasible.[14] Our observation of quantitative formation of *N*-borylenamine indicates that only insertion of ketimine into the M–B bond results in product formation.

These intriguing results prompted us to investigate the metal-catalysed hydroboration of ketimines. Uncatalysed addition of HBcat′ to **1a** in toluene, THF, or chloroform proceeds slowly (days) at 25 °C to give **3a**.[15] Using 2 mol% $RhCl(PPh_3)_3$ in toluene, however, gave a mixture of **2a** and **3a** along with a small amount of the 1,3-diboration product, cat′BN(Ph)CH(Ph)CH_2Bcat′ **4a**, derived from an unprecedented catalysed hydroboration of enamine **2a**. Remarkably, reactions carried out in $CDCl_3$ gave predominantly hydroborated ketimine **3a**, while those in THF afforded predominantly **4a** and the 1,1,3-triboration product, cat′BN(Ph)CH(Ph)CH(Bcat′)$_2$ **5a** in a 3 : 1 ratio.‡ The **4a** : **5a** ratio determined by ^{1}H NMR was confirmed by hydrolysis, which gives elimination products styrene and *E*-vinylboronate ester,[1a] respectively.[16]

Several reactivity trends were observed in the catalysed hydroborations of substituted ketimines.‡ Reaction of the electron poor ketimine, (*p*-$CF_3C_6H_4$)N=C(CH_3)Ph **1b**, with HBcat′ in THF gave more rapid conversion (*cf.* **1a**) of the intermediate enamine and afforded analogous multiply borated amines **4b** and **5b** in a 5 : 1 ratio. The sterically hindered, electron-rich ketimine, (*o*-$MeOC_6H_4$)N=C(CH_3)Ph **1c**, on the other hand, gave primarily enamine **2c** and amine **3c**. Deoxybenzoin-derived imine, (*p*-$MeOC_6H_4$)N=C(CH_2Ph)Ph **1d**, gave both *E*- and *Z*-enamines and only one isomer was hydroborated to a single diastereomer of the 1,3 diboration product **4d**. Steric hindrance also precludes formation of the triborated product and gives rise to Rh-mediated HBcat′ degradation leading to minor



Scheme 1



Scheme 2

amounts of aminoborane side-products derived from 'BH_3' addition.[11a] Propiophenone-derived imine, (p-$CF_3C_6H_4$)-N=C(CH_2CH_3)Ph **1e**, is readily converted to isomeric *N*-borylenamines, but subsequent catalysed hydroboration is accompanied by significant HBcat′ degradation.

We propose that formation of the multiply borated products is due to competitive insertion of enamine **2** into M–H and M–B bonds to give **4** and *N*,*C*-diborylenamine **6**; the latter is subsequently hydroborated to **5** (Scheme 2). The enamine hydroboration/boration ratio depends on the substrate, solvent, and catalyst, and further catalyst development is ongoing.

In summary, we have shown that metal-catalysed diboration of ketimines affords *N*-borylenamines and that catalysed hydroboration of these products gives multiply borated amines proposed to result from competing enamine insertion into M–H *vs*. M–B bonds. The first examples of metal-catalysed enamine hydroboration reported herein afford boronate esters which may subsequently be used as substrates to prepare novel functionalized amines. This work is currently in progress.

Notes and references

† Dedicated to Professor Warren R. Roper on the occasion of his 60th birthday.

‡ *Reaction of* **1** *with* $B_2cat'_2$: to a solution of ketimine **1a** (97 mg, 0.5 mmol) dissolved in 0.5 ml of C_6D_6 was added $B_2cat'_2$ (119 mg, 0.5 mmol) and catalyst (2 mol%). The reaction was monitored by ^1H and ^{11}B NMR until **1a** was consumed (*ca.* 48 h). Similar reactions were conducted for **1b**–**e** and faster rates were observed for more electron-rich imines. The ratio of **2**:**3** was 4, 3.3, 2, 1.5, and 6 for **1a**–**e**, respectively. For **1c**, one equiv. of HBcat′ was added to the reaction mixture upon completion in order to cleanly generate **4c** from **2c**.

Reaction of **1** *with* HBcat′: to a solution of ketimine **1a** (40 mg, 0.2 mmol) dissolved in 0.5 ml of [$^2H_8$]THF was added HBcat′ (106 mg, 0.6 mmol) and catalyst (2 mol%). The reaction was monitored by ^1H and ^{11}B NMR until the intermediate *N*-borylenamine **2** was entirely consumed. The ratio of **3**:**4**:**5** was determined by ^1H NMR before and after hydrolysis (see electronic supplementary material for NMR data: http://www.rsc.org./suppdata/cc/1998/2395). Product Ratios for **1a**–**e** + HBcat′ in THF after 4 days at 25 °C: **3a**:**4a**:**5a** = 3:6:2; **2b**:**3b**:**4b**:**5b** = 1:8:12:2; **2c**:**3c**:**4c**:**5c** = 6:8:2:1; **2d**:**3d**:**4d** = 2:5:1; **2e**:**3e**:**4e** = 4:4:1.

Received (in Basel, Switzerland) 21st July 1998, Accepted 23rd September 1998

The reaction of the gold(III) cyclometallated complexes [Au(L)Cl][BF_4] [L = $N_2C_{10}H_7(CHMeC_6H_4)$-6 1 or $N_2C_{10}H_7(CMe_2C_6H_4)$-6 2, where $N_2C_{10}H_8$ = 2,2′-bipy] with $AgBF_4$ in acetone solution affords the acetonyl derivatives [Au(L){$CH_2C(O)Me$}][BF_4], 3 and 4, and the dinuclear oxo-bridged complexes [$Au_2(L)_2(\mu$-O)][BF_4]$_2$, 5 and 6; the crystal structure of complex 6 gives evidence for an unprecedented unsupported Au–O–Au bridge.

Oxo-bridged units are an important structural feature in the chemistry of early transition metals.[1] These units are also present in the active sites of a number of biological systems such as metalloproteins and metalloenzymes where the μ-oxo bridged moieties are responsible for a wide range of reactions. For this reason the study of synthetic models for these functions has been well developed.[2] In contrast, the chemistry of Group 9–11 late transition metal oxo-complexes has been less investigated[3] despite indications that such complexes may be intermediates in several important catalytic processes.

In a recent paper[4] we have reported the syntheses and characterization of a series of stable gold(III) bis oxo-bridged compelxes with 6-alkyl-2,2′-bipyridines. The crystal structures of *trans*-[$Au_2\{N_2C_{10}H_7(CH_2CMe_3)-6\}_2(\mu$-$O)_2$][$PF_6$]$_2$ and *cis*-[$Au_2\{N_2C_{10}H_7(CHMe_2)-6\}_2(\mu$-$O)_2$][$AuCl_4$][$PF_6$], the first gold(III) oxo-complexes, gave evidence for an $Au_2(\mu$-$O)_2$ core. The reactivity of these species is currently under investigation.

In a preliminary study of the reactivity of a series of gold(III) C,N,N cyclometallated derivatives [Au(L)Cl][BF_4][5] (HL = 6-benzyl- and 6-alkyl-2,2′-bipyridines) we have found that in the presence of $AgBF_4$ these species can activate acetone to give the corresponding acetonyl derivatives [Au(L){$CH_2C(O)$-Me}][BF_4], similar to those described by Vicente *et al.* for C,N cycloaurated complexes and reported to be efficient starting materials for the synthesis of ketones *via* C–C coupling.[6] Now we report that from the reaction of [Au(L)Cl][BF_4] [L = $N_2C_{10}H_7(CHMeC_6H_4)$-6 **1** or $N_2C_{10}H_7(CMe_2C_6H_4)$-6 **2**] with $AgBF_4$ in acetone at room temperature, besides the acetonyl derivatives [Au(L){$CH_2C(O)Me$}][BF_4], **3**† and **4**, dinuclear oxo-bridged complexes [$Au_2(L)_2(\mu$-O)][BF_4]$_2$, **5** and **6**, are formed.‡

To the best of our knowledge, the latter compounds are the first examples of gold(III) oxo-bridged cyclometallated derivatives. The oxo species are likely to result from aqua complexes [Au(L)$(H_2O)]^{2+}$ due to adventitious water. Deprotonation of the most acidic coordinated water molecule should give mononuclear hydroxo intermediates [Au(L)OH]$^+$. An 'oxolation' reaction involving an hydroxo intermediate could give the oxo-bridged species as proposed, *e.g.* in the case of iron(III) oxo complexes.[1]

In the IR spectra a strong absorption at *ca.* 780 cm^{-1} is assigned to the asymmetric stretch of the Au–O–Au moiety by comparison with bent oxo-bridged complexes of other metals.[7] In the FAB mass spectra (positive ions) of compounds **5** and **6** peaks of medium intensity are observed at mass values that correspond to ([M + BF_4]$^+$); in addition, peaks corresponding to the species [Au(L)OH]$^+$ are found in both cases. In the ^{1}H NMR spectrum of complex **5** [$(CD_3)_2CO$ or CD_2Cl_2, room temperature] two sets of signals are observed, as expected due to the presence of diastereomers. In the spectrum of complex **6** (CD_3CN, room temp.) one set of signals is observed, nevertheless a broad signal (at δ 1.4) for the methyl substituents indicates that either rotation about the Au–O bonds or inversion of the six-membered cyclometallated ring are somewhat slowed down. In fact, two well separated singlets at δ 0.85 and 1.88 appear at −40 °C.

The crystal structure of [$Au_2\{N_2C_{10}H_7(CMe_2C_6H_4)-6\}_2(\mu$-O)][$BF_4$]$_2$·MeCN **6**·MeCN, has been determined by single crystal X-ray diffraction.§ It consists of the packing of [$Au_2(L)_2(\mu$-O)]$^{2+}$ cations, BF_4^- anions and MeCN molecules in the molar ratio 1 : 2 : 1 with normal van der Waals contacts. A perspective view of the complex dication is shown in Fig. 1 with selected interatomic distances and angles in the caption. The cation displays an idealized C_2 symmetry, with the twofold axis passing through the oxygen atom and the midpoint of the Au(1)···Au(2) vector. The environments of the two gold atoms are very similar to each other; in particular, corresponding bond lengths involving Au(1) and Au(2) are all coincident within three esds. The two gold atoms are in distorted square-planar coordinations, with Au, O, N and N atoms essentially coplanar [maximum deviations from the respective best planes being +0.009(5) for O and −0.016(1) for Au(1), and +0.004(5) for O and −0.008(1) Å for Au(2)], with C(15) and C(35) lying

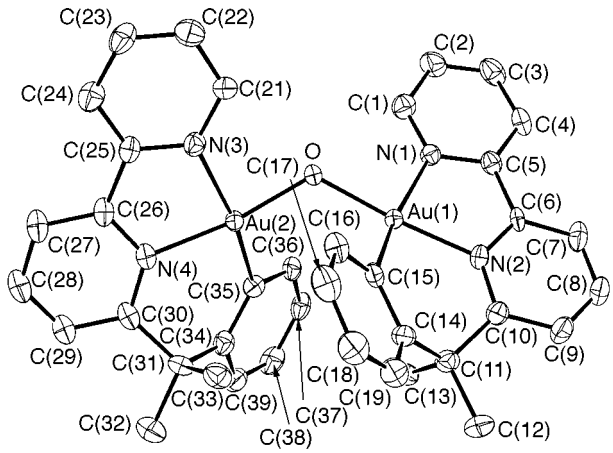

Fig. 1 Perspective view of the complex dication in **6**·MeCN. Selected interatomic distances (Å) and angles (°): Au(1)–O 1.971(5), Au(1)–N(1) 2.103(5), Au(1)–N(2) 2.029(5), Au(1)–C(15) 2.009(6), Au(2)–O 1.956(5), Au(2)–N(3) 2.096(5), Au(2)–N(4) 2.040(5), Au(2)–C(35) 2.009(6), Au(1)···Au(2) 3.422(1), Au(1)–O–Au(2) 121.3(2), O–Au(1)–N(1) 91.9(2), O–Au(1)–N(2) 172.7(2), O–Au(1)–C(15) 94.6(2), N(1)–Au(1)–N(2) 80.9(2), N(1)–Au(1)–C(15) 165.4(2), N(2)–Au(1)–C(15) 92.8(2), O–Au(2)–N(3) 90.5(2), O–Au(2)–N(4) 170.7(2), O–Au(2)–C(35) 96.8(2), N(3)–Au(2)–N(4) 80.3(2), N(3)–Au(2)–C(35) 165.9(2), N(4)–Au(2)–C(35) 92.1(2).

0.487(6) and 0.403(6) Å above these planes. The dihedral angle between these best planes is 58.0(1)°. The distortion is very similar to that found in the cation of complex **2**[5] where atom C(15) is displaced 0.417(6) Å out of the best plane of atoms Au, Cl(1), N(1) and N(2). The present Au(1)–O and Au(2)–O bond lengths, 1.971(5) and 1.956(5) Å, can be compared with the Au–O, 1.976(3), and Au–O′, 1.961(3) Å, distances found in *trans*-$[Au_2\{N_2C_{10}H_7(CH_2CMe_3)\text{-}6\}_2(\mu\text{-}O)_2]^{2+}$,[4] The Au–N and Au–C bond lengths are very similar to the corresponding distances found in **2**, *i.e.* Au–N(1) 2.121(5), Au–N(2) 2.009(4), and Au–C(15) 2.009(6) Å. As previously observed in **2**, in the present cation the six-membered metallacycles are in boat conformations, and one of the hydrogen atoms of the Me groups in pseudo-axial position is rather close to the respective gold atom: Au(1)···H(131) 2.70 and Au(2)···H(331) also 2.70 Å; the corresponding Au···H separation in**2** is 2.62 Å. The Au(1)–O–Au(2) angle is 121.3(2)° and the distance Au(1)···Au(2) 3.422(1) Å, a distance too long to be considered bonding although slightly shorter than the sum of the estimated van der Waals radii (3.60 Å).[8]

We thank the MURST (40%) and CNR for financial support.

Notes and references

† Complex **3** has been described in ref. 5. It was obtained from the reaction of complex **1** with $AgBF_4$ in refluxing acetone; under these conditions complex **5** was not isolated.

‡ Reactions of compounds **1** and **2** with $AgBF_4$: to a solution of **1** (0.289 g, 0.5 mmol) in acetone (20 cm^3) was added a solution of $AgBF_4$ (0.097 g, 0.5 mmol) in acetone (10 cm^3): a precipitate of AgCl was formed immediately. The resulting mixture was stirred for 24 h at room temperature and then filtered off. The solution was evaporated to dryness and the residue was extracted with $CHCl_3$ (3 × 10 cm^3). The filtered chloroform solution was concentrated to small volume and diethyl ether was added to give a whitish precipitate of compound **3** (0.120 g). The residue insoluble in $CHCl_3$ was dissolved in CH_2Cl_2, filtered and concentrated to small volume. Addition of diethyl ether gave a white precipitate of compound **5** (0.080 g).

Compounds **4** and **6** were obtained similarly from **2** (0.222 g, 0.37 mmol). Complex **4** was recrystallized from acetone–diethyl ether to give the analytical sample (0.091 g). At variance with complex **5**, complex **6** is insoluble in acetone so it was abstracted with MeCN from the insoluble product containing AgCl, the filtered solution was concentrated to small volume and diethyl ether added to give a white precipitate of **6** (0.098 g).

§ *Crystal data* for **6**·MeCN: $C_{40}H_{37}Au_2B_2F_8N_5O$, M = 1171.3, monoclinic, space group *Cc* (no. 9) (after refinement), a = 12.744(2), b = 22.309(3), c = 14.062(1) Å, β = 96.72(1)°, U = 3970.4(9) $Å^3$, Z = 4, D_c = 1.959 g cm^{-3}, μ = 74.4 cm^{-1}, $F(000)$ = 2240. Reflections measured 23 557, independent (Friedel pairs not merged) 9339 with R_{int} = 0.033. Empirical absorption correction, SADABS (T_{max} = 1.00, T_{min} = 0.66). Final R_2 (F^2, all reflections) = 0.044, R_{2w} = 0.062, conventional R_1 = 0.032 for 506 parameters. For the inverted structure, final R_2 = 0.047, R_{2w} = 0.071. Siemens SMART CCD area-detector, Mo-Kα radiation (λ = 0.710 73 Å), ω scan mode, θ_{min} = 3°, θ_{max} = 26°. Structure solved by Patterson and Fourier methods and refined by full-matrix least squares with anisotropic thermal parameters for cation and anions. Cation hydrogen atoms placed in calculated positions, acetonitrile hydrogen atoms ignored. Program used was Personal SDP on a PC-486 computer. An attempt to refine the structure in space group *C*2/*c* was unsuccessful (many thermal parameters of cation atoms were non-positive, heavy disorder was introduced for anions and MeCN with occupancy factors of 0.5, final R_1 was 0.12). A remarkable Mo catalyst for olefin metathesis: hexagonal mesoporous silica-supported molybdenum oxide (MoO_3/HMS)

Tooru Ookoshi and Makoto Onaka*

Department of Chemistry, College of Arts and Sciences, The University of Tokyo, Komaba, Meguro, Tokyo 153-8902, Japan. E-mail: conaka@komaba.ecc.u-tokyo.ac.jp

Received (in Cambridge, UK) 6th August 1998, Accepted 21st September 1998

Hexagonal mesoporous silica-supported molybdenum oxide exhibits much higher catalytic activity for the metathesis of oct-1-ene in the liquid phase, compared with MoO_3 on normal porous silica and MoO_3 on γ-alumina.

The application of mesoporous materials for various catalysts in organic reactions has been intensively investigated since a Japanese research group[1] and researchers at Mobil Oil[2] independently discovered mesoporous molecular sieves such as FSM-16 and MCM-41 with uniform pore openings in the range 2.0–10.0 nm as well as a tunnel pore structure. For example, acidic FSM-16 containing Al_2O_3 is an effective and recyclable solid acid promoter for *meso*-tetraarylporphyrin synthesis from the corresponding aromatic aldehydes and pyrrole.[3] It has also been shown that titanocene-derived MCM-41 shows high efficiency in the epoxidation of cyclohexene and more bulky cyclic olefins,[4] while *rac*-ethenebis(indenyl)zirconium dichloride-grafted MCM-41 provides highly isotactic polypropenes with a unique spherulite morphology.[5]

Supported molybdenum oxides have received much attention as solid metathesis catalysts because they can be practically used in industrial petrochemical processes such as the Shell higher olefin process for producing detergent-range olefins.[6] Their surface properties and catalytic activity are critically influenced by the oxide support, the surface molybdenum oxide content, the activation conditions, and the oxidation state of the molybdenum species. Supported molybdenum catalysts have generally been prepared in the following ways: (i) by impregnation of the support with molybdate solution;[7] (ii) by treatment of the support with $Mo(CO)_6$;[8] and (iii) by reaction of the support with π-allylmolybdenum compounds.[9]

This paper focuses on hexagonal mesoporous silica (HMS) in terms of developing a new silica support for molybdenum-based olefin metathesis catalysts, and demonstrates that HMS impregnated with molybdenum oxide (MoO_3/HMS) is an efficient catalyst for oct-1-ene metathesis [eqn. (1)].

$$2\ CH_2{=}CH(CH_2)_5CH_3 \xrightarrow{\text{Mo/HMS}} CH_3(CH_2)_5CH{=}CH(CH_2)_5CH_3 + CH_2{=}CH_2 \quad (1)$$

HMS was first prepared from tetraethylorthosilicate (TEOS) and primary amine as a templating agent.[10] The preparation of HMS has several advantages over that of MCM-41: (i) the use of more commercially available primary alkylamines as templating agents in place of expensive alkyltrimethylammonium halides; (ii) the applicability of shorter alkylamines as templating agents; and (iii) easier procedures for sol–gel processing than those for hydrothermal preparations for MCM-41. In work, three HMSs were synthesized by the use of three alkylamines with different alkyl chain lengths (C8, C12, C16).† HMS(C*n*) shall hereafter stand for the HMS obtained using C*n*-alkylamine.

MoO_3-supporting catalysts were prepared by impregnation of the HMSs with molybdate solution.‡ The HMS(C*n*) supports and MoO_3/HMS catalysts were characterized using powder X-ray diffraction and N_2 adsorption. As shown in Table 1, all MoO_3/HMS samples exhibited a single diffraction peak corresponding to a d_{100} spacing of > 3.0 nm,[10] and high BET surface areas of > 800 m^2 g^{-1}, proving that the MoO_3/HMSs were mainly composed of mesopores. No diffraction peaks intrinsic to MoO_3 crystallites were observed, indicating that MoO_3 was finely dispersed on the interior surface of mesoporous HMS.

As a control, MoO_3 was supported on commercially available silica, CARIACT Q-3 (Fuji Silysia Chemical), which has a narrow mesopore-size distribution centered at 3 nm, a specific surface area of 619 m^2 g^{-1}, a pore volume of 0.45 ml g^{-1}, and 75–500 μm particle sizes. The 3.5 and 7 wt% MoO_3/SiO_2 were applied to the metathesis of oct-1-ene in a similar way to MoO_3/HMS.

By the use of 7 wt% MoO_3/SiO_2 (0.15 g) and 3.5 wt% MoO_3/SiO_2 (0.3 g), the metathesis products were scarcely obtained at 323 K, as shown in Fig. 1. Surprisingly, MoO_3-supporting HMS catalysts could induce metathesis of oct-1-ene.§ The catalytic activity is critically dependent on the kind of alkylamine which functioned as templating agent in the formation of HMSs. In particular, MoO_3-supporting HMS(C8) prepared with the aid of octylamine had the highest activity. At the early stage of the metathesis, 7 wt% MoO_3/HMS(C12) and 7 wt% MoO_3/HMS(C16) converted oct-1-ene more rapidly than 7 wt% MoO_3/HMS(C8). However, after this stage on 7 wt% MoO_3/HMS(C12) and 7 wt% MoO_3/HMS(C16), the conversion

Table 1 Structural properties of HMS, MoO_3/HMS, and MoO_3/SiO_2

Mesoporous silica or Mo-supported catalyst	d_{100} Spacing/nm	Surface area/m^2 g^{-1}
HMS(C8)	3.0	1350
7 wt% MoO_3/HMS(C8)	3.0	854
HMS(C12)	3.5	1450
7 wt% MoO_3/HMS(C12)	3.4	1060
HMS(C16)	4.0	1230
7 wt% MoO_3/HMS(C16)	3.5	844
SiO_2[a]	—	619
7 wt% MoO_3/SiO_2[a]	—	514
3.5 wt% MoO_3/SiO_2[a]	—	563

[a] CARIACT Q-3.

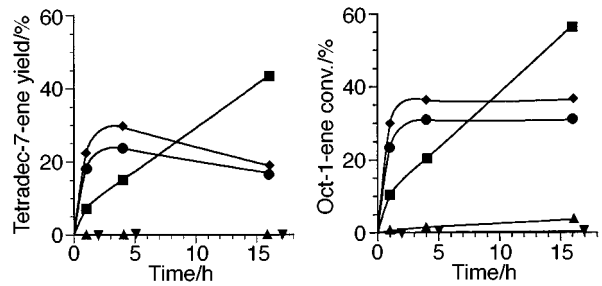

Fig. 1 Metathesis of oct-1-ene on MoO_3/mesoporous silica: ■ 7 wt% MoO_3/HMS(C8). ● 7 wt % MoO_3/HMS(C12), ◆ 7 wt% MoO_3/HMS(C16), ▲ 7 wt% MoO_3/SiO_2 (CARIACT Q-3), ▼ 3.5 wt% MoO_3/SiO_2 (CARIACT Q-3).

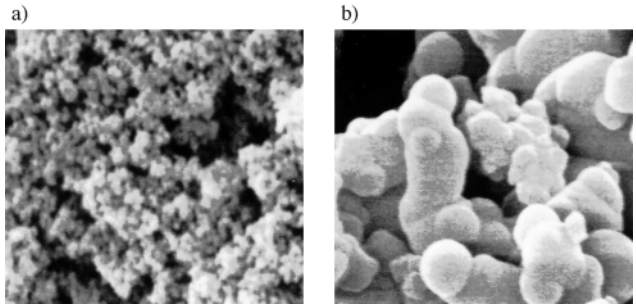

Fig. 2 SEM micrographs of (a) HMS(C8) and (b) HMS(C12) (scale: 30 mm = 1.5 μm).

reached the highest limit owing to the deactivation of the catalysts, and the yield of tetradec-7-ene and the selectivity to tetradec-7-ene decreased [7 wt% MoO_3/HMS(C12), yield: 23% (at 4 h), 17% (at 16 h), selectivity: 75% (at 4 h), 55% (at 16 h); 7 wt% MoO_3/HMS(C16), yield: 29% (at 4 h), 19% (at 16 h), selectivity: 81% (at 4 h), 52% (at 16 h)] due to the fact that the olefinic products gradually decomposed when in contact with the catalysts. In contrast, on 7 wt% MoO_3/HMS(C8), the yield of tetradec-7-ene steadily increased from 14% (at 4 h) to 44% (at 16 h) while maintaining high tetradec-7-ene selectivity [74% (4 h), 77% (at 16 h)], indicating that the metathesis product, tetradec-7-ene,¶ did not undergo further metathesis, polymerization, isomerization, or degradation on the catalyst. In this case, the products other than tetradec-7-ene are mainly highly polymerized products from oct-1-ene.

The SEMs in Fig. 2 of HMS(C8) and HMS(C12) indicate that HMS(C8) is made up of small silica particles of < 50 nm in diameter, while HMS(C12) is spherical silica of 200–700 nm. The shape and size of HMS(C16) (not shown in Fig. 2) are almost the same as those of HMS(C12). Based on the powder X-ray and SEM analysis, HMS(8) has not only smaller pore diameter, but also shorter pore length than HMS(12) and HMS(16). Therefore, it is supposed that at the initial stage of the metathesis (in Fig. 1), MoO_3/HMS(12) and MoO_3/HMS(16) showed higher conversions of oct-1-ene owing to easier passage of the olefin in the wider pores, but MoO_3/HMS(8) was suffering from less deactivation of the Mo sites or less blockage of the pores by polymeric side-products owing to the shorter channel structure, leading to retention of the high yield and high selectivity of the metathesis product.

There are also distinct differences in the catalytic activities on olefin metathesis between MoO_3-supporting HMS and normal silica. Although the reasons why the MoO_3/HMS shows much higher catalytic performance have yet to be elucidated, it is likely that silica with hexagonal channel-type pores is adequate for fixing finely dispersed molybdenum oxides and for stabilizing the molybdenum species in the oxidation state which is essential to the metathesis catalysis. Disordered normal silica could not play such a role.

Silica-supported molybdenum catalysts are normally activated by cocatalysts such as tetraalkyltin[11] or by photoreduction.[12] Neither the presence of such volatile and poisonous cocatalysts nor the photoactivation process is necessary for the MoO_3/HMS system to show high catalytic performance.

MoO_3/HMS(C8) was also compared not only with traditional Al_2O_3-supported[13] molybdenum catalyst (MoO_3/Al_2O_3)[14] but also with MoO_3/Al_2O_3 modified with CoO[14] or K_2O[15] in the metathesis of oct-1-ene at 323 K.[16] In the light of the yield of tetradec-7-ene as well as the selectivity to tetradec-7-ene, 7 wt% MoO_3/HMS(C8) is much superior to 7 wt% MoO_3/Al_2O_3 [yield: 3.8% (at 4 h), 12.5% (at 16 h), selectivity: 35% (at 4 h), 35% (at 16 h)], 7 wt% MoO_3/2 wt% CoO/Al_2O_3 [yield: 4.9% (at 3 h), 3.4% (at 16 h), selectivity: 52% (at 3 h), 27% (at 16 h)], and 7 wt% MoO_3/0.3 wt% K_2O/Al_2O_3 [yield: 3.6% (at 3 h), 4.5% (at 16 h), selectivity: 51% (at 3 h), 51% (at 16 h)].

In conclusion, MoO_3-supporting hexagonal mesoporous silica which was prepared in the sol–gel reaction directed by relatively short alkylamine shows remarkable catalysis in oct-1-ene metathesis in the liquid phase under mild conditions. The interior properties of hexagonal mesoporous silica are quite different from those of normal porous silica and γ-alumina, hence HMSs can be expected to work as effective, new supports for heterogeneous metal-catalyzed reactions.

Notes and references

† Under vigorous stirring, TEOS (100 mmol) was added to a mixture of ethanol (650 mmol), deionized water (3000 mmol) and *n*-octylamine (25 mmol). The resulting mixture was aged by stirring for 48 h at room temperature. Then, the resulting gel was filtered, washed with ethanol, dried *in vacuo* at 393 K, and calcined at 873 K for 4 h in dry air. When *n*-dodecylamine and *n*-hexadecylamine were used as templating agents, the molar compositions of TEOS : amine : EtOH : H_2O were 1.0 : 0.25 : 8.5 : 28.4 and 1.0 : 0.3 : 14 : 23, respectively.

‡ A representative preparation procedure for the 7 wt% MoO_3/HMS catalyst is given: HMS (1.0 g) was kept in contact with saturated steam in a desiccator for 12 h. To the wet HMS was added an aqueous solution (5 ml) of $(NH_4)_6Mo_7O_{24}\cdot 4H_2O$ (0.0923 g). The mixture was stirred gently for 10 min, and dried to almost complete dryness at room temperature under a stream of dry N_2. Five ml of deionized water was added to the supported HMS. The mixture was stirred for 10 min, and exposed again to a N_2 stream reaching almost complete dryness. Then, the catalyst was dried further at 393 K for 2 h under reduced pressure of 1 mmHg.

§ A representative metathesis reaction was performed as follows: the MoO_3/HMS catalyst (0.15 g), which had been predried at 873 K for 2 h in dry air, was weighed and placed in a 20 ml round-bottomed Pyrex flask. The Mo catalyst contained in the flask was again treated at 773 K under reduced pressure of 0.6 mmHg in a tubular electric furnace. After cooling, to the catalyst was added oct-1-ene (3.5 mmol) in dry *n*-heptane (5 ml), and the mixture was stirred at 323 K under a dry N_2 stream. After a specified time, the solid catalyst was filtered off, and the organic products were collected and analyzed by GC using an internal standard of *n*-decane. Tetradec-7-ene was isolated from the organic products through distillation on a Kugelrohr apparatus at 373 K bath temperature under 3 mmHg.

¶ When the distilled products from the metathesis of oct-1-ene on 7 wt% MoO_3/HMS(C8) were oxidatively cleaved upon treatment with $RuCl_3$ and $NaIO_4$, no aldehydes other than heptanal were detected. This result indicates that during the metathesis, no isomerization of the C=C bonds in the olefinic substrates or products took place.

Received (in Cambridge, UK), 17th August 1998, Accepted 30th September 1998

The compound [Hg(*o*-$C_6H_4PPh_2$)$_2$] behaves as a *trans*-spanning bidentate ditertiary phosphine in its $PdCl_2$ complex, the two metal atoms being forced into close contact; the palladium(0) complex [Pd{(*o*-$Ph_2PC_6H_4$)$_2$Hg}$_2$] undergoes reductive elimination on heating with formation of the coupled product *o*-$Ph_2PC_6H_4C_6H_4PPh_2$-*o*.

The formation of transition metal complexes containing the four-membered ring M(*o*-$C_6H_4PPh_2$) by *ortho*-metallation (C–H activation) of coordinated triphenylphosphine is well established.[1] In some cases dinuclear or polynuclear species containing bridging *o*-$C_6H_4PPh_2$[2–5] or *o*-$C_6H_4P(Ph)CH_2CH_2PPh_2$[6,7] units can be generated from coordinated PPh_3 or $Ph_2PCH_2CH_2PPh_2$, respectively. Lahuerta *et al*. have reported that the carbon–halogen bonds of *o*-$Ph_2PC_6H_4X$ (X = Cl, Br) can undergo oxidative addition to rhodium(I)[8] and palladium(0)[9] to give *o*-$C_6H_4PPh_2$ complexes of rhodium(III) and palladium(II), and we have shown that *trans*-metallation of *o*-$Ph_2PC_6H_4Li$ provides access to *o*-$C_6H_4PPh_2$ complexes of platinum[10] and gold.[11]

Aryl groups are readily transferred from mercury(II) to both divalent and zerovalent palladium and platinum;[12–14] reactions of this type have been used in the synthesis of cyclometallated N- and O-donor complexes.[15] We wondered if the method could be extended to *o*-$C_6H_4PPh_2$ complexes and report here some preliminary results.

The required bis(aryl)mercury(II), [Hg(*o*-$C_6H_4PPh_2$)$_2$] **1**, is obtained as a colourless solid in 75% yield from the reaction of *o*-$Ph_2PC_6H_4Li$ with $HgCl_2$ in a 2 : 1 molar ratio (Scheme 1).† Use of a 1 : 1 molar ratio gives mainly a poorly soluble, probably polymeric solid [HgCl(*o*-$C_6H_4PPh_2$)]$_n$ **2**, which disproportionates on heating with aqueous–ethanolic KCN to give **1**.

The small magnitude of ^3J(HgP) observed in the ^{31}P and ^{199}Hg NMR spectra of compound **1**‡ indicates that the phosphorus atoms are probably not coordinated; they readily add oxygen, sulfur and BH_3 to give the corresponding dioxide **3**, disulfide **4**, and bis(borane) adduct **5** (Scheme 1), and react with mercuric halides to form dinuclear complexes [HgX_2\{(*o*-$Ph_2PC_6H_4$)$_2$Hg\}] (X = Cl **6a**, Br **6b**) (Scheme 2).†‡ Compound **6a** is more soluble in organic solvents than its isomer **2**.

Coordination *via* phosphorus also takes precedence over aryl group transfer in the reactions of compound **1** with transition metal complexes. Thus, from [$PtCl_2$(cod)] or [$PtR_2(\mu\text{-}SEt_2)]_2$ (R = Me, Ph) colourless platinum(II) complexes of general formula [PtR_2\{(*o*-$Ph_2PC_6H_4$)$_2$Hg\}] (R = Cl **7**, Me **8**, Ph **9**) are obtained, whose Pt–P coupling constants (3624, 1802 and 1592 Hz, respectively) indicate that **1** behaves as a *cis*-bidentate ligand. Complexes **8** and **9** also show well-resolved ^{195}Pt–^{199}Hg coupling in their ^{199}Hg NMR spectra.‡ In contrast, a single-crystal X-ray diffraction study§ of the yellow complex [$PdCl_2$\{(*o*-$Ph_2PC_6H_4$)$_2$Hg\}] **10** isolated as a CH_2Cl_2 solvate from compound **1** and [$PdCl_2(SEt_2)_2$] shows the $PdCl_2$ unit to be coordinated in an only slightly distorted planar array by mutually *trans*-phosphorus atoms (Fig. 1). The coordination geometry about mercury is close to linear and the Pd–P, Pd–Cl and Hg–C distances are normal, but the atomic arrangement imposes a close contact between the metal centres, their separation [2.8797(8) Å] being only slightly greater than the sum of the covalent radii of Pd and Hg (2.77 Å). Similar distances have been reported in platinum(II) complexes that are believed to contain a $Pt^{II}\rightarrow Hg^{II}$ donor interaction,[16] *e.g.* [Pt\{$CH_2C_6H_4P$(*o*-MeC_6H_4)$_2$\}(S_2CNMe)HgI(μ-I)]$_2$ [2.768(1) Å].[17] In its geometrical features ligand **1** resembles ferrocene-1,1′-diylbis(diphenylphosphine), Fe(η^5-$C_5H_4PPh_2$)$_2$ **11**, which behaves as a *trans*-spanning ligand in the complex [Pd(PPh_3)\{(η^5-$C_5H_4PPh_2$)$_2$Fe\}](BF_4)$_2$.[18] In contrast to **1**, however, **11** adopts a *cis*-bidentate mode in its $PdCl_2$ complex.[19]

The initially formed P-donor complexes of ligand **1** can behave as precursors either for coupling or transfer of *o*-$C_6H_4PPh_2$ groups. For example, reaction of [Pd(dba)$_2$] with **1** in a 1 : 2 molar ratio gives an orange, crystalline, trimetallic palladium(0)–mercury(II) complex [Pd\{(*o*-$Ph_2PC_6H_4$)$_2$Hg\}$_2$] **12**, whose precise structure as a solid and in solution remains to

be established. In refluxing toluene, complex **12** eliminates metallic palladium and mercury, and the coupled product 2,2′-biphenyldiylbis(diphenylphosphine), *o*-$Ph_2PC_6H_4C_6H_4PPh_2$-*o* **13**,[11,20] can be isolated in 60% yield. A similar C–C bond coupling by reductive elimination occurs in the isomerisation of the digold(II) complexes $Au_2X_2(\mu$-*o*-$C_6H_4PPh_2)_2$ (X = Cl, Br, I) and Au_2X_2(*o*-$Ph_2PC_6H_4C_6H_4PPh_2$-*o*),[11] although in this case the ligand remains in the coordination sphere. Reaction of **1** with *trans*-[$PtHCl(PPr^i_3)_2$] in hot toluene gives the monomeric cycloplatinated complex [$PtCl$(*o*-$C_6H_4PPh_2)(PPr^i_3)$] **14**, again with elimination of mercury; the presumed P-donor precursor cannot be detected or isolated.

The coordination chemistry of [Hg(*o*-$C_6H_4PPh_2)_2$] and transfer reactions of *o*-$C_6H_4PPh_2$ to other transition metals are being investigated. We thank the Universidad Pública de Navarra (Spain) for a postdoctoral grant to M. C.

Received (in Cambridge) 2nd September 1998, Accepted 2nd October 1998

A novel, symmetrical trinuclear copper(I)–copper(II) complex, bis[bis(triphenylphosphine)copper(I)][bis(thiosalicylate)copper(II)], [{Cu(PPh$_3$)$_2$}$_2${Cu(C$_7$H$_4$O$_2$S)$_2$}], has been prepared by anodic dissolution of copper into a solution of triphenylphosphine and thiosalicylic acid in acetonitrile and characterized by single crystal X-ray structure determination as its acetonitrile solvate; characterized also is the 1 : 3 copper(I) complex, [tris(triphenylphosphine)(thiosalicylic acid-*S*)copper(I)], formed as an intermediate in the electrosynthesis.

In our ongoing studies on the synthesis, structural and spectroscopic characterization of the adducts of triphenylphosphine with copper(I) carboxylates, [Cu(PPh$_3$)$_n$(O$_2$CR)],[1,2] we have been investigating the feasibility of preparing the compounds by anodic dissolution of copper into an acetonitrile solution of RCO$_2$H and PPh$_3$ with concomitant reduction of the acidic protons to hydrogen gas at a platinum cathode [eqn. (1)].

$$\mathrm{Cu} + n\mathrm{PPh_3} + \mathrm{RCO_2H} \rightarrow [\mathrm{Cu(PPh_3)}_n\mathrm{(O_2CR)}] + 1/2\mathrm{H_2} \quad (1)$$

As part of this work, we recently turned our attention to the reaction with thiosalicylic acid in order to ascertain the effects on the products obtained due to the presence of the thiol group *ortho* to the carboxylic acid. Initial electrolysis† resulted in the deposition of colourless crystalline material which was shown by X-ray structure determination‡ to be the acetonitrile solvated [tris(triphenylphosphine)(thiosalicylic acid-*S*)copper(I)] complex [Cu(PPh$_3$)$_3$(C$_7$H$_5$O$_2$S)]·MeCN **1** with a four-coordinate distorted tetrahedral CuP$_3$S copper coordination sphere (Fig. 1).

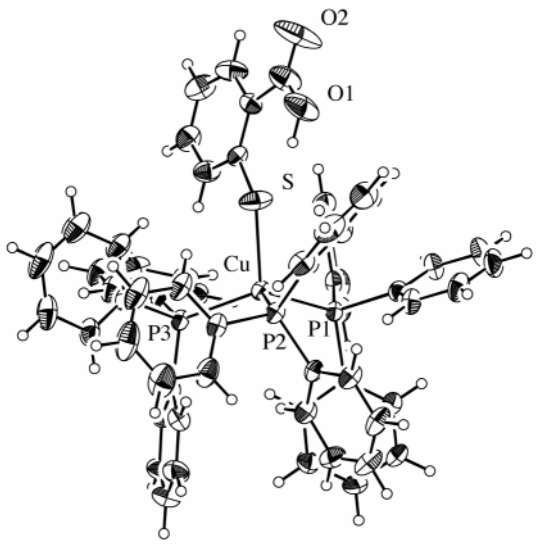

Fig. 1 View of the molecular structure of **1**. Copper coordination sphere: Cu–S 2.369(1), Cu–P(n) 2.367(2), 2.345(2), 2.362(2) Å; S–Cu–P(n) 110.71(7), 96.06(5), 108.94(8)°, P(*n*)–Cu–P(*n* + 1) 109.68(6), 112.02(6), 117.37(5)°. Carboxylate: C–O(*n*) 1.34(1), 1.197(8) Å.

In this complex the carboxylic acid proton forms a strong internal hydrogen bond (O–H···S 1.91 Å) between the oxygen and sulfur atoms. This result is reflected in the IR spectrum of the complex which shows a broad absorption band centred at 2540 cm^{-1} and ascribed to the hydrogen-bonded O–H stretching vibration, together with a moderately strong carbonyl vibration at 1703 cm^{-1}. Continued electrolysis resulted in change in colour of the solution from pale yellow to pale green and then to a darker green during which time crystals of **1** redissolved and new deep green–black crystals slowly formed in their place. The broad absorption band at 2540 cm^{-1} was absent from the IR spectrum of this compound and the band at 1703 cm^{-1} was replaced by two bands at 1620 and 1434 cm^{-1} assignable to asymmetric and symmetric carboxylate stretching vibrations with the difference in wavenumbers indicative of unidentate coordination.[3] This complex was shown by X-ray structure determination to be the acetonitrile solvate of a trinuclear copper(I)–copper(II) complex, bis[bis(triphenylphosphine)copper(I)] [bis(thiosalicylate-*O*, *S*)copper(II)] [{Cu(PPh$_3$)$_2$}$_2${Cu(C$_7$H$_4$O$_2$S)$_2$}]·MeCN **2**. Here we report a description of the structural characteristics of this unusual and interesting compound.

The structure determination shows **2** to crystallize as discrete neutral molecules with one acetonitrile molecule of solvation. Views of the molecule in Figs. 2(a) and 2(b) reveal a symmetrical cylindrical topology built about a central axis defined by the three copper atoms with approximately $D_{\infty h}$ local symmetry. The stoichiometry of the molecule and the coordination geometries about the coppers are consistent with oxidation states of +2 for the central and +1 for the two peripheral coppers. The phenyl groups on the triphenylphosphine and thiosalicylate ligands form a hydrophobic surface to the molecule which encapsulates the P$_2$CuO$_2$CuS$_2$CuP$_2$ core. The respective CuP$_2$, CuO$_2$, CuS$_2$ and CuP$_2$ planes spiral around the central copper axis with dihedral angles that appear to be determined primarily by C–H···π interactions between the phenyl groups [Fig. 2(b)]. The dianionic thiosalicylate ligands coordinate to the central copper(II) atom as bidentate ligands to give a *cis* S$_2$O$_2$ distorted square planar coordination sphere (Fig. 3). The S–Cu–S, O–Cu–O and *cis* S–Cu–O angles range from 86.2(3) to 99.7(1)° while the *trans* S–Cu–O angles are 148.1(2) and 149.0(2)°. The sulfur and oxygen atoms also function as bridging ligands between the copper(II) and copper(I) sites with the Cu(II)–S and Cu(II)–O bonds both *ca.* 0.2 Å shorter than the Cu(I)–S and Cu(I)–O bonds. The PPh$_3$ ligands coordinated to the copper(I) sites each adopt a distorted three-bladed propellor type conformation of the same chirality with each pair of ligands eclipsed with respect to each other and related by an approximate twofold rotation axis bisecting the P–Cu–P angle. We have shown previously that the transition from oxygen donor atoms in [Cu(PPh$_3$)$_2$(O$_2$CPh)] to sulfur donor atoms in the isomorphous [Cu(PPh$_3$)$_2$(S$_2$CPh)] complex results in an increase in the Cu–P distances and a decrease in the P–Cu–P angle, these variations being justified on the grounds of the greater covalency of Cu–S bonds compared to Cu–O bonds.[2] No such trends in the Cu–P bond lengths are apparent for the

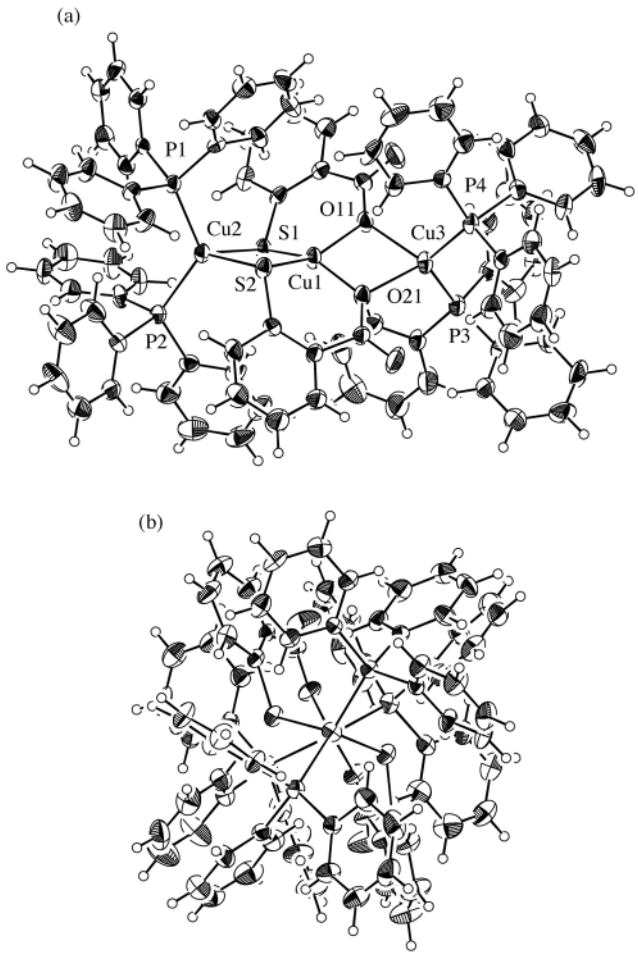

Fig. 2 View of the molecular structure of **2** (a) along and (b) down the Cu···Cu···Cu axis. Copper (II) coordination sphere: Cu(1)–O(*n*1) 1.97(1), 1.94(1) Å, Cu(1)–S(*n*) 2.196(3), 2.208(3) Å, S(1)–Cu(1)–S(2) 99.7(1)°, O(11)–Cu–O(21) 86.2(3)°; S-Cu(1)–O 148.1(2), 149.0(2), 96.4(2) and 93.6(2)°. present molecule while the P–Cu–P angle of 125.0(1)° for the P_2CuS_2 site is, in fact, greater than the value of 120.4(1)° for the P_2CuO_2 site.

Compound **2** is a new and unusual member of an interesting class of polynuclear adducts between $[M(PPh_3)_2]^+$ (M = Cu, Ag) and anionic metal complexes that were prepared over 20 years ago by Coucouvanis and coworkers by the reaction of $[MX(PPh_3)_2]$ with salts of dianionic metal dithiolate complexes (*e.g.* refs. 4 and 5). The electrochemical synthesis used in the present study provides a new, uncomplicated approach to the preparation of this type of complex with the advantage that prior

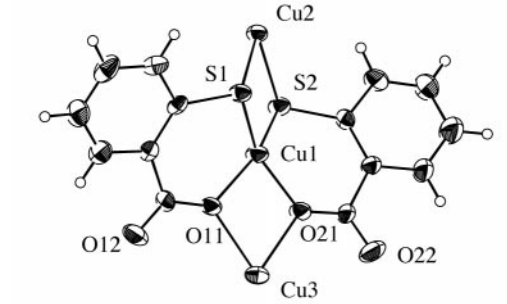

Fig. 3 View of the coordination sphere about the copper(II) atom.

synthesis of the parent dianionic copper(II) complex is not required. In addition, the formation of crystalline products from the reaction mixtures is favoured by the very slow rate of dissolution of the metal as a result of the inherently low concentration of ionic species in the solution.

Notes and references

† *Experimental details*: electrosynthesis. A copper anode and platinum coil cathode were inserted into a solution of 0.154 g (0.001 mol) of thiosalicylic acid (TSA) and 1.05 g (0.004 mol) of triphenylphosphine in 80 ml acetonitrile. Potentiostatic oxidation of the copper anode at 5 V resulted in the colourless solution initially turning a pale and then deeper shade of yellow. After 6–7 h compound **1** crystallized from the solution as large colourless blocky crystals (yield 0.6 g). After electrolysis for *ca.* 15 h, the solution changed to pale green and then to a darker green. During this time some of the crystals of **1** re-dissolved and deep green–black crystalline material (**2**) slowly formed (yield 0.2 g). Repetition of the experiment with PPh_3 to TSA mole ratios ranging from 2 : 1 to 5 : 1 resulted in the synthesis proceeding as above with only variations in the amount of **1** isolated.

Received (in Liverpool, UK) 29th July 1998, Accepted 22nd September 1998

The preparation of allylic zinc reagents using the fragmentation of sterically hindered tertiary homoallylic alcohols is described

The development and use of allylic organometallic reagents in synthesis has been an underlying theme of modern organic synthesis.[1,2] Despite the plethora of methods currently available for the introduction of allylic moieties into complex molecules several problems remain, most notably that of cross contamination of the product with the Wurtz coupling adduct. Secondly, there are the problems associated with generating stoichiometric amounts of inorganic salts and thirdly, the functionally group tolerance of the reagent due to the highly polar nature of most carbon–metal bonds.

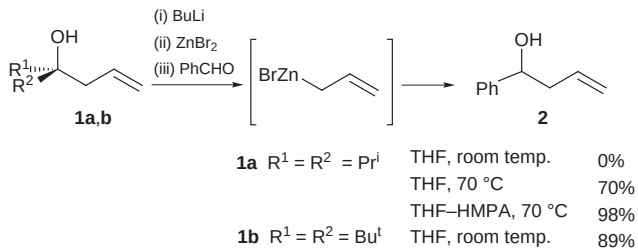
There are several reports in the literature that the addition of allylic organometallics to electrophiles is reversible;[3–6] in particular one report by Miginiac has inspired us.[5a] Therefore it was rationalised that generation of a zinc alkoxide of a sterically hindered tertiary allyl alcohol would result in decomposition to the parent ketone and an allyl zinc reagent, which in the presence of a suitable electrophile could be utilised synthetically. Recently, Nokami has described a related allyl transfer reaction of homoallylic alcohols catalysed by tin(II) triflate which has caused us to disclose our results.[7]

Accordingly a series of tertiary homallylic alcohols **1a**,**b** were prepared. Treatment of the tertiary alcohol bearing two isopropyl groups **1a** first with Bu^{n}Li and then with zinc bromide gave the zinc alkoxide. At room temperature no migration of the allyl group was observed in the presence of benzaldehyde, but after heating at reflux for 6 h the benzylic alcohol **2** could be isolated in 70% yield (Scheme 1). Clearly, as hypothesised the zinc alkoxide had fragmented *in situ* to give an allyl zinc reagent. The reaction could be improved by the addition of a polar co-solvent; after 6 h in a THF–HMPA mixture 98% of the secondary alcohol **2** was observed. Increasing the steric congestion around the zinc alkoxide also resulted in a faster reaction; by using two *tert*-butyl groups **1b** the migration was complete within 1 h at room temperature, resulting in 89% isolated yield of the secondary alcohol **2**.† In both cases, control experiments with lithium and magnesium alkoxides in the absence of zinc salts showed no migration of the allyl group.

Inspired by this reaction the compatibility of these reagents with a range of aldehydes and ketones was investigated (Table 1). Treatment of the zinc alkoxide with heptanal gave dec-1-en-4-ol in 83% yield (entry 1), whilst an α,β-unsaturated aldehyde was also tolerated (entry 2), giving exclusively the 1,2-addition product in 84% yield. In a similar manner, aldehydes bearing an α-substituent reacted well, within 2 h at room temperature, to give the desired allylated product in good yields (entries 3 and 4). Transfer of the allyl group to a ketone required slightly longer reaction times, the reaction usually taking between 2 and 4 h at room temperature to go to completion. Reaction with cyclohexanone gave the allylated adduct in 82% (entry 5), while α,β-unsaturated ketones gave the desired products in reasonable yields (entries 6 and 7). α-Tetralone also reacted well to give the desired material in excellent yield (entry 8).

The reaction is not just limited to carbonyl compounds. It was discovered that nitriles also react well to give β,γ-unsaturated ketones in good yields (Scheme 2). Generation of the zinc alkoxide as previously and addition of the nitrile generates the corresponding imine, which upon hydrolysis liberates the ketones **3a–c** in good yield; both aromatic and enolisable nitriles reacted well.

β,γ-Unsaturated amines can also be prepared using these masked organozinc reagents through reaction with imines (Scheme 3). Addition of Bu^{n}Li and then zinc chloride to a solution of the tertiary allyl alcohol **1b** in THF generates the



Scheme 1

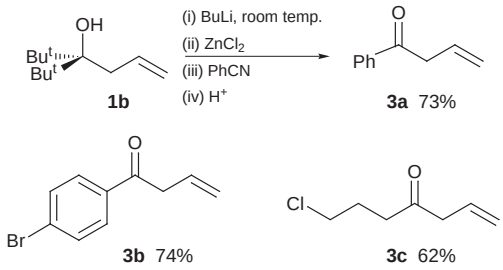
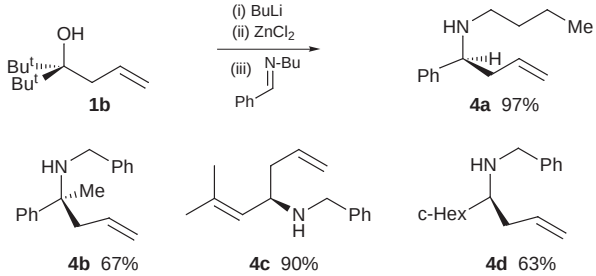


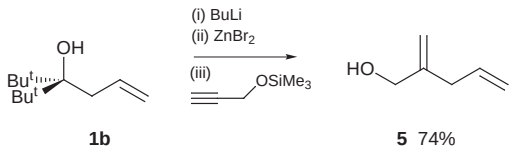
Scheme 2



Scheme 3

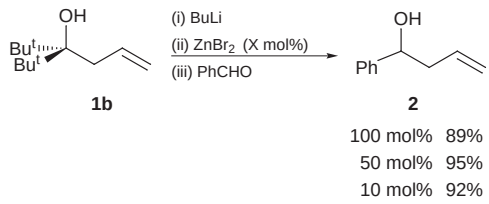
zinc alkoxide that fragments in a retro-allylation reaction to give the allylzinc reagent *in situ*; in turn this reacts with benzylidenebutylamine to give the secondary amine **4a** in 97% yield. Reaction with benzyl(1-phenylethylidene)amine generates **4b** in 67% yield, whilst the α,β-unsaturated imine, benzyl(3-methylbut-2-enylidene)amine, reacts to give amine **4c** in 90% yield. The α-substituted imine benzyl(cyclohexyl)methyleneamine also reacted in 63% yield to give **4d**.

Carbozincation reactions are also possible using this approach with masked organozinc reagents, indeed reaction of the zinc alkoxide with trimethyl(prop-2-ynyloxy)silane at room temperature gives, within 2 h, the 1,4-diene **5** in 74% yield after hydrolysis (Scheme 4).



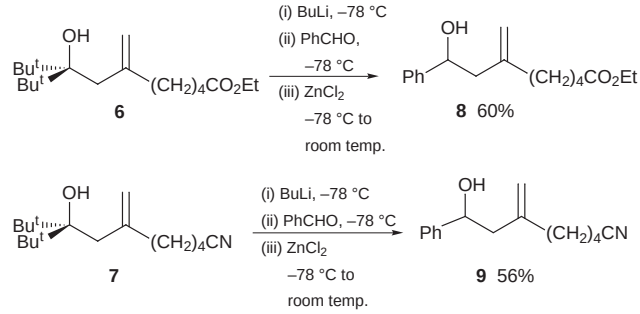
Scheme 4

Although we had eliminated the problems associated with Wurtz coupling, our reagents were not environmentally friendly, generating 1 equiv. of zinc waste; consequently we were delighted to discover that the reaction could be made to function using catalytic amounts of zinc salts—reduction to 50 mol% gave the benzylic alcohol **2** in 95% yield after 6 h, whilst further reductions to 10 mol% gave no loss in efficiency, with the secondary alcohol being isolated in 92%, again within 6 h (Scheme 5). However, all efforts to make the reaction catalytic in base have to date been unsuccessful.



Scheme 5

A further advantage with this concept is the ability of these reagents to tolerate functional groups, in a similar manner to other organozinc reagents.[8] The tertiary alcohols **6** and **7** were



Scheme 6

prepared[9] and treated with BuLi, benzaldehyde and zinc chloride at −78 °C, followed by warming the reaction mixture to room temperature. This gave the desired hydroxy ester **8** and hydroxy nitrile **9** in 60 and 56% yields, respectively.

In summary, we have developed a method for the generation of allylic organozinc reagents by exploiting a retro-addition reaction. This method avoids entirely the problem of Wurtz coupling during formation of the organometallic reagent. The reaction is also very general and addition to a range of electrophiles is possible. The mild conditions associated with this reaction also make it compatible with a range of functional groups and finally the reaction has been shown to be catalytic in zinc salts.[10]

† Typical procedure: Preparation of 1-phenylbut-3-en-1-ol **2**: A solution of Bu^{n}Li (2.71 mmol) in pentane (1.40 M, 1.94 ml) was added dropwise over 2 min to a stirred solution of 3-*tert*-butyl-2,2-dimethylhex-5-en-3-ol **1b** (500 mg, 2.71 mmol) in THF (4 ml) at 0 °C under argon. The resulting solution was then stirred for 15 min and a solution of zinc bromide (610 mg, 2.71 mmol) in THF (2 ml) was added, followed by benzaldehyde (275 μl, 2.71 mmol). The reaction was allowed to warm to room temperature and stirred for 1 h. Saturated aq. NH_4Cl solution (15 ml) was added and the resulting mixture was extracted with Et_2O (3 × 15 ml). The combined organic extracts were washed with brine (10 ml), dried and concentrated under reduced pressure to give a crude residue, which was purified by column chromatography on silica using 15% Et_2O–hexanes as eluent to give the desired alcohol **2** (356 mg, 89%) as a colourless oil.

Highly diastereoselective reactions using masked allylic zinc reagents

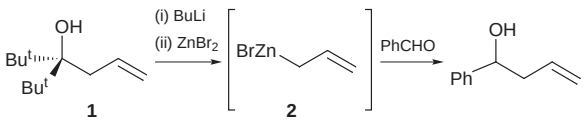
Philip Jones and Paul Knochel*

Fachbereich Chemie der Universität, Hans-Meerwein Strasse, D-35032 Marburg, Germany.
E-mail: knochel@ps1515.chemie.uni-marburg.de

Received (in Liverpool, UK) 29th July 1998, Accepted 22nd September 1998

Substituted allylic organozinc reagents have been prepared using a novel fragmentation reaction; the resulting allylic zinc species are configurationally stable and give excellent regio- and diastereo-selectivities.

We have recently documented an entirely new approach for the generation of allylic zinc reagents based on a retro-allylation, an allylation sequence starting from the sterically hindered tertiary alcohol **1** (Scheme 1).[1,2] Generation of the zinc alkoxide of this homoallylic alcohol results in fragmentation and formation of an allyl zinc reagent **2** *in situ*; this is itself able to react with a range of other electrophiles. This method avoids the problems associated with Wurtz coupling.



1 **2**

Scheme 1

Substituted allyl zinc reagents had previously been prepared by Tamura from allyl benzoates but with mixed results;[3] we hoped that our mild method would give improved selectivities.

Accordingly, the tertiary alcohol **3** bearing an α-methylallyl group was prepared (Scheme 2).[4] However, we were disappointed to find that upon deprotonation of this material at room temperature with BuLi a rapid isomerisation to the γ-substituted isomer **4** occurred.[5] Undeterred, the deprotonation was attempted at −78 °C, and we were pleased to find no isomerisation. Addition of benzaldehyde followed by a solution of zinc chloride gave within 1 h at −78 °C the benzylic alcohol **5** in 83% isolated yield.† More interestingly, the product was isolated as a 94:6 mixture of *anti*:*syn* diastereomers.[6] This reaction is in stark contrast to the addition of crotylzinc bromide to benzaldehyde, which gives approximately 1:1 mixtures of diastereomers.[7]

Inspired by this reaction, a range of aldehydes were screened (Fig. 1). Reaction of the homoallylic alcohol with cyclohexanecarbaldehyde gave the alcohol **6** in 84% yield, again with the *anti* diastereomer in excess (96:4). Similarly, reaction with 2-butylacrolein gave solely the product of 1,2-addition, giving the homoallylic alcohol **7** in 76% isolated yield as a 97:3 mixture of diastereomers. The reaction with 2-ethylbutyraldehyde and 1-naphthaldehyde gave the expected products **8** and **9** in 86 and 92% yields, respectively; in both cases only the

Fig. 1

anti-diastereomer was observed by ^{1}H and ^{13}C NMR spectroscopy. In all cases, none of the γ-substituted product was detected.

Similar results were obtained when we placed other substituents in the α-position. 3-(*tert*-Butyl)-2,2-dimethyl-4-ethylhex-5-en-3-ol **10** was prepared using identical chemistry as used in the preparation of homoallylic alcohol **3**.[4] This too was found to exhibit high levels of *anti*-selectivity. Reaction with BuLi, benzaldehyde and zinc chloride (Scheme 3) gave 2-ethyl-1-phenylbut-3-en-1-ol **11** in 91% as a 91:9 mixture of *anti*:*syn* isomers. Likewise, reaction with cyclohexanecarbaldehyde and 2-ethylbutyraldehyde gave rise to the homoallylic alcohols **12** and **13** in 83 and 81% yields, respectively, both solely as the *anti*-diastereomers.

Further synthetic investigation revealed that a benzyl group could easily be incorporated into the α-position of the homoallylic alcohol (Scheme 4). The precursor was readily prepared form 2, 2-dimethylhex-5-en-3-one **14** by deprotonation with LDA at −78 °C, followed by α-alkylation with BnBr in THF–HMPA in 65% yield. Subsequent reaction with Bu^{t}Li gave the required precursor **15** in 85% yield. As in all previous cases, deprotonation and reaction with benzaldehyde in the presence of zinc chloride gave the desired benzylic alcohol **16** in 89%, again with excellent diastereoselectivity (95:5). Aliphatic aldehydes also reacted well giving the homoallylic alcohols **17** and **18** in 88 and 80% yields, respectively.

Surprised by these results we were interested to investigate the outcome of placing substituents in the γ-position of the

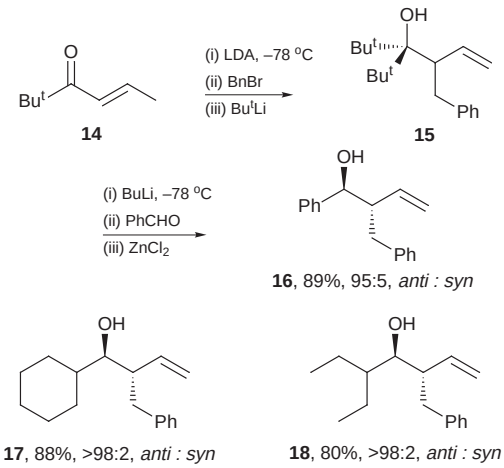
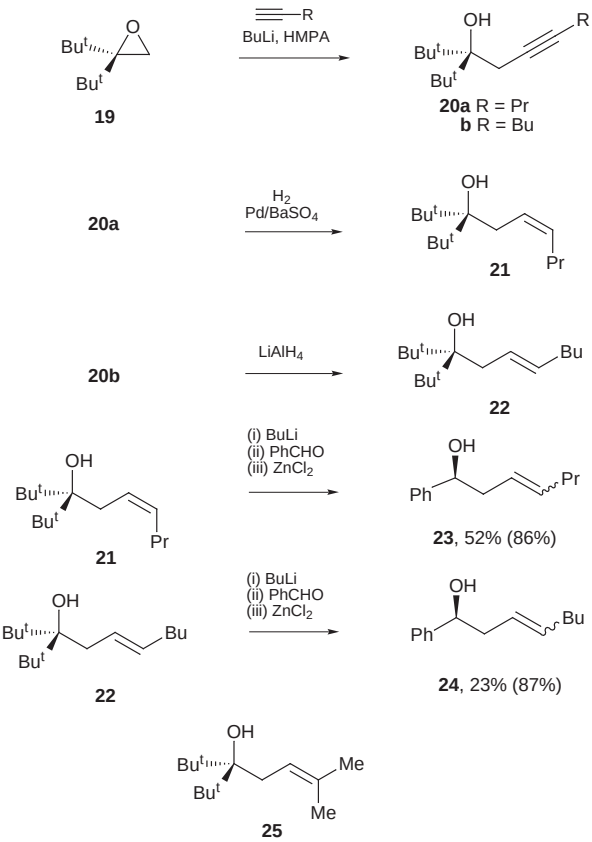
Scheme 3

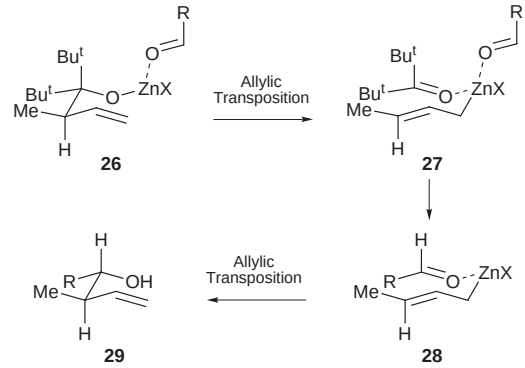


Scheme 4

allylic system. A new synthetic route needed to be adopted and oxirane **19** was prepared and opened with a variety of lithium acetylides to give the homopropargyl compounds **20a**,**b** in reasonable yields (84 and 65%) (Scheme 5). Hydrogenation with palladium on barium sulfate gave the *Z*-isomer **21** quantitatively, whilst treatment with $LiAlH_4$ gave the required *E*-isomer **22**. With these two compounds to hand the migration was investigated. The resulting zinc alkoxides were found to be less reactive. Whereas the α-substituted compounds migrated at −78 °C, these compounds required warming to room temperature before migration could be observed. With **21** migration occurred in 52% yield after 48 h (86% based on recovered starting material) to give the desired homoallylic alcohol **23**, while the *E*-isomer **22** gave the corresponding alcohol **24** in 23% yield after 12 h (87% based on recovered starting material). In both cases the products were isolated as 2:1 mixture of *Z*:*E* isomers. The γ-disubstituted compound **25** was also prepared; however, this compound proved to be stable and no migration was detected.



Scheme 5



Scheme 6

These results suggest a plausible mechanism involving a double allylic transposition. Generation of the zinc alkoxide of the alcohol **26** results in a cyclic six-membered intermediate where the zinc is complexed to the reacting carbonyl compound (Scheme 6). Allylic transposition gives rise to a crotylzinc reagent **27** complexed to the parent bis(*tert*-butyl) ketone and the reaction partner, the zinc reagent bearing solely a *trans*-configuration. At −78 °C this species is stable and undergoes no isomerisation.[8] Owing to the complexation of the reacting partner with the zinc, a new six-centred intermediate **28** is possible, whereby all the substituents lie in equatorial positions; allylic transposition then gives rise to the product **29**, predominately as the *anti*-diastereomer. This mechanism is supported by the unreactive nature of the γ-substituted isomer, whereby steric congestion prevents the first allylic transposition from occurring.

In summary, we have developed a novel method for the preparation of substituted allylic zinc reagents. This method is extremely selective, giving both excellent regiochemical selectivity and excellent diastereoselectivity. The method is extremely mild and avoids Wurtz coupling products.[9]

The authors thank the DFG (SFB 260 and Leibniz program) for generous financial support, and the Royal Society for an award (to P. J.) under the European Science Exchange Programme.

Facile oxidation of a carbaporphyrin at the internal carbon atom: synthesis of novel benzo[18]annulene ketals†

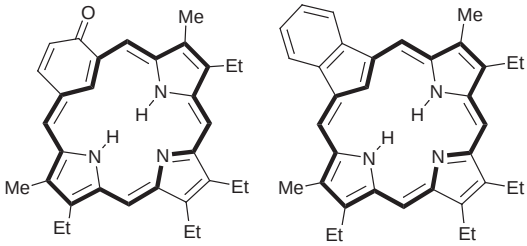
Michael J. Hayes, John D. Spence and Timothy D. Lash*

Department of Chemistry, Illinois State University, Normal, Illinois 61790-4160, USA. E-mail: tdlash@ilstu.edu

Received (in Corvallis, OR, USA) 10th August 1998, Accepted 25th September 1998

Treatment of benzocarbaporphyrin 2 with refluxing $FeCl_3$ in $CHCl_3$–alcohol mixtures leads to a remarkably selective oxidation at the interior carbon atom to produce dialkoxy products 5; these species show potentially valuable long wavelength absorptions in their UV–VIS spectra.

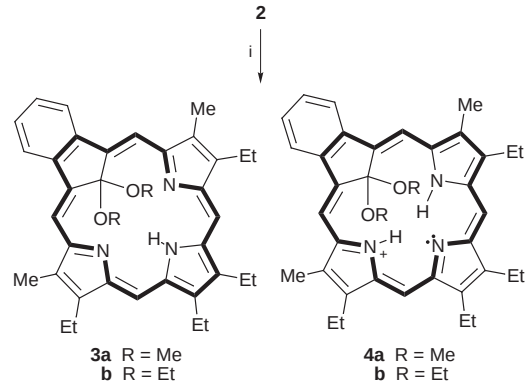
The unbounded potential for porphyrins and related macrocycles in novel technological[1] and medicinal applications[2] has lead to widespread interest in the synthesis of related systems such as expanded porphyrins[3] and porphyrin isomers.[4] The recent rediscovery of the '3 + 1' route for porphyrinoid synthesis[5] has allowed the preparation of novel aromatic species where a carbocyclic subunit replaces one of the pyrrolic moieties of the porphyrin macrocycle.[6–9] The first example of a 'carbaporphyrinoid',‡ oxybenzoporphyrin **1**, was first reported



1 **2**

in 1995 and was obtained by the acid catalyzed condensation of a tripyrrane (2,5-bis[2-pyrrolylmethyl]pyrrole) with 4-hydroxyisophthalaldehyde.[6] Several related porphyrinoids were subsequently synthesized by the '3 + 1' approach.[7–9] Perhaps the most captivating of these new aromatic systems are the true carbaporphyrins[7,9] which incorporate a cyclopentadienyl unit instead of the usual pyrrole ring. Benzocarbaporphyrin **2** is particularly easy to synthesize by condensing a tripyrrane with 1,3-diformylindene[7] and thus provides a suitable 'work horse' molecule for further investigations.

In our initial studies on the chemistry of **2**, the possibility of forming metal chelates was explored. However, attempts to isolate stable metal complexes by reacting **2** with various transition metal salts [$Zn(OAc)_2$, $Cu(OAc)_2$, $Ni(OAc)_2$, $FeCl_2$, $CrCl_3$, *etc*.] has so far been unsuccessful. On the other hand, when a solution of **2** in $CHCl_3$ was refluxed with saturated $FeCl_3$ in MeOH, the mixture rapidly turned from a deep brown to a bright green color and a polar green species could be isolated, following chromatography, in high yield.§ No reaction was observed in control experiments in the absence of $FeCl_3$. FAB MS gave an [M + H] ion at *m/z* 560 and confirmed that no Fe^{III} had been incorporated into the structure. The proton NMR spectrum for the green material (Fig. 1) showed an upfield 6H singlet at $\delta -1.32$ while the *meso*-bridge protons were strongly deshielded appearing at δ 9.7 and 10.9. The data were consistent with a dimethyl ketal derivative **3** where the interior carbon



3a R = Me
b R = Et

4a R = Me
b R = Et

Scheme 1

atom has been regioselectively oxidized (Scheme 1). However, a closer examination of the ^{1}H NMR spectrum (Fig. 1) showed that a broad peak near δ 2.15 integrated for 2H and this was assigned to two strongly hydrogen bonded NHs, thereby implying that the isolated compound was in fact a monoprotonated species **4a**. Elemental analysis further confirmed that the isolated material corresponded to the monoHCl salt.§ Additional evidence for the ketal structure was provided by NOE difference proton NMR experiments, and it is particularly noteworthy that the internal NH resonance showed a strong NOE enhancement upon irradiation of the methoxy resonance at $\delta -1.32$. The ^{13}C NMR spectrum for **4a** in $CDCl_3$ confirmed the symmetry of the macrocyclic structure, showing the 19 anticipated carbon resonances. DEPT demonstrated the presence of a quaternary carbon atom at δ 96.9, which is consistent with the presence of an allylic ketal moiety.

We speculate that the regioselectivity for this chemistry may be due to the Fe^{III} being initially coordinated to the three pyrrolic nitrogens and thereby held in proximity to the inner carbon so that oxidation is directed towards this position. The aromaticity of this structure is maintained by reorganizing the 18π electron delocalization pathway through the fused benzene ring (pathway shown in bold) and in this respect **3a** can be

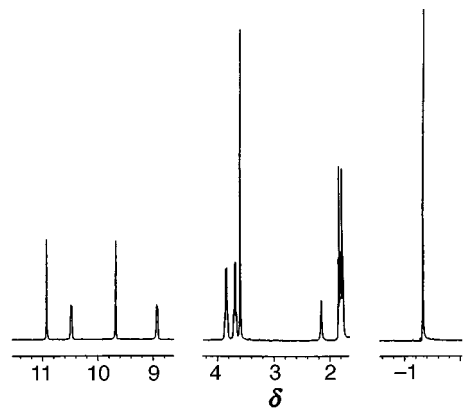


Fig. 1 400 MHz ^{1}H NMR spectrum of benzo[18]annulene **5a** in $CDCl_3$.

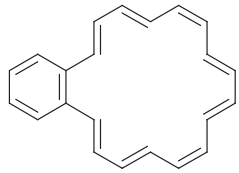
† Part 14 of the series 'Conjugated Macrocycles Related to the Porphyrins'. Part 13: T. D. Lash and D. T. Richter, *J. Am. Chem. Soc.*, 1998, **120**, 9965.

considered to be a benzo[18]annulene. Interestingly, benzo-[18]annulene **5** has been shown[10] to have a much reduced



5

diatropic ring current compared to [18]annulene itself (the difference in chemical shift between the inner and outer protons in **5** is < 2 ppm), although this is clearly not the case for the porphyrinoid structure. Protonation is most likely highly favored due to the ability of the aromatic macrocycle to delocalize the positive charge and this factor may also explain the enhanced aromatic character of **4a** compared to benzo-[18]annulene (**5**). The monocation was essentially uneffected by using [$^2H_5$]pyridine as a solvent, although addition of the stronger base Et_3N lead to decomposition possibly due to the instability of the free base **3a**. Reaction of carbaporphyrin **2** with $FeCl_3$ in refluxing EtOH–$CHCl_3$, although significantly slower than for MeOH, gave excellent yields of the diethoxy species **4b**.§

The UV–VIS spectra for **4a** and **4b** showed strong Soret bands near 423 nm, together with strong Q bands in the far red at 748 and 828 nm in the case of **4a** (Fig. 2). Addition of 5% TFA lead to the formation of a new species due to protonation of the remaining nitrogen where the longer wavelength bands underwent a hypsochromic shift (Fig. 2). Porphyrinoids with strong absorption bands in the far visible–near IR are of great current interest and have possible applications in the development of solid state optical devices[1] and as photosensitizers in photodynamic therapy.[2]

The discovery of a straightforward and highly selective method for derivatizing the inner carbon atom of the carbaporphyrin system has great potential for future studies and it should

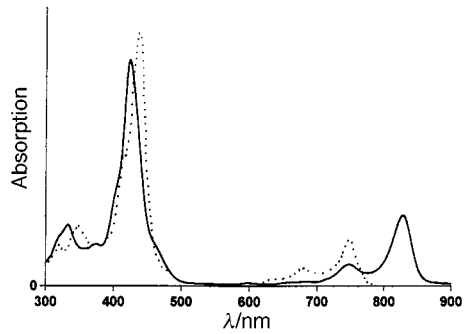


Fig. 2 Electronic absorption spectra of **5a** in $CHCl_3$ (bold line) and dication in 5% TFA–$CHCl_3$ (dotted line).

be possible to fine tune the physical properties of these novel chromophores by selecting other alcohols as reactants (*e.g.* long chain, dendritic). The versatility of this approach will also allow practical applications to be considered.

Received (in Cambridge, UK) 22nd May 1998, Accepted 26th June 1998

The chemistry of olefins in zeolites illustrates both the potential complexity and utility of zeolites as reaction media. Of particular interest are the changes in product selectivity that result from carrying out oxidation reactions in the constrained space of the zeolite cavity. Since zeolites are capable of promoting proton and electron transfer reactions one needs to be particularly careful in the choice of a zeolite as a reaction medium.

Introduction

Much of our understanding of the reactivity of organic molecules is based on experiments conducted either in the gas phase or in an isotropic liquid phase. Studies conducted in these media have provided empirical rules which help us to predict or rationalize the behavior of moelcules in new environments. Although this has been successful in some cases, it is still difficult to predict the behavior of a molecule enclosed in, for example, a biological matrix or a solid assembly. In part, this is because many interactions between the reactant and the medium are often ignored, since it is not always straightforward to predict the effect of these interactions on chemical reactions. Recognizing the complexity of natural systems, and being inspired by them, chemists have utilized a number of organized media to study, and possibly alter, the behavior of included molecules. Examples of organized media which have been investigated include molecular crystals, inclusion complexes, liquid crystals, micelles and related assemblies such as vesicles, microemulsions and membranes, monolayers, Langmuir–Blodgett films, surfaces (silica, clay and zeolites) and, more recently, natural systems such as proteins and DNA.[1] In this review we are concerned with one such organized/confined medium, namely a zeolite.[2]

In the past, most photochemistry in zeolites has been restricted to reactions of carbonyl systems.[3] The extension of these studies to olefinic systems has demonstrated the complexity of zeolites as reaction media. The chemistry is complicated by both proton and electron transfer processes in which the zeolites themselves participate. This review summarizes a number of studies carried out in our laboratories that demonstrate this complexity of the chemistry. We aim however to show that much of the chemistry can be rationalized by careful characterization of the zeolites and the reaction intermediates by a variety of techniques including MAS NMR and time resolved laser spectroscopy. X and Y zeolites are used as the reaction media.

Structural features of zeolites

Zeolites are inorganic microporous and microcrystalline materials capable of complexing or adsorbing small and medium-sized organic molecules. $[SiO_4]^{4-}$ and $[AlO_4]^{5-}$ tetrahedra form the primary building blocks of zeolites.[2] These tetrahedra are linked by all their corners to form channels and cages or cavities with discrete sizes. The total framework charge of an aluminium-

V. Ramamurthy is the Bernard–Baus Professor of Chemistry at Tulane University in New Orleans. Previously, he was on the faculty at Indian Institute of Science, Bangalore, India (1978–1987) and on the staff of Central Research, DuPont, Wilmington (1987–1994). Following his undergraduate education in India his training in photochemistry was performed under the stewardships of R. S. H. Liu (Univ. Hawaii), P. de Mayo (Univ. Western Ontario) and N. J. Turro (Columbia Univ.) His research interests include the study of molecules in constrained media, solid state photochemisty and catalysis.

Pranatharthiharan Lakshminarasimhan (known as pH) came to USA in 1996 after completing his undergraduate education in India. He obtained a BSc in chemistry (1994) from the University of Madras and a MSc in Chemistry (1996) from the Indian Institute of Technology, Madras. Currently he is working towards a PhD degree at Tulane University and his project involves photochemical studies of organic molecules within zeolites.

Clair P. Grey obtained a BA in Chemistry from the University of Oxford in 1987. Her DPhil studies were carried out with Professors A. K. Cheetham and C. M. Dobson at Oxford. After receiving a DPhil (1991), she spent a year in the University of Nijmegen in Professor W. S. Veeman's Laboratory, as a Royal Society Postdoctoral Fellow, followed by two years as a visiting scientist at DuPont CR&D, Wilmington, Delaware with Dr A. J. Vega. She joined the faculty at SUNY Stony Brook in 1994, as an Assistant Professor, and was promoted to an Associate Professor in 1997. She is the recipient of an NSF National Young Investigator Award (1994), a Cottrell Scholarship (1997), a Dupont Young Professor Award (1977), and Camille and Henry Dreyfus Teacher-Scholar Award (1998) and is currently Alfred P. Sloan Foundation Research Fellow. Her research interests include the use of solid state NMR and diffraction methods to study structure and gas adsorption on catalysts and zeolites, conductivity in ionic conductors, battery materials, and the development and application of new solid-state NMR methodology.

Linda J. Johnston obtained a PhD from the University of Western Ontario, London, Ontario in 1983 under the supervision of Professor P. de Mayo. Following postdoctoral work with Drs K. U. Ingold and J. C. Scaiano she joined the staff at the National Research Council Canada, Ottawa, in 1986. She is currently a senior research officer in the Chemical Biology Program of the Steacie Institute for Molecular Sciences. Research interests include kinetic and mechanistic studies of radical ion chemistry and photochemistry in organized media.

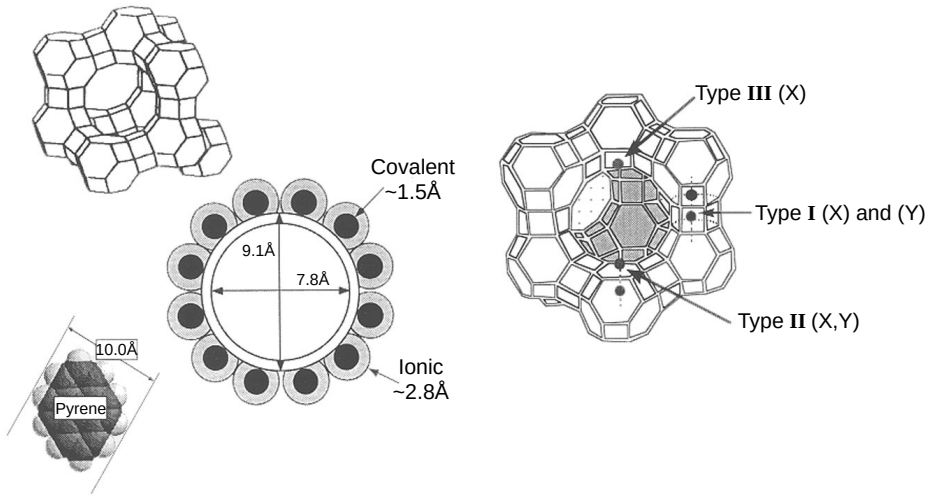

Fig. 1 The basic structural unit of X and Y zeolites. The entrance diameter of a supercage is shown on the left with the dimensions of a guest molecule, pyrene. The cation locations within a supercage are shown in colored circles.

containing zeolite is negative and hence must be balanced by an exchangeable cation, often an alkali or alkaline-earth metal cation. Zeolites can, thus, be represented by the empirical formula $M_{2/n}\cdot Al_2O_3\cdot xSiO_2\cdot yH_2O$, where M are the typically exchangeable cations of valence *n* (typically Na, Ca, Mg, *etc.*), *x* and *y* are integers. The two synthetic forms of faujasite are referred to as zeolite X and Y and have the following typical unit cell composition:

X type $M_{86}(AlO_2)_{86}(SiO_2)_{106}\cdot 264\ H_2O$

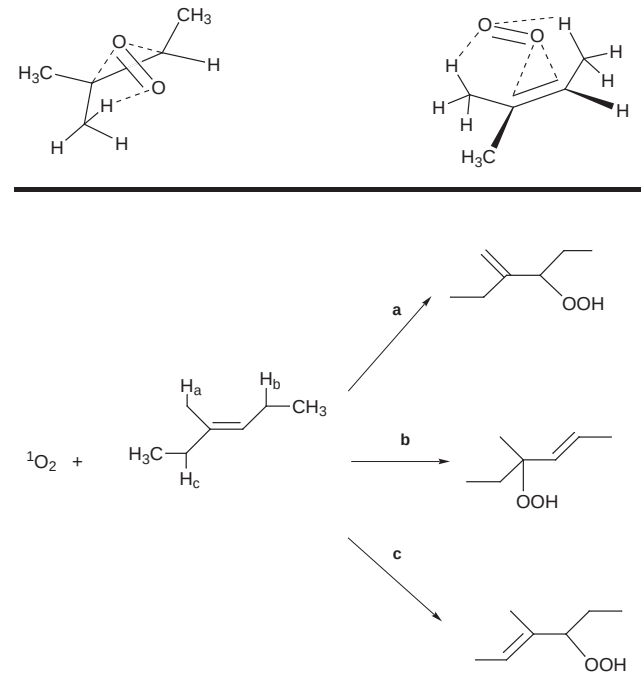
Y type $M_{56}(AlO_2)_{56}(SiO_2)_{136}\cdot 253\ H_2O$

where M is a monovalent cation. The faujasite framework has two main cages. The large supercage results from an assembly of the basic units, the 'sodalite cages'. While sodalite cages are too small to accommodate organic moelcules, the spherical supercages are approximately 13 Å in diameter. Access to the supercages is afforded by four 12-membered ring windows about 9 Å in diameter, which are tetrahedrally distributed about the center of the supercages. The supercages thus form a three-dimensional network with each supercage connected to four other supercages through the 12-ring window. The unit cell of X and Y zeolite consists of eight supercages.

The charge-compensating cations are known to occupy at least three different positions in zeolites X and Y.[4] As illustrated in Fig. 1, the first type (site I), with *ca*. 4–8 cations per unit cell, is located in the hexagonal prism faces between the sodalite units. The second type (site II), with 32 ions per unit cell (in both X and Y), is located in the open hexagonal faces. The third type (site III) is only substantially occupied in X zeolite (and CsY) and is located on the walls of the larger cavity. Other sites (II′ and I′) exist in the sodalite cage, but only cations at sites II and III are expected to be readily accessible to the organic molecule adsorbed within a supercage. Note that in certain circumstances substantial rearrangements of these cations can occur, involving migrations of cations between the cages.[5]

Selectivity during singlet oxygen mediated oxidation of alkenes

Singlet oxygen is known to react with electron-rich alkenes *via* a 2 + 2 addition process.[6] When the alkene contains allylic hydrogen atoms, however, the 'ene reaction' is the dominant pathway.[7] Alkenes with more than one distinct allylic hydrogen yield several hydroperoxides (Scheme 1). With a medium such such as a zeoilite, we envisioned that it should be possible to achieve high selectivity during the singlet oxygen ene reaction. The results of this study are presented below, as an example to illustrate the uniqueness, complexities and challenges of zeolites as reaction media.



Scheme 1

The generation of singlet oxygen for the subsequent oxidation of alkenes requires assembling three species—oxygen, alkene and a sensitizer—within the internal structure of a zeolite. Monomeric thionin is a useful sensitizer for the generation of singlet oxygen; thionin is easily exchanged into NaY zeolite by stirring the dye with hydrated NaY in water. While the dye, as exchanged, remains in the dimeric form within hydrated NaY, careful dehydration of the zeolite results in a color change.[8] The hydrated dye is violet and upon drying the dye becomes blue. Upon thorough drying, thionin adopts a monomeric structure (Fig. 2) and excitation of a blue zeolite containing monomeric thionin shows an emission from singlet oxygen. Singlet oxygen, thus generated, is capable of undergoing an ene reaction with typical alkenes such as 2,3-dimethylbut-2-ene and 2-methyl-4,4-dimethylpent-2-ene. The product distribution observed with 1,2-dimethylcyclohexene suggests that the hydroperoxides so obtained are not the result of reaction with ground-state triplet oxygen (Scheme 2).[9] These observations confirm that one can generate a reactive singlet oxygen within the confines of a zeolite and set the stage for us

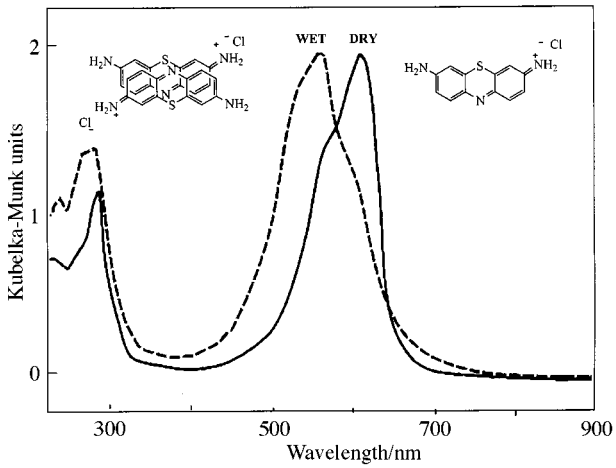


Fig. 2 The diffuse reflectance spectra of thionin included within NaY. The 'dry' and 'wet' samples show different spectra and are differently colored (for colored version of this figure please see http://www.rsc.org./suppdata/cc/1998/2411).

to explore the initial goal of achieving selectivity during the ene reaction.

A number of alkenes of structure similar to 1-methylpent-2-ene were examined. These alkenes contain two distinct allylic hydrogen atoms and, in an isotropic solution, yield two hydroperoxides with no appreciable selectivity (Scheme 3). Within NaY, a single hydroperoxide is preferentially obtained.[10,11] Similar selectivity was also observed with related alkenes such as the 1-methyl-4-arylbut-2-enes and even more impressive results were obtained with 1-methylcycloalkenes (Scheme 4).[10] These alkenes yield three hydroperoxides in solution with the hydroperoxide resulting from abstraction of the methyl hydrogens formed in the lowest yield. Surprisingly, the minor isomer in solution was obtained in larger amounts within the zeolite. Thus the selectivity is a characteristic of hydroperoxidation of alkenes within zeolites. Product hydroperoxides were isolated in *ca*. 75% yield. Generally alcohols were more easily extracted out of the zeolite than the hydroperoxides. A number of control experiments ensured that the observed selectivity is not an artifact. The yields reported in the schemes are for alcohols.

Thionin/NaY/Hexane	100	—	—

Scheme 4

The above selectivity is rationalized on the basis of two independent models.[11] In one, the zeolite is postulated to control the conformation of the reactive alkene and, in the other, the zeolite is suggested to polarize the reactive alkene. We wish to emphasize that the above models are only working hypotheses and further experiments are needed (and underway) to identify the origin of selectivity. Formation of both hydroperoxides **2** and **3** from **1** in solution has been rationalized on the basis that singlet oxygen attacks the alkene from the top-right side as shown in Fig. 3 and Scheme 1. In such an approach, the

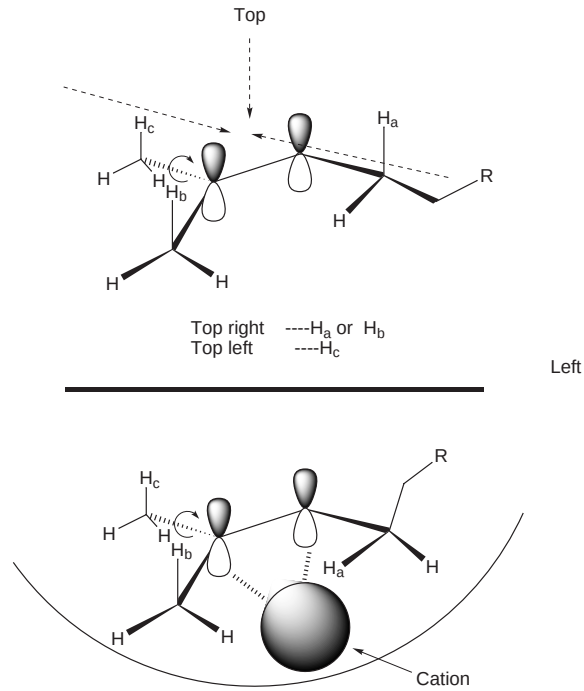

Fig. 3 Cation–alkene interaction within a supercage may control the conformations of allylic hydrogens. For allylic hydrogen abstraction H_a and H_b should be parallel to the π orbital (see top).

transition state is stabilized by secondary interactions between the oxygen and the allylic hydrogens which are situated parallel to the π–p orbitals. In this model, the methyl group on the top-left side (Fig. 3) does not participate in the oxidation process. The results within zeolites clearly suggest that the methylene hydrogens H_a of **1** and **4** (Fig. 3) are not abstracted by the singlet oxygen. While the lack of formation of **3** and **6** within zeolites is an indication that the methylene hydrogens are excluded from the reaction, selective formation of **2** and **5** does not indicate which of the two (or both) methyl groups participates in the oxidation process.

We propose that the R group in the alkene (Fig. 3) plays a crucial role in the type of product(s) formed. While in solution, the most favored conformation places both the methyl and methylene hydrogens in an appropriate geometry for abstraction (Fig. 3), it is quite likely that such a conformation is not favored

within a zeolite. In a supramolecular assembly, one must consider the interactions that arise between the adsorbent/guest and the environment. We speculate that within a zeolite, the alkene will be adsorbed to the surface *via* cation–π interactions. The rotation of the C3–C4 bond may occur under such conditions to relieve the steric strain that develops between the bulky R group and the surface. Such a rotation will place the methylene hydrogens away from the incoming singlet oxygen (Fig. 3), preventing the formation of the tertiary hydroperoxide. The extent of steric repulsion between the surface and the R group may depend on the distance between the group and the surface which, in turn, will be controlled by the size and binding strength of the cation. This model predicts that the selectivity should be directly related to the binding energy of the cation with the alkene; reactions involving larger cations such as Cs^+ ion may be expected to yield lower selectivity than those involving the smaller Na^+ ion.

In the second model, the selectivity is attributed to the polarization of the alkene by the interacting cation. As shown in Fig. 4, when the alkene is asymmetric, the interacting cation

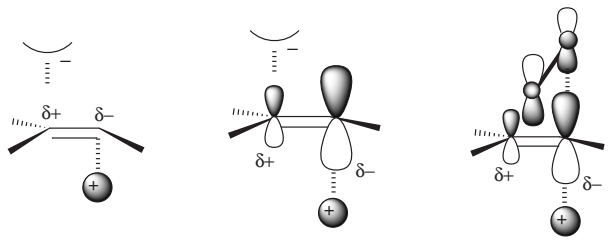

Fig. 4 Cation–alkene interaction may polarize the alkene. Polarization is represented in terms of the size of the orbital.

will be able to polarize the alkene in such a way that the carbon with the greater number of alkyl substituents will bear a partial positive charge (δ+). Singlet oxygen being electrophilic is expected to attack the less substituted electron rich carbon (δ–) and lead to an ene reaction in which the hydrogen abstraction occurs selectively from the alkyl group connected to the δ+ carbon. Polarization of molecules such as pyrene, NO, alkene–oxygen within zeolites has been previously reported.[12,13] In our system, the extent of polarizability will depend on the charge density of the cation. Smaller cations such as Li^+ would be expected to polarize the alkene more effectively than larger cations such as Cs^+. As per this model, selectivity is expected to decrease from Li^+ to Cs^+. Consistent with both the above models, the observed selectivity decreases with the size of the cation (Scheme 5; $Li^+ > Na^+ > K^+ > Rb^+ > Cs^+$).[11]

Both of the above models assume that there is an interaction between the cation and the alkene and that the interaction energy decreases with the size of the cation.[14] ^2H and double resonance NMR studies are in progress to probe the interaction between the adsorbed alkene and the extra-framework cation. Preliminary *ab initio* quantum mechanical calculations performed with several alkenes clearly show a decreasing trend in the binding energy between the cation and the alkene, the smaller cations binding more strongly.[15] Although at pesent we have no direct evidence for interaction between cations and alkenes, we have established the existence of such interactions for aromatics *via* absorption, emission and solid state NMR studies.[16] These cation–aromatic interactions, which involve the π-electrons of aromatics, are well established in the literature.[17]

Extension of the above oxidation studies to alkenes such as limonene gave a complex mixture (Scheme 6).[18] Control experiments revealed that the alkenes themselves undergo rearrangement prior to oxidation. Careful analysis indicated that the very low concentrations of acidic protons that are present in NaY (< 1 per 16 supercages, as determined by NMR and indicator studies described below), a zeolite which is usually considered to be non-acidic, are sufficient to catalyze these rearrangements.[19] Acid catalyzed rearrangement of limonene in solution is well known. In further studies, these very small concentrations of acidic sites were shown to alter the chemistry significantly and to result in a variety of unexpected products that result from the initial protonation of the alkene. We were able to switch off this chemistry, by simply neutralizing the acidic sites with stoichiometric amounts of pyridine. Once these acidic sites are neutralized, oxidation of the alkenes listed in

Scheme 6 can be readily performed without any side reactions.

A fundamental understanding of both the major reaction mechanisms, and the possible side-reactions, clearly requires a detailed study and quantification of the number of acidic and cation sites present in these materials. Details on the characterization of zeolites for Brønsted acidity are presented in the following section.

Probing $M^{2+}Y$, $H^{+}Y$ and $M^{+}Y$ zeolites for Brønsted acidity: implications for reactivity

NMR characterization

One of our laboratories has developed and applied a variety of new solid state double resonance NMR methods to probe the acidic sites present in zeolites and to study gas sorption.[20–24] TRAPDOR NMR methods were used, for example, to probe surface sites which are difficult to observe directly with ^{27}Al MAS NMR methods[20,22,23] since they are associated with large quadrupole coupling constants. Examples include sites of catalytic interest such as the aluminium atoms associated with the Brønsted acid sites in the zeolite [Si–O(H)–Al] and the Lewis acid sites created by dehydroxylation of the framework or by steaming. The TRAPDOR experiment[22,25] exploits the dipolar coupling between nearby nuclei to detect the quadrupolar nuclei (^{27}Al) indirectly. Two experiments are performed: in a ^{1}H–^{27}Al experiment, for example, the first experiment performed is a simple ^{1}H spin-echo. This is referred to as the control experiment. In the second experiment, a ^{1}H spin-echo sequence is again performed, but now the quadrupolar nucleus (in this case ^{27}Al) is irradiated for, typically, the evolution period (τ) of the spin-echo. This is shown schematically in Fig. 5.

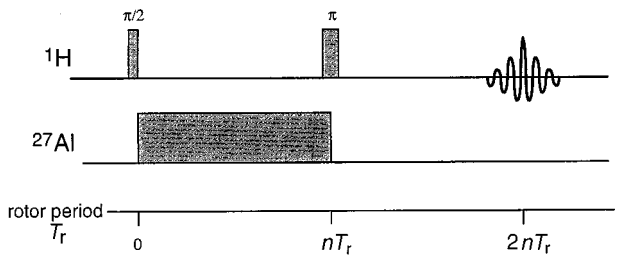

Fig. 5 The ^{1}H–^{27}Al TRAPDOR NMR sequence. An echo is formed at $2nT_r$, where T_r is the rotor period, nT_r is the evolution period, and n is an integer.

Protons nearby to aluminium spins will no longer be completely refocussed, on ^{27}Al irradiation, by the π pulse applied in the middle of this sequence (at nT_r) and their signal, at the echo (at $2nT_r$), will be reduced. This reduction depends on a variety of factors, which include the spinning speeds and ^{27}Al r.f. field strength; more importantly, the loss in signal is extremely sensitive to the ^{1}H–^{27}Al internuclear distance. This fact can be utilized to assign ^{1}H resonances to different aluminium-containing species or to probe proximity between different spins. Lewis acid sites are readily detected on absorption of bases such as trimethylphosphine (TMP) or ^{15}N-labeled monomethylamine: A ^{31}P–^{27}Al or ^{15}N–^{27}Al TRAPDOR NMR experiment is performed and the loss of the ^{31}P or ^{15}N signal at the echo, on ^{27}Al irradiation, indicates that these probe molecules are bound to the Lewis acid site.[24,25]

A simple probe of acidity involves the reaction of trimethylphosphine (TMP) with the Brønsted acid sites [Si–O(H)–Al]:

$$\text{Si–O(H)–Al + TMP} \rightarrow \text{TMPH}^{+} + \text{Si–O–Al}$$

Very different chemical shifts are observed for the TMP molecule and $TMPH^{+}$ cations (at *ca.* −67 and −2 ppm, respectively).[26,23] Since NMR is a quantitative technique, the concentration of Brønsted acid site follows directly from the intensity of the $TMPH^{+}$ resonance. Additional ^{1}H experiments have been performed to ensure that complete reaction of the TMP with the Brønsted acid sites occurred. ^{31}P–^{27}Al TRAPDOR experiments have also been carried out to assign the ^{31}P resonances due to TMP bound to the Lewis acid sites. These methods were applied to characterize HY and CaY.[27,24]

The ^{1}H–^{27}Al TRAPDOR NMR spectra of CaY, calcined in an oven at 500 °C, is shown in Fig. 6. The control experiment, (Fig. 6) obtained without ^{27}Al irradiation, shows a number of

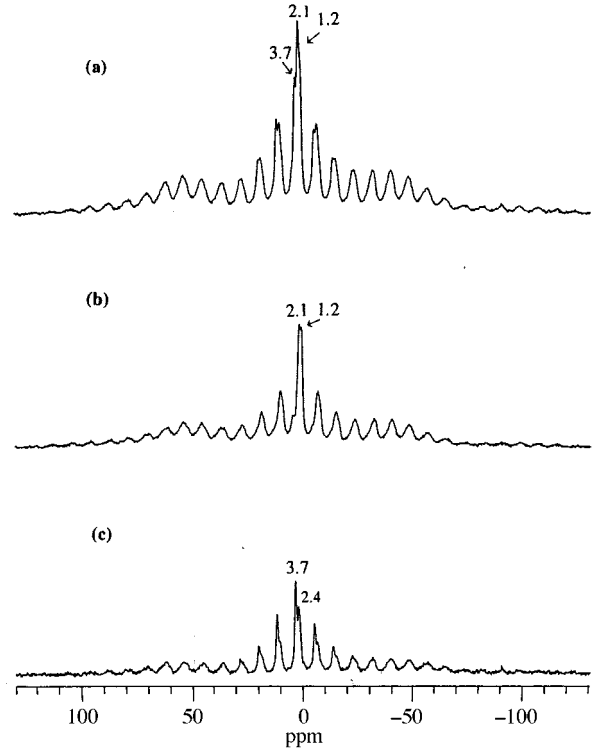

Fig. 6 ^{1}H–^{27}Al TRAPDOR spectra of CaY-500-oven at −500 °C obtained (a) without and (b) with on-resonance ^{27}Al irradiation during τ (τ = 333 μs, spinning speed = 3 kHz; ^{27}Al r.f. field strength = 55 kHz). The difference spectrum [(a) − (b)] is shown in (c). The intensity of (c) has been scaled by a factor of two with respect to (a) and (b).

different resonances at 3.7, 2.1 and 1.2 ppm. The large spinning sideband manifolds result from residual water that is bound to the calcium cations; (b) shows the spectrum obtained on ^{27}Al irradiation. ^{1}H resonances that are observed result from proton species that are distant from aluminium atoms, or that are mobile. The difference spectrum shown in (c) contains resonances from proton spins that are nearby to aluminium. The resonance at 3.7 ppm, due to the Brønsted acid sites [Si–O(H)–Al], is observed clearly in this spectrum, consistent with this. The resonance at 2.4 ppm is due to extra framework aluminium hydroxide species created during activation of the zeolite. The large sideband manifolds are visible in (c) indicating that the water molecules are also tightly bound to the zeolite framework. The resonances at 2.1 and 1.2 ppm are assigned to $CaOH^{+}$ and silanol groups, respectively. The $CaOH^{+}$ groups result from the following reaction, which is well established in CaY zeolites, and is a consequence of the large electrostatic field at the divalent cation:[28]

$$\text{Ca(OH}_2)_n^{2+} \rightarrow \text{CaOH}^{+} + \text{H}^{+} + (n-1)\text{H}_2\text{O}$$

The observation of Brønsted acid resonances at 3.7 ppm is consistent with this. TMP was sorbed on this material to titrate the acid sites and an estimate of *ca.* 16 Brønsted acid sites per unit cell was obtained for this sample by integrating the $TMPH^{+}$ resonance. ^{31}P–^{27}Al TRAPDOR NMR was performed to confirm the lack of Lewis acidity in these samples. Experiments were then carried out for samples activated under a variety of different conditions. CaY activated in an oven at higher temperatures contains less water, but all the other species are

still present. In contrast, CaY activated by slow ramping of the temperature under vacuum to 500, or 600 °C, shows a much lower concentration of Brønsted acid sites (< 1 per unit cell, from TMP titration). Again, no evidence for Lewis acidity was observed.

Similar experiments can be used to quantify the number of Brønsted acid sites in HY zeolites.[24] Typically, the number is less than the predicted amount from the Si/Al ratio, as some dehydroxylation occurs. The ^{1}H MAS NMR spectrum of monomethylamine (MMA) sorbed on an HY sample dehydrated at 400 °C under vacuum is shown in Fig. 7, as a function

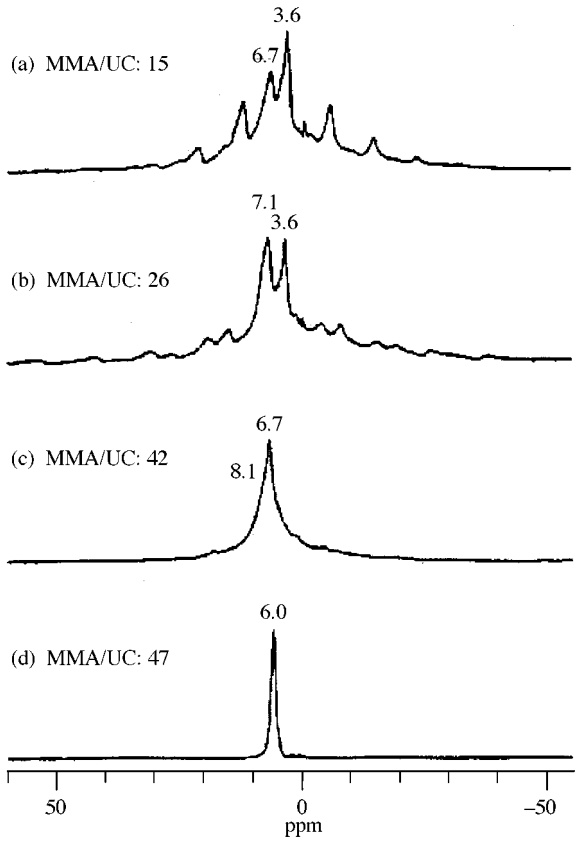

Fig. 7 ^{1}H MAS NMR spectra of [$^2H_3$]monomethyl amine–HY with different loading levels. Loading levels per unit cell are shown on the figure. Spectra were collected at spinning speeds of 3 and 4 kHz for (a) and (b)–(d), respectively. The isotropic resonances are labeled. The small peaks around 0–1 ppm are due to the background signals from the probe head, rotor and inserts. All other resonances are spinning sidebands.

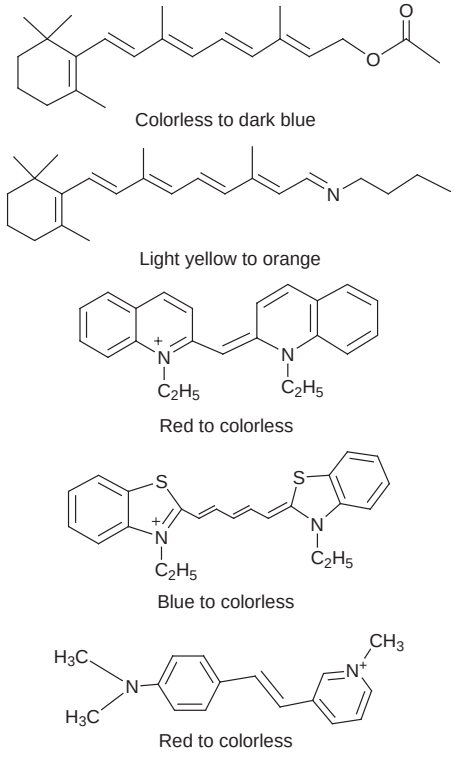
of loading level.[23] Monomethylammonium cations ($MMAH^+$) are formed (resonances at 6.7–8.1 ppm), which at temperatures below −40 °C are rigidly bound to the zeolite framework on the ^{1}H NMR timescale. At loading levels of MMA that exceed the number of Brønsted acid protons (> 42 MMA/u.c.), ^{1}H resonances intermediate in chemical shift between those of MMA (*ca.* 2 ppm) and $MMAH^+$ are observed from species undergoing rapid proton transfer reactions between MMA and $MMAH^+$. This is seen in (d) where a single resonance at 6.0 ppm is observed. Thus a concentration of between 42 and 47 Brønsted acid sites per unit cell is estimated for this sample. The Brønsted acid concentration, as a function of the dehydration temperature, has also been carefully determined from proton spin counting in ref. 29 and our ^{1}H MAS NMR results are consistent with this data. Lewis acid sites created as a result of the dehydroxylation process, are clearly observed on TMP or MMA sorption (with ^{31}P or ^{15}N MAS NMR).[22,23]

The indicator method

As discussed earlier, thermal reactions of alkenes were observed even within alkali-metal ion-exchanged X and Y zeolites, zeolites not traditionally associated with Brønsted acidity. The small concentrations of Brønsted acid sites present in these samples are thought to result from cation deficiencies (*i.e.* a $M^+ : Al^{3+}$ ratio of < 1) caused by the replacement of M^+ by H_3O^+ during ion-exchange or synthesis of the zeolites.[28,30] Quantification of these Brønsted acid sites was critical in order to rationalize the observed chemistry within M^+X and M^+Y zeolites. The materials were initially studied with ^{1}H MAS NMR with similar methods to those described above.[19] ^{1}H MAS NMR spectra of activated NaY showed a very weak resonance at 3.6 ppm which could be tentatively assigned to Brønsted acid sites. Its intensity was, however, extremely small in comparison to the intensity of the residual water and the silanol groups and it was difficult to quantify the numbers of Brønsted acid sites per unit cell. TMP was again sorbed on NaY. The ^{31}P MAS NMR at −150 °C showed a very weak signal at −2 ppm (1/50 times weaker than the main resonance at −60 ppm from weakly bound/physisorbed TMP, for the sample loaded with 26 molecules per unit cell), which was ascribed to $TMPH^+$. From the intensity of this resonance, we estimated that there could be no more than approxiamtely 0.5 Brønsted acid sites per unit cell of NaY. To check the presence of weakly acidic sites, stronger bases such as dimethylamine and methylamine were used as probes for NaY. No evidence for protonation of these probes could be detected with ^{1}H MAS NMR. Note that when these probe molecules were adsorbed in quantities that exceeded the number of Brønsted acid sites, considerable mobility of the probe molecules was typically observed, indicating rapid exchange of the protons between the probe molecules. Although the exchange process can be frozen out at low temperatures such as −150 °C, this mobility complicates the analysis of spectra obtained for samples with very low concentrations of Brønsted acid sites. Based on these studies it was concluded that the number of Brønsted acid sites within NaY was close to, or beyond, the detection limis of NMR. Therefore, we employed a different technique to detect the acidic sites within zeolites. This involved detecting differences in electronic absorption characteristics between protonated and unprotonated forms of a probe molecule.

The success of this technique depended upon finding a dye molecule that would exhibit different colors under acidic and basic conditions and would easily fit within a zeolite. The set of cyanine dyes that we used is listed in Scheme 7.[31] All are brightly colored under basic or neutral conditions and turn colorless under acidic conditions. Two dyes, retinol and retinyl acetate, are blue under acidic conditions but are light yellow under basic/neutral conditions. A preliminary test consisted of monitoring the absorption changes upon addition of a small amount (50 to 200 mg) of an activated zeolite to a standard micromolar hexane solution (5 ml) of the dye. When activated NaY was added to a standard solution of retinol or retinyl acetate, the zeolite immediately turned a dark blue color which persisted for nearly an hour. This observation was interpreted as evidence for the presence of Brønsted acidic sites that are strong enough to protonate retinol and retinyl acetate. When the cyanine dye was added to activated NaY, the bright color of the dye faded and the zeolite remained white. Consistent with this, NaX did not show a positive blue test with either retinol or retinyl acetate or with cyanine dyes. This leads us to conclude that NaX is less acidic than NaY.

The number of Brønsted acid sites was estimated by a conventional titration method. Either *n*-butylamine, diethylamine or pyridine was used as a base to quench the acidic sites present in a zeolite. A typical experiment consisted of stirring a known amount of NaY with varying amounts of the base. After at least 6 h of stirring the indicator dye was added and the visible color change was either observed or recorded. Surprisingly when the base was present in amounts more than 1 per 16 cages retinol and retinyl acetate did not become blue and the cyanine dyes maintained their bright colors. This indicated that no more than one acidic site per 16 supercages (*i.e.* 0.5 H^+ per unit cell)



Scheme 7

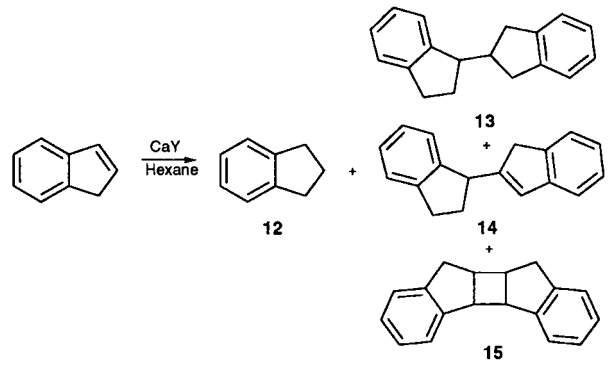
can be present in NaY. Although this number is small, it is large enough to bring about changes in the structure of guest alkenes *via* a catalytic process.

Careful characterization of CaY, HY, and NaY zeolites has shown that these zeolites contain Brønsted acid sites. Of these HY, as expected, contains the most acidic protons (42–47 per unit cell). This is followed by CaY activated in an oven which contains 16 per unit cell. Even NaY, normally considered to be non-acidic, contain 0.5 protons per unit cell. The acidity of CaY depends on the activation conditions and that of NaY depends on the source. As per our analysis NaX is least acidic. In choosing X and Y zeolites as a reaction media one must be aware of the consequences of the presence of even small numbers of Brønsted acid sites in CaY, HY, and NaY zeolites.[32–34]

Proton transfer reactions within zeolites

In this section the thermal behavior of three alkenes, indene,[35] 4-vinylanisole[36] and 1,1-diarylethylene,[37] within CaY is outlined.[38] In all cases CaY was activated in an oven at 500 °C; activation at 400 °C under vacuum resulted in a less active zeolite. Inclusion of the alkenes in activated CaY gave brightly colored samples that retained their color for several weeks and, in some cases, even months (see http://www.rsc.org/suppdata/cc/1998/2411). For example, 1,1-diphenylethylene gives a green colored zeolite while 4-vinylanisole red–violet and indene dark red. The products isolated, the characterization of the species responsible for the color and a possible mechanism for formation of both the colored species and the final products are described below.

Addition of the activated CaY to a hexane solution of indene resulted in the immediate formation of a dark red color (absorption maximum at 520 nm) that persisted for several months. Extraction of the zeolite with dichloromethane gave products **12–15** (Scheme 8) but, remarkably, did not remove the red color. The red color remained after three months under laboratory conditions and was unaffected by refluxing the zeolite in methanol or water for 24 h or by the addition of dilute HCl. The behavior of vinylanisole was similar to that of indene in that addition of activated CaY to 4-vinylanisole in hexane



Scheme 8

gave a vibrant red–violet color. The diffuse reflectance spectrum of the solid zeolite consisted of two broad absorptions at 340 and 580 nm (Fig. 8). The 580 nm absorption was not

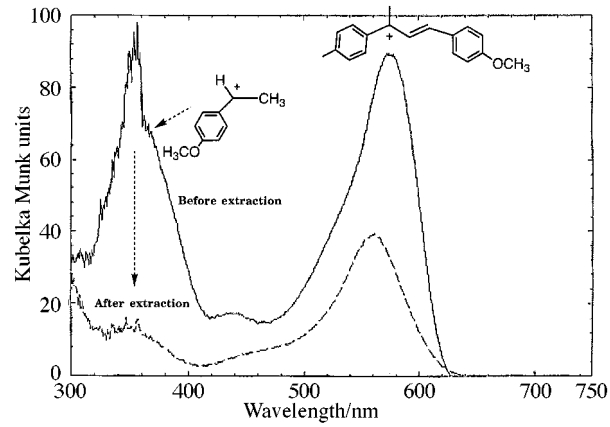


Fig. 8 Diffuse reflectance spectra of 4-vinylanisole included within 500 °C-oven-activated CaY. The sample before extraction shows absorptions due to two independent carbocations. After extraction with dichloromethane, the spectrum is mainly due to the allylic cation (see insert for structure).

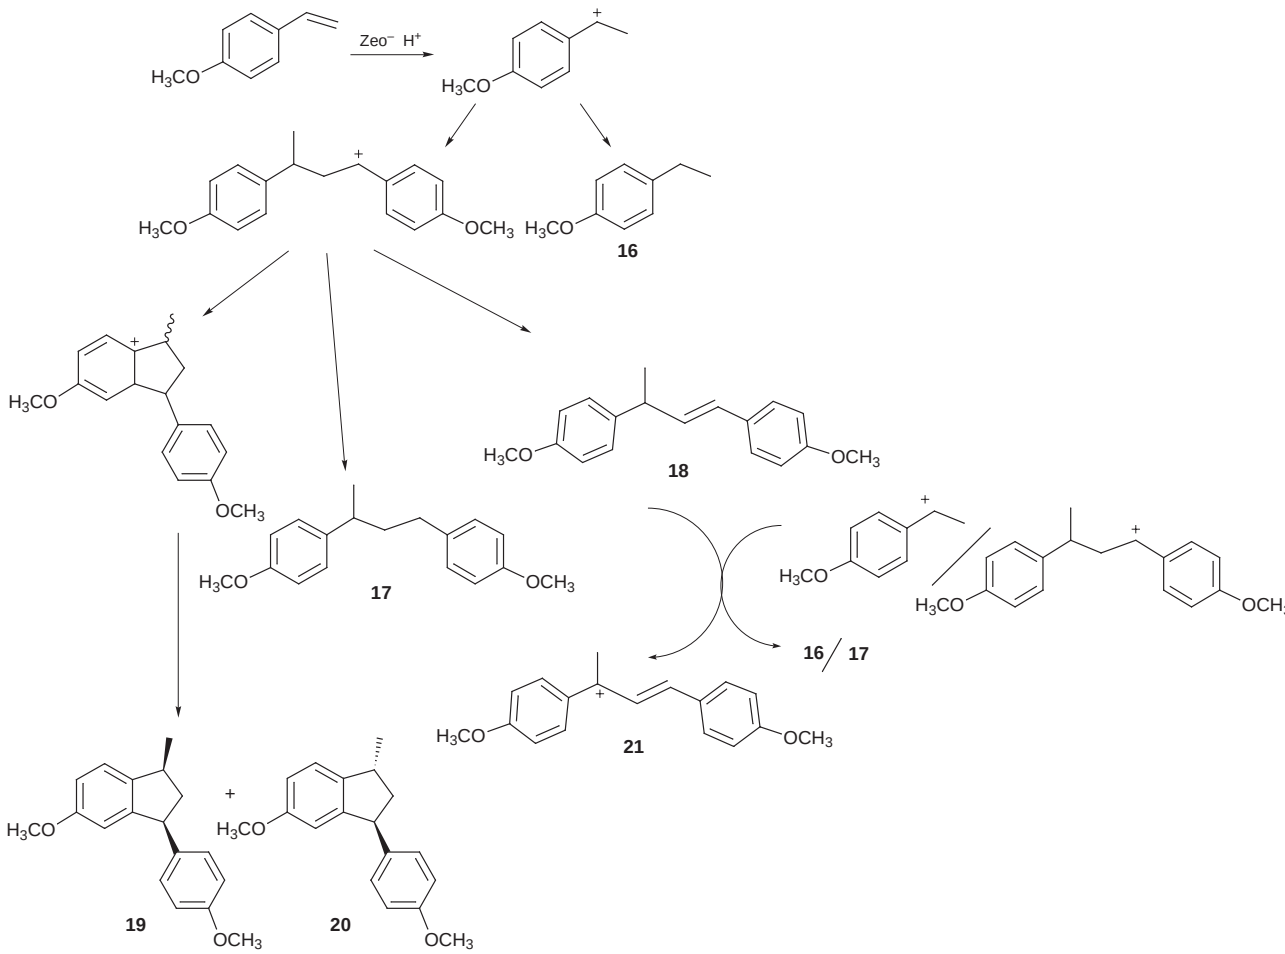
removed by any of the extraction procedures noted above for indene. In contrast, extraction of the zeolite with dichloromethane–THF eliminated the 340 nm absorption and gave products **16**–**20** (Scheme 9). The ratio of the products dependent on the loading level of 4-vinylanisole and on the mode of activaiton of CaY. Due to lack of space we will not be going into the details on the relationship between the product distribution and loading level. The 340 nm absorption is attributed to the 4-methoxyphenylethyl cation (see insert in Fig. 8), in good agreement with the literature spectrum for this species in solution.[39] While this cation has a lifetime of only a few microseconds in solution, it is stable for a few days in the zeolite.

Similarly, addition of CaY to a hexane soluton of 1,1-diphenylethylene gave a yellow slurry that turned green and remained so for several days. The diffuse reflectance spectrum (Fig. 9) showed two maxima at 430 and 610 nm. Product extraction (Scheme 10) left a blue zeolite (610 nm). The 430 absorption is attributed to the diphenylmethyl cation, in agreement with the solution spectrum for this species and its independent generation from diphenylethanol in CaY.[40]

The products shown in Schemes 7–9 can be rationalized on the basis of an initial protonation of the olefin by Brønsted acid sites in activated CaY. Detailed H, D isotope studies using D_2O and deuterated extraction solvents were carried out for diphenylethylene and indicated that the first proton comes from acidic sites and the second hydride from the solvent. Scheme 9 illustrates the sequence of reactions that we suggest to explain the formation of the products from 4-vinylanisole; similar schemes can rationalize the products observed for indene and diphenylethylene. A common feature for all three alkenes is the



Scheme 9

formation of a strongly colored stable species within CaY. The formation of a red color from indene in the presence of Lewis acids has been reported previously and attributed to carbonium ion **25** (Scheme 11) formed by abstraction of a hydride ion from 2-α-indanylindene **14**.[41] In soluiton, this cation is only stable for a short time, even under an inert atmosphere. We believe that the 520 nm absorption in CaY is due to the same cation, which is indefinitely stable in the zeolite. Similarly, the red–violet color obtained for 4-vinylanisole is assigned to the allylic cation **21** (Scheme 9). This is consistent with the expected absorption for the 1,3-diphenylpropenyl cation and was confirmed by the independent generation of this species from an alcohol precursor.

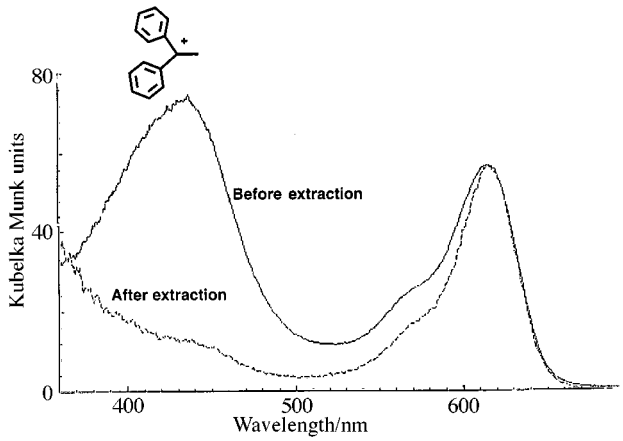


Fig. 9 Diffuse reflectance spectra of diphenylethylene included within 500 °C-oven-activated CaY. The sample before extraction shows absorptions due to two independent carbocations. After extraction with dichloromethane the spectrum is mainly due to an allylic cation.

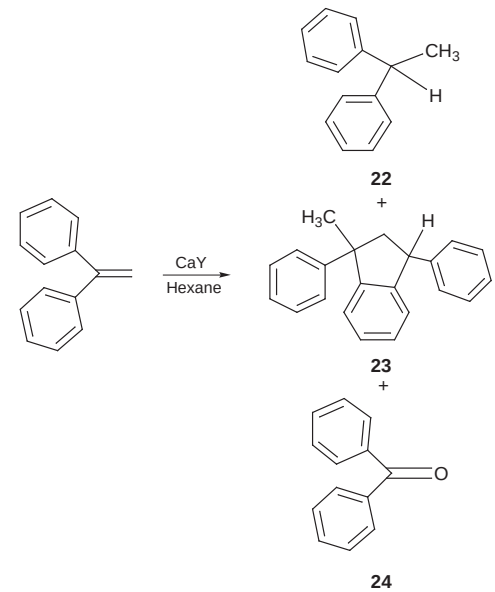
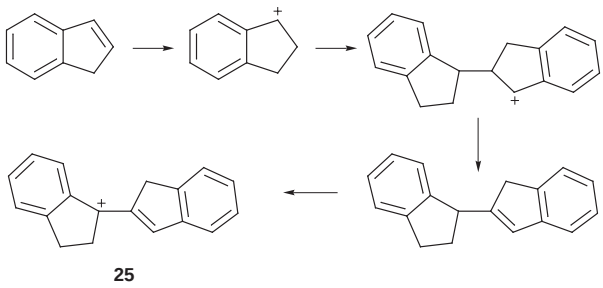
While there seems to be general agreement in the literature concerning the structure of the persistent cations from indene and 4-vinylanisole, the origin of the blue color (after extraction to remove the yellow component) from diphenylethylene is not yet resolved. A deep blue or green coloration from diphenylethylene in acidic media (both in solution and on silica-alumina surfaces) has been reported previously and several possible explanations have been suggested (Scheme 12).[42,43] One of these is the monomer radical cation, although there are conflicting reports on the solution spectrum of the diphenyl-

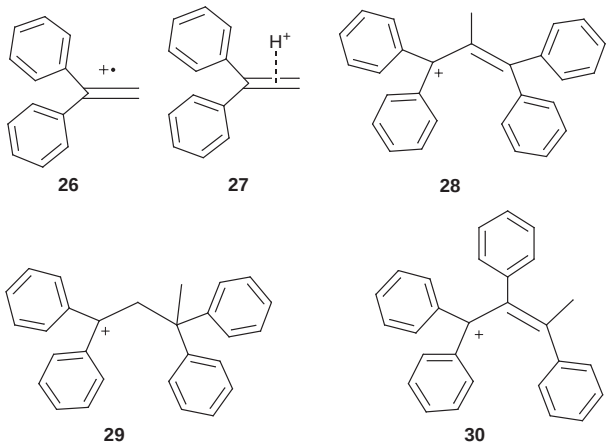


Scheme 10



25

Scheme 11



26 27 28

29 30

Scheme 12

ethylene radical cation. Although we have not been able to record the spectrum for this species in solution, we have obtained spectra for two methyl substituted derivatives. Both the 1,1-diphenylprop-1-ene and 1,1-diphenyl-2-methyl-1-ene radical cations have absorption maxima at *ca.* 400 nm with a weak absorption at > 700 nm (Fig. 10). We expect the

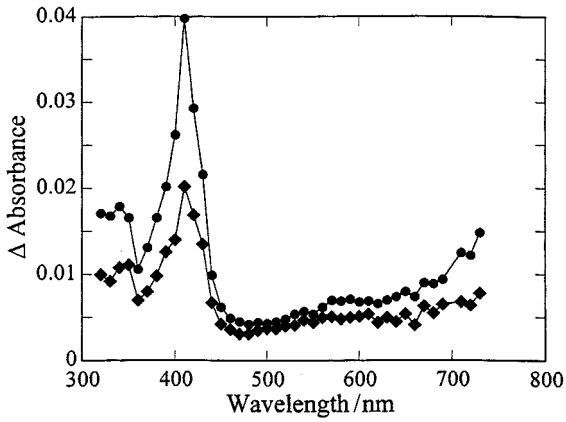


Fig. 10 Transient absorption spectra of the 1,1-diphenyl-2-methylprop-1-ene radical cation generated by 9,10-dicyanoanthracene/biphenyl sensitization in acetonitrile (●, 0.7 μs after laser excitation; ◆, 1.8 μ).

diphenylethylene radical cation to absorb in the same region, making it unlikely that the blue species in CaY is the monomer radical cation. An alternate assignment for the colored species is an olefin–acid π-complex,[42i] although this proposal has not received much experimental support. Others have suggested dimeric cations such as **28** or **29**; of these **29** is less likely to absorb above 600 nm. In fact generation of this species from alkene **32** gave an absorption identical to that of diphenylmethyl cation. Therefore, the original suggestion **28** by Rooney and Hathaway[43] is still one of the most likely structures for the blue colored species; we believe that **30** is also a reasonable possibility.

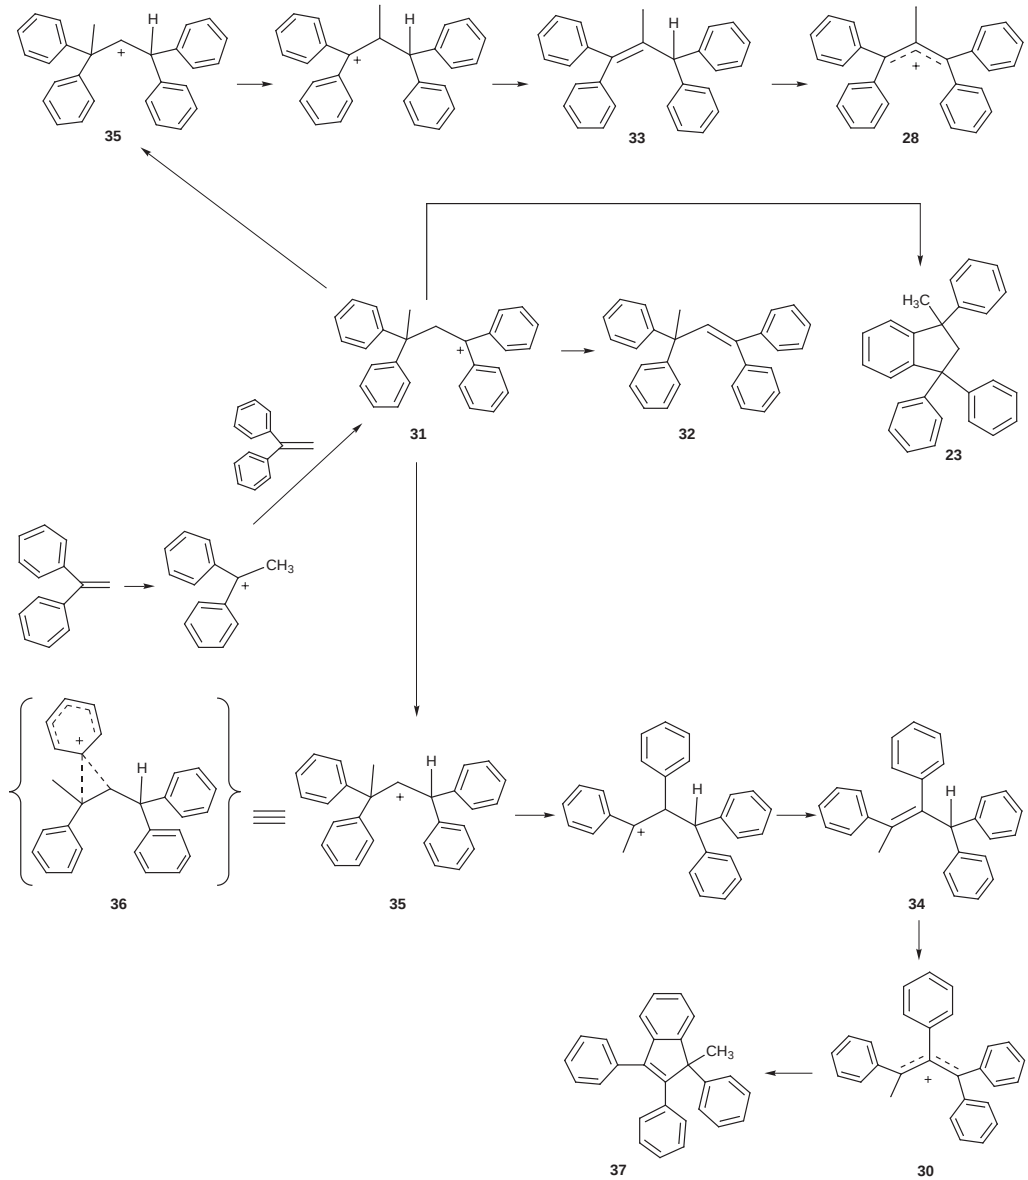
The difficulty in assigning a structure to the blue species obtained from diphenylethylene arises from the fact that a stable dimeric alkene, that is also a good hydrogen donor, has not been isolated, unlike the results for indene and 4-vinylanisole. As shown in Scheme 13, the only alkene that can be formed from the dimeric cation **31** is **32**, which has no hydrogen that can be easily removed as a hydride. However, alkenes **33** and **34** (Scheme 13) are good hydrogen donors and can give cations **28** and **30** by a similar mechanism to that shown in Schemes 9 and 11. These cations would be expected to absorb above 600 nm. The two alkenes (**33** and **34**) can be formed by rearrangement of **31** to a less stable classical cation **35**. In the absence of other competing processes, even this relatively unlikely rearrangement may occur within a zeolite. In fact if one views **35** as a non-classical phenonium ion (**36** in Scheme 13), rearrangement of **31** to **36** appears feasible. Alkenes **33** and **34** may be formed from **35** *via* migration of either a methyl or phenyl group as illustrated in Scheme 13. Thus, we believe that the colored species formed from diphenylethylene within CaY is either **28** or **30**. We are currently synthesizing precursors of these cations for studies of their absorption spectra within zeolites.

The extraordinary stability of the carbocations **21**, **25** and **28**/**30** derives partly from the π-conjugation with the aromatic substituents. This kinetic stability must be augmented by the highly polar nature of the zeolite supercage. In all these systems, the cations that are generated serve as a counter ion for the zeolite framework and thus become part of the zeolite structure. The unusual ability to stabilize certain carbocations within zeolites has allowed us to handle them as 'normal' laboratory chemicals. For example we have been able to record emission from several of these cations. One such example is provided in Fig. 11. The technique of stabilizing reactive intermediates within the structures of zeolite should allow us characterize, in the future, the excited state properties of reactive intermediates such as carbocations and radical cations.[44]

Electron transfer within zeolites

Electron transfer within zeolites has been the subject of investigation for several decades. Some studies have involved spontaneous electron transfer in which the guest, upon inclusion within an activated zeolite, transfers an electron to the zeolite to form a stable radical cation. Stamires and Turkevich were the first to observe spontaneous electron transfer between the host NH_4^+Y zeolite and the guests 1,1-diphenylethylene, triphenylamine, quinoline, perylene, aniline and *p*-phenylene diamine.[45] We have generated and stabilized radical ions from a number of polyenes and oligomers of thiophenes.[46] For example, when activated Na-ZSM-5 (Si/Al = 23) was stirred with α,ω-diphenylpolyenes (*trans*-stilbene, diphenylbutadiene, diphenylhexatriene, diphenyloctatetraene, diphenyldecapentaene, and diphenyldodecahexaene) in 2,2,4-trimethylpentane, the initially white zoelite and colorless to a pale yellow olefins were transformed into highly colored solid complexes within a few minutes. The samples all exhibited intense EPR signals with *g* values of 2.0028. Diffuse reflectance spectra of these powders (Fig. 12) were identical to the spectra of the radical cations of a few α,ω-diphenylpolyenes reported in the literature.[47] Diffuse reflectance and EPR results favor the conclusion that the colored species formed upon inclusion of α,ω-diphenylpolyenes in Na-ZSM-5 are radical cations. The radical ions thus generated were unusally long lived (several months). The exact nature of the electron acceptor within the zeolite had yet to be unequivocally identified. Although spontaneous generation of radical cations has been established for a number of substrates within Na-ZSM-5 and HY, similar results have not been reported within NaX and NaY zeolites.[48]

In addition to spontaneous electron transfer, relatively long-lived radical cations (lifetimes of milli- to micro-seconds) can be readily generated by direct laser excitation of a variety of aromatic substrates within X and Y zeolites. This phenomenon was orginally reported by Iu and Thomas with NaY and NaX



Scheme 13

zeolites as the acceptors and pyrene and anthracene as the donors.[49] Our recent results demonstate that direct excitation of aryl and diarylethylenes in zeolites also leads to radical cation formation, in competition with other excited state decay processes. For example, diffuse reflectance laser flash photolysis of *trans*-stilbene included in NaX zeolite leads to the formation of transient signals assigned to the *trans*-stilbene radical cation (475 nm) and zeolite trapped electrons (Na_4^{3+}, 500 nm).[50,51] The latter can be removed by purging the samples with oxygen, leading to the unambiguous characterizaton of the radical cation. The *trans*-stilbene radical cation was also

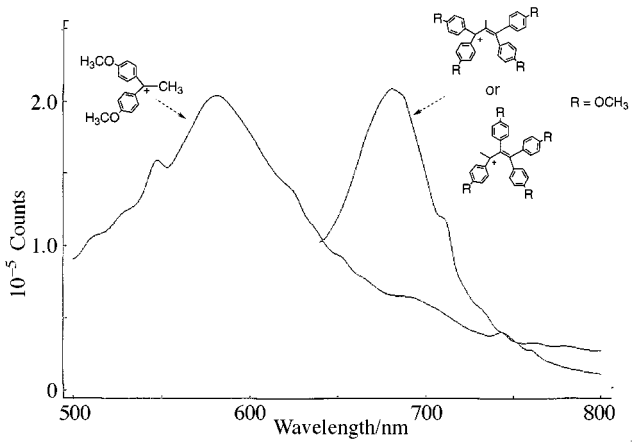


Fig. 11 Fluorescence emission from two cations trapped within CaY. Possible structures of the cations are also shown.

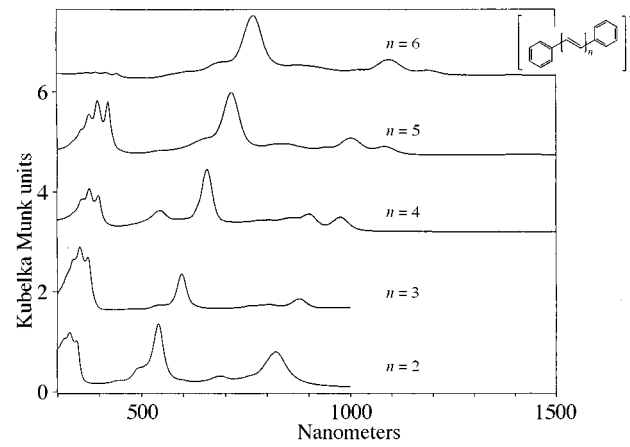

Fig. 12 Diffuse reflectance spectra of α,ω-diphenylpolyenes included within Na-ZSM-5 (Si/Al = 23). The absorption is due to stabilized radical cations of the alkanes.

observed upon excitation of *cis*-stilbene, in addition to weak signals due to photocyclizaton to give dihydrophenanthrene. There was no evidence for the generation of the *cis* radical cation (510 nm). However, a mixture of *cis* and *trans* radical cations was observed upon excitation of the *cis*-stilbene/tetranitromethane charge transfer complex in NaX zeolite, providing evidence that both radical cations were stable with respect to isomerization on the timescale of the laser experiments. Product studies carried out with laser irradiation demonstated that substantial *cis–trans* isomerization of stilbene occured within a few laser pulses. The combined results lead to the conclusion that *cis–trans* isomerization followed by photoionization of *trans*-stilbene was responsible for the observation of the *trans* radical cation upon excitation of *cis*-stilbene. We believe that an alternative possibility of photochemical isomerizaton within the laser pulse is less likely. The less efficient photoionization of *cis*-stilbene was consistent with its shorter singlet lifetime and the fact that it has an additional decay pathway involving photocyclization.

Direct excitation of 4-vinylanisole and *trans*-anethole,[52] as well as several other styrenes,[53] in zeolites also leads to the formation of the respective radical cations. For example, the *tran*-anethole radical cation has two characteristic absorption bands at 620 and 390 nm that agree well with the spectra for the same species in solution. Similar experiments using direct excitation of a number of di(4-methoxyphenyl)ethylenes in NaX zeolites provided evidence for formation of trapped electrons, indicating that photoionization also occurs for these alkenes.[54] However, the yields were considerably lower than for the styrenes, making it difficult to characterize the radical cations.

The products of direct excitation of a hexane slurry of di(4-methoxyphenyl)ethylene included within NaY zeolite are shown in Scheme 14.[55] Interestingly, no products are formed in

	Relative Yield (%)

Scheme 14

the absence of oxygen and the nature of the products depends on the excitation wavelength (Scheme 14). The key intermediate in both the reduction and the oxidation processes is believed to be the radical cation of di(4-methoxyphenyl)ethylene. The absorbing species during short and long wavelength excitations are thought to be different: at long wavelength it is in the alkene–oxygen complex and at short wavelength the uncomplexed alkene. The formation of hydrocarbon–oxygen complexes within zeolites had been extensively investigated by Frei *et al*.[56] The diffuse reflectance spectra shown in Fig. 13 indicate that di(4-methoxyphenyl)ethylene forms an oxygen complex when present within NaY. A proposed mechanism for the formation of products upon short and long wavelength excitations is shown in Scheme 15. Under both conditions an electron transfer is thought to be the primary step. During short wavelength excitation the primary electron acceptor is presumed to be the zeolite and during the long wavelength excitation the oxygen complexed to the alkene is likely the electron acceptor. Experiments aimed at a more detailed understanding of these reactions are in progress.

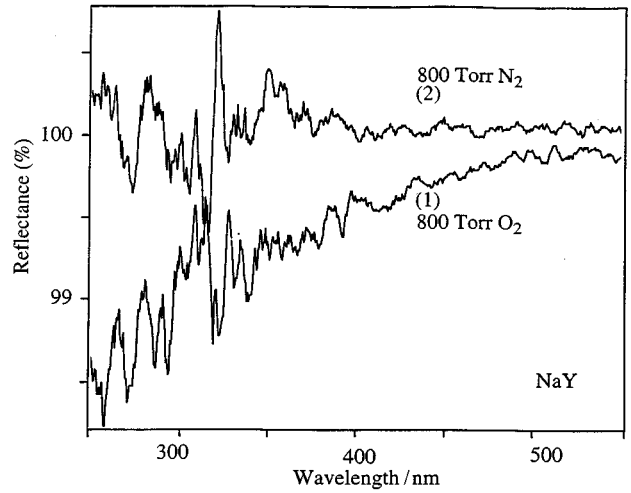

Fig. 13 Diffuse reflectance spectra of 4,4′-dimethoxydiphenylethylene included within NaY. Trace (1) is the difference of spectra taken after and before loading 800 Torr oxygen into the room temperature zeolite. Trace (2) is a control spectrum in which nitrogen was loaded instead of oxygen. Oxygen shows an absorption extending to 500 nm whereas nitrogen shows no such absorption. (We than S. Vasenkov and H. Frei, University of California, Berkeley for recording the spectra for us).

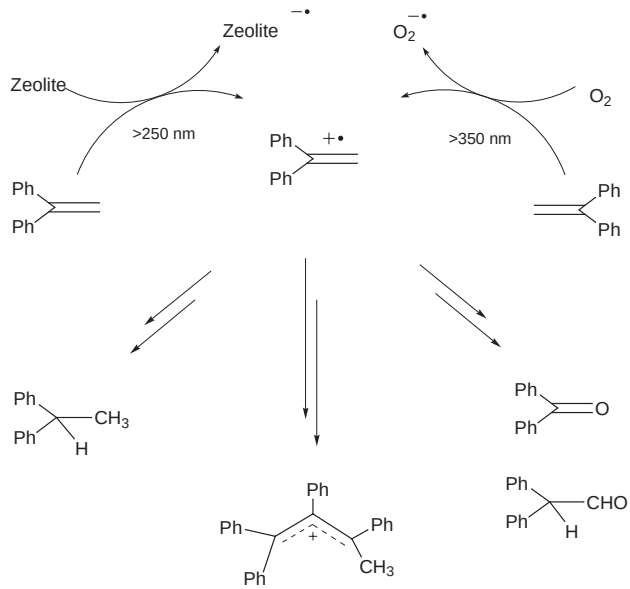

Scheme 15

The stabilization of organic radical cations within zeolites suggests that the confined interior space of a zeolite should provide an ideal environment for carrying out photosensitized electron transfer reactions. This approach has advantages in that one does not require prior preparation of an activated zeolite which may have a relatively small number of active sites as in the spontaneous electron transfer. Photosensitized electron transfer should also be applicable to a wider range of substrates. In addition, the zeolite environment promotes charge separation which is expected to be advantageous, since it will reduce the rate of the back-electron-transfer process that decreases the efficiency of these reactions in solution. We have used the dimerization of arylalkenes to demonstrate the viability of carrying out photoinduced electron transfer reactions for independently loaded sensitizers and alkene donors and to examine the effect of the zeolite environment on the product selectivity. The results obtained for *trans*-anethole using 2,3-dicyanonaphthalene and 9-cyanoanthracene as sensitizers are typical. For example, a combination of steady state and time-resolved fluorescence measurements indicated that the singlet excited state of the sensitizer was quenched by the alkene, predominantly *via* a static mechanism. Diffuse re-

flectance flash photolysis experiments were carried out using 355 nm excitation which excited the sensitizer only. The results demonstrated that the efficient singlet quenching of the sensitizer was accompanied by formation of the *trans*-anethole radical cation (Fig. 14). The latter has a spectrum similar to that

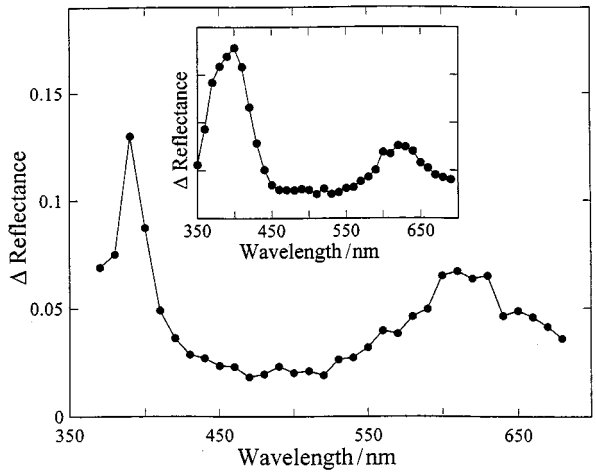

Fig. 14 Transient spectra measured after 355 nm excitation of 2,3-dicyanonaphthalene plus *trans*-anethole in NaX. The inset shows the spectrum obtained by direct 266 nm excitation of *trans*-anethole in NaX.

obtained by direct excitation of *trans*-anethole at 266 nm. The transient spectra also provided evidence for photoionization of the cyanoaromatic sensitizers in competition with electron transfer quenching in the zeolite environment. Efficient electron transfer was observed for 9-cyanoanthracene and 1-cyanonaphthalene sensitizers with *trans*-anethole and 4-vinylanisole, demonstrating the generality of these results. In each case the radical cation was relatively long-lived, illustrating the potential of the zeolite environment for overcoming the limitation of back electron transfer.

The products of the radical cation initiated dimerization of a series of arylalkenes with cyanoaromatic and quinolinium and acridinium sensitizers were examined. The results indicate that the radical cations add to the precursor alkenes to give dimeric products (Scheme 16), as has been observed in solution. In some cases oxidation of the alkenes accompanied dimer formation. A number of control experiments were carried out to ensure that the observed products resulted from sensitization rather than direct photolysis of the alkenes and to ensure that the product ratios did not reflect further reactions of the initial dimers. The product studies demonstrated that radical cation mediated dimerization occurred readily in the zeolite environment and suggested that the radical cations observed in the transient experiments are reactive. The dimer ratios also illustrated some important differences between the soluton and zeolite chemistry. For example, although both *cis*/*syn* and *trans*/*anti* dimers were formed, the zeolite favors the *cis*/*syn* product which has a more spherical shape that is similar to the geometry of the supercage. We believe that this reflects the fact that the more linear *trans*/*anti* isomers are best accommodated in two supercages whereas the *cis*/*syn* dimer can be formed within a single cage and therefore its formation is the more favorable process. It also appears that the zeolite environment is more important in determining the geometry of the dimeric products than the method (direct or sensitized photocycloaddition *vs.* radical ion initiation) used for their generation.

Concluding remarks

The chemistry of alkenes in zeolites illustrates both the potential complexity and utility of zeolites as reaction media. For example, the results discussed above demonstrate that spontaneous thermal proton and electron transfer reactions are

	Relative Yield (%)

Scheme 16

common, particularly for zeolites with relatively large numbers of active sites. NMR studies are particularly useful in correlating the number and type of active sites with the chemistry observed and permit one to select a zeolite and an activation procedure that can be used to tune the chemistry. In cases where the zeolite contains fewer active sites, stable alkenes can undergo a range of photochemical reactions, as demonstrated with the energy transfer sensitized singlet oxygen ene reaction and photoinduced electron transfer reactions that lead to dimeric products. Both examples serve to illustrate the ease with which bimolecular reactions between independently loaded donors and acceptors in zeolites can be carried out. A combination of techniques, including product studies, fluorescence and diffuse reflectance flash photolysis, can provide a detailed picture of the reactive intermediates that lead to the observed chemistry. Of particular interest are the changes in product selectivity that result from carrying out these reactions in the constrained space of the zeolite cavity. The results discussed herein provide an excellent basis for the development of sufficient predictive power that one can tune the behavior of the thermal and photochemical behavior for substrates within zeolites in order to achieve a desired product outcome.

32 Recently, there have been reports in which photochemical reactions of alkenes in H^+ zeolites have been investigated.[33] However, it has been our experience that alkenes undergo Brønsted acid catalyzed reaction in H^+Y zeolites.[34] Therefore, H^+ zeolites should be avoided as hosts when investigating the photochemical behavior of alkenes.

Cyclopentadienyl titanium chlorides containing *ortho*-(1-naphthyl)phenoxide ligation

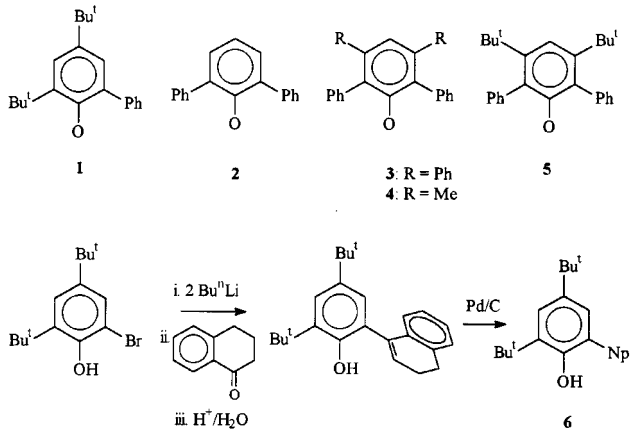
Jonathan S. Vilardo, Matthew G. Thorn, Phillip E. Fanwick and Ian P. Rothwell*

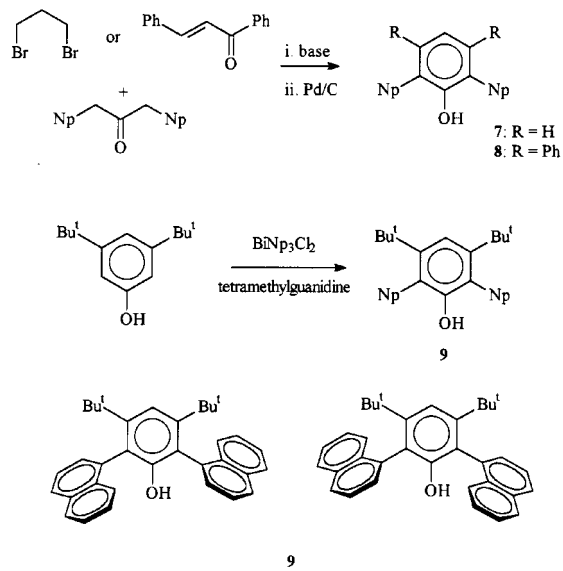
Department of Chemistry, 1393 Brown Building, Purdue University, West Lafayette, IN 47907-1393, USA. E-mail. rothwell@chem.purdue.edu

Received (in Bloomington, IN, USA) 30th June 1998, Accepted 2nd September 1998

A series of mono-cyclopentadiene derivatives of titanium containing *ortho*-(1-naphthyl)phenoxide ligands have been studied; the Ti–Ti distance in the d^1–d^1 species [Cp(Ar-O)Ti(μ-Cl)$_2$Ti(OAr)Cp] is exactly intermediate between that found in paramagnetic [Cp$_2$Ti(μ-Cl)$_2$TiCp$_2$] and diamagnetic [(ArO)$_2$Ti(μ-Cl)$_2$Ti(OAr)$_2$].

Ortho-phenyl phenoxide ligands, *e.g.* **1** (Scheme 1) and **2**, are an important subset of aryloxide ligation that have been used to support inorganic/organometallic chemistry at p-block,[1] d-block[2] and f-element[3] metal centers. Following our successful development of cyclometalation resistant, *e.g.* **3** and **4**, and immune, **5** (Scheme 1) aryloxide ligation[4] we have begun to study the chemistry of potentially chiral *o*-(1-naphthyl)phenoxide ligands. Straightforward synthetic strategies lead to the non-symmetric **6** and symmetric **7** and **8** (Scheme 1, Np = 1-naphthyl).† Both **7** and **8** are produced as a 50/50 mixture of non-chiral *meso* and DL forms. In the case of **7** inter-conversion of the two forms occurs on the NMR timescale with the barrier for naphthyl rotation estimated as 18.0(5) kcal mol^{-1} at 67 °C. Presumably a similar barrier will be present for other *o*-(1-naphthyl)phenols lacking *meta* substituents. In the case of *meta*-phenyl blocked **8** it is possible to isolate the pure, crystalline *meso* form from CH_2Cl_2–heptane and show that inter-conversion in this case requires days at 100 °C.[5] In contrast an adaptation of the chemistry of the late Sir Derek Barton[6] leads to **9** (Scheme 1) which is produced as a single isomer whose subsequent chemistry (below) shows it to be the chiral form.





Scheme 1

Reaction of phenols **1**, **4**–**6** and **9** in the presence of pyridine (py) or the lithium salt of **5** with [CpTiCl$_3$] yields the compounds **10**–**12** as orange solids in high yield (Scheme 2). The solid state structure of **12b** (Fig. 1)‡ confirms the chiral nature of the single isomer of phenol **9** generated by the particular method of synthesis. The solution NMR spectroscopic properties of **10**–**12** are as expected with single C_5H_5 resonances and a single set of aryloxide signals in each cause.† In the ^{1}H NMR spectrum of **12b** the C_5H_5 protons resonate at significantly higher field, δ 5.32 compared to the δ 5.6–5.8 region found for the other derivatives. This indicates much greater diamagnetic shielding of adjacent ligand protons and is caused by the presence of the two *ortho*-(1-naphthyl) rings, which are locked in place by the *meta*-*tert*-butyl groups.

Treatment of **10b** with sodium amalgam (1 Na per Ti) leads to a red solution of the dimeric species **13** (Scheme 2). The solid state structure of **13** (Fig. 2)‡ shows a dinuclear compound with a Ti(μ-Cl)$_2$Ti core and terminal aryloxide and Cp groups. The

$Ti(OC_6H_3Ph_2\text{-}2,6)_2Cl_2$	109	113	2.206(1)	—	8
$[Cp_2Ti(\mu\text{-}Cl)]_2$	133	79	2.55 (av.)	3.95 (av.)	9
$[CpTi(OC_6H_2Np\text{-}2\text{-}Bu^t_2\text{-}4,6)(\mu\text{-}Cl)]_2$ **13**	125	115	2.40 (av.)	3.336(1)	This work
$[Ti(OC_6H_3Ph_2\text{-}2,6)_2(\mu\text{-}Cl)]_2$	144	102	2.37 (av.)	2.9827(7)	10

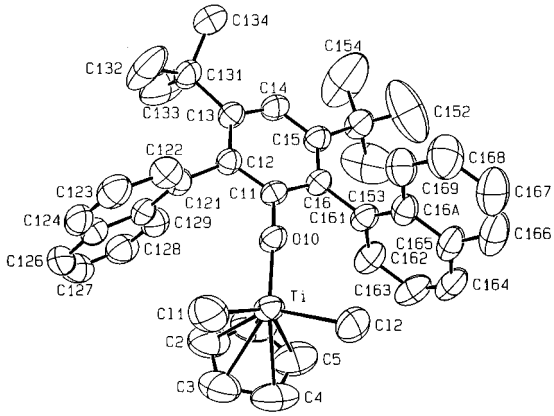

Fig. 1 Molecular structure of **12b** showing the atomic numbering scheme. Selected interatomic distances (Å) and angles (°): Ti–O(10) 1.774(3), Ti–Cl(1) 2.230(2), Ti–Cl(2) 2.244(2); Cl–Ti–Cl 102.36(7), Cp–Ti–O(10) 118.6(2), Ti–O(10)–C(11) 164.1(3).

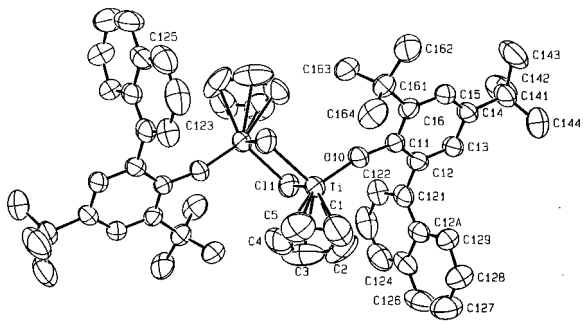

Fig. 2 Molecular structure of **13** showing the atomic numbering scheme. Selected interatomic distances (Å) and angles (°): Ti–Ti 3.336(1), Ti–O(10) 1.817(2), Ti–Cl(1) 2.400(1), 2.406(1); Cl(1)–Ti–Cl(1) 92.07(4), Cp–Ti–O(10) 125.1(3), Ti–O(10)–C(11) 166.7(2).

Cp ligands are arranged in a transoid fashion, with a crystallographic inversion center being present. The molecular structure of **13** is such that each dimeric unit contains two naphthylphenoxides of opposite chirality.

Table 1 collects some structural parameters for selected derivatives of Ti(IV/III), focusing on the effects of replacing Cp ligands by OAr groups. Some trends can be discerned. The Ti–Cl distance decreases significantly in both series of compounds as Cp is replaced by OAr, reflecting an increase in electrophilicity of the metal center. In the tetrahedral Ti(IV) series the Cl–Ti–Cl angle opens up as the corresponding X–Ti–Y angle closes down upon replacement of Cp by OAr.[7,8] The most interesting parameter is the Ti–Ti distances in the d^1–d^1 dimers.[9,10] The 3.95(av.) distance in the Cp_2Ti compounds is consistent with the complete lack of any metal–metal bonding. In contrast the short distance in the diamagnetic bis(aryloxide) is consistent with the presence of a Ti–Ti single bond.[10] In the case of the 'hybrid' paramagnetic species **13**, the Ti–Ti distance is exactly intermediate between the previous two molecules. In this case there is clearly no metal–metal bond present and the observed Ti–Ti distance possibly is purely a consequence of the Ti–Cl distances within the $Ti(\mu\text{-}Cl)_2Ti$ unit.

We thank the National Science Foundation (Grant CHE-9321906) for financial support of this research.

A series of dimethyl compounds of Ti(IV) have been isolated containing both cyclopentadiene and *ortho*-arylphenoxide ligation; reaction with $[B(C_6F_5)_3]$ generates corresponding cationic methyl species which eliminate methane and form $[Cp(ArO)Ti\{CH_2B(C_6F_5)_2\}(C_6F_5)]$ derivatives.

There is continued research interest in the chemistry of cationic Group 4 metal alkyl compounds.[1] We have recently isolated a series of titanium chloride compounds containing both cyclopentadiene and *o*-arylphenoxide ligation.[2,3] We report here on the structure, dynamics and reactivity of the corresponding neutral and cationic methyl derivatives.[4,5]

Treatment of **1**–**3** with LiMe leads to the corresponding dimethyl compounds **4**–**6** as yellow solids (Scheme 1, Np = 1-naphthyl).† The solid state structure of **4b** is shown in Fig. 1.‡ The Ti–Me distances of 2.076(4) and 2.091(4) Å are intermediate between those reported for $[Cp_2TiMe_2]$,[6] 2.170(2) and 2.181(2) Å, and values of 2.052(2) and 2.069(2) Å found in $[Ti(OC_6H_3Ph_2\text{-}2,6)_2Me_2]$.[7] There is also a corresponding opening up of the Me–Ti–Me angle upon replacing Cp by OAr; *c.f.* 91.3(1)° for $[Cp_2TiMe_2]$, 97.5(2)° in **4b** and 103.9(1)° in $[Ti(OC_6H_3Ph_2\text{-}2,6)_2Me_2]$. In the solution NMR spectra of **4a**, **5** and **6a**, only one signal is present for the Ti–Me groups in the ^{1}H and ^{13}C NMR spectra. This indicates in the case of **4a** that rotation about the Ti–O–Ar bonds is fast on the NMR timescale. In contrast two well-resolved Ti–Me resonances are observed for the *o*-(1-naphthyl) derivatives **4b** and **6b**. In the case of **6b** this is consistent with the presence of the chiral, *dl*-form of the ligand. Variable temperature NMR studies of **4b** show that the two methyl signals remain sharp even at 90 °C (toluene-d_8), indicating slow naphthyl rotation on the NMR timescale at this temperature.

Addition of $[B(C_6F_5)_3]$[8] to **4**,**5** in benzene or toluene solvent leads to the rapid (NMR) formation of the thermally unstable (*vide infra*) cationic **7**,**8**. Variable temperature spectra of these species are highly informative. Low temperature ^{1}H and ^{13}C NMR spectra of **7a** and **8** show a single set of Cp and OAr resonances along with resolved Ti-Me (sharp) and Ti-Me-B (broad) resonances. Spectra obtained for **7a** at ambient temperature show broadening of these methyl signals, but the thermal instability precludes obtaining limiting high temperature spectra. We interpret this broadening as due to exchange of the boron between methyl groups (boron exchange) which is becoming fast on the NMR time scale. For **7b**, two broad methyl signals and a single, sharp Cp resonance are present at room temperature. At −10 °C (toluene-d_8) the Ti-Me and Ti-Me-B signals sharpen up, but there is still only a single Cp resonance. At −30 °C the Cp resonance splits into two signals in the ratio of 80 : 20 representing the two, diastereoisomeric forms. The methyl signals also split into two large, equal intensity signals and one resolvable smaller peak (presumably the second methyl signal is obscured by OAr resonances). We interpret these changes as representing two distinct dynamic processes. The faster process involves exchange between the two diastereoisomers (80 : 20 ratio) of **7b** (Scheme 2) without methyl exchange. This process involves cation–anion dissociation and rearrangement and can only be detected using the chiral *o*-(1-naphthyl)phenoxide. An alternative process for exchange of diastereoisomers would involve naphthyl rotation. However, the variable temperature NMR studies on **4b** and data presented below show that this process is too slow to account for the observed process. The slower process in **7b**, which is also detected for **7a** and **8**, involves Ti-Me/Ti-Me-B exchange. In the case of **7b** this process alone cannot lead to exchange of methyl signals in the NMR spectra. However, when coupled with the faster ion-pair dissociation, it leads to methyl exchange (Scheme 2). Previous work by Marks *et al*. has shown similar dynamics are present in $[Cp'_2Zr(Me)\{MeB(C_6F_5)_3\}]$ species.[8] Based upon the spectra obtained for **7b** we estimate the free energy of activation for ion-pair dissociation to be 12.4(5) kcal mol^{-1} at −25 °C (Cp

coalescence temperature at 300 MHz) while that for the methyl exchange is 15.0(5) kcal mol^{-1} at −35 °C.

When monitored by ^{1}H NMR, solutions of **7**,**8** at ambient temperatures over hours eliminate methane and form the neutral species **9**,**10** (Scheme 2). The solid state structure of **10** (Fig. 2) confirms the molecular structure and shows that the boron atom is trigonal planar with no interaction present with the adjacent Ti-C_6F_5 unit.[9] In the ^{1}H NMR spectra of **9a** and **10**, a single set of Cp and OAr resonances are present along with well-resolved diastereotopic Ti-CH_2-B protons. In the case of **9b** containing the chiral *o*-(1-naphthyl) ligand, two sets of sharp NMR signals are present representing a 70 : 30 mixture of the two possible diastereoisomers. The fact that exchange of these isomers is slow on the NMR timescale at ambient temperature confirms that naphthyl rotation cannot account for the observed fluxionality in **7b**.

Received (in Cambridge, UK), 29th July 1998, Accepted 29th September 1998

The reaction of [$Pd_2(CH_2C_6H_4P(o\text{-tolyl})_2$-κ*C*,*P*)$_2$($\mu$-3,5-dmpz)$_2$] (1) with $AgClO_4$ renders [{$Pd_2(CH_2C_6H_4P(o\text{-tolyl})_2$-κ*C*,*P*)$_2$($\mu_3$-3,5-dmpz-*N*,*N*′,*C*^{4})$_2$Ag(η^2-μ-ClO_4)}$_2$] (2), a palladium–silver derivative displaying an unprecedented dmpz bridging ligand η^1 bonded to the Ag centers, involving only the C^4 atom of each dmpz ligand.

The chemistry of dimetallic compounds containing two μ-azolato bridging groups has been intensively developed in the last three decades,[1] especially in the case of dirhodium and diiridium derivatives.[2] Studies of these systems have included substitution reactions,[2a,b] oxidative additions,[2c,d] kinetics,[2e,f] electrochemistry,[2g] photochemistry,[2h] hydroformylation reactions[2i] and theoretical studies.[2j] Pyrazolate ligands have a proven ability to hold two metal atoms in close proximity, while permitting a wide range of intermetallic separations. Compounds with two bridging azolato groups show a boat conformation of the central 'M_2N_4' six membered ring. The π-electron rich cleft between the two azolato rings in these molecules offers a potentially interesting site for further complexation (Fig. 1). To our knowledge there has been no previous report of a complex in which a dimetallic 'M_2(μ-azolato)$_2$' moiety uses its π-electron system to accommodate a transition metal cation.

In view of the paucity of dipalladium and diplatinum complexes with μ-azolato bridging groups[3] we decided to explore the synthesis and reactivity of compounds of the type [M_2(C^P)$_2$(μ-L)$_2$] [M = Pd, Pt; C^P = $CH_2C_6H_4P(o\text{-tolyl})_2$; HL = pyrazole (Hpz), 3,5-dimethylpyrazole (H3,5-dmpz)]. The reaction of [Pd_2(C^P)$_2$(μ-3,5-dmpz)$_2$] (**1**)† with $AgClO_4$ renders **2**‡ [eqn. (1)].

$$\underset{\mathbf{1}}{2[Pd_2(C\text{^}P)_2(\mu\text{-}3,5\text{-dmpz})_2]} + 2\,AgClO_4 \rightarrow \underset{\mathbf{2}}{[\{Pd_2(C\text{^}P)_2(\mu_3\text{-}3,5\text{-dmpz-}N,N',C^4)_2Ag(\eta^2\text{-}\mu\text{-}ClO_4)\}_2]} \quad (1)$$

Compound **2**, as has been established by an X-ray study§ (Fig. 2), is formed by two {Pd_2(C^P)$_2$(μ_3-3,5-dmpz-*N*,*N*′,-*C*^{4})$_2$Ag(η^2-μ-ClO_4)} units bridged by two perchlorate groups and related to each other by a crystallographic center of symmetry. Each unit contains a dinuclear palladium fragment 'Pd_2(C^P)$_2$(μ-3,5-dmpz)$_2$' and a silver atom located in the cleft between the two dmpz groups and η^1-bonded to the C^4 atoms of the dmpz ligands.

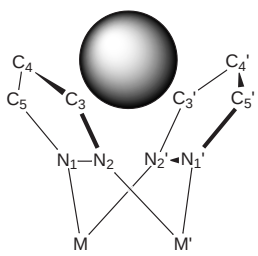

Fig. 1 Schematic diagram showing a guest atom in the cleft formed by the two pyrazolate rings of the moiety [Pd_2(C^P)$_2$(μ-3,5-dmpz)$_2$] .The atom numbering scheme used in the NMR analyses is shown.

The palladium fragment 'Pd_2(C^P)$_2$(μ-3,5-dmpz)$_2$' consists of a typical head to tail dimer with bridged 3,5-dmpz anions, with the usual boatlike conformation of the Pd_2N_4 six-membered metallocycle. The Pd···Pd distance (3.2297(7) Å) is slightly longer than those observed in other Pd (or Pt) complexes with two pyrazolate bridging ligands.[3a–c] The bond distances and angles in the metallocycles in compound **2** are similar to those observed in palladium and platinum compounds

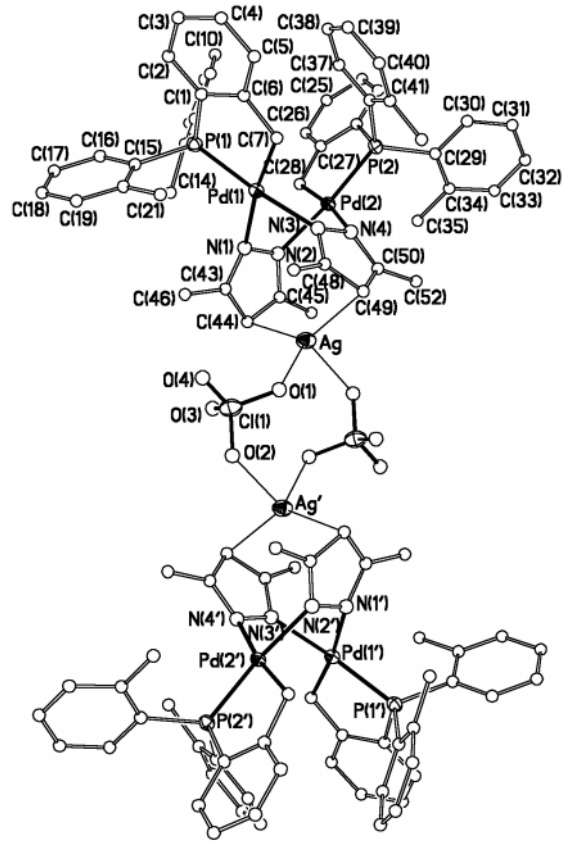

Fig. 2 Molecular structure for compound **2.** Selected bond distances: Pd(1)–C(7) = 2.034(5), Pd(1)–P(1) = 2.2251(13), Pd(2)–C(28) = 2.042(5), Pd(2)–P(2) = 2.2268(13), Pd(1)–N(1) = 2.138(4), Pd(1)–N(3) = 2.097(4), Pd(2)–N(2) = 2.092(4), Pd(2)–N(4) = 2.136(4), Ag–C(44) = 2.410(5), Ag–C(49) = 2.420(5), Ag–O(1) = 2.431(4), Ag–O(2′) = 2.464(4), N(1)–N(2) = 1.371(6), N(1)–C(43) = 1.331(6), C(43)–C(44) = 1.405(7), C(44)–C(45) = 1.410(7), N(2)–C(45) = 1.332(6), N(3)–N(4) = 1.375(6), N(3)–C(48) = 1.342(6), C(48)–C(49) = 1.405(7), C(49)–C(50) = 1.405(7), N(4)–C(50) = 1.330(7) Å. Selected bond angles: Ag–C(44)–C(43) = 94.5(3), Ag–C(44)–C(45) = 89.1(3), Ag–C(49)–C(48) = 86.7(3), Ag–C(49)–C(50) = 95.7(3)°.

containing the same C^P group.[4] The dmpz groups are planar, and the angle between them in each '$Pd_2(C\hat{}P)_2(\mu\text{-}3,5\text{-dmpz})_2$' fragment is 44.8°. Bond lengths and angles around the N and C atoms of the 3,5-dmpz are identical to those observed in other complexes.[3a]

The extraordinary structural feature of this compound is the unprecedented coordination mode of the 3,5-dmpz groups to Ag^+. The silver cation is located in the cleft between, and approximately equidistant from, the two 3,5-dmpz rings at a distance of 2.410(5) Å and 2.420(5) Å from C(44) and C(49) respectively, the C^4 atom of each dmpz ring (Fig. 1). The Ag–C(49) and Ag–C(44) vectors are nearly perpendicular to the corresponding dmpz rings, the angles between the perpendicular to the corresponding rings and the Ag–C^4 bonds being 5.9° [Ag–C(49)] and 4.0° [Ag–C(44)] respectively. The long Ag–C(48) (2.728 Å), Ag–C(50) (2.917 Å), Ag–C(43) (2.883 Å) and Ag–C(45) (2.773 Å) distances seem to exclude any bond interaction between Ag and these atoms. So, both 3,5-dmpz rings seem to be η^1-coordinated [C(44) and C(49)] to the silver atom. The Ag–C bond lengths (*ca.* 2.415 Å) are similar to the shortest values found in Ag–η^1-arene complexes such as $[AgB_{11}CH_{12}\cdot 2C_6H_6]$ [2.400(7) Å],[5a] [Ag(deltaphane)-(O_3SCF_3)] (2.41–2.48 Å),[5b] [Ag{(*Z*)-2,2,5,5-tetramethyl-3,4-diphenylhex-3-ene}(O_3SCF_3)] [2.579(4) Å],[5c] and [indene·$AgClO_4]_2$ [2.47(2) Å],[5d] and are clearly shorter than the Ag–C distances observed in Ag–η^2-arene complexes, such as [Ag(25,26,27,28-tetramethoxycalix(4)arene)$(NO_3\text{-}O,O')$] [2.504(5), 2.643(5), 2.527(5), 2.549(5) Å],[5e] $[\{AuAg(C_6F_5)_2(C_6H_6)_n\}]$ [2.48, 2.50 Å][5f] and [catena(μ-η^4-*rac*(2)(1,5-naphthalino(2)paracyclophane)(μ-perchlorato-*O*,*O*′,*O*″)silver(I)] [2.365, 2.607 Å].[5g]

Finally, the Ag coordination is completed by two Ag–O bonds [Ag–O(1) = 2.431(4), Ag–O(2A) = 2.464(4) Å], one from each of the two bridging ClO_4 groups, in such a way that Ag shows a distorted tetrahedral coordination environment. The Ag–O bond distances are in the range found in complexes with triflate,[5b] nitrate[5e] or for μ-ClO_4 bonded to silver.[6]

As has been mentioned, the bond distances and angles in the dmpz groups in **2** are very similar to those observed in uncomplexed '$M_2L_2(\mu\text{-pz})_2$' compounds, indicating that in spite of the η^1 interaction to the silver centre, the pyrazolato rings maintain their aromaticity. The mass spectrum (FAB^+) of **2** shows the molecular peak for the cation $[Pd_2(C\hat{}P)_2(\mu_3\text{-}3,5\text{-dmpz-}N,N',C^4)_2Ag]^+$ (1119). The sharp ^{31}P, ^1H and ^{13}C NMR signals of **2** at room temperature and their observed shifts with respect to those in the starting material, **1**, indicate that the silver–η^1-dmpz bonds are present in solution. Especially significant are the changes observed in the ^{13}C NMR spectrum of **2** with respect to that of **1**, mainly in the signal due to the C atoms η^1-bonded to silver, the C^4 atom of each dmpz group. For compound **2** it appears at 86.8 ppm, *i.e.*, shifted upfield by 16.34 ppm, and which becomes a multiplet, probably as a consequence of the coupling of the C^4 atoms to the P, ^{107}Ag, and ^{109}Ag nuclei. Due to the poor resolution of this spectrum, no individual values for the coupling constants could be extracted.

Studies of the reactivity of other palladium and platinum pyrazolate complexes towards other Lewis acid metal complexes are in progress.

A highly selective water-soluble dicationic palladium catalyst for the biphasic hydroxycarbonylation of alkenes

Marcel Schreuder Goedheijt, Joost N. H. Reek, Paul C. J. Kamer and Piet W. N. M. van Leeuwen*

Institute for Molecular Chemistry, Department of Inorganic Chemistry, University of Amsterdam, Nieuwe Achtergracht 166, 1018 WV Amsterdam, The Netherlands. E-mail: pwnm@anorg.chem.uva.nl

Received (in Cambridge, UK) 17th August 1998, Accepted 23rd September 1998

The application of a water-soluble diphosphine with a xanthene-type backbone in the biphasic palladium-catalysed hydroxycarbonylation reaction of alkenes leads to the selective formation of carboxylic acids.

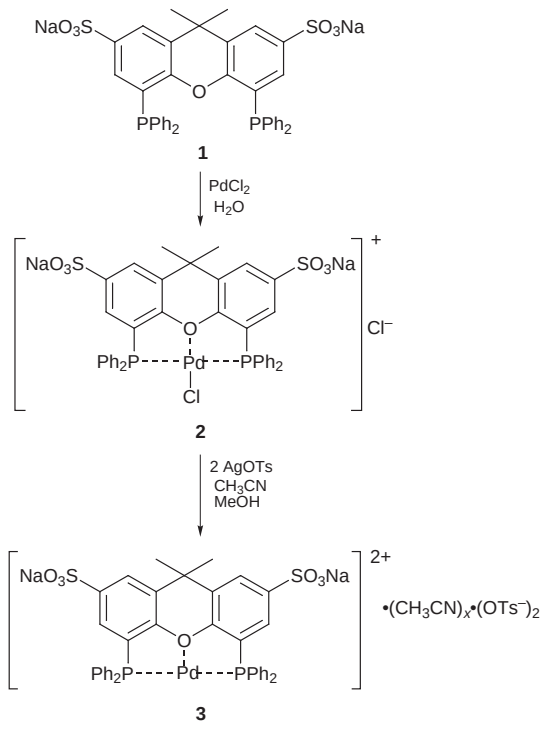
Water-soluble organometallic compounds have attracted considerable interest as catalysts.[1] Application of these compounds in two-phase catalysis results in easy separation and recycling of the catalyst.[2]

Various alkenes can be hydroxycarbonylated with carbon monoxide and water using transition metal compounds to yield the corresponding carboxylic acids.[3] Recently, the use of palladium catalysts for the biphasic hydroxycarbonylation of alkenes was reported.[4] The hydroxycarbonylation of alkenes in a two-phase system with the water-soluble palladium catalyst [Pd(TPPTS)$_3$] in the presence of a Brønsted acid as promoter yields carboxylic acids.[4,5] The catalyst predominantly affords carboxylic acids, but in most cases it suffers from low activities and selectivities. Water-soluble bidentate phosphines have been used to form active catalysts for palladium-catalysed alternating copolymerisation, *e.g.* a catalyst formed with the bidentate water-soluble phosphine C_3H_6-1,3-[P(C_6H_4-*m*-$SO_3Na)_2]_2$ (dppp-s) produces polyketone from ethylene and carbon monoxide.[6]

Recently, we developed the water-soluble bidentate diphosphine 2,7-bis(SO_3Na)-Xantphos (**1**) which was successfully applied in the two-phase rhodium-catalysed hydroformylation reaction of alkenes.[7] Here, the highly selective palladium-catalysed formation of carboxylic acids from alkenes and carbon monoxide in the presence of **1** and a Brønsted acid as a cocatalyst will be described.

Complex **2** was prepared by reaction of **1** with $PdCl_2$. Addition of two equivalents of AgOTs (OTs = *p*-$CH_3C_6H_4SO_3^-$) to a solution of **2** resulted in the dicationic palladium complex **3** which was isolated as an orange powder. The $^{31}P\{^1H\}$ NMR spectrum in CD_3OD shows only a singlet at 25.6 ppm which indicates that a *trans* complex is formed exclusively at room temperature.† This is probably due to the large natural bite angle of the xanthene backbone and the coordination of the oxygen atom to the dicationic palladium center.‡ The preferential formation of the *trans* complex, excluding copolymerisation activity which requires a *cis* coordination,[8] prompted us to investigate the applicability of **3** (and **2**) toward the selective formation of carboxylic acids. Indeed, hydroxycarbonylation of ethylene was 100% selective towards the formation of propionic acid without formation of oligomers or copolymers as indicated by ^1H NMR spectroscopy.§ The reaction proceeded at relatively low concentrations of palladium (1.6 mmol l^{-1}). As expected, the activity increased with increasing temperature. The addition of TsOH as a promoter was necessary to stabilise the catalyst as otherwise palladium black is formed during the reaction. The use of propionic acid as the proton donor instead of TsOH gave rise to formation of metallic palladium as well. More strongly coordinating anions stabilise the cationic center which results in a slower reaction and eventually in decomposition of the catalyst at elevated temperatures.[5,6] Run 1 was performed at 95 °C using 50 equivalents of TsOH and a total initial pressure of 30 bar (CO–ethylene = 1 : 1; Table 1). After the reaction very small amounts of palladium metal were formed. The activity (TOF¶ = 133 h^{-1}) increased to 180 h^{-1} when the reaction was carried out at 120 °C (run 2). When an additional equivalent of **1** was added to the catalyst solution an even higher activity was observed (TOF = 304 h^{-1}; run 3). Furthermore, no formation of palladium metal was observed during this run suggesting that the stability of the catalyst system had increased. Lower activities were found when **2** was used as the catalyst (TOF = 218 h^{-1} and 272 h^{-1}; runs 4 and 5) suggesting the higher activity for **3**. Catalysts prepared *in situ* (runs 6 and 7) gave rise to lower rates compared to **3** as well. In this case, the formation of the active catalyst is slower.

In order to investigate the regioselectivity of the catalytic system towards the formation of linear (l) and branched (b) carboxylic acids styrene and propene were also studied as substrates. The hydroxycarbonylation of styrene catalysed by **3** led to a mixture of 2- and 3-phenylpropionic acid (Scheme 2). The l/b ratio of the carboxylic acids was *ca.* 65/35 and a TOF of 40 h^{-1} was observed (run 9). A l/b ratio of *ca.* 70/30 was found when Pd(TPPTS)$_3$ was used as the catalyst (60% selectivity towards the formation of acids). This suggests that **3** does not induce higher selectivity compared to monodentate phosphines.‖ At 70 °C, 30 bar CO pressure and in the presence of 4-*tert*-butylcatechol as a polymerisation inhibitor less thermal polymerisation was observed without any change in activity and l/b ratio.



Scheme 1 Synthesis of the cationic palladium complexes **2** and **3**.

Table 1 Palladium-catalysed hydroxycarbonylation of ethylene (**4**), styrene (**5**) and propene (**6**)[a]

Run	Olefin	*p*-$CH_3C_6H_4SO_3H$/ mmol	*T*/°C	*t*/min	l/b	TOF/h^{-1}

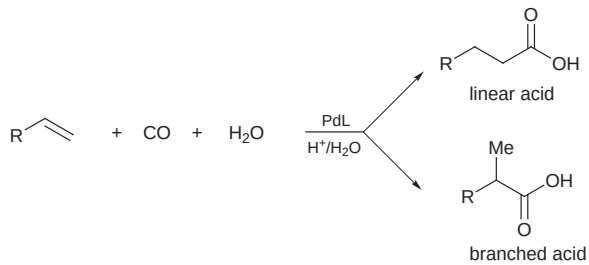
18[k]	**6**	2.7	120	180	64/36	129

[a] Reaction conditions: 15.8×10^{-3} mmol Pd complex **3**, Brønsted acid, amount of olefin (15 bar of **4** or 9 bar of **6**) without the addition of organic solvent; initial total pressure at RT: 30 bar unless otherwise stated, 10 mL of H_2O. [b] 1 equiv. Xantphos-s added to **3**. [c] Palladium complex **2** was used as precursor. [d] Catalyst prepared *in situ* from $PdCl_2$ and 1 equiv. Xantphos-s. [e] Catalyst prepared *in situ* from $Pd(OAc)_2$ and 1 equiv. Xantphos-s. [f] 35% of polystyrene formed. [g] 4-*tert*-Butylcatechol (5 mmol) was added; 19% of polystyrene formed. [h] pressure **6** = 9 bar; pressure CO = 2 bar at RT. [i] pressure **6** = 9 bar; pressure CO = 1 bar at RT. [j] L/Pd ratio = 2; no formation of palladium black observed. [k] pressure **6** = 4.5 bar.



Scheme 2 Palladium-catalysed hydroxycarbonylation of ethylene (**4**; R = H), styrene (**5**; R = Ph) and propene (**6**; R = CH_3) (L = **1**).

Propene was hydroxycarbonylated at higher temperatures (100 °C) than styrene since it is not susceptible to polymerisation (runs 11–17). Under the given reaction conditions (9 bar of propene pressure) no polymer formation was detected, but activities were low (TOF = 55 h^{-1}). At 120 °C the TOF increased significantly [373 h^{-1} after 30 min reaction (run 15) and 262 h^{-1} after 3 h reaction (run 16)]. For the $Pd(TPPTS)_3$ catalyst high rates [TOF = 2507 h^{-1} (15 min); 1307 h^{-1}(30 min)] were observed, but in contrast with our system fast catalyst deactivation was reported.[5] At lower CO pressures the rate decreased and selectivity increased towards the linear acid (runs 13 and 14). At low pressures, the observed rates suggest that the reaction has an approximate first-order dependence on CO and alkene concentrations. Higher ligand to palladium ratios did not improve the selectivity, while a somewhat lower rate was observed (run 17). With a ligand to palladium ratio of 3 (or more) no catalytic activity at all was observed which suggests that a catalytically inactive coordinatively saturated bis-ligand Pd(II) species is formed.

In conclusion, we have shown that the dicationic Pd/Xantphos-s/TsOH system is very effective and 100% selective in the hydroxycarbonylation reaction of alkenes (no traces of oligomeric or polymeric species were observed) towards carboxylic acids. Furthermore, under optimised reaction conditions, no formation of metallic palladium was observed and initial turnover frequencies dropped only slightly within hours indicating that the system is highly stable under the reaction conditions employed. The scope of this useful system is currently under investigation.

We thank the Netherlands Institute for Catalysis Research (NIOK) for financial support.

Notes and references

† *Selected data* for **2**: ^{1}H NMR (CD_3OD): δ 8.32 (s, 2H, ArH), 8.01 (d, J = 7.6 Hz, 2H, ArH), 7.32 (t, J = 5.1 Hz, 8H, ArH), 7.26 (t, J = 5.1 Hz, 8H, ArH), 7.12 (t, J = 5.1 Hz, 4H, ArH), 1.92 (s, 6H, ArH). ^{31}P{^{1}H} NMR (CD_3OD): δ 23.8. (Found: C, 42.2; H, 4.1. Calc. for $C_{39}H_{30}O_7S_2P_2PdCl_2$: C, 42.4; H, 4.2%).For **3**: ^{1}H NMR (CD_3OD; only the dication): δ 8.38 (s, 2H, ArH), 7.42–7.34 (b, 20H, ArH), 6.99 (b, 2H, ArH), 2.03 (s, 6H, CH_3). ^{31}P{^{1}H} NMR (CD_3OD): δ 25.6. (Found: C, 54.5; H, 4.2. Calc. for $C_{53}H_{44}O_{13}S_4P_2Pd\cdot 2(CH_3CN)$: C, 54.0; H, 4.0%).

‡ These type of *trans* complexes were also found in the solid state.

§ *Catalysis:* the appropriate amount of catalyst (15.8 μmol), prepared from **2**, **3** or *in situ* from $PdCl_2$ or $Pd(OAc)_2$ and **1**, was mixed with 0.9 or 2.7 mmol of TsOH. The mixture was charged into a 200 mL stainless steel reaction vessel (ethylene) or a 50 mL Hastelloy C autoclave (styrene and propene) under an atmosphere of argon. Degassed water (10 mL) was added and after five pressurizing–depressurizing cycles with CO, to remove traces of argon/air, the autoclave was pressurized with the appropriate substrates (ethylene and propene) and CO or charged with styrene and pressurized with CO. The contents were heated to the desired temperature and magnetically stirred (840 rpm). After the reaction the autoclave was cooled to room temperature in a ice bath and slowly depressurized. The hydroxycarbonylation products were analysed by ^{1}H NMR (300 MHz, $CDCl_3$).

¶ All TOFs mentioned are average TOFs calculated over the given reaction time.

‖ Since styrene is susceptible to polymerisation, reactions were carried out at lower temperatures (70–95 °C). At 95 °C the selectivity towards carboxylic acids is 65% (35% polystyrene). When no catalyst is present the same amount of polystyrene is formed thermally. The preference for the formation of the linear acid is in contrast with that reported for the $Pd(TPPTS)_3$ catalyst (l/b ratio *ca*. 27/73; TOF = 49 h^{-1}).[5]

Received (in Cambridge, UK) 4th September 1998, Accepted 6th October 1998

Reactions of glutarodihydroxamic acid with the hydrolase enzyme urease models, $[Ni_2(\mu\text{-}H_2O)(OAc)_4(tmen)_2]$ and $[Ni_2(OAc)_3(urea)(tmen)_2][OTf]$, lead to novel hydroxylamine elimination and formation of $[Ni_2(OAc)_2\{\mu\text{-}O(N)(OC)_2(CH_2)_3\}(tmen)_2][OTf]$ and the tetramer $[Ni_4(OAc)_2(gluA_2)_2(tmen)_4][OTf]_2$, respectively, both of which are structurally characterised by X-ray crystallography.

Urease is a hydrolytic metalloenzyme[1] which catalyses the hydrolysis of urea and contains a dinickel active site with a Ni–Ni distance of 3.5 Å.[2] Hydroxamic acids inhibit a number of enzymes including urease.[3] The urea complex, $[Ni_2(OAc)_3(urea)(tmen)_2][OTf]$ **A**,[4] reacts rapidly with acetohydroxamic acid (AHA) to give the monobridged hydroxamate complex $[Ni_2(OAc)_2(AA)(urea)(tmen)_2][OTf]$[5] with a very similar structure to that of the acetohydroxamate inhibited C319A variant of *Klebsiella aerogenes* urease.[6] Similarly, reaction of the hydrolase model $[Ni_2(\mu\text{-}H_2O)(OAc)_4(tmen)_2]$ **B**[7] with AHA gives the dibridged complex $[Ni_2(OAc)(AA)_2(tmen)_2][OAc]$.[5] We now report the reactions of **A** and **B** with glutarodihydroxamic acid, $(CH_2)_3(CONHOH)_2$, $gluH_2A_2$, with novel results. **B** reacts rapidly with $gluH_2A_2$ at room temperature in both methanol and dichloromethane in the presence of the triflate ion to give $[Ni_2(OAc)_2\{\mu\text{-}O(N)(OC)_2(CH_2)_3\}(tmen)_2][OTf]$ **I**,§ which contains a deprotonated bridging *N*-hydroxyglutarimide with the deprotonated N–OH oxygen O6 bridging the two divalent nickel ions Ni1 and Ni2 and the two carbonyl oxygens O5 and O7, each coordinated to their respective nickel atoms Ni1 and Ni2 (Fig. 1). Formation of **I** involves the novel elimination of hydroxylamine. We suggest that the two nickel centres in **B** act as Lewis acids polarising both carbonyl groups of $gluH_2A_2$ (**C**, Scheme 1). Subsequent protonation of one nitrogen (**D**, Scheme 1) and attack by the other nucleophilic nitrogen occurs with loss of NH_2OH, ring closure and formation of the tetrahedral intermediate (**E**, Scheme 1) which on deprotonation forms **I**. In this mechanism the dinickel centre probably prearranges the electrophilic and nucleophilic reaction centres similar to the prearrangement of water and urea in urease with the base OH^- formed by deprotonation of a coordinated water molecule replaced by the nitrogen nucleophile. The dinickel centre is essential, since reaction of $gluH_2A_2$ with nickel acetate gives simply $Ni(gluA_2)$ with properties similar to those reported previously for analogous complexes.[8] In contrast, the longer chain dihydroxamic acids, $(CH_2)_n(CONHOH)_2$, n = 4 (adipodihdroxamic acid) and n = 8 (sebacodihydroxamic acid), reacted with **B** to give $[Ni_2(OAc)\{(CH_2)_n(CONHO)_2\}(tmen)_2][X]$, n = 4 **II** and n = 8 **III**, X = OTf or BF_4^-, with no loss of NH_2OH and retention of the characteristic ν(NH) infrared absorption at 3246 cm^{-1}.§ Unfortunately, crystals of **II** and **III** were not suitable for X-ray crystallography, but most likely **II** and **III** are the longer chain analogues of **IV** described below. Molecular modelling calculations, using SPARTAN PM3(tm), predict **I** to be a stable structure for glutardihydroxamic acid but not for the longer chain sebacodihydroxamic acid, confirming the importance of steric factors.

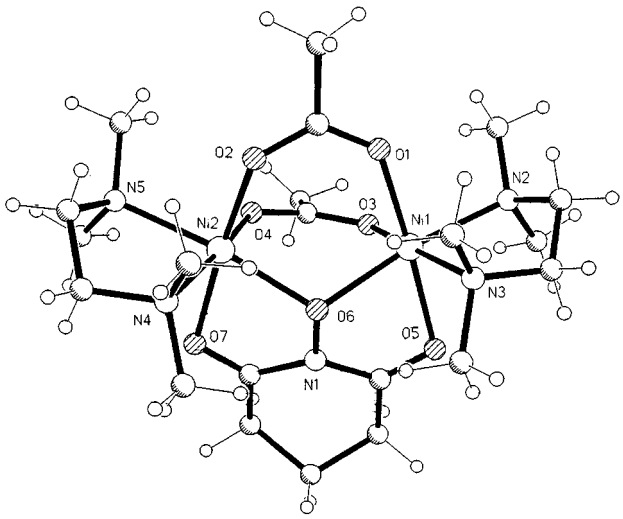

Fig. 1 Molecular structure of the cation of complex **I**. Selected bond distances (Å) and angles(°): Ni1–O6 2.059(2), Ni2–O6 2.040(3), Ni1–O5 2.155(3), Ni2–O7 2.128(3), Ni1–O1 2.019(3), Ni2–O2 2.007(3), O6–Ni1–O5 76.50(10), O7–Ni2–O6 77.97(10), Ni–Ni 3.414(1) and 3.427(1).
