Calixpyrroles

Philip A. Gale, Jonathan L. Sessler* and Vladimír Král

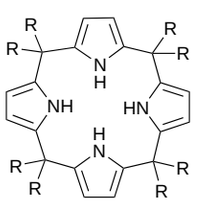
Department of Chemistry and Biochemistry, The University of Texas at Austin, Austin, Texas 78712-1167, USA

The calix[4]pyrroles are a class of old but new heterocalixarene analogues that show interesting anion and neutral substrate binding properties. Calix[4]pyrroles are easy to make and functionalize. As such, they have been employed in the production of separation media for anionic and neutral species. Calixpyrroles also provide useful precursors for the generation of novel calixpyridinopyrroles and calixpyridines.

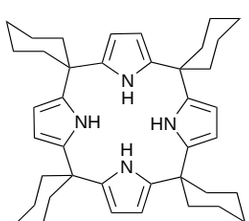
Introduction

This short review article covers the chemistry of systems that resemble calixarenes but are not calixarenes. Specifically, it discusses the synthesis and properties of calixpyrroles and other heterocyclic calixarene analogues. This story starts with Baeyer's publication of his paper on the condensation of pyrrole and acetone[1] which appeared in 1886, some fourteen years after he initiated his first studies of phenol–formaldehyde condensation chemistry.[2]

Although he did not appreciate it at the time, the white crystalline product Baeyer obtained by mixing pyrrole, acetone and hydrochloric acid was an octamethyl substituted form of porphyrinogen **1**. Porphyrinogens are naturally occurring



1 R = Me
3 R = Et



2

colourless macrocycles consisting of four pyrrole rings linked through the α (*i.e.* pyrrolic 2 and 5) or *meso*-like positions by sp^3 hybridized carbon atoms. The chemistry of porphyrinogens containing hydrogen atoms in the *meso*-position is well known as these species readily oxidize to form aromatic porphyrins. However, fully *meso*-substituted porphyrinogens have attracted much less attention, precisely because they do not constitute useful porphyrin precursors. Nonetheless, for reasons outlined in a recent communication,[3] we felt that these materials might be interesting. Specifically, we felt this class of macrocycle was perhaps mis-named and might better be referred to as calix[4]pyrroles. This renaming, which is supported by structural studies (*vide infra*), helps establish an obvious analogy to the calixarenes. It also led us to consider that this class of cyclic tetrapyrroles might display interesting anion binding characteristics. Thus, this exercise in nomenclature provided us with an incentive to begin studying further this venerable set of macrocycles.

As implied above, the chemistry of calix[4]pyrroles goes way back. Indeed, subsequent to the work of Baeyer, Dennstedt and Zimmermann also studied this reaction, using 'chlorzink' as the acid catalyst.[4–6] Thirty years later, during the First World War, Chelintzev and Tronov repeated these reactions and proposed (correctly) a cyclic tetrameric structure for a calix[4]pyrrole.[7] These same authors carried out several other reactions. These included an acid catalysed condensation of pyrrole with methyl ethyl ketone, which yielded a small quantity of a single calix[4]pyrrole configurational isomer. Additionally, methyl ethyl ketone and acetone were co-condensed with pyrrole forming a mixed *meso*-hexamethyldiethylcalix[4]pyrrole of unknown structure.[8] In the 1950s, Rothemund and Gage used methanesulfonic acid as the acid catalyst and obtained improved yields.[9] In the early 1970s, Brown *et al.* reported a refined procedure that permitted them to obtain tetraspirocyclohexylcalix[4]pyrrole **2**,[10] a compound that had previously been reported by Chelintzev, Tronov and Karmanov in 1916,[11] in decent yield. Calixpyrroles with functionalizable groups in the *meso*-positions (chloroalkyl or cyano) were also reported recently by Lehn and co-workers in a book chapter.[12–14] In work that is of a very different character, the transition metal coordination chemistry of deprotonated *meso*-octaalkylcalix[4]pyrroles, particularly *meso*-octaethylcalixpyrrole **3**, has been extensively studied by Floriani and co-workers. This chemistry has recently been highlighted in a Feature Article appearing in this journal.[15] It is, therefore, omitted from this review.

Structural studies

Several crystal structures of calix[4]pyrrole macrocycles (Fig. 1) have been elucidated. Taken in concert, these reveal that the macrocycle adopts a 1,3-alternate conformation in the solid state (*i.e.* adjacent pyrrole moieties are oriented in opposite directions).[3,16] Interestingly, in contradistinction to what is true for calix[4]arenes, in calix[4]pyrroles there is no possibility for the formation of a hydrogen bonded array between the various pyrrolic NH groups. Thus, in the absence of an added substrate there is no propensity for the free macrocycles to adopt the cone conformation, a motif so prevalent in calix[4]arene chemistry.

Anion binding properties

On a track that is very different from that of Floriani (see above), our group in Austin has focused on studying the anion binding properties of the calix[4]pyrroles. Our interest in this line of study, abetted by our renaming process (*vide supra*), came about as the result of our previous work with sapphyrins. Sapphyrin, a pentapyrrolic expanded porphyrin first synthesized by Woodward,[17] is an excellent receptor for anions (particularly fluoride) when diprotonated.[18] Knowing this, we were keen to test whether *neutral* non-aromatic polypyrrolic macrocycles, such as the calix[4]pyrroles, could also serve as anion binding agents.

The solution binding properties of **1** and **2** were studied using ^{1}H NMR titration techniques. Stability constants were then determined using the EQNMR least-squares fitting procedure.[19] The findings, summarized in Table 1, revealed that compounds **1** and **2** are not only effective 1 : 1 anion binding agents in solution, they are also selective. Specifically, they show a marked preference for F^- over other putative anionic guests (*viz.* Cl^-, Br^-, I^-, $H_2PO_4^-$ and HSO_4^-).

X-Ray crystal analyses of the Bu_4NCl complex of calixpyrrole **1** and the Bu_4NF complex of **2** revealed that in both cases the calix[4]pyrrole ligand adopts a cone-like conformation in the solid state such that the four NH protons can hydrogen bond to the halide anion (Fig. 2). While these two structures are similar, in the case of the chloride complex [Fig. 2(*a*)] the nitrogen-to-anion distances are in the range of 3.264(7)–3.331(7) Å, while for the corresponding fluoride complex they are 2.790(2) Å [Fig. 2(*b*)] (the four pyrrole groups are equivalent by symmetry). As a result, in these two complexes the chloride and fluoride anions reside 2.319(3) and 1.499(3) Å above the N_4 root mean square planes of calixpyrroles **1** and **2**, respectively. Thus, the fluoride anion appears to be more tightly bound, at least in the solid state.

Table 1 Stability constants for compounds **1** and **2** with anionic substrates[a] in CD_2Cl_2 at 298 K. For further details, see ref. 3

	Stability constant/M^{-1}	
Anion	**1**	**2**
Fluoride[b,c]	17 170 (± 900)	3600 (± 395))
Chloride	350 (± 5.5)	117 (± 4.0)
Bromide	10 (± 0.5)	[d]
Iodide	< 10	[d]
Dihydrogen phosphate[e]	97 (± 3.9)	< 10
Hydrogen sulfate	< 10	[d]

[a] Anions were added as 0.1 M CD_2Cl_2 solutions of their Bu_4N^+ salts to 10 mM solutions of the receptor in CD_2Cl_2, with concentration changes being accounted for by EQNMR. In determining the stability constants, the possible effects of ion pairing (if any) were ignored. [b] Bu_4NF was added as the trihydrate. [c] A repeat titration with compound **1** at 1.0 mM concentration gave concordant results. [d] Not determined. [e] A repeat titration with compound **1** at 100 mM concentration gave concordant results.

In an effort to study the conformational properties of the calix[4]pyrroles in solution, variable temperature ^{1}H NMR studies were carried out on a CD_2Cl_2 solution of **1** in the absence and presence of fluoride anions. In the presence of 3 equiv. of Bu_4NF, the *meso*-methyl resonance splits into two separate signals as the temperature is lowered. By contrast, in the absence of fluoride anions, there is no significant change in the ^{1}H NMR spectrum of compound **1**. The splitting seen in the presence of F^- may be due to the calixpyrrole adopting a cone conformation in solution when bound to this, and presumably other anions. Certainly, such a model is consistent with experiment. This is because it leads to the prediction that in the presence of F^- at low temperature the *meso*-methyl groups will be arranged in either axial or equatorial positions and thus resonating at different frequencies, as is indeed observed.

Surprisingly, the pyrrole NH resonance was also found to split into two peaks as the temperature was lowered in the presence of fluoride (Fig. 3). It was considered that a likely cause for this engendered splitting might be coupling between the NH protons and the ^{19}F nucleus of the bound fluoride anion. To test this supposition, a ^{19}F NMR spectrum of the fluoride complex was acquired at 193 K. The bound fluoride nucleus was found to resonate as a quintet (with a coupling constant of 39.5 Hz), confirming the proposed coupling effect (Fig. 3).

Binding of neutral substrates

In work that was designed to complement the above, it was found that the molecular recognition chemistry of the calix[4]pyrroles is not limited to anionic substrates. Indeed, the coordination of neutral species was explicitly achieved using *meso*-octamethylcalix[4]pyrrole **1**. In this instance, ^{1}H NMR titration experiments in C_6D_6 and subsequent analysis of the titration curves using the EQNMR computer program,[19] revealed that this calix[4]pyrrole forms complexes with neutral species, including short chain alcohols, amides and other oxygen-containing neutral species. Although the binding constants are modest, a clear trend is evident in both the alcohol and

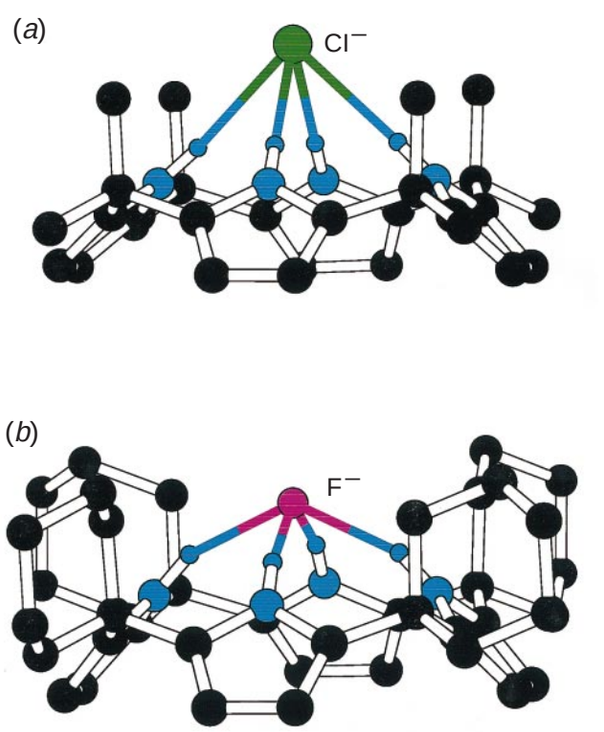

Fig. 2 X-Ray crystal structure of (*a*) the chloride complex of compound **1** and (*b*) the fluoride complex of compound **2**. Nitrogen and pyrrolic hydrogen atoms are blue, chloride is green and fluoride is magenta. This figure was generated using data originally published in ref. 3.

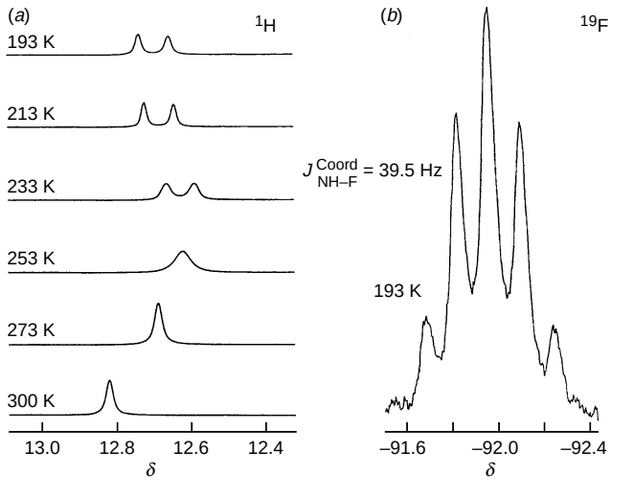

Fig. 3 (*a*) The NH resonance of **1**·F$^-$ splits as the temperature is lowered to 193 K (*b*), indicating coupling to the bound fluoride anion

amide series. Specifically, it was found that the relevant stability constants decrease as the steric bulk around the oxygen atom is increased (Table 2).[20]

The structure of **1** coordinated to two molecules of MeOH was determined by X-ray diffraction analysis. In contrast to the crystal structures of the anion-bound forms of **1** and **2** (discussed above), the calixpyrrole in this neutral substrate complex adopts a 1,3-alternate conformation in the solid state [Fig. 4(*a*)]. The two MeOH molecules are each coordinated to the calixpyrrole *via* two sets of hydrogen bonds involving the pyrrolic moieties [the $N_{pyrrole}$-O_{MeOH} distances are 3.155(4) Å].

The single crystal X-ray structure of the DMF complex of **1** was also solved. As in the bis(methanol) adduct, each of the two DMF molecules was found to be coordinated to a single calix[4]pyrrole macrocycle *via* two hydrogen bonds. However, in the case of the DMF complex the calix[4]pyrrole adopts a 1,2-alternate conformation, wherein each DMF molecule is coordinated to adjacent pyrrole moieties [$N_{pyrrole}$–O_{DMF} = 2.908(2) and 2.924(2) Å]. Each of the DMF molecules lies *ca.* 3.4 Å over the plane of one of the pyrrole rings to which it is not hydrogen bonded. This finding led us to suggest that π–π interactions help stabilize the 1,2-alternate conformation of this particular calix[4]pyrrole-neutral substrate complex [Fig. 4(*b*)].[20]

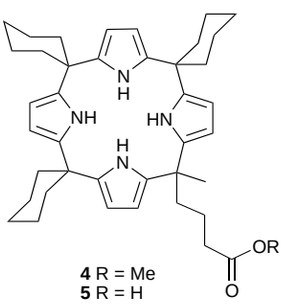
Functionalized systems

The introduction of a 'tailed' butanoate group to a calix[4]pyrrole produces an anionic calixpyrrole with interesting self-assembly properties.[21] The requisite '*meso*-hook' calix[4]pyrrole monoester **4** was synthesized by co-condensing methyl 4-acetylbutyrate, cyclohexanone and pyrrole. After column chromatography, the monoester was isolated from a mixture of calixpyrroles containing different numbers of ester functional groups in 12% yield. Subsequent hydrolysis of **4** yielded the monoacid **5**.

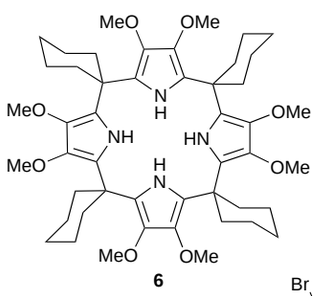


X-Ray quality crystals of the calixpyrrole carboxylate **5** were obtained by slow evaporation of a CH_2Cl_2 solution of **5** in the

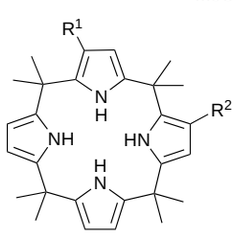
presence of excess $Bu_4NF{\cdot}xH_2O$. Interestingly, the crystals did not contain any fluoride anions within the lattice. Rather, this latter was found to be comprised entirely of the tetrabutylammonium calix[4]pyrrole carboxylate salt. The structure of the salt revealed that the calixpyrrole carboxylate self-assembles in the solid state. Specifically, the carboxylate functionality of one calixpyrrole was found to be bound to the pyrrolic array of an adjacent calixpyrrole and *vice versa*. The net result of these interactions is a dimeric cyclic structure as indicated in Fig. 5. In this instance, the calix[4]pyrrole adopts a cone conformation with four hydrogen bonds from the calixpyrrole pyrrole groups serving, as implied above, to bind the carboxylate 'tail' of a second functionalized calixpyrrole unit.[21]

A ROESY NMR spectrum of the trimethylammonium salt of **5** in CD_2Cl_2 provided evidence for aggregation in solution. Two resonances were observed between δ 7.0 and 7.5 corresponding to non-complexed pyrrole NH protons. Another resonance was observed at approximately δ 11. This was assigned to bound pyrrole NH protons, in exchange with the unbound NH resonances. As such, this datum point provides evidence in favour of aggregate formation in solution. The dimer could also be observed using FAB MS techniques.[21] In any event, to the best of our knowledge, this self-assembling calix[4]pyrrole system (**5**) represents the first and only example wherein purely anionic sub-units are seen to self-assemble.

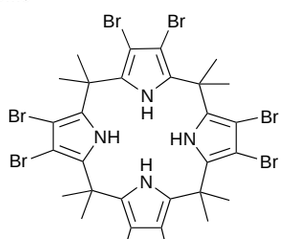
In addition to the above, we have recently described the synthesis of several novel calix[4]pyrrole molecules containing functional groups appended to the carbon- or *C*-rim of the calix[4]pyrrole 'bowl'. Two strategies were pursued in the synthesis of these materials. The first involved a direct condensation approach. Using such a strategy the β-octamethoxy-*meso*-tetraspirocyclohexylcalix[4]pyrrole **6** was prepared *via* the condensation of 3,4-dimethoxypyrrole and cyclohexanone in glacial acetic acid. The resulting calixpyrrole was then isolated in 8% yield after column chromatography.[22]



6



7 $R^1 = CH_2CO_2Et$, $R^2 = H$ (26%)
8 $R^1 = R^2 = CH_2CO_2Et$ (3%)



9

The second strategy involved modifying the *C*-rim of a presynthesized calix[4]pyrrole. In this case, *meso*-octamethylcalix[4]pyrrole was dissolved in dry THF and cooled to −78 °C. A solution of *n*-butyllithium in hexanes (4.0 equiv.) was added dropwise to the calixpyrrole solution followed by 4.0 equiv. of ethyl bromoacetate. Purification by column chromatography afforded two isolatable products, a *C*-rim monoester **7** (formed in 26% yield) and a diester **8** (3% yield). Surprisingly ^1H and ^{13}C NMR experiments showed that the diester **8** present in the fraction collected was a single isomer, with the ester groups

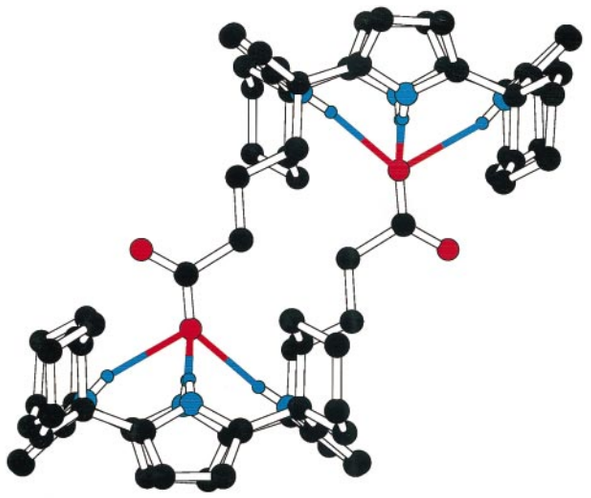


Fig. 5 X-Ray crystal structure of the calix[4]pyrrole carboxylate dimer (**5·5** − $2H^+$). Nitrogen and pyrrolic hydrogen atoms are blue and oxygen is red. This figure was generated using data originally published in ref. 21.

attached to the calixpyrrole in the 2 and 7 positions, as judged from single crystal X-ray diffraction and NMR analyses.[22]

In chemistry somewhat related to the above, β-octabromo-*meso*-octamethylcalix[4]pyrrole **9** was synthesized in 90% yield by reacting *meso*-octamethylcalix[4]pyrrole with *N*-bromosuccinimide in dry THF at reflux. In this instance, an X-ray structure (Fig. 6) revealed the calixpyrrole macrocycle **9** exists in a chair-like flattened 1,2-alternate conformation in the solid state (*i.e.*, the dihedral angles between pyrrole rings and plane through the calixpyrrole *meso*-carbon atoms are 66.8°, 5.8, −66.8 and −5.8°, respectively).[22]

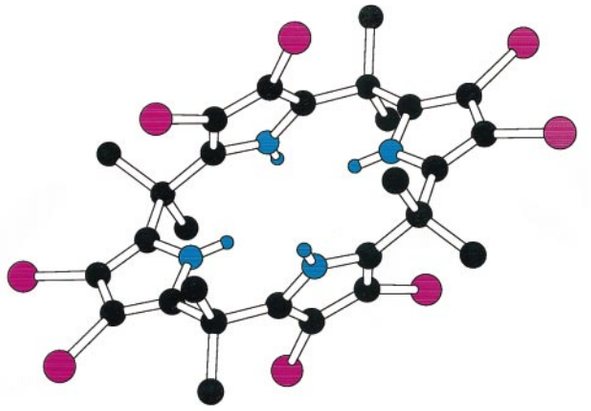

Fig. 6 X-Ray crystal structure of compound **9**. Nitrogen and pyrrolic hydrogen atoms are blue and bromine is magenta. This figure was generated using data originally published in ref. 22.

The solution anion binding properties of the β-octamethoxy derivative **6** and the β-octabromo derivative **9** have been studied in CD_2Cl_2 using ^1H NMR titration techniques (Table 3).[22] Compound **6** displays lower stability constants than the corresponding 'β-free' analogue **2**, presumably due to the electron-donating effects of the methoxy groups (this decreases the acidity of the pyrrole NH protons and therefore lowers the stabilty of the calixpyrrole–anion complex formed). By contrast, compound **9** displays higher stability constants with anions than its 'β-free' control (compound **1**) as a result, presumably, of the electron-withdrawing effect of the bromine substituents.[22]

Higher order systems

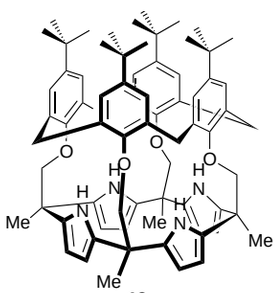
While currently the chemistry of calix[4]pyrroles is fairly well worked out, that of higher order systems (*i.e.* calix[*n*]pyrroles

Table 3 Stability constants for compounds **6** and **9** with anionic substrates[a] in CD_2Cl_2 at 298 K. For further details, see ref. 22

	Stability constants/M^{-1}	
Anion added	**6**	**9**
Fluoride	$1.7 (\pm 0.2) \times 10^2$	$2.7 (\pm 0.4) \times 10^4$[b]
Chloride	< 10	$4.3 (\pm 0.6) \times 10^3$
Dihydrogen phosphate	*c*	$6.5 (\pm 0.4) \times 10^2$

[a] Anions were added as 0.3 M CD_2Cl_2 solutions of their Bu_4N^+ salts to 3 mM solutions of the receptor in CD_2Cl_2 with concentration changes being accounted for by EQNMR. In determining the stability constants, the possible effects of ion pairing (if any) were ignored. [b] Estimated value. The NH proton resonance broadened considerably during the titration, forcing the frequency of the resonance to be noted manually. This value should therefore, be treated with caution. [c] Not determined.

with $n > 4$) is still essentially unexplored. While such species may be identified as by-products in condensations leading to the generation of calix[4]pyrroles, they have yet to be isolated cleanly.[3] Recently it occurred to us that a *p-tert*-butylcalix[*n*]arene could be used as a template around which a calix[*n*]pyrrole could form. Such a strategy could prove useful in the synthesis of higher order calix[*n*]pyrroles (*i.e.* those where $n > 4$). As a first step towards this approach, *p-tert*-butylcalix[4]arene tetramethyl ketone[23] was condensed with pyrrole in the presence of methanesulfonic acid. This afforded the cylindrical calix[4]arene-calix[4]pyrrole pseudo-dimer **10** in 32% yield.[24]



10

The X-ray structure of **10** was solved. It revealed, as expected, that the calixarene adopts a cone conformation. Further, two of the pyrrole NH groups were seen to form hydrogen bonds to the phenolic oxygen atoms at the lower rim of the calixarene (Fig. 7).

The hydrogen bonding between the pyrrole NH groups and phenolic oxygen atoms is maintained in solution, as evidenced by ^{1}H NMR spectroscopic studies.[24] Here, it was found, for instance, that the pyrrole NH protons resonate at δ 11.22. This is consistent with the proposal that they are deshielded as a result of their participation in the suggested hydrogen bonding interactions. Addition of polar solvents such as CD_3OD or anions such as fluoride does not disrupt the hydrogen bonding array. This latter finding thus supports the notion that the molecule adopts a cylindrical conformation in solution.

When *p-tert*-butylcalix[5]arene pentamethyl ketone[25] was condensed with 5 equiv. of pyrrole in the presence of $BF_3{\cdot}OEt_2$, a calix[5]pyrrole-calix[5]arene pseudo-dimer **11** was formed in 10% yield.[26] Compound **11** is, to the best of our knowledge, the first example of an expanded calixpyrrole. The intramolecular hydrogen bonding array in compound **11** appears to be weaker than that of the tetramer. For example, the NH protons resonate at δ 9.88 in the pentamer, and addition of CD_3OD or chloride anions cause shifts in the NH protons.

The use of other templates, such as cyclodextrins, using the same strategy, may lead to the synthesis of new expanded calixpyrroles and porphyrins. This approach is currently being pursued in the authors' laboratory.

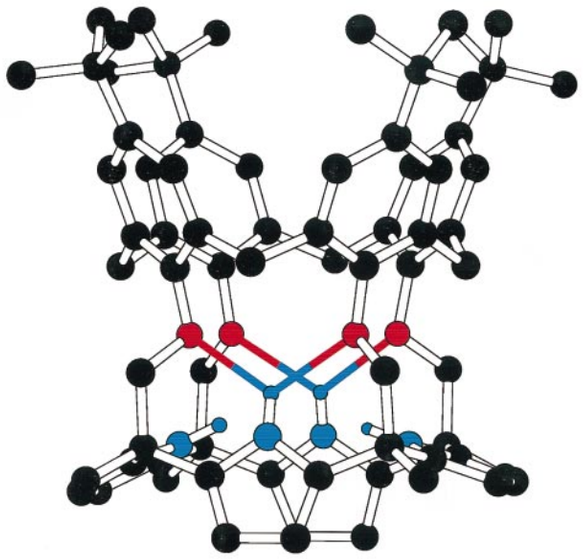


Fig. 7 X-Ray crystal structure of compound **10** showing intramolecular pyrrole NH–phenolic oxygen hydrogen bonding: N(2)···O(1) 2.701(6), N(2)···O(2) 2.739(6) Å. Nitrogen and pyrrolic hydrogen atoms are blue and oxygen is red. This figure was generated using data originally published in ref. 24.

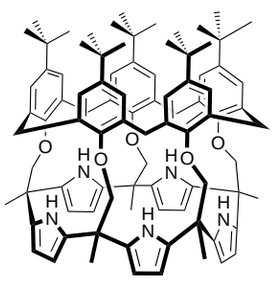

11

Towards possible commercial applications

The fact that calixpyrroles are easy to make has led us to consider that products based on the calixpyrrole technology could be commercially viable. With a view towards testing this hypothesis, we decided to investigate whether calixpyrrole-based solid supports could be used to separate oligonucleotides and other polyanionic substrates. Thus in work that is still ongoing, we have recently attached carboxylic acid functionalized calix[4]pyrroles to aminopropyl silica gel *via* both the *meso*- and β-positions. As determined from HPLC studies,[27] the resulting media allow for the ready separation of mixtures of (i) AMP, ADP, and ATP, (ii) aromatic carboxylates, and (iii) oligonucleotides of varying chain length (Fig. 8) under isochratic conditions. These same media also permit the HPLC-based separation of mixtures of neutral species such as polyfluorobiphenyls.

The synthesis of pyridine-containing macrocycles calixpyrroles as synthetic precursors

While pyridine-containing macrocycles are among the most versatile and important of all those known, in the heterocalixarene analogue area pyridine remains a minor player. Indeed, until the authors' recent contributions,[28] calix[4]pyridine was actually unknown. However a decade ago (1987), Newkome *et al.* did report the synthesis of several interesting calixpyridine analogues including compound **12**.[29]

In work that is of a very different nature, Floriani has succeeded in producing calix[1]pyridino[3]pyrroles and calix[2]pyridino[2]pyrroles. This was done by carrying out an

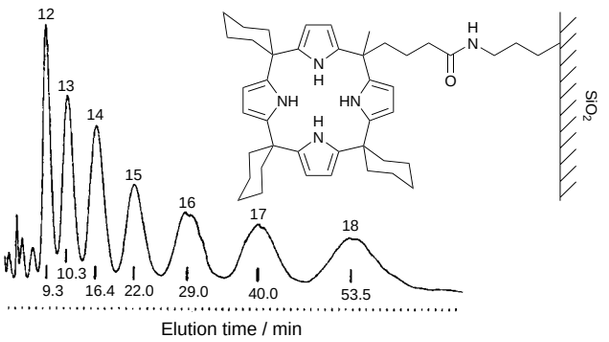

Fig. 8 Separation of $dT_{12–18}$ on calixpyrrole modified silica gel column. Flow rate 0.4 ml min^{-1}, mobile phase MeCN–[aq. NaCl (250 мм) + aq. Na_3PO_4 (50 мм)], 1 : 1 (v/v) (isochratic), pH = 7.0, column temperature 25 °C, UV detection at 265 nm.

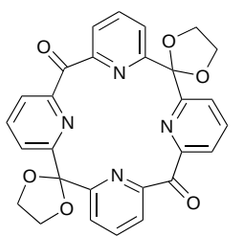


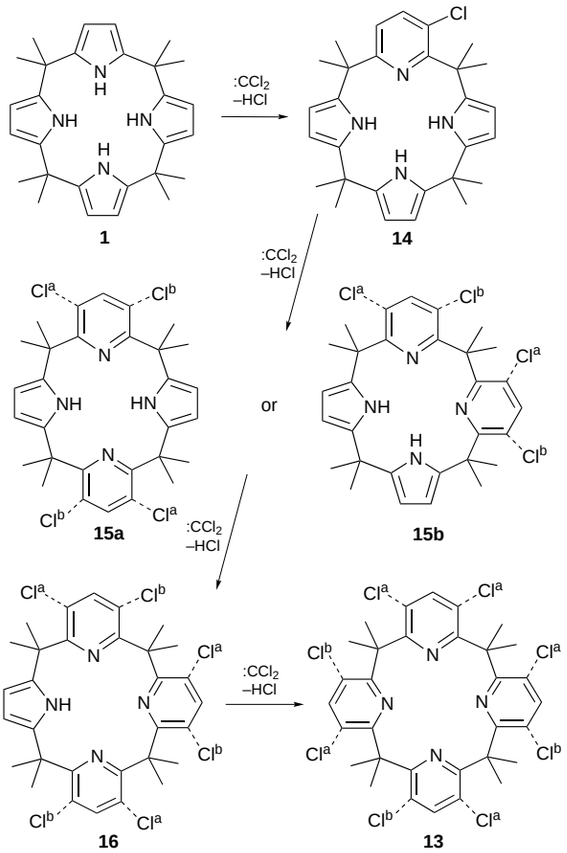
12

homologation of the pyrrole rings effected by reacting the zirconium complex of deprotonated *meso*-octaethylcalix[4]pyrrole with CO.[30]

Recently the present authors have discovered a very versatile and easy entry into the chemistry of calixpyridines. It is predicated on the use of calixpyrroles and dichlorocarbene and, as illustrated in Scheme 1, provides ready access to the previously unknown calix[3]pyridino[1]pyrrole and calix[4]pyridine families.

Our initial synthetic efforts were based on attempts to condense substituted pyridine *N*-oxides in a manner analogous to *p-tert*-butylphenol in calixarene synthesis.[31–33] However, using this approach none of the desired products could be isolated from the reaction mixtures. Our attention then turned on finding a way that would allow us to convert calix[4]pyrroles (*e.g.* **1**) into calix[4]pyridines. Here, we were inspired by the fact that the reaction of dichlorocarbene with pyrrole, imidazole or indole rings will lead to an insertion of the $:CCl_2$ unit (generated *inter alia* by heating sodium trichloroacetate under neutral conditions) into one of the double bonds.[34] In the case of pyrroles, subsequent elimination of HCl and rearrangement produces a 3-chloropyridine ring. We therefore decided to apply this methodology to calix[4]pyrrole and investigate whether a tetrachloro calix[4]pyridine derivative might not be obtainable in this way.

The conversion of *meso*-octamethylcalix[4]pyrrole **1** into tetrachloro-*meso*-octamethylcalix[4]pyridine **13** was attempted in several different solvents using a range of reaction times as well as different (excess) concentrations of sodium trichloroacetate. Using 1,4-dioxane as the solvent, and 15 equiv. of sodium trichloroacetate, a 2.4 : 1 mixture of the mono- and dipyridine macrocycles (**14** and **15**) was formed. Interestingly, when the same reaction conditions were employed using 1,2-dimethoxyethane as the solvent, a mixture of di- (**15**), tri- (**16**) and tetra-pyridine (**13**) species was obtained in a 1 : 1 : 1 ratio. The latter conditions, therefore, allowed us to obtain chlorinated derivatives of two previously unknown heterocalixarene analogues, namely, calix[3]pyridino[1]pyrrole (**16**) and calix[4]pyridine (**13**). Improved yields of the latter products could be obtained by adding separate batches of the dichlorocarbene precursor. In fact, using this approach the



Scheme 1

reaction process could be made to favour, as desired, the formation of either **15** and **16**, or just **13**. The calix[2]pyridino[2]pyrrole, calix[3]pyridino[1]pyrrole, and calix[4]pyridine products prepared in this way can be easily separated by column chromatography (silica gel, CH_2Cl_2–hexane eluent). Thus, it has proved possible, depending on the choice of conditions, to obtain **15**, **16** and **13** in optimized yields of 65, 42 and 26%, respectively. The NMR spectra of the crude products obtained from the above reactions are complicated due to the presence of isomers. This is reflected in Scheme 1 wherein each pyridine ring is bound to either Cl^a or Cl^b (not to both).

The X-ray crystal structure of **15** [Fig. 9(*a*)] reveals that there are two crystallographically distinct molecules in the unit cell. Both adopt the cone conformation in the solid state. The pyrrolic NH groups are oriented near the pyridine nitrogen atoms such that potential NH···N hydrogen bonds may be formed. These hydrogen bonds may influence the conformational properties of the macrocycle.

The X-ray crystal structure of **16** has also been elucidated [Fig. 9(*b*) and (*c*)]. As in the case of **15**, there are two molecules of **16** per asymmetric unit. However unlike **15**, where the two molecules were found to be conformationally equivalent, the two molecules of **16** assume strikingly different conformations. In Fig. 9(*b*), the molecular conformation is similar to that found in compound **13** (see below) wherein alternate rings are either parallel or nearly perpendicular. In this case, the pyrrole NH group is not hydrogen-bonded to any of the pyridine nitrogen atoms. The other molecule [Fig. 9(*c*)] in the asymmetric unit displays a dramatically different conformation.

Finally, in work that is still very recent,[28] the single crystal X-ray structure of the calix[4]pyridine **13** was solved. This structure revealed that the molecule adopts a flattened partial cone conformation in the solid state [Fig. 9(*d*)]. As importantly, by virtue of simply being solved, this structure served to confirm the existence of **13**. As such, it provides a critical proof

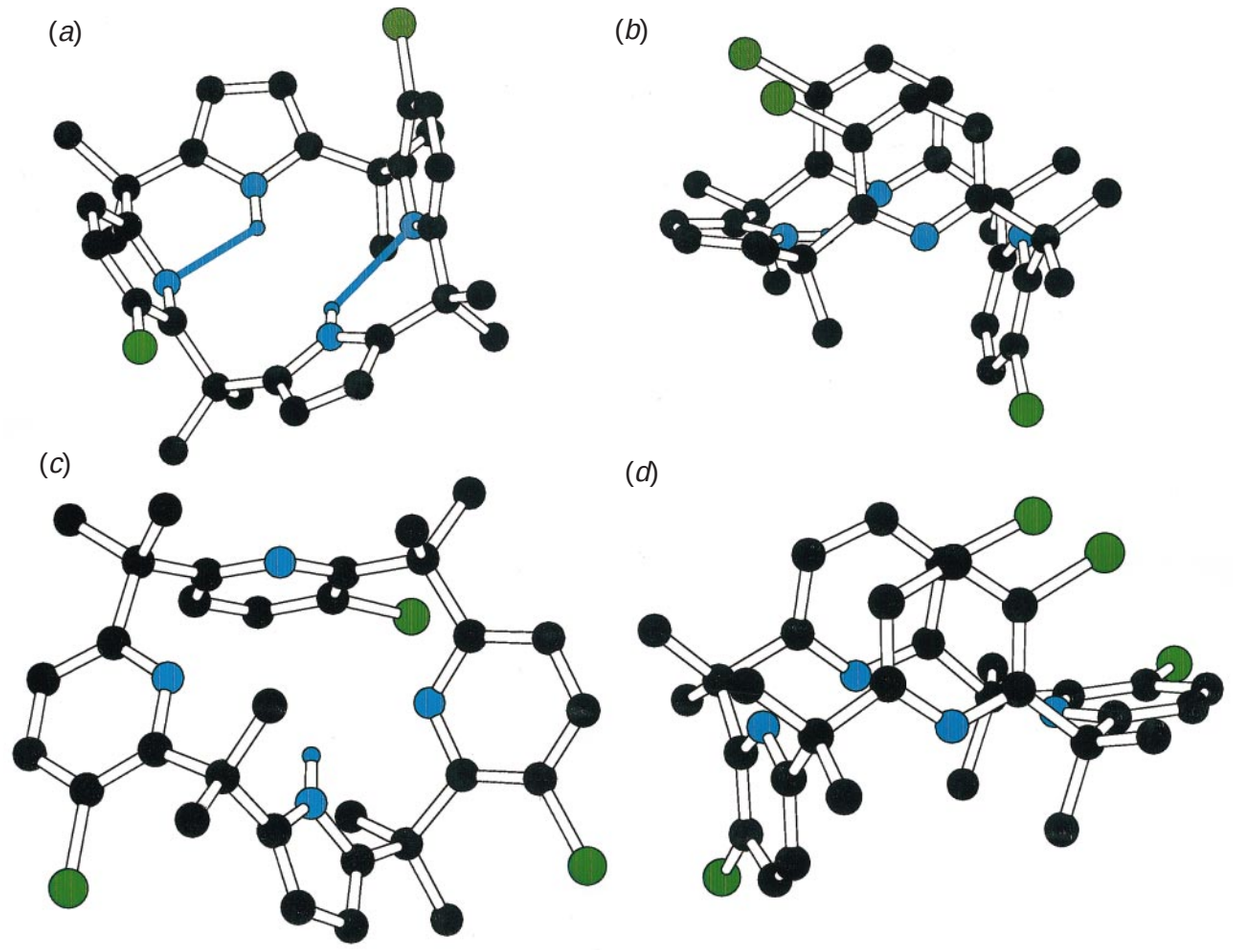


Fig. 9 X-Ray crystal structures of (*a*) bis(chloro)calix[2]pyridino[2]pyrrole **15**, (*b*) and (*c*) tri(chloro)calix[3]pyridino[1]pyrrole **16** in two conformations and (*d*) tetra(chloro)calix[4]pyridine **13**. Nitrogen and pyrrolic hydrogen atoms are blue and chlorine is green.

that calix[4]pyridines can be made and that they are potentially well-organized in the solid state.

Conclusion

The goal of this review has been to summarize the current state of calixpyrrole chemistry and, by implication, highlight the similarities and differences that exist with regard to normal calixarene chemistry. One feature that is particularly noteworthy is the fact that the calixpyrroles act as such effective receptors for neutral and anionic substrates. This finding leads us to suggest that related systems, such as the calixindoles,[35,36] might be worth studying in this regard. Indeed we think the chemistry of heterocalixarenes in general is one that is likely to be blessed with a rich supramolecular future.

K.), the National Science Foundation (grants CHE 9122161 and CHE 9725399 to J. L. S.) and the Howard Hughes Medical Institute (J. L. S. and V. K.). V. K. thanks the Grant Agency of the Czech republic for grants 203/97/1099 and 203/96/0740. P. A. G. wishes to thank the Fulbright Commission for a post-doctoral research scholarship. The authors also thank Brent Iverson for producing the excellent cover illustration.

Professor Jonathan L. Sessler was born in Urbana, Illinois, USA on May 20, 1956. He received a BS degree (with highest honors) in Chemistry in 1977 from the University of California, Berkeley. He obtained a PhD in Organic Chemistry from Stanford University in 1982 (supervisor: Professor James P. Collman). He was a NSF-CNRS and NSF-NATO Postdoctoral Fellow with Professor Jean-Marie Lehn at L'Université Louis Pasteur de Strasbourg, France. He was then a JSPS Visiting Scientist in Professor Tabushi's group in Kyoto, Japan. In September 1984 he accepted a position as an Assistant Professor of Chemistry at the University of Texas at Austin. In September 1989 he was promoted to Associate Professor and in September of 1992 was promoted to Full Professor. Professor Sessler has authored or coauthored nearly 200 research publications, written one book (with Dr Steven J. Weghorn), and been an inventor of record on over 45 issued or allowed US Patents. He has been the recipient of a Camille and Henry Dreyfus Foundation Teacher-Scholar Award (1988), a Sloan Foundation Fellowship (1989), Arthur C. Cope Scholar Award (1991) and Senior Visiting Scientist Award of the Alexander von Humboldt Foundation (1993). He is also a cofounder (with Dr Richard A. Miller, MD) of Pharmacyclics Inc., a publicly traded company (pcyc; NASDQ) dedicated to developing various biomedical applications of expanded porphyrins.

Dr Philip A. Gale was born in Liverpool, England on September 24, 1969. In 1992 he graduated with a BA (Hons) in Chemistry from Wadham College, Oxford. He remained in

Oxford (moving to Linacre College) to undertake research in calixarene chemistry under the supervision of Dr P. D. Beer. In 1995 he received an MA and a DPhil and joined Professor Sessler's research group at the University of Texas at Austin as a Fulbright postdoctoral fellow researching the chemistry of the calixpyrroles. In October 1997 he took up a Royal Society University Research Fellowship at the Inorganic Chemistry Laboratory, Oxford.

Dr Vladimír Král was born on December 26, 1949. From 1969 to 1974 he attended the Charles University, Prague where he obtained an honours degree in Chemistry and an RNDr degree in the same year. His doctoral studies were conducted under the supervision of Dr Z. Arnold at the Institute of Organic Chemistry and Biochemistry of the Czechoslovak Academy of Sciences, from where he graduated with a PhD in 1978. From 1978–1991 he worked as a research scientist at the same institute. In 1982 and 1986 he was a visiting scholar at the Zelinski Institute of Organic Chemistry, Academy of Sciences, Moscow, USSR working with Professor L. A. Yanovskaya. In 1983 and 1987 he was a visiting Scholar at the University of Kuopio, Medical School, in Finland working with Professor R. Laatikainen. From 1987 he was the recipient of an Alexander von Humboldt Stiftung, and from 1987 to 1989 worked with Professor H. A. Staab at the Max Planck Institut für Medizinische Forschung. He took up a postdoctoral position in Professor Sessler's group in 1991 where he remained until 1995. From 1995–1996 he worked with Professor F. P. Schmidtchen at the Technische Universitäte München. He is now an Assistant Professor at the Institute of Chemical Technology, Prague.

Calix[4]pyridine: a new arrival in the heterocalixarene family

Vladimír Král,[a,b] Philip A. Gale,[a] Pavel Anzenbacher Jr.,[a,b] Karolina Jursíková,[a] Vincent Lynch[a] and Jonathan L. Sessler*[a]

Reaction of dichlorocarbene with *meso*-octamethylcalix[4]pyrrole causes pyrrole ring expansion, producing chlorocalixpyridinopyrroles and chlorocalixpyridines.

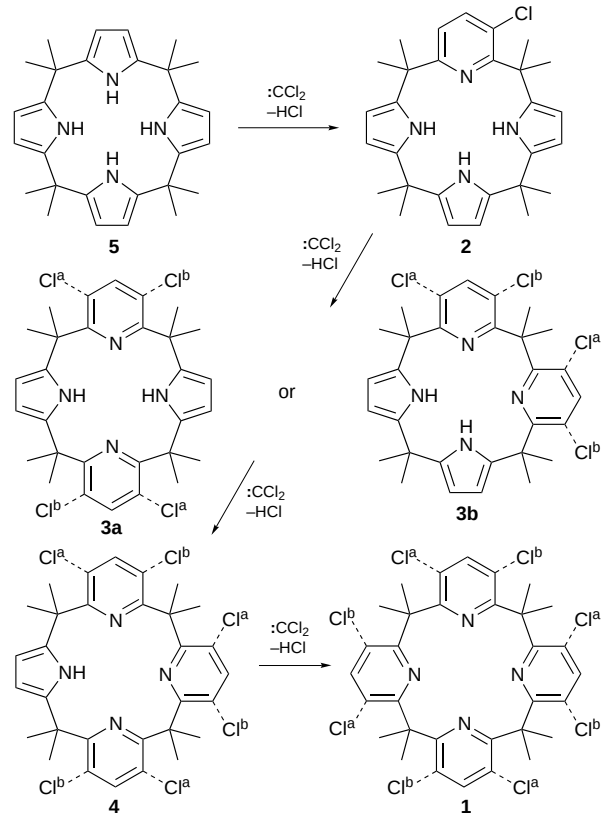
Considerable effort of late has been devoted to synthesizing new macrocycles containing pyridine subunits. While many such systems have been reported, some of considerable elegance,[1] one of the simplest conceivable pyridine-containing macrocycles, calix[4]pyridine, remains unknown.

Currently, close analogues of calix[4]pyridine, in the form of homocalixpyridines[2] and tetrapyridine tetraone[3] macrocycles are known. However, macrocyclic systems with pyridine rings linked in the 2 and 6 positions *via* a single sp^3 hybridized carbon atom have yet to be prepared. We have now discovered a general synthetic strategy that not only allows for the preparation of calix[4]pyridine derivatives (*e.g.* **1**), but also provides access to calix[*n*]pyridino[*n*]pyrroles ($m + n = 4$). While some species related to this latter set of macrocycles are known, namely mixed porphyrin-like pyrrole-pyridine systems and calixpyridinopyrroles containing one or two pyridines,[4] calix[3]pyridine[1]pyrrole derivatives (*e.g.* **4**), as reported here, appear to be without precedent in the literature.

Our initial synthetic efforts were based on attempts to condense substituted pyridine *N*-oxides in a manner analogous to *p-tert*-butylphenol in calixarene synthesis.[5] However none of the desired products could be isolated from the reaction mixtures. Our attention then turned on finding methods that would allow us to convert calix[4]pyrroles[6] (*e.g.* **5**) to calix[4]pyridines. Reaction of dichlorocarbene with pyrrole, imidazole or indole rings has been shown to cause an insertion of the CCl_2 unit into one of the double bonds.[7] In the case of pyrroles, subsequent elimination of HCl and rearrangement produces a 3-chloropyridine ring. We thus attempted the conversion of *meso*-octamethylcalix[4]pyrrole **5** into tetrachloro-*meso*-octamethylcalix[4]pyridine **1** in several different solvents using a range of reaction times as well as different (excess) concentrations of sodium trichloroacetate. Using dioxane as the solvent, and 15 equiv. of sodium trichloroacetate, a 2.4 : 1 mixture of the mono- and di-pyridine macrocycles (**2** and **3**) was formed. Interestingly when the same reaction conditions were employed using 1,2-dimethoxyethane as solvent, a mixture of di-, tri- and tetra-pyridine species **3**, **4** and **1** was obtained in a 1 : 1 : 1 ratio (Scheme 1).† The latter conditions, therefore, offer easy access to chlorinated derivatives of two previously unknown macrocycles, namely, calix[3]pyridino[1]pyrrole **4** and calix[4]pyridine **1**, in the same reaction. In any event, it was found that by adding between 3 and 6 equiv. of the carbene source in a sequential manner, isolated yields of 65, 42 and 26% could be obtained for targets **3**, **4** and **1**, respectively.

X-Ray diffraction-grade single crystals of compound **3** were grown by slow evaporation of a dilute CH_2Cl_2 solution of the macrocycle (Fig. 1).‡ The resulting X-ray structure reveals that there are two crystallographically distinct molecules in the unit cell. Both adopt the cone conformation in the solid state such that potential NH···N hydrogen bonds are formed. These hydrogen bonds may influence the conformation of the macrocycle.

Crystals of the calix[3]pyridino[1]pyrrole were grown from a MeOH–CH_2Cl_2–hexanes solvent mixture.§ As in the structure



Scheme 1 The chlorine atoms indicated may be present in position 'a' or 'b' but not both. This results in isomers, as discussed in the text.

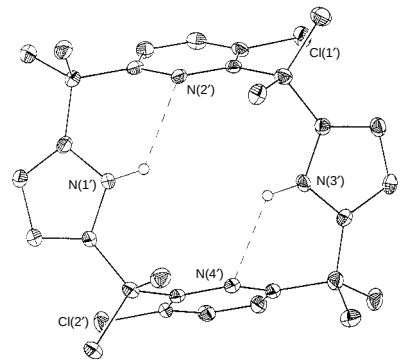


Fig. 1 X-Ray crystal structure of **3**. Intramolecular hydrogen bonds are shown by dotted lines. Thermal ellipsoids are at the 30% probability level.

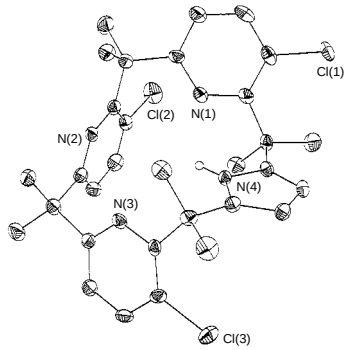

Fig. 2 X-Ray crystal structure of **4**. Only one molecule from the asymmetric unit is shown. Thermal ellipsoids are at the 30% probability level.

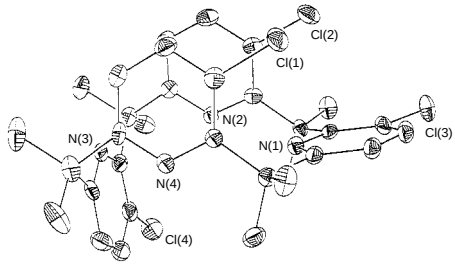

Fig. 3 X-Ray crystal structure of **1**. Intramolecular hydrogen bonds are shown by dotted lines. Thermal ellipsoids are at the 30% probability level.

of compound **3**, there are two molecules of compound **4** per asymmetric unit. The two molecules in the structure of **4** assume strikingly different conformations. For molecule 2, the molecular conformation is similar to that found in the structure of **1** (below) where alternate rings are either nearly parallel or nearly perpendicular. The dihedral angle between ring 2 (as denoted by the nitrogen atom label) and the pyrrole ring 4 is 81.9(2)°. The dihedral angle between ring 1 and ring 3 is 13.4(2)°. The dihedral angles between the rings and the plane through the bridging carbon atoms C(6′), C(12′), C(18′) and C(23′) is 81.6(2)° for ring 1, 74.9(2)° for ring 2, 85.1(2)° for ring 3 and 7.3(3)° for ring 4. Molecule 1 has a dramatically different conformation (Fig. 2). The dihedral angles between the rings and the plane through the bridging carbon atoms of molecule 1 are 51.3(2)° for ring 1, 89.3(2)° for ring 2, 55.5(2)° for ring 3 and 21.5(2)° for ring 4.

Single crystals of the calix[4]pyridine **1** were grown by slow evaporation of a CH_2Cl_2–hexane–MeOH solution of the macrocycle (Fig. 3).¶ The molecule adopts a flattened partial cone conformation in the solid state.

In summary, we have developed a universal and easy synthetic protocol for the preparation of calix[*m*]pyridino-[*n*]pyrrole ($m + n = 4$) and calix[4]pyridine systems based on a non-metal mediated ring expansion of pyrrole. We are currently investigating the molecular recognition properties of these new systems.

† Isomers are present in the reaction mixture, since the intermediate dichlorocarbene formed can insert into either of the two double bonds present in each of the various pyrrole rings under attack.

‡ *Crystal data* for **3**: Colourless plates of $(C_{30}H_{34}N_4Cl_2)_2 \cdot CH_2Cl_2$; triclinic, space group $P\bar{1}$, with a = 12.546(2), b = 15.403(2), c = 16.771(3) Å, α = 63.95(11), β = 82.953(10), γ = 76.937(9)°, V = 2835.3(8) Å^3, Z = 2, μ = 3.51 cm^{-1}, ρ_{calc} = 1.32 g cm^{-3}, M = 1127.95. There are two molecules of $C_{30}H_{34}N_4Cl_2$ along with a partially disordered CH_2Cl_2 solvate molecule per asymmetric unit. The conformations of the two macrocycles are nearly identical. The final $R_w(F^2)$ = 0.215 with a goodness of fit = 1.071, while the conventional $R(F)$ = 0.0844 for 5852 reflections with $F_o > 4[\sigma(F_o)]$.

§ *Crystal data* for **4**: Colourless needle-shaped crystals of $(C_{31}H_{33}N_4Cl_3)_2 \cdot 0.5CH_2Cl_2$ were monoclinic, space group $P2_1/c$, with a = 28.646(5), b = 10.368(2), c = 19.877(3) Å, β = 93.76(1)°, V = 5891(2) Å^3, Z = 4, μ = 3.85 cm^{-1}, ρ_{calc} = 1.33 g cm^{-3}, M = 1178.39. The pyrrolic hydrogen atoms were refined. There are two crystallographically independent molecules per asymmetric unit. The two molecules have markedly different conformations. There is a small amount of disorder of some Cl atoms on the pyridine rings in both molecules. The CH_2Cl_2 solvate molecule is disordered about a crystallographic inversion centre. The final $R_w(F^2)$ = 0.191 with a goodness of fit = 1.004, while the conventional $R(F)$ = 0.0774 for 5037 reflections with $F_o > 4$ [$\sigma(F_o)$].

¶ *Crystal data* for **1**: Colourless needle-shaped crystals of $C_{32}H_{32}N_4Cl_4$ were triclinic, space group $P\bar{1}$, with a = 9.883(2), b = 10.159(2), c = 15.720(3) Å, α = 93.66(2), β = 104.89(2), γ = 98.92(1)°, V = 1498.0(5) Å^3, Z = 2, μ = 4.24 cm^{-1}, ρ_{calc} = 1.36 g cm^{-3}, M = 614.42. The chlorine atoms, Cl(3) and Cl(4), appear to be disordered about two orientations. partial occupancy chlorine atoms appear bound to C(2) and C(16). The final $R_w(F^2)$ = 0.184 with a goodness of fit = 1.049, while the conventional $R(F)$ = 0.0750 for 2440 reflections with $F_o > 4[\sigma(F_o)]$. 182/654.

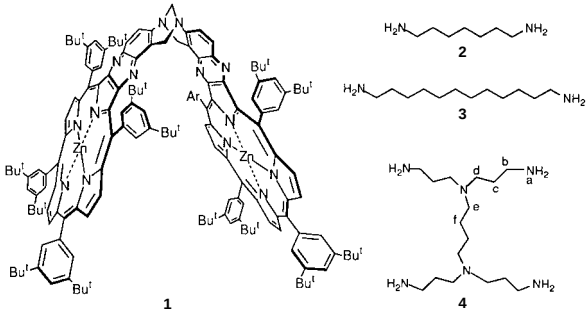
Two rigid Tröger's base dizinc(II) bis-porphyrin receptor molecules 1 and the first generation of dendrimer tetramine 4 form a 2:1 complex 5, a self-assembled spherical superstructure encapsulating the dendrimer.

Self-assembled molecular capsules have received much attention in supramolecular chemistry. Most of them are based on diphenylglycoluril building blocks in which the formation of eight (or more) hydrogen bonds favours a dimeric structure resembling a 'molecular tennis ball'.[1] These assemblies were able to reversibly encapsulate small guest molecules.[2] Recently larger dimeric structures based on calix[4]arenes have also been described, showing comparable behaviour.[3]

The use of self-assembly in the formation of porphyrin arrays to mimic some aspects of the photosynthetic machinery, has emerged in different supramolecular porphyrin structures. These porphyrin assemblies are based on hydrogen bonding,[4] metal ion coordination,[1,5] and central metal atom coordination.[6] Here, we report the formation of a self-assembled molecular capsule based on metal-to-ligand interactions of two dizinc(II) bis-porphyrins around a tetramine.

Previously we have shown that a rigid Tröger's base-like receptor strongly binds ditopic diamino ligands such as L-histidine esters[7] and α,ω-diaminoalkanes[8] in its cleft which has a Zn···Zn distance of *ca.* 8.5 Å. We have also synthesised the expanded Tröger's base dizinc(II) bis-porphyrin receptor **1**.[9] Models indicate that the Zn···Zn distance in the unbound state is *ca.* 16 Å.



Binding studies, using UV–VIS spectroscopy,† of a series of ditopic α,ω-diaminoalkanes show that 1,7-diaminoheptane **2** is the smallest guest which can bind to the receptor **1** in a ditopic manner giving a 1:1 complex with a high binding constant (1.5×10^6 dm^3 mol^{-1}). This indicates that there is some flexibility in the skeleton of **1** and that the cleft can be contracted to a Zn···Zn distance of 13 Å. The binding strength of the monodentate ligand 1-hexylamine is significantly less (5×10^4 dm^3 mol^{-1}). In the case of 1,6-diaminohexane binding is also significantly weaker and sigmoidal titration curves are observed indicating several competing modes of binding occur. Larger guests, for example 1,12-diaminododecane **3** bind significantly more strongly (7×10^7 dm^3 mol^{-1}), indicating that there is an energy penalty associated with contraction of the binding cleft.

The observation of tight binding of suitably long ditopic ligands to dizinc(II) bis-porphyrin **1** suggested to us that polyamines could be used as ligands to assemble a number of dimetallo bis-porphyrin systems around a ligand core. Dizinc(II) bis-porphyrin **1** and quatratopic ligands such as the first generation of aminodendrimer[10] **4** were expected to give a 2:1 complex by the formation of four Zn–amine bonds. Indeed, the UV–VIS titration curve of **1** with tetramine **4** showed an inflection point at 0.5 equiv. of **4** added, indicating that a 2:1 complex **5** was formed (Fig. 1). The porphyrin Q bands as well as the Soret band were shifted towards the red in the visible spectrum as ligand was added, indicating that the amines of **4** were complexed to the Zn atoms of the porphyrin units of **1**. These shifts were similar to those found for the ditopic ligands **2** and **3** upon full complexation showing that to each Zn atom of **1**, an amine was bound. The only structure which allowed a 2:1 complex and all the Zn atoms to be occupied was the molecular capsule **5** with the tetramine guest **4** inside the spherical dimer (Fig. 2). Although there are two possible forms in which the guest molecule can be bound to the tetramine, either with 9 or 14 atoms between the two Zn atoms of one unit of **1**, molecular modelling‡ studies suggest that the latter form is much more favourable, which is in line with the difference seen in binding of **2** and **3** with receptor **1**.§

In order to explore the stability of the molecular capsule **5** the titration was continued by adding further free ligand **4**. A second inflection point was observed corresponding to the addition of 1 equiv. of **4** (Fig. 1). This indicates that complex **5** dissociates to form 1:1 complexes (two Zn–amine bonds and two free amine groups per complex) at higher ligand concentration. By comparison, a titration curve of **1** with the ditopic guest **3** (or **2**) showed only one inflection point which corresponded to the addition of 1 equiv. of ligand (also two Zn–amine bonds).

To further investigate the structure of the molecular capsule **5**, 400 MHz ^{1}H NMR studies were performed (Fig. 3). To a 2.2 mmol $CDCl_3$ solution of tetramine **4** was added stepwise a 12.6 mmol solution of **1** also containing 2.2 mmol of **4**. Upon the addition of **1** the signals of **4** were broadened and upfield shifted. The NH_2 (protons a in structure **4**), α-CH_2 (protons b) and β-CH_2 (protons c) signals showed the highest shifts, being the closest protons to the porphyrin ring upon complexation. These signals shifted approximately linearly with concentration towards δ −4.68 (NH_2; total shift −5.92 ppm), −2.82 (α-CH_2; total shift −5.50 ppm) and −1.80 (β-CH_2; total shift −3.35 ppm) at 2 equiv. of **1** [Fig. 3(*c*)], indicating that all amino groups were complexed to zinc(II) porphyrins. The addition of more **1**

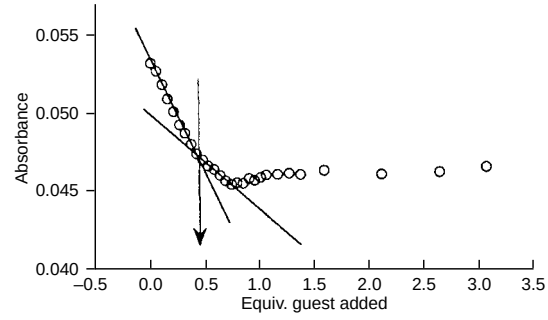


Fig. 1 UV Titration curve (616 nm) of **1** with quatratopic guest **4**

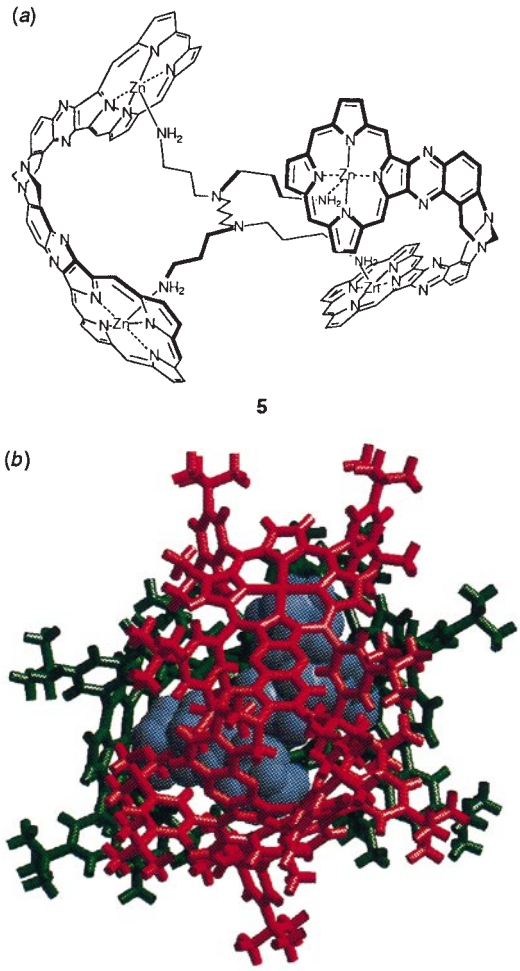

Fig. 2 (*a*) Schematic sideview with sixteen *meso* aryl groups omitted for clarity and (*b*) a modelled structure of the capsule **5** consisting of the two shape complementary receptor molecules **1** assembled around the core guest **4**. The encapsulated guest is in blue (space-filling), the receptors are in dark green and red (stick).

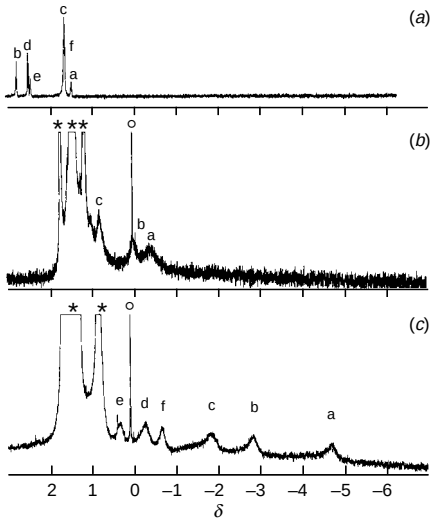

Fig. 3 ^{1}H NMR spectra of (*a*) **4**, (*b*) a 1 : 1 complex of **4** and **1**, (c) molecular capsule **5**. Peaks marked with an asterisk are from the *tert*-butyl protons of the receptor molecule and the $SiMe_4$ resonance is marked with a circle.

(up to 5.4 equiv.) did not result in significant change of chemical shifts of the protons of **4**, indicating that at these concentrations the 2 : 1 complex is stable and no higher complexes are formed. Upon the addition of just 1 equiv. of **1** the shifts of protons a, b and c of **4** [Fig. 3(*b*)] were in between the signals of free **4** [Fig. 3(*a*)] and fully complexed **4** [Fig. 3(*c*)], suggesting that a 1 : 1 complex is formed as an intermediate.

The signals of receptor **1** shifted as well. The signals of the bridging methyl groups and the β-pyrrolic protons of the porphyrin rings shifted to higher field, upon complexation. Adding more than 2 equiv. of **1** resulted in broadening of the signals of the receptor and signals of the bridging methyl groups and the β-pyrrolic protons of the porphyrin rings shifted back to lower field. These data clearly show that a 2 : 1 complex between receptor **1** and quatratopic guest **4** is formed, and that the exchange between the free components and the complex is at coalescence on the NMR timescale. At −50 °C, this equilibrium is slow and the ^{1}H NMR spectrum of a 1 : 4 mixture of **4** and **1** showed signals of the free and the complexed receptor **1**. Although the spectrum was complicated and could not be completely assigned, large downfield shifts were observed for the β-pyrrolic protons of the porphyrin rings and the other aromatic protons of the receptor. These large shifts, which were not observed for ditopic ligands, are in agreement with the structure of molecular capsule **5**.

Studies of porphyrin arrays assembled around larger dendrimers are in progress.

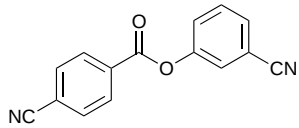
Crystallization of 3-cyanophenyl 4-cyanobenzoate with $AgSbF_6$: a polar coordination network based on the crisscrossing of intertwined helices

Keith A. Hirsch, Scott R. Wilson and Jeffrey S. Moore*

Departments of Chemistry and Materials Science and Engineering, The University of Illinois at Urbana-Champaign, Roger Adams Laboratory, Box 55-5, 600 S. Mathews Avenue, Urbana, IL 61801, USA

Crystallization of 3-cyanophenyl 4-cyanobenzoate 1 with $AgSbF_6$ yields the non-centrosymmetric, fourfold interpenetrated grid structure $[Ag(\mathbf{1})_2]SbF_6$ 2 through the crisscrossing of two-dimensional sheets.

The construction of self-assembled materials through metal coordination is an area of research that has grown tremendously in recent years.[1] The challenge that faces chemists working in this field is to identify packing trends that may allow for the rational design of functional materials. In this vein, we developed a packing model for interpenetrated diamondoid networks that was applied with success to our structures and those in the literature.[2] Also, many interesting structural studies on other coordination networks have been put forth,[3] and some have yielded materials exhibiting novel properties.[4] In order to observe packing trends such that coordination network topology may be better anticipated, systematic structural studies should continue to elucidate the role of variables such as counterion and ligand structure. In time, such studies may allow for the rational construction of materials exhibiting catalytic or nonlinear optical activity. In continuing towards this goal, we report a novel, non-centrosymmetric coordination network based on 3-cyanophenyl 4-cyanobenzoate **1**. Included here is a description of this structure that accounts for its packing in a polar space group.



1

3-Cyanophenyl 4-cyanobenzoate **1** was prepared in 92% yield by reaction of 3-cyanophenol (1.0 equiv.) and 4-cyanobenzoyl chloride (1.0 equiv.) in CH_2Cl_2 at room temperature in the presence of DMAP (0.1 equiv.) and NEt_3 (2.4 equiv.). Crystallization of ligand **1** (1.0 equiv.) with $AgSbF_6$ (1.1 equiv.) was achieved by heating and slow cooling from toluene in a programmable oven. The temperature program involved heating from room temperature to 100 °C at a rate of 20 °C h^{-1}, holding at 100 °C for 2 h, and cooling to ambient temperature at a rate of 1.2 °C h^{-1}. Colorless columnar crystals of the complex $[Ag(\mathbf{1})_2]SbF_6$ **2** were obtained and one was selected for X-ray analysis.† The resulting structure crystallizes in the non-centrosymmetric, orthorhombic space group *Ccc*2 and is composed of crisscrossing sheets that form an infinite grid.

In complex **2**, silver(I) adopts a distorted tetrahedral geometry coordinated by four nitrile nitrogen atoms of ligand **1**. The metal ion bonds to nitrile nitrogens of two cyanobenzoyl rings and two cyanophenyl rings. N–Ag–N bond angles about silver(I) range from 100.4(3) to 130.1(4)°. The SbF_6^- ions do not coordinate to silver(I) and are disordered over two sites, each of which is half-occupied. The shortest Ag···F separation is 5.30 Å.

The sheet topology of complex **2** is shown in Fig. 1. Within a sheet, the Ag–**1**–Ag distance is 16.11 Å. Twofold interpenetration is observed to partially fill void space created by a single sheet. This interpenetration may be viewed as the intertwining of two 2/1 helices (Fig. 1). Closest-packing in complex **2** is not achieved by twofold interpenetration. Rather, it results from further interpenetration of twofold interpenetrated sheets that propagate orthogonal to one another. Crisscrossing of orthogonal twofold sheets yields a fourfold interpenetrated grid structure overall (see Fig. 2). π–π Stacking is observed between molecules of ligand **1** that originate from orthogonal sheets [Fig. 2(*b*)]. Specifically, stacking occurs between cyanobenzoyl rings at a plane-to-plane distance of 3.35 Å and between cyanophenyl rings at a plane-to-plane distance of 3.44 Å.

Fourfold interpenetration in complex **2** can be viewed as arising from the crisscrossing of orthogonal pairs of 2/1 helices (see Fig. 3). Orthogonal sheets are mirror images of one another and, therefore, orthogonal helices are of opposite handedness [Fig. 3(*b*)]. The reason that this structure is polar is that helices of opposite handedness propagate orthogonal to one another. Therefore, the opposite twist sense associated with these helices does not cancel. Had helices of opposite handedness propagated

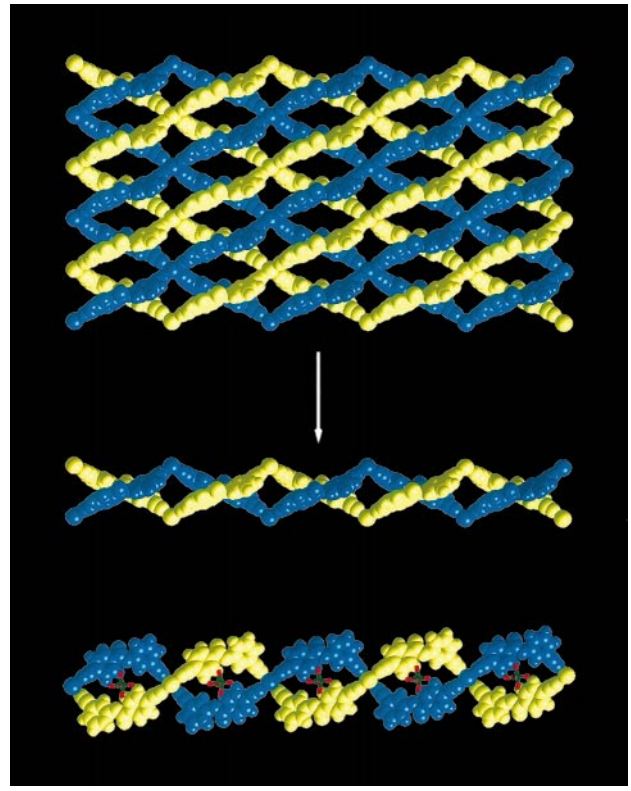


Fig. 1 Twofold interpenetrated sheets as a means to partially fill void space in the grid structure $[Ag(\mathbf{1})_2]SbF_6$ **2**. Interpenetration may be viewed as the intertwining of two 2/1 helices that are derived from the sheets as shown. The projection at the bottom is obtained by rotation of the middle figure by *ca*. 90° about the horizontal axis. The inclusion of counterions is shown in this projection (antimony is green and fluorine is red).

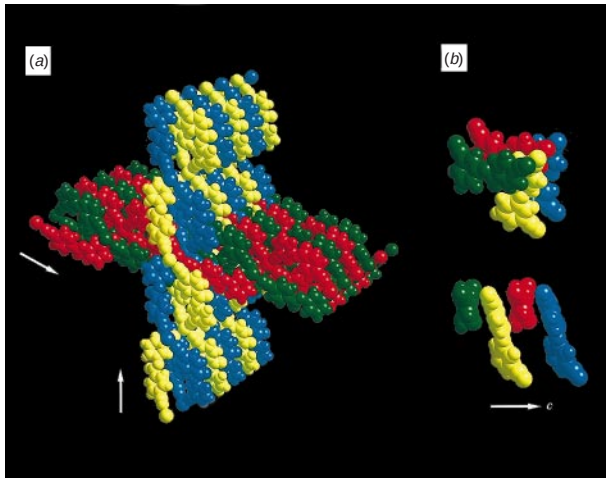

Fig. 2 (*a*) Fourfold interpenetration in $[Ag(\mathbf{1})_2]SbF_6$ **2** resulting from the crisscrossing of an orthogonal pair of twofold interpenetrated sheets. The blue and yellow networks constitute one set of twofold sheets and the red and green networks constitute the other. The arrows indicate the directions of propagation for the orthogonal sheets. Fourfold interpenetration is shown from left to right in a blue–green–yellow–red sequence where the orthogonal sheets cross. (*b*) Two views of π–π stacking of cyanobenzoyl rings of compound **1** as a result of fourfold interpenetration. Stacking occurs between ligands of orthogonal sheets along the polar *c*-axis. The direction of the *c*-axis is indicated for the bottom projection. The plane-to-plane distance for this stacking interaction is 3.35 Å.

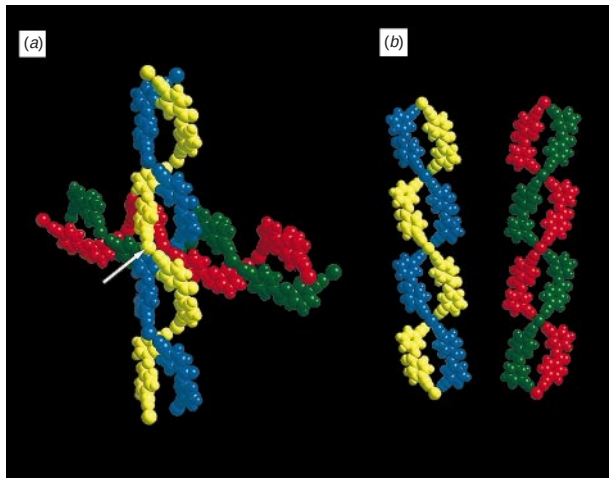

Fig. 3 The crisscrossing of orthogonal pairs of 2/1 helices in $[Ag(\mathbf{1})_2]SbF_6$ **2**. (*a*) Pairs of intertwined helices crisscross to afford fourfold interpenetration. Fourfold interpenetration is indicated by the arrow, which highlights a yellow–red–blue–green sequence of silver(I) ions (balls). Orthogonal helices are of opposite handedness. This point is clarified on the right. (*b*) Two orthogonal pairs of helices separated to reveal mirror symmetry. The blue and yellow helices are left-handed and the red and green helices are right-handed.

along the same direction, a non-polar structure could have formed. Such a packing of helices was observed in the sheet structures $[Ag(3,3'\text{-dicyanodiphenylacetylene})_2]XF_6$ (X = P, As, Sb), which we reported recently.[3a] These structures crystallized in space group $P\bar{1}$ and the topology is twofold interpenetrated sheets that are very similar to those shown in Fig. 1. However, for the 3,3′-dicyanodiphenylacetylene structures, closest-packing arises from the interdigitation of helices of opposite handedness[3a] rather than the crisscrossing of such helices. As a result, left- and right-handed helices propagate along the same axis such that the opposite twist sense associated with these helices cancel out, and the structures are non-polar ($P\bar{1}$). The difference in the packing between the structure presented here and those of 3,3′-dicyanodiphenylacetylene may be a result of the *para*-nitrile group of ligand **1**, which changes the conformation of the 2/1 helix. This comparison demonstrates the value of viewing solid-state packing in terms of helices in order to better understand gross structure. An increased understanding of solid-state packing is essential if self-assembled materials possessing novel properties are to be designed.

Novel supported catalysts: platinum and platinum oxide nanoparticles dispersed on polypyrrole/polystyrenesulfonate particles

Zhigang Qi and Peter G. Pickup*

Department of Chemistry, Memorial University of Newfoundland, St. John's, Newfoundland, Canada A1B 3X7

Platinum and platinum oxide nanoparticles are deposited on electronically and ionically conducting polypyrrole/polystyrenesulfonate particles by the reduction of $Pt(NH_3)_4Cl_2$ with formaldehyde and the oxidation of $Na_6Pt(SO_3)_4$ with H_2O_2, respectively.

Supported metal catalysts play a crucial role in many industrially important chemical reactions.[1] The support enables the metal particles to be highly dispersed and thermostable to retard sintering so that they can be used with high efficiency. This is particularly important with expensive noble metal catalysts such as platinum. The most widely used supports are carbon, SiO_2, Al_2O_3, TiO_2 and zeolites. Carbon is the only electronically conducting support in widespread use.

We introduce here a new type of support, polypyrrole/polystyrenesulfonate, which is both electronically and ionically conductive. The polypyrrole (PPy) provides electronic conductivity that can be controlled either chemically or electrochemically.[2] The polystyrenesulfonate (PSS) counter-ion, incorporated into the PPy during preparation, provides cation exchange sites. When the oxidation state of the polypyrrole is decreased, mobile cations are drawn into the particles to compensate the loss of cationic polymer sites. This causes an increase in the ionic conductivity that can be chemically or electrochemically controlled.[3]

Our primary interest in using PPy/PSS particles as a catalyst support arises from their potential application in proton exchange membrane fuel cells. The ideal catalyst support in such fuel cells would be gas and water permeable, and conduct both protons and electrons.[4] None of the conventional catalyst supports possess all these properties, but PPy/PSS does.

Although using conducting polymers as catalyst supports has been attracting research interest for more than 10 years, the deposition of metal particles has been restricted to the use of electrochemical methods and polymer films.[5] In one case, chemically prepared colloidal Pt particles were dispersed in a polypyrrole film during its electrochemical synthesis,[6] but there are no reports on the deposition of metal particles on conducting polymer particles. We have developed simple methodology that enables the fabrication of size-controllable PPy/PSS particles with dimensions ranging from *ca.* 30 to 1000 nm, and the chemical deposition of highly dispersed Pt on these particles.

The sizes of chemically synthesized PPy/PSS particles were controlled by varying the concentrations of pyrrole and the iron(III) oxidant.[7] The higher the concentration, the smaller the resulting polymer particles. The presence of PSS is essential in the size-control process. In a typical procedure (*i.e.* the preparation of the PPy/PSS particles shown in Fig. 1), a mixture consisting of 7.0 ml of 0.1 M NaPSS(aq) (0.70×10^{-3} mol, Aldrich; *M ca.* 70 000), 150 μl of neat pyrrole (2.1×10^{-3} mol), and 61 ml of water was shaken for 10 min before addition of 12 ml of 0.5 M $FeCl_3$ (6.0×10^{-3} mol) in 0.1 M HCl(aq). Following stirring for 15 min and centrifuging, the PPy/PSS particles were washed five times with water. The average diameter of the PPy/PSS particles produced under these conditions was *ca.* 500 nm, and their electronic conductivity was *ca.* 10^{-2} S cm^{-1}. Based on a model of spherical particles with a density[8] of *ca.* 1.5 g cm^{-3}, the estimated surface area is *ca.* 8 m^2 g^{-1}. The sample shown in Fig. 2 has an estimated surface area of *ca.* 100 m^2 g^{-1}.

The deposition of Pt nanoparticles on PPy/PSS particles was accomplished by the reduction of $Pt(NH_3)_4Cl_2$ with formaldehyde. PPy/PSS was heated at reflux in 60 ml of formaldehyde for 1 h to ensure full dispersion, followed by the addition of 72 mg of $Pt(NH_3)_4Cl_2$ and stirring for 30 min. The mixture was then heated at reflux for 30, 60, 90, 120 or 150 min.

Transmission electron microscopy (TEM) revealed that little Pt deposition occurred during the first 1.5 h, while large quantities of Pt nanoparticles with diameters of *ca.* 4 nm were produced after *ca.* 2 h. The reaction time had little influence on the Pt particle size. Fig. 1 shows a TEM of a Pt/PPy/PSS sample following 2.5 h of reflux. The distribution of Pt nanoparticles is quite homogeneous. Electronic conductivity measurements following Pt deposition revealed a *ca.* three order of magnitude decrease to *ca.* 10^{-5} S cm^{-1}. A similar decrease in conductivity was observed when PPy/PSS particles were treated with formaldehyde alone, suggesting that it is due to irreversible reduction of the polypyrrole.

Deposition of Pt oxide nanoparticles on PPy/PSS particles was also performed.[9] In this case, the PPy/PSS was produced from a mixture consisting of 0.14 M pyrrole, 0.70 M $Fe(NO_3)_3$ and 0.04 M PSS with a 90 min reaction time. The resulting PPy/PSS particles were of an irregular shape, with an average dimension of *ca.* 40 nm. After 0.2000 g of dried PPy/PSS and 0.1695 g of $Na_6Pt(SO_3)_4$[9] were stirred in 80 ml of water for 5

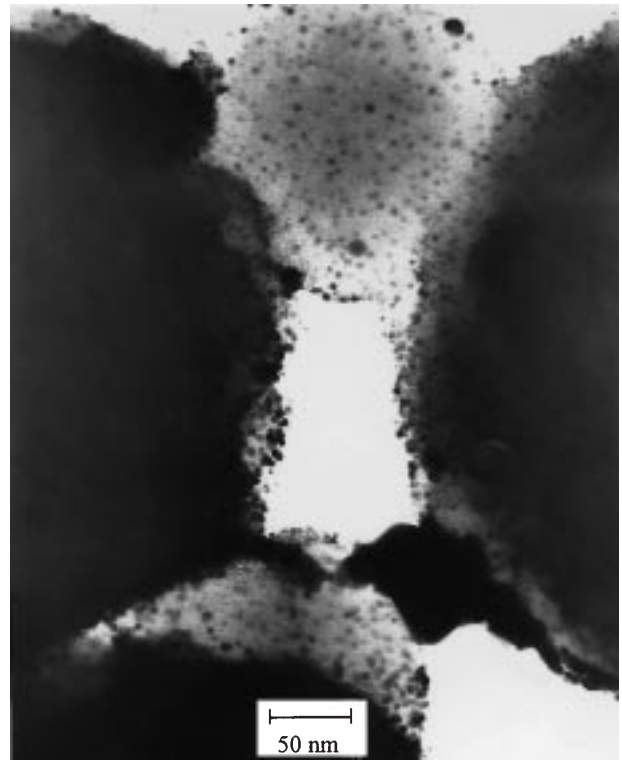

Fig. 1 TEM of Pt nanoparticles dispersed on PPy/PSS particles

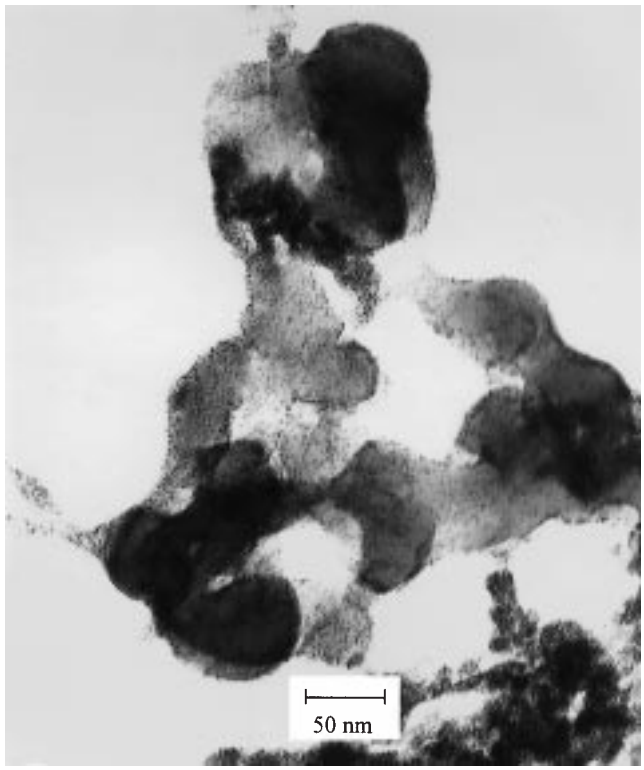

Fig. 2 TEM of Pt oxide nanoparticles dispersed on PPy/PSS particles

min, 1 M H_2SO_4 was added dropwise to adjust the pH from *ca*. 4 to 2.0, followed by the dropwise addition of 0.5 M NaOH to adjust the pH to 3.0. Then 1.00 ml of 30% H_2O_2 was added and the mixture was stirred for 1 h and then boiled. The Pt oxide/PPy/PSS particles were separated from the reaction medium by centrifuging, washed three times with water, and dried under vacuum overnight at room temperature.

Fig. 2 shows a TEM of the resulting Pt oxide/PPy/PSS particles. Pt oxide nanoparticles were *ca*. 2 nm in diameter and evenly distributed on the PPy/PSS particles. Although the exact chemical nature of the Pt oxide particles is unknown, they can be converted to highly catalytic Pt particles simply by heating.[9] This sample exhibited electronic conductivities of *ca*. 3 and 10^{-5} S cm^{-1} before and after Pt oxide deposition, respectively. The decrease in conductivity is presumably due to over-oxidation[10] of the polypyrrole by the H_2O_2.

Preliminary results (Fig. 3) have indicated that the supported catalysts described here are effective for oxygen reduction in

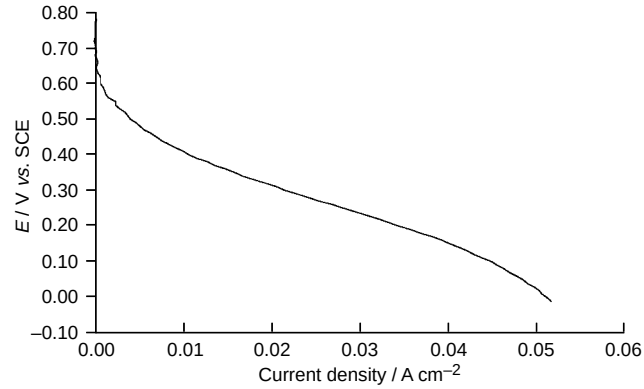

Fig. 3 Polarization curve for oxygen reduction in a C | O_2 (1 atm), PPy/PSS/Pt oxide (0.15 mg Pt cm^{-2}) | Nafion | 1 M H_2SO_4(aq), SCE | Pt cell at ambient temperature. Experimental details are reported elsewhere.[11]

proton exchange membrane fuel cells, despite their low electronic conductivities. However, significantly high conductivities are required to compete with the carbon supported catalysts currently in use.

Intramolecular coordination of an alkene to a mixed dicyclopentadienyl benzyl zirconium cation studied by NMR spectroscopy

Mikhail V. Galakhov, Georg Heinz and P. Royo*

Departamento de Química Inorgánica, Universidad de Alcalá de Henares, Campus Universitario, E-28871 Alcalá de Henares, Spain

Benzylation of $[Zr(\eta^5\text{-}C_5H_5)\{\eta^5\text{-}C_5H_4SiMe_2(CH_2CH{=}CH_2)\}Cl_2]$ 1 yields $[Zr(\eta^5\text{-}C_5H_5)\{\eta^5\text{-}C_5H_4SiMe_2(CH_2CH{=}CH_2)\}(CH_2C_6H_5)_2]$ 2, which reacts with either $B(C_6F_5)_3$ or $[Ph_3C][B(C_6F_5)_4]$ to generate the same cation, 3^+, which has been fully characterised by ^1H, ^{13}C NMR and ^1H DNMR spectroscopy.

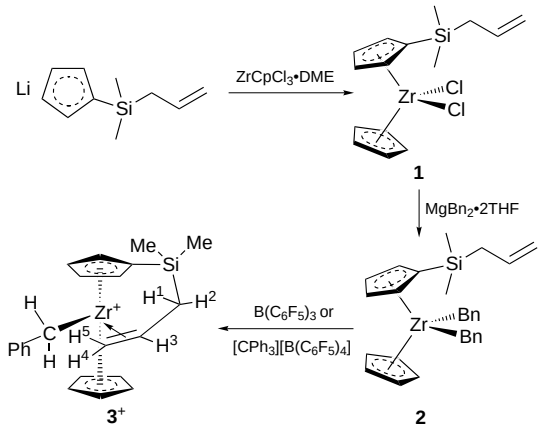
It is generally accepted[1] that a cationic 14-electron alkyl dicyclopentadienylzirconium complex of the type $[ZrCp_2R]^+$ stabilized by coordinative contact with a counter-ion $[R\text{-}MAO]^-$ (MAO = methylalumoxane), $[RB(C_6F_5)_3]^-$ or $[B(C_6F_5)_4]^-$ provides a route to $[ZrCp_2R(alkene)]^+$, a productive, active, cationic polymerization catalyst. Numerous synthetic studies involving the characterization of dicyclopentadienyl alkyl cationic group 4 metal complexes and their catalytic activity in Ziegler–Natta polymerization processes, have recently been reported.[2] Many structural techniques have been used to investigate the formation of cationic species of this type and various theoretical methods[3] have been applied to calculate the kinetic and thermodynamic parameters of their transition states and intermediate species.

However, in spite of the many attempts made,[4] the crucial cationic d^0 metal–alkene complex has only been observed and studied by X-ray diffraction[5] in the zirconium complex $[ZrCp_2(OCMe_2CH_2CH_2CH{=}CH_2)]^+$, in which the alkenic double bond shows a rather weak interaction with the metal center. The isolation of dimethyl titanium[6a] and zirconium[6b] complexes containing the 1-(but-3-enyl)-2,3,4,5-tetramethylcyclopentadienyl ligand has been reported, for which extensive low temperature NMR studies were unable to detect the alkene-coordinated metal complex. An yttrium pentenyl chelate has also been studied,[7] where the exchange between the diastereotopic C_5H_4Me ligands is proposed to occur *via* rapid and reversible alkene dissociation followed by rate limiting inversion of the pyramidal d^0 yttrium center. A related compound reported by Erker[8] was isolated by reaction of the butadiene zirconium complex $[ZrCp_2(C_4H_6)]$ with $B(C_6F_5)_3$, resulting in the formation of a betaine system in which an anionic allyl system is coordinated to the dicyclopentadienyl zirconium cation.

In order to favour alkene coordination we decided to synthesize zirconium complexes containing the more electron-withdrawing di(methyl)(allyl)silyl(cyclopentadienyl) ligand to create a more acidic metal center with a slightly longer and more fluxional pendant chain, owing to the bulkier silicon atom.

As shown in Scheme 1 the dichloro complex $[Zr(\eta^5\text{-}C_5H_5)\{\eta^5\text{-}C_5H_4SiMe_2(CH_2CH{=}CH_2)\}Cl_2]$ **1** was prepared† by reaction of the lithium salt of di(methyl)(allyl)silylcyclopentadiene[9] with stoichiometric amounts of $ZrCpCl_3{\cdot}DME$. Treatment of **1** with $MgBn_2{\cdot}2THF$ yielded the dibenzyl complex **2**.

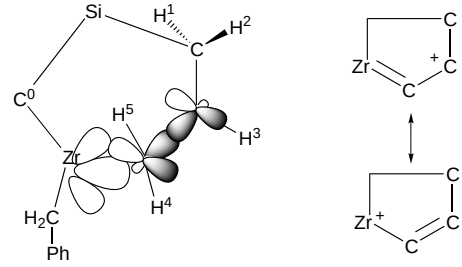
NMR spectra recorded after mixing 1 equiv. of either $[Ph_3C][B(C_6F_5)_4]$ or $B(C_6F_5)_3$ with 1 equiv. of complex **2** in CD_2Cl_2 at −70 °C demonstrate the formation of the same 14-electron cationic species 3^+. Characteristic methylene resonances of Ph_3CCH_2Ph (δ 3.90) and non-coordinated $[PhCH_2B(C_6F_5)_3]^-$ (δ 2.70, br) were observed, respectively.



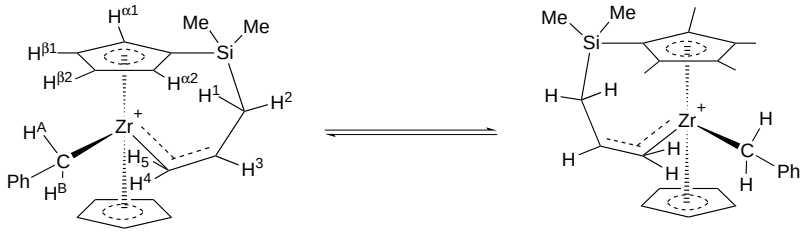
Scheme 1

Stabilization of this 14-electron cationic zirconium species is usually achieved by benzallylic coordination of the benzyl ligand, evidenced by the loss of the C_{2v} symmetry of the phenyl ring and a substantial difference between the ^1H chemical shifts for the two methylenic protons ($\Delta\delta$ = 2.80 ppm) observed[1c] in the solid by X-ray analysis and in solution by NMR spectroscopy at low temperatures. However, this behaviour is not observed in the ^1H NMR spectra of 3^+ at 203 K which shows C_{2v} symmetry for the phenyl ring, an AB spin system (δ_{av} 3.13, $\Delta\delta$ = 0.27 ppm) for the two diastereotopic methylenic protons, two SiMe signals at δ 0.31 and 0.59, and four resonances at δ 5.74, 6.13, 6.35, 7.10 due to the CpSi ring protons, consistent with an asymmetric species. The ^1H NMR spectra of 3^+ did not show a typical vinylic signal between δ 4.9 and 5.6, but instead five new multiplets were observed at δ 1.81, 2.05, 2.13, 2.78, 7.30. Table 1 summarizes the chemical shifts and proton–proton coupling constants for the allyl chain protons of complexes **2** and 3^+.

All of the spin–spin coupling constants for H^3, H^4 and H^5 in complexes **2** and 3^+ are very similar indicating that the sp^2 character of the alkenic carbon atoms is not lost. However the H^3 signal is shifted [$\Delta\delta = \delta(3^+) - \delta(2)$] to low field ($\Delta\delta$ = +1.58 ppm) whereas the terminal H^4 and H^5 signals are displaced to high field ($\Delta\delta$ = −2.08 and −2.83 ppm, respectively); the CH_2Si resonance is split and also displaced to low field ($\Delta\delta$ = +0.38, +0.46 ppm). Similar behaviour is



Scheme 2



Scheme 3

Table 1 Important ^{1}H NMR data for complexes **2** and **3**$^+$ in CD_2Cl_2 at 203 K

Assignment	δ(SSCC, *J*/Hz) **2**	**3**$^+$
H^1, H^2	1.66 (H^1, H^2–H^3 8.0)	2.05, 2.13 (H^1–H^2 11.5) (H^1–H^3 10.5) (H^2–H^3 5.2)
H^3	5.72 (H^3–H^4 10.5) (H^3–H^5 16.3)	7.30 (H^3–H^4 8.80) (H^3–H^5 16.5)
H^4	4.86 (H^4–H^5 3.8)	2.78 (H^4–H^5 4.0)
H^5	4.83	1.81

observed in the ^{13}C NMR spectra which show $\Delta\delta(CH{=}CH_2)$ = +36.2, $\Delta\delta(CH{=}CH_2)$ = −22.7, $\Delta\delta(CH_2Si)$ = +2.8 and $\Delta\delta(C_{Cp})$ = −3.1 ppm. Displacement of the terminal alkenic CH_2 moiety signals to high field is consistent with its coordination to the metal atom. This interaction is stronger than that reported by Wu and Jordan[5] and may be interpreted as the result of the interaction of the σ-bonding alkene orbital with the vacant $2a_1$ zirconium orbital and simultaneous overlapping of the HOMO π alkene orbital with the vacant zirconium orbital of the same symmetry, b_2.

As shown in Scheme 2 these interactions result in delocalized electron density in the Zr–C–C system, similar to that observed for classical allyl cations, which is favoured by the known silicon effect[9] and can be described in terms of the resonance structures of Scheme 2, where the terminal alkenic carbon is in a well known pentacoordinate situation.[10] This description is consistent with the observed displacement of the CH= and $SiCH_2$ resonances to low field and of CH_2= resonances to high field.

Variable temperature ^{1}H NMR spectra show dynamic behaviour which implies an interchange between the signals of the CH_2Ph, CH_2Si, $(CH_3)_2Si$ and the $H^{\alpha1}$–$H^{\alpha2}$ and $H^{\beta1}$–$H^{\beta2}$ protons of the C_5H_4R ring, with little exchange in the Zr–C–C system. The assignment of the $H^{\alpha1}$–$H^{\alpha2}$ and $H^{\beta1}$–$H^{\beta2}$ signals was made from the results of saturation transfer experiments at 253 K and the spin–lattice relaxation time T_1 values measured at −213 K ($H^{\alpha1}$: δ 6.30, T_1 = 1.67 s; $H^{\alpha2}$: δ = 6.10, T_1 = 1.61 s; $H^{\beta1}$: δ = 7.10, T_1 = 0.96 s; $H^{\beta2}$: δ = 5.70, T_1 = 1.26 s). The signal at δ 7.10 is assigned to the $H^{\beta1}$ proton located near the C_5H_5 moiety since is well known that proton relaxation times depend mainly on the number of adjacent protons and their distances. The $SiCH_2$ resonance is observed at 263 K as one doublet (^3J 8.3 Hz) due to spin–spin coupling with H^3. Coalescences of the $SiMe_2$ and CH_2Ph resonances are observed at 253 K with the same $\Delta G^{\ddagger}$ = 11.7 kcal mol^{-1} (1 cal = 4.184 J) calculated for the collapse of two equally populated singlets and for an AB spin system, respectively. This indicates that both are associated with a unique dynamic process involving interconversion between two enantiomers through a transition state with C_s symmetry.

The kinetic parameters for the process shown in Scheme 3 ($\log A$ = 14.4 ± 0.5, E_a = 13.4 ± 0.54 kcal mol^{-1}, $\Delta H^{\ddagger}$ = 12.9 ± 0.53 kcal mol^{-1}, $\Delta S^{\ddagger}$ = 5.0 ± 2.3 cal K^{-1} mol^{-1} and $\Delta G^{\ddagger}_{298\,K}$ = 11.4 kcal mol^{-1}) obtained from ^{1}H DNMR data for exchange of the $SiMe_2$ groups are consistent with an intramolecular process with negligible variation of entropy and are in good agreement with theoretical data reported by Bercaw and coworkers[11] for $[MCp_2Me]^+$.

$Sc(OTf)_3$-Catalyzed three-component reactions of aldehydes, amines and allyltributylstannane in micellar systems. Facile synthesis of homoallylic amines in water

Shū Kobayashi,* Tsuyoshi Busujima and Satoshi Nagayama

Department of Applied Chemistry, Faculty of Science, Science University of Tokyo (SUT), and CREST, Japan Science and Technology Corporation (JST), Kagurazaka, Shinjuku-ku, Tokyo 162, Japan

Three-component reactions of aldehydes, amines and allyltributylstannane proceeded smoothly in water without using any organic solvents, in the presence of a small amount of scandium trifluoromethanesulfonate [$Sc(OTf)_3$] and sodium dodecylsulfate (SDS), to afford the corresponding homoallylic amines in high yields.

The reaction of imines with allyltributylstannane provides a useful route for the synthesis of homoallylic amines.[1] The reaction is generally carried out in the presence of a Lewis acid in organic solvents under strict anhydrous conditions,[2] because most imines, Lewis acids and organotin reagents used are hygroscopic and easily decompose in the presence of even a small amount of water.[3] On the other hand, the utility of aqueous reactions is now generally recognized,[4] and development of carbon–carbon bond-forming reactions that can be carried out in aqueous media is one of the most challenging tasks in organic synthesis. It was believed, however, that the above reaction would remain difficult to perform in water because of the use of water-sensitive imines, Lewis acids and organotin reagents. Recently, we have found that scandium trifluoromethanesulfonate [$Sc(OTf)_3$]-catalyzed aldol reactions[5] and allylations of aldehydes[6] proceed smoothly in the presence of a small amount of a surfactant in water. It was indicated that micelles formed in these reactions and that the excellent hydrophobic reaction fields created realized the aqueous reactions. In the course of our investigations to develop new synthetic reactions in micellar systems, we have found that three-component reactions of aldehydes, amines and allyltributylstannane proceed smoothly in micellar systems using $Sc(OTf)_3$ as a Lewis acid catalyst.†

The reaction of benzaldehyde, aniline and allyltributylstannane was chosen as a model, and several sets of reaction conditions were examined. While the reaction proceeded sluggishly in the presence of $Sc(OTf)_3$ without sodium dodecylsulfate (SDS) or in the presence of SDS without $Sc(OTf)_3$, a 77% yield of the desired homoallylic amine was obtained in the presence of both $Sc(OTf)_3$ and SDS. It was suggested that an imine formed from the aldehyde and the amine rapidly reacted with allyltributylstannane to afford the desired adduct. We also examined the effect of the amount of $Sc(OTf)_3$ and SDS used and the results are summarized in Table 1. When a 70 mM SDS solution (0.4 equiv.) was used, the desired homoallylic amine was obtained in a 79% yield, and the yield remained unchanged with increasing amounts of SDS.‡ On the other hand, it was found that reduction of the amount of $Sc(OTf)_3$ decreased the yield, and that a prolonged reaction time increased the yield. Finally, a satisfactory yield was obtained when 0.2 equiv. $Sc(OTf)_3$ and 35 mM (0.2 equiv.) SDS were used and the reaction was carried out at room temp. for 20 h. No homoallylic alcohol (an adduct between the aldehyde and allyltributylstannane) was produced under these conditions.

Several examples of the present three-component reactions of aldehydes, amines and allyltributylstannane are shown in Table 2. The reactions proceeded smoothly in water without using any organic solvents in the presence of a small amount of $Sc(OTf)_3$ and SDS, to afford the corresponding homoallylic amines in high yields. Not only aromatic aldehydes but also aliphatic, unsaturated and heterocyclic aldehydes worked well. It is known that severe side reactions occur to decrease yields in the reactions of imines having α-protons with allyltributylstannane.[1] It should be noted that aliphatic aldehydes, especially non-branched aliphatic aldehydes, reacted smoothly under these conditions to afford the homoallylic amines in high yields. In all cases, no aldehyde adducts (homoallylic alcohols) were ob-

tained. It was suggested that the imine formation from aldehydes and amines was very fast in the presence of both $Sc(OTf)_3$ and SDS,[8] and that the selective activation of imines rather than aldehydes was achieved using $Sc(OTf)_3$ as a catalyst.[9] It is also noteworthy that using a small amount of a surfactant created efficient hydrophobic reaction fields[10] and achieved the dehydration and addition reactions in water.

A typical experimental procedure is as follows. To a 35 mM water solution of SDS (3 ml) and $Sc(OTf)_3$ (0.1 mmol) were added the amine (0.5 mmol), allyltributylstannane (0.75 mmol) and the aldehyde (0.65 mmol) successively, and the mixture was stirred at room temp. After 20 h, the mixture was diluted with water and ethyl acetate, and Amberlite IRA96SB was added. After being stirred for 10 min, the resin was filtered and the filtrate was extracted with ethyl acetate. The combined organic layers were dried, filtered and concentrated. The crude adduct was purified by column chromatography on silica gel to afford the pure desired homoallylic amine.

In summary, we have developed $Sc(OTf)_3$-catalyzed three-component reactions between aldehydes, amines and allyltributylstannane in micellar systems. The reactions proceed smoothly in water without using any organic solvents, to afford the corresponding homoallylic amines in high yields. In addition to the synthetic utility of these reactions, it should be noted that reactions using water-sensitive substrates have been successfully carried out in water under the present reaction conditions. Further progress is expected in this field and investigations on these micellar systems including mechanistic aspects are now underway in our laboratories.

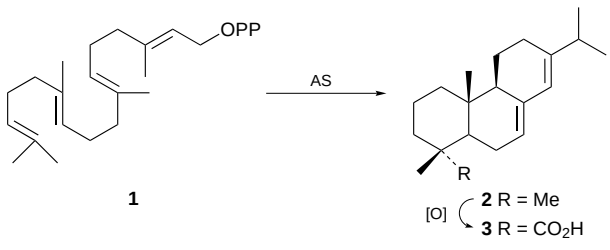
The cyclization–rearrangement of deuterated geranylgeranyl diphosphate (GGPP) and (+)-copalyl diphosphate (CPP) catalyzed by recombinant (−)-abietadiene synthase from grand fir proceeds with intramolecular proton transfer from C-19 of GGPP, and from the C-17 pro-*E* position of CPP, to form the C-16 *pro-S* methyl group of (−)-abietadiene.

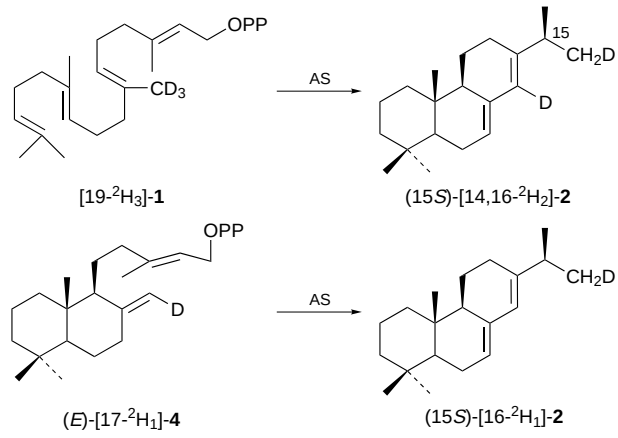
(−)-Abietic acid **3** is a major component of oleoresin exuded by conifer species, including lodgepole pine (*Pinus contorta*) and grand fir (*Abies grandis*),[1] as a defensive secretion against insect and pathogen attack. This diterpenoid resin acid is biosynthesized by cyclization of geranylgeranyl diphosphate (GGPP, **1**) to (−)-abietadiene **2** and sequential oxidations of the C-18-methyl group (Scheme 1).[2] (−)-Abietadiene synthase (AS) was purified and identified as an 80 kDa protein with general characteristics typical for terpenoid cyclases.[3]

AS from grand fir yielded internal amino acid sequence information from which a PCR-based cloning strategy was developed.[4] A 286 base-pair insert was isolated that encoded an 868-amino acid preprotein bearing a putative plastidial transit peptide. The cDNA encoded preprotein was functionally expressed in *Escherichia coli*, thereby confirming that a single enzyme catalyzes this multistep cyclization. Recent experiments with the recombinant enzyme (rAS) demonstrated that (+)-copalyl diphosphate (CPP, **4**) could serve as an efficient alternative precursor of **2**† whereas none of the four pimaradiene isomers tested were converted to abietadiene. Here we report the use of deuterated substrates to examine the mechanism of the rAS cyclization.

The synthesis of the labelled substrates [19-$^2H_3$]-**1** and (17*E*)-[17-$^2H_1$]-**4** followed analogous procedures in the literature. 19-Nor-7-methoxycarbonylgeranylgeranyl benzyl ether prepared by *Z*-selective phosphonate condensation[5] was converted to [19-$^2H_3$]geranylgeraniol by (a) AlD_3; (b) MsCl, Et_3N, CH_2Cl_2; (c) $LiBEt_3D$, THF; (d) Li, NH_3. (17*E*)-[17-$^2H_1$]Copalol was obtained from (17*E*)-17-bromocopalyl THP ether by lithiation, deuterolysis and deprotection.[6] Diphosphate esters were formed by standard methods[7] and were characterized by ^1H and ^{31}P NMR spectra. Incubation of these labelled substrates and [1-$^2H_2$]-**1** with rAS‡ gave (15*S*)-[14,16-$^2H_2$]-, (15*S*)-[16-$^2H_1$]- and (15*S*)-[16-$^2H_2$]-**2** respectively, with one deuterium located exclusively in the upfield methyl doublet of the isopropyl group according to ^1H NMR integrations and broadening from deuterium coupling (Scheme 2).§ No loss of the deuterium transferred to C-16 could be observed by GC–MS (≤1%). The absence of any detectable [$^2H_1$]abietadiene from a cross-over experiment with [19-$^2H_3$]-**1** and unlabelled **1** establishes that proton or deuteron transfer occurs within one catalytic cycle and rules out an enzyme-bound pimara-7,15-diene intermediate.



Scheme 1



Scheme 2

NMR assignments for the isopropyl methyl groups required unambiguous synthesis of stereospecifically labelled **2** (Scheme 3). Reaction of the tricyclic 8(14)-en-13-one[8] with ethyl lithioacetate·$CeCl_3$ complex provided a mixture of β-hydroxy esters (91%, 3 : 1 α-OH : β-OH) which underwent dehydration (HCl, EtOH, reflux) and saponification to give 7,13-diene acid **5** (65%).¶ Methylation of the ψ-ephedrine amide **6** afforded two diastereomers (94 : 6). The major isomer is assigned the 15*S*

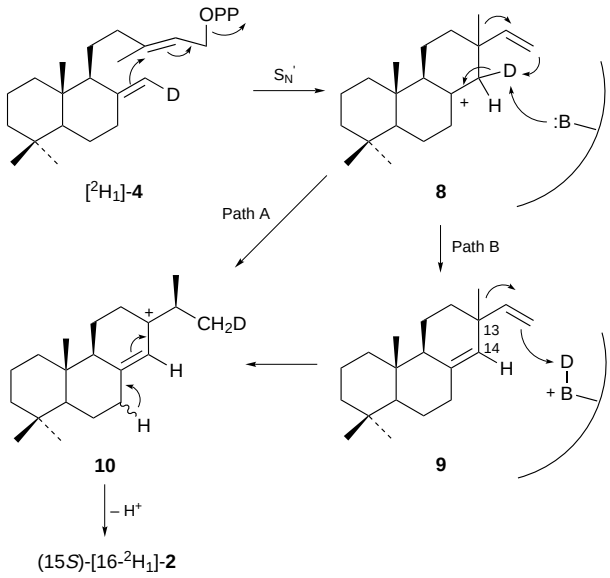

Scheme 4

configuration (**7**) based on the established stereodirecting influence of this chiral auxiliary.[9] $LiBH_3NH_2$ reduction,¶ mesylation and $LiBEt_3D$ displacement gave (15*R*)-[16-$^2H_1$]-**2** (64%). The ^1H NMR spectrum shows deuterium coupling and a characteristic upfield isotope shift for the downfield isopropyl methyl group of unlabelled **2** which is therefore assigned the *pro-R* configuration.§ It follows that rAS effects intramolecular proton transfer to the terminal carbon of the vinyl group which becomes the *pro-S* methyl, and that the methyl migration occurs to the *si* face at C-15 of the putative pimara-9(14),15-diene intermediate.

Intramolecular proton transfers to enzyme-bound polyolefin intermediates have been observed previously in pentalenene and taxadiene biosynthesis.[10] The occurrence of an analogous proton transfer to form the *pro-S* methyl of a presumptive abietadiene intermediate was inferred from the labelling pattern of ginkgolide A biosynthesized from [6,6,6-$^2H_3$]mevalonate in *Ginkgo biloba* cell cultures.[11] The same *si* face selectivity for the methyl migration presumed to occur in the biosynthesis of 12-*O*-methylferruginol and cryptotanshinone was deduced from label distributions resulting from incorporation experiments with [*U*-^{13}C]glucose in *Salvia miltiorhiza* cell cultures.[12]

Two plausible mechanisms for this novel cyclization–rearrangement are presented in Scheme 4. S_N' cyclization of **4** analogous to those involved in the biosynthesis of related pimarane and kaurane diterpenes[6,13] gives the pimaren-8-yl carbocation **8** which can undergo either intramolecular C-14-to-C-16 hydrogen transfer (Path A) or enzyme-mediated proton elimination to form a pimara-8(14),15-diene intermediate **9** that re-incorporates the proton at C-16 (Path B). Further research to elucidate the mechanism of the cyclization–rearrangement, the nature of the intermediate(s), and the identity of the participating enzyme base, if any, is underway.

A 3 : 1 mixed aggregate of diphenylamidolithium with lithium chloride: crystal structure of [$(Ph_2NLi)_3LiCl\cdot 3tmen$] (tmen = *N,N,N′,N′*-tetramethylethylenediamine)

Demonstrating a new structural type in mixed aggregate chemistry, a 3 : 1 mixture of Ph_2NLi and LiCl with 3 equiv. of *N,N,N′,N′*-tetramethylethylenediamine exists in toluene and in the solid state as a Ph_2NLi/LiCl mixed 'dimer' and a $(Ph_2NLi)_2$ homodimer linked only by a Li–Cl coordinate bond, as determined by NMR spectroscopy and X-ray crystallography.

There has been growing interest in the effect of added salts in a wide variety of chemical reactons, focused by a recent treatise on the subject.[1] One of the most intensely investigated phenomena has been the effect of added lithium halides on reactions involving lithium amides.[2] Mixed aggregates have been implicated by NMR[3] and, more recently, by crystallographic,[4] and *ab initio* computational[4d,f,5] analysis. So far for mixtures of lithium amides and lithium halides, of particular importance in modern enolisation reaction methodology, there have been examples of 1 : 1 {the 5,10-dihydrophenazine derivative[4a] [$LiCl\cdot Li(NC_{12}H_8NH)\cdot 4thf$] and the 2,2,6,6-tetramethylpiperidine (tmp) derivative[4d] [$LiBr\cdot Li(tmp)\cdot 3thf$]} and 2 : 1 {*e.g.* [$LiCl\cdot 2LDA\cdot 2tmen$] and isostructural analogues[4b,c,d,f]} aggregates. For 3 : 1 amide/halide aggregates there is no prior evidence; the only structurally characterised 3 : 1 mixed aggregate has been the organolithium heterocubane [$LiBr\cdot 3LiPh\cdot 3thf$], a structure in which the halide occupies one corner of the cube,[6] in retrospect unsurprising in view of the isostructural homo-aggregates $[LiBr\cdot Et_2O]_4$ and $[LiPh\cdot Et_2O]_4$.[7,6] While halides and carbanions are often associated with the ring stacking motif, inclusion of amides in the aggregates precludes this structural type.[8] Halides have previousl been incorporated into ladder structures,[4] including a very recent tetralithium butterfly cluster with μ_4 bromide,[4e] but we here report an alternative way for two dimers to associate *via* a single contact.

We chose the diphenylamido system as the basis for an extensive study of mixed aggregation phenomena since it is a simple model secondary amide amenable to crystallographic study. Prior to our work, only a single structure involving Ph_2NLi had been reported, that of a monomeric 12-crown-4 complex.[9] However, a thorough NMR spectroscopic investigation of the Ph_2NLi/LiBr system was also in the literature. This revealed evidence only of mixed dimeric aggregates.[3a] As this manuscript was in preparation, a further structure report appeared involving Ph_2NLi in a large aggregate with Bu^nLi and dilithiated Ph_2NH.[10]

Crystals of [$(Ph_2NLi)_3LiCl\cdot 3tmen$] **1** were grown from a toluene solution prepared from Ph_2NH, Ph_2NH_2Cl and Bu^nLi in the presence of tmen.† This hydrohalide *in situ* route has proved advantageous over 'direct' or 'ammonium salt' routes in the past for generation of crystalline mixed aggregates.[4b,d,f] Structure determination by X-ray crystallography‡ revealed the elegantly simple structure depicted in Fig. 1. Perhaps the simplest way of rationalising the molecule is to consider it as an adduct of a homodimeric amidolithium and a 1 : 1 mixed dimer. Taken in this way the mixed dimer may be compared with [$LiCl\cdot Li(NC_{12}H_8NH)\cdot 4thf$] in which each lithium is four-coordinate,[4a] as in **1**, but in which the chloride was only two-coordinate. In **1** the chloride is μ_3, as it is in [$LiCl\cdot 2LDAP\cdot 2tmen$],[4b] but in a Y-shaped rather than a T-shaped conformation. This near-planar (sum of angles 356°) Y-shape is rare for chloride. The closest analogy structurally lies in $[(LiCl)_4(pmdeta)_3]$ (pmdeta = *N,N,N′,N″,N″*-pentamethyldiethylenetriamine),[11] where the sum of angles around the three-coordinate chloride is 337°. This structure also provides the closest analogy to the two linked rhomboids of **1**. However, in $[(LiCl)_4(pmdeta)_3]$ the link is supported by a bridging pmdeta ligand.[11]

A more intriguing view of the molecule might be as a frozen analogue of a postulated intermediate in the fluxion of [$LiCl\cdot 2LDA\cdot 2tmen$] in toluene solution.[4f] In this way, inclusion of a further amidolithium unit converts this fluxion intermediate, in which chloride acts as a fulcrum around which the other ligands rotate, into a stable geometry. The retention of the double-ring structure of **1** in solution is proven by the concentration-invariant observation of three signals in a 2 : 1 : 1 ratio in the ^7Li NMR spectrum in toluene. This view of an extra amidolithium unit trapping an opened 2 : 1 aggregate is also relevant to enolisation mechanisms of 2 : 1 LDA/LiCl ag-

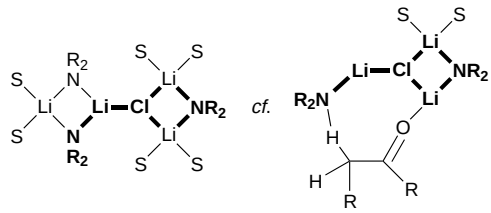

Scheme 1

gregates in solution: it has been proposed that such aggregates react *via* scission of a Li–N bond and coordination of a ketone.[4d] This proposal is further supported by the similarities between the putative opened intermediate and the stable geometry of **1** as shown emboldened in Scheme 1.

Another interesting view of the molecule is as a 'crystallographic snapshot' of the process of amidolithium ladder fragmentation by solvation, as recently discussed by Mulvey and coworkers.[12] By variation of solvent ratio and organic substituent on amido nitrogen, a series of fragmented ladders have been structurally determined, most recently by use of the primary amide PhNHLi and limited amounts of thf.[12] Inclusion of chloride in the aggregate **1** reduces the connectivity of two dimers to its minimal limit.

The success of the Ph_2N anion as a platform for mixed aggregate studies is due in large part to its favour of asymmetric solvation in the dimeric state. One four-coordinate and one three-coordinate lithium are observed in the unmixed tmen complex of this amide, just as in **1**, and in other mixed aggregates that we have structurally characterised. Details of some of these will be found in a forthcoming full paper once their solution behaviour has been fully characterised.[13]

Iron(III) 2-ethylhexanoate as a novel, stereoselective hetero-Diels–Alder catalyst

David B. Gorman* and Ian A. Tomlinson

The Dow Chemical Company, Midland, Michigan 48674, USA

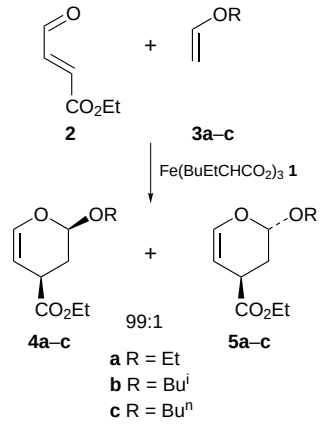
Iron(III) 2-ethylhexanoate has been used as a novel, mild Lewis acid catalyst for the stereoselective Diels–Alder reaction of ethyl (*E*)-4-oxobutenoate with alkyl vinyl ethers to stereoselectively produce *cis*-2-alkoxy-3,4-dihydro-2*H*-pyran-4-carboxylic acid, ethyl esters with diastereoisomeric excesses (de) as high as 98%.

Since its discovery over 65 years ago,[1] the Diels–Alder reaction has been one of the most versatile reactions for assembling six-membered rings. The use of Lewis acid catalysts has led to improved regio- and stereo-selectivity for many of these reactions. Lanthanide reagents have been used as very mild Lewis acid catalysts for the Diels–Alder reaction of α,β-unsaturated aldehydes or esters with vinyl ethers to give substituted dihydropyrans.[2] In a search for cost-effective alternative catalysts, we have discovered that iron(III) 2-ethylhexanoate **1** is a novel, mild and economical Lewis acid catalyst for carrying out highly stereoselective Diels–Alder reactions between ethyl (*E*)-4-oxobutenoate **2**[3] and alkyl vinyl ethers **3a**–**3c** to give 2,4-disubstituted pyrans **4a**–**c** and **5a**–**c** (Scheme 1).

Based on analogous Diels–Alder transformations to give 2,4-substituted tetrahydropyrans, the major products have been assigned as the *endo* isomers.[4] Effectively an inverse electron demand hetero-Diels–Alder reaction, cyclization occurs selectively through the *endo* transition state, regio- and stereoselectively producing the *cis*-2,4-disubstituted pyrans **4**). This *endo* selectivity is enhanced using **1** as a catalyst (Table 1), giving diastereoisomeric excesses (de) as high as 98% based on relative product peak ratios obtained by gas chromatography. Similar yields and selectivities have been obtained when ethyl, isobutyl, and n-butyl vinyl ethers are used.

The reaction of **2** and **3b** has been examined with varying amounts of **1** at various temperatures (Table 2). Clearly, selectivity and reaction rate were enhanced by the addition of **1** (entry 6 *vs.* entries 7–10). The highest selectivity was seen at room temperature. Increasing reaction temperature shortened the reaction time from a few days to a few hours, but the de decreased from 98% at room temperature to 96% at 60 °C and 90% at 80 °C (entries 2–5 *vs.* entries 7–10 *vs.* entry 15). For reaction mixtures at elevated temperatures, yields could be improved by adding a trace amount of Et_3N as an inhibitor; at levels above 1 wt% Et_3N in the reaction of **2**, yields and selectivity began to decrease, indicating Et_3N was poisoning the catalyst (entries 15–19). Reaction times could also be shortened by adding additional catalyst, but optimal yields of ⩾80% were obtained using 0.20–0.25 equiv. of **1** (entries 3, 8 and 13). Modest yield increases also were realized by increasing the amount of vinyl ether from 6 to 10 equiv. (entries 12 and 14 *vs.* entries 11 and 13).

To isolate gram quantities, the product was removed from the catalyst by selective precipitation followed by column chroma-



Scheme 1

Table 1 Comparison of vinyl ethers[a]

Entry	Ether	*T*/°C	*t*/d	Yield (%)	De (%)
1	**3a**	23	14	78	98
2	**3b**	23	14	80	98
3	**3c**	23	14	79	98

[a] Each reaction mixture contained ethyl (*E*)-4-oxobutenoate, 6 equiv. of vinyl ether and 0.1 euqiv. of iron(III) 2-ethylhexanoate. Ethyl (*E*)-4-oxobutenoate was inhibited with a trace amount of hydroquinone. Reported yields are GLC yields based on an internal standard. Yields at 66 h were calculated to be 72, 79 and 71% for entries 1, 2 and 3, respectively.

Table 2 Optimization reactions[a]

Entry	*T*/°C	*t*/h	**1** (equiv.)	Yield[b] (%)	De (%)
1	23	96	0	2	—
2	23	96	0.10	66	98
3	23	96	0.25	81	98
4	23	96	0.50	78	98
5	23	96	1.00	70	98
6[c]	60	18	0	13	66
7[c]	60	18	0.10	72	96
8[c]	60	18	0.25	80	96
9[c]	60	18	0.50	79	98
10[c]	60	18	1.00	67	98
11	60	16	0.10	72	96
12[d]	60	16	0.10	75	96
13	60	16	0.20	80	96
14[d]	60	16	0.20	84	96
15[e]	80	20	0.10	64	90
16[e]	80	20	0.10	73	92
17[e]	80	20	0.10	67	90
18[e]	80	20	0.10	56	82
19[e]	80	20	0.10	47	78

[a] Each reaction mixture contained ethyl (*E*)-4-oxobutenoate, isobutyl vinyl ether and iron(III) 2-ethylhexanoate. Ethyl (*E*)-4-oxobutenoate was inhibited with a trace amount of hydroquinone. Unless otherwise specified, 6 equiv. of isobutyl vinyl ether were used. [b] Reported yields are GLC yields based on an internal standard. [c] The reaction mixtures were stirred at room temperature for 18 h before heating to 60 °C for 18 h. [d] 10 equiv. of isobutyl vinyl ether were added instead of 6 equiv. [e] Et_3N was added in the following weight percents relative to **2**: 0% for entry 15, 1% for entry 16, 5% for entry 17, 15% for entry 18 and 25% for entry 19.

Table 3 Comparison of Iron-Based Catalysts[a]

Entry	Catalyst	*T* °C	*t*/h	**2** (%)	Yield[b] (%)	De (%)
1	Iron(III) 2-ethylhexanoate	70	6	15	58	96
2	Iron(II) 2-ethylhexanoate	70	6	29	38	92
3	Iron(III) naphthenate	70	5	21	30	92
4	Iron(III) benzoate	70	5	44	29	86
5	Iron(II) stearate	70	4	59	18	86
6	Iron(III) stearate	70	4	71	14	80
7	—	70	6	71	10	64

[a] All reactions were carried out in sealed glass tubes containing **2**, 6 equiv. of ethyl vinyl ether and 0.1 equiv. of catalyst. [b] Reported yields are GLC yields based on an internal standard.

tography on silica gel which had been deactivated by mixing with Et_3N in CH_2Cl_2 and evaporating to dryness. For larger samples, the product was isolated either by chromatography or wiped-film evaporation.

Although the exact binding nature of the catalyst is unknown, the choice of metal ligands and metal oxidation state is critical to the success of the catalytic reaction. Similar catalysts containing lower metal oxidation states and/or ligands which are bulkier and/or more rigid give lower selectivity, as well as lower reaction yields (Table 3). The bulkier/more rigid ligands may cause steric interference with the ethyl (*E*)-4-oxobutenoate, where complexation is believed to take place. A lower oxidation state may decrease the catalyst electrophilicity enough that it does not coordinate well with any of the oxygens from **2**.

In summary, iron(III) 2-ethylhexanoate is a novel, mild and relatively inexpensive Lewis acid catalyst for the stereoselective Diels–Alder reaction of ethyl (*E*)-4-oxobutenoate with alkyl vinyl ethers to give *cis*-2,4-disubstituted pyrans, extending the range of known catalysts for these types of transformations.

We thank Don Zakett for determining mass spectral data for **4a**–**c** and **5a**–**c**.

† Iron(III) 2-ethylhexanoate was purchased as a 52% solution in mineral spirits from Johnson Matthey Alfa Aesar. Ethyl (*E*)- 4-oxobutenoate was purchased from Lonza. Representative experimental procedures. (*a*) Purification by chromatography: A mixture of ethyl (*E*)-4-oxobutenoate (2.56 g, 0.02 mol): *n*-butyl vinyl ether (8.65 g, 0.12 mol) and 52% iron(III) 2-ethylhexanoate (1.86 g, 0.002 mol) in mineral spirits was stirred at room temperature for 44 h. The catalyst precipitated after adding 20 ml of 20% MeCN in water. The slurry was filtered through filter agent, rinsing the cake with 20% MeCN in water. The filtrate was saturated with NaCl. The organic layer was separated and dried ($MgSO_4$). The solution was decanted and the MeCN evaporated. The remaining brown oil was flushed through a 0.75″ × 12″ deactivated silica gel column, eluting with hexane, followed by 20% EtOAc in hexane. After concentrating, a clear yellow oil (3.36 g) was obtained, assaying at 97% of **4a** as a single isomer for a calculated yield of 3.26 g (81%).

(*b*) purification by wiped-film evaporation: A mixture of of 52% iron(III) 2-ethylhexanoate (96.5 g) in mineral spirits and (±)-bis(2-ethylhexyl) sebacate (50.3 g) was dripped down a wiped-film still over 2 h operating at a vacuum of 0.05 mmHg, a heating temperature of 60 °C, a condensing temperature of 4 °C and a spinning rate of 300 rpm. The recovered bottoms (99.4 g) were assumed to be 50% catalyst by weight. A mixture of ethyl (*E*)-4-oxobutenoate (25.7 g, 0.20 mol) *n*-butyl vinyl ether (120.4 g, 1.20 mol) Et_3N (0.3 g), hydroquinone (0.026 g), and 50% iron(III) 2-ethylhexanoate in (±)-bis(2-ethylhexyl) sebacate (18.6 g, 0.02 mol) was heated at 60 °C for 12 h. After evaporating excess vinyl ether, the residue was dripped at 1 drop per second down a wiped-film still operating at a vacuum of 0.1 mmHg, a heating temperature of 90 °C, a condensing temperature of 2 °C and a spinning rate of 300 rpm. The overheads (30.2 g) assayed at 93% of **4a** for a calculated yield of 28 g (62%).

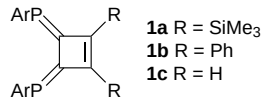
Preparation and X-ray analysis of novel carbonyltungsten(0) complexes of diphosphinidenecyclobutenes

Masaaki Yoshifuji,* Yoshito Ichikawa, Naoki Yamada and Kozo Toyota

Department of Chemistry, Graduate School of Science, Tohoku University, Aoba, Sendai 980-77, Japan

A sterically protected diphosphinidenecyclobutene 5 bearing a bulky 2,4,6-triisopropylphenyl group is prepared and allowed to react with $W(CO)_5$(thf) to give a doubly tungsten-coordinated complex 8, with chelate- and π-type coordination; the structure of the complex is confirmed by X-ray analysis.

Sterically protected phosphorus-containing multiple bonded compounds with bulky substituents are currently of interest. We have been interested in cumulated and conjugated systems[1,2] involving phosphorus atom(s) in low coordination states, as well as diphosphenes[3] and phosphaethenes.[4] Recently, Appel *et al.*,[5] Märkl *et al.*[6] and ourselves[7–9] have reported the preparation and isolation of diphosphinidenecyclobutenes (**1a**–**c**, Scheme 1) utilizing 2,4,6-tri-*tert*-butylphenyl as a protecting group (Ar), as well as their *E*/*Z* isomerization about the P=C bonds.[7,10] We have also reported on their transition metal complexes, where metals are Cr, Mo, W,[8,11,12] Pt and Pd.[13] We now report a new type of tungsten carbonyl complex ligated with diphosphinidenecyclobutenes carrying the 2,4,6-triisopropylphenyl group[14] (Tip) as well as the Ar group.



1a R = $SiMe_3$
1b R = Ph
1c R = H

Scheme 1 Ar = $C_6H_2Bu^t_3$-2,4,6

According to a slightly modified procedure employed for the preparation of **1b**, (2-phenylethynyl)(2,4,6-triisopropylphenyl)phosphinous halides **3** were prepared by the reaction of 2-phenylethynylphosphinous dichloride **2**[15] with 2,4,6-triisopropylphenylmagnesium bromide in thf at −78 °C. Then **3** was allowed to react with Bu^tLi at −78 °C or with Zn powder at room temp. to give diphosphane **4** as a diastereomeric mixture (D,L : *meso* = *ca.* 1 : 1) and the mixture was refluxed in thf to give (*E*,*Z*)-1,2-diphenyl-3,4-bis(2,4,6-triisopropylphenylphosphinidene)cyclobutene **5**.† It should be noted that only a trace amount of (*E*,*E*)-**5** was observed by ^{31}P NMR spectroscopy.

In the ^1H NMR spectrum of **5** in [$^2H_8$]toluene, there appeared six types of isopropyl peaks at 295 K. At higher temperatures, only two sets due to the *ortho*-isopropyl groups became coalesced, but the other two sets due to the other *ortho*-isopropyl groups remained magnetically non-equivalent. The remainder of the isopropyl groups assigned to the *para*-isopropyl groups remained unchanged even at 375 K. The fact suggests that one of the Tip groups, probably (*E*)-Tip, taking the steric congestion into account, starts to rotate at 323 K, while (*Z*)-Tip appears not to rotate even at 375 K.

We are now able to obtain a novel class of tungsten complex by the reaction of the diphosphinidenecyclobutene **5** with $W(CO)_5$(thf)[16] in refluxing thf.‡ The reaction gave **8** together with **6** and **7** (Scheme 2).† The ^{31}P NMR chemical shift of **8** appeared at δ_P 57, indicating that the phosphorus atom is strongly shielded compared with the value in the free ligand of either δ_P 164 for (*E*,*E*)-**5** or δ_P 169 and 183 for (*E*,*Z*)-**5**.

The structure of **8** was confirmed by the X-ray analysis§ to reveal a novel coordination type. Fig. 1 depicts an ORTEP drawing of the molecular structure for the bis-tungsten complex **8**. There are observed two WCO moieties, one is tetracarbonyl with chelate type coordination, the other is tricarbonyl with π-coordination. The two phosphorus atoms coordinate doubly on both $W(CO)_4$ and $W(CO)_3$ adopting sp^3 type configuration. The exocyclic P=C bonds are bent strongly from the ring plane [interplanar angle between the plane P(1)P(2)C(3)C(4) and the plane C(1)–C(4) 32.3°] to adopt a good interaction with the 6π system to coordinate on $W(CO)_3$, thus exhibiting a sharp contrast to the regular group 6 metal tetracarbonyl or palladium complexes of diphosphinidenecyclobutenes, where the system is planar with all sp^2 type configuration as exemplified in W,[11] Mo,[12] and Pd complexes.[13]

The P=C bond lengths of **8** [av. 1.763(10) Å] are elongated upon coordination compared to those of (*E*,*E*)-**1a** [1.677(6) Å][12] and (*E*,*E*)-**1b** [1.690(8) Å].[5] The bond length C(1)–C(2) of **8** [1.47(1) Å] is fairly elongated compared to the values of 1.400(9) Å and 1.380(9) Å for (*E*,*E*)-**1a** and (*E*,*E*)-**1b**, respectively. Thus, the interaction between the $W(CO)_3$ group and the ligand is apparently strong, since little change in bond lengths has been observed upon coordination with the chelate.[8,11–13]

Furthermore, in the case of compound (*E*,*E*)-**1c**, carrying the two Ar groups and no substituents on the cyclobutene ring, a doubly coordinated complex **9** was formed under similar conditions using $W(CO)_4(MeCN)_2$ (Scheme 3).[16] Complex **9** seems to have been formed *via* **10** as an intermediate, since **10** reacted with $W(CO)_4(MeCN)_2$ to give **9**.¶ It appeared to require less hindered environment than **1a** or **1b** to obtain double coordination products such as **8** or **9**.

Although Rau and Behrens reported on the formation and the structural analysis of (η^6-dimethylenecyclobutene)tricar-

Aziridination of naphthalene by 3-acetoxyaminoquinazolin-4(3*H*)-ones

Robert S. Atkinson,*[a]† Emma Barker,[a] Christopher K. Meades[a] and Hassan A. Albar*[b]‡

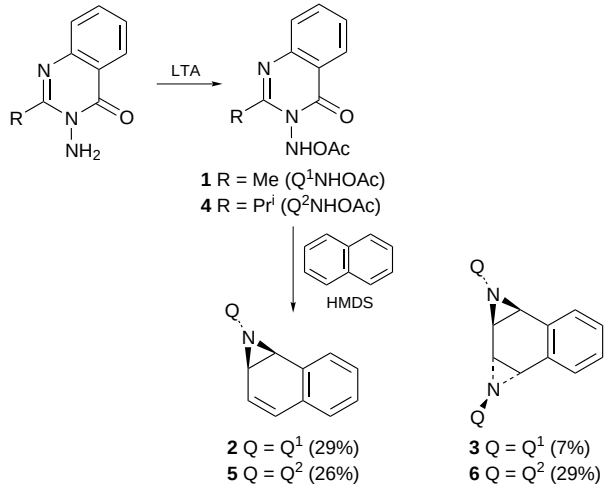
[a] *Department of Chemistry, University of Leicester, Leicester, UK LE1 7RH*
[b] *Department of Chemistry, King Abdul Aziz University, Jeddah 21413, Saudi Arabia*

Reaction of naphthalene with 3-acetoxyaminoquinazolinones 1, 4 or 8 in the presence of hexamethyldisilazane gives the corresponding mono-aziridine as the major (for 1) or exclusive (for 8) product; on heating in benzene, aziridine 5 acts as an aziridinating agent for alkenes.

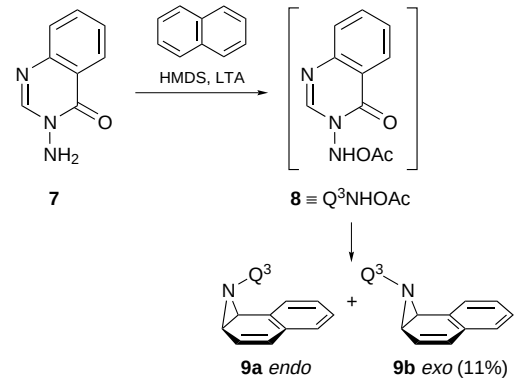
Intermolecular non-enzymic reactions of simple naphthalenes which result in exclusive 1,2-addition to a peripheral double bond are uncommon: the remaining 3,4-double bond in the functionalised six-membered ring will usually be more reactive than any bond in the parent naphthalene with the result that bis-addition (1,2 and 3,4) is the major pathway. Thus the reaction of naphthalene with *m*-chloroperoxybenzoic acid[1] or with methyl(trifluoromethyl)dioxirane[2] is reported to give the *trans*-1,2,3,4-bis-epoxide but none of the mono-epoxide. A stereoselective addition to just one double bond would be valuable because subsequent stereoselective addition to the second double bond, using a different reagent, would lead to 1,2,3,4-tetrahydronaphthalene derivatives as single diastereoisomers.

Aziridination of naphthalene (3 equiv.) with 3-acetoxyamino-2-methylquinazolinone **1** (Q^1NHOAc)[3] in the presence of hexamethyldisilazane (HMDS) (3 equiv.) in chloroform gave mono-aziridine **2** (29%) and bis-aziridine **3** (7%) from examination of the crude reaction product by NMR spectroscopy using triphenylmethane as an internal standard (Scheme 1).§ After removal of the bulk of the naphthalene by sublimation (40 °C, ~ 10^{-5} mmHg), the products **2** and **3** were isolated in 17 and 3% yields respectively after chromatography on de-activated silica.

When aziridination of naphthalene was carried out using 3-acetoxyamino-2-isopropylquinazolinone **4** (Q^2NHOAc)[4] under the same conditions, the analogous mono- and bis-aziridines **5** and **6** were present in 26 and 29% yields in the crude reaction product and isolated in 20 and 11% yields respectively (Scheme 1) after chromatography as described above.



Scheme 1

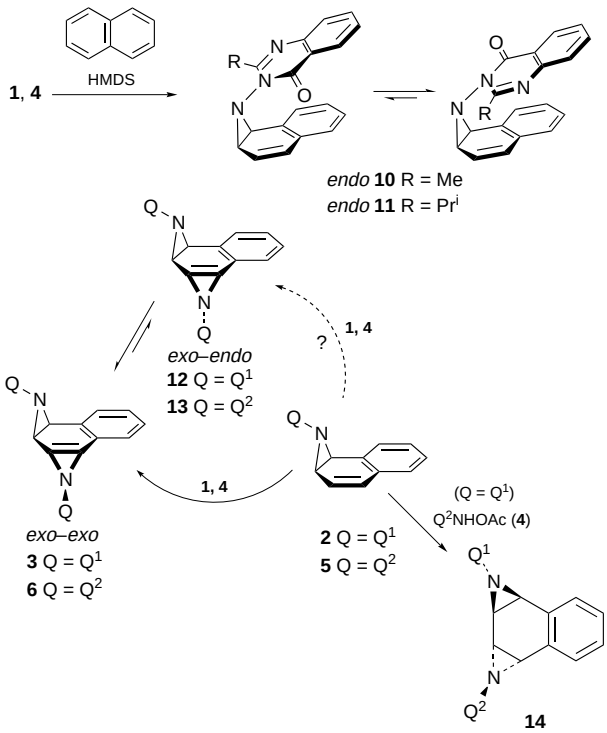


Scheme 2

The presumed 3-acetoxyaminoquinazolinone **8** (Q^3NHOAc) (Scheme 2), unsubstituted in the 2-position, is not stable under the conditions used for the preparation of Q^1NHOAc **1** and Q^2NHOAc **4**. However, *N*-acetoxylation of the corresponding 3-aminoquinazolinone **7** by lead tetraacetate (LTA) in the presence of naphthalene (3 equiv.) and HMDS (3 equiv.) gave the mono-aziridine, isolated as a mixture of *N*-invertomers **9a** (*endo*) and **9b** (*exo*) (11%) after chromatography: examination of the crude reaction product revealed that no bis-aziridine was formed.

Following the course of these aziridinations by NMR spectroscopy at temperatures from −20 °C to ambient is particularly informative and the changes observed can be interpreted as follows (Scheme 3): (a) the kinetically-formed products in each case are, as expected,[3] the *endo*-*N*-invertomers **10** and **11** (Scheme 3) and **9a** (Scheme 2) in which the quinazolinone ring and naphthalene residue are *cis*; (b) for each of the *endo*-invertomers **10** and **11** two *rotamers* around the *N–N* bond are present (ratio 3 : 1 and 5 : 1 respectively): only a single rotamer appears to be present in the case of **9a**; (c) interconversion between the *N–N* bond rotamers in **10** and **11** although slow on the NMR time-scale is fast on the *N*-inversion (*endo*→*exo*) time-scale;¶ (d) bis-aziridines **3** and **6** have the *exo–exo* configuration;‖ if the corresponding *exo–endo* stereoisomers **12** and **13** are intermediates in the formation of **3** and **6**, their concentrations are not sufficiently high for detection; (e) signals for mono-aziridines **2** and **5** (*exo*-invertomers) only become significant in these NMR spectra when signals from the respective aziridinating agents Q^1NHOAc **1** or Q^2NHOAc **4** have almost disappeared;** (f) bis-aziridination takes place predominantly or exclusively from the *exo*-invertomers **2** and **5**.

The competititve or predominant formation of mono-aziridine in these reactions arises as a consequence of (f) above together with a slow rate of *N*-inversion (*endo*→*exo*) for the mono-aziridine. Support for the conclusion in (f) comes from the absence of bis-aziridine as a product from the reaction in Scheme 2 and from the greater ratio of mono- : bis-aziridines **2** : **3** over **5** : **6**. The rates of *N*-inversion (*endo*→*exo*) in these mono-aziridines would be expected to increase in the order **9a** < **10** < **11** and this order correlates with the ratios bis- : mono-

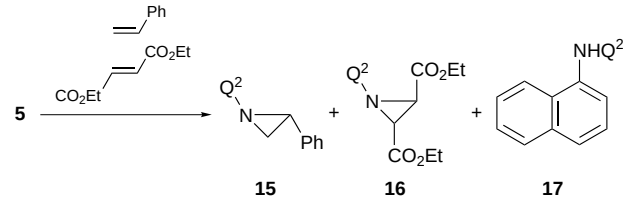


Scheme 3

aziridine obtained. The absence of any bis-aziridine in the reaction in Scheme 2 is because reaction of Q^3NHOAc with naphthalene is complete, and gives only *endo*-invertomer **9a**, before conversion of **9a** to **9b** takes place as the temperature is raised to ambient.††

syn-Addition of these 3-acetoxyaminoquinazolinones to aryl-substituted double bonds to give *endo*-substituted aziridines as kintically-formed products is well known and has been ascribed to an attractive interaction between the quinazolinone and aryl rings in the transition state.[3] Deactivation of the residual 3,4-double bond in the *endo*-configured mono-aziridines **10**, **11** and **9a** presumably arises from a similar interaction in these stereoisomers in which the aziriding ring bonds are now fully formed.

Further functionalisation of the 3,4-double bond in these mono-aziridines is under study: the mono-aziridine **2** reacts with Q^2NHOAc **4** (2 equiv.) to give the bis-aziridine **14** in 68% yield.



Scheme 4

Heating aziridine **5** in benzene containing a mixture of styrene (3 equiv.) and diethyl fumarate (3 equiv.) gave the corresponding aziridines **15** and **16** and the amine **17** in a 1 : 1 : 2 ratio (Scheme 4). It is likely that the intermediate in this aziridination is the nitrene [$Q^2\ddot{N}$:] since the same selectivity for these two alkenes is found for this species generated by other means.[5]

‡ E-mail: scf3043@kaau.edu.sa

§ In the absence of HMDS, the major product is 1-(3,4-dihydro-2-methyl-4-oxoquinazolin-3-yl)aminonaphthalene **17** (22%).

¶ As the reactions proceed the concentrations of **10** and **11** are reduced to zero but there is no change in the ratios of their two rotamers.

‖ The two aziridine rings in these bis-aziridines would be expected to be *trans*-disposed based on steric grounds and this assignment is supported by the C_{2v} symmetry present (NMR spectroscopy) in the corresponding bis-aziridine obtained from reaction of naphthalene and 3-acetoxyamino-2-[(1′*S*)-2′,2′-dimethyl-1′-hydroxypropyl]quinazolin-4(3*H*)-one (see R. S. Atkinson, A. P. Ayscough, W. T. Gattrell and T. M. Raynham, *Chem. Commun.*, 1996, 1935).

** The rates of aziridination of *exo*-*N*-invertomers **2** and **5** by Q^1NHOAc **1** and Q^2NHOAc **4** are expected to be faster than that of naphthalene.

†† Further support for the conclusion in (f) is the higher ratio mono- : bis-aziridine **5** : **6** (4 : 1) obtained using the nitrene [$Q^2\ddot{N}$:] derived from Q^2NHOAc **4** and triethylamine (ref. 5): aziridinations of alkenes using [$Q^2\ddot{N}$:] take place at slightly lower temperatures than those using Q^2NHOAc.

A porous chiral framework of coordinated 1,3,5-benzenetricarboxylate: quadruple interpenetration of the (10,3)-a network

Cameron J. Kepert and Matthew J. Rosseinsky*

Inorganic Chemistry Laboratory, University of Oxford, South Parks Road, Oxford UK OX1 3QR

The chiral and porous cubic coordination polymer $Ni_3(btc)_2(py)_6(eg)_6{\cdot}xeg\cdot yH_2$O (btc = 1,3,5-benzenetricarboxylate, py = pyridine, eg = ethylene glycol, $x \approx 3$, $y \approx 4$) is based on the interpenetration of four independent (10,3)-a networks, and contains large interconnected cavities with diameter 16 Å which may be desolvated without irreversibly destroying the porous framework structure.

The search for porous chiral solids is driven largely by a desire to perform enantioselective separations and syntheses.[1] The only two chiral zeolites known, zeolite β[2] and the titanosilicate ETS-10,[3] are both polymorphic, and samples currently retain one handedness only over a few crystallographic layers. Chiral, porous solids have very recently been resolved by the formation of single crystals: $NaZnPO_4{\cdot}H_2O$[4] consists of a tetrahedral framework containing water-filled channels, $Co(tn)_3{\cdot}Al_3P_4O_{16}{\cdot}2H_2O$[5] (GTex-2) consists of aluminophosphate layers separated by layers of the template, $Cd(tcm)[B(OMe)_4]{\cdot}x$MeOH[6] ($x \approx 1.6$) consists of sixfold helices containing methanol of solvation, and $Zn_2(btc)(NO_3){\cdot}H_2O{\cdot}5C_2H_5OH$[7] contains a single (10,3)-a network.[8] The last of these, as well as three achiral btc metallate phases,[9] shows structural stability to removal of solvent.

Here, we report the preparation of an air-stable nickel(II) salt of btc with spontaneous resolution from achiral starting materials. The material is novel in containing four interpenetrating (10,3)-a networks of the same handedness, through which lie solvent-filled pores of an unprecedented size. These pores may be desolvated completely at 115 °C to leave a poorly crystalline material with empty chiral cavities. The crystallinity of the interpenetrating lattice may be regenerated by resolvating this material with a variety of solvents.

Batches of single crystals consisting of a 50 : 50 mixture of enantiomers were synthesised by slow diffusion techniques,† and the crystal structure was determined by X-ray diffraction at 150(2) and 295(2) K.‡ $Ni_3(btc)_2(py)_6(eg)_6{\cdot}xeg\cdot yH_2$O is cubic, and is the first molecular material to crystallise in the chiral space group $P4_232$. The chiral network self-assembles due to unique interactions between the ligands in the first coordination sphere of the six-coordinate Ni^{II}. The two axial positions of the octahedron are occupied by tridentate btc anions while the equatorial positions are occupied equally by eg/H_2O and py (Fig. 1). Hydrogen bonding between the non-coordinated oxygen atom of the btc carbonyl group and the equatorial alcohol/H_2O group [O(11)···O(2) 2.60 Å] produces an approximately orthogonal orientation of the *trans* btc groups bound to Ni^{II}. This hydrogen-bonded arrangement, which appears to be highly uncommon, is the structural key to the formation of the chiral framework.

In the (10,3)-a network, chirality arises from the <100> fourfold and <111> threefold helices of the same handedness propagating in all crystallographically equivalent directions. Here the 11.3 Å separation between neighbouring btc prevents interpenetration of networks of opposite chirality (such as that resulting in a racemic crystal in $[Zn(tpt)_{2/3}(SiF_6)(H_2O)_2(MeOH)]$[10]) and four networks of the same handedness interpenetrate in such a way that each is related by unit translation or twofold rotation. Pseudo-tetrahedral cavities between the networks are bounded by the four btc anions per unit cell, and are linked by wide zigzag channels running along the <111> directions and passing through the vertices of the tetrahedra. The cavities are centred about (0,0,0) and (1/2,1/2,1/2) (Fig. 2). Approximately 28.1% of the crystal volume is occupied by free solvent,‡ so that each pore has a volume of *ca.* 600 Å^3, and a maximum diameter of *ca.* 16 Å. With the assumed Ni coordination, each contains three eg and four H_2O molecules, as determined by elemental microanalysis. The pseudo-hexagonal <111> channels have radii in the range 7–10 Å. There are narrower <100> channels with radii in the range 5–8 Å.

With heating to 115 °C, the material undergoes a colour change from blue to green. Thermogravimetry§ and elemental microanalyses§ are consistent with the loss of six eg and one py to leave $Ni_3(btc)_2(py)_5(eg)_3(H_2O)_4$. This is accompanied by a severe broadening of the X-ray powder diffraction (XRPD) pattern.¶ Exposure to eg, EtOH and MeOH vapour at ambient conditions in all cases led to a considerable sharpening of the XRPD pattern¶ indicating a drastic increase in crystallinity with the resolvation of the lattice. This implies that the partially desolvated material, $Ni_3(btc)_2(py)_5(eg)_3(H_2O)_4$, contains large

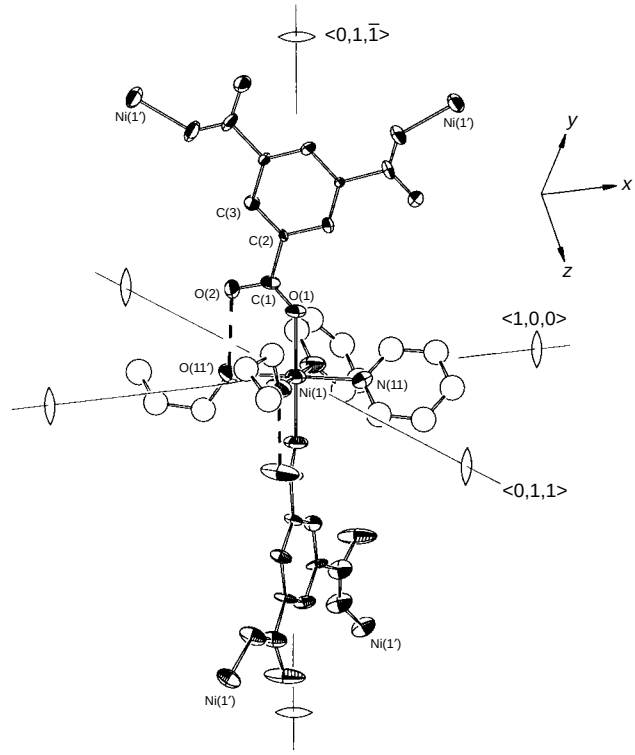

Fig. 1 The linear coordination of 1,3,5-benzenetricarboxylate to Ni^{II}, which is stabilised by hydrogen bonding to equatorial alcohol/H_2O groups (indicated by the dashed lines). The three orthogonal twofold rotation axes passing through the Ni are shown. All atoms are shown with 30% thermal ellipsoids. For clarity, only one orientation of the highly disordered fragment is shown, and hydrogen atoms have been omitted.

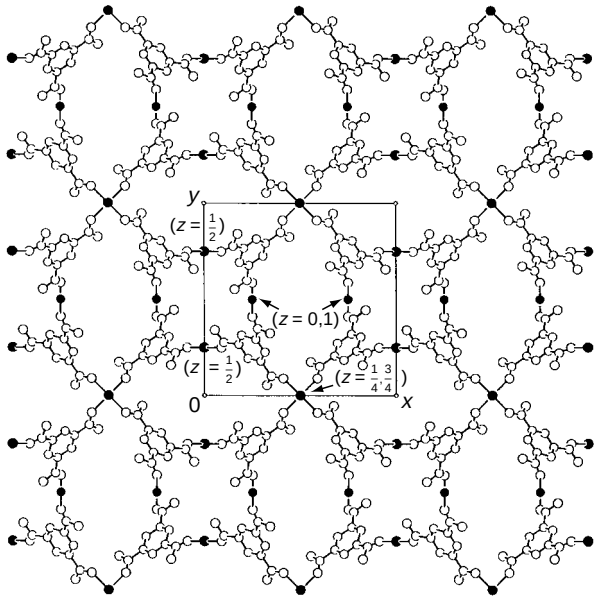

Fig. 2 Axial projection of the structure (for clarity, the equatorial ligands of the Ni^{II} cations and the solvent species occupying the pores have been removed, and only one of the two disordered orientations of the 1,3,5-benzenetricarboxylate is shown). Large, pseudo-tetrahedral solvent-filled cavities are centred about (0,0,0) and (1/2, 1/2, 1/2), and are linked by wide channels along the <111> and <100> directions. A view along (111) is presented as the graphical abstract.

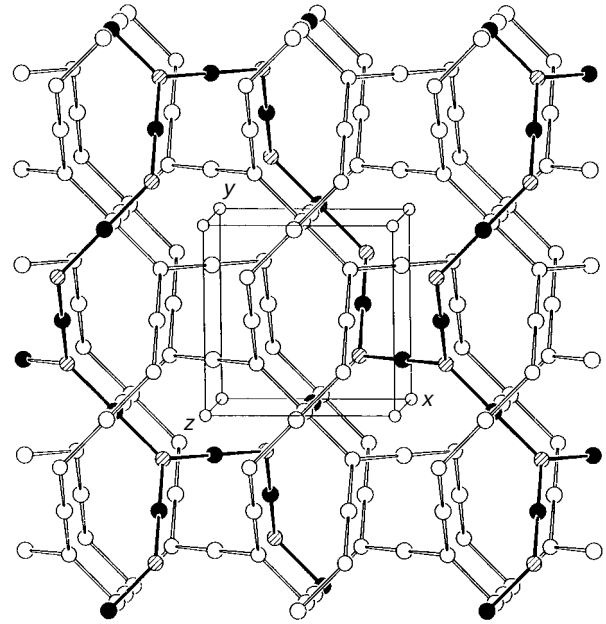

Fig. 3 Conceptual diagram showing the interpenetration of four 'clockwise' (10,3)-a networks. One of the four networks is highlighted such that the blackened circles represent Ni atoms and the hatched circles represent centres of the benzene rings.

empty chiral cavities, and that the relatively inflexible (10,3)-a network structure is retained throughout the cycle.

The chemical significance of the first-sphere hydrogen bonding in orienting the helix-forming btc anions is shown by the formation of isomorphous structures, either by resolvation or direct growth, with MeOH and EtOH replacing eg. The choice of ligands around the metal centre thus promises to greatly influence the chemical nature of the chiral pores in this new framework structure.

C. J. K. thanks Christ Church, Oxford, for a Junior Research Fellowship. We thank Professor C. K. Prout and Dr D. J. Watkin for access to the single crystal X-ray diffractometers (funded by EPSRC) and for useful discussions.

Phosphonium salts of diacetoxyiodine(I) anions, new reagents for the iodoacetoxylation of alkenes

Andreas Kirschning,* Claus Plumeier and Lars Rose

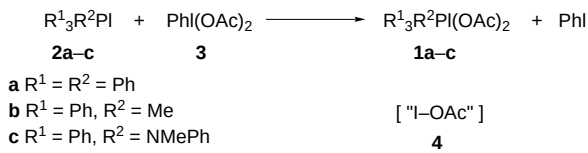
Institut für Organische Chemie, TU Clausthal, Leibnizstr. 6, D-38678 Clausthal-Zellerfeld, Germany

Novel phosphonium salts of diacetoxyiodine(I) anions 1 add to alkenes like tri-*O*-benzyl galactal 8 affording 1-acetoxy-2-iodopyranoses 12a,b which can efficiently be employed in the synthesis of 2-deoxyglycoside 14.

Stereo- and regio-selective 1,2-additions to alkenic double bonds are one of the most important transformations in organic synthesis.[1] Among this class of reactions, acetoxyiodinations are only rarely used. The α-iodo acetates which are created *via* this transformation can serve as starting materials for the preparation of allyl acetates or α-iodo alcohols with subsequent formation of oxiranes.[2] Current reagent systems in use for the acetoxyiodination of alkenes involve KIO_3 in glacial AcOH at 60 °C,[3] or various heavy metal salts[4] derived from silver(I), thallium(I), copper(II), mercury(II) or bismuth(III), all in the presence of I_2. AcOH and *N*-iodosuccinimide at 60 °C can also be used to form α-iodo acetates from the corresponding alkenes.[5] Due to the harsh reaction conditions employed and environmental problems involved with heavy metals, these methods have not found wide acceptance in reactions with multifunctional alkenes or in natural product synthesis.

Here we describe the preparation of a new class of reagents, the phosphonium salts of diacetoxyiodine(I) **1**,[6] which can be regarded as an acetyl hypoiodite **4** equivalent. Compound **4** has never been isolated, but has been postulated as an intermediate in the Hunsdiecker and Simonini reactions[7] and in the thermal decomposition of diacyliodobenzenes.[8] As is demonstrated, diacetoxyiodine(I) species **1** are ideally suited for promoting acetoxyiodination of alkenes under very mild conditions. Scheme 1 shows that these reagents are conveniently prepared from the corresponding phosphonium iodides **2a** and **2b** and diacetoxyiodobenzene **3** ($CHCl_3$, room temp., 2 h). After addition of Et_2O, the tetraphenylphosphonium salt **1a** precipitates as a light brown amorphous material [mp 145 °C (decomp.)], whereas the methyltriphenylphosphonium salt **1b** separates from the organic layer as a dark brown oil.†

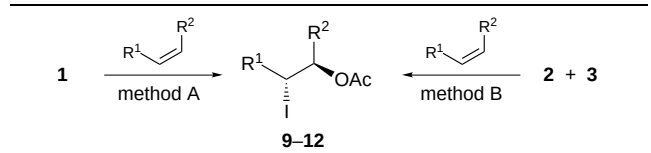
Diacyliodine(I) compounds like **1a** promote acetoxyiodination of alkenes such as cyclohexene **5** or indene **6** in a highly *anti* selective manner (Table 1). α-Iodo acetates **9**[9] and **10** are isolated in good yield. Regiocontrol is determined by the relative stability of the two possible intermediate cations. Acetoxyiodination may further be simplified by *in situ* generation of **1** from **2**,‡ including formation of **1c** from Murahashi's reagent **2c**, in various solvents followed by addition of the alkene. Under these conditions carbohydrate derived enol ethers such as **7** and **8** quantitatively afford 1-acetoxy-2-iodopyranoses **11a**,**b** and **12a**,**b**, respectively, under very mild conditions. Usually, a preference for α-glycosyl acetates is observed. Due to the reduced solubility of



Scheme 1

1a and **2a** in toluene, acetoxyiodination of **7** proceeds sluggishly. This obstacle may be circumvented by accellerating the reaction with catalytic $Me_3SiOSO_2CF_3$. Under these conditions the rare 2-deoxy β-anomer **11b** is formed in substantial amounts. The reaction exclusively furnishes 1,2-*trans* adducts, which can be rationalized by assuming a *trans*-diaxial addition of iodonium cation and acetoxy group to the electron-rich enol ether double bond.§

Table 1 Results of some acetoxyiodinations



Method[a]	1	Solvent	*t*/h	Ratio[b]	Yield (%)[c]

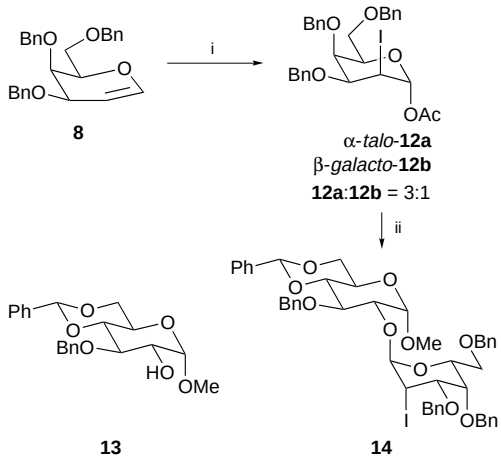
B	**1b**	PhMe	72	3.5 : 1	74[f]

[a] Method A: Preformed **1a**. Method B: **1a**–**c** generated *in situ*. All reactions carried out at room temp. [b] Determined from ^1H NMR spectra of crude product. [c] Yield of isolated product after column chromatography. [d] See footnote §. [e] Added $Me_3SiOSO_2CF_3$. [f] Crude product was contaminated with **8** (10%).



Scheme 2 *Reagents and conditions*: i, **2b**, **3**, CH_2Cl_2, 78%; ii, **12a**, **13**, $Me_3SiOSO_2CF_3$, CH_2Cl_2, −78 °C, 89%

These glycosyl acetates are ideal precursors for the construction of 2-deoxy glycosides, which occur as structural moieties of many bioactive natural products.[10] In glycosidations the 1-acetoxy group has glycosyl donor properties, while the 2-iodo substituent serves as a stereocontrol element in the glycosidation step which can be removed reductively at a later stage. In fact, acetoxyiodination of glycal **8** in CH_2Cl_2 yields glycosyl acetate **12** (α:β = 3.1:1, 78%) (Scheme 2). Separation by column chromatography gave pure α-*talo*-**12** which, after Lewis acid-promoted activation, was glycosidated in the presence of methyl glycoside **13** to afford α(1-2) disaccharide **14** as the only product in excellent yield.

In summary, phosphonium salts of diacetoxyiodine(I) represent a new class of reagents for the facile acetoxyiodination of alkenes. Starting from glycals, 1-acetoxy-2-iodo pyranoses are generated which can efficiently be employed in the synthesis of 2-deoxy glycosides.

Oxygen states present at a Ag(111) surface in the presence of ammonia: evidence for a NH_3–$O_2^{\delta-}$ complex

A. F. Carley, P. R. Davies, M. W. Roberts,* K. K. Thomas and S. Yan

Department of Chemistry, University of Wales, Cardiff, UK CF1 3TB

Molecular oxygen states present at Ag(111) surfaces when dioxygen is coadsorbed with ammonia at 80 K are characterised by vibrational loss features at 1488 and 1640 cm^{-1}. The former is suggested to be associated with the $NH_3\cdots O_2^{\delta-}$ complex, a key intermediate in the oxidation pathway.

There is now incontrovertible experimental evidence for the role of specific oxygen states present at single crystal metal surfaces (*e.g.* zinc, copper, nickel) as the active sites in oxydehydrogenation of ammonia.[1–4] In the case of Cu(110)O surfaces the isolated oxygen adatoms, or oxygens at the ends of Cu–O–Cu–O– chains, are the most active[5] but for atomically clean Cu(110) surfaces there is evidence during the coadsorption of oxygen–ammonia mixtures for a dioxygen–ammonia complex being the key intermediate. Both experimental and theoretical[6] work have supported this view and there are strong analogies with the model developed for the oxidation of ammonia when coadsorbed with dioxygen at a Zn(0001) surface at low temperatures.[2] The Ag(111)–dioxygen/ammonia system shows very similar precursor kinetics to that observed with Zn(0001) and for this reason we have searched for spectroscopic evidence, using both X-ray and vibrational electron energy loss spectroscopies (XPS and VEELS), for the presence of dioxygen states present at low temperatures when dioxygen–ammonia mixtures are coadsorbed at Ag(111) at 100 K.

The sticking probability of pure dioxygen at clean Ag(111) surfaces at 120 K is very low (*ca.* 10^{-4}); a peroxo species is observed after 3000 L exposure,[7] as evidenced by VEELS bands at 220 cm^{-1} [$\nu(AgO_2)$] and 670 cm^{-1} [ν(O–O)]. However, when dioxygen and ammonia are coadsorbed the reactivity to dissociative oxygen chemisorption is increased and the chemistry, as reflected by the O 1s and N 1s spectra, indicate that dehydrogenation has occurred. A typical set of kinetic data for the coadsorption of an ammonia–dioxygen mixture is shown in Fig. 1. The 'oxygen' uptake, calculated from the total O1s intensity data, is shown as a function of oxygen exposure in four different experiments at four different temperatures (220, 180, 150 and 120 K) using an O_2–NH_3 (1 : 3) mixture. As well as demonstrating the much increased sticking probability for oxygen adsorption [as observed at Zn(0001) surfaces[2]], these results provide strong circumstantial evidence for dioxygen–ammonia complexes participating in the oxidation pathway; this was the impetus for the VEELS investigation.

Fig. 2 shows a set of VEEL spectra when an atomically clean Ag(111) surface was exposed to an ammonia–dioxygen mixture at 100 K [Fig. 2(*a*)] and then warmed to 210 K [Fig. 2(*b*)]. The main loss features at 100 K are at 250, 700, 1120, 1480, 1640 and 3390 cm^{-1}. The assignments [Fig. 2(*a*)] are as shown; the 250 cm^{-1} feature is attributed to Ag–adsorbate stretch frequencies. A similar experiment, but replacing NH_3 with ND_3, gave rise to the spectra in Fig. 2(*c*), curves (*ii*) and (*iii*); for

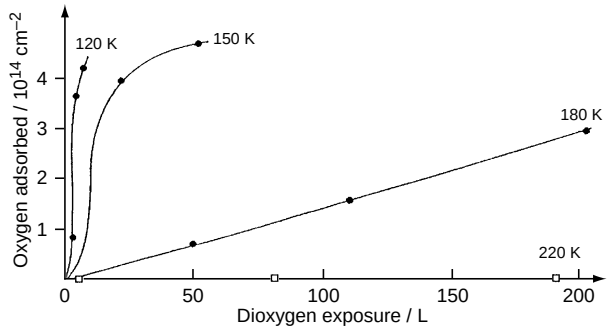

Fig. 1 Exposure of a Ag(111) surface to an O_2–NH_3 (1 : 3) mixture at four different temperatures. The graphs are plots of total concentration of oxygen adsorbed (expressed as atoms) *vs.* equivalent dioxygen exposure. The reaction of pure dioxygen leads to negligible adsorption in this exposure and temperature range.

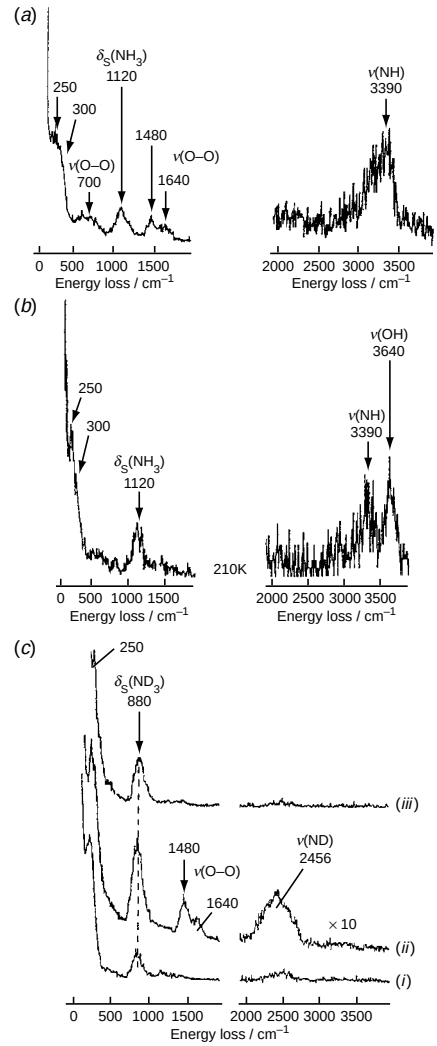

Fig. 2 VEELS spectra for (*a*) exposure of a clean Ag(111) surface to a dioxygen–ammonia mixture at 100 K; (*b*) surface in (*a*) warmed to 210 K and (*c*) VEELS spectra for (*i*) adsorption of ND_3 at Ag(111) at 100 K, (*ii*) adsorption of an O_2–ND_3 mixture at Ag(111) at 100 K and (*iii*) surface in (*ii*) warmed to 210 K

comparison curve (*i*) shows the adsorption of pure ND_3 at Ag(111) at 100 K. The spectra for deuterated ammonia confirm the assignments of the 1480 and 1640 cm^{-1} features in Fig. 2(*a*) for the ammonia–dioxygen mixture as arising from adsorbed dioxygen states. The unusually strong and broad ν(ND) feature at 2456 cm^{-1} [Fig. 2(*c*), curve (*ii*)] is the consequence of hydrogen bonding in the dioxygen–ND_3 complex.

On warming the Ag(111) surface exposed to the dioxygen–NH_3 mixture [spectrum (*a*)] to 210 K [Fig. 2(*b*)] the features assigned to the dioxygen states were not present. There was however spectroscopic evidence, from the loss feature characteristic of $\delta_s(NH_3)$ at 1120 cm^{-1}, for adsorbed ammonia present at low coverage. Also there had developed two features in the high frequency loss region, one at 3390 cm^{-1} assigned to ν(NH) and the other at 3640 cm^{-1} assigned to ν(OH).

The correlation shown to exist[8] between the O–O stretch frequencies and the electronic state of oxygen, suggests that the VEEL spectra for the coadsorbed dioxygen–ammonia system reflect the presence of two different molecular oxygen species [ν(O–O) at 1488 and 1640 cm^{-1}]. One of these (1488 cm^{-1}) is involved in a $NH_3\cdots O_2^{\delta-}$ charge transfer type complex while the other characterised by the higher frequency (1640 cm^{-1}) is a more isolated physisorbed species. There is very little charge associated with this state, its vibrational frequency being close to that reported for the gas phase molecule. It is the former that opens up a low energy oxidation pathway leading to surface OH and NH species [Fig. 2(*b*)]; in contrast, the peroxo state [ν(O–O) at 670 cm^{-1}] observed after the adsorption of pure dioxygen at a Ag(111) surface is unreactive towards ammonia. It is interesting to note that at a Cu(111) surface, exposure of an ND_3 adlayer to dioxygen at 100 K gives rise to a molecularly adsorbed oxygen species[9] characterised by a loss feature at 1500 cm^{-1}.

Hydrostannation of C–C multiple bonds with Bu_3SnH prepared *in situ* from Bu_3SnCl and Et_3SiH in the presence of Lewis acid catalysts

Vladimir Gevorgyan, Jian-Xiu Liu and Yoshinori Yamamoto*

Department of Chemistry, Graduate School of Science, Tohoku University, Sendai 980-77, Japan

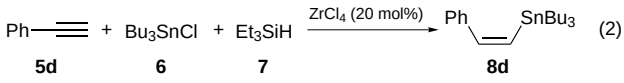
A number of alkynes 5, allene 11 and alkene 13 smoothly underwent hydrostannation with tributyltin hydride 1, prepared *in situ* from tributylchlorostannane 6 and triethylsilane 7 in the presence of catalytic amounts of Lewis acids.

Since the first synthesis of tributyltin hydride **1** by Finholt *et al.* in 1947,[1] this compound has become one of the most frequently used organometallic reagents in organic synthesis.[2] Along with wide applicability as a hydrogen source in various kinds of reductions,[2] Bu_3SnH is the most popular hydrostannation agent for the synthesis of vinyl-[3] and allyl-stannanes.[4] The latter, due to their great versatility as building blocks, are of increasing importance in modern synthetic organic chemistry.[5] Recently we reported regio- and stereo-selective methods for the synthesis of vinyl- and allyl-tributylstannanes *via* Lewis acid-catalyzed *trans*-hydrostannation of acetylenes[6] and allenes.[7] Although Bu_3SnH is commercially available, it gradually decomposes after storage in a refrigerator for a prolonged period of time;[8] consequently, distillation is needed before use. It occurred to us that *in situ* generation of **1** from stable precursors would be synthetically more convenient for the hydrostannation reaction. The generation of Bu_3SnH *in situ* from more stable stannyl precursors and hydride sources could serve this purpose.[9] In general, the preparation of commercially available tributyltin hydride **1** is carried out by the reduction of tributyltin oxide **2** with hydrosiloxane **3** [reaction (1)].[10]

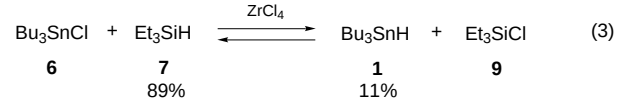
$$\underset{\mathbf{2}}{n\,(Bu_3Sn)_2O} + 2\,\underset{\mathbf{3}}{(MeSiHO)_n} \xrightarrow{\text{heat}} 2n\,\underset{\mathbf{1}}{Bu_3SnH} + 2\,\underset{\mathbf{4}}{(MeSiO_{1.5})_n} \quad (1)$$

Accordingly, we attempted to employ this method for the *in situ* preparation of **1** under the conditions of the Lewis acid-catalyzed hydrostannation reaction.[6,7] However, no hydrostannation products were detected, instead the starting alkynes were recovered quantitatively. It is probable that, due to the strong affinity of the Lewis acid for the oxygen of either the reactants (**2** and/or **3**) or of the byproduct **4**, it is deactivated and thus not effective as a catalyst in the hydrostannation reaction. Hence, a non-oxygen containing precursor should be employed for the *in situ* preparation of **1**.

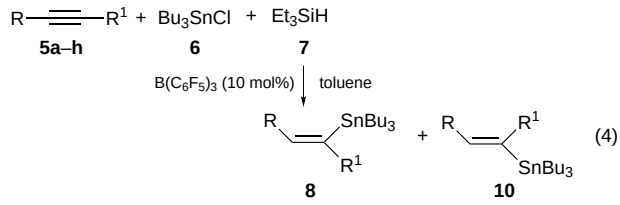
Herein we report the first example of the Lewis acid-catalyzed hydrostannation reaction of alkynes with tributyltin hydride **1**, prepared *in situ* from Bu_3SnCl **6** and Et_3SiH **7** [reactions (2) and (4)].



In our initial experiments we found that simple mixing of **6** and **7** in toluene at room temperature did not produce any detectable amount of tin hydride **1**. In contrast, a redistribution took place by the addition of 20 mol% $ZrCl_4$[11] to the same reaction mixture and noticeable amounts of **1** were detected by ^1H NMR analysis of the reaction mixture after one hour [reaction (3)]. Although the mixture contained a large amount of



silyl hydride **7** [reaction (3)], it was presumed that, due to the fact that $ZrCl_4$ is not a strong enough Lewis acid to the catalyze hydrosilylation alkynes,[12] this reaction would not compete with the desired hydrostannation process. Motivated by that we applied this method for the *in situ* preparation of **1** and subsequent $ZrCl_4$-catalyzed hydrostannation of phenylacetylene **5d**;[11] as a result the *trans*-addition product (*Z*)-β-(tributylstannyl)styrene **8d** was formed in 52% yield (by ^1H NMR analysis). A brief search for a more efficient Lewis acid catalyst pointed to $B(C_6F_5)_3$. We found that 10 mol% of $B(C_6F_5)_3$ effectively catalyzed the hydrostannation of various alkynes **5** with tributylstannane **1**, generated *in situ* from **6** and **7**, producing the hydrostannation products **8** and **10** in excellent chemical yields [reaction (4), Table 1]. The hydrostannation of



all the monosubstituted alkynes tested (**5a**–**f**) proceeded in a regiospecific manner affording the β-hydrostannation products (**8a**–**f**, **10**) exclusively (entries 1–6, Table 1). Except for the reactions with **5b** and **5g** in which small amounts of the *cis*-addition products were formed (entries 2,7), the reaction was also *trans*-stereoselective (entries 1,3–6,8, Table 1) as was reported for the conventional method for the Lewis acid-catalyzed hydrostannation of alkynes.[6] The preparation of **8a** from **5a** is representative. Tributylstannyl chloride **6** (1.5 mmol), triethylsilane **7** (1.0 mmol) and **5a** (1 mmol) were consecutively added at 0 °C to a solution of $B(C_6F_5)_3$ (0.1 mmol) in dry toluene (0.25 ml) under an argon atmosphere. After being stirred for 40 min at 0 °C the reaction temperature was allowed to warm to 25 °C and the mixture was stirred for another 3 h. The reaction was quenched by adding Et_3N (0.5 mmol) at ambient temperature. Hexane was added and the resulting mixture was filtered through Celite and concentrated under reduced pressure. Purification by column chromatography (aluminium oxide, 90 mesh, *n*-hexane as eluent) gave 220 mg (78%) of **8a**.

Finally, we disclose our initial experiments on the application of this method for the hydrostannation of an allene and alkene. We reported recently that tributyltin hydride **1** in the presence of Lewis acids reacted with a number of allenes affording the corresponding vinylstannanes in good chemical yields.[7] We found that **1**, prepared *in situ* from **6** and **7** in the presence of 10 mol% of $B(C_6F_5)_3$, smoothly reacted with phenylallene **11**

Table 1 $B(C_6F_5)_3$-catalyzed hydrostannation of alkynes with Bu_3SnH generated *in situ* from Bu_3SnCl and Et_3SiH

Entry	R	R^1		Conditions	Yield of **8** + **10**[a] (%)	Ratio **8** : **10**[b]

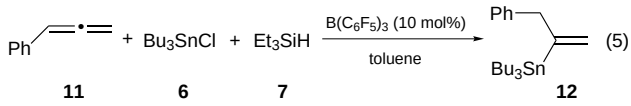
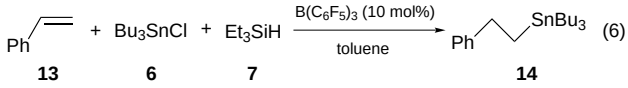
				3 h/rt	71	> 95 : 5

[a] Isolated yield. [b] Determined by ^1H NMR analysis of crude reaction mixtures. [c] rt = room temp.



affording the vinylstannane **12** in 51% yield [reaction (5)]. In addition, the same method could be employed for the hydrostannation of alkenes: styrene **13** was converted into the corresponding alkylstannane **14** in 70% isolated yield [reaction (6)]. To the best of our knowledge, reaction (6) is the first



example of the Lewis acid-catalyzed hydrostannation of alkenes.

In conclusion, a synthetically useful and convenient method for the Lewis acid-catalyzed hydrostannation of carbon–carbon multiple bonds with tributyltin hydride **1**, prepared *in situ* from easily handled and cheap chlorostannane **6** and hydrosilane **7**, has been developed. The first example of the Lewis acid-catalyzed hydrostannation of an alkene has been demonstrated.

Linear tri- and tetra-chromium(II) chains supported by four bis(2-pyridyl)formamidinium ligands

F. Albert Cotton,* Lee M. Daniels, Carlos A. Murillo* and Xiaoping Wang

Department of Chemistry and Laboratory for Molecular Structure and Bonding, Texas A&M University, College Station, TX 77843-3255, USA

Reactions of bis(2-pyridyl)formamidinium ion, $DpyF^-$, with $CrCl_2$ lead to $[Cr_3(DpyF)_4][PF_6]_2$ and $[Cr_4(DpyF)_4Cl_2]Cl_2$, both of which are structurally characterized by X-ray crystallography; the latter contains two Cr–Cr quadruple bonds even though no such bonds were preformed in the starting material ($CrCl_2$).

In our continuing study of compounds with linear chains of metal atoms,[1–3] we have employed the anion of bis(2-pyridyl)formamidine, $DpyF^-$, as a ligand and carried out reactions of the lithium salt with $CrCl_2$ under various conditions, whereby we have obtained† three new and interesting compounds, $[Cr_3(DpyF)_4][PF_6]_2\cdot 4MeCN\cdot 2Et_2O$ (**1**·4MeCN·2Et$_2$O), $[Cr_4(DpyF)_4Cl_2]Cl_2\cdot 5(Me_2CO)$ (**2**·5Me$_2$CO) and a different solvate of **2**, namely, **2**·4MeOH. The crystal structures of all three have been determined‡.

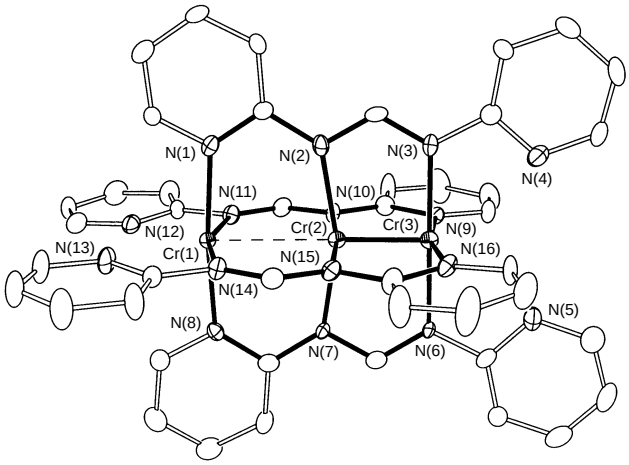

Fig. 1 Perspective view of the cation of **1**. Relevant distances (Å) and angles (°): Cr(1)–Cr(2) 2.738(7), Cr(2)–Cr(3) 1.949(7), Cr(1)–N(1) 2.054(5), Cr(1)–N(11) 2.092(6), Cr(1)–N(14) 2.074(6), Cr(2)–N(2) 2.086(5), Cr(2)–N(7) 2.102(5), Cr(2)–N(10) 2.070(5), Cr(2)–N(15) 2.068(5), Cr(3)–N(3) 2.062(5), Cr(3)–N(6) 2.031(5), Cr(3)–N(9) 2.057(5), Cr(3)–N(16) 2.078(6); Cr(1)–Cr(2)–Cr(3) 179.2(2), N(1)–Cr(1)–N(11) 88.2(2), N(2)–Cr(2)–N(10) 89.7(2), N(3)–Cr(3)–N(9) 90.4(2).

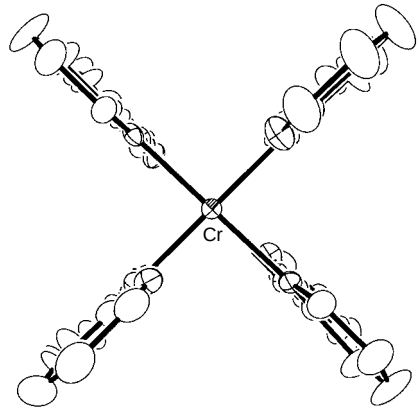

Fig. 2 The $[Cr_3(DpyF)_4]^{2+}$ cation of **1** viewed down the Cr–Cr–Cr direction

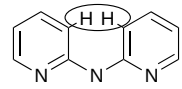
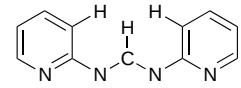
The structure of the trinuclear compound **1** is shown in Fig. 1; the Cr_3 chain is not symmetrical and can be qualitatively described as having one pair of chromium atoms quadruply bonded, Cr(2)–Cr(3) 1.949(7) Å, with the third chromium atom not significantly bonded to the central one, Cr(1)–Cr(2) 2.738(7) Å. In comparing the structure of **1** with those previously reported[2] for chromium with dpa^- [dpa^- = anion of bis(2-pyridyl)amine], the most obvious qualitative difference is that the central Cr_3N_{12} core in **1** is essentially untwisted, as shown in Fig. 2, whereas in the dpa compounds there is an overall twist of about 45°. Compound **1** is the first such linear, trinuclear species of any metal§ that is non-helical. The twist in all of the dpa^- compounds is clearly due to the H···H repulsion indicated in **I** while in **II** it is clear that there is no basis for a ligand-imposed twist.



I



II

As already reported[2] the Cr_3 chains in $Cr_3(dpa)_4X(Y)$ units may be symmetrical (X = Y = Cl, Cr–Cr 2.36 Å) or unsymmetrical (X = Cl, Y = BF_4, Cr–Cr 2.64, 2.00 Å) depending on the axial ligands. In **1** there are no axial ligands. The nearest structural comparison we can make with **1** is the structure of $Cr_3(dpa)_4Cl(BF_4)$ **3**.

To the question of whether absence of helicity is of importance to the electronic structure of the Cr_3^{6+} unit we can offer at least a partial answer at this time. The Cr_3 chain of **1**, like that in **3**, is unsymmetrical. In addition, the Cr–Cr distances in **1**, 1.949(7) and 2.738(7) Å are very similar to those in **3**, 1.995(1) and 2.643(1) Å. In these respects there is no indication that helicity in itself has a qualitative effect on the bonding in the metal atom chain. For the dpa compounds, the structure seems to be tunable, from symmetrical to unsymmetrical, by changing the axial ligands from Cl, Cl to Cl, BF_4. In the case of **1** there are no axial ligands, and thus the unsymmetrical character seems to be inherent in the $[Cr_3(DpyF)_4]^{2+}$ chain.

The cation in **2** is shown in Fig. 3; there are only slight differences between the dimensions in the two crystalline forms. There must, of course, be non-equivalent M–M distances in all M_n chains with $n > 3$. In this case the difference between the central and the outer Cr–Cr distances is very large, *ca*. 2.73 Å *vs*. *ca*. 2.01 Å. It seems reasonable to describe the bonding to a first, and probably good, approximation by saying that there are two Cr–Cr quadruple bonds and little if any bonding between the two inner chromium atoms. The short Cr–Cr distance may be compared to that in the compound $Cr_2(map)_4$[4] (map = anion of 2-amino-6-methylpyridine), where it is 1.870(3) Å. It seems reasonable to attribute the greater length of

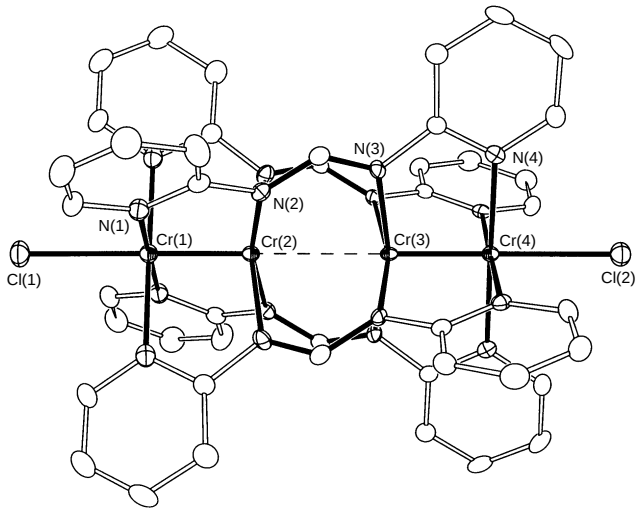


Fig. 3 Perspective view of the cation of **2**·4MeOH. Relevant distances (Å) and angles (°): Cr(1)–Cr(2) 2.013(2), Cr(2)–Cr(3) 2.726(2), Cr(3)–Cr(4) 2.001(2), Cr(1)–N(1) 2.134(4), Cr(2)–N(2) 2.036(3), Cr(3)–N(3) 2.034(4), Cr(4)–N(4) 2.135(4), Cr(1)–Cl(1) 2.545(2), Cr(4)–Cl(2) 2.564(2); Cr(2)–Cr(1)–N(1) 89.7(1), Cr(1)–Cr(2)–N(2) 97.2(1), N(2)–Cr(2)–Cr(3) 82.8(1), Cr(4)–Cr(3)–N(3) 97.3(1), N(3)–Cr(3)–Cr(2) 82.7(1), Cr(3)–Cr(4)–N(4) 90.2(1).

the bonds in **2** to the presence of the axial Cl^- ligands, whereas in $Cr_2(map)_4$ there are no axial interactions.

The observed preference of the chain of three Cr^{2+} ions to form one quadruple bond and the chain of four Cr^{2+} ions to form two separate quadruple bonds rather than to give more delocalized, and therefore evenly spaced arrangements raises the question of how general this tendency may be. It is already known, for both Cr_3 and Co_3 compounds of dpa^- that symmetrical and unsymmetrical structures both occur. In the Cr_4 case, the short–long–short structure makes all the metal chain electrons (MCEs) bonding electrons over short distances where d–d overlaps are very good.¶ It can be hypothesized that in other cases of four metal atoms, especially where MCE counts are higher, more delocalized configurations might be favored. Studies are in progress to examine this.

† Preparation of $[Cr_3(DPyF)_4][PF_6]_2$ **1** and $[Cr_4(DPyF)_4Cl_2]Cl_2$ **2**. Bis(2-pyridyl)formamidine was prepared by condensation of 2-aminopyridine with triethylorthoformate at 170 °C.[5] An solution of LiDpyF was made by adding 4.0 ml of 1.0 M methyllithium to a solution of HDpyF (0.795 g, 4.0 mmol) in THF (40 ml) at −60 °C. When the LiDpyF solution warmed to ambient temperature, it was transferred to a round-bottom flask containing $CrCl_2$ (0.528 g, 4.3 mmol). A red suspension was obtained after stirring the mixture for 6 h. At this stage, $TlPF_6$ (0.70 g, 2.0 mmol) was added to the suspension. A green solid was produced when it was heated to reflux temperature for 12 h and then cooled to room temp. The supernatant liquid was removed with a syringe and the green solid was washed with THF (15 ml) and CH_2Cl_2 (2 × 20 ml). Extraction with acetone gave a green solution. After layering with hexanes, red crystals of **2**·5Me_2CO were isolated. Yield 0.11 g, 7.7%. The remaining solid was only partially soluble in acetonitrile. After filtration, slow diffusion of diethyl ether into the filtrate changed the color of the solution from green to reddish and gave orange crystals of **1**·4MeCN·2Et_2O, yield 0.44 g, 28%. The remaining solid, which was not soluble in acetone or in acetonitrile, was dissolved in dimethyl sulfoxide to give an emerald green solution. Layering with benzene precipitated a green powder. After filtration, this was washed with diethyl ether and dried under vacuum to yield 0.64 g of green material. Red crystals of **2**·4MeOH were obtained by diffusion of diethyl ether (20 ml) into a saturated green methanol solution (25 ml) of the green powder. The combined yields for **2** are 64%. Crystals of **1** can be redissolved in acetonitrile to produce an orange solution. Red crystals of **2** are not soluble in acetonitrile but can be redissolved in methanol to give a green solution. Compound **1** is paramagnetic, μ_{obs} 4.6 μ_B; **2** is diamagnetic, ^{1}H NMR (CD_3OD, 300 MHz): δ 9.76 (s, 4 H, methine NCHN), 9.48 (d, 8 H, pyridyl CH), 7.83 (m, 16 H, pyridyl CH), 7.09 (t, 8 H, pyridyl CH). UV–VIS (λ/nm): 528, 620 (sh) for **1** in MeCN; 384(sh), 462, 616 for **2** in MeOH.

‡ *Crystal data*: $[Cr_3(DpyF)_4][PF_6]_2$·4MeCN·2Et_2O, **1**·4MeCN·2Et_2O: orange crystal, $C_{60}H_{68}Cr_3F_{12}N_{20}O_2P_2$, M = 1547.28, monoclinic, space group $P2_1/c$, a = 15.006(4), b = 14.993(2), c = 31.238(9) Å. β = 99.79(1)°, U = 6926(3) Å^3, Z = 4, D_c = 1.484 g cm^{-3}, λ = 0.710 73 Å, μ(Mo-Kα) 0.599 mm^{-1}. Intensity data were collected on a CAD4 diffractometer at −100 °C. A ψ-scan absorption correction was made. A total number of 8966 independent reflections were measured, of which 4352 were observed [$I \geqslant 2\sigma(I)$]. The structure was solved by direct methods using SHELXTL and refined using SHELXL-97. During structural refinement, it was found that the chromium atoms were disordered. The final positions of the metal atoms clearly indicate a short Cr–Cr quadruple bond and a long, non-bonded Cr–Cr interaction. The disorder arises since the ligand framework is essentially symmetric, and the short–long bond pair can sit either way in the ligand environment. In the final refinement cycles, the relative occupancy of the two metal-atom groups was refined, and converged with the major orientation having an occupancy of 0.52(1). Final full-matrix least-squares refinement on F^2 of positional and anisotropic thermal parameters for all non-hydrogen atoms converged to R_1 = 0.181, wR_2 = 0.118 for all data; and R_1 = 0.056, wR_2 = 0.102 for data with $I \geqslant 2\sigma(I)$.

$[Cr_4(DPyF)_4Cl_2]Cl_2$·5Me_2CO, **2**·5Me_2CO: red crystal, $C_{59}H_{66}Cl_4Cr_4N_{16}O_5$, M = 1429.08, monoclinic, space group $C2/c$, a = 32.988(4), b = 9.269(1), c = 26.183(7) Å, β = 127.50(1)°, U = 6351(2) Å^3, Z = 4, D_c = 1.491 g cm^{-3}, λ = 0.710 73 Å, μ(Mo-Kα) 0.896 mm^{-1}. Intensity data were collected on a FAST area detector system at −60 °C. A total number of 4145 independent reflections were measured, of which 3660 were observed [$I \geqslant 2\sigma(I)$]. The structure was solved by direct methods using SHELXTL. Full-matrix least-squares refinement on F^2 of positional and anisotropic thermal parameters for all non-hydrogen atoms converged to R_1 = 0.049, wR_2 = 0.111 for all data; and R_1 = 0.041, wR_2 = 0.103 for data with $I \geqslant 2\sigma(I)$.

$[Cr_4(DPyF)_4Cl_2]Cl_2$·4MeOH, **2**·4MeOH: red crystal, $C_{48}H_{52}Cl_4Cr_4N_{16}O_4$, M = 1266.86, tetragonal, space group $P4/n$, a = 12.8063(7), c = 16.326(2) Å, U = 2677.5(4) Å^3, Z = 2, D_c = 1.571 gcm^{-3}, λ = 0.71073 Å, μ(Mo-Kα) 1.050 mm^{-1}. Intensity data were collected on a FAST area detector system at −60 °C. A total number of 1767 independent reflections were measured, of which 1647 were observed [$I \geqslant 2\sigma(I)$]. The structure was solved by direct methods using SHELXTL. During structural refinement, it was found the crystal twinned along the (110) plane. The occupancy of both components were refined and the major component contributed to 59.5% of the structure. Final refinement converged to R_1 = 0.044 and wR_2 = 0.108 for all data, and R_1 = 0.040 and wR_2 = 0.103 for data with $I \geqslant 2\sigma(I)$. CCDC 182/652.

§ $M_3(dpa)_4X_2$ compounds, all of which are helical, have been reported for M = Cr,[2] Co,[3] Ni, Cu and Ru. Full references are found in ref. 3.

¶ Compounds containing two quadruply bonded M_2^{4+} units (M = Mo and W), end-to-end, are also known.[6] In these cases the quadruply bonded dimetal units were already present in the starting material.

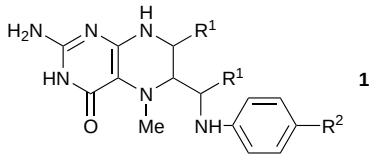
A biomimetic methyl transfer from amine to thiol

Masaru Tada,*[a] Tohru Kambe[a] and Yoshinobu Inouye[b]

[a] *Department of Chemistry, Advanced Research Center for Science and Engineering and Materials Research Laboratory for Bioscience and Photonics, Waseda University, Shinjuku, Tokyo 169, Japan*
[b] *Department of Chemistry, University of Tsukuba, Tsukuba, Ibaraki 305, Japan*

A biomimetic methyl transfer, analogous to a tetrahydrofolate-to-homocystein transfer, is simulated by the reaction of methylammonium salts with arylthiolatocobaloxime; the mechanism proposed is an electron transfer from the cobaloxime to the ammonium ion followed by radical substitution of the methyl group.

Biological methyl transfers often occur *via* methionine, $(HO_2C)(NH_2)CHCH_2CH_2SMe$,[1] and methyl coenzyme-M, $^{-}O_3SCH_2CH_2SMe$.[2] Methyl groups in these cofactors originate from N^5-methyl derivatives of tetrahydropteridine, *i.e.* N^5-methyltetrahydrofolic acid **1a**, (R^1 = H, R^2 = CONH–glutamate)[3] and N^5-methyltetrahydromethanopterin **1b**, [R^1 = Me, R^2 = $CH_2(CHOH)_3CH_2OPO_2HOCH(CO_2H)(CH_2)_2CO_2H$].[4]



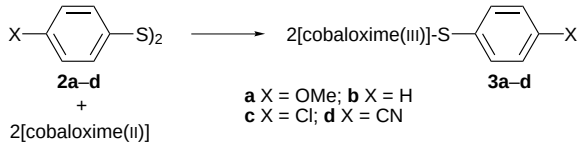
1

These methyl transfers from amine to sulfur are mediated by coenzyme-B_{12} and its congener,[5] but the participation mode of the cobalt complexes has not been clarified as yet.[6,7] The direct methyl transfer from a methyl ammonium salt to a thiolate anion is known[8] but the cobalt mediated biological methyl transfer is much faster than the direct biological methyl transfer from nitrogen to sulfur.[9]

We report here a biomimetic N–S methyl transfer which is assisted by a cobalt complex. Coenzyme-M was originally isolated in the disulfide form.[10] Thiol and disulfide forms both exist in biological systems because they are interconvertible *via* a simple biochemical redox process. We therefore started the model reaction from a disulfide and bis(dimethylglyoximato)(4-*tert*-butylpyridine)cobalt(II) [cobaloxime(II)]. Thus diaryl disulfides **2** were treated with cobaloxime(II) (0.5 equiv.) to produce arylthiolatocobaloxime(III) **3** in fair yields (Scheme 1).

Reaction† of phenylthiolatocobaloxime(III) **3b** with a trimethylanilinium salt **4** gave methyl sulfide **5** in addition to diphenyl disulfide **6**. The reaction of **3b** with a methylpiperidinium salt **7** yielded the corresponding phenyl sulfide **8** and disulfide **6** (Scheme 2).

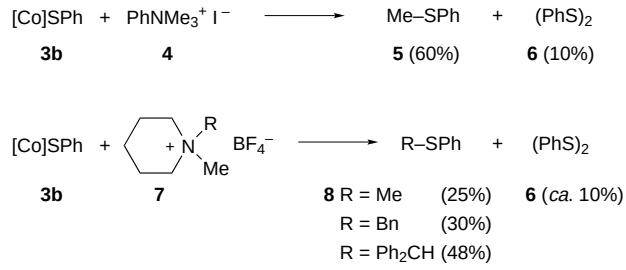
We then tested the effect of a *para*-substituent on the phenyl group of **3** and the benzyl group of ammonium salt **9**. The ammonium salt **9** having an electron-withdrawing substituent gave higher yields of the products **10** (Scheme 3 and Table 1).



2a–d + 2[cobaloxime(II)] → **3a–d**

a X = OMe; **b** X = H
c X = Cl; **d** X = CN

Scheme 1

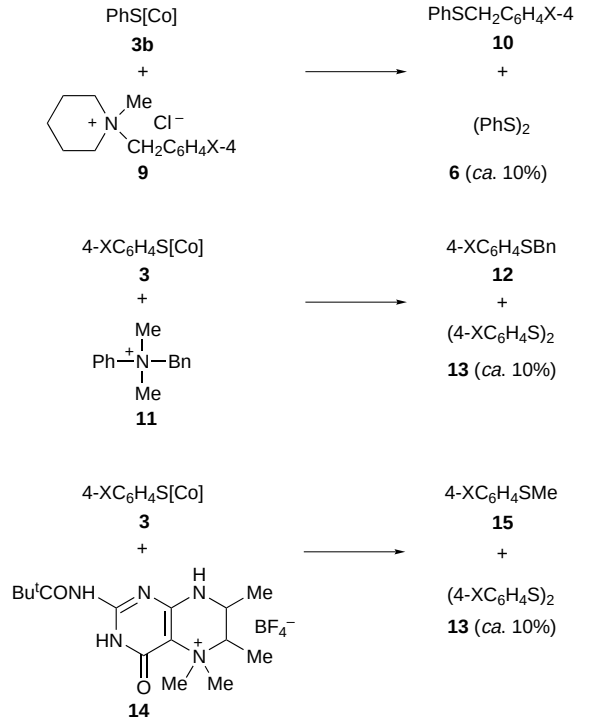


Scheme 2

On the other hand, arylthiolatocobaloxime(III) **3** having an electron-donating substituent showed higher reactivity towards benzyldimethylanilinium salt **11** to yield benzyl sulfide **12** selectively (Scheme 3). Similarly, the reaction with a folate coenzyme model **14**[8] produced methyl sulfide **15**. The time course of the reaction of **3** with benzylammonium salt **11** clearly shows the relationship between the relative rate of product formation and the substituent on **3** (Fig. 1).

The substituent effect envisages nucleophilic attack of the arylthiolate anion at the methyl or benzyl group without the assistance of the cobalt complex, as reported by Hilhorst *et al.*[8] However, the formation of the thiolate anion from arylthiolatocobaloximes **3** must precede the nucleophilic attack, and the electron-withdrawing substituent on **3** is expected to accelerate this heterolysis, contrary to the experimental findings.

If these methyl and benzyl transfer reactions start with the initial homolysis of the sulfur–cobalt bond of **3**,‡ the reactivity



Scheme 3

Table 1 Substituent effect on methyl transfer from an ammonium ion to arylthiolatocobaloximes

Starting material	Ammonium ion	X	Product	Yield (%)
3b	**9a**	OMe	**10**	19
3b	**9b**	H	**10**	30

of **3** must be inversely proportional to the bond strength and hence the bond distance of the sulfur–cobalt bond. X-Ray crystal analyses[11] determined the Co–S distance of **3** as shown in Table 2. However, this correlation between the oxidation potential (E_{ox}) and the bond distance (d_{Co-S}) breaks down upon moving from **3c** and **3d**. The X-ray analysis unexpectedly showed the Co–S bond in 4-chlorophenylthiolatocobaloxime(III) **3c** to be shorter than the others. As we pointed out earlier,[12] the strength of the cobalt–sulfur bond is a consequence of the donation and back-donation from sulfur to cobalt. Cyclic voltammetry of arylthiolatocobaloximes **3a–d** showed a reversible oxidation wave as shown in Table 2, and the reactivity of the present methyl and arylmethyl group transfer has a trend parallel with the oxidation potential (E_{ox}) of **3a–d**; a lower oxidation potential results in higher reactivity.

The substituent effects on both sides of the reactants suggest a single electron transfer (SET) mechanism. The intermediacy of the arylthiyl radical is supported by the formation of diaryl disulfide in all the reactions. As one of the plausible mechanisms for the methyl transfer, we propose a homolytic substitution by an arylthiyl radical on the methyl group of the zwitterionic species formed by SET [Scheme 4, (*a*)].‡ The migrations of the benzyl and diphenylmethyl groups are considered to proceed *via* a radical coupling mechanism

Table 2 Oxidation potentials and bond lengths of arylthiolatocobaloxime(III) **3**

Compound	X	E_{ox}/V[a]	*d*(Co–S)/Å
3a	OMe	+0.483	2.291
3b	H	+0.542	2.280

Scheme 4

[Scheme 4, (*b*)] because these migrations occur in preference to methyl group migration in spite of greater steric hindrance. In accordance with the SET mechanism, the reactions proceed more efficiently in polar MeCN than in less polar $CHCl_3$ or protic MeOH.

Direct methyl transfer to a thiolate anion[8] *via* an S_N2 mechanism cannot explain the involvement of coenzyme-B_{12} in enzymatic processes. The present experimental findings account for assistance by a cobalt complex and suggest a possible scheme for the enzymatic process, in which N^5-protonated-N^5-methyltetrahydrofolic acid and homocysteinylthiolato–coenzyme B_{12} complex are reaction partners.

We thank Waseda University and the Ministry of Education, Sports, and Culture of Japan for financial support *via* the Annual Project Program (95A-252) and a Grant-in-aid for Scientific Research (09640649), respectively.

† Reaction conditions were the same for all reactions of **3**. A mixture of **3** (0.2 mmol) and an ammonium salt (0.25 mmol) in MeCN (10 cm^3) was heated to 80 °C for 22 h and then concentrated to 1 cm^3. The concentrated mixture was subjected to Florisil chromatography (hexane–CH_2Cl_2) to remove polar non-volatile materials. The yields of **5** were obtained by GC analyses of the eluate using an internal standard, and those of **8**, **10**, **12** and **15** refer to the isolated products. In most cases the starting materials persisted but the reactions were stopped after 22 h to assess the relative reactivities.

‡ The direct attack of the arylthiyl radical on ammonium salts is ruled out by the lack of reactivity of the arylthiyl radical generated by PhSH–AIBN or photolysis of $(PhS)_2$.

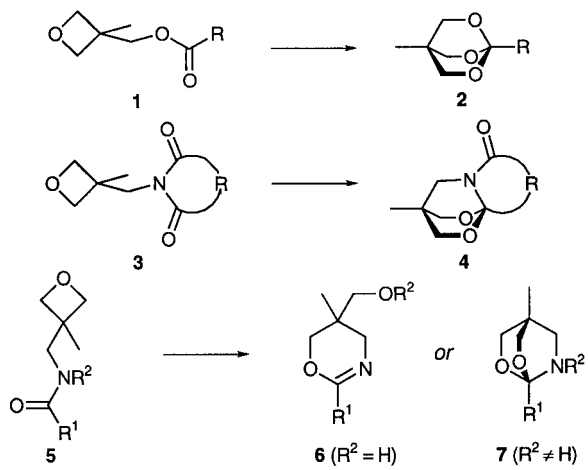
Chemoselective isomerization of amide-substituted oxetanes with Lewis acid to give oxazine derivatives or bicyclic amide acetals

Tomonari Nishimura,[a] Shigeyoshi Kanoh,*[a]† Hitoshi Senda,[a] Toshiyuki Tanaka,[b] Kohji Ando,[a] Hiroshi Ogawa[a] and Masatoshi Motoi*[a]

[a] *Department of Industrial Chemistry, Faculty of Engineering, Kanazawa University, Kodatsuno, Kanazawa 920-8667, Japan*
[b] *Department of Pharmacognosy, Gifu Pharmaceutical University, Mitahora-higashi, Gifu 502-8585, Japan*

The Lewis-acid catalyzed isomerization of secondary and tertiary amide-substituted oxetanes takes place chemoselectively, giving 5-hydroxymethyl-5,6-dihydro-4*H*-1,3-oxazines and reactive amide acetals consisting of a bicyclo[2.2.2]octane skeleton, respectively.

Oxetane and its various derivatives are well known to be polymerizable cationically *via* conventional ring-opening processes.[1,2] As an exception, certain oxetanes carrying a carbonyl-containing substituent, however, can undergo Lewis-acid catalyzed intramolecular nucleophilic attack of the unsaturated oxygen atom, for example, ester-substituted oxetanes **1** give the bridged orthoesters **2**,[3] and cyclic imide-substituted oxetanes **3** give bicyclic acetals with a lactam ring **4**[4] (Scheme 1). Here we report a novel chemoselective isomerization of oxetanes having an amide group at their 3-positions. The isomerization of the amide-substituted oxetanes **5** with Lewis acid gives two quite different types of products, depending on the structure of amide group. One type is 5-hydroxymethyl-5,6-dihydro-4*H*-1,3-oxazines **6** produced from the secondary amides of **5** by a new mode of rearrangement involving the oxetanyl group. The other type is bicyclic amide acetals, *i.e.* 2,6-dioxa-7-azabicyclo[2.2.2]octanes **7**, which are produced from the tertiary amides of **5** by a similar mode to those in the already reported cases of **1** and **3**.



Scheme 1

Starting oxetane amides **5a**–**e** were prepared *via* acylation of oxetane amine **8** derived from **3** (phthalimide), and the resulting secondary amides were *N*-alkylated under phase-transfer catalyzed conditions[5] to give the tertiary amides **5f**–**k**.‡

The isomerization of **5** was successfully carried out in anhydrous chlorobenzene or CH_2Cl_2 using Lewis acids such as $BF_3{\cdot}OEt_2$ and $AlMe_3$ (Table 1).§ Like **1** and **3** cycloacetalization occurred in the reactions of **5f**–**k**. The products (**7f**–**k**) obtained are a new series of bicyclic amide acetals.¶ Analogous amide acetals of the bicyclo[*n*.3.0] type (*n* = 3 or 4) have already been synthesized by intermolecular cycloaddition or transacetalization, and they have been reported to possess high susceptibility to nucleophiles.[6] Similarly compounds **7** were so sensitive to moisture that hydrolytic fission proceeded rapidly under normal conditions.‖ When the above isomerization was run for 24 h at 100 °C and above, most of the **7** produced was consumed. The final products were oligomers having a polyether backbone.

In sharp contrast, the isomerization of **5a** unexpectedly afforded 5-hydroxymethyl-5-methyl-2-phenyl-5,6-dihydro-4*H*-1,3-oxazine **6a** instead of a bicyclic amide acetal, and no polymerization took place.¶ The molecular structure of **6a** was established by X-ray analysis (Fig. 1).** The isomerization of the other secondary amides (**5b**–**e**) always gave oxazine derivatives (**6b**–**e**) in good yields (Table 1).¶ Compounds **6** were stable during distillation or recrystallization, but chromatographic manipulation over alumina often caused hydrolysis to propanediols with amide groups.

Table 1 Lewis-acid catalyzed isomerization of oxetane amides **5**[a]

Amide		Lewis acid				Product	
	(R^1,R^2)		(mol%)	*T*/°C	*t*/h		Yield (%)[b]
5a[c]	(Ph, H)	$BF_3{\cdot}OEt_2$	(25)	35	96	**6a**	89
5b	(H, H)	$AlMe_3$	(50)	120	24	**6b**	50[d]
5c	(Me, H)	$AlMe_3$	(5)	120	24	**6c**	92
5d	(Pr^n, H)	$AlMe_3$	(5)	120	24	**6d**	89
5e	($PhCH_2$, H)	$AlMe_3$	(5)	120	24	**6e**	71
5f	(Ph, Et)	$BF_3{\cdot}OEt_2$	(5)	120	1	**7f**	59
5g	(Ph, $PhCH_2$)	$BF_3{\cdot}OEt_2$	(5)	130	1	**7g**	61
5h	(H, $PhCH_2$)	$BF_3{\cdot}OEt_2$	(35)	70	96	**7h**	63
5i	(Me, Et)	$BF_3{\cdot}OEt_2$	(5)	130	1	**7i**	55
5j	(Me, $PhCH_2$)	$BF_3{\cdot}OEt_2$	(5)	130	1	**7j**	65

[a] In PhCl. [b] Isolated yield. [c] In CH_2Cl_2. [d] The reaction was quenched with Et_3N followed by MeOH containing a small amount of dilute NaOH.

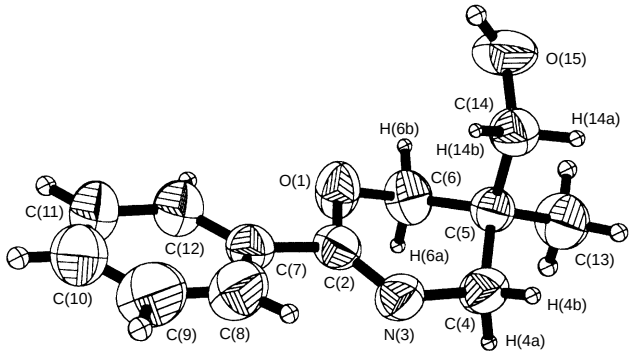

Fig. 1 ORTEP view of **6a** (30% probability thermal ellipsoids)

Although the secondary and tertiary amides of **5** are isomerized giving structurally different products, these reactions can be explained by the following mechanisms passing through a common intermediate **B** (Scheme 2). Both isomerizations begin with the coordination of Lewis acid E to oxetanyl oxygen atom of **5**, and then oxonium **A** undergoes intramolecular nucleophilic attack of the carbonyl oxygen atom by neighboring group participation. The fate of the resulting **B** determines the consequent chemoselection. For tertiary amides, subsequent ring closure of **B** gives an equilibrium mixture of **C** and **C′**. On the other hand, **B** is interconvertible to **B′** when R^2 is a hydrogen atom. The iminium and ammonium salts, **B′** and **C′**, are probably thermodynamically more stable than **B** and **C**, and the catalytic turnover of Lewis acid would decrease as the isomerization progresses. This was strongly supported by the observation that the isomerization rates of **5** steeply slowed down at increased yields of basic **6** and **7**. In order to force these reactions to completion, it was necessary to employ either high temperature or a very large amount of Lewis acid, or both (Table 1). Under such conditions, however, the yields of **7** began to decrease after reaching maxima at relatively early stages, because of inevitable polymerization as a competing reaction.

In the chemoselective isomerization of **5**, moderate to fairly good yields of **6** and **7** were obtained using simple operations. Like other bicyclic amide acetals,[6] compounds **7** are also interesting in a variety of chemical transformations not only as reactive amino ethers but also as ring-opening polymerizable monomers.[6,7] Numerous methods of preparing dihydro-1,3-oxazines appear in the literature.[8] The advantages (as well as differences) in the present reaction may be summarized as follows: (a) the preparation of dihydro-1,3-oxazines having a hydroxymethyl group, which is a useful functional group for further modification. (b) A general method for obtaining not only the phenyl- or alkyl-substituted oxzines at the 2-positions but also the unsubstituted oxazine.

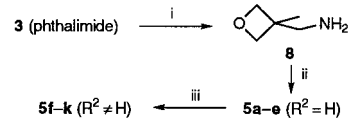
‡



Reagents and conditions: i, 3-methyl-3-(phthalimidomethyl)oxetane[4] (1.0 equiv.), hydrazine hydrate (5 equiv.), in EtOH, 60 °C, 1.5 h, and then a catalytic amount of Raney Ni (*W*-2), vigorous reflux, 81% (GLPC purity 96%), bp 90–95 °C/100 mmHg; ii, acylating reagents: $(R^1CO)_2O$, HCO_2COMe, or R^1CO_2H (DCC coupling), 76–92%; iii, **5** (1.0 equiv.), R^2Br (1.1 equiv.), K_2CO_3 (1.0 equiv.), NaOH (2.5 equiv.), $Bu^n_4NHSO_4$ (0.10 equiv.), in benzene, 40 °C to reflux, 3–15 h, 55–78%.

§ *Typical experimental procedure*: To an anhydrous PhCl (1.0 ml) solution of **5c** (150 mg, 1.1 mmol) in a tube was added 1.0 mol l^{-1} $AlMe_3$ in hexane (0.05 mmol) under nitrogen. The resulting solution was allowed to react at 120 °C for 24 h. After the reaction was quenched by addition of Et_3N (0.1 ml) followed by MeOH (3.0 ml), the solvents were replaced by CH_2Cl_2 (10 ml). Distillation of the CH_2Cl_2-soluble part afforded **6c** in 92% yield, bp 100–110 °C/0.1 mmHg. Similarly, the isomerization of **5f** was carried out in a small distillation flask at 120 °C for 1 h. After the addition of anhydrous Et_3N (0.1 ml) followed by CaH_2 (*ca.* 50 mg), distillation of the resulting mixture afforded **7f** (0.12 g, 0.52 mmol) in 59% yield, bp 110–120 °C/0.1 mmHg. The product isolated was stable under nitrogen.

¶ All compounds were characterized by ^1H NMR and IR spectroscopy, although the IR spectra of **7** were always observed as a mixture of **7** and its hydrolysis product. *Selected data* for **6a**: mp 135–136 °C (CH_2Cl_2–hexane); ν_{max}(KBr)/cm^{-1} 3400 (OH), 1650 (C=N); the atomic numbering system refers to that used in Fig. 1; δ_H($CDCl_3$, *J*/Hz) 7.89 (dd-like, *J* 6.9, 1.5, 2 H, ArH_o), 7.44–7.33 (m, 3 H, $ArH_{m,p}$), 4.23 [dd, *J* 10.7, 2.4, 1 H, H(6b)], 3.92 [d-like, *J* 10.7, 1 H, H(6a)], 3.57, 3.47 [each d, *J* 10.7, 2 H, H (14a) and H (14b), 3.48 [dd, *J* 16.9, 2.2, 1 H, H (4b)], 3.27 [d-like, *J* 16.6, 1 H, H(4a)], 2.02 (br s, 1 H, OH), 1.02 [s, 3 H, C(13) H_3]; δ_C (100 MHz, $CDCl_3$) 155.0 [C(2)], 133.3 [C(7)], 130.5 [C(10)], 128.0 [C(9), C(11)], 127.0 [C(8), C(12)], 70.1 [C(6)], 65.8 [C(14)], 51.1 [C(4)], 32.7 [C(5)], 19.0 [C(13)]. Supramolecular self-assembly of a toroidal inclusion complex, $[NH_4][Co_8(MeCO_2)_8(OMe)_{16}][PF_6]$

James K. Beattie, Trevor W. Hambley, John A. Klepetko, Anthony F. Masters* and Peter Turner

School of Chemistry, The University of Sydney, Sydney, NSW, 2006, Australia

Diamagnetic $[NH_4][Co_8(MeCO_2)_8(OMe)_{16}][PF_6]$, a compound with eight cobalt atoms bridged by methoxy and acetato ligands so as to form a planar ring with an ammonium ion at its centre, is isolated from the reaction between cobalt(III) acetate and methanol in the presence of NH_4PF_6.

We recently reported that slow recrystallisation of 'cobalt(III) acetate' in the presence of a halide source produced the mixed valence octanuclear compound $[Co_8O_4(MeCO_2)_6(OMe)_4Cl_4(OH_n)_4]\cdot 6H_2O$ (n = 1, 2).[1] Structural characterisation of this compound showed it to contain a central $[Co_8O_8]$ core consisting of a linear array of three face-sharing $[Co_4O_4]$ cubane fragments. A similar mixed valence Co_8 core had previously been reported in the compound $[Co_8O_4(MeCO_2)_6(OH)_4L_2][ClO_4]_2$ [L = tetradentate ligand, 1,2-bis(2,2′-bipyridyl-6-yl)ethane], prepared by H_2O_2 treatment of $Co(MeCO_2)_2\cdot 4H_2O$ (3 equiv.) in the presence of L (1 equiv.) and $LiClO_4$.[2] The isolation of $[Co_8O_4(MeCO_2)_6(OMe)_4Cl_4(OH_n)_4]$ suggests that supramolecular assembly of the Co_8 core (and possibly of other architectures) may occur even in the absence of polydentate ligands. Thus, another mixed valence octanuclear derivative, $[Co_8O_4(PhCO_2)_{12}L_4]$ [L_4 = $(MeCN)_3(H_2O)$], has been prepared by addition of aqueous H_2O_2 to a dmf solution of cobalt benzoate, followed by recrystallization from CH_2Cl_2–MeCN.[3,4] This material has a $[Co_8O_4]^{12+}$ framework in which trigonally bipyramidally coordinated Co^{II} atoms are bound to the oxygens of a central $[Co^{III}_4O_4]^{4+}$ cubane.

We report here the isolation and structural characterization of a second octanuclear material from 'cobalt(III) acetate', $[NH_4][Co_8(MeCO_2)_8(OMe)_{16}][PF_6]$ **1**. Reaction of 'cobalt(III) acetate' (0.5 g)[5] and NH_4PF_6 (0.61 mmol in 3 ml) in methanol over one week at ambient temperature gave an as yet unidentified green microcrystalline solid and large dark green, plate-like crystals of **1**. Pure **1** was obtained by decanting the remaining solution followed by rinsing and decanting diethyl ether suspensions of the microcrystalline solid. The initial yield of **1** was typically *ca*. 5% (0.03 mmol) based on NH_4PF_6. Although the yields have not been optimised, further, larger, crops of **1** and of the microcrystalline solid were obtained after leaving the filtrate for a period of several days to several weeks. Crystals suitable for single crystal X-ray diffraction analysis were obtained by leaving the reaction mixture undisturbed for several weeks. To prevent decomposition the crystals were kept under diethyl ether and subsequently used in single crystal X-ray diffraction measurements.† Single crystal X-ray diffraction‡ showed that **1** consists of a molecule of $[Co_8(MeCO_2)_8(OMe)_{16}]$ which functions as an inclusion host for an NH_4^+ cation. Charge balance is provided by a PF_6^- anion in the lattice. The $[Co_8(MeCO_2)_8(OMe)_{16}]$ molecule has a highly symmetric toroidal shape (Fig. 1), containing four $[Co_2(\mu\text{-}MeCO_2)(\mu\text{-}OMe)_2]$ units, forming eight edge-shared CoO_6 distorted octahedra. The cobalt atoms are situated at the vertices of a near regular planar octagon. Each pair of cobalt atoms is bridged by an acetate ligand and two stereochemically distinct methoxide ligands, one methoxide on either side of the Co_8 plane. The acetate ligands on adjacent pairs of cobalt atoms are alternatively above and below and at approximately 30° to the Co_8 plane. Of the eight methoxide ligands on each side of the Co_8 plane, four have O–C bonds perpendicular to the Co_8 plane, whereas the C–O bonds of the other four methoxide ligands are directed to the periphery of the molecule. This latter set of methoxide ligands eclipses the acetate ligands on the other side of the Co_8 plane. On each side of the Co_8 plane, then, the methoxide C–O bonds are alternatively perpendicular to (type A), and at approximately 30° to (type B) the Co_8 plane, similar to the orientation of the methoxide ligands in $[NBu_4]_2[V_8O_8(OMe)_{16}(C_2O_4)]$.[6] The NH_4^+ ion is situated at the centre of the $[Co_8(MeCO_2)_8(OMe)_{16}]$ molecule, with the nitrogen atom in the Co_8 plane. The NH_4^+ protons could not be located. Adjacent cobalt atoms are separated by an average of 2.863 Å, slightly longer than the hydroxy- and alkoxy-bridged Co···Co separations in the hydroxy-bridged dimers and most of the oxo-centred trimers.[7] The Co–O($MeCO_2$) distances are within the range 1.885(6)–1.916(6) Å, as observed in the dinuclear and trinuclear cobalt(III) complexes.[7] Bridging Co–O(OMe) dis-

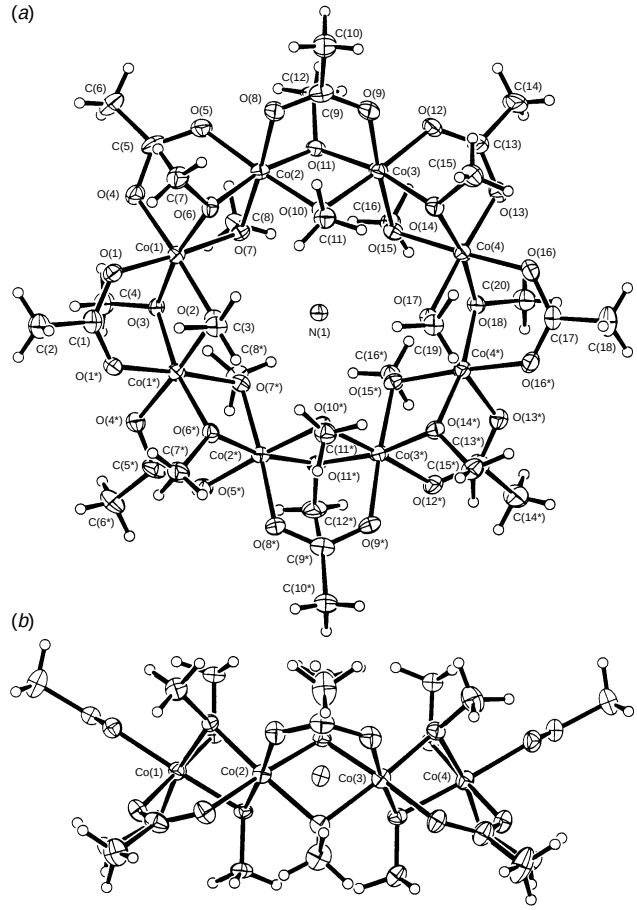

Fig. 1 ORTEP (25% probability)[17] representations of (*a*) the octanuclear $[Co_8(O_2CMe)_8(OMe)_{16}]$ host molecule and the guest NH_4^+ cation, showing the partial labelling scheme, viewed perpendicular to the Co_8 plane, and (*b*) the asymmetric unit viewed along the Co_8 plane

tances and angles are all similar and within the ranges 1.878(6)–1.918(5) Å and 97.7(4)–98.6(3)°, respectively. The Co_8 ring has a diameter of *ca*. 7.5 Å, the O_4 rings of the type A methoxides have diameters of *ca*. 5.3 Å.

The ^{1}H and ^{13}C NMR solution spectra are consistent with the solid state structure.§ Both spectra indicate a single acetate environment and equal populations of two methoxide environments. The ^{1}H NMR spectrum in CD_3OD includes a broad peak centred at δ 7.7 attributable to the protons of the NH_4^+ ion. This peak is shifted some 0.5 ppm downfield from that of NH_4PF_6 in CD_3OD (δ 7.2). The NMR spectra and the stoichiometry indicate that $[Co_8(MeCO_2)_8(OMe)_{16}]$ is diamagnetic.

Topological analogues of the $[Co_8(MeCO_2)_8(OMe)_{16}]$ structure have been reported in vanadium $\{[V_8O_8(OMe)_{16}(C_2O_4)]^{2+}$, $[MeCN(V_{12}O_{32})]^{4-}\}$,[6,8] chromium $\{[Cr_8F_8(Me_3CCO_2)_{16}]\}$,[9] molybdenum $\{[Mo_8O_{16}(OR)_8(C_2O_4)]^{2+}$; R = Me, Et$\}$,[6,10] iron $\{[Fe_8F_8(Me_3CCO_2)_{16}]\}$[11] and copper $\{[Cu_8L_8(OH)_8]$; L = 3,5-dimethylpyrazole$\}$[12] chemistries. The M_8 (M = V, Cr, Mo, Fe, Cu) rings of these compounds have diameters of some 7–9 Å.[6,9–12] The internal cavities of the similarly planar, cyclic, octameric $[Cu_8L_8(OH)_8]$ (L = 3,5-dimethylpyrazole) and $[M_8F_8(Me_3CCO_2)_{16}]$ (M = Cr, Fe) have diameters of *ca*. 6–7 Å.[9,11,12] The related $[Mo_8O_{16}(OMe)_8(PMe_3)_4]$ has a puckered Mo_8 ring with alternating five- and six-coordinated molybdenum atoms.[13] In some cases, solvent molecules are occluded in the structure, in others, oxalato ligands bridge four alternating metal atoms about the ring. The nitrogen atom of occluded Et_2NH is coplanar with the Fe_8 ring of $[Fe_8F_8(Me_3CCO_2)_{16}]$,[11] whereas occluded acetones are situated on either side of the Cr ring of $[Cr_8F_8(Me_3CCO_2)_{16}]$.[9] However, little precedent exists for this structural motif in cobalt chemistry (although compounds containing Co_6 rings are known[14–16]) and its association with the chemistry of 'cobalt(III) acetate' is completely unanticipated. It is not yet clear whether $[Co_8(MeCO_2)_8(OMe)_{16}]$ self assembles (possibly about a cationic template) as a result of a reaction between one or more constituents of 'cobalt(III) acetate' and methanol, or whether a species such as $[Co_8(MeCO_2)_8(OH)_{16}]$ self assembles in 'cobalt(III) acetate' and reacts with alcohols analogously to other species derived from 'cobalt(III) acetate'. What is clear is that the deceptively simple 'cobalt(III) acetate' can form a wide variety of ionic and neutral species and that the driving force for self assembly in these systems must be considerable, even in the presence of only the ubiquitous acetate ligand. A detailed study of related inclusion complexes will be published later.

We thank the Australian Research Council and the School of Chemistry, University of Sydney (scholarship to J. A. K.) for support.

Nickel(0) complex-catalysed detelluration of diorganyl tellurides and ditellurides with phosphines

Li-Biao Han and Masato Tanaka*

National Institute of Materials and Chemical Research, Tsukuba, Ibaraki 305, Japan

Nickel(0) complexes efficiently catalyse detelluration of diaryl tellurides and diaryl ditellurides in the presence of phosphines to afford biaryls in high yields.

Organotellurium compounds are becoming increasingly important in organic synthesis.[1] As reported by Bergman *et al.* more than two decades ago,[2] aryltelluriums undergo detelluration upon treatment with degassed Raney nickel to afford biaryls. The high accessibility of the aryltelluriums[1,2] has made the detelluration a convenient method for the synthesis of biaryls. However, attempted transition metal-catalysed detelluration has been unsuccessful to data.[2,3] Hence, although the reaction is interesting and synthetically useful, the necessity of more than a stoichiometric amount of the metal is still a serious drawback. Herein reported are (*i*) highly successful nickel-catalysed detelluration of diaryl tellurides with phosphines affording biaryls and (*ii*) its mechanism involving an unexpected disproportionation of the complexes formed by oxidative addition of C–Te bonds to $Ni(PEt_3)_4$.[4]

Heating a mixture of dianisyl telluride (**1a**, 684 mg, 2 mmol) and $Ni(PEt_3)_4$ (106 mg, 10 mol% relative to **1a**) in benzene (4 ml) at 80 °C slowly formed black precipitates to give the detelluration product 4,4′-bianisyl **2a** in 13% GC yield after 20 h.† Prolonged heating did not improve the yield, indicating a very poor turnover of the complex catalyst. However, a higher turnover was achieved when a free phosphine was added to the reaction system [eqn. (1)]. Thus, the yield of **2a** increased to

$$\underset{\mathbf{1a}}{Te(C_6H_4OMe\text{-}4)_2} + PR_3 \xrightarrow[80\ ^\circ C,\ 20\ h]{Ni(PEt_3)_4\ (10\ mol\%)} \underset{\mathbf{2a}}{(4\text{-}MeOC_6H_4)_2} + Te{=}PR_3 \quad (1)$$

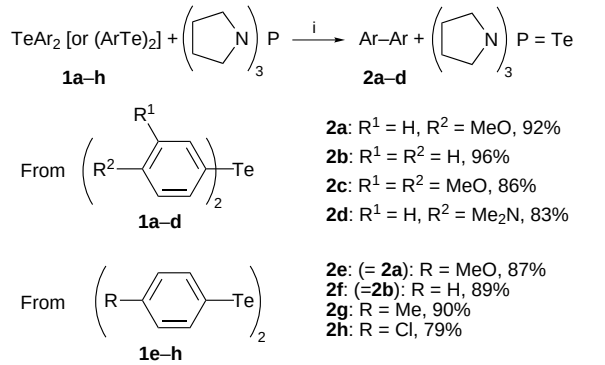
30% and further to 65% when the reaction was conducted under the same conditions in the presence of 1.2 and 3.0 equiv. (relative to **1a**) of free PEt_3, respectively (Table 1). Although reactions in acetonitrile gave slightly higher yields than those in benzene, the difference was marginal. The effect of the concentration of **1a** on the yield was not significant either at concentrations ranging from 0.8 to 2 mmol of **1a** in 4 ml of the solvent. However, the nature of the phosphine employed exerted a decisive effect. PBu_3 was as effective as PEt_3, but the use of more sterically demanding or less electron-donating phosphines such as PPr^i_3 and $PMePh_2$ reduced the yield. As compared to these triorganophosphines, however, aminophosphines proved much more efficient to achieve significant improvement in the product yield. In the presence of 1.2 equiv. of $P(pyrro)_3$ (pyrro = pyrrolidinyl), for example, starting telluride **1a** disappeared completely after 20 h (80 °C) to afford **2a** quantitatively. Note that a yield as high as 95% was obtained even when the amount of the nickel catalyst was reduced to 3 mol%. Obviously, the yield of **2a** increases in the order $PMePh_2$ < PEt_3 ≈ PBu_3 < $P(NEt_2)_3$ < $P(pip)_3$ (pip = piperidinyl) < $P(pyrro)_3$. The trend is in good agreement with the reactivity of phosphines toward tellurium to form phosphine tellurides ($Te{=}PR_3$), $P(pyrro)_3$ being most reactive.[5]‡

The Ni-catalysed detelluration could be readily applied to other diaryl tellurides affording the corresponding biaryls in good yields (Scheme 1).§ Besides methoxy group, the amino functionality was also tolerant towards the reaction, and a good yield of the corresponding product was obtained. Moreover, the new procedure could be successfully applied to diaryl ditellurides. Thus, the reactions of $(PhTe)_2$ and $(4\text{-}MeOC_6H_4Te)_2$ with 2.5 equiv. of $P(pyrro)_3$ catalysed by $Ni(PEt_3)_4$ (10 mol%) in acetonitrile under similar conditions readily afforded high yields of the corresponding biaryls in both cases. The reaction of $(4\text{-}ClC_6H_4Te)_2$ was particularly noticeable; 4,4′-dichlorobiphenyl was selectively formed in 79% yield despite the potential reactivity of chloroarenes toward Ni^0 species. Since diaryl ditellurides are more readily synthesized then tellurides, successful application of the procedure to ditellurides significantly expands the scope of the reaction.

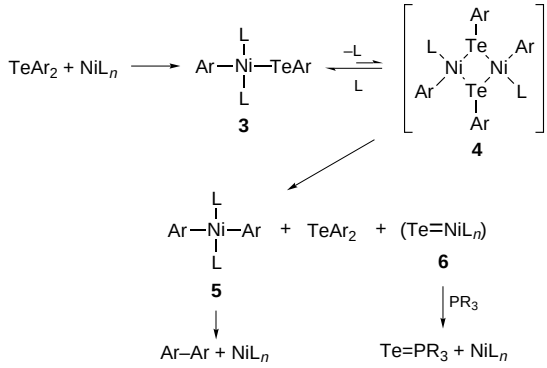
Table 1 Detelluration of dianisyl telluride **1a** catalysed by $Ni(PEt_3)_4$[a]

Run	Solvent/quantity of **1a** (mmol)/ additive (equiv. relative to **1a**)	GC yield of **2a** (%)
1	C_6H_6/2/none	13
2	C_6H_6/2/PEt_3 (1.2)	30
3	C_6H_6/2/PEt_3 (3.0)	65
4	MeCN/2/PEt_3 (1.2)	41
5	MeCN/0.8/PEt_3 (1.2)	42
6	MeCN/2/PEt_3 (3.0)	73
7	MeCN/1.2/PEt_3 (5.0)	93
8	MeCN/2/PBu_3 (1.2)	40
9	MeCN/0.8/Pi-Pr_3 (1.2)	29
10	MeCN/0.8/$PMePh_2$ (1.2)	20
11	MeCN/0.8/$P(NEt_2)_3$ (1.2)	41
12	MeCN/0.8/$P(pip)_3$ (1.2)[b]	56
13	MeCN/0.8/$P(pyrro)_3$ (1.2)[b]	*ca.* 100
14	MeCN/0.8/$P(pyrro)_3$ (0.5)[b]	70
15	MeCN/0.8/$P(pyrro)_3$ (1.2)[b]	95[c]
16	MeCN/0.8/$P(pyrro)_3$ (1.2)[b]	61[d]

[a] All reactions were run in a Schlenk flask under argon atmosphere at 80 °C for 20 h, using 10 mol% of $Ni(PEt_3)_4$ and 4 ml of a solvent. Yields of **2a** were determined by GC using biphenyl as an internal standard. [b] pip = Piperidinyl; pyrro = pyrrolidinyl. [c] 3 mol% $Ni(PEt_3)_4$ was used. [d] 3 mol% $Ni(PPh_3)_4$ was used as the catalyst.



Scheme 1 *Reagents and conditions*: i, telluride or ditelluride (2.0 mmol), $Ni(PEt_3)_4$ (10 mol%), $P(pyrro)_3$ (2.4 or 5.0 mmol for telluride or ditelluride respectively), MeCN, 80 °C, overnight



Scheme 2

The detelluration of tellurides is likely to proceed, as depicted in Scheme 2, *via* oxidative addition of a telluride to the nickel complex, disproportionation of the resulting complex **3** to generate diarylnickel species **5**, and its reductive elimination. The mechanism is substantiated by the following observations. As previously reported,[4] treatment of $TePh_2$ (340 mg, 1.206 mmol) with $Ni(PEt_3)_4$ (427 mg, 0.804 mmol) in C_6D_6 at room temp. gave complex **3b** in 10 min, which displayed a singlet at δ 10.3 in its ^{31}P NMR spectrum [eqn. (2)]. Complex **3b** was

a, Ar = C_6H_4OMe-4; **b**, Ar = Ph; **c**, Ar = $C_6H_3(OMe)_2$-3,4

liquid and rather unstable so prohibiting further purification. Telluride **1a** also reacted similarly to form oily complex **3a**. However, oxidative addition of $Te[C_6H_3(OMe)_2\text{-}3,4]_2$ **1c** with the nickel complex gave analytically pure complex **3c** (87% yield) as a black solid.¶

These nickel complexes **3** gradually decomposed even at room temp. For example, NMR spectroscopy revealed that the spontaneous decomposition of **3b** in C_6D_6 resulted in precipitation of a black solid (presumably a nickel telluride like **6**) to generate *trans*-$NiPh_2(PEt_3)_2$ **5b**[6] and $TePh_2$ (approximately 1 : 1 ratio; the conversion of **3b** was *ca.* 50% after 2 d) in solution. A very similar decomposition process was observed with complex **3c**, where the diarylnickel complex **5c** and the telluride **1c** were found by ^1H and ^{31}P NMR spectroscopy to be formed in addition to the black precipitates. As expected, the decomposition was faster at elevated temperatures. Thus, while only *ca.* 50% of complex **3c** decomposed at room temp. over 10 h, it disappeared completely within 3 h at 50 °C to afford **5c** and **1c** in *ca.* 1 : 1 ratio, which accounted for over 93% of the total aryl groups as estimated by ^1H NMR spectroscopy. Heating to even higher temperatures induced a secondary decomposition (reductive elimination); diarylnickel complex **5c** generated *in situ* through the decomposition of **3c** at 50 °C in a sealed NMR tube disappeared after overnight heating at 100 °C and the corresponding biaryl was obtained in 91% NMR yield (based on the quantity of **1c**). This reductive elimination process obviously results in regeneration of Ni^0 species, which carries the catalysis. Interaction of **6** with a phosphine molecule forming a phosphine telluride presumably is another route to the Ni^0 species. Further mechanistic detail of the decomposition of **3** leading to the generation of **5** is ambiguous at the moment. It may involve a dimeric intermediate such as **4** (Scheme 2), palladium analogues of which have been proposed.[7] A supportive observation was made in a catalytic reaction [1.2 equiv. $P(pyrro)_3$, 3 mol% $Ni(PEt_3)_4$, acetonitrile, 80 °C, 10 h] of an unsymmetrical telluride, $TeAr^1Ar^2$ (Ar^1 = $C_6H_4NMe_2$-4, Ar^2 = C_6H_4OMe-4), which gave not only Ar^1–Ar^2 but also cross-over products, Ar^1–Ar^1 and Ar^2–Ar^2 (Ar^1–Ar^1 : Ar^1–Ar^2 : Ar^2–Ar^2 = 1 : 3 : 1) in 73% total yield. The telluride recovered in *ca.* 10% was also a mixture of $TeAr^1{}_2$, $TeAr^1Ar^2$ and $TeAr^2{}_2$.

Further synthetic application of the facile oxidative addition of C–Te bonds to Ni, Pd and Pt complexes[4] is now under extensive study.

Financial support from the Japan Science and Technology Corporation (JST) through the CREST (Core Research for Evolution Science and Technology) program is gratefully acknowledged.

Footnotes and References

* E-mail: mtanaka@ccmail.nimc.go.jp

† Most of **1a** (83% based on GC) remained unreacted. In the absence of the nickel catalyst, no coupling product was formed under similar conditions, indicating that the nickel catalyst was essential for the reaction.

‡ Formation of $Te{=}P(pyrro)_3$ in the detelluration reaction with $P(pyrro)_3$ was confirmed by ^{31}P NMR. See ref. 5.

§ *Typical experimental procedure:* A mixture of telluride **1a** (684 mg, 2 mmol), $P(pyrro)_3$ (579 mg, 2.4 mmol) and $Ni(PEt_3)_4$ (106 mg, 0.2 mmol) in acetonitrile (5 ml) was heated at 80 °C overnight (20 h). The reaction mixture was poured into 10 ml of 1M HCl to liberate metallic tellurium instantly. Extraction using CH_2Cl_2, drying over $MgSO_4$ and concentration afforded crude **2a**, which was subsequently passed through a short silica gel column (ethyl acetate–chloroform–hexane = 0.5 : 1 : 8) to give pure product **2a** as a white solid (394 mg, 1.84 mmol, 92%).

¶ A mixture of **1c** (371 mg, 0.923 mmol) and $Ni(PEt_3)_4$ (500 mg, 0.941 mmol) in benzene (6 ml) was stirred at room temp. for 15 min. Concentration of the reaction mixture to *ca.* 0.5 ml resulted in the precipitation of analytically pure complex **3c** as a black solid in 87% yield (560 mg, 0.803 mmol). *Selected data* for **3c**: ^1H NMR (300 MHz, C_6D_6) δ 7.78 (d, 1 H, *J* 8.0 Hz), 7.67 (s, 1 H), 7.11 (s, 1 H), 6.89 (d, 1 H, *J* 7.8 Hz), 6.66 (d, 1 H, *J* 7.8 Hz), 6.41 (d, 1 H, *J* 8.0 Hz), 3.67 (s, 3 H), 3.52 (s, 3 H), 3.50 (s, 3 H), 3.40 (s, 3 H), 1.34–1.42 (m, 12 H), 0.90–1.09 (m, 18 H); ^{31}P (121.5 MHz, C_6D_6) δ 11.3. Chemoselective platinum(0)-catalysed hydrophosphination of ethyl acrylate

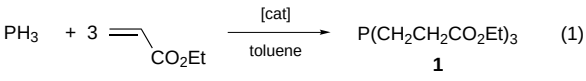
Emiliana Costa, Paul G. Pringle* and Kerry Worboys

School of Chemistry, University of Bristol, Cantocks Close, Bristol, UK BS8 1TS

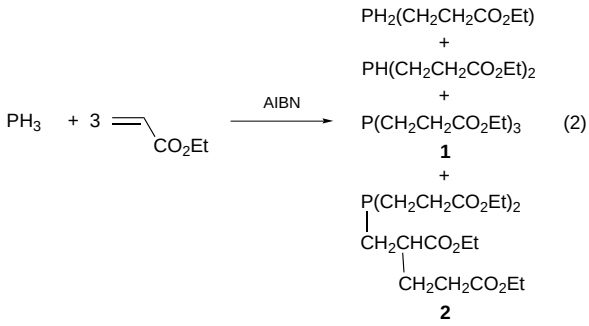
Platinum(0) complexes of $P(CH_2CH_2CO_2Et)_3$ are efficient and selective catalysts for the addition of PH_3 to CH_2=$CHCO_2Et$.

Homogeneous catalysis of the addition of Si–H,[1] B–H[2] or P–H[3–5] to C=C bonds by transition-metal complexes is a field of academic interest and industrial potential. We are interested in the additions of P^{III}–H to C=C bonds catalysed by metal–phosphine complexes and have shown that platinum(0) complexes of tris(cyanoethyl)phosphine catalyse the hydrophosphination of acrylonitrile.[3] We report here that the synthesis of the triester phosphine **1** by the addition of PH_3 to CH_2=$CHCO_2Et$ [eqn. (1)] is catalysed by platinum(0) com-



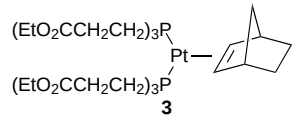
plexes of **1** and the efficiency and selectivity of this catalysis is superior to the alternative radical-initiated process. Phosphine **1** is of interest as a flame retardant intermediate[6] and as a phosphine ligand amenable to further functionalisation.[7]

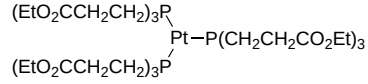
Rauhut *et al.*[8] reported that at 70 °C and *ca*. 25 atm of PH_3, hydrophosphination of ethyl acrylate [eqn. (2)] is promoted by

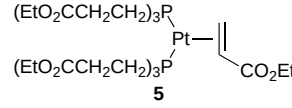


AIBN to give a mixture of primary, secondary and tertiary phosphines in the ratio of *ca*. 1 : 1 : 1. The conversion based on ethyl acrylate was 83% and the tertiary phosphine component was a *ca*. 1 : 1 mixture of phosphine **1** and the telomer **2**. Thus the overall selectivity of this radical reaction to the desired phosphine **1** is *ca*. 15%. We investigated the efficacy of platinum(0) complexes as catalysts for the hydrophosphination of ethyl acrylate in the hope that they would be more selective than the radical initiated process.

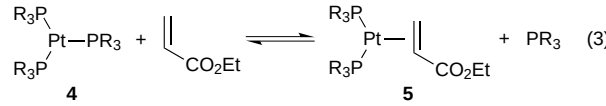
Treatment of [Pt(norbornene)$_3$] with 2 or 3 equiv. of **1** in toluene gave platinum(0) complexes assigned structures **3** and **4** on the basis of the characteristic ^{31}P NMR data and the multiplicity of the ^{195}Pt NMR signals.† Addition of further ligand **1** to solutions of **4** led to broad ^{31}P NMR signals for both **1** and **4** showing that ligand exchange takes place on the NMR timescale at ambient temperatures but there was no evidence for a stable [Pt$(PR_3)_4$] species. Addition of 1 equiv. of ethyl acrylate to a solution of **3** in toluene gave a species assigned structure **5** on the basis of the AB pattern observed in the ^{31}P NMR







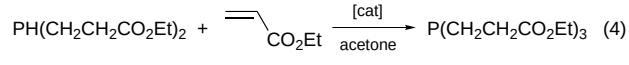
spectrum and the doublet of doublets in the ^{195}Pt NMR spectrum. Interestingly the same species **5** is obtained upon addition of 1 equiv. of ethyl acrylate to **4** but in this case the ^{31}P NMR signals are broad for both **5** and displaced **1** indicating that phosphine exchange is taking place; addition of 5 equiv. of phosphine **1** to solutions of **5** broadened the signals further but there was no evidence for reformation of **4**. It was therefore inferred that the equilibrium shown in eqn. (3) lies to the right



and K was estimated to be > 100. This suggests that complex **5** will be the predominant form of the platinum(0) during the course of the catalysis described below particularly in the initial stages when the ethyl acrylate is in abundance. Complexes **3**–**5** are very reactive and attempts to isolate them in pure form were unsuccessful; thus they have been generated *in situ* for the catalysis.

When PH_3 is bubbled through a warmed solution of ethyl acrylate, no reaction is apparent after 3 h but under similar conditions‡ in the presence of 0.002 equiv. of platinum(0), the reaction proceeded smoothly and after 8 h essentially all of the ethyl acrylate had been consumed. According to ^{31}P NMR spectroscopy, a *ca*. 10 : 1 mixture of the tertiary phosphines **1** and **2** was the product and therefore the selectivity of the platinum(0) process for **1** is > 90%. The addition of PH_3 to ethyl acrylate involves three consecutive hydrophosphinations and the preference for tertiary phosphine in the product implies that the rate of the P–H additions increases in the order PH_3 < RPH_2 < R_2PH. From the proportion of **1** obtained in the product, the average selectivity of each step is apparently *ca*. 97%.

The final step in the hydrophosphination [eqn. (4)] has been



monitored by ^{31}P NMR spectroscopy in the presence and absence of platinum(0) complex **3**. Under the conditions used,§

the P–H addition [eqn. (4)] proceeded 30% after 24 h in the absence of platinum(0) while in the presence of **3** (0.1 equiv.) the hydrophosphination had proceeded 50% after 15 min and was complete in less than 90 min with the desired phosphine **1** constituting >95% of the product according to ^{31}P NMR spectroscopy.

Platinum(0) complexes are catalysts for the hydrophosphination of CH_2=CHZ (Z = CN or CO_2Et).[3,4] Both of these Z substituents withdraw electron density from the C=C bond by virtue of their electronegativity (−I) and resonance (−R) effects. Since no catalysis was detected when PH_3 was passed through a toluene solution of CH_2=$CHCF_3$ in the presence of [Pt{$P(CH_2CH_2CF_3)_3$}$_2$(norbornene)], it is the resonance (or Michael) activation of the alkene that appears to be critical.

While the coordination chemistry of the commercially available $P(CH_2CH_2CN)_3$ has been well studied,[9] to our knowledge, the reported metal complex chemistry of **1** is restricted to one iridium cluster.[7] A study of the precious metal chemistry of **1** is in progress.

We should like to thank Albright and Wilson and EPSRC for support and Johnson-Matthey for the loan of platinum compounds.

‡ **CAUTION**: Phosphine gas is extremely toxic and should only be handled in a well ventilated fume cupboard; the exit gases were passed through a solution of commercial bleach to oxidise unreacted PH_3. Toluene (50 cm^3) was carefully deaerated by passing nitrogen through it for 1.5 h and then [Pt(norbornene)$_3$] (0.123 g, 0.257 mmol), the phosphine **1** (1.034 g, 3.093 mmol) and ethyl acrylate (13.1 cm^3, 121 mmol) were added sequentially. PH_3 gas was bubbled through the solution for 8 h maintaining the temperature at 55 °C. The solution was stirred for a further 3 h at 55 °C and the reaction was monitored throughout by ^{31}P NMR spectroscopy.

§ Oxygen was rigorously excluded from the reaction mixture. In an 5 mm NMR tube, to a solution of [Pt(norbornene)$_3$] (5 mg, 0.010 mmol) in $C_6D_5CD_3$ (0.10 cm^3), phosphine **1** (7.0 μl, 0.020 mmol) and then ethyl acrylate (35.0 μl, 0.32 mmol) were added. To this mixture a solution of $PH(CH_2CH_2CO_2Et)_3$ (50 μl, 0.21 mmol) in $C_6D_5CD_3$ (0.30 cm^3) was added in one portion and the reaction monitored by ^{31}P NMR spectroscopy.

Stereoselective formation of (*Z*)-γ-substituted allylsilanes by the titanocene(II)-promoted reaction of thioacetals with trialkyl(allyl)silanes

Tooru Fujiwara, Mayumi Takamori and Takeshi Takeda*

Department of Applied Chemistry, Tokyo University of Agriculture and Technology, Koganei, Tokyo 184, Japan

The reaction of organotitanium species prepared by the desulfurizative titanation of thioacetals with $(C_5H_5)_2Ti[P(OEt)_3]_2$ in the presence of trialkyl(allyl)silanes gives γ-substituted allylsilanes with *Z* stereoselectivity.

Since allylsilanes are useful synthetic intermediates in organic synthesis, a number of procedures for their preparation have been reported. Among them, the methods utilizing an olefination process are attractive because they enable us to prepare regioisomeric pure allylsilanes. Two types of olefination have been investigated; (i) Wittig olefination of carbonyl compounds using $Ph_3P{=}CHCH_2SiMe_3$,[1] and (ii) metal alkylidene catalysed olefin cross metathesis using trialkyl(allyl)silane. Crowe *et al.* showed that the cross metathesis of allyltrimethylsilane with terminal olefins using Schrock's molybdenum catalyst $PhMe_2CCH{=}Mo{=}N(2,6\text{-}Pr^iC_6H_3)[OCMe(CF_3)_2]_2$ gave (*E*)-γ-substituted allylsilanes predominantly.[2] On the other hand, the stereochemistry of Grubb's ruthenium $\{Cl_2[c\text{-}C_6H_{11})_3P]_2Ru{=}CHPh\}$ catalysed ring opening metathesis of strained cyclic olefins with allyltrimethylsilane is reported to be unpredictable.[3]

Recently we reported the titanocene(II)-promoted reactions of thioacetals with organic compounds having a multiple bond such as carbonyls,[4] alkenes[5] and alkynes.[6] It was suggested that these reactions proceeded through the carbene complexes of titanium **1** formed by the desulfurization of thioacetals with low valent titanium species. Since the intermediate of olefin metathesis is assumed to be a metal alkylidene species, we expected that substituted allylsilanes would be formed by the titanocene(II)-promoted reaction of thioacetals **2** with allylsilanes **3** through the metathesis process.

1

As would be expected, 1-triisopropylsilyl-5-phenylpent-2-ene **4b** was produced in 50% yield along with a small amount of the homoallylsilane **5b** (7%) when the thioacetal **2a** was treated with the titanocene(II) species $(C_5H_5)_2Ti[P(OEt)_3]_2$ **6** in the presence of a two-fold excess allyltriisopropylsilane **3b** at room temperature for 48 h (Scheme 1). The starting material disappeared within a short period of time (3 h), and **4b** was obtained in a comparable yield when the reaction was carried out in refluxing THF. The yield of **4b** was increased by increasing the molar ratio of **3b** (Table 1, entry 2).†

In a similar manner, the reactions of several thioacetals **2** with trialkyl(allyl)silanes **3** were performed, and the mixtures of the corresponding substituted allylsilanes **4** and the homoallylsilanes **5** were produced in a ratio of 7.1 : 1 to 1.9 : 1 depending on the alkyl substituents on silicon atom of **3** and the structure of thioacetal **2**. For example, the reaction using allyltriisopropylsilane gave substituted allylsilanes preferentially. On the other hand, in the case of the reaction using allyltrimethylsilane or allyldimethyl(phenyl)silane, a substantial amount of **5** was produced. What is striking is that

Table 1 Reaction of thioacetals **2** with trialkyl(allyl)silanes **3**[a]

			Products (% yield; *E* : *Z*)	
Entry	**2**	**3**	**4**	**5**[b]
1	**2a**	**3a**	**4a** (64; 13 : 87)	**5a** (13)
2	**2a**	**3b**	**4b** (64; 12 : 88)	**5b** (9)
3	**2b**	**3a**	**4c** (55; 16 : 84)	**5c** (29)
4	**2b**	**3b**	**4d** (85; 23 : 77)	**5d** (12)
5	**2b**	**3c**	**4e** (45; 14 : 86)	**5e** (23)
6	**2c**	**3b**	**4f** (78; 11 : 89)	**5f** (16)
7	**2c**	**3c**	**4g** (48; 10 : 90)	**5g** (20)
8	**2d**	**3a**	**4h** (44; 14 : 86)	**5h** (20)
9	**2d**	**3b**	**4i** (44; 14 : 86)	**5i** (18)

[a] Carried out with 5 equiv. of **3**. [b] The stereochemistry was not determined.

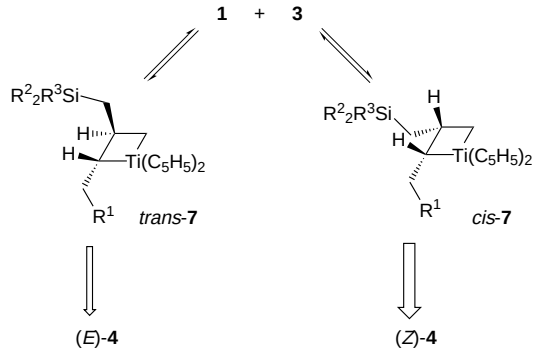
Scheme 1



Scheme 3

(*Z*)-allylsilanes (*Z*)-**4** were selectively produced by the present reaction regardless of the substituents on the thioacetals or allylsilanes.‡

The formation of organosilyl compounds **4** and **5** is explained by the following reaction pathway (Scheme 2), which involves the initial formation of α,β-disubstituted titanacyclobutane intermediate **7**.[7] The metallacycle intermediate then cleaves to form a γ-substituted allylsilane **4** and titanocene methylidene complex **8**. The homoallylsilane **5** is produced by elimination of the β-hydride from **7**, followed by elimination of the titanocene(II) species from the homoallyltitanium **9**. A similar process was observed in the reaction of carbene complexes with alkynes.[6]

As for the cleavage of α,β-disubstituted titanacyclobutane leading to the formation of a carbene complex and an olefin, it was shown that the configuration of the metallacycle derived from Tebbe's reagent, 3,3-dimethylcyclopropene and a norbornene diester was retained during the process.[8] Since the *cis*-α,β-disubstituted metallacycle is much less stable than the corresponding *trans*-isomer,[9] the preferential formation of (*Z*)-allylsilanes by the present reaction is explicable in terms of much faster cleavage of *cis*-titanacyclobutane *cis*-**7** than of *trans*-**7** (Scheme 3).

In conclusion, we have found that the reaction of titanium carbene complexes with allylsilanes affords (*Z*)-allylsilanes regio- and stereo-selectively. It should be noted that the present study first revealed the stereochemistry of the cross metathesis between an alkylidenetitanocene and an acyclic olefin. Further study on the reactions of carbene complexes formed from thioacetals with various olefins is now in progress.

† *Typical experimental procedure*: To a flask charged with finely powdered molecular sieves 4A (150 mg), magnesium turnings (3 mmol) and titanocene dichloride (1.5 mmol) was added THF (3 ml), triethyl phosphite (3 mmol) and trialkyl(allyl)silane (2.5 mmol) successively with stirring. After 2 h, a THF (1 ml) solution of **2** (0.5 mmol) was added and the reaction mixture was refluxed for 6 h. After being cooled to room temperature, the reaction mixture was diluted with pentane (30 ml). The insoluble materials were filtered off through Celite and the filtrate was concentrated. Purification was accomplished by preparative TLC providing a mixture of **4** and **5** as a clear, colourless oil; the excess trialkyl(allyl)silane was removed by distillation prior to purification when necessary. The yields of **4** and **5** were determined by NMR analysis.

‡ The configurations of **4a**–**d** were determined by comparison with authentic samples of the *E*- and *Z*-isomers. The *Z*-isomers (*Z*)-**4** were prepared by the stereoselective reduction of the corresponding prop-2-ynylsilanes with DIBAL-H reported by Rajagopalan and Zweifel,[10] and *E*-isomers (*E*)-**4** were obtained by their diphenyl disulfide mediated photoisomerization[11] [**4a** (*E*:*Z* = 74:26), **4b** (*E*:*Z* = 83:17), **4c** (*E*:*Z* = 79:21), **4d** (*E*:*Z* = 82:18)]. The configurations of other allylsilanes were assigned on the basis of the coupling constant of their vinyl protons.

Segregation of mixed micelles in the presence of polymers

Peter Griffiths,*[a] Richard Abbott,[a] Peter Stilbs[b] and Andrew Howe[c]

[a] *Department of Chemistry, University of Wales Cardiff, PO Box 912, Cardiff, UK CF1 3TB*

The diffusion behaviour of an aqueous mixture of the sugar-based non-ionic surfactant dodecylmalono-bis-*N*-methylglucamide DBNMG and the anionic surfactant of similar tail length, sodium dodecyl sulfate SDS, are examined in the presence of 5 mass% gelatin; the results clearly show that there are two types of mixed micelle present in the system arising through competition between gelatin and the non-ionic micelle for the anionic surfactant.

The interactions between common synthetic polymers, *e.g.* homopolymers,[1,2] hydrophobically modified polymers[3–5] and polyelectrolytes,[6,7] and selected surfactants have been studied extensively. Generally, the polymer/surfactant complex consists of spherical, monodisperse micelles adsorbed onto the polymer chain in a 'bead and necklace' manner.[8] The presence of the polymer stabilises the formation of the adsorbed micelles and these form at lower concentrations [denoted c.a.c. or c.m.c. (1)], compared with the polymer-free critical micelle concentration (c.m.c.). Recent theoretical modelling[9,10] of these systems is based on the fact that the polymer segments bind in the micelle palisade layer thereby partially shielding some of the hydrophobic core from contact with the continuous aqueous phase. This results in a decrease in the interfacial free energy of the system and hence, provides the driving force for the interaction.

In commercial polymer/surfactant systems, a single surfactant is rarely employed. Most often, a mixture of surfactants is present and synergistic or antagonistic effects are used to mediate and control the overall polymer/surfactant behaviour. The molecular basis for these effects is poorly understood but very important for the improvement of product formulations. It is possible however, to build up a picture of the structure of the polymer/mixed surfactant complex from a knowledge of the diffusion behaviour of the various components. Here, we present as far as we are aware, the first such attempt to do this.

The simultaneous measurement of the (self)-diffusion coefficient of each component present in a multi-component mixture can be achieved using pulsed-gradient spin-echo nuclear magnetic resonance, PGSE NMR. The normal procedure for measuring the self-diffusion coefficient of a species in a multi-component solution is to isolate a resolvable peak, extract the peak integral (intensity) or height for a series of spectra separated in time and fit the resultant exponential time decay. In many useful polymer/surfactant mixtures, resolvable peaks are not present and one must resort to the fitting of multi-exponential decays. For example, consider the data shown in Fig. 1(*a*). The most intense peak (at δ 1.45) corresponds to CH_2 groups present in both surfactants as well as the gelatin. A new data analysis has been developed however, to overcome this problem, called component resolved (CORE) PGSE NMR.[11] The fit to the data is given in Fig. 1(*b*). This approach significantly enhances the accuracy of the diffusion coefficients obtained. A further advantage of CORE PGSE NMR, is that the T_2 weighted 1D spectrum for each component is extracted from the component bandshape. Unequivocal assignment of the diffusion coefficient to each component is then possible.

Gelatin interacts strongly with SDS but not DBNMG, whilst SDS and DBNMG form mixed micelles in the absence of gelatin.[10,12–14] The self-diffusion coefficients of the three components SDS, DBNMG and 5 mass% gelatin are presented in Fig. 2 for a series of 5 mass% aqueous gelatin solutions containing 20 mM SDS and a range of DBNMG concentrations. The broken line corresponds to the diffusion behaviour of DBNMG in the presence of 5 mass% gelatin. This diffusion is slower by a factor of approximately two-thirds than that in the absence of gelatin owing to the obstructing effects of the polymer: the micelle has to diffuse around the gelatin, thereby increasing its diffusion pathlength. The diffusion of DBNMG is further retarded when SDS is present in the system indicative of binding to the much more slowly diffusing gelatin. The gelatin diffusion is an order of magnitude slower than that measured in the simple gelatin and gelatin/DBNMG solutions, again indicative of binding of surfactant micelles to the gelatin.

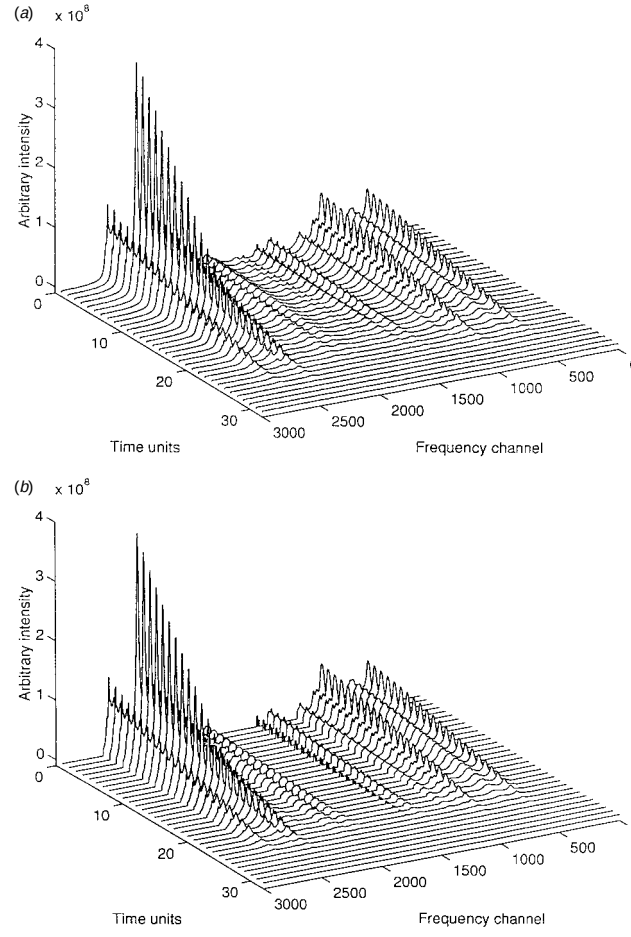

Fig. 1 (*a*) Experimental data for a 5 mass% gelatin solution containing 40 mM SDS and 5 mM DBNMG; (*b*) the CORE processed simulation

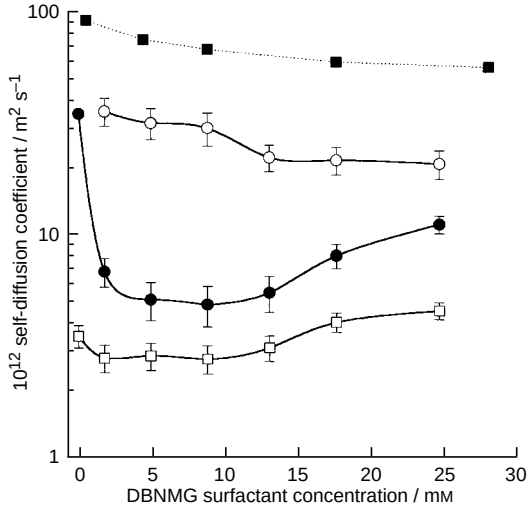

Fig. 2 Diffusion in 5 mass% aqueous gelatin/DBNMG/SDS solutions; gelatin (□), DBNMG (○), and SDS (●). The diffusion of DBNMG in the presence of 5 mass% gelatin only (■) is also shown.

The most striking conclusion however, comes from the behaviour of the SDS. If only one type of micelle is present in the system, and assuming that the unimer concentrations are low, the two surfactants should diffuse at the same rate. This is not observed. Since c.m.c.(1) for gelatin/SDS is higher than $c.m.c._{DBNMG}$, the concentration of unimeric SDS in the system should be greater than that of the DBNMG and hence, the self-diffusion coefficient of SDS should be greater than that of the DBNMG. This too is not observed. The highly unexpected, yet obvious conclusion is that two mixed micellar environments must be present, SDS-rich micelles bound to the gelatin and DBNMG-rich micelles present in solution.

At higher DBNMG concentrations, both the SDS and gelatin self-diffusion coefficients increase, the faster diffusing DBNMG-rich micelles in solution are 'pulling' SDS from the slower diffusing micelles bound to the gelatin. The SDS concentration bound to the gelatin therefore decreases, causing the diffusion of gelatin to increase.

Chiral and somewhat hydrophilic hemicarceplexes

Bong Ser Park, Carolyn B. Knobler, Clark N. Eid, Jr., Ralf Warmuth and Donald J. Cram*

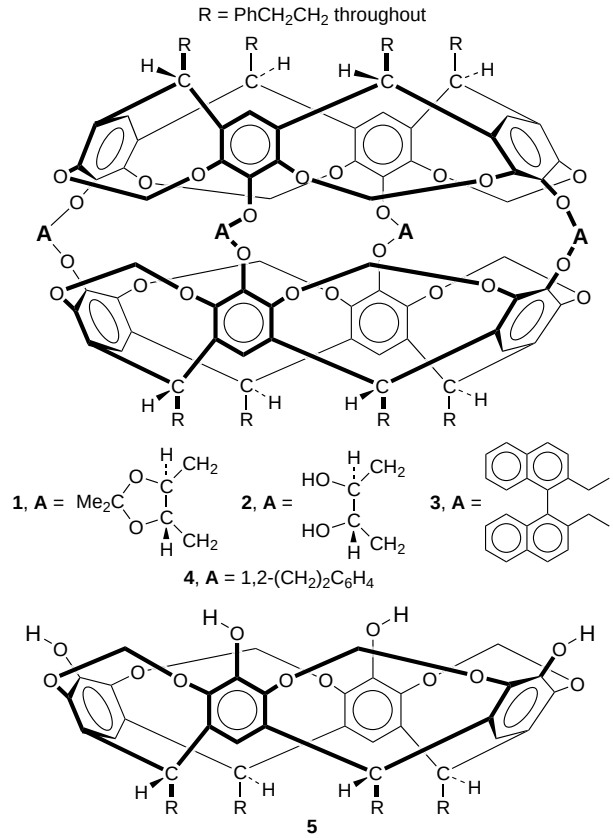
Department of Chemistry and Biochemistry, University of California, Los Angeles, CA 90095-1569, USA

Five new hemicarceplexes involving chiral hosts 1 and 2 have been synthesized and characterized, two by crystal structure determinations; chiral recognition by one host in complexing butan-2-ol is described.

This research had two objectives: to prepare chiral hemicarcerands for chiral recognition of guests in complexation studies, and to obtain hemicarcerands soluble in hydroxylic solvents for examination of solvent effects on complexation. Previously, we found that diastereomers of **3**⊙EtCHBrCH$_2$Br decomplexed at rates that differed by a factor of 9 in $CDCl_3$ at 23 °C.[1] In the present work we report the syntheses and characterizations of complexes of **1** and **2** from tetrol **5** and (*S*,*S*)-(−)-1,4-di-*O*-tosyl-2,3-isopropylidene-L-threitol.[2] The shell closures were conducted in Me_2SO to give 16% of **1**⊙Me_2SO,† in Me_2NCOMe to give 22% of **1**⊙Me_2NCOMe† and in Me_2NCHO to provide 20% of **1**⊙Me_2NCHO.† Products were separated chromatographically from substantial amounts of diol containing only three bridges, which suggests the rates of introducing the fourth bridge were substantially slower than for the first three bridges, probably for steric reasons. Complex **1**⊙Me_2SO required heating at 230 °C in Ph_2O for two days to decomplex, but considerable host decomposition accompanied decomplexation. Clean decomplexation occurred with **1**⊙Me_2NCOMe in Ph_2O or 1,2,4-$Cl_3C_6H_3$ (214 °C, 8 h) or **1**⊙Me_2NCHO in either solvent (150–160 °C, 3 d) to give empty **1**† (80–90%). The acetonide protecting groups were removed (80–90%) from **1**⊙Me_2NCOMe without decomplexation by heating its solution at reflux in $(CH_2)_4O$ containing 10 drops of concentrated aqueous HCl for 2 h to provide **2**⊙Me_2NCOMe (80%).†‡ Similar treatment of **1**⊙Me_2SO and **1**⊙Me_2NCHO gave **2**⊙$(CH_2)_4O$.† Thus decomplexation accompanied deprotection. We suggest that **1**⊙Me_2SOH^+ and **1**⊙Me_2NCHOH^+ are respective intermediates in these decomplexations, and that these cations decomplex much more rapidly than does the neutral starting material. In a different host, host⊙$Et_2NH_2^+$ decomplexed instantaneously under conditions such that host⊙Et_2NH was stable.[3]

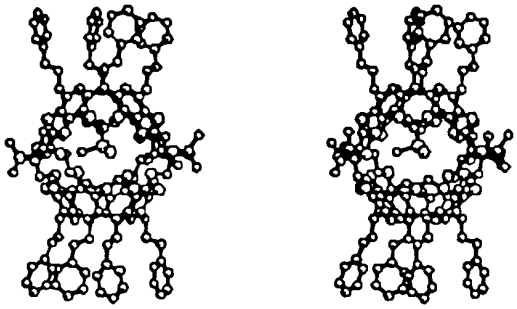
In $CDCl_2CDCl_2$ as solvent at 150 °C the appearance of free guest ^{1}H NMR signals showed half lives for decomplexation of **1**⊙Me_2NCOMe and **2**⊙Me_2NCOMe to be ~113 and ~4.5 h, respectively. The rigidity of the acetonide bridges of **1** appears to inhibit the loss of Me_2NCOMe from the inner phase of **1** more than does the more flexible acyclic bridge system of **2**. The decomplexation half-life of **1**⊙Me_2NCHO at 138 °C in $CDCl_2CDCl_2$ was ~1.5 h, reflecting the smaller size of Me_2NCHO compared to Me_2NCOMe.

Crystal structures of **1**⊙Me_2SO and **2**⊙Me_2NCOMe show the disposition of the chiral bridges.§ Side and top stereoviews are portrayed in Fig. 1, the latter including only the guest and bridges connecting the two hemispheres, whose four oxygens are each joined by lines to form two near squares. Notice the unshared electron pairs of the bridge oxygens invariably face inward toward the cavity, which orients the other atoms outward away from the cavity. The two squares are within 1–2° of occupying parallel planes, and are rotated with respect to each other about their long normal axis by 15° in **1**⊙Me_2SO and by 13° in **2**⊙Me_2NCOMe. The average distances between oxygen planes are 3.27 and 3.67 Å, respectively. The crystals are

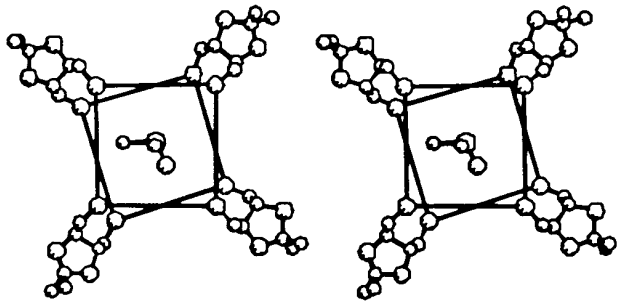


somewhat disordered in the regions of the feet and solvent and with respect to the guests' locations relative to their hosts. In the disorder model for **1**⊙Me_2SO, two Me_2SO guest locations are equally likely, either with one Me in the upper bowl (as in the drawing) or with one Me in the lower bowl of **1**. This model is in agreement with ^{1}H NMR evidence and with crystal structures of similar complexes. The plane of the Me_2NCOMe guest in either of its orientations in **2**⊙Me_2NCOMe lies nearly along one of the diagonals of the O_4 squares, and its long MeNCMe axis is essentially aligned with the host's long axis. The twisting of the two hemispheres of the hosts with respect to one another is less than the 24° observed in the crystal structure of **4**⊙Me_2NCOMe.[4]

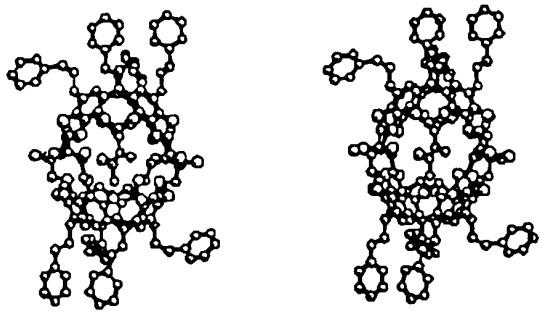
The 500 MHz ^{1}H NMR spectrum of **1**⊙Me_2SO in $CDCl_3$ gave two CH_3 singlets at δ −0.91 and −1.03 and thus $\Delta\delta$ = 0.12 ppm. Variable-temperature ^{1}H NMR spectra of **1**⊙Me_2SO in $CDCl_2CDCl_2$ from −80 to 180 °C showed no sign of either splitting or coalescence of these signals, and the whole spectrum showed little temperature dependence. Thus the two guest methyl signals reflect their enantiotopic character in the asymmetric environment of the chiral host. Separately, **1** was heated in 4:1 (v/v) Pr^iOH–Ph_2O to 80 °C for 4 d to form **1**⊙Pr^iOH,¶ which in $CDCl_3$ similarly exhibited 500 MHz ^{1}H NMR signals (two sets) for two enantiotopically related Me groups at δ −2.03 and −2.18 to give a $\Delta\delta$ = 0.15 ppm.



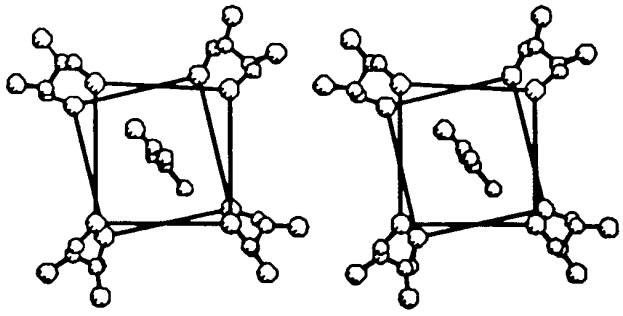
1⊙Me_2SO side stereoview of crystal structure



1⊙Me_2SO partial top stereoview of crystal structure



2⊙Me_2NCOMe side stereoview of crystal structure



2⊙Me_2NCOMe partial top stereoview of crystal structure

Fig. 1

In an exploratory chiral recognition experiment, (*S,S*)-**1** was heated in a mixture of 1 : 4 (v/v) Ph_2O–Bu^sOH (racemic) for three days at 95–100 °C, and the complex was precipitated with MeOH and submitted to TLC on silica gel plates with 20 : 1 (v/v) $CHCl_3$–EtOAc to provide a 2 : 1 ratio of diastereomeric complexes¶ (^{1}H NMR guest measurements), R_f = 0.8 major product, and R_f = 0.5 minor product. This result shows a surprisingly large sensitivity of the surface-absorption properties of the (*S,S*)-**1** host to the *configuration* of an incarcerated and largely inner-phase-mobile guest separated from the surface of the complex by the host's multi-Ångstrom-thick shell. Further chiral recognition studies involving **1** and **2** should provide interesting results. The fact that **2**⊙guests are soluble in EtOH and higher alkanols suggests that if the eight $PhCH_2CH_2$ groups of **2** are replaced by Me groups, the host might be water soluble. We are investigating this possibility.

† Elemental analyses including N and S of guests were within 0.30 of theory, FAB MS gave host⊙guest signals as the parent ion, and the expected ^{1}H NMR spectra were found in $CDCl_3$.

‡ The following experiments are illustrative. To a stirred suspension under argon of Rb_2CO_3 (2.5 g) in dry Me_2NCHO (50 ml) at 70 °C was added tetrol **5** (0.50 g, 0.50 mmol) and (*S,S*)-(−)-1,4-ditosyl-2,3-isopropylidene-L-threitol (1.16 g, 2.50 mmol) dissolved in Me_2NCHO (50 ml) over a period of 12 h. The mixture was stirred 1 d at 70 °C, 1.16 g of additional ditosylate was added, and the mixture stirred at 70 °C for 2 d and at 100 °C for 1 d. The mixture was filtered, and the filtrate was evaporated under vacuum to a solid, which was extracted with $CHCl_3$ and filtered. The solvent was evaporated and the product chromatographed on silica gel with 20 : 1 $CHCl_3$–EtOAc (v/v) to give 0.128 g (20%) of **1**⊙Me_2NCHO.† Deprotection of **1**⊙Me_2NCOMe was accomplished by heating 31 mg of the acetonide in 5 ml of $(CH_2)_4O$ and 10 drops of concentrated aqueous HCl at reflux for 2 h. The organic layer was dried ($MgSO_4$) and evaporated, and the resulting solid was chromatographed [silica gel, 10% MeOH in CH_2Cl_2 (v/v)] to give 27 mg (87%) of **2**⊙Me_2NCOMe.† Decomplexation of **1**⊙Me_2NCHO was accomplished by heating 30 mg of the complex in 2 ml of Ph_2O at 150 °C for 3 d. The product was precipitated with MeOH to give 25 mg of **1**.† Complexation of **1** with racemic Bu^sOH involved heating 20 mg of **1** in a mixture of 1 ml of Ph_2O and 4 ml of Bu^sOH for 3 d under argon at 95 °C. The solution was cooled and **1**⊙Bu^sOH was precipitated with excess MeOH and purified by preparative silica gel TLC [20 : 1 $CHCl_3$: EtOAc (v/v)] to give 15 mg of **1**⊙Bu^sOH.†

§ *Crystal data*: the crystal structures of **1**⊙Me_2SO and **2**⊙Me_2NCOMe were each determined at 25 °C from cut colorless crystals in capillaries mounted on a Syntex $P\bar{1}$ diffractometer with Cu-Kα radiation, maximum 2θ = 100°. The structure of **1**⊙Me_2SO (crystallized from CH_2Cl_2–EtOH–EtOAc) belongs to the monoclinic space group $P2_1$, a = 17.7483(7), b = 19.5425(7), c = 26.231(1) Å, β = 107.200(1)°, V = 8691 Å^3, Z = 2, 10 080 unique reflections, 5081 > 4$\sigma(F)$, was solved by direct methods (SHELXS90)[5a] and was refined to R = 0.14. Disordered or low-occupancy solvent molecules, some EtOAc and some unidentified fragments, were found in 12 regions of the unit cell.

The structure of **2**⊙Me_2NCOMe (crystallized from $CHCl_3$–Pr^nOH) belongs to the triclinic space group $P1$, a = 13.811(7), b = 16.239(9), c = 20.785(11) Å, α = 111.38(1), β = 95.13(1), γ = 110.90(1)°, V = 3924 Å^3, Z = 1, 8059 unique reflections, 4566 > 4$\sigma(F)$, was solved by direct methods (SHELX86)[5a] and was refined to R = 0.14. The solvent content is uncertain; the final model includes 2 $CHCl_3$, 1 Pr^nOH and 3 other solvent fragments. For both structures, final refinements were performed with SHELXL93[5b] with isotropic displacement parameters and hydrogen atoms in calculated positions. CCDC 182/647.

¶ FAB MS gave host⊙guest or host signals as parent ion and the expected ^{1}H NMR spectra were found in $CDCl_3$.

Surface plasmon excitation of a porphyrin covalently linked to a gold surface

Akito Ishida,* Yoshiteru Sakata and Tetsuro Majima*

The Institute of Scientific and Industrial Research, Osaka University, Mihogaoka 8-1, Ibaraki 567, Japan

Fluorescence of a porphyrin covalently linked to a gold surface is observed with surface plasmon excitation using p-polarized light to show higher excitation efficiency for the Q-bands than the Soret band.

Surface plasmon resonance (SPR) is a near-field phenomenon, in which the plasma oscillation of a metal is coupled with the incident light at the resonance angle resulting in strong polarization on the metal surface.[1] SPR has been mainly used as an excellent sensing method for biological purposes.[2,3] Since surface plasmon (SP) has field enhancement effects,[1] photochemical reactions at the surface are expected to be assisted by SPR similar to the surface enhanced spectroscopy. Here, we have studied electronic excitation of a porphyrin chromophore covalently linked to a gold surface by SPR.

SPs were generated on a gold surface with an attenuated total reflection (ATR) method using a Kretschmann–Raether configuration[4] [Fig. 1(*a*)]. The reflectivity was recorded as a function of the incident angle (θ). At the ATR minimum denoted as a SPR angle (θ_R), SPs were created on the opposite side of the gold film. A disulfide derivative of porphyrin **1** was used as a modification reagent to effectively introduce porphyrin chromophores {–S(CH_2)$_{10}$CONH–Por, Por = *p*-[tris(*p*-tolyl)porphyrinyl]phenyl} on the gold surface. The Au–S covalent bond has been confirmed by X-ray photoelectron spectroscopy by one of us (Y. S.).[5] All the measurements were performed at room temperature.

A 15 × 15 × 15 mm BK-7 right-angle prism was rigorously cleaned by ultrapure water, spectroscopic grade methanol, acetone and 1,2-dichloroethane. A 50 nm gold film was evaporated on the hypotenuse face from a 99.9995% Au source at a pressure $< 6 \times 10^{-4}$ Pa, rinsed with spectroscopic grade 1,2-dichloroethane, dried in class-100 air, and used as a control bare film. The θ_R was measured with p-polarized 632.8 nm light

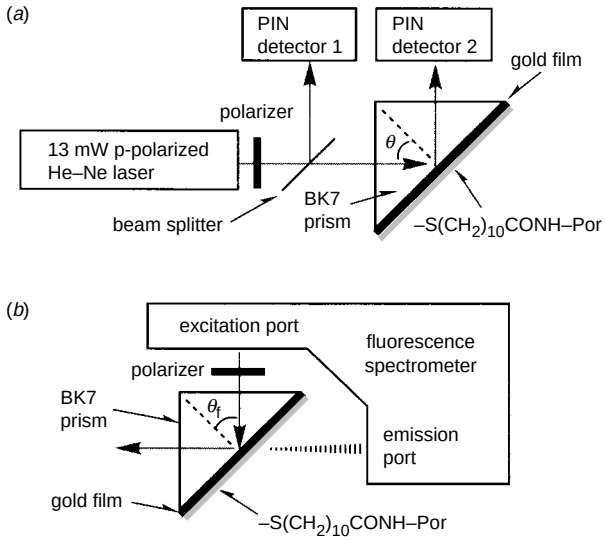

Fig. 1 Experimental configurations of ATR minimum (*a*) and fluorescence (*b*) measurements

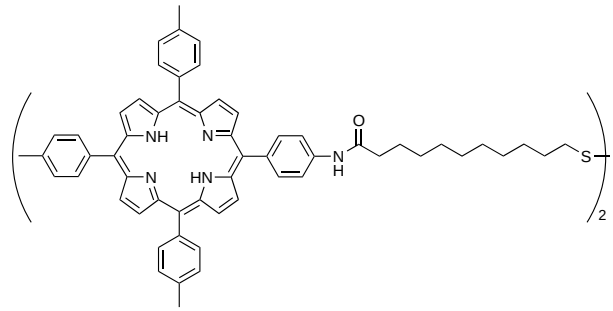

1

from a He–Ne laser. The bare film showed θ_R of 43.6° (Fig. 2) which is consistent with the reported values.[6]

Modification of the gold surface by **1** was performed as follows. The bare film was immersed in a 0.5 mmol dm^{-3} 1,2-dichloroethane solution of **1** for 2 min, washed with a sufficient amount of 1,2-dichloroethane 10 times, and dried in air. After modification, the θ_R shifted to 43.9° (Fig. 2). The shift is attributable to the change in the refractive index for the gold surface covered with –S(CH_2)$_{10}$CONH–Por. The shift required immersion for 2 min for saturation. Therefore, the gold surface was virtually covered with the porphyrin layer after 2 min immersion.

A transmission absorption spectrum of –S(CH_2)$_{10}$CONH–Por was measured using two gold films prepared on BK-7 flat plates as the sample and reference films. The sample film was modified by –S(CH_2)$_{10}$CONH–Por similarly to the prism. As shown in Fig. 3, the difference absorption spectrum showed the characteristic bands of tetraarylporphyrin and is quite similar to that of the film of tetraphenylporphyrin evaporated under vacuum on a glass.[7] Assuming the refractive index of –S(CH_2)$_{10}$CONH–Por film as 1.5, similar to those of usual organic thin films such as protein[6] and poly(methyl methacrylate),[8] the thickness was estimated to be *ca*. 2 nm. This suggests that the –S(CH_2)$_{10}$CONH–Por moiety adopts a linear conformation perpendicular to the gold surface.[9] In other words, the gold

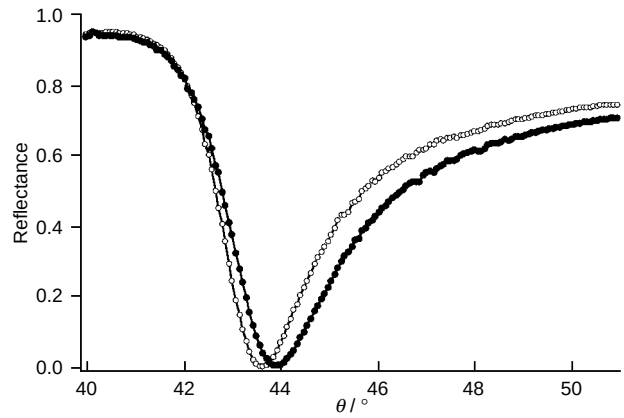

Fig. 2 SPR reflectivity curves for the gold film on a BK-7 right-angle prism (○) and that modified by –S(CH_2)$_{10}$CONH–Por (●)

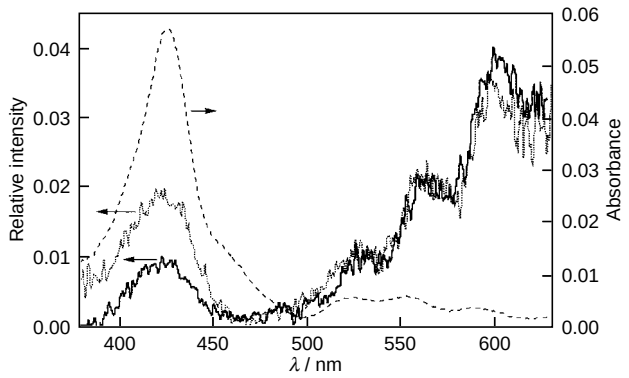

Fig. 3 The excitation spectra of the 655 nm fluorescence band in $-S(CH_2)_{10}CONH-$Por film on a gold surface with the SPR excitation at the incident angles of θ = 45° (—) and 75° (···), and a transmission absorption spectrum of the film (---)

surface is covered with the monolayer of linearly ordered $-S(CH_2)_{10}CONH-$Por.

The electromagnetic field of SP shows a maximum on the surface and decays exponentially into the space along the axis perpendicular to the surface.[8] Since the porphyrin chromophore is bonded to the gold surface at the distance < 2 nm, it can obtain effectively the energy of SP for the electronic excitation. The emission from the gold surface covered with $-S(CH_2)_{10}CONH-$Por was measured using a fluorescence spectrometer, in which the p-polarized visible light illuminated the gold film through a prism at the incident angle (θ_f) of 45° [Fig. 1(*b*)]. The characteristic fluorescence spectrum of tetraarylporphyrin was observed with maxima at 655 and 720 nm, while the fluorescence excitation spectrum using SPR was different from the absorption spectrum (Fig. 3). The intensity ratio between the $Q_x(1,0)$-band and Soret band, I_Q/I_S = 4.0 was significantly larger than that of the absorption spectrum (0.06).†

Because of the dispersion of SP, θ_R varies depending on the wavelength of the incident light. Therefore, we should consider an appropriate θ for the excitation wavelength. The excitation spectrum was measured at θ_f of 75° in order to confirm the θ dependence on the excitation wavelength. The Soret band at θ_f = 75° was certainly increased compared to that at θ_f = 45°, while the I_Q/I_S was still large, 1.8 (Fig. 3).

Since the amplitude of the electromagnetic field of SP exceeds that of the incident field, the evanescent field of SP is expected to enhance inelastic emission such as fluorescence and Raman scattering from molecules adjacent to the metal film.[10] The field enhancement effect of SP is larger in the longer wavelength region. For example, the electric field of SP on the gold surface created by 650 nm light is approximately 50 times larger than that of the incident light.[8] This is consistent with the preferable excitation at the longer wavelength light in the SPR excitation of the $-S(CH_2)_{10}CONH-$Por film.

The fluorescence lifetime with the SPR excitation was measured by a single photon counting method. The obtained decay profile was analysed by two components with 500 ps (65%) and 3.5 ns (35%),‡ both of which were longer than that (310 ps) of a film of tetraphenylporphyrin evaporated under vacuum on Pt surface with the direct photoirradiation.[7] The long lifetimes seem to be due to weak electronic interaction between the porphyrin chromophore and the gold surface through the $-S(CH_2)_{10}CONH-$ group. Recently, a $-S(CH_2)_{10}-$ spacer between a fluorophore and a gold surface has been reported to suppress energy transfer quenching by the gold surface giving high fluorescence yield.[11] Similarly, it is suggested that the $-S(CH_2)_{10}CONH-$ group interrupts the energy transfer from the porphyrin excited state to the gold surface.

The present study demonstrates that SP is an effective and specific excitation source of a porphyrin covalently linked to a gold surface. We are currently studying the effects of the spacer length and the nature of metals upon the fluorescence properties.

† The characteristic fluorescence spectrum was also observed in the direct photoirradiation of the $-S(CH_2)_{10}CONH-$Por film, while the value I_Q/I_S was smaller (0.44) than that in the SPR excitation and larger than that of the absorption spectrum.

‡ Although the fluorescence decay profile showed multi-exponential components, it was analysed by the sum of two components with χ^2 = 1.40. This suggests that the porphyrin chromophores are in different structural and electronic environments.

First innermolecular Diels–Alder reaction of *o*-benzyne inside a molecular container compound

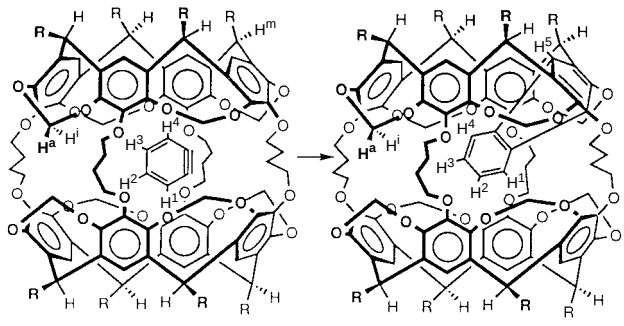
Ralf Warmuth*

Department of Chemistry and Biochemistry, University of California, Los Angeles, CA 90095-1569 USA

1,2-Didehydrobenzene 1, incarcerated in the inner phase of a hemicarcerand 2, undergoes an innermolecular Diels–Alder reaction with its surrounding host, which is a new type of reaction at the borderline between intra- and intermolecular reactions.

Previously, we reported the successful generation of the highly reactive *o*-benzyne **1** in the inner phase of a molecular container compound.[1] The synthesis and application of molecular container compounds was developed by D. J. Cram.[2] They are particularly suitable for the generation and study of highly reactive species, which cannot be isolated under usual conditions in solution.[3] *o*-Benzyne was generated inside hemicarcerand **2**[4] by UV illumination of incarcerated benzocyclopropenone **3** at 77 K in [$^2H_8$]THF. It was stable enough in solution to determine and fully interpret for the first time its solution ^{1}H and ^{13}C NMR spectra.[1] However, the high reactivity of **1**, even at low temperature, led to the inner phase reaction of the incarcerated *o*-benzyne with hemicarcerand **2**. This reaction is the first reported reaction[2c,5] where the guest reacts with the surrounding host shell. Now we report the results of a detailed investigation of this reaction.

Incarcerated *o*-benzyne **2**⊙**1** was prepared photochemically from a solution of **2**⊙**3** in [$^2H_8$]THF at 77 K as described previously.[1] During the warming of the sample to room temperature the incarcerated **1** reacts with the host to form the addition product **4** (> 90%) (Scheme 1).† This new compound **4** was isolated and analysed. The elemental analysis, FT-IR spectrum and the FAB-MS, which shows only a single peak at the expected mass of the benzyne hemicarceplex [M + 1] = 2327, are all consistent with a reaction product of *o*-benzyne with the host **2**. In the ^{1}H NMR spectrum of **4** (Fig. 1) the outward pointing hydrogens H^a of the eight methylene spanners, which are equivalent in **2**⊙**3**,[1] are split into four doublets. Each integrates for two protons. The same is true for the inward pointing methylene protons H^i and the eight methine protons, which give four triplets. The proton signals originating from *o*-benzyne were identified at δ 6.14 (d, 1 H, H^1), 5.21 (t, 1 H, H^2), 4.58 (t, 1 H, H^3) and 3.12 (d, 1 H, H^4). Their relationship was identified by ^{1}H homonuclear shift correlation experiments. The only reaction that is consistent with the observed ^{1}H NMR spectrum is the [4 + 2] Diels–Alder reaction illustrated in Scheme 1.



Scheme 1

o-Benzyne (ene component) adds to one of the aryl ether units of **2** (diene component) to give the geminal *para* adduct **4**. In the ^{13}C NMR spectrum of the $^{13}C_6$ labelled Diels–Alder product, obtained from the addition of ^{13}C labelled *o*-benzyne **5** to **2**,[1] the signals for the six carbons originating from **5** appear at δ 149.20, 142.98, 122.38 (*C*-H^2), 120.85 (*C*-H^3), 119.34 (*C*-H^4) and 117.04 (*C*-H^1). The chemical shifts agree well with the corresponding chemical shifts of benzocyclooctatriene model compounds.[6]

We studied *o*-benzyne and its reactivity in the inner phase of **2** by ^{1}H NMR spectroscopy in the temperature range between −75 and −108 °C in [$^2H_8$]THF. In this temperature range, we noticed an upfield shift of the signal assigned to the protons H^1 and H^4 and a downfield shift of the signal of the protons H^2 and H^3 with increasing temperature [Fig. 2(*a*)]. These shift differences seem to be too large to be just a temperature effect, since the downfield shift of the guest protons of **2**⊙benzene ($\Delta\delta$ 0.033 ppm) is only 8% of the shift of H^1 and H^4. We believe that upon lowering the temperature the two cavitands of **2** are squeezed together more tightly to increase the number of van der Waals contacts. As a consequence, the shape of the inner cavity, which is characterized by the ratio of the length of the polar axis l_{pa} and the equatorial axis l_{ea}, will change, leading to a smaller l_{pa}/l_{ea} ratio at lower temperature [Fig. 2(*b*)].

Due to its shape, *o*-benzyne **1** will be more likely located inside **2** with its C_2 axis parallel to the polar axis of **2** at low temperature [orientation **I** in Fig. 2(*b*)]. This leads to a stronger shielding of H^2 and H^3, which would be located in the polar region of **2**. Upon increasing the temperature, orientation **II** in Fig. 2(*b*) will be more populated, resulting in an enhanced shielding of H^1 and H^4 and a deshielding of H^2 and H^3. Orientation **I** would explain the high tendency of **1** to undergo a reaction with **2** even at very low temperatures, since in this orientation the reactive triple bond of **1** is facing into one of the polar regions of **2**. It would also explain why incarcerated *o*-benzyne does not react with water in the bulk solvent even though H_2O is small enough to pass through the equatorial portals of **2**.

The course of the Diels–Alder reaction was followed by the decrease of the signal assigned to the *o*-benzyne protons H^1 and H^4.[1] At all temperatures we observed first-order kinetics for the reaction of **1** with **2**.

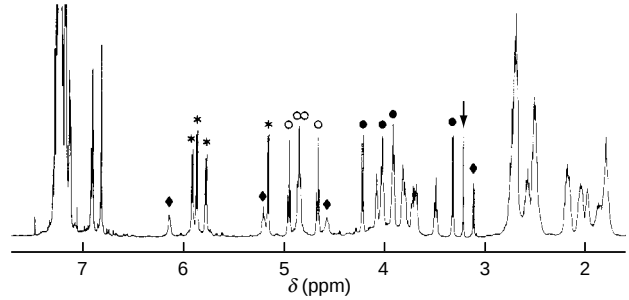


Fig. 1 ^{1}H NMR spectrum (500.113 MHz; $CDCl_3$; 25 °C) of **4**: (*) outward pointing methylene bridge protons, (●) inward pointing methylene bridge protons, (○) methine protons, and (◇) protons originating from *o*-benzyne. Arrow indicates the proton H5.

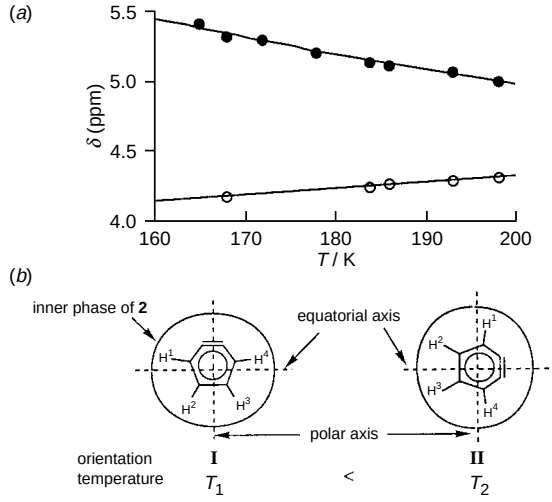

Fig. 2 (*a*) ^{1}H NMR chemical shifts of the *o*-benzyne protons (●) H^1 and H^4 and (○) H^2 and H^3 in [$^2H_8$]THF as function of the temperature. (*b*) Simplified representation of the orientation of **1** in the inner phase of **2** at different temperatures.

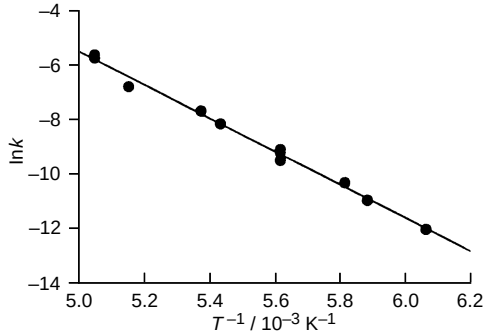

Fig. 3 Arrhenius plot for the reaction of **1** inside **2**

		ΔS‡(298)/ cal mol^{-1} K^{-1}
6		–14.4
7	(*n* = 3)	–22.9
8	(*n* = 4)	–28.0
9	(*n* = 5)	–27.8
10	(*n* = 0):	–6.05

Scheme 2

From an Arrhenius plot (Fig. 3) we determined the activation parameters of this reaction: $\Delta G^{\ddagger}$(298 K) = 14.7 kcal mol^{-1}; $\Delta S^{\ddagger}$(298 K) = −10.7 cal mol^{-1} K^{-1} and $\Delta H^{\ddagger}$(298 K) = 11.6 kcal mol^{-1}, which gives excellent agreement with the calculated $\Delta H^{\ddagger}$ (298 K) = 10.7 kcal mol^{-1} for the addition of *o*-benzyne to benzene.[7] The enthropy of activation $\Delta S^{\ddagger}$(298 K) is a good measure of the degree of preorganization of this reaction. The measured value is much smaller than the $\Delta S^{\ddagger}$(298 K) values of intermolecular Diels–Alder reactions [$\Delta S^{\ddagger}$(298 K) ≈ −40 cal mol^{-1} K^{-1}][8] and of the intramolecular Diels–Alder reactions of trienes **6**–**9**,[9,10] but much larger than the $\Delta S^{\ddagger}$(298 K) value of the Cope rearrangement of hexatriene **10** (Scheme 2).[11]

In the present case *o*-benzyne has the possibility of reacting in two different orientations, of which both differ by a 180° rotation of **1** around its C_2 axis, with eight equivalent aryl ether units of **2** to form **4**. This would favour $\Delta S^{\ddagger}$ by $\Delta\Delta S^{\ddagger}$ = Rln 16 = 5.51 cal mol^{-1} K^{-1}. Subtracting $\Delta\Delta S^{\ddagger}$ from the measured $\Delta S^{\ddagger}$ gives −16.2 cal mol^{-1} K^{-1}, which is between the $\Delta S^{\ddagger}$ values of the intramolecular Diels–Alder reactions of **6** and **7**.

According to the kinetic parameters, we place the Diels–Alder reaction of **1** with **2** in the category of intramolecular Diels–Alder reactions. Like intramolecular reactions, the reaction of **1** and **2** shows first-order reaction behaviour. However, both reaction partners, **1** and **2**, are not covalently connected but are held together by incarceration. They are separate, individual species, free to rotate in all dimensions. Hence, in this specific case we observed for the first time a bimolecular reaction which, contrary to bimolecular reactions in solution or in the gas phase, obeys first order kinetics. Reactions of this type are only possible if one reactant A is completely encapsulated inside the closed surface of inner phase[3,12] of the second reaction component B and is retained inside B by constrictive binding.[13] Therefore, we would like to introduce the name *innermolecular* reaction for this new type of reaction, which is an intermolecular reaction with a rate law of an intramolecular reaction and which is limited to the *inner phase* of molecular container compounds.[14] Since the inner phase of reactant B is the reaction medium, the course of an innermolecular reaction is expected to be independent of the bulk phase, which might be the solid, the liquid or the gas phase.[3]

The author extends special thanks to Professor D. J. Cram in whose research group this work was conducted. We are very grateful for his many helpful, critical and stimulating discussions. Furthermore, we thank Professor K. N. Houk, Dr R. C. Helgeson and Dr C. Sheu for helpful discussions and the Alexander von Humboldt Foundation for a Feodor-Lynen fellowship. We warmly thank the U.S. Public Health Service for supporting grant GM-12640 (D. J. Cram, principal investigator).

New hydrogenation and isomerization reactions involving thiaplatinacycles derived from benzothiophene

Alexei Iretskii,[a] Harry Adams,[a] Juventino J. Garcia,[b] Graciela Picazo[b] and Peter M. Maitlis[a]

[a] *Department of Chemistry, The University of Sheffield, Sheffield, UK S3 7HF*
[b] *Facultad de Química, Universidad Nacional Autónoma de México, 04510 México D.F.*

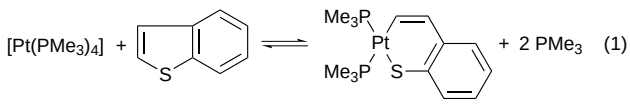
Hydrogenation of the thiaplatinacycle [Pt{*C*,*S*-(CH=CHC$_6$H$_4$S)}(dppe)] 2 (dppe = Ph$_2$PCH$_2$CH$_2$PPh$_2$) derived from benzothiophene, leads to [Pt{*C*,*S*-(CHMeC$_6$H$_4$S)}(dppe)] 3 in which 2H have added and a H-shift has occurred; the X-ray structures of 2 and 3 are reported.

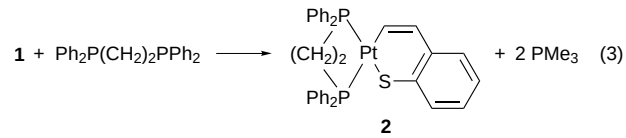
Thiophenes (T), benzothiophenes (BT), dibenzothiophenes (DBT), and their alkyl derivatives pose particular problems for hydrodesulfurization (HDS) as they occur in substantial amounts, notably in the heavier crude oils, and are rather resistant to normal HDS catalysts such as Co–Mo–S on alumina.[1] Quite recently platinum has emerged as a viable catalyst for second stage industrial hydrotreating;[2] this has allowed the production of the so-called city diesel fuel, with a very low sulfur content (⩽30 ppm).

In our researches to model such HDS reactions we have found that the platinum(0) complex [Pt(PEt$_3$)$_3$] can reversibly oxidatively insert into the C–S bonds of T, BT or DBT, giving six-membered thiaplatinacycles.[3–5] These thiaplatinacycles extrude S and Pt on reaction with sources of hydride to give hydrocarbons, thus demonstrating a full HDS sequence mediated by platinum.

Related thiametallacycles are formed by the oxidative insertion of other metals (*e.g.* Rh and Ir[6]) into the thiophene; those derived from BT generally react with hydrogen to give 2-ethylthiophenol (or a salt thereof)[7] or 2,3-dihydrobenzothiophene,[8] though ethylbenzene can be obtained under forcing conditions.[9] We have now isolated and characterised a novel isomerisation product from partial hydrogenation of a thiaplatinacycle derived from BT, which indicates that the HDS cycle may be more complex than previously proposed.

The trimethylphosphine complex **1**† was synthesised either from reaction of BT with pure [Pt(PMe$_3$)$_4$] in refluxing toluene [eqn. (1); 83%] or, more conveniently [eqn. (2); 69%] by a one-pot reaction of K$_2$PtCl$_4$, NaOH, and trimethylphosphine, forming [Pt(PMe$_3$)$_4$] *in situ*, to which BT was then added. Reaction of **1** with a small excess of dppe (Ph$_2$PCH$_2$CH$_2$PPh$_2$) gave complex **2** [eqn. (3); 89%].





The complexes were characterised by microanalysis, NMR spectra and an X-ray structure determination for **2**.‡ This showed the expected arrangement (Fig. 1) and was very similar to the structure already determined for [Pt{*C*,*S*-(CH=CHC$_6$H$_4$S)}(PEt$_3$)$_2$].[3] Complex **2** was hydrodesulfurised by reaction with LiAlH$_4$ in toluene–thf to give ethylbenzene (42%). Similar results but poorer yields were obtained for complex **1** and for [Pt{*C*,*S*-(CH=CHC$_6$H$_4$S)}(dppp)].

Complex **2** could also be hydrogenated (toluene solution, 120 °C, 20 atm H$_2$) directly to give a mixture of ethylbenzene (6%) and free BT (12%). The low yield of HDS product under these conditions is explained by the additional formation of a new platinum complex (in 74% yield). FABMS showed it to have a molecular ion at *m*/*z* 730 corresponding to [Pt(C$_8$H$_8$S(dppe)], indicating that 2 H have added to **2**. The new complex was identified as **3**§ by an X-ray determination which showed that the S-ligand did not have the expected saturated six-membered thiaplatinacycle structure; instead a ring contraction had occurred and the product had a methyl attached to CH in a five-membered thiaplatinacycle (Fig. 2).

The structure for **3** indicates that a hydrogen shift has occurred in addition to the hydrogenation so that the benzylic carbon is now attached to the metal. This also has structural consequences: the benzothiaplatinacycle in complex **2** is very nearly planar with a dihedral angle of only 3.2° between the plane C(1)–Pt–S and the best plane through S–C(8)···C(2)–C(1). By contrast, and as a consequence of the presence of the sp^3 carbon at C(1) the thiaplatinacycle in complex **3** is much more bent, with a dihedral angle of 27.8° between the planes C(1)–Pt–S and C(1)–C(2)–C(3).

The difference in the structures is also manifested in their reactions with HCl. Complex **3** was degraded to give

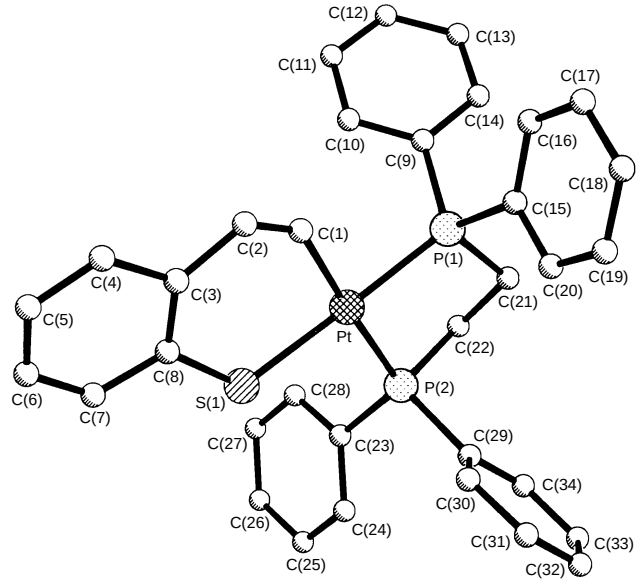


Fig. 1 The molecular structure determined for **2**. Bond lengths (Å) and angles (°): Pt–P(1) 2.2474(13), Pt–P(2) 2.2969(14), Pt–S 2.260(2), Pt–C(1) 2.054(4); C(1)–Pt–P(1) 93.1(2), P(1)–Pt–P(2) 85.20(5), C(1)–Pt–S 88.4(2), P(2)–Pt–S 93.40(5)°.

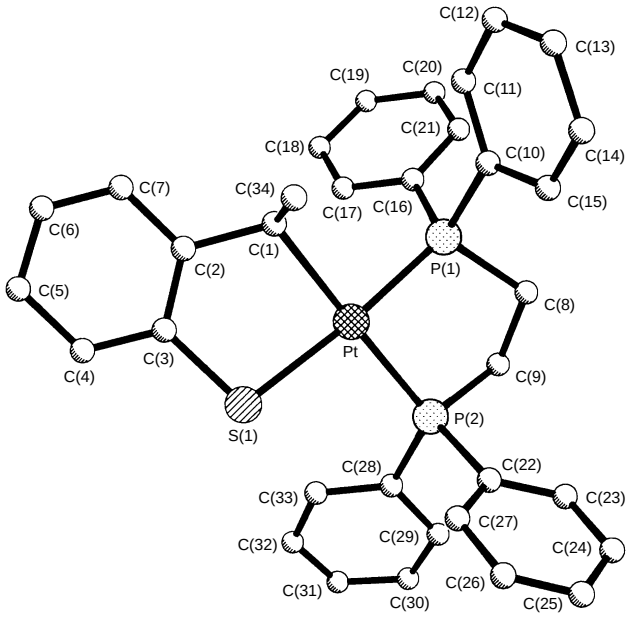

Fig. 2 The molecular structure determined for **3**. Bond lengths (Å) and angles (°): Pt–P(1) 2.232(4), Pt–P(2) 2.313(4), Pt–S 2.328(4), Pt–C(1) 2.202(14), Pt–C(34) 3.05 Å; C(1)–Pt–P(1) 93.3(4), P(1)–Pt–P(2) 85.49(13), C(1)–Pt–S, 82.7(4), P(2)–Pt–S 98.60(13)°.

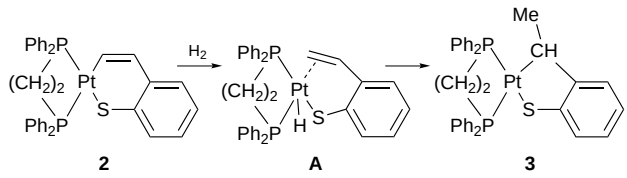

Scheme 1

2-ethylthiophenol, while the six-membered thiaplatinacycles [Pt{*C*,*S*-(CH=CHC$_6$H$_4$S)}(PEt$_3$)$_2$] and **2** gave 2-vinylthiophenol.[4]

One attractive mechanism by which the reaction **2** → **3** can occur is *via* a σ-*S* bonded π-alkene (η^3) intermediate (**A**), as shown in Scheme 1. Such species have been previously invoked in the reactions of various thiophenes with metal hydrides; a related iridium complex derived from thiophene itself has been isolated and characterised as [(triphos)Ir(η^3-S(Me)CH=CHCH=CH$_2$)]$^+$ [triphos = MeC(CH$_2$PPh$_2$)$_3$], and this shows equivalent bonding of the iridium to both the CH [2.19(3) Å] and to the CH$_2$ [2.12(3) Å].[10] That complex **3** does not have a type **A** structure is shown by the Pt···Me distance [Pt···C(34)] of 3.05 Å, which is well outside bonding; by contrast the distance Pt–C(1) is 2.202(14) Å.

Complex **3** can be hydrodesulfurised to ethylbenzene (*ca.* 80%) with LiAlH$_4$ (thf, 20 °C); this demonstrates a new HDS pathway, BT → **2** → **3** → PhEt.

We thank the EPSRC, the Royal Society, EERO, the European Community (Contract CL1*CT94-0062) and CONACYT for support and Professor W. Clegg for collecting the data for complex **2**.

Self-assembling tetranuclear copper(II) complex of a bis-bidentate Schiff base: double-helical structure induced by aromatic π··π and CH··π interactions

Noboru Yoshida,*[a] Hiroki Oshio[b] and Tasuku Ito[b]

[a] *Laboratory of Molecular Functional Chemistry, Division of Material Science, Graduate School of Environmental Earth Science, Hokkaido University, Sapporo 060, Japan*
[b] *Department of Chemistry, Graduate School of Science, Tohoku University, Sendai 980-77, Japan*

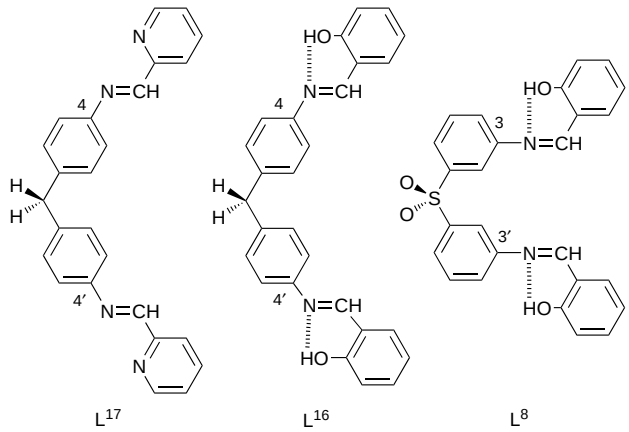
The synthesis and structure of a tetranuclear copper(II) complex of a bis-N,O-bidentate Schiff base is reported; two types of copper(II) centers and the preference for two conformational degrees of freedom in the ligand lead to the unique formation of a novel supramolecular architecture not requiring a preorganized synthetic approach.

Self-assembly and molecular recognition appear to be essential factors for the construction of supramolecular architectures utilizing the formation of non-covalent bonds in solution.[1] The use of metal ions with specific preferences for particular coordination geometries has been developed rapidly in order to produce non-covalently organized structures, resulting in self-assembly of target ligands.[2] Many types of oligopyridines have been used because of their preorganized characteristics in self-assembling processes.[3]

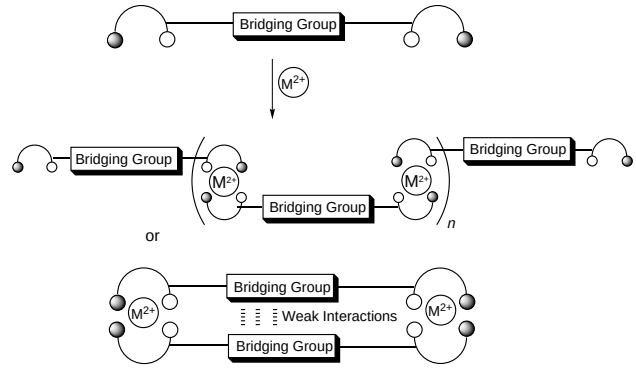
Recently, new ligand systems have been exploited to construct unprecedented structures formed by self-assembling processes in solution and in the solid phase.[4,5] The requirement of the supramolecular structure is principally controlled by the appropriate combination of various types of weak non-covalent interactions and the geometrical preference of the metal ion. Our recent investigation using bis-bidentate Schiff base ligands (Scheme 1) allows for the synthesis of a variety of metal-assisted supramolecular structures. A dinuclear triple-helical Zn^{II} complex of L^{17},[5] a dinuclear double-helical Cu^{II} complex of L^{16},[6] and polynuclear Zn^{II} complexes of L^{16},[5] have been synthesized.

Here we describe a novel and general strategy for the construction of metal-assisted supramolecular architectures using ligand L^8. This architecture is prepared readily utilizing the weak aromatic π··π and CH··π interactions operating between the bridging groups of the bis-bidentate Schiff bases (Scheme 2).

The Schiff base ligand L^8 contains two N,O-bidentate chelating moieties linked *via* the azomethine groups with bis(3-aminophenyl)sulfone (Scheme 1). Reaction of L^8 with $Cu(MeCO_2)_2 \cdot H_2O$ in a 1 : 1 molar ratio in hot ethanol (*ca.* 60–70 °C) afforded a light-green solid **1**.† Elemental analysis suggests the formation of a Cu^{II} : L^8 2 : 2 complex and fast-atom bombardment mass spectroscopy (FABMS) also indicated a 2 : 2 complex for **1**.‡ However, positive-ion electrospray MS (*m*/*z* 2073.5) suggested the existence of a 4 : 4 complex for **1**. The electronic absorption spectrum of **1** shows a π–π* band at 379.5



Scheme 1



Scheme 2

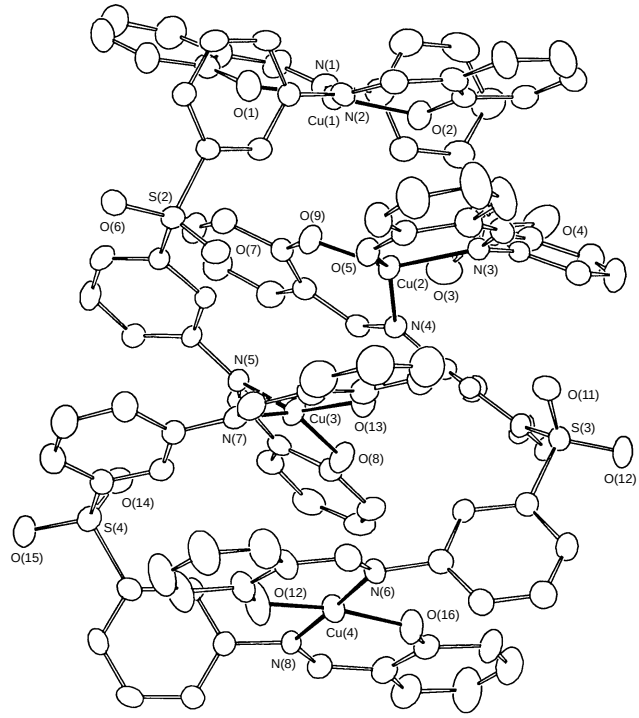


Fig. 1 Crystal structure of $[Cu(H_{-1}L^8)]_4$ **1**

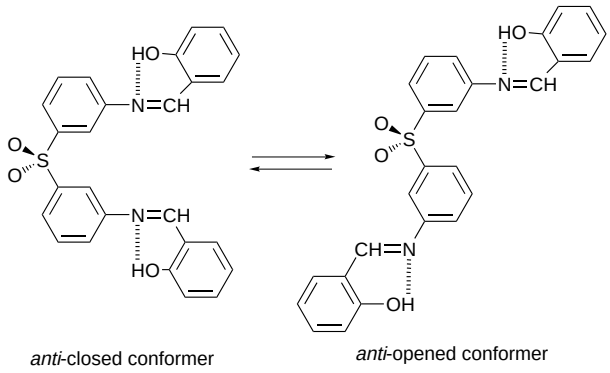

Fig. 2 Two main conformers of L^8

nm in the visible region which indicates deprotonation of the OH groups and N,O-coordination of Cu^{II}.[7]

Single crystals were obtained from chloroform–diethyl ether. An X-ray diffraction study confirms the formation of the $Cu^{II}:L^8$ 4:4 structure as shown in Fig. 1.§ The tetranuclear double helical structure appears to be stabilized by CH–π and π–π aromatic interactions (3.2–3.9 Å) between the bridging groups ($–C_6H_4SO_2C_6H_4–$). Complex **1** contains four Cu^{II} ions and four ligands. Two Cu^{II} ions at the top [Cu(1)] and bottom [Cu(4)] of the tetranuclear $(CuL^8)_4$ core adopt a square-planar (*SP*) coordination geometry, whereas the two remaining Cu^{II} ions [Cu(2), Cu(3)] in the middle adopt a tetrahedral (T_d) coordination geometry. Each Cu^{II} ion is coordinated by N,O-bidentate sites originating from two different ligands. Each ligand interacts with two Cu^{II} ions with a different coordination geometry. Furthermore, two types of conformations of L^8 are observed in this tetranuclear core (Fig. 2). The conformations of $L^8(1)$ and $L^8(4)$ are *anti*-closed (E_{steric} = −27.58 kcal mol^{-1}, 1 cal = 4.184 J) (Fig. 2), whereas the conformations of $L^8(2)$ and $L^8(3)$ are similar and *anti*-opened (E_{steric} = −27.16 kcal mol^{-1}).¶

Fig. 3 shows selected bond lengths and angles around the four Cu^{II} centers of the tetranuclear core of **1**. The Cu–N distances lie between 1.968(6)–2.024(6) Å and Cu–O is in the range 1.858(6)–1.903(5) Å. Angles O–Cu(1)–O, N–Cu(1)–N N–Cu(1)–O [O–Cu(4)–O, N–Cu(4)–N, N–Cu(4)–O] are in the range 174.9(2), 171.4(2), 88.1(2)–91.4(2)° [170.4(3), 177.6(2), 88.6(2)–91.8°], respectively. Thus, the coordination geometries around Cu(1) and Cu(4) are almost square-planar. On the other hand, O–Cu(2)–O, N–Cu(2)–N, N–Cu(2)–O [O–Cu(3)–O, N–Cu(3)–N, N–Cu(3)–O] angles are 89.6(2), 99.2(2), 147.2(2)–148.8(2)° [89.2(2), 100.1(2), 144.6(2)–148.7(2)°] which show a distorted tetrahedral geometry around Cu(2) and Cu(3). Four Cu^{II} ions having different coordination spheres lie almost in one plane and in a rhombus arrangement with Cu···Cu

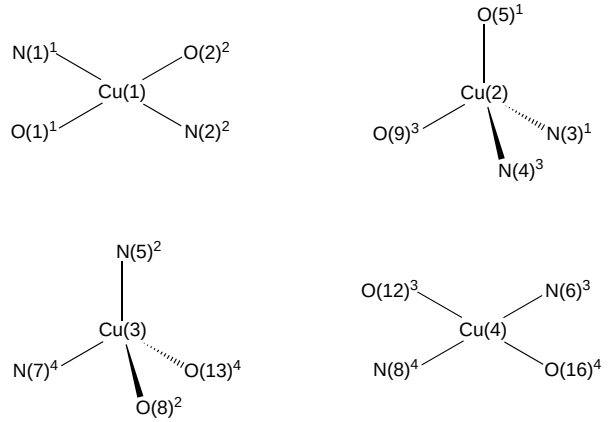

Fig. 3 Coordination geometries around the four Cu^{II} ions of **1**

distances between 4.043 and 7.659 Å. The sum of the interior angles is 353.26°. Other metal complexes with Zn^{II}, Ni^{II} and Co^{II} which are insoluble in most organic solvents appear to form $(1:1)_n$ polymeric structures (Scheme 2).

Flexible geometry of Cu^{II} (*SP* or T_d) and the flexible conformational freedom in the ligand lead to CH–π and π–π aromatic interactions between the bridging groups and the tetranulear double-helical structure. These conformational preferences in the ligand and metal-coordination geometry are an unusual example in metallosupramolecular chemistry. The subtle change in the bridging group leads to an unprecedented organized structure in the absence of a preorganized synthetic approach. The development of new ligand systems using Schiff base series is now in progress.

† 3,3′-Diaminosulfone (0.5 mol) was added gradually to an EtOH solution (100 ml) of salicylaldehyde (1 mol) and the solution was stirred for 30 min at 60 °C and the orange solid precipitate was collected by filtration. Elemental analysis was in accord for L^8. A mixture of L^8 (0.78 g, 1.72 mmol) and $Cu^{II}(MeCO_2)_2·H_2O$ (0.34 g, 1.7 mmol) was dissolved in EtOH (100 ml) and heated and the resulting green powder was collected by filtration and washed with hot EtOH. This powder dissolves readily in DMF and $CHCl_3$. X-Ray quality crystals were grown by slow diffusion of Et_2O into a $CHCl_3$ solution of **1**. Satisfactory elemental analysis was obtained.

‡ MM2 force-field calculations also suggested the possibility for the existence of $Cu^{II}:L^8$ 2:2 complexes, the minimum-energy self-assembling structures, **2** (SP–SP for two Cu^{II}) and **3** (T_d–T_d coordination geometry). The force-field structure **3** (E_{steric} = −32.212 kcal mol^{-1}) is considerably more stable than that of **2** (E_{steric} = 8.662 kcal mol^{-1}); Tektronix CAChe System, (Version 3.7).

§ *Crystal data* for **1**: $C_{104}H_{72}Cu_4N_8O_{16}S_4$, 0.50 × 0.30 × 0.25 mm, M = 2072.18, brown prismatic crystal, monoclinic, space group $P2_1/c$, a = 18.026(2), b = 23.450(3), c = 22.743(2) Å, β = 90.299(9)°, U = 9613(1) Å^3, Z = 4, D_c = 1.432 g cm^{-3}, μ(Mo-Kα) = 9.64 cm^{-1}, $F(000)$ = 4240. 17 487 data collected at −100 °C on a Rigaku AFC 7S four circle diffractometer equipped with graphite monochromated Mo-Kα radiation (λ = 0.710 73 Å). The structure was solved by direct methods with SHELX-86 (G. M. Sheldrick, University of Göttingen, 1986) and Fourier techniques, and refined by full-matrix least-squares on F^2 data using SHELXL-93 (G. M. Sheldrick, University of Göttingen, 1993). and converged at R_1 = 0.0667, wR_2 = 0.1652. CCDC 182/663.

¶ Although L^8 can adopt many conformations, molecular mechanics (MM2) calculations revealed the four minimum-energy structures as *anti*-closed and *anti*-opened conformers. These two isomers have almost the same energy. Other minimum-energy structures, *syn*-opened (E_{steric} = −27.4973 kcal mol^{-1}) and *syn*-closed (E_{steric} = −28.820 kcal mol^{-1}) conformers have similar energy.

Three step syntheses of naphthofurans and phenanthrofurans related to (−)-morphine from *ortho*-benzoquinone monoketals by Diels–Alder and Cope reactions

Rina Carlini, Kerianne Higgs, Russell Rodrigo* and Nicholas Taylor

Guelph-Waterloo Centre for Graduate Work in Chemistry, Department of Chemistry, University of Waterloo, Waterloo, Ontario, Canada N2L 3G1

Adducts of the intramolecular Diels–Alder reaction of *o*-benzoquinone monoketals are rapidly converted to oxygen heterocycles *via* Cope rearrangements.

The considerable synthetic potential of *ortho*-benzoquinonoid monoketals remains largely unexploited despite a few noteworthy applications[1] in natural product synthesis. Our laboratory has recently embarked on a program to study the inter-[2] and intra-molecular Diels–Alder (IMDA) reactions[3] of such intermediates and to evaluate the synthetic utility of the resulting adducts. We recently reported[3] the Cope rearrangement of one adduct and its use in a brief and efficient synthesis of the pentacyclic marine sponge metabolite (±)-Xestoquinone. The success of this two step IMDA–Cope sequence has prompted us to explore the Cope rearrangements of several additional bridged IMDA adducts to demonstrate their generality and illustrate their value with a convergent three-step route to a 3-hydroxy-9c-allylphenanthro[4,5-*bcd*]furan **14b** constituting rings A, B, C and E of morphine.[4]

Each of four substituted guaiacols **1a**–**d** were treated with a minimum of 5 equiv. of (*E*)-penta-2,4-dienol in the presence of bis(trifluoroacetoxy)iodobenzene (BTIB), to provide the mixed monoketals **2** that reacted *in situ* to generate the IMDA adducts **3** and **4** in combined yields of 53–88% (Table 1 and Scheme 1). After separation of the adducts, thermal Cope rearrangements of the bridged compounds **3a**–**f** were effected (Table 2).[5] Several naphtho[1,8-*bc*]furan tricycles **4a**, **b**, **e**, **f**, all *endo*† isomers and bearing a carbon substituent (R^3) at a ring junction, are thus obtainable in two steps from simple starting materials. Bridged adduct **3e** generated the naphthofuran **7e** upon heating in aromatic hydrocarbon solvents (entries 8 and 9). This is presumably the result of a facile dienone–phenol rearrangement of intermediate **5e**. We have observed that thiol esters like **5e** are particularly prone to such migrations. Acid-catalysed elimination of MeOH (using TFA) from **4f**, and subsequent alkaline hydrolysis of the ester, produced the phenol **7** (R^1 = R^3 = H) after spontaneous decarboxylation (90%).‡

The tetracyclic phenanthrofuran system is also readily accessible by application of the same chemistry. The reaction of methyl vanillate **1f** with 3 equiv. of 3-vinylcyclohex-2-enol[6] **9a** produced a mixture of *exo* (**10a**) and *endo* (**11a**) IMDA adducts, together with a small amount of the bridged adduct **12a** (Scheme 2). X-Ray crystal structures§ of **10a** and **11a** were obtained to establish their structure and relative configurations.

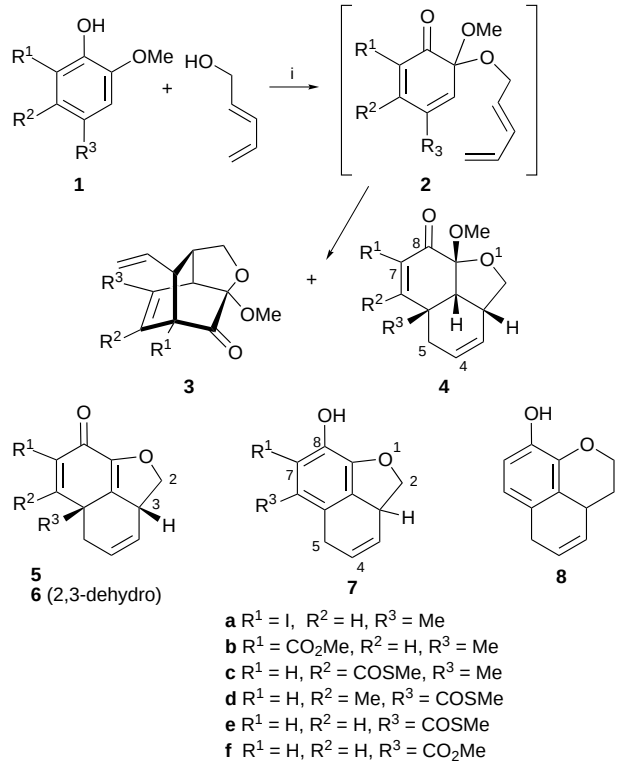
Table 1 Diels–Alder reactions of guaiacols **1** with (*E*)-penta-2,4-dienol

Substituted guaiacol[a]	Products (% yield)
1a	**3a** (72), **4a** (16)
1b	**3b** (65), **4b** (13)
1c	**3c** (65), **4c** (7)
1d	**3d** (52), **4d** (1)

[a] For three more examples, see ref. 3.

The *endo* isomer (**11a**) was easily aromatized in two steps: brief treatment with TFA to eliminate MeOH produced the dienone **13a** (92%), and saponification of the ester resulted in spontaneous decarboxylation and aromatization to **14a** (90%). The ketal moiety of the *exo* isomer (**10a**) was remarkably stable to prolonged acid treatment at room temperature.

It is generally acknowledged that acid hydrolysis of an acetal is promoted by the presence of at least one non-bonded electron pair on the endocyclic oxygen atom in an antiperiplanar relationship with the exocyclic carbon–oxygen bond that is being cleaved in the reaction.[7] Furthermore, the relationship between C–O bond lengths and O–C–O angles of acetals in the ground state and the ease of acid-catalysed hydrolysis has been convincingly demonstrated.[8,9] The relevant bond lengths and angles of **10a** and **11a** are shown in Table 3, together with projections along the O(4)–C(3a) bond derived from the X-ray structures (Fig. 1), with the non-bonding sp^3 orbitals of O(4) added in approximately tetrahedral orientations. These projections clearly show that the stereoelectronic requirements for the acid-catalysed elimination of MeOH can only be met in the *endo*-adduct **11a**, and this is reflected in the corresponding changes in bond lengths of C(3a)–OMe (longer) and C(3a)–O(4) (shorter), exactly opposite to the situation in the *exo*-

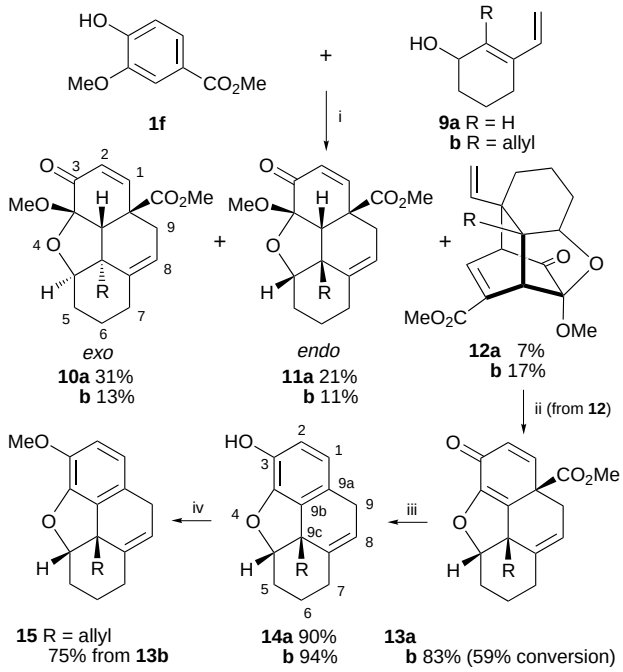


Scheme 1 *Reagents and conditions*: i, BTIB, THF, 0 °C

Table 2 Thermal Cope rearrangements of bridged IMDA adducts **3** in various solvents

Entry	Reactant	Solvent[a] (% conversion)	Products (% yield)
1	**3a**	TMB[a] (100)	**4a** (38)[b]
2	**3a**	Decane[c] (100)	**6a** (50)
3	**3a**	TCE[a] (61)	**6a** (70)
4	**3b**	TCE[c] (100)	**4b** (10), **6b** (32)
5	**3c**	Decane[c] (72)	**6c** (25)
6	**3d**	Decane	Decomposition product
7	**3e**[d]	Decane (84)	**4e** (81)
8	**3e**[d]	*p*-Xylene (100)	**4e** (6), **7e** (28)
9	**3e**[d]	TMB (100)	**7e** (42)
10	**3f**[d]	TMB (100)	**4f** (46), **5f** (20)
11	**3f**[d]	*p*-Xylene (93)	**4f** (21), **5f** (44)

[a] TMB = 1,2,4-trimethylbenzene; TCE = 1,1,2,2-tetrachloroethane. [b] Iodine was also produced. [c] Some thermal rearrangements performed in decane and TCE resulted in significant decomposition. [d] For the preparation of **3e** and **3f**, see ref. 3.



Scheme 2 *Reagents and conditions*: i, BTIB; ii, $Cl_2CHCHCl_2$, heat; iii, NaOH, MeOH; iv, K_2CO_3, Me_2SO_4, acetone

Table 3 Bond lengths and angles at the C(3a) ketal carbon atom of **10a** and **11a**

	Bond length/Å		
	C(3a)–O(4)	C(3a)–OMe	Bond angle (°) O(4)–C(3a)–OMe
10a (*exo*)	1.422	1.401	109.1
11a (*endo*)	1.407	1.416	111.6

adduct **10a**. The reluctance of the latter adduct to undergo the elimination can thus be understood.

The 2-allylcyclohexenol **9b**, prepared from 2-allylcyclohexane-1,3-dione[10] in a similar manner to **9a**, reacted with methyl vanillate **1f** to provide a mixture of three adducts **10b**, **11b** and **12b** (Scheme 2). Again, the *exo*-adduct **10b** was stable to acid while the *endo*-isomer **11b** was converted to dienone **13b** by brief exposure to TFA. When the bridged adduct **12b** was subjected to the thermal Cope rearrangement in refluxing 1,1,2,2-tetrachloroethane, elimination of MeOH also occurred

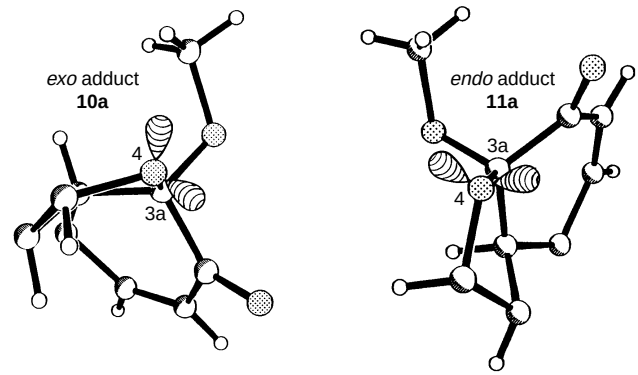


Fig. 1 Projections along the C(3a)–O(4) bonds adapted from X-ray structures of **10a** and **11a**

to produce **13b** (83% yield, 59% conversion), which was saponified as before to produce **14b** (94%).

Reduction of 2-allyl-3-vinylcyclohex-2-enone with borane and 20 mol% of the (*R*)-oxazaborolidine[11] provided the (*S*)-(−)-cyclohexenol **9b** in 84% yield and 88% ee.¶ Repetition of the same sequence of reactions with (−)-**9b** afforded **15**, the methyl ether of phenol **14b** in 75% yield (88% ee) from **13b**. Further progress in the conversion of **14b** or **15** to a morphinan[12] will be reported in due course.‖

We thank the Natural Sciences and Engineering Research Council of Canada for support of this work.

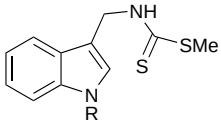
Strategies of fungal pathogens: detoxification of a cruciferous phytoalexin by mimicry

M. Soledade C. Pedras* and Francis I. Okanga

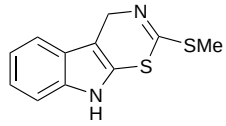
Department of Chemistry, University of Saskatchewan, 110 Science Place, Saskatoon SK, Canada S7N 5C9

Two different isolates of the phytopathogen *Phoma lingam* metabolized and phytoalexin cyclobrassinin 3 to the phytoalexins dioxibrassinin 5 and brassilexin 9; both 5 and 9 were further metabolized and detoxified by each fungal isolate.

Phytoalexins[1] are part of the induced chemical defenses produced by plants in response to several forms of stress, including fungal attack. In spite of the enormous interest in phytoalexins, cruciferous[2] phytoalexins may have further significance due to their unique chemical structures and additional biological activity.[3] Brassinin **1**, methoxybrassinin **2**



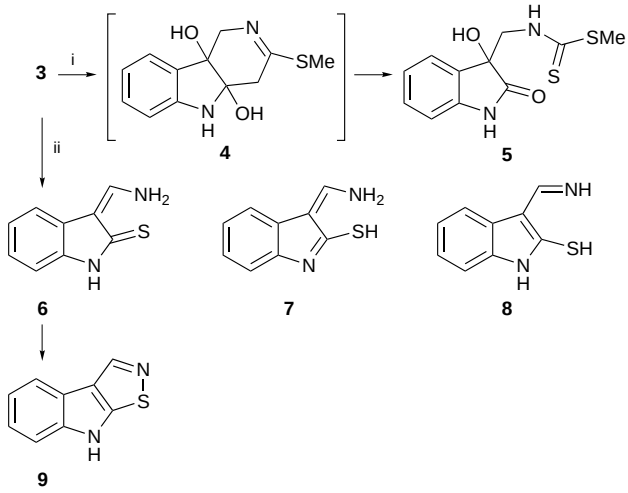
1 R = H
2 R = OMe



3

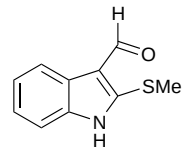
and cyclobrassinin **3** were the first reported[4] sulfur-containing phytoalexins produced by crucifers, a plant family with high sulfur requirements.[5] In general, the timing, rate of accumulation and relative amounts of phytoalexins synthesized in leaf tissues play crucial roles in plant resistance to pathogen invasion.[6] However, when pathogenic fungi can effectively disarm the plant by detoxifying phytoalexins, the outcome of the interaction can favour the pathogen and be detrimental to the plant. Although to date only a few examples demonstrate that brassica pathogens can detoxify phytoalexins efficiently,[2] multiple examples exist in other plant species.[7] We have demonstrated previously that the blackleg fungus [*Phoma lingam* (Tode ex Fr.) Desm., perfect stage *Leptosphaeria maculans* (Desm.) Ces. et de Not.], one of the most destructive pathogens of rapeseed (*Brassica napus, B. rapa*) can overcome the plant's chemical defenses by promptly transforming brassinin **1** into non-toxic indole-3-carboxylic acid.[8] Here we describe the unprecedented biotransformation of the brassica phytoalexin cyclobrassinin **3** to the phytoalexins dioxibrassinin **5** and brassilexin **9**, by the 'virulent' and 'avirulent' isolates of *P. lingam*,[9] respectively.

In initial experiments, cyclobrassinin **3**[10] was incubated with the so-called 'avirulent' isolate Unity† to establish a time-course transformation profile.[11] Analysis of organic extracts of culture samples by HPLC‡ indicated a rapid decrease in the concentration of **3** (HPLC retention time, t_r = 24.5 min) and the concurrent appearance of two additional constituents (t_r = 7.2 and 12.1 min) over a 12 h period. Subsequently, to obtain sufficient quantities of each constituent, larger-scale fungal cultures incubated with cyclobrassinin **3** were extracted with Et_2O, the extract fractionated by chromatography§ and each fraction analysed by HPLC. The fractions containing the aforementioned new constituents were analysed by standard spectroscopic methods (NMR, HRMS, FTIR, UV) for structural elucidation. Based on these results the constituent of t_r = 12.1 min was established to be the known phytoalexin brassilexin **9**,¶ whose structure we confirmed by synthesis.[2] The structure of the constituent of t_r = 7.2 min, a relatively less-stable metabolite, was assigned as a mixture of the related tautomers

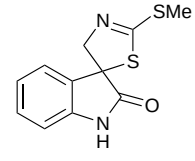


Scheme 1

3-methylenaminoindole-2-thione **6**, 3-methylenaminoindole-2-thiol **7** and 3-(methylimino)indole-2-thiol **8**, based on spectroscopic data‖ and derivatization. Two days after incubation of the isolate Unity with cyclobrassinin, no brassilexin or other phytoalexins or putative metabolites were detected in any of the cultures or their extracts. The mycelial mass of cultures incubated with cyclobrassinin **3** was similar to that of control cultures. Similar experiments carried out with the 'virulent' isolate BJ-125† incubated with cyclobrassinin **3** for 12 h afforded yet another known phytoalexin, dioxibrassinin **5**[12] (t_r = 7.5 min), whose chemical structure we confirmed by synthesis. Two days after incubation of the virulent isolate BJ-125 with cyclobrassinin **3**, no phytoalexins or derivatives were detected in any of the cultures or their extracts. In addition, the mycelial mass of cultures incubated with cyclobrassinin **3** was similar to that of control cultures. These remarkable results indicate that cyclobrassinin **3** is detoxified *via* the phytoalexins brassilexin **9** or dioxibrassinin **5**, depending on the particular fungal species, as shown in Scheme 1. The reactive intermediate **4**, similar to that proposed for the biosynthesis of a brassica phytoalexin,[12] could explain the formation of **5** through enzymatic dioxygenation of **3**. Additional experiments with other fungal isolates incubated with cyclobrassinin indicated similar results within the same species. It is worthy to note that cyclobrassinin **3** has been proposed as an *in planta* biosynthetic precursor of both brassilexin **9**[13] and brassicanal A **10**.[14]



10



11

However, *in planta*, biosynthetic relationships have only been established between brassinin **1** and cyclobrassinin **3** and brassinin **1** and spirobrassinin **11**.[12,15]

Our results suggest that two different fungal species, the so-called 'virulent' and 'avirulent' groups,† can metabolize the phytoalexin cyclobrassinin **3** 'mimicking' pathways that may operate in the plant (*i.e.* **3** to **5** and **3** to **9**, respectively).** Considering that fungal pathogens have been coevolving with plants for multiple generations, the detoxification of phytoalexins by 'mimicry' appears quite plausible. Nonetheless, because *in planta* only a part of the biosynthetic pathway of cruciferous phytoalexins has been established, such a hypothesis remains to be demonstrated. A clearer picture will eventually unfold upon tracing a complete map of phytoalexin transformation in both cruciferous plants and their pathogenic fungi.

We gratefully acknowledge the financial support of the Natural Sciences and Engineering Research Council of Canada and the University of Saskatchewan.

† The fungal species *Phoma lingam* is subdivided in various groups (see for example ref. 9); the so-called 'avirulent' group (*e.g.* isolate Unity) is now considered a species different from that of the 'virulent' group (*e.g.* BJ-125), although no formal reclassification has been done. General procedures for fungal culturing and analyses were carried out as described in ref. 11.

‡ HPLC analysis was performed with a liquid chromatograph equipped with quaternary pump, automatic injector, photodiode array detector, degasser and a Hypersil ODS column (5 μm particle size silica, 4.6 × 200 mm) equipped with an in-line filter. Mobile phase: 75% H_2O–25% MeCN to 100% MeCN, 35 min (linear gradient), flow rate = 1.0 ml min^{-1}.

§ A clean separation of the constituents could only be achieved on C-18 reversed-phase silica gel; normal silica gel chromatography lead to decomposition of the product with t_r = 7.2 min.

¶ Brassilexin **9** was first isolated from *B. juncea* (*cf.* M. Devys, M. Barbier, I. Loiselet, T. Rouxel, A. Sarniguet, A. Kollmann and J. Bousquet, *Tetrahedron Lett.*, 1988, **29**, 6447) and later synthesized (*cf.* M. Devys and M. Barbier, *Org. Prep. Proced. Int.*, 1993, **25**, 344).

‖ The ^{1}H NMR spectrum obtained (CD_3CN or CD_2Cl_2) for the tautomeric mixture of **6** and **8** displayed a doublet of doublets (dd) at δ 8.15 attributed to (=C)–*H*(NH_2); this assignment was corroborated by proton decoupling of *H*$_2$N (δ 11.15 and 6.24). Selected *spectroscopic data* for tautomeric mixture (HPLC t_r = 7.2 min): δ_H (500 mHz, CD_2Cl_2) 11.15 (br s, side-chain NH*H*), 8.98 (br s, indolic NH), 8.15 (dd, *J* 14.8, 8.2, H-1′) 7.41 (d, *J* 7.5, H-4), 7.15–7.07 (m, H-5 to H-7, 3 H), 6.24 (br s, side-chain NH*H*); δ_C (125.8 MHz, CD_2Cl_2) 179.0, 148.9, 138.0, 128.3, 124.1, 122.2, 115.3, 109.7, 108.4; δ_C (125.77 MHz, CD_3OD) (multiple signals attributable to tautomeric mixture) 177.6, 153.7, 151.7, 148.7, 140.4, 139.5, 129.9, 126.9, 125.0, 124.9, 124.1, 123.4, 122.5, 121.6, 120.9, 119.6, 115.8, 112.9, 111.7, 110.8, 110.5, 108.6; EIMS: *m/z* 176 (M^+, 100%), 149 (46), 117 (11). CIMS: *m/z* 177 (M^+ + 1, 100%), 164 (11), 145 (13).

** It is worthy to note a few examples in which fungal pathogens produce metabolites similar or identical to those of higher plants, such as some gibberellins produced by *Gibberella fukjukuroi* and a *Phaeosphaeria* sp., and abscisic acid produced by *Cercospora rosicola*. Alkyl succinimidyl carbonates undergo Lossen rearrangement in basic buffers

Samuel Zalipsky*

SEQUUS Pharmaceuticals, Inc., 960 Hamilton Court, Menlo Park, CA 94025, USA

A side reaction producing β-alanine and derivatives through Lossen rearrangement was found to accompany hydrolysis of alkyl succinimidyl carbonates in basic aqueous buffers.

Alkyl succinimidyl† carbonate (SC) derivatives are useful alkoxycarbonylating reagents. In particular, their reactivity with primary amines has found a wide use for the introduction of urethane protecting groups,[1] protein modification,[2–5] and covalent attachment of ligands to matrices for solid-phase synthesis[6] and affinity chromatography.[7] Often these carbamoylation reactions are carried out in aqueous or aqueous–organic medium at mildly basic pH. Such conditions are dictated by the solubility properties of the amino reactants, amino acids, aminosugars, proteins, *etc.* In recent years, we have used SC derivatives of poly(ethylene glycol) (SC-PEG) for attachment of the polymer residues to amino groups of proteins, lipids and various biologically-relevant ligands.[3–5,8,9] In the course of these studies it was noticed that occasionally upon completion of a protein modification reaction using an excess of SC-PEG, there were larger amounts of primary amino group-containing compounds in solution than originally present on the protein. Accurate determinations of the extent of protein modification were only realized following removal of low molecular weight amines by extensive diafiltration.[4] These observations lead to the belief that the low molecular weight amine originated from the SC reagent itself. In order to verify this hypothesis, several ^{1}H NMR experiments were performed with bis-SC-PEG-2000[3,9] and benzyl succinimidyl carbonate (Bn-SC) under conditions often used for protein modification. Herein I present the results of these experiments and their corroboration by amino acid analysis (AAA), all of which indicate that SC derivatives undergo Lossen-type rearrangement producing β-Ala and its derivatives.

Table 1 Quantities of β-Ala formed after dissolution of bis-SC-PEG (10 mg, 8.4×10^{-4} equiv. SC per g) in tetraborate or carbonate buffers (0.1 M, pH 9.3, 0.65 ml) and incubation at 23 °C for 24 h. Aliquots taken from the reaction solutions were subjected to AAA, both directly and after hydrolysis (6 M HCl, 24 h, 110 °C). Amino groups were determined by the 2,4,6-trinitrobenzene sulfonate assay[17] using β-Ala for calibration

	β-Ala/10^{-5} mol g^{-1} [% of SC group]		
Buffer type	Total (HCl hydrolysis)	Free amino acid	Amino groups/ 10^{-5} mol g^{-1}
Tetraborate	15.8 [19]	4.6 [5.5]	8.6
Carbonate	20.6 [24]	6.6 [7.8]	10.3

Hydrolysis of bis-SC-PEG in D_2O [δ 2.96 (s, Su of SC, 8H), 3.71 (s, PEG, 180H), 4.58 (m, CH_2-O$_2$COSu, 4H)] proceeded slowly over 24 h without any side reactions, yielding *N*-hydroxysuccinimide [HOSu, δ 2.77 (s)] quantitatively. Next, the degradation of SC-PEG was examined in D_2O-based potassium tetraborate buffer and monitored by ^{1}H NMR

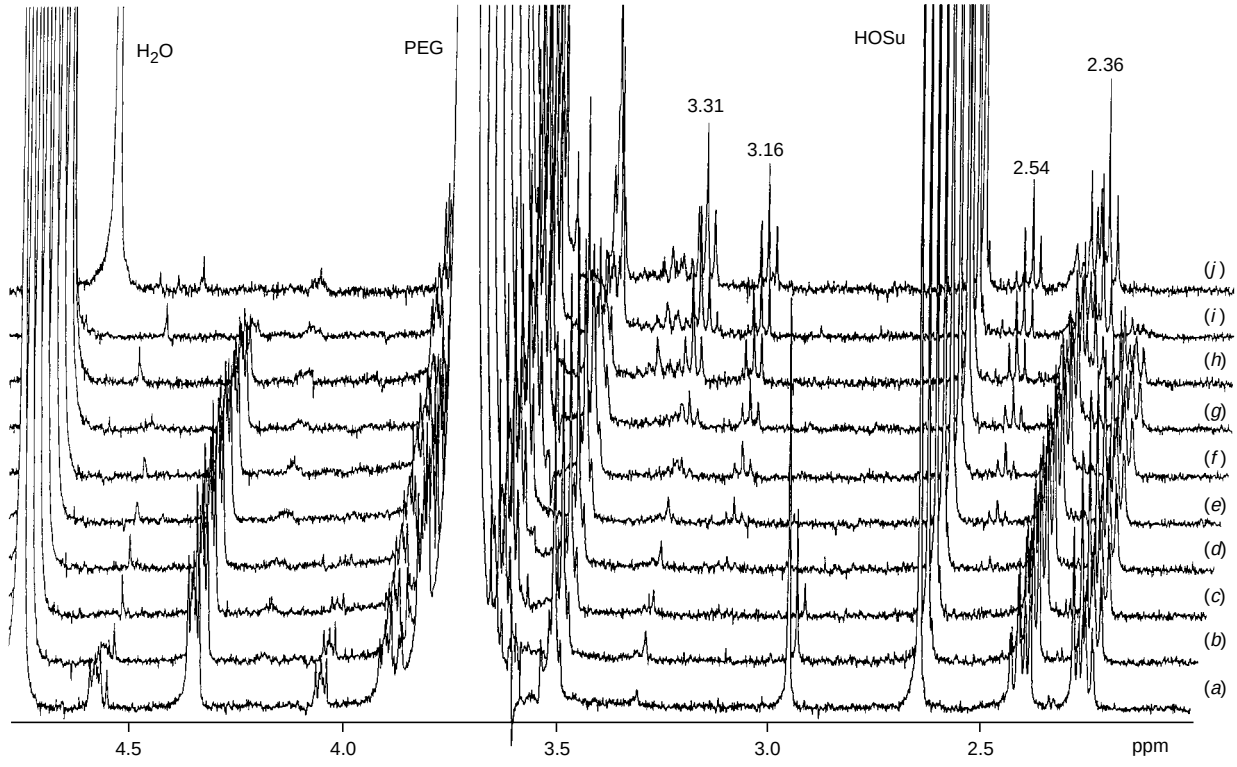

Fig. 1 Progress of the bis-SC-PEG (10 mg) decomposition monitored by 360 MHz ^{1}H NMR spectroscopy in D_2O–tetraborate buffer (0.1 M, pH 9.3, 0.65 ml). Spectra were acquired at (*a*) 3 min, (*b*) 5 min, (*c*) 8 min, (*d*) 11 min, (*e*) 16 min, (*f*) 30 min, (*g*) 45 min, (*h*) 2 h, (*i*) 4 h and (*j*) 20 h.

Scheme 1 Reaction pathways of alkyl-SC degradation through hydrolysis and through Lossen rearrangement

spectroscopy (Fig. 1). Although the disappearance of SC groups [δ 2.96 (s), 4.58 (m)] was complete within 10 min, and most of the SC was hydrolyzed to −OSu [δ 2.65 (s)], additional reactions have also taken place. Appearance of a new signal [δ 4.35 (m)] of the terminal methylene group of PEG and two symmetrical sets of peaks of type X–CH_2–CH_2–Y at δ 2.3 and 2.4 suggest that a substantial amount of the starting SC-PEG has been converted into a new derivative resulting from the succinimide (Su) ring opening. Within 16 min two triplets at δ 2.54 and 3.16, representing free β-Ala, have appeared and increased in size for the next few hours. At the end of the experiment, in addition to the β-Ala peaks, signals clustering around δ 2.3–2.5 and 3.2–3.4 with two major triplets at δ 2.36 and 3.31 were apparent. These chemical shifts are in the areas where various acylated derivatives of β-Ala yield NMR peaks.[10,11] Similar observations in the ^{1}H NMR spectra were made by following the decomposition of SC-PEG in a D_2O–carbonate buffer.

Quantitation of β-Ala in both buffer solutions by AAA (Table 1), either directly or after extensive hydrolysis, revealed that 20–25% of the original SC groups underwent conversion into β-Ala. Approximately one third of the total β-Ala was found in the free amino acid form. Amounts of primary amine somewhat higher than of free β-Ala were detected, suggesting that some of the amines were present in the form of β-Ala derivatives, *e.g.* β-Ala-β-Ala. Due to its low water solubility, Bn-SC was first dissolved in CD_3CN and then diluted ten-fold with D_2O–tetraborate buffer. ^{1}H NMR spectra again showed decomposition of the SC groups proceeded as in the case of SC-PEG yielding β-Ala and derivatives. This experiment confirmed that the observed reaction is more general, and is not exclusive to SC-PEG. The reaction pathways shown in Scheme 1 are consistent with the above observations. Opening of the succinimide ring by a nucleophile, Nu, leads to a Lossen-type hydroxamic acid intermediate, which rearranges into isocyanate *via* a scission of the N–O bond with the concomitant departure of the alkoxycarboxylate, and 1,2-migration of the outlined residue.[12] The isocyanate is expected either to hydrolyze, or to react with various nucleophilic groups (amino, carboxylate, hydroxy), yielding free β-Ala as well as its urea, amide and urethane derivatives. Specifically, β-isocyanatopropionate (Nu = OH) is known to produce 3,3′-ureylenedipropionic acid and oligo(β-Ala), among other β-Ala acylates.[10] This explains why most of the β-Ala was found in the form of acylated derivatives as revealed by AAA after hydrolysis (Table 1).

The tendency of Su-OX derivatives, where OX constitutes a good leaving group, to undergo Lossen rearrangement initiated by a nucleophilic attack on the succinimide ring by either −OH, −OSu, or even amine, is known.[12–16] Although alkoxycarboxylates are recognized as very effective leaving groups, this is the first time that alkyl-SC (Su-OCO_2R) derivatives are implicated in this process. It is pertinent to note that nucleophilic attack by an amino group on the exocyclic carbonyl of SC-derivatives, occurring during carbamoylation reactions, is a lot faster than the side reactions described here. However, the reactions described here can potentially be a source of undesirable by-products, particularly in protein modifications with an excess of alkyl-SC. Preliminary observations in our laboratory suggest that this rearrangement can be measurably suppressed by lowering the pH or the temperature of the solution.

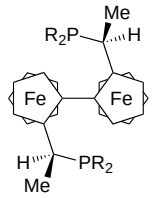
Asymmetric aldol reaction of 2-cyanopropionates catalysed by *trans*-chelating chiral diphosphine ligand TRAP–rhodium(I) complex

Ryoichi Kuwano,† Hiroshi Miyazaki and Yoshihiko Ito*

Division of Synthetic Chemistry and Biological Chemistry, Graduate School of Engineering, Kyoto University, Sakyo-ku, Kyoto 606-01, Japan

***trans*-Chelating chiral diphosphine TRAP ligands bearing *P*-aromatic groups are effective for Rh^{I}-catalysed asymmetric aldol reaction of 2-cyanopropionates with an aldehyde to give the corresponding aldol adduct with up to 93% ee.**

The asymmetric aldol reaction provides a most useful tool for stereoselective construction of α-substituted β-hydroxy carbonyl units with vicinal chiral centres, and is widely used in the synthesis of complex organic molecules.[1] Recently, it was found that some low-valent transition metal complexes catalyse aldol and Michael reactions with cyano compounds having active α-methylene groups,[2] and we developed a highly enantioselective Michael reaction of 2-cyanopropionates catalysed by a rhodium(I) complex coordinated with *trans*-chelating chiral diphosphine TRAP (**1**).[3–6] The transition metal



(*S*,*S*)-(*R*,*R*)-TRAP

c R = *p*-Cl-C_6H_4
d R = Pr^{i}
e R = Pr

catalysed reactions involve enolate intermediates of 2-cyanopropionates coordinating to the metal atom through the cyano nitrogen, which then react directly with electrophiles.[2] Herein, we report the catalytic asymmetric aldol reaction of 2-cyanopropionates **2** using a TRAP–Rh^{I} complex.

Asymmetric aldol reactions of **2** with paraformaldehyde (10 wt% in water) were carried out with a rhodium(I) catalyst generated *in situ* from Rh(acac)$(CO)_2$ and (*S*,*S*)-(*R*,*R*)-PhTRAP **1a** (Table 1).‡ The enantioselectivity of the asymmetric aldol reaction was heavily dependant upon reaction solvent. Bu_2O was the solvent of choice.§ Bulky ester groups of **2** are essential to attain high enantioselectivities for the aldol reactions (entries 1–5). 2-Cyanopropionates **2d** and **2e** bearing bulky secondary alkyl ester group gave aldol adducts (*S*)-**3d** and (*S*)-**3e** in 91 and 93% ee, respectively. Surprisingly, use of formalin hardly affected the enantiopurity of **3d** (93% ee). The enantioselectivity of the aldol reaction of **2d** was slightly increased by using **1b**, which has electron-donating aromatic groups attached to the phosphorus atoms (entry 6), while electron-withdrawing substituents on the *P*-aromatics group gave lower enantioselectivity and reactivity (entry 7). Conceivably, the *P*-aromatic substituents of TRAP play an important role in the enantioface selection of enolate of **2** coordinated to the rhodium atom, because ligands **1d** and **1e** with *P*-aliphatic substituents showed lower enantioselectivities (entries 8 and 9).

Other aldehydes **4a**–**d** were subjected to asymmetric aldol reaction with (*S*,*S*)-(*R*,*R*)-PhTRAP–Rh^{I} catalyst (Table 2). The aldol reactions of ethyl ester **2b** and isopropyl ester **2c** with acetaldehyde **4a** resulted in not only low enantioselectivities but also low diastereoselectivities (entries 1 and 2). However, the use of **2d** gave *anti*-(2*S*,3*S*)-**7a** (86% ee) with good *anti*-selectivity (*anti* : *syn* = 81 : 19) (entry 3). The aldol reaction of **2d** with **4b** proceeded, but with lower stereoselectivity (entry 4). Benzaldehyde **4c** did not react at all (entry 5). However, aldehyde **4d** smoothly reacted with **2d** giving a mixture of *anti*-(2*S*,3*R*)-**7d** (91% ee) and *syn*-(2*S*,3*S*)-**7d** (63% ee) in a ratio of 68 : 32 (entry 6).

The observed stereochemistry at the 2-position of the aldol products suggests that (*S*,*S*)-(*R*,*R*)-PhTRAP on the catalyst can differentiate between the steric bulkiness of the α-Me and ester substituents of **2**, with one of the *P*-phenyl substituents blocking the approach of the aldehyde to the *si*-face of the enolate coordinated to the rhodium atom.[4] The preferential formation of *anti*-**7** in the aldol reactions of **2d** with **4** may suggest that this reaction proceeded through antiperiplanar transition state **TS1**, which avoids the steric repulsion between the aldehyde substituent (R) and the bulky $CHPr^{i}_2$ ester (Fig. 1). The lack of diasereoselectivity in the reactions with **2b** and **2c** may be due to the lesser steric repulsion between the R and ester groups, which does not produce any enantioface selection by the aldehyde. Synclinal transition state **TS2** giving an *anti*-aldol would be sterically unfavourable due to the steric interaction between R and one of *P*-phenyl groups of **1a**.

In conclusion, we have accomplished the highly enantioselective aldol reaction of **2** with some aldehydes. Further studies are currently in progress to improve the catalyst's efficiency and to widen its applicability to a variety of aldehydes.

‡ *Typical procedure*: A suspension of paraformaldehyde (100 mg) in H_2O (1.0 ml) was heated under reflux for 1 h, giving a clear aqueous solution of paraformaldehyde. A solution of Rh(acac)$(CO)_2$ (5.0 μmol) and (*S*,*S*)-(*R*,*R*)-**1a** (5.4 μmol) in 2.0 ml of Bu_2O was stirred at room temperature for 10 min. To the solution was successively added **2** (0.50 mmol) and the freshly prepared solution of paraformaldehyde in water (0.67 mmol) at −10 °C. The mixture was stirred at −10 °C. After completion of the reaction, the mixture was diluted with brine, and extracted with EtOAc. The organic layer was washed with brine, dried over Na_2SO_4 and evaporated. After passing through a short silica gel column (EtOAc), the residue was purified *via* medium-pressure liquid chromatography MPLC.
§ The enantioselectivities of the aldol reactions of **2b** at 0 °C in various solvents were as follows: MeOH: 0; CH_2Cl_2: 11; toluene: 1; THF: 47; Et_2O: 54; Bu_2O: 60% ee.

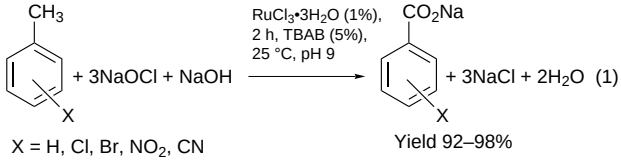
Selective oxidation of substituted xylenes to toluic acids by hypochlorite–Ru system under phase transfer conditions

Yoel Sasson,* Abed El-Aziz Al Quntar and Ami Zoran

Casali Institute of Applied Chemistry, The Hebrew University of Jerusalem, Jerusalem 91904, Israel

Instantaneous aqueous extraction of toluic acid salts is the basis for a novel selective process for the oxidation of a single methyl group of various xylenes; aqueous hypochlorite is inert towards methylbenzenes at pH higher than 9.0, however, in the presence of an organic solvent, a Ru catalyst and a phase transfer agent, rapid oxidation to benzoic acids is observed at 25 °C.

The combination of ruthenium tetroxide as catalyst with sodium hypochlorite as primary oxidant was shown to be effective in the oxidation of olefins, alkynes and aromatic rings. The system could be improved by the addition of a phase transfer catalyst (PTC).[1] We have shown that methylbenzenes can readily be transformed into benzoic acids at room temperature upon exposure to aqueous sodium hypochlorite at pH 9–10 in the presence of $RuCl_3$ and tetra-*n*-butylammonium bromide (TBAB) catalysts in a two phase system [eqn. (1)].[2]



In a recent study we subsequently observed that this system is also capable of converting alkanes and cycloalkanes into ketones accompanied by some chlorinated products,[3] similar to other ruthenium catalyzed oxidations.[4]

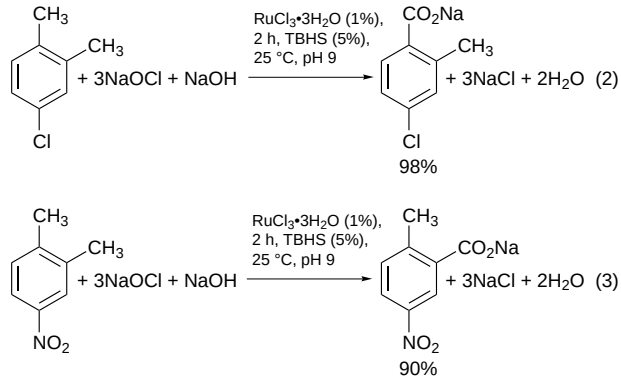
A major feature of the Ru–NaOCl–PTC system in the oxidation of methylbenzenes is the instantaneous transport of the benzoic acid product as it forms into the basic aqueous phase thus allowing the facile separation of the product from the catalysts which abide in the organic phase ready for reuse in a succeeding reaction batch. This unique characteristic can also be the foundation for the design of a continuous catalytic liquid–liquid oxidation process.

The instantaneous extraction of benzoic acids (as sodium salts) into the aqueous phase can also be utilized for a selective oxidation of one methyl group in polymethylbenzenes such as xylenes or trimethylbenzenes. This is the subject of this communication. We have found that when xylenes are reacted under the above conditions complete conversion is achieved after two hours with only one methyl group selectively oxidized to the corresponding carboxylic acid.

Toluic acids are obtained in the autoxidation of xylenes in the presence of a cobalt(II) catalyst in acetic acid solvent but high selectivity to the desired products is obtained only at relatively low conversions.[5,6] At higher conversions the major product is the dicarboxylic acid. Thus alternative methods were proposed for the preparation of substituted toluic acids. Typical examples are the hydrolysis of toluonitriles[7,8] (obtained by diazotization of anilines in presence of CuCN) and the oxidation of methylacetophenones *via* the haloform reaction.[9,10]

Our new oxidation system is demonstrated with the following typical procedure. 4-Chloro-*o*-xylene (4.6 g, 33 mmol), tetra-*n*-butylammonium hydrogen sulfate[11] (TBHS, 0.47 g, 1.6 mmol) and ruthenium chloride trihydrate (70 mg, 0.33 mmol) were dissolved in 1,2-dichloroethane (25 ml) in a 300 ml flask equipped with a mechanical stirrer, a thermometer, a pH meter and a dual dropping funnel, one filled with commercial aqueous hypochlorite and the other with 20% aqueous NaOH. Aqueous hypochlorite (200 ml) was added into the flask with stirring at a rate of 1.5 ml min^{-1} while keeping the system at 25 °C. The pH was maintained throughout the process at 9.0 by manual gradual addition of 20% aqueous NaOH (28 ml in total was added). After two hours the aqueous phase was separated, acidified with 20% aqueous sulfuric acid to pH 3 and the precipitate was filtered and dried to give 4-chloro-2-methylbenzoic acid (5.50 g, 98%), mp 170 °C, were obtained. The structure of the product was confirmed by comparison with an authentic sample.

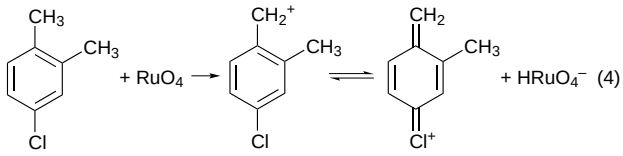
Interestingly, when 4-nitro-*o*-xylene was reacted under an identical procedure, the *meta* methyl group was oxidised to yield 2-methyl-5-nitrobenzoic acid (mp 176 °C) in 90% yield. This is shown in eqns. (2) and (3).



The reaction was found to be of a general nature with numerous substituted xylenes. These experiments have revealed the following observations. (a) When unsubstituted xylenes or xylenes bearing electron donating groups (such as methoxy-xylenes) are reacted under the above conditions, the major reaction taking place is ring chlorination accompanied with some side chain chlorination. The ring chlorinated xylenes were further oxidized to the corresponding toluic acids resulting in a mixture of toluic acids and side-chain chlorinated xylenes. (b) In oxidizing xylenes bearing an electron withdrawing substituent which also has a lone pair of electrons available to stabilize the carbonium ion, such as bromine or chlorine, the methyl group *para* or *ortho* to the substituent is oxidized. (c) In reactions of xylenes with electron withdrawing substituents not containing an unshared pair of electrons such as nitro, sulfonate or carboxylate, the methyl group *meta* to the substituent is selectively oxidized. (d) The oxidation rate is slower when substituents with stronger −I effect are present. (e) No oxidation reaction is taking place in the aqueous phase thus once the toluic acid product is extracted into the water no further oxidation is observed. (f) Non-selective oxidation was realized when 4-nitro-*m*-xylene was reacted with formation of both possible toluic acids.

These observations support our originally proposed mechanism for the Ru–NaOCl–PTC system.[2] The key step is a hydride abstraction from the substrate by RuO_4 to form a carbonium ion which is promptly hydrolyzed.

With chlorine in the 4-position the carbonium ion is more stable on the *para* methyl group due to existence of canonical structures with the positive charge on the chlorine atom. Such forms are not possible when the ion is on the *meta* methyl group [eqn. (4)]. With 4-nitro substituted xylene the −I effect of the



(4)

substituent destabilizing the carbonium ion, is more pronounced for the *para* methyl group resulting in activation of the *meta* methyl group.

Upon attempts to recycle the catalytic system for consecutive runs we have found some deactivation of the catalytic activity. This could be corrected by modifying the solvent with addition of a nitrile. When using a solvent mixture of 1 : 1 (w/w) 1,2-dichloroethane and benzonitrile (which is known to stabilize RuO_4 in the organic phase[12]) the catalysts could be recycled in the same solvent for seven consecutive runs without any apparent loss in activity.

Efficient synthesis of β- and γ-amino acid derivatives using new functionalised zinc reagents: enhanced stability and reactivity of β-amido zinc reagents in dimethylformamide

Charles S. Dexter and Richard F. W. Jackson*

Department of Chemistry, Bedson Building, The University of Newcastle, Newcastle upon Tyne, UK NE1 7RU

The new zinc reagents 3 and 4 are not sufficiently stable to be prepared efficiently in THF, but they can be prepared in DMF under mild and convenient conditions; subsequent palladium- catalysed coupling with aromatic iodides gives protected β- and γ-amino acids 11 and 12 in generally good yields.

There has been increasing interest in the development of new synthetic routes to β-amino acids, due to their importance as components of natural products and modified peptides.[1] The asymmetric synthesis of β-amino acids has most often relied on use of the chiral pool. For example, homologation of α-amino acids,[2] ring-opening of aziridine carboxylates[3] and modification of aspartic acid[4–6] and asparagine[7] have each been explored. γ-Amino acids have also been prepared using similar strategies, for example by modification of glutamic acid[4] and by homologation of α-amino acids.[8] A direct asymmetric synthesis of aryl β- and γ-amino acids has also been recently reported.[9]

In view of our development of other amino acid-derived zinc reagents, such as the nucleophilic alanine equivalent **1** prepared from protected iodoalanine **2**,[10] we have explored the potential of the related reagents **3** and **4** for the synthesis of enantiomerically pure β- and γ-amino acids. The necessary iodide precursors for the two reagents, **9** and **10**, were prepared from the protected aspartic and glutamic acid derivatives **5** and **6** by standard methods.†

7

Our initial efforts to prepare the zinc reagents **3** and **4**, by using zinc dust activated using the Knochel procedure in THF as solvent,[11] were disappointing. For example, formation and coupling of the zinc reagent **3** with *p*-iodonitrobenzene **8l**, under the conditions previously developed for the zinc reagent **1**, gave the β-homophenylalanine derivative **11l** in disappointing yield (25%). Similar results were obtained using the zinc reagent **4**.

^{1}H NMR spectroscopy of the zinc reagent **3** prepared in [$^2H_8$]THF indicated clearly that the main problem was β-elimination of the urethane group to give the alkene **7**. Examination of the ^{13}C NMR spectrum of the reagent **3** in [$^2H_8$]THF indicated that there was significant coordination of the urethane carbonyl group to zinc (implied by the downfield shift of the urethane carbon atom upon formation of the zinc reagent), whilst coordination of the ester carbonyl was much less pronounced (Table 1). We suggest that this lack of ester coordination results in a relatively facile β-elimination of the urethane group (promoted by the internal Lewis acid), since the conformation required for elimination can be easily attained. This stands in sharp contrast to the ^{13}C NMR spectrum of the serine-derived reagent **1** in [$^2H_8$]THF, which indicates that both ester and urethane carbonyl groups are coordinated to zinc, which in turn, we believe, is responsible for the significantly greater stability of this reagent than the reagent **3** in THF. In contrast to the situation in [$^2H_8$]THF, the ^{13}C NMR spectrum of **3** in [$^2H_7$]DMF showed no significant changes in the shifts of the two carbonyl carbon atoms on conversion of iodide **9** into zinc reagent **3**, which we interpret as indicating that there is no coordination of either carbonyl group to zinc in this solvent. It is interesting to note that in [$^2H_7$]DMF, the serine-derived zinc reagent **1** preserves ester coordination (Table 1), indicating that intramolecular co-ordination of an ester group which results in a 5-membered ring is especially favourable. We therefore explored the preparation of the zinc reagent **3** in dipolar aprotic solvents, and were pleased that all solvents employed (DMF, DMA, NMP and DMSO) were effective.[12] In all the solvents, preparation of the zinc reagent **3** and its subsequent coupling with iodobenzene, to give **11a**,‡ occurred at room temperature in good yield. Given the convenience of using DMF,[13] subsequent reactions were all carried out with this solvent, and are summarised in Table 2 and Scheme 1. The only disappoint-

[a] All yields are based on iodide **10**.

ing yields occur with the use of *ortho* substituents, which appear to be caused by steric problems, rather than by electronic ones. The reasonable result obtained with 2-fluoroiodobenzene is in sharp contrast to our previous complete failure to promote coupling with this substrate.[10]

In an analogous way, the iodide **10** can be converted into the zinc reagent **4**, which then undergoes coupling with a range of aromatic iodides in good yield to give a series of γ-amino acids **12**. These results are summarised in Table 3.

These results indicate that it is possible to prepare both β- and γ-amino acids using organozinc chemistry at room temperature in a straightforward manner. Further applications of zinc reagents **3** and **4**, and of related zinc/copper reagents, to the synthesis of other classes of β- and γ-amino acid derivatives will be reported in a future full paper.

We thank the EPSRC for a CASE award (C. S. D.) and for an equipment grant (NMR spectrometer), Dr N. H. Rees for NMR spectra, Merck Sharpe and Dohme, Terlings Park, for support, the EU TMR programme (ERB-FMRX-CT96-0011), Dr J. Elliott (MSD) for helpful discussions, L. Hitzel (MSD) for chiral phase capillary electrophoresis and Dr S. Connolly, Astra Charnwood, for experimental details of the preparation of iodides **9** and **10**. R. F. W. J. also thanks the Nuffield Foundation for a One Year Science Research Fellowship.

† The aspartic and glutamic acid derivatives **5** and **6** were converted into the corresponding *N*-hydroxysuccinimide esters (*N*-hydroxysuccinimide, *N*,*N*′-dicyclohexylcarbodiimide) (ref. 14), reduced to the alcohols ($NaBH_4$, H_2O–THF), and then converted into the iodides **9** and **10**, respectively (PPh_3, I_2 imidazole, CH_2Cl_2) (ref. 15).

‡ The enantiomeric purity of **11a** was determined by comparison of its specific rotation, [$[\alpha]_D$ +20.8 (*c* 1.28, MeOH)] with the literature value [+19.9 (*c* 1.29, MeOH] (ref. 16). As an additional check, the ee of this compound was determined as >98% (by comparison with a racemic sample) by capillary electrophoresis using α-cyclodextrin as chiral selector.

Novel heterocyclic betaines relevant to the mechanism of *tyrosinase*-catalysed oxidation of phenols

John Clews,[a] Christopher J. Cooksey,[b] Peter J. Garratt,[b] Edward J. Land,[c] Christopher A. Ramsden*[a] and Patrick A. Riley[d]

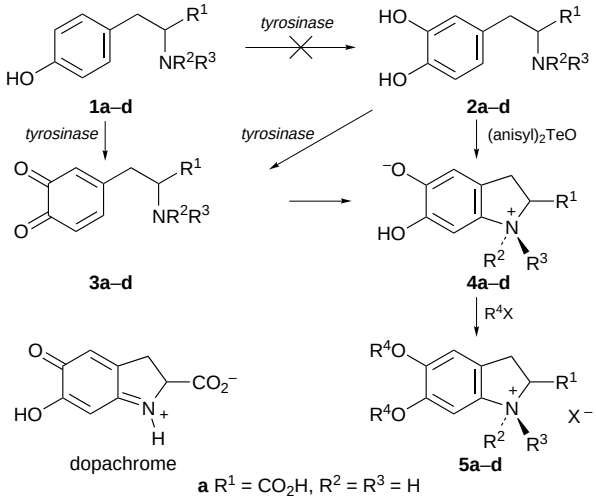
Betaines formed by dianisyltellurium oxide oxidation of *N*,*N*-dialkyldopamines are identical to the products formed by *tyrosinase* oxidation of *N*,*N*-dialkyltyramines or *N*,*N*-dialkyldopamines and provide evidence that *tyrosinase* does not act as a *tyrosine hydroxylase*; oxidations of higher homologues of *N*,*N*-diethyldopamine are also described.

Tyrosinase [EC 1.14.18.1] catalyses the formation of *ortho*-quinones **3** from both phenolic (**1**) and catecholic (**2**) substrates (Scheme 1):[1] the mechanism of the phenol oxidation (**1** → **3**) has been the subject of disagreement.[2] There is a lag phase during initial *tyrosinase*-catalysed oxidation of monohydric phenols **1** because the enzyme requires activation by a catechol: this process is believed to involve reduction of Cu^{II} ions in the active site. Once formed, initially by largely unactivated enzyme, quinone derivatives of primary amines, such as dopaquinone **3a**, undergo rapid cyclisation and subsequent disproportionation with a second molecule of quinone to give a catechol amine (*e.g.* **2a**) (eqn. 1) which then activates more enzyme. The catechol **2** is not, therefore, formed directly by the

2 dopaquinone (**3a**) → dopa (**2a**) + dopachrome (1)

enzyme acting as a *tyrosine hydroxylase*, as is widely claimed,[2] but by a subsequent sequence of non-enzymic reactions. We have recently reported oximetry studies that firmly support the exclusive operation of this indirect mechanism of auto-activation of *tyrosinase*.[3] We now report novel chemical studies relevant to these conclusions.

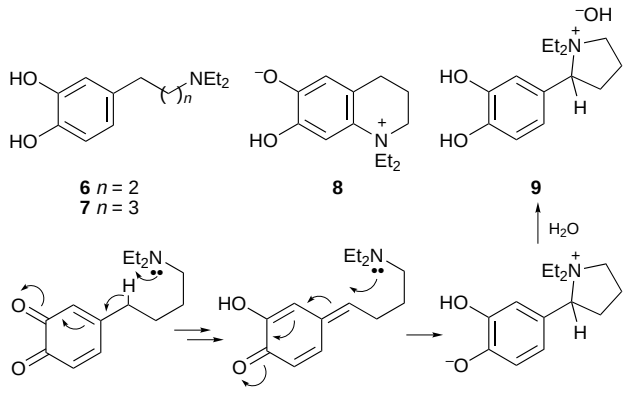


a $R^1 = CO_2H$, $R^2 = R^3 = H$
b $R^1 = H$, $R^2 = R^3 = Me$
c $R^1 = H$, $R^2 = R^3 = Pr$
d $R^1 = H$, $R^2–R^3 = (CH_2)_5$

Scheme 1

A priori it is not clear whether the *ortho*-quinone of a tertiary amine **3** (R^2 and $R^3 \neq H$) will cyclise. Other workers,[4] in a study of protein binding of oxidised catechols, have recently expressed the view that formation of 2,3-dihydroindole derivatives (*e.g.* **3** → **4**) *via* *N*,*N*-dialkylquinones **3** is unlikely. However, a close examination of the literature reveals that this type of cyclisation was encountered by Robinson and Sugasawa[5] during studies of chloranil oxidation of laudanosaline but, as far as we are aware, this remains the only example. In this context, we have observed[3] that *tyrosinase* oxidises *N*,*N*-di-*n*-propyldopamine **2c** with an oxygen stoichiometry of 0.5 to give a stable product that is not an *ortho*-quinone. Similar oxidation of *N*,*N*-dimethyltyramine **1b** by pre-activated *tyrosinase* gives a similar product with an oxygen stoichiometry of 1.0: no enzymic oxidation of this phenolic precursor **1b** occurred without pre-activation by a trace of dopa **2a**. Spectroscopic evidence suggested that these enzymic products are the betaines **4b** and **4c** formed by rapid cyclisation and aromatisation of the initially formed *ortho*-quinones **3** (Scheme 1). Significantly, oxidative cyclisation of the tertiary amines **1** does not lead to catecholic products that can function as *tyrosinase* activators. Since there is no autocatalysis using the tyramine precursor **1b** we have concluded that direct formation of catechols by *tyrosinase* acting as a hydroxylase (*e.g.* **1b** → **2b**) does not occur. We now describe the chemical synthesis and characterisation of the indol-1-ium-5-olates **4b**–**d** and products obtained by oxidation of the higher homologues **6** and **7**.

Our recent interest in hypervalent oxidising agents[6] led us to investigate the use of dianisyltellurium oxide (DAT), which has been shown to be particularly mild and selective for quinone formation.[7] Oxidations were monitored in deuterated solvents *via* ^1H NMR spectroscopy. Amine **2c** was rapidly and quantitatively transformed to the betaine **4c** upon treatment with 1 equiv. of DAT in CH_2Cl_2–MeOH (9 : 1) solution. The water soluble betaine **4c**, obtained as a crystalline solid, mp 115–120°C (90%), was easily separated from the accompanying dianisyltelluride by $CHCl_3$–water partitioning and the proposed structure is fully supported by its spectroscopic properties. The ^1H NMR (D_2O) spectrum exhibits two aromatic protons (singlets at δ 6.42 and 6.46) indicating formation of the second ring at C-5 of the catechol ring. Further evidence of ring formation is provided by the non-equivalence of each pair of methylene protons (CH_aH_b) of the *N*-*n*-propyl substituents (NCH_2CH_2Me) which, as a result of the quaternary nitrogen atom, are also significantly shifted downfield and appear as pairs of multiplets at δ 3.16 and 3.35 and at δ 1.19 and 1.40. A COSY spectrum confirmed the expected proton coupling. A high resolution mass spectrum of compound **4c** confirmed the constitution of the molecular ion (*m*/*z* 235). The UV spectrum of the betaine **4c** in 0.1 M phosphate buffer was pH dependent [pH 7.4: λ_{max} 290 (ε 4122) and 312(sh) nm (1453); pH 6.5: λ_{max} 290



Scheme 2

nm (ε 3923)] and this change is attributed to the formation of the salt **5c** (R^4 = H) at low pH.

Attempts to monomethylate the betaine **4c** using MeI were unsuccessful and gave mixtures. However, use of MeI and solid K_2CO_3 in acetone gave exclusively the dimethoxy iodide **5c** (R^4 = Me, X = I), mp 172–173 °C (95%).† Significantly, the UV spectrum of this salt **5c** was pH independent [λ_{max} 284 nm (ε 4115)] and showed no shoulder at higher wavelength. In a similar manner the betaines **4b**,**d** were prepared, characterised and converted to their dimethoxy iodides **5b**,**d** (R^4 = Me, X = I). The synthetic products **4b**,**c** were found to be identical in all respects to the material produced by *tyrosinase* oxidation of amines **1b** and **2c**.[3]

Oxidation of the higher homologue **6** resulted in a similar quantitative cyclisation giving the tetrahydroquinolin-1-ium-6-olate **8** which was obtained as a crystalline solid, mp 95–100 °C (84%). The ^{1}H NMR [δ_H(D_2O) 6.42 and 6.63 (s, 2 × arom H), 3.4–3.8 (m, 3 × CH_2N$^+$), 2.57 (t, CH_2Ar), 2.0 (m, $CH_2CH_2CH_2$) and 1.09 (t, 2 × CH_3)] and UV [pH 7.4: λ_{max} 286 nm (ε 2831)] spectra are analogous to those of the betaines **4** and fully consistent with structure **8**. Evidence of spirocyclisation was not detected by NMR spectroscopy. Methylation (MeI–K_2CO_3) gave the expected 6,7-dimethoxy iodide as a crystalline solid mp 230–231 °C (90%).

A different mode of reaction occurred when the 4-alkylamine chain was extended by an additional methylene unit. Again, clean formation of a single product was observed by ^{1}H NMR spectroscopy when the amine **7** was treated with 1 equiv. of DAT and after isolation this was identified as the quaternary salt **9**, mp 118–120 °C (86%) [*m/z* 236.1642 ($C_{14}H_{22}N_1O_2$), M − OH$^-$]. In particular the ^{1}H NMR spectrum (D_2O) showed non-equivalent ethyl groups [δ_H 0.99 and 1.25 (t, 2 × CH_2CH_3)] and a low field pseudo-triplet at δ_H 4.60 corresponding to the methine proton. There was no evidence of cyclisation to a seven-membered betaine. We rationalise the formation of the product **9** by an isomerisation of the initially formed *ortho*-quinone **10** to the quinomethane **11**, assisted by intramolecular deprotonation (Scheme 2). The quinomethane **11** then undergoes a 5-*exo*-*trig* cyclisation giving the observed product **9** *via* the betaine **12**. This cyclisation (**11** → **12**) is analogous to that proposed for the formation of the tetrahydrofuran ring in the biosynthesis of lignans (*e.g.* pinoresinol and olivil)[8] and for the epimerisation of profisetinidins.[9] The formation of a quinomethane intermediate *via* an *ortho*-quinone (**10** → **11**) is also relevant to the role of *quinone isomerase* in the sclerotization of insect cuticles.[10]

We thank the EPSRC National Mass Spectrometry Service Centre, Swansea, for high resolution mass spectra.

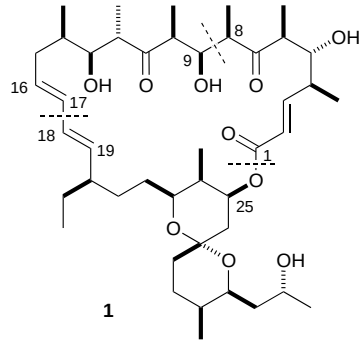
Total synthesis of rutamycin B *via* Suzuki macrocyclization

James D. White,* Thomas Tiller, Yoshihiro Ohba, Warren J. Porter, Randy W. Jackson, Shan Wang, and Roger Hanselmann

Department of Chemistry, Oregon State University, Corvallis, OR 97331-4003, USA

The macrolide rutamycin B containing 17 stereogenic centres and a 26-membered ring was synthesized by a route which features a chelate-controlled, double differentiating aldol reaction and ring closure by means of a vinyl–vinyl coupling.

Rutamycins A and B are structurally complex macrolide antibiotics isolated from *Streptomyces* species.[1] A total synthesis of rutamycin B (**1**) by Evans[2] confirmed the structural assignment,[3] and the absolute configuration of **1** was deduced from synthesis of the spiroketal segment obtained by degradation of the rutamycins.[4] Herein, we report a convergent synthesis of rutamycin B in which the 26-membered ring is closed by means of a Suzuki macrocyclization.



1

Selective silylation of triol **2**[5] took advantage of the different steric environments of the three hydroxy groups in this structure and was accomplished by reaction with Bu^tMe_2SiCl, which gave **3**, and then by treatment with $Bu^tMe_2SiOSO_2CF_3$ to yield **4** (Scheme 1). The remaining secondary alcohol was converted to its benzoate **5**, and the primary silyl ether was selectively removed by treatment with HF·pyridine complex. The resultant primary alcohol **6** was oxidized to aldehyde **7**, which was subjected to a Takai reaction[6] with CHI_3 in the presence of $CrCl_2$ to yield *trans* iodo alkene **8**. After saponification of the benzoate, the liberated alcohol **9** was reacted with diethoxyphosphorylacetyl chloride to give **10**. Horner–Emmons condensation of the lithio anion of **10** with keto aldehyde **11**, previously prepared from methyl (2*R*)-3-hydroxy-2-methylpropionate,[7] afforded α,β-unsaturated ester **12**.

Synthesis of the C9–C16 segment **26** of **1** was initiated by asymmetric crotylation of (*R*)-**13** with (*E*)-crotylboronate **14** derived from (*S*,*S*)-tartrate (Scheme 2).[8] The alcohol **15** resulting from *re* face addition to the aldehyde was converted to the bis(silyl ether) **16**, and the primary ether was selectively cleaved to give **17**. The tosylate **18** of this alcohol was displaced with cyanide and the resultant nitrile **19** was reduced to **20** and then to alcohol **21**. The latter was converted to its bis(silyl ether) **22** before ozonolysis to **23**. The reaction of **23** with (*E*)-crotylboronate **24** derived from (*R*,*R*)-tartrate[8] afforded alcohol **25** with good stereoselectivity (> 95 : 5) in this matched (Felkin) addition to the *si* face of the aldehyde. Alcohol **25** was protected as its *p*-methoxybenzyl (PMB) ether **26** and the latter upon ozonolysis yielded **27**.

Coupling of the (*Z*)-chlorotitanium enolate[9] of **12** and **17** gave the *syn*,*syn* (Felkin) aldol product **28** as the sole stereoisomer (Scheme 3).[10] A rationale for this high stereoselectivity invoking secondary complexation of the aldehyde carbonyl with the PMB ether has been suggested previously,[7] and it is noteworthy that the aldol reaction of **12** with **27** is completely nonstereoselective when the PMB group of **12** is replaced by a Et_3Si ether. Thus, it appears that the PMB ether not only obstructs the anti-Felkin pathway in this coupling, but

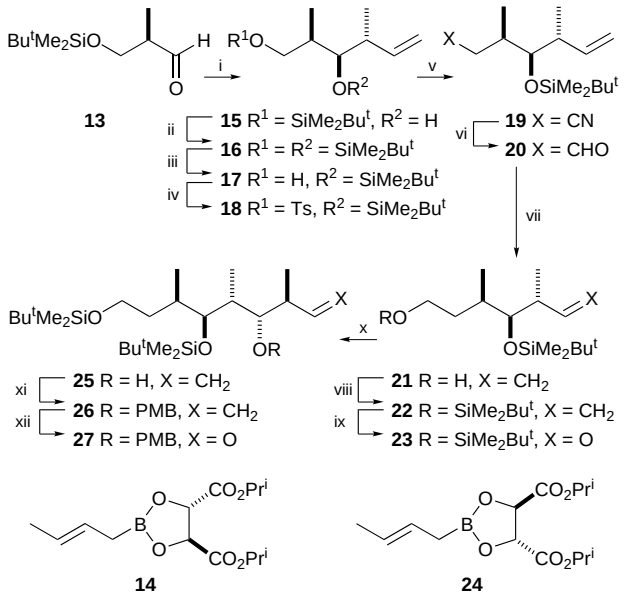

Scheme 2 *Reagents and conditions*: i, **14**, 4 Å MS (powder), toluene, −78 °C, 86% (78% de); ii, $Bu^tMe_2SiOSO_2CF_3$, Et_3N, CH_2Cl_2, 99%; iii, NH_4F, MeOH, heat, 85%; iv, TsCl, pyridine, 92%; v, NaCN, DMSO, 94%; vi, DIBAL-H, toluene, −78 °C, 75%; vii, $NaBH_4$, Pr^iOH, 0 °C, 87%; viii, Bu^tMe_2SiCl, imidazole, DMF, 96%; ix, O_3, CH_2Cl_2–MeOH, −78 °C, Me_2S, 94%; x, **24**, 4 Å MS (powder), toluene, −78 °C, 78% (> 98% de); xi, $PMBOC(=NH)CCl_3$, CF_3SO_3H, −10 °C, 68%; xii, O_3, MeOH–CH_2Cl_2, 79%

plays a positive role by favouring attack at the *re* face of the aldehyde carbonyl by the *si* face of the titanium enolate.

β-Hydroxy ketone **28** was converted to its silyl ether **29**, and the PMB ether was cleaved to give **30**, which was immediately oxidized to **31** (Scheme 4). The primary silyl ether was selectively removed from **31** and the resultant alcohol **32** was oxidized to **33**. Condensation of **33** with the dichloromethylboronic ester **34**[11] of pinacol in the presence of $CrCl_2$ and LiI afforded (*E*)-vinyl boronate **35**[12] which was subjected to palladium-catalysed intramolecular coupling[13] in the presence of Ag_2O[14] and $AsPh_3$. The ensuing macrocyclization proceeded in good yield and furnished the tetrasilyl ether **36** of rutamycin B, identical in all respects with a sample prepared from the natural material by exhaustive silylation with Bu^tMe_2SiO-SO_2CF_3. Final cleavage of the four Bu^tMe_2Si ethers from **36** by sequential addition of aq. HF in pyridine gave **1**, identical with natural rutamycin B.

We thank Dr Herbert Kirst and Ms Margaret Niedenthal, Eli Lilly Co., Indianapolis (USA) for a sample of natural rutamycin B, and Professor David Evans (Harvard University) for a generous quantity of a derivative of **2**. Directed conjugate addition of organolithium reagents to α,β-unsaturated carboxylic acids

Barbara Plunian, Michel Vaultier and Jacques Mortier*

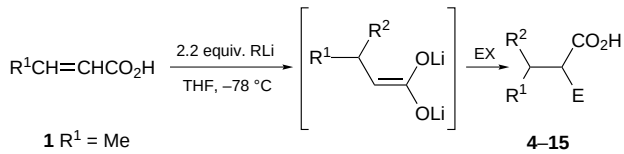
Université Rennes-I, Synthèse et électrosynthèse organiques, UMR 6510 associée au CNRS, campus de Beaulieu, 35042 Rennes Cedex, France

α,β-Unsaturated carboxylic acids undergo predominantly conjugate addition with organolithium reagents at low temperature (−78 °C) in THF and lead to various substituted alkanoic acids after quenching with electrophiles; with (*E*)-3-phenylpropenoic acid, this tandem alkylation sequence also affords significant amounts of isomeric 1,3-addition products.

1,4-Additions of organolithium reagents to α,β-unsaturated carbonyl compounds are usually promoted by steric interference of the 1,2-addition process.[1] Literature furnishes little information regarding the conjugate addition of *unprotected* α,β-unsaturated acids to organolithiums[2,3] and the data, scarce as they are, even appear to be inconsistent at first sight. Majewski and Snieckus described in 1984 the reaction in THF at 0 °C between senecioic acid [(*E*)-3-methylbut-2-enoic acid] and 2-lithiodithiane which afforded the 1,4-addition product in 65% yield.[4] Reaction of (*E*)-3-trimethylsilylpropenoic acid with *n*-butyllithium in THF–hexane at −70 °C was reported to give a mixture of 1,2-(55%) and 1,4-(45%) addition products.[5] The conjugate addition of α-silylated α,β-unsaturated acids to organolithiums appears to be a particular case.[6] Indeed the 1,2-addition is suppressed by the placement of a unit of negative charge adjacent to the carbonyl group. Furthermore the enolate dianions resulting from such additions are not efficiently intercepted with alkylating agents.

We have recently described the efficient addition of organolithium reagents to naphthalene-1- and -2-carboxylic acids followed by electrophilic trapping.[7] The diastereoisomeric ratios of 1,1,2- and 1,2,2-trisubstituted-1,2-dihydronaphthalenes were found to contain only *trans* addition products. The *trans* addition was verified in each system by single X-ray determination. Thus, in either case, the electrophile approached the naphthalene nucleus from the side opposite to the organolithium. We now describe results which demonstrate that the process can be expanded to simple α,β-unsaturated carboxylic acids.

Typical unsaturated carboxylic acids **1**–**3** underwent 1,4-addition reactions with lithium reagents in THF at low temperature (−78 °C) over the course of several minutes



1 R^1 = Me
2 R^1 = Ph
3 R^1 = H

4–15

giving carboxylic acid dilithium enolates which, when quenched with a proton source (CF_3CO_2H) or an alkyl halide (MeI),[8] gave moderate to good yields of substituted alkanoic acids **4**–**15**. These reactions almost certainly involve deprotonation of the acid first, which reduces but does not suppress the reactivity of the carbonyl towards 1,2-addition.[9] At −78 °C, *n*-butyllithium and *sec*-butyllithium added efficiently to the carboxylic acid derivatives **1**–**3**. The use of phenyllithium, however, proceeded very sluggishly to **1** and **2** and after trapping with trifluoroacetic acid gave only **6** and **11** in 40 and 20% purified yields, respectively (Table 1, entries 3 and 7). Methyllithium failed to react (entries 5 and 9) and gave mainly products resulting from carbonyl addition at higher temperatures.

Reaction of *n*-butyllithium with (*E*)-3-methylpropenoic acid **1**, followed by quenching with trifluoroacetic acid, provided the 1,4-adduct **4** in good yield (entry 1). A 1:1 mixture of the diastereoisomers **5′** and **5″** was obtained when the enolate was trapped with methyl iodide (entry 2). When **1** was treated with *sec*-butyllithium, proton quench with trifluoroacetic acid afforded the conjugate 1,4-addition product in moderate yield as a mixture of diastereoisomers (**7′** and **7″**) differing in their configuration at C-3 and C-4 (7:3 ratio, entry 4). Reactions of (*E*)-3-phenylpropenoic acid **2** with *n*-butyllithium and *sec*-butyllithium gave mixtures of the conjugate 1,4-addition products **9** and **12′**, **12″** as well as the isomeric products **10** and **13′**, **13″**, respectively. Structures of types **9**, **10** and **12**, **13** were easily distinguished by their ^{13}C NMR spectra by the multiplicity and the order of the chemical shift of the carbon in α-position of the carboxylic acid. 1,3-Addition reactions of Grignard and organolithium reagents to cinnamate derivatives, involving the addition of a free radical produced by a single electron transfer from the organometallic reagent to the alkene, are precedented.[2a,5,10] Turning to acrylic acid **3**, it was found that *n*-butyllithium with **3** in THF at −78 °C followed by hydrolysis, gave **14** and **15** (5:3) which were isolated in 50% yield (entry 10). Compound **15** resulted presumably from the double conjugate addition of the organolithium reagent to the lithium acrylate.

The following procedure for the synthesis of 3-methylheptanoic acid **4** is representative. In a 250 ml flask maintained under argon, were placed 40 ml of dry THF and 20 ml of *n*-butyllithium (1.6 M in hexanes, 33 mmol). The mixture was then cooled to −78 °C and (*E*)-methylpropenoic acid **1** (1.29 g, 15 mmol) in THF (40 ml) was slowly added. After the mixture was stirred for 1 h at −78 °C, a THF solution (20 ml) of an excess of trifluoroacetic acid (4.62 ml, 60 mmol) was added. The solution was allowed to warm slowly to room temperature with stirring, then treated with water, washed with diethyl ether, and shaken. The aqueous layer was acidified with 2 M HCl, diluted with diethyl ether, and the organic layer was separated, washed with aq. $NaHCO_3$ and water, and dried with $MgSO_4$. Filtration and concentration *in vacuo* afforded **4** which was purified by distillation (bp 75–80 °C/1 mmHg, 1.72 g, 80%).

Table 1 Additions of organolithium reagents to acyclic α,β-unsaturated carboxylic acids[a]

Entry	Acceptor	R^3Li[b]	Product(s)	Ratio[c]	Yield (%)[d]
1	**1**	Bu^nLi	 **4**	—	80 (90)

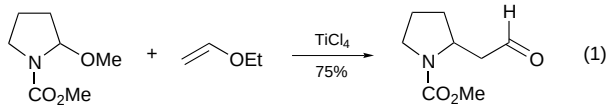
Catalytic *C*-amidoalkylations: synthesis of β-amido aldehydes by three-component condensations

Charles M. Marson*† and Asad Fallah

Department of Chemistry, University of Sheffield, Sheffield, UK S3 7HF

Primary amides condense with aliphatic aldehydes (2 equiv.) in the presence of trifluoromethanesulfonic acid to give β-amido aldehydes.

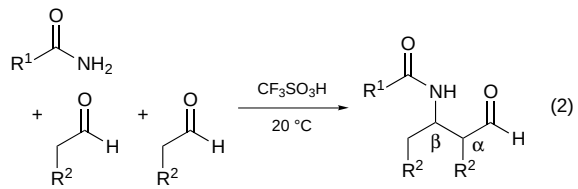
The condensation of aldehydes with primary and secondary amides can lead to valuable products by means of amidoalkylation.[1,2] However, amidoalkylation at carbon has been generally limited to the condensation of an active methylene compound *other than* an aldehyde with an imine substrate usually containing an aromatic substituent.[1,2] In most cases, the amidoalkylating agent must be separately prepared and isolated prior to reaction with the active methylene compound. Whereas amidoalkylation is well-established for cases where either the aldehyde or the amide is aromatic[1,2] (or both are), condensations involving only aliphatic reactants are rare, and appear confined to one example of a cyclic amide [eqn. (1)].[3] Such



(1)

aliphatic amidoalkyations could significantly extend the scope of aliphatic and heterocyclic N–C bond formation, with particular importance for alkaloids and related pharmaceutical products. In this area, the nature of the acid catalyst is known to be crucial; for aromatic reactants, polyphosphoric acid[4] or polyphosphate ester[5] have been shown to effect amidoalkylation followed by cyclization. However, the harshness of these reagents led to decomposition when applied to aliphatic reactants. Accordingly, trifluoromethanesulfonic acid was investigated, since its mildness, and ease of control of reagent concentration result in good yields in acid-catalyzed condensations,[6] notably in the cyclization of β,γ-unsaturated amides to lactams.[7]

Multiple component condensations offer powerful strategies in combinatorial chemistry[8a] and general synthesis.[8b] A new three-component amidoalkylation is here reported that is to the best of our knowledge the first amidoalkylation to deliver acyclic aliphatic aldehydes [eqn. (2)]. Unique features include:



(2)

(a) *in situ* formation[2] of the presumed imine substrate (from an amide and an aldehyde), (b) subsequent amidoalkylation by an aldehyde, in an overall one-pot process to give (c) an isolable β-amido aldehyde as the product, under mild conditions of acid catalysis at 20 °C. β-Amido aldehydes are protected, relatively stable forms of β-amino aldehydes which are generally only isolable with difficulty[9] or accessible *via* indirect synthetic protocol.[10] β-Acetylamino aldehydes are key intermediates in the synthesis of amino cyclitols.[11] Table 1 shows that β-amido aldehydes‡ of the form $R^1CONHCHR^2CHR^2CHO$ can be prepared from an amide R^1CONH_2 and an aldehyde R^2CH_2CHO (2 equiv.). For entries 1 and 5, the *syn* : *anti* diastereoisomer ratio is respectively 1 : 2 and 1 : 5,[12] whereas for entries 2 and 3 a 1 : 1 ratio was observed. The diastereoselection found in entries 1 and 5 can be accounted for on the basis of a Zimmerman–Traxler model, leading to preponderance of the *anti*-diastereoisomer.[13]

Notable is the variety of amides (some functionalized) and sensitive aliphatic aldehydes (or their equivalent) that participate under the mild conditions. Attempts to obtain β-amido aldehydes using polyphosphoric acid or polyphosphate ester were unsuccessful in all cases studied, and we have generally observed that simple aliphatic aldehydes and ketals are rapidly decomposed by reagents other than dilute trifluoromethanesulfonic acid. The β,γ-unsaturated amides used in entries 2, 3 and 4 have been shown to cyclize either as the sole reactant[7] or in the presence of an aromatic aldehyde;[4,5] it is noteworthy that in the present reactions the double bond does not participate in a cyclization, but remains intact.

The reaction of amides with aldehydes can give a number of products, depending on the reagent and conditions. Thus, amides have been shown to add reversibly to aldehydes,

Table 1 Condensation of amides with aldehydes in the presence of 2% v/v trifluoromethanesulfonic acid in dichloromethane at 20 °C

Entry	Amide	Aldehyde or acetal	*t*/h	β-Amido aldehyde	Yield (%)
1			16		60
2			12		50
3			24		54
4			16		51
5			48		69
6			48		66

particularly formaldehyde, to give *N*-hydroxymethylamides.[2,14] For the latter, basic conditions are usually employed because acidic catalysis is usually either ineffective or affords mixtures. In general (and depending on the stoichiometry), *N*,*N*′-alkylidenebis(amides), $R^1CH(NHCOR^2)_2$, can be prepared by condensing R^1CHO with R^2CONH_2.[15]

Preliminary experiments with α,β-unsaturated aldehydes and amides in the presence of CF_3SO_3H did not lead to β-amido aldehydes, and would appear to exclude an initial aldol condensation with dehydration, followed by conjugate addition. More probable is an initial condensation of the amide with one equivalent of aldehyde to give an acyl imine or acyl iminium intermediate which then undergoes attack by an enolic form of a second equivalent of the aldehyde, either in its enolic form, or possibly as an enamide derivative.

In conclusion, a new three-component condensation[8] is disclosed which provides a flexible route to β-amido aldehydes that have been hitherto largely inaccessible. The β-amido aldehydes are of synthetic value in themselves, being relatively stable derivatives of the difficulty isolable β-amino aldehydes.[9] These condensations of amides with aldehydes proceed at 20 °C with acid catalysis, and without the need for protection or derivatisation of the aldehyde function. The new condensation is clearly distinguishable from other related amide–carbonyl condensations; synthetic applications and mechanistic aspects are under investigation.

We thank the EPSRC for a postdoctoral fellowship to A. F.

12 ^{1}H NMR spectra of the separated diastereoisomeric acids obtained by aerial oxidation of the aldehydes in entry 1 exhibit couplings for the vicinal methine hydrogen atoms of 10 and 5 Hz (isolated as the minor diastereoisomer), and 3 and 5 Hz (major diastereoisomer). The former values are consistent with the *syn*-isomer in a preferred conformation in which the amido and aldehyde groups are antiperiplanar, and the methine hydrogen atoms are disposed *trans* (J = 10 Hz). ('*syn*' refers to relation of α-alkyl and β-amido groups, the aldehyde being drawn as part of the 'backbone' of the product.) Such assignments are consistent with those for other β-amido carbonyl compounds: H. Estermann and D. Seebach, *Helv. Chim. Acta*, 1988, **71**, 1824.

Reaction of an activated bis(pyrrolyl)ferrocene with 2,2′-(ethylenedioxy)bis(ethylamine) under standard amide-forming conditions gives rise to a novel *ansa*-ferrocene system that acts as a redox-based sensor for F^- and $H_2PO_4^-$ anions.

The construction of metallocene-based anion sensors constitutes an area of active research.[1] In general, successful systems reported in the literature have consisted of a redox active metallocene 'marker' covalently linked to an anion recognition subunit and in this context a wide range of anion binding agents have been employed. One set of anion chelating agents that appears attractive in terms of anion sensor development, but which, apparently, has yet to be explored, is polypyrroles.[2] Pyrrole-containing species, both cyclic and acyclic, often possess H-bond donating characteristics that, depending on the details of structure, can make them effective and selective as anion binding agents both in solution and in the solid state. We thus thought that combining a suitable pyrrolic anion binding entity with a ferrocene marker group could give rise to a new type of anion sensing device. Here, we report the first successful test of this hypothesis. Specifically, we describe the synthesis, solid state characterization, and solution phase anion binding behavior of the *ansa*-ferrocene system **1**; this system acts as an effective redox-based sensor for F^- and $H_2PO_4^-$.

The synthesis of **1** and its acyclic control **2**, is summarized in Scheme 1. Here, the key precursor **4** was obtained starting from an isomeric mixture of cyclopentadienyl functionalized pyrroles **3**.[3,†] Deesterification of **4** under reductive conditions led to the corresponding diacid **5**. Reaction with 2,2′-(ethylenedioxy)bis(ethylamine) under standard amide-forming conditions then gave the desired *ansa*-ferrocene system **1**, with the acyclic analog **2** being prepared from 2-methoxyethylamine in a similar way.

The *ansa*-ferrocene **1** was characterized *inter alia* by X-ray diffraction analyses. Diffraction-grade single crystals of **1** were obtained by slow diffusion of a CH_2Cl_2 solution of **1** into hexanes in the case of the solvent-free structure (Fig. 1), and by slow evaporation of a CH_2Cl_2–hexanes solution at −10 °C in the case of the water-containing structure (Fig. 2). The resulting structures revealed a *trans*-type arrangement about the ferrocene subunit and the presence of an internal 'pocket' that, depending on the anion size, might be expected to accommodate either one or two negatively charged substrates.‡ In the absence of a bound guest, this suggested propensity towards substrate binding is accommodated in the solid state *via* a dimerization process, wherein amide and oxygen atoms from one macrocyclic subunit are bound, *via* H-bonding interactions, to the pyrrolic and amido NH portions of another macrocycle (Fig. 1).§

Interestingly, the second structure alluded to above (Fig. 2) actually provided a more concrete 'hint' that receptor **1** can accommodate a substrate in its binding pocket. In this case a single water molecule is found to be bound within the macrocyclic cavity.‡ A second water molecule, not constrained within the cavity, is found H-bonded to the encapsulated water and to an amide oxygen of an adjacent macrocycle.

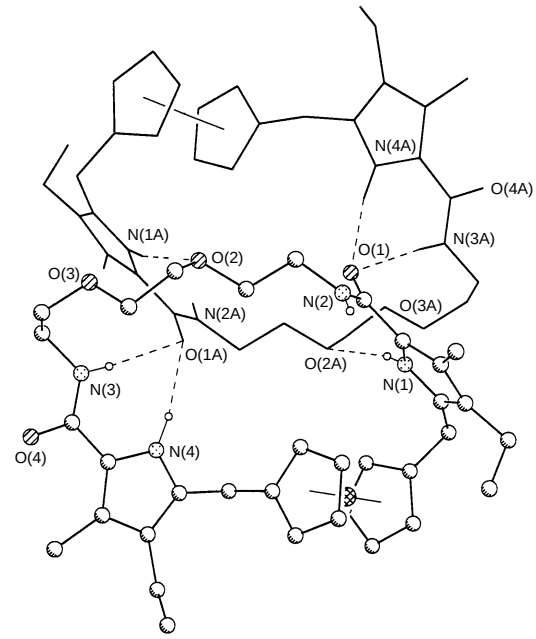

Fig. 1 View of the H-bound dimer of **1** obtained in the solid state. One molecule is shown in ball-and-stick form while a second related by $1 - x$, $1 - y$, $-z$ is shown in wireframe form. Dashed lines are indicative of a H-bonding interaction. With the exception of the amide- and amino-H all other H atoms are omitted for clarity.

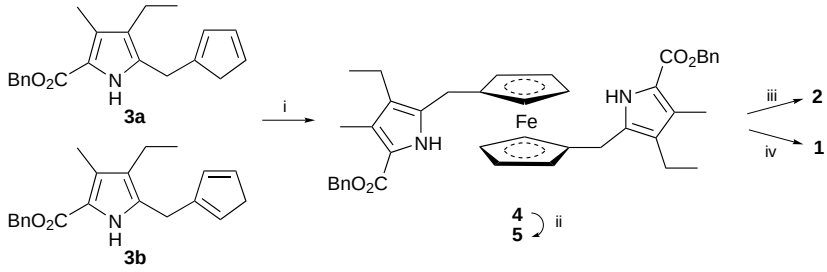
The solution phase anion-binding properties of **1** and **2** were studied by carrying out ^1H NMR spectroscopic titrations. Stability constants were then calculated using the EQNMR



Scheme 1 Syntheses of the receptor systems **1** and **2**. *Reagents*: i, TlOEt, THF then $FeCl_2$; ii, Pd/C–H_2, THF; iii, BOP, NEt_3, DMF, $H_2NCH_2CH_2OMe$; iv, BOP, NEt_3, DMF, $H_2NCH_2CH_2OCH_2CH_2OCH_2CH_2NH_2$.

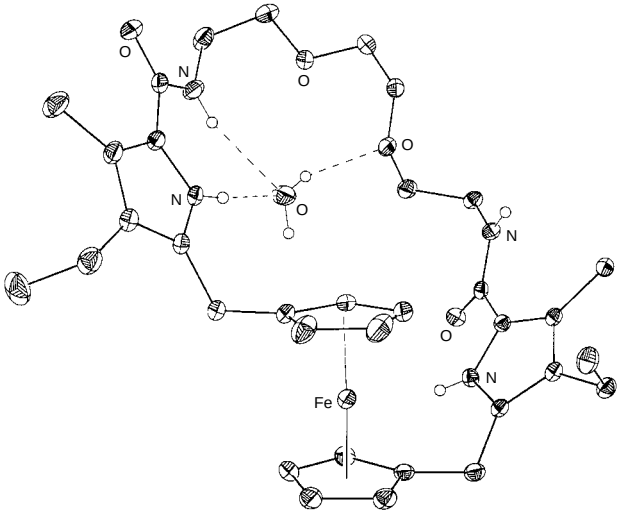


Fig. 2 Solid state structure of **1**·2H_2O (the second water molecule, not contained in the cavity, has been omitted for clarity). Thermal ellipsoids are scaled to the 30% probability level. H atoms shown are drawn at an arbitrary scale. With the exception of the amide and amino hydrogens all other H atoms are omitted for clarity.

computer program.[4] As summarized in Table 1, it was determined that **1** and **2** bind both $H_2PO_4^-$ and Cl^- anions with high affinity in acetonitrile. Although the relevant interactions are clearly weaker, effective anion binding was also observed when Br^- and HSO_4^- anions were tested as substrates. The reduced affinities observed for Br^- and HSO_4^- are ascribed to the lower basicity of these anions and a set of correspondingly weaker H-bond interactions.[1]

Not surprisingly, **2** displays overall affinity constants that are weaker for all of the anions tested. Given the fact that identical functionality is present in both **1** and **2**, this disparity in anion affinity is easily interpreted in terms of the greater preorganization (and lower flexibility) presumed to pertain in receptor **1**.

Table 1 Relevant electrochemical data and stability constants for anion complexes formed from receptors **1** and **2**

	Receptor 1				Receptor 2			
Anion[a]	K_a[b]/dm^3 mol^{-1}	$E_{1/2}$[c]/ mV	ΔE[d]/ mV	BEF[e]	K_a[b]/dm^3 mol^{-1}	$E_{1/2}$[c]/ mV	ΔE[d]/ mV	BEF[e]
None	N/A	396	—	N/A	—	424	—	N/A
F^-	$>10^5$	316	80	—[f]	$>10^5$	368	56	—[f]
Cl^-	9031	372	24	2.5	1260	388	36	4.1

HSO_4^-	889	380	16	1.9	258	392	32	8.8
$H_2PO_4^-$	11305	260	136	199.0	4181	280	144	271.7

[a] $NBu^n_4^+$ salts. [b] Association constants for anion binding; recorded in CD_3CN; errors < 15%; determined from $\Delta(\delta)$/ppm NH(amide). [c] Determined in acetonitrile containing 0.1 M $NBu^n_4PF_6$ as the supporting electrolyte. Solutions of **1**/**2** were 5×10^{-4} M and potentials were determined with reference to Ag/AgCl, 10 Hz frequency in square wave voltammetry. [d] Cathodic shift observed after the addition of 5 molar equiv. of added anion. [e] Enhancement factor (BEF) for anion coordination after oxidation. [f] Since a 2 : 1 binding mode pertains the BEF could not be defined.

As was revealed by Job plots, different binding stoichiometries are observed (for both **1** and **2**) depending on the size of the anion. In particular, F^- was determined to bind in a 2 : 1 ratio while all other anions tested were found to be bound in a 1 : 1 fashion.

The above findings led us to consider whether systems **1** and **2** could be used to detect the presence of various anions electrochemically through the species specific perturbation of the ferrocene–ferrocenium (Fc/Fc^+) redox couple. As reflected by the data summarized in Table 1, it was found that this could in fact be done. Specifically, the addition of an added, non-electrolyte anion was found to induce a cathodic shift in the reversible Fc/Fc^+ couple seen in both **1** and **2**. These studies, carried out in acetonitrile to allow the calculation of binding enhancement factors,[5] also served to highlight the facts that (*i*) among the five test anions studied, the response factor for both **1** and **2** is greatest for $H_2PO_4^-$ anion followed by F^- and Cl^- and (*ii*) the purely electrochemical sensitivity (*i.e.* $\Delta E_{1/2}$) of these two systems is similar.

In conclusion, the employment of a 1,1′-dipyrrole substituted ferrocene as a building block in an *ansa*-ferrocene type anion system leads to the generation of receptors that not only display unusually high affinities for the 1 : 1 binding of Cl^- and $H_2PO_4^-$ relative to other systems in literature[1] but also allows the detection of these species *via* electrochemical means.

This research was supported by the National Science Foundation (grant CHE 9725399 to J. L. S.). M. S. thanks the Alexander von Humboldt-Stiftung for a post-doctoral research fellowship (Feodor-Lynen stipend). We are grateful to Dr P. A. Gale for numerous helpful discussions, and for providing a copy of ref. 5 prior to publication.

V-loaded β zeolites can be prepared by a two-step post-synthesis method which consists of first creating vacant T-sites by dealumination of the β zeolite with nitric acid, then contacting them with an ammonium metavanadate solution; the SiOH consumption and the nature of the incorporated V species are characterized by IR, UV–VIS and ^{29}Si MAS NMR spectroscopies.

Transition metal cations can be efficiently dispersed in molecular sieves by using a two-step post-synthesis method.[1–3] The zeolite is first dealuminated with a strong acid (HCl, HNO_3, *etc.*) to generate vacant T-sites associated with silanol functional groups, which are then reacted with a highly reactive metallic precursor such as $TiCl_4$.[1,2] The procedures are often highly demanding, requiring both a perfectly anhydrous atmosphere and a high temperature (typically 673–773 K). The present work shows that a similar two-step method can be used to disperse vanadium species in a β zeolite even at room temp. using an aqueous solution as a V precursor.

A tetraethylammonium β zeolite (TEAβ) provided by RIPP (China) was separated into two fractions. The first fraction was calcined (12 h, 823 K) to obtain the non-dealuminated organic-free Hβ (Si/Al = 11). The second fraction was treated in a 13 M HNO_3 solution (4 h, 353 K) to give the dealuminated organic-free Siβ (Si/Al > 1300) used without further calcination. As already reported,[4] the dealumination does not affect the zeolite crystallinity of the β zeolite. The IR vibrations of the hydroxyls in these two solids are compared in Fig. 1(*a*). The three bands attributed to OH in Al–OH groups (3780, 3662, 3609 cm^{-1})[4,5] disappear after dealumination, confirming elimination of the Al atoms. Simultaneously, the intensity of several bands related to Si–OH groups increases (narrow bands of isolated silanol groups within the range 3700–3740 cm^{-1}, and a broad band of H-bonded SiOH groups centered near 3520 cm^{-1}).[6] Furthermore, a new IR peak is detected at *ca.* 960 cm^{-1} (not shown) which is assigned to uncoupled (Si–O) oscillators belonging to defective Si–OH groups.[7,8] ^{29}Si NMR spectroscopy confirms that stable silanol groups are generated by the dealumination. In all the spectra presented in Fig. 1(*b*) (MAS) and (*c*) (CP MAS), two main broad peaks, located at high field (δ −110 to −115) and downfield (δ −100 to −104) are observed. The high-field peak is due to framework Si atoms in a $Si(SiO)_4$ environment, located in different crystallographic sites.[9] For the non-dealuminated Hβ sample, the downfield peak is associated with Si atoms in $Si(OSi)_3(OAl)$ and $Si(OH)(OSi)_3$ environments.[4] The contribution from Si atoms associated with hydroxyl groups is revealed by the intense band which is detected at δ −102 when cross-polarization is applied. For the dealuminated Siβ sample, the downfield peak only corresponds to Si atoms in a $Si(OH)(OSi)_3$ environment. A small proportion of Si atoms in a $Si(OH)_2(OSi)_2$ environment is also evident (weak signal at *ca.* δ −91 in the cross-polarized spectrum of Siβ).[10]

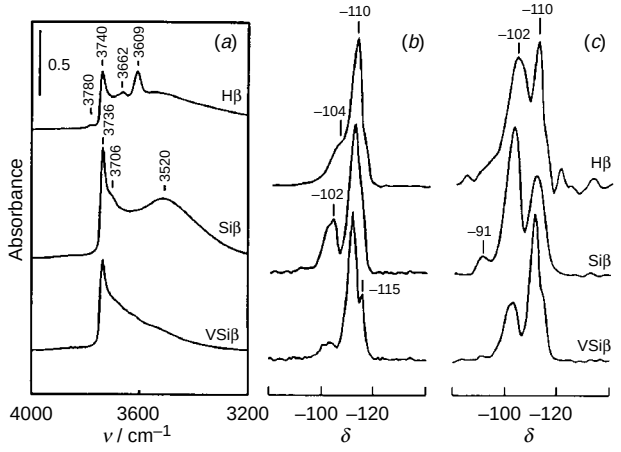

Fig. 1 (*a*) FTIR, (*b*) ^{29}Si MAS NMR and (*c*) ^{1}H–^{29}Si CP MAS NMR spectra of Hβ, Siβ and VSiβ samples (V/Si atomic ratio 0.007). The FTIR spectra were recorded on a Bruker IFS 66V FTIR spectrometer after calcination at 573 K (8 h, 120 ml min^{-1} O_2) and evacuation (10^{-5} Torr, 6 h) at the same temperature. The ^{29}Si NMR spectra were recorded on a Bruker MSL 400 at 79.5 MHz. The pulse length and recycle delay were 2.5 μs and 10 s respectively (MAS spectra). The proton π/2 pulse length, contact time, and recycle delay were 6.5 μs, 5 ms and 5 s, respectively (CP MAS).

Each sample (Hβ and Siβ) was contacted with an aqueous solution of NH_4VO_3 at 298 K (V/Si atomic ratio in the suspension within the range 0.007–0.021). Fig. 2(*a*) shows, as a function of time, the absorbance of the more diluted solution, measured at a constant wavelength of 380 nm, where the $O^{2-} \rightarrow V^{V}$ charge-transfer transitions are detected. With the Siβ zeolite, the absorbance decreases rapidly and disappears within a few hours indicating that the V ions initially present in the solution have reacted with the zeolite. With the Hβ sample, the absorbance rapidly reaches a non-zero constant value, showing that a non-negligible proportion of the V species

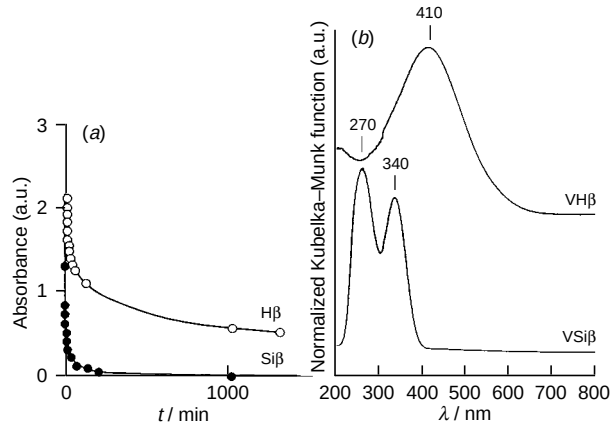

Fig. 2 (*a*) Evolution as a function of time of the UV–VIS absorbance measured at 380 nm on a 258 Ciba-Corning spectrometer, of an ammonium metavanadate solution (298 K, 7×10^{-4} mol l^{-1}) contacted with the Hβ and dealuminated Siβ samples (130 mg zeolite in 3 ml solution); (*b*) UV–VIS diffuse reflectance spectra of the VHβ and VSiβ zeolites (V/Si atomic ratios 0.013, 0.021 respectively), measured on a Cary spectrometer, using the parent V-free β zeolites as references.

remains in the solution, even after several days of contact with the non-dealuminated solid. The same trends have been observed using V solutions three times more concentrated.

After 3 days of contact with the solutions, the solids were recovered by centrifugation and dried overnight at 353 K. By chemical analysis, all the V species present in the initial solutions were detected inside the dealuminated VSiβ samples. By contrast, < 60% of the V species present in the initial solutions were found in the non-dealuminated VHβ solids. The VHβ samples were pale yellow whereas the VSiβ samples were white and their colour did not change even after several months in moist air. As indicated by Newsam *et al.*,[11] X-ray diffractograms of β materials are complex due to the intergrowth of a monoclinic and a quadratic polytype which makes unit-cell measurements difficult. For simplification, the *d*-spacings of single peaks indexed in a purely quadratic geometry are generally used to evidence lattice contraction and/or expansion.[12] On the non-dealuminated samples, no significant change in the d_{302} spacing was observed upon V incorporation (< 0.1%). In contrast, the d_{302} spacing which has decreased from 3.960 (Hβ) to 3.920 Å (Siβ) upon dealumination, increases with increasing V loading in Siβ to reach a maximum value of 3.940 Å when the atomic V/Si ratio is 0.021. Because of the relative values of the Al–O, Si–O and V–O bond distances (1.790, 1.660 and 1.755 Å, respectively),[13] these variations strongly suggest that the vanadium species have been incorporated into the zeolite framework.

To obtain more information on the microstructure of the V sites, we have compared the diffuse reflectance UV–VIS spectra of V-loaded solids [Fig. 2(*b*)]. The absence of d–d transitions within the range 600–800 nm clearly indicates that no reduced V^{IV} species is formed, oxidized V^{V} species being mainly present.[14] For the VHβ sample, the major absorption located near 410 nm is due to a low-energy charge transfer transition occurring between octahedral oxygen ligands and a central V^{V} atom.[14,15] The spectrum of the VSiβ sample is different and exhibits two bands at 270 and 340 nm. associated with pseudotetrahedral $O_{3/2}V{=}O$ species, anchored to the zeolitic walls by three Si–O–V bridges and possessing a V=O double bond.[14–16]

Chemical analysis indicates that the octahedral V^{V} species detected in the VHβ samples are almost completely leached out by washing (12 h, 298 K) in a 1 M ammonium acetate solution. By contrast, the pseudotetrahedral species present in the VSiβ samples are strongly anchored to the zeolitic walls, < 10% of them being extracted by a similar washing. Furthermore, after incorporation of V on Siβ, the intensities of the broad IR band near 3520 cm^{-1} [Fig. 1(*a*)] and the downfield ^{29}Si MAS NMR peak at δ −102 [Fig. 1(*b*)] are significantly reduced, which confirms that a specific reaction takes place between the vanadium precursor and the silanol groups. Moreover, the aspect of the IR peak near 960 cm^{-1} is strongly modified with appearance of two maxima at 950 and 978 cm^{-1} as will be described elsewhere.

The catalytic behaviour of the VSiβ materials was tested in the oxidation of toluene in aqueous solution using H_2O_2 as an oxidant (molar ratio toluene/H_2O_2 = 3; 0.1 g of catalyst for 1 g of toluene).[17] After 9 h of reaction at 80 °C, toluene conversion was *ca.* 5% and the products distribution was 5–10% cresols, 85–90% benzaldehyde, 5% benzyl alcohol and benzoic acid.

In conclusion, catalytically active vanadium species can be easily dispersed within the porosity of a β zeolite using a two-step method. Because of its stacking faults, the β zeolite accepts a high density of silanols and depletion sites generated upon elimination of Al species. The silanol groups generated upon strong dealumination react with NH_4VO_3 aqueous solution, even at room temp., thus obviating the need for a highly reactive metallic precursor such as $VOCl_3$. Pseudotetrahedral and stable V^{V} species attached to the zeolitic walls are formed with the silanol-rich dealuminated sample, whereas loosely bonded octahedral V^{V} species are mostly generated when the non-dealuminated β is used instead. This clearly illustrates the role of the vacant T-sites and their associated silanol groups in the incorporation of vanadium species. To the best of our knowledge, this is the first time that vanadium species have been incorporated into a dealuminated β zeolite, which may be of importance in mild oxidation reactions that must be performed in the absence of strong acidity, as described by Corma and coworkers for Ti-β.[29]

The Indo–French Center for the Promotion of Advanced Research (IFCPAR) is gratefully acknowledged for financial support under award IFC 1006-1. The authors thank RIPP (China) for providing the parent TEAβ zeolite.

Regioselective solvation in a polymeric lithium amide: remarkable twisted ladder structure of $[\{[PhCH_2N(H)Li]_2{\cdot}H_2NCH_2Ph\}_\infty]$

Alan R. Kennedy, Robert E. Mulvey* and Alan Robertson

Department of Pure and Applied Chemistry, University of Strathclyde, Glasgow, UK G1 1XL

The hemi-benzylamine complex of lithium benzylamide exists in the crystal as an infinite, twisted-ladder structure of fused $(NLi)_2$ rings; curiously, one edge of the ladder is solvated by benzylamine molecules, while the other is solvent-free.

Lithium amide molecules can self-assemble by the process known as 'ring-laddering' to generate ladder structures, as most recently demonstrated by the cyclic octameric ladder structure of $[\{Bu^tN(H)Li\}_8]$.[1] This primary amide represents a special case in being oligomeric, on account of the bulky steric nature of its alkyl group. Generally, the absence of solvating ligands is thought to encourage continuous ladder growth rendering many lithium amide compounds polymeric. These infinite ladder structures can be broken down to smaller, partially solvated, ladders of a finite length, when exposed to certain solvating ligands. As a rule, this partial solvation takes place at the ladder ends (outer rungs), *e.g.* as found in the pyrrolidide $[\{[H_2C(CH_2)_3NLi]_2{\cdot}tmeda\}_2]$;[2] inner-rung solvation,[3] as studied theoretically by *ab initio* MO calculations on the model ladder tetramers $[(H_2NLi)_4{\cdot}nH_2O]$ (n = 0, 2 or 4),[2] has a destabilising influence. To the best of our knowledge, the possibility of donor molecules selectively ligating the ladder framework, along one edge only, has never been considered previously. In this paper we present experimental proof of such in the remarkable twisted-ladder structure of $[\{[PhCH_2N(H)Li]_2{\cdot}H_2NCH_2Ph\}_\infty]$ **1**. What is more, the selective solvation is achieved without interrupting the infinite nature of the ladder arrangement, so providing a rare example of a crystallographically characterised polymeric lithium amide (a lithium thiolate with an infinite ladder structure of Li–S rungs has been reported[4]). This study represents the first structural investigation of a lithium (mono) benzylamide species, and it is apt that it should provide such an important finding since it follows over a decade of activity in dibenzylamido systems[5] which has contributed significantly to our basic understanding of alkali metal amide structural chemistry.

Solubility problems necessitated the deliberate use of excess benzylamine in the reaction sequence producing **1**. Pure solvent-free, lithium benzylamide, prepared by treating freshly distilled benzylamine (10 mmol) with Bu^nLi (10 mmol) under standard inert-atmosphere conditions, precipitated as a pink slurry from hexane, and could not be dissolved on addition of toluene. However, dissolution was achieved by introducing a second equivalent of benzylamine (10 mmol) dropwise and strongly heating the mixture. Pink delicate platelets of **1** crystallised on cooling the resulting solution to *ca.* −30 °C for 1 d (yield of first batch, 40%). On isolation from solution, the crystals collapse to a melt in a matter of hours. While the synthesis proved reproducible, different batches of **1** were found to contain various amounts of benzylamine and occasionally toluene, suggesting that the loss of crystallinity is due to the product losing these solvents with time.†

An X-ray diffraction study‡ revealed that **1** adopts an infinite ladder structure of fused $(NLi)_2$ rings, only one Li centre of which is solvated by a benzylamine molecule [Fig. 1(*a*)]. Therefore one ladder edge has unsolvated, three-coordinate, pyramidal Li centres [Li(3), Li(4)], while the other has solvated, four-coordinate, distorted-tetrahedral ones [Li(1), Li(2)]. The pattern of N–Li bond lengths reflects this coordinative inequality. Rungs involving Li(3), Li(4) are distinctly shorter than those involving Li(1), Li(2) (respective mean values; 1.996, 2.102 Å); edge lengths are also generally shorter for the former atoms (mean value, 2.055 Å; *cf.* 2.116 Å for the latter atoms), the exception being N(3)–Li(3) which is longer than its opposite edge [N(4)–Li(1)] although the difference [0.012(7)Å] is not statistically significant. Alternating above and below the ladder framework along one edge, the benzylamine molecules form relatively long bonds to Li (mean length, 2.130 Å). By failing to

(*b*) Stick drawing of a longer section of **1** emphasising the severe twisting within the ladder framework.

interrupt the laddering process and simply attaching itself to the ladder framework, this primary amine exhibits contrasting behaviour to that of the tertiary, chelating amines tmeda and pmdeta, which have been reported to break down (suspected) long ladders to finite ladders of limited length, *e.g.* as in $[\{[H_2C(CH_2)_3NLi]_2{\cdot}tmeda\}_2]$ and $[\{[H_2C(CH_2)_3NLi]_3{\cdot}pmdeta\}_2]$, respectively.[2] The four crystallographically distinct $(NLi)_2$ rings repeated throughout the ladder structure of **1** are non-planar. Two of them, Li(3)N(4)Li(2)N(5) and Li(2)N(5)-Li(4)N(2*), are much more distorted from planarity than the other pair, Li(1)N(2)Li(4*)N(3) and Li(1)N(3)Li(3)N(4) (respective summed bond angles: 348.5, 349.7, 356.6, 356.6°; respective mean rms deviations: 0.227, 0.212, 0.124, 0.123 Å); this factor contributes to the severe twisting within the ladder framework (symmetry code: * = $x + 1, y, z$). The twist is most pronounced at the solvated Li(2) centre [Fig. 1(*b*)]: considering only ladder framework N atoms, it is the most pyramidal of the Li centres [summed bond angle, 333.2°; *cf.* 337.9, 348.7 and 359.9° for Li(1), Li(3) and Li(4), respectively]; it also displays the smallest endocyclic N–Li–N bond angles (*i.e.* mean value, 99.1°; *cf.* range of others, 104.0–111.4°). Endocyclic angles at the N atoms cover a narrower range (69.7–73.5°) These five-coordinate N atoms have severely distorted trigonal bipyramidal geometries with the axial bonds positioned along the Li–N–Li ladder edges (range of axial bond angles, 137.0–143.3°). The benzylamine N atoms have distorted tetrahedral coordination geometries.

There is another unique feature to the ladder structure of **1**. The conformation of the bridging amido substituents ($PhCH_2$, H) with respect to the four-membered $(NLi)_2$ rings, alternates between *cisoid* and *transoid*. In the octamer $[\{Bu^tN(H)Li\}_8]$[1] the conformation is exclusively *cisoid* (the bulky alkyl substituents all project *exo* from the N_8Li_8 framework), and it is this feature which dictates that the ladder turns in on itself and cyclises. However, most discrete lithium amide ring dimers exhibit *transoid* set-ups. In the laddering principle,[6] it is reasoned that ladder structures have their origin in the lateral association of two or more dimeric rings of formula $(R^1R^2NLi)_2$, but the possible ring conformations involved were not considered. The next goal is therefore to establish a correlation between the *cisoid/transoid* nature of the constituent $(NLi)_2$ rings and the final shape and size of the ladder.

We thank the EPSRC (studentship to A. R.) for sponsoring this research.

Sorbate–framework interactions as an aid to vibrational mode assignment: FT-Raman studies of ETS-10

***p*-Xylene–framework interactions enable identification of Ti–O stretch and three-membered ring structures in the FT-Raman spectrum of ETS-10.**

In recent years there has been increasing interest in the application of Raman spectroscopy and, in particular, FT-Raman techniques to the study of the structure of molecular sieve materials and adsorption processes within them.[1–3] However, the characterisation of aluminosilicate frameworks using FT-Raman spectroscopy remains limited by the intrinsically weak Raman effect associated with these materials. Further, there exists controversy as to the ability of the technique to identify specific structural units such as three-membered rings (3MR) within aluminosilicate and related frameworks. In this study we exploit the effect of sorbate–framework interactions on the frequency of the Raman bands characteristic of the framework structure to assign bands to specific stretches and structural units. In so doing we identify specific bands associated with 3MR structures. The framework structure considered here is the microporous titanosilicate ETS-10 which consists of corner-sharing tetrahedrally coordinated silicon and octahedrally coordinated titanium linked through bridging oxygens. The structure consists of 12-, 7-, 5- and 3-membered rings.[4,5] The main pore system is a three-dimensional 12-membered ring channel network and displays a considerable degree of disorder. Every titanium atom is connected to four silicon and two titanium atoms. Each TiO_6 unit carries a -2 charge that is balanced by extraframework cations such as Na^+ and K^+. $[TiO_6]^{2-}$ units are part of the 7- and 3-membered ring channels.

The ETS-10 sample used in the present work was synthesized using the procedure reported by Anderson *et al.*[4] Phase purity was checked by powder X-ray diffraction, which confirmed the absence of any TiO_2 impurity. Contamination of the sample with ETS-4 and AM-1 phase impurities was below that reported for the sample studied by Anderson *et al.*[5] Electron microprobe analysis performed on a JEOL JXA-8600 spectrometer showed that the Si/Ti ratio was 5 : 1, consistent with the previously reported composition of ETS-10.[5] The pure ETS-10 sample was calcined overnight at 500 °C in air prior to the FT-Raman experiment. A further sample containing 0.5 mmol *p*-xylene (g dry ETS-10)$^{-1}$ was also prepared; *p*-xylene was chosen because it demonstrates significant changes in polarisability during interaction with the ETS-10 framework whilst still being small enough to move easily within the micropore structure. The *p*-xylene/ETS-10 sample was prepared by evacuating the calcined ETS-10 material at 10^{-6} Torr at 200 °C for 12 h, the required sorbate loading was then introduced using a gravimetric technique. The sample was then equilibrated at 65 °C and held at this temperature for 12 h to ensure that the adsorbate was evenly distributed within the ETS-10 framework. Raman measurements were performed at room temperature on a Nicolet-Magna-IR 750 spectrometer equipped with a Raman module and an InGaAs detector. A Nd : YAG laser was used operating at a power of 200 mW at an excitation wavelength of 1064 nm. The resolution was 4 cm^{-1}. For each spectrum, 4000 scans were co-added giving a data acquisition time of *ca*. 2 h.

Fig. 1 shows the FT-Raman spectrum of ETS-10. A very high signal-to-noise ratio, consistent with the absence of a high fluorescence background, is observed indicative of the absence of any organic impurity as expected given that ETS-10 does not require an organic template for its synthesis and is synthesised in an environment totally free of organic species. Reviews of previously published Raman studies of aluminosilicate frameworks show the most prominent band to occur in the region between 300 and 550 cm^{-1} followed by weaker bands in the 700–900 and 1000–1200 cm^{-1} regions.[6] Bands in the 300–550 cm^{-1} region have been assigned to the motion of an oxygen atom in a plane perpendicular to the T–O–T (T=Si, Al) bonds.[1,2,7] The spectrum of ETS-10 exhibits a very strong peak at 726 cm^{-1} along with a small peak to its low frequency side at 639 cm^{-1}. Given that silicates have a relatively low Raman scattering cross-section, we assign the strong band at 726 cm^{-1} to the Ti–O stretch of the $[TiO_6]^{2-}$ rod structure present in the framework. This band was not observed in the FT-Raman spectrum of Ti-silicalite-1 (TS-1); we also note that the bands seen in the present study are not characteristic of the anatase or rutile phases of titania.[8] The spectrum also contains bands of low intensity at 987 and 1104 cm^{-1}, generally ascribed to the asymmetric stretching vibration of the Si–O bond.[3] Bands at 307, 427 and 539 cm^{-1} are assigned to the various T–O–T, O–T–O bending and skeletal deformation modes of the framework. The band at 539 cm^{-1} lies to higher frequency of the bands in the 470–510 cm^{-1} region characteristic of framework structures containing rings with four or more T atoms (T = Si, Al). Previous literature suggests that this band,

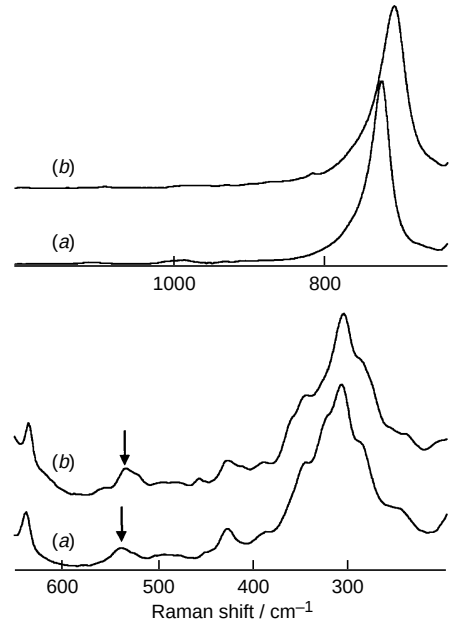

Fig. 1 FT-Raman spectra of (*a*) ETS-10 and (*b*) ETS-10 with a loading of *p*-xylene of 0.5 mmol (g dry ETS-10)$^{-1}$. The arrow indicates the band at 539 cm^{-1} in the pure ETS-10 spectrum.

as well as the band at 726 cm^{-1}, might be associated with 3MR structures. Assuming the correlation between average T–O–T (T=Si, Al) angle and Raman frequency to be valid,[2] and further that the same correlation applies to the case of the T atom being Si or Ti, a band at a frequency of 539 cm^{-1} would be consistent with a T–O–T bond angle of less than 138.1° and therefore consistent with the bond angle expected for a 3MR structure. An EXAFS analysis of ETS-10 has previously suggested a Ti–O–Si bond angle in ETS-10 of 130°.[9] Further, Annen and Davis[10] have suggested that if a band associated with a 3MR structure is observable it should occur in the frequency region of 550–800 cm^{-1}, the particular frequency being dependent upon the type of T-atoms that are contained within the ring. However, in their work no common vibrational bands assignable to 3MR structures were observed in the range of materials studied.

Assignment of the bands at 726 and 539 cm^{-1} to 3MR structures is obtained by consideration of the FT-Raman spectrum of *p*-xylene sorbed within the ETS-10 framework. Consider first the band at 726 cm^{-1} assigned to the Ti–O stretch; the Ti–O bond being part of a 3MR structure. The sorbed aromatic is expected to associate itself with the charged species within the ETS-10 framework, and this is reflected in a shift of 16 cm^{-1} in the Ti–O stretch to lower frequency upon *p*-xylene sorption. The observed shift can be interpreted as follows. The *p*-xylene must reside within the 12-membered ring channels, and will interact through the π-electrons with the Na^+/K^+ cations which are present in order to balance the −2 negative charge associated with each Ti atom.[9] The presence of sorbed *p*-xylene modifies the electrostatic interaction between the oxygens in the framework and the cations, thus causing the shift in Ti–O stretching frequency. We also note that there is a significant shift of the *p*-xylene C–H ring deformation mode from 1184 cm^{-1} in the pure liquid to 1193 cm^{-1} in the sorbed state, consistent with a strong sorbate–sorbent interaction.[11] A smaller shift in the 539 cm^{-1} band is observed again consistent with the 3MR structure, of which Ti is a constituent atom, being in close proximity to the sorbed *p*-xylene molecule; shifts in other bands are negligible.

Insertion of manganese into a C–S bond of dibenzothiophene: a model for homogeneous hydrodesulfurization

Xiao Zhang,[a] Conor A. Dullaghan,[a] Gene B. Carpenter,[a] Dwight A. Sweigart*[a] and Qingjin Meng[b]

[a] *Department of Chemistry, Brown University, Providence, Rhode Island 02912, USA*

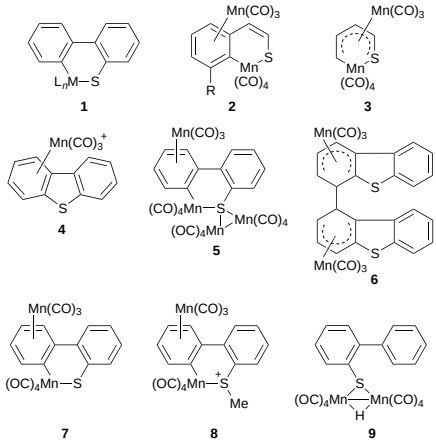
Coordination of $Mn(CO)_3^+$ to a carbocyclic ring of dibenzothiophene activates a C–S bond to reductive cleavage, affording a novel tetramanganese metallathiacycle 5 that reacts with H_2 to form a dimanganese complex 9 containing bridging hydride and thiolate ligands; methylation of 5 followed by hydrogenation results in desulfurization of the dibenzothiophene and formation of $[Mn(CO)_5(SMe)]$.

Much of the research in the field of catalytic hydrodesulfurization (HDS) has focused on the problem of sulfur removal from thiophenic molecules.[1] Benzothiophene (BT) and dibenzothiophene (DBT) are of particular interest in this regard because their substituted derivatives are difficult to desulfurize and, as a consequence, are relatively abundant in fossil fuels.[2] A key step in HDS is cleavage of the C–S bonds by insertion of a metal. A recent study indicates that the energy barrier to metal insertion is considerably greater for DBT than for BT, or for thiophene itself.[3] This higher barrier to C–S cleavage in DBT (which is probably steric in origin) most likely accounts for the relatively small number of published reports of metal insertion into DBT to give metallathiacycle **1**. Nevertheless, there are reports of metal-promoted scission of the C–S bonds in DBT to give characterizable organometallic products with systems based on Rh, Ir, Pt and Co.[3,4] We recently showed[5,6] that precoordination of a $Mn(CO)_3^+$ fragment to the carbocyclic ring in BT or the η^5 π-system of thiophene activates the C–S bonds to facile electron-transfer induced cleavage, affording the bimetallic metallathiacycles **2** and **3**, respectively. Here, we show that a C–S bond in the dibenzothiophene complex $[(\eta^6\text{-DBT})Mn(CO)_3]^+$ **4** is also activated and that chemical reduction leads (in part) to the novel metallathiacycle **5**, the multimetallic nature of which may be relevant to hydrogenolysis and desulfurization reactions occurring with industrial heterogeneous HDS catalysts (Mo/Co, *etc.*).[7] The reactions of **5** with H_2 and electrophilic reagents were investigated and are described below.

Reduction of **4**$[BF_4]$[8] with cobaltocene or Na/Hg produced as the major product an isomeric mixture of the yellow bis(cyclohexadienyl) complexes $[(\eta^5\text{-DBT})Mn(CO)_3]_2$, an example of which is shown as structure **6**.† Isomers of **6** occur because the dienyl rings can couple at various sites. Analogous ring-coupled dimeric cyclohexadienyl complexes are known to result from the reduction of $[(arene)Mn(CO)_3]^+$ (arene = benzene, mesitylene).[9] Far more interesting is a dark red minor product that was isolated† and shown by X-ray crystallography to be **5**.‡ The yield of **5** was only *ca.* 10%, but this improved to > 20% when $[Mn_2(CO)_{10}]$ was added to the reaction mixture. The structure of **5**, illustrated in Fig. 1, shows that precoordination of $Mn(CO)_3^+$ to a carbocyclic ring of DBT provides sufficient activation so that manganese can insert into the adjacent C–S bond. The transformation **4** → **5** is initiated by electron transfer, probably by a mechanistic pathway that depends on the known[10] ease with which ring slippage and arene ligand displacement occur with conjugated polyarene complexes of $Mn(CO)_3^+$.

A novel feature of **5** is the coordination of the sulfur to three metal atoms. The sulfur atom in the metallathiacyclic ring acts as a bridging ligand to $Mn_2(CO)_8$, in analogy to the bridging sulfur in $[Mn_2(CO)_8\{S(CH_2)_4\}]$, which is obtained by the reaction of tetrahydrothiophene and $[Mn_2(CO)_{10}]$.[11] Thus, the sulfur atom in **5** has significantly enhanced donor properties in comparison to the sulfur in free DBT. An attempt was made to remove the $Mn_2(CO)_8$ fragment from **5** by ligand substitution with CO at room temp., but this was unsuccessful. However, treatment of **5** in CH_2Cl_2 with HBF_4 in CH_2Cl_2 led to a change from red to yellow; after chromatography on neutral alumina, a low yield (17%) of a thermally unstable red complex was obtained that is assigned structure **7** based on comparison of spectroscopic data to that of **2** (R = H). It is likely that the initial yellow product in this reaction contained a protonated sulfur, which converted to **7** during the chromatographic procedure. In a similar vein, the reaction of **5** with methyl triflate afforded a good yield of the methylated complex **8**.§ An X-ray structural study of **8**$[CF_3SO_3]$ was plagued by disorder in the triflate anion, but the data were sufficient to establish the structure unequivocally.¶ Complex **5** has a highly non-planar metallathiacyclic ring. The twist angle between the arene rings in **5**, as measured by the C(2)–C(3)–C(9)–C(8) torsion angle, is



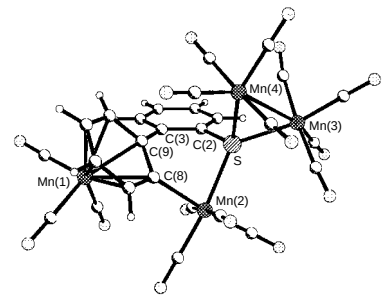


Fig. 1 Crystal structure of **5**. Selected bond distances (Å) and angles (°): Mn(2)–S 2.408(1), Mn(2)–C(8), 2.095(4), Mn(3)–S 2.301(1), Mn(4)–S 2.320(1), Mn(3)–Mn(4), 2.773(1), C(2)–S 1.804(4), C(2)–C(3) 1.394(6), C(3)–C(9) 1.499(6), C(8)–C(9) 1.447(6), S–Mn(3)–Mn(4) 53.43(3), Mn(3)–S–Mn(4) 73.76(4), S–Mn(4)–Mn(3) 52.81(3), S–Mn(2)–C(8) 80.82(11).

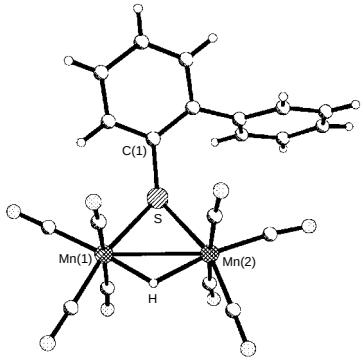

Fig. 2 Crystal structure of **9**. Selected bond distances (Å) and angles (°): Mn(1)–S 2.315(14), Mn(2)–S 2.346(2), Mn(1)–H 1.66(4), Mn(2)–H 1.75(4), Mn(1)–Mn(2) 2.883(1), S–C(1) 1.801(5), Mn(1)–S–Mn(2) 75.71(4), Mn(1)–H–Mn(2) 115(2). The twist angle between the arene rings in the thiolate ligand is 54°.

47.1(6)° and is somewhat larger than the 30–40° range found by Myers *et al.*[4j] for a series of dibenzothiophenes having the (η-C_5Me_5)Rh(PMe_3) fragment inserted into a C–S bond.

Reaction of **5** with H_2 at 500 psi and 97 °C for 3 h led to clean hydrogenolysis of the Mn–C σ-bond to afford complex **9**, which features bridging hydride and biphenyl thiolate ligands, and a Mn–Mn bond.‖ The structure and relevant intramolecular parameters for **9** are given in Fig. 2.** Interestingly, the bimetallic structural unit Mn_2(H)(SR) found in **9** also forms when the manganese thiophene and benzothiophene bimetallics **2** and **3** are hydrogenated.[5b,12] Analogous bridging species containing the fragment Ir_2(H)(SR) and RhW(H)(SR) have very recently been reported in model HDS studies of thiophene and benzothiophene complexes.[7c,13] The structural unit M_2(H)(SR) is significant because of a possible relationship to species occurring on the surface of heterogeneous HDS catalysts.[7,13] Preliminary hydrogenation experiments with **8** under conditions similar to those used with **5** gave [$Mn(CO)_5$(SMe)] rather than **9** as the major organometallic product.†† This shows that complete desulfurization of DBT can be achieved by alkylation of the multimetallic intermediate **5** (or **7**).

In conclusion, we have demonstrated that coordination of $Mn(CO)_3^+$ to a carbocyclic ring of dibenzothiophene activates a C–S bond to reductive cleavage, affording the tetrametallic species **5**. Hydrogenation of **5** produces the bridging hydride **9**, while methylation of **5** followed by hydrogenation results in desulfurization of the DBT with the concomitant formation of [$Mn(CO)_5$(SMe)].

† Cobaltocene (47 mg, 0.249 mmol) was added to a suspension of **4**[BF_4] (105 mg, 0.256 mmol) in CH_2Cl_2 (5 ml) and the mixture stirred under N_2 for 30 min at room temp. The solvent was then stripped and the residue chromatographed on deactivated neutral alumina with pentane to elute [$Mn_2(CO)_{10}$], free DBT and unidentified trace products, then with Et_2O to elute **6** (and its isomers, collectively labeled '**6**'), and finally with CH_2Cl_2 to elute **5**. The isolated yields of **6** and **5** were 45 and 5 mg, respectively. When [$Mn_2(CO)_{10}$] was added to the reaction mixture (215 mg, 0.551 mmol), the yield of **5** increased to 20 mg. The presence of an atmosphere of CO had no discernable effect on the product distribution. IR, NMR, MS and elemental analysis data for **5**–**9** and [$Mn(CO)_5$(SMe)] are available upon request from the authors.

‡ Crystal dimensions 0.11 × 0.20 × 0.34 mm, crystal system triclinic, space group $P\bar{1}$, a = 10.0482(3), b = 10.1494(3), c = 16.3738(5) Å, α = 73.532(1), β = 78.792(1), γ = 78.268(1)°, U = 1551.19(8) Å^3, Z = 2, D_c = 1.765 g cm^{-3}, μ = 1.730 mm^{-1}, θ range 2.09–26.45°, 424 variables refined with 6139 independent reflections to final R indices [$I > 2\sigma(I)$] of R = 0.0587 and wR_2 = 0.1160 and GOF = 1.113. CCDC 182/678.

§ Methyl triflate (100 μl, 0.883 mmol) was added to **5** (22 mg, 0.027 mmol) in CH_2Cl_2 (5 ml) and the solution was stirred for 18 h at room temp. under N_2, during which time it changed from red to yellow. The solution was then filtered through cotton wool and concentrated. Diethyl ether was added to precipitate the product as a yellow powder in a yield of 86% (15 mg, 0.023 mmol).

¶ The crystal structure of **8**[CF_3SO_3] was determined as described in footnote ‡. However, owing to low intensities and disorder in the triflate anion, the structure refined only to R = 0.140. Nevertheless, the atom connectivity indicated in structure **8** is unequivocal.

‖ Complex **5** (25 mg, 0.030 mmol) in dry CH_2Cl_2 (2 ml) was placed in a Parr bomb and treated with H_2 at 500 psi and 97 °C for 3 h. (A gas mixture consisting of 95% H_2 and 5% CO gave the same results.) After cooling to room temp., the product was purified by TLC on silica gel with pentane eluent. A bright yellow band separated cleanly, from which **9** was isolated in 87% yield (13.8 mg, 0.0265 mmol) as a yellow oil.

** Crystal dimensions 0.22 × 0.14 × 0.09 mm, crystal system triclinic, space group $P\bar{1}$, a = 7.1767(1), b = 15.3254(1), c = 19.6549(1), α = 90.363(1), β = 93.210(1), γ = 95.236(1)°, U = 2149.21(3) Å^3, Z = 4, D_c = 1.608 g cm^{-3}, μ = 1.316 mm^{-1}, θ range 1.68 to 24.83°, 567 variables refined with 7224 independent reflections to final R indices [$I > 2\sigma(I)$] of R = 0.0549 and wR_2 = 0.0889, and GOF = 1.005.

†† Complex **8** in CH_2Cl_2 was pressurized to 550 psi with H_2–CO (95 : 5) at 97 °C for 9 h. After solvent removal, the product, [$Mn(CO)_5$(SMe)], was extracted into hexanes.

The first sandwich silver cluster of a trinuclear cyclic gold(I) complex

A new type of metal sandwich structure [Ag{[Au(μ-N^3,C^2-bzim)]$_3$}$_2$]BF_4·CH_2Cl_2 1, is formed by reacting the neutral, triangular cluster [Au(μ-N^3,C^2-bzim)]$_3$ with Ag^+; these units stack with two short intermolecular Au···Au distances of *ca.* 3.2 Å.

In 1970 Vaughan[1] reported the synthesis of organogold derivatives of the 2-pyridyl ligands that were thought to be trinuclear cyclic gold(I) species, based upon the coordination requirements of the gold(I) atoms. In the following years analogous compounds were isolated and depending upon the types of 1,2 bridging ligands, N–Au–C^2 or N–Au–N^3 arrangements were described. Some of these were structurally characterized.[4] The structures all have nine-atom rings where the intramolecular Au···Au distances range between 3.224(1) and 3.368(1) Å. Only weak metal–metal interactions are present, hence these compounds are classified as polynuclear non-cluster species.

Reactivity investigations of these trimeric gold(I) complexes indicate that the bridging ligand plays an important role. While the carbeniato gold(I) derivatives undergo stepwise oxidative halogen addition to form three distinct complexes, [AuC(O-Me)=NMe]$_3X_n$ (n = 2,4, 6; X = Br, I),[5] the pyrazolato trimers [Au(μ-3.5-R_2pz)$_3$} (R = alky1, aryl) only oxidized at one center yielding mixed valence $Au^I_2Au^{III}$ complexes: [Au(μ-3,5-R_2pz)]$_3I_2$;[6] [Au(μ-3,5-Ph_2-4-Cl-pz)]$_3Cl_2$.[7] Additionally, [Au(μ-N^3,C^2-bzim)]$_3$ (N^3,C^2-bzim = 1-benzylimidazolate) also undergoes oxidation by only 1 equiv. of I_2 yielding the mixed-valence complex [Au(μ-N^3,C^2-Bzim)]$_3I_2$.[8] However, this complex can be oxidized completely to a Au^{III} derivative [Au(μ-N^3,C^2-bzim)]$_3C1_6$[9] by $SOCl_2$.

While reactions of metal ions such as $AuPPh_3^+$, $Ag(PPh_3)_2^+$ or Ag^+ with transition metal clusters represent a well known method for cluster expansion synthesis,[10] few examples of the addition of metal ions to dinuclear gold(I) complexes have been reported.[11] An addition strategy has not been reported at all for cyclic trimer gold(I) compounds. Here we describe the results of the reaction of [Au(μ-N^3,C^2-bzim)]$_3$ with Ag^+ to produce a novel[12] silver sandwich cluster [Ag{[Au(μ-N^3,C^2-bzim)]$_3$}$_2$]$^+$. By layering a solution of $AgBF_4$ in MeCN over a CH_2Cl_2 solution of [Au(μ-N^3,C^2-bzim)]$_3$, a yellow luminescent† precipitate was formed immediately in almost quantitative yield. After several months, the precipitate, standing in contact with the solvent was completely transformed into small yellow crystals of the cluster [Ag{[Au(μ-N^3,C^2-bzim)]$_3$}$_2$]BF_4·CH_2Cl_2 **1**. The compound is stable in the solid state‡ but dissolution in a coordinating solvent like Me_2SO yields the starting materials as determined by NMR spectroscopy.

The molecular structure§ of the cation **1** is shown in Fig. 1 while Fig. 2 presents the stacking arrangement observed. The naked silver ion center is bonded to six gold atoms to form a distorted, Ag^I centered trigonal prism of Au^I atoms with Ag–Au distances ranging from 2.731(2) to 2.922(2) Å, indicative of appreciable metal–metal bonding. These distances are close to distances observed in other gold–silver derivatives[11] wherein the silver atoms bridging two gold centers are always supported by other ancillary ligands.

The gold–silver bonds may be regarded as arising from a nucleophilic or Lewis base interaction of the gold atoms with the silver ion, which acts as a Lewis acid. The d^{10}–d^{10} closed shell Au^I–Ag^I bonds probably also relate to the weak Au···Au bonds, estimated to be 6–8 kcal mol^{-1} (1 cal = 4.184 J), which arise from correlation and relativistic effects.[13] The average Au···Au intramolecular distance in the cyclic trimer moiety

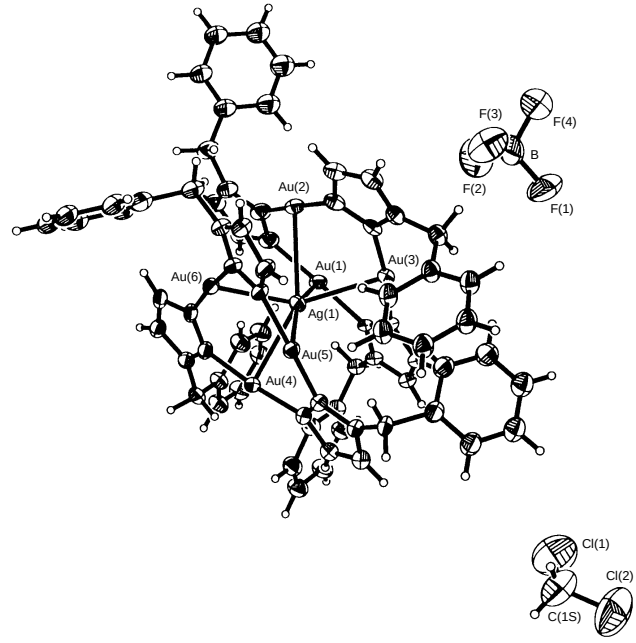

Fig. 1 Thermal ellipsoid drawing (50% probability) of the structure of [Ag{[Au(μ-N^3,C^2-bzim)]$_3$}$_2$]BF_4·CH_2Cl_2 **1**. The Ag–Au distances range from 2.731(2) to 2.922(2) Å.

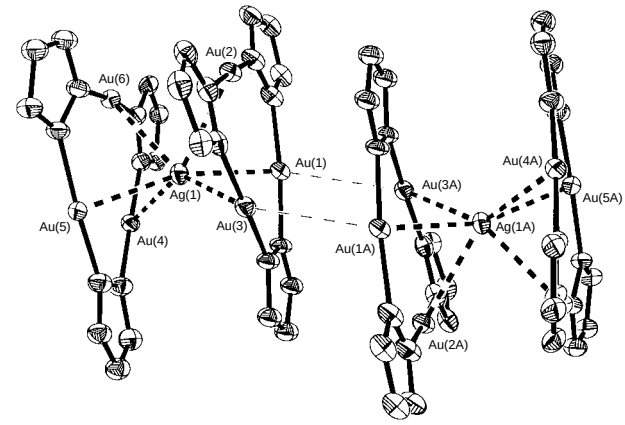

Fig. 2 Stacked sandwich structure of the cation of [Ag{[Au(μ-N^3,C^2-bzim)]$_3$}$_2$]BF_4·CH_2Cl_2 **1**. The intermolecular Au(1)···Au(3A) distance is 3.268(2) Å.

forming the sandwich unit is 3.19 Å. This is shorter than the distance observed for $Au^{I}\cdots Au^{I}$ in $[Au(\mu\text{-}N^3,C^2\text{-Bzim})]_3I_2$.[8]

In Fig. 2, the interactions between two close sandwich units can be seen. The short distances Au(3)···Au(1A) 3.268 Å and Au(4)···Au(5A) 3.116 Å, are indicative of weak intermolecular bonds between gold atoms. Considering also the atoms Au(2) and Au(2A) which are widely separated, a characteristic Au_6 cycle is formed in a chair conformation. This arrangement also was observed in the carbeniato trimer $[AuC(OEt)=NC_6H_4Me]_3$ structure.[4] The inter- and intra-molecular interactions present in **1** result in the formation of an infinite chain of gold–silver atoms which are expected to show interesting properties as observed for molecular chain compounds such as $[Rh_6(MeCN)_4]^{9+}$.[14]

In cluster **1** the bridging imidazole rings show C–Au and N–Au distances of *ca.* 2.0 Å, similar to distances found in $[Au(\mu\text{-}N^3,C^2\text{-bzim})]_3I_2$.[8] Three of the N–Au–C angles show significant distortions from linearity, namely N(1)–Au(1)–C(9) [173.9(8)], N(3)–Au(3)–C(5) [172.9(7)] and N(6)–Au(6)–C(17) [172.9(7)]. This distortion could be a result of the interaction of the silver atom with the gold atoms. Further investigations into the reactivity of other trinuclear cyclic gold(I) complex with electrophilic metal ions are underway.

The studies at the University of Camerino have been supported by MURST while those at Texas A&M University have been supported by the Robert A. Welch Foundation.

§ *Crystal data* for 1; $C_{61}H_{56}AgAu_6BC1_2F_4N_{12}$, M = 2404.57; triclinic, space group $P\bar{1}$, a = 14.4505(1), b = 15,098(2), c = 15.9571(1) Å, α = 106.189(3), β = 103.551(5), γ = 101.310(5)°, U = 3120.3(5) Å^3, Z = 2, D_c = 2.547 g cm^{-3}, F(000) 2192, λ = 0.710 73 Å , T = 213(2) K, crystal size = 0.15 × 0.10 × 0.05 mm.

Data were collected using a Siemens SMART CCD (charge coupled device) based diffractometer equipped with an LT-2 low temperature apparatus operating at 213 K. A total of 13 371 reflections were collected using ω scans with 1.40 < 2θ < 22.50°. Of these 8077 were unique (R_{int} = 0.0503 after absorption correction applied, based on ψ scans, $T_{min,max}$ 0.9361, 0.6366). The structure was solved by the direct method using the SHELXS-97 program and refined by least squares methods on F^2. SHELXL-97[16] incorporated in SHELXTL-PC V 5.03.[17] All non-hydrogen atoms were refined anisotropically. Hydrogens were calculated by geometrical methods and refined as a riding model. The crystal used for the diffraction study showed no decomposition during data collection. The refinement converged at R_1 = 0.0583 [$I > 2\sigma(I)$] and wR_2 = 0.1217 (all data). The final difference map showed no peak greater than + 0.639 e Å^{-3} and no hole larger than −0.454 e Å^{-3}. CCDC 182/688.

Catalytic hydroxylation of alkanes by immobilized mononuclear iron carboxylate

Keiji Miki* and Takeshi Furuya

National Institute for Resources and Environment, 16-3 Onogawa, Tsukuba, Ibaraki 305, Japan

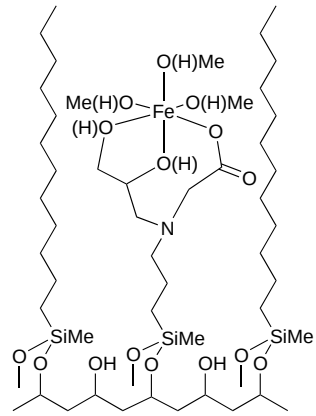
Mononuclear iron carboxylate complex immobilized and isolated on a modified silica surface (1) catalyzes oxidation of hexane to a mixture of hexan-1-ol, -2-ol and -3-ol without ketone formation in the presence of mercaptan, acetic acid, triphenylphosphine and O_2 at ambient conditions.

Biomimetic oxidation studies on non-heme iron enzymes have been extensively reported for the direct hydroxylation of saturated hydrocarbons at ambient conditions.[1,2] Most of the efforts have been focused on the modeling of dinuclear iron complexes, because of the structural correspondence to the active site of methane monooxygenase (MMO). In this report we describe a novel catalytic oxidation yielding only alcohols from alkanes by mononuclear iron carboxylate complex immobilized and isolated on a modified silica surface (**1**) in the presence of mercaptan (propane-1,3-dithiol, PDT), acetic acid (AcOH), triphenylphosphine (PPh_3) and O_2.

For the effective catalytic turnover, it was necessary to protect the complex against decomposition. Immobilization and isolation on an amorphous silica powder (Aerosil 200, specific surface area = 200 $m^2\ g^{-1}$) was employed for this purpose. A dilute solution of masked ligand, isopropylidene ketal and *tert*-butyl ester of 3-[*N*-(2,3-dihydroxypropyl)-*N*-carboxymethyl]-aminopropylmethylsilyl group,† was first anchored on the surface and the remnant silanols were subsequently blocked by diethoxydodecylmethylsilane. Removal of the protecting groups resulted in the attachment of highly dispersed ligands at a concentration of 4.8×10^{-2} mmol g^{-1} (3.2% of total silanols) as quantified by the measurement of nitrogen content. Loaded dodecylmethylsilyl groups, 3.75×10^{-1} mmol g^{-1} based on carbon content, were estimated to cover 25.3% of total silanols. The high coverage implies that long alkylsilyl groups are tightly packed in the cylindroid arrangement on the surface.[3]

Complexation in 2.5 mM $Fe(NO_3)_3$–methanol, followed by thorough washing with methanol yielded immobilization of 4.3×10^{-2} mmol g^{-1} iron (determined colorimetrically) which occupied 90% of the ligands previously anchored. The formation of complex was confirmed by the appearance of asymmetric CO vibration at 1570 cm^{-1} and a decrease in the signal representing free carboxyl groups at 1715 cm^{-1} with FTIR. Taking into account the remainder of a trace amount of ester (1740 cm^{-1}), the complexation seemed to be accomplished in almost quantitative yield. In addition treatment of the white powder in 200 mM HCl–dioxane gave three methanol molecules per iron, while the elemental analysis did not show the presence of nitrogen derived from NO_3. The EPR spectrum revealed a broad signal at $g = 4.2$ which was assigned to a high spin mononuclear iron(III). We thus propose the structure shown in Scheme 1 for synthesized complex **1**.

Oxidation of alkanes was carried out in an acetonitrile solution as described in Table 1. No oxidation took place if either O_2 or PDT was omitted. In the presence of PDT alone or AcOH/PDT without PPh_3, hexane was not oxidized, but cyclohexane yielded a trace of cyclohexanol. By contrast, assay containing PPh_3 remarkably improved the reaction. Without AcOH, conversion was low, but in the complete system, hexane was selectively oxidized to hexanols with a total turnover number of 59 in the ratio of 1-ol (14%), 2-ol (44%) and 3-ol (42%). Similarly cyclohexane was converted to cyclohexanol alone with a turnover of 109. Catalyst recovered by acetonitrile washing after the assay showed a slight decrease in iron content,‡ but there was no change in the hydroxylation activity. The catalytic turnover is evidently due to the immobilized mononuclear iron carboxylate. Recovered catalyst, however, showed an iron : methanol molar ratio of 1 : 1 which differed from the original 1 : 3. Since this phenomenon was not observed in the catalyst recovered from an anaerobic assay, the change in the iron environment can be accounted for through the



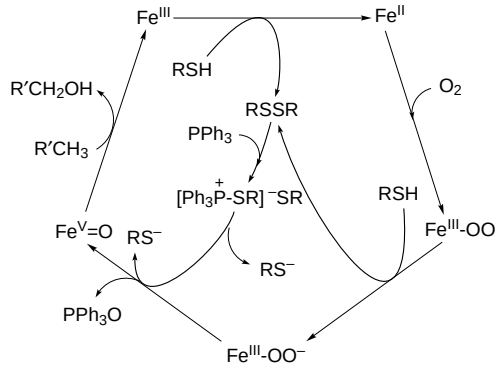
1

Scheme 1 Proposed structure for immobilized iron carboxylate

Table 1 Hydroxylation of alkanes by immobilized mononuclear iron carboxylate (**1**)[a]

Run	Substrate	Additives	Products (yield)[b]	Total yield
1	Hexane	PDT, PPh_3	1-ol (1.0), 2-ol (1.7), 3-ol (1.4)	4.1
2	Hexane	AcOH, PDT, PPh_3	1-ol (8.1), 2-ol (26.0), 3-ol (25.3)	59.4
3[c]	Hexane	AcOH, PDT, PPh_3	1-ol (8.3), 2-ol (25.5), 3-ol (24.8)	58.6
4	Cyclohexane	PDT, PPh_3	Cyclohexanol (10.0)	10.0
5	Cyclohexane	AcOH, PDT, PPh_3	Cyclohexanol (109.2)	109.2

[a] Catalyst (0.5 μmol iron), substrate (3.5 mmol), AcOH (0.25 mmol), PDT (0.25 mmol), PPh_3 (0.25 mmol) were placed into a 20 ml vial containing acetonitrile (2.6 ml) and sealed with a Teflon septum. After replacing the gas phase by O_2, the vial was shaken at 180 strokes min^{-1} and 25 °C for 4 h using a Bioshaker. [b] Moles of product per mole of iron. [c] Catalyst recovered from the assay scaled up tenfold was used.



Scheme 2 Hypothetical catalytic cycle of immobilized mononuclear iron carboxylate (**1**) for alkane hydroxylation

participation of oxygen during the catalytic cycle. After release of oxygen, acetonitrile may serve as alternative ligands.

When oxidation was carried out without substrate, PPh_3 was converted to PPh_3O with a turnover number of 136. Also we can not rule out unavoidable oxidation of the alkane chains adjacent to the active center in **1**, considering the strong oxidative capability toward primary C–H. Such competitive oxidation explains the rapid consumption of PPh_3 causing unexpected termination of the catalytic turnover as well as the requirement of high concentration of substrate for effective hydroxylation in our system.

A hypothetical mechanism for this notable catalytic hydroxylation is illustrated in Scheme 2. The reduction of Fe^{III} to Fe^{II} by mercaptan initiates the reaction. Mercaptan consumed at this stage is converted to alkyl disulfide which is subsequently attacked by the PPh_3 nucleophile to form thioalkoxyphosphonium cation intermediate.[4] Since the intermediate is known to be readily trapped by a carboxylic acid in refluxing acetonitrile to yield mercaptan, thioester and PPh_3O,[5] a similar reaction could be possible in the presence of AcOH. On the other hand, the assay using $^{18}O_2$ demonstrated almost quantitative ^{18}O incorporation into both PPh_3O and hexanols regardless of the AcOH addition. Accordingly the intermediate is directly attacked by a dioxygen– metal adduct, presumably a peroxoiron species, to release PPh_3O. The resulting O–O bond scission is thought to allow the generation of an iron–oxo species from which oxygen is transferred to the substrate. The role of AcOH is therefore assumed to protonate the thiolate anion and promote its dissociation from the intermediate ion pair.

The participation of PPh_3 in the O–O bond cleavage is similar to that of acylating reagents in cytochrome P450 model studies.[6] In fact we could detect the same hexanols in the hydroxylation of hexane using **1**, KO_2–18-crown-6 and acetic anhydride in benzene although the yield was low (total turnover number = 0.12). Furthermore [tetrakis(pentafluorophenyl)porphyrinate] iron(III) hydroxide instead of **1** oxidized hexane to only hexanols in comparable product yield and distribution in our system. The results again support the formation of a high-valent iron–oxo species being responsible for the hydroxylation of alkanes by **1**.

Interestingly a hydroperoxoiron(III) species was identified by EPR spectroscopy at 77 K (g = 2.27, 2.20, 1.97)[7] when the porphyrin iron complex was reduced with an equivalent of PDT and then exposed to O_2. Addition of H_2O_2 gave an identical EPR signal. The same intermediate has been reported in the model studies of bleomycin with mononuclear iron coordinating nitrogen ligands.[8] By contrast this phenomenon was not found in the investigation using **1**, and there was no effect of the intermediate on the hydroxylation of alkanes even with the addition of PPh_3 or AcOH–PPh_3. The fact may reflect a characteristic nature of the iron complex with oxygen-rich ligands involving carboxylate different from those bearing a porphyrin or nitrogen ligands.

It now appears that mononuclear iron carboxylate can catalyze highly selective hydroxylation of alkanes by reductive dioxygen activation. The key reaction is assumed to be the efficient heterolytic scission of the O–O bond by the PPh_3 participated deoxygenation. However, regarding the generation of putatively unstable Fe^{V}=O species in a mononuclear iron core, there is an argument against delocalization of the oxidizing equivalents.[2] This point contrasts to a Fe^{IV}=O dinuclear cluster which has been reported recently as the critical intermediate of MMO.[9] The results obtained in this work could be attributed to unique properties of the complex with predominantly oxygen ligation in a hydrophobic microenvironment analogous to the active site of an enzyme buried in a protein matrix.

Control of ligand–metal interaction at the lower rim of *p-tert*-butylcalix[5]arene

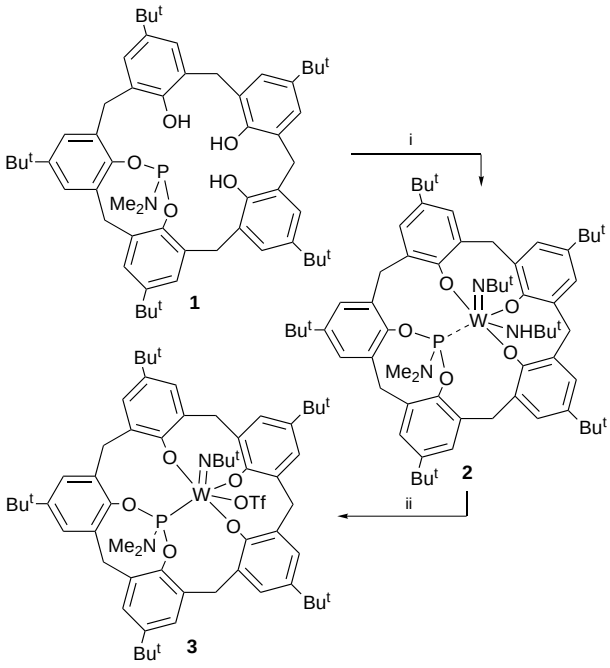
Maomian Fan, Hongming Zhang and Michael Lattman*

Department of Chemistry, Southern Methodist University, Dallas, Texas 75275-0314, USA

The lower rim of *p-tert*-butylcalix[5]arene is able to accommodate both a ligand and metal in close proximity allowing subtle electronic changes to dramatically affect ligand–metal interaction.

The ability to constrain the mobility of a ligand relative to a metal can have far-reaching applications from catalysis to molecular devices. This is particularly true when such systems can stabilize relatively weak ligand–metal interactions. Herein we report the synthesis of such a system based on a calix[5]arene and demonstrate the control of ligand–metal bonding *via* small electronic changes at the metal.

Treatment of *p-tert*-butylcalix[5]arene[1] with tris(dimethylamino)phosphine[2] inserts a Me_2NP moiety into the calixarene.† The ^{1}H NMR spectrum of **1** is consistent with the symmetry of the proposed structure: three singlets in the *tert*-butyl region in a 2 : 1 : 2 ratio and six doublets in the methylene region owing to the fact that the two hydrogens on each methylene carbon are non-equivalent. Also, the ^{31}P NMR signal at δ 131 is in the region for a three-coordinate phosphorus with two phenolic groups and a dialkylamino group.[3] If the cavity of the calix[5]arene is large enough, the three remaining hydroxyls should be able to bind a metal. In fact, insertion of tungsten proceeds smoothly by the reaction of **1** with $(Bu^tN)_2W(NHBu^t)_2$[4] *via* elimination of 2 moles of *tert*-butylamine (Scheme 1).‡ As expected, the ^{1}H NMR spectrum of **2** is similar to **1** in the *tert*-butyl and methylene regions. In addition, two new Bu^t singlets are present due to the tungsten-bound *tert*-butyl-amido and -imido ligands. The ^{31}P NMR signal at δ 116 is only 15 ppm upfield of **1**. More importantly, this signal shows a small coupling to W of 43 Hz, significantly smaller than usual $^1J_{PW}$ values.[5] This suggests a weak (through-space?) P–W interaction. Amido and imido ligands are known to be excellent π donors to high-oxidation-state metals.[6] If one of these ligands could be replaced with another that puts less electron density at the metal, this might increase the P–W interaction. This is exactly what occurs when triflate replaces *tert*-butylamido *via* the reaction of **2** with an excess of trifluoromethanesulfonic acid in refluxing toluene to give **3**.§ The $^1J_{PW}$ value in **3** of 352 Hz is in the usual range of P–W bonds which is indicative of a significantly stronger P–W interaction.



Scheme 1 *Reagents and conditions:* i, $+(Bu^tN)_2W(NHBu^t)_2$, -2 H_2NBu^t; ii, excess HOTf, reflux, $-H_2NBu^t$

The X-ray crystal structures¶ of **2** and **3** substantiate the above spectral interpretations and provide detail on the structural changes associated with increasing the P–W interaction. The structures of **2** and **3** are illustrated in Figs. 1 and 2, respectively. Selected bond lengths and angles are given in the captions. In **2**, the calix[5]arene backbone adopts a somewhat flattened conformation. The phosphorus has a distorted pyramidal geometry, while the tungsten adopts a distorted square-pyramidal geometry. The phosphorus lone pair is oriented towards the vacant sixth coordination site at the tungsten with a P···W distance of 3.15 Å, well outside the longest bond lengths reported for P–W bonds;[7] however, it is close enough to exhibit a small through-space PW coupling in the NMR spectrum. After

ligand exchange, the calix[5]arene backbone in **3** adopts the cone conformation with the phosphorus bound to the tungsten at the 'lower' rim. The P–W distance is 2.74 Å which is long but still within reported ranges for P–W bonds. The triflate lies outside the cavity of the calixarene, while the imido is within the cavity. As expected, the W–O(6) (triflate) distance is longer than the other W–O distances, indicative of a more weakly bound group.

The structures of **2** and **3** also account for certain anomalies in their ^{1}H NMR spectra. The dimethylamino group resonance in **2** at δ 1.53 is about 1.5 ppm upfield of its usual position, and the (imido) *tert*-butyl group resonance in **3** at δ − 1.03 is about 2 ppm upfield of its usual position. Figs. 1 and 2 show that the protons of these groups lie above and inside the aromatic rings of the calix[5]arene resulting in upfield ring current shifts for these signals.

We have demonstrated that a calix[5]arene is large enough to bind both a ligand and metal at the lower rim. Moreover, the macrocycle appears to orient the ligand and metal toward one another. This constraint supports both a weak and strong ligand–metal interaction, depending on the electron density at the metal. It may also be useful to view the tri-deprotonated form of **1** as a tetradentate ligand with three hard (oxygen) binding sites and one soft (phosphorus) binding site. Work is currently under way to determine how general this chemistry is by incorporating other metals and ligands.

Subvalent germanium and tin complexes supported by a dianionic calixarene ligand: structural characterization of *exo* and *endo* isomers of [Bu^{t}calix$^{(TMS)2}$]Ge

Tony Hascall,[a] Arnold L. Rheingold,[b] Ilia Guzei[b] and Gerard Parkin*[a]

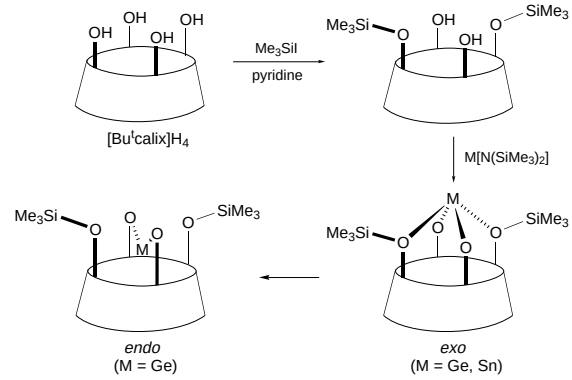
[a] *Department of Chemistry, Columbia University, New York, New York 10027, USA*
[b] *Department of Chemistry and Biochemistry, Univesity of Delaware, Newark, Delaware 19716, USA*

The 1,3-bis(trimethylsilyl) ether of *p-tert*-butylcalix[4]arene, [Bu^{t}calix$^{(TMS)2}$]H$_2$, has been synthesized and used as a dianionic ligand for Ge and Sn; notably, the Ge complex [Bu^{t}calix$^{(TMS)2}$]Ge exhibits *exo*/*endo* isomerism, and provides the first calixarene system for which both isomers have been structurally characterized.

The calix[*n*]arenes are a class of 'chalice-like' macrocyclic molecules that have recently attracted widespread attention.[1] In particular, these molecules have been extensively studied as receptors for small organic molecules and simple cations.[1] By comparison, however, calix[*n*]arenes have been infrequently used as ancilliary ligands for studying the chemistry of transition and main group metals.[2,3] Moreover, for those situations where calix[*n*]arenes have been employed as supporting ligands, their application has been mainly restricted to the use of *p-tert*-butylcalix[4]arene in its tetraanionic form.† 1,3-Dialkyl ethers of calix[4]arenes, [calix^{R2}]H$_2$, on the other hand, offer the potential for providing dianionic macrocyclic ligands which may be considered as oxygen relatives of well known N-containing macrocycles, such as porphyrins, phthalocyanines and tetraazaannulenes. Despite such analogies, the application of 1,3-diethers of calix[4]arenes as ligands for main group metals has been limited to recent reports concerned with the 1,3-dimethyl ether of *p-tert*-butylcalix[4]arene.[3*a*–*c*] Here, we report the synthesis of a more sterically demanding, 1,3-disubstituted calix[4]arene, namely bis(trimethylsilyl)-*p-tert*-butylcalix[4]arene, its use as a ligand for divalent Ge and Sn, and the first structural characterization of a pair of *exo* and *endo* isomers of a calix[*n*]arene derivative.

Our particular interest in the use of 1,3-dialkylcalix[4]arenes as O-donor macrocyclic ligands derives from recent studies concerned with Ge and Sn complexes supported by the octamethyldibenzotetraaza[14]annulene dianion, *e.g.* the subvalent and terminal chalcogenido complexes [η^4-Me$_8$taa]M and [η^4-Me$_8$taa]ME (M = Ge, Sn; E = S, Se, Te).[4–6] In order to extend this chemistry, we sought to synthesize analogous complexes derived from related macrocycles which contain O (rather than N) donor functionalities. For this purpose, 1,3-dialkyl ether calix[4]arene derivatives incorporating bulky substituents (*e.g.* SiMe$_3$) appeared ideal. Although 1,3-diethers of *p-tert*-butylcalix[4]arene incorporating primary alkyl substituents have been synthesized previously by the reaction of the calix[4]arene with 2 equiv. of alkyl halides in the presence of a weak base,[1*c*] the bis(trimethylsilyl) derivative [Bu^{t}calix$^{(TMS)2}$]H$_2$ could not be isolated using such procedures.‡[8] Nevertheless, we have found that the reaction of *p-tert*-butylcalix[4]arene with Me$_3$SiI (2 equiv.) in the presence of pyridine (2 equiv.) affords a useful synthesis of [Bu^{t}calix$^{(TMS)2}$]H$_2$ (Scheme 1).

Divalent Ge and Sn complexes [Bu^{t}calix$^{(TMS)2}$]M are readily obtained by the reaction of [Bu^{t}calix$^{(TMS)2}$]H$_2$ with M[N(SiMe$_3$)$_2$]$_2$ (M = Ge, Sn) as illustrated in Scheme 1. Each of the products has been structurally characterized by X-ray diffraction, as shown in Fig. 1 and 2.§ Interestingly, for the Ge



Scheme 1

system, the reaction yields sequentially two isomers, namely *exo*- and *endo*-[Bu^{t}calix$^{(TMS)2}$]Ge, which differ in the location of the Ge atom with respect to the calixarene cavity (Figs. 1 and 2).¶ *Exo* and *endo* isomerism of this type has previously been suggested for the aluminium hydride complex [Bu^{t}calix^{Me2}]-AlH, for which the Al–H moiety may be directed into, or away from, the calixarene cavity.[3*b*] However, only the structure of *exo*-[Bu^{t}calix^{Me2}]AlH has been determined by X-ray diffraction, with the nature of the *endo* isomer having been inferred by NMR spectroscopy. The Ge complexes described here, therefore, constitute the first pair of *exo* and *endo* isomers to be structurally characterized.

The coordination geometries about Ge in *exo*- and *endo*-[Bu^{t}calix$^{(TMS)2}$]Ge are summarized in Table 1, from which it is evident that both complexes exhibit Ge–O bond lengths to the phenoxide moieties which are comparable to, but slightly shorter than, the sum of their covalent radii (1.96 Å).‖ For the *endo* isomer, the Ge center is located *ca.* 3.5 Å from the O atoms of the trimethylsilylether groups, so that it is appropriately

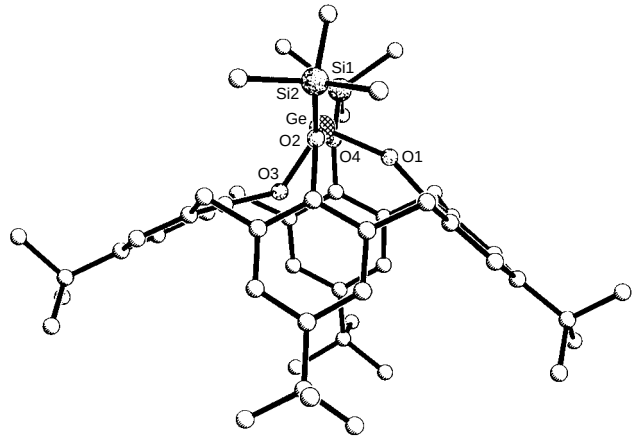


Fig. 1 The molecular structure of *exo*-[Bu^{t}calix$^{(TMS)2}$]Ge (the Sn analogue is similar)

Table 1 Metrical data for [Bu^{t}calix$^{(TMS)_2}$]M (M = Ge, Sn)

	d(M–O^1)/Å	d(M–O^3)/Å	d(M···O^2)/Å	d(M···O^4)/Å	O–M–O/°
exo-[Bu^{t}calix$^{(TMS)_2}$]Ge	1.765(6)	1.842(6)	2.421(5)	2.486(5)	100.2(3)
endo-[Bu^{t}calix$^{(TMS)_2}$]Ge	1.841(5)	1.853(5)	3.460(5)	3.565(6)	92.81(22)
	1.840(5)	1.849(5)	3.454(6)	2.458(5)	92.02(23)
exo-[Bu^{t}calix$^{(TMS)_2}$]Sn	1.956(7)	2.011(9)	2.521(6)	2.532(6)	96.3(4)

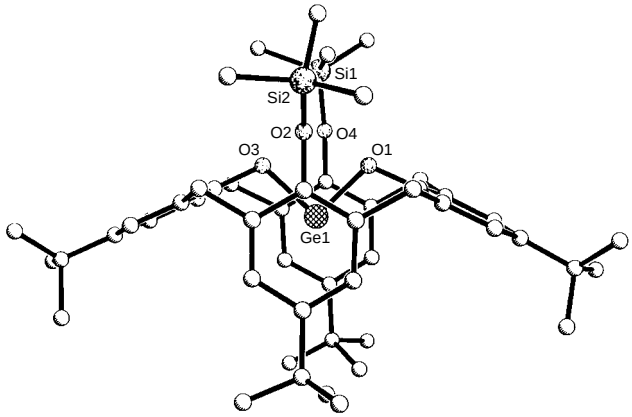

Fig. 2 The molecular structure of *endo*-[Bu^{t}calix$^{(TMS)_2}$]Ge (only one of the crystallographically independent molecules is shown)

considered to be two-coordinate, with the dianionic calixarene acting as a bidentate, rather than tetradentate, ligand. As such, the coordination environment offered by the dianionic calixarene provides a contrast with the tetracoordination provided by related macrocyclic derivatives, *e.g.* [η^4-Me$_8$taa]Ge.[4] The ability of the calixarene to sustain monomeric two-coordinate Ge^{II} centers is of interest since complexes with such coordination environments are uncommon; for example, only two two-coordinate Ge^{II} alkoxide complexes are listed in the Cambridge Structural Database (Version 5.13), namely (ArO)$_2$Ge (Ar = C$_6$H$_2$MeBu$^t_2$) and (Bu$^t_3$CO)$_2$Ge.‖ In contrast to the two-coordinate *endo* isomer, the *exo* isomer does exhibit interactions with the O atoms of the trimethylsilylether groups (*ca.* 2.45 Å) that are shorter than the sum of their van der Waals radii (3.40 Å).‖

It is interesting to note that, despite the observation that the dative interaction between Ge and the trimethylsilyl ether groups is shorter for the *exo* isomer, the *endo* isomer is evidently the more thermodynamically stable, as judged by the observed *exo* to *endo* isomerization.**,†† Thus, the [O→Ge] dative interactions in the *exo* isomer are presumably weak and insufficient to compensate for other structural changes which accompany the isomerization. For example, one factor which favors the *endo* isomer being the more stable is concerned with the possibility that the calixarene conformation is such that it furnishes a more appropriate bite angle for Ge in the *endo* position than for Ge in the *exo* position (compare Figs. 1 and 2). Supporting this notion, the O–Ge–O bond angle for the *exo* isomer [100.2(3)°] is notably larger than is observed for simple (RO)$_2$Ge complexes (*ca.* 86–92°)‖ which are not subject to the constraints of the macrocyclic configuration. In contrast, the *endo* isomer does exhibit a O–Ge–O bond angle (*ca.* 92.4°) that is comparable to the values for (RO)$_2$Ge derivatives, thereby suggesting that there is less strain for the *endo* isomer, so that it may be more thermodynamically favored.‡‡

† For the use of neutral calixarene ligands, see ref. 3(*f*).

‡ Specifically, only recovered *p-tert*-butylcalix[4]arene was obtained from the reaction of (*i*) *p-tert*-butylcalix[4]arene with Me$_3$SiCl and (Me$_3$Si)$_2$NH, and (*ii*) *p-tert*-butylcalix[4]arene with Me$_3$SiCl and Li$_2$S. The latter reaction, however, did provide evidence for formation of the bis-(trimethylsilyl) ether derivative, but the product could not be isolated.[7a] Tetrakis(trimethylsilyl)-*p-tert*-butylcalix[4]arene has, however, been obtained by the reaction of the calix[4]arene with N,O-tris(trimethylsilyl)-acetamide.[7b]

§ *Crystallography. exo*-[Bu^{t}calix$^{(TMS)_2}$]Ge·C$_6$H$_5$Me is monoclinic, $P2_1/c$ (no. 14), a = 23.275(3), b = 18.829(2), c = 13.245(1) Å, β = 105.059(7)°, U = 5605(1) Å^3, Z = 4, R [$I > 2\sigma(I)$] = 0.0738. *endo*-[Bu^{t}calix$^{(TMS)_2}$]Ge is monoclinic, $P2_1/c$ (no. 14), a = 28.2718(3), b = 18.4591(1), c = 20.5583(1) Å, β = 111.245(1)°, U = 9999.7(1) Å^3, Z = 8, R [$I > 2\sigma(I)$] = 0.1027. *exo*-[Bu^{t}calix$^{(TMS)_2}$]Sn·C$_6$H$_6$ is monoclinic, $P2_1/c$ (no. 14), a = 23.339(7), b = 18.684(4), c = 13.204(3) Å, β = 105.98(1)°, U = 5535(1) Å^3, Z = 4, R [$I > 2\sigma(I)$] = 0.0744. CCDC 182/655.

¶ In contrast, for the Sn system, only the *exo* isomer has been isolated so far.

‖ For comparison, the following metrical data have been reported for two-coordinate Ge and Sn alkoxide and aryloxide complexes: (*i*) (ArO)$_2$Ge (Ar = C$_6$H$_2$MeBu$^t_2$): (Ge–O) 1.802(8), 1.812(7) Å; O–Ge–O 92.0(4)°;[9–a] (*ii*) (ArO)$_2$Sn (Ar = C$_6$H$_2$MeBu$^t_2$): (Sn–O) 1.995(4), 2.022(4) Å; O–Sn–O 88.8(2)°;[9a] (*iii*) (Bu$^t_3$CO)$_2$Ge: (Ge–O) 1.896(6), 1.832(11) Å; O–Ge–O 85.9(4)°.[9b]

** The conversion of *exo*-[Bu^{t}calix$^{(TMS)_2}$]Ge to its *endo* isomer (*ca.* 95%) has been observed to occur over a 1 h at *ca.* 80 °C, as monitored by ^{1}H NMR spectroscopy.

†† The *endo* isomer of [Bu^{t}calix^{Me_2}]AlH has also been reported to be more stable than its *exo* isomer. See ref. (3*b*).

‡‡ Other factors, such as the small conformational differences of the calixarene ligand, may also influence the stability of the *endo* with respect to *exo* isomer.

A coordination network based on d^0 transition-metal centers: synthesis and structure of the [2,4]-connected layered compound $[(TiCl_4)_2Si(C_6H_4CN\text{-}p)_4]\cdot 1.5C_7H_8$

The tetrafunctional silane $Si(C_6H_4CN\text{-}p)_4$ forms a coordination network with $TiCl_4$ consisting of 4,2-connected layers containing large (56 atom) rings.

There has been considerable recent interest in the construction and study of coordination networks based on coordinate bonds between polyfunctional ligands and various metal centers.[1–8] These materials often possess well defined (crystalline) structures which are related to those for more condensed mineral phases such as diamond,[1] $SrSi_2$,[9] α-$ThSi_2$,[10] rutile[11] and PtS.[12] Since coordination networks may possess large pores or channels,[12,13] which in principle might contain strategically located transition metal centers, there is interest in developing such systems as selective, heterogeneous catalysts.[14] A few reports have appeared on the use of tetrahedral ligands, in combination with Cu and Ag, as building blocks for construction of coordination networks.[1,2] Our work in this area is based on the tetrafunctional silane $Si(C_6H_4CN\text{-}p)_4$ **1**, which has been used to prepare Ag-containing networks.[15]

To our knowledge, there have been no reports on three-dimensional coordination networks based on early transition metal d^0 centers. Such materials might be expected to function as catalysts for a variety of reactions, including alkene polymerization.[16] Here we report initial efforts in this area, involving the synthesis and characterization of the titanium-containing network solid $[(TiCl_4)_2Si(C_6H_4CN\text{-}p)_4]\cdot 1.5C_7H_8$, which has a layered structure related to that of α-HgI_2.

Layering a solution of $TiCl_4$ (2 equiv.) in benzene over a solution of **1** in dichloromethane resulted in the slow precipitation of a yellow solid, which was isolated by filtration after 5 d and dried under vacuum for 4 h. By combustion and ^1H NMR analysis, this material is formulated as $(TiCl_4)_2Si(C_6H_4CN\text{-}p)_4\cdot 0.6C_6H_6$ **2a**.† Light-yellow crystals of **2b** were obtained in 55% yield by heating a sealed tube containing **2a** and toluene to 140 °C for 10 h, followed by slow cooling over 6 h to room temp.‡ The IR spectrum of **2b** exhibits bands for the nitrile groups which are blue shifted to 2231 and 2271 cm^{-1} with respect to the band for the tetrahedral ligand **1** (ν_{CN} 2229 cm^{-1}).[17]

The structure of **2b** consists of [4,2]-connected infinite layers formed by the linking of molecules of **1** by $TiCl_4$ units (Fig. 1).§ Each molecule of **1** is coordinated to four Ti centers, each of which links two units of **1** *via cis*-coordination of nitrile groups in the roughly octahedral titanium coordination sphere. There are two independent Ti centers in the unit cell, which possess slightly different bond distances and angles. The octahedral coordination geometries for the independent titanium centers are significantly distorted such that the '*trans*' chloride ligands form Cl–Ti–Cl angles of 162.31(3) and 160.67(7)°. These chloride ligands are associated with Ti–Cl distances [2.253(2)–2.310(2) Å] which are longer than those for chloride ligands *trans* to the nitrile groups [2.209(2)–2.241(2) Å]. The silicon centers are in distorted tetrahedral environments, such that the C–Si–C bond angles range from 103.2(2)–113.7(2)°. The N–Ti–N angles for the two pseudo-octahedra are 78.0(2) and 81.4(2)°. For comparison, Zaworotko has previously reported two-dimensional frameworks based on tetrahedral building blocks.[6]

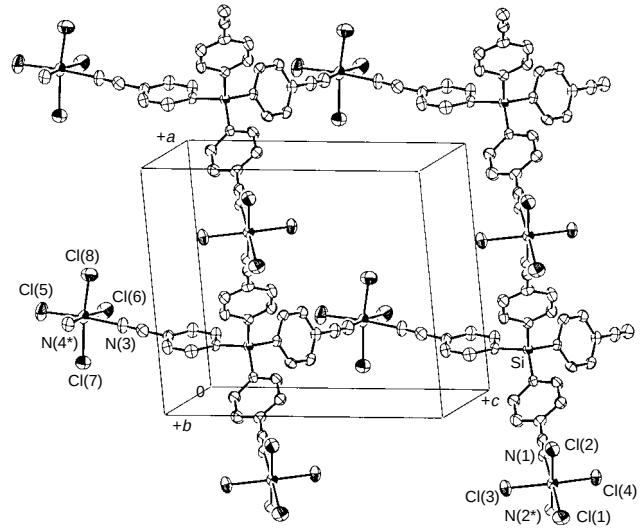

Fig. 1 ORTEP diagram illustrating part of a net in the structure of **2b**

The layers in the structure lie in the *ac* plane, and there are two such layers in each repeat along the *b*-axis, which are overlapping and related by centers of inversion in the structure. The tetrahedral ligands **1** form a square network in each net, with $TiCl_4$ groups protruding above and below the planes. A simplified drawing of two overlapping nets, illustrating their 'buckled' character, is given in Fig. 2. All of the 'upward' $TiCl_4$ groups pack in a rough column along the *b*-axis, as do all the 'downward' $TiCl_4$ groups. Disordered toluene molecules are packed between the layers, to fill voids in the structure. The two-dimensional framework of **2b** may therefore be described as a [4,2]-connected net, with tetraconnected silicon centers and biconnected titanium centers in a 1:2 ratio.[18] Thus, this

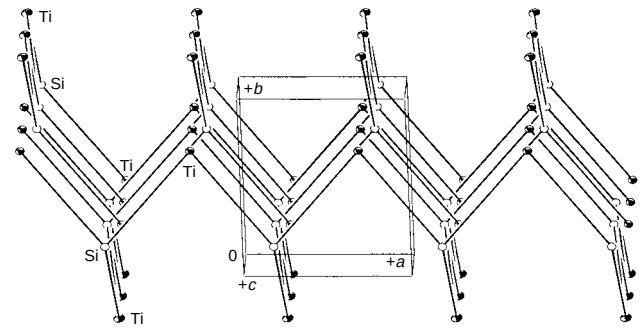

Fig. 2 A view of two overlapping nets in the structure of **2b**. The $-NCC_6H_4-$ linkages are depicted as long 'bonds', the titanium centers are shown as shaded ellipsoids, and the silicon atoms appear as unshaded ellipsoids.

structure is related to those adopted by some binary compounds with the AX_2 formula. Since the titanium centers link the tetrahedral building blocks **1** *via cis*-bonding of nitrile groups, the structure of **2b** is similar to that of α-HgI_2 in which the tetrahedral Hg centers lie in a plane.[19]

Thermogravimetry (TG) of **2a** and **2b** indicate that these networks are somewhat thermally unstable. Thus, the TG traces for these materials exhibit significant mass losses (*ca*. 32 and 35%, respectively) over the temperature range 25–280 °C, but **2a** loses mass much faster than **2b** during this step, which corresponds to loss of solvent as well as some decomposition of the framework. Both **2a** and **2b** exhibited the same decomposition step over the temperature range 340–500 °C.

A preliminary test of **2b** as a catalyst for the polymerization of propylene in the presence of triethylaluminium as cocatalyst (heptane solvent, 1 atm propylene) produced only 0.400 g of polypropylene from 0.190 g of **2b**.[20,21] The heptane-soluble fraction (atactic, M_n = 24 400; PDI = 3.3, by gel permeation chromatography using polystyrene standards) represented 75% of the sample by mass and the remaining (presumably isotactic) heptane-insoluble fraction (M_n = 93 000; PDI = 2.1) was slightly soluble in THF.

Binuclear cyclopalladated cyclophanes: towards a new family of metallomesogens

Bernhard Neumann,[a] Torsten Hegmann,[a] Raik Wolf[b] and Carsten Tschierske*[a]

[a] *Martin-Luther-Universität Halle-Wittenberg, Institut für Organische Chemie, Kurt-Mothes-Straße 2, D-06120 Halle, Germany*
[b] *Martin-Luther-Universität Halle-Wittenberg, Institut für Pharmazeutische Technologie und Biopharmazie, Wolfgang-Langenbeck-Straße 4, D-06120 Halle, Germany*

Macrocyclic liquid crystals consisting of a biphenyl rigid core and a 2-phenylpyrimidine unit are fused by cyclopalladation giving a novel type of metallomesogens with nematic and smectic mesophases.

The continuing development of liquid-crystal-based technologies requires novel mesomorphic materials with special physical properties and much research has been carried out to prepare new types of liquid crystalline materials. In recent years metal containing liquid crystals have been developed and intensively investigated.[1] These metallomesogens allow the creation of quite unusual molecular geometries, which are difficult to achieve with purely organic materials. Additionally, interesting electronic and magnetic properties have been reported. Recently, another type of unconventional liquid crystals has been described. These are macrocyclic compounds incorporating conformationally flexible[2] or rigid[3] rod-like groups connected by appropriate flexible spacer units. It was found that they exhibit mesophases that are more stable than those of the corresponding low and high molecular mass open chain liquid crystals. Based on this observation we decided to synthesise macrocycles incorporating two different units. One of them is mainly responsible for the liquid crystalline properties whereas the other one should introduce a certain functionality, such as electron acceptor/donor properties,[4] photosensitivity or molecular recognition ability. Using the macrocycle approach these functional units can be connected with the mesogenic groups in a side specific manner, which should allow the tailoring of specific properties hopefully without losing the liquid crystalline properties.

Here, we describe the synthesis and the liquid crystalline behaviour of novel macrocyclic compounds which combine a 4,4′-substituted biphenyl core with a 2-phenylpyrimidine unit connected by polyether chains. The 2-phenylpyrimidine units can serve as ligands for the formation of liquid crystalline organometallics by orthopalladation.[5,6] In this way it should be possible to fuse two macrocyclic liquid crystals side by side. This novel molecular architecture combines a flat metallomesogenic heart with two additional calamitic mesogens.

The synthesis of the macrocycles **1** and **2** was carried out as outlined in Scheme 1 by cyclisation of 4,4′-bis[13-(toluenesulfonyloxy)-2,5,8,11-tetraoxatridecyl]biphenyl[7] or 4,4′-bis[12-(toluenesulfonyloxy)-4,7,10-trioxadodecyloxy]biphenyl† with 2-(hydroxyphenyl)-5-hydroxypyrimidine under high dilution conditions in the presence of potassium toluene-*p*-sulfonate (K^+OTs^-) as a template resulting in a yield of 21 and 35%, respectively. Correct spectral data which support the cyclic structure were obtained for both compounds.‡ The $[M + H]^+$, $[M + Na]^+$ and $[M + K]^+$ peaks in the electrospray MS§ correspond to the cyclic structures. No additional peaks could be detected in the scanned range up to $m/z = 2000$. Therefore other macrocycles with larger sizes should be absent.

The phase behaviour of the macrocycles was investigated by polarising microscopy. Compound **1** shows a monotropic nematic phase with a clearing temperature at 142 °C. The isotropic melt of compound **2** in which the polyether chains are connected *via* flexible methylene units with the biphenyl core can easily be supercooled to room temp. without transition to a liquid crystalline phase.

The orthopalladation reaction was carried out by reaction of the macrocyclic ligands **1** and **2** with $Pd(PhCN)_2Cl_2$[8] which leads in moderate yields (63 and 42%, respectively) to the corresponding metallomesogens **Pd1** and **Pd2** (Scheme 1). The ^1H NMR spectra of the complexes show a substitution pattern expected for palladium attack at C-2′ and one of the nitrogen atom of the phenylpyrimidine core. In negative ionization ESMS several peaks with typical isotopic pattern corresponding

[a] Decomposition.

to $[Pd_2(Cl)_2L_2 + Cl]^-$ occur.¶ From these results and from the structures of related 2-phenylpyrimidine-Pd^{II} complexes[5] we assume the complexes contain a dimetallic core in which each Pd^{II} atom is in a square geometry.

The phase transition temperatures of **Pd1** and **Pd2** are shown and compared with the free ligands in Table 1. Compound **Pd1** exhibits an enantiotropic nematic phase indicated by the typical *schlieren* texture and marbelled textures observable between crossed polarizers. The clearing temperature of the nematic phase is significantly enhanced in comparison to the parent macrocycle **1**. On cooling below 208 °C the transition to another enantiotropic phase takes place which is indicated by the occurrence of a focal conic fan texture. This can easily be homeotropically aligned and thus clearly indicates a smectic A phase.

The metallomesogen **Pd2** obtained from the non-mesomorphic cyclophane **2** shows exclusively a monotropic nematic phase with a clearing temperature at 91 °C.

The higher clearing temperatures of the complexes in comparison with the ligands, the formation of an S_A layer structure in the phase sequence of compound **Pd1**, and the induction of a liquid crystalline nematic phase in the metallomesogen **Pd2** indicate a significant mesophase stabilisation caused by the orthopalladation with formation of a fused macrocyclic ring system. The amount of mesophase stabilisation corresponds to that observed for the orthopalladation of conventional 2-phenylpyrimidines[5] and should result from the better intermolecular interaction due to the $Pd(\mu\text{-}X)_2Pd$ core as well as from their rigid molecular structure.

The unusual molecular shape of compounds **Pd1** and **Pd2** imposes the question concerning the type of the observed nematic phases. One can assume that they represent uniaxial nematic phases made up by the individual rod-shaped rigid building blocks. On the other hand the molecules as a whole can probably adapt a disc- or a board-like shape. Thus, the nematic phases could also be made up by disc-shaped molecules. However, the occurrence of a smectic layer structure as a low temperature mesophase in the phase sequence of compound **Pd1** and the complete miscibility of the nematic phases of **Pd1** and **Pd2** with those of calamitic compounds are in line with a nematic phase made up of rod like molecules.

Interestingly, a biaxial nematic phase was recently proposed for a macrocyclic liquid crystal.[9] However, no hint of the presence of a biaxial nematic phase‖ has been found for the macrocyclic metallomesogens **Pd1** and **Pd2**.

In summary, the macrocyclic 2-phenylpyrimidine derivatives **1** and **2** are able to form dinuclear metallomesogens. The orthopalladated compounds **Pd1** and **Pd2** represent a novel type of metallomesogens and form more stable liquid crystalline phases than the parent macrocyclic ligands.

Mechanism of low thermal expansion in the cation-ordered Nasicon structure

David A. Woodcock,[a] Philip Lightfoot*[a] and Clemens Ritter[b]

[a] *School of Chemistry, University of St. Andrews, St. Andrews, Fife, UK KY16 9ST*
[b] *Institut Laue Langevin BP 156, 38042, Grenoble Cedex 9, France*

Variable temperature neutron powder diffraction data are used to pinpoint the mechanism of low thermal expansivity in the Nasicon-related material $Sr_{0.5}Ti_2(PO_4)_3$; this behaviour is contrasted with that of the parent phase $NaTi_2(PO_4)_3$.

There has recently been considerable interest in materials displaying the remarkable property of negative, or very low, thermal expansivity. New materials displaying this property include $ZrP_{2-x}V_xO_7$[1] and ZrW_2O_8,[2] but by far the most widely studied types have been the Nasicon or NZP family, based on the $NaZr_2(PO_4)_3$ structure.[3–5] The NZP structure is a three-dimensional lattice consisting of vertex-linked TiO_6 and PO_4 polyhedra, with the large Na cation occupying interstitial trigonal prismatic (MI) sites spaced at intervals along the *c*-axis (Fig. 1). $NaZr_2(PO_4)_3$ itself crystallises in space group $R\bar{3}c$, having only one crystallographically distinct Na site. A wide variety of adaptations may be made to the basic NZP stoichiometry by substitutions at all three non-oxygen sites. One such series is $M_{0.5}Ti_2(PO_4)_3$, where M is a divalent cation (Ca, Sr, Ba). The Ca and Sr compounds adopt the lower symmetry $R\bar{3}$ space group owing to alternate ordering of M and vacancy along the *c*-axis, leading to crystallographically distinct MIa and MIb sites. Measurements of lattice parameter evolution *vs.* temperature, by X-ray powder diffraction, have shown that, in general, the thermal expansivity behaviour of the $R\bar{3}c$ and $R\bar{3}$ families is different, with the former showing a positive coefficient of the *c*-axis expansivity (α_c) and a negative coefficient of the *a*-axis expansivity (α_a), while the situation for the $R\bar{3}$ family is reversed.[5,6] Although a very elegant general model has been proposed to describe the thermal behaviour of these materials, in terms of cooperative rotations of linked polyhedra,[7,8] the specific issue of the contrasting behaviour of the $R\bar{3}c$ and $R\bar{3}$ series has not been satisfactorily addressed. Here, we show that this behaviour is directly related to the cation-vacancy ordering, and is due to the compressibility of the vacant site along the *c*-axis.

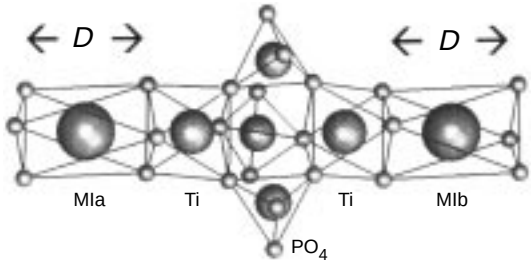

Fig. 1 Portion of the ideal NZP structure showing packing of polyhedral units along the *c*-axis. In $Sr_{0.5}Ti_2(PO_4)_3$ the MIa site (0,0,0) is fully occupied while the MIb site (0,0,1/2) is vacant. The parameter *D* refers to the O···O distance along the *c*-axis.

Samples were prepared from stoichiometric quantities of TiO_2, $(NH_4)_2HPO_4$ and Na_2CO_3 or $SrCO_3$. Thoroughly ground mixtures were preheated at 200 °C, followed by subsequent heat treatments at 600, 900 and 1000 °C with intermediate regrinding. For the Sr sample a final treatment at 1200 °C was required. Neutron diffraction data were collected on the high flux diffractometer D1B at the ILL, Grenoble, using a wavelength of 2.522 Å and a fixed detector bank covering 80° in 2θ. In order to determine the thermal evolution of the lattice parameters, a series of 123 short (*ca.* 10 min) scans was collected over the range $25 < T < 835$ °C. These scans were refined with the cyclic version of the refinement program FULLPROF[9] using the result for a run at a given temperature as input file for the following run with slightly higher temperature. Runs at selected temperatures were then chosen for detailed structural analysis. Rietveld refinement was carried out using the GSAS package.[10] The starting model for the refinement of the $Sr_{0.5}Ti_2(PO_4)_3$ structure was taken from Senbhagaraman *et al.*[11] A typical refinement consisted of 17 structural para-

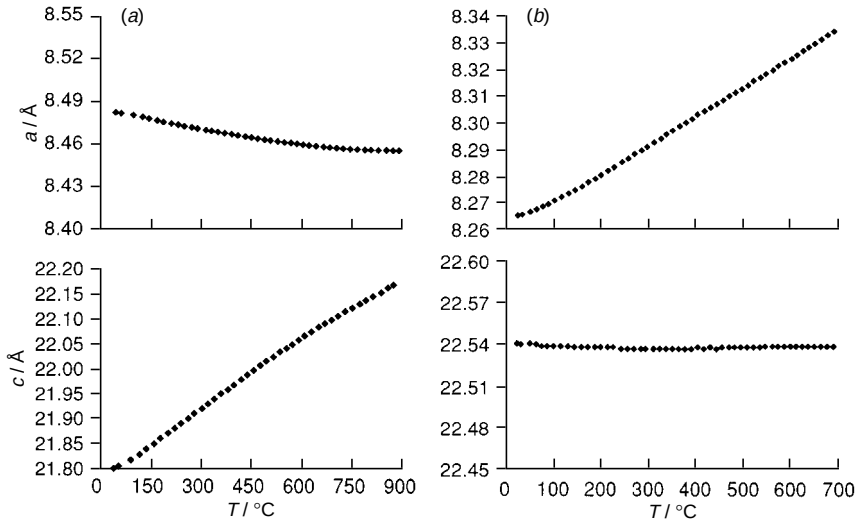

Fig. 2 Thermal evolution of lattice parameters for (*a*) $NaTi_2(PO_4)_3$ and (*b*) $Sr_{0.5}Ti_2(PO_4)_3$

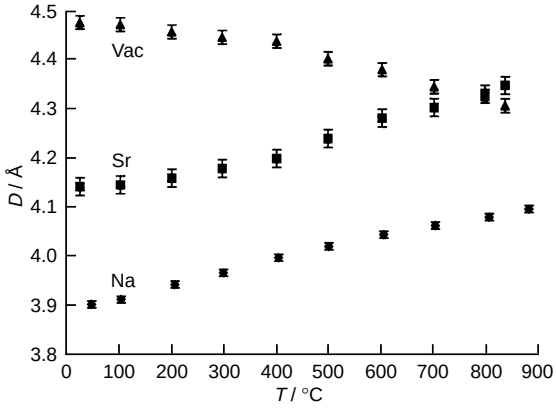

Fig. 3 Thermal evolution of the trigonal prismatic MI sites (*i.e.* O···O distance, *D*, along the *c*-axis). In $NaTi_2(PO_4)_3$ the *c*-axis expansivity is governed by $2 \times D$(Na), in $Sr_{0.5}Ti_2(PO_4)_3$ by *D*(Sr) + *D*(vac).

meters, with 400 data points and 80 contributing reflections over the range $18 < 2\theta < 98°$.

Plots of the thermal evolution of the lattice parameters for both compounds are shown in Fig. 2. Values of α_a and α_c are -5.3 and 20.8×10^{-6} °C^{-1} for $NaTi_2(PO_4)_3$ in the range 25–500 °C and 13.2 and -0.02×10^{-6} °C^{-1} for $Sr_{0.5}Ti_2(PO_4)_3$ in the range 25–800 °C, which are in good agreement with those reported by earlier studies.[5,6,12] Although thermal evolution of lattice parameters by X-ray powder diffraction has been carried out for both these samples, the present study provides, for the first time, precise structural details by neutron diffraction, which allows us to pinpoint the mechanism of their behaviour. One of the most significant trends is the near-zero expansivity of the *c*-axis for the Sr compound. It has previously been suggested that the largest contribution to the expansivity in NZP materials is the expansion of the Na–O bond itself. This governs the 'size' of the trigonal prismatic site along the *c*-axis (*i.e.* the O–O contact), which is plotted in Fig. 3. In the case of the Sr compound in $R\bar{3}$ there are two such sites to consider, the Sr site and the vacancy site, which are confirmed to be completely ordered from the refinements. It can be seen that, in the Na compound this site expands, by *ca*. 0.20 Å over the full temperature range, accounting completely for the overall expansivity α_c (two per unit cell), whereas in the Sr compound there is an expansion of the Sr site but a contraction of the vacancy site. These two almost exactly cancel out, resulting in the observed near-zero expansion coefficient, α_c. These parameters in turn result in the cooperative polyhedral rotations described by earlier workers, and lead to the expansivities along the *a*-axis. A full analysis of these effects will be the subject of a later paper, but the fundamental explanation of the *c*-axis expansivity lies simply in the relative expansion/contraction of the occupied and vacant MI sites. The anomaly previously observed in the case of $Ca_{0.5}Zr_2(PO_4)_3$, which shows the behaviour of an $R\bar{3}c$ structure rather than an $R\bar{3}$ structure[13] lies in the fact that in that case both the Ca site and the vacancy site expand with temperature, resulting in a net expansion of the *c*-axis. Apparently the smaller vacancy site in that case (*ca*. 4.1 Å at 25 °C) is not as compressible as the vacancy site in the present phase. A diffraction experiment cannot differentiate whether the unusual behaviour of the Sr phase is due to cation-ordering *per se* or merely the presence of equal numbers of filled and vacant MI sites. However, it is interesting to note that a larger value of $\alpha_c = 1.37 \times 10^{-6}$ °C^{-1} has been reported for $Ba_{0.5}Ti_2(PO_4)_3$, which crystallises in the disordered $R\bar{3}c$ structure type.[6] A comparative, detailed neutron diffraction study of the Sr and Ba materials is therefore currently in progress.

We would like to thank the EPSRC for the provision of a studentship to D. A. W., and Mr C. J. Milne for help in collecting the neutron diffraction data.

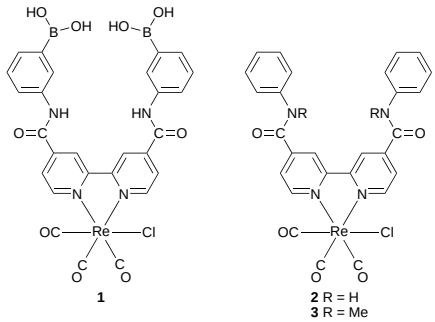
Synthesis and optical sensing properties of a boronic acid appended rhenium(I) complex for sugar

Vivian Wing-Wah Yam* and Alex Sze-Fai Kai

Department of Chemistry, The University of Hong Kong, Pokfulam Road, Hong Kong, PR China

A rhenium(I) complex with boronic acid pendant is synthesized and characterized; the complex is shown to exhibit pH dependent electronic absorption characteristics; the photophysical properties and sugar sensing behaviour are also investigated.

Boronic acids, which have been known to form covalently bonded complexes with diols in aqueous system, have attracted a great deal of attention as an interactive tool for sugar recognition.[1,2] Much attention has been focused on the application of boronic acids with organic backbones as fluorescent chemosensors for sugars.[2] Although there were reports on the synthesis of iron(II) complexes with boronic acid-containing ligands, they were mainly confined to those of electrochemical[3] and circular dichroism (CD) spectroscopic studies.[4] There has been, to the best of our knowledge, no report of transition metal coordination/organometallic compounds of this kind employed as absorbance or luminescence probes. With our recent interest in the utilization of metal-to-ligand charge transfer (MLCT) excited states as spectrochemical and luminescence probes as well as in the study of host–guest interactions,[5] an attempt to extend our attention to sugar recognition was pursued. Herein are reported the synthesis and luminescence behaviour of a rhenium(I) complex **1** with boronic acid pendant. The changes in the electronic absorption and luminescence properties induced by the presence of various types of mono- and di-saccharides have been investigated and the binding constants determined using spectrochemical methods. Complexes **2** and **3** have also been synthesized for comparative spectrochemical studies. All complexes **1**–**3** have been characterized by ^{1}H NMR, IR spectroscopy and positive FAB mass spectrometry, and gave satisfactory elemental analyses.†



The UV–VIS spectrum of complex **1** shows a low energy absorption band at *ca*. 370 nm, typical of the MLCT transition of rhenium(I) diimines.[6] Excitation of an aqueous solution of **1** at λ = 430 nm showed an intense luminescence at *ca.* 620 nm, which is typical of the phosphorescence derived from the triplet rhenium-to-diimine metal-to-ligand charge transfer (^{3}MLCT) excited state.[6] Both the MLCT absorption and emission bands in Me_2SO–H_2O (1 : 1 v/v) were found to show a blue shift in energy as the pH[7] was increased. Besides the blue shift from *ca.* 670 nm in acidic medium to *ca.* 620 nm in alkaline medium was observed in the emission maxima, a rise in emission intensity was found to occur as the pH increased. The pK_a of **1** was found to be 5.9, which we attributed to hydroxide capture by the boronic acid group. A typical pK_a of *ca.* 9 was reported for phenylboronic acid in aqueous solution,[8] quite different from the medium used in the present system. It is believed that coordination of the ligand to the metal centre would stabilize the boronate pendant and hence lowered its pK_a value. A similar pK_a has been obtained in a separate experiment using a universal phosphate–citrate buffer with constant ionic strength.[9] In order to choose an optimum working pH for the sugar binding studies, the absorption spectra of **1** at pH 5.5–10.5 both in the absence and in the presence of 0.2 mol dm^{-3} D-fructose were measured. D-Fructose was chosen as it has previously been reported to show the largest spectral change among the various types of saccharides studied.[1,2,8] The largest spectral change induced by D-fructose was observed at pH 8.3 for **1**, which was thus employed for our subsequent measurements.

The UV–VIS spectral traces of **1** in glycine–NaOH buffer[10] at pH 8.3 in the presence of various amounts of added D-fructose showed an isosbestic point at *ca*. 350 nm. Fig. 1 depicts the titration curve of **1** with different sugar substrates. D-Fructose was found to induce the largest spectral change of **1**. By applying the equation $A_0/(A_0 - A) = (\varepsilon_0/\varepsilon_0 - \varepsilon)[(1/K[S]) + 1]$[11] and a plot of $A_0/(A_0 - A)$ *vs.* $[S]^{-1}$, the stability constants K could be obtained from the ratio slope/*y*-intercept, where A_0 and A are the respective absorbances at 376 nm in the absence and in the presence of saccharide S with concentration [S], and ε_0 and ε are the absorption coefficients for the free and sugar-bound rhenium(I) complex, respectively. The stability constants for 1 : 1 complexation in glycine–NaOH buffer : Me_2SO (1 : 1 v/v) are: D-fructose (log K = 2.40); L-arabinose (log K = 1.56); D-galactose (log K = 1.54); D-mannose (log K = 1.29); D-glucose (log K = 1.18); maltose (log K = 0.91); lactose (log K = −0.37). It was found that D-fructose gives the largest log K value. Similar trends have also been observed in the related organic systems.[1,2]

The selective preference of **1** for mono- over di-saccharides has been attributed to the covalent bonding interaction of the hydroxyl groups on the saccharides to the boronate ions; the

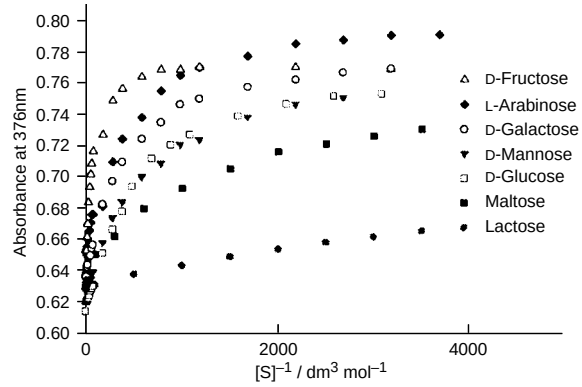


Fig. 1 Plot of absorbance of **1** (0.1 mM) at 376 nm in glycine–NaOH buffer : Me_2SO (1 : 1 v/v) at pH 8.3 as a function of sugar concentration for selected sugars

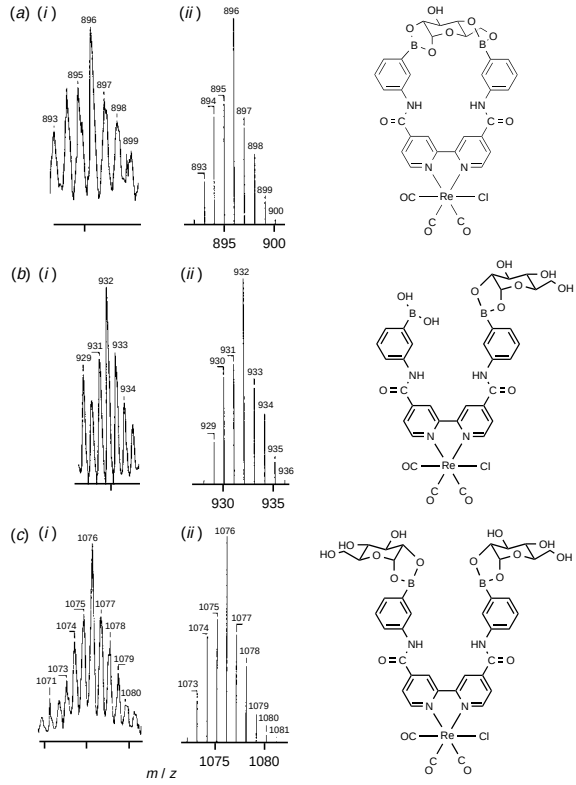

Fig. 2 Expanded ion cluster from the negative FAB mass spectrum of a buffered solution containing **1** and D-glucose. (*a*) (*i*) *m*/*z* 896, (*ii*) simulated isotope pattern for $ReB_2C_{33}ClH_{24}N_4O_{11}$; (*b*) (*i*) *m*/*z* 932, (*ii*) simulated isotope pattern for $ReB_2C_{33}ClH_{28}N_4O_{13}$; (*c*) (*i*) *m*/*z* 1076, (*ii*) simulated isotope pattern for $ReB_2C_{39}ClH_{36}N_4O_{17}$.

selectivity of which is controlled by the size of cavity as governed by the two boronate groups. The existence of the 1:1 complex of **1** with D-glucose was established by negative FAB mass spectrometry. Fig. 2 shows the expanded ion clusters observed in the mass spectrum of a mixture of **1** and D-glucose. The binding of monosaccharides, like D-glucose, to **1** gave both 1 : 1 cyclic and 1 : 1 non-cyclic bound species at low saccharide concentrations. At high concentration of saccharides, apart from the 1 : 1 complexes, the 1 : 2 complex also exists. The site of binding has also been confirmed by related studies using the analogous complex **2** in which the boronic acid groups were absent as a control. Unlike **1**, addition of D-fructose to **2** at pH 8.3 induces no spectral change, indicative of the importance of the boronic acid pendants in the binding action. However, as the pH is increased to 12.1, both **1** and **2** showed a similar increase in the absorbance upon addition of D-fructose with the absence of isosbestic points in the electronic absorption spectral traces. It is likely that under such high pH conditions, deprotonation of the amide group would occur to bind the saccharides. Deprotonation of the amido proton has been reported to occur at high pH. Organic amides such as benzanilide and *p*-bromobenzanilide showed pK_a values of 16.53 and 15.73, respectively;[12] the pK_a values are dependent on the electronic factors with electron withdrawing substituents stabilizing the imide anion, and lowering the pK_a value. The emissive behaviour of **1** and **2** is similar, each showing an emission maximum at *ca*. 620 nm, the intensity of which increased significantly upon addition of sugars. Similar changes in the emission behaviour were not observed for **1** and **2** at pH 8.3. In order to investigate the behaviour of complex **2** under high pH condition, complex **3** was prepared in which the amido protons were replaced by methyl substituents. Unlike complexes **1** and **2**, the addition of D-fructose to **3** at pH 12.1 induces no spectral change. It is worth noting that the role played by the amido group in sugar binding at high pH values should not be overlooked. Work is in progress to explore the potential of such binding properties.

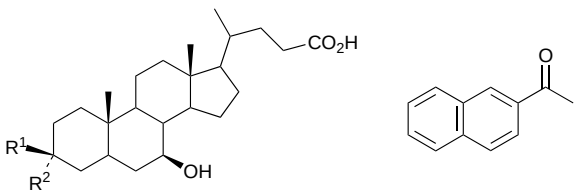
Novel channel-type inclusion compounds of 3-epiursodeoxycholic acid

Yasuhito Miyake, Junji Hirose, Yasuhiro Hasegawa, Kazuki Sada and Mikiji Miyata*

Material and Life Science, Graduate School of Engineering, Osaka University, Yamadaoka, Suita, Osaka 565, Japan

A new host, 3-epiursodeoxycholic acid, forms inclusion crystals with naphthalene derivatives with 1 : 1 stoichiometry.

Ursodeoxycholic acid (3α,7β-dihydroxy-5β-cholan-24-oic acid **1**), one of the bile acids, is well-known as a medicine,[1] originally isolated from the gall of bears.[2] Compound **1** and its 3β-isomer, 3-epiursodeoxycholic acid **2**, were believed to yield only guest-free crystals in the presence of organic substances,[3,4] although other bile acids, such as deoxycholic acid and cholic acid, tend to form inclusion crystals.[5] In contrast, our recent research has revealed that **2** includes a wide range of organic compounds. Here we report that **2** forms a layered assembly with large channels where naphthalene derivatives are included in a 1 : 1 host-to-guest ratio.



1 R^1 = H, R^2 = OH
2 R^1 = OH, R^2 = H

3

Compound **2** was prepared from commercially available **1** as described in the literature.[6] The acid was recrystallized from neat organic liquids, or from alcoholic solvents dissolving the third solid components.[7] The resulting crystals were characterized by thermogravimetric analysis, and solid state IR and ^{1}H NMR spectroscopy. A wide variety of organic compounds, such as aromatic and aliphatic alcohols, ketones, ethers, esters and so on, were included by **2** as a host, whereas they were not included by **1**. Table 1 shows a number of the inclusion compounds. It is noteworthy that **2** includes both small ketones such as pentan-3-one and naphthalene derivatives such as 2′-acetonaphthone **3** in a 1 : 1 molar ratio of host to guest. We did not observe such an inclusion in the case of other bile acids and their derivatives. For example, deoxycholic acid formed inclusion compounds with **3** in a 3 : 1 molar ratio of host to guest.

Table 1 Inclusion ability of **2** with various organic compounds

Guest	Host–guest ratio
4-Methylpentan-2-ol	1 : 1 [a,b]
2-Methylpentan-1-ol	1 : 1 [a,b]
Isobutyl acetate	1 : 1 [a,b]
Propyl propionate	1 : 1 [a,b]
Ethyl benzoate	1 : 1 [a,b]
Pentan-2-one	1 : 1 [a,b]
Pentan-3-one	1 : 1 [a,b]
4-Methylcyclohexanone	1 : 1 [a,b]
Acetophenone	1 : 1 [a,b]
Anisole	1 : 1 [a,b]
Ethylbenzene	1 : 1 [a,b]
n-Propylbenzene	1 : 1 [a,b]
Styrene	1 : 1 [a,b]
o-Xylene	1 : 1 [a,b]
2′-Acetonaphthone	1 : 1 [b]
1′-Hydroxy-2′-acetonaphthone	1 : 1 [b]
2-Methylnaphthalene	1 : 1 [b]
1-Methoxynaphthalene	1 : 1 [b]

[a] Determined by thermogravimetric analysis–differential scanning calorimetry. [b] Determined by ^{1}H NMR spectroscopy.

X-Ray powder diffraction studies showed that the inclusion compounds have very similar structures, indicating that the inclusion crystals have similar molecular assembly modes. This was confirmed by single crystal X-ray structural analysis. Single crystals suitable for analysis were obtained by recrystallization of **2** with **3**.† Fig. 1 depicts the crystal packing of the inclusion compound viewed along the crystallographic *c* axis. It can be seen that the host molecules are arranged in a 'chicken-wire' network with large channel-type inclusion spaces. The molecular assembly mode is quite unique, as inclusion crystals of other bile acids tend to form bilayered structures.[5] All the host molecules are connected by hydrogen bonds. The helical network has the sequence O(3)H··O(7)H··O(24a)=C–O(24b)H··O(3)H, where the hydrogen bonding distances are 2.744(5), 2.894(5) and 2.595(4) Å, respectively.

The channel was analysed as a space filling model, which showed that the channel could be described as a straight pillar with a rectangular cross-section of approximate dimensions 7.4 × 11.5 Å. The guest molecules are accommodated in the channels with only van der Waals contacts. It is interesting that **3** arranges perpendicular to the channel and forms a column along the crystallographic *c* axis. In the column, **3** stacks with a distance of 3.51 Å, which corresponds to half of the crystal *c* dimension (7.020 Å). The space filling model of one column is depicted in Fig. 2.

In addition, we obtained single crystals *via* recrystallization of **2** from pentan-3-one. The X-ray measurement at 193 K indicated that the guest molecules were disordered in the channels. This indicates that the guest molecules are too small in size to provide thermally stable inclusion compounds.

In conclusion, this study demonstrates that **2** forms inclusion compounds with a wide range of organic compounds. These form a new channel-type large inclusion space as compared with any other bile acids, enabling the inclusion naphthalene derivatives with 1 : 1 stoichiometry.

Novel synthesis of calamitic and discotic liquid crystalline derivatives of tetrathiafulvalene (TTF)

Richard A. Bissell,[a] Neville Boden,[a] Richard J. Bushby,*[a] Colin W. G. Fishwick,[a] Edward Holland,[a] Bijan Movaghar[a] and Goran Ungar[b]

[a] *Centre for Self-Organising Molecular Systems (SOMS), University of Leeds, Leeds, UK LS2 9JT*
[b] *Department of Engineering Materials, University of Sheffield, Sheffield, UK S1 3JD*

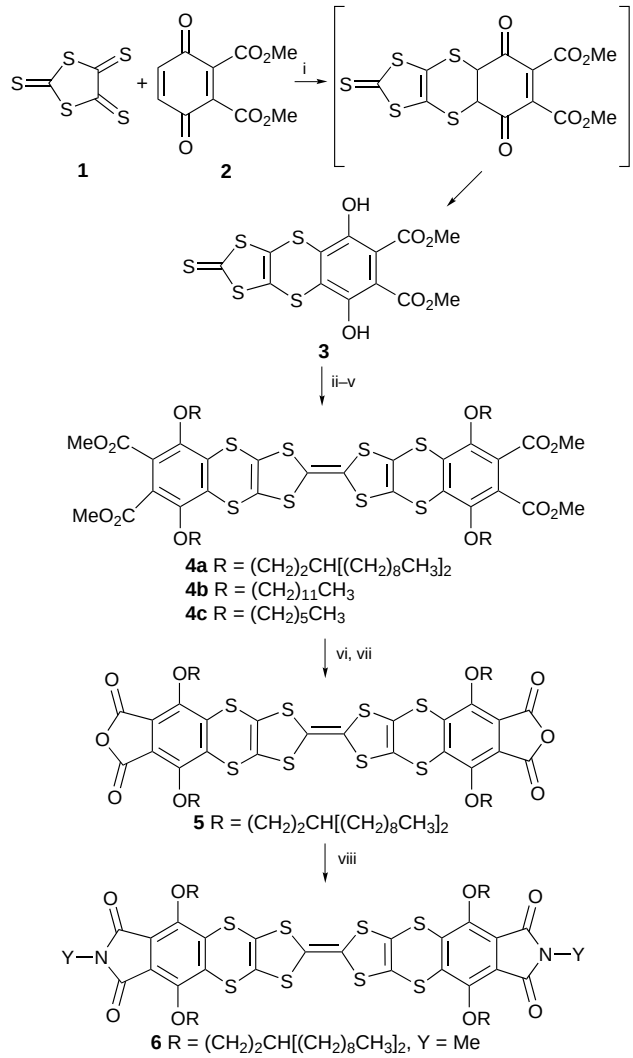
A synthesis has been developed for both calamitic and discotic mesogens based on the bis(phenylenedithio-TTF) (BPhDT-TTF) nucleus.

Only recently has attention been given to the charge transport properties of liquid crystals and the new applications that could stem from them.[1] Well defined hole transits have been obtained from the columnar phases of discotic liquid crystals[2] and it has been shown that quasi-one-dimensional electronic conduction can be induced in these systems either by n-doping[3] or by p-doping.[4] More recently it has been shown that phenylbenzothiazole-based calamitic smectic A phases (quasi-two-dimensional) give both electron and ion transits.[5] The highly efficient, anisotropic charge transport obtained suggests applications in photosensors, light-emitting diodes,[6] electrophotography and many other areas. There is, however, a need for new molecular systems. Although the success of crystalline TTF conductors[7] makes liquid crystalline derivatives of TTF an obvious synthetic target little progress has been made in this area.[8]

Our synthesis, which is shown in Scheme 1, enables us to make both calamitic and discotic mesogens based on the bis(phenylenedithio-TTF) (BPhDT-TTF) nucleus. The novel step involves a cycloaddition between 2,3-bis(methoxycarbonyl)benzoquinone **2** and 1,3-dithiole-2,4,5-trithione [depolymerised oligo(1,3-dithiole-2,4,5-trithione)] **1**.[9] Addition of simple four π electron components to 2,3-disubstituted quinones normally yields adducts of the 2,3-double bond[10] (in this case the 'wrong' regioisomer) but, fortunately, the sole product obtained was the desired hydroquinone **3**. The remainder of the synthesis, shown in Scheme 1, uses well-established reactions and procedures. Compounds **4a**, **4b** and **4c** were non-liquid crystalline (**4a**, mp 48 °C; **4b**, mp 129–130 °C and **4c**, mp 182–184 °C) but the bis(anhydride) **5** and the bis(imide) **6** both displayed enantiotropic liquid crystalline behaviour.

Force field (MM2) calculations on the BPhDT-TTF nucleus and crystal structures of related compounds suggest that it adopts the elongated shallow 'chair' conformation shown in Fig. 1 making it, perhaps, a more obvious choice for creating calamitic than discotic liquid crystals.

Compound **5** gives a smectic A phase between 91.5 and 107.3 °C, with a layer repeat distance of 24.3 Å, comparable to the length of the molecules. More surprisingly, compound **6** behaves as a discogen, giving a D_r columnar phase between room temperature and 64.7 °C. This is unusual, but not unprecedented, for a molecule with such a non-planar, elongated core.[11] When viewed between cross polarisers, thin films of compound **6** obtained by slow cooling from the isotropic phase showed the characteristic dendritic structures of a columnar mesophase and the X-ray analysis of this phase is detailed in Table 1. Compounds **4a**, **5** and **6** are soluble in common organic solvents and solutions display two reversible one electron oxidation waves in the anodic window showing the formation of stable radical cations. The dc and ac conductivity response of thin films (12 μm) of compounds **5** and **6** has been investigated using a variety of electrode types (indium tin oxide, gold and aluminium).[12] The liquid crystalline phase of compound **5** did not align under these conditions but compound **6** aligned homeotropically when annealed at 55 °C. Dc studies showed that both materials gave a linear (Ohmic) response up to an applied voltage of 1 V.[12] As expected, the ac conductivities (10^1–10^6 Hz, 1 V) were very low (10^{-12}–10^{-7} S cm^{-1}) and



Scheme 1 *Reagents and conditions*: i, THF, reflux, 8 h, 24%; ii, Ac_2O, DMAP, CH_2Cl_2, 2 h, 94%; iii, $Hg(OAc)_2$, AcOH, CH_2Cl_2, 4 h, 94%; iv, $P(OMe)_3$, C_6H_6, reflux, 5 h, 60%; v, RX, K_2CO_3, DMF, heat, 74–94%; vi, KOH, THF, MeOH, reflux, 5 h, 78%; vii, 90 °C, vacuum, 5 h, 88%; viii, $MeNH_2$·HCl, K_2CO_3, DMAP, DMF, $CHCl_3$, 3 Å molecular sieves, 80 °C, 3 days, 60%. All new compounds gave satisfactory combustion analyses and spectroscopic data.

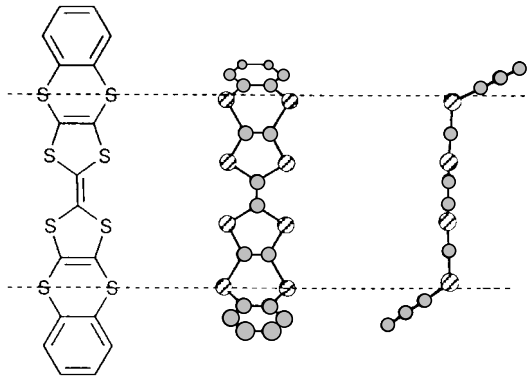


Fig. 1 Optimised geometry of BPhDT-TTF obtained using the MM2 force field method

Table 1 Powder X-ray diffraction data for the D_r phase of the diimide **6**. The calculated data is that expected for a two-dimensional cell, a = 27.3, b = 22.9 Å. Additionally there is a rather broad reflection at 4.00 Å corresponding to the separation between the rings within the stacks. It is greater than that found in crystalline TTF derivatives (ref. 13)

Reflection	Calculated/Å	Observed/Å
10	27.3	27.3
01	22.9	absent
11	17.5	17.8
20	13.7	13.7
02	11.4	11.4
21	11.7	11.4
12	10.6	10.8
30	9.1	9.7

dominated by trace ionic impurities. More surprising was the finding that, when a sample of compound **6** was p-doped with 2 mol% of antimony pentachloride, giving a radical cation concentration ~ 10^{20} cm^{-3} (EPR), the ac conductivity (10^{1}–10^{6} Hz, 1 V) only increased to 10^{-11}–10^{-6} S cm^{-1}. This is very much lower than that normally found in doped discotics[2,3] and the reasons for this are not immediately apparent. It may imply that the radical cations formed are highly localised (small polarons) and/or pinned by the counterions. Alternatively it may be that there is a major difference in geometry between the neutral molecule and the radical cation resulting in large local lattice distortions (a structural polaron). Experiments aimed at resolving this problem and at producing related TTF derivatives with higher conductivities are in progress.

We thank the EPSRC and Leeds University for financial support and the Royal Society for a fellowship to R. A. B.

Observation and quantification of a chiral medium induced difference in rate of enantiomerization

Kai Rossen,* Jess Sager and Yongkui Sun

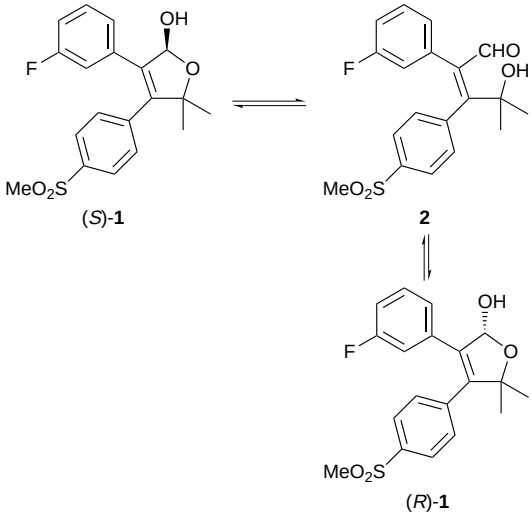
Process Research and Development, Merck Research Laboratories, PO Box 2000, Rahway, NJ 07065, USA

A chiral stationary phase HPLC column has been used both to separate the enantiomers of a γ-lactol and also to observe the rate of enantiomerization of the individual enantiomers; the rate of enantiomerization differed for both enantiomers in the presence of the chiral stationary phase.

A chiral medium interacting with a pair of enantiomers results in energetically differentiated, diastereomeric complexes and this differential stabilization of the enantiomers will contribute to the different reaction rates of the enantiomers in the chiral medium.[1] Chiral stationary phases (CSPs) have developed into very useful and reliable tools for the determination of the enantiomeric composition of mixtures. One of the most successful types of chiral stationary phases for HPLC and SFC (supercritical fluid chromatography) is prepared from crystalline carbamoylated or acylated cellulose or amylose deposited on SiO_2 (commercially available as Chiralcel and Chiralpak columns).[2]

The combination of these columns with the use of supercritical CO_2 as eluent is a particularly powerful tool for enantiomer separation.[3] The chromatographic separation of the enantiomers results from the formation of energetically different diastereomeric complexes between the enantiomers and the CSP and it would therefore appear reasonable to expect that enantiomers react at different rates in the presence of a chiral stationary phase.[4] We have examined this premise using the enantiomerization of γ-lactol **1** as a model reaction (Scheme 1) where (*R*)-**1** and (*S*)-**1** are chiral but the reaction intermediate hydroxy aldehyde **2** is not.†

Examination of **1** by ^{1}H NMR spectroscopy shows that it is exclusively present in the closed form, as would be expected from a *gem*-dimethyl substituted five-membered lactol. The enantiomers of **1** are separated on a Chiralpak AD column [25 cm length, supercritical CO_2 at 300 bar with 8% modifier (Pr^iOH–H_2O 95 : 5), flow 1 ml min^{-1}, 40 °C, retention time



Scheme 1

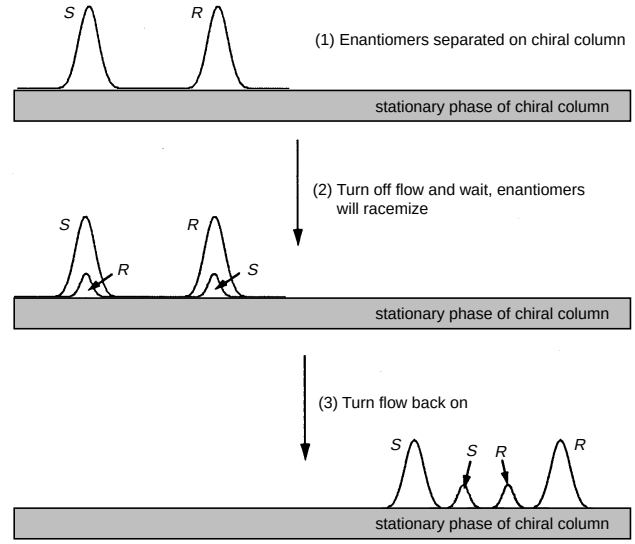


Fig. 1

t_R = 21.0 min, t_S = 29.8 min, dead volume time t_0 = 3.3 min, assignment of first peak as the *R*-isomer is arbitrary].‡ The procedure for measuring the rates of enantiomerization is described in Fig. 1. The flow of the mobile phase is turned off at a fraction of the regular run time when the enantiomers are already spatially separated on the column (*e.g.* at t_X = 0.33 t_R). The enantiomers are then allowed to partially enantiomerize in the presence of the chiral medium for a period of time *t* before the flow resumes.[5] A four-peak pattern is obtained, with the inside peaks resulting from the enantiomerization of the previously separated peaks.§

By varying the time *t* for which the flow is turned off, the rate of enantiomerization of each enantiomer in the presence of the chiral stationary phase can be determined. A plot of conversion R/R_0 and S/S_0 *vs. t* (Fig. 2) shows that the enantiomers react at

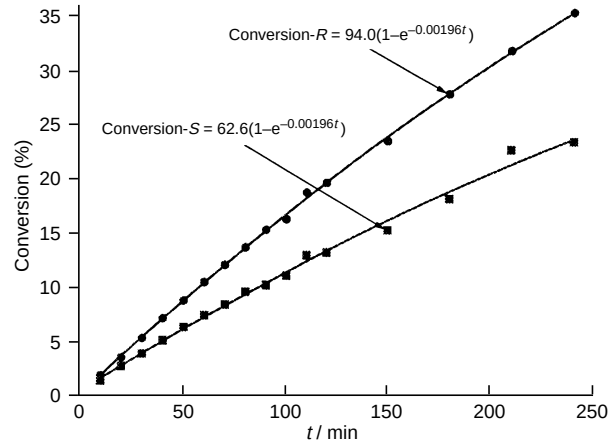

Fig. 2

different rates! Least square fit of the data to the kinetic equations of a reversible first-order system gives $k_R = 1.19 \times 10^{-3}$ min^{-1} and $k_S = 7.75 \times 10^{-4}$ min^{-1}.¶ This rate difference can be used to calculate the difference in Gibbs energy of activation for the enantiomerization of (*R*)- and (*S*)-**1** in the presence of the chiral medium at 40 °C: $\Delta G^{\ddagger} = \Delta G_R^{\ddagger} - \Delta G_S^{\ddagger} = -RT\ln k_R/k_S = -1.10$ kJ mol^{-1}. However, the differential binding energy of the two enantiomers on the CSP is responsible for the separation of the enantiomers on the column. It can be calculated from the observed chromatogaphic separation factor $\alpha = (t_S - t_0)/(t_R - t_0) = 1.50$ according to $\Delta G = -RT\ln \alpha$ and gives $\Delta G = -1.06$ kJ mol^{-1} (40 °C). As the intermediate hydroxy aldehyde **2** is achiral, the difference in Gibbs energy of activation $\Delta G^{\ddagger}$ obtained from the kinetic measurements will result from the differential binding strength of the two enantiomers of **1** on the chiral column as long the influence of the chiral medium on the energy of the transition states leading to the achiral intermediate **2** is negligible. Indeed, the value obtained from the kinetic measurement ($\Delta G^{\ddagger} = 1.10$ kJ mol^{-1}) is in good agreement with the number obtained from the chromatographic separation factor ($\Delta G = 1.06$ kJ mol^{-1}). Thus, the different rates of enantiomerization are caused by the differential binding of the enantiomers of the lactol **1** with the chiral medium and the transition states leading from **2** to the enantiomers of **1** are of nearly identical energy in the presence of the chiral medium.

In summary, we have demonstrated that the enantiomers of a chiral compound react at different rates in the presence of a CSP and that this rate difference is caused by the differential energetic stabilization of the individual enantiomers of the γ-lactol by the chiral medium. This example adds to the list of examples[6] where enantiodifferentiating reactivity is achieved by performing a reaction in the chiral environment provided by a chiral host.

† An alternative mechanism would involve the oxonium ion, which is also achiral.

‡ All experiments were performed with the Hewlett Packard SFC (HP 1205) system with a HP 1050 diode array detector and instrument control and data analysis with the HP Chemstation Software. The Chiralpak AD column was obtained from Chiral Technologies, Exton, PA 19341. The lactol **1** was prepared by DIBAL-H reduction of the corresponding lactone.

§ The retention times of the middle peaks can be calculated as $t_R + (t_R - t_X)(t_S - t_R)/t_R$ and $t_R + t_X(t_S - t_R)/t_R$, where the retention times of the outer peaks are t_R and t_S, and the flow is stopped at time t_X. The timespan t during which the flow is stopped is obviously subtracted from the observed times and the issues involved with regaining equilibrium when the flow of the column is resumed are ignored. This is reasonable as the Hewlett Packard SFC instrument controls the pressure at the end of the column.

¶ The data were fitted to the equations of a reversible first-order reaction [eqns. (1) and (2)]

$$\text{conversion-}S = k_R/(k_R + k_S)\,[1 - e^{-(k_R + k_S)t}]$$

$$\text{conversion-}R = k_S/(k_R + k_S)\,[1 - e^{-(k_R + k_S)t}]$$

to give $k_R + k_S = 1.96 \times 10^{-3}$ min^{-1} and $k_R/k_S = 1.53$.

Micro-single crystal diffraction techniques employing synchrotron radiation are used to determine the structures of the disordered template (4-piperidinopiperidine) within the recently synthesised, chabazite-related cobalt aluminium phosphate known as DAF-5; the structural details revealed are inaccessible by high-resolution powder diffraction.

In the search for microporous solids possessing unusual catalytic and other properties[1] accurate knowledge of template–host interaction is of crucial importance. Computational techniques[2,3] are indeed able to design templates for the synthesis of specific microporous architectures. Experimental determination of the location, orientation and disorder of templates within the microporous host is however, necessary for improving our ability to predict and optimise the appropriate templates. Recently[4] the *de novo* design code ZEBEDEE led to the choice of 4-piperidinopiperidine ($C_{10}H_{20}N_2$) as the template for producing a chabazitic cavity which is more symmetrical than that achieved in the open-structured cobalt phosphate known as DAF-4, a solid-acid catalyst (closely related in structure to the zeolitic mineral levyne) that shape-selectively converts methanol preferentially to ethene and propene.[5] Here, microcrystalline diffraction techniques, feasible only with synchrotron radiation, are used to establish the structural properties of the template within this new chabazitic aluminophosphate.

DAF-5 was crystallised from a gel of composition 0.4 CoO : 0.8 Al_2O_3 : 1.5 P_2O_5 : 30 H_2O : 2.5 $C_{10}H_{20}N_2$ which was heated under hydrothermal pressure at 160 °C for 3–6 h. A phase-pure material was produced which gave a unique X-ray powder diffractogram collected on station 2.3 of the Daresbury Synchrotron radiation source (which operates at 2 GeV with a typical current between 120 and 250 mA) in capillary mode using a wavelength of 1.399 94 Å. Unit cell parameters were obtained using the auto-indexing program TREOR.[6] Structure factor amplitudes were extracted using a Le Bail decomposition.[7] These data were used to solve the structure by direct methods using the program SIRPOW,[8] the starting model so obtained being utilized for subsequent Rietveld refinement.[9,10] This clearly established the nature of the framework [the best fit is shown in Fig. 1 and the framework structure, as subsequently determined together with the template, in Fig. 2(*a*)]. Difference Fourier maps indicated that the organic molecule experiences extensive disorder; but detailed structural information could not be derived from the powder diffraction data.

To determine the nature of the disorder of this template and find its possible orientations we employed single-crystal diffraction methods on a microcrystal of DAF-5 having dimensions close to 30 × 30 × 30 μm.‡ Collection of accurate data on such small crystals can be best performed using synchrotron sources,[11–13] such as the facility recently commissioned at station 9.8 of the Daresbury SRS,[14] where focusing optics ensures high photon flux on the sample. Data were collected on a Siemens SMART CCD Area detector at a wavelength of 0.6889 Å. The structure was again solved by direct methods.[15] The location of the template molecule could

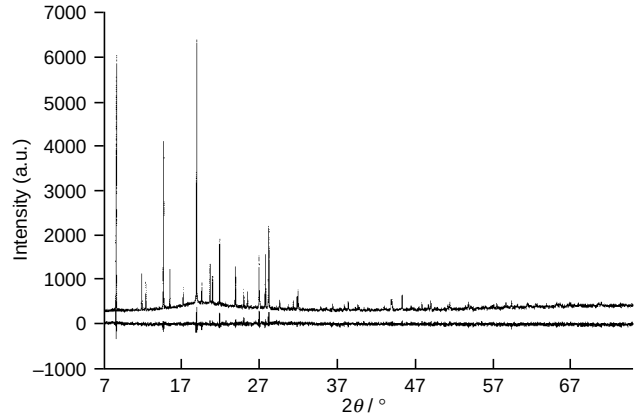

Fig. 1 High-resolution X-ray powder diffraction pattern (solid line) recorded at station 2.3 of the Daresbury Synchrotron radiation source employing a wavelength of 1.3999 Å. The dashed curve shows the best fit to the experimental data generated using the Rietveld analysis program GSAS. The difference profile is shown in the bottom of the figure.

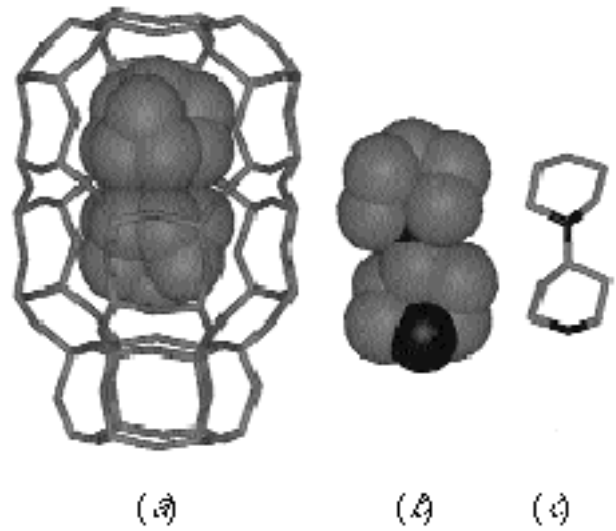

Fig. 2 Graphical representation of the structures of DAF-5 derived from the single crystal experiment is shown in (*a*). For clarity only one of the cages is given which contains all possible conformations of the occluded template molecule 4-piperidinopiperidine. One of the possible conformations of the template molecule is also shown using ball (*b*) and stick (*c*) representations where carbon atoms are shown in grey and nitrogen in black.

be ascertained from a careful interpretation of the difference Fourier map in terms of the possible conformers. This approach yielded plausible template orientations shown in the location inside the cage in Fig. 2, which also depicts one of the orientations of the single template molecule. The calculated position of the template[5] has six equivalent, statically disordered positions. Furthermore, molecular dynamics simulations (using Discover[16]) indicate independent rotation around the C–N bridge in the molecule as well as a precessional motion. However, the symmetry of the molecule is such that the extremes of the molecule and bridging atoms show small amplitudes of thermal motion. These findings are consistent with the atomic positions found in the diffraction study.

Our study demonstrates the power of microcrystalline diffraction techniques together with computer modelling in revealing complex structural features of templated microporous solids.

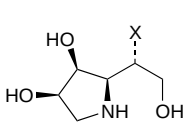
Synthesis of iminopolyols *via* Henry reaction: a short route to the α-mannosidase inhibitor 1,4-dideoxy-1,4-imino-D-mannitol and to amino analogues†,[1]

Frank-Michael Kieß,[a] Philip Poggendorf,[a] Sylviane Picasso[b] and Volker Jäger*[a]

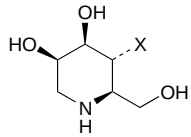
[a] *Institut für Organische Chemie der Universität Stuttgart, Pfaffenwaldring 55, D-70569 Stuttgart, Germany*
[b] *Institut de Chemie Organique, Université de Lausanne, CH-1015, Lausanne-Dorigny, Switzerland*

The α-mannosidase inhibitor 1,4-dideoxy-1,4-imino-D-mannitol (DIM) as well as amino analogues of DIM and of deoxy-*manno*-nojirimycin, respectively, have been prepared using a diastereoselective nitroaldol addition as the key step.

Many polyhydroxy-pyrrolidines and -piperidines (iminoglycitols) act as strong and specific inhibitors of glycosidases,[2–4] *e.g.* 1,4-dideoxy-1,4-imino-D-mannitol **1**[3] or deoxy-*manno*-nojirimycin **2**.[4] Due to their potential as anti-diabetic, anti-viral or anti-tumour agents,[2c] many efforts have been directed towards syntheses of this class of compounds, usually based on modification of carbohydrate precursors or cycloaddition methods.[5]



1 X = OH
3 X = NH_2

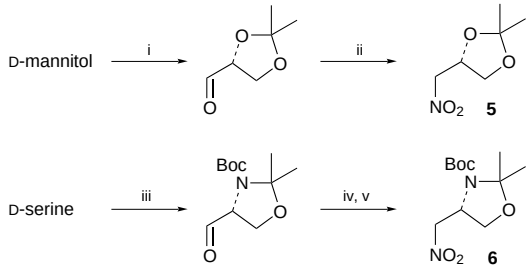


2 X = OH
4 X = NH_2

For some time, we have been studying the diastereoselectivity of the nitroaldol addition (Henry reaction),[6] with a view to efficient construction of nitro- and amino-polyols and further uses in the preparation of various amino- and imino-polyols.[7] We now report a simple synthesis of DIM **1**, and of new amino analogues **3**, **4** of DIM and of **2**, respectively, based on diastereoselective nitroaldol additions catalyzed by tetrabutylammonium fluoride trihydrate.[7,8] (C_3 + C_3)-Assembly of nitro compounds, bearing an α-oxy or α-amino function, and the glyceraldehydes **7** leads to nitrohexitols (see Scheme 2), which can be reduced to the corresponding amino compounds. Cyclization would then give access to iminopolyols. Thus, the question should be replaced by an amino function, to retain or alter inhibition of glycosidases.

The optically active nitro compounds **5**, **6** were prepared from the corresponding aldehydes[9,10] by oximation,[9d,10c] followed by oxidation with trifluoroperacetic acid[11] (Scheme 1).

For the aldehyde part, 2-*O*-benzylglyceraldehyde **7** was chosen, readily available in both enantiomeric forms from



Scheme 1 *Reagents and conditions*: i, ref. 9(*a*), (*b*), 53%; ii, ref. 9(*d*), 11, 67%; iii, ref. 10(*a*), (*b*), 84%; iv, NH_2OH·HCl, K_2CO_3, MeOH, H_2O, 0 °C, 2 h; [ref. 10(*c*)]; v, H_2O_2 (85%), $(CF_3CO)_2O$, Na_2HPO_4, MeCN, 0 °C, 2 h, 76% (iv, v)

Table 1 Nitroaldol addition of **5** and **6** to **7**

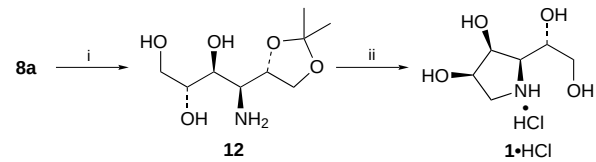
Reactants	Conditions	Products	Yield[a] (%)	Dr[b]	Major isomer
D-**7** + **5**	−20 °C, 6 d	**8a,8b,8c**	90	67 : 22 : 11	D-*manno*
L-**7** + **5**	−20 °C, 6 d	**9a,9b,9c**	92	69 : 18 : 13	D-*gulo*
D-**7** + **6**	0 °C, 7 d	**10a,10b**	88	90 : 10	D-*manno*
L-**7** + **6**	0 °C, 7 d	**11a,11b**	81	90 : 10	D-*gulo*

[a] Pure material after flash chromatography on silica. [b] From ^{13}C NMR and/or HPLC analyses of crude mixture; other diastereomers < 5%.

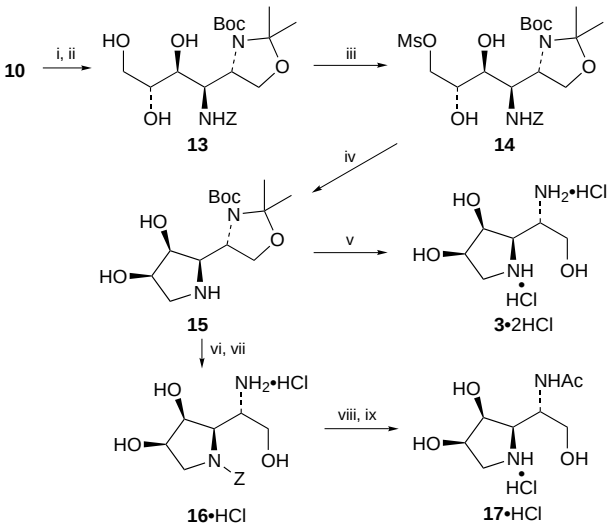
tartrates,[12] which had given the best diastereomer ratios in related cases.[7] The addition of **5** to D- or L-**7** afforded the nitro alcohols **8** and **9** in high yields as mixtures of diastereomers,[7c] from which the major isomers **8a** (D-*manno*) and **9a** (D-*gulo*) were separated by chromatography (Scheme 2, Table 1). As seen earlier,[7] 1,2-induction from the aldehyde stereocentre strongly favoured 2,3-*erythro* formation, and the non-induced stereoselection concerning C3/C4 preferentially led to a *threo* relationship. Double stereodifferentiation, as observed in related cases,[1,7b,c] was not operative here.

The nitroaldol **8a** was converted into the amine **12** by catalytic hydrogenation.[13] Cyclization of **12** with the Appel reagent (Ph_3P, CCl_4, Et_3N),[14] followed by ion exchange chromatography and hydrochloric acid treatment, afforded the D-iminomannitol **1** in 74% yield after conversion into the hydrochloride (Scheme 3); the overall yield from D-mannitol was 10% (seven steps). Starting from **9a**, the D-*gulo* isomer[15] was accessible likewise, as confirmed by crystal structure analysis.[16]

Addition of the nitro compound **6** to D-**7** occurred with a considerably higher diastereomer ratio: the 5-amino-4-nitrohexitol **10** was preferred by 90 : 10 (D-*manno* : D-*talo*; from L-**7**: **11a** and **11b**, D-*gulo* and D-*allo* were formed; Table 1). The nitro alcohol mixture **10** was converted to the corresponding amines



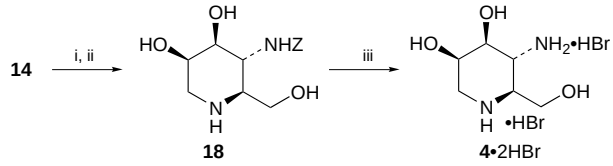
Scheme 3 *Reagents and conditions*: i, H_2 (4 bar), Pd–C, MeOH (*cf.* ref. 13), 25 °C, 21 h, 84%; ii, Ph_3P, CCl_4, Et_3N, pyridine, 25 °C, 2 d; Lewatit S 100 (H^+ form); 1 M HCl; 74% **1**·HCl, mp 147–148 °C, $[\alpha]_D^{20}$ −15.8 (*c* 0.97, H_2O) {lit.[3] mp 148–149 °C, $[\alpha]_D^{20}$ −16.3 (*c* 1.00, H_2O)}



Scheme 4 *Reagents and conditions*: i, H_2 (4 bar), Pd–C, MeOH, 25 °C, 22 h; ii, ZCl, $NaHCO_3$, dioxane, H_2O, 0 to 25 °C, 24 h, then crystallization (hexanes–EtOAc), 61% (**10**→**13**); iii, MsCl, NEt_3, CH_2Cl_2, −10 to 25 °C, 22 h, 84%; iv, H_2 (4 bar), Pd–C, MeOH, 25 °C, 18 h, 96%; v, 5 M HCl, 0 °C, 2 h, 90%; vi, ZCl, $NaHCO_3$, dioxane, H_2O, 0 to 25 °C, 20 h, 91%; vii, 3 M HCl, MeOH, 0 to 25 °C, 3 h, 98%; viii, Ac_2O, $KHCO_3$, dioxane, H_2O, 0 to 25 °C, 3 h, 87%; ix, H_2, Pd–C, 0.1 M HCl, MeOH, 18 h, 96%

by hydrogenation, followed by *N*-protection with benzyl chloroformate (ZCl) (Scheme 4). The major diastereomer **13** (D-*manno*) was separated by crystallization. Regioselective mesylation of the primary hydroxy group then led to the methanesulfonate **14**. Hydrogenolysis of the Z group was accompanied by *N*-cyclization[7] to afford the pyrrolidine **15**. On treatment of **15** with hydrochloric acid, the amino analogue of DIM **3** was obtained as the bis(hydrochloride). The configuration of **3** was again secured by X-ray crystallography.[7c] Due to orthogonal protection, the two amino groups of **14** could be functionalized individually, as is shown by the syntheses of the 5-acetylaminopyrrolidine **17** and the 4-aminopiperidine **4**. After Z protection of the ring nitrogen in **15**, the 5-amino function was liberated with aqueous acid to yield **16**. *N*-Acetylation and finally removal of Z furnished the 5-acetamido target compound **17** in the form of its hydrochloride (Scheme 4).

Next, the isomeric structure of the piperidine **4** was sought from the methanesulfonate **14**, by changing the order of steps. After removal of both the Boc and the acetonide protecting groups with acid, cyclization to the piperidine **18** took place on treatment with base. Catalytic hydrogenation under acidic conditions, followed by ion exchange chromatography, and subsequent reaction with hydrobromic acid led to the piperidine **4** in form of the bis(hydrobromide) (Scheme 5). The L-*manno* enantiomers of **3** and **4** were prepared according to the same protocol, starting with D-**6**, readily accessible from L-serine.



Scheme 5 *Reagents and conditions*: i, 3 M HCl, MeOH, 0 to 25 °C, 6 h, quant.; ii, $KHCO_3$, H_2O, 25 °C, 18 h, 92%; iii, H_2, Pd–C, 1 M HCl, MeOH, 25 °C; 2.5 h; Dowex 50 W (H^+ form); 1 N HBr; 94%

The iminopolyols were tested concerning their inhibitory activity on 24 glycosidases.[17] While DIM **1**, in accord with the literature,[3] showed strong and very selective inhibition of α-mannosidases [jack bean, IC_{50}/μM 3, K_i /μM 1.6; almond, IC_{50} 6, K_i 1.6], the 5-amino analogues **3** and **17** were inactive; this emphasizes the crucial role of the 5-hydroxy function in **1**.[18] The piperidines **4** and **18** showed no activity either, nor did the L-enantiomers of **3**, **4** and **18**. In contrast, the *N*-protected intermediates **16**, **18** proved moderately active towards β-galactosidases [**16**: bovine liver, IC_{50}/μM 460, K_i/μM 228; *Aspergillus orizae*, IC_{50} 540, K_i 705; **18**: bovine liver, 31% inhibition at 1 mM].

In summary, short and efficient syntheses of 1,4-imino-D-mannitol and -D-gulitol as well as of new amino analogues of DIM and of deoxy-*manno*-nojirimycin are presented, demonstrating the potential of the Henry reaction for the diastereoselective assembly of iminopolyols.

Financial support by the Landesgraduiertenförderung Baden-Württemberg (doctoral fellowship to F.-M. K.) and by the Fonds der Chemischen Industrie is gratefully acknowledged.

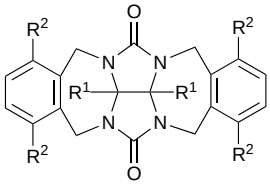
New concave host molecules show strong noncovalent binding of hydroxybenzene derivatives by an induced fit mechanism (K_a up to 3.4 × 10^6 dm^3 mol^{-1}).

The design and synthesis of host molecules for neutral guests continues to be an area of great interest in supramolecular chemistry.[1] In recent years a series of receptors derived from the concave molecule glycoluril (see **1**) have been developed in our



1a R^1 = Ph, R^2 = H

laboratory.[2] These receptors, which are U-shaped, bind dihydroxybenzenes by hydrogen bonding interactions between the hydroxy groups of the guest and the urea carbonyl groups of the host and by π–π stacking interactions between the guest and the host side-walls. Although the supramolecular chemistry of glycoluril-based clips has been widely explored, and their sidewalls extensively varied,[2] relatively little attention has been given to variations in the diphenylglycoluril part of the clip molecules. Here we describe the synthesis, X-ray structures and binding properties of a new type of related molecular clips derived from 2,4,6,8-tetraazabicyclo[3.3.1]nonane-3,7-dione (propanediurea, see **2**). Molecular modelling studies suggested that the *o*-xylylene side walls of these new clips would be more parallel than the walls of glycoluril derived clips, which would result in better π–π stacking interactions with an aromatic guest molecule sandwiched between the side walls of the clip and hence lead to increased binding affinities for aromatic molecules. Here we show that compound **2** indeed binds aromatic guest molecules with very high association constants (K_a > 10^6 dm^3 mol^{-1}).

Clip molecules **2a**,**b** were prepared in *ca*. 20% yield by reacting the respective propanediurea derivatives **3a**,**b** with α,α′-dibromo-*o*-xylene in DMSO in the presence of NaH. Compound **3a** was accessible following a literature procedure,[3] and compound **3b** was synthesized in 90% yield by refluxing 2,2-dimethyl-3-oxobutanal with urea in toluene in the presence of TFA with azeotropic removal of water. Clip molecule **2c** could be obtained in 20% yield by reacting **3a** with 2,3-bis-(bromomethyl)-1,4-dimethoxybenzene in DMSO in the presence of NaH. The latter compound was prepared from 3,6-dimethoxyphthalic anhydride[4] by reduction with $LiAlH_4$ followed by reaction with PBr_3. Full experimental details will be reported in a forthcoming paper.‡

Single crystals of **2a** were obtained by vapour diffusion using $CHCl_3$ as the solvent and hexane as the precipitant and of **2c** by vapour diffusion using CH_2Cl_2 as the solvent and Et_2O as the precipitant. The crystal structure of **2a** revealed that this clip molecule has a U-shaped cavity similar to that of diphenylglycoluril derived clips.[2a] In contrast to previous clip molecules of type **1** the crystal structure of **2c**§ shows an asymmetric geometry with respect to the side walls (Fig. 1), which is attributed to its greater flexibility. The clip molecule dimerizes to give a 'head-to-head' packing, with the wall of one clip molecule being buried in the cavity of another clip. This dimerization was not observed in $CDCl_3$ solution.

The binding properties of hosts **2** and, for comparison, hosts **1** with a number of hydroxybenzene derivatives (**4a**–**f**, **5**–**7**), were measured by NMR titration experiments in $CDCl_3$ using the outer wall protons of the host and the aromatic protons of the guest as probes.¶ The results are summarized in Table 1. The new clip molecules bind resorcinol derivatives significantly more strongly than diphenylglycoluril molecular clips. The binding constant is a factor of three higher for hosts **2a**,**b** when compared to host **1a**.‖ In the case of **2c** the increase in binding constant strongly depended on the type of guest used (see Table 1). For guests **4a**–**c** the binding was increased by a factor of three, five and twelve respectively when compared to host **1b**. For guests **4d**–**f** the binding constants were so large that they could not be measured by standard NMR titrations.[5] We therefore determined the binding constants of **4d**,**e** by competition experiments with **4c**, and of **4f** by a competition experiment with **4e**.[6] A plot of the binding free energies of guests **4a**–**f** as a function of the Hammett parameter [σ_m (R)] of the guest's substituent (Fig. 2) reveals a linear correlation which has been previously observed for clip **1b**.[2b] From the gradients of the

Fig. 1 X-Ray structure showing a dimer of clip **2c**

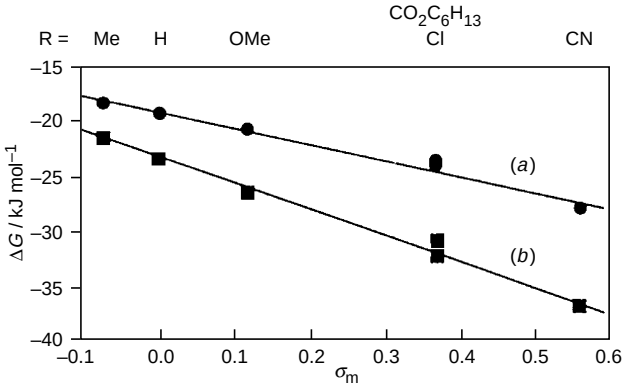

Fig. 2 Binding free energies of guests **4a**–**f** in clips (*a*) **1b** and (*b*) **2c** as a function of the Hammett parameter [σ_m(R)] of the guest's substituent

plots it is clear that binding of guests in clip **2c** is more sensitive to the substituent on the guest than binding in clip **1b**. Previous analysis of the binding properties of clips of type **1** showed that the steeper the gradient the greater the hydrogen bonding contribution is to the overall binding.[2b] One of the reasons for the stronger binding of **2c** is the fact that the carbonyl oxygens atoms are situated slightly higher with respect to the cavity walls than the carbonyl oxygens atoms in clip **1b**, as is clear from the X-ray structures. Previously it has been shown that the optimal distance for π–π interaction of a guest in clips **1** is at a position further out of the cavity than that for optimal hydrogen bonding.[2b] This means that in clip **2c** the complexation geometry is more ideal for optimum π–π interactions than in clip **1b**. Furthermore, the carbonyl–carbonyl distance in clip **2c** (5.2 Å) is closer to the ideal value for resorcinol binding (3.9 Å)** than this distance in clip **1b** (5.5 Å). Although the difference is small, it is significant since **1b** is shown to be better suited for binding of guest molecules with relatively large OH–OH distances such as 2,7-dihydroxynaphthalene **5** than **2c** (Table 1); this guest prefers a carbonyl–carbonyl distance of 6.3 Å.** The enhanced binding of catechol **6** in **2c** can be explained by the smaller carbonyl–carbonyl distance.‖ Other factors, apart from the position of the carbonyl groups, also contribute to the difference in binding properties of the clips. The binding of 4-nitrophenol **7**, which has only one hydroxy group and hence forms one strong optimum hydrogen bond, is stronger in clip **2c** than in clip **1b** (Table 1), suggesting that additional factors, *e.g.* the possibility of a guest to adopt a more parallel orientation with respect to the cavity walls, play a role in the enhanced binding.††

The NMR data suggest that the binding of a guest in clips of type **2** takes place *via* an induced fit mechanism, which is in agreement with the increased flexibility predicted by molecular modelling and suggested in the asymmetry observed in the X-ray crystal structures. The signals due to the benzylic protons of clip **2c** were found to shift considerably upon binding of a guest (**4d**: up to +0.44 ppm for the upfield benzylic proton signals and −0.29 ppm for the downfield benzylic proton signals), in contrast to those of clips **1**, for which virtually no shifts were observed. These shifts indicate that the conformation of the clip's side walls changes upon binding of a guest and are consistent with a tightening of the cavity upon binding of an aromatic guest.

In conclusion, a new type of molecular clips is presented which show enhanced binding of aromatic guest molecules. Applications of these receptor molecules in the construction of new supramolecular architectures are under investigation.

‡ All new compounds were fully characterized by ^{1}H and ^{13}C NMR and mass spectroscopy and elemental analysis. *Selected data* for **2c**: δ_H (300 MHz) 6.74 (s, 4 H), 5.43 (d, 2 H, ^2J 15.1), 4.32 (s, 2 H), 3.90 (d, 4 H, ^2J 15.2), 3.78 (s, 12 H), 1.35 (s, 6 H).

§ *Crystal data and data collection parameters* for **2c**: $C_{27}H_{32}N_4O_6$, M = 508.57, monoclinic, a = 11.760(2), b = 15.300(3), c = 14.574(7) Å, β = 106.849(12)°, V = 2509.7(14) Å^3, T = 293(2) K, space group $P2_1/a$, λ = 1.54184 Å, Z = 4, D_c = 1.346 Mg m^{-3}, F(000) = 1080, colourless crystal with dimensions 0.29 × 0.19 × 0.16 mm, μ(Cu-Kα) = 0.791 mm^{-1}, Enraf-Nonius CAD4 diffractometer, θ–2θ scans, 3.17 < θ < 62.19°, +h, +k, ±l, maximum drift 14.526%, 4186 reflections measured, 3967 unique (R_{int} = 0.0098). The structure was solved using the program CRUNCH (ref. 8), and refined anisotropically, by full-matrix least squares on F^2 [program SHELXL (ref. 9)]. The final $wR(F^2)$ was 0.1991, with conventional $R(F)$ 0.0549.

¶ NMR titration experiments were performed as described in ref. 2(*a*). The chloroform used was standard NMR grade and predried on molecular sieves (4 Å) before use. The NMR spectra used for the determination of the binding constants showed only a small water peak.

‖ For example: for **4d**: K_a = 2000 M^{-1} with clip **2a** and 600 M^{-1} with clip **1c**; for **4b**: K_a = 550 M^{-1} with clip **2b** and 165 M^{-1} with clip **1c**.

** Assuming that the hydrogen bonds are linear and that the O–H–O distance is 2.7 Å (ref. 7).

†† Since clip molecules **1a** and **1c** have different groups at their convex sides, we compared the binding affinities of **1a** and **1c** with guests **4b**, **4d** and **4f**. The binding constants were the same within the experimental error (*e.g.* K_a = 165 and 175 M^{-1}, respectively, for **1a** and **1c** with guest **4b** and K_a = 3600 and 3500 M^{-1}, respectively, with guest **4f**), which indicates that the groups at the convex side of clips **1** do not contribute significantly to the binding. Clip molecule **1c** was prepared in 60% yield from dimethylglycoluril and α,α′-dibromo-*o*-xylene in DMF at room temperature in the presence of NaH.

Highly enantioselective chiral base mediated [2,3]-Wittig rearrangement

Susan E. Gibson (née Thomas),*[a] Peter Ham[b] and Gary R. Jefferson[a]

[a] *Department of Chemistry, Imperial College of Science, Technology and Medicine, South Kensington, London, UK SW7 2AY*
[b] *SmithKline Beecham Pharmaceuticals, Discovery Research, New Frontiers Science Park, Third Avenue, Harlow, Essex, UK CM19 5AW*

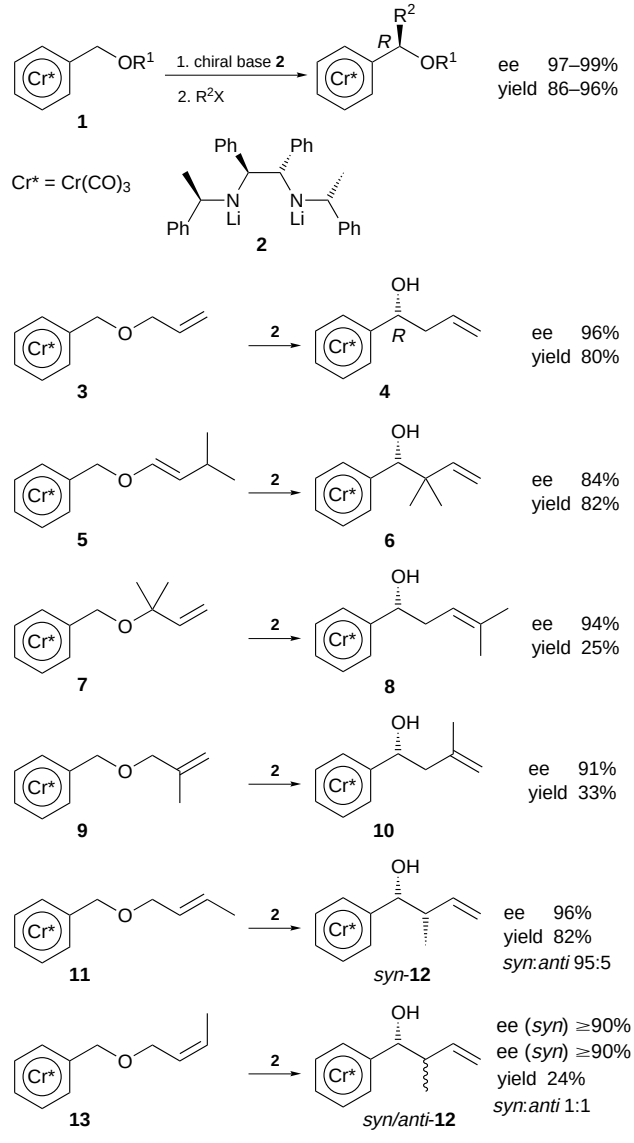
A chiral non-racemic base promoted [2,3]-Wittig rearrangement of a series of (allyloxymethylbenzene)tricarbonylchromium(0) complexes proceeds with remarkably high enantioselectivity.

The [2,3]-Wittig (sigmatropic) rearrangement is a useful carbon–carbon bond-forming reaction.[1] As such, asymmetric versions of it are a desirable goal and research in recent years has produced several approaches to such systems.[2] The greatest success has been achieved using chiral auxiliaries.[3] For example, rearrangement of a range of α-allyloxy ketone hydrazones derived from a non-racemic chiral hydrazine proceeded in excellent yield (89–100%), with very good *syn*/*anti* selectivity (80–94% de) and good enantioselectivity (63–90% ee).[3a] Enantioselective versions of the [2,3]-Wittig rearrangement involving an achiral substrate and a chiral non-racemic base are synthetically more attractive but this approach has been much less successful, providing very moderate yields, diastereoselectivities and enantioselectivities.[4] The best results to date for a linear† system were obtained very recently using diprop-2-ynyl ethers as substrates.[4a] These rearranged in modest yield (29–57%) and with moderate enantioselectivity (46–62% ee) on treatment with a base derived from norpseudoephedrine. In view of the moderate success achieved so far for the chiral non-racemic base mediated [2,3]-Wittig rearrangement, we reveal herein a rearrangement that proceeds with relatively high enantioselectivity (84–96% ee) and, with appropriate substitution, very good yield (80–82%).

Our recent observation that the benzylic methylene group in tricarbonylchromium(0) complexes of alkyl benzyl ethers **1** may be functionalised asymmetrically in high yield and enantiomeric excess by treatment with the chiral non-racemic base **2** and an external electrophile,[6] together with earlier reports that tricarbonylchromium(0) complexes of allyl benzyl ethers undergo [2,3]-Wittig rearrangements,[7] suggested to us that the action of base **2** on allyl benzyl ether complexes may lead to a highly enantioselective [2,3]-Wittig rearrangement. Accordingly a series of allyl benzyl ether complexes were synthesised using standard procedures‡ and the outcome of their reactions with base **2** determined (Scheme 1).

Initially the reaction of parent complex **3** with base **2** was examined. Complex **3** was added dropwise to a mixture of 1.1 equiv. of base **2**[8] and 1 equiv. of LiCl in THF at −78 °C. The reaction mixture was allowed to warm to −50 °C over 2 h and then stirred at −50 °C for a further 5 h. Addition of methanol and work-up gave a yellow oil that was identified as the [2,3]-Wittig rearrangement product **4** by comparison of its spectroscopic data with literature values.[7d] The enantiomeric purity of **4** was readily assessed by chiral HPLC (Chiralpak AD) and, to our delight, was found to be 96%. In order to determine the absolute configuration of product **4**, the tricarbonylchromium(0) unit was removed (*hν*, 83% yield) and the $[\alpha]_D$ of the resulting alcohol compared with literature values.[9] This revealed that the absolute configuration of **4** was *R*, a result consistent with the sense of asymmetric induction observed for the functionalisation of complexes **1** with external electrophiles.[6]

The effect of substituents on the chemical yields and enantioselectivity of the [2,3]-Wittig rearrangement were examined next starting with substituent patterns that would lead to products containing just one chiral centre. Complexes **5**, **7** and **9** rearranged to give the novel§ alcohol complexes **6**, **8** and **10** with very good enantioselectivity (84–94%).¶ Although the chemical yield of **6** was good (82%), the yields of **8** and **10** were relatively poor (25 and 33% respectively) probably reflecting, for **8**, the hindered trajectory presented to the base by **7** and, for **10**, the extra electron donating substituent on an already electron-rich centre[10] in the transition state leading to **10**.



Scheme 1

Finally complexes **11** and **13** were reacted with base **2** in order to determine the level of stereochemical control this asymmetric [2,3]-Wittig rearrangement would exert over the generation of two adjacent chiral centres. The (*E*)-but-2-enyl complex **11** rearranged smoothly to give a good yield (82%) of alcohol **12**. The diastereomeric ratio of the product complex was found to be 95 : 5 and the relative stereochemistry of the major isomer was identified as *syn* by comparison of the ^{1}H NMR spectroscopic data of **12** and its decomplexation product with literature values obtained from a racemic sample.[7c] Chiral HPLC analysis revealed that the ee of **12** was 96%. In contrast the (*Z*)-but-2-enyl complex **13** rearranged to give a relatively poor yield of a 1 : 1 mixture of diastereomers,‖ although it was noted that the ee of each of the diastereomers was ⩾90%.

The authors thank Nichola C. Stevens of SmithKline Beecham Pharmaceuticals for several chiral HPLC analyses. G. R. J. also gratefully acknowledges a CASE award from SmithKline Beecham Pharmaceuticals.

† The best result recorded to date for a *cyclic* system is the conversion of a 13-membered prop-2-ynylic ether into a 10-membered prop-2-ynylic alcohol in 69% ee and 82% yield using lithium bis[(*S*)-1-phenylethyl]amide.[5] This success was attributed to special conformational effects as the same base gave a poorer result with a 17-membered homologue (30% ee, 78% yield), and racemic products when applied to acyclic α-(allyloxy)acetic acids and amides.[5]

‡ The novel complexes **5** and **7**, and the known complexes **11** and **13**[7c] were synthesised by heating $Cr(CO)_6$ with the appropriate allyl benzyl ether (62–78%), whilst the uncharacterised complex **3**[7d] and the novel complex **9** were made by reacting (hydroxymethylbenzene)tricarbonylchromium(0) with NaH–allyl bromide (86%) and $ZnCl_2$–2-methylprop-2-en-1-ol (54%) respectively.

§ The novel complexes **3**, **5**–**10** and **12** all gave satisfactory microanalytical and spectroscopic (IR, ^{1}H NMR, ^{13}C NMR, *m/z*) data.

¶ The absolute stereochemistry of products **6**, **8**, **10** and **12** has been assigned by analogy with the rearrangement of complex **3** to **4** under the influence of base **2**.

‖ The clean rearrangement of the (*E*)-but-2-enyl complex **11** to a *syn* product and the uncontrolled rearrangement of the (*Z*)-but-2-enyl complex **12** is consistent with results obtained with racemic complexes[7] and contrasts with the (*Z*)-*syn* selectivity normally observed for the [2,3]-Wittig rearrangement of but-2-enyl systems.[1,7,10]

Synthesis of a mordenite/ZSM-5/chabazite hydrophilic membrane on a tubular support. Application to the separation of a water–propanol mixture

Miguel A. Salomón, Joaquín Coronas, Miguel Menéndez and Jesús Santamaría*

Department of Chemical and Environmental Engineering, University of Zaragoza, 50009, Zaragoza, Spain

A selectivity of 71 is achieved in the separation of a gas phase water–propanol mixture, using a mordenite/ZSM-5/chabazite membrane that is hydrothermally synthesized onto the inner surface of a porous α-alumina tubular support.

In recent years, the synthesis of zeolite membranes on porous inorganic substrates (disks or tubes) has received much attention. To prepare such a membrane, the crystals must form a continuous, defect-free two-dimensional layer, so that only transport through the zeolite pores takes place. Several methods have been proposed for the preparation of zeolite membranes. For ZSM-5 membranes, it was demonstrated that permeation and separation properties depend strongly on the preparation procedure used.[1] The most usual liquid-phase preparation method involves immersing the porous support into the zeolite precursor gel. With this method MFI-type zeolite,[1,2] zeolite A[3] and zeolite Y[4] tubular or flat membranes have been prepared. It is noticed that, although tubular supports are more interesting from an industrial point of view, there are still very few examples of zeolite membranes synthesized on them. This is due to the development of mechanical tensions during the drying/calcination steps, that often result in the formation of defects such as cracks and pinholes. The vapour phase method has been used to prepare ZSM-5 and ZSM-35,[5] ferrierite[6] and mordenite[7] flat membranes, where vapors containing amines and water were employed to zeolitize silica and/or alumina layers previously deposited onto the support.

Most of these zeolite membranes have been used for separations of organic–organic,[1] water–organic[3,4,8] and permanent gas–organic[2] mixtures. When there are significant differences in polarity between the components of a mixture (*e.g.* water–alcohol mixtures), the organophilic or hydrophilic character of the zeolite can play an important role. For instance, water permeated faster than ethanol through membranes of zeolites A and Y (both of them hydrophilic),[3,4] while through silicalite membranes the permeation of ethanol was faster.[8] Here we present the synthesis and some permeation properties of a mordenite/ZSM-5/chabazite membrane on a tubular α-alumina support. To our knowledge this is the first report on the preparation of such a tubular membrane. The constituting zeolites differ in their physical properties: ZSM-5 is a high-silica zeolite (Si/Al ratios between 2.5 and 100), with a structure consisting of straight channels of 0.54 × 0.56 nm, intersecting with sinusoidal channels of 0.53 × 0.55 nm; with mordenite, the Si/Al ratio is around 5, and there are large channels of 0.67 × 0.7 nm, and small channels of 0.26 × 0.57 nm; finally, chabazite is a smaller pore size zeolite (its larger channels are 0.38 × 0.38 nm), but in this case the Al content is higher, with a Si/Al ratio between 1.6 and 3. Since the hydrophilicity of a zeolite increases with its Al content, it can be expected that the presence of mordenite and chabazite increase the selectivity for the separation of water, with respect to what could be achieved on a pure ZSM-5 membrane.

The synthesis method employed 0.65 mm id asymmetric porous α-alumina microfiltration tubes with a 200 nm pore diameter separation layer (US Filter, SCT). An aluminosilicate gel was prepared using Aerosil 300 (Degussa) and sodium aluminate (Carlo Erba) as silica and alumina sources, respectively, tetraethylammonium hydroxide (TEAOH) solution 35 mass% in water (Aldrich) as template, NaOH and distilled water. A gel was prepared with a molar composition 80 SiO_2 : 2080 H_2O : 32 NaOH : 40 TEAOH : 1 $Na_2Al_2O_4$. The starting solution consisted of Aerosil 300 and approximately two thirds of the above amount of deionized water. This solution was kept under vigorous stirring for 5 h. Then, a solution containing the other substances was added, one fifth every 30 min, to the first solution. The resulting gel was aged under stirring for 3 days. The gel was cloudy but not thick, and had a pH of *ca*. 12.1. The gel was not completely stable, and two different phases appeared a few hours after stirring was stopped. Before synthesis, the outer surface of the dry alumina tube was wrapped with Teflon tape to avoid penetration of the gel from this side, and the tube was then immersed in the synthesis gel filling a Teflon-lined autoclave. The tube was fixed axially, and the autoclave was placed horizontally in a convection stove at 443 K for 21–23 h. The synthesis was repeated four times, with the tube–autoclave ensemble rotated 90° in each step. After the last synthesis, the tube was tested for permeability to N_2, at room temp. and pressure differences of up to 3 bar. Strict impermeability was required, which sometimes required a fifth synthesis. Finally, to remove the template, the membrane was calcined, at 753 K for 8 h using 1 K min^{-1} heating and cooling rates. The composition of the gel used for the synthesis is optimized to obtain mordenite. However, during the synthesis of the membrane on an Al_2O_3 support, it can be expected that part of the support is dissolved and incorporated into the synthesis gel, and thus other compositions such as ZSM-5 and chabazite are possible.

The zeolite mass gain and the N_2 permeance were measured for several membranes, samples M1–M3 (Table 1) to characterize initially the membrane and assess the reproducibility of the synthesis method. After the hydrothermal synthesis, crystals not attached to the support were recovered from the autoclave. These crystals which should have a composition similar to the material deposited as a continuous layer on the alumina support, were characterized by XRD analysis (Rigaku/Max System, Cu-Kα radiation, graphite monochromator). XRD patterns of the composite membrane and of zeolite crystals prepared by homogeneous synthesis (*i.e.* in the absence of a porous alumina support) using the same gel were also obtained. Fig. 1(*a*) shows the XRD pattern of zeolite crystals prepared by homogeneous synthesis. By comparison with XRD data in the literature[9] it can be seen that the pattern is practically coincident with that of a pure mordenite zeolite. On the other hand, Fig. 1(*b*) indicates that the XRD pattern of the crystals collected in the remaining liquid after the synthesis of the membrane in the presence of α-Al_2O_3 contains a significant amount of other zeolites (ZSM-5 and chabazite), in addition to mordenite. Finally, the pattern shown in Fig. 1(*c*) corresponds to composite membrane M3 (see Table 1), and is a combination of α-alumina (marked with an asterisk), and the ZSM-5, chabazite and mordenite crystals already shown in Fig. 1(*b*). The zeolite peaks in the XRD diagram corresponding to the composite membrane are smaller than those shown in Fig. 1(*b*), because the zeolite contributed only 7% to the total membrane mass, the rest being α-Al_2O_3. A closer examination of the XRD pattern of the composite

Table 1 Some characteristics of the composite zeolite membranes

Membrane	Mass gain/ mg zeolite (g support)$^{-1}$	N_2 single gas permeance/ mol (s m^2 Pa)$^{-1}$	Water–propanol–air mixture[a]		
			H_2O permeance/ mol (s m^2 Pa)$^{-1}$	Water/ propanol selectivity	Water/O_2 selectivity
M1	67	3.0×10^{-7}	2.0×10^{-7}	50	5.3
M2	79	2.5×10^{-7}	2.7×10^{-7}	71	10
M3	69	Not measured	2.8×10^{-7}	16	13

[a] Partial pressure (kPa): water = 2.4; propanol = 0.36.

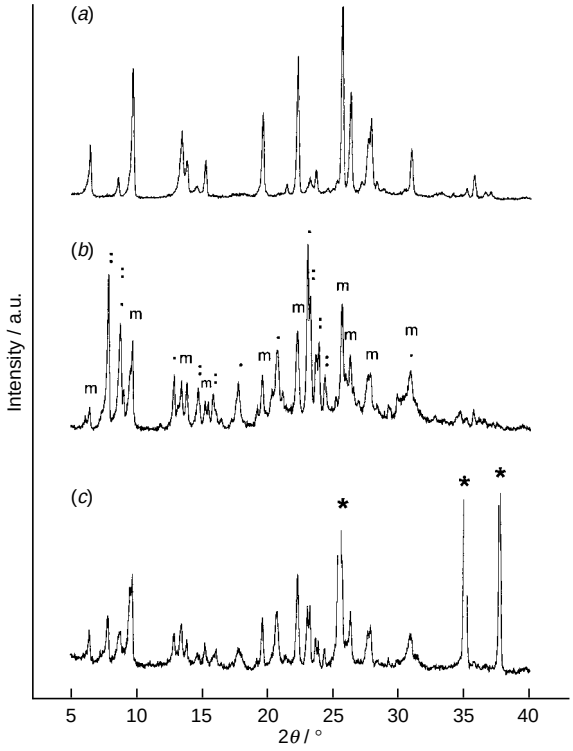

Fig. 1 X-Ray diffraction patterns of (*a*) mordenite powder; (*b*) powder collected in the remaining liquid after the synthesis of the composite zeolite membrane, ● = chabazite, ●● = silicalite, m = mordenite; (*c*) composite zeolite membrane, * = Al_2O_3 support. For clarity, zeolite peaks have not been marked.

membrane shows some additional interesting features: first, the orientation of the zeolite crystals does not change from Fig. 1(*a*) to Fig. 1(*b*) and (*c*). Second, a comparison of the intensities of the main characteristic bands in the XRD diagram gives a rough estimation of the relative proportions of the different zeolites as mordenite : ZSM-5 : chabazite = 2 : 1 : 1, *i.e.* mordenite is the preponderant species, but there are very significant amounts of ZSM-5 and chabazite.

SEM (JEOL JSM-6400) observations of cross-sections of the composite membranes (not shown) indicated that the zeolite crystals formed a continuous layer 10 μm thick, on top of the inner surface of the alumina support. Further SEM observations showed that zeolite crystals also dispersed among the large α-alumina particles of the support, indicating that the hydrothermal synthesis took place not only on the support but also inside its pores. The thickness of the mordenite layer estimated by SEM agrees well with the Si/Al profile across the membrane measured by EPMA (not shown). The Si/Al ratio in the zeolite film was lower than in the gel, as noted in other case of hydrothermal synthesis of zeolite membranes on alumina supports.[1] This indicates that a part of the alumina support was leached during the synthesis procedure, being incorporated into the composite membrane, and is consistent with the appearance of high alumina zeolites such as chabazite. The preparation procedure (in which the tube was placed horizontally and rotated 90° after every synthesis) was successful in dealing with the instability of the synthesis gel, and allowed deep penetration of the gel into the alumina support, as the 67–79 mg mass gain per g of support indicates (Table 1).

In the water–propanol separation experiments, the membrane was sealed with silicon o-rings in a stainless steel module. A gaseous mixture containing a predetermined proportion of water and propanol was obtained by mixing two air streams after passing them through two saturator trains containing liquid water and propanol respectively. This mixture was fed into the tube side of the membrane, and permeated through the membrane wall. The shell side was swept with a N_2 stream. Both the air and the N_2 streams were mass-flow controlled at approximately 34 cm^3(STP) min^{-1}. The total pressure (*ca.* 1 atm) and the pressure differential between both sides of the membrane (close to zero) were accurately maintained by means of an automated control system. When the steady state was reached, as indicated by GC analysis of both exit streams (usually after keeping the membrane under the mixture stream for around 2 h), the separation selectivities were calculated as the ratios of permeances for water and propanol, using the log(mean partial pressure) difference in the calculations. Table 1 shows the results of the water–propanol separation experiments performed with membranes M1–M3. The highest water–propanol selectivity was 71 at room temp. for membrane M2. The high selectivity of the composite membrane in the water–propanol separation may be attributed to the selective sorption of water in this hydrophilic membrane.

Zwitterionic alkene polymerization catalyst derived from $Cp_2Zr(\eta^2\text{-}C_2H_4)PPh_2Me$ and $B(C_6F_5)_3$

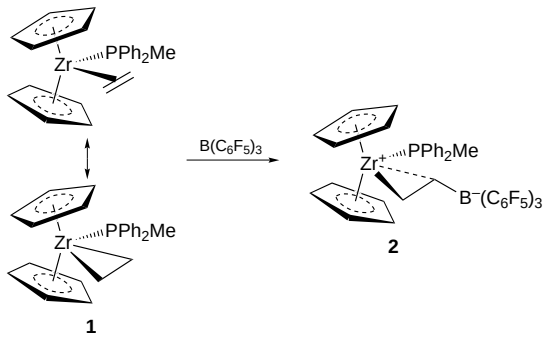
The phosphine stabilized ethylene complex of zirconocene, Cp_2Zr, reacts with 1 equiv. of $B(C_6F_5)_3$ to form the girdle-type zwitterion $Cp_2Zr^+(PPh_3Me)CH_2CH_2B^-(C_6F_5)_3$ 2, which serves as an ethene polymerization catalyst either with or without added $B(C_6F_5)_3$.

Bent metallocenes[1] are highly active for the polymerization of alkenic monomers to important commodity plastics.[2] Two principal factors contribute to this molecular fragment's ability to circumvent the barrier associated with the exothermic alkene enchainment process: the high electrophilicity of the formally 14 electron $[Cp_2M–R]^{n+}$ species and the ideally configured frontier orbital structure of the bent metallocene unit.[3] Since the former attribute is enhanced when $n = 1$, most commercially viable catalysts are based on group 4 metal cations; use of sufficiently weakly ccordinating counter-anions is necessary in order to attain high activities.

Zwitterionic analogs of cationic metallocenes, in which the counter-anion and the active cation are covalently linked in some fashion, have been touted as a way to modulate ion pairing in these catalysts, thus increasing activity.[4] Two classes of zwitterionic metallocenes have been reported: ring-type zwitterions in which the anion is affixed to one of the Cp donors,[5] and girdle-type betaines, where the counter-anion is located on the alkyl group occupying the reactive wedge of the metallocene.[6] In the latter type, the zwitterionic nature of the catalysts lasts only until the first termination step, while in the former, the charge separated structure is maintained throughout the polymerization process.

Girdle-type zwitterionic compounds have been accessed mainly through electrophilic attack by $B(C_6F_5)_3$[7] on suitable hydrocarbyl ligands of neutral group 4 bent metallocenes. Herein we report the reaction of the phosphine stabilized zirconocene ethylene complex, $Cp_2Zr(\eta^2\text{-}C_2H_4)PPh_2Me$[8] **1**, with this borane; the product may be considered to be the 'parent' girdle-type zwitterionic zirconocene.

When **1** is treated with one equivalent of $B(C_6F_5)_3$ in toluene, the zwitterionic product **2** is isolated as an orange solid in 92% yield (Scheme 1).† Although the phosphine ligand in the starting material is labile,‡ the electrophile preferentially attacks the coordinated alkene; no formation of $Ph_2MeP{\cdot}B(C_6F_5)_3$ was observed. The ^{11}B chemical shift of δ −10.8 for **2** is diagnostic for anionic, four-coordinate boron,[9] supporting the formulation of **2** as a zwitterionic species with a high degree of charge separation. For comparison, a ^{11}B NMR chemical shift of δ 2.0, more closely associated with neutral four-coordinate boron, was found for the product formed from reaction of **1** with $HB(C_6F_5)_2$,[10] which features a strong borate–zirconium cation interaction.[11]



1 **2**

Scheme 1

Although the ^{11}B NMR chemical shift of **2** is suggestive of significant charge separation, several spectral criteria are met which are suggestive of a strong β-CH agostic interaction[12] which electronically compensates the cationic zirconium center. Signals for the β-CH_2 protons and carbon atom appear upfield of the resonances for the α-methylene atoms in the ^1H and ^{13}C NMR spectra. At room temp., the averaged J_{CH_β} coupling constant is 105 Hz, indicative of weakened C–H bonds at this position.[13] The coupling constant of 145 Hz for the α-C–H bonds is characteristic of an acute $Zr–C_\alpha–C_\beta$ bond angle, expected in the event of a β-agostic interaction.[12,14] Furthermore, when the ^1H NMR spectrum is monitored as the temperature is lowered, the signals for the $ZrCH_2CH_2B$ unit undergo decoalescence behavior until at −90 °C four signals reappear at δ 2.24 and 0.75 for the Zr–CH_2 pair and δ −0.05 and −1.55 for the two CH_2B hydrogens. From the NMR data, the rate of exchange at coalescence (−67 °C) was determined[15] to be 1.46×10^3 s^{-1} and a $\Delta G^‡$ of 9.0(5) kcal mol^{-1} (1 cal = 4.184 J) was calculated for this exchange using the Eyring equation. This is a relatively high barrier for interchange of β-agostic protons in zirconocene cations, which is typically faster than the NMR timescale.[12,16]

The solid state structure of **2** also features this agostic motif. Suitable crystals of the compound were obtained from toluene; protons associated with the $ZrCH_2CH_2B$ moiety were located and refined isotropically.§ An ORTEP diagram of the compound is shown in Fig. 1 and pertinent metrical parameters are summarized in Table 1, along with analogous data for two related, non-zwitterionic compounds reported previously by Jordan and coworkers. Compound **2** is a zwitterionic analog of Jordan's ethyl cation[12] but is structurally more similar to the trimethylsilyl substituted derivative[16] in that the β-agostic alkyl group adopts an *endo* coordination geometry rather than the *exo* structure seen in the ethyl complex. Since the Me_3Si group was essentially coplanar with Zr, C_α and C_β, Jordan proposed an organometallic γ silicon effect, in which the back lobe of the Si–C_β bond donates to the zirconium center, as the basis for this observation. In **2**, the borate boron is tilted *ca.* 17° out of the Zr–C(12)–C(11) plane and the C_β–H bond is clearly involved in an agostic interaction with the deficient zirconium center. It is, however, feasible that the back lobe of the B–C_β carbon may also be involved in the Zr–C_β contact. At any rate, the observed strength of the β-agostic interaction in **2** suggests that the negative charge of the borate group is substantially localized on C_β, rendering it a more effective donor than the C_β–$SiMe_3$ group in Jordan's compound.

Although it could be argued that attack by $B(C_6F_5)_3$ at the *exo* carbon of the coordinated ethylene in **1** should be preferred on steric and electronic grounds,¶ the *endo* isomer of **2** appears to

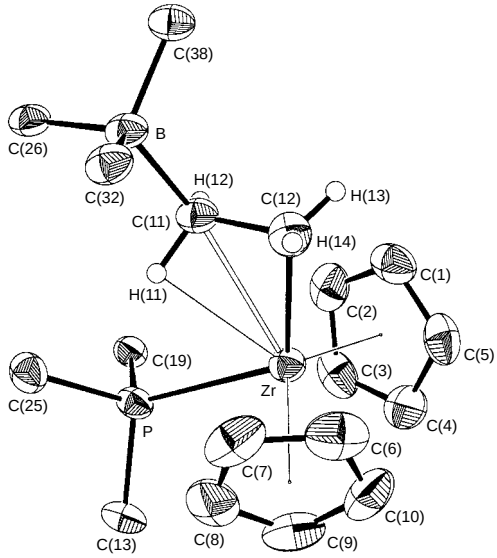


Fig. 1 ORTEP diagram of girdle zwitterion **2**. Phenyl and pentafluorophenyl groups have been omitted for clarity. Key metrical parameters are given in Table 1.

Table 1 Metrical parameters for **2** and related compounds

	2	$Cp_2Zr^+(PMe_3)(H)(H)$	$Cp_2Zr^+(thf)(H)(H)(SiMe_3)$
Zr–C_α/Å	2.260(4)	2.290(9)	2.26(2)
Zr–C_β/Å	2.607(4)	2.629(2)	2.57(2)
Zr–H_β/Å	2.39(3)	2.16	—
Zr–P,O/Å	2.828(1)	2.691(3)	2.320(11)
Zr–C_α–C_β/°	85.3(2)	84.7(5)	84(1)
P,O–Zr–C_α/°	119.0(1)	73.6(3)	115.9(5)
Zr–C_β–B,Si/°	164.9	—	174.1

be the kinetic as well as the thermodynamic product. Thus, when the reaction was monitored at −90 °C by ^{1}H or ^{31}P NMR spectroscopy, no intermediates were observed and only *endo*-**2** was formed. If attack at the *exo* carbon is preferred, rearrangement to *endo*-**2** must be very fast.

The zwitterion **2** polymerizes ethylene under ambient conditions,[17] although for optimal activity, an additional equivalent of $B(C_6F_5)_3$ is required. Activities of $3.2(4) \times 10^4$ g polymer (mol Zr atm h)$^{-1}$ (M_w = 26 100, M_w/M_n = 2.2) were observed in the absence of added $B(C_6F_5)_3$, while productivities more in line with expected values [$9.4(4) \times 10^5$; M_w = 133 700; M_w/M_n = 2.0] were found when **2** was treated with borane in the presence of ethene. Presumably, the added $B(C_6F_5)_3$ serves to sequester the phosphine ligand blocking the coordination site necessary for optimal polymerization rates. In the absence of ethene, a complex mixture of products results when **2** is treated with $B(C_6F_5)_3$, indicating that the 'naked' zwitterion is not stable in solution under these conditions.

Financial support for this work was provided by the Novacor Research and Technology Corporation of Calgary, Alberta and by the Natural Sciences and Engineering Council of Canada's Research Partnerships program. W. E. P. thanks the Alfred P. Sloan Foundation for a Research Fellowship (1996–98).

† *Synthesis* of **2**. Toluene (20 ml) was condensed into an evacuated flask cooled to −196 °C containing **1** (609 mg, 1.35 mmol) and $B(C_6F_5)_3$ (693 mg, 1.35 mmol). The mixture was warmed to −78 °C, stirred for 30 min and then warmed to room temp. The yellow slurry was concentrated and filtered. The solid was washed with hexane (15 ml) and **2** (1.2 g, 92%) was obtained as yellow powder. Partial ^{1}H NMR (C_6D_6, 23 °C): δ 1.50 (t, J_{HH} 6.5 Hz, 2 H, $ZrCH_2CH_2B$), −0.74 (br, 2 H, $ZrCH_2CH_2B$). Partial $^{13}C\{^1H\}$ NMR (C_6D_6, 23 °C): δ 41.6 (s, J_{CH} 145 Hz, $ZrCH_2CH_2B$), −14.0 (br m, J_{CH} 105 Hz, $ZrCH_2CH_2B$).

‡ For example, the reaction of PPh_2Me stabilized **1** with the more basic phosphine PMe_3 gave the trimethyl phosphine adduct $Cp_2Zr(\eta^2\text{-}C_2H_4)PMe_3$ essentially upon mixing.

§ *Crystal data* for **2**: $C_{43}H_{27}BF_{15}PZr$, M = 961.67, orthorhombic, *Pbca*, a = 18.782(1), b = 22.5024(9), c = 18.740(2) Å, U = 7920.3(9) Å^3, D_c = 1.613 Mg m^{-3} for Z = 8. $F(000)$ = 3840.00, μ(Cu-Kα) = 36.71 cm^{-1}, λ = 1.541 78 Å, T = 294 K. A total of 8944 reflections were collected using the ω–2θ scan technique to a maximum 2θ value of 155°. The data were corrected for Lorentz and polarisation effects and the structure solved by heavy-atom Patterson methods and expanded using Fourier techniques. The non-hydrogen atoms were refined anisotropically. The hydrogen atoms associated with the β-ethyl moiety were refined isotropically, the rest were fixed in idealized positions with C–H = 0.98 Å. The final cycle of full-matrix least-squares refinement was based on 4690 observed reflections [$I > 3\sigma(I)$] and 567 variable parameters and converged (largest parameter shift was 0.003 times its esd) with R = 0.034, R_w = 0.034, GOF = 1.88. CCDC 182/687.

¶ A MacSpartan Plus *ab initio* calculation on $Cp_2Zr(PH_3)(\eta^2\text{-}C_2H_4)$ at the 3-21G* level showed that the HOMO is roughly equally distributed on the *exo* and *endo* carbons; a slightly higher charge density exists on the *exo* carbon, which is also sterically much more accessible.

Alkali metal cation cooperative iodide anion recognition by new heteroditopic bis(calix[4]arene) rhenium(I) bipyridyl receptor molecules

Paul D. Beer* and James B. Cooper

Inorganic Chemistry Laboratory, University of Oxford, South Parks Road, Oxford, UK OX1 3QR

New heteroditopic bis(calix[4]arene) rhenium(I) bipyridyl receptors are synthesised and shown to simultaneously bind alkali metal cations and iodide anion with positive cooperativity.

The design of new ditopic[1] ligands for the simultaneous complexation of anionic and cationic guest species is a new exciting area of coordination chemistry of significant relevance to the selective extraction and/or transportation of metal salts across lipophilic membranes. Rare examples of receptors containing appropriate covalently linked binding sites for anions and cations include Lewis-acidic boron,[2] uranyl,[3] polyammonium[4] centres combined with crown ether moieties and crown ether or urea functionalised calix[4]arene ionophores[5,6] which are capable of solubilising alkali metal salts into organic solvent media. We have shown that charged or neutral transition metal organometallic and coordination amide containing receptor systems can selectively bind and sense anions.[7] Lower rim ester functionalised calix[4]arenes are known to coordinate alkali metal cations.[8] Incorporating these two types of recognition sites on to the calix[4]arene building block will create potential heteroditopic receptors capable of binding anions and cations. We report here the syntheses of new heteroditopic bis(calix[4]arene) rhenium(I) bipyridyl receptors which display positive cooperative upper rim binding of the iodide anion *via* lower rim complexation of alkali metal cations.

The new upper rim mono-amine–lower rim ester substituted calix[4]arene derivatives **1** and **2** were prepared according to Scheme 1. Condensation reactions of 2 equiv. of **1** and **2** with 4,4′-bis(chlorocarbonyl)-2,2′-bipyridine **3**[9] followed by complexation with $Re(CO)_5Cl$ gave the new receptors L^1 and L^2 in good yields (Scheme 2).

The cation and anion coordination properties of both receptors were investigated by ^1H NMR titration experiments in CD_3CN solution. The addition of $LiClO_4$, $NaClO_4$ and KPF_6 salts typically caused the ester methylene receptors' protons to initially broaden and sharpen again after 2 equiv. suggesting complexes of $2M^+:L$ stoichiometry are being formed in

Receptor	Metal cation[b]	K[a]/dm^3 mol^{-1}
L^1	None	67
L^1	Li^+	294
L^1	Na^+	202
L^1	K^+	100
L^2	None	40
L^2	Li^+	305
L^2	Na^+	322
L^2	K^+	209

[a] Errors estimated to be ⩽5%. [b] Titration carried out in the presence of 2 equiv. of alkali metal cation salt, perchlorates for lithium, sodium and hexafluorophosphate for potassium.

solution, with the alkali metal cations coordinated at the lower rim ester recognition sites. The addition of tetrabutylammonium chloride, iodide and benzoate salts caused substantial downfield perturbations of the respective receptor's amide, H_3bipyridyl and aryl calix[4]arene protons indicating anion binding is taking place at the upper-rim bis(calix[4]arene) vicinity of the receptor. In all cases the resulting titration curves indicated 1 : 1 complex stoichiometry. Stability constants were calculated from the titration data using EQNMR[10] for complexation with iodide (Table 1). Unfortunately the anion complexes with Cl^- and $PhCO_2^-$ are so strong in CD_3CN that only a semi-quantitative estimate of the value of $K > 10^4$ dm^3 mol^{-1} could be made. The ^{1}H NMR iodide titration experiments were repeated in the presence of 2 equiv. of alkali metal salt and the stability constant values are presented in Table 1. Clearly with both receptors there is a significant increase in the strength of iodide binding when the alkali metal cations are co-bound by nearly an order of magnitude in the case of L^2 and sodium cations. This positive cooperative binding of the iodide anion may be attributed to each lower rim ester complexed metal cation rigidifying the calix[4]arene structure in such a way as to preorganise the upper rim for anion binding.[11] Also through bond electrostatic effects of the complexed metal cation may enhance the relative acidity of the receptors' amide protons and lead to stronger hydrogen bonding with the iodide guest anion. Interestingly Table 1 shows that receptor L^2 exhibits the largest positive cooperative iodide anion binding effect with the sodium cation, which is known to form highly selective complexes with lower rim tetrasubstituted ethyl ester calix[4]arenes.[8]

In conclusion these new heteroditopic bis(calix[4]arene) rhenium(I) bipyridyl receptors are capable of simultaneously binding alkali metal cations and iodide anion with positive cooperativity.

We thank the EPSRC for a studentship and for use of the mass spectrometry service at University College, Swansea.

Synthesis of spherical particulate polysiloxane resins as catalyst supports

Katherine I. Alder and David C. Sherrington*

University of Strathclyde, Department of Pure and Applied Chemistry, 295 Cathedral Street, Glasgow, UK G1 1XL

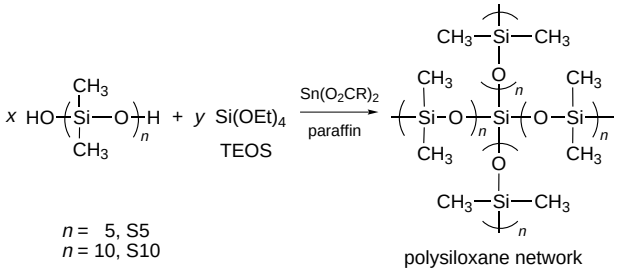
Spherical particulate polysiloxanes are synthesised for the first time, chemically derivatised and employed as a support in molybdenum(VI) catalysed alkene epoxidation.

The use of polymer supports in organic synthesis is escalating.[1,2] Currently a particularly active area of research is polymer-supported metal complex catalysts,[3] including asymmetric catalysts.[4] In the case of oxygenation reactions thermo-oxidatively stable supports such as polybenzimidazoles[5,6] and polyimides[7,8] are very attractive.

Polysiloxanes also offer potential in this context, and although these species have been used in a membrane form as metal complex catalyst supports[9–13] and some largely silica-based precipitates have been so described,[14] as far as we are aware these materials have never been produced in a spherical particulate form of dimensions suitable for direct and independent use as heterogeneous supports. This work describes our recent synthesis and characterisation of such spherical particulate polysiloxanes.

The synthetic strategy (Scheme 1) involves the suspension polycondensation of a dispersion of a pre-formed silanol S10 or S5 with tetraethoxysilane (TEOS) catalysed by tin(II) octanoate in an immiscible continuous phase, such as liquid paraffin, ethylene glycol, or water. The product is essentially a spherical particulate crosslinked polydimethylsiloxane elastomer. The reaction is carried out in a thermostatted 250 ml flanged glass parallel-sided reactor with efficient overhead stirring.[5] Typical reaction conditions are summarised in Table 1 using *e.g.* 25 g of S10. Fig. 1 shows an optical micrograph of resin 8. Aggregation of the product and fouling of the stirrer and reactor can be a problem in small-scale suspension polymerisations. None of the stabilisers we examined to minimise this showed any significant effect [*e.g.* resin 3, Akcros Chem. Monolan E80, polyethylene oxide-polypropylene oxide diblock; resins 7 and 8, Dow Corning Siloxane 2-2502, C_{18} trimethoxysilane], and in our standard procedure (*e.g.* resins 1 and 4) we use no stabilising additives in the continuous phase. Yields of beaded product vary typically from 30 to 70%, average particle diameters were *ca.* 50–200 μm and C, H analysis confirmed the organic content to be close to theoretical.

In all cases the resins formed are elastomeric since the glass transition temperature, T_g, of the polydimethylsiloxane constituting the network is −125 °C. Resins 1 and 4 were prepared with mole ratios of silanols (S10 and S5) and TEOS, such that on average a highly uniform network would result with one S10 or S5 residue between each TEOS derived crosslink. Resins 2 and 3 were prepared with higher levels of TEOS in an attempt to produce some degree of homo-polycondensation of the latter, and hence generate some more rigid silica-like domains in the networks. In practice there is little physical difference between resins 1–4 and this may be due to loss of some TEOS into the continuous phase (liquid paraffin) in which it has some solubility. Resins 5 and 6 were prepared using a slightly different strategy involving dimethyldimethoxysilane (DMDMS) condensed with TEOS under hydrolysing conditions (Scheme 2). Water proved to be a convenient continuous phase in this case and the mole ratio for DMDMS/TEOS was chosen in an attempt to achieve a single dimethylsilanoxy residue between all crosslinks. These products proved to be very



Scheme 1

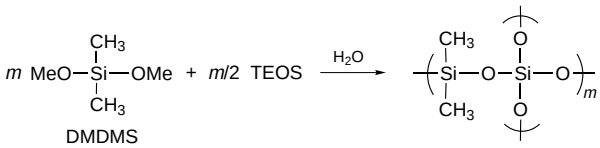

Scheme 2

emulsion-like owing to the very small particle sizes. The latter approach is related to the procedure described by Yacoub-George *et al.*[15] which yields essentially a silica-based species with a very low level of organic functionality.

Resin 7 was prepared from silanol S5 but with the TEOS crosslinker replaced by chloromethylphenyltrimethoxysilane (CMPTMS) (with adjustment to the molar ratio) in order to generate functionality in the product. The polycondensation was as before and the content of chloromethyl groups was found to be close to the theoretical value (Calc. from Cl: 1.44 mmol CH_2Cl g^{-1}. Found: 1.55 mmol CH_2Cl g^{-1}), the functionality being located on the crosslinks. Resin 8 was prepared from silanol S10 and TEOS but with half of the latter replaced by trimethoxysilyl-2-ethylpyridine (TMOSEP). Again the polycondensation proceeded as before yielding a content of 0.69 mmol of pyridine per g of resin 8 calculated from N% (theoretical content 0.36 mmol g^{-1}). This higher than expected incorporation of TMOSEP may reflect loss of some of the main components S5/TEOS to the continuous phase. In all cases the resins were found to absorb significant levels (typically *ca.* 4 ml g^{-1} resin) of non-polar solvents (toluene, dichloromethane, light petroleum) but very low levels of ethanol and, of course, water. Thermogravimetry (TG) indicates that all the resins are stable in O_2 to well above 200 °C, with 10% mass loss not occurring typically until *ca.* > 400 °C. All the resins were unaffected by 2 M H_2SO_4 but in common with the susceptibility of SiO_2 to dissolve in aqueous alkali, these resins also digested readily in 2 M NaOH.

Amination of resin 7 with an excess of trimethylamine in ethanol at room temp. appears to proceed essentially quantitatively (%Cl, theoretical 5.0; found 4.8: %N, theoretical 2.0, found 2.1), whereas the alkylation of resin 8 with excess MeI in toluene was less efficient (%I theoretical 4.3; found 0.9: %N theoretical 0.5, found 0.65). This was a little surprising since toluene swells the resins better than ethanol. However, the content of chloromethylphenyl groups in resin 7 is substantially higher than the pyridine contents in resins 8, and so overall accessibility may be more impaired in the latter case.

Resin 8 was also treated with a 2 molar excess (relative to pyridine residues) of $[MoO_2(acac)_2]$ in refluxing toluene. Following exhaustive extraction with toluene and vacuum drying, dark blue (typical of mixed Mo^{VI}–Mo^{VI} species) somewhat aggregated elastomeric beads were recovered. Through we have not been able to demonstrate unambiguously coordination of resin-bound pyridine to Mo, non-functional supports have previously been shown to be unable to retain such complexes on extraction in a Soxhlet.

Alkaline alcoholic digestion of the resin supported Mo complex and analysis of ICP-AAS yielded a Mo content of 0.43 mmol g^{-1}, corresponding to a pyridine ligand : Mo ratio of 1.5 : 1. This particulate polysiloxane-supported Mo complex turned bright yellow (characteristic of Mo^{VI}) on contact with *tert*-butyl hydroperoxide (*t*-BHP) and showed very high activity and selectivity as a catalyst in the epoxidation of cyclohexene by *t*-BHP, under conditions very similar to those we have used before. Furthermore, the activity was superior to that of soluble $[MoO_2(acac)_2]$ used at the same molar level. Very surprisingly, however, the supported catalyst was also more active than our previously reported polybenzimidazole-supported Mo system since it was used at a much lower level (Mo : *t*-BHP 1 : 450) than we have used previously (Mo : *t*-BHP 1 : 80).[16] Mo analysis of the supernatant solution from the epoxidation indicated that < 0.02% of the Mo was leached from the support and there is little doubt that the major catalytic component is Mo heterogenised on the polysiloxane.

Further details on the synthesis, characterisation and exploitation as catalyst supports of these spherical particulate polysiloxanes will be reported in due course.

K. A. is grateful to the EPSRC for a research assistantship under the ROPA scheme supported by ICI. We are also grateful to Dr Robert Drake of Dow Corning for the supply of precursors S5 and S10 and for useful discussions.

Active catalysts prepared using a vanadium-containing oligosilsesquioxane for selective photo-assisted oxidation of methane into methanal

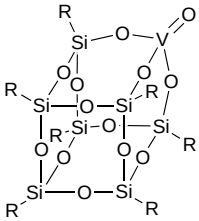
K. Wada, M. Nakashita, A. Yamamoto and T. Mitsudo*

Department of Energy and Hydrocarbon Chemistry, Graduate School of Engineering, Kyoto University, Sakyo-ku, Kyoto 606-01, Japan

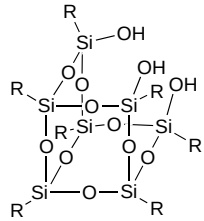
Catalysts of characteristic pore structure derived from silica-supported vanadium-containing silsesquioxane show excellent activity towards the selective photo-assisted catalytic oxidation of methane into methanal (at 493 K, 139 μmol h^{-1}, TON *ca.* 9 h^{-1}, selectivity 81%), indicating its potent abilities as an excellent precursor for porous oxide catalysts.

Supported vanadium oxide catalysts are very important in the chemical industry, especially for the selective oxidation of hydrocarbons.[1] We have reported the excellent activities of silica-supported vanadium oxide catalysts towards the selective photo-assisted catalytic oxidation of methane, ethane and propane at relatively high temperature into the corresponding aldehydes.[2] Only highly dispersed, isolated tetrahedral VO_4 species were considered to be active species, and the reactions were quite sensitive to the state of the surface. However, strict control of the surface structure is generally quite difficult.[3] Thus the development of novel methods for the preparation of catalysts which have well ordered surface species is desirable.

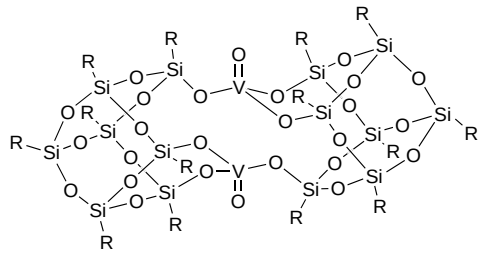
On the other hand, oligometallasilsesquioxanes such as compound **1a** have attracted attention from the viewpoint of



1a (R = c-C_6H_{11})
b (R = c-C_5H_9)



2b (R = c-C_5H_9)



3b (R = c-C_5H_9)

well defined, homogeneous models for surface active sites of supported catalysts or metal-containing zeolites.[4] The catalytic activities of these oligometallasilsesquioxanes, however, have been mainly focused on alkene polymerization and metathesis. Their activities for other reactions were not well investigated.[5] It should be noted that the activity of a titanium-containing silsesquioxane towards the epoxidation of alkenes was recently reported.[6]

From the background described above, we have reported the fair to excellent activity of a vanadium-containing silsesquioxane **1b**, a cyclopentyl derivative of **1a**, for the photooxidation of benzene and cyclohexane, indicating its ability as a homogeneous analog of silica-supported catalysts.[7] Here, in order to investigate the possibility of **1b** as a precursor for heterogeneous catalysts, we prepared supported **1b**-based catalysts, and found that thermal treatment of the catalysts induces high activities towards the selective photo-assisted catalytic oxidation of methane into methanal.

Preparation of a vanadium-containing silsesquioxane **1b** was based on the procedure reported by Feher *et al.*[5a] The reaction of vanadyl triisopropoxide with incompletely condensed silsesquioxane **2b**, which was prepared by the hydrolytic condensation of cyclopentyltrichlorosilane, gave a white powder of dimer **3b** in 44% yield.[5a,7] The resultant product exists as a monomer **1b** in organic solutions at above room temperature. **1b** shows an absorption at *ca.* 252 nm in cyclohexane solution (ε = 4840 dm^3 mol^{-1} cm^{-1}). The silica-supported catalysts were prepared by incipient wetness impregnation from a pentane solution of **1b** using silica (Alfa, evacuated at 423 K for 2 h, mass ratio **1b**:silica = 1:3, V 1.9 mol%). The vacuum dried catalyst was designated **A**. We also prepared catalysts **B** and **C** by air-flow treatment (20 cm^3 min^{-1}) for 2 h at 523 and 723 K, respectively. It should be noted that heat treatment of **3b** without silica support often produced non-porous glassy materials.

The reaction was performed by using an upstream flow fixed-bed reactor made of silica glass. The catalyst was mounted in a flat cell (10 × 20 mm, inner thickness 1.5 mm), and covered by another silica glass tube. UV irradiation was performed from the outer side of the reactor using a 200 W high-pressure mercury lamp with a water filter. Details of the reaction apparatus were described elsewhere.[2] Chemical actinometry using iron(III) ammonium oxalate revealed that the number of photons irradiated into the catalyst bed is 6.6×10^{-7} einstein s^{-1} (250–500 nm, 1.6×10^{-7} einstein s^{-1} for 250–300 nm).

Liquid and gaseous products were collected in cold traps and gas sampling bags, respectively, followed by analysis using gas chromatography, GC–MS and ^{1}H NMR spectroscopy.

Silica-supported vanadium-containing silsesquioxane-based catalysts showed fair to excellent activities for photooxidation of methane into methanal [eqn. (1); see Table 1] and results are shown in Table 1. Preliminary experiments showed that catalyst

Table 1 Photo-assisted catalytic oxidation of methane[a]

$$CH_4 + O_2 \xrightarrow[493\ K,\ [cat.]]{h\nu} HCHO + H_2O \qquad (1)$$

Run	Catalyst	Yield/μmol h^{-1}		
		HCHO	CO	CO_2
1	None	0	0	0
2	**B**	7.2	9	18
3	**C**	139	26	6
4	V_2O_5/SiO_2[b]	61	13	7

[a] Typical reaction conditions: amount of catalyst 50 mg, molar ratio methane:O_2:He = 12:1:11, total gas flow rate 20 cm^3 min^{-1}, reaction temperature 493 K, reaction time 1 h.

A afforded very small amounts of the products. The result without catalyst shown in run 1 exhibits the absence of the photo-chemical reaction of methane. Control experiments without alkanes afforded none of the products, eliminating the contribution by the oxidation of organic groups of the silsesquioxane moiety. Reaction using silica support also did not afford the products.

The reaction using catalyst **C**, calcined in air at 723 K, produced methanal in a yield of 139 μmol h^{-1} (0.56% of fed methane) with the selectivity of > 80%. Turnover frequency for the formation of methanal was *ca*. 9 h^{-1}. Only a trace amount of methanal was formed by the reaction at *ca.* 300 K, indicating the necessity of a reaction temperature as high as 493 K. Reaction without UV irradiation did not proceed at all. For comparison, we examined the performance of a silica-supported vanadium oxide catalyst prepared by evaporation-to-dryness impregnation using ammonium metavanadate, which showed the highest activity in the previous study.[2] However, it gave only 61 μmol h^{-1} of methanal under the same reaction conditions, indicating the excellence of catalyst **C**. It should be noted that catalyst **B** including organic substituents (*vide infra*) also produced methanal, but the yield and the selectivity were low. This probably indicates the difference of the activity between the surface vanadium species on silica and that on the silsesquioxane moiety.

Then we investigated various properties of the supported catalysts. The XPS spectra of the catalysts **A** and **B** showed almost the same ratio of C 1s, corresponding to organic substituents of the silsesquioxane moiety, to Si 2p, indicating the absence of oxidation of organic substituents by treatment at 523 K in air. On the other hand, catalyst **C** was found to consist of oxides, since only trace amounts of carbonaceous materials were detected on the surface of catalyst **C**. While the BET surface area of original silica support was 259 m^2 g^{-1}, those of catalyst **A** (180 m^2 g^{-1}) and **B** (171 m^2 g^{-1}) were smaller. On the other hand, catalyst **C** had a larger surface area (349 m^2 g^{-1}). Fig. 1 shows the pore size distribution of the catalysts estimated from the desorption isotherm of nitrogen at 77 K by Dollimore–Heal method. It should be noted that the catalyst **C** was more rich in mesopores around 30 Å than the parent silica support. These characteristic features indicate the possibility of oligometalla-silsesquioxanes as novel precursors for porous oxide materials.

In conclusion, we have shown fair to excellent activities of the heterogeneous catalysts prepared using a vanadium-containing silsesquioxane **1b** for the selective photo-assisted oxidation of methane into methanal. The present results indicate the possibility of oligometallasilsesquioxanes as excellent precursors for porous oxide catalysts. We are now investigating not only the detailed structure, but also the shape selectivity of the supported catalysts.

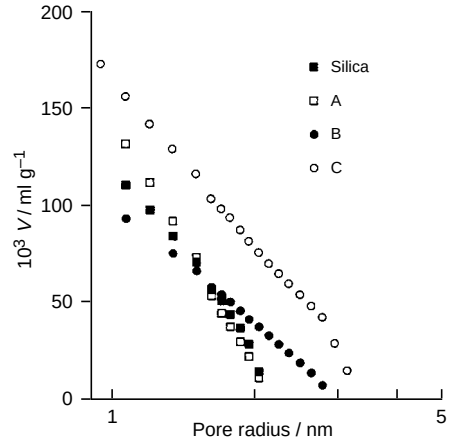


Fig. 1 Pore size distribution of silica and supported catalysts estimated by the Dollimore–Heal method (desorption, integral data)

Synthesis and structure of a novel binuclear rhenium(I) complex containing an unusual bridging ligand derived from coordinated acetonitrile. Unusual reactivity of $[Re(CO)_3(bpy)(MeCN)]^+$

Vivian Wing-Wah Yam,* Keith Man-Chung Wong and Kung-Kai Cheung

Department of Chemistry, The University of Hong Kong, Pokfulam Road, Hong Kong, PR China

$[Re(CO)_3(bpy)(MeCN)]^+$ forms a novel binuclear rhenium(I) complex containing a N≡CCH=C(CH_3)NH bridge derived from the reaction of the coordinated acetonitrile with NaH; the crystal structure of which has been determined.

There has always been considerable interest in transition metal nitriles which are extensively used as starting materials for a large variety of coordination and organometallic complexes, as well as in the activation of organonitriles in organic transformation reactions, which result from changes in the electrophilicity or nucleophilicity of the nitrile upon coordination to the metal center.[1,2] The coordination chemistry of coordinated nitriles at rhenium(I) centers has recently been reviewed,[1f,2] in which the coordinated nitrile carbon has been observed to be prone to attack by electrophiles such as H^+. Although there have been reports on the nucleophilic attack on nitriles coordinated to electron-deficient metal centers such as those of Co^{III},[3] to the best of our knowledge, there has been no report on reactions involving nucleophilic attack on the nitriles coordinated to rhenium(I) metal centers, which are normally accepted as being electron rich. Complexes such as $[ReCl(NCR)(dppe)_2]$ have been reported to undergo protonation at the nitrile carbon, due to the strong π electron releasing ability of the Re^I center to the NC π* orbitals of the coordinated nitrile,[1f,2] to yield azavinylidene derivatives. Herein we report the unusual reactivity of $[Re(CO)_3(bpy)(MeCN)]^+$ and the first example of a nucleophilic attack at the nitrile coordinated to the rhenium(I) center. The crystal structure of the novel binuclear rhenium(I) product, $[\{Re(CO)_3(bpy)\}_2\{NHC(CH_3)CHCN\}]^+$ **1** has also been determined.

Reaction of $[Re(CO)_3(bpy)(MeCN)]OTf$ (0.5 mmol) with NaH (0.3 mmol) in thf (20 ml) at room temp. for 2 min under nitrogen afforded a reddish brown solution, which was then purified by column chromatography on silica gel using dichloromethane–acetone (1 : 1 v/v) as eluent to yield $[\{Re(CO)_3(bpy)\}_2\{NHC(Me)CHCN\}]^+$ as dark red crystals; the identity of which has been confirmed by characterization with ^1H NMR, ^{13}C NMR, IR, FABMS, elemental analyses,† and X-ray crystallography.‡

The perspective drawing of the complex cation of **1** is depicted in Fig. 1. The structure of the complex consists of two rhenium diimine moieties bridged by an enamino–nitrile ligand. The coordination geometry at each Re atom is distorted octahedral with the three carbonyl ligands arranged in a *fac* fashion.[4] Bond distances worthy of special comment are N(4)–C(16) [1.29(1) Å], which is indicative of a C–N bond intermediate between those of single and double bond character, C(14)–C(15) [1.40(1) Å] and C(15)–C(16) [1.41(2) Å] which are intermediate between those expected for single and double bonds and are closer to that expected for alkenes. Although the bond distance N(3)–C(14) [1.13(1) Å] is quite short, the IR stretching frequency for the C≡N bond is 2194 cm^{-1}, which is at lower frequency than that found in $[Re(CO)_3(bpy)(MeCN]^+$ (2315 cm^{-1}),§ and may be suggestive of a bond weaker than that for a true triple bond character. These data strongly suggest that the π bonding or electron is extensively delocalized over the NCCCN moiety of the bridging ligand (Scheme 1). Such delocalization has also been observed in other systems.[5] The enamino–nitrile ligand containing N(3), C(14), C(15), C(16) and N(4) shows a coplanar arrangement with a mean deviation of 0.0114 Å from the least-squares plane, which is in accordance with the π bonding being delocalized over the NCCCN moiety.

The room temp. ^1H NMR spectrum shows two sets of chemical shifts for each resonance signal of CH_3, NH and CH groups. This has been attributed to the presence of two conformers existing in equilibrium in solution. The two

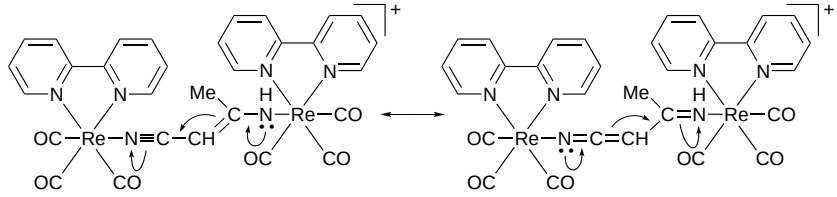
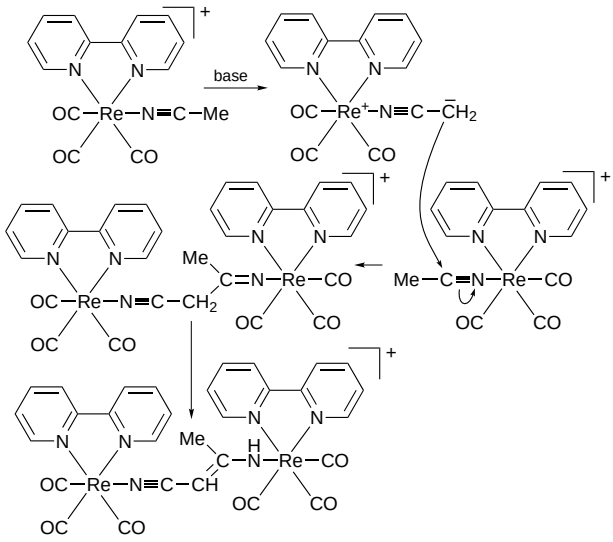


Scheme 1



Scheme 2

conformers or rotamers are the *cis*- and *trans*-isomers owing to the restricted rotation about the C=C bond in the N≡CC=CN system. The two isomers are in equilibrium, resulting from the mesomerism, and the relative populations of the isomers change with different solvent polarities, which are common in organic compounds with the O=CC=CN moiety.[6] The relative populations of the *cis*- and *trans*-isomers are *ca*. 7 : 1 in acetonitrile and *ca*. 5 : 1 in acetone. The ^{13}C NMR spectrum also shows two distinct resonances for CH_3 and CH groups which are in accord with results obtained from ^{1}H NMR spectroscopy; the identities of the CH_3 and CH signals have also been confirmed by DEPT-135 NMR spectroscopy.

A mechanism involving the initial deprotonation of the α-methylene proton in the coordinated acetonitrile in the presence of a strong base to give the carbanion $[Re(CO)_3(bpy)(N{\equiv}CCH_2)]$, followed by its attack on the electrophilic nitrile carbon of a second molecule of $[Re(CO)_3(bpy)(MeCN)]^+$, is proposed. The imine group in the bridging ligand finally tautomerizes to the enamine, despite the fact that imine is commonly more stable than enamine (Scheme 2). It is likely that the presence of delocalization of electron over the bridging ligand in this enamino–nitrile form favors the tautomerism. The deprotonation step has also been proposed to occur in other electron-deficient transition metal nitrile complexes.[3] It is likely that the Re$^{\text{I}}$ center in $[Re(CO)_3(bpy)(MeCN)]^+$ which carries a positive charge and contains strong π-accepting CO groups, unlike the neutral $[ReCl(RCN)(dppe)_2]$, is fairly electron deficient, and is thus capable of activating the coordinated acetonitrile towards deprotonation. The electrophilic nature of Re$^{\text{I}}$ has been reflected by the higher ν(C≡N) stretching frequencies observed in $[Re(CO)_3(bpy)(MeCN)]^+$ than in free acetonitrile.[7] Similar frequency shifts have been reported for the cobalt(III) complexes which have been proposed to undergo base hydrolysis *via* an initial deprotonation step.[3] Preliminary studies show that $[\{Re(CO)_3(bpy)\}_2\{NHC(Me)CHCN\}]^+$ is strongly luminescent, typical of triplet MLCT emission in related rhenium(I) diimine systems.[5,8]

The detailed photophysical and reactivity studies of this complex, as well as the preparation of related complexes containing different bridging ligands by employing coordinated nitriles other than acetonitrile, are in progress.

Racemisation behaviour of trinuclear helicates formed from ethylene-bridged tris(catechol) ligands and titanium(IV) ions

Markus Albrecht* and Matthias Schneider

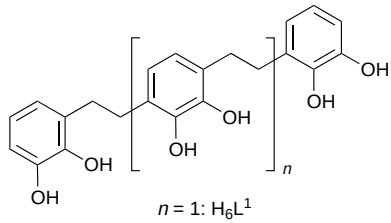
Institut für Organische Chemie, Universität Karlsruhe, Richard-Willstätter-Allee, D-76131 Karlsruhe, Germany

Trinuclear helicates are self-assembled from ligand H_6L^1 and Ti^{IV} ions in the presence of sodium or potassium carbonate and they racemise by consecutive inversion of the three complex units.

Movement, flexibility and dynamic behaviour are important features of chemical compounds. Although we tend to rationalise and visualise molecules as rigid structures, their behaviour very often is dominated by their ability to move or to undergo conformational changes. A very simple dynamic process of a supramolecular aggregate which is formed in a metal-directed self-assembly process is the racemisation of helicates.[1–3] In some special cases this process can be followed by NMR spectroscopy using diastereotopic protons as a stereochemical probe.[1,2] Just recently Raymond and coworkers showed that the racemisation of dinuclear gallium helicates with bis(catecholate) ligands proceeds by stepwise inversion of the two chiral metal complex units. The energy barrier for a simultaneous inversion of the two moieties should be twice as high as those of analogous mononuclear compounds. However, very similar barriers are observed for the mono- and di-nuclear complexes.[1] Additionally we could show that the racemisation barrier of dinuclear triple-stranded cryptand-type alkyl-bridged titanium(IV) helicates depends on the length of the spacer as well as the counter-ion which is present.[2]

Herein, we present the first self-assembly of a trinuclear triple-stranded helicate, which is formed from oxygen-donor ligands.[4] Analogous trinuclear double- or triple-stranded systems which contain nitrogen donor ligands have already been described in the literature.[5] Additionally we investigated the racemisation behaviour of the coordination compounds and we can show that the racemisation of the triple-stranded helicate occurs by a stepwise inversion of the complex units.

Preparation of the coordination compounds $M_6(L^1{}_3Ti_3)$ (M = Na, K) is done by simple mixing of ligand H_6L^1 (1 equiv.), $TiO(acac)_2$ (1 equiv., acac = acetyl acetonate) and alkali-metal carbonate (1 equiv.) in methanol. Red solutions are formed



$n = 1$: H_6L^1
$n = 0$: H_4L^2

overnight and solvent is evaporated *in vacuo*. The residue is purified by chromatography (Sephadex LH 20, methanol) to obtain red complexes $M_6(L^1{}_3Ti_3)$ [M = Na (20%), K (33%)].† Owing to the high charge of the complex salts, it is difficult to obtain satisfactory mass spectra. However, for $K_6(L^1{}_3Ti_3)$ a positive FAB MS spectrum could be obtained with glycerine as matrix showing at high molar masses only characteristic peaks at *m/z* = 1430 $[K_4(L^1{}_3Ti_3H_3)^+]$, 1469 $[K_5(L^1{}_3Ti_3H_2)^+]$ and 1507 $[K_6(L^1{}_3Ti_3H)^+]$.

The ^{1}H NMR spectra (CD_3OD, 500 MHz) of the sodium *cf.* the potassium salt possess different features. NMR signals of the sodium salt $Na_6(L^1{}_3Ti_3)$ are observed at δ = 6.42 (dd, *J* 7.6, 1.6 Hz, 6 H), 6.36 (s, 6 H), 6.36 (t, *J* 7.6 Hz, 6 H) and 6.25 (dd,

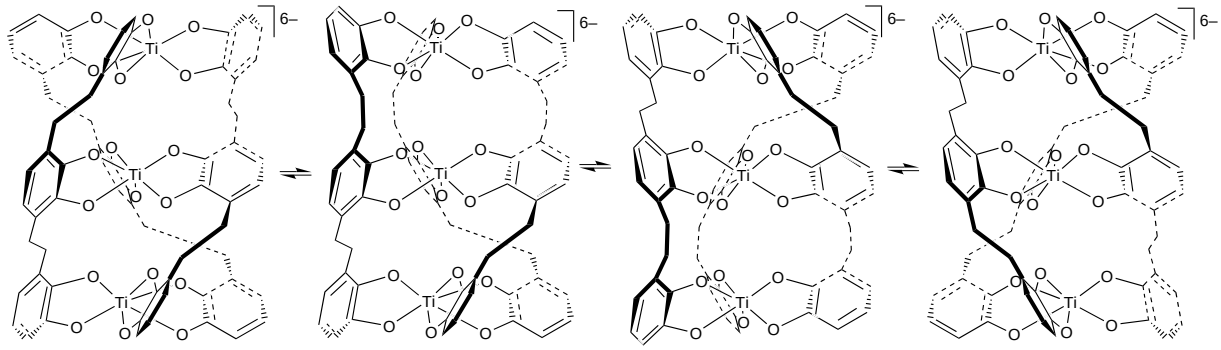

Scheme 1 Mechanism of the stepwise racemisation of ΔΔΔ-$[L^1{}_3Ti_3]^{6-}$ to ΛΛΛ-$[L^1{}_3Ti_3]^{6-}$

J 7.6, 1.6 Hz, 6 H) for the aromatic protons. The spacer protons lead to a multiplet at δ 2.66 (24 H). In contrast, $K_6(L^1{}_3Ti_3)$ exhibits resonances at δ 6.52 (dd, *J* 7.6, 1.2 Hz, 6 H), 6.46 (s, 6 H), 6.44 (t, *J* 7.6 Hz, 6 H) and 6.25 (dd, *J* 7.6, 1.2 Hz, 6 H) for the ligand moieties and two multiplets at δ 2.90 (m, 12 H) and 2.33 (m, 12 H) for the spacer protons. The observed NMR spectroscopic results show that for the potassium salt $K_6(L^1{}_3Ti_3)$ the racemisation of the helicate at room temp. is slow with respect to the NMR timescale while the inversion of the corresponding sodium salt is fast. This is in agreement with results obtained for the analogous dinuclear complexes $M_4(L^2{}_3Ti_2)$ (M = Na, K).[2] As we showed previously, the difference in the dynamic behaviour of different alkali-metal salts of helicates is due to inclusion of the counter-ions in the cryptand-type interior.[6]

Inclusion of counter-ions in the cavities of the trinuclear helicate $[L^1{}_3Ti_3]^{6-}$ was indicated by titration of the sodium salt with potassium chloride. ^{23}Na NMR spectroscopy [D_2O–H_2O (1 : 1), 105.8 MHz, Fig. 1)] at room temp. shows that the initial broad signal at δ −2.4 ($\Delta\nu_{\frac{1}{2}}$ = 625 Hz) sharpens upon addition of KCl and is shifted towards the typical resonance for solvated sodium cations at δ −0.3. This observation is due to the binding of potassium cations in the interior of the cavities and removal of sodium.[6]

Fig. 2 presents the result of a low temperature NMR spectroscopic study of $Na_6(L^1{}_3Ti_3)$ in CD_3OD (500 MHz). While cooling the NMR sample, the signal of the protons of the spacer at δ 2.66 starts to broaden and at 236 K coalescence is observed. At lower temperatures (218 K) two multiplets can be detected at δ 3.02 and 2.31 for the diastereotopic spacer protons of the chiral helicate. From those NMR spectroscopic findings a free energy barrier of $\Delta G^{\ddagger}$ = 43.9 kJ mol^{-1} can be estimated for the racemisation of the hexaanionic helicate with sodium counter-ions, $Na_6(L^1{}_3Ti_3)$.

Upon heating of $K_6(L^1{}_3Ti_3)$ in CD_3OD (500 MHz) coalescence can not be reached. However, if the same experiment is performed in D_2O, coalescence is observed at 364 K, indicating a racemisation barrier of $\Delta G^{\ddagger}$ = 70.7 kJ mol^{-1}.

As can be seen from Table 1, the observed $\Delta G^{\ddagger}$ values of the trinuclear complexes $M_6(L^1{}_3Ti_3)$ are very similar to those detected for the corresponding dinuclear compounds $M_4(L^2{}_3Ti_2)$. The largest deviation is found for the potassium salts with $\Delta G^{\ddagger}_{tri}/\Delta G^{\ddagger}_{di}$ = 1.1. If the racemisation proceeds by a simultaneous mechanism *via* an achiral coordination compound with three trigonal prismatic complex moieties, a ratio of $\Delta G^{\ddagger}_{tri}/\Delta G^{\ddagger}_{di}$ = 1.5 would be expected. The observed ratios of approximately 1.0 show that the racemisation takes place by a stepwise mechanism. This means that the helicate starts to invert at one terminus of the complex followed by inversion of the central complex unit and final racemisation of the second terminus (Scheme 1). (It is unlikely that the inversion starts at the central unit. This would lead to two *meso*-type relations of this unit to the two other complex moieties and would build up a high strain energy.[7])

To rule out a dissociative mechanism for the racemisation of the helicate,[1,3] NMR experiments were performed in the presence of an excess of ligand. No exchange of free and bound ligand could be observed.[6] Spin saturation transfer NMR experiments proved to be negative and thus supported our interpretations.

Using Raymond's strategy, we could show that the racemisation of flexible alkyl-bridged trinuclear tris(catecholato) titanium helicates proceeds similarly to the one of dinuclear gallium helicates with more rigid aryl amid linkages between the complex units.[1] However, in the case of $M_6(L^1{}_3Ti_3)$ the counter-ions are binding to the hexaanion and thus are influencing the racemisation barrier.

This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank Dr Herbert Röttele for the measurement of the NMR spectra.

Syntheses and characterizations of two copolymers containing cone conformations of calix[4]arenes in the polymer backbone

Michael T. Blanda* and Eba Adou

Department of Chemistry, Southwest Texas State University, San Marcos, TX 78666, USA

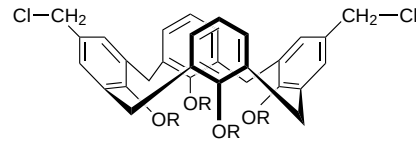
Two new polymers containing calix[4]arenes in the cone conformation were synthesized *via* condensation reactions.

Calix[4]arenes are cyclic tetramers of *tert*-butylphenol and formaldehyde which can be synthetically manipulated to assume rigid, cone-like structures which possess an upper rim defined by the *para*-positions of the aromatic rings, and a lower rim defined by the oxygen atoms. This conformation of calix[4]arenes is highly preorganized and forms complexes with neutral molecules or metal ions.[1] In order to enhance the affinity of calix[4]arenes towards certain metal ions (in particular sodium) ionophoric groups containing carbonyl or ether functionality may be appended to the lower rim.[2]

We report a new application for the well established binding properties of calix[4]arenes that involves incorporating them into polymers. These new polymers may then be processed into materials suitable for chemical sensor devices such as ion-selective electrodes and filtration/extraction membranes. Previously reported sensor devices based on calixarenes have been fabricated by blending the calixarene molecules into polymer melts or other membrane composites.[3,4] Blending methods have several drawbacks including non-uniform ordering of the calixarene units, leaching, and difficulty in reproducing a given set of properties in the blend.

Calixarene-based polymers have just begun to receive attention, and of the few reported, the calixarene moieties have been appended to the polymer *via* the lower rim of the calixarene monomers.[5] A calixarene-based water soluble polymer has also been reported in which the upper rim of the calixarene was used as the site of attachment to the polymer.[6] Until very recently, no polymers have been reported in which the calixarenes were part of the polymer backbone. Dondoni *et al.* have successfully copolymerized a calixarene monomer in the 1,3-alternate conformation with Bisphenol A to yield a calixarene-based polymer which exhibited a higher binding affinity for silver ions than the individual calixarene monomer from which it was derived.[7] We report the syntheses of two calixarene-based copolymers with the following features: (1) the calixarene monomers are in the cone conformation, (2) the site of polymerization is located on the upper rim of the calixarene monomers and (3) the calixarene units are part of the polymer backbone.

The scarcity of calixarene-based polymers is in part due to the difficulty in synthesizing rationally designed monomers. The key intermediate to both monomers, 5,17-dichloromethyl-25,26,27,28-tetraethoxyethylcalix[4]arene† **1**, was derived from the principal starting material 5,11,17,23-tetra-*tert*-butyl-25,26,27,28-tetrahydroxycalix[4]arene.[8] The conformationally

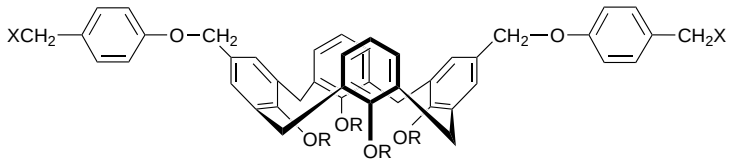


1
Cone conformation
R = CH_2CH_2OEt

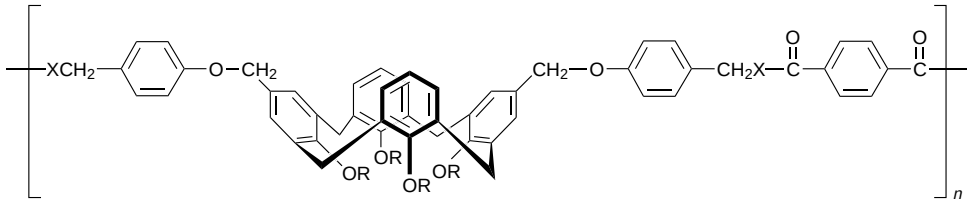
mobile *tert*-butylcalixarene was first dealkylated at the upper rim using $AlCl_3$, then treated with 2-bromoethyl ethyl ether in the presence of sodium hydride to yield the tetraethoxyethyl calixarene which assumed the cone conformation.‡ The alkali metal binding properties of this ether-functionalized calix[4]-arene were investigated by Shinkai and showed high selectivity for the sodium ion, prompting us to elaborate on its structure so that it could be incorporated into different types of polymers.[9]

The tetraethoxyethylcalixarene was selectively formylated on the upper rim by treatment with dichloromethyl methyl ether in the presence of tin(IV) chloride followed by hydrolysis of the geminal dichloride.[10] The aldehyde groups were then reduced to alcohols and the corresponding diol was transformed into the dichloride **1** by treatment with thionyl chloride. The dichloride **1** was next transformed into the two penultimate monomer compounds by reacting it with either *p*-bromo- or *p*-cyanophenol in the presence of sodium hydride to yield the corresponding dibromo and dicyano compounds which were converted into the diol monomer **2** and diamine monomer **3**, respectively. The extension of the 'arms' at the upper rim proved to be critical in the subsequent condensation copolymerization reactions because initial attempts to copolymerize various calixarene monomers with shortened 'arms' did not yield high molecular weight polymers.

Both calixarene monomers **2** and **3** were condensed with equal molar amounts of terephthaloyl chloride in dimethylacetamide. The polyester reaction was heated at 60 °C while the polyamide reaction was run at room temperature. Both copolymerization condensation reactions were allowed to react for 36 h. After that time, the solvent volume was reduced and methanol was added to the reaction mixtures to precipitate the copolymers, **4** and **5**.§ The isolated yields of the two white amorphous copolymers were 66 and 50% for the polyester **4** and polyamide **5**, respectively. The glass transition temperatures (T_g) were measured using differential scanning calorimetry and the T_g for **4** was found to be 141 °C and that of **5** was determined to be 100 °C. Due to the amorphous structure of the copolymers, no melting transitions (T_m) were observed in the thermograms.



2 X = OH
3 X = NH_2



4 X = O
5 X = NH

The thermal stabilities of each copolymer were determined by thermal gravimetric analyses (TGA) in a nitrogen atmosphere. The temperatures at which 10% weight loss occurred were 352 and 380 °C, respectively, for **4** and **5**. The inherent viscosities for the copolymers were measured using an Ostwald viscometer with chloroform as the solvent at 25 °C and were found to be 0.12 dl g^{-1} for **4** and 0.14 dl g^{-1} for **5**.[11] The fact that both copolymers were completely soluble may provide additional evidence that the copolymers are amorphous.[11b] The molecular weights for each copolymer were determined by size exclusion chromatography (SEC) against polystyrene standards. The eluent used in the SEC analyses was THF and the samples were run at room temperature. The chromatograms for each polymer showed only one broad signal from which the number-average molecular weights (M_n) were determined to be 29 000 Da for the polyester **4** and 52 000 Da for the polyamide **5**. Qualitatively the broadness of the signals reflects a certain degree of polydispersity. However, since no experimental determination of the weight-average molecular weight (M_w) was made, a quantitative value of the polydispersity was not obtained. Based on the step-growth nature of the copolymers *via* the condensation reactions, the polydispersity is likely to be *ca*. 2.[11c] Even though the signals in the ^{1}H NMR spectrum for **4** and **5** were broadened at room temperature, it was possible to discern that the calixarene moieties were still in the cone conformation. We are currently investigating the alkali metal binding properties of each copolymer in comparison with the tetraethoxyethylcalixarene previously studied in order to determine if any cooperativity is displayed.[12]

The very unusual complex $[Pt(C{\equiv}CBu^t)_2(PPh_2O)_2Li_2(\mu\text{-}H_2O)(Me_2CO)_2]_2$ 2 is obtained by the reaction of '$Li_2[Pt(C{\equiv}CBu^t)_4]$' with an excess of PPh_2H in acetone–ethanol and possesses an unusual linear chain of four Li atoms sandwiched between two square planar dianionic units *trans*-$^-OPPh_2\{Pt(C{\equiv}CBu^t)_2\}PPh_2O^-$, to which it is bound through $\mu_3\text{-}PPh_2O^-$ bridging ligands.

Platinum–alkynyl chemistry has long been the subject of intensive study[1] and recently there has been a growing interest in the synthesis of polymetallic species derived from dianionic (C_2^{2-}, $C_2RC_2^{2-}$, *etc.*) or substituted (pyridyl, bipyridyl, ruthenocenyl, ferrocenyl, *etc.*) building blocks due to their increasing importance in materials science.[1,2] The family of alkynyl Pt complexes, particularly that of mononuclear heteroleptic derivatives which are stabilised by tertiary phosphine ligands is now quite large.[1,2d,e,3] The chemistry of monomeric derivatives containing other types of ligands is comparatively less developed[1,3a,4] and analogous complexes containing secondary phosphines as additional ligands have not been explored. The presence of acidic protons in this type of ligand (PR_2H) probably prevents the use of the most general synthetic routes such as the reaction of halides with alk-1-ynes (base, CuI-catalysed)[1,2d,e,3b,4d] or with metal acetylide reagents.[1,4] Recently, we have reported the preparation of *trans*-$[Pt(C{\equiv}CBu^t)_2(PPh_3)_2]$[5] in high yield by partial displacement of the alkynyl groups with PPh_3 from the reactive species $Li_2[Pt(C{\equiv}CBu^t)_4]$, prepared '*in situ*'. We report here the application of this method to the diphenylphosphine ligand, which allows not only the preparation of the homologous complex *trans*-$[Pt(C{\equiv}CBu^t)_2(PPh_2H)_2]$ **1** but also the synthesis of an unexpected tetralithium diplatinum compound **2**, which contains lithium atoms in the form of an unusual linear chain of four Li atoms stabilised by $\mu_3\text{-}PPh_2O^-$ and $\mu\text{-}OH_2$ bridging ligands. Complex **2** represents the second alkynyl–platinum lithium complex crystallographically characterised,[6] and also the second example reported containing one small chain of four sandwiched Li ions.[7]

The tetraalkynylplatinatelithium species '$Li_2[Pt(C{\equiv}CBu^t)_4]$' was initially formed by addition of $LiC{\equiv}CBu^t$ to $[PtCl_2(tht)_2]$ (molar ratio 5.5 : 1) as previously reported.[5,8] Treatment of the colourless solution obtained by dissolving $Li_2[Pt(C{\equiv}CBu^t)_4]$ in acetone–ethanol with an excess of PPh_2H (1 : 3, N_2 atmosphere) causes the slow precipitatiion (7 h of stirring) of *trans*-$[Pt(C{\equiv}CBu^t)_2(PPh_2H)_2]$ **1** as a white microcrystalline solid (25% yield on the Pt starting material). Prolonged stirring (7 h) of the resulting filtrate under aerobic conditions produces the separation of a new white solid. Recrystallization of this solid from hot acetone yields the crystalline tetralithium diplatinum diphenylphosphinite complex **2** in *ca.* 45% yield. During our efforts to optimise the synthesis of complex **1** we observed that the relative yields of **1** and **2** vary with the presence of air in the reaction system (25–52% **1** to 45–11% **2**, on the Pt starting material). This fact clearly indicates that the presence of PPh_2O^- ligands in complex **2** stems from the partial oxidation of the PPh_2H ligand to PPh_2OH under the reaction conditions employed.[9] Complex **1** was characterised analytically and spectroscopically.

The identity of complex **2** has been established by X-ray structure analysis† which revealed the unexpected tetralithiumdiplatinum species $[Pt(C{\equiv}CBu^t)_2(PPh_2O)_2Li_2(\mu\text{-}H_2O)(Me_2CO)_2]_2$.‡ Molecule A (Fig. 1) is formed by two identical dianionic fragments '*trans*-$^-OPPh_2\{Pt(C{\equiv}CBu^t)_2\}PPh_2O^-$' which act as didentate ligands, bridging the four Li centers pairwise through the oxygen atoms. Each PPh_2O^- ligand is Pt–P bonded [Pt(1)–P(1,2) 2.301(2), 2.306(2) Å] and as mentioned bridges two Li centres [Li–O range 1.907(10)–1.969(10) Å], giving two planar Li_2O_2 rings, Li(1,2)O(1,2′) and Li(1′,2′)O(1′,2), which are rigorously coplanar. The central atoms are connected by two H_2O molecules [O(5), O(5′)]. All this results in a final linear disposition of four non-bonded Li atoms [Li(2)···Li(1,2) 2.610(13), 2.848(19) Å], Li(1)–Li(2)–Li(2′) 176.7(6)°], which is very similar to the Li disposition in the compound recently described by Roesky and coworkers,[7] $Li_4[(MeGa)_6(\mu_3\text{-}O)_2(Bu^tPO_3)_6]\cdot 4thf$. This structural feature contrasts with the most prevalent structural motif, cubane-like, found in other tetralithium derivatives[10] which has been rationalised using ring-stacking ideas.[11] The Li atoms in

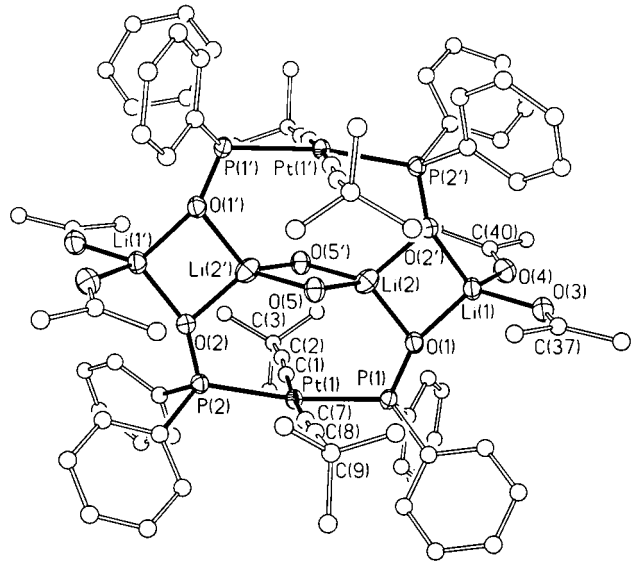

Fig. 1 Molecular structure of **2**. Ellipsoids depicted at their 50% probability level. Important molecular geometry parameters include: interatomic distances (Å): Li(1)–O(1) 1.907(10), Li(1)–O(2′) 1.927(10), Li(2)–O(2′) 1.957(11), Li(2)–O(1) 1.969(10), Li(2)–O(5) 2.0481(10), Li(2)–O(5′) 2.048(10), Pt(1)–C(1) 2.001(6), Pt(1)–C(7) 2.006(6), C(1)–C(2) 1.207(8), C(7)–C(8) 1.203(8). Bond angles (°): O(3)–Li(1)–O(4) 99.0(4), O(1)–Li(1)–O(2′) 96.9(4), Li(1)–O(1)–Li(2) 84.6(4), Li(1)–O(2′)–Li(2) 84.4(4), O(1)–Li(2)–O(2′) 93.9(4), O(5)–Li(2)–O(5′) 91.9(4), Li(2)–O(1)–P(1) 119.1(4), O(1)–P(1)–Pt(1) 111.65(15), O(2)–P(2)–Pt(1) 112.62(15), Pt(1)–C(1)–C(2) 175.8(5), C(1)–C(2)–C(3) 173.4(7), Pt(1)–C(7)–C(8) 177.0(5), C(7)–C(8)–C(9) 175.0(7). Primed atoms are related by inversion centre to unprimed ones.

each [Li(1,2)O_2] unit are chemically different. Thus the internal Li atoms [Li(2), Li(2′)] have tetrahedral coordination, being bonded to the O atoms [O(5), O(5′)] of the two bridging water ligands, while the external Li atoms [Li(1), Li(1′)] interact with two terminal acetone molecules [Li(1)–O(3),(4) 1.981(10), 1.997(10) Å]. Both the distortion from tetrahedral geometry at the Li centres and the Li–O bond lengths are in good agreement with those observed in other Li compounds containing similar LiO_4 tetrahedral coordination environments.[10–12] On the other hand, it is also remarkable that although a variety of metal coordination modes have been observed for diorganophosphinite ligands,[9a,12b,13] to our knowledge, complex **2** is the first example in which this ligand acts with a μ_3-κ^3:P,O,O′ bonding mode, bridging two hard Li atoms (μ-O) and also being P-bonded to a soft Pt centre. The P–O bond distances in **2** [1.537(4), 1.539(4) Å] are comparable to those observed for structurally characterised $[PPh_2–O]^-$ complexes displaying a μ-O,μ-P metal bridging mode.[13] The square-planar coordination at Pt is unexceptional, exhibiting, as expected, essentially linear acetylenic fragments (see Fig. 1).

In accord with the solid structure, the IR spectrum of **2** shows, in addition to a medium ν(C≡C) band at 2092 cm^{-1}, the presence of water (3646, 3402, 1611 cm^{-1}) and typical absorptions for ν(P=O) (996, 1006, 1030 cm^{-1}), characteristic of phosphinito-bridged complexes.[13] In the ^{31}P NMR spectrum a singlet shifted far downfield (δ 67.37, $^1J_{PtP}$ 2510 Hz) is observed,indicative of P oxidation to P^V.[13] The ^1H NMR spectrum of **2** in CD_3COCD_3 exhibits a singlet at δ 0.46 due to equivalent alkynyl groups (C_2Bu^t); however, the difficulty in assigning OH bands, even after addition of D_2O, does not allow us to determine with certainty whether the H_2O molecules remain coordinated in solution.

The Li-ionic conductivity of the Li derivative **2** has also been measured using the well known complex impedance method,[14] but it is near zero. This fact is in agreement with previous results obtained for other tetrahedral LiO_4 derivatives.[15]

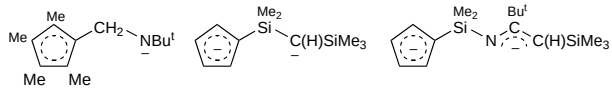
Lithium and zirconium complexes $[Li_2(B)(tmen)]_2$ 4, $[Li_4(C)_2(tmen)]$ 5, $[Zr(B)_2]$ 7 and $[Zr(C)_2]$ of the new ligands η^5-$\bar{C}_5H_4Si(Me)_2\bar{C}(H)SiMe_3$ ($\equiv$[B]$^{2-}$) and η^5-$\bar{C}_5H_4Si(Me)_2\{NC(Bu^t)C(H)SiMe_3\}^-$ ($\equiv$[C]$^{2-}$) are reported, as well as the X-ray structures of the centrosymmetric dimer 4 and of 5 (having each of the four Li atoms in a different environment) and the catalytic activity of 7 for α-alkene polymerisation.

Examples of cyclopentadienyl ligands bearing a neutral Lewis base substitutent include those containing an amine,[1a] ether,[1b] pyridyl,[1c] phosphine,[1d] or vinyl[1e] side chain. Analogues having an anionic substituent are rare. The earliest examples are the 'tucked-in' metal complexes, such as $[\bar{W}(\eta^5\text{-}C_5Me_4\bar{C}H_2)(\eta^5\text{-}C_5Me_5)H_2]$,[2] but the cyclopentadienyl amide [**A**]$^{2-}$ is noteworthy,[3] because its derived Ti^{IV} complex [Ti(**A**)Cl_2] is the Dow catalyst for the production of ethylene–styrene copolymer.[4] A cyclopentadienyl(iminoacyl) ligand has been found in a number of Ti^{IV} and Zr^{IV} complexes.[5]

We now draw attention to two new dianionic cyclopentadienyl ligands [**B**]$^{2-}$ and [**C**]$^{2-}$, having an alkyl and a

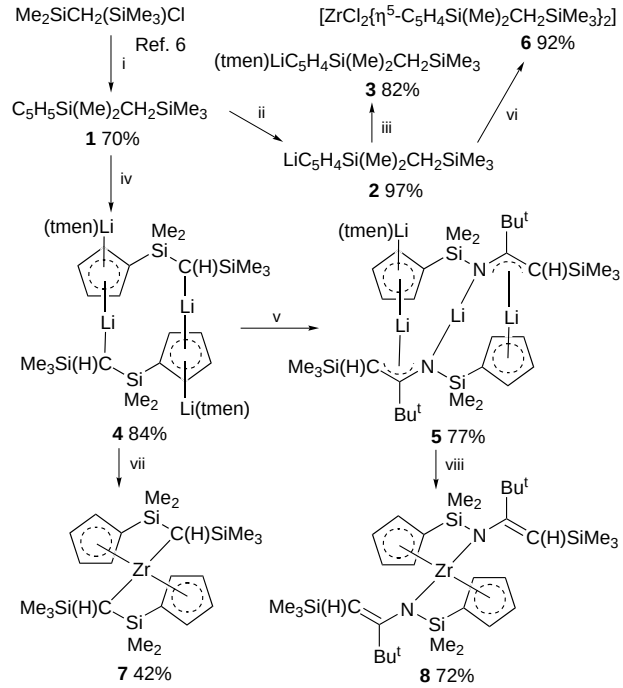


[**A**]$^{2-}$ [**B**]$^{2-}$ [**C**]$^{2-}$

1-azaallylsilyl side-chain, respectively, which may well find a useful role in organometallic chemistry.

Treatment of Cl_2SiMe_2 with $LiCH_2SiMe_3$ gave $ClSi(Me)_2CH_2SiMe_3$,[6] which with NaC_5H_5 gave **1** (Scheme 1, step i). From **1** and $LiBu^n$ (even when used in excess) in tetrahydrofuran (thf), only the monodeprotonated complex $LiC_5H_4Si(Me)_2C(H)_2SiMe_3$ **2** was obtained (step ii), derivatised (step iii) as the 1 : 1tmen adduct **3** [tmen = $(Me_2NCH_2)_2$]. However, from **1**, 2 $LiBu^n$ and 2 tmen, the dimeric complex $[Li_2(\mathbf{B})(tmen)]_2$ **4** was isolated (step iv). Reacting **4** with Bu^tCN led (step v) to the tetranuclear complex $[Li_4(\mathbf{C})_2(tmen)]$ **5**. The reaction between $ZrCl_4$ and each of the lithium compounds **2**, **4** and **5** gave (steps vi–viii, respectively) **6**–**8**, respectively. Complexes **6** and **7** (but not **8**) with methylaluminoxane (MAO) were shown to be effective catalysts for the polymerisation of C_2H_4, and **7** also for $MeCH{=}CH_2$ and $PhCH{=}CH_2$.

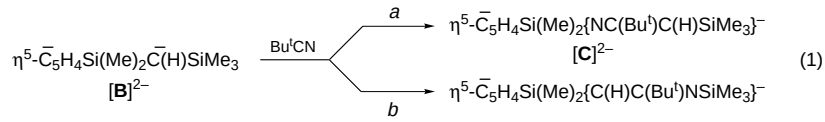
Since treatment of $Li\{CH(SiMe_3)_2\}$ with Bu^tCN readily gave the 1-azaallyllithium compound $[\bar{L}i\{N(SiMe_3)C(Bu^t)\bar{C}(H)SiMe_3\}]_2$,[7] in which a 1,3-$SiMe_3$ migration from C → N had taken place, there appeared to be two possible pathways upon reacting **4** with Bu^tCN, *a* and *b* in eqn. (1). In the event, Scheme 1, step v, as ultimately the X-ray structure of **5** revealed (*vide infra*) migration of the η^5-$C_5H_4SiMe_2$ group (pathway *a*) was preferred over $SiMe_3$.



Scheme 1 *Reagents and conditions*: i, NaCp, thf, 24 h, 0 °C; ii, $LiBu^n$, C_6H_{14}, 24 h, 0 °C; iii, tmen, C_6H_{14}, 3 h, 25 °C; iv, 2 tmen, 2 $LiBu^n$, C_6H_{14}, 24 h, 0 °C; v, Bu^tCN, Et_2O, 24 h, 25 °C; vi, 1/2 $ZrCl_4$, C_6H_{14}, 48 h, 25 °C; vii, or viii, $ZrCl_4$, C_6H_{14}, 48 h, 25 °C

Each of the compounds **1** and **3**–**8** gave satisfactory microanalysis, as well as multinuclear NMR spectra. For **1** [bp 93–98 °C (13 mmHg)], GCMS confirmed its purity and EI mass spectra showed the parent molecular ion to be the highest *m/z* peak for each of the zirconium compounds **6**–**8**. Compounds **3**–**8** were isolated as crystals and X-ray diffraction data‡ on **4** (Fig. 1) and **5** (Fig. 2) established their molecular structures; such data for **6** and **8** will be presented in a full paper.

Crystalline **4** is a centrosymmetric dimer. Each cyclopentadienyl group bridges two Li one of which Li(2)/Li(2′) has its coordination environment completed by a chelating tmen ligand, while the other Li(1)/Li(1′) has the carbanionic carbon C(1)/C(1′). Atoms Li(1)/Li(1′) are arranged in an almost linear fashion with respect to C(1)/C(1′) and the centroid M(1′)/M(1) of the cyclopentadienyl ring, C(1)–Li(1)–M(1′) 178.5. The Li(1)–C(1) bond of 2.075(8) Å is longer than the Li(1)–M(1′) distance of 1.93 Å. The former may be compared with the Li–C



(1)

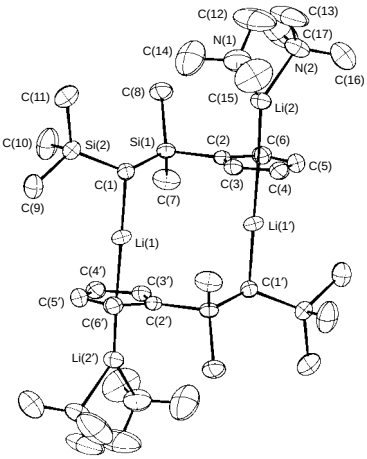


Fig. 1 The molecular structure of **4**. Selected bond lengths (Å) and angles (°) (also see text): Li(2)–M(1) 1.96, Li(2)–N(2) 2.092(8), Li(2)–N(1) 2.108(9); M(1) is the centroid of the C(2)–C(6) ring.

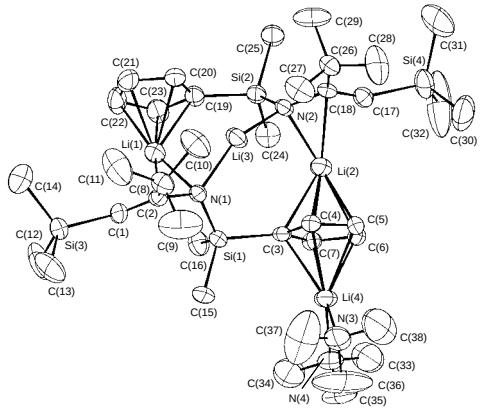

Fig. 2 The molecular structure of **5**. Selected bond lengths (Å) and angles (°) (see also **5a** and **5b**, and text): Li(4)–M(1) 2.004, Li(4)–N(3) 2.104(10), Li(4)–N(4) 2.093(10); M(1) is the centroid of the C(3)–C(7) ring, M(2) of the C(19)–C(23) ring.

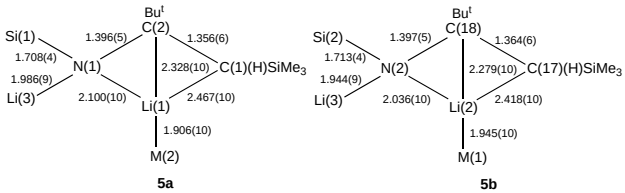
bond lengths in $[Li\{CH(SiMe_3)_2\}]_\infty$ [av. 2.19(5) Å][8] and $Li\{CH(SiMe_3)_2\}\{N(Me)(CH_2CH_2NMe_2)_2\}$, 2.13(5) Å.[9] The Li(1)–M(1′) distance is similar to that in $Li(\eta^5\text{-}C_5H_4SiMe_3)$-(tmen), 1.928 Å;[10] the latter has average Li–N bond lengths of 2.13(1) Å, compared with 2.100(9) Å in **4**.

Crystalline **5** is a tetranuclear complex in which each of the four Li atoms is in a different environment. Li(1) and Li(2) are somewhat similar (see **5a** and **5b**), except that the cyclopentadienyl having the centroid M(1) bridges Li(2) and Li(4), whereas the cyclopentadienyl having the centroid M(2) acts as a terminal ligand with respect to Li(1). The coordination environment around Li(4) is completed by a chelating tmen. The situation regarding Li(3) is the most unusual: it is two-coordinate, being the bridge between N(1) and N(2) of the two 1-azaallyl moieties, N(1) and N(2) being four-coordinate and N(1)–Li(3)–N(2) 145.2(5)°. The azaallyl–lithium environment around L(1) and Li(2) is similar to that in $[Li\{N(SiMe_3)C(Bu^t)C(H)SiMe_3\}]_2$.[7]



The catalytic activity of the zirconocene(IV) chloride **6** (with MAO) for polymerisation of ethylene was comparable to that of $[Zr(\eta^5\text{-}C_5H_5)Cl_2]$.§ While this is not surprising, the activity of **7** (with MAO) for C_2H_4 (mp of polymer: 138 °C by DSC), C_3H_6 (atactic oligomer of low average molecular mass) and PhCH=CH_2§ (atactic polymer of high average molecular mass) was unexpected. The high activity combined with the relatively low chain lengths for the latter two suggests that chain transfer is frequent, consistent with the high polydispersity. As far as we are aware, a zirconium(IV) bis(chelate) catalyst has not previously been reported.

Ligands related to $[\mathbf{B}]^{2-}$ and $[\mathbf{C}]^{2-}$, including $\eta^5\text{-}\overline{C}_5H_4Si(Me)_2\overline{C}(SiMe_3)_2$ are being explored, as are extensions to their role in titanium chemistry.

We thank EPSRC for providing a fellowship for J. H., and Mr D. Whiteman and Dr N. C. Billingham and RAPRA for the characterisation§ of the polymers.

Engineering layers in molecular solids with the cyclic dipeptide of (*S*)-aspartic acid

G. Tayhas R. Palmore* and Mary T. McBride

Department of Chemistry, University of California, Davis, CA 95616, USA

Hydrogen-bonded tapes formed by the cyclic dipeptide of (*S*)-aspartic acid 1 are used as a scaffold on which to build two-dimensonal layers that vary in size, shape and chemical composition.

Numerous research groups have demonstrated considerable success at using non-covalent interactions to build supramolecular structures in crystalline solids.[1] The most common interaction in these structures is the hydrogen bond, which occurs between functional groups strategically located on the constituent molecules.[2–5] Several molecules have been investigated, including a few that form robust supramolecular structures that can be modified in terms of their size and shape (*i.e.* modular). The advantage of a supramolecular structure that is both robust and modular is that it provides a scaffold with which to engineer the structure (and possibly the function) of molecular solids.

We have initiated a program of research aimed at understanding the influence of molecular structure on the kinetics of crystal growth using atomic force microscopy. To simplify these studies, we require molecular solids with a common supramolecular structure whose dimensions can be modified systematically. Our approach to preparing a series of related solids is to use the strength and directional character of hydrogen bonds to build the supramolecular structure, and exploit the selectivity of hydrogen bonds for different hydrogen-bond donors and acceptors to modify the supramolecular structure. We have focused our efforts on the cyclic dipeptide of (*S*)-aspartic acid **1** based on the following rationale.[6] First, **1** is representative of a family of molecules known to form hydrogen-bonded tapes in their crystalline solids [Fig. 1(*a*)].[1,7] Tapes are one-dimensional aggregates that typically pack with their long axes parallel. Second, **1** contains two types of functional groups (*cis*-amide and carboxylic acid) that contain both a hydrogen bond donor and a hydrogen bond acceptor.

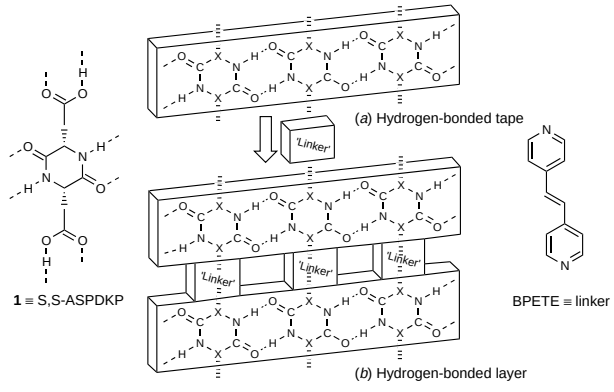

Fig. 1 (*a*) Tape that results when the *cis*-amides of (*S,S*)-ASPDKP (**1**) form a pair of hydrogen bonds (dashed lines) with the *cis*-amides of two adjacent molecules. X represents a substituted carbon atom. (*b*) Layer that forms when parallel tapes are cross-linked either directly through functional groups on X or indirectly through cocrystallization with 'linker' molecules (*e.g.* BPETE).

Functional groups such as *cis*-amides and carboxylic acids are known to form an $R_2^2(8)$ pattern of hydrogen bonds—a two-point interaction that is stronger and orientationally more restrictive than chains of hydrogen bonds.[8–10] Third, the hydrogen-bonding functional groups in **1** are positioned to preorganize the direction of their hydrogen bonds mutually orthogonal, which will promote the formation of hydrogen-bonded layers through the cross-linking of tapes [Fig. 1(*b*)]. Layers are two-dimensional aggregates that should pack with their planes parallel. Fourth, *cis*-amides and carboxylic acids have different selectivities for hydrogen-bond donors and acceptors.[10] With cocrystallization techniques, this difference in selectivity can be exploited to modify the interdigitation of tapes or the shape of the hydrogen-bonded layers.

Our first objective was to demonstrate that the two *cis*-amide functional groups in **1** form a symmetric $R_2^2(8)$ pattern of hydrogen bonds with adjacent molecules to generate the tape motif in the solid state. Based on Etter's rules for hydrogen-bonds, where the strongest hydrogen bond donor (acid hydroxy) preferentially interacts with the strongest hydrogen bond acceptor (amide carbonyl), carboxylic acids crystallized in the presence of amides should form an asymmetric $R_2^2(8)$ pattern of hydrogen bonds.[10,11] Further evidence that supports the preferential formation of an asymmetric $R_2^2(8)$ pattern of hydrogen bonds is the packing modes of monocarboxamide derivatives of dicarboxylic acids.[8] Due in part to restrictions in the conformation of **1** imposed by its stereochemistry, the crystalline solid of **1** contains the tape motif generated from a *symmetric* $R_2^2(8)$ pattern of hydrogen bonds between the *cis*-amide functional groups. The asymmetric unit cell contains two crystallographically distinct molecules of **1** that generate two distinct tapes, labelled A and B (Fig. 2).† Tapes pack with their long axes parallel. The hydrogen bond distances and angles between the *cis*-amides depend on the tape to which **1** belongs: N–H···O = 2.860 Å, 166° and 2.868 Å, 167° for tape A; 2.864 Å, 163° and 2.871 Å, 163° for tape B. Although a C_2-axis of symmetry is present in a two-dimensional drawing of **1**, this symmetry element is absent in the solid state due to the different conformations adopted by the two side-chains. Consequently, a

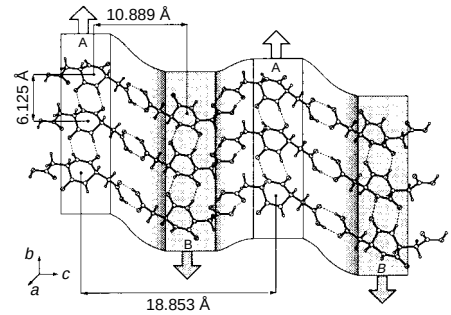

Fig. 2. Layer in crystal structure of **1**. The asymmetric unit cell contains two molecules of **1**, each of which generate a distinct tape (A and B), which alternate in their direction of propagation (arrows). Each tape is cross-linked to adjacent tapes through an $R_2^2(8)$ pattern of hydrogen bonds between the carboxylic acid groups to form a *non-planar* layer.

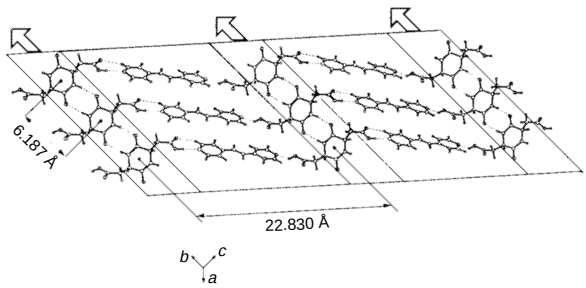

Fig. 3 Layer in crystal structure of **1**–**BPETE**. A symmetric $R_2^2(8)$ pattern of hydrogen bonds between the *cis*-amides of **1** form tapes, which are cross-linked into planar layers through an $R_2^2(7)$ pattern of hydrogen bonds between the carboxylic acid functional groups on **1** and the nitrogen atom and *ortho* carbon atom on BPETE. All tapes propagate in the same direction relative to tapes in the same layer and in adjacent layers (arrows).

non-planar layer results when each tape is cross-linked to adjacent tapes through a symmetric $R_2^2(8)$ pattern of hydrogen bonds between carboxylic acid functional groups (O–H···O interactions: 2.665 Å, 176°; 2.633 Å, 161°; 2.753 Å, 174°; and 2.740 Å, 175°). Layers pack with a slippage of 3.737 Å along the *c* axis while maintaining a periodicity of 4.985 Å between layers. Close contacts between layers include: O9–H16···O4, 2.886 Å and C15–H15···O2, 3.088 Å.

For the purpose of engineering related solids, the formation of a symmetric $R_2^2(8)$ pattern of hydrogen bonds in the crystalline solid of **1** is significant in that it suggests the tape motif can be used as a scaffold on which to build layers with different repeat distances between tapes. For example, a guest molecule can be inserted within the layer of **1** by cocrystallization techniques, which allows for systematic modification of the periodicity of tapes within the layer. We illustrate this point in Fig. 3, which shows the crystal structure of **1** cocrystallized with (*E*)-1,2-bis(4-pyridyl)ethene (BPETE).‡ In this example, parallel tapes are cross-linked into a planar layer through hydrogen bonding interactions between the carboxylic acid functional groups on **1** and the nitrogen and *ortho* carbon atoms of BPETE (O–H··N = 2.893 Å, 162°; and 2.633 Å, 143°; C–H··O = 3.103 Å, 126°; and 3.511 Å, 116°). The carboxylic acid functional groups do not form an $R_2^2(8)$ pattern of hydrogen bonds in the presence of BPETE because the pyridyl nitrogen atom is a stronger hydrogen-bond acceptor than the carbonyl oxygen atom of carboxylic acids.§ Moreover, the interaction is not ionic; proton transfer from the carboxylic acid to BPETE does not occur. We base this assertion on the similar C–N–C bond angles of BPETE in the presence (115.8°) or absence (115.4°) of **1**.[12] In a manner similar to the crystalline solid of **1**, the crystalline solid of **1**–**BPETE** contains an $R_2^2(8)$ pattern of hydrogen bonds between *cis*-amides of adjacent molecules to give tapes (N1–H1··O2 = 2.857 Å, 166°, N2–H2··O1 = 2.829 Å, 167°). Tapes lie with their long axes parallel. Layers pack with slippage of 4.511 Å along the *c*-axis and a periodicity of 4.211 Å between adjacent layers. The closest contact between layers is 3.203 Å (C20–H20··O5).

Several research groups have demonstrated that hydrogen-bonded layers can be assembled in crystalline solids from molecules that are designed to form hydrogen bonds in two directions. Compound **1** is a new addition to this type of molecule. An important feature of **1** is that the presence of competing hydrogen-bonding functional groups, either as part of (carboxylic acid) or external (pyridyl) to the molecular structure of **1**, does not preclude the formation of tapes defined by an $R_2^2(8)$ pattern of hydrogen bonds between *cis*-amide functional groups. Consequently, these tapes can be modified in terms of their interdigitation or used as scaffolds on which to build layers (or three-dimensional structures) that systematically differ in their size, shape and chemical composition. We demonstrate the use of tapes as scaffolds with the two examples shown, which are representative of the tremendous potential that molecules such as **1** have in engineering layers in the solid state. Studies of other layered solids built with **1** are currently in progress and will be the subject of future reports.

We thank Dr Marilyn M. Olmstead for helpful discussions and the PRF for financial support.

†All data were collected at 130 K on a Siemens P4/RA diffractometer with graphite-monochromated Cu-Kα radiation (λ = 1.541 78 Å) using 2θ scans over the range 2–57°. Lattice parameters were determined from least-squares analysis of 30–35 reflections. Two standard reflections were measured every 198 reflections. Structures were solved by direct methods and refined by full-matrix least-squares on F^2 using SHELXTL, Version 5.03. All non-hydrogen atoms were refined anisotropically. All hydrogen-bonded hydrogen atoms were refined after location on a difference map with isotropic temperature factors. Other hydrogen atoms were placed in idealized positions with assigned isotropic thermal parameters. *Crystal data* for **1**: $C_8H_{10}N_2O_6$, M = 230.18 g mol^{-1}, triclinic $P\bar{1}$, colorless needle measuring 0.18 × 0.06 × 0.04 mm, a = 4.985(1), b = 5.039(1), c = 18.853(4) Å, α = 82.50(3), β = 88.47(3), γ = 75.33(3)°, V = 454.2(2) Å^3, Z = 2, D_c = 1.683 Mg m^{-3}, μ = 1.275 mm^{-1}; T_{max} = 0.96, T_{min} = 0.93, GOF on F^2 = 1.083; R_1 = 0.0344, R_{all} = 0.0346 for 1215 independent observed reflections, based on $I > 2.0\sigma(I)$.

‡ Cocrystals of **1** and BPETE were obtained by slow evaporation from a methanol solution containing an equimolar mixture of **1** and BPETE. *Crystal data* for cocrystal of **1**–**BPETE**: $C_{20}H_{20}N_4O_6$; M = 412.40 g mol^{-1}, triclinic $P\bar{1}$, yellow needles measuring 0.52 × 0.14 × 0.08 mm, a = 6.1779(13), b = 6.187(2), c = 13.404(3) Å, α = 82.63(2), β = 83.92(2), γ = 68.23(2)°, V = 471.0(2) Å^3, Z = 1, D_c = 1.454 Mg m^{-3}, μ = 0.919 mm^{-1}; T_{max} = 0.94, T_{min} = 0.89, GOF on F^2 = 1.043; R_1 = 0.0860, R_{all} = 0.0982 for 1240 independent observed reflections, based on $I > 2.0\sigma(I)$.

Hydrolysis of an RNA dinucleoside monophosphate by neomycin B

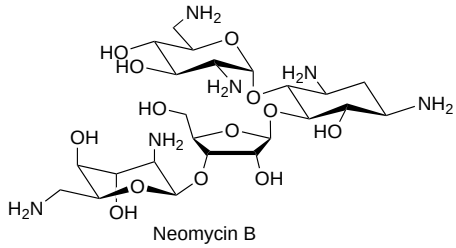
Sarah R. Kirk and Yitzhak Tor*

Department of Chemistry and Biochemistry, University of California, San Diego, La Jolla, CA 92093-0358, USA

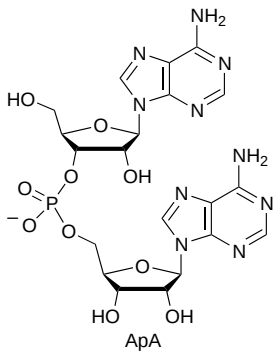
Neomycin B is shown to accelerate the phosphodiester hydrolysis of adenylyl(3′–5′)adenosine (ApA) more effectively than a simple unstructured diamine.

Current approaches to site-directed RNA hydrolysis involve the conjugation of a reactive moiety capable of cleaving phosphodiester bonds to a recognition element capable of sequence-specifically hybridizing to RNA.[1] In most cases, a metal complex is covalently attached to a DNA strand which forms a stable heteroduplex. Upon hybridization, a Lewis acid is placed in close proximity to the RNA backbone to effect hydrolysis.[2] In a similar fashion, DNA–polyamine conjugates have been demonstrated to induce site-directed RNA strand scission.[3] While these high molecular-weight conjugates are promising sequence-specific RNA cleavers, combining recognition and catalysis in a single small organic molecule has remained a challenging problem.[4]

The discovery that aminoglycoside antibiotics interact specifically with diverse RNA molecules such as group I introns,[5] hammerhead ribozymes[6] and the HIV-1's TAR[7] and RRE[8] sites has attracted considerable interest and stimulated studies attempting to identify the elements involved in these recognition phenomena.[9–11] As highly functionalized polycationic oligosaccharides, interactions between the aminoglycosides' polar residues (*i.e.* amino and hydroxy groups) and the RNA backbone and/or heterocyclic bases are likely to occur. Since simple unstructured polyamines[12,13] as well as basic polypeptides[14] have been shown to catalyze RNA hydrolysis, we hypothesized that aminoglycoside antibiotics may exhibit similar effects. As a first step toward developing small molecules capable of both recognizing RNA and cleaving it, we demonstrate that neomycin B is able to accelerate the hydrolysis of a ribodinucleoside monophosphate.



Neomycin B



ApA

The hydrolysis rate of adenylyl(3′–5′)adenosine (ApA) in the presence of 0.3 M neomycin B, 1,3-diaminopropane and 3-aminopropan-1-ol was investigated at pH 8.0 and 50 °C.† Reversed-phase HPLC was employed to measure the rate of appearance of adenosine (A) against the loss of ApA.‡ Neomycin B hydrolyzes ApA with a pseudo-first-order rate constant of $1.6 \pm 0.1 \times 10^{-5}$ min^{-1}, approximately three times faster than 1,3-diaminopropane ($5 \pm 1 \times 10^{-6}$ min^{-1}) and more than 50 times faster than Tris buffer alone or 3-aminopropan-1-ol ($3–4 \pm 2 \times 10^{-7}$ min^{-1}) (Fig. 1).§ The observed hydrolysis rates were not significantly altered when 2 mM EDTA was added, excluding metal ion-mediated hydrolysis. Furthermore, the observed formation of adenosine 2′,3′-cyclic monophosphate (A > p) and its subsequent degradation to adenosine 2′-phosphate (A′2p) and 3′-phosphate (A′3p) rules out the possibility of nuclease-mediated hydrolysis that would generate A′3p exclusively.[15] These observations clearly show that an aminoglycoside antibiotic is capable of significantly accelerating the hydrolysis of a ribodinucleoside phosphate.

The rate of ApA hydrolysis by neomycin B is pH dependent. When the pH of the buffered 0.3 M neomycin B was lowered from 8.0 to 7.0, the rate of hydrolysis was slowed down by a factor of three. As demonstrated earlier for simple diamines, the hydrolysis rate acceleration is dependent on the relative abundance of the neutral, monoprotonated and diprotonated forms.[13] While the uncharged form has the highest hydrolytic activity and the dicationic form is essentially inactive, the monocationic form—which is the most populated form at pH 7—is the major contributor to the observed catalysis. Neomycin B contains six amino groups with pK_a values between 5.7 and 8.8.[16] As the pH is lowered and neomycin B becomes highly protonated, the rate of ApA hydrolysis is expected to decrease, which indeed is observed.

Neomycin B has three times as many amines as 1,3-diaminopropane, yet the three-fold rate enhancement observed for ApA hydrolysis may be coincidental. *A priori*, several factors may contribute to the observed rate acceleration: the number of amino groups, their stereochemical relationships, as well as

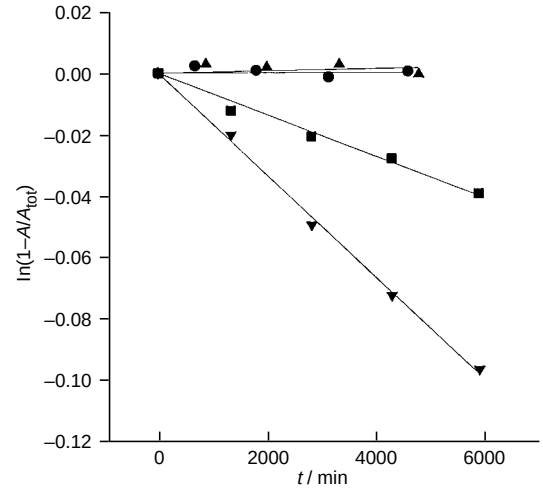


Fig. 1 Kinetic analysis of ApA hydrolysis by (▼) 0.3 M neomycin B, (■) 0.3 M 1,3-diaminopropane, (▲) 0.3 M 3-aminopropan-1-ol and (●) 50 mM Tris·HCl at pH 8.0 and 50 °C (see footnotes † and §)

their individual pK_a values. As reported earlier,[13] simple oligoamines such as diethylenetriamine and triethylenetetramine are essentially as effective as 1,3-diaminopropane in hydrolyzing ApA. This suggests that the number of amino groups may not be the major factor distinguishing neomycin B from 1,3-diaminopropane. Since the observed rate is a combination of individual hydrolysis rates mediated by various pairs of amino groups, it is likely that some pairs are much more active than others. This may be due to their spatial positioning and individual pK_a values, as well as the lower conformational freedom of neomycin B when compared to simple unstructured diamines. Since cyclohexane-1,3-diamine has been found to be as effective as 1,3-diaminopropane in hydrolyzing ApA,[13] we favor the modulation of individual pK_a values as the likely source for the rate enhancement observed with neomycin B. While the amines in 1,3-diaminopropane are rather basic, (pK_a 8.1 and 9.8),[13] certain pairs in neomycin B are less basic and display a wider difference in their pK_a. For example, the pK_a values reported for N^1 and N^3 are 8.04 and 5.74, respectively.[16] This may lead to a higher population of a monocationic form at a given pH compared to 1,3-diaminopropane, and therefore to a faster hydrolysis.

Neomycin B has been shown to bind to various RNA sequences[5–8] and now to hydrolyze an RNA dinucleoside phosphate. These observations provide new leads for the design of small molecules that combine RNA recognition with hydrolysis. Such molecules may become useful chemical probes for RNA structure and folding.[17] We are currently exploring these possibilities with larger and well-defined RNA structures.

† All samples contained 50 mM Tris and 0.1 mM ApA. The pH was adjusted to 8.0 at room temperature (21 °C) with highly pure HCl (low trace metals: iron < 1 ppb, lead < 0.01 ppb, lutetium < 0.005 ppb, zinc < 0.02 ppb). At 50 °C, there is a drop of approximately 0.5 pH unit.

‡ HPLC analysis was performed using a C18 reversed-phase column with 25 mM sodium phosphate buffer, pH 3.5, containing 2% MeCN as the initial eluent, at a flow-rate of 1 ml min^{-1}. Gradient elution up to 50% MeCN was used to optimize separation.

§ The chromatograms were monitored at 260 nm and the resolved peaks were integrated and corrected for any volume changes against a peak of 2′-deoxyadenosine used as an internal standard. Plotting $\ln(1 - A/A_{tot})$ *vs.* t (min), where A = integration for adenosine, and A_{tot} = sum of integrals for all species, gives a straight line with a slope of $-k$. The linear correlation coefficient was > 0.99 for samples with substantial hydrolysis (*e.g.* neomycin B and 1,3-diaminopropane) and somewhat lower for control samples with very little hydrolysis, as expected. The rate constants reported for the neomycin B and 1,3-diaminopropane samples are the average of four independent runs.

A novel synthesis of unsymmetrical tertiary phosphines: selective nucleophilic substitution on phosphorus(III)

Sumita Singh and Kenneth M. Nicholas*

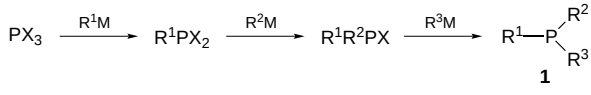
Department of Chemistry and Biochemistry, University of Oklahoma, Norman, OK, 73019, USA

A new synthesis of unsymmetrical tertiary phosphines has been developed employing selective, sequential alkylation of chloroaminophosphines by Grignard and organolithium reagents.

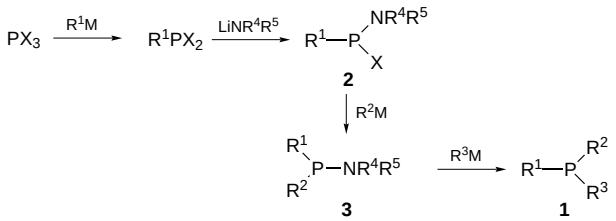
Phosphines constitute the most important class of ligands used in transition metal catalysed reactions.[1] The activity and selectivity of such catalysts are often acutely sensitive to the structure of the phosphine, necessitating the synthesis and testing of a variety of ligands to optimize the catalyst. Hence, the development of efficient and selective preparative routes to structurally diverse phosphine libraries, both in solution and on solid supports, is an important objective. Initial approaches to high throughput parallel syntheses of peptide-derived chiral phosphines[2] and of other ligands[3] and catalysts[4] for asymmetric synthesis have been reported recently.

We sought to develop a general and efficient preparation of tertiary phosphines which ultimately would be adaptable for solid phase parallel synthesis. Solution phase preparation of phosphines usually involves displacement of halide or alkoxide using organometallic reagents[5] (Scheme 1) but access to unsymmetrical tertiary phosphines **1** is complicated by polysubstitution. Selective displacement of chloride in the presence of alkoxide is sometimes possible using a combination of organocadmium and Grignard reagents,[6] organozinc and organolithium reagents,[7] and *via* other approaches[8] but these methods often employ inconvenient organometallics, require multiple steps, and/or lack selectivity or generality. We describe herein a new approach (Scheme 2) which exploits the vastly different leaving group abilities of chloride *vs.* amide and the differential reactivity of organolithium *vs.* organomagnesium reagents.

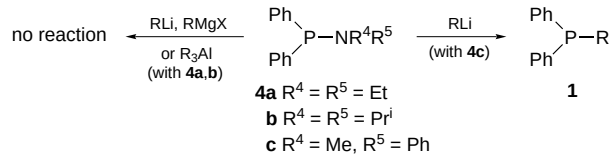
To first establish the leaving group ability of the dialkylamino unit, the interaction of **4a**–**c**[9] with representative RLi, RMgX, and R_3Al reagents was investigated. Dialkylaminophosphines **4a**,**b** proved unreactive even when these organometallics were employed in excess at elevated temperature.† *N*-Methyl-*N*-phenylaminodiphenylphosphine **4c**[9] possessing an expectedly better leaving group, however, reacted extremely slowly with excess MeMgCl at high temperature but rapidly



Scheme 1



Scheme 2



Scheme 3

with MeLi at room temperature, yielding the desired phosphine (Scheme 3).

The key chloroaminophosphines **2** (**a** R = Ph; **b** R = Et) are efficiently prepared (*ca.* 75%) by reaction of readily available organodichlorophosphines‡§ with LiNMePh[9] (THF, 20 °C, Scheme 2).¶ These, in turn undergo selective reaction with Grignard reagents (1.5 equiv, THF, 20 °C) producing aminophosphines **3a**–**j** in excellent yields following aqueous workup (Table 1).‖ A variety of substituents, including alkyl, vinyl and aryl groups, are efficiently incorporated.

Organolithium reagents readily react with the aminophosphines **3** (THF, 20 °C) giving unsymmetrical tertiary phosphines **1a**–**j** (Scheme 2, Table 1).** Although isolated yields of volatile dialkylaryl phosphines were only fair, diarylalkyl derivatives, including sterically hindered ones (*e.g.* **1e**–**g**), could be obtained in high yield.

Finally, we note that the complete sequence from PR^1Cl_2 to $PR^1R^2R^3$ can be conveniently accomplished without the isolation of intermediates. In this way phosphine **1f** was obtained in 59% yield by sequential treatment of $PhPCl_2$ with LiNMePh, *o*-tolMgBr and then MeLi.††

Application of this methodology for the solid-phase synthesis of phosphine libraries is under investigation.

We thank the National Science Foundation (in part) and the University of Oklahoma Research Council for financial support of this work.

† Synthesis of tertiary phosphines *via* reaction of Grignard reagents with aminoarylphosphines bearing a coordinating heteroatomic group at the *ortho* position on the phenyl ring has been previously reported (ref. 10). Based on the non-reactivity of unsubstituted aryldialkylaminophosphines observed by us, the ligating *ortho* substituent seems to be a prerequisite.

‡ Some organodichlorophosphines are commercially available; they also can be obtained *via* reaction of phosphorus trichloride with organometallic reagents (ref. 5).

§ Reactions and transfers for the preparation of **1**–**3** were conducted under N_2. All compounds exhibited satisfactory ^{1}H and ^{31}P NMR spectra.

¶ *Preparation* of **2**: Bu^{n}Li (35 mmol in hexane) was added slowly to PhNHMe (30 mmol) in THF (5 ml) at 0 °C and the resulting white suspension was stirred at room temp. for 45 min. The solvent was evaporated, the white solid was dissolved in THF (150 ml), and the solution was added dropwise to $RPCl_2$ in THF (1.25 M, R = Et, Ph) at 0 °C. After stirring at room temp. for 2 h, the solvent was evaporated, CH_2Cl_2 (40 ml) was added, the mixture filtered, and the solvent evaporated to provide crude **2a**,**b** which could be purified by vacuum distillation.

‖ *Preparation* of **3**: To a stirred solution of **2a** or **b** in THF (1 M) at 0 °C was added 1.5 equiv. of Grignard reagent. The mixture was stirred at room temp. until all of **2** had reacted (by ^{1}H and ^{31}P NMR spectroscopy). The mixture was then cooled in ice and 1 M NH_4Cl was added slowly for complete neutralization. The organic layer was separated, dried over Na_2SO_4, and the solvent evaporated to give the aminophosphines **3a**–**j** as pale yellow liquids which could be used in the next step without further purification.

** *Preparation* of **1**: To a solution of **3** in THF (1 M) at 0 °C was added 1.5 equiv. of RLi. After warming to room temp., the mixture was stirred until reaction completion was indicated (by ^{1}H and ^{31}P NMR spectroscopy). The solvent was evaporated and hexane (30–40 ml) was added. After stirring for a few minutes, the mixture was filtered, and the solvent was evaporated to yield the phosphines.

†† *'No isolation' preparation* of **1**: PhMeNLi was prepared and added to $PhPCl_2$ in THF as described for the preparation of **2**. When the starting material was consumed (2 h, by NMR spectroscopy), *o*-tolylMgBr (1.5 equiv.) was added at 0 °C and the reaction mixture was then warmed to room temperature. Once the formation of aminophosphine was complete (1.5 h), the solvent was evaporated and the residue was triturated with 50 ml benzene. The combined extracts were evaporated and the residue was dissolved in 10 ml THF, treated with MeLi (5.5 equiv.) at 0 °C, and then stirred at room temperature for 3 h. Phosphine **1f** was isolated as described for the preparation of **1** above.

Unambiguous synthesis of stromal cell-derived factor-1 by regioselective disulfide bond formation using a DMSO–aqueous HCl system

Hirokazu Tamamura,* Fumihiro Matsumoto, Kyoko Sakano, Akira Otaka, Toshiro Ibuka and Nobutaka Fujii*†

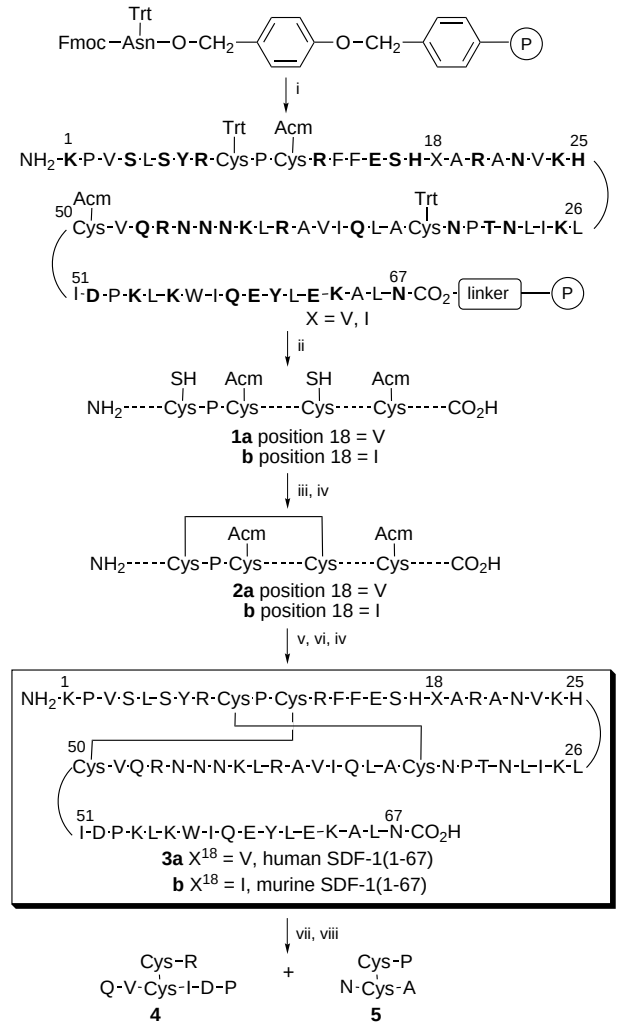
Graduate School of Pharmaceutical Sciences, Kyoto University, Sakyo-ku, Kyoto 606-01, Japan

Total synthesis of human and murine stromal cell-derived factor-1s (SDF-1s) (residues 1–67) containing two disulfide bonds and an oxidation-sensitive Trp residue was achieved unequivocally by stepwise disulfide-forming reactions: A silver trifluoromethanesulfonate (AgOTf)–(DMSO)–aqueous HCl system was used in combination with air oxidation to form regioselectively each disulfide bond.

SDF-1,[1] a lymphocyte chemoattractant, belongs to the CXC-chemokines between two subfamilies, the CXC- and CC-chemokines.[2] Recently, it was reported that the CXC-chemokine receptor, CXCR4/fusin, and the CC-chemokine receptor, CCR5, serve as coreceptors in association with CD4 for the entry of T-cell line-tropic (T-tropic) and macrophage-tropic (M-tropic) strains of HIV-1, respectively,[3] and that SDF-1 blocks infection of T-cells by T-tropic HIV-1.[4] Thus, SDF-1 and its derivatives have the potential to become attractive candidates for the chemotherapy and prophylaxis of HIV-1 infection. The human SDF-1 (residues 1–67), having two intramolecular disulfide bonds and Trp (the sequence shown in Scheme 1), was synthesized by Springer and co-workers, and was identical in activity to the purified natural murine SDF-1.[4a] For the synthesis of human SDF-1, the researchers employed random disulfide bond formation of the fully reduced SDF-1 ([Cys(SH)^{9,11,34,50}]-SDF-1) by air oxidation. However, it is desirable that each disulfide bond be formed regioselectively in order to suppress the formation of disulfide isomers, particularly since Cys^{9} and Cys^{11} are present in close proximity in human SDF-1. The natural SDF-1 contains two disulfide bonds between Cys^{9} and Cys^{34} and between Cys^{11} and Cys^{50}.[5] It would be valuable to define the activity of this peptide whose disulfide bridges are correctly formed. Thus, we attempted to synthesize SDF-1(1–67) by regioselective disulfide bond formation. The differential *S*-protection of four Cys residues and the following stepwise disulfide bond formation must be carried out regioselectively. Several disulfide bond-forming reactions, *i.e.* iodine,[6] thallium(III) trifluoroacetate,[7] DMSO[8] and sulfoxide-silylating reagents,[9] have been found to convert some *S*-protected Cys into cystine by us and others. The regioselective syntheses using these reactions in combination with a conventional air oxidation method have been reported; however, one potential limitation to the use of these reactions is the oxidative decomposition of Trp.

We have recently developed a new procedure for disulfide bond formation in *S*-Acm-containing‡ peptides[10] using an AgOTf– DMSO–aq. HCl system.[11] In this protocol, *S*-Acm groups are removed from Cys(Acm) residues by AgOTf[12] and subsequent DMSO–aq. HCl treatment effects two reactions: the conversion of Cys(Ag) residues into Cys(SH) residues besides precipitation of AgCl by the action of HCl, and the disulfide bond formation of Cys(SH) residues by the action of DMSO in aqueous media.[13] Under these reaction conditions, no significant side reactions are observed with oxidation-sensitive amino acids such as Met, Tyr and Trp. Thus, in the present study, we synthesized human and murine SDF-1s(1–67) by the regioselective disulfide bond formation using a combination of the AgOTf–DMSO–aq. HCl system with air oxidation in order to investigate the feasibility of practical applications of this strategy to relatively large and complicated peptides.

SDF-1(1-67) has a single substitution of Ile to Val at a position 18 between mouse and human. The peptidyl resins of human and murine SDF-1s were constructed by Fmoc-based† solid-phase synthesis on *p*-alkoxybenzyl alcohol resins[14] (Scheme 1). To form regioselectively two disulfide bridges, two different protecting groups were employed with suitable pairs for the protection of four SH groups of the Cys residues: Trt‡ groups for Cys^{9} and Cys^{34}, and Acm groups for Cys^{11} and Cys^{50}. *S*-Trt groups are removable *via* Me_3SiBr treatment,[15]



Scheme 1 *Reagents and conditions*: i, Fmoc-based solid phase synthesis; ii, Me_3SiBr–thioanisole–TFA; iii, air oxidation; iv, HPLC purification; v, AgOTf–TFA; vi, DMSO–aq. HCl; vii, trypsin; viii, prolyl endopeptidase. Bold letters indicate protected amino acids.

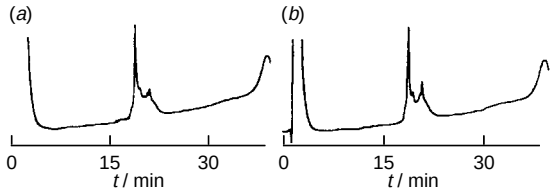


Fig. 1 Analytical HPLC of the crude (*a*) human and (*b*) murine SDF-1s. HPLC conditions: a μBondasphere 5 μC18-100 Å (3.9 × 150 mm) column, a linear gradient of MeCN (25–55%, for 30 min) in 0.1% aq. TFA at a flow rate of 1 cm^3 min^{-1}, a Waters LC module 1 equipped with a Waters 741 Data Module, UV absorption measurement at 220 nm.

whereas *S*-Acm groups are stable during to Me_3SiBr treatment, but can be removed *via* AgOTf treatment. For the side-chain protection of the other amino acid residues, the following groups were used: Trt groups for Asn and Gln, Boc groups for Lys and His, Bu^t groups for Glu, Tyr, Asp, Thr and Ser, and Pmc‡ groups for Arg. The protected resins were treated with 1 mol dm^{-3} Me_3SiBr–thioanisole–TFA to cleave peptides from the resins and remove all the protecting groups except for the *S*-Acm groups.[15] The resulting crude dihydropeptides, [Cys(SH)^{9,34}, Cys(Acm)^{11,50}]-SDF-1s (Scheme 1, **1a**,**b**), were air-oxidized to establish the first disulfide bond. After HPLC purification, monocyclic products, [Cys(Acm)^{11,50}]-SDF-1s (**2a**,**b**), were subjected to sequential treatment with AgOTf–TFA and 50% DMSO–1 mol dm^{-3} aq. HCl (v/v) to establish the second disulfide bond. Each crude bicyclic product exhibited a sharp main peak on analytical HPLC (Fig. 1) without significant side products. HPLC purification gave human and murine SDF-1s (**3a**,**b**) in satisfactory yields.§ The effective concentrations (EC_{50}) of the synthetic human and murine SDF-1s for 50% protection in an assay of HIV-induced cytopathogenicity were 463 and 201 μmol m^{-3}, respectively, and for 50% inhibition of HIV-1 p24 antigen production were 630 and 750 μmol m^{-3}, respectively. Furthermore, these peptides have the ability to induce an increase in intracellular Ca^{2+} through CXCR4/fusin (data not shown). These activities are comparable with those reported by Springer and co-workers.

In conclusion, total synthesis of human and murine SDF-1s (1-67) has been accomplished by stepwise and regioselective disulfide bond formation using air oxidation and the AgOTf–DMSO–aq. HCl system. This combination protocol has proven to be useful for preparation of relatively large and complicated bis(disulfide) peptides, particularly when Trp residues are present.

We are grateful to Professor N. Yamamoto and Dr T. Murakami, Tokyo Medical and Dental University, Tokyo, Japan, and Professor H. Nakashima and Dr R. Arakaki, Kagoshima University Dental School, Kagoshima, Japan, for the anti-HIV assay.

‡ *Abbreviations*: Acm = acetamidomethyl, Fmoc = fluoren-9-ylmethoxycarbonyl, Trt = triphenylmethyl, Pmc = 2,2,5,7,8-pentamethylchroman-6-ylsulfonyl.

‡ Human SDF-1(1-67) **3a** was prepared by the following procedure: The protected human SDF-1(1–67) resin (203 mg, 13.5 μmol) was treated with 1 mol dm^{-3} Me_3SiBr–thioanisole–TFA (20 cm^3) in the presence of *m*-cresol (1 cm^3, 860 equiv.) and ethane-1,2-dithiol (0.4 cm^3, 520 equiv.) at 4 °C for 2 h. After removal of the resin by filtration, the filtrate was concentrated *in vacuo*. Ice-cold dry Et_2O (30 cm^3) was then added, and the resulting powder was collected by centrifugation. After washing three times with ice- cold dry Et_2O (3 × 20 cm^3), the product **1a** was dissolved in 50% AcOH (2 cm^3). Subsequently, the total solution volume was adjusted to 400 cm^3 with H_2O and the pH was then adjusted to 8 with conc. NH_4OH. After 1 day of air oxidation, the pH of the solution was adjusted to 5 with AcOH. The crude product was purified by preparative HPLC [Waters Delta Prep 4000 on a Cosmosil packed column (5 μC18-100 Å, 20 × 250 mm) using a linear gradient of MeCN (31–33%, for 30 min) in 0.1% aq. TFA at a flow rate of 7 cm^3 min^{-1}]. The solvent was removed by lyophilisation to give [Cys(Acm)^{11,50}]-human SDF-1 **2a** as a fluffy white powder: (17.4 mg, 1.80 μmol). [Cys(Acm)^{11,50}]-human SDF-1 (17.2 mg, 1.78 μmol) was treated with AgOTf (45.6 mg, 100 equiv.) in TFA (2 cm^3) in the presence of anisole (0.02 cm^3) at 4 °C. After 2 h, ice-cold dry Et_2O (30 cm^3) was then added. The resulting product was washed three times with ice-cold dry Et_2O (3 × 20 cm^3), and then treated with 50% DMSO–1 mol dm^{-3} aq. HCl (v/v, 17 cm^3) at room temperature for 7 h. After removal of the AgCl precipitate by filtration, the filtrate was diluted with H_2O (150 cm^3). The crude peptide was purified by preparative HPLC [a linear gradient of MeCN (30–32%, for 30 min)] to give human SDF-1 **3a** as a fluffy white powder [2.1 mg, 0.245 μmol, 13.8% (calculated from **2a**)]: [IS-MS (reconstructed): Found, 7827.5. Calc. for $C_{350}H_{566}N_{104}O_{92}S_4$, 7826.5]. Its disulfide pairings proved to be identical with those of the natural peptide based on ion spray mass analysis of peptide fragments (**4** and **5** in Scheme 1) derived from the successive digestion treatment of the synthetic peptide by trypsin (TRCK-treated type XIII from bovine pancreas) and prolyl endopeptidase (from Flavobacterium). $[\alpha]_D^{28}$ −92.3 (*c* 0.1, H_2O).

Murine SDF-1(1-67) **3b** was prepared by the same procedure as described above, [16.4% (calculated from (**2b**)]: [IS-MS (reconstructed): Found, 7841.0. Calc. for $C_{351}H_{568}N_{104}O_{92}S_4$, 7840.6]. Its disulfide pairings proved to be identical with those of the natural peptide. $[\alpha]_D^{28}$ −84.8 (*c* 0.1, H_2O).

Electrochemical syntheses and doping properties of poly(3,3′-dialkylsulfanyl-2,2′-bithiophene)s: novel materials which exhibit facile n- and p-dopability

Siu-Choon Ng,* Ping Miao and Hardy S. O. Chan

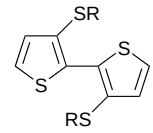
Department of Chemistry, National University of Singapore, Singapore 119260

Novel and stable electroactive polymer films which can undergo facile electrochemical p- and n-doping are successfully prepared for the first time from the electrochemical polymerization of symmetrical 3,3′-dialkylsulfanyl-2,2′-bithiophenes with long pendant chains.

In the course of our ongoing investigations into novel electrically conducting polymers, it was found that, in striking contrast to 3-alkylsulfanylthiophenes,[1–8] 3,3′-dialkylsulfanyl-2,2′-bithiophenes (DSABT) can be successfully polymerized by both chemical (using $FeCl_3$ as oxidant) and electrochemical approaches. Apart from the formation of stable films, the electrochemically derived polymers demonstrated reversible electrochemical p- and n-dopability. For most polymers, although p-doping activity has been well researched, n-type doping studies are comparatively rare due to the poor stability of the polymers at extreme negative potentials. However, from an application viewpoint, materials which are both p- and n-dopable are important, for example as light-emitting diode materials,[9] electrochemical cells[10] or in the construction of type III capacitors,[11] wherein one electrode is p-doped and the other is n-doped when the capacitor is charged. Studies on polythiophenes and polybithiophenes[12,13] have shown that p-doping generally occurs at high positive potentials whilst n-doping occurs at large negative potentials. Although introduction of pendant alkoxy groups at the 3-position of thiophene significantly reduced the oxidation potential, the n-doping process was found to be irreversible with a very small anodic current.[14] To the best of our knowledge, the electrochemical n-doping properties of alkylsulfanyl functionalized polythiophenes have not been studied.

The synthesis of monomers was accomplished starting from 3,3′-dibromo- 2,2′-bithiophene as reported previously.[15] Electrochemical polymerization of DSABTs was performed either by *via* cyclic voltammetry (CV), with the sweep potential varied from 0 to 1.1 V [*versus* a saturated calomel electrode (SCE)] at a scan rate of 20 mV s^{-1}, or by the galvanostatic method at a current density of 100 μA cm^{-2}. The monomers and electrolyte (Bu_4NBF_4 in MeCN) concentrations were 0.002 and 0.1 M, respectively. The resulting polymer films were rinsed carefully with absolute ethanol and acetone and then dried in an argon steam prior to the cyclic voltammetry studies and spectrophotometric analyses.

In contrast to 3-alkylsulfanylthiophenes, symmetrical 3,3′-dialkylsulfanyl-2,2’-bithiophenes with long pendant chains can undergo a facile oxidative polymerization *via* both the CV and galvanostatic methods, with the resulting polymers exhibiting excellent film formation behaviour. The monomer oxidation potential in $Bu^n_4N^+BF_4^-$ (0.1 M) at a scan rate of 20 mV s^{-1} was *ca*. 1.10 V. In the CV polymerization approach, a cathodic peak (*ca*. 0.75 V) was observed during the first scan, which increased in intensity with increasing number of scans. One main anodic peak at approximately 0.80 V with two shoulder peaks at 0.75 and 0.85 V were evident after the second scan. The increase in peak currents observable with the number of scans, is indicative of progressive polymer growth on the surface of the electrode. Polymer film prepared *via* galvanostatic polymerization methods exhibited a monomer oxidation potential at *ca*. 1.0 V at a current density of 100 μA cm^{-2}. The film quality was found to be dependent on the alkylsulfanyl chain lengths. Hence, monomers with lengthy alkylsulfanyl moieties (*e.g.* DSDeBT) can be electrochemically polymerized to afford excellent films with good stability on both platinum foil and ITO glass. These electrochemically generated films are completely soluble in $CHCl_3$, partially soluble in acetone, but insoluble in MeCN, MeOH and EtOH. On the other hand, electrochemical polymerization of DSABTs with short pendant chains (*e.g.* DSBuBT), results only in oligomers which are soluble in MeCN and alcohol. In this instance, even though a film can be obtained, it is not stable for long periods of time in the electrolyte solution. The p-doping mechanism for all four polymer films is highly reversibly with strong electrochromistic behaviour, being dark blue in the doped oxidised state and lilac in the neutral undoped state. The peak anodic potentials (E_{pa}) of the polymers range from 0.66 to 0.82 V and the peak cathodic potentials (E_{pc}) from 0.62 to 0.72 V. Long pendant groups resulted in a slightly increased oxidation potential of polymers, due presumably to accentuated steric effects exerted *via* the head-to-head linkages. The values of E_{pa} and E_{pc} increased slightly, whilst both the anodic and cathodic peak currents were found to scale linearly with increasing scan rate, which is characteristic of an electroactive polymer film grafted on to a electrode where the current is not diffusion controlled.[15]



DSBuBT R = C_4H_9
DSOcBT R = C_8H_{17}
DSDeBT R = $C_{10}H_{21}$
DSDoBT R = $C_{12}H_{25}$

Fig. 1 depicts the cyclic voltammograms of thin films of poly(DSOcBT), poly(DSDeBT) and poly(DSDoBT) deposited on the platinum in the potential range −2.3 to + 1.1 V at a scan rate of 100 mV s^{-1}. Both p- and n-type redox cycles exhibit characteristic wave shapes between sharp reduction peaks and the corresponding sharp oxidation peaks. The stability of p- and n-doping is related to the quality of the films. As discussed above, electrochemical polymerization of DSOcBT, DSDeBT and DSDoBT afforded high quality films. Thus, both p-doping and n-doping are stable and highly reversibly with strong electrochromism, from dark blue (p-doped) → lilac (neutral state) → dark blue (n-doped) → transparent (neutral state). On the other hand, only p-doping is observable for poly(DSBuBT), as the film is unstable in MeCN. The electrochemical oxidation potentials (E_p) of poly(DSOcBT), poly(DSDeBT) and poly(DSDoBT) are 0.75, 0.75 and 0.82 V. These three polymers have the same onset potential (E_{on}) value (0.49 V) and consequently the same ionisation potential (IP) (4.89 eV),

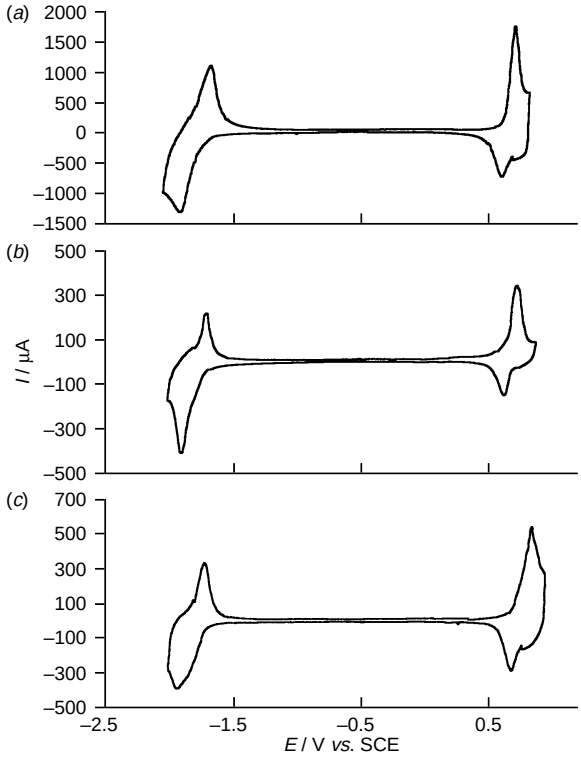


Fig. 1 CVs of (*a*) poly(DSOcBT), (*b*) poly(DSDeBT) and (*c*) poly(DSDoBT)

suggesting that the IP of DSABTs is independent of the pendant chain lengths. The peak potentials for the electrochemical reduction of the above polymers are −1.94, −1.89 and −1.98 V, with onset potentials of −1.41, −1.41 and −1.46 V, respectively. The corresponding electron affinities (EA) of these polymers are therefore 2.99, 2.99 and 2.94 eV. The observed electrochemical band gaps (the difference between the IP and the EA) are 1.90 eV for poly(DSOcBT) and poly(DSDeBT) and 1.95 eV for poly(DSDoBT). In addition, at sweep rates of 50 to 100 mV s^{-1}, both cathodic and anodic peak currents of the n-type redox cycle were found to scale linearly with respect to the sweep rate, suggesting that kinetic limitation of the electrochemical reduction of these two polymers is not significant.[16]

Fig. 2 depicts the optical absorption spectra of a typical poly(DSDeBT) film. All neutral polymer films exhibited absorption maxima at *ca*. 480, 520 and 570 nm with bandgap values between 1.77 and 1.82 eV, as derived from extrapolation of the low-energy absorption edges,[17] which agree well with the electrochemically-determined bandgap values. The high degree of conjugation in these head-to-head polymers might be ascribable to a relatively low energy barrier between their most stable configuration and the coplanar conformation.[18] Consequently, a coplanar conformation is readily attainable for poly[DSABT]s in their condensed film state. The polymer films were found to be soluble in $CHCl_3$ with solution UV absorption maxima in the range 408–450 nm depending on the length of

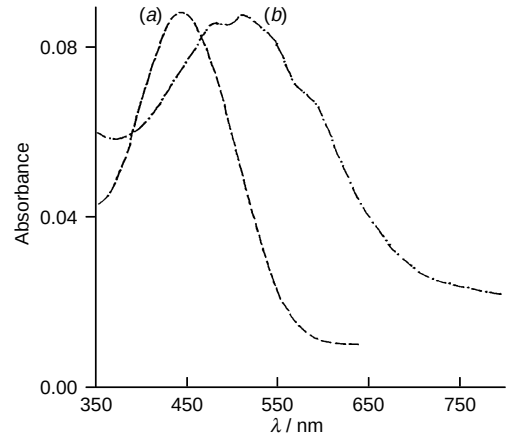

Fig. 2 UV–Visible spectra of poly(DSDeBT) in (*a*) $CHCl_3$ (λ_{max} = 441 nm) and (*b*) film state (λ_{max} at 482, 514 and 584 nm)

alkylsulfanyl moiety. Thus, these pendant groups affect the conformation of polymer both in solution and the solid state.

The authors thank the National University of Singapore for financial support through research grant RP960613. P. M. is grateful to NUS for the award of a research scholarship.

Stereoselective synthesis of highly functionalized *cis*-decalins from masked *o*-benzoquinones

Polisetti Dharma Rao, Chien-Hsing Chen and Chun-Chen Liao*

Department of Chemistry, National Tsing Hua University, Hsinchu, Taiwan 30043

Highly functionalized *cis*-decalins are prepared from commercially available 2-methoxyphenols and acyclic 1,3-dienes.

The decalin skeleton features in a large variety of natural products with interesting biological properties, *e.g.* kaurenes, aphidicolanes, quassinoids and azadirachtins.[1,2] A functionalized decalin has often been the starting point for the synthesis of the above mentioned classes of terpenoids. Owing to this, there is continued interest in the stereoselective synthesis of decalins, as is amply evidenced by the recent flurry of reports by various groups including ours.[3,4] Herein we report a novel method for the preparation of highly functionalized decalins from commercially available 2-methoxyphenols and acyclic 1,3-dienes.

Masked *o*-benzoquinones, *i.e.*, 6,6-dialkoxycyclohexa-2,4-dienones **1**, when compared to their counterparts derived from *p*-benzoquinones,[5] are a relatively underutilized class of compounds. Prior to our studies, there have been only sporadic reports on their chemistry.[6,7] The main reason for this could be their high propensity to dimerize. In most cases, they were isolated in poor yields as dimers. For the last ten years we have been interested in exploiting the synthetic potential of this neglected class of compounds. We have already shown that the masked *o*-benzoquinones **1**, generated *in situ* by the oxidation of 2-methoxyphenols **2** with (diacetoxy)iodobenzene (DAIB) or [bis(trifluoroacetoxy)]iodobenzene (BTIB) in presence of a dienophile in MeOH, an allyl alcohol in CH_2Cl_2 or a 2,4-dienol in THF, undergo Diels–Alder reactions to provide compounds of the types **3**, **4**, and **5** and **6**, respectively (Scheme 1).[4,8]

Masked *o*-benzoquinones, or cyclohexa-2,4-dienones in general, are commonly used as dienes.[7,9] We and others have recently found that they can also act as dienophiles in an intramolecular sense when forced by their structures.[4,10] We now report that masked *o*-benzoquinones **11**–**14**, generated *in situ* from phenols **7**–**10**, exhibit sufficient dienophilicity to react even with unactivated acyclic dienes such as 2,3-dimethylbutadiene **15**, *trans*-piperylene **16** and 1-acetoxybutadiene **17** to provide highly substituted *cis*-decalins with very high regio- and stereo-selectivity (Scheme 2). To the best of our knowledge, these findings are unprecedented.

Phenols **7**–**10** were oxidized by slow addition of a solution of DAIB in MeOH in presence of an excess of a diene in MeOH at

[a] Oil bath. [b] During which DAIB is added. [c] Yields are of isolated products and unoptimized. [d] Reaction conditions: **18** + $HC(OMe)_3$ (1 equiv.), mesitylene, heat. [e] Based on consumed starting material. [f] An inseparable mixture of bicyclo[2.2.2]octenones is obtained.

appropriate temperature to obtain compounds **18** and **19**.† In all the cases, the bicyclo[2.2.2]octenone derivatives **18a**–**j** underwent Cope rearrangement, smoothly providing *cis*-decalins **19** in very high yields.† The total yields of decalins are quite high and hence a new efficient method for the stereoselective preparation of *cis*-decalins has been developed. Although many isomers are possible, we generally isolate only two products, except in case of phenol **10**, showing that these reactions are highly regio- and stereo-selective and obey the ground rules of the Diels–Alder reaction.

The *cis*-decalins **19** could result from either direct Diels–Alder reactions, in which masked *o*-benzoquinones behave as dienophiles, or from tandem processes involving Diels–Alder reactions, in which masked *o*-benzoquinones act as dienes and the resultant vinylbicyclo[2.2.2]octenones **18** then undergo Cope rearrangement. In order to ascertain the actual pathway, the bicyclo[2.2.2]octenones **18e** and **18g** were subjected to heating in MeOH containing AcOH and the corresponding diene in the appropriate proportions for 3 h. In the case of **18e**, the crude reaction mixture was found to contain compounds **18e** and **19e** in a 97 : 3 ratio *via* ^{1}H NMR spectroscopy. On the other hand, compound **18g** remained unchanged. We therefore believe that the decalins **19** are generally primary products. Nevertheless the aforementioned tandem process can not be completely ruled out.

All the compounds were characterized by ^{1}H and ^{13}C NMR, IR and mass spectral analysis. The structural assignments of bicyclo[2.2.2]octenones **18** are based on the fact that they isomerize to *cis*-decalins **19** smoothly. The stereochemical assignments of the decalins are based on NOE studies and coupling constants. Closely related compounds can be obtained *via* the reaction of *o*-benzoquinones with acyclic dienes, but the senstive α-dicarbonyl moiety makes these compounds less attractive. Moreover, they aromatize to naphthalene derivatives very easily.[11]

It is quite clear from Table 1 that the masked *o*-benzoquinones can be good dienophiles. Apparently, it is difficult to predict whether a masked *o*-benzoquinone would behave as a diene or a dienophile in its reactions with added dienes. It is obviously linked to the structure of added diene and the nature and/or the position of the substituents present on the masked *o*-benzoquinone. For example, the methoxycarbonyl group on masked *o*-benzoquinone **13** diminishes the dienophilicity due to cross conjugation, which reinforces the diene character. Similarly, the methyl group on masked *o*-benzoquinone **14** increases the diene character, possibly *via* hyperconjugation.

Masked *o*-benzoquinone **11** is undoubtedly the best, exhibiting optimum reactivity and very high selectivity in all respects. On the other hand, **14** showed very poor selectivity, providing mixtures of bicyclo[2.2.2]octenones under various conditions except with 2,3-dimethylbutadiene.

In conclusion, our studies throw light on the nature of masked *o*-benzoquinones and have resulted in the development of a simple method for the synthesis of highly functionalized *cis*-decalins. More detailed studies on the nature of masked *o*-benzoquinones and the transformation of decalin **19f** into (±)-vernolepin are in progress in our laboratory.

† *General procedure* for the Diels–Alder reaction: In a preheated oil bath was placed a flask containing phenol (2 mmol) and diene (20 mmol) in MeOH (8 ml) was immersed. DAIB (2.4 mmol) in MeOH (6 ml) was added over the period given in the Table 1. The reaction was stirred for 10 min, and then MeOH and excess diene were removed and the residue was dissolved in CH_2Cl_2 (20 ml). The solution was washed with saturated aq. $NaHCO_3$ and brine, and dried ($MgSO_4$). Removal of the solvent followed by column chromatography yielded compounds **18** and **19**. The ratio of **18** and **19** was determined by ^{1}H NMR analysis of the crude reaction mixture.

An oligooxamacrocycle containing a π-donor tetrathiafulvalene and a π-acceptor quinone. Molecular and supramolecular structure

Robert M. Moriarty,*[a] Anping Tao,[a] Richard Gilardi,[b] Zhengzhe Song[a] and Sudersan M. Tuladhar[a]

[a] *Department of Chemistry, University of Illinois at Chicago, Chicago, Illinois 60608, USA*

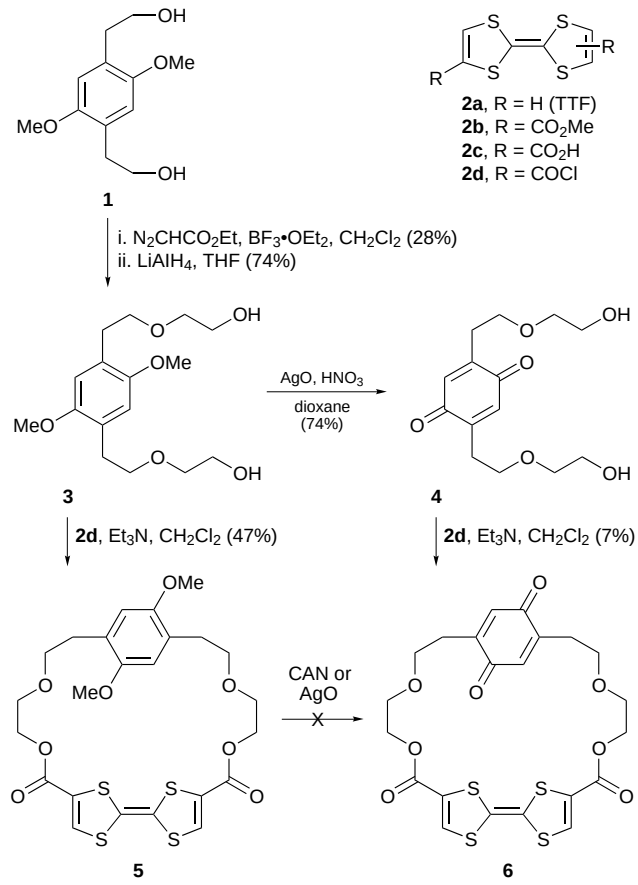
Tetrathiafulvalenedicarbonyl chloride reacts with 2,5-bis[(2-hydroxyethoxy)ethyl]-1,4-benzoquinone to afford a novel charge-transfer oligooxamacrocycle whose molecular and supramolecular structure are reported.

The π-donor charge transfer role of tetrathiafulvalene (TTF) (**2a**) as a molecular redox component is a key feature of organo-electrochemical devices such as conducting and super-conducting materials, sensors, molecular shuttles, NLO materials, organic ferromagnets and C_{60}-complexes.[1] An important structural feature in these materials is the spatial arrangement of the TTF with respect to the π-acceptor unit, either a non-covalent self-assembled array, or a covalently bonded system in which the position of the interacting (charge transfer groups) is fixed by synthetic design. Structures of increasingly evolved synthetic design have been reported, notably, the synthesis of tetrathiafulvalenoparacyclophanes and tetrathiafulvalenophanes by Staab *et al*.,[2] the joining of TTF-thiols by Hg^{2+} or Ni^{2+},[3] the incorporation of TTF into crown ethers,[4] cages[5] and [3]-pseudocatenanes,[6] the coupling of TTF to a ferrocenyl unit,[7] and the incorporation of TTF into a dimacrocycle with a catenated cyclobis(paraquat-*p*-phenylene).[8] Incorporation of TCNQ into a [2.2]paracyclophane has been accomplished; however, the π-donor was not TTF but the essentially irrelevant phenyl[9] and 1,4-dimethoxyphenyl groups.[10]

These molecules and others[11] represent only partial solution to the synthetic problem of fixing both the π-donor TTF and π-acceptor within the same molecule. We now report the synthesis of such a molecule as embodied in the oligooxamacrocycle **6** (Scheme 1).

Macrocycle **5** is a yellow crystalline material which could not be oxidized to **6** using ceric ammonium nitrate (CAN) or AgO. Charge transfer complex **6** is a black crystalline material.† The UV-VIS spectrum of **6** in chloroform shows absorptions at 252, 285, 302, 314 and 424 nm. There is no difference in the UV-VIS spectrum of **6** when measured as a film made by spin-coating from chloroform solution. In the VIS-NIR range no absorption appears between 600–2500 nm. The position of the ^{1}H NMR chemical shift for the TTF portion in **6** is at 7.44 ppm compared with 7.35 ppm for **2b**. Likewise, the quinone hydrogen is at 6.65 ppm in **4** and 6.79 ppm in **6**. The conductivity of a film of **6** (0.1 mm thick, 4 probe method) is $\sigma = 2.1\times 10^{-5}$ S cm^{-1}, which reveals the material to be a semiconductor.

The X-ray structure‡ of **6** may be discussed in terms of the unit molecule **6** (Fig. 1), an arbitrary dimer and its stacking (Fig. 2), and the supramolecular crystalline architecture (Fig. 3). Fig. 1 shows the unit molecular structure. In agreement to expectation, the quinone and TTF do not lie directly above and below each other, although they do lie in parallel planes. The distance between the centres of the non-overlapping quinone and TTF is 6.869 Å. The quinone occupies a plane about 3.6 Å above the extended parallel plane of the TTF. Fig. 2 shows a stack of three pairs of 'dimers.' Each pair is composed of two almost parallel planes of quinone and TTF. Going from the left to the right of Fig. 2, the first two molecules of **6** nestle together to afford partial overlap of TTF and quinone. These two are related by a crystal inversion center [1.0 − *x*, 1.0 − *y*, *z*] in the cell. However, the relationship between the second and the third molecule is such that there are certain close atom contacts, but the quinone and TTF of adjacent molecules do not overlap. They are related by a different inversion centre [1.0 − *x*, 1.0 − *y*, 1.0 − *z*]. Repeats of these operations produce an oblique stack of pairs (dimers that possess quinone–TTF overlaps) culminating in the depicted array of six stacks (including solvent $CHCl_3$) as shown in Fig. 3.



Scheme 1

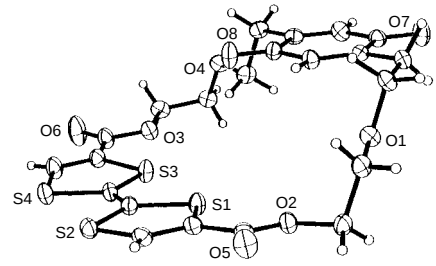


Fig. 1 X-Ray structure of the unit molecule **6**

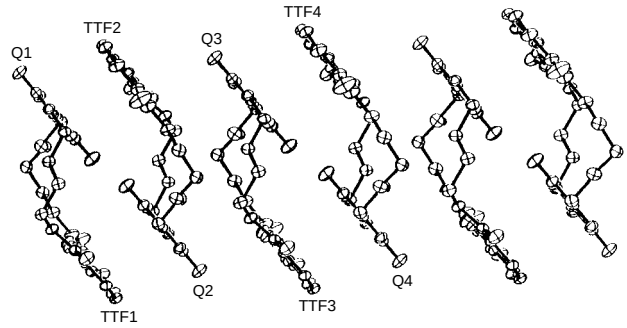

Fig. 2 Stack of three dimers. Hydrogens and solvent ($CHCl_3$) are removed for clarity

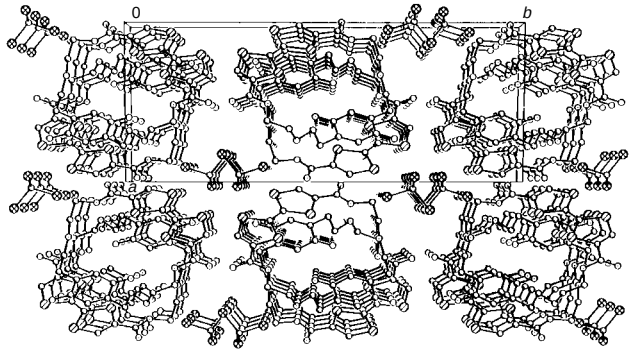

Fig. 3 Six stacks viewed down the *c* axis of the unit cell. Solvent chloroform is included in channels.

The basic molecule **6** and higher oligooxa homologue tethers of increasing $–OCH_2CH_2O–$ units available by modification of the synthetic route offer the interesting possibility of complexation of alkali metal ions. Finally, the design of **6** owes much to the pioneering work of Staab and coworkers on oligooxaparacyclophane charge-transfer quinhydrones.[12]

Generous support of this work by the National Science Foundation under grant CHE-9520157 is gratefully acknowledged. We thank Nicholas Castellucci of Northrop Grumman Co. for important advice and suggestions. We also thank Dr Larry L. Miller and Yoshihito Kunugi for measuring the electrical conductivity and UV-VIS spectra.

Counterattack reagents in organic synthesis: versatility and efficiency

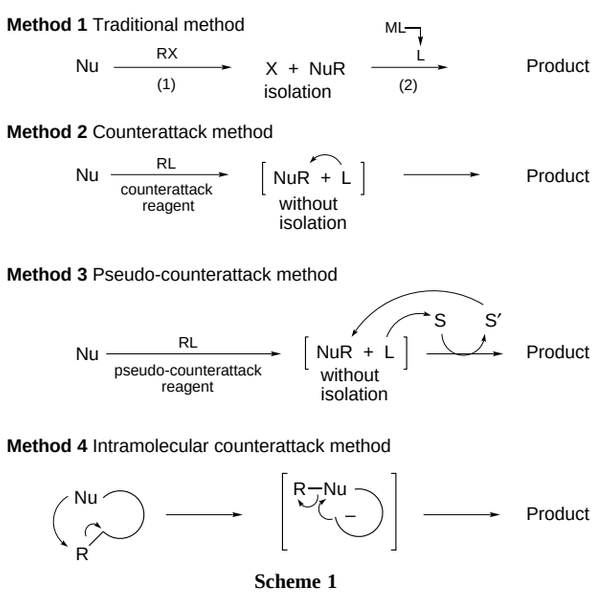
Jih Ru Hwu*[a,b] and Shwu-Chen Tsay[c]

[a] *Organosilicon and Synthesis Laboratory, Institute of Chemistry, Academia Sinica, Nankang, Taipei, Taiwan 11529, Republic of China*
[b] *Department of Chemistry, National Tsing Hua University, Hsinchu, Taiwan 30043, Republic of China*
[c] *Development Center for Biotechnology, Taipei, Taiwan 10671, Republic of China*

The concept of 'counterattack reagents' has been applied in the development of various chemical transformations. The use of counterattack reagents allows complicated reactions to be accomplished in a single flask without the isolation of intermediates. Thus multistep transformations can be simplified to 'one-step' operations. Representative examples of applications illustrated herein include oxidation, reduction, C–C single and double bond formation, cyclization, C–Si bond formation, *O*- and *N*-silylations and allylsilylation, as well as dealkylation. Comparisons are made between the results from traditional and 'counterattack' methods. Examples also include the utilization of 'pseudo-counterattack' and 'intramolecular counterattack' strategies in organic synthesis. The 'counterattack reagents' involved in those reactions are often, but not limited to, silicon-containing compounds.

Synthetic chemists are always seeking processes that lead from starting materials to target molecules with efficiency and a minimum number of operations. Here we describe the application of the concept of 'counterattack reagents' which provides a method to improve the efficiency of organic syntheses.

A synthetic sequence involving two steps often requires two individual reactions by traditional approaches. Method 1 in Scheme 1 shows an example in which a nucleophile Nu is treated with the reagent RX to give X and NuR in the first reaction. After isolation, the intermediate NuR is allowed to react with nucleophile L (from another source ML) to give the desired product in the second reaction. For certain synthetic sequences, one may combine these two reactions into one by using the 'counterattack strategy', as shown in Method 2.[1] The reagent RL is chosen with care; it is first attacked by Nu to give NuR and L. The leaving group L then counterattacks the intermediate NuR *in situ* to afford the final product. The reagent RL is thus referred to as a 'counterattack reagent'.[1]



Scheme 1

Method 3 in Scheme 1 shows another efficient way that sequential reactions can be combined into a 'one-flask' process.[2] The first step, analogous to that in Method 2, involves the reaction between Nu and RL to give NuR and the leaving group L. This leaving group then reacts with compound S to generate an active species S′, which subsequently attacks the intermediate NuR *in situ*. Because L does not counterattack NuR directly as in Method 2, we refer to the compound RL as a 'pseudo-counterattack reagent'.[2] Furthermore, Method 4 in Scheme 1 represents an 'intramolecular counterattack process'.[3] It involves attacking and subsequent counterattacking processes occurring in one molecule.

In the past fifteen years, our research group has applied the concept of 'counterattack reagents' to organic reactions of various types. Here, twelve novel and efficient chemical transformations will be illustrated which involve the use of various organic compounds in a counterattack, pseudo-counterattack or intramolecular counterattack process.[2–15]

Counterattack *versus* traditional methods

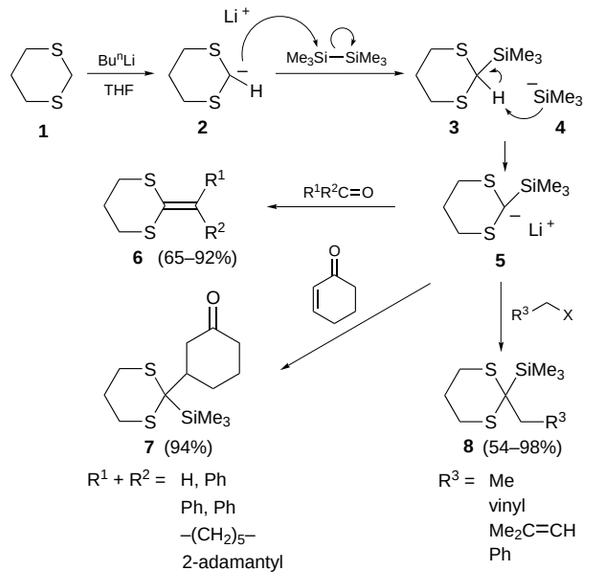
Given the potential advantages associated with counterattack reagents, we will first make a direct comparison of their results with those from traditional methods.

Direct synthesis of ketene dithioacetals and 2-trimethylsilyl-1,3-dithiane derivatives from 1,3-dithiane[4]

Ketene dithioacetals **6** are useful synthetic intermediates.[16] Traditionally, the preparation of ketene dithioacetals involves two steps. The first step involves generation and isolation of 2-trimethylsilyl-1,3-dithiane **3** (71% yield) from 1,3-dithiane **1**.[17] The second step involves reaction of its corresponding lithium salt **5** with various carbonyl compounds to give the desired ketene dithioacetals **6** in 62–80% yield.[18–20] The overall yields are in the range 40–57%. In comparison, use of the 'counterattack strategy', as shown in Scheme 2, allows a 'one-flask' synthesis of **6** in 65–92% yield from 1,3-dithiane **1**.

Scheme 2 depicts the mechanism, which includes an intriguing role for $Me_3SiSiMe_3$. Bu^nLi is used to remove a C-2 proton from 1,3-dithiane **1** to give anion **2**, which attacks $Me_3SiSiMe_3$ to produce 2-trimethylsilyl-1,3-dithiane **3** and Me_3Si^- **4**. This anionic silyl leaving group then counterattacks compound **3** to generate the Me_3Si-stabilized anion **5**. Thus $Me_3SiSiMe_3$ can be regarded as a 'counterattack reagent'.

Using this 'one-flask' synthetic strategy, α,β-unsaturated ketones can act as Michael acceptors for **5** to give ketones **7** in 94% yield. Furthermore, alkyl, allyl and benzyl bromides undergo substitution to produce Me_3Si-containing 1,3-dithianes **8** in 54–98% yields.

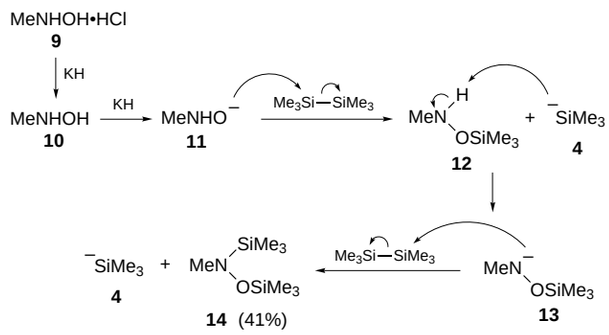


Scheme 2

Preparation of N-*methyl*-N,O-*bis(trimethylsilyl)-hydroxylamine from hydroxylamine*[5]

N-Methyl-*N*,*O*-bis(trimethylsilyl)hydroxylamine **14**, which is widely used in organic synthesis,[21] is the trimethylsilylated equivalent of *N*-methylhydroxylamine **10**. Silylated hydroxylamine **14** can be prepared from anhydrous *N*-methylhydroxylamine **10**.[22] Nevertheless, the route used to obtain **10** is tedious. Alternatively, hydroxylamine **14** can also be synthesized *via* use of hexamethyldisilazane; however, the yield is only 18%.[23,24] A way to solve these problems is to apply the concept of 'counterattack reagents'.

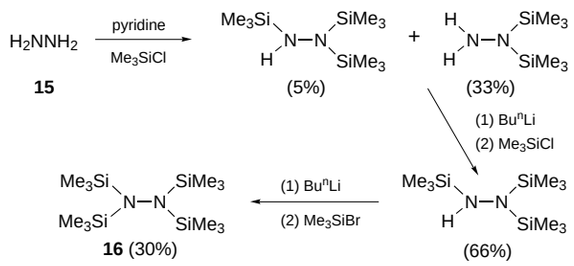
Thus, MeNHOH·HCl **9** is treated with KH and then $Me_3SiSiMe_3$ in a mixture of Et_2O and HMPA to give the desired hydroxylamine **14** in 41% yield. The mechanism is depicted in Scheme 3. After removal of the acid (*i.e.* HCl) in salt **9** and the OH proton in **10** using KH, the resultant oxide **11** attacks $Me_3SiSiMe_3$ to generate monosilylated hydroxylamine **12** and $^-SiMe_3$ **4**. This silyl anion **4**, acting as a base, counterattacks compound **12** to give amide **13**. Reaction of **13** with a second equivalent of $Me_3SiSiMe_3$ affords the desired product **14** and $^-SiMe_3$ **4**, which could substitute for KH to convert **10** to **11** by proton abstraction. Therefore **14** can be obtained from a mixture of **10** and $Me_3SiSiMe_3$ by use of a catalytic amount of KH.



Scheme 3

Direct preparation of polysilylated hydrazines from hydrazines:[6] *a consecutive triple-counterattack process*

Polysilylated hydrazines are ideal starting materials for the generation of various organic species.[25,26] Nevertheless, it is tedious to prepare these compounds by classic means.[27] A typical way to prepare $(Me_3Si)_2NN(SiMe_3)_2$ **16** from H_2NNH_2 **15** includes three separate silylations, utilizes two different bases (pyridine and Bu^{n}Li), requires strong silylating agents (Me_3SiCl and Me_3SiBr) and gives only a *ca.* 8% overall yield (see Scheme 4). Use of hexamethyldisilane as a 'counterattack reagent', however, allows the hydrazines to be polysilylated in one reaction without isolation of any of the intermediates, and provides the target **16** in an excellent yield (91%).



Scheme 4

Scheme 5 illustrates this 'one-flask' preparation of tetrakis(trimethylsilyl)hydrazine **16** from hydrazine **15** and Me_3Si-$SiMe_3$ under alkaline conditions. The disilane, $Me_3SiSiMe_3$, plays a dual role in this reaction: silylating agent and source of base. In the overall process, proton abstraction alternates with silylation. This alternation is repeated four times and thus allows H_2NNH_2 **15** to be converted to $(Me_3Si)_2NN(SiMe_3)_2$ **16** in an efficient way.

With regard to both the manipulation and the yield (91 *versus* 8%), the counterattack method shown in Scheme 5 is much more efficient than the classic procedure shown in Scheme 4. It also represents an example of a 'consecutive triple-counterattack process.'

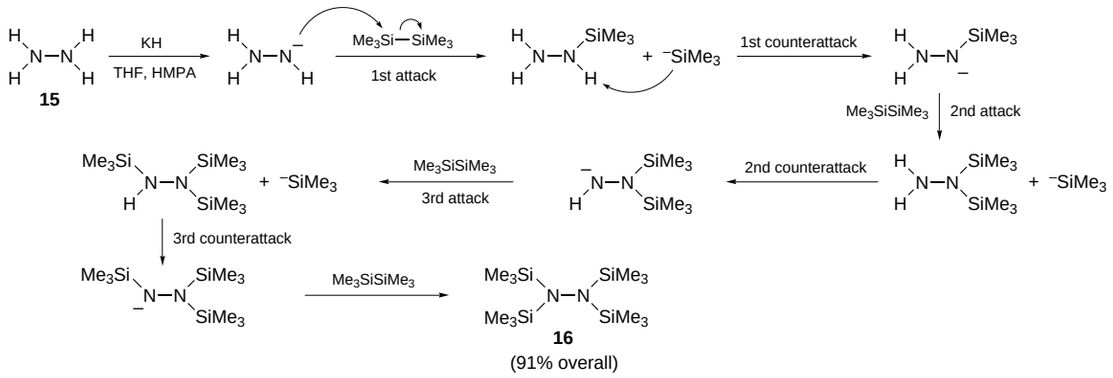
New counterattack methods

The concept of 'counterattack reagents' has also been applied to new methods for the generation of molecules with synthetically valuable functionalities or biological significance. Scheme 6 shows an example in which various starting materials are converted to an important class of products. Scheme 8 shows examples of how a simple starting materials can be transformed into products of various kinds.

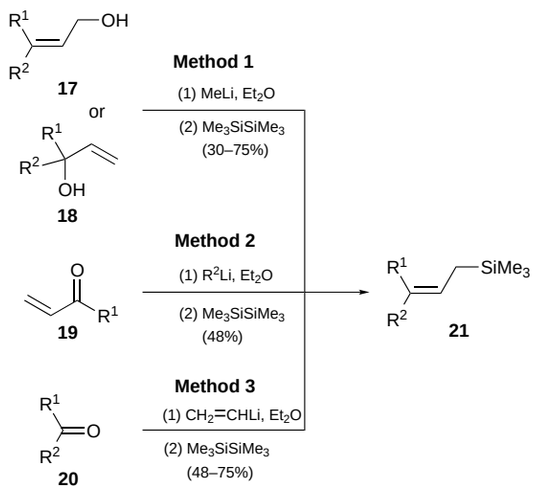
Direct conversion of aldehydes, ketones and allyl alcohols to allyltrimethylsilanes[7]

The allyltrimethylsilane moiety possesses umpolung character and is regarded as a synthon for allyl cations and anions.[28,29] Use of the counterattack method facilitates the preparation of allyltrimethylsilanes from allyl alcohols, enals, enones, aldehydes or ketones, as shown in Scheme 6. Treatment of allyl alcohols (*i.e.* **17** and **18**) with MeLi and $Me_3SiSiMe_3$ in a mixture of HMPA and Et_2O gives the desired allylsilanes **21** (Method 1). The substrates include primary allyl alcohols **17** [*e.g.* geraniol, (−)-myrtenol], secondary allyl alcohols **18** (*e.g.* linalool), benzyl alcohol and homobenzylic alcohol (*e.g.* phenylethyl alcohol). Method 2 in Scheme 6 shows a new method for the preparation of allylsilanes **21** from enals and enones (*i.e.* **19**) by use of alkyllithium and $Me_3SiSiMe_3$. Acrolein and methyl vinyl ketone are converted to allylsilanes by use of Bu^{n}Li and $Me_3SiSiMe_3$. Moreover, reactions of saturated aldehydes and ketones (*i.e.* **20**) with vinyllithium and $Me_3SiSiMe_3$ generate allylsilanes **21** as indicated in Method 3. The starting materials include hexanal, heptan-2-one, and cyclohexanone.

For the preparation of allyltrimethylsilanes by Methods 1–3, the first step is to generate an allyl alkoxide: removal of a proton from an allyl alcohol with MeLi in Method 1; 1,2-addition of RLi to an α,β-unsaturated aldehyde or ketone in Method 2; or addition of vinyllithium to a saturated carbonyl compound in

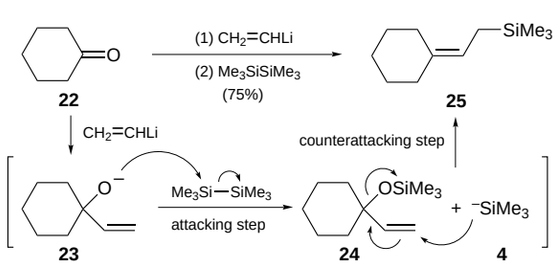


Scheme 5



Scheme 6

Method 3. The allyl alkoxides then react with $Me_3SiSiMe_3$ by a novel pathway to give allyltrimethylsilanes *in situ*, as represented in Scheme 7. Hexamethyldisilane is attacked by allyl alkoxides **23**, generated by addition of vinyllithium to ketone **22**, to give allyl trimethylsilyl ether **24** and Me_3Si^- **4**. An *in situ* substitution reaction subsequently occurs between **24** and **4** to produce allyltrimethylsilanes **25** in 75% yield. Hexamethyldisilane acts as an 'electrophilic counterattack reagent' in these one-flask reactions.

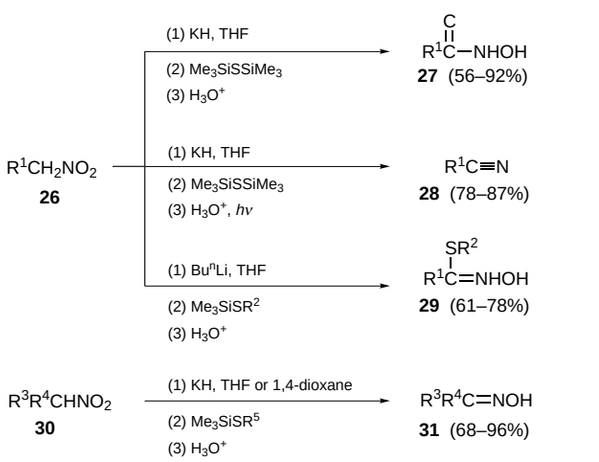


Scheme 7

Formation of thiohydroxamic acids, thiohydroximates, nitriles and oximes from nitro compounds[8,9]

Thiohydroxamic acids [RC(=S)NHOH] and thiohydroximates [RC(SR′)=NOH] contain a moiety with three adjacent nucleophilic atoms (*i.e.* N, O and S). Thiohydroxamic acids play various roles in analytical and biological chemistry. Phenylacetothiohydroximate exists in *Tropaeolum majus*;[33,34] it is also an intermediate in the biosynthesis of benzyl glucosinolate, a mustard oil glucoside.[33] Thiohydroximates are also used as starting materials for the synthesis of the carbamate derivatives $R^1C(SR^2)=NOC(=O)NR^3R^4$.[35] Some carbamates are utilized as pesticides.

The counterattack strategy has been applied in the syntheses of thiohydroxamic acids from readily available nitro compounds (Scheme 8). Thus reaction of various primary nitro compounds **26** with KH and hexamethyldisilathiane in THF gives thiohydroxamic acids **27** in 56–92% yield. The substrates, including esters, acetals, arenes and thiols, are all stable to the reaction conditions. By the same strategy, a thiohydroxamic acid is obtained in 50% yield after treatment of *trans*-β-nitrostyrene with Pr^iSLi and $Me_3SiSSiMe_3$ in THF.



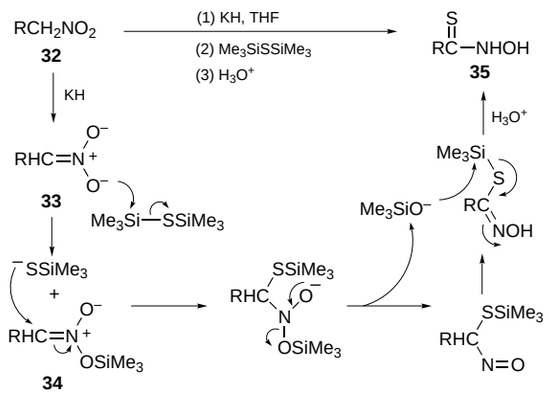
R^1 = Me, C_5H_{11}, $MeO_2C(CH_2)_2$, $THPOCH_2$, Bn, PhMeCH, $Ph(Pr^iS)CH$
R^2 = Me, Ph
$R^3 + R^4$ = Me + Me, Me + C_5H_{11}, Me + Ph, Me + $Ph(CH_2)_2$, $-(CH_2)_5-$, $-(CH_2)_4CHMe-$, 1,7,7-trimethylbicyclo[2.2.1]heptan-2-yl
R^5 = $SiMe_3$, Me

THP =

Scheme 8

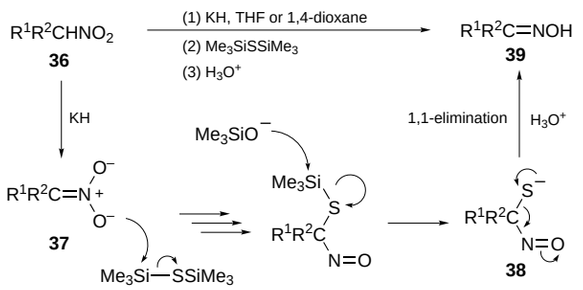
Moreover, primary nitro compounds **26** can be converted to nitriles **28** under UV irradiation. The first step is to generate potassium thiohydroxamates in the dark as previously described. These salts are then neutralized with an acid and desulfurized by light to afford nitriles **28** in 78–87% yield (Scheme 8).[9] On the other hand, treatment of primary nitro compounds **26** with Bu^nLi and thiosilanes (*i.e.* $MeSSiMe_3$ or $PhSSiMe_3$) in THF generates the corresponding thiohydroximates **29** in 61–78% yield. Secondary nitro compounds **30** are converted to oximes **31** in 68–96% yields by reaction with KH and $Me_3SiSSiMe_3$ or $MeSSiMe_3$ in THF or 1,4-dioxane.

The role of $Me_3SiSSiMe_3$ is depicted in Scheme 9 for the 'one-flask' conversion of primary nitro compounds **32** into thiohydroxamic acids **35**. The entire transformation involves multiple steps and the formation of several intermediates, of which isolation is unnecessary. Scheme 10 illustrates a mechanism for the conversion of secondary nitro compounds **36** into oximes **39** *via* reaction with $Me_3SiSSiMe_3$. In this transformation, a 1,1-elimination occurs in the intermediate $R^1R^2C(N{=}O)S^-$ **38** to give sulfur and an oxime.



Scheme 9

A common feature of the reactions shown in Scheme 8 is the generation of a nitronate intermediate (*cf.* **33** in Scheme 9 and **37** in Scheme 10). Reagents $Me_3SiSSiMe_3$, $MeSSiMe_3$ and $PhSSiMe_3$ are first attacked by nitronates (*i.e.* **33** and **37**) at a silicon centre. The leaving group, Me_3SiS^-, MeS^- or PhS^-, then counterattacks the silylated nitronate intermediates (*e.g.* **34**). Thus $Me_3SiSSiMe_3$, $MeSSiMe_3$ and $PhSSiMe_3$ can be regarded as 'counterattack reagents'.



Scheme 10

Protection and deprotection of hydroxy groups

The protection and deprotection of hydroxy groups are common synthetic processes. Traditional methods for the disilylative protection of diols and bis-*O*-demethylation of protected aromatic diols are performed stepwise. The disadvantages include low yields and tedious transformations. The concept of counterattack reagents can be applied to perform the protection and deprotection in an efficient manner.

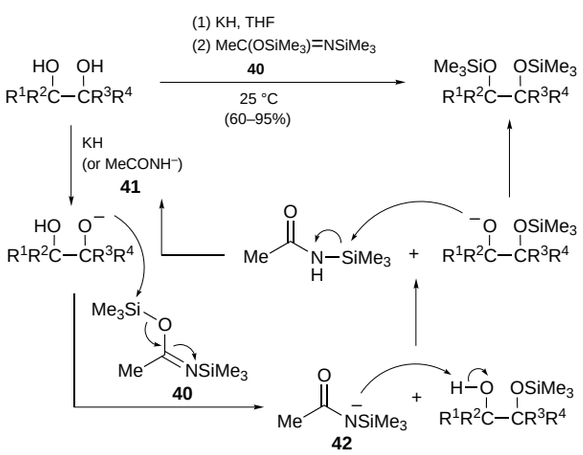
Disilylation of diols by use of MeC(OSiMe₃)=NSiMe₃:[10] *a tandem double-counterattack process*

Trimethylsilylation is useful in the protection of functional groups bearing labile protons. Silylation of alcohols, especially diols, polyols and carbohydrates, can increase their volatility and thermal stability. Consequently, the silylated species are more suitable than the parent alcohols for analysis by GC and mass spectrometry.[36]

Reaction of various diols with bis(trimethylsilyl)acetamide **40** in THF under alkaline conditions gives the corresponding bis(trimethylsilyl) ethers in good to excellent yields (60–95%). The diols may contain other functionalities, such as amides, amines, ethers and thioethers.[10]

Stepwise silylations of resorcinol with hexamethyldisilathiane give the corresponding disiloxylbenzene in 55% overall yield;[37] however, the counterattack method leads to an 80% yield. Use of chlorotrimethylsilane and pyridine to silylate the diols in a carbohydrate gives the corresponding bis(trimethylsilyl) ether in 41% yield;[38] the counterattack method results in a 65% yield. These results clearly indicate the efficiency of the counterattack method.

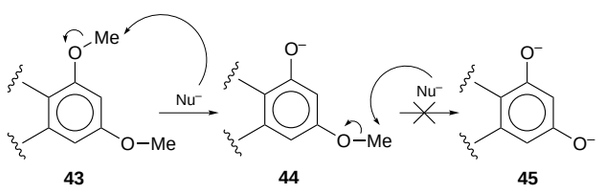
In the disilylation, $MeC(OSiMe_3){=}NSiMe_3$ **40** acts as a counterattack reagent and exhibits multiple functions (see Scheme 11). In addition to transferring both Me_3Si groups onto the diol, reagent **40** provides amide anions **41** and **42**. These anions deprotonate the intermediates and the starting diols. Therefore, only a catalytic amount of base (*i.e.* KH) is needed for initiation of the disilylation. This 'one-flask' disilylation involves sequential deprotonation–silylation–deprotonation–silylation. This double trimethylsilylation also represents an example of a 'tandem double-counterattack process', in which bis(trimethylsilyl)acetamide offers three reacting centres (*i.e.* two electrophilic silicon atoms and one nucleophilic nitrogen atom).



Scheme 11

Deprotection of aryl methyl ethers by sodium trimethylsilanethiolate and hexamethyldisilathiane[11]

Commonly used reagents for demethylation of aryl methyl ethers give mono-*O*-demethylated products; a few of them can bis-*O*-demethylate substrates.[39] Sequential demethylation of dimethoxybenzenes in one flask is difficult using nucleophilic reagents, as shown in Scheme 12. The first demethylation involves attack of a nucleophilic reagent on a methyl group of dimethoxybenzenes **43** to give methoxyphenolates **44**. It is unlikely that nucleofuge **44** could be demethylated by another nucleophile in an efficient manner (*i.e.* **44** → **45**) because the resultant species **45** would bear two negative charges.



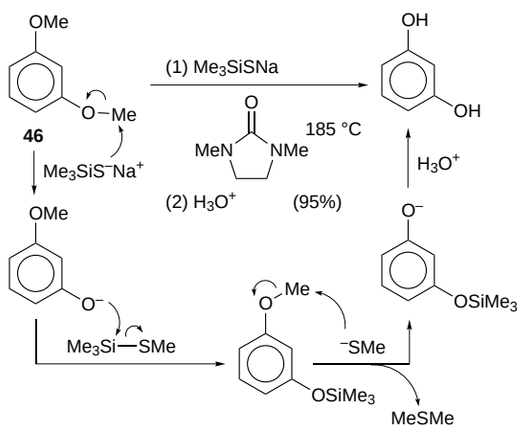
Scheme 12

This problem can be circumvented by utilization of the 'counterattack reagent' concept. Use of Me_3SiSNa and Me_3-

$SiSSiMe_3$ as counterattack reagents causes aryl methyl ethers to bis-*O*-demethylate efficiently under alkaline conditions. Treatment of an aryl methyl ether containing two methoxy units with *ca*. 2.5 equiv. of Me_3SiSNa in 1,3-dimethyl-2-imidazolidinone at 185 °C in a sealed tube gives the corresponding aryl diols in 78–96% yield after aqueous workup. The starting materials also include an aryl alcohol containing a biphenyl or naphthalene unit.

Moreover, $Me_3SiSSiMe_3$ is used to bis-*O*-demethylate aromatic compounds containing one free hydroxy group and two methoxy units, which react with 1.5 equiv. of NaH and then with 1.5 equiv. of $Me_3SiSSiMe_3$ at 185 °C in a sealed tube to afford the corresponding triols in 78–83% yield. Sodium trimethylsilanethiolate and hexamethyldisilathiane can be used to remove two methyl groups *in situ* from an aryl methyl ether. In these bis-*O*-demethylations, Me_3SiSNa and $Me_3SiSSiMe_3$ act as 'counterattack reagents'.

Scheme 13 shows the mechanism for the bis-*O*-demethylation of 1,3-dimethoxybenzene **46**, in which Me_3SiSNa acts as a 'nucleophilic counterattack reagent'. This reagent contains both a nucleophilic centre (*i.e.* S) and an electrophilic centre (*i.e.* Si), which react with the intermediates at different points in the reaction. Furthermore, Scheme 14 depicts an example involving $Me_3SiSSiMe_3$ as an 'electrophilic counterattack reagent', which is used for the bis-*O*-demethylation of dimethoxyphenol **47**. The reactions shown in Schemes 13 and 14 share common features—the design is complicated and the manipulation is simple.



Scheme 13

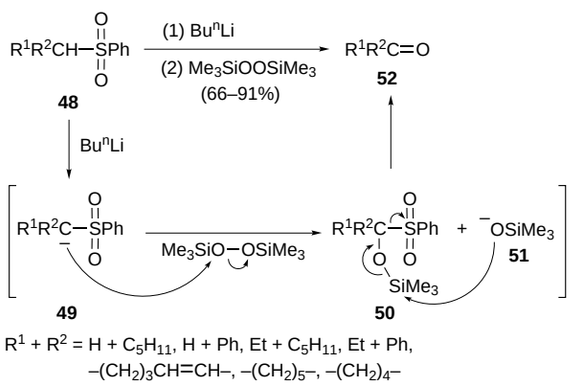
Similarly, this demethylation procedure is also applicable to pyridines with two methoxy groups, using Me_3SiSNa.[40] Furthermore, chlorotrimethylsilane, in combination with sodium sulfide, can be used as the equivalent of sodium trimethylsilanethiolate in the demethylation of dimethoxybenzenes.[41]

Oxidation reactions involving counterattack strategy

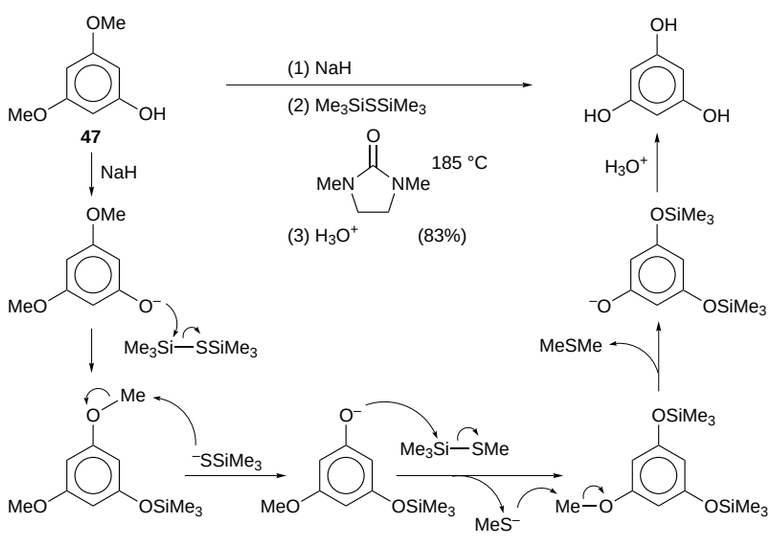
Counterattack strategy can also be applied to oxidation reactions. Examples include the oxidative desulfonylation of sulfones to aldehydes or ketones, oxidation of hydrazines to 2-tetrazenes, and conversion of benzyl alcohols to phenones or benzaldehydes. In these transformations, silicon reagents are utilized both as an oxidant and as a 'counterattack reagent'.

Oxidative desulfonylation of sulfones to aldehydes or ketones by use of $Me_3SiOOSiMe_3$[12]

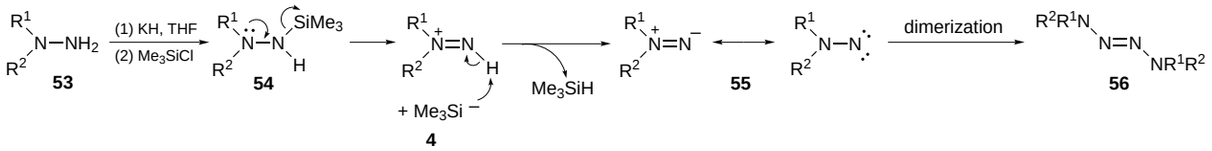
The sulfone group is commonly used in organic synthesis. This group generally has to be removed after the desired transformations have been accomplished. An efficient method for the oxidative desulfonylation of sulfones to aldehydes or ketones is reported, which uses $Me_3SiOOSiMe_3$ under alkaline conditions. As shown in Scheme 15, removal of a proton in sulfone **48** with Bu^nLi in THF at −78 °C generates the corresponding carbanion **49**. $Me_3SiOOSiMe_3$ is then attacked by the sulfonyl carbanion **49** to generate siloxy sulfone **50** and Me_3SiO^- **51**. Without isolation, the siloxy sulfone **50** is counterattacked by Me_3SiO^- to give the desired carbonyl product **52**.



Scheme 15

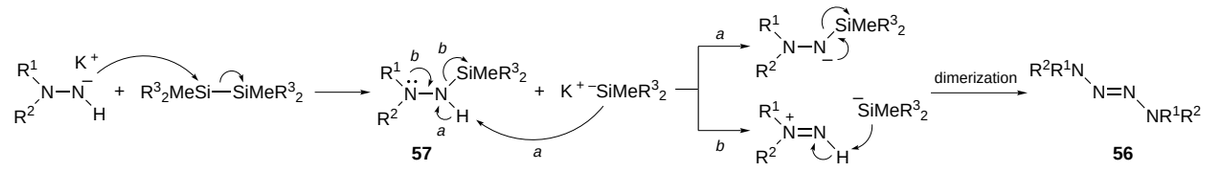


Scheme 14



$R^1 + R^2$ = Ph + Me, $–(CH_2)_5–$, $–CHMe(CH_2)_3CHMe–$, $–CH_2CH_2OCH_2CH_2–$, $–(CH_2)_6–$

Scheme 16



$R^1 + R^2$ = Ph + Me, $–(CH_2)_5–$, $–CHMe(CH_2)_3CHMe–$, $–CH_2CH_2OCH_2CH_2–$, $–(CH_2)_6–$

R^3 = Me, Ph

Scheme 17

This 'one-flask' method can be used to convert alkyl, allylic, benzylic and cycloalkyl sulfones to aldehydes or ketones in 66–91% yield. In the attacking step (**49** → **50**) as shown in Scheme 15, the trimethylsiloxy moiety in $Me_3SiOOSiMe_3$ behaves like a leaving group. In the counterattacking step (**50** → **52**), Me_3SiO^- **51** acts as a nucleophile. Therefore $Me_3SiOOSiMe_3$ is an 'electrophilic counterattack reagent' in this oxidative desulfonylation.

Conversion of hydrazines to 2-tetrazenes by use of Me_3SiCl, $Me_3SiSiMe_3$ and $Ph_2MeSiSiMePh_2$ as oxidizing agents[13]

Silicon compounds Me_3SiCl, $Me_3SiSiMe_3$ and $Ph_2MeSiSiMePh_2$ are commonly used as silylating or reducing agents. By use of a 'counterattack procedure', these silicon reagents can be utilized as oxidants. Reaction of 1,1-disubstituted hydrazines **53** with Me_3SiCl, $Me_3SiSiMe_3$ or $Ph_2MeSiSiMePh_2$ in the presence of KH gives the corresponding 2-tetrazenes **56** in fair to good yields (Schemes 16 and 17). In these reactions, Me_3SiCl, $Me_3SiSiMe_3$ and $Ph_2MeSiSiMePh_2$ behave as oxidizing agents.

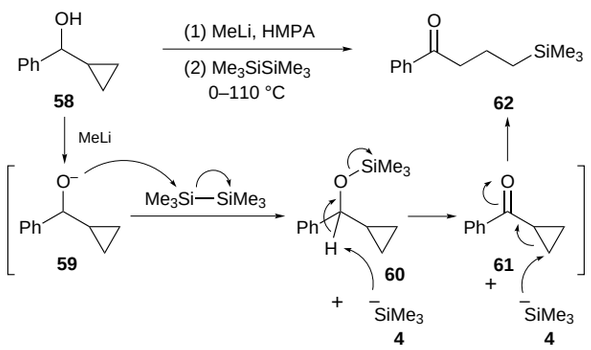
These new methods for the formation of 2-tetrazenes **56** involve several transformations: silylation of hydrazines **53** to give monosilylhydrazines **54**, decomposition of monosilylhydrazines **54** to generate amino nitrenes **55**, and dimerization of amino nitrenes **55** to afford 2-tetrazenes **56**. The characteristic feature of these reactions is that the R_3Si^- species can depart from the $NSiR_3$ moiety in **54** and **57**. Schemes 16 and 17 depict the 'counterattack processes' for the oxidation of hydrazines to 2-tetrazenes by Me_3SiCl and disilanes, respectively.

Oxidation of benzyl alcohols to phenones[14] *or benzaldehydes*[15] *by use of $Me_3SiSiMe_3$: a tandem double-counterattack process*

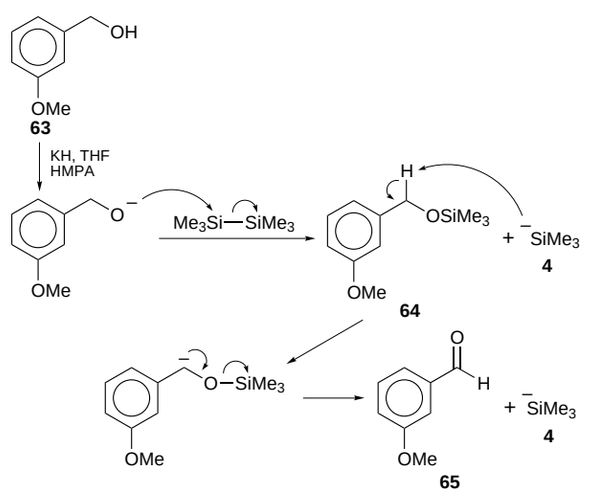
Hexamethyldisilane can also act as an oxidant in the conversion of benzyl alcohols to carbonyl compounds. Under basic conditions, reaction of α-cyclopropylbenzyl alcohol **58** or 3-methoxybenzyl alcohol **63** with $Me_3SiSiMe_3$ generates γ-trimethylsilylbutyrophenone **62** or 3-methoxybenzaldehyde **65**, respectively.

The mechanism for the one-flask oxidation and cyclopropyl ring opening procedure is depicted in Scheme 18.[14] Disilane $Me_3SiSiMe_3$ is attacked by alkoxide **59** to produce silyl ether **60** and Me_3Si^- **4**. Subsequently, Me_3Si^- counterattacks the benzylic proton in **60** to give cyclopropyl phenyl ketone **61** and regenerates Me_3Si^-. Me_3Si^- then re-counterattacks intermediate **61** to give γ-silylphenone **62** as the major product. The entire mechanism includes two counterattack processes. The first is to convert **59** to **61** using $Me_3SiSiMe_3$; the trimethylsilyl moiety serves as a leaving group in $Me_3SiSiMe_3$ and as a counterattack species for intermediate **60**. The second is to transform **60** to **62** using Me_3Si^- **4**; the trimethylsilyl moiety behaves as a leaving group in **60** and as a counterattack species for intermediate **61**. This sequence provides an example of a 'tandem double-counterattack process'.

Similarly, the oxidation of 3-methoxybenzyl alcohol **63** to 3-methoxybenzaldehyde **65** by use of $Me_3SiSiMe_3$ under basic conditions occurs *via* the mechanism shown in Scheme 19.[15] In these transformations, the Me_3Si^- species is utilized as a catalyst, which can also oxidize trimethylsilyl ethers (*i.e.* **60** in Scheme 18 and **64** in Scheme 19) possessing acidic protons at the position α to the corresponding carbonyl compounds (*i.e.* **62**

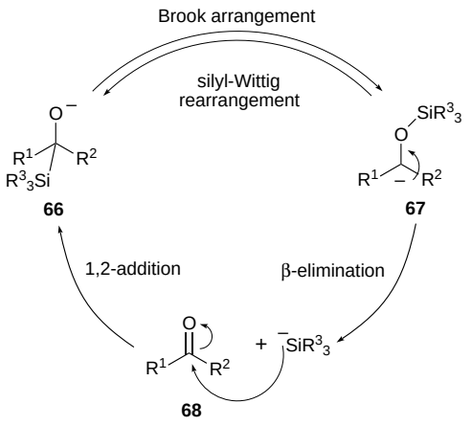


Scheme 18



Scheme 19

and **65**). Thus the interconversions can constitute a novel cycle among α-silylalkoxides **66**, α-siloxy carbanions **67** and carbonyl compounds **68** accompanied by R_3Si^-, as shown in Scheme 20.[15] This newly established cycle involves Brook rearrangement, the silyl-Wittig rearrangement, a β-elimination and a 1,2-addition.

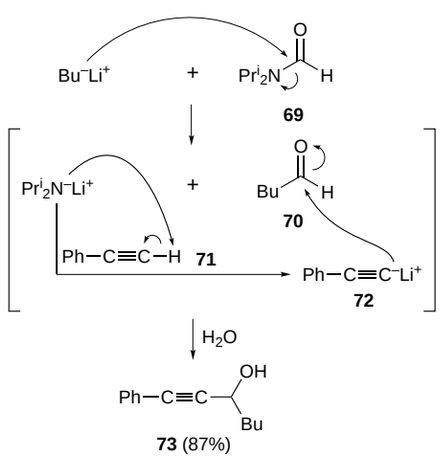


Scheme 20

Preparation of prop-2-ynylic alcohols by use of organic amides as pseudo-counterattack reagents[2]

Prop-2-ynylic alcohols can be used in the synthesis of pheromone components[42] and the ω-chain in prostaglandins.[43] For the preparation of prop-2-ynylic alcohols, a one-flask method has been established by use of a 'pseudo-counterattack process'. Reaction of an organolithium reagent, an organic amide and phenylacetylene generates prop-2-ynylic alcohols in 71–93% yield. The amides, including *N*,*N*-dimethyl-, *N*,*N*-diethyl- and *N*,*N*-diisopropyl-formamide, 1-formylpyrrolidine, 1-formylpiperidine, *N*,*N*-dimethylacetamide and *N*,*N*-diethyldodecanamide, behave as pseudo-counterattack reagents in this transformation.

The mechanism is illustrated in Scheme 21 for the reaction involving Bu^nLi, *N*,*N*-diisopropylformamide **69** and phenylacetylene **71**. In the first step, *N*,*N*-diisopropylformamide **69** is attacked by Bu^nLi to give the stable intermediate valeraldehyde **70**. The $Pr^i_2N^-$ anion formed from the amide reacts with phenylacetylene **71** to generate lithium phenylacetylide **72**. This nucleophilic species attacks the intermediate valeraldehyde **70** *in situ* to afford the desired prop-2-ynylic alcohol **73** in 87% yield. Thus, *N*,*N*-diisopropylformamide serves both as a substrate for the organolithium reagent and as the solvent. In the entire transformation, the organic amide can be considered as a 'pseudo-counterattack reagent'.

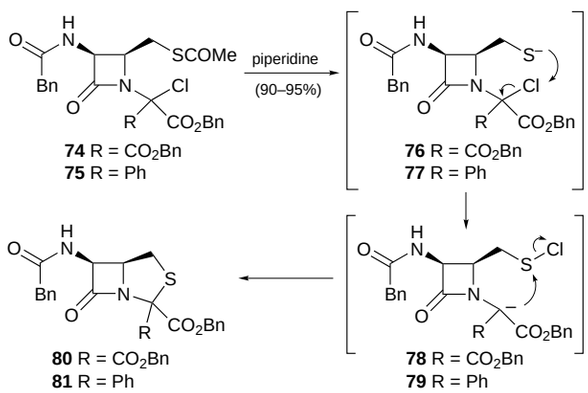


Scheme 21

Intramolecular counterattack strategy in the synthesis of biologically active isopenams[3]

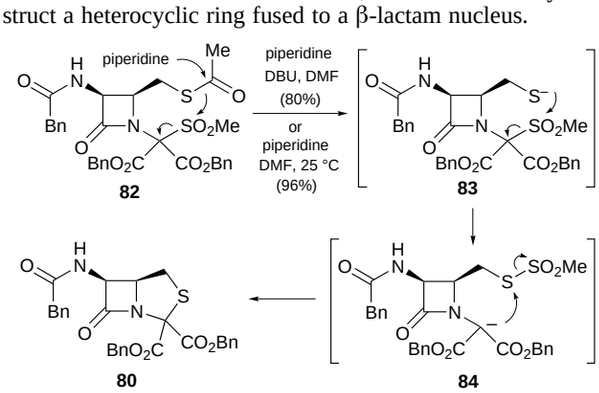
The concept of counterattack reagents can be extended to the performance of chemical transformations in one molecule. Use of this method allows the synthesis of isopenams having important biological activities in high yields.

The synthesis of isopenams, involving an 'intramolecular counterattack process', is illustrated in Scheme 22. Formation of the thiazolidine ring in isopenams **80** and **81** from the corresponding thioesters **74** and **75**, respectively, is accomplished under basic conditions. Accordingly, the sulfides **76** and **77** are generated by deacetylation of thioesters **74** and **75**, respectively, with piperidine. The α-chloro ester moiety in **76** and **77** is first attacked intramolecularly by the sulfide moiety. The resultant carbanions **78** and **79** then counterattack the S–Cl unit to form the thiazolidine ring in **80** and **81**. Thus the thioesters **74** and **75** act as 'intramolecular counterattack reagents'.



Scheme 22

A similar mechanism, shown in Scheme 23, is responsible for the transformation of sulfone malonate **82** to isopenam **80** *via* sulfide **83** and malonate anion **84**. The key steps involve the sulfone moiety in **83** being attacked by the sulfide unit, and the resultant carbanion **84** counterattacking the S–SO_2Me unit to form the thiazolidine ring in **80**. Thus sulfone **82** also functions as an 'intramolecular counterattack reagent'. Using this intramolecular counterattack mechanism, we can efficiently construct a heterocyclic ring fused to a β-lactam nucleus.



Scheme 23

Conclusions

Twelve examples have been given which demonstrate the efficient ways counterattack reagents can be used in organic synthesis. These reagents function either as electrophilic or nucleophilic 'counterattack reagents'. Their structures can be symmetric or non-symmetric. In addition to being attacked by substrates and then counterattacking the intermediates *in situ*, some counterattack reagents can follow very complicated

reaction pathways, such as the 'tandem double-counterattack process' and the 'consecutive triple-counterattack process'. This new concept has also been extended to the 'intramolecular counterattack strategy' and the 'pseudo-counterattack process' in the synthesis of valuable organic targets.

A multistep chemical transformation can be simplified into a 'one-flask' reaction using a counterattack reagent. In comparison with established classic methods, this new approach often gives higher yields with less manipulation. There is a bright future for the application of counterattack reagents to transformations of various types. An extreme example might involve hundreds or thousands of consecutive attacking and counter-attacking processes in polymer syntheses. The deliberate design of the reagent applied in each transformation is the key to the creation of new 'counterattack reagents'.

We thank the National Science Council of Republic of China and Academia Sinica for financial support.

Professor Jih Ru Hwu was born in Taipei, Taiwan, in 1954. He received his BS degree from the National Taiwan University (1972–1976) and PhD degree from Stanford University (1978–1982), during which time he worked under the guidance of Professor Eugene E. van Tamelen. Upon graduation, he joined the faculty at The Johns Hopkins University (1982–1991). He moved to the National Tsing Hua University as a professor in 1990 and has held a joint appointment as Research Fellow at Academia Sinica since then. Professor Hwu has been awarded an Alfred P. Sloan Research Fellowship for 1986–1990, the 1992/1993 Distinguished Young Chemist Award by the Federation of Asian Chemical Societies, a Ten Outstanding Young Persons of the Republic of China award (1993), two Distinguished Research Awards (1992–94, 1995–97) from the National Science Council, The Outstanding Young Persons of the World award for 1994 in the category of scientific and technological development by Junior Chamber International and the 1997 Third World Academy of Sciences Award in Chemistry. He was elected as the president of the Chinese American Chemical Society, USA (1991, 1992) and as an Associate Member of the IUPAC Commission on Nomenclature of Organic Chemistry (1989–97). He has also served as a Regional Advisory Editor for *Chemical Communications* (1994–1997). His research interests include silicon chemistry, organic synthesis, polymer science and genetic engineering.

Dr Shwu-Chen Tsay was born in Taipei, Taiwan, in 1962. She received her BS degree from the National Taiwan University (1981–1985) and PhD degree from The Johns Hopkins University (1986–1990, with Professor J. R. Hwu). Upon graduation, she joined the research group of Professor K. C. Nicolaou at The Scripps Research Institute as a Research Associate (1991–1992). Currently she is a Research Fellow at the Development Center for Biotechnology and an Associate Professor at Fu Jen Catholic University. In 1996 she was awarded a Ten Outstanding Young Women of the Republic of China award. Currently, she is an Associate Member of the IUPAC Commission on Nomenclature of Organic Chemistry. Her research interests include organic synthesis, bioorganic chemistry, medicinal chemistry and biotechnology.

Biosynthesis of (−)-β-barbatene from ^{13}C- and ^{2}H-labelled acetate, mevalonate and glycerol†

Kensuke Nabeta,*[a] Kaori Komuro,[a] Tomoaki Utoh,[a] Hiroyuki Tazaki[a] and Hiroyuki Koshino[b]

[a] *Department of Bioresource Science, Obihiro University of Agriculture and Veterinary Medicine, Obihiro, 080 Japan*
[b] *The Institute of Physical and Chemical Research, (Riken) Wako, 351-01 Japan*

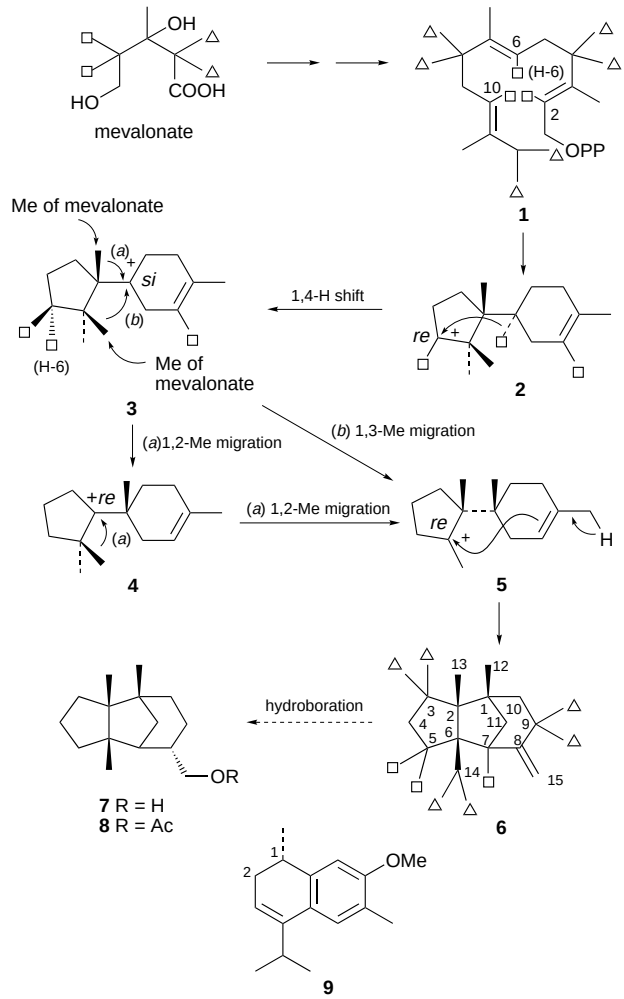
The ^{2}H and ^{13}C enrichment, ^{13}C–^{13}C coupling patterns and β-^{2}H isotope shifts observed in β-barbatanol prepared from (−)-β-barbatene incorporating variously ^{2}H- and ^{13}C-labelled mevalonates, acetates and glycerol verifies a 1,4-hydrogen shift and a double 1,2-methyl migration in the formation of β-barbatene in cultured cells of *Heteroscyphus planus*, and also indicates the diversity of regulation and the sole operation of the mevalonate pathway in extrachloroplastidic sesquiterpene biosynthesis.

The irregular sesquiterpene, β-barbatene **6**, has been proposed to be related biogenetically to the trichothecanes and cuparanes, the biosynthesis of which apparently involves a usual 1,4-hydride shift.[1] β-Barbatene is formed by further methyl migration by two routes, one involving a double 1,2-methyl migration [route (*a*) in Scheme 1], while the other features 1,3-methyl migration [route (*b*)]. Further cyclization and deprotonation of **5** affords β-barbatene. We fed deuteriated mevalonates (MVA) ([2,2-$^{2}H_2$] and [4,4-$^{2}H_2$]), ^{13}C- and ^{2}H-labelled acetates ([2-^{13}C], [1,2-$^{13}C_2$] and [2,2,2-$^{2}H_3$, 1-^{13}C]), [2-^{13}C]glycerol and [6,6-$^{2}H_2$]glucose to cultured cells of *Heteroscyphus planus* to elucidate the details of these steps and to determine whether extrachloroplastidic terpenoids are produced *via* a non-mevalonate-utilizing pathway.[2]

Cell cultures of *H. planus* were grown in MSK-4 medium[3] (75 ml), and fed 1.0 mmol of the potassium deuteriated MVAs (isotopic purity 99 atom%), 0.5 mmol of labelled acetate (isotopic purity 99 atom%), 0.5 mmol of [2-^{13}C]glycerol (60 atom%) and 11.1 mmol of [6,6-$^{2}H_2$]glucose (20 atom%) under continuous light at 25 °C. After extraction with methanol, the labelled β-barbatene was partitioned with pentane and separated by silica gel chromatography. The partially purified β-barbatene was then converted to β-barbatanol **7**, by reaction with borane–methyl sulfide, to avoid loss of volatile β-barbatene during further purification. β-Barbatanol was finally purified by repeated HPLC. Full assignment of the natural abundance ^{1}H and $^{13}C\{^{1}H\}$ NMR spectra of β-barbatanol and its acetate **8** was achieved by ^{1}H–^{1}H 2D COSY, ^{1}H–^{13}C 2D COSY, DEPT, differential NOE, DQF-COSY, PFG- HMQC and PFG-HMBC NMR studies.

$^{2}H\{^{1}H\}$ NMR spectra of β-barbatanyl [4,4-$^{2}H_2$]mevalonate indicated that ^{2}H-6 and ^{2}H-10 retained in farnesyl diphosphate **1** were incorporated into the C-5 position of β-barbatanol [δ_D 1.05 and 2.05 ($CDCl_3$), see Scheme 1] *via* the 1,4-hydride shift from cation **2** to **3** and ^{2}H-2 was incorporated into the C-7 (δ_D 1.61) position, while deuterium atoms of [2,2-$^{2}H_2$]MVA were incorporated into C-3 , C-9 and C-14 positions of β-barbatanol. ^{2}H enrichment of β-barbatanol (10.3 atom% excess) incorporating deuteriated MVA was determined by GC–MS analysis.[4] These labelling patterns indicated the 1,4-hydride shift and migration of the methyl group originating from the C-3 methyl of MVA. $^{13}C\{^{1}H\}$ NMR examination of the β-^{2}H isotope shifts[5] in β-barbatanyl [1-^{13}C, 2,2,2-$^{2}H_3$]acetate indicated the retention of two ^{2}H atoms at C-5 (ratio of $C^{2}H_2 : C^{2}H^{1}H : C^{1}H_2$ of C-4 = *ca.* 1 : 2 : 5, $\Delta\delta$ −0.22 and −0.11 ppm, Table 1) which supports the 1,4-hydride shift. No apparent ^{13}C signals due to a β-isotope shift of the C-2 carbon by $^{13}C^{2}H_3$ were observed.

The $^{13}C\{^{1}H\}$ NMR spectrum of β-barbatanyl [1,2-$^{13}C_2$]acetate showed three ^{13}C enriched peaks with doublets due to ^{13}C–^{13}C coupling (C-1–C-12, C-2–C-13 and C-8–C-15, see footnote of Table 1). The relative peak intensity of doublet to the central ^{13}C peak of C-13 (0.17) was much lower than that of C-15 (0.77) or that estimated on the basis of average ^{13}C enrichment (0.76 atom% excess), indicating that [1,2-$^{13}C_2$]acetate was not incorporated into the C-2 and C-13 positions. Intense ^{13}C–^{13}C couplings between C-1–C-10, C-4–C-5,



Scheme 1 Biosynthetic pathway of (−)-β-barbatene from deuteriated mevalonate in cultured cells of *H. planus*. Relative peak intensity of ^{2}H peaks at δ_D 1.73, 1.52 and 0.96 = 1 : 2 : 3 and that at δ_D 2.05, 1.61 and 1.05 = 1 : 1 : 1. H-6 in the carbocation **3** corresponds to H-6 in farnesyl diphosphate **1**.

[b] Ratio of carbon peak intensities for β-isotope shifted signals. [c] β-Isotope shifts due to ^{2}H. [d] Coupling constant in β-barbatanol incorporating [2-^{13}C]acetate, $J_{C,C}$/Hz, C-1–C-12 31.4. [e] $CD_2:CDH:CH_2$.

C-7–C-11 and C-8–C-15 were confirmed by a PFG-INADEQUATE experiment.[6]

Despite the low level of incorporation, the results of feeding cultured cells with [1,2-$^{13}C_2$]acetate demonstrated that all the carbon atoms in β-barbatanol were coupled with every adjacent carbon atoms. Couplings were observed between carbon atoms of different acetate units or those of different isoprene units, C-2–C-13, C-3–C-4 and C-9–C-10 (see footnote of Table 1). This suggests that β-barbatene biosynthesis is compartmentalized and occurs rapidly, *e.g.* within organelles.[7] However, in the formation of labelled (1*S*)-7-methoxy-1,2-dihydrocadalene[3] (cadinane **9**, 0.80 atom% excess) incorporating [1,2-$^{13}C_2$]acetate, which was isolated together with labelled β-barbatanol from the pentane extract of cultured cells fed with [1,2-$^{13}C_2$]acetate, no coupling was observed between the carbons of the different isoprene units. Contrasting results for β-barbatene and the cadinane suggest that their biosynthesis is regulated differently. These findings suggest a diversity of regulation in sesquiterpene biosynthesis. Although cultured cells of *H. planus* accumulate both cadinanes and bisabolanes,[3] only cadinane synthases have been detected in the 40 000 g supernatants.[8] This observation supported the suggestion that the cyclases which form bisabolanes including β-barbatene are associated with organelles, while cadinane synthases are localized in cytosol.

Labels were detected as intense singlets at C-2, C-4, C-6, C-8, C-10 and C-11 of β-barbatanol incorporating [2-^{13}C]glycerol, all of which were observed as intense singlet peaks. No deuterium atoms from [6,6-$^{2}H_2$]glucose were incorporated into β-barbatanol.

The labelling pattern supported the sole operation of the mevalonate pathway in biosynthesis of the extrachloroplastidic sesquiterpenes. In contrast the simultaneous operation of two distinct pathways, a mevalonate- and a non-mevalonate-mediated pathway, has been identified in the formation of the phytyl side-chain within chloroplasts.[9]

These obsevations are consistent with the occurrence of a 1,4-hydride shift and double 1,2-methyl migration during formation of β-barbatene and exclude the possibility of 1,3-methyl migration. They also suggested that the diversity of regulation and the sole operation of the mevalonate-utilizing pathway in the extrachloroplastidic biosynthesis of sesquiterpenes.

We are grateful to Professor H. Seto (Tokyo University) and Professor K. Kakinuma (Tokyo Institute of Technology) for the generous gift of [6,6-$^{2}H_2$]glucose. These investigations were supported by Grants-in-aid for Scientific Research (A. No. 08306021) and (C. No. 08660125), from the Ministry of Education, Science and Culture, Japan.

Very long C–H···O contacts can be weak hydrogen bonds: experimental evidence from crystalline [Cr(CO)$_3${η^6-[7-*exo*-(C≡CH)C$_7$H$_7$]}]

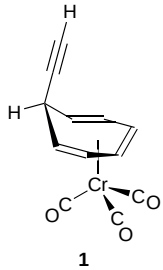
The crystal structure of the title compound contains a very long C–H···O contact from the ethynyl group to a carbonyl ligand with a H···O separation of 2.92 Å; weakly hydrogen bonding character of this contact is inferred from the Raman and the IR absorption spectra, showing the long range nature of the C–H···O hydrogen bond.

Terminal alkynes are among the best studied donors of C–H···X hydrogen bonds.[1,2] This is because of two reasons: one is the high acidity and hence the strong donor potential, and one is the good and robust suitability for vibrational spectroscopic experiments.[3] In C–H···O hydrogen bonds donated by terminal alkynes, H···O separations are typically in the range 2.1–2.6 Å, with the mean value 2.37(4) Å.[1,4] If particularly strong acceptors like P=O are involved, H···O distances can be as short as 2.0 Å.[5] Whereas no conceptual problems arise for strong acceptors and short C≡C–H···O contacts, very little is known about long C–H···O (and more generally on long D–H···A) contacts. The open question is very simple: to which distances can C–H···O interactions be elongated before losing their hydrogen bond character? Currently, there seems to be consensus that no clear distance limits can be given, and that for increasing H···O and C···O separations, there is a gradual transition from hydrogen bond interactions to 'nothing'.[1] Still, the question remains: to which distances can physical effects of C–H···O interactions be detected, and when do the effects become more or less undetectable? In this contribution, we report structural and spectroscopic data on the longest alkynyl C–H···O contact discussed so far, which can still be reasonably regarded as a weak 'hydrogen bond'.

As part of our studies on ligands containing cycloheptatrienylium rings,[6] we prepared compound **1**.†



1

In terms of hydrogen bond potentials, the strongest donor in **1** is the ethynyl group and as hydrogen bond partners, there are the weak C≡C,[7] C=C[8] and CO[9] acceptors available. In this situation, it is impossible to predict which of the potentially resulting hydrogen bond types would eventually be formed in the solid state (if one is formed at all). In the crystal structure,‡ **1** is found in the expected conformation, Fig. 1(*a*). The shortest intermolecular contact of the ethynyl group is with a CO ligand of a neighboring molecule, Fig. 1(*b*). This contact is very long with H···O 2.92 Å (for C–H 1.08 Å) and C···O 3.71 Å, and the C–H···O angle is bent far from linearity, 130°.§ When looking only at the geometry, it is questionable how to interpret this contact: the distance is very long, much longer than van der Waals separation, the angle is strongly bent, and the CO ligand is one of the weakest O-acceptors known. No C–H···O contact of such a geometry has ever been clearly identified as a hydrogen bond. On the other hand, weak hydrogen bond nature has been shown for similarly long C≡C–H··π contacts,[7,8] suggesting this matter should be followed in further depth.

In vibrational spectroscopic experiments,¶ the alkynyl C–H stretching frequency $\nu_{\equiv C-H}$ was determined under a variety of sampling conditions in the crystalline state and in apolar solvents. This is to exclude possible matrix or solvent effects on $\nu_{\equiv C-H}$. Most important is the data on matrix-free polycrystalline **1** (determined by FT-Raman spectroscopy), which was obtained from small crystals taken without further sample treatment from

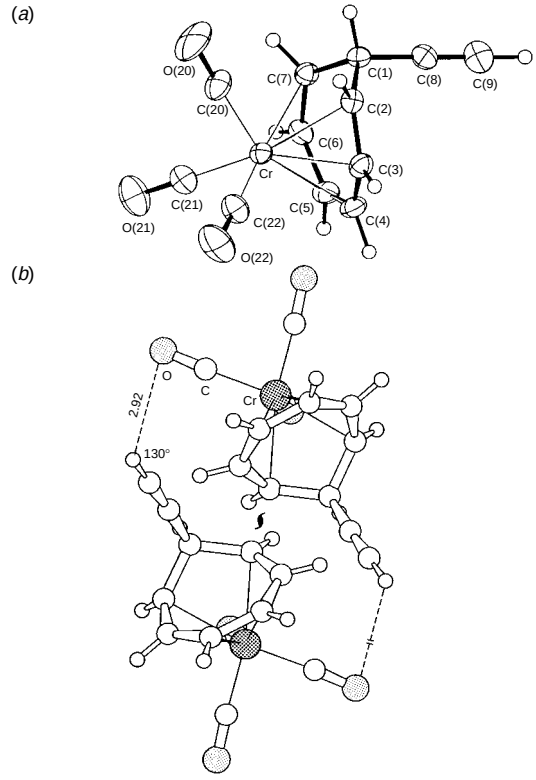


Fig. 1 (*a*) Molecular structure and atomic numbering scheme of **1**. (*b*) The very long C–H···O contact in crystalline **1**, numerical data is given for C–H 1.08 Å. The projection is along the screw axis of the space group; the apparently cyclic motif is therefore in fact a screw.

Table 1 IR alkynyl C–H stretching frequencies (cm^{-1}) of **1** in different environments

Sample of **1**	Spectrum	$\nu_{\equiv C-H}$
Polycrystalline matrix-free	FT-Raman	3293
Polycrystalline in poflu-oil[a]	FTIR	3293
Polycrystalline in KBr	FTIR	3293
Solution in *n*-hexane	FTIR	3315
Solution in CCl_4	FTIR	3310

[a] Poly(chlorotrifluoroethylene).

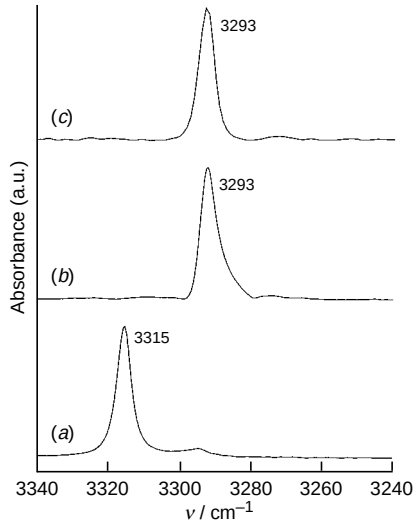

Fig. 2 Alkynyl C–H stretching region of the vibrational spectrum. (*a*) FT-Raman spectrum of a matrix-free polycrystalline sample. (*b*) FTIR spectrum of a polycrystalline sample in a poly(chlorotrifluoroethylene) mull. (*c*) FTIR spectrum of a dilute solution in *n*-hexane.

the same batch as the crystal used for X-ray data collection. FTIR spectra of polycrystalline samples in an inert mull and in KBr were also determined. All three $\nu_{\equiv C-H}$ values are identical at 3293 cm^{-1} (Table 1 and Fig. 2), which is slightly but significantly reduced compared to the *ca.* 3315 cm^{-1} which are typical for 'free' alkynyl $\nu_{\equiv C-H}$.[3] The identity of the three values under different sampling conditions makes matrix and sample preparation artifacts unlikely. Since $\nu_{\equiv C-H}$ of 'free' molecules R–C≡C–H can slightly depend on the nature of R and also on the experimental conditions, IR absorption spectra were determined of dilute solutions in the apolar solvents *n*-hexane and CCl_4. The $\nu_{\equiv C-H}$ values of 3315 and 3310 cm^{-1}, respectively, correspond to alkynyl groups which experience only very small (but necessarily non-zero) intermolecular interactions with 'inert' solvent molecules. The reduction of $\nu_{\equiv C-H}$ in the crystalline state of *ca.* 20 cm^{-1} shows that in crystals, the alkynyl covalent C–H bond is slightly but detectably weakened owing to its intermolecular interactions. This bond weakening is an appropriate (and normally used[3]) indicator of C–H···X hydrogen bonding. A red-shift of 20 cm^{-1} is only a small effect. In 'normal' alkynyl C–H···O interactions, the corresponding red-shifts are in the range 40–100 cm^{-1}, and for strong C≡C–H···O=P hydrogen bonds, they can be 145 cm^{-1} and more.[3,5] This means that the intermolecular interactions in **1** do have an effect on the vibrational spectum, but this effect is small. We see no other interactions that the C–H···O contact that might be responsible, and therefore call it a 'weak hydrogen bond' (the terminologic classification, though, is of minor importance here).

The discussed contact with H···O 2.92 Å, is, to our knowledge, the longest C–H···O interaction for which effects on vibrational spectra have been experimentally shown. This is strong support for the long-range nature of C–H···O interactions, and clearly disfavours views that hydrogen bond character stops at the distance of the sum of van der Waals radii. On the other hand, one must consider that the red-shift of IR wavenumbers is only *ca.* 20 cm^{-1}, which is much smaller than for C–H···O interactions in optimal geometry: the strength of C–H···O hydrogen bonds at such distances is already very small. Since the donor studied here, C≡C–H, is stronger than most other C–H groups,[1] C–H···O contacts of similar geometries with less acidic C–H groups will be correspondingly weaker. We explicitly do not conclude that 'every C–H···O contact with H···O 2.9 Å is a hydrogen bond', but we state (based on experimental evidence) that such a contact can be a hydrogen bond.

A novel and direct α-azidation of cyclic sulfides using a hypervalent iodine(III) reagent

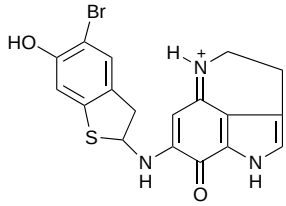
Hirofumi Tohma, Masahiro Egi, Makoto Ohtsubo, Hiroaki Watanabe, Shinobu Takizawa and Yasuyuki Kita*

Faculty of Pharmaceutical Sciences, Osaka University, 1-6, Yamada oka, Suita, Osaka 565, Japan

A novel and direct α-azidation of cyclic sulfides using a hypervalent iodine(III) reagent in the presence of Me_3SiN_3 is described; the present method is applicable to substrates which are easily aromatized under oxidative conditions.

α-Azido sulfides have attracted much attention because of their interesting reactivities under various conditions (*e.g.* photochemical, thermal, and other conditions[1]) and their utility as amino cation equivalents.[2] Furthermore, α-azido sulfides have potential for the synthesis of various *N*,*S*-acetals, since the azido moiety can be changed to other aza substituents *via* PPh_3 and catalytic hydrogenation.[3] Generally, *N*,*S*-acetals[4] are difficult to synthesize because of their instability. However, several methods have appeared for the syntheses of *N*,*S*-acetals, *e.g.* addition of thionucleophiles to imine intermediates[5] and addition of aza nucleophiles to thionium intermediates.[6] However, most of the methods have problems in terms of yield and vigorous reaction conditions. Hence, subsequent to the first report[7] by Böhme and Morf, acyclic α-azido sulfides have usually been synthesized stepwise,[1,8] *via* halogenation followed by azidation of sulfides, or *via* thioketals.[9]

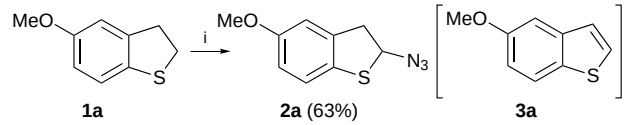
On the other hand, α-azidation of cyclic sulfides, especially dihydrobenzothiophenes, has never been reported, probably due to readily occuring side reactions such as aromatization, sulfoxide formation, benzylic oxidation and α-oxidation of the sulfur atom under oxidative conditions. In particular, α-azidohydrobenzothiophene is thought to be a suitable precursor for the total synthesis of the recently isolated marine anti-cancer alkaloids, discorhabdin A,[10] B,[11] D[12] and makaluvamine F,[13]



Makaluvamine F

whose total syntheses have yet to be accomplished owing to difficulties in constructing their *N*,*S*-acetal skeletons. This prompted us to develop an efficient and general α-azidation method for cyclic sulfides. First, we examined the known stepwise methods to obtain α-azidohydrobenzothiophene. The initial chlorination of **1a** by *N*-chlorosuccinimide (NCS) or SO_2Cl_2,[7,8] however, exclusively gave 5-methoxybenzothiophene **3a**, and oxidation of **1a** to the sulfoxide followed by Pummerer-type azidation gave predominantly **3a** and not **2a**. As part of our continuing studies of hypervalent iodine(III) oxidation,[14] we report here a novel and direct α-azidation method for cyclic sulfides using a combination of PhI=O and Me_3SiN_3 (Scheme 1).

A typical experimental procedure is as follows. To a stirred solution of **1a** in MeCN, Me_3SiN_3 (4.0 equiv.) was added dropwise at −40 °C under nitrogen atmosphere. Iodosylbenzene (2.0 equiv.) was added to the reaction mixture, which was then slowly warmed to −25 °C with stirring for 1–2 h.



1a **2a** (63%) **3a**

Scheme 1 *Reagents and conditions*: i, PhI=O (2 equiv.), Me_3SiN_3 (4 equiv.), MeCN, −40 to −25 °C

Evaporation of solvent followed by preparative TLC or column chromatography gave **2a** in 63% yield. Of the combination of reagents investigated, PhI=O with Me_3SiN_3 was the best since using $PhI(OCOCF_3)_2$–Me_3SiN_3 or other combined reagents† gave **3a** as the main product. Although the reaction of dihydrobenzothiophene bearing alkoxy substituents with hypervalent iodine(III) reagents has various possibility for (i) α-azidation, (ii) aromatic azidation,[15] (iii) benzylic azidation,[16] (iv) sulfoxide formation,[17] and (v) aromatization to benzothiophene, the present method makes the α-azidation of cyclic sulfides possible predominantly by the use of the combined reagent, PhI=O–Me_3SiN_3. The structure of **2a** was unambiguously established by ^1H NMR, IR and mass spectral and elemental analysis.‡

Table 1 shows that the present method is also applicable to mono- and bi-cyclic sulfides **1b**–**i** including dihydrobenzothiophene to give the corresponding α-azido sulfides **2b**–**i** in moderate to good yields. Among the substrates bearing an alkoxy group at the *para* position of the alkyl side chain, benzylic azidation products have also been obtained. In such cases, α-azidation proceeded after protection of the phenolic OH group with an acetyl group (runs 2 and 4).

A plausible reaction mechanism is proposed in Scheme 2. Iodosulfonium cation **4** initially formed from the reaction of

Table 1 α-Azidation of cyclic sulfides using PhI=O–Me_3SiN_3

Entry	Substrate **1**	*n*	R^1	R^2	R^3	Product **2**	Yield (%)

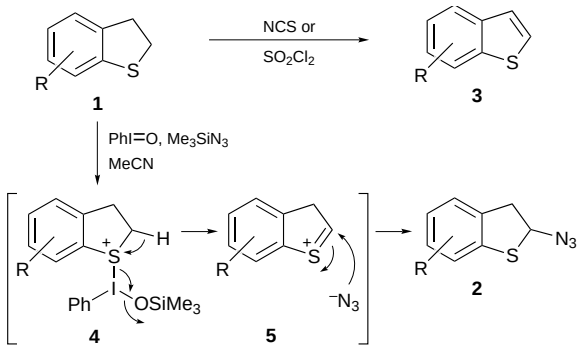

Scheme 2

sulfide **1** with PhI=O–Me_3SiN_3, a mechanism well studied by Magnus and co-workers,[18] is then deprotonated to give cation intermediate **5**. Azido anion attack on the α-position of **5** gives the α-azido sulfide **2**. On the other hand, NCS or SO_2Cl_2 causes β-proton abstraction of **5** to give benzothiophene **3** exclusively rather than a nucleophilic attack on the α-carbon. This is probably because the chloride anion is more basic than the Me_3SiO^- anion, generated in the azidation step, and also because Me_3SiO^- is readily neutralized to the siloxane under the reaction conditions used.

In conclusion, a novel and direct α-azidation of cyclic sulfides has been accomplished. This work opens the way to effective syntheses of biologically active natural products carrying *N*,*S*-acetal structures, and provides a direct and efficient method for the synthesis of cyclic α-azido sulfides.

Two new gallium phosphonates $Ga(OH)(O_3PC_2H_4CO_2H)\cdot H_2O$ 1 and $Ga_3(OH)_3(O_3PC_2H_4CO_2)_2\cdot 2H_2O$ 2 are prepared and characterized, using ^{31}P MAS and ^{71}Ga static NMR spectroscopy, showing a good correspondence between the fitted NMR parameters and the crystallographic data.

In recent papers, we have demonstrated that catalytic complexes (*i.e.* manganese porphyrins)[1] could be efficiently heterogenised as divalent metal phosphonates, in which significant shape selectivity effects imposed by the inorganic framework were observed. The key feature of this approach is to functionalize the catalytic complex by phosphonic acid PO_3H_2 moieties, that are then 'polymerised' by reaction with a metal (M) salt in solution, to build up a $M(RPO_3)_x$ network.[2] Taking into account that the resulting immobilised catalysts are usually poorly crystalline, our interest was to find a good method for the characterisation of such materials (*i.e.* get information about both the metal and the PO_3 group environments). One attractive solution to achieve that goal should be to use solid state NMR, provided that the metal atom reacted with the PO_3 groups can be observed by this technique, with the potential advantage (in comparison with EXAFS) to be able to determine the number of metallic sites and their relative amounts, as well as their coordination. In this paper, we describe our attempts in this field, by studying gallium phosphonate systems, the preparation of which seemed possible by analogy with gallium phosphates.[3] As a matter of fact, the stabilities of these materials towards acidic and basic media are higher than the divalent metal analogues and this can be of interest, as far as catalytic applications are concerned. Thus, by reaction of (2-carboxymethyl)phosphonic acid with gallium(III) nitrate in water in an autoclave, two novel gallium hydroxyphosphonates were prepared: $Ga(OH)(O_3PC_2H_4CO_2H)\cdot H_2O$ **1** and $Ga_3(OH)_3(O_3PC_2H_4CO_2)_2\cdot 2H_2O$ **2**. It is worth noting that the presence of hydroxide groups in phosphonates is unusual, except for recent examples described by us in the copper(II) system.[4]

Solid state NMR study of gallium is rendered difficult as it undergoes strong quadrupolar couplings, which give rise to severe second order broadening of the powder spectrum of its central $<1/2>$ transition. Gallium has two NMR active isotopes, ^{69}Ga and ^{71}Ga, both having $I = 3/2$ spins with higher gyromagnetic ratio and lower quadrupolar momentum for ^{71}Ga, which is thus the easiest to observe. At the principal magnetic field of 9.4 T (122 MHz Larmor frequency for ^{71}Ga), the width of the ^{71}Ga spectra of these two new gallium phosphonates (400 **1**, 600 **2** kHz) exceeds the bandwidth accessible with a single experiment (typically 300 kHz). The spectra have thus been acquired in static conditions as a sum of nine full echo signals obtained by varying the offset of the carrier frequency (with a 100 kHz step), according to the VOCS protocol that we have recently described in a study of ^{69,71}Ga in β-Ga_2O_3.[5] The second order quadrupolar broadening is so high in these compounds that MAS experiments cannot give resolution (unlike aluminophosphonates, for which MQ ^{27}Al MAS has proved to be efficient),[6] while the possible DAS[7] or newly described QPASS[8] experiments remain ineffective.

Owing to these intrinsic experimental difficulties, there is little known on Ga solid state NMR, even though there is a well established and confirmed correlation that links gallium and aluminium chemical shifts for four- and six-fold coordination in silicate, phosphates, zeolites and organic complexes.[5,9,10] The results obtained from the simulation of the two observed ^{71}Ga spectra (Fig. 1) are summarized in Table 1, showing two different Ga sites for **1** in a 1 : 1 ratio and one single site for **2**. The chemical shifts of these signals can be unambiguously

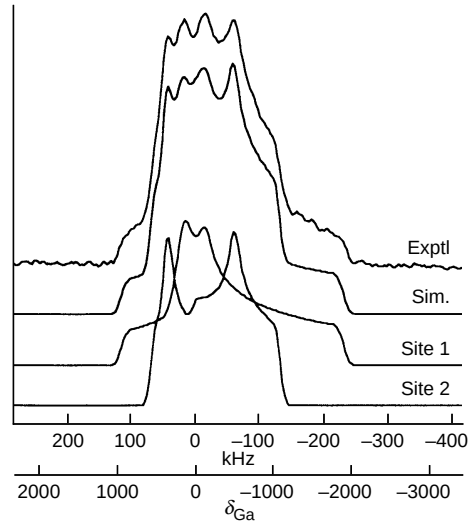

Fig. 1 Experimental ^{71}Ga static NMR spectrum of **1**, and simulated spectrum with second order quadrupolar broadened shape, according to parameters described in Table 1

Table 1 Experimental values for chemical shift and electric field gradient for compounds **1** and **2**

	δ_{iso}[a]	C_Q[b]/MHz	ηQ[c]
1	−6 (site 1: 50%)	13.5	0.85
	2 (site 2: 50%)	12.0	0.35
2	−3	17.0	0.9

[a] Chemical shifts are referenced to ^{71}Ga resonance in a 1 M gallium nitrate solution; error in the measured value: ±10 ppm. [b] Quadrupolar coupling constant ($C_Q = e^2qQ/h$); error in the measured value: ±0.25 MHz. [c] Asymmetry factor.

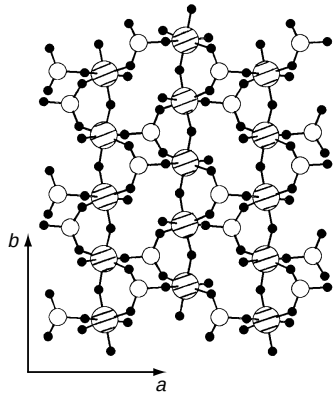

Fig. 2 Schematic representation of a $Ga(OH)(O_3P(CH_2)_2CO_2H)\cdot H_2O$ layer as seen perpendicular to the *c*-axis; Ga (hatched), P (white), O (black) and carbon atoms omitted for clarity. Selected interatomic distances (Å): Ga(1)–O 1.889(7), 1.906(6) (OH), 1.926(7) (OH), 1.978(8), 2.019(7), 2.061(7) (H_2O); Ga(2)–O 1.913(7) (OH), 1.922(6) (OH), 1.949(7), 1.965(7), 2.018(7), 2.060(7) (H_2O).

assigned to sixfold coordination, while their respective electric field gradient tensors characterize the asymmetry of their local environments. In the case of **1**, the presence of the two GaO_6 sites was confirmed by a structure determination from its powder X-ray diffraction pattern (Fig. 2).† On the other hand, even if six-coordinate gallium centres were clearly evidenced from the XANES–EXAFS spectra of this compound, it was however not possible to detect the two different independent metal atoms in this layered compound. Moreover, it is reasonable to think that in compound **1**, the most distorted gallium site Ga(1) [Ga–O bond lengths ranging from 1.889(7) to 2.061(7) Å; see Fig. 2] corresponds to the highest value measured for C_Q (13.5 MHz, site 1 in Table 1). For compound **2**, the observed value for C_Q (17 MHz) is significantly higher, thus giving evidence of a probably more distorted GaO_6 environment present in this latter phase. The structure of **1** consists of GaO_6 octahedra (composed of three phosphonate oxygens, two hydroxide groups and one water molecule) sharing two opposite vertices, thus forming chains parallel to the *b*-axis. These chains are connected by O–P–O bridges in the *a*-direction, to build a two-dimensional network. The organic chains are oriented roughly perpendicular to the layers, and the CO_2H groups are not coordinated, in contrast with **2** [ν(CO) 1590 cm^{-1}], for which a pillared layered structure is likely to be present, resulting from **1** by a probable coordination of the carboxylic acid moieties with gallium atoms. These two layered structures are in contrast to the only other reported gallium phosphonate, $Li_4[(MeGa)_6(\mu_3\text{-}O)_2(Bu^tPO_3)_6]\cdot 4thf$, an anionic molecular cage containing sandwiched lithium ions.[11]

Finally, from the simulation of the static and MAS ^{31}P spectra of gallium phosphonates **1** and **2**, the number of independent PO_3 groups was extracted together with their relative amounts and their respective chemical shift anisotropy parameters[12] [δ_{iso}, Ω (span), κ (skew)]. In a recent paper devoted to zinc phosphonates,[13] we have demonstrated that the κ parameter (chemical shift asymmetry) gave a good signature of the connectivity of the PO_3 groups (*i.e.* the number of zinc atoms connected to each of the three oxygen atoms bound to phosphorus). The value of κ is directly related to the range of variation of the bond strength at the phosphonate oxygens (Δ_pO^{2-}),[14] that in this case, was different for the various types of connectivity, that were thus easily determined: (111) connectivity [$\kappa = -0.6$ to -0.5; $\Delta_pO^{2-} \approx 0.05$ to 0.1], (112) [$\kappa = -0.2$; $\Delta_pO^{2-} \approx 0.2$] and (122) [$\kappa = 0.05$–0.1; $\Delta_pO^{2-} \approx 0.3$]. Similarly in compound **1**, the highest value of the κ parameter is probably found for the highest Δ_pO^{2-} (0.29). As the two PO_3 sites exhibit the same (111) coordination mode, we can see, for a given connectivity, that the range of variation of

Table 2 ^{31}P chemical shift tensor data for gallium phosphonates **1** and **2**

	δ_{iso}	Ω^b	κ^c	Δ_pO^{2-} (v.u.)^d
1	14.9 (site 1: 50%)	76.5	−0.3	0.29
	12.0 (site 2: 50%)	74.5	−0.5	0.15
2	25.3 (site 1: 50%)	53.1	0.0	—
	23.9 (site 2: 50%)	52.6	−0.2	—

[a] Chemical shifts are referenced to ^{31}P resonance in 85% H_3PO_4. [b] Chemical shift span defined as $\delta_{11} - \delta_{33}$ with $\delta_{11} \geqslant \delta_{22} \geqslant \delta_{33}$, see ref. 12(*b*). [c] Chemical shift skew defined as $3(\delta_{22} - \delta_{iso})/\Omega$. [d] Bond strength range at oxygens, see ref. 14(*b*).

Δ_pO^{2-} is far larger than it was in the case of zinc phosphonates. It would be very helpful to know if the differentiation of the various connectivities from the κ parameter is still possible in gallium phosphonates, but additional crystallographic references are necessary, and work is in progress for this purpose. Nevertheless, if we look at the κ values measured for compound **2** (Table 2), it is reasonable to think that the site at δ 25.3 ($\kappa = 0.0$) denotes a PO_3 group with a connectivity higher than (111).

In summary, the work reported here illustrates that original gallium phosphonates can be obtained and efficiently characterized using ^{31}P MAS and ^{71}Ga static NMR spectroscopy.

Enzymatic epoxidation of polybutadiene

Ann W. P. Jarvie,* Nigel Overton and Christopher B. St Pourçain†

Division of Chemical Engineering and Applied Chemistry, Aston University, Aston Triangle, Birmingham, UK B4 7ET

An immobilised lipase isolated from *Candida antarctica* (Novozym 435) catalyses the selective epoxidation of polybutadiene.

The use of enzymes in organic synthesis is becoming increasingly widespread. There are previous reports of the use of lipases in polytransesterification reactions, but their application to the modification of the backbone of synthetic polymers has not been explored.[1] We now report the enzyme catalysed epoxidation of a monophenyl terminated polybutadiene ($M_n \simeq$ 1300; 45% 1,2-vinyl, 35% 1,4-*trans*, 20% 1,4-*cis*) in a three phase system, under very mild conditions. The polybutadiene was treated with a 27.5 wt% aq. solution of hydrogen peroxide, catalytic quantities of acetic acid, and an immobilised lipase isolated from *Candida antarctica* (Novozym 435), in CH_2Cl_2 at room temperature.‡ The reaction proceeded rapidly over 24 h. Little further epoxidation and no opening of the epoxide rings (absence of OH absorptions in the infrared spectra) occurred over an additional 72 h. Reactions carried out in the absence of enzyme showed no evidence of epoxidation. The molecular weight of the polymer, determined by GPC, did not alter significantly during the epoxidation procedure, indicating the absence of chain scission and coupling reactions. The degree of epoxidation was readily calculated from the ^{1}H NMR spectrum and the elemental analysis of the polymer. The results from both techniques were in close agreement. It was found that 29% of the double bonds had been oxidised over 24 h. The ^{1}H NMR spectra also allowed the relative numbers of 1,4-*cis*, 1,4-*trans* and 1,2-vinyl double bonds to be calculated. The signals arising from the phenyl end group were vital to this procedure. It was apparent that the reaction was highly selective, and under all conditions studied the 1,4-*cis* and 1,4-*trans* double bonds of the backbone were epoxidised whilst the 1,2-vinyl groups remained untouched. Thus the epoxidation of 29% of all the double bonds in the polymer after 24 h corresponds to 52% of the backbone double bonds being epoxidised.

Some selective preference for epoxidation of the double bonds of the backbone (1,4-*cis* > 1,4-*trans* ⩾ 1,2-vinyl) has been observed in previous attempts to epoxidise polybutadiene.[2–4] In these systems the vinyl groups began to react before all of the backbone double bonds had reacted and some of the backbone double bonds remained unreacted. Small amounts of ring opened products were also observed in the epoxidation of polybutadiene with a 1 : 2 mixture of acetic acid and 60 wt% hydrogen peroxide.[2] The mild conditions of the enzymatic epoxidation procedure allowed the selective epoxidation of the backbone double bonds without opening the epoxide rings. Only one approach, using a molybdenum catalyst, has shown both high selectivity and complete conversion.[5] With this catalyst the backbone double bonds were completely epoxidised within 3 h at room temperature and there was no further change in the next 70 h. No epoxidation of the 1,2-vinyl groups was observed.

The conditions of the reaction were varied in the hope that the selective epoxidation of all the backbone double bonds would be achieved. It has been reported that for monomeric systems the dropwise addition of the hydrogen peroxide over the course of the reaction gives better yields of epoxides than the addition of the oxidant in one portion at the beginning of the reaction.[6] We found that the percentage of epoxidised double bonds was reduced from 29 to 18% using this procedure. Changing the solvent from CH_2Cl_2 to toluene, while using the same dropwise addition procedure, increased the percentage of epoxidation from 18 to 30%. In contrast, using hexane gave only 2% epoxidation. The poor yield of epoxide obtained with hexane as solvent was surprising as hexane had been reported to be amongst the best solvents for the epoxidation of monomeric systems with this enzyme.[6] It is known that the enzyme is deactivated during the course of the reaction.[6] It was anticipated that increasing the amount of enzyme would increase the reaction rate, and more double bonds would be epoxidised in the time taken for the enzyme to become inactive. In fact, doubling the amount of enzyme had no effect and the yield of epoxide was virtually unchanged.

It has been established that the role of the enzyme in this system is to catalyse the synthesis of peracid, the actual species which attacks the double bond.[6] The enzyme plays no part in the actual epoxidation step. The generation of peracid *in situ* removes the need for handling these potentially hazardous compounds. Medium chain alkanoic acids (C_8 to C_{16}) were used with this enzyme in previous epoxidation reactions of monomeric systems.[6] With polymeric systems we found that very stable emulsions were formed, making the work up procedure extremely difficult. The use of acetic acid, instead of medium chain alkanoic acids, allowed the reaction to proceed efficiently and greatly simplified the work up procedure. Confirmation that the enzyme plays no part in the epoxidation of alkene by peracetic acid was obtained by epoxidising the polymer in CH_2Cl_2 with a 32% solution of peracetic acid in acetic acid with and without enzyme present. In both cases, over 96 h polybutadiene was completely epoxidised and the majority of the epoxide rings opened and esterified [ν_{max} (thin film) 1736 cm^{-1}]. There was no evidence of residual acid being retained by the polymer. Interestingly, the epoxide groups of polyepoxide polymers derived from polybutadiene have been reported to be relatively inert to ring opening reactions with carboxylic acids, requiring forcing conditions.[7]

Table 1 Enzymatic epoxidation of polybutadiene

Run	*t*/h	Solvent	Hydrogen peroxide addition[a]	Enzyme/ wt%	Yield of epoxide (%)[b]	Yield of 1,4-*cis* and 1,4-*trans* epoxide (%)[b]
1	2	CH_2Cl_2	A	10	~0	~0
2	6	CH_2Cl_2	A	10	12	21
3	24	CH_2Cl_2	A	10	29	52
4	96	CH_2Cl_2	A	10	31	57
5	24	CH_2Cl_2	B	10	18	33
6	24	Hexane	B	10	2	4
7	24	Toluene	B	10	30	55
8	24	CH_2Cl_2	B	20	21	39

[a] A: Oxidant added in one portion at the start of the reaction. B: Oxidant added dropwise over the course of the reaction. [b] Determined *via* ^{1}H NMR spectroscopy.

Further investigation of this intriguing approach to polymer modification and its potential for modifying polymers for speciality materials applications, such as biomaterials, and polymer degradation are currently underway.

We thank the EPSRC for a studentship (to N. O.) and Novo Nordisk for the gift of Novozym 435.

‡ A typical procedure is as follows: Polybutadiene (5.0 g, 92 mmol of double bonds) was dissolved in CH_2Cl_2 (100 cm^3). AcOH (0.23 cm^3, 9 mmol), a 27.5 wt% aq. solution of H_2O_2 (17.0 cm^3, 0.14 mol) and Novozym 435 (0.5 g) were added and the mixture stirred for 24 h in the dark. The mixture was then filtered, extracted with saturated aq. $NaHCO_3$ and sodium metabisulfite, and dried ($MgSO_4$). The solvent was removed and the polymer dried in a vacuum oven at 55 °C and 1 mmHg.

Theoretical and experimental studies of the unprecedented spin-dependent structures of $[Cp_2Fe_2(CO)_2]$, the double-CO-loss product of $[Cp_2Fe_2(CO)_4]$

Marcello Vitale, Marsi E. Archer and Bruce E. Bursten*

Department of Chemistry, The Ohio State University, Columbus, OH 43210, USA

Photochemically generated $[(\eta\text{-}C_5R_5)_2Fe_2(CO)_2]$, which is a triplet molecule with terminal CO ligands, undergoes thermal relaxation to the singlet ground state of the molecule, which has bridging CO ligands.

Dinuclear organometallic complexes (DOCs) demonstrate remarkably rich and diverse photochemistry.[1] This paper focuses on new aspects of the photochemistry of one of the best studied DOCs, namely the diiron complex $[Cp_2Fe_2(CO)_4]$ (**1**, Cp = η^5-C_5H_5), and its half-methylated and permethylated derivatives $[Cp(Cp^*)Fe_2(CO)_4]$ (**1′**, Cp* = η^5-C_5Me_5) and $[Cp^*_2Fe_2(CO)_4]$ **1***.[2] We report evidence here for a remarkable and unprecedented spin-dependent structural change in an organometallic photoproduct.

In 1983, Rest and coworkers[3] and Wrighton and coworkers[4] demonstrated that irradiation of **1** in frozen hydrocarbon matrices leads to CO loss and the formation of $[Cp_2Fe_2(\mu\text{-}CO)_3]$ **2**, which has a formal Fe–Fe double bond and three symmetrically bridging CO ligands (ν_{CO} = 1812 cm^{-1}). Complex **2** is unusual inasmuch as it has a triplet ground state owing to its high, pseudo-D_{3h} symmetry.[5] We demonstrated that irradiation of **1** in softer hydrocarbon matrices leads to subsequent loss of CO from **2**, yielding the double-CO-loss product $[Cp_2Fe_2(CO)_2]$ **3**:[6]

$$\underset{\mathbf{1}}{[\{CpFe(CO)\}_2(\mu\text{-}CO)_2]} \xrightarrow{h\nu,\,-CO} \underset{\mathbf{2}}{[(CpFe)_2(\mu\text{-}CO)_3]} \xrightarrow{h\nu,\,-CO} \underset{\mathbf{3}}{[\{CpFe(CO)\}_2]} \quad (1)$$

Based on the positions and near-equal intensities of its IR bands in the CO-stretching region (1904, 1958 cm^{-1}), we proposed that **3** has a C_2 structure in which two equivalent CpFe(CO) fragments are bonded together *via* an unsupported Fe–Fe triple bond, with a dihedral angle of *ca*. 90° between the two CO ligands.[6] Compounds **1′** and **1*** exhibit wholly analogous matrix photochemistry, with methylation of the Cp ligands leading to the expected red-shift of the CO-stretching bands in the IR.†

The presence of terminal CO ligands in **3**, **3′** and **3*** is highly unusual. Other $[\{CpM(EO)\}_2]$ complexes of first-row transition elements, such as $[\{CpCo(CO)\}_2]$, contain bridging EO ligands.[7] $[\{CpPt(CO)\}_2]$ does have terminal CO ligands, but it seems likely that the Pt–Pt single bond in the latter is too long to support bridging CO ligands.[8]

In order to add insight into the unusual structure of **3**, we have performed electronic structure calculations of **3** using density functional theory.‡ We and others have used this methodology to predict the structures of metal carbonyl complexes with good success.[9] The calculated lowest-energy structure of **3** has C_{2v} symmetry with two symmetric bridging CO ligands [Fig. 1(*a*)], corresponding to a $^1A_1$ closed-shell electron configuration. The calculated dihedral angle between the two Fe–C(O)–Fe planes is 125°; it can therefore be viewed as structurally analogous to **2** with the removal of one of the μ-CO ligands.

We were initially puzzled by the apparent disagreement between this calculated structure of **3** and the one indicated by experiment. However, **3** is produced by a triplet precursor (**2**), and **3** readily back-reacts to form **2**, even in frozen matrices at < 90 K. These observations suggest that the conversion **3** + CO → **2** is a spin-allowed reaction, which would require that **3** be a triplet molecule. Our calculations on excited triplet states of **3** indicate that a low-lying ^3B state has a C_2 structure in perfect accord with that proposed from the matrix experiments, *viz.* terminal CO ligands and a dihedral angle of 86° [Fig. 1(*b*)].§ These calculations provide support for the notion that the double-CO-loss products **3**, **3′** and **3*** are produced as excited triplet molecules.

Our calculated Fe–Fe bond lengths for *trans*-**1** (2.548 Å) and **2** (2.274 Å)[10] are in good agreement with the crystallographic Fe–Fe bond lengths in *trans*-**1** (2.534 Å)[11] and **2** (2.265 Å).[5] These results give us confidence in the reliability of our calculated Fe–Fe bond lengths in the singlet and triplet forms of **3**, which are 2.116 Å and 2.189 Å, respectively. Both of these are significantly shorter than the Fe–Fe bond length in **2**, consistent with an increase in the formal Fe–Fe bond order from two in **2** to three in **3**.

The gross structural change predicted between the ground-state bridging-CO singlet form of **3** (denoted ^{1}**3**) and the terminal-CO triplet form of **3** (^{3}**3**) is unprecedented and suggests that ^{3}**3** is the kinetically favored product of the irradiation of **2**.

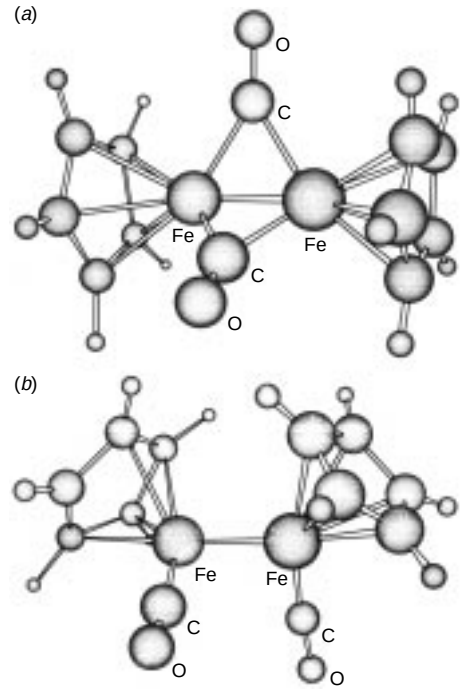

Fig. 1 (*a*) Calculated structure of the singlet ground-state structure of $[Cp_2Fe_2(CO)_2]$ **3**. Selected calculated metric parameters: Fe–Fe 2.116 Å, Fe–C(CO) 1.926 Å, Fe–(Cp centroid) 1.773 Å, Fe–Fe–(Cp centroid) 174°, dihedral angle between Fe–C(CO)–Fe planes 125°. (*b*) Calculated structure of the unbridged ^{3}B excited state of **3**. Selected calculated metric parameters: Fe–Fe 2.189 Å, Fe–C(CO) 1.778 A, Fe–(Cp centroid) = 1.850 A, Fe–Fe–(Cp centroid) 141°, dihedral angle between Fe–Fe–C(CO) planes 86°.

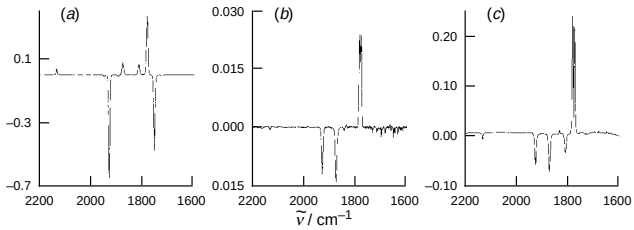

Fig. 2 Difference IR spectra of the CO-stretching region of a frozen solution of **1*** in 3-methylpentane at 98 K. (*a*) Difference spectrum obtained by subtracting the initial spectrum prior to irradiation from the spectrum obtained after 150 min irradiation. (*b*) Difference spectrum obtained by subtracting the spectrum immediately following 150 min irradiation from the spectrum obtained after 150 min irradiation followed by 5 min of thermal (dark) reaction at 98 K. (*c*) Difference spectrum obtained by subtracting the spectrum immediately following 150 min irradiation from the spectrum obtained after 150 min irradiation followed by dark warming of the matrix to 163 K and cooling back to 98 K.

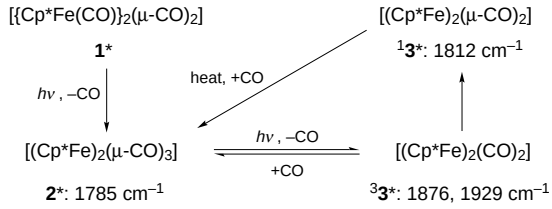
It also suggests that, under appropriate conditions, ^{3}**3** should relax to form ground-state ^{1}**3**. We now believe that we have observed ^{1}**3*** in new matrix photochemical experiments.

When a frozen solution of **1*** (1 mM) in neat 3-methylpentane is irradiated for 150 min, we observe IR bands for free CO (2132 cm^{-1}), **2*** (1785 cm^{-1}), and ^{3}**3*** (1876 cm^{-1}; the 1929 cm^{-1} band of ^{3}**3*** is obscured by a band of **1***). We also observe a new bridging-CO band at 1812 cm^{-1} [Fig. 2(*a*)]. Observation at short irradiation times (< 5 min) indicates that the species that causes the band at 1812 cm^{-1} is formed only after ^{3}**3*** is formed. If the irradiation is discontinued and the matrix maintained at 98 K, we observe, *via* difference IR spectroscopy, only the thermal back-reaction ^{3}**3*** + CO → **2***, as was the case in the original report of **3** [Fig. 2(*b*)].[6] The band at 1812 cm^{-1} does not disappear on standing at 98 K. However, if the dark matrix is warmed to 163 K, we observe that free CO, ^{3}**3***, and the species at 1812 cm^{-1} are consumed as **2*** is produced [Fig. 2(*c*)]. We see analogous results upon prolonged irradiation of a matrix of **1′**, with the new band blue-shifted to 1833 cm^{-1}.

These new experimental data are consistent with the slow thermal or photochemical formation of ^{1}**3*** and ^{1}**3′** from ^{3}**3*** and ^{3}**3′**, respectively, and the slower (higher activation energy) back-reactions of ^{1}**3*** and ^{1}**3′** with CO to reform **2*** and **2′**. The slowness of these conversions is expected given that they are spin-forbidden. If our calculated structure of ^{1}**3** is correct, then the 1812 and 1833 cm^{-1} bands are likely the antisymmetric (B_1 under C_{2v} symmetry) stretching mode of the bridging CO ligands in ^{1}**3*** and ^{1}**3′**, respectively. The symmetric A_1 mode for each molecule should be at higher energy and, assuming the dipole moment changes are similar, will be only about half as intense as the B_1 mode. We have not yet observed the A_1 band for either ^{1}**3*** or ^{1}**3**. Our proposed series of transformations in the matrix photochemistry of **1*** is summarized in Scheme 1.



Scheme 1 Summary of proposed matrix photochemistry of **1*** in frozen 3-methylpentane

Direct kinetic access to the triplet double-CO-loss photoproducts such as **3** is a consequence of the symmetry-driven triplet ground state of the single-CO-loss photoproduct **2**. Lowering the symmetry of the initial precursor should favor the formation of singlet rather than triplet products. We believe that we have observed such an effect in the photochemistry of the lower-symmetry precursor [{Cp*Fe(CO)}$_2$(μ-CO)(μ-CH$_2$)], which forms a double-CO-loss product with a bridging or semi-bridging CO ligand.[12] We will continue to explore this interplay between spin state and structure in the photochemistry of other DOCs.

† IR data in the CO-stretching region for relevant species in frozen 3-methylpentane at 90–100 K: **2′**, 1797 cm^{-1}; **2***, 1785 cm^{-1}; **3′**, 1886, 1942 cm^{-1}; **3***, 1876, 1929 cm^{-1}.

‡ *Computational details*: density functional calculations were carried out using the Amsterdam Density Functional (ADF) package, Version 2.1 (Theoretical Chemistry, Vrije Universiteit, Amsterdam, The Netherlands). The calculations employed the local density functional of Vosko, Wilk, and Nusair (S. H. Vosko, L. Wilk and M. Nusair, *Can. J. Phys.*, 1980, **58**, 1200). Non-local corrections to the exchange and correlation used the methods of Becke (A. D. Becke, *Phys. Rev. A*, 1988, **38**, 3098) and Perdew (J. P. Perdew, *Phys. Rev. B*, 1986, **33**, 8822), respectively. The atomic basis sets used were triple-ζ for the Fe atoms, double-ζ plus polarization for the CO ligands, and double-ζ for the Cp ligands. Geometries were fully optimized using gradient techniques under the constraint of C_2 symmetry.

§ The ^{3}B state is not the lowest energy triplet state of **3**. The lowest-energy triplet state, $^3B_1$, which we calculate to be *ca*. 20 kcal mol^{-1} (1 cal = 4.184 J) lower than the ^{3}B state, corresponds to a doubly bridged C_{2v} structure, like the ground state. We propose that the irradiation of **2*** produces both ^{3}B unbridged and $^3B_1$ bridged **3***. We further propose that the latter state, which we do not observe experimentally, undergoes a rapid, essentially barrier-free back-reaction with CO to reform **2***. A complete analysis of the excited states will be provided in a separate publication.

One-step synthesis of a quaternary tetrapyridinium macrocycle as a new specific receptor of tricarboxylate anions

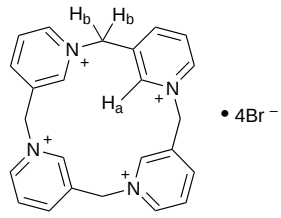
Satoshi Shinoda,*[a] Makoto Tadokoro,[a] Hiroshi Tsukube[a] and Ryuichi Arakawa[b]

[a] *Department of Chemistry, Faculty of Science, Osaka City University, Sugimoto, Sumiyoshi-ku, Osaka 558, Japan*
[b] *Department of Applied Chemistry, Kansai University, Yamate-cho, Suita 564-80, Japan*

A new type of quaternary tetrapyridinium macrocycle has been readily prepared *via* a one-step reaction, which showed characteristic selectivity for certain tricarboxylate anions upon 1 : 1 complexation.

Because anion recognition plays an important role in many biological processes, much effort has been devoted to designing specific anion receptors in molecular recognition chemistry.[1,2] In most of the reported receptors, positively charged groups such as ammonium and guanidinium units have been commonly introduced as binding sites, with electrostatic attraction between ion pairs predominantly contributing to the stability of the complexes.[3] Structural complementarity also affects both the selectivity and stability of the anion complexation. Kimura and Hosseini and Lehn demonstrated[4] that some protonated polyazamacrocycles bound carboxylates and phosphates, and exhibited interesting anion selectivity. Since the number of synthetic receptors specific for anions is still limited, a new class of macrocycles having well-defined geometrical and binding features should be developed, especially for specific recognition of biologically important organic polyanions.

Here, we present the one-step synthesis, crystal structure and anion binding property of a new macrocyclic receptor **1**.† Although polyammonium macrocycles have been presented as effective anion receptors, macrocycle **1** is remarkable for the following reasons. (1) Macrocycle **1** was directly derived from 3-bromomethylpyridine and its synthetic procedure was extremely simple. (2) The macro-ring is composed of four pyridinium rings having structurally and electrostatically well-defined features. (3) The positive charge of **1** is permanent and active even under neutral or weakly alkali conditions, while corresponding aliphatic polyammoniums are not fully protonated under such conditions.

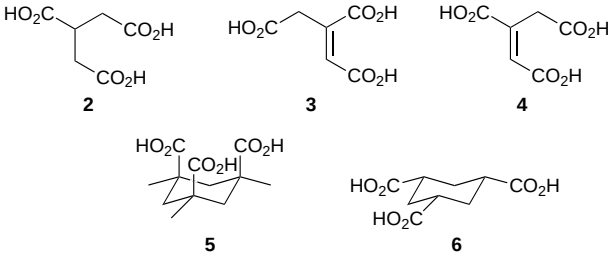


1

An aqueous solution of 3-bromomethylpyridinium bromide (4.5 g, 18 mmol) was neutralized with $NaHCO_3$ and the resulting 3-bromomethylpyridine was immediately extracted in CH_2Cl_2 (40 ml). When the solvent was evaporated at room temperature, *N*-alkylation vigorously occurred to yield a mixture of quaternary pyridinium salts. Hydrated single crystals of the tetrapyridinium bromide **1**, $C_{24}H_{24}N_4Br_4{\cdot}2H_2O$,‡ were isolated by recrystallization from water (230 mg, 0.32 mmol). A mixture of linear oligomeric pyridinium salts was obtained as major products, but product analysis by capillary electrophoresis revealed that cyclic compounds having different ring sizes were not formed under the employed conditions. *N*-Alkylation also occurred in refluxing CH_2Cl_2, which gradually yielded cyclic tetramer and linear polymer.

The crystal structure§ of **1**·$2H_2O$, determined by an X-ray diffraction study, indicates that the 16-membered ring containing four pyridine nitrogen atoms with positive charges is almost in one plane (Fig. 1). Of the four counter bromide anions, two are located inside the macrocycle, while the others are located outside the macrocycle. The distances between these bromide anions and the H_a protons of the pyridine rings are in the range 2.65–2.79 Å, which are shorter than the sum of the van der Waals radius of a hydrogen atom and the ionic radius of a bromide anion (3.17 Å).[5]

The binding property¶ of **1** for tricarboxylate anions was investigated by ^1H NMR titration experiments in D_2O in which the pH value was initially adjusted to be 7–8 with $NaHCO_3$ to make guest anions in the trivalent forms. Five tricarboxylic acids were employed: acyclic tricarboxylic acids **2**–**4** and cyclohexane tricarboxylic acids **5** and **6**. When **3** was employed as a guest, large downfield shifts ($\Delta\delta$ = 0.83 ppm, 1 equiv.) were observed for the H_a proton signal†† while the signals for other aryl protons shifted slightly upfield ($\Delta\delta$ = 0.13 ppm, 1 equiv.). Other tricarboxylates **2**, **4** and **5** gave similar ^1H NMR spectral changes and the observed titration curves showed saturation and were well fitted by the 1 : 1 complexation, although **6** provided too small changes in the ^1H NMR spectra to precisely analyze. The binding constants *K* were calculated



2

5

6

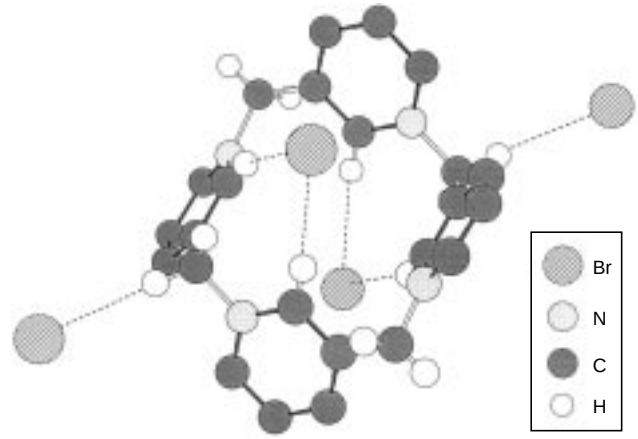

Fig. 1 Crystal structure of **1**·$2H_2O$. Hydrogen atoms other than H_a and H_b are omitted for clarification.

from the computer analysis,[6] indicating that **1** offered interesting anion selectivity for the four tricarboxylates; **3** (log K = 5.1) > **4** (4.5) ≈ **2** (4.4) > **5** (4.1). Among the acyclic tricarboxylates **2**–**4**, **3**, having two carboxylates fixed at the *cis*-1,2 positions, offered the largest K value. Because the employed tricarboxylates have the same net charges, the geometry of the three carboxyl groups should be an important factor for determining the stability and selectivity.[7] The order of the log K values parallels that of the chemical shift changes ($\Delta\delta$) of the H_a protons.‖

We have successfully prepared a new type of macrocyclic receptor *via* a one-step synthesis. Because of the pre-organized macrocyclic structure and highly positive charge, it specifically binds tricarboxylate anions at pH 7. Since its anion recognition behavior varied considerably from those observed with common protonated macrocyclic polyamines,[4,7] this study presents a new aspect of anion recognition chemistry with wide applications in related fields.

We thank Ms. S. Takeda of the Osaka National Research Institute, AIST, and Professor Akio Ichimura of Osaka City University for their helpful discussions. The facile loss of formic acid from an anion system in which the charged and reacting centres cannot interact

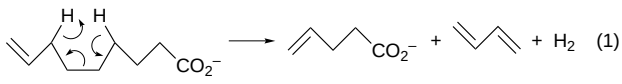
Suresh Dua,[a] John H. Bowie,[a] Blas A. Cerda[b] and Chrys Wesdemiotis[b]

[a] *Department of Chemistry, The University of Adelaide, Adelaide, South Australia, 5005, Australia*
[b] *Department of Chemistry, The University of Akron, Akron, Ohio, 44325-3610, USA*

Both the 3-[2-(2-formyloxy-1,3-[$^2H_6$]propyl)]adamantane carboxyate anion and cation undergo loss of HCO_2D from the 3 substituent by processes which occur remote from and uninfluenced by the carboxylate charged centre.

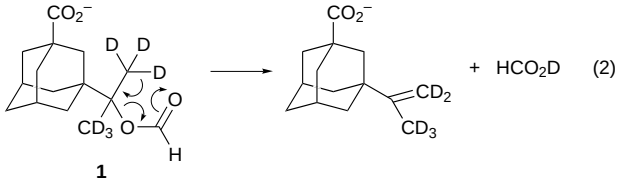
It has been proposed that reactions which occur remote from and uninfluenced by the charged centre (charge-remote reactions) can occur following collisional activation of even electron organic anions in the gas phase.[1,2] In support of this, charge-remote loss of a radical from an $(M - H)^-$ ion is sometimes observed when the product formed is a stable radical anion.[3] The evidence in favour of the loss of (even electron) neutrals commonly occurring by charge-remote processes from even electron anions is not strong however.[4] One such process which has been substantiated is the Gross reaction:[1,2,5,6] the particular example shown in eqn. (1) is energetically unfavourable (calculations indicate that $\Delta H = +209$ kJ mol^{-1} while the activation barrier is some 370 kJ mol^{-1}), and occurs following extensive hydrogen exchange along the carbon skeleton.[6] It appears that charge-remote reactions may occur when anion directed fragmentations are energetically unfavourable in comparison.



(1)

We have continued our search for charge-remote reactions utilising a system in which the anion site is unable to approach the reacting centre. Certain 1,3-disubstituted adamantanes fulfil this prerequisite, and we have chosen the carboxylate group as the anion site.

When cyclohexyl acetate is heated to 160 °C in solution, cyclohexene and acetic acid are formed in almost quantitative yield.[7] The reaction is slightly endothermic [$\Delta G = +18$ kJ mol^{-1} (ref. 8)] and the barrier is calculated [at MP4 (SDTQ)/6-31G* level for the model system ethyl formate] to be near 220 kJ mol^{-1}.[9] We have synthesised **1**† as an anion model for this reaction. The two substituents in **1** can neither interact through bonds, nor approach through space. The parent $(M - H)^-$ ion fragments by exclusive loss of HCO_2D (Fig. 1): this charge-remote reaction (which shows similarities to both the McLafferty rearrangement of a radical cation, and the Norrish 2 rearrangement of a diradical) is summarised in eqn. (2).



(2)

1

The neutrals formed following collisional activation of the unlabelled analogue corresponding to **1** have also been studied: the $^-N_fR^+$ spectrum (the compositive positive ion spectrum produced by ionisation of all neutrals formed following collisional activation of the parent negative ion)[5,6] of these shows a small peak on the side of the $CO_2^{\cdot+}$ peak which corresponds to *m/z* 46 ($HCO_2H^{\cdot+}$), establishing that formic acid is amongst the neutrals formed during fragmentation of unlabelled parent anion corresponding to **1**.

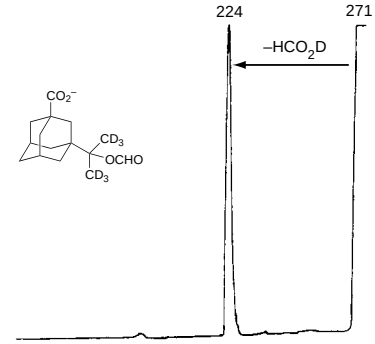


Fig. 1 Collisional activation mass analysed ion kinetic energy spectrum of **1**. VG ZAB 2HF mass spectrometer operating in negative chemical ionisation mode. The carboxylic acid precursor is deprotonated by HO^- (from H_2O), source pressure *ca.* 10^{-1} Torr (1 Torr = 133.322 Pa), collision gas Ar (pressure 5×10^{-7} Torr), for full experimental details see ref. 6.

Finally, if this reaction is uninfluenced by the charged centre, then it should also operate for the cognate species containing a carboxylate cation centre, provided of course that there is no low energy positive ion fragmentation which occurs in preference to the charge-remote reaction. A carboxylate cation cannot be formed by conventional positive ion mass spectrometry, but it is accessible by charge reversal[11] of anion **1**. The charge reversal spectrum of **1** (Fig. 2) [a charge reversal spectrum is the positive ion spectrum resulting from the energised $(M - H)^+$ species formed following collision induced charge stripping of the $(M - H)^-$ ion] shows small peaks due to $(M - H)^+$, $[(M - H)^+ - CO_2]$ and $[(M - H)^+ - HCO_2D]$

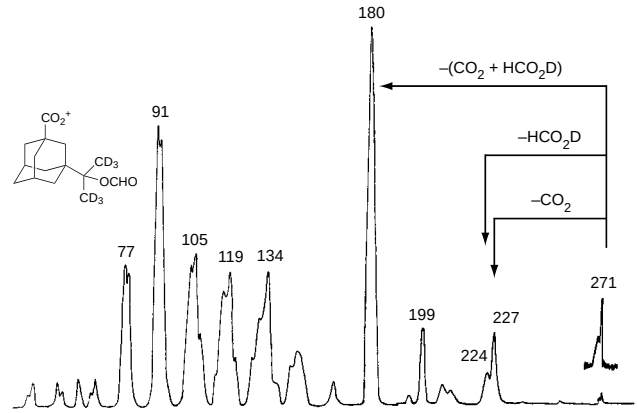

Fig. 2 Charge reversal (positive ion) mass spectrum of anion **1**. VG ZAB 2HF spectrometer. Experimental conditions as for Fig. 1 except that the voltage of the electric sector is reversed to allow the transmission of positive ions.

ions. The base peak is produced by the overall process [$(M - H)^+ - (CO_2 + HCO_2D)$] but it is not known whether loss of HCO_2D in this instance occurs from the $(M - H)^+$ and/or the [$(M - H)^+ - CO_2$] ions.

It is thus established experimentally that charge-remote loss of HCO_2D occurs from anion **1**, and also *via* the corresponding carboxylate cation.

Tandem Michael-aldol induced ring closure of dimethyl 2-phenylselenofumarate: a diastereoselective entry to novel 4-phenylseleno butano-4-lactone derivatives, versatile precursors of naturally occurring compounds

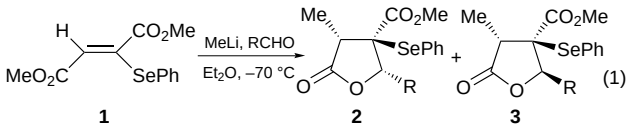
Franco D'Onofrio,*[b] Roberto Margarita,[a,b] Luca Parlanti,*[a,b] Giovanni Piancatelli[a] and Maurizio Sbraga[a]

[a] Dipartimento di Chimica and [b] Centro CNR di Studio per la Chimica delle Sostanze Organiche Naturali (Istituto Nazionale di Coordinamento 'Chimica dei Sistemi Biologici'), Università 'La Sapienza' P.le A. Moro 5, 00185 Roma, Italy

Tandem Michael-aldol induced ring closure of dimethyl 2-phenylsenofumarate gives, with good yields and diastereoselectivities, highly substituted 4-phenylselenobutano-4-lactones, which can be further transformed into naturally occurring substances.

The synthesis of trisubstituted butenolides and butano-4-lactones, in particular of their 4-carboxy-derivatives (paraconic acids), has attracted considerable attention in recent years, because of the wide range of biological activities exhibited by this class of compounds,[1] which includes substances such as lichesterinic, protolichesterinic, dihydroprotolichesterinic,[1b,2h,i] roccellaric,[2j] nephromopsinic,[2f] pertusarinic[2k] and phaseolinic[2l] acids. Many synthetic approaches to these molecules have been developed by a number of research groups over the past decades.[2,3]

In connection with our previous studies on the reactivity of dimethyl 2-phenylselenofumarate **1** as a Michael acceptor,[4b,c] we describe here a simple method for the diastereocontrolled synthesis of the novel highly functionalized 4-phenylselenobutano-4-lactones **2a–d**, **3a–d**, which involves a tandem Michael-Aldol induced ring closure [reaction (1), Table 1]. We



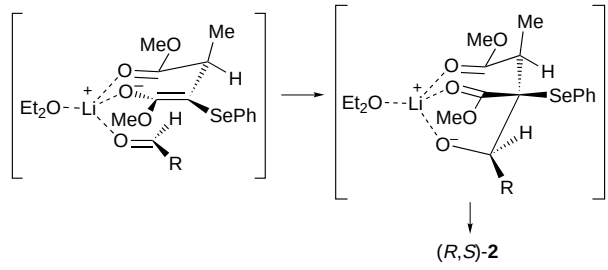
1 **2** **3**

also show the synthetic utility of the new molecules, which can be easily transformed into naturally occurring products, such as saturated and unsaturated paraconic acids.

As we described in a previous paper, the diester **1**, which is easily available from dimethyl maleate,[4a] reacts with MeLi in a Michael reaction, with no trace of the 1,2 addition products.[4b]

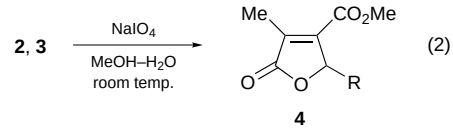
The anion resulting from this Michael addition can be easily trapped by adding an aldehyde to the reaction mixture; the resulting aldol adduct then instantaneously undergoes lactonization affording 4-phenylselenobutano-4-lactones **2a–d**, **3a–d** with good overall process yields [reaction (1), Table 1].†

As summarized in Table 1, the reaction proceeds with excellent diastereoselectivities when R = *n*-alkyl, aryl or 2-furyl; a lower diastereoselectivity is observed when an α,β-unsaturated aldehyde is used. The stereochemistry of the process could be rationalised assuming the formation of the chelated intermediate **A** resulting from the attack of MeLi and the subsequent approach of the aldehyde from the favoured *si*-face (Scheme 1).[5] However, the assignment of the relative stereochemistries of diastereoisomers **2** and **3** is based upon the following chemical evidence arising from further transformations of these compounds.



Scheme 1

First, **2** and **3** gave butenolides **4** *via* selenoxide *syn*-elimination when treated with $NaIO_4$,[6] [reaction (2), Table 2],



4

indicating that the phenylselenenyl and methyl groups in **2** and **3** must be in a *trans* relative configuration. Using **2a** and **3a** as starting compounds in this reaction allowed the synthesis of (*R*,*S*)-lichesterinic acid methyl ester **4a**; (*R*,*S*)-lichesterinic acid has been isolated from Icelandic moss *Cetraria islandica*.[7] This paraconic acid shows antibacterial activity towards Gram positive organisms,[7c] and various syntheses have already been reported in the literature.[3d,7c,8]

Secondly, in order to determine the relative configurations at C-5 in lactones **2** and **3**, hydrogenolysis of the C–Se bond of **2a**,**b** was carried out.[9] The resulting products were identified as

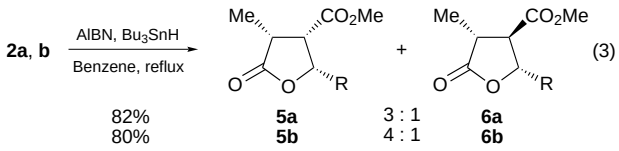
Table 1 Synthesis of γ-lactones **2a–d**, **3a–d**

R	**2** + **3**	Yield (%)	**2** : **3**
n-$C_{13}H_{27}$	**a**	71	93 : 7
Ph	**b**	58	89 : 11
2-Furyl	**c**	55	91 : 9
CH_3CH=CH	**d**	66	71 : 29

Table 2 Transformation of γ-lactones **2a–d**, **3a–d** to butenolides **4a–d**

R	**4**	Yield (%)
n-$C_{13}H_{27}$	**a**	92
Ph	**b**	73
2-Furyl	**c**	81
CH_3CH=CH	**d**	82

5a,**b**, **6a**,**b** by comparison with the literature data [reaction (3)];[2k] this outcome was interpreted in terms of a structure for



(3)

82% **5a** 3 : 1 **6a**
80% **5b** 4 : 1 **6b**

compound **2** in which the substituent at C-5 and the methyl group at C-3 are in a *cis* relative configuration. Consequently, the lactone **3** must have the same groups in a *trans* configuration.

In addition, as the predominant isomer **5a** can be easily epimerized to **6a**,[2k] this transformation also has synthetic relevance, as **6a** is the methyl ester of the naturally occurring roccellaric acid, isolated from the chilenic lichen species *Roccellaria mollis*.[2b]

In conclusion, we have described a facile diastereoselective synthesis of novel highly functionalized 4-phenylselenobutano-4-lactones and their application in the synthesis from **1** of racemic paraconic acids esters *e.g.* **4a** and **6a**, with good overall yields (65 and 58%, respectively). Furthermore, this strategy allows good flexibility with respect to the substituent at C-5, which is characteristic of paraconic acids.

Development of a stereocontrolled methodology to prepare enantiomerically pure compounds[2] *via* this sequential process and extension of the methodology are underway in our laboratory.

† Typical experimental procedure: MeLi (1.1 mmol) was added to a stirred solution of **1** (1 mmol, 300 mg) at −70 °C in 10 ml of dry Et_2O, under argon atmosphere; the reaction mixture was allowed to react for 10 min and then the aldehyde (1.2 mmol), dissolved in 2 ml of dry Et_2O, was added. The resulting mixture was stirred at −70 °C for 1 h after which the temperature was raised to 0 °C and water was added. The solution was then extracted with ethyl acetate and the combined organic extracts were washed with aqueous $NaHCO_3$ and brine, dried over anhydrous Na_2SO_4 and concentrated under reduced pressure. Column chromatography on SiO_2 (hexane–ethyl acetate 9 : 1) afforded pure products **2** and **3**. Synthesis, structure and properties of $[Cr_2(PS_4)_4]^{6-}$; the first discrete transition metal cluster from thiophosphate flux reactions

Volkmar Derstroff, Vadim Ksenofontov, Philipp Gütlich and Wolfgang Tremel*

Institut für Anorganische Chemie und Analytische Chemie, Universität Mainz, Becherweg 24, D-55099 Mainz, Germany

The molecular cluster compound $[Cr_2(PS_4)_4]^{6-}$ forms by the reaction of Cr metal with thiophosphate fluxes.

Understanding the structural and reactivity relationships between molecules and extended solids of comparable compositions is a major challenge of synthetic inorganic chemistry. Many molecular cage and cluster compounds whose structural, and sometimes reactivity, features are comparable to those of metal oxide/chalcogenide/halide solids have been reported.[1–3] The well known behavior of metal alkoxides to oligomerize both in solution and in the solid state[4] has triggered studies on systems where a facile conversion of molecules to solids under mild conditions is possible, *e.g.* by using the sol–gel process[5] or by pyrolysis[6] of suitable precursors to achieve the desired solid product. The reverse process, an excision[7] of discrete metal clusters from extended solids, has received less attention so far.[8] Pioneering work has been done by the groups of Corbett[9] and Holm[10] who used solid state compounds containing discrete clusters as precursors for the synthesis of soluble species that are not accessible by solution methods. In contrast to tetrathiometalate complexes[11] metal coordination compounds with group 15 tetrathio anions as ligands (so-called Zintl-type ligands) are extremely difficult to stabilize in solution[12] because of their high negative charge and the lack of charge delocalization. The first representatives of this class of compounds are, however, easily accessible through solid state reactions† using polythiophosphate fluxes.[13]

The facile syntheses of the one-dimensional chain compounds $A_3[Cr_2(PS_4)_3]$ (A = K, Tl) whose structures contain the polymeric $^1_\infty[(Cr_2(PS_4)_3]^{3-}$ species[14] indicated that discrete $[Cr_2(PS_4)_4]^{6-}$ units might form from reaction systems containing a higher tetrathiophosphate content. In one Cr–P_2S_5–K_2S system containing the reactants in a 1 : 2 : 3 ratio at 600 °C the title compound formed in 85% yield after one week. The structure‡ of the title compound contains binuclear $[Cr_2(PS_4)_4]^{6-}$ clusters which are well separated from each other by K^+ cations. The anion portion of the clusters is shown in Fig. 1. The centrosymmetric $[Cr_2(PS_4)_4]^{6-}$ cluster consists of a $Cr_2(PS_4)_2$ core which is terminated on each side by two $[PS_4]^{3-}$ thiophosphate ligands in a bidentate fashion. In the core two $[PS_4]^{3-}$ ligands bridge two octahedrally coordinated Cr atoms employing three S atoms each. The remaining S atom is nonbonding. Relative to the idealized T_d anion symmetry, metal coordination decreases the S–P–S angle while the angle unbridged by Cr is considerably expanded. The Cr atoms are coordinated by three $[PS_4]^{3-}$ ligands where each thiophosphate group furnishes two S atoms to complete the octahedral S coordination of the metal. The Cr···Cr distance within the dimer is 3.523(1) Å. The unique Cr–S distance is comparable to that in CrP_3S_{9+x}[15] the individual Cr–S distances ranging from 2.387(1) to 2.485(1) Å.

Magnetic susceptibility measurements in the temperature range 4–300 K show that the Cr^{3+} centers within the binuclear units are antiferromagnetically coupled. This can be ascribed to a small antiferromagnetic exchange coupling between the Cr atoms in the dimeric units. The magnetic behavior can be modeled with the use of an isotropic Heisenberg–Dirac–Van Vleck dimer model for an $S_1 = S_2 = 3/2$ and an exchange coupling constant $J = -4$ cm^{-1}. The corresponding room temp. moment corrected for diamagnetism, $\mu_{eff} = 3.78\ \mu_B$, is slightly smaller than the spin-only value of 3.87 μ_B for Cr^{III} with $S = 3/2$. The optical spectrum of $K_6[Cr_2(PS_4)_4]$ exhibits a sharp optical gap consistent with semiconducting behavior. The experimentally determined value is $E_g = 1.36$ eV. Thermal analysis shows that $K_6[Cr_2(PS_4)_4]$ melts without decomposition at 433.8 °C.

$K_6[Cr_2(PS_4)_4]$ easily dissolves in DMF or acetonitrile upon addition of 2,2,2-cryptand, although so far we were unable to obtain precipitates with large cations in single-crystalline form. This behavior indicates the potential of $[Cr_2(PS_4)_4]^{6-}$ as a precursor for the synthesis of Zintl anion complexes in solution. The solutions of $K_6[Cr_2(PS_4)_4]$ in DMF are stable according to UV–VIS for 1–2 days. In DMF solution the $[Cr_2(PS_4)_4]^{6-}$ chromophore shows one strong absorption at 615 nm.

$K_6[Cr_2(PS_4)_4]$, the first transition metal thiophosphate with PS_4^{3-} ligands has been synthesized from molten polythiophosphate fluxes. Its structure contains the $[Cr_2(PS_4)_4]^{6-}$ cluster as a molecular analogue of the $[Cr_2(PS_4)_3]^{3-}$ units observed in the one-dimensional chain compound $K_6[Cr_2(PS_4)_4]$.[14] The $[Cr_2(PS_4)_4]^{6-}$ cluster is one of the few known complexes with a complete Zintl anion coordination sphere; it is stable in solution and may be useful as a synthon for 'wet' chemistry.

Steric acceleration in the reaction of aryl bromides with tributylstannyl radicals

David Crich* and Francesco Recupero

Department of Chemistry, University of Illinois at Chicago, 845 West Taylor Street, Chicago, IL 60607-7061, USA

Approximate absolute rate constants for the abstraction of bromine from a series of aryl bromides by stannyl radicals have been determined: 2,4,6-tri-*tert*-butylbromobenzene and 2,4,6-triphenylbromobenzene are found to be unusually reactive, most likely owing to steric acceleration.

Like many radical reactions,[1–5] the abstraction of a halogen atom from an aryl or vinyl halide by a stannyl radical is subject to polar effects. This much was demonstrated by Curran who showed that aryl halides carrying electron-withdrawing groups in the *ortho* or *para* positions react more rapidly with tin hydrides than do their unsubstituted congeners.[6] This is readily understood in terms of a polar transition state [eqn. (1)] with a partial negative charge on the sigma framework of the developing aryl radical.[6] We had therefore anticipated that 2,4,6-tri-*tert*-butylbromobenzene, with its sterically bulky, electron-donating alkyl groups, would be considerably less reactive than bromobenzene itself toward stannyl radicals. In the event, as we report here, the opposite was found to be the case: the abstraction of bromine from 2,4,6-tri-*tert*-butylbromobenzene by $Bu_3Sn\cdot$ is subject to a considerable acceleration due to the relief of steric strain.

In the course of an ongoing investigation, we had occasion to prepare 2,4,6-tri-*tert*-butyl- and 2,4,5-tri-iso-propylbromobenzene and to compare their reactivity toward tributyltin hydride with that of bromobenzene itself. Crude competition experiments revealed that, contrary to expectation, both were consumed somewhat more rapidly than the parent compound. We therefore undertook a more thorough investigation, comprising a series of competition experiments for a limited quantity of stannane. The initial and final ratios of both substrates in a given competition were determined by capillary GC or ^{1}H NMR spectroscopy, as appropriate, and the relative rates (k_{Rel}) computed using eqn. (2).[6,7]

$$k_1/k_2 = \{\ln[[Ar^1Br]_i/([Ar^1Br]_i - [Ar^1H])]\}/ \{\ln[[Ar^2Br]_i/([Ar^2Br]_i - [Ar^2H])\} \quad (2)$$

In this manner the relative rates set out in Table 1 were obtained.† The approximate absolute rate constants were then obtained using the known bimolecular rate constant for reaction of $Bu_3Sn\cdot$ with 1-bromodecane.[6] As is clear from Table 1, 2,4,6-tri-*tert*-butylbromobenzene is indeed considerably more reactive toward bromine abstraction by the stannyl radical than is 2,4,6-tri-iso-propylbromobenzene, being only slightly less reactive than 1-bromodecane. 2,4,6-Tri-iso-propylbromobenzene has comparable reactivity to 2-phenylbromobenzene and is some 2.6 times less reactive than 2-acetylbromobenzene. As this latter was found to be 6.7 times more reactive than 4-*tert*-butylbromobenzene, considered to be a model for bromobenzene itself, by Curran,[6] we conclude that 2,4,6-tri-iso-propylbromobenzene is some 2.6 times more reactive than bromobenzene. 2,4,6-Triphenylbromobenzene[8,9] was found to have identical reactivity to 1-bromodecane. We also studied pentafluorobromobenzene and found that it was so reactive toward the stannyl radical that we were unable to determine accurate ratios in competition experiments with 2-acetylbromobenzene; consequently we report a only minimum relative rate. With the likely exception of the perfluoroalkyl bromides,[10] pentafluorobromobenzene is the most reactive aryl or alkyl bromide toward stannyl radicals studied to date.

The reactivities of 2-phenyl- and 2-acetyl-bromobenzene are fully in accord with the polarized transition state [eqn. (1)] proposed by Curran. That of pentafluorobromobenzene likewise fits this model, although we cannot rule out an electron transfer chain mechanism in this case. The enhanced reactivity of 2,4,6-tri-iso-propylbromobenzene and especially that of 2,4,6-tri-*tert*-butylbromobenzene we attribute to acceleration due to relief of steric strain.‡ Such examples of steric acceleration of bimolecular radical reactions are much less common[1,11] than their unimolecular counterparts.[12] The reactivity of 2,4,6-triphenylbromobenzene can be ascribed to the symbiosis of three effects: (i) the stabilization of the polar transition state by the three phenyl groups phenyl substituents, (ii) relief of steric strain and (iii) relief of steric inhibition of resonance. However, as with pentafluorobromobenzene, we cannot rule out a single electron transfer mechanism in this case.

In conclusion, we have provided evidence that the abstraction of bromine from aryl bromides by stannyl radicals is accelerated when it leads to a relief of steric strain with bulky *ortho* substituents. Moreover, this acceleration is sufficient to overcome unfavourable polar effects in the transition state.

We thank the NSF (CHE 9625256) for partial support of this work. F. R. thanks the Politecnico di Milano for study leave and support.

Table 1 Relative reactivity of aryl bromides toward tributyltin radicals

Entry	Bromide	k_{Rel}	k/M^{-1} s^{-1}
1	Pentafluorobromobenzene	> 50	$> 1 \times 10^8$
2	1-Bromodecane	15.2	5.8×10^7
3	2,4,6-Triphenylbromobenzene	15.2	5.8×10^7
4	2,4,6-Tri-*tert*-butylbromobenzene	9.5	2.9×10^7
5[a]	2-Acetylbromobenzene	6.7	1.6×10^7
6	2-Phenylbromobenzene	2.6	6.2×10^6
7	2,4,6-Tri-iso-propylbromobenzene	2.6	6.2×10^6
8[a]	4-*tert*-Butylbromobenzene	1	2.4×10^6

† All experiments were conducted a minimum of two times with good reproducibility.

‡ Space filling molecular models (CHEM3D) show that while the bromine atom in both 2,4,6-tri-*tert*-butylbromobenzene and 2,4,6-triphenylbromobenzene is in a very congested environment, it is sufficiently well-exposed to permit abstraction by $Bu_3Sn\cdot$ through a linear transition state.

Cobaltabis(dicarbollide) derivatives as extractants for europium from nuclear wastes

Clara Viñas,[a] Sílvia Gomez,[a] Josep Bertran,[a] Francesc Teixidor,*[a]† Jean-François Dozol*[b]‡ and Hélène Rouquette[b]

[a] *Institut de Ciència de Materials de Barcelona, Campus de la U.A.B., 08193 Bellaterra, Spain*
[b] *D.C.C./D.E.S.D./S.E.P., C.E.A. Cadarache, 13108 Saint Paul lez Durance, France*

Carbon substituted derivatives of [3,3′-Co(1-Me-2-R-1,2-$C_2B_9H_9)_2$]$^-$ incorporating lipophilic chains [R = $(CH_2)_3O(CH_2)_2OMe$ 1, $(CH_2)_3OCH_2CHMe_2$ 2, $(CH_2)_6O(CH_2)_3Me$ 3, $(CH_2)_3Me$ 4], are synthesized for the first time and tested for extraction of ^{152}Eu; compound 3 showed the best performance, and it proved to have higher efficiency in transport at low acidity than the well known calixarene derivatives.

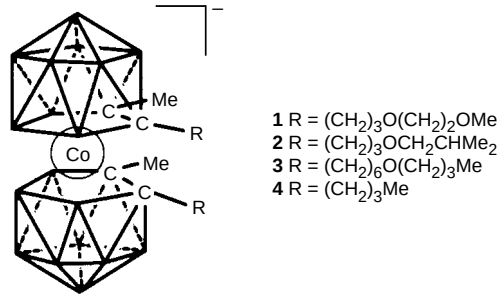
Up to now, a large variety of metallacarboranes have been prepared using the [7,8-$C_2B_9H_{11}$]$^{2-}$ (dicarbollide) ligand.[1,2] Of them, [3,3′-Co(1,2-$C_2B_9H_{11})_2$]$^-$ [cobaltabis(dicarbollide)] has attracted the most attention, as it is very robust, withstanding strong acid, moderate base, high temperatures and intense radiation.[3] The stability of this ion makes it interesting in nuclear waste remediation.[3,4]

Cobaltabis(dicarbollide) is capable of removing caesium ions (and with much less efficiency strontium and trivalent lanthanides and actinides) with high selectivity from acidic fission product solution.[3,4]

The problem of removing caesium and strontium from nuclear wastes has been widely treated previously.[3–7] However, the extraction of trivalent actinides has still to be investigated. Since the properties of lanthanides and trivalent actinides are very similar, and handling of lanthanides is easier, the transplutonium elements were simulated by the γ emitter ^{152}Eu. We report here on some C-substituted derivatives of [3,3'-Co(1,2-$C_2B_9H_{11})_2$]$^-$, which in addition to maintaining the extracting properties of ^{137}Cs and ^{90}Sr, have proven to be very efficient in the extraction of ^{152}Eu.

Following a synthetic procedure developed previously in our group,[8] the reaction of [7-Me-8-R-7,8-$C_2B_9H_{10}$]$^-$ [R = $(CH_2)_3O(CH_2)_2OMe$, $(CH_2)_3OCH_2CHMe_2$, $(CH_2)_6O(CH_2)_3Me$, or $(CH_2)_3Me$],[9] with KOBu^t and $CoCl_2$ in dimethoxyethane at reflux for 30 h leads, after precipitation with aqueous CsCl, to a set of new products which are purified by TLC [ethyl acetate–acetonitrile (10 : 2)]; R_f (**1**) = 0.38, R_f (**2**) = 0.62, R_f (**3**) = 0.65, R_f (**4**) = 0.65 (Fig. 1).

A mixture of two geometric isomers were produced in this synthesis, which we were not able to separate (racemic mixture and *meso* form), owing to their extremely similar physical properties, however, chemical analyses establish their stoichiometric formulae. The shape of the NMR resonances clearly suggests the existence of more than one isomer.§



1 R = $(CH_2)_3O(CH_2)_2OMe$
2 R = $(CH_2)_3OCH_2CHMe_2$
3 R = $(CH_2)_6O(CH_2)_3Me$
4 R = $(CH_2)_3Me$

Fig. 1 Cobaltabis(dicarbollide) derivatives

Table 1 lists the distribution coefficient of europium, D_{Eu}, defined as the equilibrium ratio of europium between the organic and the aqueous phases. These were determined as previously described,[12] with the feed phase being an aqueous HNO_3 solution containing the radionuclides and the organic receiving phase being nitrophenyl hexyl ether.

At pH 3, compound **4** shows a very low D_{Eu}. The values of D_{Eu} are much better for compounds **2** and **3** which have only one oxygen atom in the alkylic chain. When a second oxygen atom is incorporated, as for compound **1**, D_{Eu} decreases. The results of the tests also show that the larger the exocluster chain the better the performance of the extracting agent. Compound **3** gives the best extraction coefficient. Attempts to synthesize cobaltabis(dicarbollide) derivatives with longer exocluster chains led to products which were difficult to isolate.

The distribution coefficient of the cation strongly decreases as acidity increases in the feeding solution.[4b] Despite this decrease of extracting ability in acidic medium, compounds **2** and **3** display good efficiency for the extraction of ^{152}Eu at pH 3.

The excellent results obtained for compound **3** prompted us to use it in transport tests at pH 3 using a reported method.[12] The transport of ^{152}Eu from aqueous HNO_3 solutions was followed by regular measurement of the decrease of radioactivity in the feed solution by γ spectrometry analysis. This allowed determination of the permeability constants P (cm h^{-1}) of ^{152}Eu permeation through the supported liquid membrane (SLM) for 3.5 h, as is described in the model of mass transfer proposed by Danesi[10]

$$\ln(C/C^0) = -\varepsilon\frac{S}{V}Pt$$

where C^0 and C are the concentrations of the cation in the feed solution at time t = 0 and t (mol dm^{-3}); ε is volumic porosity of the SLM (%); S is membrane surface area (cm^2); V is volume of feed and stripping solutions (cm^3); and t is time (h).

Transport experiments were carried out with addition of a linear polyether, nonylphenylnonaethylene glycol (Slovafol 909) to the organic phase (0.003 M) and using aqueous 1 M methylene diphosphonic acid (MDPA) as complexing agent in the stripping phase, to improve the transport of Eu.

Table 1 Distribution coefficients of ^{152}Eu (D_{Eu}) in aqueous HNO_3–nitrophenyl hexyl ether

	D_{Eu}		
Compound	pH = 3	pH = 2	pH = 1
1	16	9	0.06
2	> 1000[a]	> 1000[a]	0.05
3	> 1000	—	0.15
4	3.5	0.09	0.05

[a] A precipitate appears, which leads to a lack of precision in the determination of the distribution coefficient D.

It is found that transport is very rapid at pH 3. Under these conditions, compound **3** shows a permeability P of 8.9 cm h^{-1}, *i.e.* an extraction of 31.2% after 1 h or 91.3% after 3.5 h. Calixarene derivatives, which are known as excellent extractants for this type of radionuclides, show a value of 7.0 cm h^{-1} for ^{239}Pu (feeding phase: aqueous 1 M HNO_3),[11] *i.e.* lower than the value obtained with compound **3**. Furthermore, with other carriers such as diphosphine dioxides under similar conditions, transport is much slower: a permeability of 1.4 cm h^{-1} for ^{237}Np and 3.4 cm h^{-1} for ^{239}Pu were reported (feeding phase: aqueous 1 M HNO_3).[12]

This report shows that the efficient ^{137}Cs extractants, $[3,3'\text{-Co}(1,2\text{-}C_2B_9H_{11})_2]^-$, can be adequately tuned by appropriate cluster C-substitution to enhance ^{152}Eu and hopefully transplutonides. By this monoxygen C-substitution, the ^{152}Eu affinity of the $[3,3'\text{-Co}(1,2\text{-}C_2B_9H_{11})_2]^-$ derivatives has been extraordinarily enhanced with respect to the non-substituted parent compound, and its affinity towards ^{137}Cs and ^{90}Sr has not been decreased. For instance, **3** displays $D_{Cs} > 1000$ and $D_{Sr} = 8$ at pH 3, with $P = 15.8$ and 22.3 cm h^{-1}, respectively. Owing to the existence of more specific ^{137}Cs extracting agents such as calixarene or $[3,3'\text{-Co}(1,2\text{-}C_2B_9H_{11})_2]^-$, it should be possible to separate the elements. However, many questions arise in terms of the coordinating mode of these ligands towards ^{152}Eu that require further work, such as the position of the oxygen in the organic chain, or why the membrane transport is accelerated when polyethyleneglycols are incorporated in it.

Homogeneous catalysis. Mechanisms of the catalysed Mukaiyama cross-aldol reaction

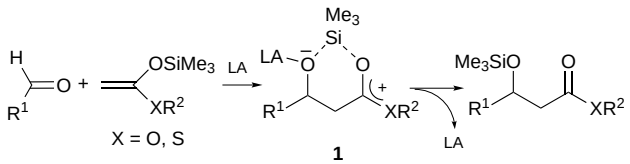
William W. Ellis and B. Bosnich*

Department of Chemistry, The University of Chicago, 5735 South Ellis Avenue, Chicago, Illinois 60637, USA

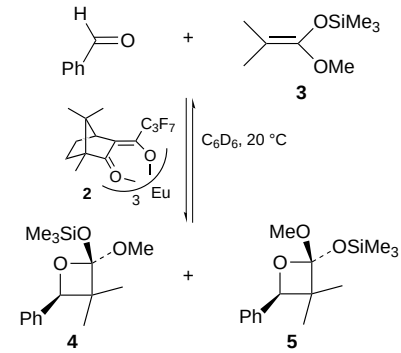
It is shown that [2 + 2] addition intermediates can form reversibly in the catalysed Mukaiyama reaction; these serve to prevent formation of the catalyst Me_3Si^+ and the reactivities of the [2 + 2] intermediates can affect the enantioselectivity of the reaction.

The Mukaiyama cross-aldol reaction is a versatile carbon–carbon bond-forming reaction which is catalysed by a variety of Lewis acids.[1] It is generally assumed to proceed by way of a cyclic intermediate **1** which allows for transfer of the silyl group (Scheme 1). For certain Lewis acids, however, intramolecular silicon transfer does not occur, rather the trimethylsilyl group is captured by the carbonyl substrate[2,3] and catalysis occurs by means of the powerful Me_3Si^+ catalyst.[2] Despite the possible widespread intervention of the (achiral) Me_3Si^+ catalytic path, there are a number of reports of chiral Lewis acid catalysts which give excellent enantiomeric excesses (ees),[4] indicating that for these catalysts, the unwanted Me_3Si^+ path is suppressed. The question then arises as to which type of Lewis acids will allow for one or other of the possible catalytic paths. It is probable that if the Lewis acid–oxygen bond of the aldolate **1** is weak and the bound oxygen atom is a good nucleophile, the rate of the silyl transfer step will be enhanced and consequently the capture of the Me_3Si^+ group by external nucleophiles will be suppressed. The direct silyl transfer path as illustrated in Scheme 1, however, may not be the only component of the mechanism because it is possible that an oxetane could form by capture of the carbenium ion of the intermediate. It is known that oxetanes are formed by Lewis acid-catalysed coupling of aldehydes and dialkyl ketene acetals.[5] The formation of the oxetane would be the equivalent of the Mukaiyama reaction, as an acidic workup would provide the desired aldol product. We report here on the detection of oxetanes in the Mukaiyama reaction using lanthanide and zinc complexes, both of which were expected to form aldolate intermediates with weak metal–oxygen bonds.

In benzene solution at 20 °C, the catalyst [Eu(hfc)$_3$] **2** (4 mol%) promotes the reaction between benzaldehyde and the ketene acetal **3** to give initially the two oxetane isomers **4** and **5** (Scheme 2). We have not been able to isolate these oxetanes in pure form but they have been characterized by their ^{1}H and ^{13}C NMR spectra, although the identity of the isomers **4** and **5** was not established.† The initial (kinetic) ratio of the isomers is 48 : 52 which slowly reaches an equilibrium ratio of 38 : 62. At 1 M concentration of each of the substrates, a maximum yield of 56% for the two oxetanes is obtained after 1 h in benzene solution at 20 °C using 4 mol% catalyst. Isomer equilibrium occurs over 2 h. The maximum yield of oxetanes (**4** and **5**) decreases upon dilution of the reaction solution, indicating that



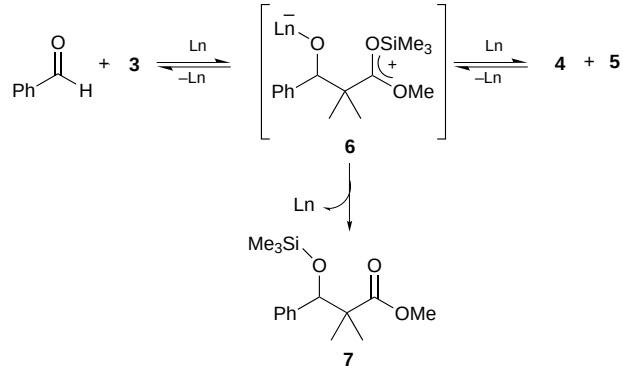
Scheme 1



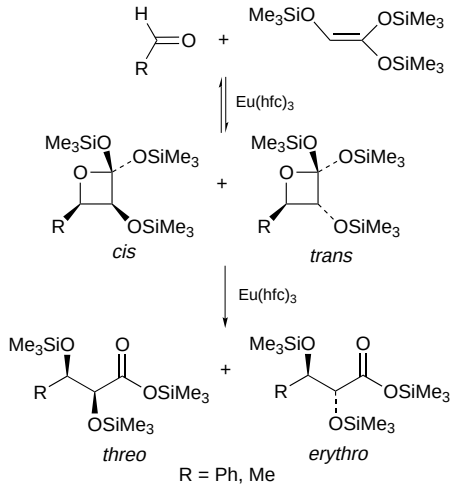
Scheme 2

the equilibrium illustrated in Scheme 2 obtains ($K \approx 3$ at 20 °C). Addition of 1 M pyridine quenches catalysis, but the addition of the hindered base, 2,6-di-*tert*-butyl-4-methylpyridine, does not affect the rate of catalysis. This latter observation indicates that the reaction in Scheme 2 is neither proton-initiated nor proton-catalysed. Under these conditions—4 mol% catalyst, 1 M each of substrates, benzene solution, 20 °C—the Mukaiyama product begins to appear after several hours and, after seven days, all of the substrates and intermediates are converted to this product. The Mukaiyama product is irreversibly formed because a 15% ee (*S*)[6] was found using the (+)-hfc catalyst, and the ee of the product did not change in the presence of the catalyst after two weeks. It was found that, after equilibration of the two oxetanes, their hydrolysed product had 0% ee using the (+)-hfc catalyst but a 5% ee (*S*) was observed for the hydrolysed products derived from the kinetically formed oxetanes (*ca.* 10% conversion to oxetanes).‡ This observation also supports the view that equilibration between substrates and oxetanes exists (Scheme 2).

The results are consistent with the mechanism outlined in Scheme 3 (Ln = **2**). In this case, the rate of production of the oxetanes by carbenium ion capture and the reverse reaction are faster than silyl transfer to produce the Mukaiyama product **7**. As might be expected, these relative rates vary according to the nature of the substrates and the catalyst. This is illustrated by a



Scheme 3



Scheme 4

comparison of the reactions shown in Scheme 4, where it is found that in catalysis of benzaldehyde, a *cis*:*trans* ratio of 80:20 is observed for the Mukaiyama product. For 1 mol% catalyst at 20 °C in benzene solution, the benzaldehyde reaction gives a *cis*:*trans* ratio of 75:25 at 40% conversion to the two oxetanes and 55:45 after 60% conversion.§ This change in isomer ratio occurs before significant amounts of the Mukaiyama products are formed, indicating that equilibration between the substrates and oxetanes occurs. Final equilibrium may not be established under these conditions, however, because a constant *cis*:*trans* ratio was not observed before the Mukaiyama product began to appear. For the analogous reaction with acetaldehyde (Scheme 4), under the same conditions, the rates of formation of the oxetanes and the Mukaiyama product are comparable. Similarly, the [Zn(facac)$_2$·2H$_2$O] (facac = hexafluoroacetylacetonate) complex catalyses the coupling between benzaldehyde and **3** but the equilibrium **4** ⇌ **5** is not established before significant amounts of the Mukaiyama product is formed (Scheme 2). With this zinc catalyst, no [2 + 2] addition products are observed in the coupling of benzaldehyde and CH$_2$=C(OSiMe$_3$)SBu^t indicating that catalysis proceeds either wholly by direct silyl transfer or, if [2 + 2] products are formed, their concentrations are very low. We note that neither the Eu nor the Zn catalysts lead to coupling of ketones with silyl ketene acetals nor coupling of silyl enol ethers with aldehydes or ketones.

The discovery of the [2 + 2] addition path for the catalysed Mukaiyama is significant in a number of respects. For cases where silyl transfer is slow in the intermediate **6** (Scheme 3), the more rapid oxetane formation will reduce the life-time of this intermediate. Consequently, the probability of Me_3Si^+ capture in **6** by external nucleophiles will be reduced. The Me_3Si^+ group is stable in the oxetanes. As was noted earlier, the mechanism illustrated in Scheme 3 is more likely to occur when the Lewis acid–alkoxide bond of the intermediate **6** is weak. Intermediates having strong alkoxide–Lewis acid bonds are unlikely to lead to oxetane formation or to silyl transfer. This appears to be the case for many catalysts which only serve as initiators for the production of Me_3Si^+ catalyst.[2]

These results suggest that identification of the enantioselective step can be a complicated problem because the ee will depend on the relative rates of formation of the various species. If equilibration between the substrates and oxetanes is much faster than formation of the Mukaiyama product, the ee will depend on the relative rates of silyl transfer which lead to the formation of the two enantiomers of the product. If, however, the rates of equilibration and product formation are comparable, the ee will depend on a complex mix of rates associated with all of the diastereomeric species in the mechanism. Under these circumstances, there would not be a single chirality-controlling step. The observations presented here may help in the design of effective enantioselective catalysts for the Mukaiyama reaction.

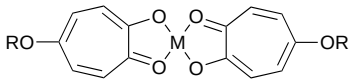
New metallomesogens core. New copper complexes with calamitic mesophases using tropolone based ligands. Crystal structure of bis(5-octyloxytropolonato)copper

John R. Chipperfield, Steve Clark, James Elliott and Ekkehard Sinn*

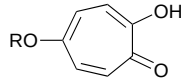
Department of Chemistry, University of Hull, Hull, UK HU6 7RX

A new class of metallomesogens based on 5-substituted tropolones with both enantiotropic and monotropic mesophase behaviour are prepared, the mesogenic properties are in line with the rod-like, calamitic nature of bis(5-octyloxytropolonato)copper shown in its crystal structure.

Most metallomesogens[1–4] have made use of benzene rings as integral parts of the rigid core. Seven-membered ring cores in metallomesogens are reported here for the first time. Tropolone-based organic liquid crystals have been reported by Uemura *et al.*,[5] and Mori *et al.*[6–9] Tropolone forms complexes with many metals in a manner analogous to acetylacetone,[10] but none were reported to be metallomesogens. We report here the first syntheses and studies of mesogenic complexes **1** based on tropolone.

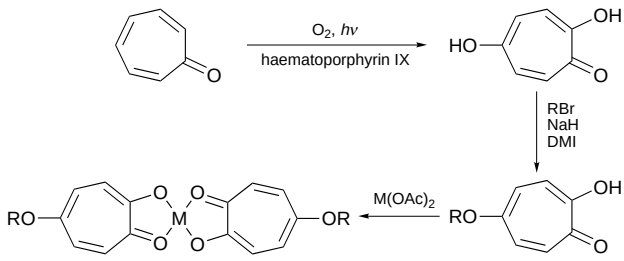


1 R = C_nH_{2n+1} (n = 8, 10, 12, 14, 16); M = Cu, Ni, VO



2a R = H,
b R = alkyl

We have modified the literature method[8] to make 5-substituted tropolones, **2b**, from 5-hydroxytropolone, **2a**, by using dimethylimidazolidinone (DMI) as solvent for alkylation of the 5-position to replace the carcinogenic HMPA.[8] DMI has in the past been reported as replacement for HMPA,[11–14] but we believe that this is the first reported use for tropolone derivatives Scheme 1.



Scheme 1

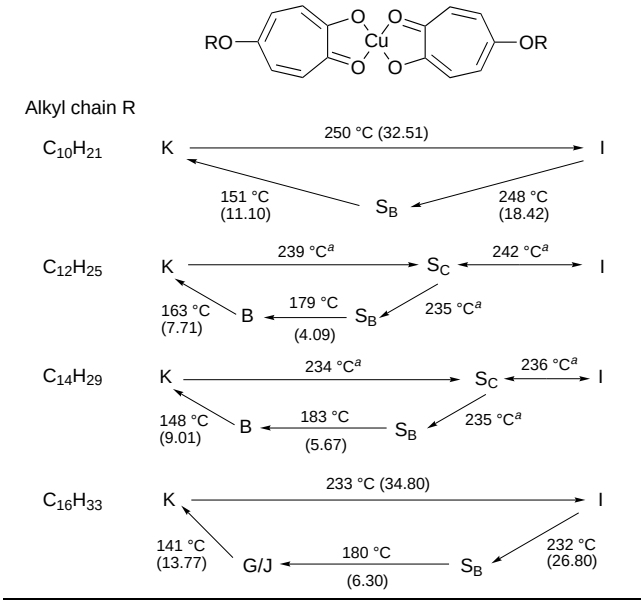
The copper complexes of these 5-substituted tropolones (**1**, M = Cu) have been synthesised in the usual way† and their mesomorphic nature has been studied using polarised optical microscopy and differential scanning calorimetry. Variable temperature X-ray powder studies are in progress.

The decyl substituted copper complex displays a monotropic S_B phase. Both the dodecyl and tetradecyl copper complexes exhibit a short range S_C mesophase (which despite the high temperatures are stable) as well as S_B and crystal G phases. The hexadecyl substituted copper complex exhibits a S_B phase and an anisotropic plastic crystal phase which cannot be pinpointed. The mesogenic data are summarized in Table 1.

Long chain alkoxy derivatives are very difficult to crystallise in forms suitable for X-ray structure determination. Generally very fine needles are obtained. Crystallisation of bis(5-octyloxytropolonato)copper from 1,4-dioxan containing 10% acetic acid in a similar way to that used for bis(tropolonato)-copper(II)[15] yielded a suitable crystal for an X-ray diffraction study.‡ The CuO_4 centre is required by crystallographic symmetry to be precisely planar, and the entire molecule is planar within 7%. The ligand plane O(1)C(1)C(7)O(2) attached to the Cu makes an angle of 2° with the tropolone ring. The molecular structure shown in Fig. 1 confirms the calamitic nature of the tropolone derivatives, while the packing in the crystal shows a similar arrangement to that in the smectic C phase. No solvent molecules are incorporated into the structure and there is no Cu–Cu interaction, the closest Cu···Cu approach being along the *c*-axis at 6.413(4) Å. The alkyl chain thermal parameters are interesting in that they exhibit partial melting at room temperature.

NMR analysis of 5-alkoxy tropolones confirmed their structure. Satisfactory analyses were obtained for the complexes. Over a period of time, the copper complexes are prone to hydrate, making them difficult to dry. However, because of the high transition temperatures, all water will have evaporated from the copper complex and have no effect on the mesophase behaviour. This is confirmed by uniform phase identification (and transition temperatures) of the copper complexes when dry and hydrated. IR data for bis[5-(decyloxy)tropolonato]-copper(II) (KBr disc): 2918s, 2850s, 1516s, 1432vs, 1350s, 1241s, 1204s, 789w.

Table 1 Phase transition temperatures and corresponding enthalpies (kJ mol^{-1}) of copper tropolonate complexes



[a] Overlapping peaks, enthalpies could not be resolved.

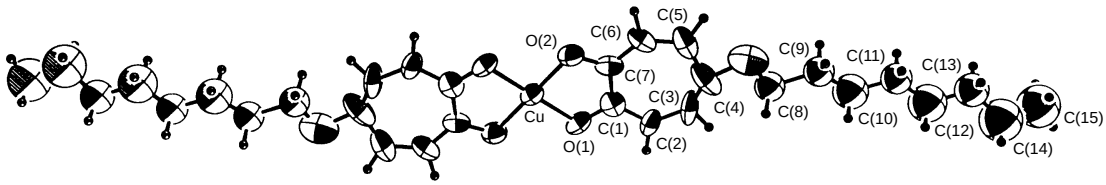


Fig. 1 View of bis(5-octyloxytropolonato)copper(II) from X-ray data

Nickel and oxovanadium(IV) complexes of the 5-substituted tropolone ligands have been prepared. However, despite having melting points which are 50 and 90 °C lower respectively than their copper complex counterparts, none have displayed any mesophases. For the nickel complexes, IR spectra suggest octahedral nickel.

While mesophases are still at high temperatures, appropriate substitution on the tropolone rings enables the length-to-breadth ratio to be adjusted, and initial work gives the promise of metallotropolonates with much lower mesophase transition temperatures. The use of tropolone derivatives in medicine (colchicine is a valuable anti-tumour agent while hinokitiol has strong biocidal properties), indicates potential uses for metal tropolonate derivatives outside the field of display devices.

The authors would like to thank EPSRC for financial support, and Professor J. Goodby and Dr P. Styring for help with phase identification.

† *Example*: bis[5-(decycloxy)tropolonato]copper(II): 5-decyloxytropolone (0.18 g, 0.71 mmol), sodium acetate (0.1 g, 1.4 mmol) and copper acetate (0.072 g, 0.359 mmol) were dissolved in methanol (15 cm^3). The mixture was refluxed for 3 h before cooling and filtration of the copper complex as a green powder. Recrystallisation in dichloromethane yielded bis[5-(decycloxy)tropolonato]copper(II) as green needles.

‡ *Crystal data*: $C_{80}H_{42}CuO_6$, triclinic, space group $P\bar{1}$, a = 7.607(4), b = 15.871(8), c = 6.413(4) Å, α = 96.32(4), β = 105.46(3), γ = 97.449(3)°, U = 731(1) $Å^3$, Z = 1, T = 24 °C, μ(Mo-Kα) = 7.84 cm^{-1}, R, R_w = 0.055 for 990 independent reflections collected on a Rigaku AFC6S diffractometer. The small crystal size led to a relatively small data set. The copper, oxygen and ring carbons were refined with anisotropic thermal parameters. Cu lies on a special position (origin): Cu–O(1) 1.916(2) Å, Cu–O(2) 1.902(9) Å; O(1)–Cu–O(2) 85.0(4)°. CCDC 182/694.

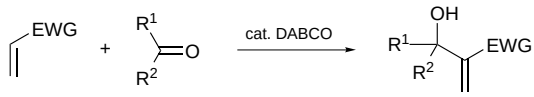
The chalcogeno-Baylis–Hillman reaction: the first examples catalysed by chalcogenides in the presence of Lewis acids

Tadashi Kataoka,* Tetsuo Iwama and Shin-ichiro Tsujiyama

Gifu Pharmaceutical University, 6-1, Mitahora-higashi 5-Chome, Gifu 502, Japan

The chalcogeno-Baylis–Hillman reaction catalysed by sulfides and selenides, the group 16 element compounds, in the presence of Lewis acids gave coupling products in moderate to good yield even after only 1 h at room temperature.

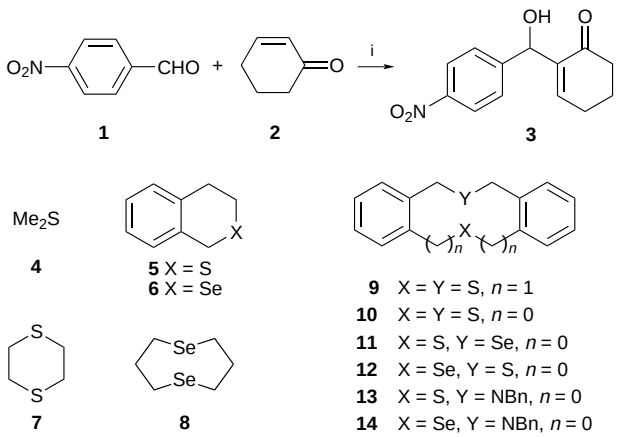
The coupling of activated alkenes with aldehydes or ketones is referred to as the Baylis–Hillman reaction (Scheme 1).[1] The reaction requires a compound containing a tertiary group 15 element as a catalyst. Generally tertiary amines are utilised as catalysts, and 1,4-diazabicyclo[2.2.2]octane (DABCO) is the most popular. There are some known examples which utilise tertiary phosphine catalysts.[2] Although the Baylis–Hillman reaction provides useful building blocks for organic synthesis,[1] it has a number of disadvantages. The main drawback is the slow reaction rate, and much attention has been paid to accelerating such reactions.[2c,3–8] Recently, Aggarwal *et al.* reported that lanthanides and group 3 metal triflates accelerate the Baylis–Hillman reaction, and that standard Lewis acids such as $TiCl_4$ and $BF_3{\cdot}Et_2O$ decelerate the reaction due to formation of an amine–Lewis acid complex.[6] Imagawa *et al.* described the Baylis–Hillman reaction promoted by a phosphine catalyst and Et_2AlCl due to activation of the aldehyde by coordination with the Lewis acid.[9] Therefore, we aimed to develop new catalysts other than those containing group 15 elements. We report here a preliminary study on the first chalcogeno-Baylis–Hillman reaction catalysed by sulfides and selenides, compounds containing group 16 elements, in the presence of Lewis acids.



Scheme 1

We examined the reaction of *p*-nitrobenzaldehyde **1** and 3 equiv. of cyclohex-2-en-1-one **2** in the presence of chalcogenides **4**, **5**,[10] **6**,[11] **7**, **8**,[12] **9**,[13] **10**,[14] **11**,† **12**,[15] **13**[14] and **14**‡ in CH_2Cl_2 at room temperature for 1 h (Scheme 2, Table 1).§ First, **4** was used in order to confirm the possibility of sulfide catalysts for the Baylis–Hillman reaction. A mixture of compounds **1** and **2** was treated with 1 equiv. of the sulfide **4** at room temperature for 4 days, and no coupling product **3** was obtained (entry 1). For the purpose of enhancing the reactivity of the enone towards the Michael addition of the sulfide, 0.1 equiv. of $TiCl_4$ was used and the Baylis–Hillman product **3** was produced in 17% yield (entry 2). Therefore, we examined the reaction with a catalytic amount of **4** (0.1 equiv.) in the presence of 1 equiv. of $TiCl_4$ and obtained the adduct **3** in 60% yield (entry 3). The reaction time was reduced to 10 min in refluxing CH_2Cl_2 (entry 4). It is significant that the reaction rate was dramatically accelerated in comparison to reactions utilising amine catalysts. Generally, it takes a few days or more to complete reactions catalysed by tertiary amines.[1] In addition it is also noteworthy that 1 equiv. of $TiCl_4$ is necessary for smooth reaction even though deceleration of the reaction has been observed when using an amine catalyst and $TiCl_4$ because of the formation of a deactivated amine–Lewis acid complex.[6]

A plausible mechanism is shown in Scheme 3. Activation of enone **2** by coordination with $TiCl_4$ allows addition of methyl sulfide **4** to complex **I** to generate an enolate intermediate **II**. The aldol reaction of the enolate **II** and aldehyde **1** gives an adduct **III**, which provides a Baylis–Hillman product–$TiCl_4$ complex **3′** *via* β-elimination and regeneration of methyl sulfide **4**. Formation of the complex **3′** requires a stoichiometric amount of $TiCl_4$ for a smooth reaction. Next, we examined several Lewis acids under standard conditions. The use of $BF_3{\cdot}Et_2O$ and $SnCl_4$ gave no coupling product (entries 5 and 6). The yields of the adduct **3** increased with increasing Lewis acidity in the cases



Scheme 2 *Reagents and conditions*: i, **1** (1 equiv.), **2** (3 equiv.), chalcogenide, Lewis acid, CH_2Cl_2, room temp., 1 h

Table 1 Chalcogeno-Baylis–Hillman reaction in the presence of Lewis acids[a]

Entry	Chalcogenide (equiv.)	Lewis acid (equiv.)	**3** (% yield)[b]
1[c]	**4** (1)	—	—
2	**4** (1)	$TiCl_4$ (0.1)	17
3	**4** (0.1)	$TiCl_4$ (1)	60
4[d]	**4** (0.1)	$TiCl_4$ (1)	58
5	**4** (0.1)	$BF_3{\cdot}Et_2O$ (1)	—

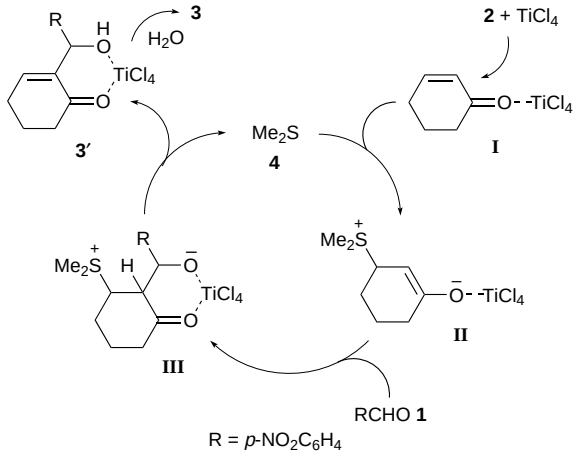
19	**14** (0.1)	$TiCl_4$ (1)	69

[a] 3 equiv. of enone **2** was used against aldehyde **1**. Reactions were carried out in CH_2Cl_2 at room temperature for 1 h. [b] Isolated yield based on aldehyde **1**. [c] The reaction was carried out at room temperature for 4 d. [d] The reaction was carried out in refluxing CH_2Cl_2 for 10 min.



Scheme 3

Table 2 Reactions of some enones and aldehydes catalysed by Me_2S–$TiCl_4$[a]

Entry	Aldehyde	Enone	Product (% yield)[b]
1	PhCHO	**2**	**17** (25)
2	*p*-ClC_6H_4CHO	**2**	**18** (43)
3	*p*-MeC_6H_4CHO	**2**	**19** (13)
4	*p*-$NO_2C_6H_4CHO$	**15**	**20** (68)
5	*p*-$NO_2C_6H_4CHO$	**16**	**21** (63)

[a] Conditions: 1 equiv. of aldehyde, 3 equiv. of enone, 0.1 equiv. of Me_2S, 1 equiv. of $TiCl_4$, CH_2Cl_2, room temp., 1 h. [b] Isolated yield based on the aldehyde.

of aluminium Lewis acids (entries 7–9). The best result was obtained when using $TiCl_4$. Chalcogenide catalysts **5**–**14** were examined in the presence of 1 equiv. of $TiCl_4$. Cyclic monochalcogenides **5** and **6** catalysed the chalcogeno-Baylis–Hillman reaction to provide the adduct **3** in 71 and 70% yield, respectively. We considered that the electron-releasing ability of the chalcogenide might promote the Michael addition step, and selected bis-chalcogenides **7**–**12** and related chalcogenides **13** and **14** are expected to donate electrons to a cationic species by transannular interaction of a chalcogen and a heteroatom.[16] Some (**8**, **10**, **11** and **13**) gave better results than monochalcogenides **5** and **6**, and others (**7**, **9**, **12** and **14**) gave similar results. The best result was obtained using bis-selenide **8**, probably due to transannular interaction (entry 13). In the cases of aromatic chalcogenides **9**–**14** steric interaction, for example between *peri*-hydrogens of the aromatic rings and the enone, may prevent the Michael addition step.

Various aldehydes and enones were applied to the chalcogeno-Baylis–Hillman reaction under standard conditions (Table 2).§ The yields of the adducts **4**, **18**, **17** and **19** decreased with the decreasing electrophilicity of the aldehydes (entry 3 in Table 1, entries 2, 1 and 3 in Table 2, respectively). Reactions of *p*-nitrobenzaldehyde **1** with enones **15** and **16** gave coupling products **20** and **21**, respectively, in moderate yields.

Reactions of other substrates such as acrylonitrile and an aliphatic aldehyde using the Me_2S–$TiCl_4$ system resulted in low (< 24%) yields. Further examination of different combinations of chalcogenides and Lewis acids, and extension of the chalcogeno-Baylis–Hillman reaction to various substrates, is now under investigation.

† Chalcogenide **11** was prepared by the reaction of bis(2-bromomethylphenyl) sulfide and Na_2Se (prepared from Se and $NaBH_4$ in EtOH) in EtOH by a procedure similar to that for compound **10** (ref. 14).

‡ Selenide **14** was prepared from bis(2-bromomethylphenyl) selenide (ref. 15) and benzylamine by the same procedure as for sulfide **13** (ref. 14). The *N*-methyl derivative of selenide **14** has been synthesised: H. Fujihara, H. Mima, T. Erata and N. Furukawa, *J. Chem. Soc., Chem. Commun.*, 1991, 98.

§ *Typical procedure* for the chalcogeno-Baylis–Hillman reaction: To a stirred solution of *p*-nitrobenzaldehyde (151 mg, 1 mmol), cyclohex-2-en-1-one (0.29 ml, 3 mmol) and methyl sulfide (7 μl, 0.1 mmol) in CH_2Cl_2 (2 cm^3) was added a 1 M solution of $TiCl_4$ in CH_2Cl_2 (1 ml, 1 mmol) at room temperature. The mixture was stirred for 1 h at ambient temperature, and the reaction was quenched by addition of water (5 cm^3). The precipitate of inorganic material was removed by filtration through Celite, and the filtrate was extracted with CH_2Cl_2 (20 ml × 2). The extracts were dried ($MgSO_4$) and the solvent was evaporated under reduced pressure. The residue was purified by preparative TLC on silica gel eluting with ethyl acetate–hexane (1 : 1, v/v) to give 148 mg (60%) of an adduct **3**.

Synthesis of group 4 complexes that contain the tridentate diamido ligands $[(ArNCH_2CH_2)_2O]^{2-}$ (Ar = C_6H_3-Me_2-2,6 or $C_6H_3Pr^i_2$-2,6)

Richard R. Schrock,* Florian Schattenmann, Michael Aizenberg and William M. Davis

Department of Chemistry 6-331, Massachusetts Institute of Technology, 77 Massachusetts Avenue, Cambridge, MA 02139, USA

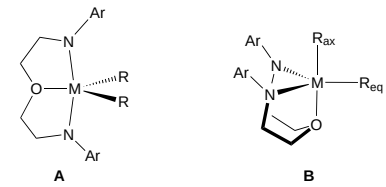
Complexes of Zr and Hf of the type $[(2,6\text{-}R_2C_6H_3NCH_2CH_2)_2O]ZrMe_2$ (R = Me or Pr^i) can be activated by $[PhNMe_2H][B(C_6F_5)_4]$ or $[Ph_3C][B(C_6F_5)_4]$ in chlorobenzene or bromobenzene to yield catalysts for the polymerization of hex-1-ene, but analogous titanium catalysts are relatively poorly behaved.

Significant advances have been made in the synthesis of 'well defined' alkene polymerization catalysts of the early metals (largely group 4) in the last 15 years, the vast majority of which contain two cyclopentadienyl-like rings.[1–3] (See, however, ref. 4, and references therein.) Recently group 4 complexes that contain chelating diamido ligand systems have received increased attention as potential alkene polymerization catalysts.[5–13] The most successful so far appear to be dialkyl complexes of Ti that contain diamido ligands such as $[ArNCH_2CH_2CH_2NAr]^{2-}$ (Ar = $C_6H_3Pr^i_2$-2,6),[5,6] and dialkyl complexes of Zr that contain the 'diamido/donor' ligand, $[(o\text{-}[^2H_6]Bu^tNC_6H_4)_2O]^{2-}$ ($[NON]^{2-}$).[10] Both types can be activated to yield (presumably) cationic catalysts for the living polymerization of hex-1-ene. We report here Ti, Zr and Hf complexes that contain potentially interesting 'diamido/donor' variations of the $[NON]^{2-}$ ligand, $[(2,6\text{-}R_2C_6H_3NCH_2CH_2)_2O]^{2-}$ (R = Me, Pr^i), and preliminary experiments concerning their use as catalysts for the polymerization of hex-1-ene.

The diamines, $(2,6\text{-}Me_2C_6H_3NHCH_2CH_2)_2O$ (H_2L^{1a}) and $(2,6\text{-}Pr^i_2C_6H_3NHCH_2CH_2)_2O$ (H_2L^{1b}), can be prepared readily from $(TsOCH_2CH_2)_2O$ (TsO = tosylate) and 2 equiv. of $LiNH(C_6H_3Me_2$-2,6) or $LiNH(C_6H_3Pr^i_2$-2,6), respectively, in thf.† Compound H_2L^{1a} can be obtained in 60% yield as colorless crystals upon crystallization from pentane.‡,§ Compound H_2L^{1b} is obtained in 80% yield as an oil that has crystallized in some instances upon standing for several days, and that can be crystallized from pentane in low yield at −30 °C.†,‡ Crude H_2L^{1b} can be used in subsequent reactions.

The reaction between H_2L^{1a} or H_2L^{1b} and $Zr(NMe_2)_4$ in pentane at room temp. yields crystalline $ZrL^{1a}(NMe_2)_2$‡ or $ZrL^{1b}(NMe_2)_2$‡ readily. The dimethylamido compounds react with excess $SiMe_3Cl$ in ether overnight at room temp. to yield $ZrL^{1a}Cl_2$‡ and $ZrL^{1b}Cl_2$‡ as colorless, relatively insoluble crystals. NMR spectra of $ZrL^{1b}(NMe_2)_2$ and $ZrL^{1b}Cl_2$ show two sets of isopropyl methyl groups, but only one methine resonance, consistent with restricted rotation of the aryl ring about the N–C_{ipso} bond, a phenomenon that was also noted by McConville and co-workers[5–8,14] in complexes containing the $[ArNCH_2CH_2CH_2NAr]^{2-}$ and related ligands. Only a single amido methyl resonance is observed in all dimethylamido compounds at room temp. in C_6D_6.

Alkylation of $ZrL^{1a}Cl_2$ with MeMgBr in ether gives $ZrL^{1a}Me_2$ **1a**‡ in good yield, while alkylation of $ZrL^{1b}Cl_2$ with Me or Bu^i Grignard reagents in ether yields $ZrL^{1b}Me_2$ **1b**‡ or $ZrL^{1b}(CH_2CHMe_2)_2$ **2b**,‡ respectively, in good yields as colorless cubes. NMR spectra are again consistent with slow rotation around the N–C_{ipso} bond on the NMR timescale. In all dialkyl compounds the alkyl groups are equivalent, consistent either with a pseudotrigonal bipyramidal structure of type **A** or a pseudotrigonal bipyramid of type **B** in which the alkyl groups become equivalent on the NMR timescale *via* a rapid 'flipping' of the ligand backbone through an intermediate with structure **A**.



An X-ray study of $ZrL^{1a}Me_2$ (Fig. 1)¶ showed it to have structure **A** with 'axial' Zr–N bond distances of 2.084(3) Å and a Zr–O(2) bond length of 2.336(3) Å. The compound has a crystallographic mirror plane defined by Zr, O(2), C(5) and C(6). The planes of the aryl rings are perpendicular to the ZrO(2)N(3)N(4) pseudo-plane. The structure is closely related to that of $[(2,6\text{-}Et_2C_6H_3NCH_2)_2NC_5H_3]ZrMe_2$ [N–Zr–N 139.6(2)° and C–Zr–C 102.4(3)°][8] and contrasts markedly with that of $\{[(o\text{-}[^2H_6]Bu^tNC_6H_4)_2O]ZrMe\}\{MeB(C_6F_5)_3\}$,[10] in which $B(C_6F_5)_3$ has partially removed Me_{ax}. The two Me groups are technically inequivalent in the solid state structure of $ZrL^{1a}Me_2$ [C(8)–O(2)–C(18) 113.7(4)°] as a consequence of C(18) and C(8) not lying in the ZrN_2 plane.

Reactions similar to those employed to prepare Zr compounds can be employed to prepare $HfL^{1a}(NMe_2)_2$,‡ $HfL^{1a}Cl_2$,‡ and $HfL^{1a}Me_2$ **3a**.‡ The Hf compounds are virtually identical to the Zr compounds in physical properties and NMR characteristics.

Addition of Li_2L^{1a} to $TiCl_4(thf)_2$ in diethyl ether at −30 °C led to formation of a deep red precipitate, which could be recrystallized from CH_2Cl_2 to yield $TiL^{1a}Cl_2$ in 57% yield. Alkylation of $TiL^{1a}Cl_2$ in ether with MeMgCl in thf at −30 °C gave $TiL^{1a}Me_2$ **4a** in 53% yield as a yellow powder from pentane. Red, crystalline $TiL^{1a}(CH_2Ph)_2$ **5a** was prepared in low yield (*ca*. 15%) *via* the reaction between $Ti(CH_2Ph)_4$ (2 mmol)

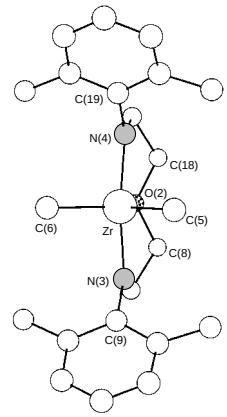


Fig. 1 A view of the structure of $ZrL^{1a}Me_2$ nearly opposite the Zr–O bond in the ZrC_2 plane. Bond lengths (Å) and angles (°): Zr–C(5) 2.253(6); N(4)–Zr–N(3) 139.1(2), C(8)–O(2)–C(18) 113.7(4), Zr–N(3)–C(9) 120.2(2), C(5)–Zr–C(6) 100.0(2)°.

Table 1 GPC and yield data for poly(hex-1-ene)[a]

Complex	Activator	M_n(theory)	M_n[b]	M_w[b]	M_w/M_n[b]	Yield (%)
$ZrL^{1b}Me_2$	$[NHMe_2Ph]^+$	13 440	2 670	3 560	1.33	96
$ZrL^{1b}Me_2$	$[CPh_3]^+$	16 800	2 460	4 220	1.72	96
$ZrL^{1b}(CH_2CHMe_2)_2$	$[NHMe_2Ph]^+$	16 800	2 650	8 550	3.23	94

[a] Dialkyl complex (44 μmol), activator (40 μmol), 200 equiv. hex-1-ene (except first entry = 160 equiv.), 10 ml chlorobenzene. [b] Determined by GPC coupled with on-line light scattering (Wyatt Technology).

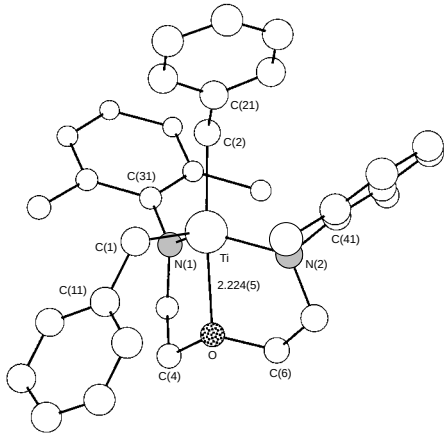

Fig. 2 A view of the structure of $TiL^{1a}(CH_2Ph)_2$. Bond lengths (Å) and angles (°): Ti–C(1) 2.129(10), Ti–N(1) 1.962(6), C(2)–Ti–O 169.3(3).

and H_2L^{1a} (2 mmol) in pentane (*ca*. 15 ml) in 40 h. In **4a** and **5a** the alkyl groups are equivalent on the NMR timescale at room temp., although several proton and carbon resonances in **5a** are broad at 22 °C. The structure of $TiL^{1a}(CH_2Ph)_2$ (Fig. 2)¶ is best described as type **B** in which O and C(2) are in the apical position and N(1), N(2), and C(1) are in the equatorial positions of a pseudotrigonal bipyramid. Surprisingly, the benzyl groups are bound only in an η^1 fashion; if two Ti–N π bonds can form, the metal should be viewed as having a 14 electron count, an electron deficiency that has led in many situations to η^2 or η^3 binding of benzyl ligands.[15]

Activation of alkyl complexes **1a**,**b**, **2b** and **3a** by either $[PhNMe_2H][B(C_6F_5)_4]$ or $[Ph_3C][B(C_6F_5)_4]$ yields initiators for the polymerization of hex-1-ene in chlorobenzene at 0 °C.‖ Polymerization yields are high, but the molecular masses of the polymers were found to be significantly smaller than expected when $ZrL^{1b}Me_2$ and $ZrL^{1b}(CH_2CHMe_2)_2$ were employed (Table 1). These results suggest that chain termination competes with propagation, but that the catalyst remains active thereafter and polymerization of a new chain is initiated. The $[PhNMe_2H]^+$ and $[Ph_3C]^+$ activators seem to be equally efficient. The number average molecular mass of poly(hex-1-ene) prepared using $ZrL^{1a}Me_2$ is approximately that expected if no significant chain termination is taking place. In all cases polymerization activity ceases when 2,4-dimethylpyridine is added to the catalyst mixture, consistent with competitive binding of the nitrogen base to a cationic metal center. Analogous experiments employing $HfL^{1a}Me_2$ yielded results similar to those employing $ZrL^{1a}Me_2$, but use of $TiL^{1a}Me_2$ (activated by $[PhNMe_2H][B(C_6F_5)_4]$ in $[^2H_5]$bromobenzene) led to only *ca*. 75% consumption of 25 equiv. of hex-1-ene to give poly(hex-1-ene).

We conclude that $[(2,6\text{-}R_2C_6H_3NCH_2CH_2)_2O]^{2-}$ ligands produce stable five-coordinate dialkyl complexes of Ti, Zr and Hf, and that 'cations' formed by protonation or oxidative cleavage of an alkyl group from Zr or Hf are initiators for the polymerization of hex-1-ene. These results should be contrasted with results obtained by McConville and co-workers[5,6] where Ti is the most successful when the diamido ligand does not contain an additional donor.

For $TiL^{1a}(CH_2Ph)_2$: Siemens SMART/CCD, orthorhombic, space group *Fdd*2, a = 32.803(8), b = 42.342(13), c = 8.547(4) Å, U = 11872(7) Å^3, Z = 16, D_c = 1.210 g cm^{-3}, R = 0.0609, R_w = 0.1269, GOF = 1.095. CCDC 182/679.

‖ In a typical experiment a chilled (−30 °C) solution of **1b** (19 mg, 44 μmol) in chlorobenzene (3 ml) was added to a suspension of $[PhNMe_2H][B(C_6F_5)_4]$ (32 mg, 40 μmol) in chlorobenzene (6 ml) at −30 °C. The reaction mixture was allowed to warm to room temp. and was stirred for 15 min. The reaction mixture was cooled to 0 °C and hex-1-ene (1.0 ml, 8.0 mmol) was added all at once. After stirring for 1 h at 0 °C the reaction was quenched with HCl (1.0 M in ether, 4 ml). In a typical experiment employing $[Ph_3C][B(C_6F_5)_4]$ the reaction mixture was stirred for 2 min at −30 °C and allowed to equilibrate at 0 °C before hex-1-ene (1.0 ml, 8.0 mmol) was added all at once.

Lithium enamides, β-diketiminates and 1,3-diazaallyls from the 1 : 1 insertion of an isonitrile into the Li–C bond of $LiCH(SiMe_3)_2$†‡

Peter B. Hitchcock, Michael F. Lappert* and Marcus Layh

The Chemistry Laboratory, University of Sussex, Brighton, UK BN1 9QJ

The diverse behaviour of $LiCHR_2$ A towards an isonitrile R′NC is unravelled; depending on reaction conditions and choice of R′, the product was an enamide Li[N(R′)C(R)=C(H)R](tmen), a β-diketiminate Li[N(R′)C(R)C(H)C(R)N(R′)], a 1,3-diazaallyl (with additionally PhCN) Li[N(Ph)C(R)NC(Ph)=C(H)R](tmen) or a 1 : 1 adduct of A and Li[N(R′)C(R)C(H)C(R)N(R′)](CNR′) (R′ = Bu^t), (R = $SiMe_3$, tmen = $Me_2NCH_2CH_2NMe_2$ and R′ = Bu^t, Ph or $C_6H_3Me_2$-2,6).

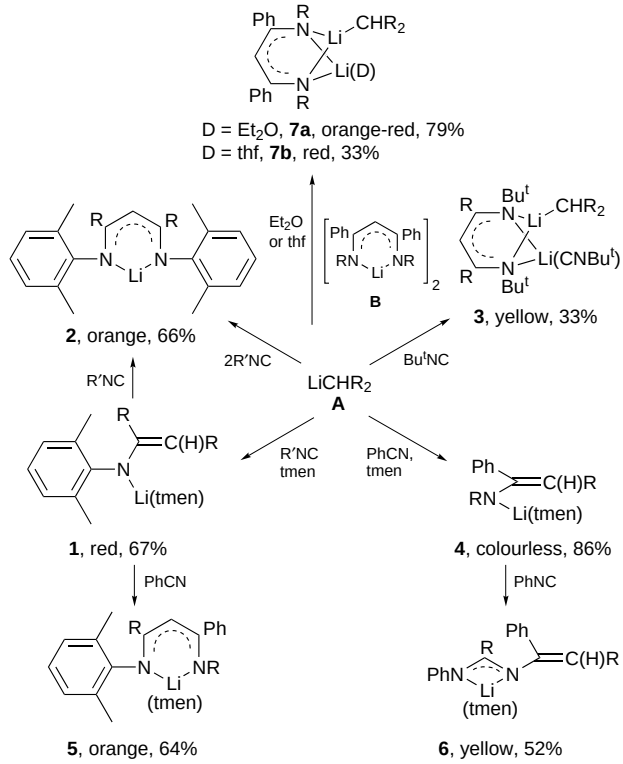
We have previously noted that the reaction between bis(trimethylsilyl)methyllithium $LiCHR_2$ **A** and the α-H-free nitrile PhCN or Bu^{t}CN gave under ambient conditions and irrespective of stoichiometry the 1 : 2 or 1 : 1 adduct, the lithium β-diketiminate $[LiN(R)C(Ph)C(H)C(Ph)N(R)]_2$ **B**[1] or 1-azaallyl $[LiN(R)C(Bu^t)C(H)R]_2$[2] (R = $SiMe_3$). We now report new findings on the $LiCHR_2$–PhCN system and on the variety of reactions between $LiCHR_2$ and the isonitrile R′NC (R′ = Ph, Bu^t or $C_6H_3Me_2$-2,6).

Treatment of a lithium alkyl LiR[1] and an isonitrile R^2NC was shown by Walborsky *et al.* to give the lithioaldimine $LiC(R^1)=NR^2$, which was not isolated, but used *in situ* as a source of an aldehyde, ketone, α-keto acid, β-hydroxyketone or a heterocycle.[3]

We now report (*i*) the synthesis of three diverse adducts **1**, **2** and **3** formed from $LiCHR_2$ **A** and R′NC (R′ = Bu^t or $C_6H_3Me_2$-2,6); (*ii*) that the previously examined $LiCHR_2$–PhCN system[1] is modified in the presence of $(Me_2NCH_2)_2$ (= tmen) to yield the 1 : 1 adduct **4**; (*iii*) that the enamide **1** with PhCN or **4** with PhNC yields the lithium β-diketiminate **5** or 1,3-diazaallyl **6**, respectively; (*iv*) that the β-diketiminate **B**[1] with $LiCHR_2$ and 1 equiv. of Et_2O or thf (OC_4H_8) gives the dilithium [bis(trimethylsilyl)methyl-β-diketiminate] donor (Et_2O or thf) adduct **7a** or **7b** (similar in type to the *tert*-butyl isonitrile adduct **3**); and (*v*) the characterisation of each of **1**–**7**,§ including the X-ray structures of **6** (to be published in the full paper) and **7b**.¶ The reactions leading to compounds **1**–**7** are summarised in Scheme 1.

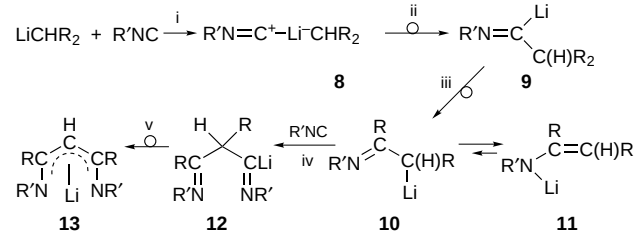
It is noteworthy (Scheme 1) that the nature of the product, a lithium enamide **1** or β-diketiminate **2**, or (irrespective of stoichiometry) an isonitrile adduct of a dilithium [bis(trimethylsilyl)methyl-β-diketiminate] **3**, obtained from $LiCHR_2$ **A** and the isonitrile R′NC, in good yield under ambient conditions in Et_2O, was dependent on one or more of the variables: the nature of R′, the stoichiometry and the presence or absence of tmen. A transient lithium β-diketiminate may well have been an intermediate along the pathway to **3**, as evident from the isolation of the related dilithium compounds **7a** and **7b** from **A** and **B**.

The formation of the stable compound **4** (from $LiCHR_2$–PhCN–tmen) lends credence to the suggestion that the previously reported $LiCHR_2$–PhCN reaction (which gave the lithium β-diketiminate **B**)[1] proceeded *via* a transient η^3-1-azaallyl (an isomer of the tmen-free **4**). The function of the tmen may have been to have promoted the $\eta^3 \rightarrow \eta^1$ isomerisation. This is also consistent with the present observation that **4** + PhNC gave the Li(tmen) 1,3-diazaallyl compound **6** rather than the isomer 0.5 **B** (tmen) (*cf.*, the reaction of the Li enamide **1** + 2,6-$Me_2C_6H_3NC \rightarrow$ Li β-diketiminate **2**). The possibility (*cf.*, ref. 5) that in this reaction PhNC was initially isomerised into PhCN is discounted because **4** + PhCN gave an isomer of **6**, in which the Ph and Me_3Si groups at N(1) and C(2) were exchanged.



Scheme 1 Synthesis of the crystalline compounds **1**–**7** from $LiCH(SiMe_3)_2$. Reactions carried out in C_5H_{12} or Et_2O (**2**–**4**) at −78 °C to *ca.* 25 °C; yields refer to recrystallised complexes; R′ = $C_6H_3Me_2$-2,6.

The multifarious reaction products observed in the $LiCHR_2$–R′NC system (Scheme 1) may be accommodated by the pathways shown in Scheme 2. Thus, we propose that (i) an initial 1 : 1 complex **8** is (ii) transformed into the lithioaldimine **9**, which (iii) induces a C(1) → C(2) shift of an Me_3Si (= R) group yielding the lithium 1-azaallyl **10** ⇌ **11**, this (iv)



Scheme 2 Reaction pathways in the $LiCHR_2$–R′NC systems

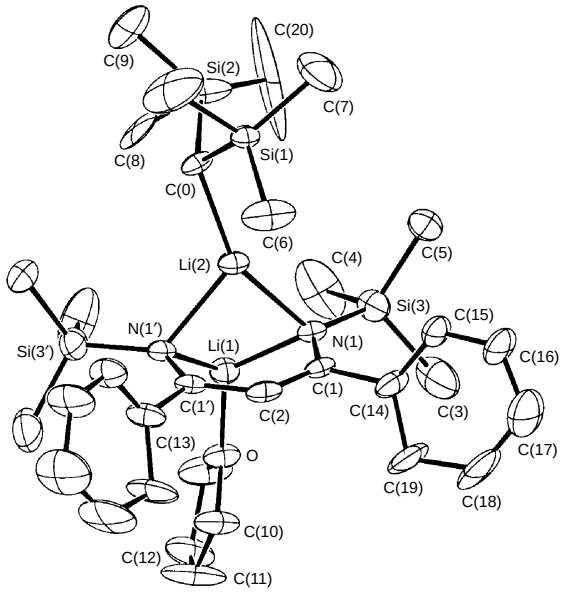


Fig. 1 Molecular structure of **7b** with selected bond distances (Å): N(1)–Li(1) 2.00(2), N(1)–Li(2) 2.13(2), C(0)–Li(2) 2.07(3), N(1)–C(1) 1.32(1), C(1)–C(2) 1.41(1), O–Li(1) 1.86(3).

behaving as a C-centred nucleophile adds to R′NC giving the lithiodiimine **12**, which (v), by a process similar to (*iii*), yields the lithium β-diketiminate **13**.

Although isonitrile complexes of certain transition metals are established, isonitrile adducts of a main group metal are rare {see, *e.g.*, [6a] $Ph_2CNCLi[(-)$-sparteine$](thf)_2$ and [6b] $AlPh_3(CNC_6H_{11}$-*c*$)$}, complex **3** may serve as a model for **8**. The propensity for an Me_3Si group to undergo a 1,2- or 1,3-shift in an anionic complex is well documented[4] [*e.g.*,[1,2] 1,3-C → N in the $LiCHR_2$–R′CN systems], and this provides support for propositions (iii) and (v) of Scheme 2. The isolated complexes **1**, **2** and **3** correspond to a tmen adduct of **11**, **13** and a composite of **8** and **13**, respectively.

The nature of the donor adducts **3**, **7a** and **7b**, of a dilithium [bis(trimethylsilyl)methyl-β-diketiminate] requires comment. In principle, each may be regarded as being either a 1 : 1 cocrystal of $LiCHR_2$(donor) and Li(β-diketiminate) or a discrete compound. We favour the latter for the following reasons. First, repeated recrystallisation of **3** from different solvents led in each case to a product of precise 1 : 1 composition. Second, their colours (Scheme 1) are distinct from those of their possible factors (**B** is pale yellow). Third, the X-ray structure of **7b** (Fig. 1) shows each lithium atom to be closely bound to the two nitrogen atoms of the β-diketiminate moiety [as, indeed, appears to be the case for **3**, but the quality of the crystals was such that an accurate structure was not established, R_1 {$I > 2\sigma(I) \approx 0.20$}]. Finally, the $^7Li\{^1H\}$ NMR spectrum of **7a** in $C_6D_5CD_3$ showed a single signal at δ 2.30 at 293 K, but three separate signals at δ 2.36, 1.44 and 1.37 at 193 K; this is attributed to there being an equilibrium between **7a** and its factors **A** and **B**. Variable temperature NMR spectra of **3** and **7b** are under investigation.

Crystalline **7b** has a mirror plane containing the atoms O and C(13) of the thf molecule, the two lithium, the two silicon atoms and the methyl group C(6), as well as C(2) [corresponding to the C(H) of the β-diketiminate moiety]. The methine carbon, C(0) of the CHR_2 group, and the remaining atoms C(10), C(11) and C(12) of the thf molecule are disordered across the mirror plane. The nitrogen atoms N(1) and N(1′) are bridged by Li(1) (bonded to thf) and Li(2), one above and the other below the nearly planar and completely delocalised diketiminato skeleton, with Li(1)–N(1) 2.00(2) and Li(2)–N(1) 2.13(2) Å. This contrasts with the situation in the dimeric lithium β-diketiminate **B**, which has only one of the two nitrogen atoms of each boat-shaped, incompletely delocalised lithiated ligand in a bridging mode with Li–N 1.952(9) and 2.095(9) Å, for the four- and three-coordinate nitrogens, respectively.[1] The Li(2)–C(0) distance of 2.07(3) Å may be compared with 2.14(3)–2.27(2) Å in crystalline $[LiCHR_2]_\infty$.[7]

The lithium compounds **1**–**7** are available as ligand transfer agents to provide a variety of new s-, p-, d- and f-block metal coordination compounds. We also conclude that isonitriles have an as yet unexplored potential for main group metal chemistry.

We thank ESPRC for a fellowship for M. L. and for other support.

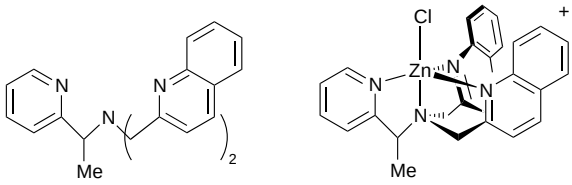
A chiroptically enhanced fluorescent chemosensor

Jesus M. Castagnetto and James W. Canary*

Department of Chemistry, New York University, New York, NY 10003, USA

One sensor molecule gives both fluorescence and exciton-coupled circular dichroism signals upon metal ion complexation, suggesting a novel strategy for detection, identification and quantification of multiple analytes.

One important strategy for the design of efficient sensors for the determination of metal ion concentrations in solution utilizes fluorescent chemosensors in which a metal ion binding event is coupled to a change in the luminescence behavior of the ligand upon forming a complex.[1–4] The classic approach to selective metal ion sensor design involves the engineering of selectivity through control of ligand stereoelectronic features including donor atoms and geometry. Sensor arrays with multivariate calibration offer especially exciting potential in this field.[5] Recently, multiple wavelength excitation[6] and ratiometric detection[7] schemes have offered sophisticated analysis of two metal ions with a single ligand. Here, we wish to report a strategy wherein both isotropic and anisotropic absorption signals from the optical response of a single sensory molecule provide not only detection but also differentiation of multiple analytes.



1 α-MeBQPA **2** [Zn(α-MeBQPA)Cl]$^+$

The ligand **1** {α-MeBQPA, bis[(2-quinolyl)methyl][1-(2-pyridyl)ethyl]amine} generates strong signals in exciton-coupled circular dichroism spectra (ECCD) upon formation of complexes with trigonal bipyramidal metal ions (Zn^{II}, Cu^{II}) as shown in Fig. 1.[8] Contrastingly, complexes with octahedral metal ions (Cd^{II}, Fe^{II}) do not give strong CD signals. The physical basis for tripodal ligand ECCD response to metal ion geometry has been discussed.[8,9]

Since quinoline ligands were employed in the development of practical fluorescent sensors for ions such as Ca^{II}, Mg^{II} and Mn^{II},[10,11] we envisioned that **1** might also display useful fluorometric sensory properties. Fig. 1 shows fluorescence spectra of the free ligand and four coordination complexes in aqueous solution at pH = 7.1; the fluorescence intensities of diamagnetic complexes increase relative to the free ligand,[12] with observed enhancements (378 nm, H_2O, pH = 7) of 30 : 1 (Zn^{II}) and 6 : 1 (Cd^{II}). The fluorescence enhancement derives from an N-heterocycle characteristic change from an n–π* electronic transition (leading to phosphorescence)[10,13] to a π–π* transition upon metal ion complexation, resulting in fluorescence.[10,13] The observed binding of Zn^{II} and Cd^{II} to the α-MeBQPA is strong ($K_a > 10^6$ dm^3 mol^{-1}) as expected,[14] which was evidenced by the linear response of the fluorescence enhancement at micromolar concentrations [*e.g.* Fig. 2(*b*)].

The fluorescence and ECCD properties of the complexes result in the interesting situation that the ligand can not only signal the presence of a metal ion, but evaluation of both properties can allow identification of the metal. Detection of both fluorescence enhancement and anisotropic absorption distinguish, for example, Zn^{II} (strong fluorescence and ECCD response), Cu^{II} (strong ECCD but no fluorescence), Cd^{II} (strong fluorescence but no ECCD) and Fe^{II} (neither fluorescence nor ECCD). These results illustrate for the first time the principle that both isotropic and anisotropic detection may be utilized to maximize the information transmitted by a single sensor molecule.

The optical behavior of the ligand upon presentation of Zn^{II} and Cd^{II} mixtures serves to illustrate the approach. The overall ratio of fluorescence signals of the Zn^{II} and Cd^{II} ions at micromolar concentrations is 5 : 1 at 378 nm. However, the circular dichroic responses are more highly differentiated; at 242 nm (H_2O, pH = 7) the ratio of $\Delta\varepsilon(ZnL) : \Delta\varepsilon(CdL)$ is 12 : 1. The relative fluorescence measured follows eqn. (1)

$$I = \chi_{Zn} I_0^{ZnL} + (1 - \chi_{Zn}) I_0^{CdL} \quad (1)$$

$$\theta = A[Zn^{2+}] + B \quad (2)$$

where I_0^{ZnL} and I_0^{CdL} are the intensities for the 1 : 1 M : L complex, and χ_{Zn} the mole fraction of Zn^{II} in the mixture. The CD signal is mainly sensitive to [Zn^{II}]; assumption that Cd^{II}

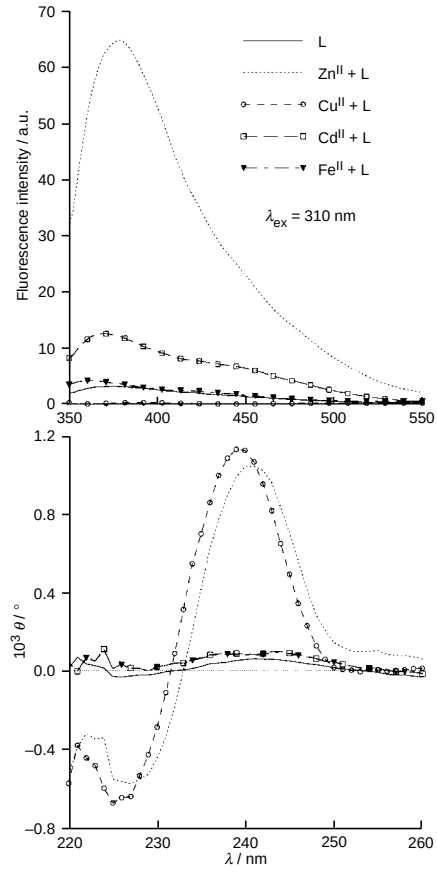


Fig. 1 Fluorescence and circular dichroism spectra of (*R*)-α-MeBQPA (5.1 μM) and complexes with $Zn(ClO_4)_2$ (5.1 μM), $Cd(NO_3)_2$ (5.1 μM), $Cu(ClO)_4)_2$ (5.2 μM) and $FeCl_2$ (5.0 μM) in aqueous HEPES buffer (0.1 M), pH = 7.09, 25 °C (λ_{ex} = 310 nm)

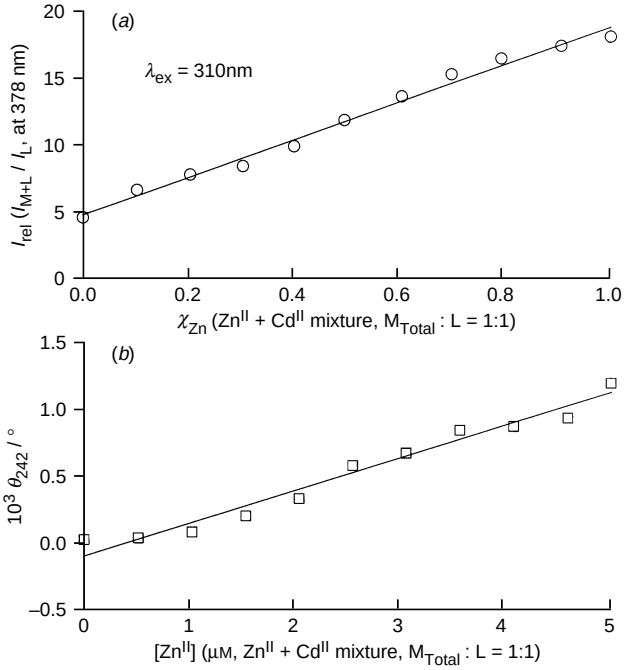

Fig. 2 Change in fluorescence intensity (378 nm, r = 0.995) and CD signal (242 nm, r = 0.984) of a 5 μM solution of (*R*)-α-MeBQPA in water (0.1 M HEPES, pH = 7.09)

does not contribute gives eqn. (2). Rearranging eqn. (1) into linear form and combining with eqn. (2) we obtained eqn. (3) which will give the [Cd^{II}] as a function of the two observables.

$$[Cd^{2+}] = \left(\frac{I_0^{ZnL} - I}{I - I_0^{CdL}}\right)\left(\frac{\theta - B}{A}\right) \quad (3)$$

Based on this chemistry, a device measuring both isotopic and anisotropic absorbance would permit the calculation of the concentrations of two species. This may be done by measurement of light absorption (UV–VIS and CD) or emission (*e.g.*, fluorescence and fluorescence-detected CD) since all four responses are proportional to absorption of the light.

We thank the National Institutes of Health (GM49170), for support of this work. Some mass spectra were obtained at the Michigan State University Mass Spectrometry Facility (supported in part by grant DRR-00480, from the Biotechnology Research Technology Program, NCRS, NIH).

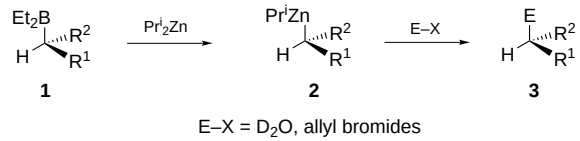
Stereoselective preparation and reactions of configurationally-defined mixed acyclic dialkylzincs

Christophe Darcel, Felix Flachsmann and Paul Knochel*

Fachbereich Chemie der Philipps-Universität Marburg, Hans-Meerwein-Strasse, D-35032 Marburg, Germany

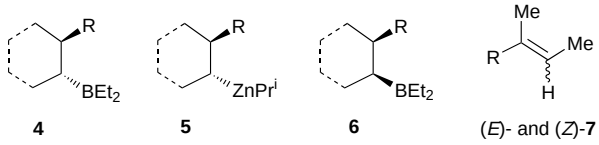
Mixed acyclic dialkylzincs are stereoselectively prepared from *E*- and *Z*-trisubstituted alkenes.

The preparation of configurationally defined reactive organometallics is of great interest,[1] since it offers the potential of transferring the stereochemical information at the α-carbon of the metal to a variety of organic compounds *via* reaction with various electrophiles. Recently,[2] we have shown that organoboranes **1** can be converted by an exchange reaction[3] with Pr^i_2Zn to configurationally stable[4] mixed diorganozincs **2**. These zinc reagents can be reacted with electrophiles like D_2O or allylic halides, providing products of type **3** (Scheme 1).



Scheme 1

In all these experiments, *trans*-cycloalkylborane derivatives **4** were used and converted to *trans*-cycloalkylzinc compounds **5**. To demonstrate the stereoselectivity of the boron–zinc exchange, the use of *cis*-cycloalkylboranes **6** would have been necessary. Since these molecules are not available by hydroboration with Et_2BH, we examined the hydroboration of open-chain trisubstituted *E*- and *Z*-olefins **7**. Herein, we report the stereoselective preparation of open-chain secondary dialkylzincs and their stereoselective deuterolysis and allylation.

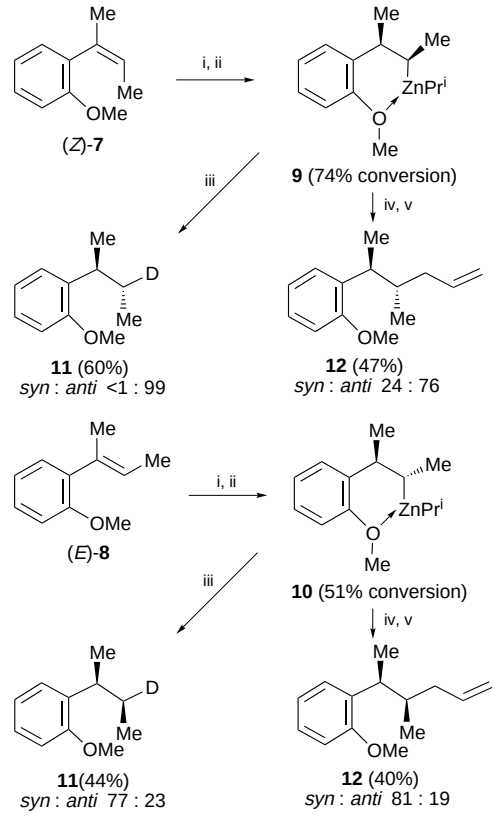


Thus, the hydroboration of *E*- and *Z*-styrene derivatives **8** with Et_2BH was complete after 14 h at 25 °C; the intermediate diethylorganoboranes were treated with Pr^i_2Zn, furnishing the mixed diorganozincs **9** and **10**, which were quenched with D_2O resulting in the formation of the deuterated product **11** (Scheme 2). The presence of the *o*-methoxy group was found to accelerate significantly the rate of the boron–zinc exchange reaction, allowing the completion of this exchange starting from (*Z*)- or (*E*)-**8** within 3 h at 0 °C. Under these conditions, the deuterolysis of **9** provides mainly the *anti*-deuterated product **11** (*syn* : *anti* < 1 : 99) whereas the deuterolysis of **10** furnishes the product **11** as a *syn* : *anti* mixture of 77 : 23. The *syn* : *anti* ratio of the deuterated products was determined by ^2H NMR spectroscopy. These experiments demonstrate for the first time the stereoselectivity of the boron–zinc exchange reaction for open-chain systems. It is interesting to note that performing the boron–zinc exchange at 25 °C instead of 0 °C leads to lower stereoselectivities, *i.e.* a *syn* : *anti* ratio of 22 : 78 starting from (*Z*)-**8** and 73 : 27 starting from (*E*)-**8**.

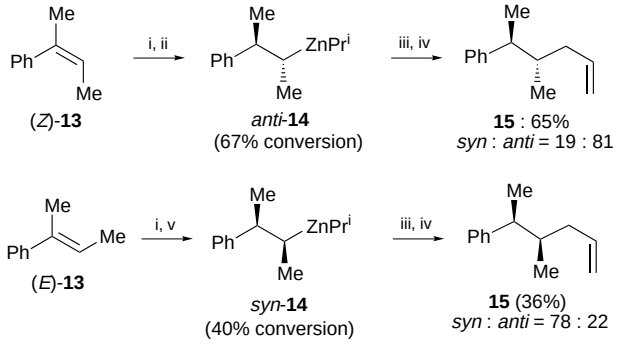
The mixed dialkylzincs **9** and **10** could also be transmetalated to copper–zinc compounds *via* reaction with CuCN·2LiCl, leading after treatment with allyl bromide to the desired allylated products **12** with a *syn* : *anti* ratio of 24 : 76 starting from the zinc intermediate **9** and 81 : 19 starting from the zinc reagent **10**. The lower stereoselectivity of the allylation of **9** compared to the deuterolysis may be due to a slow isomerization of **9** during the allylation reaction.†

Whilst the presence of the *o*-methoxy group of **8** facilitates the subsequent boron–zinc exchange, it is possible to extend the reaction to (*E*)- and (*Z*)-styrenes **13** with similar selectivities. This proves that the configurational stability of the organozinc intermediates does not depend on the presence of a heteroatom in close proximity. In this case, the deuterium signals after quenching of the intermediate zinc reagent **14** were not separated, so that the selectivity could not be determined. However, after transmetalation with CuCN·2LiCl and allylation the desired allylated product **15** was obtained stereoselectively. The *Z*-olefin **13** gave allylation product **15** with a *syn* : *anti* ratio of 19 : 81, whereas the *E*-olefin **13** gave a *syn* : *anti* ratio of 78 : 22 for **15** (Scheme 3).

The relative stereochemistry of the product **15** (*syn* : *anti* ratio of 78 : 22) was determined by converting it to 3,4-dimethyl-1-tetralone **18** by ozonolysis followed by oxidation of the

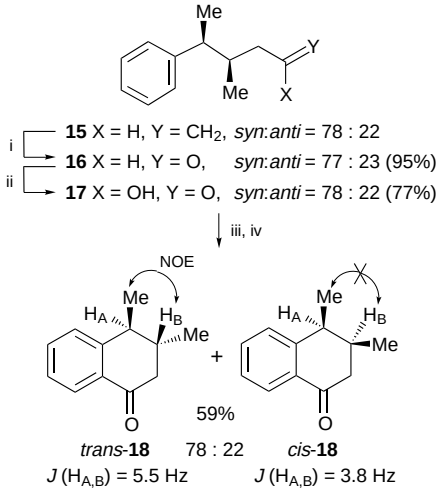


Scheme 2 *Reagents and conditions*: i, $HBEt_2$ (3 equiv.), 25 °C, 14.5 h; ii, Pr^i_2Zn (2 equiv.), 0 °C, 3 h; iii, D_2O, THF, −78 °C; iv, CuCN·2LiCl; v, allyl bromide, −78 to 25 °C



Scheme 3 *Reagents and conditions*: i, $BHEt_2$ (3 equiv.), 25 °C, 13 h; ii, Pr^i_2Zn (2 equiv.), 25 °C, 3 h; iii, CuCN·2LiCl, −78 °C; iv, allyl bromide, −78 to 25 °C; v, Pr^i_2Zn (2 equiv.), 25 °C, 4 h

resulting aldehyde **16** to the acid **17**. Friedel–Crafts cyclization of the corresponding acid chloride furnishes the *cis*- and *trans*-ketones **18** (*cis*:*trans* = 22:78). Both the major *trans* isomer and the minor *cis* isomer could be unequivocally identified by NMR spectroscopy (Scheme 4).



Scheme 4 *Reagents and conditions*: i, O_3, then Me_2S; ii, $NaClO_2$, $Me_2C{=}CHMe$, NaH_2PO_4, Bu^tOH, 25 °C, 1 h; iii, $SOCl_2$, 60 °C, 1 h; iv, $AlCl_3$ (1.25 equiv.), $ClCH_2CH_2Cl$, 25 °C, 4 h

In conclusion, we have shown that the boron–zinc exchange performed with Pr^i_2Zn on open-chain secondary zinc reagents proceeds stereoselectively. Although the relative stereochemistry of the zinc reagents could not be directly determined, we assume that this exchange reaction proceeds with retention of configuration as well as the allylation (and deuterolysis),‡ since an overall retention of configuration is observed. Current work in order to improve the level of stereoselectivity and to extend the number of electrophiles that can quench stereoselectively the intermediate organozinc reagents is underway.

The authors thank the Deutsche Forschungsgemeinschaft (SFB 260 and Leibniz program) and the Fonds der Chemischen Industrie for generous support of this research. We thank the A. von Humboldt-Stiftung for a fellowship to C. D., and BASF (Ludwigshafen), Witco (Bergkamen), Chemetall (Frankfurt) and Sipsy (Avrillé) for generous gifts of chemicals.

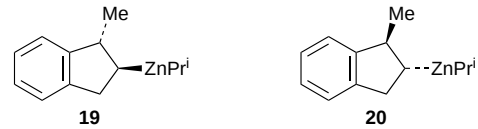
† We have observed in separate experiments that secondary copper–zinc reagents are more prone to epimerization than the organozinc precursors. Treatment of *trans*-1-methylindanyl)(isopropyl)zinc **19** (see ref. 2) with D_2O affords the corresponding *trans*-deuterated indane **20** with a *cis*:*trans*



ratio of 1:99. Treatment of this zinc reagent with stoichiometric amounts of CuCN·2LiCl provides a copper–zinc reagent which was slowly warmed to 0 °C. After deuterolysis a *cis*:*trans* ratio of 11:89 was obtained. However, keeping this copper–zinc reagent at −78 °C and treating it with another equivalent of $ZnBr_2$ provides a *cis*:*trans* ratio of 1:99, showing that the zinc–copper reagent has good configurational stability at −78 °C and that, at this temperature, the zinc salts produced during the allylation reaction are not responsible for the epimerization reaction.

‡ The relative configuration between the methyl group and the deuterium atom in **20** was proven to be *trans* by comparison of NOE measurements for dihydro-1-methylindane and **20**.

$Cp^*TaCl_2B_4H_8$: synthesis, crystal structure and spectroscopic characterization of an air-stable, electronically unsaturated, chiral tantalaborane

Simon Aldridge, Hisako Hashimoto, Maoyu Shang and Thomas P. Fehlner*

Department of Chemistry and Biochemistry, University of Notre Dame, Notre Dame, Indiana, 46556, USA

Reaction between Cp^*TaCl_4 ($Cp^* = \eta^5$-C_5H_5) and BH_3·thf at 40 °C yields the pale red electronically unsaturated cluster $Cp^*TaCl_2B_4H_8$ 1 which despite having two electrons fewer than the seven pairs required for the observed square pyramidal geometry is stable in air; viewed as a cluster, 1 is the first example of an unsaturated cluster containing a single metal atom; viewed as a chiral 16-electron organometallic complex it is isoelectronic with $Cp(C_2B_9H_{11})TaCl_2$ and $Cp[(Me_3Si)_2C_2B_4H_4]TaCl_2$.

The rôle of unsaturated species in catalyzing or mediating industrially important transformations has long been acknowledged,[1] although examples of such species in transition metal cluster chemistry are rare.[2] Within the realms of metallaborane chemistry unsaturated species, that is those which are formally electron deficient with respect to the number of skeletal pairs required to sustain the observed molecular geometry, are limited to the sensitive group 6 metallaboranes $(Cp^*Cr)_2B_4H_8$[3] and $(Cp^*MoCl)_2B_3H_7$[4] both of which, having five skeletal electron pairs are formally two electrons deficient in terms of Wade's rules.[5] We now report the synthesis of the six-electron pair cluster $(Cp^*TaCl_2)B_4H_8$ **1** which has a *nido* structure formally derived from B_5H_9 by replacement of a basal BH fragment by Cp^*TaCl_2. Although **1** has two fewer electrons than the seven pairs expected for such a geometry, it is remarkably stable in air and sufficiently thermodynamically robust that it can be sublimed *in vacuo* at 230 °C.

Reaction of Cp^*TaCl_4 with 3.5 equiv. of BH_3·thf at 40 °C leads initially (4 h reaction time) to an extremely air- and moisture-sensitive deep blue intermediate thought to be a BH_3 adduct of the known dimeric tantalum hydride $(Cp^*TaCl_2H)_2$.[6] Longer reaction times lead to the isolation of the pale red air-stable cluster $Cp^*TaCl_2B_4H_8$ **1**.† **1** has been characterized by ^1H and ^{11}B NMR, IR spectroscopy and high-resolution mass spectrometry and by single crystal X-ray diffraction.‡ Consumption of BH_3·thf during the reaction is accompanied by evolution of BH_2Cl; the effective use of BH_3·thf as a dual reagent to build up a metallaborane cluster and to remove Cl as BH_2Cl has been demonstrated previously for cobalt[7] and molybdenum[4] metallaboranes. In addition, the reaction of Cp^*TaCl_4 with BH_3·thf contrasts with the analogous reaction with the more strongly reducing BH_4^-, which we find to give the known compound $(Cp^*TaB_2H_6)_2$.[8] The differing reactivities of BH_3·L and BH_4^- towards Cp^*MX_n species have been demonstrated previously for M = Cr, Mo and Co.[3,4,7]

The crystal structure of **1** is illustrated in Fig. 1 and can be interpreted as a *nido* cluster formally derived from B_5H_9 by replacement of a basal BH group by Cp^*TaCl_2. The skeletal electron count for such a molecule is six pairs, one pair short of the seven required for a square pyramidal geometry.[5] That the molecule is indeed square pyramidal, rather than trigonal bipyramidal (as would be expected for six pairs) is reflected by Ta–B(4) and B(1)–B(3) distances [3.338(12), 2.59(2) Å, respectively] which are sufficiently long to preclude any significant bonding interaction. Cluster **1** is therefore electronically unsaturated and is the first example of an unsaturated cluster containing a single metal atom.

The square pyramidal geometry of **1** is further confirmed by similarities with the only other crystallographically characterized 2-metallapentaborane, 2-$CpCoB_4H_8$.[9] The two clusters display similar B–B distances and B–B–B angles. Although the metal–apical boron distances are consistent with the differences in the covalent radii of the metals, the metal–basal boron distance for **1** is longer than expected from the structure of the cobalt compound. However, as M–B distances for hydrogen-bridged interactions exhibit large variations for the same metal, this difference is difficult to interpret.

A comparison of the molecular orbital schemes for **1** and 2-$CpCoB_4H_8$ calculated by Fenske–Hall methods[10] offers some insight into the nature of the unsaturated tantalaborane.§ For 2-$CpCoB_4H_8$ the SHOMO is an antibonding combination consisting mainly of a metal-based d orbital along with a minor contribution from a borane-based fragment orbital which is symmetric with respect to the molecular mirror plane and has a high percentage of apical boron 2p character. In the tantalum case the corresponding MO has similar character but is shifted to much higher energy (+0.41 for **1** *vs.* −12.47 eV) principally because the participating metal-based orbital is itself at much higher energy (−5.99 for **1** *vs.* −13.09 eV). In essence the significantly higher energy of the early transition metal d orbitals shifts a predominantly metal-based MO to much higher energy such that it is unoccupied, and **1** is stable despite one skeletal electron pair fewer than 2-$CpCoB_4H_8$. Although **1** is unique in being an unsaturated cluster featuring a single metal atom, the electronic factors underlying its apparent stability, the high-lying nature of the metal d orbitals and their ability to overlap well with borane-based orbitals, have much in common

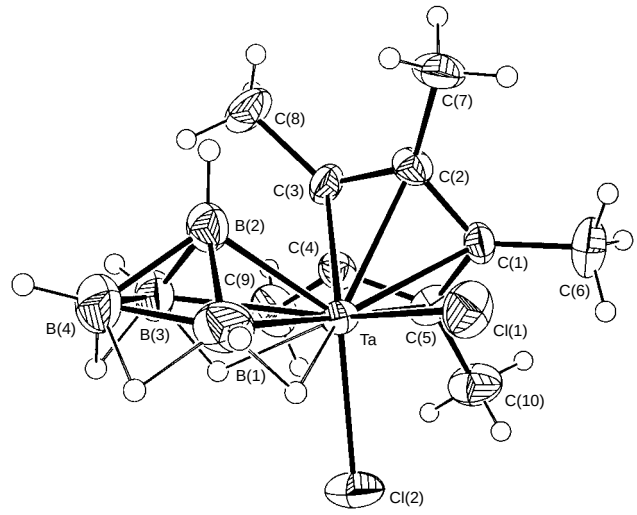

Fig. 1 The molecular structure of **1**. Relevant bond lengths (Å) and angles (°): Ta–Cl(1) 2.341(2), Ta–Cl(2) 2.370(2), Ta–Cp*(centroid) 2.123(9), Ta–B(1) 2.495(12), Ta–B(2) 2.249(12), Ta–B(3) 2.495(14), B(1)–B(2) 1.70(2), B(1)–B(4) 1.77(2), B(2)–B(4) 1.71(2), B(1)–H(11) 1.33(4), B(1)–H(12) 1.34(5), B(1)–H(13) 0.98(6), Ta–H(11) 1.88(5); Cl(1)–Ta–Cl(2) 99.20(10), H(11)–Ta–H(31) 79(3), B(1)–Ta–B(3) 62.4(5), B(1)–B(2)–B(3) 99.9(10), B(1)–B(4)–B(3) 94.0(9).

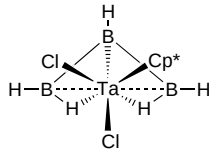

Fig. 2 Structure of **1** viewed along the Ta–B(4) axis showing the non-symmetrical distribution of ligands about the tantalum centre

with the factors stabilizing other unsaturated early transition metal metallaboranes featuring two metal centres *i.e.* $(Cp^*Cr)_2B_4H_8$[3] and $(Cp^*MoCl)_2B_3H_7$.[4]

Cluster **1** represents a rare example of a structurally characterized molecule containing a Ta–B bond[8,11–14] and comparison with $(Cp^*TaBr)_2B_2H_6$[8] (which contains both Ta–B and Ta–H–B linkages) shows similar hydrogen-bridged Ta···B distances [2.495 Å for **1**; 2.41 Å for $(Cp^*TaBr)_2B_2H_6$][8] but a significantly shorter direct Ta–B linkage (2.249 *vs*. 2.37 Å). The Ta–B bond is also decidedly shorter than those found in η^5 bound tantalum carborane complexes (which are typically in the range 2.4–2.5 Å),[11,13,14] but of similar length to that found in both isomers of the η^1 complex $Cp_2Ta(H)_2(BO_2C_6H_4)$ (2.263, 2.295 Å[12]).

An alternative view of **1** is as a 16-electron organometallic complex containing either a d^0 Ta^V centre coordinated to a six-electron $B_4H_8^{2-}$ ligand or a Ta^{III} centre and a four-electron neutral B_4H_8 ligand. The $B_4H_8^{2-}$ ligand is comparable to the six-electron units $C_2B_9H_{11}^{2-}$ or $(Me_3Si)_2C_2B_4H_4^{2-}$ in the analogous molecules $Cp(R)TaCl_2$ [R = $C_2B_9H_{11}$[13] or $(Me_3Si)_2C_2B_4H_4$[14]]. In contrast to these carborane complexes, however, **1** is chiral with the plane of mirror symmetry present in other 2-metallapentaboranes such as 2-$CpCoB_4H_8$[9] being eliminated by the non-symmetrical distribution of ligands about the tantalum centre (see Fig. 2). This results in non-equivalence of borons B(1) and B(3) which consequently give rise to two distinct ^{11}B NMR signals (at δ_B −2.9, 0.5). A similar situation arises in the osmapentaborane *nido*-$[(OC)(Ph_3P)_2OsB_4H_8]$ which also gives rise to four distinct ^{11}B signals;[15] in the case of **1** the barrier to rotation is sufficiently high that no hint of coalescence is observed even at 90 °C.

Although reactions of monocyclopentadienylmetal halides, $CpMX_n$, with nucleophiles have been extensively investigated,[16] reactions with electrophiles have received comparatively little attention to date. Reaction of one such transition metal complex, Cp^*TaCl_4 with the electrophile BH_3·thf yields the highly unusual cluster $(Cp^*TaCl_2)B_4H_8$ **1**. Cluster **1** is remarkable enough in being an electronically unsaturated mono-metallated borane cluster, but its thermodynamic stability, together with its stability in air, make it unique. The synthesis and on-going investigation of the chemistry of **1** [with particular emphasis on the synthesis of chiral tantalum(v) alkyl derivatives] represents an exciting development in the little investigated area of early transition metal metallaboranes.

The support of the National Science Foundation is gratefully acknowledged. S. A. also thanks the J. William Fulbright Scholarship Board for the award of a research scholarship. We thank Professor R. N. Grimes (University of Virginia) for providing fractional atomic coordinates for 2-$CpCoB_4H_8$.

† Reaction of Cp^*TaCl_4 (300 mg, 0.66 mmol) with 3.5 equiv. of BH_3·thf in toluene at 40 °C for 96 h, followed by removal of volatiles (including BH_2Cl) *in vacuo* and extraction with hexane gives an orange–red solution from which pale red crystals of $Cp^*TaCl_2B_4H_8$ **1** can be grown by controlled cooling; **1** can also be isolated from the reaction of $Cp^*TaCl_2(CO)_2$(thf) with a fivefold excess of BH_3·thf in toluene at 40–50 °C over a period of 24 h. **1** is stable to air in both solid and solution phases (toluene or hexane), is obtained in yields of up to 45% (based on boron) and can be sublimed under continuous vacuum at *ca*. 230 °C without significant decomposition. **1** has been characterized by ^{1}H and ^{11}B NMR (including selective decoupling experiments), IR, high-resolution mass spectrometry and single crystal X-ray diffraction. *Spectroscopic data* for **1**: MS (EI), M^+ = 438, 1 Ta, 4 B, 2 Cl atoms, calc. *m/z* 438.1029, obs. 438.1041. ^{11}B NMR (toluene 21 °C), [J(^{11}B–^{1}H) in parentheses] δ 6.3 [d, 1B, B(2) (150 Hz)], 4.8 [d, 1B, B(4) (160 Hz)], δ 0.5 [d, 1B, B(1) or B(3) (160 Hz)], −2.9 [d, 1B, B(1) or B(3) (140 Hz)]. ^{1}H NMR ([$^2H_6$]benzene, 21 °C), δ −1.24 [partially collapsed quartet (pcq), 2 H, accidental overlap of both TaHB signals (80 Hz)], −0.67 (br, 2 H, overlap of both BHB signals), 1.85 (s, 15 H, Cp*) δ 2.81 [q, 1 H, terminal H attached to B(2) (150 Hz)], 4.52 [overlapping pcq, 3 H, overlap of terminal H attached to B(1), B(3) and B(4) (*ca*. 150 Hz)]. IR (KBr, cm^{-1}) 2996w (sh), 2965m, 2912m, 2863w (sh), ν(CH); 2567s, 2544s, 2530m (sh), ν(B–H$_t$); 2076w (sh), 2057m (br), 1646m (br), ν(B–H$_b$); 1443m (br); 1378s, δ(CH$_3$); 700m, 614w, ρ(CH$_3$). (ν = stretching mode, δ = deformation mode, ρ = rocking mode).

‡ *Crystallographic data* for **1**: monoclinic, space group $P2_1/c$, a = 14.149(2), b = 8.6357(12), c = 14.328(2) Å, β = 116.981(13)°, U = 1560.1(4) Å^3, Z = 4, D_c = 1.866 g cm^{-3}. Of the 2744 reflections collected [CAD4 diffractometer, Mo-Kα radiation (λ = 0.710 73 Å, 293 K)], all were independent and 2430 were observed [$I > 2\sigma(I)$]. All non-hydrogen atoms were anisotropically refined and difference Fourier synthesis located all hydrogen atoms. Both methyl and borane hydrogens were included in the final refinement, the former as idealized riding atoms [r(C–H) = 0.96 Å, U_{iso}(H) = 1.5 U_{eq}(C)], the latter isotropically with three free-variables to restrain B–H(terminal) B–H(bridging) and Ta–H bond lengths. R_1 = 0.0433, wR_2 = 0.1118 for observed unique reflections [$I > 2\sigma(I)$] and R_1 = 0.0494, wR_2 = 0.1199 for all 2744 unique reflections including those with negative intensities. The max., min. residual electron densities on the final difference Fourier map were 2.037 and −1.750 e Å^{-3}, respectively. The first five peaks were all within 1.4 Å of the heavy Ta atom and might have been caused by satellite diffraction and/or imperfection in the empirical absorption correction. Since no observable abnormality of the structure details was found, no further effort was made to improve the index for residual electron density. CCDC 182/705.

§ Fenske–Hall calculations were carried out on the 2-$CpTaCl_2B_4H_8$ and 2-$CpCoB_4H_8$ molecules, with coordinates taken from the results of single crystal X-ray diffraction studies. In the tantalum case the simplification was made that the Cp* (η^5-C_5Me_5) ligand was replaced by Cp (η^5-C_5H_5).

Electron transfer-induced sequential transformations of malonates by the ferrocenium ion

Ullrich Jahn* and Philip Hartmann

Institut für Organische Chemie, Technische Universität Braunschweig, Hagenring 30, D-38106 Braunschweig, Germany

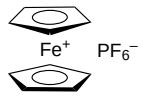
Malonate enolates undergo single electron oxidation with the ferrocenium ion followed by radical cyclisation and radical or cationic termination of the reaction sequence.

In the course of investigations towards the incorporation of oxidative electron transfer in tandem reactions, we became interested in the development of general strategies for the use of enolates as precursors for the generation of radicals, with the choice of subsequent oxidation of the latter to carbocations in 'heterointermediate reaction sequences' [eqn. (1)].

$$\text{Educt} \rightarrow (R^1)^- \rightarrow (R^2)^- \xrightarrow{-e^-} (R^3)^{\cdot} \rightarrow (R^4)^{\cdot} \xrightarrow{-e^-} (R^5)^+ \rightarrow (R^6)^+ \rightarrow \text{Product} \quad (1)$$

Enolates have been used in oxidative dimerisations involving various metal salts.[1] Cyclisations of highly acidic β-dicarbonyl compounds onto phenolates with alkaline $K_3[Fe(CN)_6]$ were reported by Kende.[2] The electrochemical oxidation of enolates is known, but these reactions are often limited by low yields and competing reaction pathways.[3] For the generation of α-carbonyl radicals from neutral carbonyl compounds, $Mn(OAc)_3$[4] or cerium ammonium nitrate (CAN)[5] were employed, but these reagents are not applicable to enolates.

Here we introduce ferrocenium hexafluorophosphate **1** as an efficient and selective single electron oxidant for enolates and certain radical types in reaction sequences.† In addition to its mildness, **1** is easily recovered and recycled and is thus more economical than other heavy metal oxidants.



1

The starting point of our studies was the 5-*exo* cyclisations of the substituted malonates **2a**–**e** (Scheme 1). After deprotonation with $(Me_3Si)_2NLi$ or LDA at −78 °C in DME (50 mM), the enolate solutions were treated with portions of **1** at 0 °C.‡ The course of the reactions was easily monitored by the colour change of the mixtures. The reactions were finished when the colour of the solution remained green.

Depending on the structure of the acceptor double bonds in **2**, different products were obtained (Scheme 1, Table 1). Malonate **2a** gave a single bicyclic lactone **3a**§ in 64% yield (entries 1 and 2). The dimethyl derivative **2b** yielded the lactone **3b** and the elimination product **4b** together with a small amount of the disproportionation product **5b**. $(Me_3Si)_2NLi$ was the more efficient base for the bicyclisation to lactone **3b** (entries 3 and 4). Oxidative cyclisation of the phenyl compounds **2c** or **2d** afforded a partly separable mixture of the diastereoisomerically pure lactone **3c** and the dimer **6c** (entries 5 and 6). The

Entry	Educt	Base (equiv.)	Equiv. TEMPO	Product (%) **3**	**11**	**12** (dr)[a]	Cyclic : acyclic
1	**2a**	$(Me_3Si)_2NLi$ (1.75)	2	26	33	—	1 : 1.3
2	**2a**	LDA (1.75)	2	25	47	—	1 : 1.9
3	**2b**	$(Me_3Si)_2NLi$ (1.75)	2	—	—	87	100 : 0
4	**2c**,**d**	$(Me_3Si)_2NLi$ (1.75)	2	—	—	72 (100 : 0)	100 : 0
5	**2e**	$(Me_3Si)_2NLi$ (1)[b]	1	—	—	69 (1.8 : 1[c])	100 : 0
6	**2e**	$(Me_3Si)_2NLi$ (2)	2	—	41	42 (2 : 1[c])	1 : 1

[a] Diastereoisomeric ratio. [b] 6% Educt recovered. [c] Stereochemistry could not be assigned.

stereochemical assignment is based on spectral data and is in agreement with the stereochemistry of the TEMPO-trapping product (*vide infra*). The (*E*)-Hex-4-enylmalonate **2e** provided the disproportionation products **4e** and **5e** and a diastereomeric mixture of the dimer **6e** in a ratio of 1.5 : 1.5 : 1 (entry 7).

Clear trends emerge from these results. Enolates **2** are efficiently oxidised to radicals **7** by **1** (Scheme 2). The 5-*exo* cyclisation provides the rearranged radicals **8**. The structure of **8** determines their stabilisation. Radicals **8a,b** are oxidised to carbocations **9a,b**, which undergo intramolecular nucleophilic trapping to lactones **3a,b** or elimination to **4b**, respectively. The endergonic oxidation of the benzylic radical **8c** occurs,[6] but is slower than radical dimerisation and yields a mixture of **3c** and **6c**. Secondary alkyl radicals are not oxidised and undergo typical radical processes to products **4e**, **5e** and **6e**.

Trapping experiments with TEMPO **10** confirm these hypotheses and give rise to an efficient oxidative radical cyclisation/termination process with remote oxy-functionalisation (Scheme 3, Table 2). Addition of **1** to the reaction mixtures in the presence of 1–2 equiv. of **10**, as described above, gave the following results. Malonate **2a** yielded a mixture of the acyclic TEMPO adduct **11a** and lactone **3a** (entry 1). Substrates **2b**–**e** provided the cyclised TEMPO adducts **12** with moderate to excellent stereoselectivity (entries 2–5). The acyclic compounds **11** were detected in traces if at all, but by using a larger excess of **10** their amount increased (entry 6). The structure and stereochemistry of **12c** was proved by X-ray analysis.§ Thus on one hand, radical 5-*exo* cyclisation of **7** is (except in the case of **7a**) faster than their trapping by **10**. On the other hand, trapping of the cyclised radicals **8b**,**c** is strongly favoured over their oxidation and allows selective remote oxygenation.

Reductive N–O bond cleavage of **12b**,**e** with spontaneous lactonisation was achieved with Zn–AcOH and allows the preparation of **3b** and the otherwise not accessible lactone **3e** (*vide supra*) in a two-step procedure in 86 and 84% yield .

In conclusion, we have shown that enolates serve as a convenient source of radicals. Electron transfer-induced reaction sequences provide a simple access to bicyclic lactones with **1** as oxidant.

We thank the Fonds der Chemischen Industrie (Liebig-Stipendium for U. J.) for financial support and Professor Dr H. Hopf for ongoing support of this project.

† Salt **1** has found widespread use in transition metal oxidation (ref. 7), although applications in organic chemistry are scarce (ref. 8). Ferrocenes have been employed as redox catalysts for enzymatic oxidations (ref. 9).

‡ The excess of base was applied to ensure complete deprotonation under dilution conditions. A control experiment showed that the free base was also oxidised with **1**. The outcome of the cyclisations was, however, only slightly influenced by the amount of base.

§ All new compounds exhibit satisfactory analytical data. X-Ray analyses of **3a** and **12c** proved their structures and will be published separately.

First blue luminescent diborate compound: $B_2(\mu\text{-}O)Et_2(7\text{-azain})_2$ (7-azain = 7-azaindole anion)

Abdi Hassan and Suning Wang*

Department of Chemistry, Queen's University, Kingston, Ontario, Canada K7L 3N6

A novel blue luminescent diborate compound $B_2(\mu\text{-}O)Et_2(7\text{-azain})_2$ (7-azain = 7-azaindole anion) is synthesized and characterized structurally; it emits a blue color at λ_{max} = 422 nm in the solid and at λ_{max} = 419 nm in solution and is stable under air as a solid.

Blue luminescent compounds are among the most sought-after materials by scientists in both academia and industry because of their potential applications in electroluminescence displays.[1] Most of the previously reported blue luminescent compounds in electroluminescent displays are either aromatic organic molecules or organic polymers.[1] Blue luminescent inorganic and organometallic complexes are rather rare and have been limited to 8-quinoline or azomethine based complexes where either Al or Zn ions are involved.[2] During our investigation of alkylaluminium amido and imido chemistry, we have discovered two families of blue luminescent aluminium complexes based on either the deprotonated di-2-pyridyl amine ligand or 7-azaindole ligand.[3] Both di-2-pyridyl amine (Hdpa) and 7-azaindole (7-Hazain) have no visible blue luminescence under UV radiation at ambient temperature. Upon reaction with $AlMe_3$, these two ligands produce a variety of blue luminescent aluminium complexes.[4] One weakness associated with these aluminium compounds is their tendency to undergo hydrolysis upon exposure to air. Although we have found that the incorporation of alkoxo and oxo ligands into the complexes enhances their thermal and air stability without destroying the blue luminescence,[4] they are, however, still vulnerable, to some extent, to air and moisture. In contrast to organoaluminium compounds, organoboron compounds are in general more stable owing to the increased covalency of B–C and B–N bonds,[5] in comparison to those of Al–C and Al–N bonds. We therefore explored the synthesis of boron compounds containing either the di-2-pyridylamine or the 7-azaindole ligand. We report here the first example of a blue luminescent diborate compound, $B_2(\mu\text{-}O)Et_2(7\text{-azain})_2$ **1**.

The colorless diborate compound was isolated in *ca*. 30% yield from the reaction of BEt_3 with 7-azaindole and 1,1,1,3,3,3-hexafluoropropan-2-ol in a 2 : 2 : 1 ratio in toluene at 25 °C. This compound can also be obtained by the reaction of BEt_3 with 7-azaindole and water in a 2 : 2 : 1 ratio in *ca*. 10% yield. The role played by 1,1,1,3,3,3-hexafluoropropan-2-ol in the synthesis has not, as yet, been understood. ^{1}H NMR spectroscopy, single-crystal X-ray diffraction and elemental analyses† established the formula of this compound to be $B_2(\mu\text{-}O)Et_2(7\text{-azain})_2$ **1**. The crystal structure along with important bond lengths and angles are given in Fig. 1. Compound **1** contains two B atoms in a tetrahedral environment. The 7-azaindole ligand is bound to the B centers *via* both N atoms. Both 7-azaindole ligands are disordered with 50% occupancy for each of the disordered sites. Consequently, the B–N bond lengths are the average of B–N(indole) and B–N(pyridyl) bonds, ranging from 1.604(5) to 1.612(5) Å, which are consistent with the typical B–N bond lengths reported previously.[6,7] Each B is also bound by an ethyl group with a normal B–C bond length. The most interesting structural feature of this molecule is the bridging O atom which can be considered as the consequence of the reaction of two ethyl groups with one water molecule. A similar oxygen bridge has been observed in the compound $B_4(2,2'\text{-biimidazole})_2(O)Et_6$ reported by Niedenzu *et al.*[6a] The B–O bond lengths in compound **1** are typical[6,7] and similar to those found in Niedenzu's compound. The B–O–B angle [151(3)°] in Niedenzu's compound is, however, much larger than that in compound **1** [119.6(3)°] which can be attributed to the different steric strain imposed by the 2,2′-biimidazole and the 7-azaindole ligands. As a result of the bridging oxygen atom, compound **1** has a bicyclo[3.3.1]nonane-like structure. Similar B–O–B bridges have also been observed previously in heterocycles of boric or boronic acids or their acyloxy or acylamino derivatives based on the bicyclo-[3.3.1]nonane framework.[7] To our knowledge, compound **1** is the first example of biheterocycles involving 7-azaindole, boron and oxygen atoms.

The most exciting property of **1** is that it emits an intense blue color upon irradiation by UV light. The emission maximum in the solid is at λ = 422 nm. The free 7-azaindole does not have any observable blue luminescence in the solid state. The toluene solution of compound **1** emits at λ_{max} = 419 nm at 23 °C while the toluene solution of the free 7-azaindole ligand has an emission band at λ_{max} = 357 nm which is in the colorless UV region. In addition to the dramatic shift of the emission band, the relative emission intensity† of compound **1** in solution also appeared to be much greater than that of the free ligand (Fig. 2). The role of the boron atom in the blue luminescence of **1** was therefore considered to be perhaps twofold. First, the formation of covalent bonds between the B and N atoms *via* the donation of lone-pairs of the N atoms to the B atoms changes the emission energy from UV to blue, perhaps owing to the lowering of the energy gap between π^* and π. Second, the

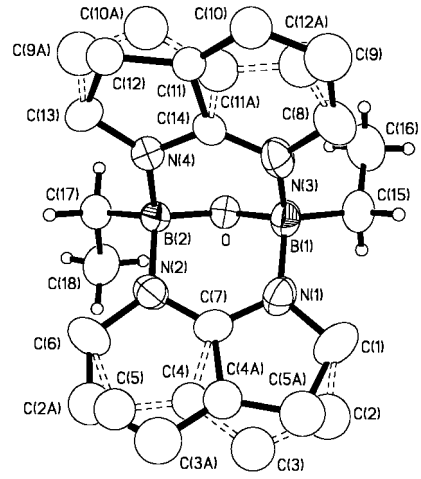

Fig. 1 The molecular structure of compound **1** with 50% thermal ellipsoids and labelling scheme. The second set of positions of the disordered 7-azaindole ligands are shown as dashed lines. Important bond lengths (Å) and angles (°): B(1)–O 1.430(5), B(1)–N(1) 1.604(5), B(1)–N(3) 1.609(5), B(1)–C(15) 1.595(6), B(2)–O 1.431(5), B(2)–N(2) 1.612(5), B(2)–N(4) 1.604(5), B(2)–C(17) 1.592(5); B(1)–O–B(2) 119.6(3), N(1)–B(1)–N(3) 104.6(3), O–B(1)–C(15) 115.9(4), N(2)–B(2)–N(4) 105.2(3), O–B(2)–C(17) 115.9(3)°.

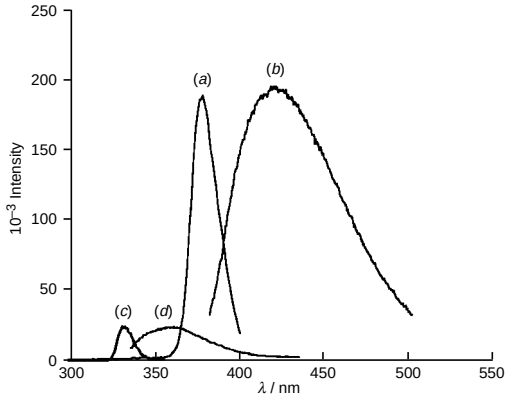

Fig. 2 Excitation and emission spectra of **1** and 7-azaindole in solution at 23 °C: (*a*) and (*b*) are the excitation and emission spectra of compound **1** (6.75×10^{-3} M in toluene); (*c*) and (*d*) are the excitation and emission spectra of 7-azaindole (3.67×10^{-2} M in toluene)

binding of the 7-azaindole ligand to two B atoms increases the rigidity of the ligand, thus reducing the loss of energy *via* vibrational motions and increasing the emission efficiency,[8a] a phenomenon well known to coordination compounds containing luminescent chelating ligands.[8b,c] However, our attempt to measure the quantum yields of the free ligand and the boron compound against a common reference compound was unsuccessful because they absorb at different regions. The emission quantum yield of compound **1** was determined to be 0.47, relative to that of 9,10-diphenylanthracene while the quantum yield of the free ligand was determined to be 0.92, relative to that of naphthalene. Efforts to gain a better understanding of the luminescent mechanism of **1** are being undertaken by our group.

As we anticipated, compound **1** is remarkably stable towards air in the solid state. In fact, it can be kept under air for days without decomposition. Compound **1** is also thermally stable. It melts at 290 °C without decomposition and can be sublimed at *ca*. 150 °C and 0.06 mmHg. The high stability of compound **1** can be attributed to both the presence of the bridging O atom and the covalency of B–C and B–N bonds, in comparison to the corresponding aluminium compounds. To our best knowledge, compound **1** is the first example of blue luminescent boron compounds. The high stability and volatility of **1** make it a good candidate as an emitter in electroluminescence display devices, which is being investigated in our laboratory.

We thank the Natural Science and Engineering Research Council of Canada for financial support, Dr Steven Brown and Samir Tabash for recording the excitation and emission spectra, as well as Drs Linda Johnston and Lorenzo Branealeon for assistance in quantum yield measurements.

Synthesis of soluble conjugated metalloporphyrin polymers with tunable electronic properties

Biwang Jiang, Szu-Wei Yang, Denis C. Barbini and Wayne E. Jones Jr.*

Department of Chemistry and Institute for Materials Research, State University of New York at Binghamton, Binghamton, NY 13902-6016, USA

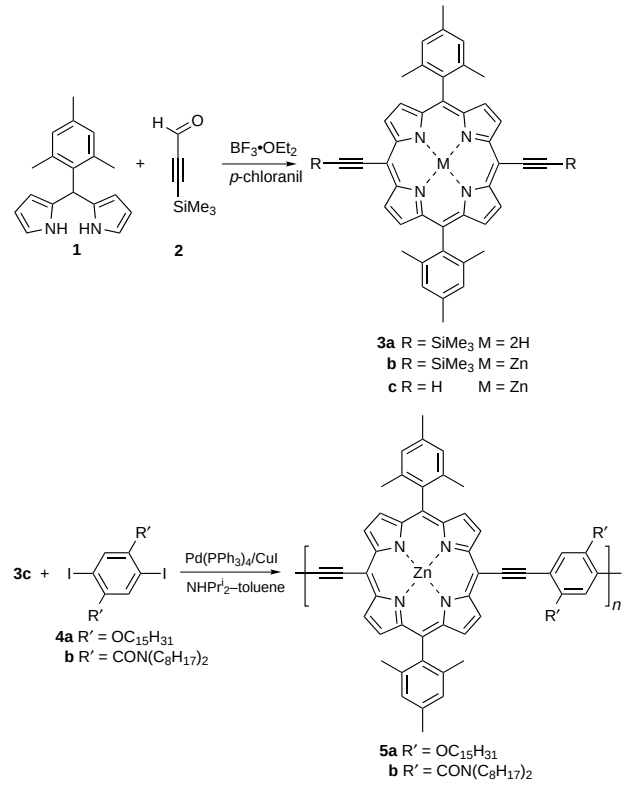
New linear conjugated porphyrin polymers are synthesized by a palladium-catalyzed cross-coupling reaction of [5,15-bis(ethynyl)-10,20-bis(mesityl)porphyrin]zinc and diiodobenzene derivatives; enhanced solubility of the conjugated porphyrin polymers is achieved by attachment of long alkyl ether or dialkyl amide groups to the aryl moiety, resulting in unambiguous characterization by ^{1}H NMR, IR, GPC, UV–VIS and fluorescence spectroscopy; in addition, the introduction of alkyl ether (electron donor) or dialkyl amide (electron acceptor) results in significant modulation of the electronic properties of the conjugated porphyrin polymers owing to strong electronic coupling.

Conjugated porphyrin polymers and oligomers are an attractive new class of materials with potential applications in the fields of electronics, optical devices, sensors and solar energy conversion.[1–7] Although the synthesis of a wide variety of porphyrin dimers or oligomers *via* the building block approach is well developed, relatively few soluble conjugated porphyrin polymers have been studied.[1] Anderson *et al*. have synthesized a soluble, linear conjugated *meso*-butadiyne-linked porphyrin polymer with long alkyl chains on the porphyrin periphery. The polymer exhibits an unusually high susceptibility $\chi^{(3)}$ and strong electronic communication as well as electronic absorption in the near IR.[1*a*] However, the electronic tuning of the *meso*-butadiyne-linked porphyrin polymers is synthetically challenging. Therien and DiMagno also reported the synthesis of poly(diethylnylaryl porphyrin) with limited characterization.[1*b*] Recently, we synthesized a series of soluble *meso*-phenylporphyrin-based polymers with tunable electronic and photophysical properties.[5,6] Unfortunately, the electronic communication along the polymer backbone was limited due to steric interactions between the phenyl *ortho* proton and the porphyrin β-hydrogen, resulting in a large dihedral angle between the porphyrin ring and the phenylenevinylene unit.[5–8] We present here a modified approach to soluble and fully conjugated porphyrin polymers with tunable electronic and optical properties that builds on previous efforts.

The design and synthesis of the new conjugated porphyrin polymers and their precursor porphyrin monomers are outlined in Scheme 1. The *meso*-(mesityl)dipyrromethane **1** was synthesized from pyrrole according to a literature procedure.[9] Condensation of **1** with (trimethylsilyl)propynal **2** gives trimethylsilyl-protected porphyrin **3a** in 30% yield.[10] Metallation of porphyrin **3a** with $Zn(OAc)_2$, followed by deprotection of the terminal acetylene with tetrabutylammonium fluoride leads to **3c**. Porphyrin polymers **5a** and **5b** were synthesized from palladium-catalyzed cross-coupling reaction of porphyrin monomer **3c** and the corresponding diiodoaryl compounds **4a** or **4b**[11] in 90% yields.† The high solubility of the polymers was achieved by attaching long pendant chains to the aryl units. The mesityl substituents on the porphyrin moiety also contribute to the solubility of the polymers.[12]

^{1}H NMR spectra of the polymers in $CDCl_3$ demonstrated the expected polymer structure (Scheme 1). For polymer **5b**, two broad peaks at δ 9.7 and 8.8 are observed and assigned to the β-pyrrole protons of the porphyrin subunits. The resonance of the two aromatic protons corresponding to aryl units appears at δ 8.1, much further downfield from δ 7.55 as seen in monomer **4b**. No signal was observed near δ 4.1 for an acetylenic proton, supporting the formation of the diethynylaryl-linked porphyrin polymer. Also no absorbance was observed at 2091 cm^{-1} in the IR spectrum due to acetylene end-groups, consistent with ^{1}H NMR results. The formation of the ethynyl link was further confirmed by absorbance at 2184 cm^{-1} in the IR spectrum. The NMR and IR data suggest a high degree of polymerization in these materials. The average molecular mass was determined by GPC to be M_w = 5.17 × 10^4, M_n = 2.45 × 10^4, using polystyrene standards. Attempts at using multi-angle light scattering to independently determine molecular mass were unsuccessful due to competitive absorption.

The insertion of a triple bond between the porphyrin and aryl subunits was expected to enhance electronic interaction in the main polymer chain as demonstrated previously for dimeric systems.[8] Fig. 1(*a*) shows the absorption spectra of polymers **5a** and **5b** compared with the monomer **3c**. In both cases, the porphyrin polymers exhibit dramatic red-shifts and broadening in both the B- and Q-type transition bands in comparison to porphyrin monomer **3c**. This would indicate strong electronic interactions along the conjugated porphyrin backbone.[1–3]



Scheme 1 Synthesis of conjugated porphyrin polymers and their precursors

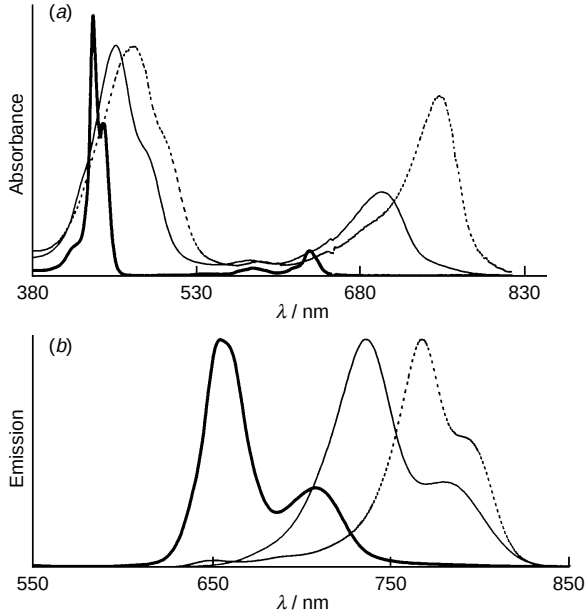


Fig. 1 (*a*) UV–VIS absorption spectra of monomer **3c** and polymers **5a** and **5b** in THF solution and (*b*) emission spectra of monomer **3c** and polymers **5a** and **5b** in THF solution (465 nm excitation); (—) monomer **3c**, (- - - -) polymer **5a**, (—) polymer **5b**

In the presence of strong electronic coupling, introduction of the aryl units into the porphyrin polymer main chain allows for facile modification of the electronic properties through the pendant aryl substituent. The observed decrease in absorption energy on going from polymer **5b** to **5a** is consistent with the electron donating character of the ether alkyl substituent and electron withdrawing character of the dialkyl amide substituent on the aryl 'bridge' units. Cyclic voltammetry measurements in 0.5 M tetrahydrofuran and dichloromethane solution show a shift in the oxidation potential from 0.94 to 0.75 V *vs.* SCE on going from polymer **5b** to **5a**. As compared to the monomer electrochemical oxidation at 0.95 V *vs.* SCE under similar conditions, substantial broadening in ΔE_p was observed. The observed modulation of ground-state electronic properties of the polymer suggests high electron coupling along the conjugation of the polymer backbone.

The emission spectra of the polymers and the monomer are shown in Fig. 1(*b*). Both polymers exhibit significant red-shifts in comparison to that of the monomer. Polymer **5a** displays a larger red shift than polymer **5b**, consistent with the electronic absorption spectra. The emission lifetimes of polymers **5a** and **5b** were 0.92 and 1.1 ns respectively, which is shorter than that of the porphyrin monomer (2.5 ns) measured in THF at room temp. The fluorescence quantum yields of the monomer and polymers **5a** and **5b** are 0.071, 0.028 and 0.069, respectively. The decrease in emission lifetime and the observed shifts in the emission spectra upon bridge substitution are also consistent with increased electronic delocalization in the polymer excited state relative to the *meso*-phenylene vinylene linked porphyrin polymers reported previously.[5] Enhanced exciton mobility in these soluble one-dimensional systems would also be consistent with these fluorescence data, but more information is necessary before this mechanism can be confirmed.

The electronic absorption and emission spectra of both polymers also display significant solvent dependence. The emission maximum shifts to lower energy on going from chloroform (704 nm) to *n*-butylamine (741 nm). This is related to the well known axial complexation ability of the central metal cation of the porphyrin toward different solvent ligands.[13] The electron-donating ability of the solvent ligand increases as the solvent basicity increases. Complexation of the solvent to the metal cation results in increased electron density on the porphyrin units. It is important to note that either an increase in the electron density of the diethynyl aryl unit through pendant groups or the porphyrin units through axial solvation leads to a red shift in the absorption and emission bands.

In summary, we have developed a modified approach to synthesizing a family of fully conjugated, soluble porphyrin polymers in which the porphyrin units are connected by the diethynylaryl group. The porphyrin monomers are easily synthesized, and the high solubility of the polymers in common organic solvents allows routine manipulation, chemical characterization and spectroscopic analysis. The ground and excited state electronic properties suggest enhanced delocalization which can be fine-tuned through the structural modification of the more synthetically accessible aryl bridge units, rather than by direct modification of the porphyrin moiety. The unique coordinating ability of the central metal cation, combined with the high electronic coupling and fluorescence in the polymers, may provide an opportunity to develop optical sensors based on this family of conjugated porphyrin polymers.[13]

We thank Dr Milissa Bolcar for helpful discussions. This research was funded by the Integrated Electronics and Engineering Center (IEEC) at the State University of New York at Binghamton. The IEEC receives funding from the NY State Science and Technology Foundation, the National Science Foundation and a consortium of industrial members.

† *Preparation of polymers (typical procedure)*: under an atmosphere of argon, diisopropylamine (1.5 ml) in THF (3 ml) was added to a 15 ml Schlenk flask containing porphyrin **3c** (0.05 g, 0.0076 mmol), diiodobenzene **4a** or **4b** (0.076 mmol), CuI (5 mg) and $Pd(PPh_3)_4$ (6.5 mg). This mixture was refluxed for 24 h and then subjected to $CHCl_3/H_2O$. The combined organic phase was washed with NH_4OH (50%), H_2O and dried over $MgSO_4$. Most of the solvent was evaporated in under vacuum and the concentrated solutions poured into MeOH. The polymer precipitated as a green solid in 90% yield.

Simple routes to supramolecular squares with ligand corners: 1 : 1 Ag^{I} : pyrimidine cationic tetranuclear assemblies

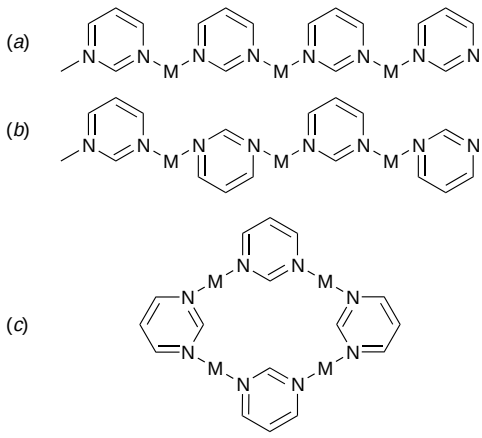
C. V. Krishnamohan Sharma, Scott T. Griffin and Robin D. Rogers*

Department of Chemistry, The University of Alabama, Tuscaloosa, AL 35487, USA

Simple, tetranuclear cationic supramolecular squares with ligands at the corners can be constructed using the geometry of the pyrimidine ligand and the directional tendencies of Ag^{I} coordination; the 1 : 1 Ag^{I} : pyrimidine squares have an open channel structure which facilitates selective ion exchange of pertechnetate over nitrate.

Discrete macrocyclic metal complexes and coordination polymers with open networks constitute a new family of inorganic host materials.[1,2] While inorganic macrocycles with their conformational rigidity provide an alternative to organic macrocycles such as, crown ethers, cyclophanes, and calixarenes, the open network coordination polymers represent zeolite-like materials with fine-tunable cavities and/or ion exchange properties.[1–3] The robustness of inorganic frameworks and their ability to selectively bind anionic species make them particularly suitable to extract a variety of anions.[3] Here, we report crystal engineering strategies for synthesizing novel supramolecular squares through tetranuclear self-assembly of Ag^{I} cations and pyrimidine ligands.[1] These supramolecular squares may be used to selectively remove the radioactive TcO_4^- anion from solution, currently a technological challenge in the clean-up of the Hanford radioactive waste tanks in the US.[4]

In general, formation of cyclamers, oligomers, or polymers in transition metal complexes depends on the coordination geometry of the metal, the metal to ligand ratio, the chemical structure of the organic ligands, and the donicity of counterion.[2,5] The 1 : 1 transition metal complexes of linear bifunctional ligands such as pyrazine and 4,4′-bipyridyl are known to form one-dimensional coordination polymers, but the possible network topologies for analogous metal complexes with simple angular bifunctional ligands, *e.g.* pyrimidine, are not well studied.[3,5b,6]† However, one can reasonably anticipate three different networks, or supramolecular isomers, for 1 : 1 pyrimidine metal complexes as delineated in Scheme 1.[7] Indeed, one type of isomer, discrete supramolecular squares [Scheme 1(*c*)], is of current interest owing to their potential host properties. Current synthetic strategies focus on using metal ions at the corners and linear ligands as the spacers, which often requires occupying several of the metal's coordination sites with chelating ligands to force discrete macrocycle formation.[1] We undertook the inverse, construction of such squares utilizing a ligand with angular geometry (pyrimidine) at the corners and a metal with a tendency for linear coordination (Ag^{I}) as the spacer.



Scheme 1 M = Metal atom

Crystals of [Ag(pyrimidine)][NO_3] **1**, were obtained when methanolic solution (15 ml) of pyrimidine (0.08 g, 1 mmol) was reacted with $AgNO_3$ (0.169 g, 1 mmol) dissolved in acetonitrile (15 ml) through careful layering in a test tube at room temp. Complex **1** is an interesting cyclic self-assembly of pyrimidine and Ag^{I} forming a supramolecular square with H···H contacts within the cavity *ca.* 3.8 × 3.8 Å [Scheme 1(*c*), Fig. 1].‡ The squares exist in planar sheets with each square face-to-face stacked to six other squares (one edged stacked and two corner stacked each, in the sheets above and below the square plane, Fig. 2) at 3.45 Å. The planar sheets coincide every fifth sheet, thus the channels perpendicular to each plane of squares, are actually formed both by open squares and by an edge and two corners of three squares in the planes above and below. The NO_3^- anions are inside the channels and are weakly coordinated with the Ag^{I} cations (nine Ag···O interactions in the range 2.6–3.2 Å) and accept aromatic C–H···O hydrogen bonds. There are as many as 18 C–H···O hydrogen bonds with C···O

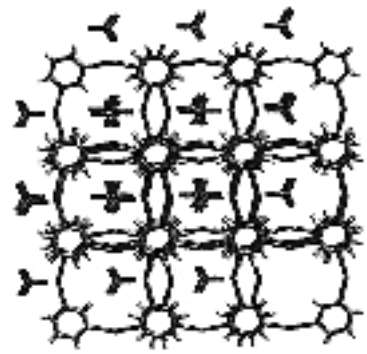


Fig. 1 Packing diagram of **1**. The channels depicted are formed from the supramolecular square in every fifth plane and by an edge and two corners of a total of three squares in all other planes. Additional channels through the centers of the squares exist at an angle to the square plane.

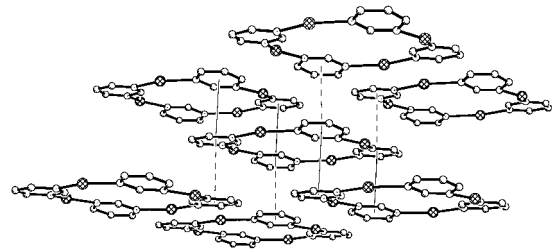

Fig. 2 The face-to-face stacking of a supramolecular square to six other squares is indicated with solid (square edges stacked) and dashed (square corners stacked) lines

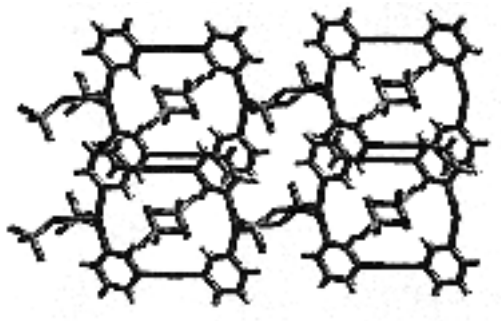

Fig. 3 The 1D coordination polymers of **2** are stacked to form open channel networks

distances and C–H···O angles in the range 3.0–3.5 Å and 110.7–150.4°.[8]

Because of the open and hydrophobic nature of the channels and the weak cation and anion interactions, we attempted to exchange the nitrate anions with larger softer anions such as ReO_4^- and TcO_4^-. 0.0158 g of complex **1** crystals were suspended in 1 ml of MeOH containing 0.114 μCi of $NH_4{}^{99}TcO_4$. After stirring for 2 h the activity of the solution was reduced by 12%. A significant reduction in the activity, *ca*. 40%, was observed after 24 h and the distribution ratio for TcO_4^- was calculated to be 95.§ We also examined the radioactivity of the above crystals after washing them thoroughly with fresh MeOH. A 0.008 g sample of the crystalline material used above showed an activity of 885 counts min^{-1} confirming the presence of TcO_4^-. Further, dissolution of complex **1** (0.062 g, 0.25 mmol) in 25 ml of MeOH–H_2O (3 : 1) containing $NaReO_4$ (0.068 g, 0.25 mmol) and recrystallization at room temp., yielded crystals of [Ag(pyrimidine)][ReO_4] **2**. Complex **2** also consists of supramolecular squares (internal cavity H···H separations*ca*. 3.3 × 4.3 Å) as observed in **1** with ReO_4^- both in the open channels and forming a 1D coordination polymer [Ag–O, 2.413(8), 2.480(10) Å] as shown in Fig. 3. The ReO_4^- anions in the channels form 15 C–H···O hydrogen bonds (C···O distances and C–H···O angles are within the ranges of 3.1–3.5 Å and 110.0–143.5°, respectively) in addition to long Ag···O contacts (four contacts found between 2.8 and 3.0 Å). The 3D structure of **2** is stabilized by face-to-face stacking of square edges (3.44 Å) such that each square stacks with only two other squares in a stair-step fashion (one above and one below the square plane, Fig. 3).

Our attempts to grow single crystals of the 1 : 1 complex of $AgClO_4$ (0.207 g, 1 mmol) and pyrimidine (0.08 g, 1 mmol) from MeOH (25 ml, room temp.) resulted in an unexpected 5 : 6 complex, $[Ag_{2.5}(pyrimidine)_3][ClO_4]_{2.5}$ **3**. The crystal structure of **3** is a 1D coordination polymer with supramolecular squares similar to **1** and **2** (internal cavity H···H separation,*ca*. 2.8 × 4.8 Å) but the squares are crosslinked by a dimeric pyrimidine unit vertically in a staircase fashion as shown in Fig. 4. Indeed, this is a combination of possible isomers outlined for 1 : 1 metal complexes in Scheme 1. One of the ClO_4^- anions is coordinated to Ag [Ag–O 2.496(7) Å] and one is found to be disordered. Further, the anions have eight Ag···O contacts between 2.7 and 3.2 Å and 20 C–H···O hydrogen bonds (C···O distances and C–H···O angles are within the ranges 3.1–3.5 Å and 113.0–172.5°, respectively). The 1D layers of **3** are face-to-face stacked on square edges in a stair-step fashion as observed for **2**, but at a longer 3.87 Å separation.

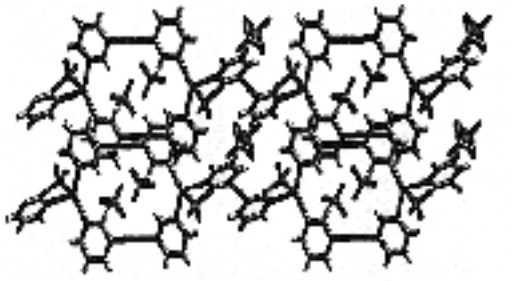

Fig. 4 The supramolecular squares of **3** are vertically crosslinked by dipyrimidine units in a staircase fashion to form 1D coordination polymers. The polymers are face-to-face stacked on edge in a stair-step fashion as observed in **2** albeit at a longer aromatic···aromatic separation. Note that one of the ClO_4^- anions is disordered.

In conclusion, the angular geometry of pyrimidine or of any other simple angular bifunctional ligands may be readily exploited to construct discrete inorganic macrocyclics and a variety of coordination polymers as well, by making subtle changes in the metal/ligand ratio (including the uncommon ratios as observed for complex **3**) or donicity of the anion. Currently, we are investigating the conditions required for preferential formation of the descrete supramolecular square *vs*. the 1D/2D coordination polymers in complexes of pyrimidine and its derivatives.

† A survey of the Cambridge Structural Database (April, 1997 release) for simple pyrimidine metal complexes resulted in five hits. Of these, only two complexes contain pyrimidine exclusively as a ligand, *i.e.*, with no other ligands additionally bonded to the metal (Refcodes: PMDPTA, PMDPTB). However, recently, pyrimidine has been used to generate an acentric 3D coordination polymer of Cu^I, S. W. Keller, *Angew. Chem., Int. Ed. Engl.*, 1997, **36**, 247.

Regiocontrol in palladium-catalysed allylic alkylation by addition of lithium iodide

Motoi Kawatsura, Yasuhiro Uozumi and Tamio Hayashi*

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo, Kyoto 606-01, Japan

Regioselectivity in the palladium-catalysed allylic alkylation of 1-arylprop-2-enyl acetates [ArCH(OAc)CH=CH_2] or (*E*)-3-phenylprop-2-enyl acetate (PhCH=$CHCH_2OAc$) with sodium enolates of soft carbon nucleophiles is controlled by addition of a catalytic amount of lithium iodide to give lienar products [(*E*)-ArCH=$CHCH_2$Nu] exclusively; their branch isomers [ArCH(Nu)CH=CH_2] were not detected.

In synthetic organic chemistry, palladium-catalysed allylic alkylation of allyl esters is a useful reaction for the formation of carbon–carbon bonds.[1] One of the challenging problems in catalytic allylic alkylation is control of the regiochemistry in the reaction that proceeds through unsymmetrically substituted π-allylpalladium intermediates. For example, the π-allylpalladium complex containing one substituent at the C-1 position usually produces both linear and branch isomers, the ratio being dependent on the substituents, nucleophiles and reaction conditions.[1–3] Here we report exclusive formation of the linear isomer in a palladium-catalysed allylic alkylation, which is realized by addition of a catalytic amount of lithium iodide.[4]

In the presence of 2 mol% of the palladium catalyst generated by mixing $[PdCl(\pi\text{-}C_3H_5)]_2$ with PPh_3 (2 equiv. to Pd), allyl acetates **1**–**4** were allowed to react with soft carbon nucleophiles in THF at 0 °C (Scheme 1). The regioselectivity of the reaction was found to be dramatically changed by the addition of lithium iodide. Thus, the reaction of 1-phenylprop-2-enyl acetate **1** with the sodium salt of dimethyl methylmalonate in the absence of lithium iodide gave a 96% yield of alkylation product; consisting of linear isomer (*E*)-**5a** and branch isomer **6a** in a ratio of 77 : 23 (entry 1, Table 1). On the other hand, the reaction carried out in the presence of 10 mol% of lithium iodide gave a quantitative yield of linear isomer **5a** with 100% regioselectivity (entry 2). The regioselectivity was not strongly affected by the addition of lithium fluoride, chloride or bromide, branch isomer **6a** being formed with about 20% regioselectivity (entries 3–5). High linear selectivity was also observed in the reaction in the presence of sodium iodide (entry 6), indicating that the iodide anion is important for control of the regioselectivity. The amount of lithium iodide additive can be decreased to 2 mol%, which is the same amount as that of the palladium catalyst (entry 7). Use of the palladium catalyst generated from $[PdI(\pi\text{-}C_3H_5)]_2$ instead of $[PdCl(\pi\text{-}C_3H_5)]_2$ showed the same linear selectivity in the absence of additional iodide anion (entry 8).

The selectivity in forming the linear isomer in the presence of lithium iodide was also observed in the reaction of 1-arylprop-2-enyl acetates **2** and **3** and 3-phenylprop-2-enyl acetate **4** with the sodium salt of dimethyl methylmalonate (entries 9–13) and

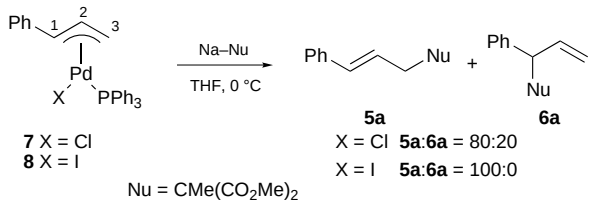
[a] All reactions were carried out in THF under nitrogen: THF (1.0 ml), allylic acetate (0.20 mmol), NaNu (0.40 mmol), $[PdCl(\pi\text{-}C_3H_5)]_2$ (0.002 mmol) and phosphine ligand at 0 °C. [b] The ratio of Pd : Phosphine = 1 : 2. [c] Isolated yield by silica gel column chromatography. [d] The ratio was determined by ^1H NMR analysis of the products. [e] $[PdI(\pi\text{-}C_3H_5)]_2$ was used. [f] Carried out at 20 °C.



Scheme 2

in the reactions with dimethyl malonate and methyl acetoacetate (entries 14–17).

It is noteworthy that the addition of lithium iodide is not effective for the reaction catalysed by a palladium–bisphosphine complex. Thus, the reaction of **1** with dimethyl methylmalonate in the presence of a palladium catalyst prepared from $[PdCl(\pi\text{-}C_3H_5)]_2$ and 1,2-bis(diphenylphosphino)ethane (dppe) gave a mixture of **5a** and **5b** in a ratio of 89 : 11, irrespective of the addition of lithium iodide (entries 18 and 19). These results suggest that, in the reaction catalysed by triphenylphosphine–palladium, the iodide coordinates to the π-allylpalladium intermediate to form the intermediate $PdI(\pi\text{-allyl})(PPh_3)$, and that the iodide on the palladium controls the regioselectivity of the nucleophilic attack. Using the dppe ligand, the intermediate will be the cationic complex $[Pd(\pi\text{-allyl})(dppe)]^+X^-$, where iodide is not directly bonded to palladium.

Palladium complex $PdCl[\pi\text{-}(1\text{-phenyl})allyl](PPh_3)$ **7** and its iodide analogue **8** were prepared by mixing $[PdX[\pi\text{-}(1\text{-phenyl})allyl]]_2$ (X = Cl and I)[5] with PPh_3 (1 equiv. to Pd) and were characterized by ^{31}P, ^1H and ^{13}C NMR spectroscopy.† Both have the substituted carbon (C-1) of the π-allyl *trans* to the phosphorus atom of PPh_3 and the unsubstituted carbon (C-3) *cis* to phosphorus, as determined by the large coupling constants (J = 10.1 Hz in **7** and 10.5 Hz in **8**) between the C-1 proton and phosphorus, and no coupling between the C-3 protons and phosphorus. Stoichiometric reaction of chloride complex **7** with the sodium enolate of dimethyl methylmalonate in THF at 0 °C gave **5a** and **6a** in a ratio of 80 : 20, while the reaction of iodide complex **8** gave **5a** with 100% regioselectivity (Scheme 2). These selectivities are in good agreement with those observed in the catalytic reactions, demonstrating that the iodide ligand bonded to the π-allylpalladium intermediate controls the regioselectivity. Comparing the ^{13}C NMR spectra of **7** and **8**, the chemical shift for C-3 of the π-allyl group of **8** appears at lower field than that for **7** by 6.5 ppm and the chemical shift for C-1 of **8** appears at higher field than that for **7** by 3.1 ppm. The difference in the chemical shifts may support the idea that the C-3 carbon of the iodide complex **8** undergoes the nucleophilic attack giving linear isomer **5a** more selectively than that of **7**.[6]

If Watson–Crick and Hoogsteen sites of guanine are blocked, hydrogen bonding with cytosine is *via* N^2 and N^3

Roland K. O. Sigel, Eva Freisinger and Bernhard Lippert*

Fachbereich Chemie, Universität Dortmund, D-44221 Dortmund, Germany

A novel hydrogen bonding scheme between cytosine and guanine nucleobases is observed if both N^1 and N^7 positions of the guanine are blocked by a metal entity and a methyl group, respectively.

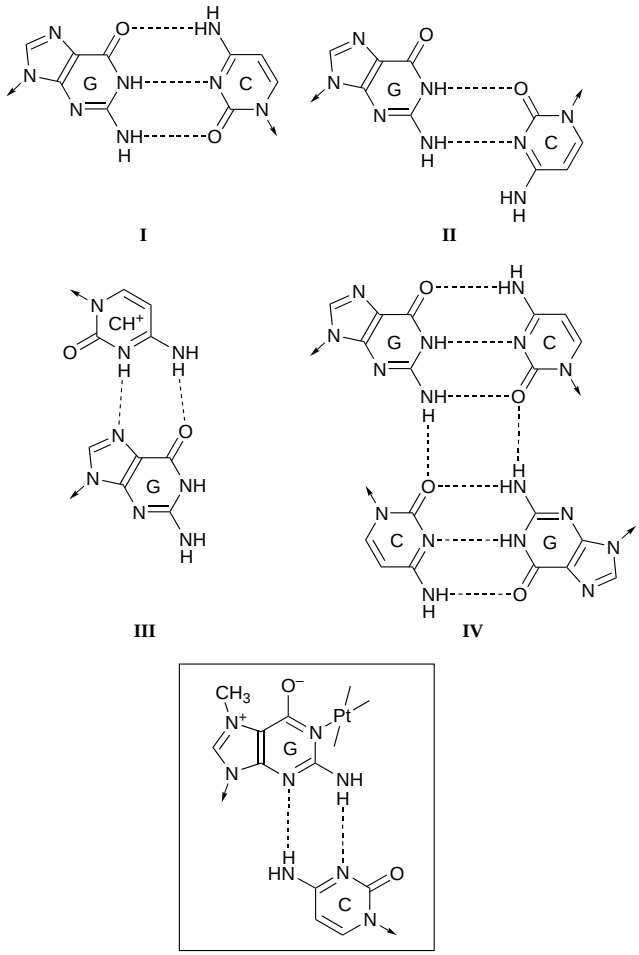
Chemical modification of nucleobases can result in severely altered hydrogen bonding patterns as far as base selectivity and/or hydrogen bonding sites are concerned. When occurring in DNA, potentially dangerous consequences can be expected, as known in the case of guanine methylated at the 6-position.[1] Here we demonstrate, on a model nucleobase level, that the complementary nucleobases guanine (G) and cytosine (C) associate in a hitherto unknown fashion if both Watson–Crick, and Hoogsteen hydrogen bonding sites are blocked.

Base pairing between G and C is predominantly according to the Watson–Crick scheme (Scheme 1, **I**), and very rarely, *e.g.* between G_{15} and C_{48} in yeast $tRNA^{Phe}$, of the reversed Watson–Crick type (**II**).[2] With protonated cytosine, and possibly also with neutral cytosine in a rare tautomeric form,[3] pairing is of the Hoogsteen type (**III**). In addition to these principal hydrogen bonding patterns, there is also the possibility of association to quartet structures through dimerization of two Watson–Crick pairs *via* hydrogen bonds (**IV**).[4]

Metal binding at the N^7 site of G still permits types **I** and **IV** hydrogen bonding patterns.[5,6] Alternatively it can lead to a 'metal-modified' Hoogsteen pattern[5] or, upon guanine deprotonation at N^1, to either mispairing with free guanine[7] or formation of a quite unusual nucleobase quartet.[8] Additional blockage at N^1 leads to the pattern **V** hereafter.

7,9-Dimethylguanine (7,9-dmgua), a model of the rare nucleobase 7-methylguanosine, forms 2:1 complexes with *trans*-$Pt^{II}am_2$ (am = NH_3 or NH_2Me) of composition *trans*-$[Ptam_2(7,9\text{-dmgua-}N^1)_2]X_2{\cdot}nH_2O$. Recently we have published the X-ray structure analyses for the combination am = NH_2Me, X = NO_3^-, n = 0.[9] With am = NH_2Me, X = ClO_4^- cocrystallization with the model nucleobase 1-methylcytosine (mcyt) from water† gave crystals suitable for X-ray crystallography.‡

As can be seen in Fig. 1, each mcyt molecule forms two strong hydrogen bonds; one to a coplanar 7,9-dmgua ligand, N(3a′)···N(2) 2.881(8) Å, and the second one to the amine group of NH_2Me of another cation lying below the pyrimidine [O(2′)···N(10) 2.878(6) Å]. Furthermore the pyrimidine rings are stacking (3.4 Å) with the platinated purine ligands leading to an arrangement like tiles of a roof. These strong intermolecular interactions bring the exocyclic amino group of mcyt in relatively close proximity to N(3) of 7,9-dmgua [N(3)···N(4a′) 3.194(8) Å] leading to an arrangement as shown in Fig. 2. Although the latter distance is at the upper end of a hydrogen bond, the sum of the van der Waals radii of H and N (1.20 Å + 1.55 Å = 2.75 Å)[10] is still larger than the distance between the H and the acceptor N [2.340(8) Å], so it can still be considered as such,[11] especially in view of the near-coplanarity of the two bases [dihedral angle 2.3(3)°].



Scheme 1

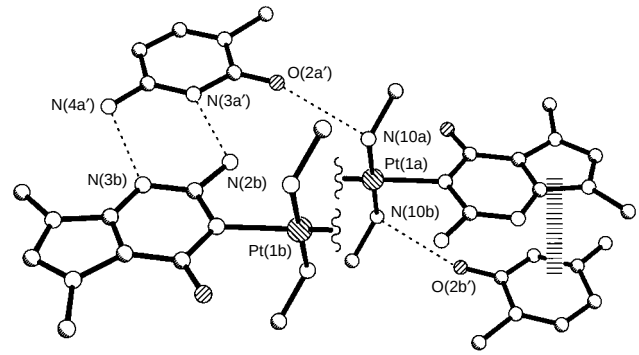


Fig. 1 Section of packing of cations and mcyt in the crystal lattice of *trans*-$[Pt(MeNH_2)_2(7,9\text{-dmgua-}N^1)_2][ClO_4]_2{\cdot}2$mcyt. There is stacking between 7,9-dmgua ligands and mcyt (distance 3.4 Å), one hydrogen bond of 2.878(6) Å between O(2a′) of the free mcyt and N(10a) of the NH_2Me group and another short hydrogen bond between N(3a′) and N(2b) [2.881(8) Å]. At each cation one 7,9-dmgua ligand is omitted for clarity.

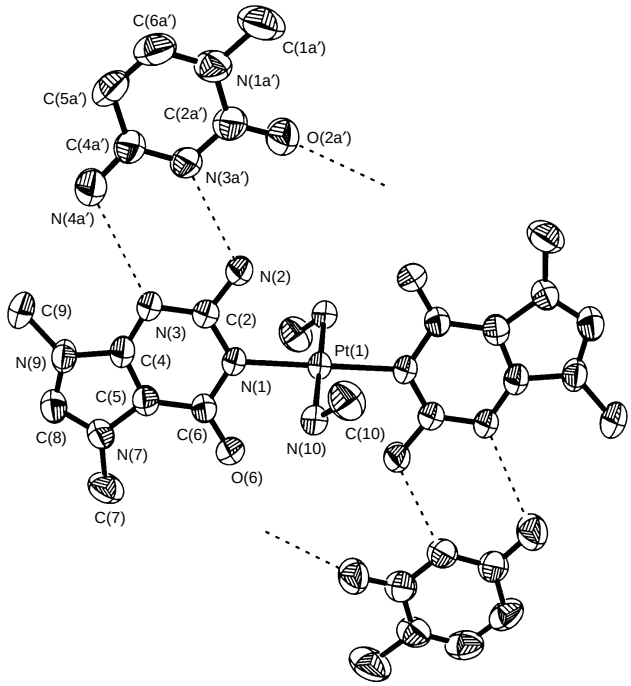

Fig. 2 Hydrogen bonding scheme between 7,9-dmgua and mcyt in *trans*-[Pt(MeNH$_2$)$_2$(7,9-dmgua-*N*^{1})$_2$][ClO$_4$]$_2$·2mcyt with two hydrogen bonds, N(2)···N(3′) 2.881(8) Å and N(3)···N(4′) 3.194(8) Å, between the two nucleobases. Hydrogen bond formation between O(2) sites and N(10) groups is schematically shown.

Involvement of guanine N^2 and N^3 sites in hydrogen bonding with another nucleobase has some precedence, although not with cytosine. In one of the four types of GA mispairs found in RNA,[12] as well as in a base quartet formed as a consequence of crystal packing, the guanine N^3 positions act as hydrogen bond acceptors.[13]

Differential incorporation of 1-deoxy-D-xylulose into monoterpenes and carotenoids in higher plants

Silvia Sagner,[a] Christoph Latzel,[a] Wolfgang Eisenreich,[b] Adelbert Bacher[b] and Meinhart H. Zenk*[a]

[a] *Lehrstuhl für Pharmazeutische Biologie, Universität München, Karlstrasse 29, D-80333 München, Germany*
[b] *Institut für Organische Chemie und Biochemie, Technische Universität München, Lichtenbergstr. 4, D-85747 Garching, Germany*

1-Deoxy-D-xylulose labelled with ^{13}C or ^{14}C is incorporated into the monoterpenoids menthone, menthol, menthofuran, eucalyptol, pulegone, geraniol and thymol by higher plants, however, the rate of incorporation was lower as compared with incorporation into carotene and phytol.

Recent evidence indicates that 1-deoxy-D-xylulose (DX) or a derivative such as the 5-phosphate is the committed precursor for the biosynthesis of isoprenoids in some bacteria.[1,2] The deoxyxylulose pathway is also operative in higher plants.[3–9] Thus, pigments of life, such as chlorophyll and carotenoids are formed in plants from the pentose derivative and not from mevalonate.[7,8] Recent incorporation experiments with ^{13}C-labelled glucose have also shown that essential oils in plants are formed *via* the alternative pathway.[9]

In order to study in more detail the involvement of DX in monoterpenoid biosynthesis, we prepared [1-^{13}C]- and [2-^{13}C]DX by condensation of D-glyceraldehyde with [3-^{13}C]- and [2-^{13}C]pyruvate, respectively, using pyruvate dehydrogenase as catalyst.[10,11] The spectral characteristics of the deoxypentulose obtained were identical to published values.[12] [1,2-$^{14}C_2$]DX was obtained similarly from [U-^{14}C]pyruvate (yield 75–83%; spec. act., 62.5 μCi μmol^{-1}).

Shoots of peppermint (*Mentha x piperita*) with a length of about 5 cm were cut and were allowed to form roots in hydroponic culture. A solution containing 27 μM [1,2-$^{14}C_2$]DX was applied to the rooted shoots for 48 h. The monoterpenes were obtained by steam distillation, and the metabolites were isolated as described earlier.[9] Relative specific activities of 0.1% for menthone, 0.2% for menthol, 0.3% for menthofuran and 0.3% for eucalyptol were observed. In similar experiments, *Mentha pulegium* showed incorporation into pulegon (0.2%), *Pelargonium graveolens* into geraniol (0.3%), and *Thymus vulgaris* into thymol (0.2%).

^{13}C-Labelled DX samples were supplied to *M. piperita* shoots at a concentration of 25 mM. Menthone was isolated[9] and was subjected to NMR analysis as described earlier.[7] Relative ^{13}C abundance of individual carbon atoms was calculated from the NMR signal integrals of biosynthetic samples by comparison with the natural abundance sample (% ^{13}C in Table 1). The values were referenced to 1.10% for the carbon with the lowest ^{13}C enrichment. In the experiment with [1-^{13}C]DX, the carbon atoms 7 and 9 of menthone were enriched with 1.49 and 1.41% ^{13}C abundance, respectively. The other atoms were virtually unlabelled with 1.16 ± 0.06% ^{13}C abundance. On the other hand, [2-^{13}C]DX labelled the carbon atoms 1 and 8 of menthone with 1.39 and 1.41% ^{13}C abundance, whereas the other atoms had a ^{13}C abundance of 1.20 ± 0.05% (Table 1). On the basis of the established isoprene dissection of the cyclic monoterpene it follows that [1-^{13}C]DX enriched C-5 of IPP/DMAPP and that [2-^{13}C]DX enriched C-3 of IPP/DMAPP, respectively (Fig. 1). This labelling pattern is in full accordance with terpenoid formation *via* the deoxyxylulose pathway.

It should be noted that the observed incorporation rates of DX into the monoterpenes under study are low. However, they exceed the rates achieved with labelled acetate or mevalonate by factors of at least 10 to 100 fold.[13] This indicates that the deoxyxylulose pathway is the dominant metabolic route for essential oil formation. Based on the incorporation of ^{13}C- and ^{14}C-labelled DX and on our previous [^{13}C]glucose feeding experiments using the same plants,[9] we conclude that the deoxyxylulose pathway leading to isopentenyl pyrophosphate (IPP) and dimethylallyl pyrophosphate (DMAPP) is operative in essential oil formation, which is at variance with previous reports.[14]

In experiments using *M. piperita* it was observed that [1,2-$^{14}C_2$]DX was incorporated with considerably higher rates into chlorophyll a and b (13%) and into β-carotine (10%) than into the monoterpenes. This is in accordance with incorporation rates of DX into chlorophylls and carotenoids in a cell culture of *Catharanthus roseus*.[7] The different incorporation rates of DX into monoterpenes and into chlorophylls/carotenoids could indicate that an enzyme involved in the utilization of exogenous DX (*e.g.* a kinase) is limiting in the plant glandular trichomes which have been recognized as sites of monoterpenoid biosynthesis,[14,15] but not in the chloroplasts where chlorophylls and carotenoids are synthesized. Limited transport of labelled DX into the plant glandular trichomes might also explain the discrepancy of incorporation rates.

Table 1 ^{13}C NMR analysis of menthone from *Mentha x piperita* supplied with ^{13}C labelled 1-deoxyxylulose (DX). Values indicative for IPP formation *via* the deoxyxylulose pathway are shown in bold type. The signal with lowest ^{13}C enrichment (marked by asterisk) was referenced to 1.1% ^{13}C abundance

Oligomerisation of ethene in polar solvents at higher temperatures is achieved using new palladium iminophosphine catalysts and the oligomer selectivity can be controlled by the nature of the ligand substituents.

Oligomerisation and polymerisation of alkenes by early[1] and late transition metal catalysts[2] leads to important commercial products and currently much effort is devoted towards the development of more efficient and selective catalysts. Commonly, late transition metal complexes produce dimers of alkenes due to fast β-hydrogen abstraction.[3] Until now, only a limited number of oligomerisation or polymerisation reactions by late transition metal catalysts are known. An example is the ethene oligomerisation process with a nickel catalyst developed by Keim *et al.*,[4] well known as SHOP[1a] (Shell Higher Olefin Process). Recently, Brookhart and coworkers have reported on ethene polymerisation with bisimine Pd^{II} or Ni^{II} complexes in CH_2Cl_2 or toluene.[5] Furthermore, bisimine and bisphosphine Pd^{II} complexes are highly efficient in alkene/CO copolymerisation.[6] We report here new palladium catalysts based on iminophosphine ligands which result in the unexpected switch to oligomerisation of ethene in polar solvents.

Bidentate iminophosphine ligands are known to bind to Pd in a unique way: the soft P atom coordinates very strongly to Pd whereas the hard N donor is weakly bound.[7] We envisaged that these features might be exploited in tuning the reactivity of Pd complexes in alkene coupling reactions. For this purpose, we synthesised new iminophosphine ligands **3** from the corresponding amine and aldehyde[8] as shown in Scheme 1.

The catalysts were formed by the combination of the bidentate ligands **3**, $Pd(OAc)_2$ and a weakly or non-coordinating anion (X^-) for instance toluene-*p*-sulfonic acid (TsOH), *via* an anion exchange reaction. The oligomerisation reactions

Scheme 1 Synthesis of **3**

performed under 20 bar ethene with these complexes gave remarkable results: at a high temperature (100 °C) and in a polar solvent (MeOH) higher alkenes were obtained (Table 1). In sharp contrast with these results, diphosphines show higher conversion rates at these temperatures, but only dimers are obtained[3d] whereas Brookhart's diimine system[5] polymerises ethene at 25 °C. In the latter case, chain transfer took place only a few times (for 0.1 mmol Pd catalyst, 45.3 g polyethylene was obtained with $M_w = 11.2 \times 10^4$), while for the new ligand system this feature was observed many times (for **3i** *ca*. 250 times).

Table 1 shows the product ratios for various iminophosphine ligands.† Increasing the steric bulk at the nitrogen donor site, results in higher molecular masses (compare entries 1 and 2 with 3 and 7 with 9). Furthermore, when more steric bulk on the phosphorus site is introduced (in the case of *o*-OMe analog **3i**) the molecular mass is increased again (compare entries 3, 4, 5 and 9). This is in accordance with observations by Brookhart and coworkers, who found with bisimine ligands, that blocking of the axial positions led to polymers with higher molecular mass.[5]

To obtain more insight into the structure of the catalyst, an X-ray analysis was performed on [Pd(L)Me(Cl)] **4** (L = **3i**),‡ which was synthesised from **3i** and [Pd(cod)Me(Cl)] (cod = cycloocta-1,5-diene). In structure **4** (Fig. 1) Pd is coordinated by N, P, Cl and a Me group in a square planar mode. Examination of the space filling model of **4** showed that one axial position of Pd is blocked effectively by an Pr^i group and one *o*-OMe group (Fig. 2). The other axial position is partly blocked by the second *o*-OMe group.

Remarkably, the activity is increased dramatically (turnover number from 250 to 1100), by replacing the two Ph groups on P by *o*-OMePh groups (Table 1, entry 8). This is due to a steric effect because no higher activity was obtained for the *p*-methoxyphenyl analogue. The catalytic activity is furthermore influenced by electronic effects in the imino donor site; in particular electron releasing groups enhance the rate. For instance by changing R^3 from Cl **3f** to OMe **3h** an increase of turnover from 150 to 800 is observed.

Selected bond lengths (Å) and angles (°): Pd–P 2.2092(10), Pd–N 2.170(3), Pd–Cl 2.3734(11), Pd–C(34) 2.062(4); Cl–Pd–P 168.85(4), Cl–Pd–N 92.08(9), Cl–Pd–C(34) 88.29(10), P–Pd–N 89.72(9), P–Pd–C(34) 90.86(10), N–Pd–C(34) 175.08(12).

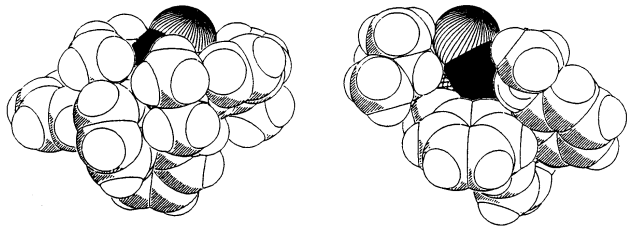

Fig. 2 CPK plots of **4** (top and bottom view, Pd = black)

A tremendous activity increase could be obtained by change of solvent. For instance, in ethylene glycol the activity increased to 1100 turnovers in 1.5 h by using ligand **3h**.

With all ligands, the molar growth factor K (moles C_{n+2}/mol C_n) is dependent on the chain length. When the chain length is higher, K decreases; for example **3i** gave $K(C_8/C_6) = 1.14$ while $K(C_{14}/C_{12}) = 0.6$ (Table 1). This suggests that chain migration takes place, giving branched alkyl fragments. This branching leads to a decreased propagation and increased termination owing to steric hindrance. This is confirmed by the observation that for longer chains, more branched products were found (Table 2). Furthermore, the isomerisation increased (K decreased) at higher temperatures [*e.g.* **3i** gave $K(C_8/C_6) = 1.46$ at 70 °C and 0.88 at 120 °C, Table 3] as well as the amount of branched products (Table 2). Decrease of the steric hindrance in the ligand, resulted also in more branched products (compare **3c** and **3i**).

Table 2 Percentage linearity of C_6–C_{12}

3	120	5	1650	32	28	20	11	6	3

In conclusion, a new palladium based catalyst system for ethene oligomerisation has been developed. Remarkable features are the excellent stability in polar solvents at high temperatures, the formation of C_6–C_{16} oligomers at these temperatures and the possibility to tune the oligomer selectivity by the iminophosphine ligands.

† The amount of butenes was not measured due to the volatility. Therefore, the combined C_6–C_{16} fractions are set at 100%; the relative mol percentages for the alkenes in this range are given. However, it should be noted that in case the amount of octenes is larger than the amount of hexenes, the amount of butenes is expected to be lower than the amount of hexenes.

‡ *Crystal data* for **4**: $C_{34}H_{39}ClNO_2PPd{\cdot}CH_2Cl_2$, M_r = 751.47, yellowish block shaped crystal (0.13 × 0.20 × 0.50 mm), monoclinic, space group $C2/c$, a = 38.074(5), b = 10.851(1), c = 17.661(1) Å, β = 111.10(1), U = 6807.2(1) Å^3, Z = 8, D_c = 1.467 g cm^{-3}, $F(000)$ = 3088, μ(Mo-Kα) = 8.6 cm^{-1}; 8340 reflections ($1.15 < \theta < 27.50°$; ω scan; T = 150 K) were measured on an Enraf-Nonius CAD-4T diffractometer (rotating anode, graphite-monochromated Mo-Kα radiation [λ = 0.71073 Å]). Data were corrected for L_p effects, for the linear decay (0.4%) of the intensity control reflections during 19 h of X-ray exposure and merged into a dataset of 7671 unique reflections. The structure was solved with standard Patterson methods (DIRDIF 96) and difference Fourier techniques. Hydrogen atoms were introduced at calculated positions and refined riding on their carrier atoms. All non-H atoms were refined on F^2 (SHELXL-96) using all 7671 unique reflections, with anisotropic thermal parameters. Convergence was reached at R_1 = 0.0460 for 5757 reflections with $I > 2.0\sigma(I)$ and 421 parameters; wR_2 = 0.1065, S = 1.011 for all 7671 reflections, $w = 1/\sigma^2(F_o^2) + (0.0488P)^2 + 5.42P$. A final difference Fourier map shows residual densities between −1.11 and +0.70 e Å^{-3}. CCDC 182/690.

NMR spectroscopic evidence for chromium(VI) alkoxides with α-hydrogen atoms

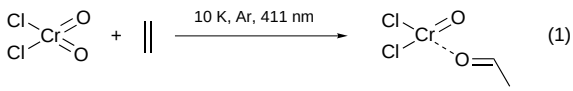
Christian Limberg,* Sven Cunskis and Axel Frick

Universität Heidelberg, Anorganisch-Chemisches Institut, Im Neuenheimer Feld 270, D-69120 Heidelberg, Germany

Selective insertion of epoxides into one Cr–Cl bond of chromyl chloride at −50 °C enabled, for the first time, the spectroscopic identification of Cr^{VI} alkoxides with α-hydrogen atoms.

For quite some time alkene oxidation with chromyl chloride seemed to proceed completely unspecifically and uncontrollably.[1] In 1977 Sharpless *et al.* made an attempt to explain the occurrence of the various products and the stereochemistry involved *via* several intermediates[2] which subsequently aggregate to the Etard complex and none of which have ever been characterised.

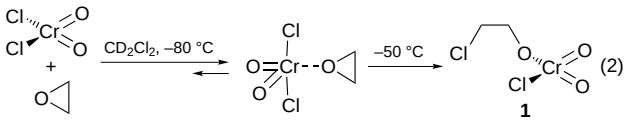
Recently, with the aid of matrix isolation an alkene oxidation by chromyl chloride could be stopped before aggregation and the species $O{=}CrCl_2\cdots O{=}CHCH_3$ [eqn. (1)] was identified.[3]



(1)

This finding could provide an explanation for the isolation of carbonyl compounds after such reactions, which had previously been understood as a result of the rearrangement of chlorohydrins and epoxides in solution.[1]

Formation of this complex could be considered *via* photolysis of the intermediate $O{=}CrCl_2\cdots\overline{OCH_2CH_2}$ stimulating an investigation concerning the behaviour of ethylene oxide in the presence of Lewis acids at low temperatures. Since $O{=}CrCl_2$ is not available on a preparative scale, in search of an appropriate reagent which could model some of the properties of $O{=}CrCl_2$, the initial starting material, CrO_2Cl_2, was studied. After co-condensation of this reagent with 1 equiv. of ethylene oxide and CD_2Cl_2 in an NMR tube and flame-sealing the sample was investigated at −80 °C. ^{1}H NMR spectra (Fig. 1) showed that ethylene oxide co-ordinates to CrO_2Cl_2, as indicated by a broad resonance at δ 3.29 for the ethylene oxide protons.† This signal remains at this position if a second equiv. of ethylene oxide is added meaning that CrO_2Cl_2 is capable of co-ordinating up to two epoxide molecules. Consequently the complex shown in eqn. (2) must be in equilibrium not only with free CrO_2Cl_2 but



(2)

1

also with $CrO_2Cl_2{\cdot}2OC_2H_4$. Correspondingly, if 4 equiv. of ethylene oxide are reacted with CrO_2Cl_2 a signal at δ 3.01, intermediate between free and co-ordinated oxirane, is observed. Photolysis at this stage resulted in C–H activation and formation of paramagnetic compounds. However, warming of a 1 : 1 sample to −50 °C triggered a cleavage reaction of the three-membered ring[4] by one Cl ligand of CrO_2Cl_2 producing the species $O_2Cr(OCH_2CH_2Cl)Cl$ **1**. After 60 min the yield of **1** amounts to 75%, however, at this stage the decomposition rate of **1** becomes faster than its formation.

Dark red **1** has been characterised by ^{1}H, ^{13}C (135° DEPT), ^{1}H/^{13}C-HMQC and ^{1}H/^{1}H-COSY NMR spectra showing two coupling CH_2 groups‡ both of which appear in the characteristic regions for the proposed connectivity. In addition ^{17}O NMR data of concentrated samples were recorded: the initial signal of the CrO_2 group of the CrO_2Cl_2–oxirane complex (one broad resonance at δ 1476) decreased at −50 °C in favour of a new signal for the terminal oxygens in **1** at δ 1429 indicating that the CrO_2 group has been preserved. Signals for the oxirane and alkoxide oxygens could not be detected in accordance with the results of investigations concerning molybdate esters.[5] Concentration dependent experiments in the presence of a standard (CH_2Cl_2) confirmed that only 1 equiv. of ethylene oxide per Cr centre is consumed during the formation of **1** and that accordingly ethylene oxide inserts into only one Cr–Cl bond excluding the formation of the bis(2-chloroethyl) chromate ester. Instead, increasing the initial concentration of the oxirane decreases the lifetime of **1**, which decomposes to paramagnetic dark brown compounds, so terminating the NMR experiments. These species, small amounts of which are constantly generated at −50 °C at any ethylene oxide concentration, can explain the continuous broadening of the signal of ethylene oxide and its shifting to higher field (Fig. 1): ethylene oxide equilibrating rapidly between its free state and complexation to CrO_2Cl_2 and **1** also binds reversibly to the paramagnetic compounds and therefore the averaged signal observed in the experiment is increasingly broadened with time. In $CFCl_3$ the paramagnetic complexes precipitate as brown solids and accordingly the ethylene oxide signal does not shift or broaden significantly. The positive results after replacement of CD_2Cl_2 additionally rule out its participation in the reaction sequence leading to **1**.

1 is contaminated by only one other compound, **2** (*ca*. 8% in the experiment shown in Fig. 1), whose identification proved difficult because of its low concentration, limited stability and

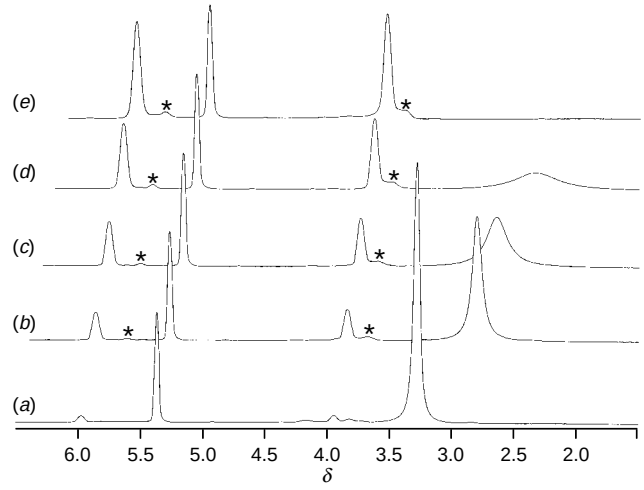


Fig. 1 ^{1}H NMR spectra of a mixture of 0.8 mmol CrO_2Cl_2 and 0.8 mmol of ethylene oxide in CD_2Cl_2 (*a*) at −80 °C and after annealing to −50 °C for (*b*) 10 min, (*c*) 20 min, (*d*) 40 min and (*e*) 60 min. The signals marked with an asterisk belong to **2**.

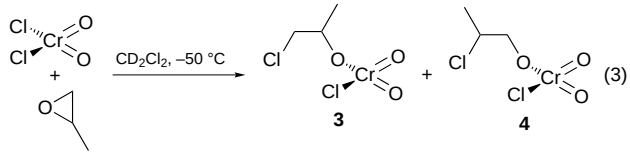
considerable linewidths of its signals thwarting all attempts to record COSY spectra. Its ^{1}H and ^{13}C NMR data may be interpreted in terms of the compound $O_2Cr(Cl)OCH_2CH_2OCH_2CH_2Cl$ being formed by insertion of two ethylene oxide molecules into one Cr–Cl bond. This is supported by the fact that $FeCl_3$ has been found to react with ethylene oxide to give uncharacterised chloroferric alkoxides producing chloroethanol and 2-(2-chloroethoxy)ethanol upon hydrolysis.[6] However, due to the insufficient spectroscopic data the assignment of **2** is speculative.

Scheme 1

Compound **1** is remarkable because it is the first Cr^{VI} alkoxide with α-hydrogens whose existence has been proved spectroscopically.§ It is well known that Cr^{VI} compounds oxidise primary and secondary alcohols to carbonyl compounds[8] and recent DFT calculations by Deng and Ziegler[10] have shown that the key step in CrO_2Cl_2 oxidations is probably that shown in Scheme 1. While chromate esters of tertiary alcohols[11] are protected against this decomposition route the activation of α-hydrogens by terminal Cr=O groups is possible for **1** so that its thermal sensitivity (decomp. within 15 min at −30 °C) is not a surprise. However, the smooth synthesis presented above which can be performed at low temperatures without simultaneous formation of by-products allows its NMR spectroscopic characterisation. Attempts to isolate **1** and **2** at −50 °C by removal of all volatiles led to a brown glass, whose hydrolysis yielded, as expected, 2-chloroethanol and chloroacetaldehyde contaminated by small amounts of compounds of unknown composition, some of which were identical with the chromyl chloride oxidation products of 2-(2-chloroethoxy)ethanol, supporting the assignment of **2**. When the brown glass is annealed to room temp. in the absence of any reactant a heterogeneous decomposition product is obtained in which the organic oxidation products remain coordinated to the chromium centres as they do in the Etard complex.[12] Accordingly its IR spectrum is dominated by strong bands at 3301 [ν(OH)], 1640/1570/1430 [ν(C=O)] and 1066 cm^{-1} [ν(C–O)].

Surprisingly, when propylene oxide was reacted with CrO_2Cl_2 at −50 °C both possible regioisomers[12] were found in a close to 1 : 1 ratio [eqn. (3)]. A similar lack of selectivity has



(3)

been found *e.g.* in epoxide cleavages using VCl_3·3thf.[13] The reaction mechanism and the stereochemistry involved in epoxide opening by CrO_2Cl_2 are under current investigation. Further research also concerns the expansion of this novel route yielding oxochromium(VI) alkoxides to the syntheses of stable candidates of this class of compounds, *i.e.* those eluding α-hydrogens, which find application as useful oxidation reagents.[10]

C. L. thanks the Deutsche Forschungsgemeinschaft for a scholarship as well as funding and Professor Dr G. Huttner for his generous support.

† Free ethylene oxide shows a singlet at δ 2.58.

‡ Owing to the linewidths of the signals no coupling information could be deduced from the COSY experiments. In Fig. 1 no coupling is resolved, in other experiments, however, a triplet structure for the two signals became obvious. ^{1}H NMR (200 MHz, CD_2Cl_2, −50 °C, $SiMe_4$): δ_H 5.96 [2 H, br t, ^3J(HH) 4.8 Hz, OCH_2], 3.95 [2 H, br t, ^3J(HH) 4.8 Hz, $ClCH_2$]; ^{13}C NMR (200 MHz, CD_2Cl_2, −50 °C, $SiMe_4$): δ_C 94.22 (OCH_2), 46.06 ($ClCH_2$).

§ Chada *et al.*[7] claim to have prepared oligomers of $O_2Cr(OCH_2CH_2Cl)_2$ (said to show just one singlet by ^{1}H NMR) by refluxing CrO_2Cl_2 with the corresponding alcohol in CCl_4 and **1** (neither analytical nor spectroscopic data are given) by treatment of CrO_2Cl_2 with $Li(OCH_2CH_2Cl)$ in CCl_4. Since primary and secondary alcohols are oxidised by Cr^{VI} compounds at room temp.[8] it did not surprise us that these rather drastic conditions in our hands did not yield the compounds mentioned above rather than green solids with strong ν(C=O) bands in the IR spectra. An NMR spectroscopic investigation showed that $HOCH_2CH_2Cl$ reacts with CrO_2Cl_2 already at temperatures below −80 °C producing paramagnetic species. Westheimer *et al.*[9] reported the *in situ* preparation of bisisopropyl chromate from CrO_3 and Pr^iOH which was characterised by elemental analyses of its decomposition products.

Highly diastereoselective synthesis of β-hydroxy carbonyl compounds using π-allyltricarbonyliron lactone complexes: a formal 1,7-asymmetric induction of chirality in a Mukaiyama aldol reaction

Steven V. Ley* and Liam R. Cox

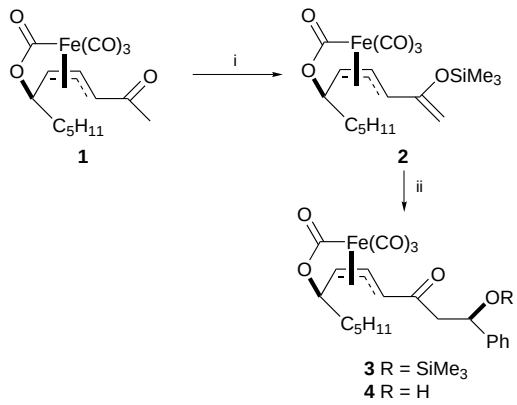
Department of Chemistry, University of Cambridge, Lensfield Road, Cambridge, UK CB2 1EW

The reaction of π-allyltricarbonyliron lactone complex 2 with a variety of achiral aldehydes affords the corresponding aldol products in good yields and with good to excellent levels of stereocontrol.

The aldol reaction remains one of the most important C–C bond constructing processes in modern organic synthesis. While many methods towards the preparation of diastereoisomerically pure aldol products have been developed,[1] the direct synthesis of isomerically pure β-hydroxy ketones lacking an α-substituent has proved to be much more difficult, since the α-substituent is often a key stereocontrolling requirement in the addition event.[2]

We now report that a trimethylsilyl enol ether **2** appended to the side-chain of a π-allyltricarbonyliron lactone complex undergoes a Mukaiyama aldol reaction[3] with a range of achiral aldehydes, affording β-hydroxy ketone products in good yield and with good to excellent levels of stereocontrol. The reaction constitutes what is formally a 1,7-asymmetric induction of chirality[4] and as such is quite unprecedented in aldol chemistry.[5]

π-Allyltricarbonyliron lactone complexes bearing ketone functionality in the side-chain are readily prepared *via* a four-step sequence starting from an allylic alcohol.[6] The ketone group positioned in the side-chain of the allyl ligand preferentially adopts an s-*cis* conformation.[6] This, combined with the steric bulk of the tricarbonyliron moiety, ensures that nucleophiles add to the ketone to afford a single diastereoisomeric product.[6,7] Starting from (*E*)-oct-2-en-1-ol, the model methyl ketone complex **1** was prepared and treated with $Me_3SiOSO_2CF_3$ and Et_3N in CH_2Cl_2 at 0 °C to afford the remarkably stable trimethylsilyl enol ether **2** in excellent yield (Scheme 1). We envisaged that this silyl enol ether functionality would also adopt a preferred conformation and therefore might react with aldehydes producing the corresponding aldol products with some degree of stereocontrol.



Scheme 1 *Reagents and conditions*: $Me_3SiOSO_2CF_3$ (1.2 equiv.), Et_3N (1.4 equiv.), CH_2Cl_2, 0 °C, 1 h, 89%; ii, PhCHO (1.5 equiv.), $BF_3{\cdot}OEt_2$ (1.4 equiv.), Et_2O–CH_2Cl_2 (5 : 1), −78 °C, 5 h, then Et_3N (1.4 equiv.), −78 °C, 61% (**3**), 20% (**4**)

Addition of an ethereal solution of benzaldehyde and $BF_3{\cdot}OEt_2$ to a solution of silyl enol ether **2** at −78 °C afforded the aldol products **3** and **4** in good yield and, in both cases, mainly as one diastereoisomer (Scheme 1). Treatment of the crude reaction mixture with HF·pyridine allowed quantitative conversion of the silyl aldol product **3** to the free alcohol **4**† and subsequent determination of the overall diastereoselectivity of the aldol reaction by high field ^{1}H NMR analysis.‡

Encouraged by this result, we applied the same reaction conditions to a range of achiral aldehydes and the results are outlined in Table 1.§ Aldehydes with α-branching (entries 3–5) showed the best levels of diastereocontrol, with the sterically encumbered pivalaldehyde affording only one diastereoisomer as evidenced by ^{1}H NMR analysis on the crude reaction mixture. α,β-Unsaturated aldehydes reacted in high yield but showed decreased levels of diastereocontrol.

The relative stereochemical outcome of the aldol addition was determined as follows: reduction of the ketone group in **3** with $AlPr^n_3$ proceeded stereoselectively, in accord with earlier results, producing one diastereoisomer **5**.[6] Protection of the 1,3-diol unit as the acetonide **6** revealed a *syn* relationship between the alcohol functionalities as determined by characteristic shifts for the acetal carbon at δ 99.7[8] and the acetal methyl groups at δ 19.9 and 29.6 (Scheme 2).[9] By induction the relative configuration of the stereogenic centre formed in the aldol reaction to that at the lactone tether was determined.

In summary, the lactone tether imparts, *via* the tricarbonyliron moiety, a high degree of 1,7-induction of chirality in the Lewis acid-mediated reaction between silyl enol ether **2** and a wide range of achiral aldehydes. In general, the more sterically bulky the aldehyde, the greater the diastereoselectivity of the reaction. Such remote induction in an acyclic system is very unusual. The generated β-hydroxy carbonyl or *syn* 1,3-diol units are ubiquitous motifs in many biologically important molecules and since π-allyltricarbonyliron lactones are easily prepared in

Table 1 Mukaiyama aldol reaction of achiral aldehydes with π-allyltricarbonyliron lactone complex **2**

Entry	Aldehyde	Overall yield (%)[a]	Ratio of **3** : **4**[b]	De (%)[c]
1	PhCHO	81	75 : 25	86
2	$CH_3(CH_2)_4CHO$	74	23 : 77	82
3	$CH_3CH(CH_3)CHO$	66	39 : 61	94

A novel decomplexation of π-allyltricarbonyliron lactone complexes using borohydride reagents: a new route to stereodefined acyclic 1,5-diols and 1,5,7-triols

Steven V. Ley,* Svenja Burckhardt, Liam R. Cox and Julia M. Worrall

Department of Chemistry, University of Cambridge, Lensfield Road, Cambridge, UK CB2 1EW

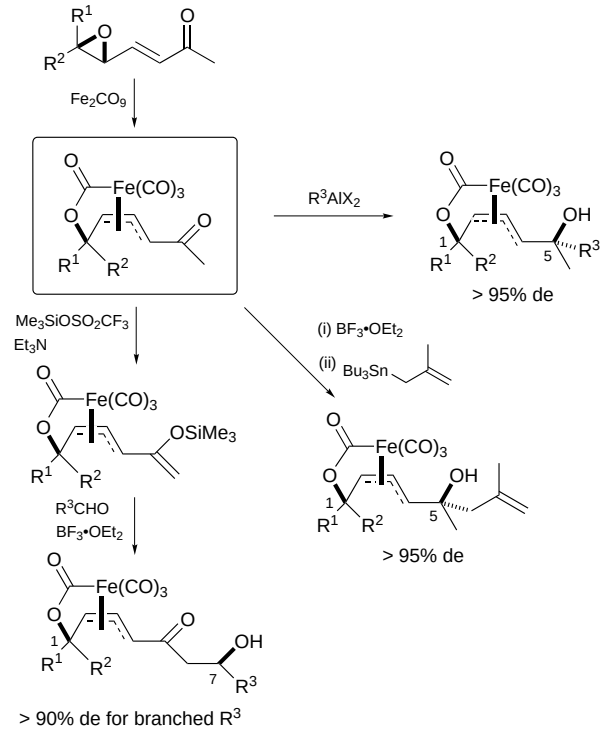
π-Allyltricarbonyliron lactone complexes undergo a highly stereoselective decomplexation reaction on treatment with sodium triacetoxyborohydride to afford acyclic alcohols in excellent yields.

Remote asymmetric induction in acyclic systems remains a challenging problem in contemporary organic synthesis. The use of a complexed transition metal as a temporary structural feature is a strategy which is finding increasing utility in addressing this problem.[1] The higher level of organisation and rigidity in such an organometallic system can allow the transfer of stereochemical information across distances of several atoms, for a variety of different bond forming reactions and functional group transformations.

We have previously shown that the use of a π-allyltricarbonyliron lactone complex as a scaffold affords excellent diastereoselectivity in the manipulation of a ketone group appended to the allyl unit (Scheme 1). Thus a 1,5 stereochemical relationship of oxygen functionalities may be established in a controlled manner by the addition of organoaluminium reagents[2] or allylstannanes[3] into the side-chain ketone. We have now also demonstrated high diastereocontrol in Mukaiyama aldol reactions of aldehydes with π-allyltricarbonyliron lactone complexes bearing a silyl enol ether functionality in the side-chain.[4] The products of these reactions have a 1,7 stereochemical relationship between the new chiral centre and the lactone tether.

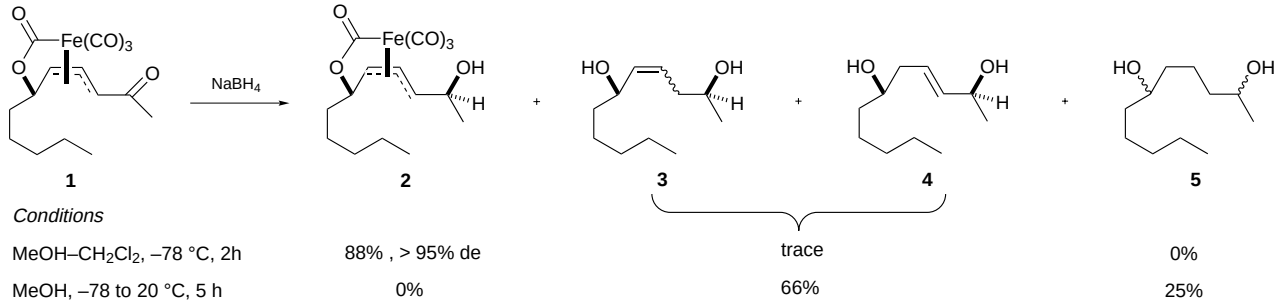
Existing methods for the removal of the iron carbonyl moiety are limited in scope.[5] Treatment with ceric ammonium nitrate leads to the stereoselective formation of β-lactones,[6] while δ-lactones can be accessed under exhaustive carbonylation conditions.[7,8] Treatment with barium hydroxide affords (η⁴-diene)tricarbonyliron complexes.[2b,7] We now report a new decomplexation reaction which effectively unwraps the carbon chain from the iron centre to reveal a linear molecule, with the chiral centre at the lactone tether preserved as a free alcohol and the side-chain functionality intact.

Our interest in hydride donors as potential decomplexing agents was initially aroused by the reaction between ketone **1** and sodium borohydride in 50% MeOH–CH_2Cl_2 at −78 °C.[9] After 1 h the ketone group was completely reduced to afford a single diastereoisomer of the corresponding secondary alcohol **2** in 88% yield. Over longer reaction times, however, the product began to react further and small quantities of chromatographically inseparable decomplexation products, tentatively assigned as **3** and **4**, could be isolated (Scheme 2).



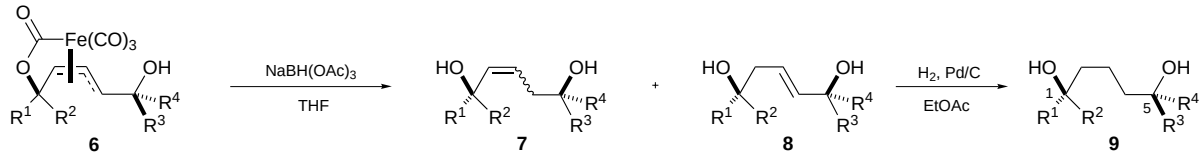
Scheme 1

In order to drive the decomplexation reaction to completion it was necessary to use a large excess of sodium borohydride, added portionwise to a methanolic solution of the diastereomerically pure secondary alcohol complex at room temperature. Under these conditions a further, saturated product **5** could be detected in the diol mixture (Scheme 2). Hydrogenation of the mixture afforded exclusively saturated diol, but with a diastereomeric excess of only 56%. These results indicate



Scheme 2

Table 1 Decomplexation of a range of functionalised π-allyltricarbonyliron lactone complexes using $NaBH(OAc)_3$



Complex	R^1	R^2	R^3	R^4	Yield of **9** (%)[a]	De (%)[b]
6a	C_5H_{11}	H	H	H	59	—
6b	C_5H_{11}	H	Ph	H	71	96
6c	Me	H	$(CH_2)_4OBn$	H	63	> 96
6d	H	C_5H_{11}	Me	H	82 (97)[c]	> 96
6e	H	C_5H_{11}	Me	Pr^n	52 (67)[c]	> 96
6f	H	C_5H_{11}	$CH_2CH(OH)Ph$	H	65[d] (87)[c]	> 96

[a] Isolated yield of **9** over two steps from **6**. [b] Diastereomeric excess of **9** determined by comparison of integrals in the 600 MHz ^1H NMR spectra. [c] Yield based on recovered starting material. [d] The OH at C-7 was lost during hydrogenation; see text.

that positional isomerisation of the double bonds in products **3** and **4** had taken place during decomplexation. Formation of the saturated product **5** could then be explained by initial iron carbonyl catalysed double bond isomerisation to form an enol,[10] followed by decomplexation and non-stereospecific borohydride reduction of the tautomeric ketone.

Extensive screening of different reducing systems revealed that decomplexation could be achieved without isomerisation using sodium triacetoxyborohydride in dry THF. A variety of different lactone complexes were exposed to these conditions and the results are shown in Table 1. In each case, the major component of the product mixture was *cis*-**7** which could generally be isolated by careful flash chromatography; the proportion of *cis*-**7** : (*trans*-**7** + **8**) was typically around 2 : 1. The products were combined and hydrogenated in order to facilitate characterisation and determination of the diastereomeric excesses.

In the case of the *syn* 5,7-diol complex **6f**, prepared by a Mukaiyama aldol reaction followed by stereoselective reduction of the C-5 ketone group,[4] the 1,5,7-triol decomplexation product *cis*-**7f** was isolated in 55% yield. After recombination with the other ene triol products and hydrogenation according to the standard procedure, however, a fully saturated 1,5-diol was obtained, which was formed by elimination of the C-7 hydroxy group during hydrogenation. This problem should be avoidable by variation of the hydrogenation conditions.

In summary, a new decomplexation reaction has been developed which allows removal of the iron carbonyl moiety from functionalised π-allyltricarbonyliron lactone complexes and conversion into functionalised alcohols without loss of stereochemical integrity. Application of this procedure to the nucleophilic adducts of ketone complexes constitutes an expedient route to stereodefined 1,5-diols, while application to the products of Mukaiyama aldol reactions allows access to stereodefined 1,5,7-triols. Studies on the mechanism of the decomplexation reaction and its utility in natural product synthesis will be published in due course.

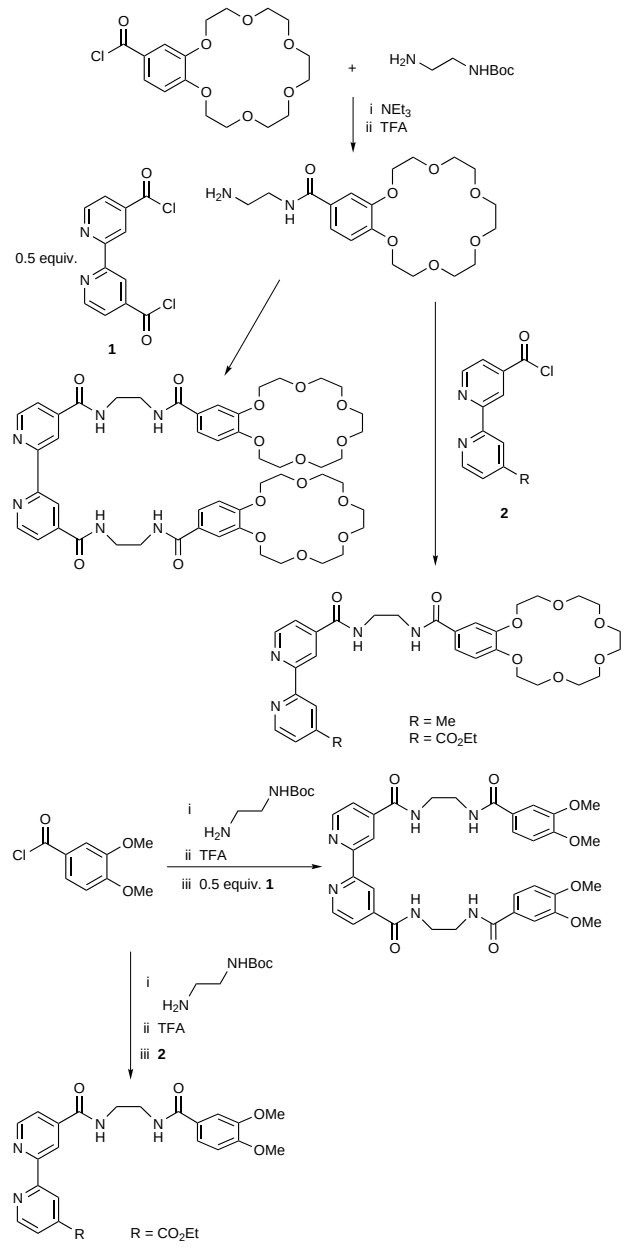
New rhenium(I) bipyridyl amide crown ether receptors are prepared and shown to complex K^+Cl^- ion pairs in which crown ether complexation of the potassium cation co-operates in the binding of chloride anion.

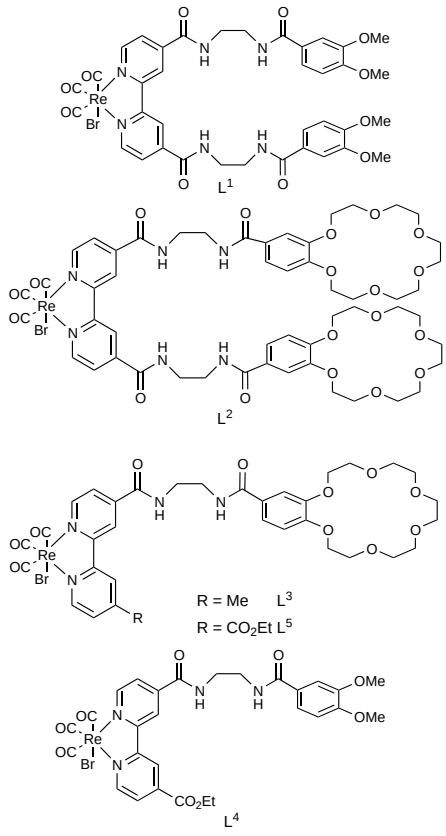
Ion pair recognition, the simultaneous binding of cationic and anionic guest species by ditopic receptors is a new emerging field of coordination chemistry.[1–5] These multisite ligand systems as well as being potential selective extraction/membrane transportation reagents for metal salts can also be designed to exhibit allosteric and cooperative behaviour whereby the binding of one charged guest can influence the subsequent coordination of the pairing ion. We have recently shown that charged or neutral transition metal organometallic and coordination amide containing receptors can selectively bind and sense anionic guest species.[6] The covalent attachment of benzo crown ether metal cation recognition sites to these anion receptors will create novel ion pair binding reagents. We report here the synthesis and preliminary coordination chemistry of new neutral rhenium(I) bipyridyl amide crown ether receptors that complex potassium cations and simultaneously bind chloride anions with positive cooperativity which is a first step towards the design of ion pair recognition systems.

The bipyridyl amide functionalised benzo-18-crown-6 and 3,4-dimethoxyphenyl ligands were prepared in good yields according to Scheme 1. Reaction of each of these bipyridyl ligands with $[Re(CO)_5Br]$ in THF produced the target receptors L^1–L^5 as yellow solids (Scheme 2). The potassium cation and chloride anion coordination properties of the receptors were investigated by ^1H NMR titration experiments in $(CD_3)_2SO$ solution. The addition of KPF_6 to ^1H NMR solutions of L^2, L^3 and L^5 caused the crown ether methylene protons to significantly shift to lower field. Analysis of the resulting titration curves with the computer program EQNMR[7] suggested the respective crown ether recognition site of each receptor to form a 1 : 1 complex with the potassium cation, with stability constant values of *ca.* 500 $dm^3\ mol^{-1}$ for L^3 and L^5. Negligible shifts were observed with L^1 and L^4 suggesting K^+ complexation only takes place at the crown ether binding sites. The addition of tetrabutylammonium chloride to $(CD_3)_2SO$ solutions of L^1–L^5 caused significant downfield perturbations of the respective receptor's amide and H^3-bipyridyl protons by up to $\Delta\delta = 0.55$ ppm, indicating anion binding is taking place exclusively in the amide-bipyridyl vicinity of the receptor. In all cases the titration curves suggested 1 : 1 complex stoichiometry. The titrations with chloride were repeated in the presence of 2 equiv. of KPF_6 and EQNMR[7] determined stability constant values for both titration experiments are presented in Table 1. Table 1 clearly shows the addition of KPF_6 to the crown ether containing receptors L^2, L^3 and L^5 leads to a substantial increase in the magnitude of stability constant, by nearly threefold for L^2, for the respective chloride anion receptor-complex. It is noteworthy that receptors L^1, L^4, lacking crown ether moieties, do not exhibit such an increase in stability constant in the presence of KPF_6 which suggests the origin of positive co-operativity is an intramolecular electrostatic attraction between a simultaneously crown ether bound potassium cation and bipyridyl amide complexed chloride anion.

Receptor L^3 was co-crystallized with KCl and the X-ray crystal structure of the ion-pair complex $[L^3KCl]_2 \cdot 2H_2O$ which has a crystallographic centre of symmetry is shown in Fig. 1 and 2.†‡



Scheme 1



Scheme 2

Table 1 Stability constants for chloride anion binding in the presence and absence of potassium cations in $(CD_3)_2SO$

Receptor	K^a/dm^3 mol^{-1}
L^1	44
$L^1 + KPF_6$ (2 equiv.)	46
L^2	48
$L^2 + KPF_6$ (2 equiv.)	120
L^3	24
$L^3 + KPF_6$ (2 equiv.)	57
L^4	15
$L^4 + KPF_6$ (2 equiv.)	15
L^5	—[b]
$L^5 + KPF_6$ (2 equiv.)	35

[a] Errors estimated to be ⩽5%. [b] Very weak binding, a stability constant could not be determined.

In the $Re(CO)_3$(bipy) moieties, the environment of the metal is octahedral with dimensions in the expected range. Each bipy is linked *via* an amide group to a benzo-18-crown-6 in which is encapsulated a potassium ion. The benzo crown has a planar conformation with the six oxygens coplanar to within 0.10 Å with the potassium 0.24 Å from the plane. The hexagonal bipyramidal potassium coordination is completed by two axial bonds to a water molecule and to an amide oxygen atom from another substituted $Re(CO)_3$(bipy) moiety, thus forming the centrosymmetric dimer. The chloride anion is disordered over two positions 1.07 Å apart with relative occupancies 56 and 44%, but each anion is hydrogen bonded to both amide nitrogen atoms, Cl(21) to N(63) at 3.25 and N(66) at 3.41 Å and Cl(22) to N(63) 3.12 and N(66) at 3.29 Å.

In summary, these new rhenium(I) bipyridyl amide crown ether receptors are capable of binding K^+Cl^- ion pairs in which crown ether complexation of the potassium cation co-operates in the complexation of chloride anion.

We thank Kodak Ltd for a studentship (S. W. D.) and the EPSRC for use of the mass spectrometry service at University College Swansea. The University of Reading and EPSRC are gratefully acknowledged for funding towards the crystallographic image-plate system.

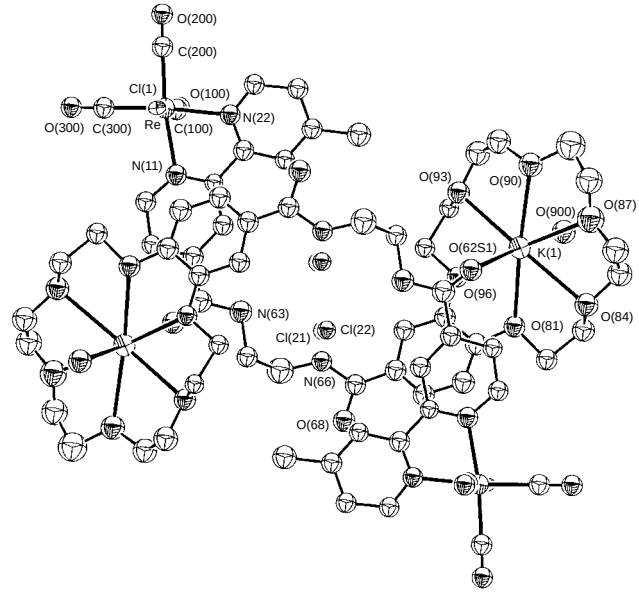


Fig. 1 The centrosymmetric dimer $[L^3KCl]_2 \cdot 2H_2O$ with ellipsoids shown at 20% probability together with the atomic numbering scheme. Bond lengths from the potassium to crown oxygens are to O(81) 2.752(13), O(84) 2.913(15), O(87) 2.76(2), O(90) 2.801(16), O(93) 2.881(13), O(96) 2.722(14) Å and to the amide oxygen O(62S1) 2.654(17) and to the water molecule O(900) 2.753(17) Å.

Isomeric clusters $[Ru_4(\mu_4\text{-}PPh)(\mu_4\text{-}C_4H_3N)(CO)_{11}]$ containing diagonal C,C and parallel C,N bonded pyrrolyne ligands

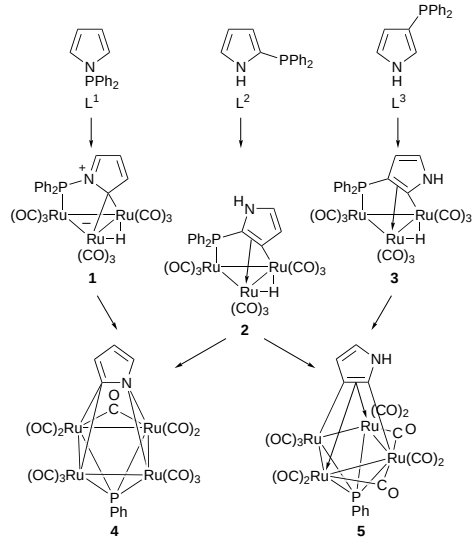
The three isomeric tertiary phosphines, diphenyl-*n*-pyrrolylphosphine (*n* = 1, 2 or 3) lead to two isomeric tetranuclear clusters $[Ru_4(\mu_4\text{-}PPh)(\mu_4\text{-}C_4H_3N)(CO)_{11}]$ which contain the diagonal C,C bonded and parallel C,N bonded pyrrolyne ligands.

The organometallic chemistry of pyrrole is important from the point of view of the hydrodenitrogenation (HDN) process.[1] There are few examples of mononuclear pyrrole complexes but it coordinates as pyrrolyl in complexes related to cyclopentadienyl compounds.[2] However, in clusters there are both aromatic and non-aromatic, doubly and triply bridging ligands derived from pyrrole, mostly by C–H bond activation and hydrogen atom transfer.[3] Up to now it has been unknown as a μ_4 ligand. This paper describes the synthesis and structure of two isomeric pyrrolyne ligands that bridge square faces of tetranuclear ruthenium complexes.

Treatment of $[Ru_3(CO)_{12}]$ with equimolar amounts of any of the three isomeric pyrrolyl phosphines, $Ph_2P(n\text{-}C_4H_4N)$ (L^1, n = 1; L^2, n = 2; L^3 n = 3),[4] leads firstly to simple substitution products $[Ru_3(CO)_{11}L^n]$ with L^n coordinated through phosphorus, closely related to known tertiary phosphine clusters.[5] The clusters $[Ru_3(CO)_{11}L^n]$ were only formed in small quantities because they readily lose CO to allow metallation at the pyrrolyl rings, in preference to the phenyl rings, to give products **1**–**3** (Scheme 1). For **2** and **3** pure samples were isolated and in the case of **3** the crystal structure has been determined (to be reported elsewhere). Compound **1** was not detected, however, and its intermediacy can only be reasoned from the isolation and full characterisation, including X-ray structure, of the corresponding osmium complex formed from L^1 and $[Os_3(CO)_{12}]$.[6] Compounds **1** to **3** react further with $[Ru_3(CO)_{12}]$ under the reaction conditions to give isomers of $[Ru_4(\mu_4\text{-}PPh)(\mu_4\text{-}C_4H_3N)(CO)_{11}]$, C,N-bonded **4** or C,C-bonded **5** as shown in Scheme 1. Clusters **4** and **5** gave similar but different IR ν(CO) spectra, both showing bridging CO bands.† Whereas **4** showed three sharp ^{1}H NMR signals for the pyrrolyne ligand at δ 7.43, 6.19 and 7.07 consistent with these all being CH groups, **5** gave signals at δ 6.62, 5.90 and 7.90. The broad signal at δ 7.90 for **5** is assigned to NH, while the other two signals are much sharper.



Scheme 1 Formation of clusters **4** and **5** from L^n and $[Ru_3(CO)_{12}]$

The X-ray structures of two red crystalline modifications of **4** have been determined: a triclinic crystal deposited from heptane on cooling and a monoclinic crystal formed by evaporation of a hexane–CH_2Cl_2 mixture.‡ Their molecular structures are very similar and only one is shown (Fig. 1). The molecular structure of **5** is shown in Fig. 2.

Fig. 3 shows the cores of these molecules to emphasize the clearly different ways that the C_4H_3N ligands coordinate in clusters **4** and **5**. In the C,C-bonded form **5** [Fig. 2 and 3(*b*)] the geometry is closely related to known structures of the type $[Ru_4(\mu_4\text{-}PR)(\mu_4\text{-}X)(CO)_{11}]$, where X = alkyne,[7] thiophyne,[8] *etc.*, with the diagonal vertical arrangement with the ligand vertical. Like other diagonally coordinated complexes of the type, there are two bridging CO ligands along the shorter Ru–Ru edges. The angle between the C_4H_2NH plane and the Ru_4 plane is 90.3°. Benzyne analogues $[Ru_4(\mu_4\text{-}PR)(\mu_4\text{-}C_6H_4)(CO)_{11}]$ **6** have been synthesised from $[Ru_3(CO)_{12}]$ and arylphosphines[9] and are also formed as a minor byproduct from $[Ru_3(CO)_{12}]$ and L^2. The μ_4-C_6H_4 ligand behaves as a six-electron donor and adopts a parallel tilted orientation; the

Selected bond lengths (Å) are given for the monoclinic crystal with those for the triclinic crystal in square brackets: Ru(1)–Ru(2) 2.8316(7) [2.8035(9)], Ru(2)-Ru(3) 2.8752(8) [2.8318(7)], Ru(3)–Ru(4) 2.9069(7) [2.8637(9)], Ru(4)–Ru(1) 2.8720(8) [2.8522(8)], Ru(1)–N(1) 2.211(4) [2.177(5)], Ru(2)–C(1) 2.217(4) [2.188(5)], Ru(3)–C(1) 2.193(4) [2.178(5)], Ru(4)–N(1) 2.194(4) [2.170(5)], C(1)–N(1) 1.462(6) [1.441(7)], C(1)–C(4) 1.400(7) [1.374(8)], C(2)–C(3) 1.388(9) [1.381(10)], C(3)–C(4) 1.385(8) [1.400(9)], C(2)–N(1) 1.407(7) [1.373(8)].

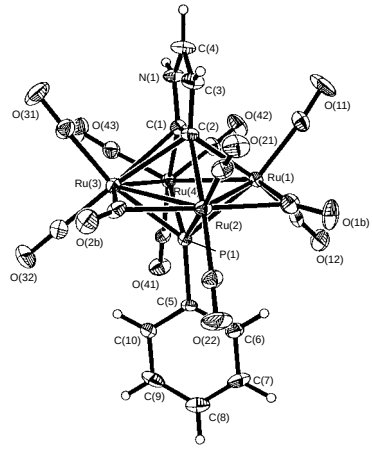


Fig. 2 Molecular structure of **5**. Selected bond lengths (Å) and angles (°): Ru(1)–Ru(2) 2.7553(13), Ru(2)–Ru(3) 2.7533(11), Ru(3)–Ru(4) 2.9035(13), Ru(1)–Ru(4), 2.8730(11), Ru(1)–C(1) 2.456(8), Ru(1)–C(2) 2.372(7), Ru(2)–C(2) 2.182(7), Ru(3)–C(1) 2.468(8), Ru(3)–C(2) 2.366(8), Ru(4)–C(1) 2.081(8), C(1)–C(2) 1.418(11), C(1)–N(1) 1.383(11), C(2)–C(3) 1.450(10), C(3)–C(4) 1.350(12), C(4)–N(1) 1.367(11).

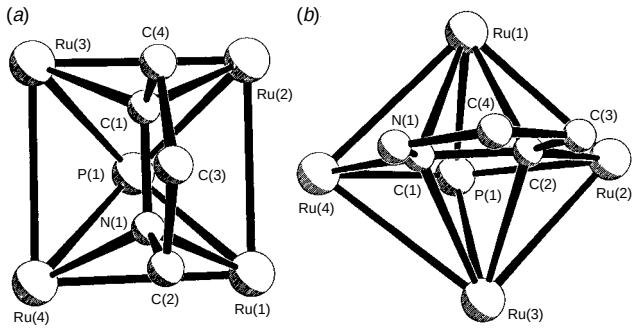

Fig. 3 A comparison of (*a*) the C,N bonded **4** and (*b*) the C,C bonded **5**

coordinated C–C bond is parallel to a Ru–Ru edge and the C_6H_4 plane is 49.7 and 54.7° to the Ru_4 plane (two independent molecules) when R = Ph. A related 1,2-naphthyne cluster is also known.[10] In C,N-bonded pyrrolyne cluster **4** [Fig. 1 and 3(*a*)] a parallel arrangement is found with the C(1)–N(1) bond parallel to the Ru(1)–Ru(2) and Ru(3)–Ru(4) edges of the Ru_4 square. However, in this case the organic ring is essentially vertical with a dihedral angle to the metal plane of 84.2° (monoclinic form) and 85.2° (triclinic form). In many ways the isomers **4** and **5** correspond to the C,N-bonded (ligand vertical) and the C,C-bonded (ligand tilted) forms of pyrrolyne in trisomium clusters $[Os_3(\mu\text{-}H)(\mu\text{-}C_4H_3N)(CO)_9]$ **7**[3c] and $[Os_3(\mu\text{-}H)(\mu\text{-}C_4H_2NMe)(CO)_9]$ **8**.[3b] The existence of these different isomers at both triangular and square metal faces in trinuclear and tetranuclear clusters respectively strongly points to the possibility of having similar isomeric forms for pyrrolyne at metal surfaces.

We thank the EPSRC, the British Council and CONICIT (Venezuela) for support for this work

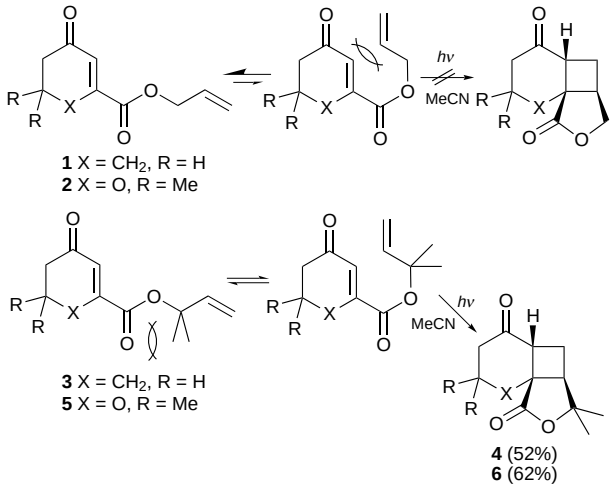
Conformational effects and cyclodimer formation in intramolecular [2 + 2] photocycloadditions

Sylvie Piva-Le Blanc, Jean-Pierre Pete and Olivier Piva*

Unité mixte de recherche CNRS, Université de Reims Champagne Ardenne, BP 1039, 51687 Reims Cedex 2, France

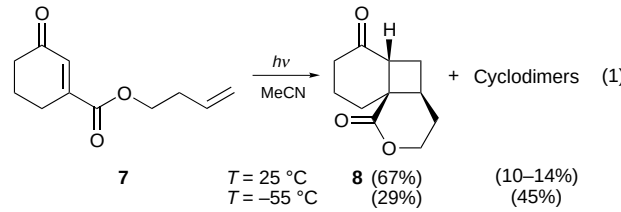
Cyclodimer formation competes with intramolecular [2 + 2] photocycloaddition during the photolysis of ω-alkenyl 3-carboxylatocyclohexenones.

Intramolecular [2 + 2] photocycloadditions are very useful reactions for multistep syntheses of polycyclic molecules.[1] The efficiency of the process depends mainly on the length of the chain between the enone and the alkene moiety and on the strain involved during the cycloaddition process. Intramolecular photocycloadditions can be disfavoured when medium ring cycles would otherwise be formed simultaneously to the formation of cyclobutane. In these cases, hydrogen abstraction[2] or polymerization[3] predominate when conformational restrictions decrease the rate of the intramolecular cycloaddition process. Since they should be good candidates for asymmetric [2 + 2] photocycloadditions,[4] we have studied the reactivity of unsaturated esters of 3-carboxylatocyclohex-2-enone and we now report the unusual effect of the ester linkage on the photocycloaddition process. (Scheme 1).

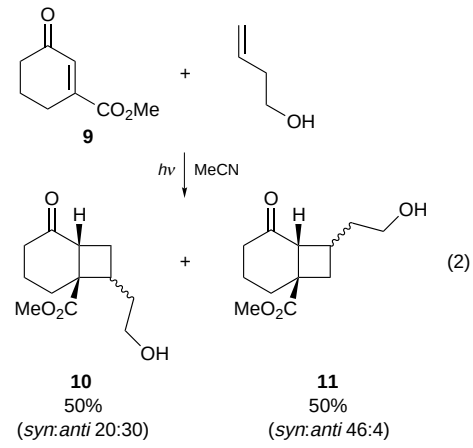


Scheme 1

Intermolecular photocycloadducts could not be isolated from allyl esters **1** or **2** and photodimerization of the enone chromophore (< 5%) was the main reaction observed. The absence of intramolecular photocycloaddition might result from conformational effects as already pointed out by Pirrung and Thomson with other types of carboxylic derivatives.[5] Due to the large preference for an s-*trans* conformation around the CO–O bond of the ester group,[6] the ethylenic bond would be situated too far from the excited enone to allow an intramolecular photocycloaddition process to occur. The conformational origin of the absence of cycloadducts from **1** and **2** was verified by using the *gem*-dimethyl effect.[7] Introduction of two Me groups into the chain of 1,1-dimethylallyl esters **3** and **5** restores its conformational mobility and, as expected, adducts **4** and **6** were isolated in good yields. Use of butenyl esters should minimize the conformational restrictions associated with an ester group and indeed, irradiation at room temperature of butenyl ester **7** (10^{-2} mol l^{-1}) in MeCN or CH_2Cl_2, led to the expected cycloadduct **8** [reaction (1)].[8]

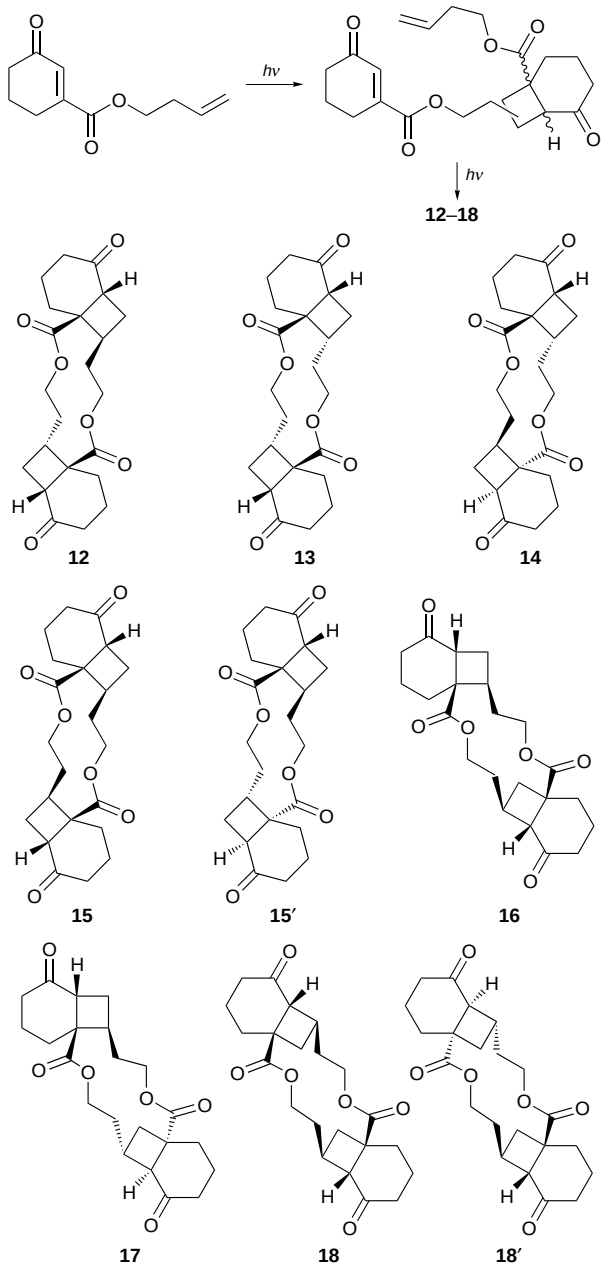


Interestingly, the chemical yield of **8** decreased at low temperatures and a mixture of cyclodimers (up to 45%) was obtained at −55 °C. Analysis of the crude reaction mixture by NMR spectroscopy, at high conversion yields, showed no ethylenic bonds.† Methanolysis of the mixture of oligomers afforded **10** and **11** which were prepared independently by an intermolecular photocycloaddition of oxo ester **9** with but-3-en-1-ol [reaction (2)].



ESMS confirmed the dimeric nature of the isolated oligomers and detected some trimers of the starting material in the reaction mixture. By successive chromatography, crystallization and NMR studies, seven cyclodimers **12**–**18** were isolated‡ and characterized§ (Scheme 2). Formation of these adducts can be rationalised by a succession of intermolecular and intramolecular photocycloadditions, none of which appeared to be regio- or stereo-selective.[9] In order to increase the yield of macrocyclic structures, we performed the reaction at higher concentration (10^{-1} mol l^{-1}). Unfortunately, photodimerization between the two cyclohexenone moieties was preferred.

To the best of our knowledge, formation of cyclic photodimers has not yet been reported for cycloalkenone derivatives. That an intermolecular process competes with the expected intramolecular cycloaddition probably results from a relatively unfavourable conformation of the substrate. The observed temperature effect might indicate that the reactive conformer for an intramolecular process is more easily accessible at higher temperatures. The unexpected formation of 12-membered ring



Scheme 2

bis-lactones in cyclodimers rather than linear oligomers, in the second photocycloaddition process, indicates that due to steric restrictions, the two reactive entities of the same molecule should be very close in the opened dimer favouring a further intramolecular process.

† Even at conversion yields of about 50% of the starting material, linear photodimers remained very minor compounds in the reaction mixture.

‡ The solvent was first concentrated and the residue dissolved in MeOH. After partial evaporation, macrolide **12** readily crystallized. The MeOH was removed and the mixture chromatographed on silica (eluent: AcOEt–hexanes : 10–60 to 90–40) in order to separate the monomeric lactone **8** and an unseparable fraction of cyclodimers **13**–**18**. The macrocyclic compounds were totally or partially separated using HPLC with a Lichrosorb Si 60-7 column. By NMR analysis of each compound, and by comparison with spectra of the monomeric adduct and also those of compounds **10** and **11**, we were able to attribute the regiochemistry and relative stereochemistry.

High-temperature reactions of $Mo_3Te_7I_4$ or WTe_2 with KCN at 450 °C produce M_4Te_4 cubane-type complexes, isolated here as $K_7[Mo_4(\mu_3\text{-}Te)_4(CN)_{12}]\cdot 11H_2O$ and $K_6[W_4(\mu_3\text{-}Te)_4(CN)_{12}]\cdot 5H_2O$ in high yields, and characterized by X-ray crystallography.

Homo- and heterometallic cuboidal cluster complexes with bridging chalcogenide ligands are known for a wide variety of transition metals, and appear to be one of the most important common basic structures of transition metal cluster complexes. Homometallic Mo_4S_4 cubane-type clusters have been known for some 20 years.[1–6] They have the general formula $[Mo_4Y_4L_{12}]$, where L denotes the ligating atoms, either neutral or anionic. Cubane-type molecular cluster complexes $[Mo_4Se_4(H_2O)_{12}]^{4+/5+/6+}$ have been reported.[7,8] Solid-state compounds $Mo_4S_4X_4$ (X = Cl, Br, I) and MMo_4Y_8 (M = Al, Ga, Y = S; M = Ga, Y = Se) containing Mo_4Y_4 clusters, with Mo atoms coordinated octahedrally by either three chalcogen and three halogen atoms or six chalcogen atoms have been isolated.[9–12]

Preparative routes to $[Mo_4Y_4(H_2O)_{12}]^{4+/5+/6+}$ (Y = S, Se) clusters by dimerization of chalcogenide Mo^V_2 complexes under reducing conditions, and from Mo_3Y_7 and Mo_3Y_4 cores, have been reported. Self-assembly routes have also been developed.[13] There are as yet no examples of cuboidal $[W_4Y_4(H_2O)_{12}]^{4+/5+/6+}$ clusters and the number of W_4 chalcogenide complexes is limited. Examples are (*i*) the raft-type complex $[W_4S_6(SH)_2(PMe_2Ph)_6]$,[14] (*ii*) the tetrahedral complex $[W_4S_6(PMe_2Ph)_4]$[14] having a $W_4(\mu_2\text{-}S)_6$ adamantane-like core, and (*iii*) $[W_4S_8(H_2NCH_2CH_2NH_2)_4]S$[15] which has a cuboidal $W_4S_4^{10+}$ core.

No Mo and W cubes, M_4Y_4 with Y = telluride, have as yet been prepared. Many of the traditional reagents used in the development of the sulfide/selenide chemistry, *e.g.* H_2Y or $[MY_4]^{2-}$ (M = Mo, W; Y = S, Se), are simply not known in the case of Y = Te.[16,17] Our recent research has therefore focused on the development of high-temperature techniques to synthesize solid-state molybdenum/tungsten tellurides as starting materials for the preparation of molecular telluride containing complexes.[18,19] The first complex having an M_3Te_7 core $Mo_3(\mu_3\text{-}Te)(\mu_2\text{-}Te_2)_3^{4+}$, was synthesized by extrusion of the polymeric solid-state product $Mo_3Te_7I_4$ from the high-temperature reaction of molybdenum, tellurium and iodine, with cyanide.[19]

Here we report the high-yield synthesis and crystal structure determination of the first complexes with Mo_4Te_4 and W_4Te_4 cluster cores. Cuboidal M_4Te_4 complexes are known for transition metals M = Mn, Re, Fe, Ru, Rh, Ir, Ni and Pt, but with the exception of Fe these do not have as highly developed M_4S_4 and M_4Se_4 chemistry as in the case of Mo.[20]

We have used a simple procedure starting from the elements for the synthesis of the title telluride cluster complexes of molybdenum and tungsten. Dark red–brown crystals of $K_7[Mo_4(\mu_3\text{-}Te)_4(CN)_{12}]\cdot 11H_2O$ **1** and $K_6[W_4(\mu_3\text{-}Te)_4(CN)_{12}]\cdot 5H_2O$ **2** were obtained in high yields by the high-temperature reaction of $Mo_3Te_7I_4$ or WTe_2 with KCN at 450 °C and further crystallization from aqueous solutions.† Complete X-ray structural determinations have revealed that the structures of **1** and **2** consist of discrete cluster anions of $[Mo_4(\mu_3\text{-}Te)_4(CN)_{12}]^{7-}$‡ or $[W_4(\mu_3\text{-}Te)_4(CN)_{12}]^{6-}$‡ and K^+ cations, and solvent water molecules. Fig. 1 and 2 show perspective views of the cluster units with important bond distances. The cluster anions display a cubane-like geometry, with the M_4Te_4 (M = Mo, W) cores constituted by two concentric interpenetrating tetrahedra of molybdenum/tungsten and tellurium. The tellurium atoms cap in a symmetrical manner the triangular faces of the molybdenum/tungsten tetrahedron [the mean Mo–Te distance is 2.674(1) Å; the mean W–Te distance is 2.686(2) Å]. The octahedral coordination of each molybdenum/tungsten center is completed by three cyanide ligands. For **1**, the distortion of the Mo_4 tetrahedron from ideal T_d symmetry is irregular, giving a relatively narrow range of Mo–Mo distances from 2.967(1) to 3.002(1) Å. Some notable differences, however, can be found for W–W bond distances: the W(1)–W(4) distance of 2.839(1) Å is significantly shorter than the W(2)–W(4) distance of 3.054(1) Å. The average oxidation state of the molybdenum atoms in **1** is 3.25 and the complex has one unpaired electron. The average oxidation state of the tungsten atoms in **2** is 3.5 and the complex is diamagnetic. The M_4Te_4 clusters of 5+ and 6+ charges, respectively, provide interesting comparisons with $[Mo_4Y_4]^{5+}$ and $[Mo_4Y_4]^{6+}$ (Y = S, Se) clusters.[8,13,21,22] The higher charge on the W_4Te_4

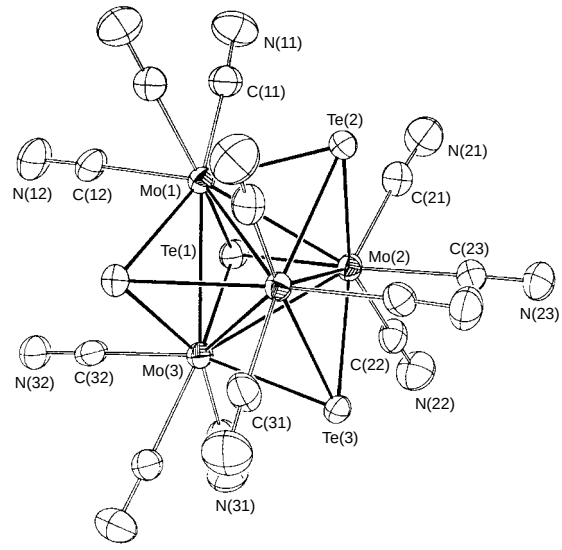

Fig. 1 Anion in **1** (thermal ellipsoids at 50% probability level). Some geometrical parameters (Å): Te–Mo 2.6663(8)–2.686(1), av. 2.674(1); Mo–Mo 2.967(1)–3.002(1), av. 2.993; Mo–C 2.14(1)–2.176(8), av. 2.162(9); C–N 1.13(1)–1.17(1), av. 1.15(1).

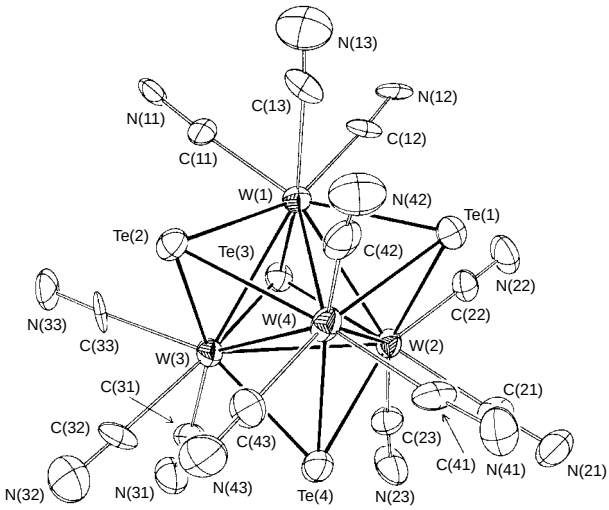

Fig. 2 Anion in **2** (thermal ellipsoids at 50% probability level). Some geometrical parameters (Å): W(1)–W(2) 2.957(1), W(1)–W(3) 2.923(1), W(1)–W(4) 2.839(1), W(2)–W(3) 3.054(1), W(2)–W(4) 3.008(1), W(3)–W(4) 2.991(2), W–Te 2.674(2)–2.704(2), av. 2.686(2); W–C 2.10(3)–2.20(3), av. 2.15(3); C–N 1.07(3)–1.20(3), av. 1.16(3).

cluster is consistent with the greater difficulty in reducing W to its lower oxidation states.

The cluster compounds **1** and **2** are stable indefinitely in air at 95 °C, and dissolve in aqueous solution, with no tendency to lose core atoms. Further studies on the reactivities of the telluride clusters, including an investigation of NMR and EPR spectra, and magnetic properties are in progress.

† *General method* for preparation of $K_7[Mo_4(\mu_3\text{-}Te)_4(CN)_{12}]\cdot 11H_2O$ **1** and $K_6[W_4(\mu_3\text{-}Te)_4(CN)_{12}]\cdot 5H_2O$ **2**: a mixture of $Mo_3Te_7I_4$ (3.00 g) and KCN (3 g) or a mixture of WTe_2 (5.00 g) and KCN (5 g) was heated (450 °C; 2 days) in a sealed quartz tube. The product of the reaction was added to 50 ml of water and the mixture was refluxed for 3 h. After filtration, the solution was kept at 80 °C. During this time, the volume was decreased to 10 ml. After allowing to stand at 20 °C for 1 day, dark red–brown crystals were filtered off, washed with cold water and dried in air. Yield: 1.86 g of $K_7[Mo_4(\mu_3\text{-}Te)_4(CN)_{12}]\cdot 11H_2O$ (83%), 4.73 g of $K_6[W_4(\mu_3\text{-}Te)_4(CN)_{12}]\cdot 5H_2O$ (88%). Satisfactory elemental analyses (C, H, N, Mo, W and Te) were obtained. In order to ensure product homogeneity, the X-ray powder diffraction diagrams of **1** and **2** were obtained, and found to be identical with diagrams calculated from the single-crystal data. The UV–VIS absorption spectrum of **1** in H_2O gave peak positions [λ/nm (ε/M^{-1} cm^{-1} per M_4)] at 382 (6100), 535 (2080), 769 (420). The UV–VIS absorption spectrum of **2** in H_2O gave peak positions at 357 (8000), 382 (sh), 474 (3140), 869 (440). IR (KBr pellet): ν(CN) 2086 cm^{-1} (**1**); ν(CN) 2108, 2097 cm^{-1} (**2**). The magnetic susceptibility of **1** was measured at 77 K: μ = 2.03 μ_B. The magnetic susceptibility of **2** was measured at 300 K: $\chi_M = -360 \times 10^{-5}$ cm^3 mol^{-1}.

‡ *Crystallography*: **1**: single crystal (0.14 × 0.38 × 0.44 mm) obtained by recrystallisation from an aqueous solution of KCN. *Crystal data*: orthorhombic, space group *Pnma*, a = 12.112(1), b = 21.736(2), c = 16.109(1) Å, U = 4241.0(6) Å^3, Z = 4, D_c = 2.632 g cm^{-3}. Total 5874 reflections [in which 4707 $F_o > 4\sigma(F)$] were collected using standard techniques at room temperature on an Enraf-Nonius CAD4 diffractometer with Mo-Kα radiation (λ = 0.710 69 Å) up to $2\theta_{max}$ = 60°. The structure was solved by direct methods and refined in anisotropic approximation by full-matrix least-squares on F_o^2 using the SHELX-97[23] package. Absorption corrections were made using five azimuthal scan curves. Some hydrogen atoms of the solvent water molecules were found on Fourier map, but our attempts to refine these were unsuccessful. Final R values: $R(F)$ = 0.0473, $wR(F^2)$ = 0.1239 for 4707 $F_o > 4\sigma(F)$, $R(F)$ = 0.0612, $wR(F^2)$ = 0.1276, GOF = 1.153 for all data.

2: Single crystal (0.26 × 0.32 × 0.76 mm) obtained from recrystallisation from an aqueous solution of KCN. *Crystal data*: triclinic, space group $P\bar{1}$, a = 12.399(1), b = 13.187(1), c = 13.496(1) Å, α = 83.712(8), β = 66.575(8), γ = 63.223(9)°, U = 1801.1(2) Å^3, Z = 2, D_c = 3.471 g cm^{-3}. Total 8464 reflections (in which 8103 unique, R_{int} = 0.0594) were collected using standard techniques at room temperature on an Enraf-Nonius CAD4 diffractometer with Mo-Kα radiation (λ = 0.710 69 Å) up to $2\theta_{max}$ = 56°. The structure was solved by direct methods and refined in anisotropic approximation by full-matrix least-squares on F_o^2 using the SHELX-97[23] package. Absorption corrections were made using six azimuthal scan curves. Hydrogen atoms of solvate water molecules were not located. Final R values: $R(F)$ = 0.0696, $wR(F^2)$ = 0.2151 for 6752 $F_o > 4\sigma(F)$, $R(F)$ = 0.0796, $wR(F^2)$ = 0.2213, GOF = 1.143 for all unique data. CCDC 182/712.

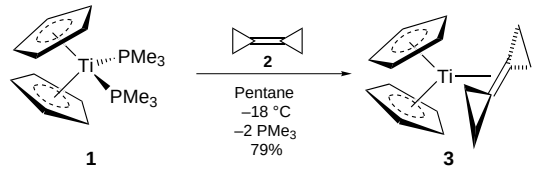
The reactions of bicyclopropylidene 2 with bis(cyclopentadienyl)bis(trimethylphosphane)titanium(II) 1 and with the cobalt chelate 4 give the first known metal complexes of bicyclopropylidene 3 and 7, respectively, in good yields; the bicyclopropylidene cobalt complex 7 is characterized by an X-ray crystal structure analysis which shows a severe out-of-plane bending of the alkenic ligand, indicating considerable back-bonding which goes along with a release of strain in the ligand.

The organometallic chemistry of cyclopropane derivatives is dominated by ring opening reactions.[1,2] However, metal-mediated substitutions on vinylcyclopropane derivatives[3] and cycloadditions with methylenecyclopropane **5** and its derivatives[4–7] can also be achieved with retention of the ring. In view of their high-lying HOMOs,[8,9] methylenecyclopropane **5** and especially bicyclopropylidene **2** should be strong π-bases capable of efficiently donating electron density into the vacant orbitals of transition metals. In particular, strained alkenes have an increased ability to accept back-bonding and therefore are preferentially coordinated to transition metals,[10–13] and it is this feature which is frequently used to stabilize otherwise unstable alkenes and alkynes by complexation.[14,15] Indeed, some transition metal, including cobalt, complexes of methylenecyclopropane have been reported.[4,16]

Here, we report on the synthesis and the structural characterization of the first transition metal complexes of **2**,[17] which contains a more highly strained double bond[18] than methylenecyclopropane **5**.

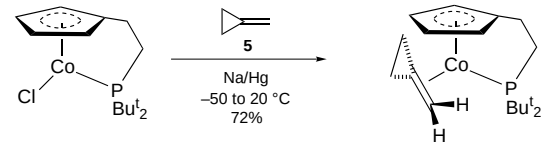
A first attempt to bind an intact bicyclopropylidene unit to a metal was made by use of the titanocene fragment. (Alkene)-bis(cyclopentadienyl)titanium(II) complexes are known, and they are 16e complexes.[19] If there were a tendency towards ring opening of a bicyclopropylidene ligand by oxidative addition, it should happen with this complex fragment attached. One way to prepare titanium complexes with sensitive ligands starts from titanocene dichloride, which can easily be converted to $Cp_2Ti(PMe_3)$ **1**.[20,21] Treatment of **1** with 1.16 equiv. of **2** in pentane gave (η²-bicyclopropylidene)(bis-η⁵-cyclopentadienyl)titanium(II) **3** in 79% yield as a green solid (Scheme 1), which was characterized by its ^1H and ^{13}C NMR spectra‡ as well as by a correct elemental analysis. While signals for the CH_2 and cyclopentadienyl carbon atoms are clearly observed at δ 15.3 and 116.7 as a triplet and a doublet, respectively, the signal assigned to the coordinated quaternary carbon atoms of the bicyclopropylidene ligand appears as a singlet of only low intensity at δ93, a value which is in accord with those observed for related compounds.[22] A structural investigation of **3** has so far been precluded because suitable crystals for an X-ray structure analysis could not be obtained. Anyhow, **3** is the first example of an (alkene)bis(cyclopentadienyl)titanium(II) complex without a supporting PR_3 ligand or stabilizing methyl groups on the cyclopentadienyl ligands.[22]



1 **3**

Scheme 1

Complexation of sensitive ligands without subsequent reactions is also possible with the {[2-(di-*tert*-butylphosphanyl)-*P*-ethyl]-η⁵-cyclopentadienyl}cobalt(I) fragment (CoCp#), with which the cyclopentadienyl ligand and the pending phosphane side arm coordinate at the metal to form a rather stable chelate.[23–25] For oligomerization reactions, frequently observed at normal cyclopentadienyl cobalt, to occur with this complex fragment, an advance decomplexation of the phosphane side arm would be necessary. In this case the phosphane side arm normally wins the competition with an external ligand for entropic reasons. A reliable method for the preparation of such complexes is the reductive complexation starting with the paramagnetic chloro complex **4** in the presence of sodium amalgam and the new ligand.[26] As a first test, **2** was treated with **4** at low temperature in this manner and gave a 72% yield of complex **6** (Scheme 2), which was identified by its spectral data. The NMR spectra show two signals for alkenic protons and two signals for non-alkenic cyclopropyl carbon atoms indicating an orientation of the methylenecyclopropane ligand as in formula **6**. In the mass spectrum the molecular ion peak is observed (*m*/*z* 350, 19%), the base peak resulting from decomplexation of **1**.



4 **6**

Scheme 2

Next, **2** was treated with **4** in the presence of sodium amalgam, and the corresponding cobalt complex **7** (Scheme 3) was obtained in even higher yield (83%) as large brown crystals of up to 7 mm edge length after crystallization from diethyl

Scheme 3

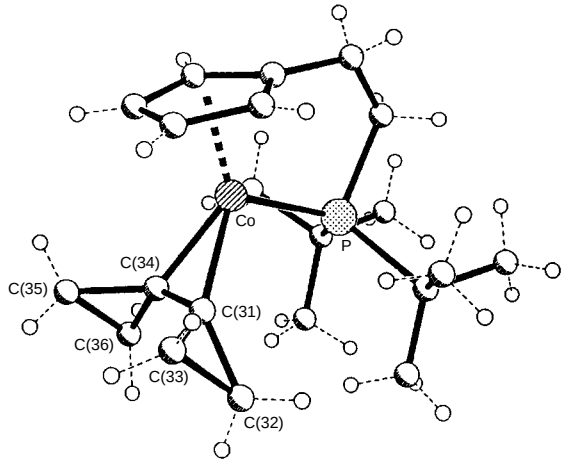

Fig. 1 Structure of the bicyclopropylidene cobalt complex **7** in the crystal.‡ Selected bond lengths (Å) and angles (°): Co–C(31) 1.956(4), Co–C(34) 1.965(3), C(31)–C(34) 1.401(5), C(31)–C(32) 1.482(5), C(32)–C(33) 1.499(12), C(33)–C(31)–C(32) 61.2(5), C(33)–C(31)–C(34) 129.5(5), C(32)–C(31)–C(34) 131.5(5), C(31)–C(34)–C(36) 133.8(3), C(31)–C(34)–C(35) 129.8(3).

ether. The NMR spectra indicate a plane of symmetry through the cobalt atom and the center of the double bond as in formula **7**. As for **6**, in the mass spectrum of **7** the molecular ion peak is observed (*m*/*z* 376, 27%), and the base peak also results from bicyclopropylidene decomplexation.

A suitable crystal of compound **7** was subjected to an X-ray structural analysis (Fig. 1). According to this the bicyclopropylidene ligand has undergone a remarkable out of plane bending by 40° at both termini of the double bond. This indicates a large back-bonding effect accepted by bicyclopropylidene, which is also documented by the long bond length of the coordinated double bond (1.401 Å) as compared to that in uncoordinated **2** (1.314 Å[27]). As a result of the complexation the double bond of bicyclopropylidene is expanded by *ca.* 6.6%. It is instructive to compare these numbers with those of ethene and the ethene complex corresponding to **7**. The bond length of ethene is 1.330 Å, in the ethene complex corresponding to **7** this value is 1.396 Å,[24] an increase of only 5.0%. The bonds in **2** and **7** adjacent to the double bond are of similar length, whereas the single bond opposite the double bond is significantly shortened from 1.544 Å in **2** to 1.499 Å in complex **7**. This is a consequence of the change in hybridization of the coordinated carbon atoms from sp^2 towards sp^3, causing a smaller endocyclic interorbital angle and thus shorter distal bonds in the ring.

A DTA–TG analysis revealed the remarkable thermal stability of **7**, as it can be heated up to 160 °C without decomposition. At 168 °C a strongly exothermic reaction takes place [$\Delta H = -52.1$ kcal mol^{-1} (1 cal = 4.184 J)]. A relative loss of mass of 11.5% is measured which, with a molecular mass of **7** of 376 g mol^{-1} corresponds to a loss of 40 g mol^{-1}, the molecular mass of cyclopropene. This suggests that the bicyclopropylidene ligand decomposes at elevated temperature. After the DTA–TG analysis the material was analyzed by FAB–MS indicating an M^+ peak at *m*/*z* 1304. This hints towards the formation of a $(CoCp\#)_4$ cluster with three cyclopropane rings.

In conclusion, bicyclopropylidene can be used as a ligand in transition metal complexes of early and late transition metals. The ligand displays a strong back-bonding effect as evidenced by the X-ray crystal structure analysis of the cobalt complex. We are currently investigating the chemistry of bicyclopropylidene complexes and related compounds with special emphasis of their thermochemical behaviour.

Synthesis of highly active tungsten-containing MCM-41 mesoporous molecular sieve catalyst

Zhaorong Zhang, Jishuan Suo, Xiaoming Zhang and Shuben Li*

State Key Laboratory for Oxo Synthesis and Selective Oxidation, Lanzhou Institute of Chemical Physics, Chinese Academy of Sciences, Lanzhou, 730000, P.R. China

A tungsten-containing MCM-41 mesoporous molecular sieve is synthesized by the hydrolysis of tetraethylorthosilicate and ammonium tungstate in the presence of cetylpyridinium bromide as template in acidic medium and found to be more active than the conventional WO_3 catalyst in the hydroxylation of cyclohexene using H_2O_2 as oxidant.

WO_3-based catalysts are important not only in hydrodesulfurization and alkene metathesis[1] but also in hydroxylation of unsaturated compounds.[2] Recently, the breakthrough discovery of silica-based mesoporous molecular sieves M41S, including the hexagonal MCM-41,[3,4] offered new opportunities for creating highly dispersed and more accessible catalytic sites by incorporating transition-metal ions into their silica-based frameworks.[5–9] Many of the mesoporous molecular sieve catalysts thus obtained therefore showed quite good catalytic properties in different reactions.[10,11] Here, we report the synthesis, characterization and catalytic performance of the tungsten-containing MCM-41 mesoporous molecular sieve catalyst (W-MCM-41) in the hydroxylation of cyclohexene with 30 mass% H_2O_2.

In a typical synthesis of the W-MCM-41, 5.67 g (20 mmol) of ammonium tungstate [Aldrich, 99.99% $(NH_4)_2WO_4$] was dissolved in 100 ml of water to prepare solution A; 6.2 g (15 mmol) of cetylpyridinium bromide (Aldrich, 98% $C_{16}H_{33}NC_5H_5Br{\cdot}H_2O$, CPBr) was combined with 60 ml of HCl (5 mol dm^{-3}) to form solution B. Then 11.4 g (50 mmol) of tetraethylorthosilicate [Aldrich, 98% $Si(OEt)_4$, TEOS] and a determined amount of solution A were simultaneously introduced into solution B under vigorous stirring to give the following composition: 1 TEOS : 0.3 CPBr : 0.02 W : 6 HCl : 60 H_2O. After allowing the resulting gel to age at 323 K under gentle stirring for 22 h, the solid product was centrifuged, washed with distilled water and air-dried. The calcination of the W-MCM-41 sample was carried out in air at *ca.* 533 K for 1.5 h, then at 873 K for 4 h.

The calcined W-MCM-41 sample was colorless, indicating the absence of colored crystalline WO_3 species outside the framework. This result was verified by Raman and UV–VIS spectroscopy.

An X-ray powder diffraction pattern (Rigaku, D/Max-2400, with Cu-Kα radiation; λ = 0.154 18 nm) of the calcined sample is depicted and indexed in Fig. 1 and corresponds to MCM-41 mesoporous silicas reported previously.[4,5]

Fig. 2 shows the Raman spectra (Nicolet, Raman 910) of W-MCM-41 and crystalline WO_3. Crystalline WO_3 is a very strong Raman scatterer, so the absence of intense peaks at *ca.* 804, 714, 327, 267 and 137 cm^{-1} (in WO_3) corresponding to octahedral WO_6 groups[13] in the spectrum of W-MCM-41 indicated that the W was highly dispersed in the silica-based framework structure. This result was also supported by the diffuse reflectance (DR) spectra of W-MCM-41 and WO_3 crystals in the UV–VIS region. In the DR UV–VIS spectrum of the calcined W-MCM-41 sample, there is no absorption band corresponding to crystalline WO_3.

The chemical analysis using ICP atomic emission spectroscopy (ARL 3520) showed the WO_3 content in the W-MCM-41 to be 7.1 mass% (SiO_2 : WO_3 *ca.* 50). The HK mean pore size and BET surface area of the as-synthesized W-MCM-41 calculated on the basis of nitrogen adsorption–desorption isotherms (Coulter, Omnisorp 360CX) were *ca.* 2.9 nm and 1059 $m^2\ g^{-1}$, respectively.

As mentioned above, different physicochemical characterizations confirmed that in the W-MCM-41 sample prepared, the W was highly dispersed in the silica-based framework structure, and it was found to be active for carrying out catalytic oxidations of unsaturated hydrocarbons using H_2O_2 as oxidant. Here the H_2O_2 hydroxylation of cyclohexene was carried out over W-MCM-41, Si-MCM-41 and conventional WO_3 catalysts suspended in acetic acid (HAc) media; where Si-MCM-41 was a pure silica sample synthesized by the method described above but leaving out the tungsten ion precursor. Since H_2O_2 in HAc alone is a hydroxylating agent,[2] a comparative experiment was also made in the absence of any catalyst. The results summarized in Table 1 clearly show that W-MCM-41 is a good catalyst for the test reaction, on which the hydroxylation rate of

5	None	50	65	240	94.1	*ca.* 100	74.0	6.7

[a] *Reaction conditions*: substrate/solvent: 1 : 20 (v/v), catalyst: 0.2 g, *T*: 353 K, H_2O_2: 30 mass% aqueous solution; C_6H_{10}: cyclohexene; *t*: time required for completing the reaction. [b] Calculated on alkene consumed; glycol: *trans*-cyclohexane-1,2-diol; ester: *trans*-cyclohexane-1,2-diol monoacetate.

cyclohexene could be increased significantly without decreasing the yields of *trans*-cyclohexane-1,2-diol. However, the Si-MCM-41 catalyst is equivalent to the blank H_2O_2–HAc system and inferior to the conventional WO_3 catalyst in activity. These data indicated that the highly dispersed W in silica-based molecular sieve might play a critical role in promoting the reaction. Systematic investigations toward understanding the mechanism for this catalytic reaction are still in progress.

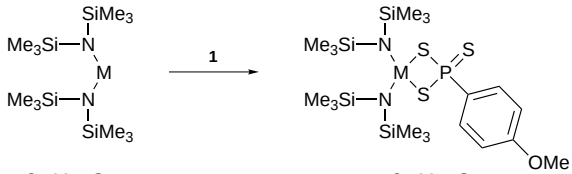
Germylene and stannylene cleavage of Lawesson's reagent

Claire J. Carmalt, Jason A. C. Clyburne, Alan H. Cowley,* Viviana Lomeli and Brian G. McBurnett

Department of Chemistry and Biochemistry, The University of Texas at Austin, Austin, Texas, 78712, USA

Lawesson's reagent undergoes cleavage reactions with bis[bis(trimethylsilyl)amino]germanium(II) and bis[bis(trimethylsilyl)amino]tin(II) whilst with 1,3-di-*tert*-butyl-1,3,2-diazagermol-2-ylidene the product is a novel spirocyclic germanium derivative.

Lawesson's reagent **1** is one of the most versatile thiation reagents available and is highly effective, for example, for the conversion of aldehydes and ketones to the corresponding thio derivatives.[1] However, much less information is available regarding the interaction of **1** with transition metal[2] or main group reagents. Herein we describe the unusual reactions of **1** with some coordinatively unsaturated group 14 compounds.



2a M = Ge
b M = Sn

3a M = Ge
b M = Sn

The reaction of **1** with stannylene **2b**[3] in THF solution resulted in a >90% isolated yield of **4b**.† Interestingly, the corresponding reaction of **1** with **2a**[3] produced a much smaller yield (*ca.* 10%) of the Ge analogue **3a**. ^{31}P NMR and HRMS(CI$^+$) data were consistent with the formulae proposed above for both compounds, and ^{1}H and ^{13}C NMR spectra indicated the presence of one *p*-MeOC$_6$H$_4$ and two (non-equivalent) N(SiMe$_3$)$_2$ groups.‡ However, in order to ascertain the atom connectivity, it was necessary to appeal to X-ray crystallography. Suitable single crystals of **3b** were obtained from CH_2Cl_2 solution. The central feature of the molecular structure of **3b**§ (Fig. 1) comprises a planar PS_2Sn ring [sum of angles = 360.00(3)°]. Such rings are rare as indicated by a search of the Cambridge Data Base which revealed only one previous example.[4] As expected, the average P–S$_{ring}$ bond distance [2.1125(9) Å] is longer than that of the external P–S bond [1.9315(9) Å]. Although the phosphorus and tin centres are four-coordinate, there is considerable deviation of the bond angles from the ideal tetrahedral value and the N–Sn–N angle in **3b** [116.07(7)°] is larger than that in **2b** [104.7(2)°].[5]

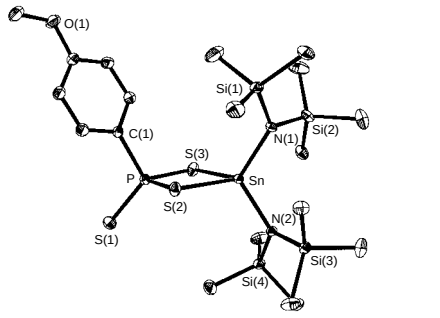


Fig. 1 Molecular structure of **3b** showing the atom numbering scheme. Selected distances (Å) and angles (°): P–C(1) 1.804(2), P–S(1) 1.9315(9), P–S(2) 2.1168(9), P–S(3) 2.1018(9), Sn–S(2) 2.4188(6), Sn–S(3) 2.4358(6), N(1)–Sn 2.015(2), N(2)–Sn 2.023(2), N–Si(1) 1.764(2), N–Si(2) 1.757(2), N(2)–Si(3) 1.757(2), N(2)–Si(4) 1.761(2); C(1)–P–S(1) 112.05(8), S(2)–P–S(3) 101.32(3), P–S(2)–Sn 87.17(3), P–S(3)–Sn 87.06(3), N(1)–Sn–N(2) 116.07(7), Sn–N(1)–Si(1) 122.83(10), Sn–N(1)–Si(2) 115.15(9), Sn–N(2)–Si(3) 116.33(9), Sn–N(2)–Si(4) 120.37(10), Si(1)–N(1)–Si(2) 120.73(10), Si(3)–N(2)–Si(4) 121.35(10).

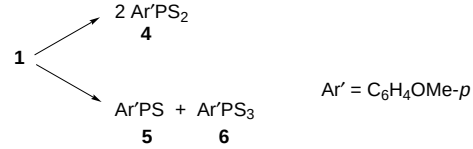
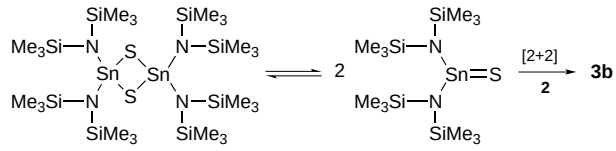
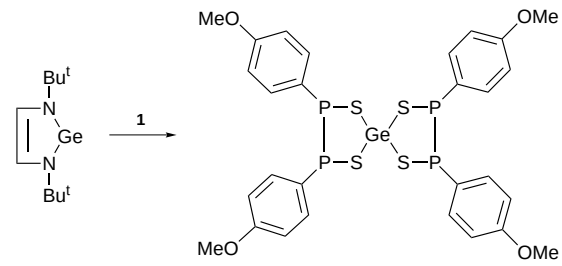


The mechanism of formation of **3a**,**b** is not clear, but plausible routes to these products include (*i*) oxidative addition of **2a**,**b** to **4**, which results from symmetrical cleavage of **1**, followed by addition of sulfur to phosphorus, (*ii*) addition of **2a**,**b** to an Ar′PS$_3$ (**6**) fragment resulting from unsymmetrical cleavage of **1**, and (*iii*) addition of sulfur to **2a**,**b** followed by reaction of the resulting germa- or stanna-thione with **4**. In an attempt to clarify this point, **7**,[6] which can be viewed as a cyclic dimer of the requisite stanna-thione **8**, was treated with an equimolar quantity of **1** in CD_2Cl_2 or C_6D_6 solution at 25 °C. NMR (^{31}P and ^{1}H) assay indicated quantitative conversion to **3b**. This observation is consistent with route (*iii*), and as such would represent a novel formal [2 + 2] cycloaddition involving P=S and Sn=S bonds.[7]



7 **8** **2**

In sharp contrast to the results obtained with **2a**, the cyclic germylene **9**[8] undergoes a completely different type of reaction with **1** and affords **10** as the major product. Whilst not appropriate as a mechanism, one way of thinking of this reaction is to consider that the cyclic germylene **9** serves as a source of Ge atoms for transfer to four Ar′PS (**5**) moieties. As pointed out above, **5** could arise *via* unsymmetrical cleavage of **1**.



9 **10**

The X-ray crystal structure of **10** revealed an interesting spirocyclic geometry (Fig. 2). Individual molecules of **10** reside on a crystallographic twofold axis. The GeS_2P_2 rings are slightly puckered and the dihedral angle between the S–Ge–S planes is 81.7°. The geometry at Ge is essentially tetrahedral;

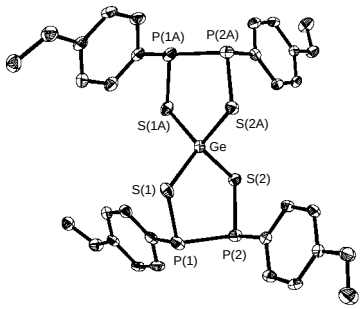


Fig. 2 Molecular structure of **10** showing the atom numbering scheme. Selected distances (Å) and angles (°): Ge–S(1) 2.222(1), Ge–S(2) 2.223(1), P(1)–S(1) 2.103(2), P(2)–S(2) 2.098(2), P(1)–P(2) 2.220(2); S(1)–Ge–S(2) 105.89(4), P(1)–S(1)–Ge 104.69(5), S(1)–P(1)–P(2) 104.46(6), S(2)–P(2)–P(1) 103.50(6), P(2)–S(2)–Ge 105.07(5).

however, the endocyclic S–Ge–S angles [105.89(4)°] are more acute than the exocyclic angles [117.10(6)°]. The average Ge–S [2.222(1) Å], P–S [2.100(2) Å] and P–P [2.220(2) Å] distances each correspond to a bond order of unity. Finally, the $R_2P_2S_2$ ligand does not appear to have been described previously; although a phosphorus–sulfur heterocycle is known[9] in which the $Ph_2P_2S_2$ ligand is associated with a PhP(S) moiety, *i.e.* $(PhPS)_3$.

† *Experimental procedure*: **3a**: compound **2a** (0.81 g, 2.1 mmol) in 50 cm³ of THF was added to a stirred slurry of **1** (0.80 g, 2.0 mmol) in 10 cm³ of THF. The solution was warmed to 60 °C for 20 min. The solvent was removed *in vacuo* and the resulting yellow residue was dissolved in 30 cm³ of CH_2Cl_2. After filtration through Celite the filtrate was concentrated and stored at −25 °C to afford a small quantity of yellow powder **3a** (0.09 g, 0.15 mmol, 8%), mp 132–136 °C.

3b: compound **2b** (1.25 g, 2.8 mmol) in 50 cm³ of THF was added to a stirred slurry of **1** (1.15 g, 2.8 mmol) in 10 cm³ of THF. The solution was warmed to 60 °C for 20 min. The solvent was removed *in vacuo* and the resulting pale yellow powder was dissolved in 30 cm³ of CH_2Cl_2. After filtration through Celite the filtrate was concentrated and stored at −25 °C to afford pale yellow crystals of **3b** (0.90 g, 1.3 mmol, 92% yield based on **1**), mp 140–143 °C.

10: compound **9** (0.67 g, 2.80 mmol) was dissolved in 30 cm³ of toluene and added to a stirred suspension of **1** (0.78 g, 1.94 mmol) in 40 cm³ of toluene at 25 °C. Over a 20 min period, the originally yellowish solution turned red as the solids dissolved. After 4 h a precipitate formed and the reaction mixture was allowed to stir for an additional 12 h. After filtration, the solvent and volatiles were removed from the filtrate and the residue was dissolved in CH_2Cl_2 and this solution was covered with a layer of hexane. Colourless crystals of **10** formed over a period of several days (0.15 g, 20% yield based on **1**), mp 200 °C (becomes opaque at 170 °C). HRMS: calculated for $C_{28}H_{28}GeO_4P_4S_4$ (M^+), 754.9111; found 754.9125.

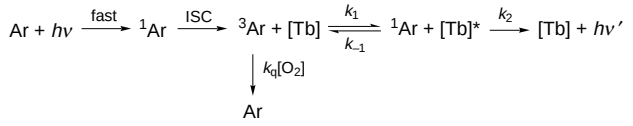
Taking advantage of the pH and pO_2 sensitivity of a luminescent macrocyclic terbium phenanthridyl complex

David Parker* and J. A. Gareth Williams

Department of Chemistry, University of Durham, South Road, Durham, UK DH1 3LE

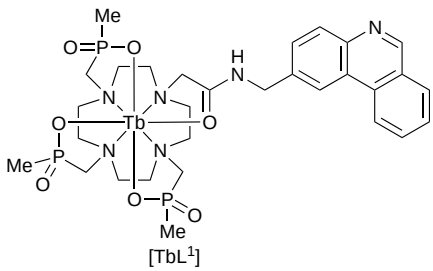
Strong metal-based emission with [TbL^1] in aqueous media occurs in the absence of protons and oxygen; dissolved molecular oxygen quenches the phenanthridyl triplet ($1/K_{SV}$ = 58 Torr O_2) but back-energy transfer to the organic triplet occurs efficiently only with the excited protonated complex (pK_a'' = 5.7).

Responsive luminescent probes that signal the presence of molecules or ions in aqueous solution are of current interest because of their application to the analysis of biological or environmental samples.[1] There have been some recent reports of pH responsive luminescent lanthanide complexes[2] in which the delayed luminescence from the metal allows time-gating in monitoring the emission, so that problems such as autofluorescence and Rayleigh-scattering are obviated. As a consequence of the low absorption coefficients associated with lanthanide f–f transitions, a sensitising chromophore needs to be built in to such complexes, preferably one that can efficiently absorb incident light at wavelengths greater than 340 nm.[3] Several different aromatic chromophores can be used under ambient conditions, provided that they possess a triplet energy *ca.* 1500 cm^{-1} greater than that of the emissive lanthanide state. If this condition is not fulfilled, then competitive thermally activated back-energy transfer will occur and the metal-based luminescence will become sensitive to the presence of dissolved O_2.[3,4] Such a situation is depicted in Scheme 1, wherein molecular oxygen may quench the aromatic triplet excited state and similarly affect the lanthanide luminescence, depending on the relative magnitude of k_1, k_{-1}, $k_q[O_2]$ and k_2. Of course, sensors for molecular oxygen that operate on the quenching of an aromatic triplet excited state are well known and include polyaza ruthenium and palladium porphyrin complexes,[5] where values of k_q are typically of the order of 1.5×10^9 dm^3 mol^{-1} s^{-1}.[6]



Scheme 1

The complex [TbL^1]† was prepared by reaction of the triphosphinate-phenanthridine ligand H_3L^1 reported previously[2a] with $Tb(OAc)_3$ in water, followed by purification by alumina chromatography. The fluorescent emission from the phenanthridine group at 403 nm was monitored together with the delayed luminescence from the terbium centre (λ_{em} = 547 nm) as a function of pH (Fig. 1), following excitation at the isosbestic wavelength (304 nm). The ligand-based fluorescence increases in intensity by a factor of 3 as the phenanthridyl nitrogen is protonated, consistent with the suppression of photoinduced electron transfer associated with protonation. The apparent pK_a was 4.2(1), in reasonable agreement with the value of 4.4(1) obtained with the analogous europium complex.[2a] The metal-based luminescence showed a luminescence enhancement of 125 but in the opposite sense. The neutral complex was highly emissive (φ_{H_2} = 0.025, τ_{H_2O} = 0.98 ms) and the protonated complex was not ($\varphi_{H_2O} = 9 \times 10^{-4}$, $\tau_{H_2O} < 0.1$ ms).



[TbL^1]

The phenanthridine triplet energies were estimated from the phosphorescence spectra of [GdL^1] at 77 K in an MeOH–EtOH glass and were found to be 22 000 cm^{-1} for the unprotonated form and 21 300 cm^{-1} for the protonated complex. These values are 1500 and 800 cm^{-1} higher than the energy of the Tb^{3+} emissive state ($^5D_4$, 20 500 cm^{-1}), respectively. Deactivation of the terbium complex by back-energy transfer to the organic triplet is thus much more significant for the protonated form. The excited-state pK_a of 5.75(10) for [TbL^1] is close to the pK_a reported for the triplet state of phenanthridine itself (5.7),[7] and is consistent with the establishment of an equilibrium between the triplet phenanthridyl excited state and the terbium $^5D_4$ excited state (Scheme 1). Further support for this hypothesis came from the effect of varying the partial pressure of O_2 in the sample. Removal of dissolved oxygen led to an increase in the overall quantum yield {φ = 0.12, pO_2 = 0, (H_2O)} and a concomitant increase in the terbium luminescent lifetime [τ_{H_2O} = 1.82 ms (pO_2 = 0)].† The triplet phenanthridyl excited state is quenched by O_2, and the extent of quenching is a function of dissolved [O_2] and is reported by changes in the terbium lifetime and emission intensity.‡ The N-methylated complex [TbL^2]$^+$ (prepared by alkylation in MeI–MeCN at 20 °C) also behaved as an oxygen sensor, with pO_2 ($S = \frac{1}{2}$) of 58 Torr, and an associated linear Stern–Volmer plot (Fig. 2).

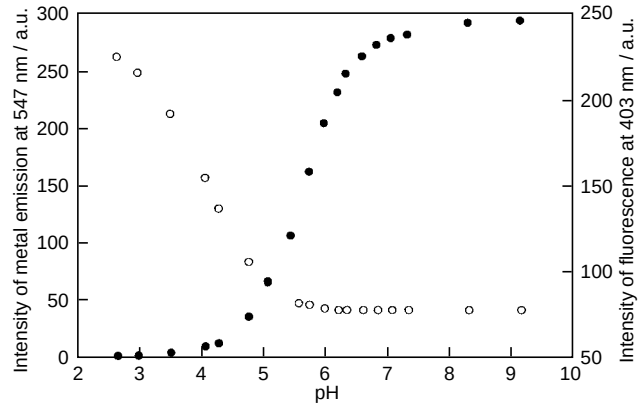


Fig. 1 Delayed luminescence emission intensity (●) and ligand-based fluroescence intensity (○) as a function of pH for [TbL^1], following pulsed excitation at 304 nm (isosbestic wavelength) and using a delay time of 0.1 ms [293 K, I = 0.1 (NMe_4ClO_4)]

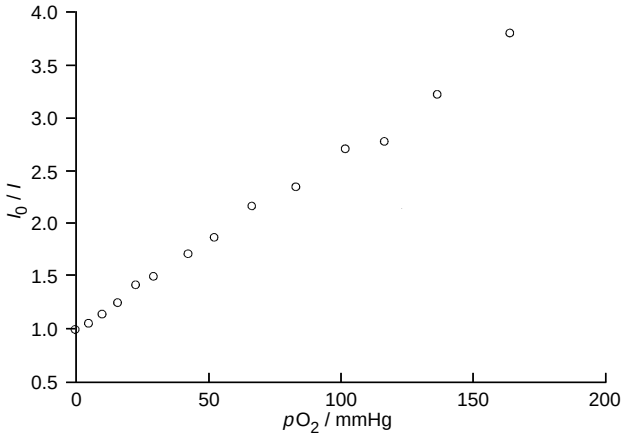

Fig. 2 Stern–Volmer plot of I_o/I *vs.* pO_2 for $[TbL^2]^+$ [293 K, I = 0.1 NMe_4ClO_4)]. Similar behaviour was exhibited by $[Tb(HL^1)]^+$.

The luminescence of this N-alkylated complex was independent of pH in the range 2–9.

The complex $[TbL^1]$ possesses several attractive sensory features. It exhibits a pH dependence in aqueous solution that embraces the range 3–7, because of the ability to examine either the ligand based fluorescence ($pK_a' = 4.2$) or the metal-based phosphorescence ($pK_a'' = 5.75$). Moreover, the luminescent enhancement factors for the former are at least 500, when an excitation wavelength of 375 nm is used, because the unprotonated complex does not absorb at this wavelength {*cf.* $\varepsilon_{375} = 3 \times 10^3$ dm^3 mol^{-1} cm^{-1} for $[Tb(HL^1)]^+$}, as was found for the analogous complex $[EuL^1]$.[2a]

The change in the lifetime of the terbium excited state upon protonation ($\Delta\tau_{H_2O}$ = 1 ms), means that lifetime measurements, rather than luminescence intensity measurements, may be used to characterise the pH dependence over the range 5–7, which may be usefully applied to biological systems. In addition, in the pH range 2–9 the sensitivity of the N-methylated salt to dissolved oxygen may be harnessed to determine pO_2 in aqueous solutions, measuring the lifetime or emission intensity from the Tb excited state. Finally, given that strong terbium luminescence (Table 1), occurs only when both acid and O_2 are not present, the complex $[TbL^1]$ could be construed as behaving as a molecular NAND logic gate[8] with H^+ and O_2 as the 'inputs' and delayed terbium luminescence as the signal 'output'.

Table 1 Lifetimes and quantum yields for lanthanide complexes (H_2O, 293 K, λ_{exc} 304 nm)[a]

Parameter	$[TbL^1]$	$[TbHL^1)]^+$	$[EuL^1]$[b,c]	$(Eu(HL^1)]^+$
φ_{aer}	2.5×10^{-2}	9.1×10^{-4}	0.011	0.03
$\varphi_{degassed}$	0.12	4.6×10^{-2}	0.011	0.03
$\tau_{H_2O_{aer}}$/ms	0.98	*ca.* 0.1	0.71	0.71
$\tau_{H_2O_{degassed}}$/ms	1.82	0.83	0.71	0.71

[a] Lifetimes were obtained using a Perkin-Elmer LS50B (gate time 0.1 ms); [b] Data from ref. 2(*a*); [c] In D_2O, τ = 1.92 ms for the free and 1.95 ms for the protonated complex.

First electrochemical synthesis of network silane and silane–germane copolymers: $(C_6H_{11}Si)_x(PhSi)_y$ and $(C_6H_{11}Si)_x(PhGe)_y$

Kui Huang and Lori A. Vermeulen*

Department of Chemistry and Biochemistry, Southern Illinois University at Carbondale, Carbondale, IL, 62901-4409, USA

An electrochemical technique is demonstrated for the synthesis of Si–Si and Si–Ge network copolymers poly(cyclohexylsilyne-*co*-phenylsilyne) and poly(cyclohexylsilyne-*co*-phenylgermyne); the molecular mass distributions of the electrochemically prepared polymers are more narrow in comparison to similar polymers prepared by the Wurtz coupling reaction.

Silicon-based polymers have attracted considerable attention owing to their interesting optical and electronic properties, which are strongly related to the dimensionality of the silicon backbone.[1] Polysilanes $(SiR^1R^2)_n$ which consist of a one-dimensional backbone structure exhibit intense near-UV absorption bands and sharp UV emission attributed to the Si backbone σ–σ* transition.[2] The network or crosslinked polysilynes $(SiR)_n$ in which each silicon atom is bonded to three other silicon atoms and one organic side group R are typically yellow materials that photoluminesce in the visible region of the spectrum.[3] It has been proposed that the structure of the network polysilynes consists of rings of different sizes and shapes that are fused together in a random arrangement. The optical features are attributed to the decrease in the Si σ–σ* bandgap compared to the linear polymers, which is caused by increasing the dimensionality of the silicon backbone from a 1D linear structure to a 2D cross-linked structure. Furthermore, it has been reported that Ge three-coordinate polymers (polygermynes)[4] as well as some silicon and germanium copolymers[5] can also be synthesized. The ability to tune the optical properties of these polymers by manipulation of the backbone architecture and composition is an intriguing challenge for the development of these polymers as optoelectronic materials.

The most general synthetic method for the preparation of these metallic backbone polymers is the Wurtz coupling reaction of organo-dichloro- or trichloro-silanes (or germanes) with a sodium dispersion in toluene at refluxing temperature.[2] However, there are several problems with the Wurtz coupling method, most notably the extreme difficulty in controlling the rate of the reaction and thereby obtaining polymers with reproducibly narrow molecular mass distributions. In particular, the network polysilynes that have been prepared by the Wurtz coupling reaction exhibit very broad electronic absorption and NMR spectra. These observations are attributed to the wide variety of macrostructures that are obtained in the Wurtz coupling reaction. Thus, alternative methods of synthesis are desirable for the preparation of materials with structural and optical properties that can be more precisely controlled. To this end, there have been several reports of employing electrochemical techniques for the synthesis of linear polysilanes and germane–silane copolymers.[6]

Scheme 1†

In the present study, we describe the synthesis and optical properties of two new network copolymers poly(cyclohexylsilyne-*co*-phenylsilyne) $(C_6H_{11}Si)_x(PhSi)_y$ **1** and poly(cyclohexylsilyne-*co*-phenylgermyne) $(C_6H_{11}Si)_x(PhGe)_y$ **2** by an electrochemical reduction utilizing copper electrodes and constant applied potential.† The network polymers were synthesized by the electrochemical reduction of 1,2-dimethoxyethane (DME) solution of a 1 : 1 mixture of the trifunctional monomers as depicted in Scheme 1.

Molecular mass, yield, NMR data, and optical properties of **1** and **2** are provided in Table 1. Notably, the ^{29}Si NMR spectrum

Table 1 Physical and optical properties of **1** and **2**

	x/y^a	Yield[b] (%)	M_n[c]	M_w/M_n	^{29}Si, δ	λ_{em}[d]/nm	λ_{ex}/nm
1	1.25	49	5839	1.4	−55, −65, −76(br)	470	350
2	1.04	23	3147	2.0	−50 to −80(br)	490	350

[a] Monomer ratio determined by ^1H NMR. [b] Isolated yield obtained by precipitation from toluene–methanol (1 : 8). [c] M_w determined by GPC *vs.* polystyrene. [d] Excitation λ = 300 nm.

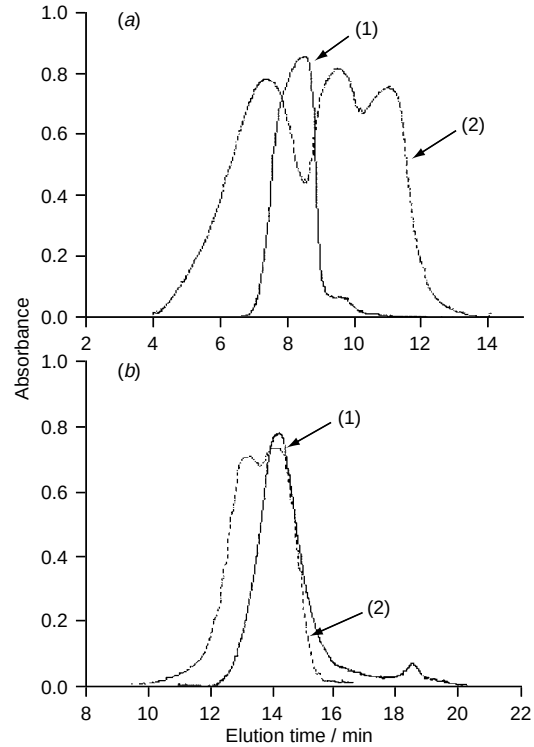

Fig. 1 GPC chromatogram for (*a*) poly(cyclohexylsilyne-*co*-phenylsilyne) (1) electrochemical product, (2) Wurtz product; (*b*) poly(cyclohexylsilyne-*co*-phenylgermyne) (1) electrochemical product, (2) Wurtz product. [Different columns were used for (*a*) and (*b*) and time scales are therefore different]

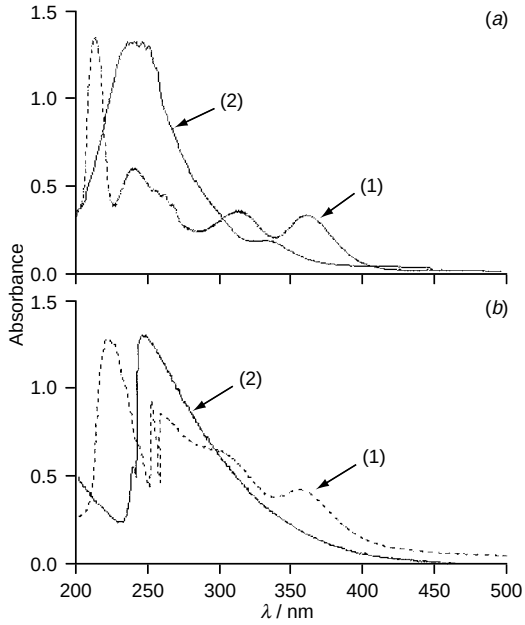

Fig. 2 Absorption spectra of (*a*) poly(cyclohexylsilyne-*co*-phenylsilyne) reaction mixture (1) immediately after quenching with methanol, (2) after ageing in the dark; (*b*) poly(cyclohexylsilyne-*co*-phenylgermyne) reaction mixture (1) immediately after quenching with methanol; (2) after ageing in the dark

of **1** exhibits three broad resolvable peaks in the region typical for tertiary Si atoms (Si bonded to three other Si atoms). Thermally prepared network polymers typically exhibit an extremely broad resonance in this region (δ −20 to −80, with no resolvable peaks).[3] The broad resonance typically observed is attributed to overlapping peaks corresponding to the wide variety of ways that the Si atoms can be bonded together in a random network arrangement. There are no resonances observed which would be typical for linear polysilylene segments.

For comparison, these two copolymers, which are not reported in the literature, were also prepared by the thermal reduction method under typical Wurtz conditions.[2]‡ The molecular mass distributions of all four polymers are shown in Fig. 1. As can be seen, the GPC for the same products obtained by the thermal Wurtz coupling reaction are broader and polymodal compared to those prepared electrochemically.

These network copolymers have optical properties which are typical for this class of materials, exhibiting both a broad absorption band edge that tails into the visible region and a broad emission band. The Ge–Si backbone polymer exhibits a broader emission which is slightly red-shifted compared to the Si backbone polymer, as expected.[4]

Because of the mild reaction conditions, we were able to observe precursors to the isolated products spectroscopically, which can not be observed from the Wurtz product mixture. Discrete peaks are observed in the absorption spectra of the two electrochemically prepared copolymers prior to work-up as shown in Fig. 2. Both samples were quenched with methanol and stored in the dark and the absorption spectrum was re-checked periodically. Over a period of two weeks, the discrete peaks gradually disappear and the spectrum begins to resemble that of the isolated polymer. The slow conversion to products provides an opportunity to more easily study the reaction mechanism, which is not readily accomplished with the thermal Wurtz reaction. The origin of the discrete peaks in the electronic spectra and a study of the reaction pathway are currently being investigated.

The authors gratefully acknowledge financial support from the National Science Foundation (NSF-CHE-9510481), an Oak Ridge Associated Universities Junior Faculty Award, and the Office of Research and Development Administration (ORDA) at SIU. We also acknowledge Dr. Bill Stevens for assistance with the NMR experiments.

† *Conditions*: undivided electrolytic cell equipped with coiled copper wire 1 mm in diameter for both the cathode (14 cm^2) and anode (34 cm^2), constant applied potential (−3.0 V), ultrasound, TBAP supporting electrolyte (1.0 g), dry DME solvent (30 ml), cyclohexyltrichlorosilane (0.45 ml), phenyltrichlorosilane (0.40 ml). Reaction was continued until GPC no longer changed and then quenched with methanol. After removal of volatiles and electrolyte, product was purified by precipitation with methanol. Similar procedure was used for the preparation of **2**.

‡ A mixture of monomers in toluene was added slowly to a refluxing sodium dispersion under an atmosphere of Ar. The reaction was carried out at reflux for 5 h. The reaction was quenched by adding methanol and water. The organic layer was separated and washed with water and the isolated polymers were obtained by precipitation from the solution with methanol.

Selective formation of HCO_2^- and $C_2O_4^{2-}$ in electrochemical reduction of CO_2 catalyzed by mono- and di-nuclear ruthenium complexes

Electrochemical reduction of carbon dioxide catalyzed by mono- and di-nuclear ruthenium complexes produced HCO_2H with trace amounts of CO and $C_2O_4^{2-}$ in the presence and absence of H_2O, respectively, in MeCN.

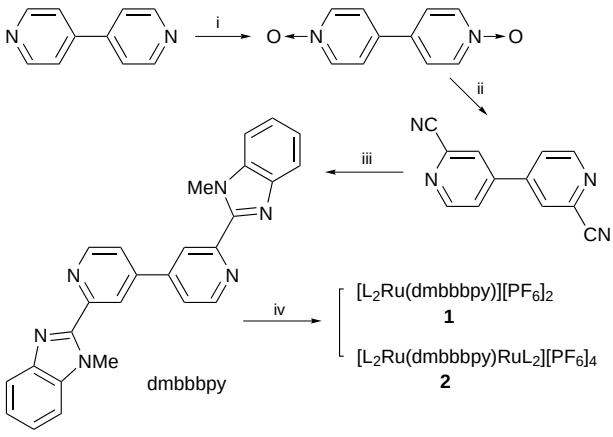
Reduction of CO_2 accompanied by carbon–carbon bond formation is highly desired because the electrochemical reduction of CO_2 catalyzed by metal complexes usually produces only CO and/or HCO_2H.[1–6] A key process for the activation of CO_2 on metals is how to create coordinately unsaturated low valent metal centers under mild conditions. We have found that $[(CpM)_3(\mu_3\text{-}S)_2]^{2+}$ (M = Co, Rh, Ir)[7] catalyzes electrochemical reduction of CO_2 to produce oxalate selectively, where the reaction sites for the first catalytic formation of $C_2O_4^{2-}$ are presumed to be created by an M–M bond cleavage upon the two-electron reduction of these M_3S_2 clusters. Metal complexes with unsymmetrical chelating rings may also provide sites for activation of CO_2 by dechelation in the electrochemical reduction of CO_2. We introduced 2,2′-bis(1-methylbenzimidazol-2-yl)-4,4′-bipyridine (dmbbbpy) as an unsymmetrical chelating ligand into a $Ru(bpy)_2$ moiety to aim not only to create reaction sites by opening the chelate ring but also to accumulate electrons into the ligand required in the reduction of CO_2. Here, we report almost selective HCO_2H and $C_2O_4^{2-}$ formation depending on the presence and the absence of H_2O in electrochemical reduction of CO_2 catalyzed by mono- and di-nuclear Ru complexes.

Scheme 1 shows the synthetic route for 2,2′-bis(1-methylbenzimidazol-2-yl)-4,4′-bipyridine (dmbbbpy) and the mono- and di-nuclear ruthenium complexes. Mono- (**1**) and di-nuclear Ru complexes (**2**) were synthesized by the reaction of $[Ru(bpy)_2Cl_2]$ with dmbbbpy with mol ratios of 1 : 1 and 2 : 1, respectively, in ethylene glycol. Both complexes were purified by column chromatography and characterized by electrospray MS and elemental analyses.

The cyclic voltammogram (CV) of **1** exhibited three reversible one electron redox couples at $E_{1/2}$ = −1.45, −1.75 and −1.99 V in MeCN resulting from dmbbbpy and two bpy based reductions, respectively. Complex **2** also showed three reversible redox couples with a small positive shift (0.2 V) of the dmbbbpy based redox wave. Introduction of CO_2 by bubbling into the solutions of **1** and **2** results in an increase in the cathodic currents at potentials more negative than −1.60 and −1.50 V, respectively, indicating that two-electron reduced forms of **1** and **2** have an ability to catalyze the reduction of CO_2 (Fig. 1).

Controlled potential electrolysis of **1** and **2** (0.2–0.3 mmol dm^{-3}) at −1.65 and −1.55 V (*vs.* Ag/AgCl) was conducted in CO_2 saturated MeCN (20 ml) in the presence of H_2O (0.5 ml). After 91 C was passed in the electrolysis of **1**,† HCO_2^- was produced with a current efficiency (η) of 89% together with a trace amount of CO (η = 2–3%). On the other hand, the similar electrochemical reduction of CO_2 in dry MeCN selectively produced oxalate‡ with an η of 64% without forming HCO_2^- and CO after 50 C was passed in the electrolysis. The electrochemical reduction of CO_2 catalyzed by **2** also generated almost selectively HCO_2^- (η = 90%) and $C_2O_4^{2-}$ (η = 70%) in the presence and the absence of H_2O, respectively, under similar conditions.

The reaction of CO_2 catalyzed by **1** was monitored in an IR cell with KBr windows equipped with a gold mesh for the working electrode, a platinum wire for a counter electrode and an Ag/AgCl reference electrode.[8] Reductive electrolysis at −1.65 V§ of **1** in CO_2-saturated CD_3CN solution resulted in the appearance of three bands at 1684, 1633 and 1603 cm^{-1} [Fig. 2(*b*)]. Reoxidation at −0.70 V causes the disappearance of the 1684 and 1603 cm^{-1} bands, while the 1633 cm^{-1} band assigned to $C_2O_4^{2-}$ remained unchanged. The three bands at 1684, 1633 and 1603 cm^{-1} shifted to 1638, 1600 and 1540 cm^{-1}, respectively, under similar electrolysis using $^{13}CO_2$



Scheme 1 Synthesis route for the bridging ligand, Ru mono- and di-nuclear complexes. *Reagents and conditions*: i, $MeCO_2H + H_2O_2$; ii, $(MeO)_2SO_2$, KCN; iii, *N*-methyl-1,2-phenylenediamine; iv, $[RuL_2Cl_2]$ (L = bpy).

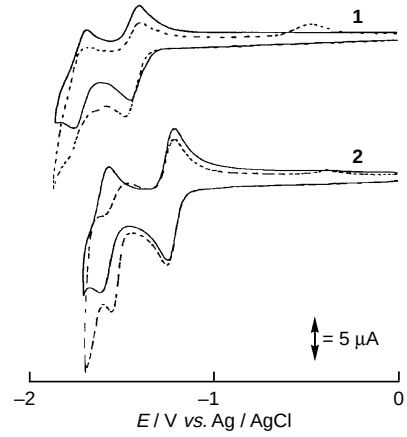


Fig. 1 Cyclic voltammograms of 0.3 mM **1** or **2** in 0.1 M NBu_4BF_4MeCN at glassy carbon electrode (id = 3.0 mm) under N_2 (——) and CO_2 (------) atmospheres. Scan rate = 50 mV s^{-1}.

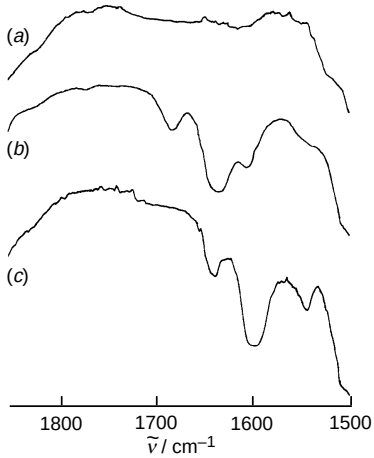

Fig. 2 IR spectra of **1** (0.8 mM) during a thin-cell bulk electrolysis in CD_3CN with $LiBF_4$. (*a*) Starting scan, (*b*) using $^{12}CO_2$, (*c*) using $^{13}CO_2$.

[Fig. 2(*c*)]. The bands at 1638 and 1540 cm^{-1} also disappeared upon reoxidation at −0.70 V suggesting that a CO_2 adduct probably formed by an attack of two molecules of CO_2 to the two-electron reduced form of **1** which acts as a precusor to oxalate in the electrochemical reduction of CO_2 in dry MeCN.

It is noteworthy that any interaction between reduced forms of $[Ru(bpy)_2L]^{2+}$ (L = bpy or 2-pyridyl-1-methylbenzimidazole¶) and CO_2 was not observed at all in the CV in MeCN. Indeed, these complexes have no ability to catalyze the electrochemical reduction of CO_2 under controlled potential electrolysis even at −1.80 V in the absence or presence of H_2O in MeCN. Moreover, $[Ru(bpy)_2(CO)X]^{n+}$ (*n* = 2, X = CO; *n* = 1, X = Cl)[9] works as an effective catalyst producing CO and/or HCO_2H in the electrochemical reduction of CO_2 under protic conditions, but the complex readily decomposes in the similar reduction of CO_2 in the absence of proton donor. Savéant and coworkers have shown that aromatic nitriles and esters with redox potentials more negative than −1.93 V mediate electrochemical reduction of CO_2 affording oxalate. The reaction is explained by an electrophilic attack of CO_2 to oxygen or nitrogen of the anion radicals followed by homolytic cleavage of the ArX–CO_2^- [X = OC(O)R, CN] bond and the subsequent coupling of free $CO_2^{\cdot -}$.[10] On the other hand, the IR spectra of **1** showed the two $\nu(CO_2)$ bands (1684, 1603 cm^{-1}) assignable to the precursor for oxalate under electrolysis at −1.65 V, suggesting that oxalate generation in the present study does not result from dimerization of free $CO_2^{\cdot -}$. If two-electron reduction of **1** and **2** causes dechelation of dmbbbpy, the resultant five-coordinate Ru and monodentate dmbbbpy$^-$ may provide two binding sites for an attack of CO_2, which would facilitate a coupling reaction of CO_2 affording oxalate. Thus, dmbbbpy of **1** and **2** greatly contributes to the first selective formation of $C_2O_4^{2-}$ and HCO_2^- depending upon the absence and the presence of H_2O, respectively, in the electrochemical reduction of CO_2.

Interpenetrating three-dimensional rutile-like frameworks. Crystal structure and magnetic properties of $Mn^{II}[C(CN)_3]_2$

Jamie L. Manson,[a] Charles Campana[b] and Joel S. Miller*[a]

[a] *Department of Chemistry, University of Utah, 315 s. 1400 E. RM Dock, Salt Lake City, UT 84112-0850, USA*
[b] *Brucker Analytical X-ray Systems, Inc., 6300 Enterprise Lane, Madison, WI 53719-1173, USA*

The interpenetrating double-density rutile-like structure and magnetic properties of $Mn^{II}[C(CN)_3]_2$ are determined.

Molecule-based magnetic materials have been the focus of intense investigations since the ferromagnetic electron transfer salt $[FeCp^*_2]^{\cdot+}[TCNE]^{\cdot-}$[1,2] and the ferrimagnetic $Mn^{II}Cu^{II}$ chains[2,3] were discovered to magnetically order.[1,2] In the meantime, numerous one-, two-, and three-dimensional coordination polymers comprising paramagnetic transition metal cations and diamagnetic organic ligands exhibiting a wide variety of cooperative phenomena have been reported.[2,4] Furthermore, several diamagnetic examples of molecular materials that mimic three-dimensional inorganic network solids (*e.g.* α Po, diamond, α-$ThSi_2$, *etc.*) have also been described including systems in which interpenetration of two or more identical lattices occurs.[5] The majority of these polymeric frameworks are comprised of Ag^+ cations because of their propensity to afford multiple coordination geometries. Notable examples where Ag^+ possesses octahedral, tetrahedral, and trigonal planar geometries include $[Ag(pyz)_3]SbF_6$ (pyz = pyrazine),[6] $[Ag(DCPA)_2]ClO_4{\cdot}H_2O$ (DCPA = 3,3′-dicyanodiphenylacetylene),[7] and $[Ag_2(pyz)_3](BF_4)_2$,[8] respectively.

In order to construct new molecule-based magnetic materials it is important to assemble solid state structures analogous to those just described. To do this, appropriate paramagnetic transition metal ions and organic bridging ligands capable of significant spin coupling are required. Conjugated bridging ligands, such as cyanide and oxalato, have been shown to provide spin coupling between metals sites and extension to other classes of ligands are sought.[4] We selected tricyanomethanide, $[C(CN)_3]^-$, due to its ability to bind to three metal sites, and the aqueous reaction of $Mn^{II}(NO_3)_2$ and $[C(CN)_3]^-$ leads to the formation of $Mn[C(CN)_3]_2$.‡ The tricoordinate $[C(CN)_3]^-$ could lead to geometrical spin frustration.[10]

$Mn[C(CN)_3]_2$ has a complex interpenetrating network structure.‡ Each Mn^{II} bonds to six $[C(CN)_3]^-$ anions, Fig. 1, and each $[C(CN)_3]^-$ is μ_3-bonded to three Mn^{II} ions, Fig. 2, forming a rutile-like (TiO_2) lattice and is isomorphous to $Zn[C(CN)_3]_2$.[11] $[C(CN)_3]^-$ is planar with C(1)–C(3) and C(2)–C(3) bond distances of 1.404(2) and 1.412(2) Å (av. 1.408 Å), and C(1)–N(1) and C(2)–N(2) distances of 1.151(2) and 1.149(2) Å (av. 1.150 Å), respectively, as is typical of $[C(CN)_3]^-$.[11,12] The Mn^{II} cation occupies a 2/*m* special position while C(2) and N(2) reside on mirror planes, all on the crystallographic *a*-axis. Each Mn^{II} center is slightly elongated from octahedral symmetry with Mn–N(1) and Mn–N(2) bond distances of 2.222(1) and 2.272(2) Å, respectively, and averaging 2.247 Å. These Mn–N distances compare favorably to those found in related materials.[13] This distortion is significantly less than that observed for $Zn[C(CN)_3]_2$ with Zn–N(1) and Zn–N(2) distances of 2.120(2) and 2.211(2) Å,[11] respectively. Hence, the distortion is not a consequence of ligand-field effects, but is imposed by steric constraints. Likewise, owing to crystal packing forces the *cis*-N–M–N′ bond angles demonstrate a marked distortion from 90° and range from 88.9 to 96.7° for $Mn[C(CN)_3]_2$ and 84.4 to 95.6° for $Zn[C(CN)_3]_2$,[11] respectively. Additionally, the large $Mn\cdots C_{centroid}$ separations (*ca.* 4.8 Å) provide cavities of sufficient size for interpenetration of a second identical lattice, Fig. 2. Furthermore, the shortest intra- and inter-network Mn···Mn separations are 7.679 and 5.383 Å, respectively.

The rutile structure is a fundamental solid state structure-type and is one way to connect octahedral centers with trigonal planar ligands to form three-dimensional networks for spin coupling. Antiferromagnetic coupling between spin sites coupled *via* the D_{3h} μ_3-bridging $[C(CN)_3]^-$ ligand should lead to geometrical spin frustration akin to a Kagomé lattice.[10] Additionally, the interpenetrating rutile-like frameworks may lead to enhanced or unusual magnetic properties that may arise if communication between them is sufficient, thus leading to effective dipolar exchange.

The temperature dependence (2–300 K) of the magnetic susceptibility of $Mn[C(CN)_3]_2$ was measured and can be fit by the Curie–Weiss expression, $\chi \propto (T - \theta)^{-1}$, with $\theta = -5.1$ K indicative of finite antiferromagnetic coupling between the Mn^{II}

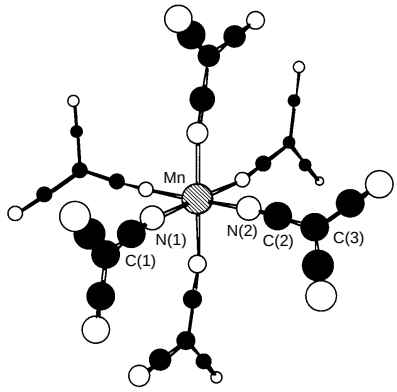

Fig. 1 Illustration showing only the first coordination sphere of the Mn^{II} cation (shaded). Filled and unfilled spheres represent C and N atoms, respectively. Bound nitriles do not coordinate linearly as can be seen clearly here in this view: Mn–N(1)–C(1) 170.03(10), Mn–N(2)–C(2) 166.4(2)°.

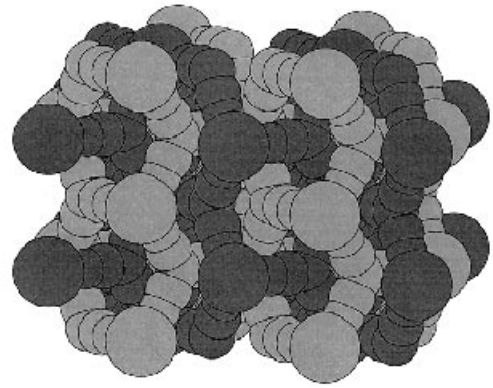

Fig. 2 Space filling model of $Mn^{II}[C(CN)_3]_2$ emphasizing the interpenetrating nature of the two identical rutile-like frameworks

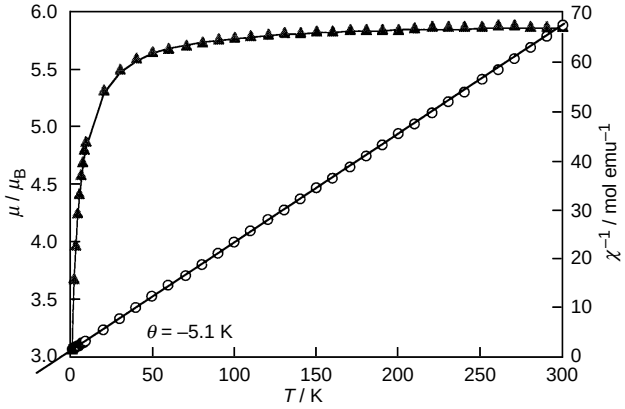

Fig. 3. Temperature dependence of the moment and the reciprocal molar magnetic susceptibility for $Mn^{II}[C(CN)_3]_2$. The data were fitted to the Curie–Weiss law (—) using the following parameters: S = 5/2, g = 2.00 and θ = −5.1 K.

metal centers, Fig. 3. At 300 K the effective moment is 5.86 μ_B, in good agreement with the expected value (5.92 μ_B) for isolated S = 5/2 Mn^{II} ions and decreases at lower temperatures owing to antiferromagnetic coupling. The −5.1 K θ-value is larger than expected for isolated Mn^{II} ions and suggests that (*a*) the diamagnetic $[C(CN)_3]^-$ ligand mediates a superexchange interaction between the Mn^{II} ions, and/or (*b*) owing to shorter internetwork Mn···Mn separation with respect to intranetwork separation, through-space (dipolar) antiferromagnetic coupling between the interpenetrating rutile networks may dominate and lead to bulk antiferromagnetic coupling. Both mechanisms are expected to contribute as the internetwork Mn···Mn separations leading to dipolar interactions are shorter than the intranetwork Mn···Mn separations leading to superexchange.

The authors gratefully acknowledge the ACS-PRF (Grant #30722-AC5) and the US Department of Energy (Grant #DE-FG03-93ER45504) for support of this work.

Cleavage of the Pt–S bond of thiolated terpyridine–platinum(II) complexes by copper(II) and zinc(II) ions in phosphate buffer

Chien-Chung Cheng* and Yen-Lin Lu

Institute of Chemistry, Academia Sinica, Taipei, Taiwan 11529, Republic of China

Using the chelation of a triamine moiety and an S-bridged heterodinuclear unit, cleavage of the Pt–S bond in the thiolate–platinum complexes, $[Pt(terpy)(BAT)]^{4+}$ and $[Pt(terpy)(AET)]^{+}$ is induced by adding transition metals such as Cu^{2+} or Zn^{2+} in phosphate buffer (pH 7–8) at room temp.

Many efforts in the development of platinum complexes as anticancer drugs have been contemplated in order to reduce the cytotoxicity and to improve the platin drug-resistance.[1] Since sulfur-containing compounds such as glutathione and metallothioneins are rich in cells, the formation of the S–Pt bond is generally believed to be one of the major mechanisms in the resistance to *cis*-platin drugs in biological processes.[2] In contrast, recent NMR studies by Sadler and coworkers reveal that S-bound L-methionine on Pt^{II} acts as a reversible binding ligand and is capable of undergoing intermolecular replacement by 5′-GMP in phosphate buffer (pH 7.2).[3] In fact, the concentration of glutathione (GSH) in intracellular cells is commonly high (> 1 mM). Therefore, in the reaction with platin drugs, the formation of thiolate–platinum adducts is inevitable.[4] The thiolate ion is capable of providing a stronger binding affinity owing to its better σ-donating ability.[5] Such a Pt–S bond is considered relatively inert, which may cause the inhibition of the anticancer activity of platin drugs. Thus, the great challenge is to break the Pt–S bond in the thiolate–platinum adducts.

To approach this goal, thiolated derivatives of terpy–platinum(II) complexes are used as a source to study the Pt–S bond owing to their characteristic electronic absorption and NMR spectra.[6–8] Here, we report that transition metals such as Cu^{II} or Zn^{II} are capable of inducing cleavage of the Pt–S bond of thiolated terpyridine platinum(II) complexes, $[Pt(terpy)(AET)]^{+}$ (AET = 2-aminoethanethiol) and $[Pt(terpy)(BAT)]^{4+}$ [BAT = *N*,*N*′-bis(aminoethyl)aminoethanethiol], particularly in phosphate buffer as shown in Fig. 1. The introduction of a triamine moiety to the complex structure increases the dissociation rate and the selectivity of the Pt–S bond cleavage in thiolate–platinum complexes. To our knowledge, this is the first reported example of Pt–S bond cleavage among thiolate–platinum(II) complexes in phosphate buffer.

$[Pt(terpy)(AET)]^{+}$ was prepared by published methods.[11] The synthesis of a triamine derivative, $[Pt(terpy)(BAT)]^{4+}$, was achieved by the coupling reaction of $[Pt(terpy)Cl]^{+}$ with the modified multistep synthesis[12–15] of triaminothiol, **1**, in water as illustrated in Scheme 1. The NMR spectrum of $[Pt(terpy)(BAT)]^{4+}$ in D_2O showed a new downfield peak at δ 8.82 and the UV–VIS spectrum displayed the absorbances at 486 nm (ε = 698 dm^3 mol^{-1} cm^{-1}), 342 (12 959), 329 (12 397) and 311 (11 903) in phosphate buffer (pH 8.0), which agreed with the characteristic features for establishing the formation of thiolate–platinum bonds in the previous report.[11] In addition, the integration ratio of protons of terpyridine and the triamine moiety in NMR spectra (D_2O) was approximately 0.93, suggesting no S-bridged diplatinum complex was generated.[14]

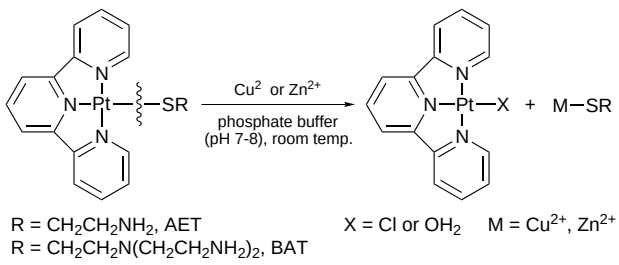

Fig. 1 General equation representing the cleavage of the Pt–S bond

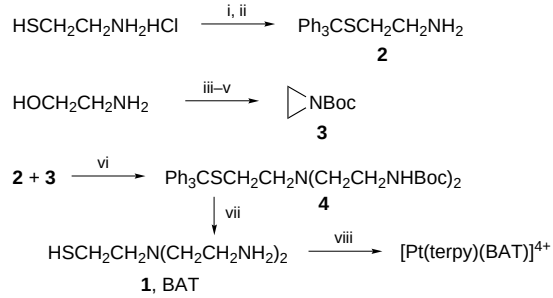
In the presence of $CuCl_2 \cdot 6H_2O$ (42 μM), the solution of $[Pt(terpy)(BAT)]^{4+}$ (40 μM) exhibited a decreasing UV–VIS absorption at 342 nm accompanied by an increasing absorption at 329 nm in phosphate buffer (10 mM, pH 8.0). An isosbestic point was observed at 337 nm in the spectrum, suggesting no intermediate had been generated in the reaction with metal ions. Also, no significant alteration was observed in the absence of Cu^{II}. The cleavage of the Pt–S bond of $[Pt(terpy)(BAT)]^{4+}$ (40 μM) in the titration with Cu^{II} (10–84 μM) was found to require 1 equiv. of Cu^{II} to complete the reaction in 120 min. This dissociation of the Pt–S bond of $[Pt(terpy)(BAT)]^{4+}$ was revealed to be a pH dependent process in the range pH 4.8–10.0. The reactivity of the Pt–S bond cleavage was reduced with a decreasing pH and ceased at pH < 6, implying that the participation of the amino group plays a vital role in the cleavage. In fact, when a hydroxylthiol derivative of $[Pt(terpy)(SCH_2CH_2OH)]^{+}$, was used instead of an amino derivative, under the same conditions, no cleavage of the Pt–S bond was observed.

The isolation of the cleavage product was performed in MeOH in order to simplify the product analysis. After the addition of $CuCl_2 \cdot 6H_2O$, a red solution of $[Pt(terpy)(BAT)]^{4+}$ turned into a blue-green suspension containing orange solid. This orange solid was isolated in a yield of 75–80% with electronic absorptions at 382, 332 and 320 nm in phosphate buffer (pH 8) and NMR peaks in D_2O at δ 7.8 (m), 7.5 (m) and 7.2 (t), suggesting it lacked the Pt–S bond linkage. Furthermore, FAB mass and isotope abundance simulation studies disclosed that the molecular ion at 464 contained a chloride ion, suggesting that $[Pt(terpy)Cl]^{+}$ was one of the cleavage products.



Scheme 1 *Reagents and conditions*: i, triphenylmethanol, neat TFA, 25 °C, 30 min, 89%; ii, NaOH(aq), 92%; iii, conc. H_2SO_4; vacuum (0.1 mmHg) at 80 °C, overnight, 62%; iv, KOH(aq), distillation; v, $(Boc)_2O$, dioxane–H_2O, 0 °C, warming to room temp. overnight; vi, MeCN, reflux, 3 days, 75–80%; vii, TFA, triethylsilane 84%; viii, deionized H_2O, $[Pt(terpy)Cl]Cl$, N_2, 25 °C, 5 h; recrystallization with MeOH–MeCN, 40%.

The chloride ion in the isolated product may be acquired from the use of metal chloride salt as the starting material. In addition, the residual Cu complex in the solution was determined to be a symmetric dimer of copper–triaminothiol complex by NMR and FAB MS analysis. The dimer adduct may be obtained by the coupling reaction with monomer of copper–triaminothiol once released from the platinum–thiolate complexes.

Furthermore, a comparison of the reactivity using different metals Ni^{II}, Cu^{II} and Zn^{II} in the Pt–S bond dissociation in $[Pt(terpy)(BAT)]^{4+}$ in phosphate buffer is also examined. Interestingly, the result shows that the dissociation induced by transition metals varied in a descending order: $Zn^{II} > Cu^{II} > Ni^{II}$, as illustrated in Fig. 2. The rate constant has been estimated under the first-order condition[15] to give a value of 7.9×10^{-3} s^{-1} for Zn^{II}, 5.3×10^{-4} s^{-1} for Cu^{II} and 1.9×10^{-4} s^{-1} for Ni^{II}. Moreover, the same cleavage product, $[Pt(terpy)Cl]^+$, also can be obtained from $[Pt(terpy)(BAT)]^{4+}$ using $ZnCl_2$ in phosphate buffer. Zn^{II} had the strongest preference for promoting Pt–S bond cleavage, and was about 15 times faster than $CuCl_2$. Besides, Zn^{II} also exhibited the highest selectivity in the cleavage of the Pt–S bond of the triaminothiol species, $[Pt(terpy)(BAT)]^{4+}$, but produced no reaction with the aminothiol species, $[Pt(terpy)(AET)]^+$.

In order to eliminate the possibility of the aggregation of polyaromatic compounds,[10] which may enhance the cleavage by neighboring complexes, the dissociation process was also examined at a low concentration (10–12 μM) of $[Pt(terpy)(BAT)]^{4+}$. The result showed no significant difference in the dissociation rate of the Pt–S bond at either a low or high concentration of polyaromatic compounds. Moreover, the preliminary cleavage mechanism has been studied using Cu^{II} in NMR. In phosphate buffer, one of the terpyridine peaks and all of the aliphatic protons are shifted from δ 8.88 and 2.2–2.7 to δ 9.06 and 2.7–3.1 respectively, indicating the S-bridged heterodinuclear moiety is generated while Cu^{II} is coordinating to the triamine moiety. As a result, it will weaken the Pt–S bond, resulting in Pt–S bond dissociation by the other nucleophiles such as Cl^-. Thus, the different coordination of triaminothiol to tetrahedral Zn^{II}, square-planar Cu^{II} and octahedral Ni^{II} in the transition state may be attributed to the different reactivity and selectivity of different metal ions in the Pt–S bond cleavage. The detailed mechanism is under current investigation.

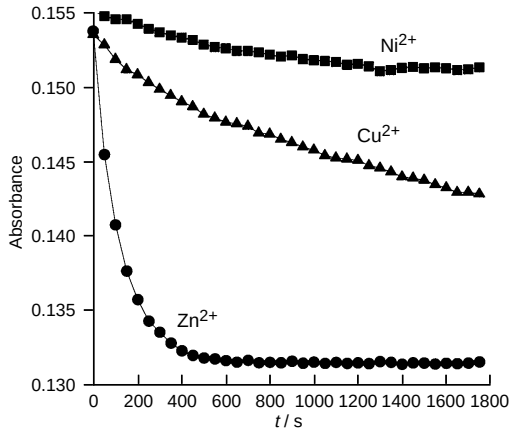


Fig. 2 Comparison of the reactivity in the cleavage of the Pt–S bond by Zn^{2+}, Cu^{2+} and Ni^{2+} ions. These data were collected at a fixed absorption wavelength of 342 nm at intervals of 50 s per cycle at a concentration of $[Pt(terpy)(BAT)]^{4+}$ (40 μM) and metal ion (40–42 μM) in 10 mM phosphate buffer (pH 8.0) at room temp. (●) Zn^{2+}, (▲) Cu^{2+}, (■) Ni^{2+}.

In summary, we have demonstrated that the cleavage of the Pt–S bond of $[Pt(terpy)(AET)]^+$ and $[Pt(terpy)(BAT)]^{4+}$ can be achieved by the addition of transition metal ions such as Zn^{II} or Cu^{II} in either phosphate buffer or MeOH. Importantly $[Pt(terpy)Cl]^+$ is isolated and identified as one of the major products in the dissociation of the Pt–S bond of $[Pt(terpy)(BAT)]^{4+}$ in the presence of $ZnCl_2$ or $CuCl_2$. In fact, the Cl ligand is very labile and readily replaced by other nucleophiles such as H_2O or imidazole.[6] Namely, in the biological system, the replacement of the labile Cl ligand may be achieved by surrounding guanine residues[2] resulting in the recovery of anticancer activity of platin drugs. Interestingly, the dissociation of the Pt–S bond and the formation of a labile chloro species can also be detected using $[Pt(dien)(BAT)]^{4+}$, (dien = diethylenetriamine) in phosphate buffer in the presence of Zn^{II} or Cu^{II} ions. Therefore, these results may provide an alternative pathway in the regeneration of the active Pt complexes from the platinum–thiolate adduct, which may relate to the restoration of the anticancer activity of platin drugs in biological systems.

Inclusion of symmetry for the enhanced determination of crystalline structures from powder diffraction data using simulated annealing

Luis Reinaudi,[a] Raúl E. Carbonio*[b] and Ezequiel P. M. Leiva[a]

[a] Unidad de Matemática y Física, and [b] Departamento de Fisicoquímica, INFIQ, Facultad de Ciencias Químicas, Universidad Nacional de Córdoba, Agencia Postal 4, C.C. 61, 5000 Córdoba, Argentina

Significant improvements compared with the results obtained by other authors are achieved when space symmetry information obtainable from powder diffraction data is applied to the calculation of the TiO_2(anatase) and TiO_2-(rutile) structure; imposing symmetry conditions increases the number of times that the correct structure is generated in a set of runs and leads to more accuracy in the atomic positions.

Simulated annealing techniques have been shown to be very efficient for calculating crystal structures with only knowledge of the unit cell dimensions and content.[1,2] However, the computational demand of the method does not allow it to be applied to very complex structures. As the complexity of the structure increases, not only the computing time increases but also the number of times the system gets trapped in local minima. To avoid this problem it is necessary to impose more constraints to the system to force convergence to the global minimum. Concerning this subject, Deem and Newsam successfully made use of the known symmetry in their study of zeolites;[3] but these prediction methods, which are based on empirical relationships, seem to be more appropriate for specific families of materials, such as zeolites, whose topologic characteristics are well known.

In the present work we propose to optimise the method by using symmetry information, which is easily obtainable from a powder diffraction experiment, in such a way that it can be applied to a wide range of systems for which less restrictive assumptions can be made. To this purpose we chose TiO_2 (anatase), and TiO_2 (rutile) which have been already calculated by Freeman *et al.*[1]

Calculations of the lattice energy (which was initially used as the cost function) were performed using a code developed by us, which uses an Ewald summation for the coulombic term and a real space evaluation of the short range terms. Formal charges were used (Ti^{4+} and O^{2-}). Parameters for short range potentials are listed in Table 1. The minimisation was carried out using the Metropolis importance sampling algorithm.[4,5] We used a cooling algorithm defined by $T_{n+1} = \alpha T_n$, ($\alpha = 0.90$) with a starting temperature $T_0 = 1.0 \times 10^6$ K.

For anatase and when no symmetry restriction was imposed, over a total amount of 50 runs, we obtained the real structure only four times, in agreement with Freeman *et al.*[1] By imposing symmetry restrictions the number of independent variables in the cost function significantly decreases. The reason for this is that during simulation only the coordinates of a group of atoms are randomly generated, the rest are determined through space symmetry operations and consequently, those configurations with atomic coordinates which are not correlated by these symmetry operations are excluded from the configurational space.

Table 1 Short range potential model for TiO_2 (taken from ref. 6); $V(r) = A \exp(r/\rho) - Cr^{-6}$

A(Ti–O)/eV	754.2
ρ(Ti–O)/Å	0.3879
A(O–O)/eV	22764.3
ρ(O–O)/Å	0.1490
C(O–O)/eV Å^{-6}	27.88

From all the space symmetry operations present in each space group, only centring (A, B, C, I, F), screw axes of the type X_1 and glide planes can be used, the rest of space symmetry operations and all the point symmetry operations may produce the overlapping of one atom with its image generated by the symmetry operation (Deem and Newsam overcome this by using a merging term in the cost function[3]). All these particular space symmetry operations are, in principle, obtainable from the extinctions in the powder diffractogram.

We have calculated the structure of TiO_2(anatase) imposing I centring or 4_1 screw axis. By doing this, over a total of 50 runs we obtained the correct structure 30 times with the I centring and 37 with the 4_1 screw axis; which is a significant improvement compared with the results obtained with no symmetry imposition (4 out of 50). Moreover, the atomic positions are more accurate, (as compared with the experimental ones) (Table 2) obtaining thus a better starting structural model for Rietveld refinement. Fig. 1 compares the structures predicted by the calculations with and without symmetry restrictions. The former is indistinguishable from the experimental one within the accuracy of the plot.

Space symmetry operations sometimes might not be so easily obtained from the extinctions in a powder diffractogram because in structures with low symmetry the overlapping of reflections might not allow to do this unambiguously. Besides, for a primitive structure without screw axes and glide planes, all atoms contained in the unit cell must be considered in the calculations. For these reasons we also propose an additional term for the cost function, which takes into account the minimum symmetry of the crystal system independently of the Bravais lattice or space group.

This term is based on the fact that, for a given crystal structure, the structure factors [$F(hkl)$] of most sets of equivalent reflections which have the same d spacing and belong to different crystal planes must all be the same (the fact that the structure factors of a given set of reflections are all the same or not, depends on the point group; however, for each crystal system, it is always possible to find such a set of reflections).[7] For example, in the orthorhombic crystal system, the reflections 123, $\bar{1}23$, $1\bar{2}3$, $12\bar{3}$, $\bar{1}\bar{2}3$, $\bar{1}23$, $1\bar{2}\bar{3}$, $\bar{1}\bar{2}\bar{3}$ all must have the same $F(hkl)$ values. This will be true only if the distribution of atoms in the unit cell is consistent with the crystal system, otherwise different values will be obtained. In order to obtain the same weight for the different atoms within the cell we defined an $F'(hkl)$ value in which all the atomic scattering factors (f) are set equal to one. The proposed term is:

$$E_{\text{sym}} = \sum_{i_{\text{ref}}} \sum_{i_{\text{at}}} W_{i_{\text{ref}} i_{\text{at}}} \quad (1)$$

where i_{ref} runs over each set of equivalent reflections and i_{at} runs

Table 2 Atomic coordinates: experimental and calculated by different means for TiO_2 (anatase) ($a = b = 3.785$, $c = 9.515$ Å). In the last two sets (centring and screw axis) the letters show atoms related by symmetry imposed to the system

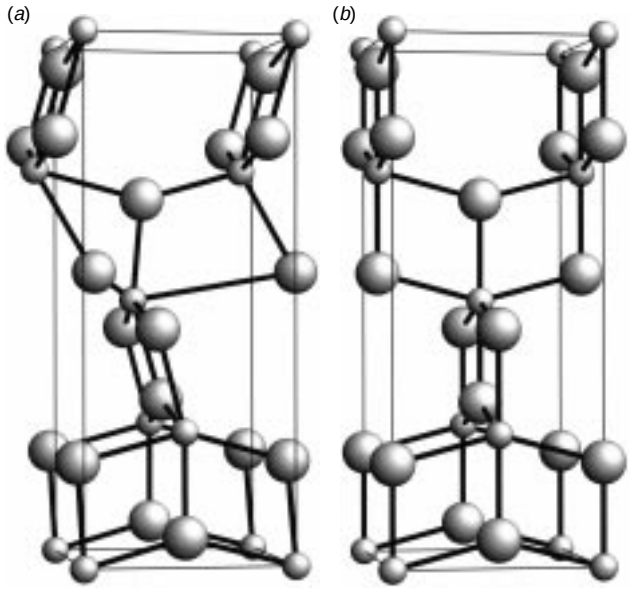

Fig. 1 Structures calculated without symmetry restrictions (*a*), and imposing I centring (*b*) for TiO_2 (anatase). Small spheres represent titanium atoms and large spheres, oxygen atoms.

over each kind of atom (in this case Ti^{4+} and O^{2-}). *W* is given by:

$$W = b\left(1 - \frac{1}{1 + a\sum_{j=1}^{K-1}\left|\left|F'_{j+1}\right| - \left|F'_j\right|\right|^n}\right) \qquad (2)$$

where *b*, *a* and *n* are adjustable parameters and F'_j is the modified structure factor corresponding to the *j*th reflection of a group of *K* equivalent reflections (reflections which should have the same structure factor for all the point group within this crystal system) and *K* is the multiplicity factor used in the powder method.[7] Each F'_j is then given by:

$$F'_j = \sum_{m=1}^{N} \exp\left[i2\pi(h_j x_m + k_j y_m + l_j z_m)\right] \qquad (3)$$

where *m* runs over the *N* atoms of a same kind and h_j, k_j, l_j are the Miller indexes of the *j*th reflection.

In eqn. (2) is observed that *W* tends to zero for distributions of atoms that are consistent with the crystal system symmetry and tends to *b* for distributions far from required symmetry.

For this particular case (tetragonal system) some of the {*hhl*} and {*h*0*l*} groups of equivalent reflections (which have a multiplicity of eight) were used[7] (use of the {*hkl*} reflections, with a multiplicity of 16, would imply a previous assumption about the point group).

For anatase, a new set of calculations was run adding an E_{sym} term corresponding to the reflections {112}, {304} and {221} and imposing I centring. The values used were $a = 1.0 \times 10^{-3}$, $b = 20.0$ eV, $n = 3$. These values were those, which led to the best minimisation of all *W* values for a set of 50 runs.

Over a total of 50 runs we obtained the correct structure 36 times. Atomic positions thus obtained are the same as those obtained with I centring only (Table 2).

For rutile, over a total of 50 runs and with no imposition of symmetry we obtained the correct structure 44 times; and when we added this symmetry term to the cost function we obtained the correct structure in all of the 50 runs, with atomic coordinates being the same as those obtained by Freeman *et al.*[1]

The predictions of crystal structures by simulated annealing based only on energetic considerations is impracticable for very complex structures, because of the large amount of local minima, which causes that incorrect structures are obtained in a large number of runs. The imposition of symmetry restrictions may decrease this number of local minima and in consequence may increase the number of times that the correct structure is obtained. Although these symmetry restrictions are expected to be more effective when dealing with a more symmetric structure, their application is general and, as these results suggest, may extend the use of simulated annealing to more complex systems.

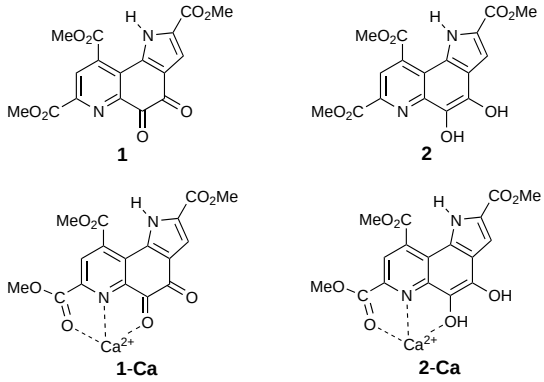
Is the calcium-ion catalysis of biological reoxidation of reduced PQQ purely electrostatic?†

Gudrun Schürer and Timothy Clark*

Computer-Chemie-Centrum, Institut für Organische Chemie, Friedrich-Alexander-Universität Erlangen-Nürnberg, Nägelsbachstraße 25, D-91052 Erlangen, Germany

Semiempirical (PM3) molecular orbital calculations on the mechanism of reoxidation of PQQ by triplet dioxygen suggest that the reaction can proceed purely by hydrogen-atom-transfer steps that are catalysed by the electrostatic effect of a coordinated calcium ion, rather than by an electron-transfer mechanism.

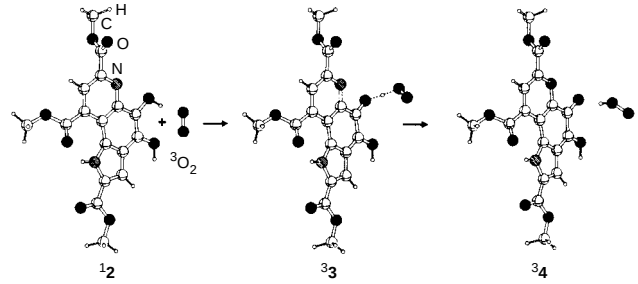
Pyrroloquinolinequinone (PQQ) **1** acts as the coenzyme in several bacterial oxidations.[1–3] It has been proposed[1–3] that the reoxidation of reduced PQQ ($PQQH_2$ **2**) is Ca-ion dependent.



Itoh *et al.*[4] recently demonstrated the catalytic effect of Ca^{2+} on the oxidation of **2** in MeCN solution by triplet O_2. They proposed an electron-transfer mechanism on the basis of earlier suggestions[5,6] that the reaction of 1,5-dihydroflavin with $^3O_2$ must occur by a single electron-transfer (SET) mechanism. However, reaction of **2** with $^3O_2$ to give a triplet radical pair is a perfectly spin-allowed reaction and the electrostatic effect of an adjacent positive charge should be to bind electrons tighter than in the neutral compound. Furthermore, we have pointed out[7–9] that reactions of closed shell molecules with $^3O_2$ should be strongly favoured by complexation with metal cations. We now suggest that the role of Ca^{2+} in the biological reoxidation of reduced PQQ is that of an electrostatic catalyst,[9] and that the Ca-dependent enzymes that use PQQ as a coenzyme are possibly the best documented examples of this type of catalysis in biological systems.

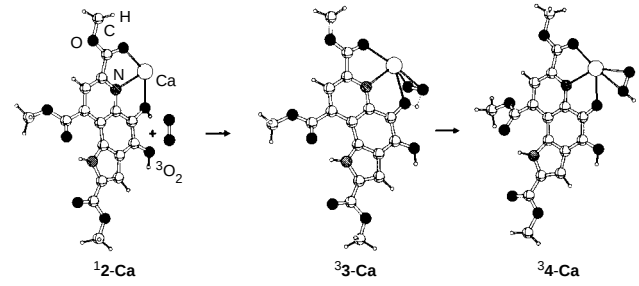
The reaction system **2** + $^3O_2 \rightarrow$ **1** + H_2O_2 with and without complexation to Ca^{2+} was investigated using standard PM3 semiempirical MO theory[10] with VAMP6.5.[11] The unrestricted Hartree–Fock (UHF) formalism was used throughout (for both singlets and triplets) and relative energies of different spin states were also checked using configuration interaction (CI) calculations. The Ca PM3 parameters are those developed by Hehre *et al.*[12] and made available *via* the Wavefunction website. All stationary points were characterised by calculation of their normal vibrations and the reaction paths were checked by internal reaction coordinate (IRC) calculations.

The calculations were carried out with the conformations shown in the Schemes. Complexation with Ca^{2+} gives structures **1-Ca** and **2-Ca**, as found in X-ray structures of bacterial methanol dehydrogenase.[13,14] Abstraction of the OH hydrogen on C-5 in ^{1}**2** by $^3O_2$ occurs *via* transition state ^{3}**3** to give ^{3}**4** (Scheme 1; superscripts before structure numbers indicate the spin multiplicity) in the uncomplexed case with a calculated activation energy of 44.1 kcal mol^{-1} (1 cal = 4.184 J) in a reaction that is found to be endothermic by 12.1 kcal mol^{-1}, neither thermodynamically nor kinetically favourable enough to occur at room temperature in an enzymatic system.



Scheme 1

The Ca-catalysed reaction **2-Ca** + $^3O_2 \rightarrow$ **4-Ca** *via* transition state **3-Ca** (Scheme 2), in contrast, requires an activation energy of only 3.9 kcal mol^{-1} and is exothermic by 33.2 kcal mol^{-1} and thus very favourable under biological conditions. Hence, both the kinetic stabilisation of the transition state arising from the charge effect on odd-electron bonds[15–18] and the thermodynamic effect of adding polar bonds to oxygen[7–9] are very effective in accelerating the reaction.

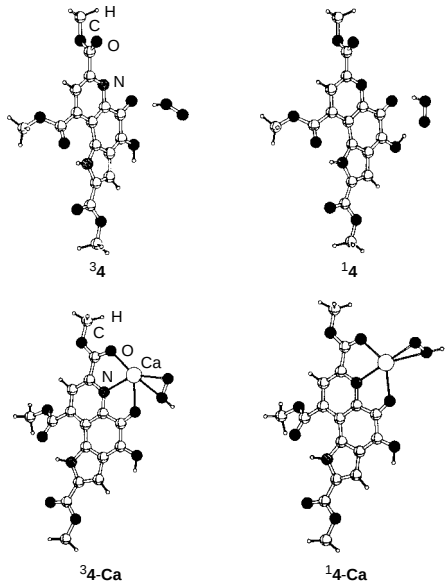


Scheme 2

Both single point CI calculations and UHF geometry optimisations of the singlet radical pairs corresponding to ^{3}**4** (^{1}**4** and ^{1}**4-Ca**) give energies that are almost degenerate with the triplet radical pairs. After geometry optimisation, ^{1}**4-Ca** is found to be 2.7 kcal mol^{-1} more stable than ^{3}**4-Ca**, so that intersystem crossing (ISC) to the singlet state should be fast, especially given the presence of the calcium ion and the oxygen centres.

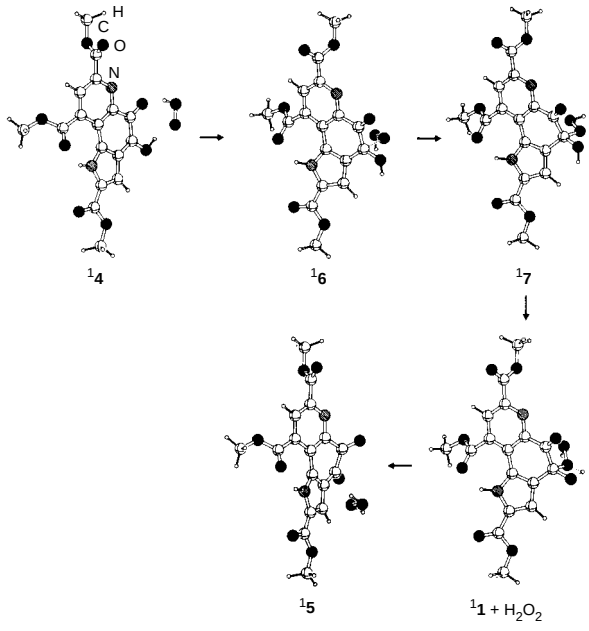
After ISC, the system can transfer the second OH hydrogen to the hydroperoxy radical to give the product. In the uncomplexed system, however, this reaction occurs in two steps, as shown in Scheme 3 and Fig. 1.

In contrast, the Ca-catalysed reaction proceeds directly *via* transition state ^{1}**5-Ca** to the final product ^{1}**1-Ca** + $^3O_2$ in a

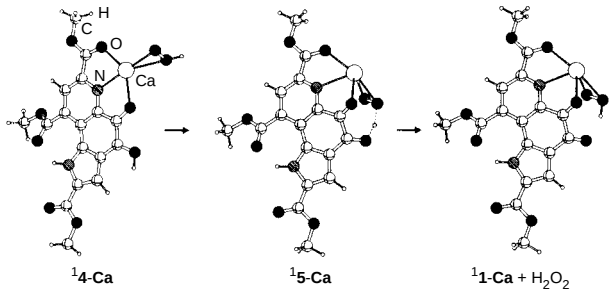


classical H-atom transfer step (Scheme 4). This reaction is calculated to have a barrier of 15.0 kcal mol^{-1}. The product is 55.2 and 19.3 kcal mol^{-1} more stable than ^{1}**4-Ca** and ^{1}**2-Ca** + $^3O_2$, respectively. The energy profiles for the two reaction paths are shown schematically in Fig. 1.

Although the SET mechanism has not been tested specifically, we believe that our calculations provide a strong indication that the role of the Ca ions in these systems is that of an electrostatic catalyst, as proposed in our model studies on



Scheme 3



Scheme 4

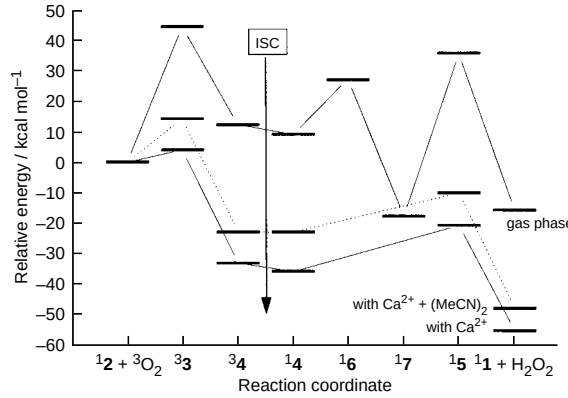


Fig. 1

methane oxidation and ethene epoxidation.[7–9] The PQQ-dependent systems therefore represent experimental examples of an effect first pointed out on the basis of model *ab initio* calculations.[7–9] We note especially that the direct formation of a covalent bond in such systems is not only spin-allowed, but is also a very facile process. There is no need to invoke an SET mechanism, especially in view of the likely fast ISC in **4-Ca**.

In order to investigate the effect of solvent, which would compete with oxygen for the complexation sites on the metal ion, we added two molecules of MeCN to the Ca-catalysed system. The energetic results are shown in Fig. 1. Although the effect of the metal is weakened somewhat, the total activation energy (14.1 kcal mol^{-1}) remains low enough for a very fast reaction at room temp.

Synthesis of MCM-48 single crystals

Ji Man Kim, Seong Kyun Kim and Ryong Ryoo*

Materials Chemistry Laboratory, Department of Chemistry and Center for Molecular Science, Korea Advanced Institute of Science and Technology, Taeduk Science Town, Taejon, 305-701, Korea

Truncated rhombic dodecahedral crystals of the mesoporous molecular sieve MCM-48 are synthesised by a hydrothermal procedure using sodium silicate, hexadecyltrimethylammonium bromide and various kinds of alcohol.

The materials designated MCM-41 and MCM-48 are large-pore molecular sieves attracting much recent attention in catalysis and nanoscience.[1,2] The structure of MCM-48 consists of two independent and intricately interwoven networks of mesoporous channels,[2–5] while the structure of MCM-41 consists of hexagonal packing of one-dimensional channels. The three-dimensional channel network of MCM-48 is much more desirable than the one-dimensional channel of MCM-41 from a diffusional and catalytic point of view. However, surprisingly little research has been reported on MCM-48, compared with research on MCM-41.[6,7] We believe that this is due to the difficulty of the MCM-48 synthesis.

Here, we present a hydrothermal synthesis procedure to obtain MCM-48 readily using a sodium silicate solution as the silica source, hexadecyltrimethylammonium bromide (HTABr) as the structure-directing agent, and various kinds of alcohol such as methanol, ethanol and 2-methylpropan-2-ol as an additive for the mesophase control. The resultant MCM-48 material exhibits not only excellent structural order but also the unique crystalline morphology of a cube truncated by rhomb dodecahedron.

To prepare the silica source, colloidal silica, Ludox HS40 (39.5 mass% SiO_2, 0.4 mass% Na_2O and 60.1 mass% H_2O, Du Pont), was preheated to 343 K in a Erlenmeyer flask. An aqueous solution of 1.00 M NaOH was slowly added to the heated Ludox with vigorous magnetic stirring, to give a molar composition of 0.25 Na_2O : 1.0 SiO_2 : 12.5 H_2O for the resultant mixture. The resultant mixture became a clear sodium silicate solution after stirring continuously for *ca.* 1 h with heating to 343–353 K.[8] After further stirring for 1 h at the same temperature, the solution was cooled to room temp. and stored in a polypropylene bottle until used as the silica source.

In a typical synthesis batch, HTABr (Aldrich) was dissolved, by heating and magnetic stirring if necessary, in a mixture of doubly distilled water and ethanol to give the resulting molar composition of 1.0 HTABr : 5.0 EtOH : 120 H_2O. The above silica source was added to this surfactant solution at room temp., dropwise with vigorous magnetic stirring. The resulting gel mixture, with a molar composition of 1.4 SiO_2 : 1.0 HTABr : 0.35 Na_2O : 5.0 EtOH : 140 H_2O, was heated for 4 days at 373 K in an autoclave and subsequently cooled to 340 K. The supernatant liquid in the reaction mixture was quickly removed by decantation and filtration before further cooling. The solid product was washed quickly with hot distilled water before cooling. The product was then slurried in EtOH–HCl, filtered, washed with EtOH, dried in an oven, and calcined in air under static conditions, in the same way as described in our recent report.[9]

The product yield in a typical synthesis batch was *ca.* 50% on the basis of the silica recovery. About 50% of silica was dissolved in the supernatant liquid under the hydrothermal reaction condition. The dissolved silica had to be removed from the MCM-48 phase before cooling to below 340 K, because the cooling resulted in the formation of insoluble silicate gel and made it difficult to separate from the MCM-48 phase afterward.

Fig. 1 shows typical powder X-ray diffraction (XRD) patterns and field emission scanning electron micrographs (SEM) for MCM-48 samples obtained following the above procedure. The XRD patterns were obtained with a Cu-Kα X-ray source using a Rigaku D/MAX-III (3 kW) instrument. The field emission SEM images were obtained with a Hitachi S800 instrument. The XRD patterns in Fig. 1(*a*) indicate excellent structural order for the cubic crystallographic space group $Ia\bar{3}d$.[2–5] Fig. 1(*b*) shows a narrow distribution in the particle size around 0.3 μm for the present MCM-48 sample synthesised at 373 K. The SEM image in Fig. 1(*c*) was obtained from a MCM-48 sample after hydrothermal synthesis over 16 h at 413 K. The particle size increased markedly, compared with the sample synthesised at 373 K. It is very remarkable that the MCM-48 particles obtained at 413 K have the crystal shape of a cube truncated by rhomb dodecahedron. An activation energy of 14 kcal mol^{-1} (1 cal = 4.184 J) has been obtained from the Arrhenius plot between the crystallisation rate and the inverse of the synthesis temperature.[10] All these results show remark-

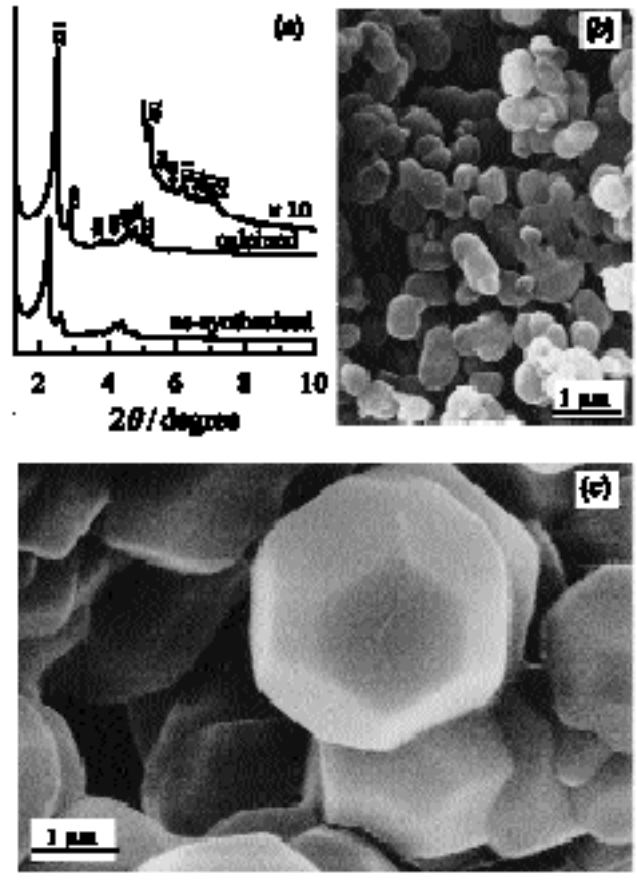

Fig. 1 (*a*) XRD patterns, (*b*) field emission SEM image for MCM-48 synthesised at 373 K and (*c*) at 413 K

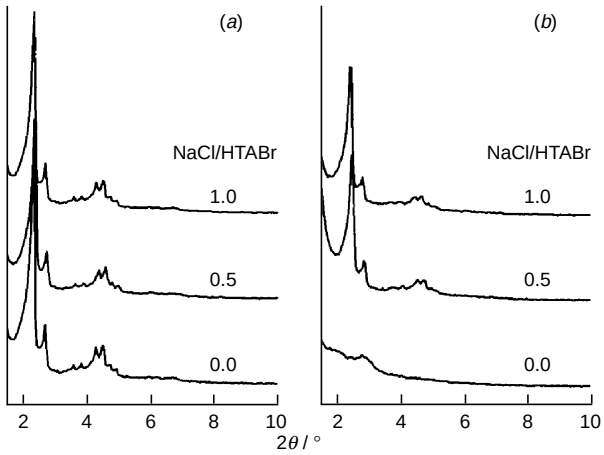

Fig. 2 XRD patterns for MCM-48 samples: (*a*) calcined and (*b*) after heating the calcined samples in distilled water at 373 K for 12 h. Numbers given to XRD patterns denote the NaCl/HTABr molar ratios used for the synthesis.

able similarities between the formation of MCM-48 particles under the present hydrothermal conditions and hydrothermal growth of other conventional zeolite crystals.

The MCM-48 phase was converted to a disordered phase when ethanol was allowed to evaporate under the present hydrothermal synthesis conditions. The role of the added ethanol in the formation of MCM-48 is the ability to cause a systematic rearrangement in the structure of the micelle by penetrating the micelle surface, just the same way as ethanol which is formed by the hydrolysis of tetraethylorthosilicate (TEOS) during the synthesis of MCM-48 with TEOS. The latter has been clarified recently by Huo *et al.*[11] using Cab-o-sil in place of TEOS as the silica source in the presence of other polar organic additives such as $Me_2NCH_2CH_2OH$ and $N(CH_2CH_2OH)_3$. The use of tetramethylorthosilicate instead of TEOS did not give MCM-48, and the result was attributed to the high polarity and hydrophilicity of the resulting methanol so that it could not penetrate the micelle surface. However, methanol is more effective for the formation of MCM-48 than ethanol. The substitution of 5.0 EtOH with 3.0 MeOH in our synthesis procedure described above gave just the same high-quality MCM-48 material. The EtOH could also be substituted by appropriate amounts of higher alcohol such as 1.5 Pr^iOH, 0.3 Bu^sOH and 0.3 Bu^tOH. All MCM-48 materials obtained with the alcohol showed similar BET surface areas in the range of 1000 ± 50 m^2 g^{-1}. However, the use of the higher alcohol resulted in a somewhat lower XRD peak resolution, compared with the use of EtOH and MeOH.

MCM-41 or a disordered mesoporous material[12] was obtained instead of MCM-48 when the amount of alcohol was insufficient. The use of excess alcohol resulted, on the other hand, in the formation of a lamellar phase. We have confirmed that MCM-48 can be obtained within a wide range of the gel composition, $x\ SiO_2 : 0.25x\ Na_2O : 1.0\ HTABr : 0.035y\ EtOH : y\ H_2O$ in a temperature range of 373–413 K, where x and y can be varied over 1.2–3.0 and 70–400, respectively. The formation of the MCM-48 phase followed a typical zeolite crystallisation curve, reaching a maximum in 4 d at 373 K. Subsequently, the MCM-48 phase was converted to a lamellar phase. At 413 K, the MCM-48 formation was accomplished in 16 h.[10]

After heating in boiling water for 12 h, our calcined samples gave no XRD patterns indicating the MCM-48 structure. This was due to the low hydrothermal stability of the MCM-48 samples.[13] The hydrothermal stability of the MCM-48 can be improved by using NaCl, similar to the salt effect for MCM-41.[14] To demonstrate this, the autoclave was cooled to room temp. after heating for 3.5 d at 373 K. The reaction mixture in the autoclave was then added to a conc. NaCl solution with magnetic stirring, to give NaCl/HTA = 0.1–1.0. The autoclave was closed and heated again for 1.5 d. The results are shown in Fig. 2.

Synthesis and structure of [{$(Bu^tO)_2Sb_3(\mu\text{-}NCy)_3(\mu_3\text{-}NCy)$}K·$\eta^6$-$C_6H_5Me$]; a sandwich complex containing a unique Sb^{III} *nido* cage anion (Cy = cyclohexyl, C_6H_{11})

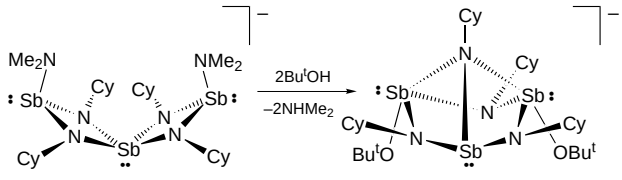
Michael A. Beswick,[a] Nick Choi,[b] Alexander D. Hopkins,[a] Mary McPartlin,[b] Michael A. Paver[a] and Dominic S. Wright*[a]

[a] *Chemical Laboratory, University of Cambridge, Lensfield Road, Cambridge, UK CB2 1EW*
[b] *School of Applied Chemistry, University of North London, Holloway Road, London, UK N7 8DB*

Reaction of the terminal NMe_2 groups of the *spiro* antimony(III) imido anion [{$(Me_2N)Sb(\mu\text{-}NCy)$}$_2$Sb]$^-$ with Bu^tOH results in major rearrangement in the Sb–N framework as witnessed in the structure of the sandwich complex [{$(Bu^tO)_2Sb_3(\mu\text{-}NCy)_3(\mu_3\text{-}NCy)$}K·$\eta^6$-$C_6H_5Me$] 1, containing the novel *nido* cage anion [$(Bu^tO)_2Sb_3(\mu\text{-}NCy)_3(\mu_3\text{-}NCy)$]$^-$.

We have recently investigated the structures and coordination chemistry of imido and phosphinidene anions of p block metals (group 13–15).[1–3] These species are readily prepared by the reactions of primary amido or phosphido lithium complexes, [REHLi] (E = N, P), with dimethylamido metal reagents or neutral metal imido cages and function as relatively robust ligands for a range of main group and transition metal ions.[4] For example, the transmetallation reaction of [{$Sb(NCy)_3$}$_2$$Li_6$] (Cy = cyclohexyl) with [$PbCp_2$] gives the cage [Pb_3{$Sb(NCy)_3$}$_2$], in which the [$Sb(NCy)_3$]$^{3-}$ trianions of the alkali metal precursor are transferred intact to Pb^{II}.[4a] Reactions of this type therefore provide a general strategy for the assembly of heterometallic cage compounds containing diverse mixed-metal stoichiometries. A current interest in this area concerns the factors controlling the formation and stability of these new ligand systems.[5] To this end we report here the investigation of the effects of ligand substitution on the SbN framework of one such anion arrangement, the *spiro* monoanion [{$(Me_2N)Sb(\mu\text{-}NR)_2$}$_2$Sb]$^-$.[3b]

The reaction of [{$(Me_2N)Sb(\mu\text{-}NR)_2$}$_2$Sb]K with [$Bu^tOH$] (1 : 2 equiv.) gives [{$(Bu^tO)_2Sb_3(\mu\text{-}NCy)_3(\mu_3\text{-}NCy)$}K·$\eta^6$-$C_6H_5Me$] **1**, for which spectroscopic and analytical analysis suggests that simple ligand exchange of the terminal NMe_2 groups of the precursor has occurred.† However, subsequent X-ray structural investigation of **1** reveals that ligand substitution is accompanied by isomerism of the initial *spiro* structure of the anion in to a *nido* cage arrangement (Scheme 1). It is interesting to note that the *spiro* structure of the precursor is preserved upon substitution with NHR groups.[4a] It therefore appears that this rearrangement is a consequence of the increased Lewis acidity of the O-attached Sb centres, with the *nido* structure of the anion of **1** maximising their coordination numbers. The same effect can also be seen to underlie the coordination of $NHMe_2$ to Sb^{III} in [$(Me_2NH)ClSb(\mu\text{-}NBu^t)$]$_2$ (during the reaction of [$(Me_2N)_2ClSb$] with NH_2Bu^t)[6] and the aggregation of [Cl_3SbNMe]$_4$ in to a cubane (as opposed to a dimer) structure.[7] However, the formation of **1** provides, to our knowledge, the first intramolecular example of the structure-directing influence of the electronegativity of substituents on cage geometry within such a p-block metal system.



Scheme 1

The low-temperature X-ray structure of **1**‡ shows it to be the ion-contacted complex [{$(Bu^tO)_2Sb_3(\mu\text{-}NCy)_3(\mu_3\text{-}NCy)$}K·$\eta^6$-$C_6H_5Me$], in which the K^+ cation is coordinated at the open Sb_3N_3 face of the *nido* [$(Bu^tO)_2Sb_3(\mu\text{-}NCy)_3(\mu_3\text{-}NCy)$]$^-$ anion and by a π-bonded toluene molecule (Fig. 1). The [$(Bu^tO)_2Sb_3(\mu\text{-}NCy)_3(\mu_3\text{-}NCy)$]$^-$ anion of **1** is composed of three Sb^{III} centres which are linked together in the equator by three μ-NCy groups and capped by a μ_3-NCy group. In addition, Sb(1)

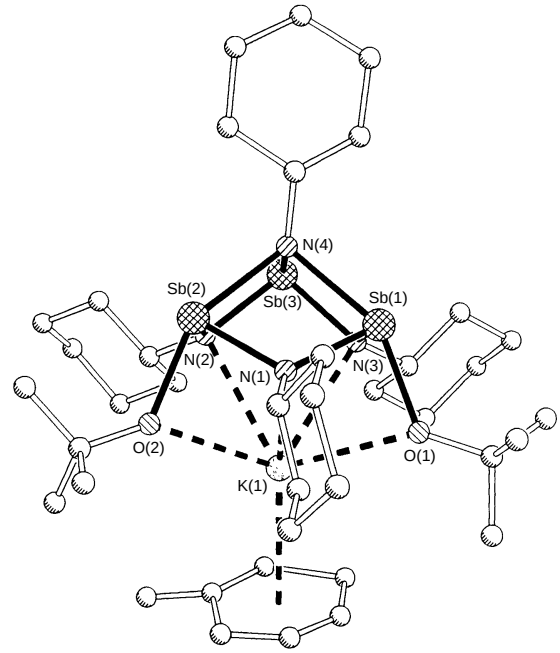


Fig. 1 Structure of **1**. H atoms have been omitted for clarity. Only major core components of the Bu^t group [on O(2)] and of the toluene molecule are shown. Key bond lengths (Å) and angles (°): Sb(1)–N(1) 2.064(5), Sb(1)–N(3) 2.090(5), Sb(1)–N(4) 2.335(5), Sb(1)–O(1) 2.113(4), Sb(2)–N(1) 2.061(5), Sb(2)–N(2) 2.077(5), Sb(2)–N(4) 2.311(4), Sb(2)–O(2) 2.122(4), Sb(3)–N(2) 2.027(5), Sb(3)–N(3) 2.025(5), Sb(3)–N(4) 2.033(5), K(1)–N(1) 2.718(5), K(1)–N(2) 2.991(5), K(1)–N(3) 2.953(5), K(1)–O(1) 2.942(4), K(1)–O(2) 2.865(4), K(1)···C 3.20–3.47, arene(centroid)···K 3.03; N(1)–Sb(1)–N(3) 98.9(2), N(1,3)–Sb(1)–N(4) av. 74.3, O(1)–Sb(1)–N(4) 147.6(2), N(1,3)–Sb(1)–O(1) av. 85.0, N(1)–Sb(2)–N(2) 100.5(2), N(1,2)–Sb(2)–N(4) av. 75.0, O(2)–Sb(2)–N(4) 146.0(2), N(1,2)–Sb(2)–O(2) 83.5(2), N(2)–Sb(2)–N(3) 92.5(2), N(2,3)–Sb(3)–N(4) av. 81.6, Sb(1)–N(4)–Sb(2) 95.3(2), Sb(1)–N(4)–Sb(3) 98.2(2), Sb(2)–N(4)–Sb(3) 97.9(2), N(1)–K(1)–N(2) 67.6(1), N(1)–K(1)–N(3) 67.5(1), N(1)–K(1)–O(1) 60.0(1), N(1)–K(1)–O(2) 59.8(1), O(1)–K(1)–N(3) 107.6(1), O(2)–K(1)–N(2) 107.9(1), O(1)–K(1)–O(2) 118.7(1).

and Sb(2) are bonded to terminal OBu^t groups [Sb(1,2)–O av. 2.12 Å], resulting in 10e pseudo-trigonal bipyramidal geometries for these centres and with Sb(3) adopting an 8e pyramidal geometry. Although the majority of the Sb–N bond lengths in **1** fall in a narrow range [2.027(5)–2.090(5) Å], longer Sb–N bonds occur between the μ_3-NCy group and the four-coordinate Sb centres [Sb(1)–N(4) 2.335(5), Sb(2)–N(4) 2.311(4) Å]. These correspond to the use of orbitals by Sb(1) and Sb(2) at an axial position of their pseudo-trigonal bipyramidal environments. The overall arrangement of the imido antimony(III) anion fragment of **1** is similar to that occurring in the neutral, isoelectronic complex $[Cl_2Sb_2Se(\mu\text{-}NBu^t)_3(\mu_3\text{-}NBu^t)]$, formed by the desilylation reaction of $[Se\{NBu^t(SiMe_3)\}_2]$ with $SeCl_2$.[8]

The bonding of the imido antimony(III) anion of **1** to the K^+ cation is very asymmetrical. The shortest contact between the imido antimony(III) anion and the K centre occurs with N(1) [2.718(5) Å] and is typical of those found in a range of amido potassium compounds.[9] However, far weaker interactions occur between the K^+ cation and the remaining N centres of the Sb_3N_3 face of the anion [N(2)–K(1) 2.991(5), N(3)–K(1) 2.953(5) Å]. In addition, the O atoms of the pendant OBu^t groups only weakly coordinate the K^+ cation {O(1)–K(1) 2.942(4), O(2)–K(1) 2.865(4) Å; *cf.* 2.788(8) Å for the thf O–K bonds in $[\{(RNH)Sb(\mu\text{-}NR)_2\}_2Sb]K\cdot 2thf$[10]}. This arrangement leaves the K^+ cation open to further coordination by the η^6-toluene ligand. Similar ion–dipole interactions of aromatic ligands with K^+ are well known in a variety of complexes, with typical centroid···K^+ distances lying in the range 3.18–3.59 Å.[11] The shortness of the arene···K interactions in **1** [centroid···K(1) 3.03 Å, K···C 3.20–3.47 Å] is a further reflection of the overall weakness of the interaction of the imido antimony(III) anion with the K^+ cation and of its sterically uncongested environment.

Clearly there are considerable differences between the electron-precise bonding present in the *nido* $[(Bu^tO)_2Sb_3(\mu\text{-}NCy)_3(\mu_3\text{-}NCy)]^-$ anion of **1** and structurally similar electron deficient borane ligands such as *nido*-2,3- and 2,4-$[R_2C_2B_4H_4]^{2-}$.[12] However, their geometric similarity and the fact that the $[Sb(\mu\text{-}NCy)]_3$ face (although localised) is isoelectronic with the open C_2B_3 face of the latter suggests that the *nido* $[(Bu^tO)_2Sb_3(\mu\text{-}NCy)_3(\mu_3\text{-}NCy)]^-$ anion may perform an analogous structural role as a building block in metal complexes.[13] In this regard, the structure of **1** which can be viewed as a mixed-ligand sandwich complex of K^+, provides an initial indication of this behaviour.

† *Synthesis* of **1**: to a solution of $[\{(Me_2N)Sb(\mu\text{-}NCy)_2\}_2Sb]Li$ (0.77 g, 0.91 mmol) in toluene (10 ml) was added Bu^{t}OK (0.10 g, 0.91 mmol). Stirring the solution at room temp. gave a change from yellow to orange. To this was added Bu^{t}OH (0.18 ml, 1.82 mmol) and the mixture was brought briefly to reflux and stirred at room temp. (24 h). The solvent was removed under vacuum and the colourless solid produced was dissolved in hexane (5 ml) and toluene (2 ml). Storage at −18 °C (48 h) gave colourless crystals of **1**. The low yield of crystalline **1** (0.22 g, 23%) is due to its high solubility; mp 130 °C; ^{1}H NMR (250 MHz, C_8D_6, 25 °C), δ 7.0 (m, 5 H, aryl C–H, toluene), 2.40 (m, 4 H, C$^\alpha$-H, μ-NCy), 2.11 (s, 3 H, Me, toluene), *ca.* 1.9–0.9 (overlapping m, 40 H, CH_2, Cy), 1.49 (s, 18 H, Bu^t). Found: C, 43.1; H, 6.6; N, 5.3. Calc. for $[C_{32}H_{62}KN_4O_2Sb_3.C_7H_8]_n$: C, 45.4; H, 6.8; N, 5.4%.

¶ *Crystal data* for **1**: $C_{39}H_{70}KN_4O_2Sb_3$, M = 1031.34, monoclinic, space group $P2_1/c$, a = 18.749(1), b = 13.113(1), c = 18.848(2) Å, β = 103.831(7)°, U = 4499.5(7) Å^3, Z = 4, D_c = 1.522 Mg m^{-3}, λ = 0.710 73 Å, T = 203(2) K, μ(Mo-Kα) = 1.915 mm^{-1}, $F(000)$ = 2080. Data were collected on a Siemens P4 diffractometer using an oil-coated rapidly cooled crystal[14] of dimensions 0.60 × 0.50 × 0.40 mm by the θ–2ω method (1.91 ≤ θ ≤ 25.00°). Of a total of 9158 collected reflections, 7727 were independent (R_{int} = 0.0512). The structure was solved by direct methods; all non-hydrogen atoms were refined with anisotropic displacement parameters and all hydrogen atoms were placed in idealised geometry riding on the relevant carbon atoms. The structure has a disordered Bu^t group [on O(2)] (*ca.* 60 : 40); the ring atoms of each disordered toluene component were fixed in a regular hexagonal geometry (C–C 1.39 Å). In the crystal the ion-contacted units of **1** are arranged in centrosymmetric pairs held together by π stacking interactions of the aryl rings with centroid offset distance of 1.27 Å (mean) and centroid···centroid distance 3.80 Å (mean). 421 parameters were refined on F^2 to final conventional R_1 = 0.043 [$F > 4\sigma(F)$] and wR_2 = 0.120 (all data) [$R_1 = \Sigma|F_o - F_c|/\Sigma F_o$ and $wR_2 = [\Sigma w(F_o^2 - F_c^2)^2/\Sigma w(F_o^2)^2]^{0.5}$, $w = 1/[\sigma^2(F_o^2) + (xP)^2 + yP]$, $P = F_o^2 + (2F_c^2/3)$], x = 0.0636, y = 5.28, $P = (F_o^2 + 2F_c^2)/3$;[15] largest peak and hole in the final difference map, 0.999 and −0.897 e Å^{-3}. Two new nickel–dmit-based molecular conductors based on heteroleptic polymetallic complexes: synthesis, structures and electrical properties

Tianlu Sheng, Xintao Wu,* Wenjian Zhang, Quanming Wang, Xiancheng Gao and Ping Lin

State Key Laboratory of Structural Chemistry, Fujian Institute of Research on the Structure of Matter, The Chinese Academy of Sciences, Fuzhou, Fjuian, 350002, PR China

Two heteroleptic dmit complexes of polynuclear nickel(II), $[NEt_4]_2[Ni_5(edt)_4(dmit)_2]$ and $[AsPh_4]_2[Ni_3(pdt)_2(dmit)_2]\cdot 0.5MeOH$ (dmit = 2-thione-1,3-dithiole-4,5-dithiolate, H_2edt = ethane-1,2-dithiol, H_2pdt = propane-1,2-dithiol) are synthesized and characterized by X-ray crystallography and display room-temperature conductivities of 1.75×10^{-4} and 1.52×10^{-5} S cm^{-1}; this is the first report of semiconducting heteroleptic dmit complexes consisting of more than two nickel(II) centres.

During the search for new complexes with novel electric properties, metal complexes of the dmit ligand have received considerable attention[1,2] since some of them were reported to exhibit conductivities and even superconductivities.[3–7] Some non-planar metal–dmit complexes have also been reported to exhibit high conductivities.[8] Recently, it has been shown that intermolecular interactions in transition metal bis(dithiolate) complexes of this type are also important for the assembly of molecular ferromagnets.[9] A large number of metal–dmit complexes have been synthesized and structurally characterized but many of them are homoleptic. To our knowledge, heteroleptic polymetallic complexes of dmit in particular, are rare. These types of complexes reported in the literature are restricted to $[NBu_4]_2[Ni_2(C_2S_4)(dmit)_2]$,[10] $[Au_4(dmit)_2(Ph_2PCH_2PPh_2)_2]$ and $[Au_3(PPh_3)_3(dmit)]$.[11] We have now investigated whether dithiolate can be used as a bridging ligand to synthesize heteroleptic polymetallic complexes with dmit. As two examples, two heteroleptic nickel(II) derivatives $[NEt_4]_2[Ni_5(edt)_4(dmit)_2]$ **1** and $[AsPh_4]_2[Ni_3(pdt)_2(dmit)_2]\cdot 0.5MeOH$ **2**, were formed by using edt or pdt as bridging ligands; this is the first report of heteroleptic dmit complexes consisting of more than two nickel(II) centres.

4,5-Bis(benzoylthio)-1,3-dithiole-2-thione (prepared according to the detailed procedures described by Steimecke *et al.*[12]) (0.408 g, 1.0 mmol) was dissolved in a methanol solution (30 ml) containing sodium (0.046 g, 2.0 mmol). To the resulting purple–red solution of Na_2dmit was added H_2edt (0.06 ml, 1.4 mmol) and then $NiCl_2\cdot 6H_2O$ (0.24 g, 1.0 mmol) to give a purple solution. After stirring for 6 h at room temp. a methanol solution (10 ml) of NEt_4Br (0.2 g, 1.0 mmol) was added leading to the precipitation of a purple product. This was collected by filtration and redissolved in dmf (10 ml); then it was filtered after stirring for several minutes. This filtrate was diffused with Et_2O at room temp. for ten days, after which 0.12 g of black crystals of **1** were obtained. The preparation of complex **2** was similar to that of **1**, H_2edt and NEt_4Br being replaced by H_2pdt and $AsPh_4Cl$, respectively. The red precipitate was collected by filtration and redissolved in Me_2CO (10 ml) and then filtered after stirring for several min. The filtrate was diffused with Et_2O at room temp. for ten days after which 0.35 g of black crystals of **2** were obtained.†

The structures of **1** and **2** were established by single-crystal X-ray diffraction analysis‡ and reveal the edt or pdt ligands in bridging modes chelated to Ni atoms and dmit ligands coordinated to edge Ni atoms. The anions of **1** and **2** together with selected bond parameters are depicted in Figs. 1 and 2. In **1**, the anion occupies a crystallographic inversion center, the five Ni atoms are bridged by four edt ligands, Ni(1), Ni(2) and Ni(2′) are square-planar coordinated to four S atoms of edt ligands and both the edge Ni atoms are square-planar coordinated to two S atoms of edt ligands and to two S atoms from one dmit ligand. From the configuration of the five Ni atoms and two dmit ligands, the anion can be described as consisting of an $Ni_3(edt)_4^{2-}$ unit to which are *trans* attached two $Ni(dmit)_2$ fragments, the angle Ni(1)–Ni(2)–Ni(3) [Ni(1)–Ni(2′)–Ni(3′)] being 102.83°. The Ni···Ni bond distances are 2.852(1) and 2.817(1) Å and are slightly shorter than that in $[PPh_4]_2[Ni_2(edt)_3]$ **3**[17] [2.914(1) Å] and comparable to the distances in $[PPh_4]_2[Ni_3(edt)_4]$ **4**[18] [2.856(1) Å]. The Ni–S bond distances vary from 2.151(3) to 2.227(3) Å which are comparable to the Ni–S bond distances in **3**[17] [2.158(2)–2.221(2) Å] and **4**[18] [2.174(1)–2.210(1) Å] as well as

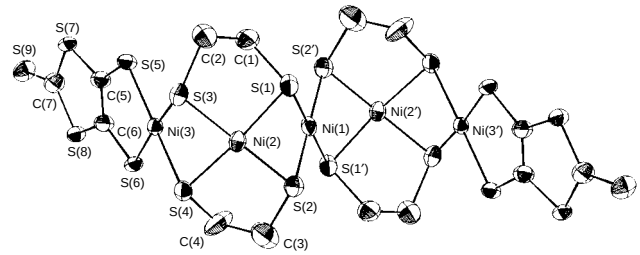

Fig. 1 ORTEP diagram of the anion of **1** (25% displacement ellipsoids). Selected bond lengths (Å) and angles (°): Ni(1)–Ni(2) 2.852(1), Ni(2)–Ni(3) 2.817(1), Ni(1)–S(1) 2.213(3), Ni(1)–S(2) 2.215(3), Ni(2)–S(1) 2.169(3), Ni(2)–S(2) 2.151(3), Ni(2)–S(3) 2.159(3), Ni(2)–S(4) 2.160(3), Ni(3)–S(3) 2.222(3), Ni(3)–S(4) 2.227(3), Ni(3)–S(5) 2.174(3), Ni(3)–S(6) 2.171(3); Ni(1)–Ni(2)–Ni(3) 102.83.

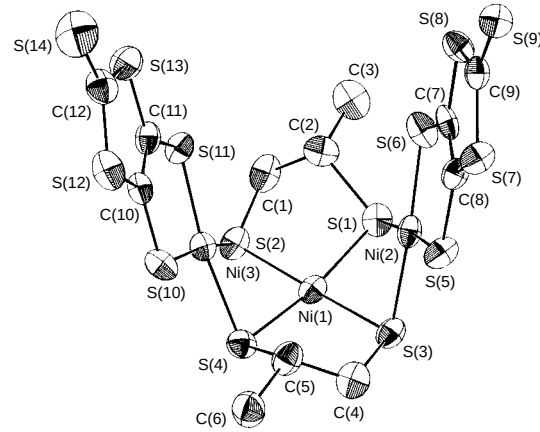

Fig. 2 ORTEP diagram of the anion of **2** (25% displacement ellipsoids). Selected bond lengths (Å) and angles (°): Ni(1)–Ni(3) 2.792(2), Ni(1)–Ni(2) 2.812(2). Ni(1)–S(1) 2.143(3), Ni(1)–S(2) 2.149(3), Ni(1)–S(3) 2.156(3), Ni(1)–S(4) 2.184(3), Ni(2)–S(5) 2.161(3), Ni(2)–S(6) 2.167(3), Ni(2)–S(1) 2.244(3), Ni(2)–S(3) 2.245(3), Ni(3)–S(11) 2.151(3), Ni(3)–S(10) 2.176(3), Ni(3)–S(2) 2.223(3), Ni(3)–S(4) 2.240(3); Ni(3)–Ni(1)–Ni(2) 102.47(5).

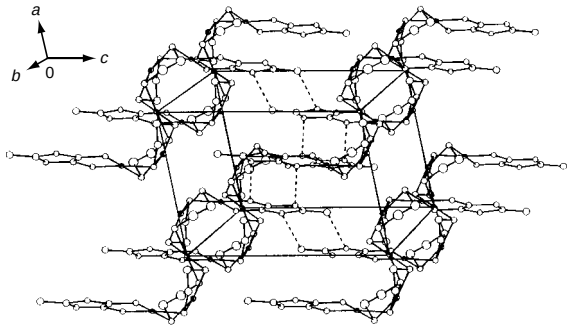

Fig. 3 The packing of **1** in the crystal. Dashed lines indicate non-bonded S···S contacts < 3.7 Å, the cations are omitted for clarity.

in $[AsPh_4]_2[Ni_2(S_2C_4)\{S_2C_2S_2C_2(CO_2Me)_2\}_2]$[19] and $[NBu_4]_2[Ni_2(C_2S_4)(dmit)_2]$.[10]

As shown in Fig. 2, the geometry around the Ni atoms in **2** is similar to those in **1**, the three Ni atoms adopt a V shape with the angle Ni(2)–Ni(1)–Ni(3) being 102.47°. In contrast to **1**, complex **2** can be achieved as an $Ni(pdt)^{2-}$ unit to which two $Ni(dmit)_2$ fragments are *cis* bonded. Compared to **1**, the Ni···Ni bond distances [Ni(1)–Ni(2) 2.812(2), Ni(1)–Ni(3) 2.792(2) Å] are slightly shorter, whereas the Ni–S bond lengths are almost the same as those in **1**.

In the crystal of complex **1** (as shown in Fig. 3), the anions interact with each other through S···S contacts of < 3.7 Å between the thiole and thione groups or the thiole and thiole groups of the dmit ligands on adjacent molecules to form a two-dimensional molecular interaction net. However, in the crystal of complex **2**, no S···S contacts < 3.7 Å are observed (the shortest intermolecular S···S distance is 3.92 Å); this may result from using the larger $AsPh_4^+$ ion.

The electrical conductivities of complexes **1** and **2** were measured with pressed pellets (two probe). Both complexes show semiconducting behaviour with room-temperature conductivities of 1.75×10^{-4} and 1.52×10^{-5} S cm^{-1}, respectively. The fact that the conductivity of **1** is higher than that of **2** may be the result of shorter intermolecular non-bonded S···S contacts.

This research was supported by State Key Laboratory of Structural Chemistry, Fujian Institute of Research on the Structure of Matter, the Chinese Academy of Sciences, and the Science Foundation of Nation and Fujian Province.

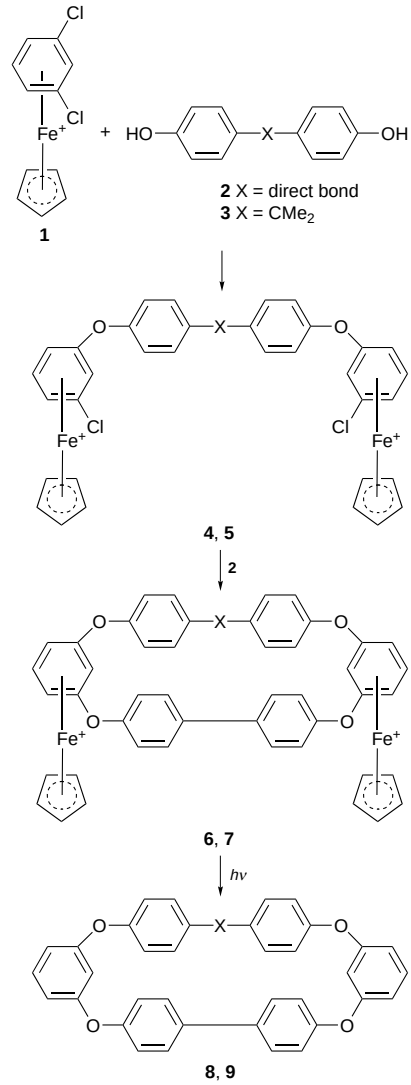
The facile preparation of macrocyclic ethers is achieved using S_NAr reactions of (dichlorobenzene)$CpFe^+$ complexes with various dinucleophiles, followed by photolytic demetallation; X-ray crystallography gives unequivocal structural proof for one of these macrocycles.

Cyclic polyethers are important synthetic targets owing to their selective complexation and chiral recognition.[1–3] Interest in these materials originates from the size and nature of their cavity, which dictates whether or not such materials are capable of binding with other compounds.[2] Although a great deal of attention has been directed toward the encapsulation abilities of supramolecules, there is a growing interest in the synthesis of cyclic aryl ethers.[3–5] These compounds are appealing since the rigidity and stability of their structures greatly reduces conformational freedom which may allow chiral recognition or catalysis at high temperature or in hostile environments.[4a] Mullins *et al.* reported that cyclic aryl ethers may be subjected to ring-opening polymerization to produce linear polyethers without the release of side-products.[4b] Here, we report the synthesis of four new cyclic aryl ethers, and the crystal structure of **8** utilizing temporary complexation to the cyclopentadienyliron ($CpFe^+$) moiety.

The molecular design and controlled synthesis of aromatic polyethers with pendant $CpFe^+$ moieties has been a focus of our recent research. The complexation of chloroarenes to the $CpFe^+$ moiety has allowed nucleophilic aromatic substitution (S_NAr) reactions to take place with a large number of dinucleophiles.[6] This methodology has enabled us to prepare a number of oligomeric ethers, thioethers and amines under very mild experimental conditions. Owing to the paucity of existing methods for the preparation of cyclic aryl ethers, we have been exploring new routes for the synthesis of such materials. A drawback of the existing methods is the need for electron withdrawing substitutents on the haloarene ring to promote the substitution reactions.[5] The ease of complexation and decomplexation of the $CpFe^+$ to the arene systems shows the advantages of our methodology. The stepwise displacement of both chloro groups in [(η^6-1,2-dichlorobenzene)(η^5-cyclopentadienyl)]iron(II) hexafluorophosphate **10** or [(η^6-1,3-dichlorobenzene)(η^5-cyclopentadienyl]iron(II)hexafluorophosphate **1** with a variety of dinucleophiles has allowed for the facile preparation of macrocycles **8**, **9**, **17**, and **18**. To our knowledge there are few reports which outline the preparation of macrocyclic materials using S_NAr reactions of substituted chlorobenzenes activated by temporary complexation to a metal moiety.[7] The preparation of dibenzo crown ethers was achieved *via* the S_NAr reactions of (*o*-dichlorobenzene)-$Cr(CO)_3$ with diethylene glycol and bis(2-mercaptoethyl) ether.[7a] A disadvantage of this particular synthetic method is the implementation of harsh reaction conditions in order to obtain the desired products in rather modest yields.

Scheme 1 outlines the reaction sequence employed for the preparation of cyclic aryl ethers **8** and **9**. The initial reaction of complex **1** and dinucleophile **2** or **3** in a 2 : 1 molar ratio was carried out in order to obtain the bimetallic complex (**4** or **5**) in high yield. The reaction of **4** or **5** with **2** in an equimolar ratio led to the formation of complexed cyclic aryl ethers **6** and **7** in yields of 86 and 89%, respectively. The rigid nature of these complexed macrocycles introduces both *cis*- and *trans*-orientations of the $CpFe^+$ moieties attached to the arene ring.[8] The presence of two different cyclopentadienyl (Cp) resonances as well as a complex aromatic region in the ^1H NMR spectra indicated that there was a mixture of both *cis* and *trans* products present. Based on the integration of the respective Cp resonances, it was determined that for complex **6** the ratio was 3 : 1 while it was 1 : 1 for complex **7**. The major structure was predicted to be *trans* based on previous findings.[8]

Photolytic demetallation was implemented to allow for the recovery of the free organic macrocycles **8** or **9** in yields of 64 and 58%, respectively, which may be attributed to the poor solubility of these macrocyclic materials in most organic



Scheme 1

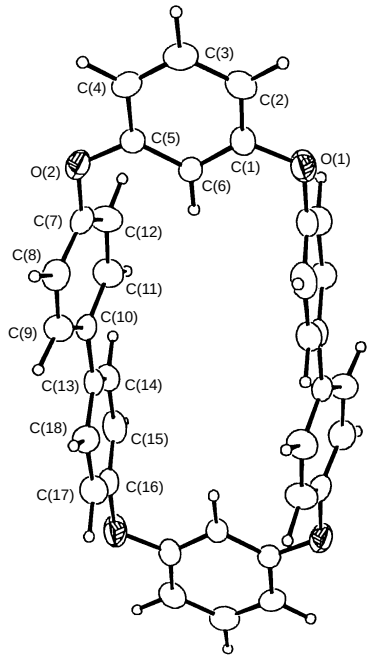


Fig. 1 ORTEP plot of cyclic aryl ether **8**. Selected bond lengths (Å) and angles (°): O(2)–C(5) 1.384(10), O(2)–C(7) 1.416(9), O(1)–C(1) 1.396(9), O(1)–C(16) 1.417(10), C(10)–C(13) 1.504(11); C(5)–O(1)–C(7) 117.7(5), C(1)–O(1)–C(16) 118.0(6), C(10)–C(13)–C(14) 121.0(7), C(10)–C(13)–C(18) 120.3(7).

solvents. The ^{1}H NMR spectra indicated the symmetric nature of these materials. It was noted that a triplet was present at a rather high field chemical shift of δ 5.6 (**8**) or 6.2 (**9**) which was attributed to the inner-ring protons of the benzene ring. This shift is explained by the large diamagnetic shielding caused by the two adjacent biphenyl rings on the inner-ring protons. Our observation is in accordance with similar cyclic aryl ether NMR shifts.[5] Unequivocal proof of the structure of **8** was obtained by an X-ray crystallographic study.† Single crystals suitable for X-ray analysis were obtained by slow evaporation of a chloroform solution of the cyclic aryl ether at room temp. Fig. 1 illustrates the rigidity imparted in the structure by the biphenyl and benzene rings, respectively. The biphenyl groups of the macrocycle are separated by 5.2 Å while the diagonal distance of oxygen atoms was found to be 10.9 Å.

Scheme 2 illustrates that an analogous sequence of reactions may be employed with the (*o*-dichlorobenzene)CpFe$^+$ complex (**10**) and dinucleophiles containing both aliphatic and aromatic bridges. In this fashion, macrocyclic compounds **17** and **18** with both oxygen and sulfur bridges were prepared. Once again NMR spectroscopy and elemental analyses were used to confirm the structure of all new materials. Unlike the rigid macrocycles prepared in Scheme 1, these structures have no inner ring protons and as a result no high field chemical shifts were observed.

This is the first example of iron cyclopentadienyl mediated cyclic aryl ether synthesis. The presented methodology will enable us to prepare a variety of these cyclic compounds under mild experimental conditions and in very high yields. An additional benefit of this process is the ability to isolate the intermediate bimetallic complex prior to ring closure. It has been demonstrated that it is possible to prepare both symmetric and asymmetric cyclic aryl ethers depending on the nucleophile used to close the macrocycle. Further investigations aimed at increasing the cavity size and varying the nature of the substituents are in progress and will be reported in due course.

Financial support provided by the Natural Sciences and Engineering Research Council of Canada (NSERC) and the University of Winnipeg is gratefully acknowledged. C. R. D. (graduate student, University of Manitoba) also thanks NSERC for a postgraduate scholarship.

The immobilisation of molybdate on Mg,Al-LDH leads to an active, heterogeneous catalyst that generates singlet molecular oxygen from hydrogen peroxide in the absence of soluble base.

Molecular oxygen in the singlet state ($^1O_2$) is a unique reagent for oxyfunctionalisation, as its product distributions essentially differ from those of radical or electrophilic agents such as RO* radicals or (in)organic peracids.[1] Singlet O_2 can be generated from $^3O_2$ *via* visible excitation of dissolved or heterogenised photosensitisers (*e.g.* porphyrins or rose bengal), but the need for an efficient illumination and the photolability of many dyes are major drawbacks for scale-up of such systems.[2–5] An alternative pathway is the catalysed production of $^1O_2$ from alkaline H_2O_2.[6] Several metal ions can act as homogeneous catalysts for this reaction, in particular molybdate and calcium. This contribution presents a new solid catalyst for $^1O_2$ generation, consisting of active molybdate centers embedded in a layered double hydroxide (LDH) matrix. Such catalytic design eliminates the need for a soluble base. The production of $^1O_2$ is evidenced by spectral observations and by oxygenation of characteristic substrates.

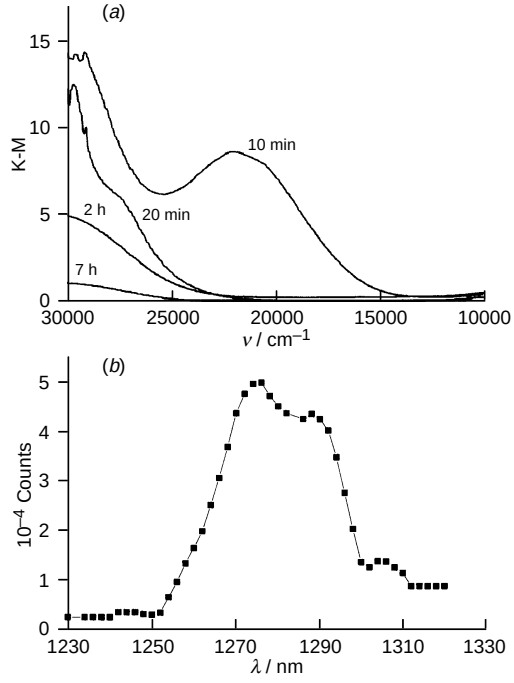

Fig. 1 Exposure of $Mg_{0.7}Al_{0.3}$-LDH-MoO_4 (37.5% AEC), suspended in 1,4-dioxane, to H_2O_2 (0.5 mmol, as 35% in water). (*a*) Diffuse reflectance UV–VIS spectrum recorded at different times after H_2O_2 addition (0.1 g LDH in 0.5 ml solvent; K–M = Kubelka–Munk). (*b*) IR luminescence spectrum, recorded with a liquid N_2 cooled Ge detector (0.025 g LDH in 1.75 ml solvent).

LDHs are analogues of the mineral hydrotalcite, and can be synthesised in a variety of elemental compositions, depending on the desired surface pH and anion exchange capacity.[7] For the present work, a $Mg_{0.7}Al_{0.3}$-LDH was precipitated in degassed water at pH 10, ion-exchanged with MoO_4^{2-} in the same conditions, and isolated by freeze-drying. A typical Mo loading of 5.5 mass% corresponds to occupation of 37.5% of the anion exchange capacity with divalent molybdate anions. When this catalyst is exposed to aqueous H_2O_2 in dioxane, the suspension turns brick-red. This colour change was studied with time-resolved diffuse reflectance spectroscopy [Fig. 1(*a*)]. Bands are observed at 330 and 450 nm. Especially the latter band is typical of polyperoxomolybdate species, *e.g.* $[MoO(O_2)_3]^{2-}$ and $[Mo(O_2)_4]^{2-}$. Such Mo species are formed in particular at high peroxide : Mo ratios and at high pH.[8] Monitoring the spectrum as a function of time shows a steady decrease of the intensity of the polyperoxo bands. This decay corresponds to the disproportionation of the peroxo groups into oxo groups and singlet oxygen, as is proved unequivocally by the near infrared luminescence spectrum. Simultaneously with the UV–VIS spectral change, an emission peak is observed at 1276 nm, which is in satisfactory agreement with the reported energy of the $^1\Delta_g \rightarrow {}^3\Sigma_g^-$ transition [Fig. 1(*b*)].[9] The smooth release of $^1O_2$ and the formation of the polyperoxomolybdates are in agreement with the basic nature of the LDH surface; in solution, the same processes would require addition of additional NaOH. When the $[MoO_4]^{2-}$ exchanged LDH is removed by filtration, the H_2O_2 decomposition stops completely. This proves that the Mo is really heterogeneous, even if the singlet oxygen may diffuse into the solution.

As the production of $^1O_2$ was firmly established from the physicochemical methods, we turned to the application of the material in $^1O_2$ mediated (per)oxidations (Scheme 1).† The 1,3-diene α-terpinene (**1**) was selected as a substrate for [2π + 4π] cycloaddition; the feasibility of $^1O_2$ 'ene' type reactions was tested with 1-methylcyclohexene **2** and 2,3-dimethyl-but-

[a] *Reaction conditions*: 2.5 mmol substrate, 5 mmol H_2O_2 35% in water, 0.05 g catalyst containing 10 μmol $[MoO_4]^{2-}$, 3 ml of 1,4-dioxane, 293 K. Product yields on substrate basis. [b] Subscripts for Mg and Al refer to molar fractions in LDH octahedral layer. [c] TON = moles of $^1O_2$ products per mol of Mo. [d] **2a** = 1-hydro(pero)xy-1-methylcyclohex-2-ene; **2b** = 1-hydro(pero)xy-2-methylcyclohex-2-ene; **2c** = 1-hydro(pero)xy-2-methylenylcyclohexane. [e] 28 μmol $[MoO_4]^{2-}$ on 0.05 g LDH, or 37.5% of the anion exchange capacity. [f] 18 μmol MoO_4^2 on 0.05 g LDH, or 25% of the anion exchange capacity. [g] Values between brackets: distribution of $^1O_2$ oxidation products (%). [h] Photosensitisation with rose bengal (3.10^{-5} M in ethanol), cold light source Schott KL 1500, 293 K.

2-ene **3** (Table 1). The endoperoxide ascaridole is obtained from **1** with a 98% selectivity. With **2** and **3**, hydroperoxide formation is accompanied by a double-bond shift, as expected for a non-free radical, $^1O_2$ mediated peroxidation. Characteristically, the double bond also shifts to the exocyclic position in the case of **2**; the product distribution is essentially the same as for a photosensitised reaction. While the recovered enols undoubtedly originate from the corresponding hydroperoxides, the only competing side reaction is a limited epoxidation. Such an epoxidation of double bonds by peroxo d^0 metals is well documented; however, in our reactions, epoxides in all cases amount to $< 20\%$ of the formed products.

A principal advantage of LDHs over other supports (*e.g.* polymers) is that the characteristics of the catalytic site's environment are easily modified. For instance, co-exchange of the LDH with $[MoO_4]^{2-}$ and an organic anion such as toluene-*p*-sulfonate (Ts) transforms the polar layered double hydroxide into a much more lipophilic material. With ($[MoO_4]^{2-}$,Ts)-LDH as a catalyst, the consumption of H_2O_2 is more gradual, which is undoubtedly due to a repulsion of the primary oxidant H_2O_2 by the apolar surface. While this catalyst modification increases the eventual conversion of *e.g.* 1-methylcyclohexene, this increase is almost totally accounted for by a fivefold multiplication of the epoxide yield. A more successful catalyst modification is the dilution of the $[MoO_4]^{2-}$ active centers over the hydrophilic support. When the occupancy of the anion exchange capacity by $[MoO_4]^{2-}$ is lowered from 37.5 to 12.5%, the yield of $^1O_2$ oxidation products almost doubles (Table 1). Apparently, a slow release of $^1O_2$ from well-dispersed active centers ensures an optimal capture of the $^1O_2$ by the organic substrate. A supplementary improvement of the catalyst is achieved by modification of the elemental composition of the LDH. Thus when the molar fraction of Al in the octahedral layer of the LDH is lowered to 10%, the epoxide formation becomes marginal, while the peroxidation yield further increases. Typically, up to 100 mol of $^1O_2$ product are formed per mol of Mo, proving that the process is truly catalytic in Mo.

Summarizing, this system is the first heterogeneous catalyst for $^1O_2$ generation from a peroxide for which the performance can be easily tuned by modification of the support. A soluble base, as required for the homogeneous molybdate system, becomes superfluous because of the basic characteristics of the LDH surface. The key to achieving high peroxidation yields is a gradual release of $^1O_2$ from a hydrophilic surface.

We thank the Belgian Government for supporting this work in the frame of an I.U.A.P.-P.A.I. project. We thank I.W.T. (F. v. L., D. V., B. S.), F.W.O. (D. D. V) and F.R.I.A. (F. P.) for fellowships, the Luxembourg Ministry of Education and Vocational Training (A. D. G.) for a research training grant and F.N.R.S. for a position of director of research (A. K. D. M.).

Detection of low levels of Brønsted acidity in Na^+Y and Na^+X zeolites

By using retinyl acetate, retinol and retinyl Schiff base as probes, zeolites NaY and NaX are demonstrated to possess a small number of Brønsted acidic sites; the color test employed here is potentially simple and may be universally applied.

Zeolites are finding increasing favor as supramolecular hosts for investigation of the photochemical and photophysical behavior of organic guests.[1] In this context, one would like to employ a reaction cavity that is 'passive'.[2] A set of zeolites that is commonly used as a reaction medium is M^+X and M^+Y.[3] The molecular formula as written for these X and Y zeolites, $M^+_x(AlO_2)_x(SiO_2)_y$, does not give any indication that they may possess reactive Brønsted acid sites.[4] However, it is becoming increasingly clear that the characteristics, especially Brønsted acidity, of commonly used monovalent cation exchanged zeolites can vary significantly from source to source. Even the presence of very small numbers of acidic sites may act in a catalytic manner and complicate the desired chemistry.[5] The characterization of the very small concentrations of Brønsted acid sites present in different samples of X and Y zeolites was, therefore, critical in order to rationalise the observed chemistry. Results of our investigation of Na^+X and Na^+Y zeolites are presented here.

One of our laboratories has recently developed new solid state double resonance NMR methods to probe the acidic sites present in zeolites.[6] Prompted by the success with H^+Y and $Ca^{2+}Y$ zeolites, we proceeded to investigate Na^+Y zeolites with solid state NMR. The basic probe molecules trimethylphosphine (TMP), dimethylamine and methylamine were used to test both Brønsted and Lewis acidity in these materials. Both room and low temperature studies were performed. Zeolite samples (obtained from Aldrich and Zeolyst International) were activated both in an oven at 500 °C in air or at *ca*. 300 °C under a vacuum, in order to mimic activation conditions used for the alkene reactions.[5] ^{1}H MAS NMR spectra of activated Na^+Y showed a resonance at δ 3.6 (both at −80 and −120 °C) possibly due to Brønsted acid sites.[7] The area underneath the peak was extremely small in comparison to the intensity of the residual water and the resonance due to the silanols. Hence it was very difficult to quantify the numbers of Brønsted acid sites per unit cell. A very weak signal was observed at $\delta -2$ in the ^{31}P MAS NMR spectrum (collected at −100 °C) of Na^+Y (from Aldrich) loaded with 26 molecules per unit cell of trimethylphosphine. This resonance was approximately 1/50 that of the main resonance at δ −60 from weakly bound/physisorbed TMP. Resonances from $TMPH^+$, formed by the protonation by the Brønsted acidic sites typically appear in the range δ 0 to −5.[6] Although the resonance at $\delta -2$ seen in the case of Na^+Y, cannot be definitely attributed to $TMPH^+$, it is clear that the number of acidic sites within Na^+Y is very small. From the intensity of this resonance, we estimate that there can be no more than *ca*. 0.5. Brønsted acid sites per unit cell in this sample. No resonances from $TMPH^+$ were observed in samples from Zeolyst (CBV-100) and Engelhardt (EZ-150). To check the presence of weakly acidic sites, stronger bases such as dimethylamine and methylamine were used as probes for Na^+Y. No Brønsted acid sites were detected in the ^{1}H MAS NMR with these probes. Based on these studies we conclude that the number of Brønsted acid sites in Na^+Y (CBV-100 and EZ-150) are small and beyond the detection limits of NMR when using these probe molecules (*i.e.* < *ca*. 0.5 acid sites per unit cell).

In spite of the above discouraging observations, we remained convinced that both Na^+Y and Na^+X contain acidic sites based on their influence on various alkenic substrates.[5] We, therefore, employed a different technique to detect the acidic sites within the zeolites. This involved detecting differences in electronic absorption characteristics between protonated and unprotonated forms of a probe molecule. Three probe molecules (**1a**, **1b** and **1c**) with different basicities were used (Scheme 1).

Both retinol (**1a**) and retinyl acetate (**1b**) in an acidic medium generate a blue color due to the formation of a short lived retinyl carbocation [Scheme 1, eqn. (1)].[8] We have adopted this color change to monitor the Brønsted acidity within zeolites. Four samples of Na^+Y (Aldrich, CBV-100, EZ-150 and LZY-52 from Union Carbide) and Na^+X (Aldrich) were tested for Brønsted acidity. The test consisted of monitoring the absorption changes upon addition of a small amount (50–200 mg) of an activated zeolite to a standard micromolar hexane solution (5 ml) of retinol or retinyl acetate. When activated Na^+Y was added to a standard solution of retinol or retinyl acetate, the zeolite immediately adopted a dark blue color. The color

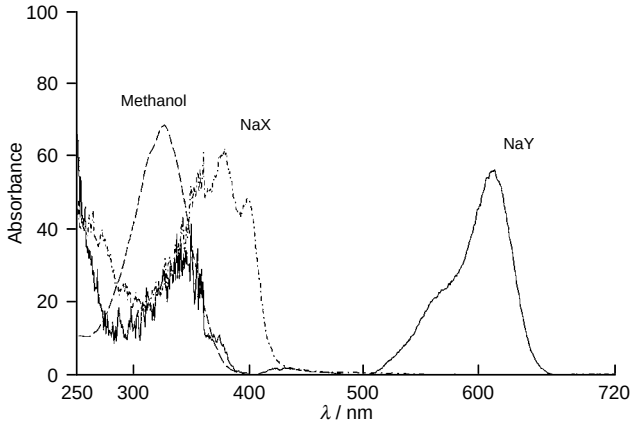

Fig. 1 The spectral change upon inclusion of retinyl acetate within NaY and NaX zeolites. A comparative spectrum in methanol solution is included. Absorption due to retinyl cation is observed in NaY. In NaX the absorption due to retinyl acetate is red shifted but no absorption due to retinyl cation is seen.

persisted for nearly an hour and the diffuse reflectance spectra of these samples are displayed in Fig. 1. The observed λ_{max} within zeolites is in the same range reported in solution.[8] The above observations can be interpreted to mean that Na^+Y contains Brønsted acidic sites that are strong enough to protonate **1a** and **1b**. Na^+X did not show a positive blue test with either **1a** or **1b**, indicating that Na^+X does not contain any protons that are sufficiently acidic to protonate **1a** and **1b**.

Another probe we employed to test the acidity is the more basic retinyl Schiff base **1c** [Scheme 1, eqn. (2)]. In methanol solution, the protonated Schiff base shows an absorption with a λ_{max} at 440 nm. Addition of the above four activated Na^+Y and Na^+X zeolites to a standard micromolar hexane solution of retinyl Schiff base resulted in a color change of the zeolite from white to light yellow orange. The orange colored species absorbs in the same region as the protonated retinyl Schiff base in CH_2Cl_2 solution (Fig. 2). The emission spectra recorded at 77 K are consistent with those reported for the protonated Schiff base.[9] As expected, addition of a large amount of *n*-butylamine displaced the Schiff base from the zeolite. Furthermore, while retinol and retinyl acetate did not indicate the presence of acidic sites within Na^+X, the more basic retinyl Schiff base showed that Na^+X zeolite is also acidic in nature. The difference is likely

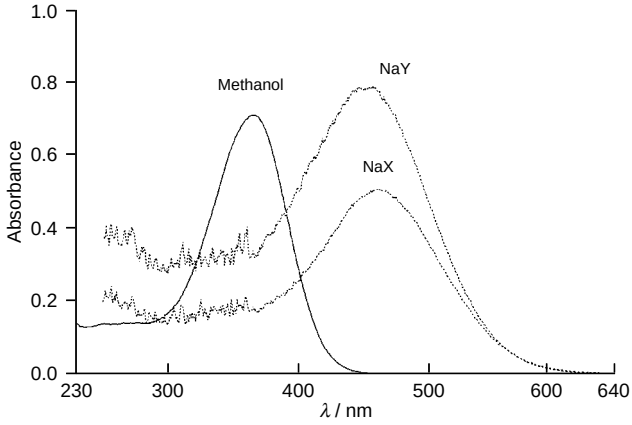

Fig. 2 The spectral change upon inclusion of retinyl Schiff base within NaY and NaX zeolites. A comparative spectrum of unprotonated Schiff base in methanol solution is included. Absorption due to protonated Schiff base is observed in NaY and NaX.

to result from the difference in strength of acidity of the sites present in these two structures.[10]

Diethylamine, a stronger base than **1a**, **1b** and **1c**, was added before the indicator, to react with the Brønsted acid sites, allowing us to estimate the number of acidic sites present in Na^+Y. Titration of the Brønsted acid sites was conducted with diethylamine as the base and **1a** and **1c** as the indicators.† Addition of 1 molecule of diethylamine per 12 supercages of Na^+Y completely quenched the protonation of the probe molecules **1a** and **1c**. This represents a maximum limit of acidic sites within NaY since the estimation assumes that all molecules of diethylamine are protonated under the experimental conditions.

Although extremely low levels of Brønsted acidity were detected, these levels were sufficient to alter the reaction pathways for a number of alkenic systems. We are in the process of characterizing the acidity distribution within different samples of Na^+Y and Na^+X with indicators of different basity. Our initial results suggest that these probes may serve to not only quantify the number of sites but to distinguish between sites of different acidity. Finally, because the method relies on the color changes of highly absorbent dye molecules, it extremely sensitive to low concentrations of acid sites.

Acknowledgement is made to the Donors of PRF-ACS for partial support of this research. † A known amount (1–10 μl) of diethylamine was added to the dried NaY (200 mg) in hexane and the mixture was stirred for 1 h; then 1 ml of a standard solution of **1a**, **1b** or **1c** was added to this slurry and stirred. The slurry was filtered and the diffuse reflectance spectrum of the solid was recorded. The intensity of the absorption due to the retinyl cation was dependent on the amount of the added diethylamine.

Coupling reaction of terminal allenes with themselves or acetylenes mediated by (η^2-propene)Ti(OPr^i)$_2$: some new selectivities and synthetic application

Daigaku Hideura, Hirokazu Urabe and Fumie Sato*

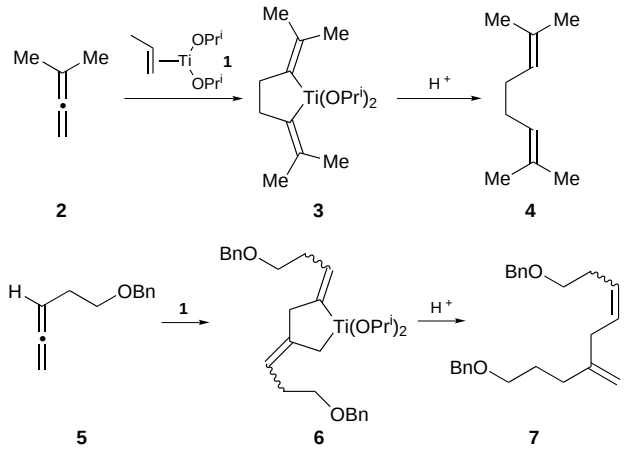
Department of Biomolecular Engineering, Tokyo Institute of Technology, 4259 Nagatsuta-cho, Midori-ku, Yokohama, Kanagawa 226, Japan

Treatment of an allene alone or with an acetylene with (η^2-propene)Ti(O-i-Pr)$_2$ generates a new titanacycle, which reacts with some electrophiles to give useful intermediates for organic synthesis.

Low-valent early transition metal complexes are well known to effect the coupling reactions of olefins and acetylenes to yield metallacycles *via* olefin– (or acetylene)–metal intermediates, which show wide application in organic synthesis.[1] Although some examples of allene coupling reactions based on (C_5H_5)$_2$Ti– or (C_5H_5)$_2$Zr–allene complexes have been documented,[2–4]† the small number of reactions utilizing just allenes as the starting material (rather than any other appropriate precursors) and, accordingly, the critical issues in organic synthesis of regio- and stereo-selectivity and the feasibility of the reaction with respect to various substrates, have not been sufficiently investigated. As some of the aforementioned cyclometallation reactions have recently been carried out with an inexpensive, readily available low-valent titanium species, (η^2-propene)Ti(OPr^i)$_2$ **1**,[5] we reinvestigated the coupling reaction of allenes themsleves and with other unsaturated compounds by taking advantage of this new method.

The homo-coupling reaction of 1,1-dimethylallene **2** with **1** proceeded at −50 °C for 2 h to give the symmetrically substituted **3** having two vinyl–metal bonds as a virtually single isomer (Scheme 1) as shown by the production of **4** (Table 1, entry 1) in accord with precedents of the (C_5H_5)$_2$Ti- or (C_5H_5)$_2$Zr-mediated reactions.[2,3a,4b] However, mono-substituted allene **5**[6] showed a completely different regioselectivity from **2** to give the titanabicycle **6**, which was identified by isolation of **7** as a mixture of *E*- and *Z*-olefinic isomers after aqueous workup (Table 1, entry 2). The latter regioselectivity is not seen in the homo-coupling reactions of representative types of allenes mediated by a low-valent titanium complex having cyclopentadienyl ligands.[2]

The *E*/*Z* ratio of the double bond in the above product could be controlled by the use of a silylallene.[7c] Thus, treatment of **8**[8]



Scheme 1

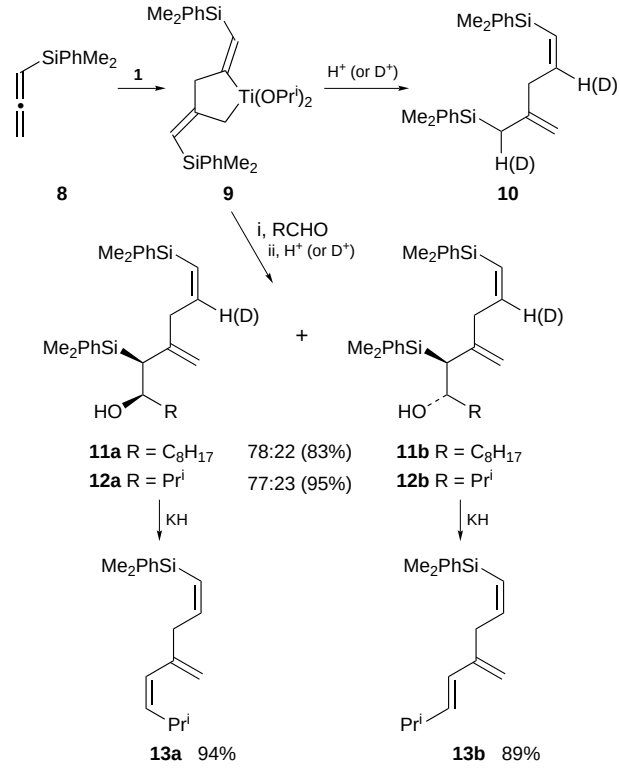
Table 1 Coupling of allene mediated by **1**

Entry	Allene	Product	Yield (%)
1	**2**	**4**	75
2	**5**	**7**	65[a]
3	**8**	**10**	80[b]

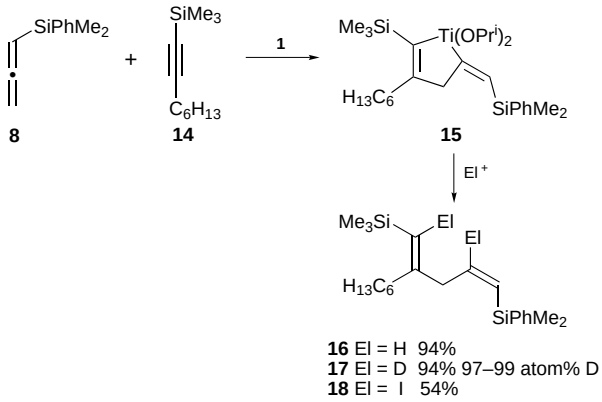
[a] *E*:*Z* ratio = 24:76 (or *vice versa*). [b] *Z* isomer only.

with **1** under the same conditions as above initiated cyclization to afford the single product **10** after aqueous workup (Scheme 2 and entry 3, Table 1). The internal double bond of **10** had exclusively the *Z* configuration, as determined *via* examination of the coupling constants and an NOE study in the ^{1}H NMR spectrum. The titanacycle structure **9**‡ was verified by deuterolysis that gave the bis-deuterated product [$^2H_2$]-**10** (93 atom% at each position) as a single regioisomer.

More importantly, addition of **9** to aldehydes proceeded in a regioselective manner to give the adducts **11** and **12** as an approximately 3:1–4:1 mixture of diastereoisomers, which could be separated on silica gel. The addition of the vinyl–titanium bond in **9** to the aldehyde was not observed,[5b,9] although its presence was confirmed by the subsequent workup with deuteriochloric acid to give the product **12** having vinylic deuterium (93 atm%). Upon treatment with KH in THF,[10] the



Scheme 2



Scheme 3

major stereoisomer **12a** afforded the *Z,Z*-triene **13a**, while the minor **12b** gave *Z,E*-**13b**. These results not only established the orientation of the hydroxy group in **12** (and, hence, **11** by analogy) based on the well-precedented stereochemical course of the Peterson olefination,[10] but also demonstrated a synthetic application of the homo-coupling of the allene followed by aldehyde addition for the stereoselective preparation of trienes.

The hetero-coupling reaction between an allene and an acetylene is another important feature of the transformation involving allenes.[3a,4]† However, little information is available on the regio- and stereo-chemical aspects of the coupling reaction starting from unsymmetrical allenes and acetylenes.[4b] Thus, we first attempted the reaction of unsymmetrical substrates, a mono-substituted allene **8** and silylacetylene **14**, and found that the desired products **16** could be obtained in good yield and as an essentially single stereoisomer (Scheme 3). The stereochemistry of both double bonds in **16** was elucidated by ^{1}H NMR analysis. The high regioselectivity found for this unsymmetrical acetylene, as verified by the absence of another regioisomer, is also noteworthy. The presence of the intermediate titanacycle **15** was confirmed by the deuterolysis (1 M DCl) and iodinolysis (excess I_2) to give the bis-deuterated **17** and diiodide **18** in good yields.

This coupling reaction seems to be general for various substrates, as shown in Table 2. Alkylallene **5** preferentially affords the product **20** having an *E*-disubstituted double bond when reacted with di*alkyl*acetylene **19** (Table 2, entries 1 and 2), but gives **21** carrying a *Z*-disubstituted olefin with *silyl*acetylene **14** (entry 3), both in good yields. Alkoxyallene **22**[11] was able to participate in this coupling reaction as well. Although the yield of **23** is not particularly good due to partial decomposition of the allene in the presence of the titanium alkoxide, the exclusive *Z*-olefinic preference found in the product is somewhat amazing, provided that the stereoselectivity was simply controlled by the steric hindrance of the allenic substituent, which is usually less pronounced in the following order: trialkylsilyl > *n*-alkyl > *n*-alkyloxy (*cf.* entries 3–5). The resultant *cis*-vinyl ether moiety may be stereospecifically replaced by a carbon chain with a Grignard reagent under nickel catalysis[12] or hydrolyzed to aldehyde.

The coupling reaction based on allenes described herein, which enables the selective construction of a carbon framework and the facile introduction of an electrophile, is a synthetically useful entry to the metal-promoted coupling reactions of unsaturated compounds.

We thank the Ministry of Education, Science, Sports and Culture (Japan) for financial support.

The biosynthesis of pramanicin: origin of the carbon skeleton

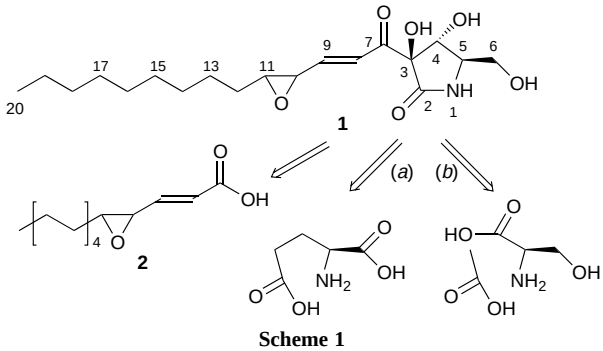
Paul H. M. Harrison,* Donald W. Hughes and R. William Riddoch

Department of Chemistry, McMaster University, 1280 Main Street West, Hamilton, Ontario, Canada L8S 4M1

Incorporation of labelled acetates and serine into pramanicin 1 in *Stagonospora* sp. ATCC 74235 shows that the carbon skeleton of 1 is derived from eight acetate units and a serine residue, implying that the biosynthesis of 1 proceeds *via* an acyl–tetramic acid intermediate 3.

Pramanicin **1** (Scheme 1), an inhibitor of *Cryptococcus neoformans*, and the closely related fatty acid epoxide **2** were isolated by Schwartz *et al.*[1] from a sterile fungus which has subsequently been identified as a species of *Stagonospora*. Our biomimetic template-directed synthesis of **2**[2] was based on a presumed biosynthetic pathway in which seven acetate units combine in a manner typical of fatty acids and polyketides[3] to give tetradeca-2,4-dienoyl-CoA; however, the biosynthetic origin of the pyrrolidone ring in **1** is not clear. Thus, this polar headgroup could be derived from a suitable five-carbon amino acid precursor such as proline or glutamate *via* pyroglutamate and a further Claisen-like condensation onto the CoA ester of fatty acid **2** [Scheme 1, path (*a*)]. On the other hand, **1** could also be viewed as being related to the tetramic acid family of natural products which contains the 3-acyl-Δ^3-pyrrolin-2-one moiety. Biosynthetic studies on erythroskyrine,[4] β-cyclopiazonic acid,[5] tenuazonic acid,[6] malonomicin,[7] streptolydigin,[8] ikarugamycin,[9] the cytochalasans,[10] and recently a preliminary report on aflastatin A[11] have shown that the five atoms of the pyrrolinone ring in these metabolites derive from C-1 and C-2 of one acetate unit and the carboxy- and α-carbon as well as the nitrogen of the appropriate amino acid (Val, Trp, Ile, 2,3-diaminopropanoate, β-methyl-Asp, ornithine, Trp and Ala, respectively). Tetramic acid intermediates have also been proposed in the biosynthesis of, for example, tenellin[12] and ilicicolin H.[13] Thus another potential pathway to **1** would involve the formation of a linear octaketide and cyclization with, presumably, serine as the amino acid [Scheme 1, path (*b*)]. Therefore we sought to determine which pathway was operational in formation of **1**, and describe herein the results of preliminary labelling experiments which establish the origin of the carbon skeleton of **1**.

Cultures of *Stagonospora* sp. ATCC 74235 were grown, and pramanicin was isolated with minor modifications† of the literature procedure.[1] When sodium [1-^{13}C]acetate was added to the cultures, enhanced signals in the {^{1}H}^{13}C NMR spectrum were observed in the resulting **1**, compared with an unlabelled control sample (Table 1). Labelling was observed at the unambiguously assigned sites 2, 7, 9, 11, 13 and 19, as well as at two other sites within the heavily overlapped region corresponding to C-14 to C-18. Therefore, eight acetate units are incorporated into **1**. When sodium [1,2-$^{13}C_2$]acetate was incorporated into **1**, the pulsed field gradient 2D INADEQUATE NMR spectrum of the resulting sample showed seven of the eight expected couplings within acetate-derived units (Table 1).†



Scheme 1

These results show that the 4,5-epoxytetradec-2-enoyl hydrophobic tail of **1** is indeed derived from the expected 'head-to-tail' condensation of seven acetate units,‡ and at first sight imply a further cycle of chain extension on the fatty acid synthase to give a sixteen-carbon β-ketoacyl chain. However, acetate can enter the tricarboxylic acid cycle and can label glutamate and hence proline: [1-^{13}C]- and [1,2-$^{13}C_2$]-acetates give [5-^{13}C]- and [4,5-$^{13}C_2$]-glutamates, respectively, which are expected to label C-2 and C-2,3 of pramanicin if path (*a*) is operational. Hence, exactly the same labelling pattern is predicted for the direct chain extension pathway as is expected for indirect incorporation *via* glutamate, and these experiments cannot distinguish between the two proposed putative biogenetic pathways.

Incorporation of DL-[1-^{13}C]serine proceeded efficiently: only C-4 of **1** was labelled (Table 1). Although serine can be converted to glutamate or proline, the intermediacy of acetate is

Table 1

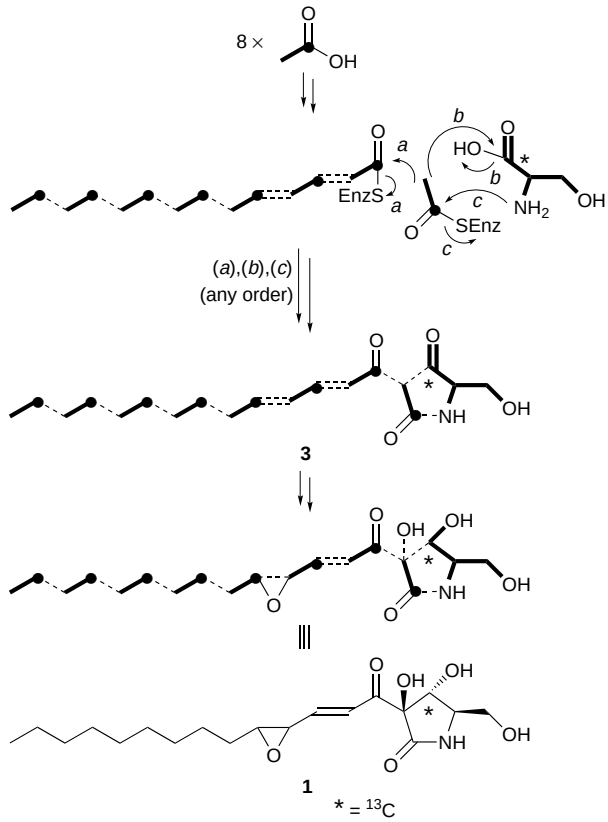
[a] The numbering system is based on ref. 1. [b] Determined in CD_3OD. [c] Expressed as number of fold increase in the height of the carbon-13 resonance relative to unlabelled **1**, with correction by standardizing the two samples using the mean peak height for all unlabelled carbons. [d] Determined by dividing the sum of the coupled peak heights by the height of the uncoupled, natural abundance peak. [e] Values which are stated to 0.1 Hz accuracy determined from a narrow-window high-resolution ^{13}C NMR experiment. [f] Coupled partner from 2D gradient INADEQUATE experiment. [g] Values averaged over two overlapping carbons. [h] ND = not determined. [i] Multiplet; coupling patterns could not be deduced in this region.



Scheme 2

required in this process, and label is expected to appear at C-5 of **1**. Since no incorporation into acetate-derived sites was observed in this experiment, glutamate and proline cannot be precursors of the pyrrolidone moiety in **1**. Rather, the results are consistent with formation of a linear octaketide; amide formation with the amino group of serine and cyclization by formal Claisen-like condensation of the β-ketoacyl enolate onto the presumably activated serine carboxy group would generate **3**, which contains the carbon skeleton and ring of **1** (Scheme 2). The order of these events [events (*a*), (*b*) and (*c*) in Scheme 2] remains to be established. Net addition of water across the C-3–C-4 bond, presumably by oxidative hydroxylation at C-3 and reduction at C-4 of intermediate **3**, and epoxidation gives **1**. Further investigation of this pathway is being undertaken, and will be reported in due course.

† *Stagonospora* was cultured in liquid medium LCM,[1] with the glucose content reduced to 40 g l^{-1} (100 ml in each of twelve 500 ml Erlenmeyer flasks). Sodium [1-^{13}C]- and [1,2-$^{13}C_2$]-acetate (1 g each) or DL-[1-^{13}C]-serine (0.25 g) were added as sterile solutions in water at 24 h intervals over days 2–6. After seven days, the culture was worked up as previously described.[1] Final purification was by MPLC on a Merck LOBAR RP-8 column in MeOH–H_2O (70 : 30), giving 75 mg of **1**.

‡ The remaining correlation for the eighth unit corresponds to two carbon nuclei at *ca.* δ 30; these are strongly coupled and thus this correlation is not observed in the INADEQUATE spectrum. Careful examination of the 1D spectra shows that the two units C-17,18 and C-15,16 are each derived from an *intact* acetate unit; however, the *direction* of these units, implied in Scheme 2 in accord with biosynthetic convention,[3] is not unambiguously proven by these experiments.

Formation of bridged bicycloalkenes *via* ring closing metathesis

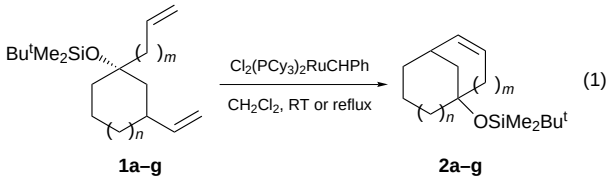
Andrew Morehead, Jr. and Robert Grubbs*

The Arnold and Mabel Beckman Laboratory of Chemical Synthesis, Division of Chemistry and Chemical Engineering, California Institute of Technology, Pasadena, California 91125, USA

Ring closing metathesis may be used in the formation of small ring bicycloalkenes from monocyclic diene precursors.

Ring closing metathesis (RCM), catalyzed by transition metal carbenes, has recently become an established method for the conversion of dienes to cyclic olefins.[1] While many applications of RCM have been reported,[2] only a few have involved the formation of bridged bicyclic compounds. The reported examples all involved macrocyclization (ring sizes > 12 atoms) except one, which involved the formation of a seven-membered ring leading to a bicyclo[9.5.1]alkene ring system.[3] Since small ring bridged bicycloalkanes and heterocycles are ubiquitous in natural products, the application of RCM in ring closures of this type would potentially lead to greatly broadened utility of this method.

A series of monocyclic diene substrates was synthesized† and the ring closure promoted by the well-defined ruthenium benzylidene complex[4] was examined [eqn. (1)].‡ The results of



1a–g **2a–g** (1)

the cyclization reactions are summarized in Table 1.

The ring closure of five-, six- and seven-membered rings to form [3.*x*.1], [4.*x*.1] and [5.*x*.1] bicycloalkenes is a relatively facile process (entries 1, 2, 5, 6 and 8), while ring closure of eight-membered rings to give bicyclo[5.*x*.1]alkenes does not occur (entries 3, 9 and 10). Variation of the reaction temperature, concentration of the diene and catalyst type (Mo catalyst[5]) had no influence on the formation of the eight-membered rings, as starting material and oligomers were the only products isolated.

Formation of the bicyclo-[3.2.1]- and -[3.3.1]-alkenes when the six-membered ring is being closed is extremely facile (entries 1 and 6). In general, as the ring closure becomes slower, other processes such as dimerization may start to compete. Lower concentration disfavors the intermolecular coupling relative to the intramolecular ring closure, and allows clean formation of the products. Raising the temperature to that of refluxing CH_2Cl_2 was necessary only when the substrate was sterically hindered (entries 4 and 5) or the cyclization was very slow (entry 8).

The enthalpies of ring closure (including formation of ethylene) were calculated using the MM2 forcefield and are included in Table 1.[6] In general, if the calculated enthalpy is less than *ca.* 10 kcal mol^{-1}, the ring closure should be favorable due to the entropy gain from the generation of ethylene. An interesting comparision may be made between entry 5 and entry 3, both of which are calculated to have $\Delta H \approx 13$ kcal mol^{-1}. For substrate **1** (entry 5), the kinetic favorability of ring closure for five-membered rings, coupled with the loss of ethylene to the atmosphere, drives the reaction to completion. Note that at higher concentrations (entry 4), the yield is much lower, as a result of a significant amount of polymer being formed, suggesting that endothermic ring closures are possible if the concentration is kept below the critical concentration for polymerization. In the case of the eight-membered ring (entry 3), although the same loss of ethylene would occur, the ring closure is sufficently slow as to be non-competitive with polymerization. Linderman *et al.* have recently reported the use of removable Bu$^t_3$Sn groups to overcome the entropic barrier allowing formation of eight-membered rings,[7] a strategy that could potentially be applied here. The molecular mechanics also suggest that the silyl-protected alcohol plays a small role in the cyclization by decreasing the enthalpy of the ring flip to the bis-axial conformer needed for the ring closure by *ca.* 1 kcal mol^{-1} relative to the unprotected alcohol.

In conclusion, a number of small ring bridged bicycloalkenes have been synthesized from monocyclic dienes, demonstrating the power of ring closing metathesis to form carbocycles that contain a significant amount of strain.

† The substrates were synthesized by addition of the appropriate Grignard reagent to 3-vinylcyclohexanone or cyclopentanone, and protection of the tertiary alcohol with the *tert*-butyldimethylsilyl group. The *cis* and *trans* isomers could be separated for the six- membered ring substrates, but not the five-membered ring substrates. The five-membered ring substrates were cyclized as mixtures and the product separated from the uncyclized *trans* diene by chromatography.

‡ *Typical experiment procedure* for **1**-(*tert*-butyldimethylsilyloxy)-bicyclo[3.3.1]non-6-ene (**2e**). The silyl ether protected diene **1e** (630 mg, 2.25 mmol) was dissolved in 45 ml CH_2Cl_2 and treated with [Cl_2(Cy-$_3$P)$_2$RuCHPh (ref. 5) 92.4 mg, 0.11 mmol, 0.05 equiv.]. The initial red solution rapidly turned light brown, was stirred for 4 h, and the solvent was removed. The brown oil was purified by filtration through silica gel using hexane as the eluent to give a clear oil (540 mg, 2.14 mmol, 95%): δ_H (300 MHz, $CDCl_3$) 0.08 (s, 6 H), 0.86 (s, 9 H), 1.34–1.38 (m, 2 H), 1.45–1.86 (m, 6 H), 2.13–2.32 (m, 2 H), 2.56–2.60 (m, 1 H), 5.52–5.57 (m, 1 H), 5.69–5.74 (m, 1 H); δ_C (75 MHz, $CDCl_3$) −1.7, 17.9, 19.7, 25.8, 28.1, 34.2, 41.0, 42.4, 42.7, 71.9, 127.8, 129.0; ν(film)/cm^{-1} 3023, 2930, 2855, 1472, 1253, 1112, 1013, 835.

Diastereoselective homogeneous hydrogenations without direction by substituents

Edward Farrington,[a] Mauro Comes Franchini[a,b] and John M. Brown*[a]

[a] *Dyson Perrins Laboratory, South Parks Road, Oxford, UK OX1 3QY*
[b] *Dipartimento di Chimica Organica 'A. Mangini', Università degli Studi di Bologna, 40136 Bologna, Italy*

The Rh complex catalysed hydrogenation of an α-(hydroxyalkyl)-*N*-methoxyacrylamide and the Ru complex catalysed hydrogenation of an α-(fluoroalkyl)acrylate both proceed with ⩾90% selectivity to give the *syn*-isomer.

In the directed hydrogenation of alkenes, coordination of a polar functionality to the catalyst leads to enhanced diastereoselectivity in the reduced product. Stereochemical control may arise by complexation of an alcohol, amide, ester or sulfoxide group.[1] The vast majority of substituent-directed diastereoselective reactions follow similar principles.[2] For the common case of an acyclic alkene with an allylic stereogenic centre, a simple model based on the constrained conformation of the complexed alkene **1a** suffices [Fig. 1(*a*)]. This model, for which the torsional angle H–C—**C**=C is 180°, is calculated to be 5 kJ mol^{-1} higher in enthalpy than the rotamer (H–C–C=C = 0°).[3] In the absence of complexation by a polar functional group, diastereoselectivity will be controlled by steric factors. An alternative mode of complexation, shown in Fig. 1(*b*), was required to test this prediction. In practice this was realised by synthesis of the corresponding *N*-methyl-*N*-methoxyamide according to Nahm and Weinreb.[4] In a related unsaturated amide, the preferred conformation of the amide side-chain has N–O *anti* to C=O, thus permitting the desired complexation.[5]

The synthetic route[6] from compound **1a** provides access to both alcohol **2a** and its Bu^{t}Me$_2$Si ether **2b**. Hydrogenation of **2a** was carried out with the Rh complex **3** as previously described[1] in either MeOH or ClCH$_2$CH$_2$Cl and gave a near-equal mixture of *syn*- and *anti*-diastereomers **4a** and **5a** (Scheme 1). This is in contrast to the results observed for hydrogenation of all other α-(hydroxyalkyl)acrylates under related conditions, where the *anti*-isomer predominates. The contrasting result obtained here suggests that there are two competing pathways in hydrogenation which operate in opposite senses, one involving N–O participation, the other O–H participation. Support for this proposal stems from hydrogenation of silyl ether **2b**, which gives 92% of the corresponding *syn*-product **4b**. In separate experiments it was verified that the α-silyloxyalkyl acrylates **1b**–**d** gave mixtures of both *syn*-**6b**–**d** and *anti*-**7b**–**d** on hydrogenation, confirming that the reduced basicity and increased bulk of the silyl ethers attenuates their complexation to rhodium relative to OH. Both the selectivity and the rate depend on the size of the siloxy group in the manner expected if the stereoselectivity is controlled by the relative steric bulk of the substituents at the α-stereogenic centre.

The hydrogenation of compound **2b** can be interpreted in accord with the model in Fig. 1(*b*). It is assumed that the side-chain can adopt its minimum energy conformation with α-C–H eclipsing C=C, and there are then two diastereomeric sets of intermediates which lead on to the diastereomeric products **4b** and **5b**. The proportions will be determined primarily by the perceived bulk of the two non-hydrogen substituents at the stereogenic centre. As would be expected on the basis of relative *A* values (1.79 for Et *vs.* 0.74 for OSiMe$_3$),[7] the ethyl group prefers to be remote from the metal complex (Scheme 2), leading to the observed preference for *syn* hydrogenation.

A further example of *syn*-directed hydrogenation was discovered adventitiously, in a search for fluorine participation in catalysis. There are precedents for C–F activation by several transition metal complexes, but none which demand C–F

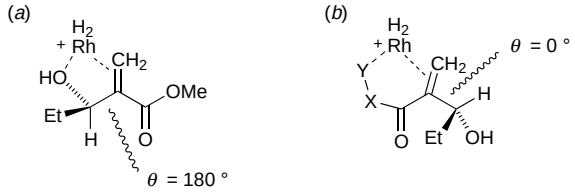

Fig. 1 Alternative reactant chelates in hydrogenation

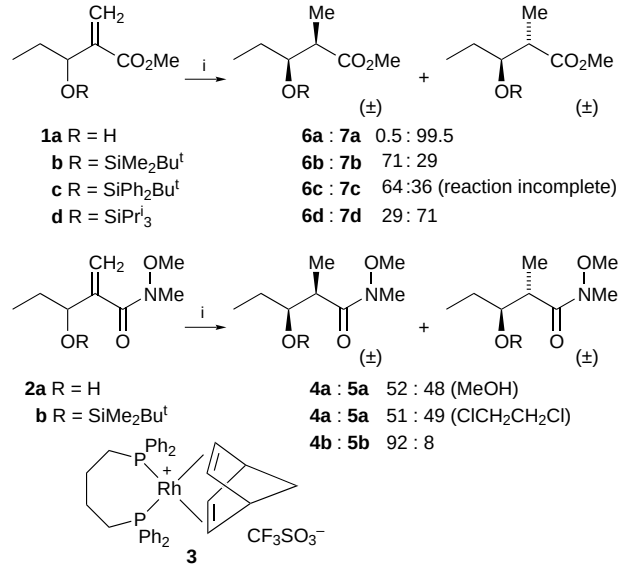
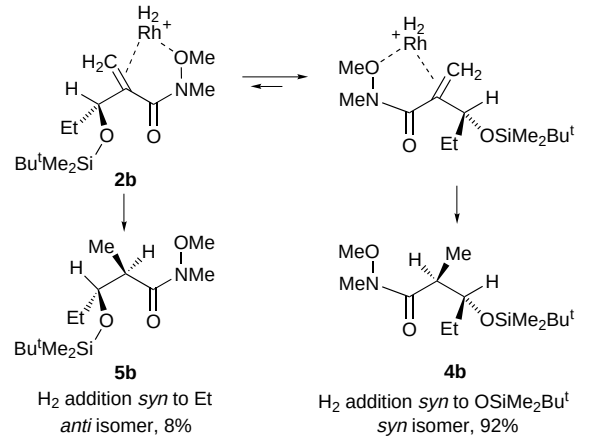
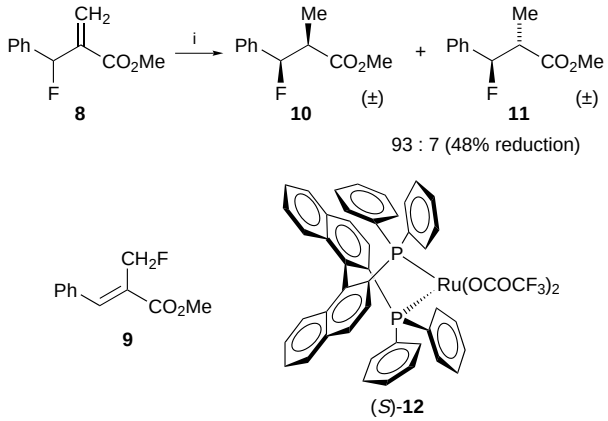


Scheme 1 *Reagents and conditions*: i, **3** (1–4 mol%), H_2 (1.5 atm)



Scheme 2



Scheme 3 *Reagents and conditions*: i, **12** (4 mol%), H_2 (3 atm), ClH_2CCH_2Cl, 40 h

participation to augment the selectivity of a catalytic process. Some examples of C–F···M interactions in organometallic crystal structures, and indeed the only two derived from late transition metals, involve Ru;[8] the Ru···F bond lengths are 2.366 and 2.489 Å, much longer than other bonds from Ru to second-row elements. These observations guided our approach.

The phenyl analogue of compound **1a** reacted with diethylaminosulfur trifluoride (DAST)[9] to produce the corresponding allyl fluoride **8** with *ca.* 5–10% competing allylic isomerisation to the primary fluoride (*Z*)-**9** (Scheme 3). In initial studies it was found that hydrogenation of compound **8** with Crabtree's catalyst[10] (25 °C, 2 atm, CH_2Cl_2) occurred cleanly with low diastereoselectivity. The diastereomers *syn*-**10** and *anti*-**11** were separately identified from independent synthesis of the *anti*-isomer **11** by DAST fluorodehydroxylation of its *anti*- alcohol precursor, which occurred with 75% retention of configuration,[11] verified by spectral comparison with literature assignments which are based on an X-ray analysis.[12] When hydrogenation of the allyl fluoride **8** was carried out with (*S*)- or *rac*-BINAP–Ru complexes **12**, the *syn*-diastereomer **10** was formed as 90% of the reduced product, but in a slow reaction sustained for up to 20 turnovers. The ee of recovered allyl fluoride was low when enantiomerically pure catalyst was employed. Since Ru and Rh give parallel stereoselectivity in directed hydrogenation,[13] this result cannot be the consequence of a fluorine-directed hydrogenation but rather reflects the preferred coordination of the reactant in the C=C–C–H = 0° conformation,[14] and the relative steric size of fluoro and phenyl substituents. The failure to observe clear-cut evidence for C–F participation at a potentially fluorophilic metal site has origins related to the reluctance of C–F to act as an hydrogen-bond acceptor.[15]

It has been a general rule that diastereoselectivity in organometallic catalysis requires substituent participation through complexation.[1,2] Although modest specificity has been obtained here, it is useful to realise that significant stereocontrol in homogeneous hydrogenation can arise from the intrinsic conformational preferences of the reactant.

We thank Dr Uma Sharma for NMR experiments and Johnson-Matthey for loans of precious metal salts. Dr D. J. Bayston made useful suggestions. A visit by M. C.-F. to Oxford was supported by the European Community HCM programme (CRTX-920067).

Organically templated layered uranium(VI) phosphates: hydrothermal syntheses and structures of $[NHEt_3][(UO_2)_2(PO_4)(HPO_4)]$ and $[NPr_4][(UO_2)_3(PO_4)(HPO_4)_2]$

Robin J. Francis,[a] Mark J. Drewitt,[a] P. Shiv Halasyamani,[a] Charusheela Ranganathachar,[a] Dermot O'Hare,*[a]† William Clegg[b] and Simon J. Teat[b]

Two organically templated layered uranium(VI) phosphates have been prepared under hydrothermal conditions from U_3O_8 and H_3PO_4 using either NPr_4^+ or $NHEt_3^+$ ions as structure directing agents; both compounds have layered structures which contain infinite chains of edge-sharing $[UO_7]$ pentagonal bipyramids cross linked by bridging $[PO_4]$ tetrahedra to form two dimensional sheets of $[(UO_2)_n(HPO_4)_{n-1}(PO_4)]_m^{m-}$ anions.

Crystalline layered and microporous phosphates have attracted great attention owing to their rich chemistry based on the intercalation, ion-exchange, or absorption of guest molecules into the host framework.[1,2] This has led to interest in the synthesis of new metal phosphates with novel layered and open-framework structures. Recently a wide variety of new compounds have been synthesized in which metals such as Be,[3] Ga,[4] In,[5] Zn,[6] V,[7] Fe,[8] Co,[9] and Mo[10] have been incorporated into the phosphate framework. When the syntheses are performed under hydrothermal conditions in the presence of organic templates both layered and microporous phases are formed, which often display unusual framework topologies. To date, however, we are not aware of any organically templated hydrothermal syntheses of new phosphate materials incorporating actinide elements. It is expected that the incorporation of bulky organic templates in an actinide phosphate framework could result in new and unusual framework topologies. Clearfield and co-workers have synthesised a number of uranyl phosphonates in which the presence of the bulky organic substituents on the phosphonate groups leads to the formation of novel structure types.[11,12] We have been exploring the hydrothermal synthesis of uranium phosphate based materials in the presence of organic templates. We report here the synthesis and structural characterization of the first examples of organically templated layered uranium(VI) phosphates to be isolated, namely $[NHEt_3][(UO_2)_2(PO_4)(HPO_4)]$ **1** and $[NPr_4][(UO_2)_3(PO_4)(HPO_4)_2]$ **2**.

Single crystals of **1** were grown by heating mixtures of composition $U_3O_8 : 9H_3PO_4 : 3NEt_3 : 240H_2O$ under autogenous hydrothermal conditions in Teflon lined autoclaves at 180 °C for 3 d.‡ The crystals formed as flat plates together with a small amount of microcrystalline impurity. Single crystals of **2** were grown by heating mixtures of composition $U_3O_8 : 6H_3PO_4 : 3NPr_4OH : 240H_2O$ at 180 °C for 3 d.‡ The crystals formed as thin needles together with a small amount of a microcrystalline impurity.

Compound **1** adopts a layered structure§ in which the two unique U atoms are both coordinated in a slightly distorted pentagonal bipyramidal arrangement by seven O atoms, a common coordination environment for U. The axial O and the U atoms form almost linear [angles of 178.8(4)° and 169.1(3)°] uranyl UO_2^{2+} units with a mean U–O distance of 1.77 Å with the five equatorial O at a larger mean distance of 2.40 Å. These values are typical for U^{VI} in this coordination environment.[13] Valence sum calculations are consistent with this assignment.[14] Zigzag $PaCl_5$ type chains are formed along the (101) direction by UO_2O_5 pentagonal bipyramidal units sharing opposite edges. $(UO_2O_5)_n$ chains such as these are a common structural unit found in other uranium oxides and phosphates such as α-U_3O_8, UVO_5,[15] $U_2V_2O_{11}$,[15] and $U(UO_2)(PO_4)_2$.[16] Individual chains are cross-linked through O atoms of bridging tetrahedral phosphate units to form a corrugated layer structure in the [010] plane. Each phosphate group bonds to a U atom in one chain *via* two O atoms and also bonds to a second U atom in an adjacent chain *via* a third O atom (Fig. 1). The fourth O of the phosphate group does not bridge but instead projects above and below the phosphate layers. These layers are stacked along the (010) direction and are separated from adjacent layers by charge balancing $NHEt_3^+$ cations to form a structure consisting of alternating inorganic and organic layers. The separation between adjacent phosphate layers is 9.2 Å. To maintain charge balance, one of the phosphate groups must be protonated, giving the indicated formula $[NHEt_3][(UO_2)_2(PO_4)(HPO_4)]$. The IR spectrum of **1** also revealed broad weak bands at 2750 and 1620 cm^{-1} that are consistent with P–OH vibrations. The location of the OH proton could not be determined from the X-ray analysis, and a consideration of the P–O distances did not reveal any obviously longer bonds indicative of a P–OH group. The P–O distances range from 1.50(1) to 1.56(1) Å with an average of 1.54 Å. However, valence sum calculations indicate that the terminal O atoms projecting above and below the layers have unsatisfied valence and these calculations are consistent with the assumption that the proton is likely to be located on these atoms. However, it is not possible to determine which of the two unique phosphate groups contains the OH group. It seems likely that the H is disordered over both sites.

Compound **2** also forms as a layered structure.§ As in **1** the layers consist of $PaCl_5$ type $(UO_2O_5)_n$ chains formed from edge sharing pentagonal bipyramidal (UO_2O_5) units which are then further cross-linked by phosphate groups to form uranium

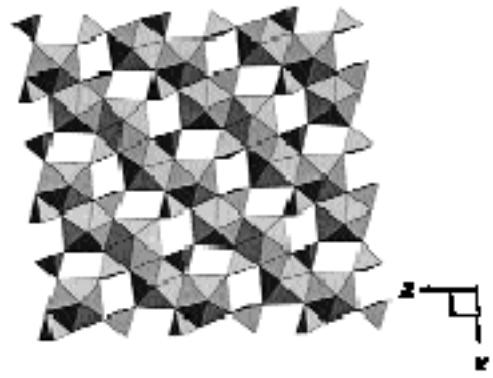

Fig. 1 A view of the structure of the layers in $[NHEt_3][(UO_2)_2(PO_4)(HPO_4)]$ **1** parallel to the *b* axis, showing the chains of edge-sharing $[UO_7]$ pentagonal bipyramids and bridging $[PO_4]$ tetrahedra

phosphate layers similar to those in **1** in the [01$\bar{1}$] plane. There are three unique U atoms in the asymmetric unit. The coordination around all three is again typical for a U^{VI} atom in this environment, with a mean uranyl U–O distance of 1.75 Å and a mean equatorial U–O distance of 2.40 Å. Valence sum calculations are consistent with this assignment.[14] Each tetrahedral phosphate group bonds to one U atom *via* two O atoms and another U atom in the next $(UO_2O_5)_n$ chain *via* a third O atom. The fourth O atom projects above and below the phosphate layers. Each phosphate layer is separated from the next by intercalated NPr_4^+ cations forming alternating inorganic–organic layers along the (01$\bar{1}$) direction. The separation between adjacent phosphate layers is 12.2 Å. As in **1**, to maintain charge balance the existence of protonated P–OH groups must be inferred.

Although the coordination of the uranium and phosphate species in both **1** and **2** are the same, subtle differences in the geometry of the bridging phosphate groups leads to differences in the structures of the layers. In **1** chains of bridging phosphate groups running along the (100) direction [*ca*. 45° to the $(UO_2O_5)_n$ chains] have terminal P–O bonds that either stick 'up' or 'down' from the layers in a strictly alternating [all-up : all-down : all-up] manner along the (001) direction. However, in **2** the same chains of bridging phosphates alternate in the sequence [all-up : both up and down : all-down] along (011). This has the effect that in **1** the layers are corrugated in an approximately sinusoidal manner, whereas in **2** the layers consist of approximately flat sections connected by 'steps' (Fig. 2).

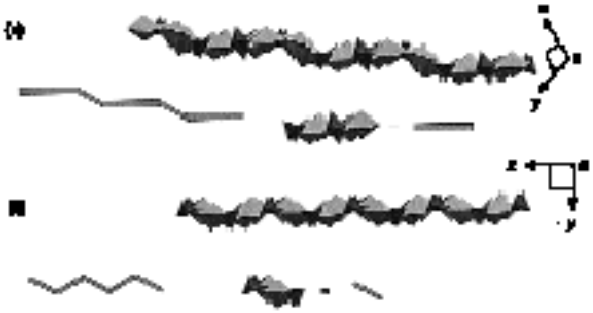

Fig. 2 View of a single layer of $[(UO_2)_n(HPO_4)_{n-1}(PO_4)]^-$ in **1** (*a*) and **2** (*b*) along the (100) direction; also shown is a schematic representation of the layer structure

The charged framework and large interlayer spacing found in these materials suggested that they may be capable of undergoing ion-exchange reactions with other charged species. Preliminary experiments indicate that the template molecules can indeed be exchanged for a variety of alkali metal, transition metal and other quaternary ammonium cations, such as Na^+, Co^{2+} and NMe_4^+, whilst still retaining the integrity of the uranium phosphate layers.

The isolation and characterization of **1** and **2** demonstrate that organic templates can be used to hydrothermally synthesize new hybrid inorganic–organic uranium phosphate materials in which the structure directing organic species is incorporated into the U/P/O framework. Furthermore, these materials show that the detailed structure of the inorganic layers can be influenced by the precise nature of the organic template used. Given the variety of coordination modes and framework topologies[13] displayed by uranium minerals and inorganic phases, there appears to be much scope for synthesizing new materials displaying novel structural features and properties using this methodology. We are currently investigating further the absorption, catalytic, and ion-exchange properties of **1** and **2**.

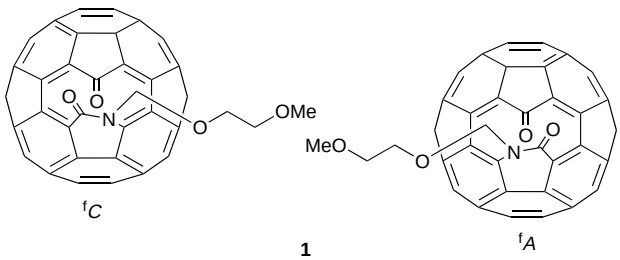
The enantiomers of the first cagewise *inherently* asymmetric C_{60} derivative, *i.e.* *N*-MEM (MEM = 2-methoxyethoxymethyl) keto lactam 1, have been separated by HPLC and their chiroptical properties compared with data obtained from C_{60} derivatives that are dissymmetric or asymmetric due to chiral addends.

N-MEM keto lactam **1** (Fig. 1) is the first example of a well-defined open-cage derivative of C_{60}.[1] It is obtained from C_{60} in two synthetic steps, and (±)-**1** serves as the key intermediate in the synthesis of azafullerenes, *e.g.* $(C_{59}N)_2$,[2] $C_{59}NH$[3] and $K_6C_{59}N$.[4] Stereochemically, **1** is an interesting molecule, because it can be regarded as a (highly symmetrical) sphere with a chiral orifice. A larger version could be envisioned as a chiral selector, operating by enantioselective endohedral complexation.

Various chiral C_{60} derivatives have been prepared thus far.[5,6] Chirality can be introduced into C_{60} derivatives *via* chiral addends, either asymmetric[7,8] or C_2-symmetric,[9] as well as *via* an inherently asymmetric addition or substitution pattern, such as in 2 : 1 adducts with C_2-symmetry.[10,11] Higher fullerenes and carbon nanotubes can be inherently chiral.[12] C_2 C_{76}, D_3 C_{78} and D_2 C_{80} have been obtained in enantiomerically pure form *via* kinetic resolution by asymmetric osmylation, providing optically active forms of carbon.[13] Since keto lactam **1** is the first open-cage C_{60} derivative with an inherently asymmetric cage functionalization pattern, it is of interest to determine a possible resemblance of the chiroptical properties of **1** with those of the chirally modified C_{60} compounds. Here we present the successful resolution of (±)-**1** and the chiroptical properties of the individual enantiomers.

Chromatography of racemic **1**[1] as a 0.3 mg ml^{-1} solution in toluene–1,2-dichlorobenzene (2 : 1 v/v) on an analytical chiral stationary phase HPLC column [Bakerbond Pirkle Type DNBPG 5 μm (4.6 × 250 mm)], using *n*-hexane–$CHCl_3$–Pr^{i}OH (70 : 30 : 1 v/v/v) as the eluent (flow rate 1 ml min^{-1}) and UV detection at λ = 328 nm, gave enough separation to yield the enantiomers in 80 and 92% ee (as inferred from a second HPLC experiment, Fig. 2), respectively. The two fractions were assigned to (+)-**1** and (−)-**1**, respectively, by determining their specific rotations at 589 nm.



1

Fig. 1 Molecular structure of the two enantiomeric forms of **1** with configurational description ^fC and ^fA according to ref. 6

The UV–VIS spectrum of (±)-**1**, the circular dichroism (CD) spectrum and the resulting *g* value ($g = \Delta\varepsilon/\varepsilon \approx \Delta A/A$) of (+)-**1** are shown in Fig. 3. The CD spectrum of (−)-**1** was found to have a mirror image relation to that of (+)-**1**. Similar to the UV–VIS absorption, the CD spectrum of (+)-**1** extends throughout the 200–700 nm spectral range. The strongest Cotton effect is found at λ = 325 nm ($\Delta\varepsilon$ = +29 M^{-1} cm^{-1}), coinciding with the lowest energy dipole-allowed transition of **1** (λ = 328 nm). Comparison with, for example, (+)-hexahelicene, which has a *g* value of +7.0 × 10^{-3} at λ = 325 nm for the π–π* transition, shows however that the *g* value of (+)-**1** (g_{325} = +6.4 × 10^{-4}) is an order of magnitude lower and represents a typical value for a noninherently dissymmetric chromophore.[14] Various chirally modified [6,6]-dihydrofullerene derivatives show a diagnostic CD band at about λ = 430 nm, whose sign has been taken as an indicator for the absolute configuration.[8,15–17] For (+)-**1**, a local extreme in the CD spectrum is found at λ = 426 nm, where the Cotton effect is negative. Tentatively applying the sector rule of Wilson *et al.* to **1** suggests that (+)-**1** corresponds to the ^fA configuration (Fig. 1).[15] The largest *g* values of (+)-**1** are found in the wavelength range λ = 600–700 nm, with a maximum of $g = -1.7 \times 10^{-2}$ at 659 nm, a typical value for a magnetically-allowed dipole-forbidden transition.

In summary, we have separated the two enantiomers of the C_{60} derivative (±)-**1** using chiral HPLC, providing a first example of an open-cage fullerene with a chiral orifice. The inherently chiral functionalization of the eleven-membered ring causes a dissymmetric perturbation on the π system of the fullerene, resulting in optical activity extending over the entire

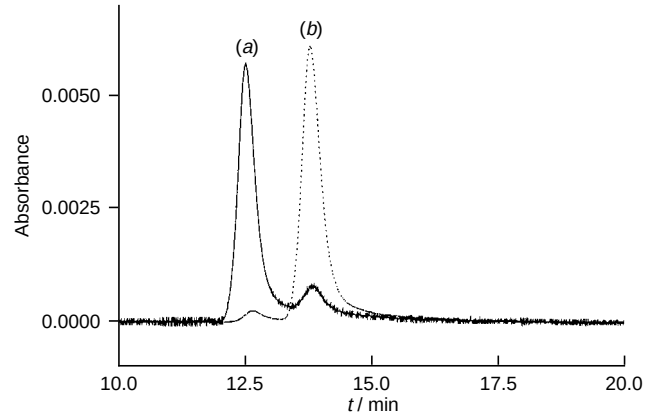


Fig. 2 Chiral HPLC chromatogram of separated samples of (*a*) (+)-**1** and (*b*) (−)-**1** (Bakerbond Pirkle Type DNBPG, eluent: *n*-hexane–$CHCl_3$–Pr^{i}OH (70 : 30 : 1 v/v/v), flow rate 1 ml min^{-1}, UV detection at λ = 328 nm)

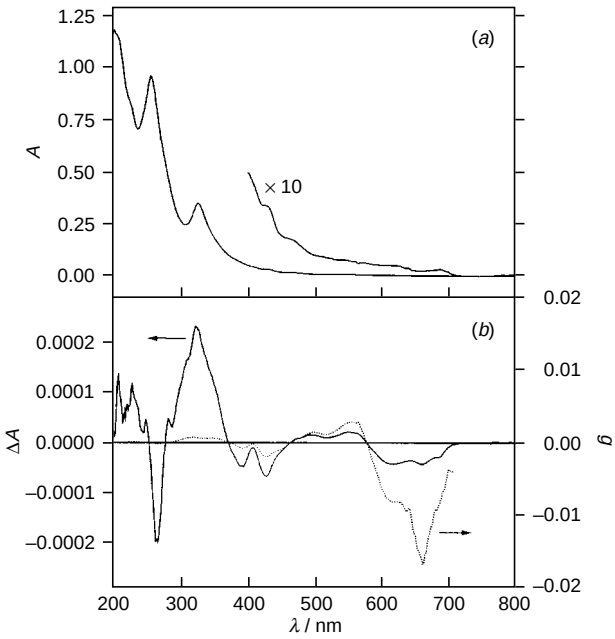

Fig. 3 (*a*) UV–VIS absorption spectrum of (±)-**1** ($c = 7.6 \times 10^{-6}$ M) [λ_{max}/nm = 204 ($\varepsilon = 1.5 \times 10^5$ M^{-1} cm^{-1}, *n*-hexane), 260 (1.2×10^5, $CHCl_3$), 328 (4.5×10^4, $CHCl_3$), 428 (4.7×10^3, $CHCl_3$) and 688 (4.2×10^2, $CHCl_3$)]. (*b*) CD spectra (left axis) and *g* value (right axis) of (+)-**1** ($c = 7.6 \times 10^{-6}$ M). The UV–VIS and CD spectra were recorded using a solution in *n*-hexane for the region $\lambda = 200$–248 nm and in $CHCl_3$ for the region $\lambda = 248$–800 nm. The $CHCl_3$ spectra were recorded at higher concentrations and mathematically scaled to the spectrum in *n*-hexane for representation.

absorption spectrum, with high *g* values in the low-energy region.

Dedicated to Professor Dr Hans Wynberg on the occasion of his 75th birthday on 28th November 1997.

Macrocyclic aromatic thioether sulfones

Ian Baxter,[a] Howard M. Colquhoun,[b]† Philip Hodge,[c]‡ Franz H. Kohnke,[c]§ and David J. Williams[a]

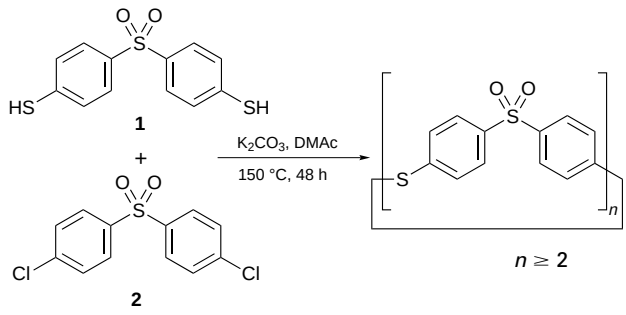
Reaction of 4,4′-sulfonylbis(thiophenol) with 4,4′-dichlorodiphenyl sulfone under pseudo-high-dilution conditions leads to a novel family of all-*para* macrocyclic thioether sulfones [-SϕSO$_2$ϕ-]$_n$ (ϕ = 1,4-phenylene); these include a highly strained [1 + 1] cyclodimer (*n* = 2), a cyclotrimer resulting from thioether exchange reactions, and a [2 + 2] cyclotetramer which can adopt two distinctly different conformations, one having molecular D_{2d} ('tennis-ball-seam') symmetry, in the crystalline state.

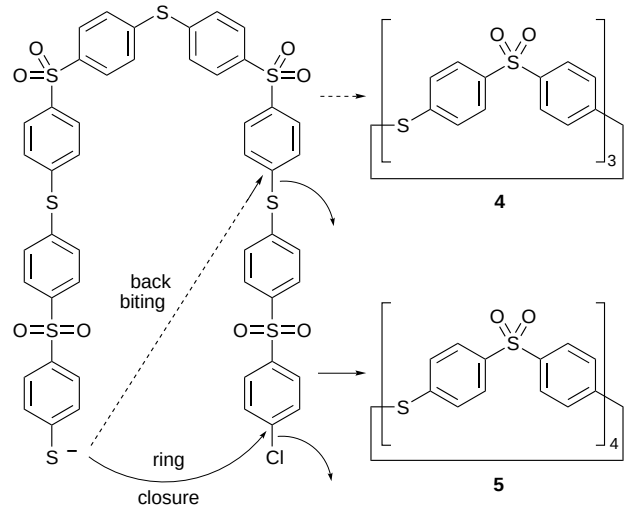
There is considerable and growing interest in the synthesis and ring-opening polymerisation chemistry of macrocyclic aromatic ethers[1] and thioethers.[2] The very low viscosities of such macrocycles, together with the absence of by-products during polymerisation, offer new possibilities for *in situ* fabrication of high-performance materials. We now report the discovery of a new class of potentially polymerisable macrocyclic aromatic thioethers, including an extremely strained cyclodimer, formed by polycondensation of 4,4′-sulfonylbis(thiophenol) **1**[3] with 4,4′-dichlorodiphenyl sulfone **2** under pseudo-high-dilution conditions.

A dimethylacetamide (DMA) solution containing equimolar quantities of **1** and **2** (0.13 M in each) was added *via* syringe-pump over 48 h to a refluxing suspension of K_2CO_3 in DMA–benzene (7.5 : 1, v/v). By-product water from the reaction was continuously removed by azeotropic distillation of benzene. After a further 2 h the reaction mixture was cooled and the products precipitated in water. Analysis by HPLC and FAB-mass spectrometry demonstrated the formation of a new family of macrocyclic oligomers [-SϕSO$_2$ϕ-]$_n$ (ϕ = 1,4-phenylene) in *ca*. 30% yield (Scheme 1), the remaining material being high molecular weight polymer. The principal macrocyclic product (*ca*. 15% yield) is the cyclic trimer, a result which indicates that cyclisation must be accompanied by extensive thioether exchange. Macrocycles where *n* is odd cannot be formed directly by condensation of **1** and **2**, and must therefore arise by redistribution or back-biting reactions (Scheme 2).

Extraction of the product mixture with $CHCl_3$ followed by gradient elution column chromatography on silica gel with CH_2Cl_2–EtOAc as eluent allowed several of the macrocyclic oligomers to be isolated as pure crystalline compounds, including the cyclodimer [-SϕSO$_2$ϕ-]$_2$ **3**, the cyclotrimer **4** and the cyclic tetramer **5**. Macrocycles were identified by ^{13}C and



Scheme 1



Scheme 2

^{1}H NMR spectroscopy and FAB-mass spectrometry. The cyclic trimer and tetramer give ^{1}H NMR spectra virtually identical to that of the linear polymer [-SϕSO$_2$ϕ-]$_n$, which shows a well-resolved AA′BB′ system at δ 7.85, 7.82, 7.44 and 7.41. In contrast, the ^{1}H NMR resonances for cyclic dimer **3**, where the effects of ring-closure are likely to be greatest, occur in a very much narrower range at δ 7.61, 7.58, 7.55, and 7.52.

The structures of **3**, **4** and **5** were investigated by single crystal X-ray methods.¶ The cyclic dimer **3** adopts a centrosymmetric, box-like conformation (Fig. 1) in which adjacent aromatic rings are orthogonal to within 1°. Although this 'open-book' type of conformation is well established in diaryl sulfones,[4] diaryl thioethers have up until now invariably displayed a 'skewed' conformation, even in the related cyclic oligomer [1,4-C$_6$H$_4$S]$_4$.[5] It thus appears to be the conformational preferences of the sulfone linkage which dominate the present structure.

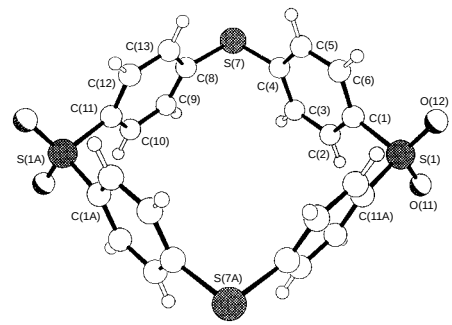


Fig. 1 Molecular structure of the cyclic dimer **3**: bond angles within the macrocycle at S(1) and S(7) are 101.4(2) and 96.4(2)°; the C(1)–C(6) and C(8)–C(13) rings are inclined by 88 and 81°, respectively, to the plane of the four sulfur atoms

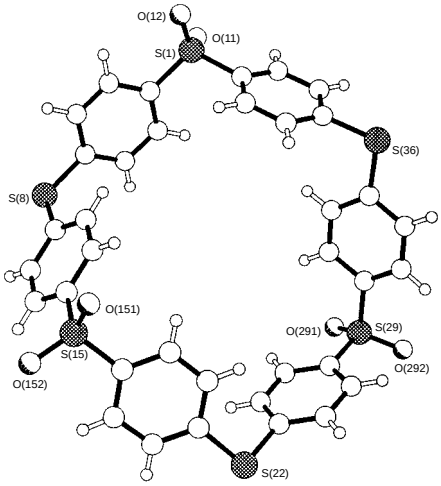

Fig. 2 Molecular structure of the cyclic trimer **4**: bond angles within the macrocycle at the sulfone sulfur atoms S(1), S(15) and S(29) are 105.7(4), 106.5(4) and 105.1(5)°, and those at the thioether sulfur atoms S(8), S(22) and S(36) are 101.5(4), 101.1(5) and 103.0(5)°

In the cyclic dimer **3**, C–S–C bond angles at thioether and sulfone are compressed by some 8 and 3°, respectively, from their normal open-chain values around 105°. Moreover, a distinct 'bowing' of the macrocycle is evident such that 1,4-related C–S bonds, which would normally be co-linear, here subtend an angle of *ca*. 171°. The very low yield of cyclodimer **3** (< 1%) thus clearly reflects the high strain-energy associated with formation of a cyclic thioether–sulfone oligomer containing only two repeat units.

The cyclotrimer **4** and cyclotetramer **5** were isolated in very much higher yields (*ca*. 15 and 10%, respectively), but despite the increased ring size, there is still evidence of some steric strain in the structure of **4**, all three independent thioether C–S–C bond angles being compressed by *ca*. 3° (Fig. 2).

The cyclic tetramer **5** adopts two entirely different conformations in the solid state, depending on the solvent of crystallisation. In the benzene solvate (**5a**) the oligomer displays a rather flattened conformation with the macrocyclic cavity being occupied by two of the five solvating benzene molecules. In another solvate (**5b**), however, the macrocycle adopts a 'tennis-ball-seam' conformation having non-crystallographic D_{2d} symmetry (Fig. 3). The solvent in **5b** is very substantially disordered and appears to comprise a mixture of both solvents used in its recrystallisation ($CHCl_3$ and CH_2Cl_2), limiting the overall precision of the structure. It is nevertheless evident from their bond and torsion angles that both **5a** and **5b** are virtually unstrained. In both conformers all diphenyl sulfone units have the conventional open-book geometry, so that interconversion between the two structures may be achieved simply by rotation about the thioether linkages.

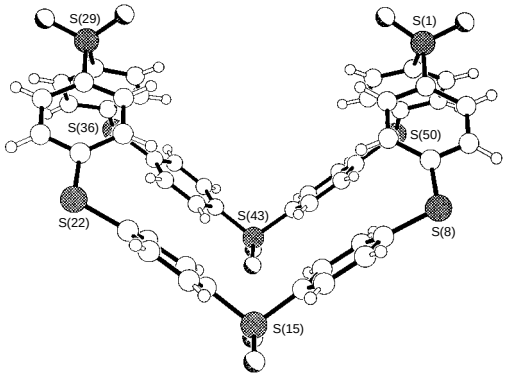

Fig. 3 The D_{2d} ('tennis-ball-seam') conformation adopted by the cyclic tetramer **5** in solvate **5b**: bond angles within the macrocycle at the sulfone sulfur atoms S(1), S(15), S(29) and S(43) are 103.7(4), 104.9(3), 103.9(3) and 104.6(3)°, and those at the thioether sulfur atoms S(8), S(22), S(36) and S(50) are 104.5(4), 104.3(4), 104.0(3), and 106.3(3)°

We have found that peroxide oxidation of the cyclic thioether sulfones $[\text{-S}\phi\text{SO}_2\phi\text{-}]_n$ affords a further series of macrocycles $[\text{-}\phi\text{SO}_2\text{-}]_{2n}$. These novel, cyclic oligomers of the highly crystalline and intractable polymer poly(1,4-phenylene sulfone)[6] will be described in a future communication.

We thank the Engineering and Physical Sciences Research Council for financial support of this research.

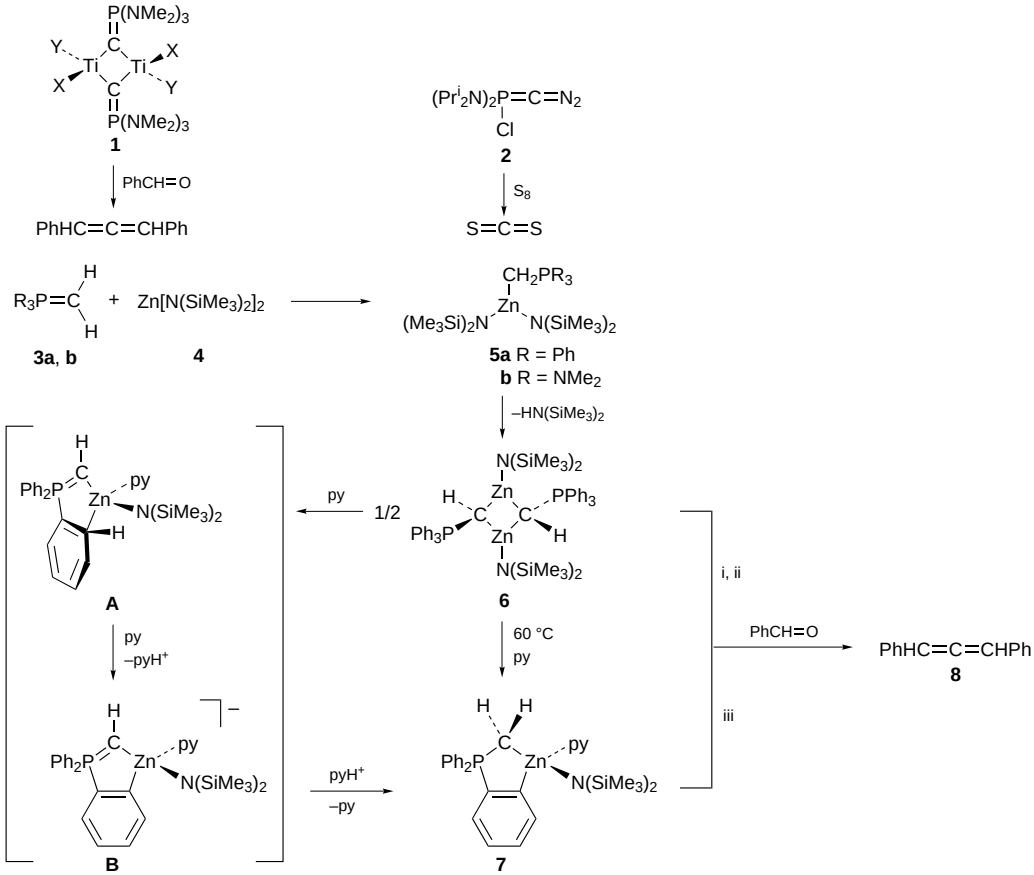
1,3-Dizincata-2,4-diphosphoniacyclobutane rearranges into a zincataphosphoniaindane which reacts with benzaldehyde to give 1,3-diphenylallene.

By reacting phosphorus ylides (R = aryl) with mercury bis(trimethylsilyamide) we found a simple synthesis of α-mercurated phosphorus ylides, $Ph_3P{=}CR[HgN(SiMe_3)_2]$, which react in a Wittig type alkenation reaction with aldehydes to give vinylmercury compounds.[1] We explored the possibility of synthesising comparable organozinc compounds in a similar way. These reagents seemed promising to us since they contain two oxophilic sites (P and low coordinated Zn) for the attack of a carbonyl oxygen centre. Like titanacycles **1**[2] or allenic diazophosphorus ylides **2**[3] they may serve as synthons for carbon atoms (Scheme 1). In the course of the studies, we observed an unprecedented cyclometallation reaction[4] involving, presumably, a low coordinated zinc centre.

When a toluene solution of ylides **3a**,**b** is added to zinc amide **4** at room temp. in toluene the expected adducts[1] **5a**,**b** are formed. They can be isolated as colourless precipitates after short reaction times (10 min) by concentrating the volume of the reaction mixture to 20% and adding *n*-hexane.†

While **5a** is thermally unstable, **5b** could be recrystallised from *n*-hexane and its structure determined by an X-ray analysis.‡ All bonds [av. Zn–N 1.956(3) Å, Zn–C 2.077(4) Å] to the slightly pyramidalised zinc centre (0.138 Å above the N(1)N(2)C(1) plane] are *ca.* 0.1 Å longer than comparable Zn–N (av. 1.857 Å) and Zn–C (av. 1.952 Å) bonds in other tricoordinated zinc compounds.[5] The P(1)–C(1) distance [1.738(3) Å] is slightly longer than corresponding distances in a lithium phosphorus ylide complex[6] (P–C 1.702 Å) or uncomplexed ylides themselves (*i.e.* **3a**: 1.693 Å).[7] Keeping solutions of **5a** at room temp. or adding pyridine causes loss of 1 equiv. of $HN(SiMe_3)_2$ and leads almost quantitatively to zincatacyclobutane **6** which precipitates as colourless crystals from the reaction mixture. Compound **6** can be recrystallised from THF–*n*-hexane (1 : 6 v/v). X-Ray analysis of **6**‡ reveals a four-membered planar centrosymmetric Zn_2C_2 heterocycle in which the Ph_3PCH units adopt bridging positions between the tricoordinated zinc centres. The Zn–N [1.931(3) Å] and Zn–C distances [2.068(4) Å] being again longer than in other low coordinated zinc compounds compare well with the ones in **5b**. The Zn–C–Zn angles [84.5(1)°] are smaller than the C–Zn–C angles [95.5(1)°]. In order to extrude 1 more equiv. of



Scheme 1 *Reagents and conditions*: i, 60 °C, 24 h, no py, 7%; ii, 60 °C, 16 h, py, 12%; iii, 60 °C, 16 h, 31%

$HN(SiMe_3)_2$ we warmed **6** to 60 °C in presence of pyridine. A clean reaction was evidenced by one new ^{31}P resonance at δ 34.8 (**6**: δ 25.9). The new product **7** was purified by recrystallization from toluene–*n*-hexane and completely characterised including an X-ray analysis. In order to explain the formation of zincataphosphoniaindane **7**, we assume that pyridine cleaves the four-membered Zn_2C_2 heterocycle **6** to give intermediate **A** which corresponds to an η^1-arene complex to an electrophilic metal centre. Precedence for such a Zn–arene interaction is found in $ZnPh_2$ which forms a trapezoid dimer in the solid state with two *ipso*-carbon centres of the phenyl substituents adopting an unsymmetrical bridging binding mode (Zn–C 2.01, 2.40 Å).[8] Being an intramolecular organometallic σ-complex, **A** possesses a *ortho*-hydrogen centre which becomes sufficiently acidic to be abstracted by pyridine to give intermediate **B**. Reprotonation at the C(1) centre yields the thermodynamically more stable product **7**. Unfortunately, we could not isolate compound **B** by deprotonation of **7** with a strong base like $NaN(SiMe_3)_2$. Earlier work showed that **1a** may be lithiated by Bu^nLi either at the CH_2 group or at the *ortho*-position of one of the phenyl groups attached to the phosphorus centre.[9] Our results confirm that the first product may be obtained under kinetic control while the second one is thermodynamically more stable.

When zincatacyclobutane **6** is reacted with 4 equiv. of benzaldehyde in toluene at 60 °C, a pale yellow oil is obtained after hydrolysis from which *ca.* 7% diphenylallene **8** were isolated by column chromatography (*n*-pentane–Et_2O 7 : 1 v/v). Other products could not be identified. If the reaction is performed in presence of pyridine, the yield of allene **8** is augmented to 12%. Suspecting compound **7** may be involved in the formation of allene we reacted the zincataindane **7** with 2 equiv. of benzaldehyde. Indeed, the allene was formed in 31% yield. The mechanism of the seemingly simply Wittig alkenation is still not known with certainty[10] and our results show that reactions between metallated ylides and carbonyl compounds may be even more complex.

The structure of **7** is shown in Fig. 1. The five-membered heterocycle including a tetrahedrally distorted coordinated, chiral zinc centre (racemic mixture in the crystal) adopts an envelope conformation [angle between P(1)C(1)Zn and the ZnC(3)C(2)P plane = 30°].

The Zn–C(3) (aryl) bond length [2.049(3) Å] is normal while the Zn–C(1) (alkyl) bond [2.138(4) Å] is long. The Zn–$N(SiMe_3)_2$ bond [1.982(3) Å] is 0.1 Å shorter than the Zn–N_{py} bond. Owing to electrostatic interactions between the negatively charged carbon center C(1) (being bonded to the electropositive Zn centre) and the highly positively charged λ^5,σ^4-phosphorus centre, the P–C(1) (sp^3) bond [1.732(4) Å] is significantly shorter than the P–C(2) (sp^2) bond [1.803(3) Å].

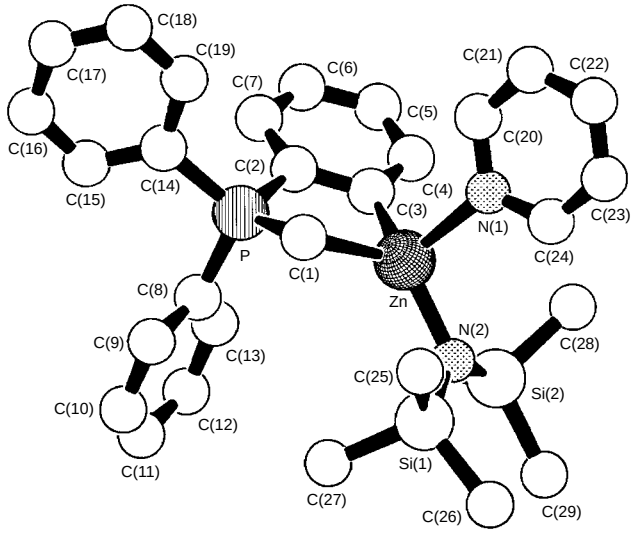


Fig. 1 Molecular structure of **7**: hydrogen atoms have been omitted for clarity. Selected bond lengths (Å) and angles (°): Zn–N(1) 2.174(3), Zn–N(2) 1.982(3), Zn–C(1) 2.137(4), Zn–C(3) 2.050(3), P–C(1) 1.733(4), P–C(2) 1.803(3), C(2)–C(3) 1.409(4); N(1)–Zn–N(2) 103.4(1), N(1)–Zn–C(1) 101.5(1), N(1)–Zn–C(3) 102.2(1), N(2)–Zn–C(1) 122.4(1), N(2)–Zn–C(3) 130.1(1), C(1)–Zn–C(3) 92.9(1), Zn–C(3)–C(2) 113.3(2), C(3)–C(2)–P 114.9(2), C(1)–P–C(2) 108.3(2), P–C(1)–Zn 100.8(2).

Self-organization of small organic molecules in liquids, solutions and crystals: static and dynamic calculations

A. Gavezzotti[a]† and G. Filippini[b]

[a] *Dipartimento di Chimica Strutturale e Stereochimica Inorganica, University of Milano, via Venezian 21, 20133 Milano, Italy*
[b] *Centro CNR per lo Studio delle Relazioni tra Struttura e Reattività Chimica, University of Milano, via Golgi 19, 20133 Milano, Italy*

The phase behaviour of organic compounds is at the same time rich, appealing and complicated. From the properties of the pure liquid, to molecular recognition, aggregation and nucleation, both as a liquid and in solution, a number of different paths can be followed whose thermodynamics and kinetics are still to a large extent a mystery. Very little is known at a molecular level about the selective process that causes some nuclei to grow into crystals, while other aggregates are unproductive; similarly, the molecular details of the melting and dissolution processes are missing. Since the dimensions of objects and the timescale of events are scarcely or not at all accessible to experiment, computational simulation seems a viable alternative for the investigation of these phenomena.

Introduction

Modern chemistry has developed an extraordinary capability in the manipulation of molecular structures, and the synthesis of compounds of unusual or extreme chemical bonding (*e.g.* cubane), or stereochemical fine tuning (*e.g.* the total synthesis of taxol) are now within the range of possible, if not common, achievement. However, much less progress has been made in the control of molecular aggregation, and very little is known about the mechanisms of such commonplace events as melting, nucleation, growth and crystallization from the pure liquid or from solution. The main reason for this uneven development is that ordinary chemical bonding occurs in the range 10^2–10^3 kJ mol^{-1}, while molecular recognition and condensation lie in the range 10^0–10^1 kJ mol^{-1}; transformations among bonding patterns have therefore a much more predictable and reproducible course than intermolecular rearrangements, whose energetic landscape is but slightly undulated.

Of course, X-ray diffraction on single crystals has provided a tremendous amount of direct structural information on solids, and has fostered great advances also in our understanding of intermolecular interactions. Liquids and solutions are much less amenable to such detailed analysis, and, correspondingly, our knowledge of their intimate structure and properties is much less developed. It is perhaps obvious that studying intermolecular phenomena requires a knowledge of intermolecular potential energies and forces, out of which the fabric of macroscopic objects is woven. It is perhaps less frequently appreciated that thermal (*i.e.* kinetic) energy and entropy are also involved in determining the behaviour of matter. A 1985 textbook[1] appropriately stated: 'there is a big gap between knowing what the forces between two isolated molecules are and understanding how an assembly of such molecules will behave . . . even today there is no simple formula for deriving the properties of condensed phases from their intermolecular potentials . . .'. Much of this review will be devoted to the use of computer resources to bridge that gap and understand that derivation.

A first conceptual divide is the distinction between methods which explicitly include kinetic energy and account for thermal motion, and those which do not. For example, quantum chemical (QC) calculations can reproduce or predict structures, energies and activation barriers, but not the effects of thermal libration. The same applies to empirical calculations dealing, for example, with lattice energies of crystals and energy differences between polymorphs, using crystal structures frozen in the configuration derived from X-ray diffraction analyses or from some geometrical structure-guessing procedure. The effects of molecular librations may be somehow incorporated in the force field parameters, by calibrating them to reproduce specific volumes, but the description of libration itself is missing in the entirely static setup of both parametrization and modeling: all such calculations formally refer to a temperature of 0 K. Monte Carlo (MC)-type calculations include to some extent thermal energies, in that the Metropolis algorithm introduces a temperature-dependent Boltzmann factor for acceptance or rejection of phase space sampling steps. A full account of the dynamical evolution of a system under the action of potentials and including kinetic energies is given only by molecular dynamics (MD) calculations, which, at least in principle, allow a complete sampling of phase space and a *de novo* derivation of structural, thermodynamic and kinetic parameters.

The availability of accurate and easily applicable potential formulae and parameters is one of the key points in any theoretical treatment of condensed phases. In fact, one could contend that even in quantum chemical calculations the choice of the basis set and of the method for treating electron correlation are the equivalent of empirical parametrizations in classical force fields. However, the subject of potential formulation and optimization will not be considered here, since such a topic, even if schematically treated, would take up all the journal space allotted to this review. The problem of potentials will be addressed, in a cursory fashion, at some places, but the main emphasis will be on a perspective of what can or could be done to simulate, rationalize, predict or control molecular self-organization under the assumption that a suitable potential has indeed been made available. The reader should be conscious that this is not equivalent to saying that suitable potentials can always be derived, or, worse, that the power of MC, MD or quantum chemical algorithms is such that any potential formulation will do.

As is usual in these days of massive publication policies, the literature survey will be representative, rather than exhaustive.

Molecular recognition

Consider two molecules of different species, A and B, in the gas phase or in any condensed phase which allows substantial diffusional freedom. The most elementary definition of molecular recognition is the following aggregation step (1), neglecting the effects of the surrounding medium.

$$A + B \rightarrow AB \quad (1)$$

If this reaction describes hetero-recognition, self-recognition, relevant to condensation, nucleation and crystal growth in pure

substances, is given instead by step (2) where the expression [*n*A] denotes an aggregate of *n* identical molecules of species A.

$$A + A \rightarrow [2A] \qquad (2a)$$

$$[nA] + A \rightarrow [(n+1)A] \qquad (2b)$$

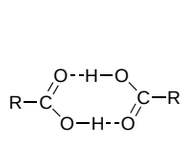
Processes (1) and (2*a*) can be studied quantum chemically, if the sizes of A and B are affordable (a base pair, but not a DNA strand and a ligand) given the required accuracy in the treatment of electron correlation. Process (2*b*) becomes quickly too expensive to be tackled by QC methods for molecular sizes (10–50 atoms) and *n*-values (10–100) of chemical significance.

High quality QC calculations on systems like (1) and (2*a*) can be used to derive cohesive energies and equilibrium distances which can then be exploited in the parametrization of empirical potentials. Typical results[2] indicate that, for example, the energies of C–H···C, C–H···S and S···S interactions are −2.9, −1.9 and −1.5 kJ mol^{-1}, respectively, an energy range which is consistent with that indicated in the opening statement of this review.

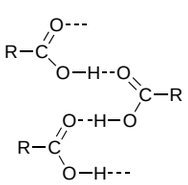
If a more realistic picture of the molecular recognition proceedings is desired, including solvation effects, one can use MC or MD calculations. Potentials here must be empirical, including usual intramolecular force field contributions plus intermolecular contributions, the latter being generally treated as a series of inverse powers of atom–atom distances, *i.e.* terms of the type CR^{-n} where *C*s are calibrating constants and the exponents are integers in the 1–12 range. Such events as solvation, dimerization and further aggregation can be simulated comfortably over systems consisting of a few thousand atoms. Using such techniques, for example, the optimized interaction energies of the benzene dimer in solution have been shown[3] to be within −7.1 and −9.6 kJ mol^{-1}, for widely different dimer structures; differences in stability between these aggregates are, again, in the range of a few to a few tenths of a kJ mol^{-1}.

A substantial drawback in this kind of calculation is that empirical potentials cannot account for molecular polarizability, at least for larger molecules with complex chemical features, since most force fields—at least the ones of more widespread applicability—are invariant with time and chemical environment. Indeed, describing steps (2*a*) and (2*b*) with the same force field for molecule A is unrealistic, and even less realistic is the use of an invariant field for molecule A when it is exposed to a strongly polarizing solvent, water to mention an obvious case.

A bonus of MD is that, besides thermodynamics, a picture of the interaction kinetics is obtained: this is vital if one considers molecular recognition as the preliminary step of condensation, ideally looking for liquid phase or solution precursors to crystal nucleation. Simulations of molecular aggregation by hydrogen-bonding in carboxylic acids and amides prove that in solution an equilibrium exists between cyclic and periodic chain arrangements.



Cyclic dimer



Chain ('catemer') motif

Thus, the relatively high abundance of the chain dimer for tetrolic acid in CCl_4 solution, predicted by MD,[4] is in agreement with the existence of two crystal polymorphs, one with the cyclic and one with the catemer motif. Understandably, such hydrogen-bonded aggregates survive in the apolar solvent, but break apart almost instantly in water. For 2-pyridone in CCl_4, the frequency of events in which one of the two hydrogen bonds of the cyclic dimer is cleaved,[5] most likely due to transfer of kinetic energy from solvent to solvate molecules, agrees with the significant dipole moment observed for the dimer in solution;[6] however, the high stability of the dimer is in contrast to the observed crystal structure, which exhibits the catemer motif. Fig. 1 shows typical time evolution graphs for the relevant hydrogen-bonding distances; such information is in principle very valuable for structural predictions, but clearly yields only a preliminary picture of the subsequent nucleation and growth processes.

Condensation; liquids

The notion that with an appropriate reduction in temperature and/or increase in overall pressure any vapor will condense into a liquid is trivial even in everyday words. Less widespread is the notion that even this familiar process requires a preliminary recognition leading to molecular clustering, a not so intuitive process for matter in the gas phase. Simulation studies of clustering from vapor have been presented,[7] but this topic will not be further pursued in this paper, which is mostly oriented towards molecular aggregation equilibria in condensed phases.

Organic compounds which are in the liquid state at around room temperature are made of small or apolar molecules. For these, the bulk liquid can be studied rather comfortably by MC or MD (*e.g.* ref. 3) with excellent results on the thermodynamics (heats of vaporization and C_p values) and on the structure (radial distribution curves). A recent MD study of liquid ethanol[8] afforded accurate estimates of thermodynamic and transport properties, of molecular conformations and orientational order,

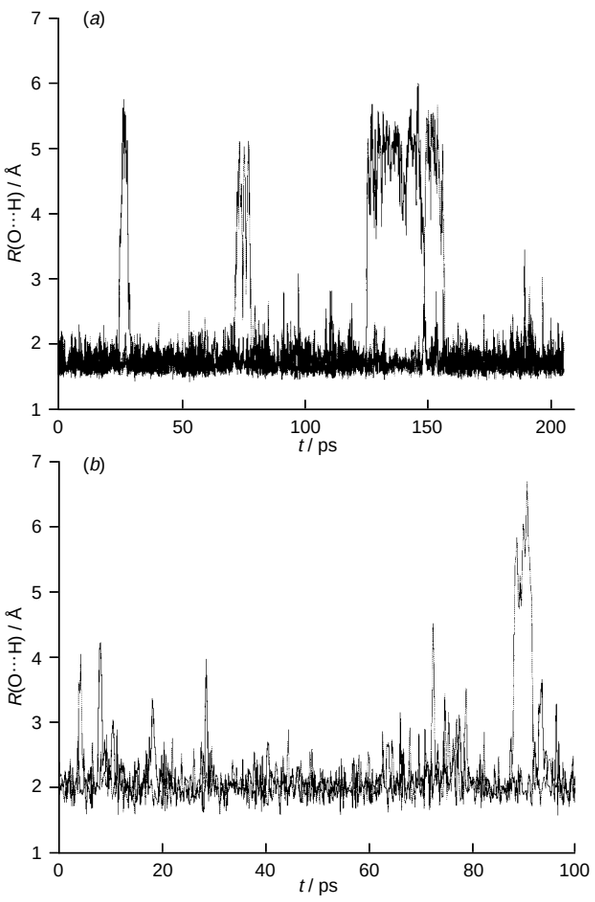


Fig. 1 Time evolution of the hydrogen-bonding O···H distances during MD simulations for cyclic dimers of (*a*) tetrolic acid (ref. 4) and (*b*) 2-pyridone (ref. 5)

as well as a description of the characteristics of hydrogen bonding states. Liquid phenol was studied[9] using an intermolecular potential derived from accurate QC calculations on the isolated molecule or dimers and trimers (remarkably, four dimers of widely different geometries span a cohesive energy range of just 4 kJ mol^{-1}, and the three most stable trimers of just 10 kJ mol^{-1}). MC simulations of the hydrogen bonding patterns in liquid formic acid[10] reveal that cyclic dimers occupy only 7% of the phase space, while in methanol clusters of 5 to 256 molecules,[11] small monocyclic aggregates were found to exhibit considerable persistency, presumably correlated with the high percentage of alcohol crystals with multimolecular asymmetric units composed of such cycles.[12]

The vast majority of organic compounds of molecular weight over 100 are solid at room temperature, and experimental measurements of the properties of their liquids can be awkward. Computer simulation can be very helpful here: test MD calculations[13] show that even simple 6–12 or 6–exponential atom–atom potentials, calibrated using static crystal structure data, can reliably estimate the density and heats of vaporization of comparatively large compounds, *e.g.* benzamide or coumarin. The complete calculation of specific volume as a function of temperature for liquid and crystal phases is also feasible (*e.g.* Fig. 2). Note that no timescale problem exists in the MD simulation of equilibrium bulk liquids, since experimental time constants for molecular diffusion span the 90 ps–20 fs range,[14] quite within the possibilities of today's MD. Presumably, the computational estimation of the thermochemical properties of small to medium-size organic molecules successfully competes, on the basis of cost : quality ratio, with experimental determinations.

Nucleation and the solid–liquid interface

A bulk liquid at a temperature much higher than its freezing point should ideally be completely disordered and hence perfectly homogeneous. Quite a different situation must arise when the temperature is lowered to the freezing point, and, even more, below it. An undercooled liquid must experience fluctuations towards the thermodynamically stable crystalline phase, and, if the size of nuclei formed during these fluctuations exceeds a certain critical threshold, evolution to the crystal is observed; otherwise, the subcritical nuclei merge back into the bulk fluid.[15] The theoretical study of these nucleation phenomena can proceed at an almost entirely macroscopic level, using comprehensive descriptors without regard to molecular structure,[15–17] or through several kinds of computational guinea pigs such as the Lennard–Jones system or other, similarly oversimplified (at least, with respect to ordinary organic chemistry) interaction sites.[18–20] Macroscopic theories of crystal growth have been developed mostly using cell models (like the Burton–Cabrera–Frank model), and models intermediate between the macroscopic and the molecular level exploit simple concepts such as the relationships between the growth speed of different crystal faces and the interplanar spacing (the Hartmann–Perdok model) or molecular attachment energies; however, these approaches lack resolution on the detail of molecular recognition, and hence are beyond our present scope. Heterogeneous nucleation, induced by interactions with random impurities, and hence orders of magnitude more complicated than homogeneous nucleation, will not be considered here for obvious reasons.

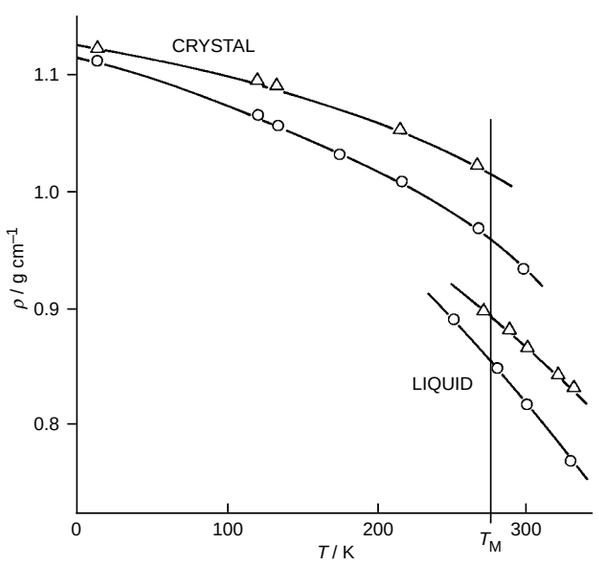

Fig. 2 Specific volume *versus* temperature for benzene from MD simulations of the liquid and crystal phases (from ref. 13). (○) calculated; (△) observed.

Progress on systems composed of real molecules has been made by joint experimental and theoretical studies of molecular clusters.[21] Clusters can be prepared in such conditions as to have nucleation rates as high as 10^{30} m^{-3} s^{-1}, perhaps 15 orders of magnitude larger than those in bulk liquids, and this is what makes them especially attractive targets for nucleation studies. For example, MD simulations on clusters including a few hundred molecules correctly reproduced solid–liquid transitions, and, even more significantly, an MD simulation on a cluster of 188 *tert*-butyl chloride molecules showed stability in the observed plastic crystalline tetragonal phase as well as spontaneous transformation to a low-temperature ordered, monoclinic crystalline phase, in agreement with electron and neutron diffraction data.[21] *tert*-Butyl compounds have a rich phase behaviour with several solid–solid and solid–liquid features, which have been studied by thermal analysis and theoretical dynamical methods (see ref. 22 for results and related literature).

While a complete phase diagram in the P–T plane can be obtained for a system of Lennard–Jones spheres,[23] solid–liquid equilibrium in molecular systems of moderate complexity is also almost within reach of present day computer capabilities. The nucleation and melting of linear C_n alkanes has been studied[24] by MD using an *n*-site Lennard–Jones representation of the molecules, in the NPT ensemble, *i.e.* at constant pressure, in a box with periodic boundary conditions resembling the bulk more than a cluster. The time evolution of thermodynamic and structural parameters could be monitored on line, in what can be considered an ideal computational experiment in nucleation. Similarly, encouraging results have been obtained for the liquid–solid phase transition of cyclohexane, with a six-site molecular model.[25] Using MD, the freezing of supercooled water, induced by an electric field, has been successfully simulated[26] over a period of a few hundred picoseconds, a quite affordable timescale for present-day computers.

Simulations of this kind, when extended to larger molecules, and analyzed for the identification of crystallization precursors, can be of extreme value in the progress of our understanding of nucleation from the melt.

Nucleation and crystallization from solvent

Nucleation of organic molecules within a solution is at present an essentially unaccessible phenomenon. The nuclei are too small to be seen by direct or scattered light, and their size distribution and dynamic growth properties cannot be determined experimentally. Computer experiments are therefore the only means to probe this elusive reality.

A first attempt to study the behaviour of elementary nuclei in solution was made[4] on dimers of tetrolic acid, as discussed previously in this paper. For a more comprehensive and significant test, an MD simulation was run on a computational box initially consisting of $9 \times 9 \times 9$ cells about 7 Å wide, 20 of which, picked at random, were occupied by (solute) acetic

acid molecules, the others being occupied by (solvent) CCl_4 molecules; no solute–solute distances below 15 Å were present in the starting configuration. Crystal potentials[27] were used for intermolecular interactions of the solute, and standard potentials[28] for the united-atom solvent molecules, applying the usual averaging rules for cross interactions and a 30 Å cutoff in intermolecular summations. The intramolecular geometry of the acetic acid molecules was frozen, except for the wagging motions of the acidic proton. Several runs were conducted at constant temperature between 200 and 300 K; the 200 K results are discussed, but the results did not change significantly with temperature. The GROMOS96 package[29] was employed.

The results are, if not conclusive, at least stimulating. Since no periodic boundaries were imposed, the starting box quickly relaxed into a pseudospherical shape [Fig. 3 and 4(*a*)], and at the same time a very fast condensation of solute molecules into small clusters made of 2–5 molecules was observed [Fig. 4(*b*) and 5], with geometries ranging from head-to-head dimers over the COOH function, to small hydrogen-bonded oligomers bound into cyclic structures. Not unexpectedly, no trace of intermolecular symmetry was found within these prototypical droplets, in which the molecular centers of mass stayed within cohesive distance during the simulation, while the detailed structure exhibited a highly fluxional behaviour. The solute potentials were of the 6–exp type,[27] transformed to 6–12 for compatibility with GROMOS; their well depth corresponds to a hydrogen-bonding energy (about 30 kJ mol^{-1}), but they fall off very quickly with distance. Therefore, to probe the efficiency of molecular attraction at long range, the computer experiment was then repeated supplementing the 6–exp potential with coulombic terms computed with the GROMOS96 charge distribution over the COOH group, thus increasing artificially, and even unrealistically, the intermolecular attractive forces. The stronger potentials bring molecules together more rapidly and hold them more tightly together within the droplets; although energies and trajectories differ somewhat, however, the final results in terms of structure and the total number of hydrogen bonds were essentially the same. One possible interpretation is that solute condensation is helped by solvent reorganization, besides solute–solute attractive interactions; in other words, some of the driving force for the segregation of solute molecules may come from the tendency of the solvent to squeeze out the disturbance to its own structure. If and how these conclusions can stand the trial of changes in the solute potential, in the length of the simulation, or in boundary conditions, remains to be seen; the example proves the feasibility, and hints to a possible usefulness, of this kind of simulation.

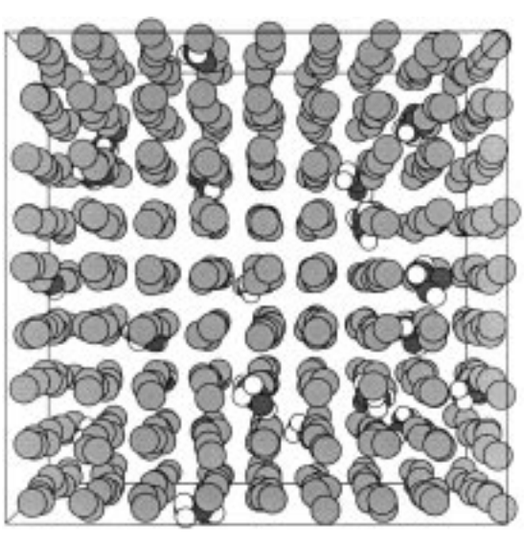

Fig. 3 Starting configuration within the computational box for 20 AcOH and 709 CCl_4 molecules; large circles are united-atom solvent molecules

The other relevant aspect of the solute–solvent equilibrium is the growth of macroscopic crystals once the nucleation stage has been overcome, and template crystal surface(s) are available within the solution. The timescale of events involved in crystal growth goes from (presumably) picoseconds for structural relaxation of molecules adsorbed on growing surfaces, to nanoseconds for molecular diffusion over the surface, to seconds for the growth of several monolayers; the first two steps are easily manageable by MD, but not the third. The so-called kinetic MC method can be employed, in which, roughly speaking, transition probabilities among configurations are weighted by estimated rates of the transition events, rather than by the Metropolis test as is the case in thermodynamic MC. Apparently, KMC simulations span formal times of the order of hundreds of seconds (see ref. 30 for further description and a review).

For chemical purposes, growth from solution is the method of choice. The concept of a relationship between a given crystal structure and the structure of precursor nuclei in solution has

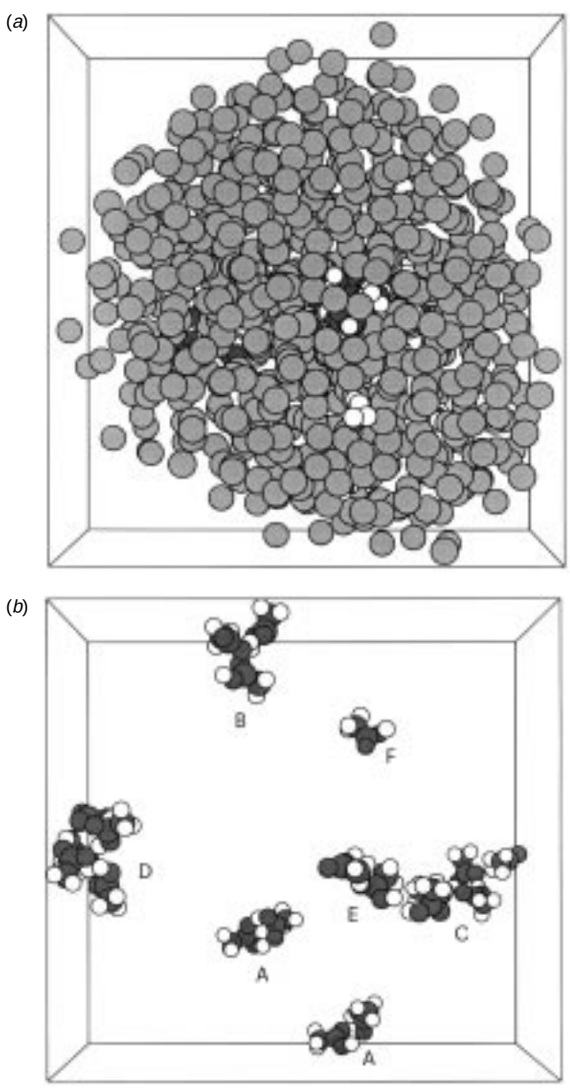

Fig. 4 (*a*) Overall view of the AcOH–CCl_4 system after 400 ps; 10 solvent molecules (not appearing) have departed from the drop, simulating evaporation. (*b*) Detail of the arrangement of AcOH molecules. A denotes cyclic dimers, B a chain trimer, C a four-molecule structure with bifurcated H-bonding and D a cyclic pentamer. In E, two molecules are close together but not H-bonded. F is an isolated molecule.

been introduced and exploited by the Weizmann school in a series of beautiful experiments, in which nucleation inhibitors were designed, on the basis of molecular structure, to bind stereospecifically at the surface of the stable polymorph, thus preventing its growth and enhancing the growth of metastable polymorphs (see ref. 31 for a recent account on the control of glycine polymorphism). At the other extreme, holistic analyses of the nucleation and growth kinetics produce phenomenological equations which lack molecular detail, but can be used[32] to study the rate-controlling processes in solvent-mediated phase transformations (Ostwald cycles).

Several experimental techniques are nowadays available for the *in situ* monitoring of crystal growth at atomic level; among others, atomic force microscopy[33] and laser interferometry.[34] The ideal computational experiment in crystal growth and dissolution involves the preparation of a computational box in which one or more crystal faces are exposed to either the pure solvent or a solution of the crystallizing substance, and the monitoring of the evolution in time of the system by MD. Problems of potentials (polarizability) and of timescale concur in making this experiment a very awkward one, *e.g.* given an elongation rate of 0.3 μm min^{-1} on a needle of the diameter of 10 μm,[35] a simple calculation shows that on a computational surface 100 × 100 Å wide, one should wait 3×10^8 ps to observe the attachment of a single molecule. This experimental result obviously incorporates an unknown time lag due to diffusional barriers within the solution; attachment and detachment events within the microscopic layer in intimate contact with the crystal surface may proceed at a much higher rate. In fact, MD simulations of the interface between a saturated urea solution and the urea crystal[36] revealed, at least, interesting preorganization details within the adsorbed layers. Well within the range of MD is instead the equilibration of water over crystal surfaces, or an essentially surface phenomenon, revealing details of the interaction with relevance to morphology[37] and wettability.[38]

Crystals

The final product of molecular recognition can be comfortably examined in the crystal structure, thanks to X-ray diffraction—at least in the majority of occurrences, but not always, since for yet unknown reasons a small but significant percentage of organic molecules refuse to organize into suitable single crystals. Present-day diffraction facilities, using stronger sources and two-dimensional detectors, have considerably reduced the number of inaccessible crystalline materials.

The dynamics of molecules in crystals far from transition temperatures is essentially harmonic, and hence rather uninspiring. Intermolecular librations can be successfully modeled by harmonic lattice dynamics, while extensive MD simulations are rather a tool for a more accurate calibration of potentials than for the discovery of new facts.[39]

Long before MD methods were devised, extensive computational work had been conducted on molecular crystals, dealing successfully with crystal packing analysis and crystal thermodynamics (see ref. 40 for a historical perspective). The background was thus laid for tackling more ambitious goals, like the enforcement of close-packing in translationally symmetrical molecular assemblies, and eventually, the computational prediction of crystal structures.

In the last five years or so, computational methods have been developed for guessing the crystal structure a compound will adopt, starting from the bare molecular constitution, and not without some success.[41–48] Such methods completely overlook all preliminary, dynamic molecular recognition stages, and rely on astute algorithms and shortcuts to assemble the crystal structure like a sort of molecular LEGO puzzle, the guiding concept being that the predicted crystal structure must be the one with the most stabilizing lattice energy. These procedures rely sometimes on random, Monte Carlo-type, or even brute force searches through the potential energy hypersurface, or on energy minimizing algorithms, and sometimes on symmetry considerations with an exploitation of close-packing principles; they are therefore essentially static in nature, although at some stages dynamic reshuffling in the form of simulated annealing may be applied, to facilitate the crossing of barriers and the unification of apparently different valleys. Typically, hundreds or thousands of plausibly close-packed structures are generated, and clustering of equivalent ones is problematic—consider, for example, just the problem of cell reduction in triclinic space groups. The basic result, common to all of these procedures, is a portrait of the potential energy landscape in the proximity of its minima, a picture that invariably reveals shallow regions among which the recognition of absolute stability is impossible. Fig. 6 and Tables 1–4 demonstrate this assertion.

Things could not be different, given the unavoidable physical nature of weak intermolecular interactions, and their energy range (see the introduction to this paper). The energetic resolution of empirical intermolecular potentials is presumably of the same order of magnitude as the energy differences they try to gauge; entropy differences are neglected. Besides, the starting molecular geometry is assumed *in vacuo*, and a reliable account of the interplay between the intra- and inter-molecular force field is awkward. Nevertheless, these structure prediction

algorithms are extremely valuable in that they usually can narrow down the choice to a few, typically 5–10 possible crystal structures, and this is an important result which should not be overlooked. Besides, when coupled with partial X-ray diffraction data (*e.g.* from faulty crystals or from powders) they lead to consistent structure prediction, the discrimination between computationally generated structures being taken care of by the reliable (often indisputable) experimental crystallographic information.[49,50] These facts are more than enough to foresee a wide impact of computational techniques, in the near future, on the design of novel molecular materials with desirable structure–property relationships. And, after all, with some luck and a modicum of chemical or crystallographic intuition, some of these methods can actually lead to a real *de novo* crystal structure prediction for some molecules; the trouble is, success or failure depends on still uncontrolled factors, and the success rate cannot be assessed in a systematic way, so that weak spots cannot be clearly identified and ameliorations cannot be rationally planned, at least thus far.

Phase behaviour of organic compounds

The study of organic molecules in the 100–1000 Da molecular weight range[51] is full of richness and fascination, although more so as regards their aggregation properties than the bare molecular structure, *i.e.* more in the inter- than in the intramolecular arena. The definition and modeling of weak recognition forces pose a great theoretical challenge, but also the applicative side is full of promise.

The *in vacuo* theoretical chemistry of small molecules includes a design step, done by sketching a molecular composition and connectivity on paper, and a structural exploration stage, in which quantum chemical or force field methods are used to define the conformation(s) and overall shape of the molecule in the absence of surrounding fields. If a high-quality wavefunction is available, the main features and even some detail of the molecular electrostatic field can be obtained for each conformation.

The study of the intermolecular theoretical chemistry of organic small molecules hits a big stumbling block in its very first stage, which is the polarization of the *in vacuo* molecular field by the environment. The study of condensed phases should start from the simplest one, a pure liquid; from there on, a wide range of possible paths can be envisaged in the modeling of the phase domain, using temperature/kinetic energy as a guideline. Several degrees and types of structuring and ordering set in as the temperature of the liquid decreases, from molecular clustering, to one- or two-dimensional translational ordering in liquid crystals (LC), to three-dimensional translational ordering with rotational disorder in plastic crystals; further on, or alternatively, a glassy state could be reached. All of these mesophases could be either thermodynamically stable or metastable with respect to the crystalline solid. At this stage the system assumes the status of a material with a macroscopic molecular assembly which can be used for specific purposes, since its texture interferes and specifically interacts with electromagnetic waves (LC display devices, non-linear optics), or with electric and magnetic fields (electrets and organic magnets).

In a conceptually final condensation stage, with further reduction of translational and rotational kinetic energies, the crystalline state is accessed, whose complete anisotropy of course enhances all possibilities for practical uses of the material. Even here, some flexibility is left in the consideration of possible polymorphism.

Binary solutions are just the two-component equivalent of the already immense one-component problem outlined above. Although neither pure liquids nor solutions can compete with solids for applicative purposes, the liquid state holds the premises for our comprehension of solidification. The basic dissolution–segregation process is in fact the key to an

understanding of the mechanisms of formation of the vast majority of organic solids.

Summary

Thus, the phase–mesophase behaviour of organic compounds is an inextricable tangle of kinetics and thermodynamics. We would like to conclude this article with some assessment of present or near-future computational approaches to its prediction and control. We assume that molecular structure and intermolecular potentials have been somehow established using the procedures and within the limitations outlined in the preceding sections.

Fairly accessible would be the prediction of the densities and cohesive energies of the liquid, liquid crystal, glassy and crystalline states of the substance. For the first three, dynamic calculations are necessary, but the corresponding computational boxes could be rather easily set up and equilibrated at any desired temperature. At least for the crystal, prediction could also go through static calculations, using one of the several algorithms described in a former section of this paper. Although the detailed geometrical structure of the crystal may not be accurately and reproducibly predicted, the available methods can usually produce 5–10 structures among which the possible polymorphs would almost certainly be included.

Quite a different problem would be the prediction of relative thermodynamic stabilities and of transition temperatures, for which an accurate evaluation of the enthalpies and entropies of all phases as a function of temperature would be needed. This is, so far, a prohibitive task. The dynamic simulation of the detailed transformation paths and of their kinetics is also so far extremely demanding, but steps are already being taken in this direction, and the promise for very quick development in the near future is high.

Control is a step beyond prediction. It would certainly be desirable to learn how to design the molecular architecture so as to engineer a certain property within the material, *e.g.* its propensity to form liquid crystal phases, or the presence or absence of a center of symmetry in the crystal, up to a fine tuning of molecular orientation in the solid to produce a certain electrooptical effect. A structural approach to crystal structure prediction and control makes use of the concept of crystal synthons, or basic recognition blocks which, when implanted in molecular objects, drive their spatial recognition to pre-established goals.[52] Its success depends on some systematization and much chemical intuition.

There is little that can be done directly, in terms of control of the properties of a material, by pure calculations; a computer computes properties, but cannot be confidently taught to appreciate the influence of molecular chemistry on them, a task which is more appropriate to the human than to the electronic mind (the crystal packing modes of primary amides had been codified and to some extent predicted[53] in times when computers were in their infancy). It is still for the human to line up all the computational information and to organize it towards comprehension. In this respect, what computers can easily do, besides brute force exploration of the phase space, is to gather at a fantastic speed, for the use of a human operator, information that would be too tedious or quite impossible to obtain by hand. Using computer-accessible collections of crystal information, like the Cambridge Structural Database,[54] one learns for instance[55] (after having programmed computers for decades to explore all the cell space) that molecular centers of mass must lie in special positions within the crystal cell, *i.e.* roughly halfway between inversion centers or between screw axes. Also, crystal structure prediction algorithms can be designed to learn from the structural or energetic properties of existing structures.[56] Together with the exponential increase in mere computing power, the near future should see a more and more widespread cooperation of human and electronic mindpower towards a more comprehensive understanding of the phase behaviour of organic compounds.

Angelo Gavezzotti graduated in Chemistry in 1968 at the University of Milano. He started his scientific career in X-ray crystallography and theoretical chemistry, under the supervision of Massimo Simonetta. His interests moved later to the simulation and prediction of organic crystal structures and properties, and, more recently, to computer techniques in the study of the physical chemistry of condensed phases of organic compounds.

Giuseppe Filippini received his degree in Chemistry from the University of Milano with a thesis in Crystallography (1968), under the supervision of Massimo Simonetta. He spent one postdoctoral year in Manchester with Professor D. W. J. Cruickshank. Currently, he is senior research scientist at the CNR Center for the Study of the Relationships between Structure and Chemical Reactivity. His active interests cover correlation and systematics of intermolecular interactions in organic crystals trough lattice dynamics and atom–atom potential calculations.

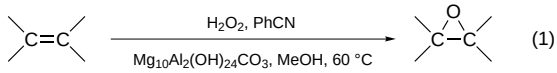
Hydrotalcite catalysis: heterogeneous epoxidation of olefins using hydrogen peroxide in the presence of nitriles

Shinji Ueno, Kazuya Yamaguchi, Kazushi Yoshida, Kohki Ebitani and Kiyotomi Kaneda*

Department of Chemical Science and Engineering, Graduate School of Engineering Science, Osaka University, 1–3 Machikaneyama, Toyonaka, Osaka 560, Japan

The layered hydrotalcite, $Mg_{10}Al_2(OH)_{24}CO_3$, acts as an efficient base catalyst for the epoxidation of various olefins using hydrogen peroxide in the presence of benzonitrile and with MeOH as solvent.

Hydrotalcites consist of Brucite-like layers having positive charge with anionic species in the interlayer, forming neutral materials.[1,2] Combination of different elements, changing the element ratios in the Brucite-like layer and selection of different anionic species can tune up the basicity of the hydrotalcites and the interlayer distance.[3] Recently, we found that hydrotalcites show high catalytic activities for the Baeyer–Villiger oxidation of various ketones using a combined oxidant of molecular oxygen and benzaldehyde or MCPBA; the surface hydroxy groups of the hydrotalcites acted as basic sites to promote the above oxidations.[4–7]Here, in relation to our studies on the base catalysis of hydrotalcites, we report that the heterogeneous epoxidation of various olefins using hydrogen peroxide is catalysed by hydrotalcites to give the corresponding epoxides [eqn. (1)].



(1)

There are few reports concerning the oxidation of olefins by hydrotalcite catalysts using hydrogen peroxide.[8–11] Shape selective epoxidation was observed in the case of polyoxometalate-intercalated hydrotalcites. But diols and oxolanes were formed to some degree by successive cleavage of the epoxides. Notably, our oxidation system using hydrotalcites exculsively gives epoxides without other products.

Various hydrotalcites used in Table 1 were prepared by the literature procedures.[1,12,13] Elemental analyses for the hydrotalcites are in good agreement with literature values. After drying the hydrotalcites at 110 °C, they were stored in air and used without further pretreatment.†

Table 1 The epoxidation of cyclohexene catalysed by various hydrotalcites and NaOH using H_2O_2 and benzonitrile[a]

Catalyst	Conversion (%)	Yield (%)[b]	Heat of Adsorption[c]/ J g^{-1}
$Mg_{10}Al_2(OH)_{24}CO_3$	100	< 99	14.0
$Mg_5Al(OH)_{11}CO_3$	80	79	8.1
$Mg_6Al_2(OH)_{16}CO_3$	69	67	6.3
$Mg_6Al_2(OH)_{16}SO_4$	58	54	5.1
NaOH[d]	95	53[e]	—
Without catalyst	20	15	—

[a] Reaction conditions: cyclohexene (3.9 mmol), benzonitrile (10.5 mmol), hydrotalcite (0.05 g), MeOH 10 (ml), 30% aq. H_2O_2 (2.4 ml), 60 °C, 24 h. [b] Yields of epoxides were determined by GC analysis using internal standards, based on the olefins. [c] The basicity of the hydrotalcites was estimated by calorimetric heats of benzoic acid adsorption. [d] NaOH was equivalent to the amount of hydroxy functions in hydrotalcites (1.5 mmol). [e] Ring opening products of the epoxide, *e.g.* cyclohexane-1,2-diol and 2-methoxycyclohexan-1-ol, were formed.

In the presence of $Mg_{10}Al_2(OH)_{24}CO_3$, oxidations of cyclohexene using hydrogen peroxide with benzonitrile were carried out in various solvents such as methanol, benzene, toluene and 1,2-dichloroethane.‡ MeOH gave the highest yield of cyclohexene oxide. However, the oxidation hardly occurred in the absence of benzonitrile. Table 1 shows the catalytic effect of various hydrotalcites on the epoxidation of cyclohexene using benzonitrile in MeOH. Yields of cyclohexene oxide increased with increasing heat of benzoic acid adsorption on the hydrotalcites. The basicity of these hydrotalcites was estimated by a measurement of calorimetric heats of benzoic acid adsorption using microdifferential scanning calorimetry.[7] It is likely that the basic hydroxy groups of the hydrotalcites play an important role in the epoxidation. Bases such as NaOH and KOH catalyse the epoxidation of olefins using hydrogen peroxide in the presence of nitriles.[14,15] However, NaOH was not an effective base for our epoxidation.§

Table 2 shows results of the oxidation of olefins with benzonitrile in MeOH. Common linear and cyclic olefins such as oct-1-ene and cyclohexene gave the corresponding epoxides as sole products in excellent yield, respectively (entries 1–7). Norbornene gave only *exo*-norbornene oxide in quantitative yield (entry 8). Remarkably, styrene was oxidized to give styrene oxide in a high yield without formation of other oxidation products, *e.g.* acetophenone and benzaldehyde (entry 9). In the case of an α,β-unsaturated ketone, cyclohex-2-en-1-one, the epoxidation exclusively occurred without formation of the Baeyer–Villiger oxidation products (entry 10). This epoxidation proceeds stereospecifically with retention of configuration at the double bonds (entries 2 and 3).

Interestingly, we found that adding sodium dodecyl sulfate and sodium dodecylbenzene sulfate to the above oxidation system markedly increased the rates of the epoxidation; cyclooctene oxide was obtained quantitatively within 2 h.¶ This epoxidation consists of two phases; the olefin and nitrile are in the organic phase, while the hydrogen peroxide and hydrotalcite are in the aqueous phase. The above additives might act as a surfactant to form reverse micelles (aqueous phase in organic medium), which helps to increase contact area of the interface between the two phases. The detailed role of the additives in this epoxidation system is under investigation in our laboratory.

This epoxidation involves the following two steps; (i) formation of peroxycarboximidic acid by the reaction of a nitrile with hydrogen peroxide, and (ii) oxygen transfer from peroxycarboximidic acid to olefin, in which step (i) is promoted by bases.[14] It is likely that the hydrotalcite acts as a solid base and promotes the formation of peroxycarboximidic acid, leading to high yields of the epoxides.

In conclusion, we have developed an efficient heterogeneous catalyst system utilising hydrotalcites for epoxidation and using a combined oxidant of aqueous hydrogen peroxide and benzonitrile. The solid hydrotalcites are easily separated from the reaction mixture *via* filtration, which makes the work-up procedure simple. The hydrotalcite can be reused without an

appreciable loss of catalytic activity. This system should prove useful for many base-catalysed selective oxidations.

Notes and References

* E-mail: kaneda@cheng.es.osaka-u.ac.jp

† *A typical procedure* for the epoxidation of cyclooctene: Into a reaction vessel with a reflux condenser were successively placed the hydrotalcite of $Mg_{10}Al_2(OH)_{24}CO_3$ (0.15 g), MeOH (40 ml), cyclooctene (14 mmol), benzonitrile (17 mmol) and 30% aq. H_2O_2 (7.5 ml). The resulting mixture was stirred at 60 °C for 24 h. The hydrotalcite was separated by filtration and the filtrate was treated with MnO_2 (0.03 g) to decompose the remaining H_2O_2. GC analysis of the filtrate showed a quantitative yield of cyclooctene oxide. The filtrate was diluted with deionized water (50 ml) and extracted with $CHCl_3$ (50 ml × 3). The extract was concentrated under reduced pressure and subjected to a silica gel chromatography using a mixture of *n*-hexane–Et_2O (40 : 1, v/v) as an eluent to give cyclooctene oxide (1.5 g, 87% yield). The isolated hydrotalcite can be reused without loosing its high catalytic activity.

‡ The order for yields of cyclohexene oxide using different nitrile compounds is as follows; benzonitrile > acetonitrile > propionitrile.

§ Under our reaction conditions, use of NaOH in place of the hydrotalcites resulted in a 53% yield of cyclohexene oxides, as shown in Table 1.

¶ Use of cationic surfactants, *e.g.* cetylpyridinium chloride monohydrate and tetra-*n*-propylammonium bromide, did not increase yields of cyclooctene oxide.

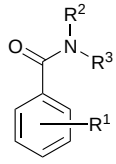
Anionic cyclisations of an *N*-benzyl naphthamide: a route to benzo[*e*]isoindolones

Anjum Ahmed,[a] Jonathan Clayden*[a] and Michael Rowley[b]

[a] *Department of Chemistry, University of Manchester, Oxford Road, Manchester, UK M13 9PL*
[b] *Merck Sharp and Dohme Neuroscience Research Centre, Terlings Park, Harlow, Essex, UK CM20 2QR*

On treatment with Bu^{t}Li and HMPA, *N*-*tert*-butyl-*N*-benzyl-1-naphthamide undergoes cyclisation to a tricyclic enolate which reacts diastereoselectively with electrophiles to give substituted 2,3,3a,9b-tetrahydro-1*H*-benzo[*e*]-isoindol-1-ones, the first example of an anionic cyclisation onto an aromatic ring.

When tertiary aromatic amides **1** are treated with organolithium bases, they are usually *ortho*-lithiated.[1–3] Amides bearing 2-alkyl groups may be laterally lithiated[4,5] and, in exceptional cases (for example if the 2 and 6 positions are blocked,[6–9] if the nitrogen bears an activating group such as benzyl[10] or with a lithium amide base[1,11]), lithiation may take place α to nitrogen.[12,13] Alkylation of these dipole-stabilised anions is well known,[13] and both *ortho*-lithiation[14] and lateral lithiation[15] followed by electrophilic quench have been made enantioselective by the addition of (−)-sparteine.[16]

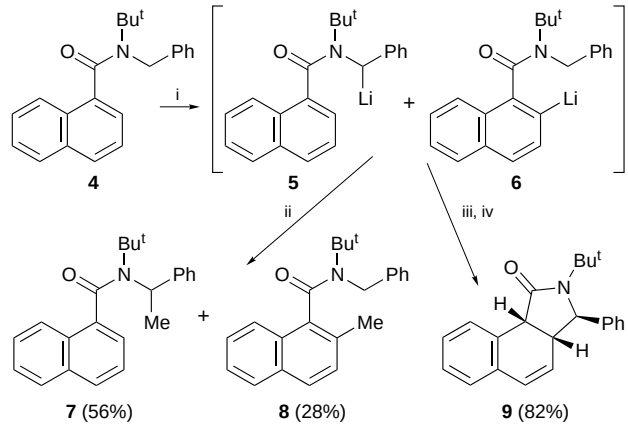


1

We have shown that both *ortho*-lithiated[17,18] and laterally lithiated[19] tertiary 1-naphthamides can react atroposelectively with electrophiles—frequently only one of two possible atropisomeric products (which arise from restricted rotation about the aryl–carbonyl bond) is formed.[19] For example, the 2-ethyl-*N*,*N*-diisopropylnaphthamide **2** reacts with Bu^{s}Li to give a single, configurationally stable (at both stereogenic axis and centre) organolithium[20] which reacts stereospecifically with many electrophiles to give a single atropisomer of the product **3** (Scheme 1).

In connection with this work, we lithiated *N*-*tert*-butyl-*N*-benzyl-1-naphthamide **4** with Bu^{t}Li and quenched the resulting red solution with MeI. We obtained two compounds, in a ratio of about 2 : 1: compound **7** results from methylation α to nitrogen, and **8** from methylation on the aromatic ring *ortho* to the amide group.† Lithiation of **4** therefore apparently gives a mixture of α- and *ortho*-lithiated compounds **5** and **6**.

When we treated this mixture of organolithiums with HMPA (6 equiv.), it underwent a remarkable cyclisation reaction.‡ After an aqueous quench, we isolated the tricyclic 2,3,3a,9b-tetrahydro-1*H*-benzo[*e*]isoindol-1-one **9** as a single diastereoisomer in 82% yield (Scheme 2). Nuclear Overhauser enhancement (NOE) experiments showed that the 6,5-ring junction was *cis*, with the phenyl group on the *exo* face. This is the more stable of the two ring-junction isomers: **9** was recovered as a single unchanged diastereoisomer after stirring overnight with Bu^{t}OK in Bu^{t}OH at 40 °C.§



4 **5** **6** **7** (56%) **8** (28%) **9** (82%)

Scheme 2 *Reagents and conditions*: i, Bu^{t}Li (1.3 equiv.), THF, −78 °C, 2 h; ii, MeI, −78 °C; iii, HMPA (6 equiv.), −78 °C, 16 h; iv, NH_4Cl

The initial product of the cyclisation triggered by the HMPA is an enolate **10** which we could alkylate with MeI, Bu^{n}Br or BnBr, giving compounds **11** as shown in Scheme 3. Diastereoselectivity depended on the size of the electrophile, with BnBr being the most selective—**11** (R = Bn) was obtained as a single isomer **11a** (R = Bn) only. MeI gave a 3 : 1 ratio of **11a** and **11b**, and the same ratio of diastereoisomers is obtained by methylating the lithium enolate formed from **9** with LDA in the absence of HMPA: HMPA does not affect the diastereoselectivity of the

reaction. The identity of the diastereoisomers was determined by NOE experiments, and the major one in each case results from alkylation from the less hindered *exo* face of the enolate as shown (**12**), giving a *cis* 6,5-ring junction.

The cyclised enolate **10** also underwent clean aldol reactions (Scheme 4). A reaction with benzaldehyde gave the alcohol **13** as a single diastereoisomer in 81% yield. Tricycle **13** has four new adjacent chiral centres, and its relative stereochemistry was proved by X-ray crystallography (Fig. 1). An aldol reaction with *n*-butyraldehyde was somewhat less stereoselective, although NMR correlation indicated that again the major product **14** arose from attack of the aldehyde on the less hindered face of the enolate.

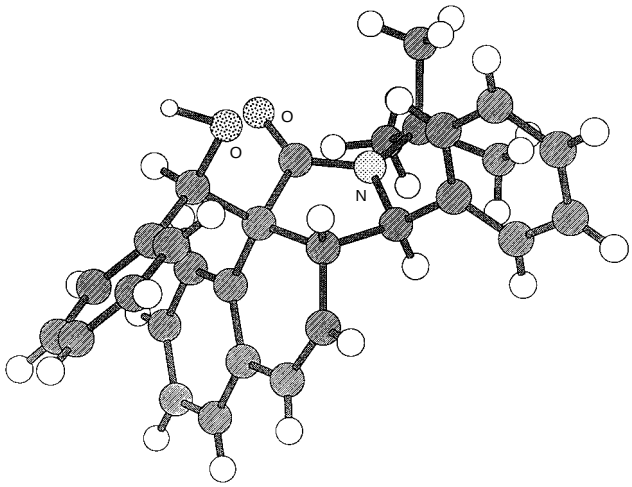

Fig. 1

While additions onto aromatic rings which result in loss of aromaticity are rare,[21] the addition of organometallic nucleophiles to electron-poor naphthalenes is precedented.[22] However, our cyclisation is, as far as we are aware, the first example of an *anionic cyclisation* onto an aromatic ring of any sort. Anionic cyclisation onto π systems is turning out to be a useful way of making rings, both carbocyclic[23,24] and heterocyclic,[25] but is invariably initiated by transmetallation and not deprotonation.[26] We are currently extending the scope and applicability of this new reaction as a promising method for the stereocontrolled synthesis of fused five-membered nitrogen heterocycles.[27]

We are grateful to the University of Manchester for a Research Support Grant, to the EPSRC for a CASE award (to A. A.) and to Dr Madeleine Helliwell for determining the X-ray crystal structure of **13**.

Stereoselective intramolecular aldol reactions of (4*R*)-3-(3-oxobutanoyl)-1,3-thiazolidine-4-carboxylates believed to be directed by 'self-induced' axial chirality

Andrew G. Brewster,[a] Christopher S. Frampton,[b] Jay Jayatissa,[c] Mark B. Mitchell,[b] Richard J. Stoodley*[c]† and Shaheen Vohra[c]

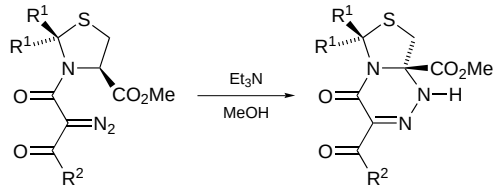
Essentially complete retention of configuration accompanies the base-induced aldol reaction of the thiazolidinecarboxylate 6c to give the fused heterocycles 7c and 8c and their retroaldol–acylation reactions to give the bicycle 9c.

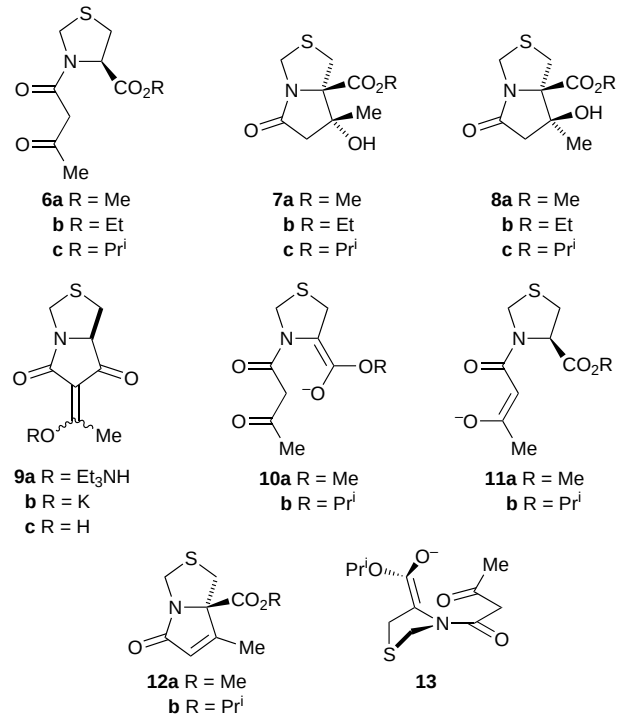
Recently we showed[1] that the diazo esters **1a–c** underwent cyclisations under basic conditions to give the bicyclic compounds **2a–c** in a state of high enantiomeric purity (Scheme 1). We postulated that the reactions proceeded by way of planar ester enolate (or enol) intermediates that possessed axial chirality. For example, the species **3** (arbitrary enolate geometry) was considered to be involved in the **1a** → **2a** cyclisation. The marked kinetic preference for the diazo ester **1a** to undergo deprotonation to give the enolate **3** rather than its enantiomer was attributed to the greater ease in attaining the geometry **4** compared with the geometry **5** (in which a severe $A^{1,2}$ interaction exists between the *N*-acyl substituent and the CO_2Me group) required for the deprotonation reactions.



Scheme 1

Whilst the aforecited findings were of significant mechanistic interest in that they exemplified a new stereoinduction principle, they were of limited synthetic impact because a C–N bond had been generated at the expense of a C–H bond at the thiazolidine stereocentre. Obviously, the ability to develop a C–C bond would notably enhance the technology, particularly because of the high interest in enantiopure α-*C*-substituted α-amino acids.[2] We now report studies that have led to the achievement of this objective.

Seeking to prepare the bicycle **7a** and/or **8a**, the acetoacetyl thiazolidine **6a**[1] was treated with NEt_3 (300 mol%) in MeOH for 17 h. Subjection of the product to silica gel column chromatography led to the isolation of two fractions. The first fraction (10% yield), $[\alpha]_D$ −85 (*c* 0.34, CH_2Cl_2) was identified as a 75 : 25 mixture of the desired aldol products **7a** and **8a**.‡§ The second fraction was considered to be the triethylammonium salt **9a**;§ treatment of an ethereal solution of the material with potassium 2-ethylhexanoate (in BuOH–Et_2O) gave the potassium salt **9b**‡ (66% yield), mp 251–252 °C, $[\alpha]_D$ −116 (*c* 0.39, H_2O). When resubjected to the cyclisation conditions, the aldol products **7a** and **8a** were unaffected, establishing that the thiazolidine **6a** underwent two competing cyclisations by way of the enolates **10a** and **11a** (arbitrary enolate geometries).



A study of the behaviour of the thiazolidine **6a** towards a variety of base/solvent combinations revealed that KCN (150 mol%) in MeOH was the most effective in promoting the desired cyclisation reactions, giving the results shown in Table 1. A simple work-up¶ provided a 76 : 24 mixture of the aldol products **7a** and **8a** in 32% yield {after chromatography, 29% yield; $[\alpha]_D$ −88 (*c* 0.25, CH_2Cl_2)}.

The slow step in the **6a** → **9b** transformation is likely to involve an intramolecular reaction of the intermediate **11a** in which the enolate adds to the ester carbonyl group. Hoping to dampen this reaction, the ethyl ester **6b**,‡‖ $[\alpha]_D$ −123 (*c* 0.41, CH_2Cl_2), and the isopropyl ester **6c**,‡‖ $[\alpha]_D$ −128 (*c* 0.59, CH_2Cl_2), were prepared. The outcomes of their cyclisation

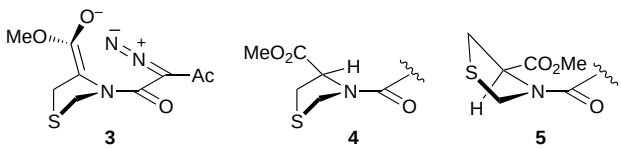


Table 1 Cyclisation reactions of thiazolidines of type **6**

Reactant	R	Conditions	*t*/h	Products	Ratio[a]
6a	Me	KCN–MeOH	2	**7a**,**8a**,**9b**	27 : 9 : 64
6b	Et	KCN–EtOH	4	**7b**,**8b**,**9b**	39 : 20 : 41
6c	Pr^i	KCN–MeOH	2	**7c**,**8c**,**9b**	69 : 23 : 8

[a] Determined by 300 MHz ^{1}H NMR spectroscopic analysis.

reactions are shown in Table 1. Work-ups provided a 72 : 28 mixture of the aldol products **7b** and **8b**‡ (47% yield after chromatography), mp 91–93 °C, $[\alpha]_D$ −98 (*c* 0.38, CH_2Cl_2), and a 72 : 28 mixture of the aldol products **7c** and **8c**‡ (68% yield after chromatography), mp 85–87 °C, $[\alpha]_D$ −95 (*c* 0.29, CH_2Cl_2). Clearly, the desired intramolecular aldol reactions became more favourable as the size of the ester group increased.

The similar optical rotations of the comparable mixtures of the aldol products **7a**/**8a**, **7b**/**8b** and **7c**/**8c** suggested common enantiomeric purities. This was substantiated by a chemical correlation involving the mixtures **7a**/**8a** and **7c**/**8c**. Thus, sequential treatment of the former mixture with Ac_2O–perchloric acid and DBU in CH_2Cl_2 gave the alkene **12a**,‡ mp 73–74 °C, $[\alpha]_D$ +228 (*c* 0.33, CH_2Cl_2). A similar sequence performed on the **7c**/**8c** mixture afforded the alkene **12b**,‡ mp 124–126 °C, $[\alpha]_D$ +215 (*c* 0.41, CH_2Cl_2), which was converted into the methyl ester **12a**, $[\alpha]_D$ +221 (*c* 0.27, CH_2Cl_2), under transesterification conditions (KCN in MeOH). On the basis of HPLC analysis,** compounds **7c** and **8c** were shown to have ees of 99%. It is concluded, therefore, that the aldol products **7a**–**c** and **8a**–**c** are essentially enantiopure.

It remained to establish that the intramolecular aldol reactions had occurred with retention of configuration at the thiazolidine stereocentre. Crystallisation of a 72 : 28 mixture of compounds **7c** and **8c** from hot water provided the major diastereomer, mp 104 °C, $[\alpha]_D$ −108 (*c* 0.33, CH_2Cl_2), which was shown to possess the absolute stereochemistry **7c** by X-ray crystallography†† (Fig. 1). Clearly, the C–H bond adjacent to the alkoxycarbonyl group had been replaced by a C–C bond with retention of configuration. Moreover, there was a kinetic preference to generate the aldol product **7c** over its diastereomer **8c** (and, similarly, of aldols **7a**,**b** over their diastereomers **8a**,**b**).

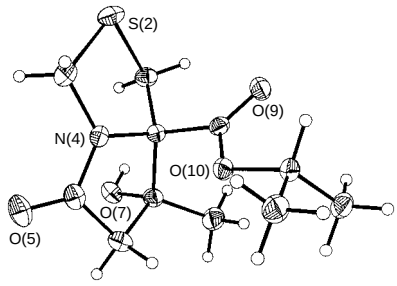

Fig. 1 Molecular structure of compound **7c**

Although stable to the cyclisation conditions, compounds **7c** and **8c** did react with KCN in refluxing MeOH to give mainly the potassium salt **9b**.‡‡ Acidification of an aqueous solution of the salt with Amberlite IR–120 (H^+) ion-exchange resin and subjection of the residue obtained after evaporation to silica gel column chromatography gave the enol **9c**‡ (82% yield), mp 142 °C, $[\alpha]_D$ −89 (*c* 0.51, CH_2Cl_2), as a 72 : 28 mixture of diastereomers, with an ee of 99%.** Evidently, under more forcing conditions, the aldol reaction can be reversed and the enolate intermediates **10a** and **10b** can be reprotonated with essentially complete retention of configuration to regenerate the thiazolidines **6a** and **6c**. Subsequent production of the enolates **11a** and **11b** then leads, by intramolecular acylation reactions, to the salt **9b** with no loss of stereochemical integrity.

As before,[1] we suggest that the stereochemical memory of the enolate **10b** can be accounted for by postulating its generation in an axially chiral form, *e.g.* **13**.

Recently, Fuji reported[3] examples of intermolecular alkylations of *N*-alkoxycarbonyl-*N*-methylphenylalanine esters that proceed with up to 82% ee. In reactions induced by lithium 2,2,6,6-tetramethylpiperidide in THF at −78 °C, they favoured the involvement of a *C*-lithiated intermediate formed with retention of configuration.

The aforecited results are of note in a number of respects. The finding that C–C bonds can be constructed stereoselectively considerably extends the scope of self-induced axial chirality as a stereocontrol element in synthesis.§§ Compounds **7a**–**c**, **8a**–**c** and **12a**,**b** are interesting classes of essentially enantiopure fused heterocycles; by appropriate manipulation they should be convertible into α-*C*-substituted 4-thiaprolines and 5-oxoprolines. Finally, the discovery that the kinetic cyclisation products **7c** and **8c** of the thiazolidine **6c** can be converted into the thermodynamic cyclisation product **9b** provides a striking illustration of stereoretentive protonation accompanying the retroaldol reaction.

We thank the Link Asymmetric Synthesis New Core Programme for a studentship (to J. J.) and the EPSRC/Zeneca Pharmaceuticals for a CASE studentship (to S. V.). We are also grateful to Dr C. M. Raynor (UMIST) and Mr J. A. Whatley (Roche) for the HPLC analyses.

Notes and References

Cycloaddition of *o*-benzyne to benzene and the inner phase of a hemicarcerand

Brett R. Beno, Chimin Sheu, K. N. Houk,* Ralf Warmuth and D. J. Cram

Department of Chemistry and Biochemistry, University of California, Los Angeles, Los Angeles, CA 90095-1569, USA

Becke3LYP/6-31G* calculations predict a small energy of concert for the Diels–Alder reaction of *o*-benzyne with benzene, and force-field calculations indicate that steric interactions and transannular strain are responsible for the regiospecificity of the Diels–Alder reaction between *o*-benzyne and its host hemicarcerand.

In a previous communication, Warmuth reported the Diels–Alder (DA) reaction of an *o*-benzyne guest with an aromatic ring of its hemicarcerand host.[1] We have studied the DA reaction of *o*-benzyne with benzene,[2] and the hemicarcerand using computational methods.[2]

The narrow frontier orbital gap, and especially the low LUMO energy, of *o*-benzyne make it a good dienophile.[3] Owing to the poor overlap of the sp^2 orbitals which combine to form the in-plane π-bond, *o*-benzyne also has a significant amount of diradical character.[4] The *o*-, *m*-, and *p*-isomers of benzyne have been the subject of extensive high-level theoretical studies,[5] and the reactivity of *o*-benzyne as a DA dienophile is well known experimentally,[6] but no computational studies of DA reactions involving *o*-benzyne have been reported.

The benzene–*o*-benzyne DA reaction has been observed experimentally. Miller and Stiles isolated benzobicyclo-[2.2.2]octatriene **4**, biphenyl and benzocyclooctatetraene in a ratio of 1 : 3 : 4, respectively, from the thermal decomposition of benzenediazonium-2-carboxylate in benzene at 45 °C.[7a] The product ratio for the reaction is strongly influenced by Ag^+, a possible contaminant in the Miller and Stiles experiment.[7b,c] In its absence, **4** is the major product.

These results are remarkable, since the DA reactions of benzene are expected to strongly favor closed-shell concerted over stepwise diradical mechanisms.[8] The barrier for the concerted pathway of the benzene–ethene DA reaction is estimated to be 23 kcal mol^{-1} (1 cal = 4.184 J) below that of the stepwise diradical pathway.[8a] However, the diradical character of *o*-benzyne may allow a stepwise mechanism to compete more effectively with a concerted mechanism.

The concerted and stepwise DA reactions were studied using the Becke3LYP hybrid HF-DFT method[9] and 6-31G* basis set.[10] All DFT calculations were carried out using Gaussian 94.[11] RBecke3LYP and UBecke3LYP methods were used for closed- and open-shell species, respectively. Stationary points were characterized with vibrational frequency calculations and thermodynamic quantities were calculated from unscaled frequencies. The hemicarceplex and possible *o*-benzyne–hemicarcerand DA regioadducts were calculated with Macro-Model using the MM2*, MM3* and AMBER* force-fields.[12]

The Becke3LYP/6-31G* optimized geometries of benzene **1**, *o*-benzyne **2**, the concerted transition structure **3**, and cycloadduct **4** are shown in Fig. 1. The length of the partial triple bond in **2** is predicted to be 1.251 Å, in excellent agreement with the experimental value of 1.24 ± 0.02 Å .[13] The DFT structure of **1** is also in good agreement with experiment.[14]

Concerted transition structure **3** occurs early along the reaction coordinate. The forming C(1)–C(7) and C(4)–C(8) bonds are 2.383 Å in length. The benzene moiety is relatively undistorted in the transition structure: the C(2)–C(3) and C(5)–C(6) bonds have decreased in length by 0.024 Å, about 38% of the total difference of their lengths in benzene and cycloadduct **4**. The other four C–C bonds in the benzene moiety have increased in length by 0.025 Å in the transition structure, or 18% of the total change from reactants to products. The deviation of the benzene moiety from planarity is also small. These factors allow a substantial amount of the aromaticity of benzene to be conserved in the transition structure. The largest change in benzyne is a 0.037 Å elongation of the partial triple bond.

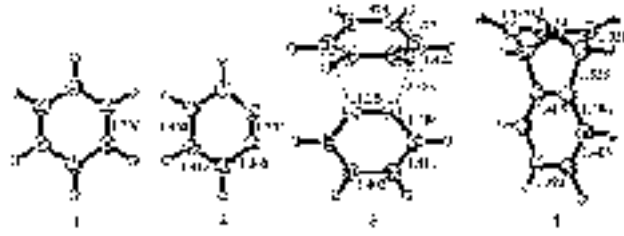

Fig. 1 RBecke3LYP/6-31G* optimized structures of the reactants (**1** and **2**), transition structure **3** and product **4** of the concerted Diels–Alder reaction of benzene with *o*-benzyne. All bond lengths are in Å.

The Becke3LYP/6-31G* $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ (298 K) are 10.7 kcal mol^{-1} and −36.2 cal mol^{-1} K^{-1} and the $\Delta H_{rxn.}$ is −48.7 kcal mol^{-1}. The $\Delta H^{\ddagger}$ for the concerted pathway of the butadiene–ethene DA reaction is 23.4 kcal mol^{-1} at the same level.[2a] Since benzene is not an especially good DA diene, the low barrier can be attributed to the high reactivity of *o*-benzyne as a dienophile.

The $\Delta H^{\ddagger}$ predicted for the benzene–*o*-benzyne DA reaction is coincidentally close to the 12 kcal mol^{-1} experimental value determined by Warmuth for the DA reaction of *o*-benzyne with the aromatic ring of the hemicarcerand (**5**).[1] The aromatic ring in **5** is highly substituted with electron donors, and should be electronically more reactive than benzene. However, steric effects and the difficulty of bending the aromatic ring toward the transition state should decrease its reactivity as a DA diene.

The predicted $\Delta S^{\ddagger}$ for the concerted benzene–*o*-benzyne DA reaction is 25.5 cal mol^{-1} K^{-1} more negative than the $\Delta S^{\ddagger}$ for the *o*-benzyne–hemicarcerand DA reaction.[1] This reflects the greater loss of mobility of the benzene in the intermolecular DA reaction, relative to the reaction within the hemicarcerand where the aryl moiety is already constrained within the framework of the host.

A diradical transition structure **6** and intermediate **7** for the stepwise addition of *o*-benzyne to benzene are shown in Fig. 2. In transition structure **6**, σ bond formation is more advanced than in concerted transition structure **3**, as shown by the relatively short C–C forming bond length of 1.976 Å. As with **3**, the benzyne moiety is relatively undistorted, except for a 0.06 Å lengthening of the partial triple bond.

The $\Delta H^{\ddagger}$ for formation of intermediate **7** is 13.1 kcal mol^{-1}; only 2.4 kcal mol^{-1} above the $\Delta H^{\ddagger}$ for the concerted addition of benzene to *o*-benzyne. The energy of concert is nearly zero. The energy of concert for the DA reaction of ethene with cyclobutadiene, which has significant diradical character, is also smaller.[15]

The $\Delta H_{rxn.}$ for formation of diradical intermediate **7** from **1** and **2** is predicted to be 2.3 kcal mol^{-1}, in good agreement with

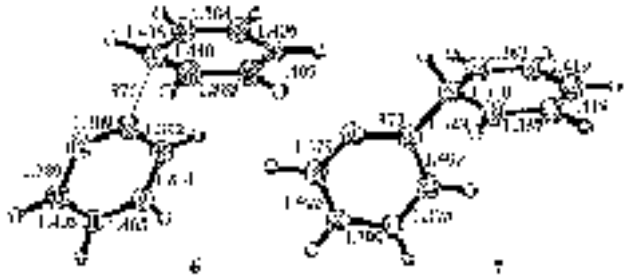

Fig. 2 UBecke3LYP/6-31G* diradical transition structure **6** and intermediate **7** in the stepwise diradical addition of *o*-benzyne to benzene. All bond lengths are in Å.

an estimate based on Benson equivalents[16] and the CASPT2 ΔH_f of benzyne.[5]

Intermediate **7** may lead to biphenyl by hydrogen atom abstraction from C(1) by the C(12) phenyl radical moiety, or [2 + 2] or [4 + 2] cycloadducts *via* rotation about the C(1)–C(7) bond followed by ring closure. These mechanistic pathways are currently being explored.

NMR evidence indicates that of the two possible regioisomeric *o*-benzyne–hemicarcerand DA adducts (Fig. 4), only **8** is formed experimentally.[1] The origin of this regiospecificity was probed using force-field methods. The minimum energy conformer of hemicarceplex **10** was located using molecular dynamics and simulated annealing techniques with the MM3* force-field (Fig. 3). This force-field was also used to obtain optimized geometries and steric energies of DA adducts **8** and **9** (Fig. 4). AMBER* and MM2* gave similar results.

In **10**, the orientation of benzyne is favorable for formation of **8**, *via* a concerted DA reaction (Fig. 3). However, both carbons of the benzyne partial triple bond are > 4 Å from the hemicarcerand atoms to which they are bound in **8**, and substantial motion is required to bring benzyne within bonding distance. Formation of **9** from **10** through a concerted pathway requires benzyne to rotate around its C_2 axis by *ca*. 120°. This should be sterically unfavorable. Either stepwise or concerted mechanisms should be possible.

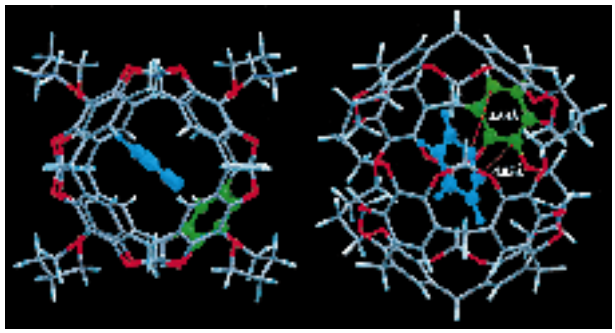

Fig. 3 MM3* minimum energy conformer of the *o*-benzyne hemicarceplex

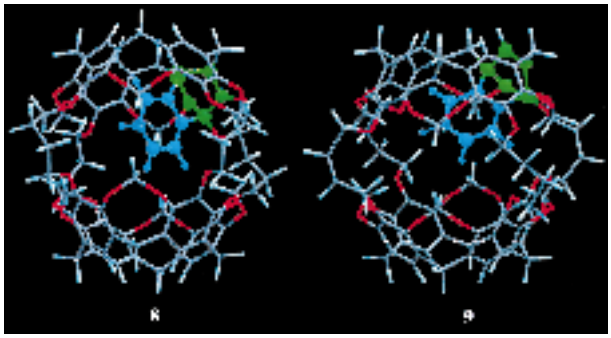

Fig. 4 MM3* optimized stuctures of *o*-benzyne–hemicarcerand Diels–Alder adducts **8** and **9**

Regioisomer **8** is predicted to be 20.0 kcal mol^{-1} more stable than **9**. It is likely that a significant fraction of this energy difference will be felt in the transition state, as well.

Unfavorable steric interactions and greater strain in **9** contribute to the thermodynamic preference for formation of **8**. The Ph group of the benzobicyclo[2.2.2]octatriene moiety is crowded into the top hemisphere of the hemicarcerand in **9**, and several unfavorable steric interactions result. In **8**, the Ph group of the benzobicyclo[2.2.2]octatriene moiety is in a less sterically hindered environment.

Calculations with MM3* on various DA adducts show that the greater transannular strain in **9** contributes significantly to the overall thermodynamic preference for formation of **8**.

We are grateful to the National Science Foundation for financial support of this research, and to the National Center for Supercomputing Applications (NCSA) and UCLA Office of Academic Computing for computer time and facilities.

Statistical analysis of C–H···N hydrogen bonds in the solid state: there*are* real precedents

Mark Mascal*

Department of Chemistry, University of Nottingham, Nottingham, UK NG7 2RD

A survey of the Cambridge Structural Database reveals hundreds of C–H··N contacts which are significantly shorter (< 2.45 Å) than the sum of the van der Waals radii (2.75 Å), effectively refuting recent claims to the contrary and supporting the description of this interaction as a hydrogen bond.

The nature of nonbonded C–H··N interactions has been called into question in the form of a recent publication which has appeared in this Journal.[1] Based on a self-declared 'superficial check of the literature', the authors of this work manage to discredit certain observations of C–H··N hydrogen bonds, while at the same time putting forward their own example of an apparently uncommon and authentic case of this phenomenon. A more thorough search however indicates that the published structure is not extraordinary, rather only one among nearly a thousand such cases.

We were first alerted to problems with the aforementioned paper by simple comparison with some of our own work. The authors make two major assertions, that: (i) 'in most, if not all, of the previously claimed examples of C–H··N "hydrogen bonds" the contact is little (or no) different from that expected for an ordinary, classic van der Waals contact,' and (ii) the C–H··N distance in $Co(dpa)_2$ 'is among the shortest of the C–H··Y, Y = N or O distances'. The $Co(dpa)_2$ complex has a C–H··N distance of 2.44 Å and C–H–N angle of 177°.[1] By way of comparison, the triazine–$2Br_2$ complex[2] has a C–H··N distance of 2.42 Å and a C–H–N angle of 180°, and, indeed, even this is not a particularly remarkable example of such nonbonded contact when the literature on the matter is properly consulted. A statistical analysis of the problem using the Cambridge Structural Database[3] currently indicates no less than 967 observations of intermolecular C–H··N contact with distances (r) less than 2.45 Å and C–H–N angles (α) between 120 and 180°, as identified using the query dialogue within QUEST3D[3] represented in Fig. 1. Histograms for both variables r and α are illustrated in Figs. 2 and 3. The mean C–H···N separation within the sample taken is 2.38 Å,[4] effectively disputing point (ii). Yet another claim, that 'the angles at the H atom are well below (often far below) 180°'[1] is also called into question by the data in Fig. 3, which show that over 100 entries have C–H–N angles between 170 and 180°. In fact, the mean α value of 155° is not far off that for classic N–H··O interactions, which is 161°.[5]

Another difficulty with such a sweeping statement as (i) above is that it entirely ignores the fact that C–H bonds can under some circumstances be as polar as a hydroxy group, whose capacity to participate in hydrogen bonding is not in question. A good example of an interaction involving an acidic C–H is seen in the crown ether **1**–nitromethane complex[6] (Fig. 4) with its C–H··N distance of 2.21 Å and C–H–N angle of 178°.

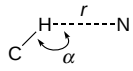

Fig. 1 The QUEST3D query, with conditions $r \leqslant 2.45$ Å and $120 \leqslant \alpha \leqslant 180°$

An entirely systematic study of this phenomenon would involve sampling the nearest neighbour contacts for every (C–)H atom in every structure containing C, H and N and demonstrating that the proportion of close approaches to nitrogen is statistically greater than the stoichiometric content of N in the database. In consideration of the number of structures involved this is clearly not practicable. However, in ground-breaking work, Taylor and Kennard,[7] using a small but representative subset of the databse (relevant neutron diffraction structures), were able to show that 'counterintuitive' C–H··C and C–H··H close contacts are comparatively rare,[8] and one could reason that the profusion of short C–H··N distances strongly implies a tendency for (C–)H to interact with nitrogen in preference to non-H-bond acceptors. Because such a strong case for C–H··O hydrogen bonding has already been made,[8,9] it is logically contentious to challenge the existence of C–H··N hydrogen bonds, since N is generally a more effective hydrogen acceptor than O.[10] Thus, although it is not possible to

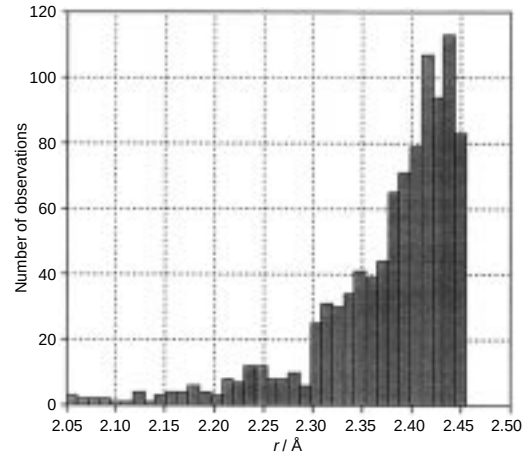

Fig. 2 Histogram for r (C–H···N)

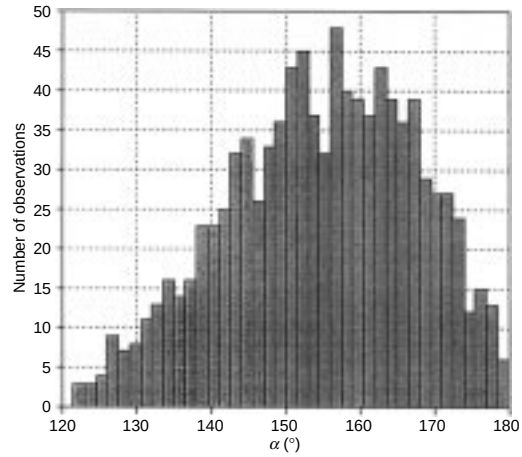

Fig. 3 Histogram for α (C–H–N)

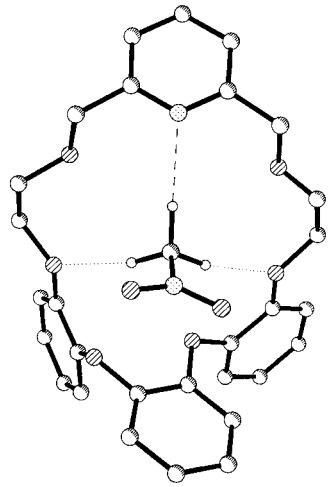

Fig. 4 Crystal structure of the **1**–$MeNO_2$ complex (ref. 6). The C–H··N distance (2.21 Å, dashed line) is actually shorter than the C–H··O distances (2.39 and 2.44 Å, dotted lines).

deliberate over the precise nature of these contacts without individually examining the many hundred occurrences of C–H··N relationships in the literature, the fact that such a large number are significantly shorter than the 2.75 Å sum of the van der Waals radii[11] indicates that the distinction between the classical van der Waals interaction and the hydrogen bond is not necessarily being 'blurred',[1] at least not when all of the available data are taken into consideration.

Dr A. J. Blake is thanked for helpful discussions, and the use of the EPSRC's Chemical Database Service[12] at Daresbury is gratefully acknowledged.

4 Twenty-one entries with r values between 1.47 and 1.99 Å were found dubious and therefore not used in the final analysis. If the range is increased to $r \leqslant 2.50$ Å with $120 \leqslant \alpha \leqslant 180°$, a total of 1841 observations are found with $r = 2.42$ and $\bar{\alpha} = 154°$. An identical search involving neutron diffraction structures (in which all protons are accurately located) produces 13 observations with $\bar{r} = 2.43$ Å (range 2.32–2.50 Å) and $\bar{\alpha} = 150°$ (range 139–166°).

A new route towards deep desulfurization: selective charge transfer complex formation[1]

Valérie Meille,[ab] Emmanuelle Schulz,[a] Michel Vrinat[b] and Marc Lemaire*

[a] *Laboratoire de Catalyse et Synthèse Organique, IRC, UCBL, CPE, 43 Bd du 11 Novembre 1918, 69622 Villeurbanne Cedex, France*

[b] *Institut de Recherches sur la Catalyse, 2, Avenue A. Einstein, 69626 Villeurbanne Cedex, France*

An alternative to the classical hydrodesulfurization process is proposed, based on the formation and subsequent removal of insoluble charge-transfer complexes between suitable π-acceptors and alkylated dibenzothiophenes.

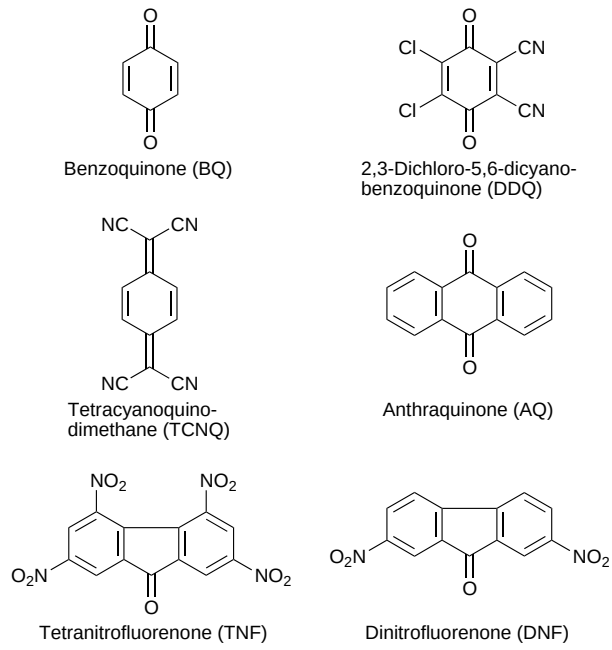
Due to more stringent environmental regulations to protect urban areas and new legislation in Europe, the sulfur level in diesel fuel is now limited to 0.05 wt%, and will certainly be lowered in the near future. However, present refinery diesel hydrodesulfurization (HDS) processes can only be achieved under severe conditions, leading to shorter catalyst life. It is now well established that the achievement of deep HDS is prevented by one type of sulfur compound, namely alkyldibenzothiophenes.[2,3] These molecules have been subject of numerous studies as models to improve the properties of HDS catalysts.[4–6] Recently, a new method has been proposed[7] where the hydrodesulfurized stream is treated with a solid material (activated carbon, alumina, zeolite *etc.*) capable of adsorbing substituted dibenzothiophenes (DBT) by 'form selectivity' and steric hindrance. However, this interesting method presents some limitations because the capacity of the described (weight percent DBT on adsorbent) does not exceed 12% and furthermore, the selectivity factor α [eqn. (1)] toward aromatic system models (1-methylnaphthalene, MN) is just 7.

$$\alpha = \frac{\mathrm{DBT}_{\mathrm{adsorbed}} \cdot \mathrm{MN}_{\mathrm{solution}}}{\mathrm{DBT}_{\mathrm{solution}} \cdot \mathrm{MN}_{\mathrm{adsorbed}}} \quad (1)$$

Considering the electron-rich structure of alkylated DBT, we have studied its ability for form charge-transfer complexes with π-acceptors in order to describe a new method for their specific removal from gas oil.

Electron donor–acceptor complexes are easily detected *via* UV–VIS spectroscopy because their formation is generally accompanied by the appearance of a new absorption band (Benesi–Hildebrand band). Following the method of Foster–Hammick–Wardley,[8] this phenomenon allows the calculation of the association constant (and hence the free enthalpy) characterizing the new complex.

DDQ was tested as a π-acceptor due to its easy availability and its known ability to form charge-transfer complexes. Indeed, a mixture of 4,6-dimethyldibenzothiophene (DMDBT)[9] and DDQ in $CHCl_3$ gave rise to a new absorption wave (λ_{max} 633 nm) corresponding to a ΔG of 15 kJ mol^{-1} (see Fig. 1). 1-Methylnaphtalene was chosen as a model to represent the aromatic compounds contained in the gas oil which are capable of complexing DDQ competitively with DMDBT to form charge-transfer complexes. Using the same procedure as for DMDBT, DDQ and MN formed a charge-transfer complex showing a maximum absorption at 654 nm (ΔG = 7.3 kJ mol^{-1}) (see Fig. 2). This result indicates stronger complexation of DDQ with the sulfur compound than with the aromatic one. Complexation thus appears to be selective toward alkyl–DBT species, although the π-acceptor's chosen structure had not been optimized.



Having demonstrated the possibility of forming selectively a charge-transfer complex between DMDBT and DDQ, we have tested several other π-acceptors. The properties required are a high selectivity factor α for DMDBT toward the aromatics, and complete insolubility in alkanes in order to easily remove the complex formed from the gas oil.

The procedure used to test the different π-acceptors is as follows: an equimolar solution of DMDBT and MN in heptane (11 mmol l^{-1}) was stirred at room temperature in the presence of dodecane (1 equiv.) as the internal reference. The addition of the π-acceptor (1 equiv.) was followed by the immediate

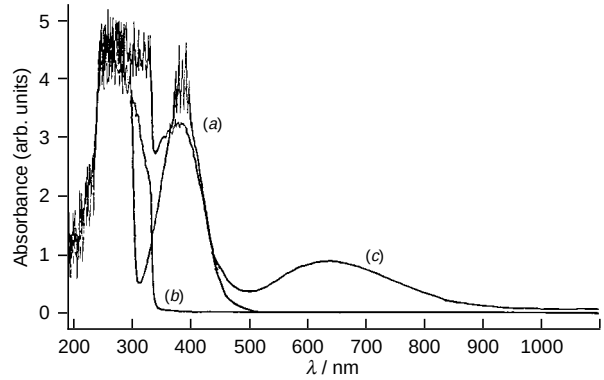


Fig. 1 UV–VIS spectrum from the donor–acceptor complex DMDBT–DDQ in $CHCl_3$; (*a*) DDQ, (*b*) 4,6-DMDBT and (*c*) complex

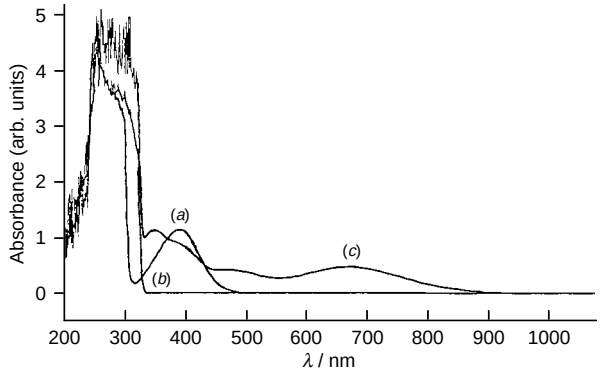

Fig. 2 UV–VIS spectrum from the donor–acceptor complex MN–DDQ in $CHCl_3$; (*a*) DDQ, (*b*) MN and (*c*) complex

formation of a coloured precipitate (except for *p*-benzoquinone). The samples were removed and the composition of the resulting solution analysed by gas chromatography to determine the amount of unreacted MN and DMDBT. The capacity value *C* [eqn. (2), where MW equals molecular weight] and the

$$C = \frac{\mathrm{MW_{DBT}}}{(\mathrm{MW_{DBT}} + \mathrm{MW_{acceptor}})} \times 100 \qquad (2)$$

separation factors α were calculated for each complexing material and are reported in Table 1 (for a direct comparison with results reported with solid materials as adsorbent, see ref. 7). Among all the π-acceptors tested, tetranitrofluorenone (TNF) seems to have the best characteristics, with a maximum factor of separation (rapidly reached) and a satisfactory capacity.

Fluorene was then used instead of MN to check the selectivity for DMDBT in the presence of a molecule rich in electrons with a similar geometry.[10] In this case, the selectivity factor was only 80 after 60 h stirring. Even if this value is lower than the previous one with MN, the selectivity remains higher than that obtained with adsorbent materials by shape selectivity.[7]

Following the results of this preliminary study on model molecules, the possible selective complexation of substituted DBT from a gas oil, already hydrodesulfurized (960 ppm) by classical methods, was examined. Firstly, the gas oil was diluted in heptane (15 g in 200 ml) and analysed by X-ray fluorescence spectroscopy, which showed a sulfur level of 214 ppm. Taking into account that this value is representative of the quantity of alkyldibenzothiophenes (and more precisely 4,6-DMDBT) present as refractory molecules, an equimolar quantity of TNF was added and the heterogeneous mixture was stirred at room temperature. After 74 h, the sulfur level of the solution obtained after filtration was only 120 ppm.

A similar experiment was conducted with pure gas oil (1920 ppm sulfur, at least 50% being 4,6-DMDBT) and the same π-acceptor, leading to 840 ppm sulfur after 92 h stirring. In these two examples, we have been able to remove 60 wt% of the initial sulfur containing compounds by formation of insoluble charge-transfer complexes. A detailed GC analysis would provide us with a precise distribution of the sulfur compounds contained in the residual gas oil. This work is in progress.

Table 1 Capacity and selectivity factor values for DMDBT and MN for different complexing materials depending on the stirring time

	α			
π-Acceptors	4 h 30 min	29 h	96 h	*C* (%)
BQ	Soluble	—	—	—
DNF	—	—	—	—
AQ	—	—	3	50
DDQ	28	35	> 1000	48
TNF	137	> 1000	> 1000	37
TCNQ	10	132	191	51

We have thus demonstrated that the sulfur compounds remaining in the gas oil after deep HDS (*i.e.* alkyldibenzothiophenes) are able to form stable electron donor–acceptor complexes with common π-acceptor compounds. These complexes are then easily separated from aliphatic/aromatic mixture by simple filtration. This behaviour is of major importance to the development of an analytical method for the determination of the exact composition and structure of the sulfur compounds contained in such mixtures. Work is in progress to create a polymer containing such a π-acceptor structure (and which is thus easily regenerated) and then a new process for limiting the sulfur level in the gas oil by formation and subsequent removal of charge–transfer complexes.

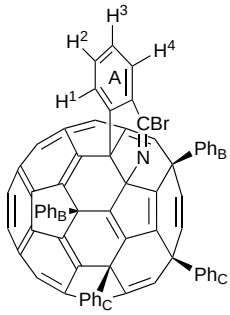
Novel formation of a phenylated isoquinolino[3′,4′ : 1,2][60]fullerene

Ala'a K. Abdul-Sada, Anthony G. Avent, Paul R. Birkett, Adam D. Darwish, Harold W. Kroto, Roger Taylor,* David R. M. Walton and Oliver B. Woodhouse

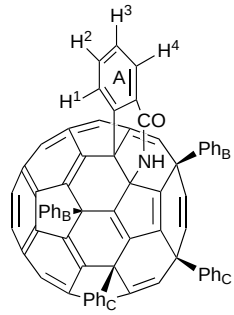
The Chemistry Laboratory, CPES School, University of Sussex, Brighton, UK BN1 9QJ

Reaction of $C_{60}Ph_5Cl$ with cyanogen bromide results in replacement of the chlorine by BrCN and ring closure between the addend and an adjacent phenyl ring, giving a 1-bromoisoquinoline derivative of [60]fullerene; this readily undergoes nucleophilic replacement of Br by OH to give the corresponding 1-isoquinolone derivative.

Recently we described a novel spontaneous oxidation of $C_{60}Ph_5X$ (X = H, Cl) into a benzo[*b*]furan derivative of [60]fullerene, whereby oxygen forms a bridge between the cage and one of the phenyl rings.[1] We now report a related ring closure whereby reaction of BrCN with the above chloro precursor results in chlorine loss, and formation of a bromine-substituted CN bridge between the cage and the *ortho* position of the adjacent phenyl ring. This product is a 1-bromoisoquinoline derivative of [60]fullerene **1**. The resulting product then undergoes nucleophilic substitution of the bromine by hydroxide followed by tautomerism to give the isoquinolone derivative **2**, the spectroscopic data for which further confirm the precursor structure.



1



2

Cyanogen bromide (660 mg) and $FeCl_3$ (106 mg) were added to a solution of $C_{60}Ph_5Cl$ (52 mg) in dry benzene (50 cm^3). The mixture was heated under reflux for 4 h, during which time it was monitored by TLC. After *ca*. 45 min an orange microcrystalline solid began to form. The reaction mixture was cooled to room temperature, and the solvent removed under reduced pressure to give a dark residue which was washed with Et_2O to remove $FeCl_3$ and CNBr. The remaining orange–red solid was dissolved in CCl_4 (this can be helped by sonication) and then column chromatographed (SiO_2, CCl_4) to remove a small amount of $C_{60}Ph_5Cl$, giving a single orange fraction which, after solvent removal, produced an orange crystalline solid (80%). Washing the column with CH_2Cl_2 yielded a second orange fraction which, after solvent removal, was allowed to crystallise from benzene.

The FAB mass spectrum showed the parent ion at 1211 amu, which indicated overall replacement of Cl by CNBr. The IR spectrum showed a strong peak at 1646 cm^{-1} indicative of a C=N stretch and a band at 616 cm^{-1} attributable to a C–Br stretch (Fig. 1). This strongly suggests the presence of a C(Br)=N group in the molecule, and NMR spectroscopic analysis revealed the compound to be **1**.

The ^{13}C NMR spectrum shows **1** to have C_s symmetry, with four peaks in the sp^3 region for the cage carbons appearing at δ 74.84 (1 C), 59.77 (2 C), 57.77 (2 C) and 57.36 (1 C) [*cf.* 75.91 (1 C), 60.39 (2 C), 57.72 (2 C) and 62.98 (1 C) for the chloro precursor].[2] Previously we assigned the most downfield resonance to C-2 from a comparison of the resonance changes on replacing Cl by H (which causes an upfield shift of δ 17.5). The results suggest that the bromocyano group is likewise attached to C-2, and *via nitrogen*. For the cage the required 28 lines for sp^2 carbons (2 × 1 C, 26 × 2 C) appear (all 2 C except where indicated) at δ 161.10 154.21, 151.81, 148.65, 148.21, 148.16, 148.10, 148.04, 147.94, 147.76 (1 C), 147.64, 147.20, 146.86 (1 C), 146.82, 146.54, 146.42, 145.0, 144.74, 144.14 (4 C), 143.99, 143.67 (4 C), 143.48, 143.37, 143.26, 142.74 and 142.17. The spectrum also shows two *ortho* (4 C) peaks at δ 128.36/127.33, two *meta* (4 C) peaks at δ 127.81/127.24, two *para* (2 C) peaks at δ 127.33 (coincident)/126.87, four ipso peaks at δ 146.55 (1 C), 139.18 (2 C), 136.88 (2 C) and 132.07 (1 C) and five other peaks (all 1 C) at δ 131.49, 130.81, 127.04, 124.77 and 124.22 (one of this group being the carbon of the C(Br)N group). This shows that one phenyl ring has *two* substituents attached, namely the fullerene cage and the C(Br)N group.

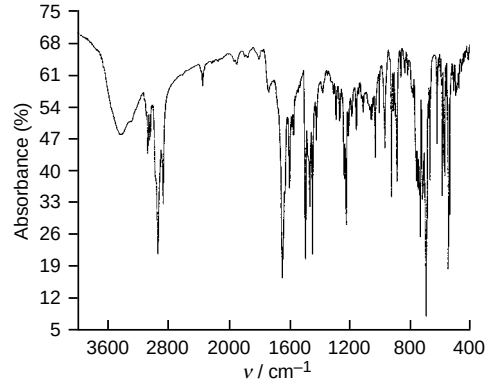


Fig. 1 IR spectrum (KBr) for $C_{91}H_{24}NBr$ (**1**)

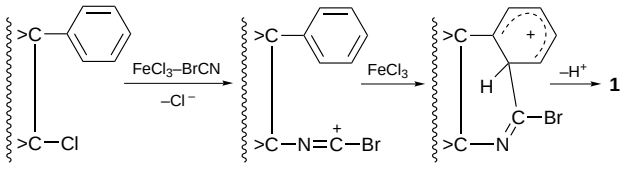
The ^1H NMR spectrum is assigned as follows (aryl ring notation as in **1**): (i) rings B, δ 7.61–7.59 (4 H, dd, *o*-H), 7.34–7.31 (2 H, m, *p*-H), 7.26–7.22 (4 H, m, *m*-H); (ii) rings C, δ 7.21–7.19 (4 H, dd, *o*-H), 7.075–7.055 (2 H, m, *p*-H), 7.00–6.96 (4 H, m, *m*-H); (iii) ring A, δ 7.91 (1 H, dd, H^4), 7.79 (1 H dd H^1), 7.20 (1 H, dd, H^3), 7.17 (1 H dd, H^2); the couplings were approximately 7.5 and 1.5 Hz, but could not in some cases be accurately given because of peak coincidences.

The locations of the hydrogens in ring A were determined by 2D-COSY and NOE analysis, which showed interaction between H^1 and the *ortho* hydrogens of rings B. The downfield resonance for h^1 is consistent with our previous observation that resonances for hydrogens pointing towards the cage are shifted downfield,[3] whilst that for H^4 is attributable to the adjacent C–Br substituent.

The mechanism proposed (Scheme 1) is supported by the following: (i) reaction will not occur with the corresponding 4-fluoro derivative [$C_{60}(4\text{-}FC_6H_4)_5Cl$] and (ii) no reaction takes place in the absence of $FeCl_3$. If nucleophilic substitution by the nitrogen of the BrCN group were to take place on the aryl



Scheme 1

addend (giving, ultimately, a quinoline derivative), this would be enhanced in the fluorophenyl compound and would occur *meta* to fluorine, *i.e. ortho* to the fullerene cage, which is the site required for the subsequent ring closure. Since reaction does not occur, electrophilic substitution by the carbon of the BrCN group into the aryl ring (giving an isoquinoline derivative) is indicated. However, this is unlikely to occur as a first step since substitution would in general take place at the more accessible position *para* to the cage. It is probable therefore that the initial step involves nucleophilic replacement of the cage-attached chlorine by BrCN, giving an intermediate fullerene–N=C$^+$–Br moiety, followed by electrophilic substitution by the imino carbocation of this group into the phenyl ring; $FeCl_3$ will aid polarisation of the cage–Cl bond just as it does in nucleophilic replacement of cage chlorines by phenyl groups.[2] Electrophilic substitution in aryl rings attached to fullerenes is normally difficult owing to the very strong electron withdrawal by the cage. However, the above intermediate will be strongly electrophilic, and the electrophilicity may be increased further through polarisation of the C–Br bond by $FeCl_3$. A related Lewis acid-catalysed intramolecular electrophilic aromatic substitution of isocyanide dihalides has also been described recently.[4] It is probable that the present reaction is synchronous and synergistic, since $C_{60}Cl_6$ itself does not react with cyanogen bromide–$FeCl_3$.

Confirmation of the structure comes from nucleophilic replacement of the bromine by hydroxide to give **2**, which has the low solubility typical of amides, obtained as orange–red plates from benzene. This occurs both on standing in air and was observed to result from reaction with either Zn–AcOH or HCl–AcOH. (Zinc accelerates the reaction, although the reason for this is unclear.) The mass spectrum of **2** gives the parent ion at the required 1148 amu. The IR spectrum (Fig. 2) shows a new C=O band at 1669 cm^{-1}, an N–H stretch at 3368 cm^{-1} and no C–Br stretch. The correct location of the carbon and nitrogen of the bridge with respect to the cage and phenylene group are confirmed by both the ^{13}C and ^{1}H NMR spectra.

The ^{13}C NMR spectrum shows the product to have C_s symmetry, the four peaks in the sp^3 region appearing at δ 65.56 (1 C), 60.74 (1 C), 60.57 (2 C) and 58.30 (2 C). Thus, whereas the ring carbons bearing the two pairs of phenyl rings have very similar shifts to those in the precursor, one of the two unique carbons has shifted markedly upfield whilst the other has shifted downfield (and to a smaller extent). This is entirely consistent with the proposed structure of **2** compared to that of **1**. The sp^2-hybridised nitrogen on the cage has changed to sp^3 hybridisation (thereby resulting in a marked upfield shift of the attached carbon), whereas the phenyl group now has an electron-withdrawing CO group attached, so that the fullerene carbon attached to this ring experiences a downfield shift. Since the electron withdrawing CO moiety is more remote than the electron-withdrawing –N= moiety, the downfield shift should be smaller than the upfield one, as observed.

For the cage, the required 28 lines for sp^2 carbons (2 × 1 C, 26 × 2 C) appear (all 2 C except where indicated) at δ 160.86, 154.22, 152.10, 148.62, 148.52 (4 C), 148.36, 148.22, 148.04 (1 C), 147.94, 147.84, 147.48, 147.35 (1 C), 147.01, 148.86, 146.77, 145.43, 144.79, 144.46, 144.38, 144.21, 143.99, 143.93, 143.90, 143.77, 143.17, 142.83 and 142.53; the resonance for the C=O group appears at δ 161.34. The ipso peaks appear at δ 133.78 (1 C), 139.42 (2 C), 136.99 (2 C) and 132.08 (1 C), and it can be seen that the last three values are

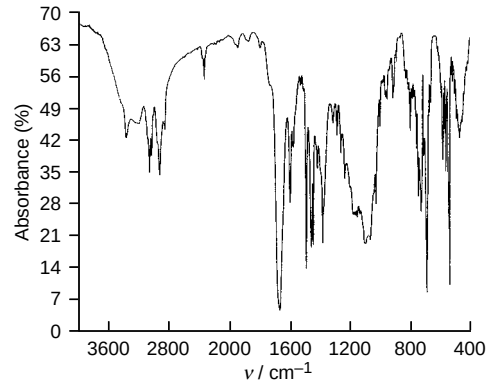


Fig. 2 IR spectrum (KBr) for $C_{91}H_{25}NO$ (**2**)

almost identical to those in the precursor **1**. The first value can be assigned to the aryl ring carbon which is adjacent to the C–Br group in **1** and the C=O group in **2**. The normally stronger electron withdrawing effect of the carbonyl group[5] is evidently moderated through resonance with the adjacent nitrogen lone pair.

The ^{1}H NMR spectrum is assigned as follows, the hydrogen locations being identified by 2D-COSY and NOE analysis. Ring notations are as in **2**; couplings are not given due to peak coincidences, and splitting could not be resolved for H^3 and H^2: (i) rings B, δ 7.66–7.64 (4 H, d, *o*-H), 7.36–7.33 (2 H, t, *p*-H), 7.29–7.25 (4 H, t, *m*-H); (ii) rings C, δ 7.27–7.25 (4 H, d, *o*-H), 7.09—7.06 (2 H, t, *p*-H), 7.01–6.98 (4 H, t, *m*-H); (iii) ring A, δ 8.12 (1 H, dd, H^4), 7.92 (1 H, dd, H^1), 7.28 (1 H, H^2), 7.23 (1 H, H^3); (iv) δ 7.03, (1 H, s, –CONH–).

This identification for H^1 was confirmed by NOE enhancement (4.1%) of the signal for the *ortho* hydrogens of ring B. The resonances for hydrogens in ring A are all shifted downfield relative to those in the precursor, which is consistent with CO being substituted on this ring, but not with –N= being attached originally to this ring and then converted to –NH– on hydrolysis. The relatively greater downfield shift in **2** compared to **1** of the resonance for H^1 relative to that of H^3 (both positions being *meta* to the substituent) is consistent with C–N bond lengthening in the quinolone relative to the quinoline, forcing H^1 slightly nearer to the cage. AM1 calculations indicate that the cage–H^1 distance is reduced from 2.634 Å in the bromoisoquinoline to 2.61 Å in the isoquinolone. Similarly, the greater downfield shift for H^4 (*ortho*) relative to H^2 (*para*) is consistent with the calculated H^4–O distance (2.49 Å) in **2** compared to the H^4–Br distance (2.63 Å) in **1**.

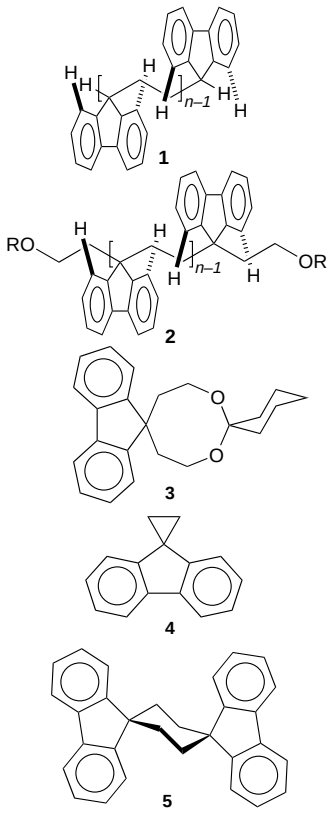
Polymers and oligomers with transverse aromatic groups and tightly controlled chain conformations

Roger W. Alder,*† Kevin R. Anderson, Paul A. Benjes, Craig P. Butts, Panayiotis A. Koutentis and A. Guy Orpen

School of Chemistry, University of Bristol, Cantock's Close, Bristol, UK BS8 1TS

Anionic ring-opening polymerisation of spiro[cyclopropane-1,9′-fluorene] with fluorenyl anion as initiator yields polymers 1 with chains which are essentially all-*anti* and have transversely-oriented fluorenyl groups, as shown by strong upfield shifts for the mid-chain methylene and 1,8-fluorenyl protons; synthetic routes to some specific oligomers are also reported.

Controlling the secondary structure of acyclic molecules and polymers is important for many applications. We have shown that quaternary centres exert extensive conformational effects on adjacent chains.[1,2] Combining these effects with the rigid side groups provided by transversely-oriented fluorene rings should lead to a polymer **1** with a highly-constrained all-*anti* (extended chain) secondary structure; any *gauche* bonds in the chain create strong interactions between CH_2 groups in the chain and the 1,8-CH groups on the fluorene rings. Calculations on oligomers using the MM3 force field[3,4] predict that all-*anti* structures are 9–10 kJ mol^{-1} more stable than the next best conformation, which has one *gauche* bond in the terminal section of the chain. Introduction of *gauche* bonds in the interior parts of these oligomers costs 13.5–14 kJ mol^{-1}, corresponding to a > 200 : 1 preference for all-*anti* conformations at ambient temperature in these parts of the chain. In structures like **1**, *anti* conformations can be readily recognised from the upfield shifts in ^{1}H NMR spectra due to aromatic ring current effects. Thus the CH_2OH protons in diol **2** (n = 1, R = H), whose X-ray structure‡ is shown in Fig. 1, resonate at δ 2.85, whereas in acetal **3** the corresponding protons occur at δ 3.95.



Anionic ring-opening polymerisation is a common process for heterocyclic monomers like epoxides, but it has barely been explored for hydrocarbon monomers like cyclopropanes. [1.1.1]Propellane[5] and some bicyclobutanes[6] (which have much higher strain energies) and a few vinylcyclopropanes[7] have been polymerised by this process. Simple 1,1-disubstituted cyclopropanes with two anion-stabilising groups appear good candidates, but the only example in the literature is with CO_2Me as the stabilising group.[8]

We find that polymerisation of spiro[cyclopropane-1,9′-fluorene][9] **4** can indeed be initiated by an S_N2 reaction with fluorenyllithium. Temperatures > 100 °C are required; we have used DMPU as solvent, but HMPA is also effective. During polymerisation reactions with monomer : initiator ratios > 3 : 1, a precipitate appears after about 10 min at 150 °C, raising concern that chain growth may be limited by the insolubility of the product. This insolubility precludes any simple determination of the degree of polymerisation (DP), but NMR data (see below) indicate that oligomers below the octamer **1** (n = 8) are almost absent in products from reactions with monomer : initiator ratios > 12 : 1, so polymerisation probably continues in spite of the precipitation. Further optimisation of this polymerisation will be undertaken and we intend making modified monomers with flexible chains on the periphery of the aromatic rings to improve solubility.

We found a much improved synthesis of **4** in > 90% yield from fluorene, BuLi and ethylene sulfate.[10] Ethylene sulfate is much more efficient in this reaction than 1,2-dibromoethane, which gives mixtures of dimer **1** (n = 2),[11] **4** and cyclohexane derivative **5**,§ even when fluorenyllithium is added slowly to excess dibromide. Ethane-1,2-diyl dimesylate only gives **4**, without **1** (n = 2) or **5**, but is relatively unreactive. We are investigating the reasons for the effectiveness of ethylene

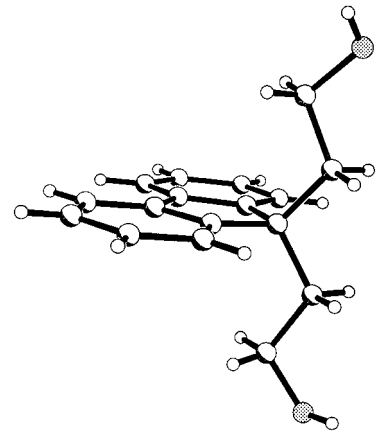


Fig. 1 X-Ray structure of diol **2** (n = 1, R = H) showing the all-*anti* aliphatic chain

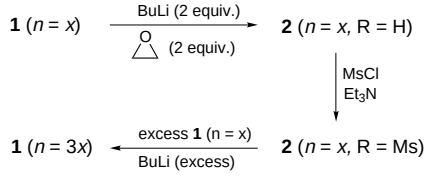

Scheme 1

sulfate in this cyclisation, and whether this observation has more general implications.

In order to examine the physical properties of the novel structure represented by **1**, we have prepared some specific oligomers by a general route. Thus reaction of an excess of the monoanion of dimer **1** (n = 2) (prepared using BuLi) with dimesylate **2** (n = 1, R = OMs) gives the pentamer **1** (n = 5), along with small amounts of the octamer from reaction of 3 equiv. of **1** (n = 2) with 2 equiv. of **2** (n = 1, R = OMs). Similarly, reaction of excess fluorenyl anion with dimesylate **2** (n = 2, R = OMs) gives the tetramer **1** (n = 4) and reaction of an excess of the monoanion of dimer **1** (n = 2) with dimesylate **2** (n = 2, R = OMs) gives the hexamer **1** (n = 6). Since mesylates **2** (R = OMs) are readily prepared from the hydrocarbons **1**, this route can potentially be used repetitively with a rapid growth in DP, as shown in Scheme 1, so long as starting oligomer can be separated from the product. Reaction of excess fluorenyl anion with dimesylate **2** (n = 1, R = OMs) only gives **5**, with no observable trimer formation, but trimer can be isolated by preparative TLC from polymerisation runs with 2 : 1 ratios of **4** : fluorenyllithium. These oligomers can be capped at both ends by double deprotonation with BuLi, and reaction with electrophiles [*e.g.* MeI, MEMCl, oxirane and $(PhS)_2$], and many of these derivatives show improved solubility.

Somewhat surprisingly, the best solvent for **1** is $CHCl_3$, the solubility of the tetramer, pentamer and hexamer are > 45, 31 and 26 mg ml^{-1} respectively; the heptamer is very insoluble. In the ^{1}H NMR spectra of oligomers **1** (n = 2–6) in $CDCl_3$, CH_2 groups and some aromatic protons are shifted upfield substantially, with shifts increasing towards the middle of the molecule and with increasing chain length. The shifts for CH_2 groups range from δ 1.75 for the dimer to δ 0.42 for the central CH_2CH_2 in the hexamer. As might be expected, the largest upfield shifts for the aromatic protons are observed for the 1,8-fluorenyl protons (Table 1), with progressively smaller shifts for the 2,7-, 3,6- and 4,5-protons.Upfield shifts for the 1,8-fluorenyl protons are predictable to within 0.02 ppm from a simple additivity scheme based on the number of fluorene units which are α (adjacent), $\Delta\delta$ −0.38, β (next to adjacent) $\Delta\delta$ −0.26, γ $\Delta\delta$ −0.11, δ $\Delta\delta$ −0.04, ε $\Delta\delta$ −0.02 and ϕ $\Delta\delta$ −0.01; this scheme allows us to identify the heptamer from polymerisation reactions and the octamer as a by-product of the preparation of the pentamer. It predicts that the 1,8-fluorenyl protons in the middle of the polymer should resonate at δ 6.04, and we believe that it provides excellent evidence for a strong preference for the all-*anti* conformation in solution. These polymers and oligomers therefore possess a novel architecture (flexible, but possessing many of the attributes of a rigid rod). They could be useful as molecular spacers, and the regular array of aligned aromatic rings is an intriguing feature. The distance between two aromatic rings on the same side of the polymer chain, calculated to be 7.71 Å, gives enough room to intercalate another aromatic ring between them. Furthermore, the intervening chains, while saturated, are perfectly aligned for maximum through-bond coupling,[12] and electron- and energy-transfer down these chains may well be rapid. Finally, we point out that anionic ring-opening polymerisation of 1,1-disubstituted cyclopropanes has now been observed for cases where the growing anion is a malonic ester derivative[8] (pK_a ~ 13) and where it is a fluorenyl anion (pK_a ~ 22). We are exploring the limits for this process, but we believe that many novel polymeric structures might be made this way.

Table 1 ^{1}H NMR chemical shifts in $CDCl_3$ for 1,8-fluorenyl protons in oligomers **1**

	δ_H(ppm)			
	Ar^1 (Terminal rings)	Ar^2	Ar^3	Ar^4
Dimer	7.28			
Trimer	7.01	6.89		
Tetramer	6.90	6.63		
Pentamer	6.86	6.53	6.39	
Hexamer	6.84	6.48	6.28	
Heptamer	6.83	6.46	6.24	6.18
Octamer	6.83	6.45	6.22	6.14

A new approach to steroid ring construction based on a novel radical cascade sequence

Sandeep Handa, Gerald Pattenden*† and Wan-Sheung Li

Department of Chemistry, Nottingham University, Nottingham, UK NG7 2RD

A new approach to steroid ring construction based on sequential cascade 6-*endo-trig* cyclisation/macrocyclisation/ transannulation reactions and exemplified in the synthesis of the *cis, anti, cis, anti, cis* tetracycle 17 from 15, is presented.

Since their structures were firmly established some fifty years ago, there have been a wide range of imaginative approaches to the total synthesis of natural steroids and to steroidal ring systems. Perhaps paramount amongst the methods that have been developed are those based on either Diels–Alder reactions (inter- and intra-molecular, including transannular based)[1] or biomimetic-type electrophilic cyclisations of polyene precursor compounds.[2] In recent years our own research group has been examining the scope for a range of cascade radical processes in the synthesis of steroids, including those based on consecutive 6-*endo-trig* cyclisations from appropriate polyene acyl radical precursors,[3] and those based on radical macrocyclisations in tandem with radical transannulations.[4] Indeed, these approaches have led to some highly efficient routes to steroids, including aza-steroids[5] and some natural products.[6] We have now conceived a new approach to steroid constructions, based on these earlier studies, whereby the A/B ring system is elaborated by consecutive 6-*endo-trig* cyclisations (**1** → **2**), *in concert with* formation of the C/D ring system *via* a macrocyclisation/ transannulation sequence (**3** → **4** → **5**), from an appropriately functionalised cyclopropyl-based polyene precursor **1** (Scheme 1).

Thus we chose the cyclopropyl substituted trienone selenyl ester **7** as the starting point for our cyclisation studies. The selenyl ester group was chosen as the radical precursor because of the known propensity for hex-5-enoyl radicals to undergo 6-*endo* cyclisations,[3,7] and the conjugated enone group was incorporated in the substrate **7** to facilitate the 9-*endo-trig* cyclisation[8] following ring-opening of the cyclopropylcarbinyl radical intermediate (*cf.* **2** → **3** → **4**, Scheme 1). The synthesis of **7** was achieved in fifteen steps from the known bromo alcohol **6** (Scheme 2).[9,10] When a solution of the selenyl ester **7** in dry degassed benzene (4 mM), at reflux, was treated with Bu_3SnH (syringe pump addition over 4 h) in the presence of AIBN, one major product was isolated in *ca*. 40% yield. Analysis of the spectroscopic data for the compound showed that, instead of generating the steroid dione structure **9** resulting from the predicted cascade highlighted in Scheme 1, the acyl radical intermediate **8** had undergone a single 14-*endo-trig* cyclisation producing the macrocyclic 1,4-dione **10**.[11]

The efficient 14-*endo-trig* macrocyclisation of the nucleophilic acyl radical **8**, leading to **10**, over the competing 6-*endo-trig* cascade is no doubt a consequence of the electrophilicity of the terminal enone in **8**. In light of this we designed a new cyclisation precursor to avoid the competing pathway. The designed polyene selenyl ester **15** incorporates two carboxylate ester moieties, the first of which [at C(5)] was introduced in order to increase the rate of 6-*endo-trig* cyclisation of the acyl radical precursor and the second [at C(13)] was incorporated to lower the electrophilicity of the terminal olefin (with respect to **7**). The new precursor **15** was prepared as shown in Scheme 3. Thus formation of the Normant Grignard reagent from 3-chloro-

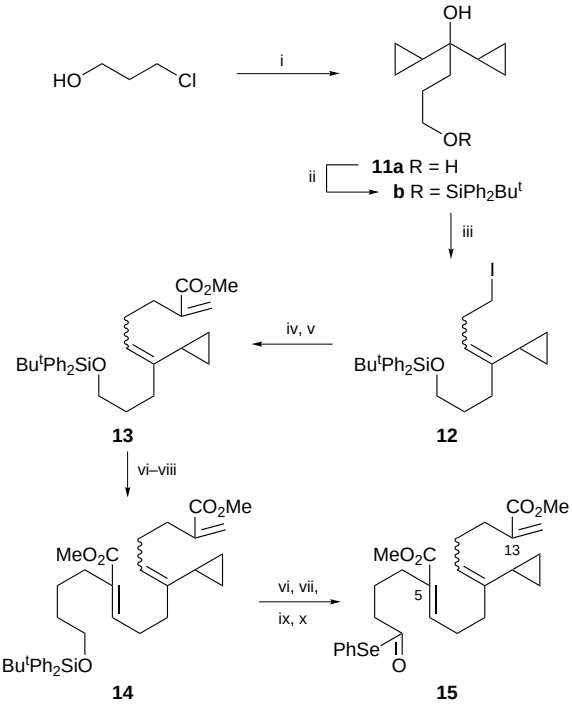

Scheme 3 *Reagents and conditions*: i, MeMgBr, THF, −30 °C, Mg, 70 °C, then dicyclopropyl ketone, 68%; ii, Bu^tPh_2SiCl, imidazole, 97%; iii, NIS, PPh_3, CH_2Cl_2 −30 °C, 64%; iv, NaH, trimethyl phosphonoacetate, DMSO, 73%; v, NaH, $(CH_2O)_3$, 85%; vi, TBAF, 91–95%; vii, Dess–Martin periodinane, 90–92%; viii, NaH, $Bu^tPh_2SiO(CH_2)_4CH(CO_2Me)PO(OMe)_2$ **16**, 0 °C, 87%; ix, KH_2PO_4, Bu^tOH, H_2O, $NaClO_2$, 2-methylbut-2-ene, 95%; x, *N*-(phenylseleno)phthalimide, PBu_3, −30 °C, 72%

propanol followed by reaction with dicyclopropyl ketone first gave the diol **11a** which was then protected selectively as its TBDPS ether **11b**. Selective ring opening of one of the cyclopropane rings in **11b** was achieved by treatment with *N*-iodosuccinimide (NIS)–PPh_3 to produce the vinyl cyclopropyl intermediate **12** as a 1 : 1 mixture of *E*- and *Z*-isomers. Nucleophilic displacement of the homoallylic iodide in **12** by the anion generated from trimethyl phosphonoacetate and subsequent Wadsworth–Emmons reaction with paraformaldehyde next installed the terminal methacrylate residue in the form of intermediate **13**. The silyl ether group in **13** was converted into the corresponding aldehyde which was then used in a further Wadsworth–Emmons olefination with the phosphate **16** giving the triene **14** as a mixture of separable isomers about the newly formed double bond. Finally, a series of functional group interconversions then led to the target selenyl ester **15**.

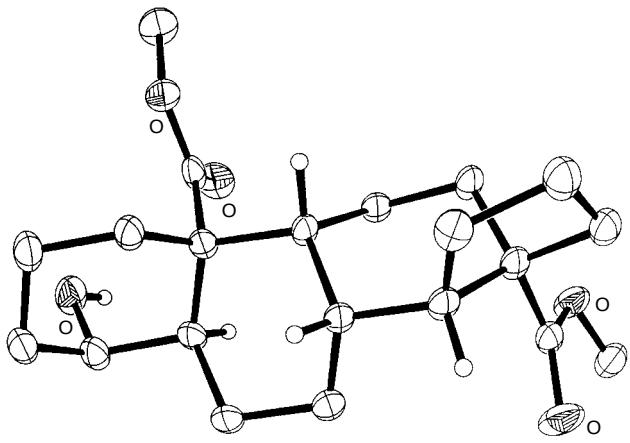

Fig. 1 X-Ray crystallographic structure of **18**

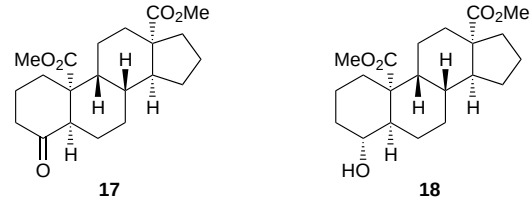
Treatment of the selenyl ester **15** with Bu_3SnH–AIBN under conditions similar to those which produced **10** from **7** led to the formation of one major product in *ca*. 45% yield, and some minor products. Detailed analysis of the NMR data for the separated major product indicated that the compound had the hoped-for tetracyclic (steroid) ring system, but the data could not define its stereochemistry unambiguously. Fortunately, the tetracyclic ketone product could be reduced selectively using $NaBH_4$ leading to the crystalline carbinol **18**, mp 126–128 °C (Et_2O–light petroleum). An X-ray crystallographic analysis of this tetracycle showed, surprisingly, that it had the very unusual *cis, anti, cis, anti, cis*-stereochemistry, *viz*. **17** and **18** (Fig. 1). Thus we had not only demonstrated the scope for the new strategy for steroid ring construction enunciated in Scheme 1, but we have also uncovered a route to the unusual all *cis*-stereochemistry for the steroid ring system produced when **15** undergoes a radical cascade cyclisation to **17**. Further studies are now in progress to develop this novel stratagem for polycycle construction in other fused ring systems.



We thank the EPSRC for support of this work *via* a Postdoctoral Fellowships (to S. H. and W-S. L.) and purchase of the X-ray diffractometer.

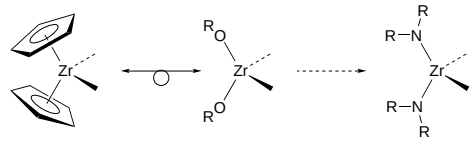
Treatment of $Zr(NMe_2)_4$ with $RNH(SiPh_2)NHR$ and $RNH(Me_2SiCH_2CH_2SiMe_2)NHR$ (R = 2,6-$Me_2C_6H_3$) affords the four- and seven-membered chelate complexes $\{Zr[RN(SiPh_2)NR](NMe_2)_2(HNMe_2)\}$ and $\{Zr[RN(Me_2SiCH_2CH_2SiMe_2)NR](NMe_2)_2\}$ respectively; a dramatic effect of chelate ring size on ethylene polymerisation activity and kinetic profile is found.

There is considerable interest in the development of new generation 'non-metallocene' catalysts for the polymerisation of α-olefins. Chelating diamide complexes of the Group 4 metals have recently become the focus of much attention,[1–10] partly because of their close relationship to the commercially significant half-sandwich metal amido 'constrained geometry' catalyst system,[11,12] and more generally due to a relationship to metallocenes that may be traced through alkoxide relatives (Scheme 1).† A potential advantage of the bis(amido)metal system relative to the constrained geometry half-sandwich metal amide catalyst family is a lower formal electron count [$(R_2N)_2Zr$ is formally a $10e^-$ fragment, *cf.* $12e^-$ for $CpZr(NR_2)$] which is likely to result in a more electrophilic and therefore potentially more active catalyst fragment. However, it must be recognised that the bis(amido)metal system is sterically more open and may need steric tuning to minimise deactivation processes.

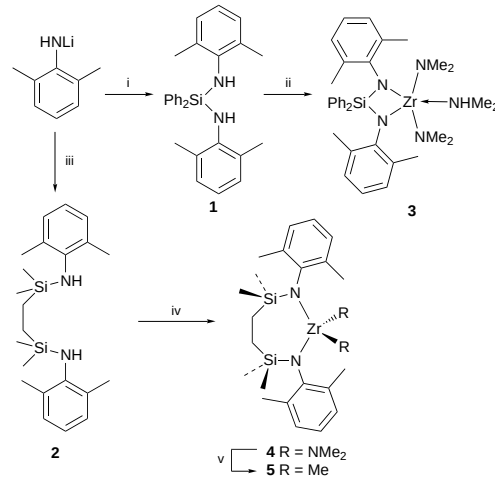


Scheme 1

We report a surprisingly active zirconium ethylene polymerisation catalyst system based on chelating diamide ligands. Of particular significance is the observation of dramatically enhanced activity and a more stable kinetic profile upon increase in the chelate ring size. Compounds **1** and **2** are readily synthesised in high yield *via* reaction of LiNHR (R = 2,6-$Me_2C_6H_3$) with the appropriate dichlorosilane (Scheme 2). Treatment of **1** and **2** with $Zr(NMe_2)_4$ in toluene at 90 °C leads to elimination of 2 equiv. of Me_2NH and formation of four- and seven-membered chelate complexes **3** and **4** in excellent yield.‡

The structures of **3** and **4** have been determined by X-ray crystallography.§ The structure of **3** reveals the formation of a distorted trigonal bipyramidal Zr complex (Fig. 1), the Zr being bonded to the bidentate chelating diamide **1**, two Me_2N groups and a molecule of Me_2NH. The equatorial plane is defined by N(2), N(6) and N(9), the axial positions being occupied by N(1) and N(3). The principal distortion in the coordination geometry is due to the small bite [71.3(1)°] of the chelating diamide, a consequence of which is 'reduced' steric congestion of the Zr centre allowing retention of three of the original four Me_2N ligands (rather than the expected two). The N_2SiZr chelate ring is planar to within 0.01 Å.

By contrast, the structure of **4** (Fig. 2) reveals a slightly distorted tetrahedral coordination at Zr, comprising the bidentate disilyldianilide [bite angle 109.2(1)°] and just two



Scheme 2 *Reagents and conditions*: i, Cl_2SiPh_2 (0.5 equiv.), Et_2O, room temp., 12 h, 79%; ii, $Zr(NMe_2)_4$, toluene, 90 °C, 12 h, 98%; iii, $ClSi(Me)_2CH_2CH_2Si(Me)_2Cl$ (0.5 equiv.), Et_2O, room temp., 12 h, 74%; iv, $Zr(NMe_2)_4$, toluene, 90 °C, 12 h, 97%; $AlMe_3$ (5.0 equiv.), toluene, room temp., 30 min, 98%

Me_2N ligands. An important effect of increasing the size of the chelate ring in **4** (now seven-membered, *cf.* four-membered in **3**) is for the two aryl rings to partially envelop the Zr centre and one of the Me_2N ligands [N(10)]. The geometry of the seven-membered chelate ring appears to be somewhat strained, the internal angles at the N (131°) and C (117°) centres being significantly enlarged from normal trigonal and tetrahedral geometries, respectively. The reason(s) for these distortions are not immediately evident, although they are clearly a factor in the envelopment of the Zr centre described above. Complex **4** is readily converted to complex **5** upon reaction with excess $AlMe_3$.[13]

The results of preliminary studies on their activities for ethylene polymerisation are collected in Table 1. For the monosilyl bridged species **3**, pretreatment with Bu^nLi, to remove the bound Me_2NH, and prealkylation with excess $AlMe_3$, followed

by exposure to ethylene (10 atm) in the presence of MAO (750 equiv.) at 50 °C gave an active, although short-lived (< 15 min) catalyst; 450 mg of polyethylene was isolated, corresponding to an activity of 3 g $mmol^{-1}$ h^{-1} bar^{-1}. By contrast, under identical conditions of temperature, pressure and cocatalyst concentration (entry 2), complex **4** afforded a steady uptake of ethylene over the 60 min duration of the run at an activity of 490 g $mmol^{-1}$ h^{-1} bar^{-1}. Increasing the temperature (entries 2–4) gave a corresponding increase in activity, although a noticeable deactivation occurs over the course of the 60 min run at 50 °C, which becomes even more enhanced at 75 °C. The effect of MAO cocatalyst concentration can be seen from entries 3, 5 and 6, the more MAO the higher the activity and also the more stable the kinetic profile. If the procatalyst is not pre-alkylated with $AlMe_3$ (entry 7) reduced activity is found, consistent with the necessity for efficient alkylation of the Me_2N complex;[13] MAO on its own is known to be a relatively poor alkylating agent. The molecular weights of the polyethylenes generated using the most active catalysts are in the region of 10^5 (M_w) with relatively broad molecular weight distributions (PDIs 5–9). These will be discussed in more detail in a future publication.

Treatment of dimethylzirconium procatalyst **5** with trityltetrakis(pentafluorophenyl)borate at 50 °C initially gives a highly active catalyst that rapidly deactivates over 10 min. The same procatalyst in the presence of MAO gives a much more stable kinetic profile and an activity figure of merit comparable to prealkylated **4** (entry 3). This is consistent with the general stabilising effect found for MAO with metallocene catalyst systems.

The dramatically more favourable activity and kinetic profile characteristics found for **4** relative to **3** may be attributed to the steric protection of the zirconium centre by the bulky aryl substituents of the large ring chelate ligand. Not only do these prevent the binding of small base molecules such as Me_2NH, they also undoubtedly lend protection to the active catalyst site.

Table 1 Ethylene polymerisation characteristics[a] for **3**–**5**

Entry	Procatalyst	Cocatalyst (equiv.)	T/°C	Activity/ g $mmol^{-1}$ h^{-1} bar^{-1}
1	**3**	MAO (750)	50	3[b]
2	**4**	MAO (750)	25	250[c]
3	**4**	MAO (750)	50	490[d]
4	**4**	MAO (750)	75	680[e]
5	**4**	MAO (100)	50	140[b]
6	**4**	MAO (2000)	50	990[d]
7	**4**	MAO (750)[f]	50	70
8	**5**	$[Ph_3C][B(C_6F_5)_4]$	50	60[b]
9	**5**	MAO (750)	50	400[d]

[a] General conditions: procatalyst dissolved in toluene for runs 1–7 and 9, CH_2Cl_2 for run 8, pretreatment with excess $AlMe_3$ (10 equiv.) for runs 1–6, 1 litre autoclave, 10 atm ethylene pressure, isobutane solvent, $AlMe_3$ scavenger, runs carried out over 60 min. [b] Rapid deactivation. [c] Stable ethylene uptake over 1 h duration of run. [d] Slow deactivation over 1 h duration of run. [e] Deactivation more rapid than in footnote (*d*). [f] No prealkylation.

† The similar 1σ,2π bonding characteristics of the cyclopentadienide and alkoxide ligands affords a direct isolobal relationship. It should be noted that, whilst closely related to the alkoxide moiety, the amide ligand is formally a 1σ,1π unit and therefore is not strictly isolobal; as a 1σ,1π ligand it also donates two fewer electrons to the metal centre.

Either γ-*syn*- or γ-*anti*-selective palladium-catalysed carbonyl allylation by mixed (*E*)- and (*Z*)-1,3-dichloropropene with tin(II) halides

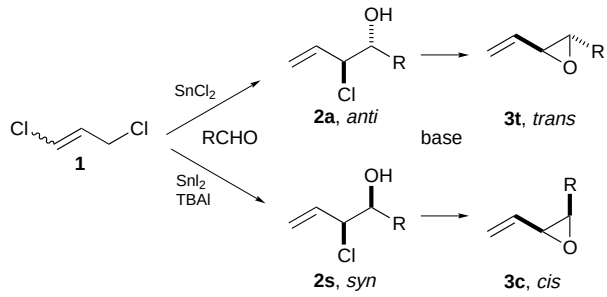
Yoshiro Masuyama,* Akihiro Ito and Yasuhiko Kurusu

Department of Chemistry, Sophia University, 7-1 Kioicho, Chiyoda-ku, Tokyo 102, Japan

Palladium-catalysed carbonyl allylations by mixed (*E*)- and (*Z*)-1,3-dichloropropene with SnI_2–Bu_4NI and $SnCl_2$ diastereoselectively produce *syn* and *anti* 1-substituted 2-chlorobut-3-en-1-ols, respectively. These are transformed into *cis* and *trans* 1-substituted 2-vinyl epoxides.

Barbier-type carbonyl allylations by (*E*)-γ-substituted allylic metal reagents, derived from (*E*)-γ-substituted allylic halides with metals or metal halides, usually add *anti*-diastereoselectively at the γ-position of the allylic metal reagents to aldehydes; γ-*anti*-selective carbonyl allylation.[1] γ-*syn*-Selection is difficult for the Barbier-type carbonyl allylations by (*E*)-γ-substituted allylic metal reagents. We have found that halogens on the tin of but-2-enyltin reagents, prepared from (*E*)-rich 1-bromobut-2-ene and tin(II) halides, affect the diastereoselectivity in the γ-regioselective carbonyl allylation in THF–H_2O at room temperature; *anti*-selection with tin(II) chloride and *syn*-selection with tin(II) iodide–tetrabutylammonium bromide (or iodide).[2] We thus hoped that palladium-catalysed carbonyl allylation[3] by (*E*)-rich 3-chloroprop-2-enyltin reagents, derived from (*E*)- and (*Z*)-mixed 1,3-dichloropropene (**1**)† with $SnCl_2$ or SnI_2–Bu_4NI *via* the formation of 1-chloro-*syn*-π-allylpalladium complex, could lead to halogen-coordination controlled diastereoselectivity to produce diastereo-defined 1-substituted 2-chlorobut-3-en-1-ols, which could be transformed into the corresponding 1-substituted 2-vinyl epoxides (Scheme 1).[5]

Diastereoselectivity in the allylation of benzaldehyde by (*E*)- and (*Z*)-mixed 1,3-dichloropropene (**1**) in 1,3-dimethylimidazolidin-2-one (DMI)–H_2O‡ was investigated with tin(II) halides (SnX_2) and tetrabutylammonium halides (TBAX′). To a solution of SnX_2 (2.0 mmol) and TBAX′ (2.0 mmol) in DMI (3 ml)–H_2O (0.1 ml) in the presence or absence of a catalytic amount of $PdCl_2(PhCN)_2$ (0.02 mmol) was added **1** (2.0 mmol), and the solution was stirred at room temperature for 24 h. Benzaldehyde (1.0 mmol) was added to the solution, which was then stirred at room temperature. After the usual work-up, 2-chloro-1-phenylbut-3-en-1-ol (**2**, R=Ph) was obtained. The results are summarized in Table 1. The palladium-catalysed carbonyl allylation with $SnCl_2$ in DMI without H_2O led to usual *anti*-selectivity.[3] For addition of TBAX′, the carbonyl allylation with $SnBr_2$ or SnI_2 proceeded without any palladium catalyst. Use of either iodide (SnI_2 or TBAI) enhanced both the yield and the *syn*-selectivity. Addition of a catalytic amount of



Scheme 1

Table 1 Allylation of benzaldehyde by 1,3-dichloropropene (**1**)

X	X′	*t*/h	Yield[a] of **2** (R = Ph) (%)	**2s**:**2a**[b]
Cl[c]	[d]	24	88	41:59
Cl[e]	[d]	65	70	22:78

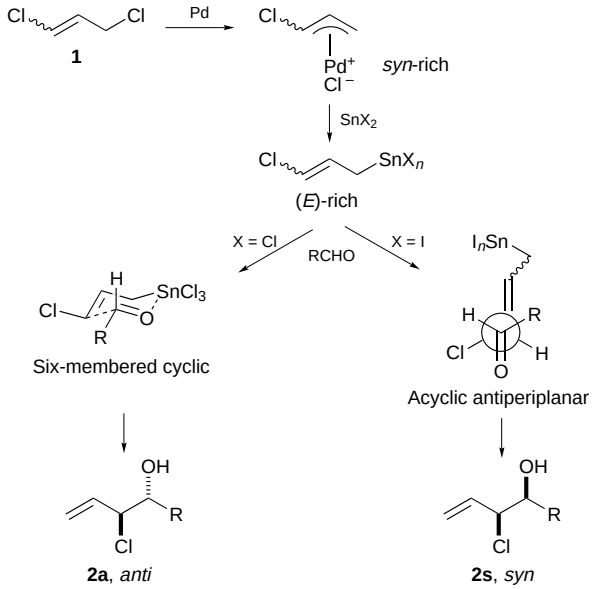
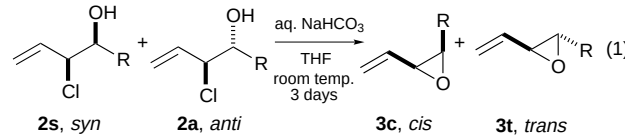
[a] The allylation of aldehydes (1.0 mmol) by **1** (2.0 mmol) was carried out with $PdCl_2(PhCN)_2$ (0.02 mmol), SnX_2 (2.0 mmol), TBAI (0.2 mmol) and NaI (2.0 mmol) in DMI (3 ml) and H_2O (0.1 ml). [b] Isolated yields. [c] The ratio was determined by ^1H NMR spectroscopy (JEOL GX-270).§ [d] The ratios (*cis*:*trans*) refer to the corresponding vinyl epoxides.



Scheme 2 Plausible mechanism in either γ-*syn*- or γ-*anti*-selective palladium-catalysed carbonyl allylation by mixed (*E*)- and (*Z*)-1,3-dichloropropene (**1**)

NaI and $SnCl_2$ in DMI–H_2O and DMI, respectively, as shown in Table 2. Any aldehyde, such as aromatic aldehydes bearing either an electron-donating group or an electron-withdrawing group, α,β-unsaturated aldehydes, and aliphatic aldehydes, can be used for the diastereo-defined carbonyl allylation. 1-Substituted 2-chlorobut-3-en-1-ols **2**, which are chlorohydrins, were transformed into the corresponding 1-substituted 2-vinyl epoxides **3** with aqueous $NaHCO_3$–THF solution in 70–90% yields [reaction (1)]. The *cis : trans* ratios of **3** were similar to the *syn : anti* ratios of **2**.§

The *anti*-selection with $SnCl_2$ probably occurs *via* the usual six-membered cyclic transition states (coordination) between (*E*)-rich 3-chloroprop-2-enyltrichlorotin, derived from *syn*-rich 1-chloro-π-allylpalladium chloride and tin(II) chloride, and aldehydes.[1] The coordination suggests high Lewis acidity of tin



in (*E*)-3-chloroprop-2-enyltrichlorotin, as shown in Scheme 2. However, *syn*-selectivity with SnI_2–TBAI (–NaI) probably occurs *via* acyclic antiperiplanar transition states between pentacoordinate 3-chloroprop-2-enyltetraiodotin, in which the tin has no Lewis acidity, and aldehydes.[2] The *syn*-selection *via* the acyclic antiperiplanar transition state is independent of the olefinic geometry of 3-chloroprop-2-enyltin intermediate, in contrast to the *anti*-selection *via* the six-membered cyclic transition state.[1] Thus the *syn*-selectivity with SnI_2–TBAI is probably superior to the *anti*-selectivity with $SnCl_2$.

Sulfonic acid functionalised ordered mesoporous materials as catalysts for condensation and esterification reactions

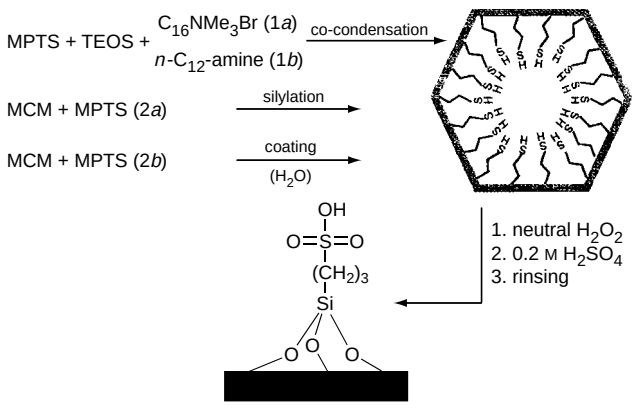
Wim M. Van Rhijn,* Dirk E. De Vos, Bert F. Sels, Wim D. Bossaert and Pierre A. Jacobs

Centre for Surface Science and Catalysis, KU Leuven, Kard. Mercierlaan 92, B-3001 Heverlee, Belgium

Mesoporous silicas were functionalised with sulfonic acid groups; the resulting materials are excellent catalysts for formation of bisfurylalkanes and polyol esters.

The discovery of mesoporous materials has raised the general expectation that the catalytic efficiency of microporous zeolites can be expanded to mesoporous dimensions.[1] It is necessary to introduce functionality into MCM or HMS structures, so surface modification techniques are enjoying a renewed interest, and it is clear that the pore walls of mesoporous materials are easily modified with either purely inorganic or with hybrid, semi-organic functional groups.[2,3] Reports on Ti–MCM-41 prove that this oxidation catalyst can indeed handle voluminous substrates such as alkylated phenols.[4] We recently illustrated the potential of a guanidine-functionalised MCM-41 in base-catalysed condensations.[5] Progress in acid catalysis is lagging behind, largely because of the low acid strength of Al-substituted mesoporous silicas such as Al–MCM-41.[6] As an alternative, we now propose the covalent attachment of alkylsulfonic acid groups to the surface of MCM and HMS molecular sieves, *via* secondary synthesis as well as *via* direct one-step synthesis. The resulting MCM–SO_3H and HMS–SO_3H materials perform well in typical strong-acid catalysed reactions. The hydrophobic nature of the active sites' environment can be exploited to perform reactions which are outside the reach of other inorganic solid acid catalysts.

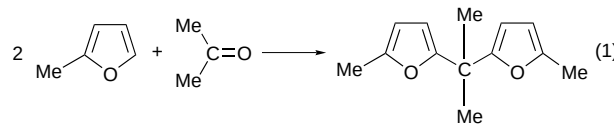
The key precursor in the synthesis of alkylsulfonic acid functionalised mesoporous materials is 3-mercaptopropyltrimethoxysilane (MPTS). This molecule contains an SH group, a stable propyl spacer and a hydrolisable $Si(OMe)_3$ moiety. Hybrid mesoporous silicas were prepared either *via* silylation of preformed mesoporous silica, or *via* co-condensation of the primary building blocks.† First, MPTS and $Si(OEt)_4$ were hydrolysed together in the presence of an ionic or a non-ionic surfactant (*viz.* $C_{16}NMe_3Br$ and *n*-C_{12}-amine), leading to MCM or HMS type materials, respectively (Scheme 1, route 1). Alternatively, secondary modification comprised the silylation of a vacuum-dried pre-existing MCM support with MPTS in dry toluene, or the coating of a partially hydrated support with an MPTS layer (Scheme 1, routes 2*a* and *b*).[3] Both primary and secondary syntheses lead to materials functionalised with largely intact SH groups, as is evidenced by an IR ν_{S-H} vibration of medium intensity at 2575 cm^{-1}, and by the solid state ^{13}C NMR shifts [δ 11 (C_3), 27 (C_1, C_2)]. The MeO groups of the liquid MPTS spectrum are absent, while the CH_2(–Si) is slightly shifted downfield (from δ 8 to 11). These SH groups are easily converted into sulfonic acid groups by mild oxidation with neutralised H_2O_2, acidification and finally, thorough washing to remove all liquid acid. In view of the high loading of the material with functional groups, it is not surprising that some disulfide is observed in the final product (δ 41, 23). However, the major signals are observed at δ 54, 18 and 11. These are consistent with those calculated for *e.g.* propanesulfonic acid and give strong proof for the prevalence of $(CH_2)_3SO_3H$ surface groups.



Scheme 1

In ambient conditions, the water affinity of the material is remarkably low, as proved by thermogravimetric analysis (less than 1 wt% H_2O) and by the weakness of the IR δ_{OH} vibration (1638 cm^{-1}). Typical loadings, as measured by thermogravimetry or *via* titration of the SO_3H groups, vary between 1.0 and 1.5 mequiv. g^{-1}. Sorption characteristics depend strongly on the preparation method. For instance, an MCM–SH material prepared *via* silylation (route 2*a*) displays a BET surface of 740 $m^2\ g^{-1}$ and a pore volume of 0.51 ml g^{-1} with a radius between 2 and 4 nm (from the Kelvin equation and the BJH method). These data evidence the mesoporous nature of the material, even if the specific surface and mesoporous volume are somewhat lower than for a typical MCM-41. However, coating of the material with an MPTS layer (route 2*b*) leads to a reduction of BET surface (510 $m^2\ g^{-1}$), average pore radius (< 2 nm) and pore volume (0.25 ml g^{-1}), as determined from T-plot analysis). Oxidation of the latter material to its sulfonic acid form leads to further minor changes of BET (399 $m^2\ g^{-1}$) and pore volume (0.19 ml g^{-1}). Isolated silanol groups, which reportedly absorb at 3740 cm^{-1},[7] were not detected in the IR spectra of MCM–SO_3H upon evacuation at 373 or 473 K. The absorption between 3500 and 2700 cm^{-1} may rather be assigned to hydrogen-bonded SO_3H groups. Summarising, the catalyst design leads to a hydrophobic mesoporous material, with uniform and well-characterized SO_3H groups.

The catalytic properties of the new materials were first tested in the synthesis of 2,2-bis(5-methylfuryl)propane (DMP). Bisfurylalkanes are relevant intermediates for macromolecular chemistry.[8] DMP is produced from 2-methylfuran (MF) and acetone in a strong acid catalysed condensation [reaction (1)].



Zeolites may seem accomplished catalysts for such reactions. However, exposure of zeolites such as H-β or H-US-Y to furans leads to immediate formation of tarry oligomeric products, even for the substituted compounds such as MF.[9] Addition of acetone

Table 1 Solvent-free reaction of MF (1.8 g) with acetone (3.2 g) (molar ratio = 1 : 2.5) in the presence of 0.18 g acid catalyst (323 K, 24 h)

9	MCM–SO_3H (silylated)[c]	57	92

[a] Conversion of MF. [b] Selectivity for DMP, based on MF. [c] Si : Al = 12.5 (PQ). [d] Si : Al = 22.5. [e] Prepared *via* secondary modification with MPTS.† [f] Prepared *via* co-condensation of MPTS and TEOS (10 : 90). [g] As in *f*, with MPTS : TEOS = 20 : 80.

partially suppresses MF oligomerisation. As a result, catalyst deactivation is fast, and DMP selectivities are limited even at moderate conversions (Table 1, entries 2, 3). Moreover, the strong adsorption of DMP or other reaction intermediates in the relatively narrow zeolite pores leads to detectable secondary condensation products, which desorb with even greater difficulty than DMP itself. Such observations have led previous workers to use elevated catalyst concentrations;[10] in our reaction conditions, the side-reactions impose an upper limit of 45% on the overall DMP yield. While the DMP selectivity is better on Al–MCM-41, the low acid strength causes an unsatisfactory MF conversion. In contrast, the sulfonic acid MCMs combine a remarkable DMP selectivity (often up to 95%) with elevated MF conversions (entries 5–9). Apparently the hydrophobic surface prevents a too strong MF adsorption and oligomerisation, while the larger dimension of the pores facilitates product desorption. The highest DMP yield on MF basis, a remarkable 82%, is obtained with an MCM–SO_3H prepared *via* the surface coating procedure (entry 5). Thus, polarity, rather than the activity, makes the sulfonic MCMs superior to zeolites for this particularly demanding reaction.

Another application of the new materials may be found in polyol esterification. These reactions produce valuable products such as emulsifiers, detergents or low-calorific fats. The use of (preferably heterogeneous) catalysts may allow lower reaction temperatures, but the intrinsic immiscibility of the polyol and fatty acid phases is a major problem. Thus, in the esterification of *e.g.* D-sorbitol with lauric acid, zeolites such as H-β reside exclusively in the polyol layer. The only reaction is sorbitol degradation, and the fatty acid conversion is zero even after prolonged reaction times (Table 2, entry 2). In contrast, the much more hydrophobic MCM–SO_3H readily effects formation of a small amount of monoacylated products, and because of the detergency of the latter, homogenisation of the reaction medium. Main products are monolauroylisosorbide, which is an important detergent precursor,[11] or in a later stage, the isosorbide diester (entry 3).

In conclusion, sulfonic acid functionalised MCM or HMS materials are new and worthwhile materials for reactions in which zeolites fail.

This work is sponsored within a IUAP program of the Belgian Federal Government. W. V. R. and B. S. acknowledge IWT and D.D.V. FWO for fellowships. We thank B. Wouters for recording NMR spectra.

† Preparation of MCM–SO_3H and HMS–SO_3H *via* co-condensation (Scheme 1, route 1): MCM-41 type materials were synthesized from a mixture of MPTS (20 mol%) and $Si(OEt)_4$ (TEOS, 80 mol%). The molar gel composition was 0.12 $C_{16}NMe_3Br$: 0.5 NaOH : 1.0 total siloxane : 130H_2O (24 h, 293 K). An acid solvent extraction technique was used to remove the ionic surfactant. Mercaptopropyl-modified HMS was obtained from the following gel composition: 0.9 (or 0.8) TEOS : 0.1 (or 0.2) MPTS : 0.275 *n*-C_{12}-amine : 8.9 EtOH : 29.4 H_2O (24 h, 293 K). *n*-C_{12}-Amine was extracted with boiling EtOH (12 h, 3 times).

Silylation (Scheme 1, route 2*a*) was performed on a calcined and evacuated (393 K) MCM-41 (synthesised from Ludox), using excess MPTS in dry toluene (4 h, reflux), followed by Soxhlet extraction with Et_2O and CH_2Cl_2. For coating with an MPTS layer (route 2*b*), the MCM was refluxed in water (3 h), filtered and suspended in toluene. Part of the water was removed in an azeotropic distillation with a Dean–Stark trap. Further preparation followed route 2*a*.

Mercaptopropyl groups were oxidised with a three-fold excess of neutralised H_2O_2. After washing with H_2O and EtOH, and acidification in 0.2 M H_2SO_4, the powder was rinsed thoroughly with distilled H_2O and dried at 333 K.

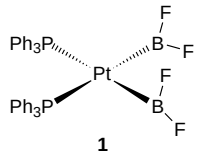
The platinum compound [Pt(PPh$_3$)$_2$(η-C$_2$H$_4$)] reacts with B$_2$F$_4$ affording the BF$_2$ complex *cis*-[Pt(BF$_2$)$_2$(PPh$_3$)$_2$] which is characterised by multinuclear NMR studies and X-ray crystallography.

A key step in many transition metal catalysed diboration reactions is oxidative addition of the B–B bond of a diborane(4) compound (R$_2$B–BR$_2$) to a low-valent transition metal centre affording a metal bis-boryl complex of the form L$_n$M(BR$_2$)$_2$.[1] Amongst the many studies which have been carried out,[1] one of the more thoroughly examined reactions, particularly in terms of this B–B bond oxidative addition step, has been the platinum catalysed diboration of alkynes described recently by the groups of Miyaura and Suzuki,[2] Smith[3] and Marder and Norman.[4] These and other studies[5,6] have resulted in a number of crystallographically characterised platinum bis-boryl species of the type *cis*-[Pt(BR$_2$)$_2$(PR′$_3$)$_2$]. In seeking to further explore the oxidative addition of B–B bonds to Pt^0, we examined the reaction between [Pt(PPh$_3$)$_2$(η-C$_2$H$_4$)] and diboron tetrafluoride, B$_2$F$_4$, and report herein the preparation and structural characterisation of the complex *cis*-[Pt(BF$_2$)$_2$(PPh$_3$)$_2$], the first example of a compound containing the BF$_2$ ligand.

The reaction between [Pt(PPh$_3$)$_2$(η-C$_2$H$_4$)][7] and a slight excess of B$_2$F$_4$[8] in toluene solution afforded, after work-up,† pale yellow crystals of the complex *cis*-[Pt(BF$_2$)$_2$(PPh$_3$)$_2$] **1**. The formula of **1** was evident from multinuclear NMR data‡ and the structure was confirmed by X-ray crystallography§ the results of which are shown in Fig. 1. The Pt centre in **1** adopts the expected square-planar coordination geometry (maximum atom deviation from the PtP$_2$B$_2$ mean plane is 0.025 Å) with the BF$_2$ groups in a *cis* configuration. Metric parameters of note are the Pt–B bond distances [Pt–B(1) 2.058(6) and Pt–B(2) 2.052(6) Å] together with the B–Pt–B [78.2(3)°] and P–Pt–P angles [99.4(1)°]. These values fall in or close to the range observed for other structurally characterised platinum(II) *cis* bis-boryl compounds[2–6] in which the boron atoms carry oxygen or sulfur substituents (Pt–B distances, B–Pt–B angles and non-chelate P–Pt–P anlges are in the range 2.03–2.076 Å, 73.0–81.0 and 100.38–107.14°, respectively).¶ There is no decisive crystallographic evidence for platinum-to-boron π-back-bonding in **1**.



1

In **1**, the angles defined by the boron ligand planes and the mean platinum square plane are 81.1 and 87.4° for B(1) and B(2), respectively, therefore showing that the boryl ligands are essentially orthogonal to the platinum square plane [as observed for most platinum(II) *cis* bis-boryl complexes[2–6,9]]. Whether or not an electronic origin exists for the acute B–Pt–B angles (and large P–Pt–P angles) and/or the orientations of the boryl ligands is unclear at present, although we note that recent theoretical studies on model (PH$_3$)$_2$ platinum(II) *cis* bis-boryl complexes do reproduce the experimentally observed geometries.[10] Further insight into this matter, including the extent of any platinum-to-boron π-back-bonding, will have to await a more detailed theoretical analysis. The B···B distance in **1** [2.591(9) Å] is also typical (*cf.* the range 2.514–2.667 Å for the complexes described in refs. 2–6); for comparison and the B–B bond distance in crystalline B$_2$F$_4$ is 1.67 Å.[11]

It is noteworthy that **1** is isoelectronic with the product of double oxidation of the η^2-alkene complex [Pt(PPh$_3$)$_2$(η-C$_2$F$_4$)] {whose arsine analogue, [Pt(AsPh$_3$)$_2$(η-C$_2$F$_4$)],[12] has been structurally characterised; C–C 1.447(18) Å} implying that such a complex would be a bis-carbene species, [Pt(PPh$_3$)$_2$(CF$_2$)$_2$]$^{2+}$, with a significantly longer, non-bonding C···C interaction. The electronic requirements for this kind of alkene cleavage (as studied by Lappert and others; see ref. 13 and references therein) or its reverse, carbene coupling, have been examined by Hoffmann and coworkers.[13]

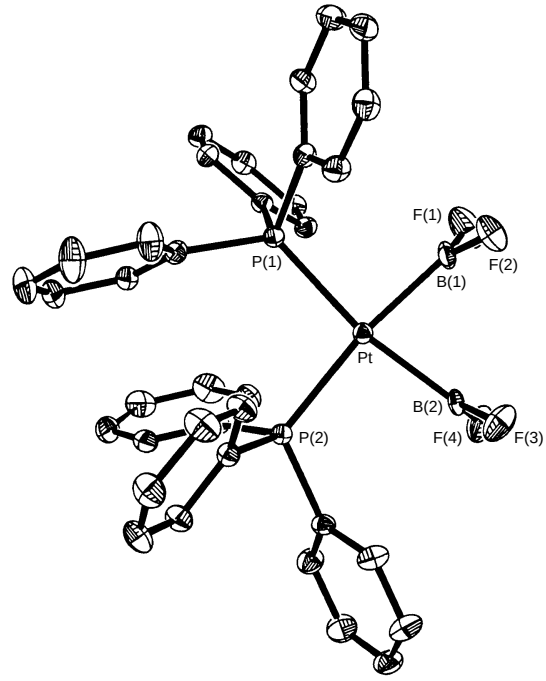


Fig. 1 A view of the molecular structure of **1** with key atoms labelled. Hydrogen atoms are omitted for clarity. Ellipsoids are drawn at the 50% level. Selected bond lengths (Å) and angles (°): Pt–B(1) 2.058(6), Pt–B(2) 2.052(6), B(1)–F(1) 1.324(7), B(1)–F(2) 1.342(7), B(2)–F(3) 1.327(6), B(2)–F(4) 1.330(7); B(1)–Pt–B(2) 78.2(3), P(1)–Pt–P(2) 99.35(5), F(1)–B(1)–F(2) 110.6(5), Pt–B(1)–F(1) 124.6(5), Pt–B(1)–F(2) 124.7(4), F(3)–B(2)–F(4) 110.8(5), Pt–B(2)–F(3) 125.7(4), Pt–B(2)–F(4) 123.5(4).

To the best of our knowledge, there are no previous reports of metal–BF_2 complexes although we note that a number of BCl_2 (and some BBr_2 and BI_2) complexes have been described, but not structurally characterised, by Nöth and coworkers.[14] Further studies are in progress to examine the reactivity of B_2F_4 towards a range of transition metal compounds with a view to preparing further examples of complexes containing BF_2 ligands; we have recently structurally characterised the complex *cis*-[$Pt(BF_2)_2$(dppb)] [dppb = 1,2-bis(diphenylphosphino)butane] full details of which will be described in a future full paper.[15]

† A sample of [$Pt(PPh_3)_2(\eta$-$C_2H_4)$] (0.080 g, 0.011 mmol) was dissolved in toluene (5 cm^3) in a Young's tap tube after which the reaction flask was cooled in a liquid-nitrogen Dewar. A sample of B_2F_4 (*ca*. 0.03 mmol) was then condensed into the Young's tap tube and the contents allowed to warm to room temp. with stirring once the solvent had melted. A white precipitate formed at *ca*. −50 °C and once at room temp., stirring was continued for 30 min. After this time, the solvent volume was reduced slightly by vacuum and the reaction flask sealed under dinitrogen and cooled to −30 °C for *ca*. 24 h. The mother liquor was then removed by syringe and the remaining white solid dried under vacuum. Dissolution of this solid in CH_2Cl_2 (2 cm^3) afforded a cloudy pale yellow solution which was filtered affording a yellow filtrate to which a toluene overlayer (5 cm^3) was added. Solvent diffusion over a period of 7 days at −30 °C afforded pale yellow crystals of **1** (0.086 g, 97%) one of which was used for X-ray crystallography.

Phase transition of ZnS nanocrystallites induced by surface modification at ambient temperature and pressure confirmed by electron diffraction

Kei Murakoshi,[a] Hiroji Hosokawa,[a] Naoko Tanaka,[a] Miwa Saito,[a] Yuji Wada,[a] Takao Sakata,[b] Hirotaro Mori[b] and Shozo Yanagida*[a]

Pentafluorothiophenol, thiophenol, 1-decanethiol, 1-hexanethiol, benzoic acid and cyanoacetic acid, which are confirmed to bind to the surface of ZnS nanocrystallites, induce phase transition of ZnS nanocrystallites from the hexagonal to the cubic phase, with retention of the crystalline size of 3 nm at ambient temperature and pressure.

The crystalline structure of quantum-confined semiconductor nanocrystallites is one of the important factors for determining their photophysical properties.[1] Generally, the difference in the crystalline structure of the solid leads to considerable change in the effective masses of electrons and holes in their electronic bands.[2] Although it is important to control the crystalline structure of semiconductor nanocrystallites with a definite size, phase transition whilst retaining their size has not been reported at ambient temperature and pressure. There are only a few reports concerning phase transitions at high pressure.[3] Generally, the surface of nanocrystallites plays a dominant role in determining the thermodynamics of the system because of their large surface-to-volume ratios. We recently revealed that coordination of solvent molecules, such as *N*,*N*′-dimethylformamide (DMF), to the surface of CdS[4] or ZnS[5] nanocrystallites also plays a crucial role in stabilizing nanocrystallites. In such systems, the crystalline structure as well as size of the CdS[6] or ZnS[7] nanocrystallites differs with the choice of solvent used for preparation. Here, we report the first control of the crystalline structure of size-controlled nanocrystallites at ambient temperature and pressure by surface modification.

As reported previously,[5] transparent colloidal ZnS nanocrystallites (ZnS–DMF) were prepared by introducing H_2S gas to a DMF solution (5 ml) of $Zn(MeCO_2)_2 \cdot 2H_2O$ (5 mM) with vigorous stirring on an ice bath. After purging ZnS–DMF with N_2 gas for 1.5 h to remove unreacted H_2S, a DMF solution (5 ml) of an organic molecule (2.5 mM), such as thiol, carboxylic acid, or phenol, was added into the 5 ml N_2-purged ZnS–DMF solution ([Zn] = 5 mM) with stirring on an ice bath for 30 min. Normalized absorption spectra of the ZnS–DMF solution after combination with the organic molecules were the same as those before the combination,[5] indicating that dissolution or growth of the ZnS nanocrystallites in DMF is negligibly small (the change of the size should be within a few Å) under the experimental conditions. The resulting transparent solution was placed on a copper grid covered with amorphous carbon, and dried carefully *in vacuo* at room temp. for transmission electron microscopy (TEM) and electron diffraction measurements (Hitachi H-9000, operating at 300 kV) to determine the size and crystalline structure of the resulting ZnS nanocrystallites, respectively. Their size and crystalline structure did not depend upon the choice of the observed areas, and were not changed by the irradiation by the electron beam in the TEM measurements. FTIR spectra of the ZnS powders dried *in vacuo* were obtained on a Perkin Elmer 2000 FTIR spectrophotometer using the KBr method.

Fig. 1 shows typical TEM images and the size distributions of ZnS–DMF and ZnS–DMF combined with C_6F_5SH. TEM observation revealed that both ZnS–DMF and ZnS–DMF combined with C_6F_5SH consisted of nanocrystallites with a mean diameter of *ca.* 3 nm. The size distribution and the mean diameter of the ZnS nanocrystallites (2.9 nm before combination) were not significantly changed after combination with the thiol (2.7 nm after combination). However, there lies a crucial difference in the crystalline structure between ZnS–DMF and ZnS–DMF combined with C_6F_5SH. In the electron diffraction pattern of ZnS–DMF [Fig. 2(*a*)], the apparent diffraction rings assigned to (100), (002), (101), (102), (110) and (103) of the hexagonal ZnS crystallites show that ZnS–DMF has a hexagonal crystalline structure. On the other hand, the diffraction rings assigned to (111), (200), (220) and (311) of cubic ZnS crystallites were observed, while the characteristic ring, (102), which was observed in the hexagonal ZnS crystallites, was not apparent for ZnS–DMF combined with C_6F_5SH [Fig. 2(*b*)]. The observation of the clear difference in the electron diffraction patterns indicates that the hexagonal structure of ZnS–DMF undergoes a phase transition when combined with C_6F_5SH, giving mainly (> 50%) the cubic phase at ambient temperature and pressure.[8]

It is seem that the crystalline structure of the resulting ZnS nanocrystallites depended on the choice of the added molecules (Table 1). All the thiols, *i.e.* pentafluorothiophenol, thiophenol, 1-decanethiol and 1-hexanethiol, induced the phase transition

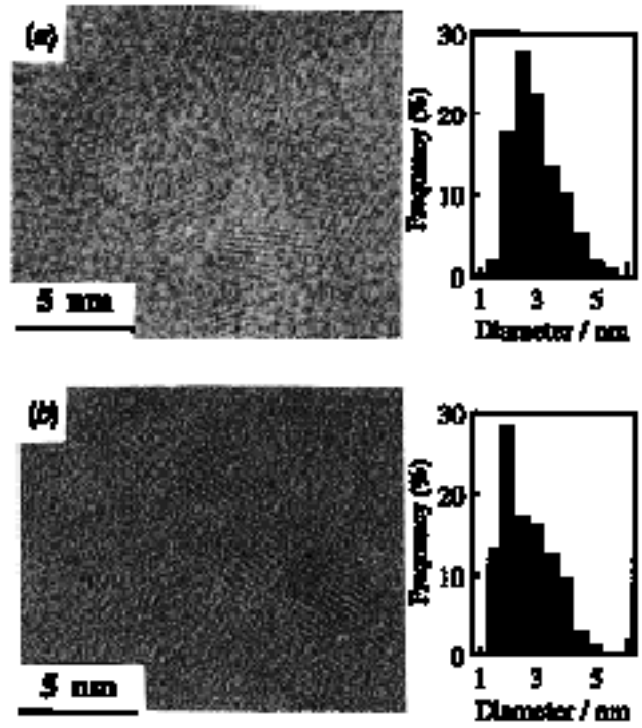

Fig. 1 TEM images and size distributions of (*a*) ZnS–DMF and (*b*) ZnS–DMF combined with C_6F_5SH

from the hexagonal to the cubic phase of the ZnS nanocrystallites without changing the crystallite size (3 nm). Additionally, the addition of carboxylic acid, *e.g.* benzoic acid and cyanoacetic acid, could also induce the phase transition. In contrast, combination with phenol, octanoic acid or acetic acid gave the same hexagonal phase as that of 'as-prepared' ZnS–DMF. The behavior of the phase transition depends on the pK_a value of the carboxylic acids and phenol. The carboxylic acids, *e.g.* benzoic acid (pK_a = 4.19) and cyanoacetic acid (pK_a = 2.45), which have lower pK_a values than acetic acid (pK_a = 4.76), were capable of inducing the phase transition, while neither acetic acid, octanoic acid (pK_a = 4.89), nor phenol (pK_a = 9.89) with higher pK_a values could induce the phase transition.[9] On the other hand, the phase transition did not depend on the pK_a value of the thiols.[10] These results suggest that the behavior of the phase transition is affected by interactions of the dissociated anions of the respective organic molecules with the surface of ZnS nanocrystallites.

The modified surface of the resulting ZnS nanocrystallites was characterized by FTIR spectroscopy. The surface zinc atoms of ZnS nanocrystallites in DMF are solvated by the oxygen atoms of DMF molecules, and interact with acetate anions derived from the starting zinc acetate;[5] FTIR analyses of powdered ZnS–DMF combined with carboxylic acid revealed that benzoate and cyanoacetate anions coordinated to the surface of ZnS nanocrystallites *via* the oxygen atoms since the peaks assigned to the C=O stretching vibration of the carboxylate (benzoate, 1536 cm^{-1}; cyanoacetate, 1623 cm^{-1}) were shifted to lower frequency than those of the free carboxylic acids (benzoic acid, 1688 cm^{-1}; cyanoacetic acid, 1736 cm^{-1}). In contrast, non-coordination of phenol, octanoic acid and acetic acid molecules was confirmed by FTIR spectra. These observations lead to the conclusion that the phase transition could be induced only when the added molecules react with the surface of ZnS nanocrystallites to form covalent or ionic bonds. For carboxylic acids with lower pK_a values than that of acetic acid, they must dissociate into the corresponding carboxylate anions in basic DMF to an appreciable extent; the carboxylate anions then coordinate to the ZnS nanocrystallite surface, resulting in the phase transition. On the other hand, since a thiolate anion has high nucleophilicity as a soft base, the thiolate anion readily binds to the surface zinc atom which is a soft acid, even when the concentration of the dissociated thiolate is low.[11] As a consequence, the phase transition of ZnS nanocrystallites was independent of the pK_a value of the thiol.

Generally, ZnS crystallizes to form the cubic structure at room temp. because the internal energy of the cubic phase is slightly lower than that of the hexagonal phase.[12] Thus, the hexagonal structure of ZnS–DMF must be formed due to the metastability caused by the effective coordination of DMF molecules to the ZnS nanocrystallite surface,[5] which should stabilize the phase during growth. The formation of nanocrystallites with metastable crystalline structure is often observed.[13] The formation of chemical bonds between the surface zinc atom of ZnS nanocrystallites and the added thiolate or carboxylate anion should lead to a change of the surface energy of ZnS nanocrystallites. This change of the surface energy could induce the phase transition from the metastable phase (hexagonal) to the stable phase (cubic) at ambient temperature and pressure, because the difference in the internal energy of ZnS between the hexagonal and the cubic phase is quite small (13.4 kJ mol^{-1}).[12] Further study is required for quantitative description of the surface energy to induce the phase transition.

In conclusion, control of crystalline structures of quantum-confined semiconductor nanocrystallites was achieved at ambient temperature and pressure through the phase transition from the hexagonal to the cubic structure by the chemical modification of the ZnS nanocrystalline surface with organic molecules for the first time.

This work was supported in part by the 'Research for the Future' Program of JSPS.

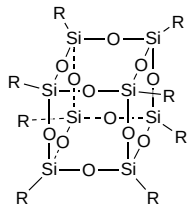
Amine and ester-substituted silsesquioxanes: synthesis, characterization and use as a core for starburst dendrimers

Frank J. Feher* and Kevin D. Wyndham

Department of Chemistry, University of California, Irvine, CA 92697-2025, USA

Practical procedures are reported for the syntheses of amine and ester-substituted silsesquioxane frameworks with the formula $R_8Si_8O_{12}$ with R = $CH_2CH_2CH_2NH_2$ (2), $[CH_2CH_2CH_2NH_3]Cl$ (3) and $CH_2CH_2CMe_2CH_2CO_2Me$ (4); the use of 2 as a core for starburst dendrimers with R = $CH_2CH_2CH_2N(CH_2CH_2CO_2Me)_2$ (5) and $CH_2CH_2CH_2N(CH_2CH_2C(O)NHCH_2CH_2NH_2)_2$ (6) is also described.

Polyhedral oligosilsesquioxanes (POSS) are an interesting class of clusters derived from the hydrolytic condensation of trifunctional organosilicon monomers.[1–3] Cube-octameric clusters (*e.g.* **1**) are most common, but a wide variety of other polyhedral frameworks have been identified. Interest in POSS has grown rapidly over the past several years, particularly for polymer-related applications, where several families of POSS monomers have been developed as precursors to hybrid inorganic–organic polymers.[4] Many other applications for POSS have emerged and developed rapidly as straightforward procedures have been devised for preparing frameworks with synthetically useful pendant groups.[5–9] Here, we report practical syntheses of several new silsesquioxanes that are attractive starting materials for more elaborate molecules, including amine- and ester-substituted frameworks that have excellent potential as cores for starburst dendrimers.

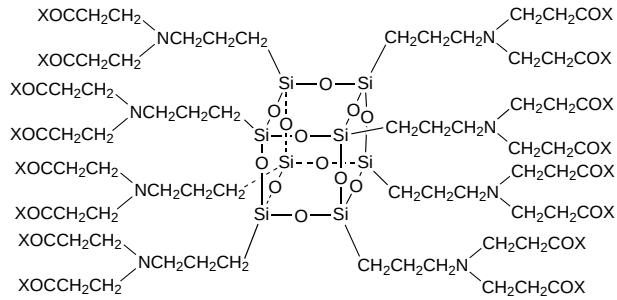


1 R = alkyl, vinyl or aryl
2 $CH_2CH_2CH_2NH_2$
3 $[CH_2CH_2CH_2NH_3]Cl$
4 $CH_2CH_2CMe_2CH_2CO_2Me$

Wacker-Chemie's 1991 US patent[10] claimed the preparation of **2**. This compound is ideally suited for many purposes, but no experimental details or characterization data were provided in the patent. We reinvestigated these claims and now confirm that the hydrolytic condensation of γ-aminopropyltriethoxysilane in MeOH–conc. HCl does indeed provide easy access to an amine-substituted framework,† but the product obtained under conditions reported by Wacker-Chemie is **3** rather than **2** (*i.e.* the free amine).[11] This hydrochloride is highly soluble in water (> 0.9 g ml^{-1}), poorly soluble or insoluble in most organic solvents and is somewhat hygroscopic. It is also surprisingly difficult to neutralize without destroying the Si/O framework, but neutralization of **3** to **2** can be accomplished by eluting solutions of **3** in methanol or 14 : 1 ethanol–water solutions across a column of Amberlite IRA-400 resin.‡ The resulting solution of **2** appears to be stable for 1–2 days at 25 °C, but decomposes to an ill-defined T-gel upon prolonged storage at 25 °C or when the solvent is removed.

It is interesting to note that a ^{29}Si NMR spectrum of the decomposition product is nearly identical to the published spectrum for products from the uncatalyzed hydrolysis γ-aminopropyltriethoxysilane in 14 : 1 EtOH–H_2O.[12] Both spectra exhibit several sharp resonances between δ −60 and −72, including a large resonance at δ −68.5 previously assigned[12] to **2**, but the characteristic resonance for pure **2** only appears as a minor resonance at δ −66.8. In light of the fact that MALDI-TOF mass spectra of both samples exhibit many peaks at $m/z < 3000$, but no large peaks attributable to $R_nSi_nO_{3n/2}$ (n = 6, 8, 10, 12), it appears that fully condensed frameworks containing free aminopropyl groups are not stable relative to incompletely condensed frameworks and/or T-gels.

Platinum-catalyzed hydrosilylation reactions of $H_8Si_8O_{12}$ provide convenient access to a wide variety of functionalized silsesquioxanes,[5,6,9,13,14] but in most cases the products are complicated mixtures of isomers because both α- and β-addition to the alkene are observed. Gentle and Bassindale[5] noted that β-addition and a number of side-reactions can be suppressed by increasing steric bulk on the γ-position and avoiding the use of vinyl silanes as alkenes. We have found that β-addition can be completely eliminated by using 3,3-disubstituted α-alkenes. In the case of $H_8Si_8O_{12}$[15] and readily available $H_2C{=}CHCMe_2CH_2CO_2Me$ (Aldrich), hydrosilylation with Speier's catalyst is complete within 48 h in refluxing hexanes to produce high yields of **4**, which spontaneously crystallizes from solution as large colorless crystals.§ We have not examined other hydridosilsesquioxanes (*e.g.* $H_{10}Si_{10}O_{15}$, $H_{12}Si_{12}O_{18}$, $H_{14}Si_{14}O_{21}$),[15,16] but these compounds should react similarly with $H_2C{=}CHCMe_2CH_2CO_2Me$ to produce isomerically pure derivatives containing ester-substituted pendant groups on each vertex. Ester-substituted frameworks should also be available from analogous Pt-catalyzed reactions of $H_2C{=}CHCMe_2CH_2CO_2Me$ with readily available hydride-substituted spherosilicates [*e.g.* $(HSiMe_2O)_8Si_8O_{12}$].[10]



5 X = OMe
6 $NHCH_2CH_2NH_2$

An interesting ester-substituted framework can also be prepared *via* the reaction of **2** with methyl acrylate. When performed under conditions typically used to prepare PAMAM dendrimers from polyamine cores,[17,18] this reaction produces excellent yields of **5**; subsequent reaction of **5** with an excess of ethylenediamine produces **6**. Both **5** and **6** were identified on the basis of multinuclear NMR data and MALDI-TOF mass spectra.¶ Higher generation PAMAM dendrimers with a Si_8O_{12} core can presumably be synthesized by further synthetic iterations.

In summary, we have developed straightforward procedures for the synthesis of amine and ester-substituted silsesquioxane frameworks. We have also demonstrated that silsesquioxanes can be used as cores for the preparation of amine or ester-terminated starburst dendrimers. The use of silsesquioxanes as cores for dendrimers is particularly attractive[6] because their polyhedral structures should produce spherically symmetric dendrimers with smaller generation numbers then more conventional cores.[19] Our efforts to use amine and ester-substituted silsesquioxanes as building blocks for hybrid inorganic–organic materials[4,20] and as platforms for biologically active pendant groups will be reported separately.

These studies were supported by the National Science Foundation and Phillips Laboratory (Edwards AFB). We thank Dr Keith J. Weller (Witco/OSi Specialities) for a generous gift of silanes.

Remarkable activity enhancement by trimethylsilylation in oxidation of alkenes and alkanes with H_2O_2 catalyzed by titanium-containing mesoporous molecular sieves

Takashi Tatsumi,* Keiko A. Koyano and Naoko Igarashi

Engineering Research Institute, School of Engineering, The University of Tokyo, Yayoi, Tokyo 113, Japan

Titanium-containing mesoporous materials, Ti-MCM-41 and Ti-MCM-48, have been successfully modified by trimethylsilylation to exhibit enhanced catalytic activity in the oxidation of alkenes and alkanes with H_2O_2.

The recent discovery of a new family of mesoporous molecular sieves has received much attention.[1,2] Ti-substituted MCM-41[3] and MCM-48[4] and Ti-substituted hexagonal mesoporous silica (Ti-HMS[5]) have been synthesized, and pioneered the potential to oxidize bulky molecules which cannot enter into the micropores of zeolites such as TS-1, TS-2 and Ti-β. However, it has been reported that Ti-MCM-41 samples show a lower intrinsic activity and lower selectivity toward the use of H_2O_2 for alkene oxidation than either TS-1 or Ti-β owing to their high hydrophilicity.[6] It has been recently proposed that the hydrophilic/hydrophobic property of Ti zeolites plays an important role in their activity for liquid phase oxidations.[7] We have conducted trimethylsilylation of Ti-MCM-41 and Ti-MCM-48 in order to enhance activity in oxidation with dilute H_2O_2 through increasing their hydrophobicity. Here, we report that trimethylsilylation of Ti-containing mesoporous molecular sieves, Ti-MCM-41 and Ti-MCM-48, resulted in a remarkable enhancement of catalytic activity in oxidation of alkenes and alkanes with H_2O_2.

Ti-MCM-41 was synthesized as previously described.[8] Tetraethylorthosilicate, tetrabutylorthotitanate and cetyltrimethylammonium chloride (CTMACl) were used, and the molar composition of the gels subjected to hydrothermal synthesis was SiO_2 : 0.01 TiO_2 : 0.6 CTMA : 0.3 NMe_4OH : 60 H_2O. Ti-MCM-48 was similarly synthesized by using CTMACl/OH (Cl/OH = 70/30) as a template.[9] The molar composition of the gels was: SiO_2 : 0.02 TiO_2 : CTMA : 46.5 H_2O. Trimethylsilylation was conducted according to literature;[2] 0.5 g Ti-MCM-41 or -48, 10 g Me_3SiCl and 15 g $(Me_3Si)_2O$ were refluxed for 16 h under N_2. The HCl produced was stripped off and the dry powder obtained was thoroughly washed with dry acetone with centrifuging, and dried at 393 K for 3 h. The samples before and after trimethylsilylation are denoted Ti-MCM-41 or -48 (non-sil) and Ti-MCM-41 or -48 (sil), respectively. A typical oxidation run used 50 mg of a catalyst in 25 mmol of substrate in a round-bottom flask, to which was added 5 mmol of H_2O_2 (30% aqueous solution). The resulting mixture was stirred at various temperatures.

The X-ray diffraction patterns of Ti-MCM-41 and Ti-MCM-48 materials closely matched those of the pure silica isomorph.[1,2] Although the X-ray diffraction patterns and the *d* spacings were virtually unchanged after trimethylsilylation, the pore diameter determined by the Dolimore–Heal method, the BET surface area, and the pore volume decreased upon trimethylsilylation (Table 1). These observations could be accounted for by assuming that the silanol groups inside the pore were trimethylsilylated.

In the IR spectra of Ti-MCM-41 samples the band at 960 cm^{-1}, which is used as evidence for Ti incorporation into the framework in Ti-containing microporous molecular sieves such as TS-1 and Ti-β,[10,11] has significantly decreased upon trimethylsilylation. Similar phenomena were also observed with Ti-MCM-48. The band was also detected in the spectra of pure silica MCM-41 or -48 (non-sil) and completely disappeared upon trimethylsilylation. Moreover, the intensity of a broad peak in the range 3700–3500 cm^{-1} corresponding to silanol groups and adsorbed water in the spectra of both Ti-MCM-41 and Ti-MCM-48 decreased significantly upon trimethylsilylation. To determine the concentration of surface trimethylsilyl groups ^{29}Si MAS NMR measurements were carried out. Before trimethylsilylation, the ^{29}Si MAS NMR spectrum of Ti-MCM-41 (non-sil) exhibited two broad resonances, at δ −108.7 (73.7%) for the Q^4 silicate unit and at δ −100.5 (26.3%) for the Q^3 environment. After trimethylsilylation, a new peak ascribed to the silicon atoms of TMS appeared at δ 14.3 and the ratio of Q^3 silicate was significantly decreased. Deconvolution of the spectrum into three peaks (TMS, Q^3, Q^4) was made; the molar ratio of TMS : Q^3 : Q^4 was 17.2 : 11.7 : 71.1, indicating that the content of silanol groups after trimethylsilylation was 0.208 mol (mol Si)$^{-1}$ [mol Si for Ti-MCM-41 (non-sil)], while that of silanol groups before trimethylsilylation was 0.263 mol (mol Si)$^{-1}$. Thus a part of original silanol groups could not be trimethylsilylated and furthermore, the increase in Q^4 species was moderate compared to the expected increase resulting from the substitution of trimethylsilyl groups for silanol H atoms, suggesting that some silanol groups were newly formed during the trimethylsilylation. The incomplete trimethylsilylation is considered to be due to the bulkiness of the trimethylsilyl group (*ca*. 0.6 nm). Despite the incomplete modification of silanol groups, Ti-MCM-41 (sil) was highly hydrophobic; the amount of adsorbed water was measured by TG after exposure to moisture over saturated aqueous solution of NH_4Cl at room temperature for 24 h; Ti-MCM-41 (sil) adsorbed only 0.29 mass% H_2O, whereas Ti-MCM-41 (non-sil) adsorbed 55 mass% H_2O.

We performed oxidation of cyclohexene, hexane and pent-2-en-1-ol with H_2O_2 on Ti-MCM-41 and Ti-MCM-48 samples. The results are summarized in Table 2. Neither Ti-MCM-41 (non-sil) nor Ti-MCM-48 (non-sil) exhibited significant activity in the oxidation of cyclohexene. However, trimethylsilylation of these Ti-containing mesoporous solids resulted in a *ca*. 20-fold increase in the activity in the oxidation of cyclohexene. Furthermore, non-productive decomposition of H_2O_2 was inhibited by the trimethylsilylation. The turnover number

Table 1 Properties of Ti-containing mesoporous molecular sieves before and after trimethylsilylation

Catalyst	Si/Ti	BET surface area/m^2 g^{-1}	Pore diameter/nm	Pore volume/ml g^{-1}
Ti-MCM-41 (non-sil)	123	1015	2.32	0.88
Ti-MCM-48 (non-sil)	47	1048	2.32	0.91
Ti-MCM-41 (sil)	139	879	1.90	0.82
Ti-MCM-48 (sil)	51	839	1.90	0.71

Table 2 Effect of trimethylsilylation on catalytic activity of Ti-containing mesoporous molecular sieves

Catalyst	Conversion (mol% of max.)	TON/ mol (mol Ti)$^{-1}$	Selectivity (%)				H_2O_2 decomposition (%)

Ti-MCM-48 (sil)[b]	20.7	59.3	73.4		26.5		0

[a] Catalyst 50 mg, substrate 25 mmol, H_2O_2 5 mmol, 323 K, 3 h. [b] Catalyst 50 mg, substrate 25 mmol, H_2O_2 5 mmol, 323 K, 2 h. [c] Catalyst 50 mg, substrate 100 mmol, H_2O_2 20 mmol, 353 K, 16 h.

(TON) per hour was even higher than that observed with Ti-β at 333 K.[12] The selectivity for epoxide/diol was increased at the expense of allylic oxidation. In the oxidation of hexane, no products were obtained with the non-trimethylsilylated samples, where H_2O_2 was mostly decomposed. On the other hand, hexane was oxidized on the trimethylsilylated samples with retarded decomposition of H_2O_2. The turnover number increased to 6.8 mol (mol Ti)$^{-1}$ with increasing reaction temperature, while the rate of H_2O_2 decomposition increased. The difference in the activity for cyclohexene and hexane oxidation between non-trimethylsilylated and trimethylsilylated samples may be explained in terms of hydrophobicity/hydrophilicity; excess water should prevent non-polar cyclohexene or hexane from adsorbing into the pores of the non-trimethylsilylated catalysts and/or approaching active sites inside the pores. It has been observed that trimethylsilylated catalysts exist in the organic phase because of their hydrophobicity, resulting in mitigation of the inhibition of oxidation caused by water. No leaching of Ti was observed during the oxidation.

As shown in Table 2, pent-2-en-1-ol was oxidized with H_2O_2 on both Ti-MCM-41 and -48 (non-sil) at a much higher rate than cyclohexene. The enhanced reactivity of this OH-containing alkenes may be due to the possible formation of a ring structure where alcoholic OH is bound to Ti as previously proposed.[13,14] It should be noted that the difference in the reactivity between alkenes and allylic alcohols on TS-1 was not so marked compared to this case.[15] Thus it is conceivable that, because of the presence of a considerable amount of silanol groups, pent-2-en-1-ol containing a polar hydroxyl group more easily migrates into the pores of non-trimethylsilylated catalysts than simple alkenes in competition with water, showing a much higher reactivity than cyclohexene. Trimethylsilylated samples Ti-MCM-41 (sil) and Ti-MCM-48 (sil) exhibited lower activity in the oxidation of pent-2-en-1-ol than the corresponding non-trimethylsilylated samples. Partial removal of silanol groups would reduce the capability to absorb the allylic alcohols through hydrogen bonding. The decreased activity might be also due to the difficulty in access to the active site caused by the introduction of rather bulky trimethylsilyl groups. Studies on the steric environment of the Ti site are in progress using a variety of reactants as probe molecules.

Trimethylsilylation leads to a further advantage: the mesoporous structure of Ti-containing samples is much less resistant to moisture than that of pure silica samples.[8] For example, the d_{100} peak height of Ti-MCM-41 (non-sil) decreased by 80% upon exposure to moisture over saturated aqueous solution of NH_4Cl for 3 days. In contrast the ordered structure of both Ti-MCM-41 (sil) and Ti-MCM-48 (sil) was found to be intact upon exposure to moisture for 30 days.

The authors are grateful to Dr S. Nakata and Mr Y. Tanaka (Chiyoda Corp.) for measuring ^{29}Si MAS NMR spectra. This work was supported in part by Grant-in-aid for Scientific Research on Priority Areas (No. 0742104) from the Ministry of Education, Science and Culture, Japan.

Solution processible poly(1-alkyl-2,5-pyrrolenevinylenes): new low band gap conductive polymers

In Tae Kim and Ronald L. Elsenbaumer*

Department of Chemistry and Biochemistry, The University of Texas at Arlington, Arlington, Texas 76019, USA

Bis(phenylthiomethylene) derivatives of 1-alkylpyrroles afford conjugated polymers by base induced elimination of thiophenyl groups.

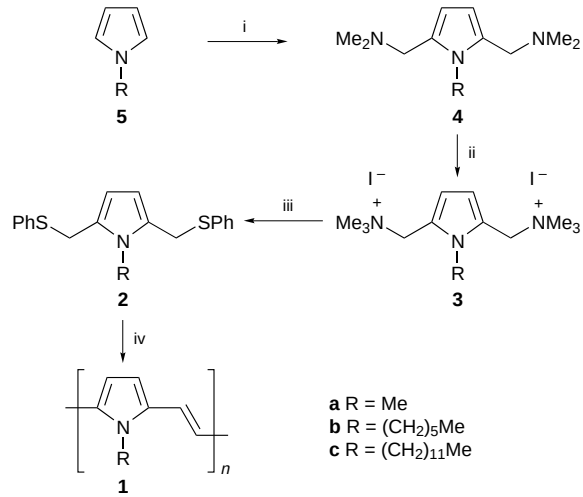
Electrochemically prepared polypyrrole is employed as an electrode in capacitors and batteries owing to its high conductivity (> 100 S cm^{-1}), relative stability to air and moisture in its oxidized form, ability to form strong coherent films and ease of synthesis.[1] Conductive properties are related to the nature of the counter anions in polypyrrole films.[2] Properties have also been modified by polymerizing pyrrole derivatives with 3-methyl and 3,4-dimethyl substituents. Conductivities of these polymers are 4 and 10 S cm^{-1}, respectively.[3,4] However, the room temperature conductivities of poly(1-alkyl-2,5-pyrrolylene) (alkyl = methyl, hexyl, dodecyl) prepared by chemical oxidation fall in the range 10^{-3} to 10^{-6} S cm^{-1}.[5,6] The large decrease in conductivity of doped poly(pyrrolylenes) with an *N*-alkyl substitutent and an increase in size of the alkyl substituent has been rationalized on a steric basis.[7]

Reduction of band gaps in conjugated polymers such as poly(*p*-phenylene) and poly(thienylene) has been achieved by the insertion of vinylene linkages between the aromatic rings in the polymer chain to give poly(phenylenevinylene) and poly(thienylenevinylene),[8–10] respectively. The backbone of these polymers is made of aromatic rings bridged by vinylene linkages wherein the vinylene linkage not only reduces steric hindrance between backbone rings attached to them, but also has a beneficial effect on electronic properties as evidenced by experimental and theoretical data on both poly(*p*-phenylenevinylene)[4] and poly(thienylenevinylene).[11]

Recently, we reported a new precursor and polymerization route for the preparation of high molecular mass poly(3,4-dialkoxy-2,5-thienylenevinylene)s as low band gap conductive polymers made by base/acid and thermally induced elimination of sulfoxide groups.[12] We now report a convenient synthesis of 1-alkyl-2,5-bis(phenylthiomethylene)pyrroles (**2a**–**c**) using the Mannich reaction.[13] These can be readily polymerized using 4 equiv. of Bu^{t}OK (Scheme 1). The present account is the first report of the use of phenylthio as a leaving group in forming poly(1-alkyl-2,5-pyrrolenevinylene)s (**1a**–**c**).

1-Alkylpyrroles (**5a**–**b**) were prepared as described in the literature.[14] Treatment of **5a**–**c** with aq. HCHO and $Me_2NH{\cdot}HCl$ at room temperature for 7 d, the Mannich reaction, gave 70–85% yields of 1-alkyl-2,5-bis[(dimethylamino)-methyl]pyrroles (**4a**–**c**) and these, in turn, were converted into bisquaternary ammonium salts (**3a**–**c**) (yield: 75–92%) after reaction with MeI in THF at room temperature. We chose 1-alkyl-2,5-bis[(trimethylammonio)methyl]pyrrole diiodide (**3a**–**c**) as initial target monomers because of their crystallinity and good stability. However, attempts to polymerize these monomers (**3a**–**c**) with 5–10% aq. NaOH in a temperature range from 0 °C to reflux have not been successful. Manipulation of the bisquaternary ammonium salt functional groups in **3a**–**c** into a phenylthio leaving group **2a**–**c** (yield: 55–70%) provided a facile approach to a new class of polymerizable monomers (Scheme 1).†

The bis(phenylthiomethylene) derivative **2b** of 1-alkylpyrrole was treated with Bu^{t}OK (4 mol) in THF at room temperature and then gradually warmed to reflux. This monomer polymerized to give poly(1-hexyl-2,5-pyrrolylenevinylene) (PHxPyV), **1b**. This polymer was purified by four reprecipitations from THF into MeOH and acetone and had a deep blue color with a gold luster. On exposure to air, the polymer became slightly doped reaching a limiting conductivity of 10^{-6} S cm^{-1}. On doping with $AuCl_3$, PHxPyV films (cast on quartz) exhibited conductivities of 2.5 S cm^{-1} (four-in-line probe) in air. The undoped conjugated polymer **1b** was soluble in many common organic solvents. Conversion from the bis-phenylthio monomer **2b** afforded PHxPyV in 72% yield, which is considerably higher than that typically obtained for poly(phenylenevinylene) prepared from bis-sulfonium salt precursors (20–40%).[15] As indicated by the UV–VIS–NIR spectrum shown in Fig. 1(*a*) on an undoped film of cast polymer **1b**,



Scheme 1 *Reagents and conditions*: i, aq. CH_2O, $HClHN(CH_3)_2$, 0–25 °C; ii, MeI, THF, room temp.; iii, PhSNa, THF, reflux; iv, Bu^{t}OK, THF, reflux

Table 1 Properties of polymers **1a–c**

Polymer	λ_{max}/nm		Onset optical gap/eV	Solubility[a]	Doped conductivity/S cm^{-1} (dopant)
	THF	Film			
1a	500[b]	—	1.89	Insoluble	0.02 ($AuCl_3$), 0.001 ($FeCl_3$)[c]
1b	550	569	1.69	Very soluble	2.5 ($AuCl_3$), 0.15 ($FeCl_3$)[d]
1c	548	563	1.65	Very soluble	0.48 ($AuCl_3$), 0.11 ($FeCl_3$)[d]

[a] Solubility in moderately polar solvent such as $CHCl_3$, THF, CH_2Cl_2. [b] NMP. [c] Pressed powder pellet. [d] Cast film.

the onset band gap (low energy absorption edge) was determined to be 1.69 eV for PHxPyV. Poly(1-dodecyl-2,5-pyrrolylenevinylene) (PDoPyV), **1c**, was prepared from bis-phenylthio monomer **2c** as indicated in Scheme 1. This polymer had an onset band gap of 1.65 eV and had, by GPC using polystyrene standards, a number average weight (M_n) of 1.6×10^4 and a polydispersity (PD) of 1.16. This band gap is similar to that observed with PHxPyV. A comparison of the properties of **1a–c** made by the same route are summarized in Table 1.

The difference in conductivity between poly(1-alkyl-2,5-pyrrolylene) [$\sigma = 10^{-3}$ (methyl), 4.3×10^{-5} (hexyl) and 1.2×10^{-6} S cm^{-1} (dodecyl)] and **1a–c** suggests that the low conductivities of *N*-substituted polypyrroles as prepared by oxidative polymerization arise from a combination of steric interactions between adjacent rings[7] and from a mixture of α–α′, α–β′, and β–β′ coupled monomer.[16]

We have found the polymerization of bis-phenylthio monomers (**2a–c**) to be general for the electron rich 1-alkylpyrroles. Also, we fully expect that this polymerization process will be suitable for the preparation of other electron rich polymers, and we are presently in the process of attempting to prepare representative examples.

We thank the Robert A. Welch Foundation for support of this work. We also thank Professor Michael P. Cava, Professor Martin Pomerantz and Dr Haitao Cheng for helpful discussions.

The oxa-di-π-methane rearrangement of β,γ-unsaturated ketones induced by the external heavy atom cation effect within a zeolite

R. Sadeghpoor,[a] M. Ghandi,*[a] H. Mahmoudi Najafi[a] and F. Farzaneh[b]

[a] *Department of Chemistry, University of Tehran, Tehran, Iran*
[b] *Department of Chemistry, University of Az-Zahra, Tehran, Iran*

Photolyses of β,γ-unsaturated ketones 1 and 2 included in MY zeolites gave the oxa-di-π-methane products, which are believed to originate from the triplet state caused by heavy atom cations present within the supercage.

Recent application of zeolites in organic photochemistry,[1] and our interest in the chemistry of zeolites[2] and the photochemistry of β,γ-unsaturated ketones,[3] has prompted us to investigate the photochemistry of these compounds within the supercages of zeolite Y. We report here the observation of a 1,2-acyl shift, or oxa-di-π-methane (ODPM) rearrangement, of bicyclo-[2.2.1]hept-5-en-2-one (BHO) **1**† and bicyclo[2.2.2]oct-5-en-2-one (BOO) **2**[4] included in heavy cation-exchanged zeolite Y.

The chemistry of β,γ-unsaturated ketones is well-known and many publications on this subject have been published during the last two decades.[5] Upon direct irradiation, the majority of β,γ-unsaturated ketones undergo a singlet-mediated 1,3-acyl shift reaction to produce a rearranged β,γ-unsaturated ketone.[6] Triplet-sensitized photolysis of these compounds, on the other hand, leads to the well known and synthetically useful ODPM rearrangement.[7] Investigation of the extent of singlet–triplet interconversion of the excited guest molecule within a cage, channel or pore has been limited to the study of the photophysical processes of some aromatics and olefins,[8] and photochemical reactions like photodimerization of acenaphthylene [9] and photolysis of 2,3-diazabicyclo[2.2.2]oct-2-ene.[10] We felt that the heavy cations present within the Y-type faujasite supercage could provide interesting results for the photochemistry of β,γ-unsaturated ketones. Because LiY and NaY were not effective for ODPM rearrangement, and KY did not show more than 15% activity for this reaction,‡ we concentrated our experiments on CsY and TlY. It should be emphasized that the absence of triplet formation in LiY and NaY is consistent with their solution behaviour in which the intersystem crossing yields from singlet to triplet is reported to be near zero.[11] This led us to conclude that rearrangement in the supercages of LiY, NaY and mostly in KY is from the singlet excited state.‡

The Cs^+ and Tl^+ cations were exchanged into the NaY zeolite by mixing the powder with the appropriate 10% nitrate solution at 90 °C for 1 h. For each gram of zeolite, 10 ml of the cation nitrate solution was used. This cycle was repeated three times. The zeolite was filtered, washed thoroughly, and then held at 500 °C for 12 h. A typical procedure for the preparation of zeolite-guest complexes is provided below. Dry zeolite (2.1 g) and the ketone (30 mg)§ were stirred in dry hexane (30 ml) for about 2 h under a dry nitrogen atmosphere. The complex was filtered and washed several times with dry hexane to remove any surface adsorbed materials. GC analysis of the filtrates showed that most of the ketone had been introduced into the cavities. The dry solid inclusion complexes were then placed in a quartz tube and photolyzed at 253.7 nm in a Rayonet photoreactor with five lamps for 10–35 h.¶ The photolyses were carried out either in hexane slurry or in the solid state. The products were extracted by stirring the complex in 30 ml of dry Et_2O for *ca*. 12 h or dissolution of the zeolite framework with 1 M HCl. Mass balance in all cases was *ca*. 90%. Identification of products was made by GC (Perkin-Elmer 3920 gas chromatograph equipped with TCD detection and a packed column of 3% OV-17 on Chromosorb W) and comparison of retention times with those of authentic samples. The concentrations were determined by an internal standard procedure using cyclohexanone as the internal standard.‖ The results are shown in Tables 1 and 2.

Table 1 Photolyses results for BHO **1** under various conditions

	Solution[a]		Slurry[b]		Solid	
Medium	*t*/h	Yield (%)	*t*/h	Yield (%)	*t*/h	Yield (%)
Acetone	15	41				
CsY			10	21.4	25	39.2
CsY			15	24	30	40.4
CsY			20	27	35	41.9
TlY			10	33.6	25	55.5
TlY			15	34.3	30	57.8
TlY			20	35	35	61.1

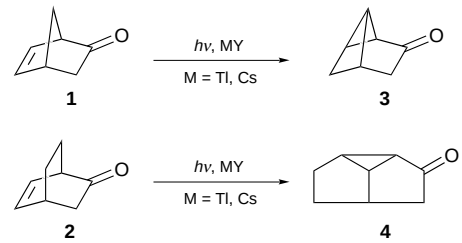
[a] Yield based on photolysis at 253.7 nm (quartz). Photolysis with a low pressure merucury lamp led to 70.4% of **3**. [b] Increasing the photolysis time to more than 20 h did not improve the results.

Table 2 Photolyses results for BOO **2** under various conditions

	Solution[a]		Slurry[b]		Solid	
Medium	*t*/h	Yield (%)	*t*/h	Yield (%)	*t*/h	Yield (%)
Acetone	15	37.3				
CsY			10	12.2	25	29.1
CsY			15	18.6	30	30.6
CsY			20	20.5	35	32.1
TlY			10	24.1	25	38.6
TlY			15	25.6	30	40.5
TlY			20	26.1	35	44.7

[a] Yield based on photolysis at 253.7 nm (quartz). Photolysis with a low pressure mercury lamp led to 66.2% of **4**. [b] Increasing the photolysis time to more than 20 h did not improve the results.

Photolyses of either the hexane slurry or the solid complexes led to the ODPM ketones **3** and **4** as the sole products (Scheme 1). Only traces of 1,3-acyl shift ketones could be detected as byproducts.



Scheme 1

Since intersystem crossing of β,γ-unsaturated ketones is usually slow following direct irradiation, population of the triplet excited state requires either to use of triplet energy sensitizers or the introduction of heavy atoms to decrease the barrier to the singlet–triplet transition (the heavy atom effect).[12] Because sensitization techniques have been difficult to apply in the crystalline state until now, the triplet state photochemistry of such compounds has not been studied in this medium, except for the remarkable work of Ramamurthy, who investigated the photolyses of Li^+, Na^+, K^+, Rb^+ and Cs^+ salts of a β,γ-unsaturated keto acid and found that there is a strong cation effect in the crystalline state but none in solution.[13]

The formation of the ODPM ketones under the effect of heavy cations within the Y zeolite in our system, particularly the 60% yield of the 1,2-acyl shift product in the presence of TlY, is strong support for the heavy atom cation effect in solid systems. The trends observed in the variation of the triplet yields with increasing mass, *i.e.* Li^+, $Na^+ < K^+ < Cs^+ < Tl^+$, is consistent with the expected spin-orbit coupling-induced triplet formation. The reason for the greater effect of heavy atom castions in the solid state than in the slurries might be attributed to the increased triplet lifetime of the ketone in the solid state, and the reduced diffusional mobility of the guest molecule toward the heavy cations when the channels are filled with solvent molecules. Such behaviour has been observed in the di-π-methane rearrangement of 11-hydroxymethyl-9,10-dihydro-9,10-ethanoanthracene within zeolite KY by the triplet–triplet energy transfer of several sensitizers to the guest molecule within the supercages.[14]

In conclusion, we believe that zeolite–guest complexes containing heavy cations can be considered as remarkable singlet–triplet transition matrices. Our results show it to be an efficient approach to energy transfer from a donor to an acceptor in the solid state. To the best of our knowledge, this is the first report of an ODPM rearrangement arising from an external heavy atom cation effect within a zeolite.

Stereoselective preparation of quaternary benzylic centres using chiral imidazolines†

Peter I. Dalko and Yves Langlois*‡

Laboratoire de Synthèse des Substances Naturelles, associé au CNRS, ICMO, Bâtiment 410, Université de Paris-Sud, 91405 Orsay, France

Dianions derived from C_2 symmetric chiral imidazolines provide good to excellent stereocontrol in alkylation reactions affording fully substituted benzylic centres.

Stereoselective preparation of quaternary centres, particularly in benzylic positions, remains a challenge. Carbometallation followed by nucleophilic substitution is seemingly a simple method, however, difficulties arise in both the preparation of the organometallic intermediate and also in the control of the stereoselectivity of the carbometallation in an inherently crowded position. Reports of the asymmetric preparation of vicinal heteroatom-stabilized tertiary organolithium compounds[1,2] are still scarce, although it is being actively studied by a number of groups.[2] Furthermore, stereoselective formation of fully *C*-substituted carbons *via* deprotonative carbolithiation remains elusive.[3]

In the wake of other studies on five-membered heterocycles as chiral auxiliaries,[4] we were interested in testing imidazolines in asymmetric substitution reactions. We observed that dianions derived from C_2 symmetric chiral imidazoline **1**§ undergo diastereoselective alkylation in the presence of 1.1 equiv. of alkyl halides **2a**–**d** and afforded the corresponding fully *C*-substituted centres **3a**–**e** in good yield. The reaction was performed in THF and the dimetallated intermediate was formed without addition of supplementary complexing agents such as TMEDA or other additives.[5] Some representative examples are given in Table 1. Quaternary centres were obtained with good acyclic diastereoselectivity¶ and in good yield, as illustrated in entries 1–4. The presence of electron-donating substituents on the aryl side chain resulted in a drop in selectivity (entry 5).

Alkylation of monoanions derived from *N*-alkylated imidazolines such as **4a** proceeded with slightly lower diastereoselectivity. However, good stereocontrol was observed using the conformationally restrained bicyclic imidazoline **4b** (Table 2). Surprisingly, the diastereoselectivity in these reactions was the opposite to the observed for non-substituted C_2 symmetric imidazolines **3a**–**e**, as was ascertained by chemical correlation between **3a** and **5a**: imidazoline **3a** was *N*-methylated using 1.1 equiv. of Bu^nLi and 1.1 equiv. of MeI at −78 °C, and the ^1H and ^{13}C MNR spectra of the resultant product were compared with that of **5a**.

Table 2 Alkylation of monoanions derived from *N*-substituted imidazolines using methyl iodide

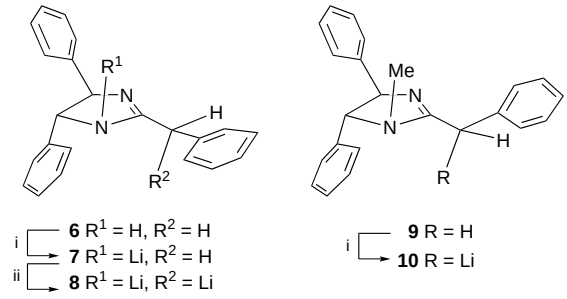
In order to provide a structural basis for the stereodifferentiation, the question of the *C-versus N*-lithiation dichotomy was addressed. A ^{13}C NMR study[6] of selected compounds **6** and **9** was undertaken (Scheme 1). The ^{13}C NMR spectrum at −69 °C of the monolithiated intermediate **7** shows in a single set of well-resolved signals which were in accord with the expected *N*-lithiated product [C_α δ 40.2 (t, $^1J_{C-H}$ 125 Hz)]. Dimetallation using the standard procedure afforded a single, unsymmetrical product whose ^{13}C NMR signals at −69 °C were in accord with those of the *N* and C_α bis-lithiated compound **8**. The lithiated carbon [C_α δ 64.2 (d)] was shown to be slightly pyramidalised ($^1J_{C-H}$ 157 Hz)[7] and thus is stereogenic. The two *ortho* carbons of the benzylic side chain were found to be magnetically non-equivalent at this temperature, which indicates restrained conformational freedom of the side chain.



Scheme 1 *Reagents and conditions*: i, Bu^nLi (1.1 equiv.), −69 °C; ii, Bu^nLi (1.1 equiv.), −25 °C, 25 min, then −69 °C

Monolithiation of **9** under standard conditions afforded a single product whose ^{13}C NMR signals at −69 °C were in accord with those of the *C*-lithiated compound **10** [C_α δ66.4 (d, $^1J_{C–H}$ 158 Hz)], structurally similar to the dimetallated counterpart **8** (Scheme 1). These results suggest in both cases the presence of carbometallated species prior to alkylation rather than the formation of *N*-metallated aza-enolates. The stereoselectivity of the alkylation reaction is thus dependent to the stereochemistry of this carbolithiated species[1a,1b,8] and is currently being investigated in our laboratory.‖

In summary, the method described here allows the stereoselective preparation of either stereoisomeric quaternary benzylic centre independently of the stereochemistry of the inducting chiral auxiliary, using non-complexing alkyl halides.[8] Beyond the perspective of building fully *C*-substituted benzylic quaternary carbons[9] the method could also be useful in providing access to other, covalently linked stereodefined tertiary organometallic compounds useful in asymmetric synthesis.

Notes and References

§ Racemic imidazolines were used as starting materials for the alkylation reactions. Starting materials were prepared by classical condensation of the corresponding imino ether hydrochloride, itself obtained from arylacetonitrile, and *trans*-1,2-diphenylethylenediamine, see ref. 4(*c*).

¶ The diastereoselectivity of the reaction was measured by ^1H NMR analysis by integrating the α-methyl or other characteristic signals.

‖ The configuration of the newly formed stereocentre was established by chemical correlation. This synthesis will be presented in due course.

New synthetic methodology utilising 1,2-dioxines and stabilised phosphorus ylides: a highly diastereoselective cyclopropanation reaction

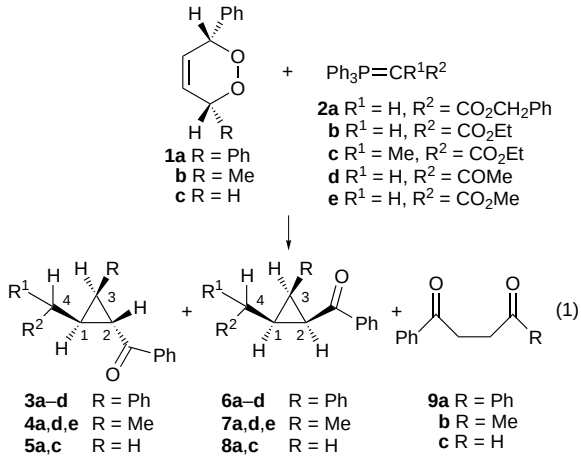
Thomas D. Avery,[a] Thomas D. Haselgrove,[a] Tanya J. Rathbone,[b] Dennis K. Taylor*[a] and Edward R. T. Tiekink[a]

[a] *Department of Chemistry, The University of Adelaide, Adelaide, Australia, 5005*
[b] *Department of Chemistry, Monash University, Clayton, Victoria, Australia, 3168*

A new method is described for the synthesis of diastereomerically pure cyclopropanes from substituted 1,2-dioxines 1a–c and stabilised phosphorus ylides 2a–e.

In 1994 the group of Adam and Treiber established for the first time that the peroxide bond of 1,2-dioxetanes is susceptible to nucleophilic 'attack' by simple diazoalkanes.[1] In this first report, 1,2-dioxetanes upon treatment with diazoalkanes afforded a mixture of products including 1,3-dioxolanes. More recently, the reactions between various methyl-substituted 1,2-dioxetanes and simple triphenylalkylidenephosphoranes were explored by the same group.[2] Initial nucleophilic 'attack' on the O–O linkage was proposed for the observed formation, at low temperature, of 2,2,2-triphenyl-1,4,2λ^5-dioxaphosphorinanes which, upon warming, ring-opened affording dipolar phosphonium alkoxides.

Herein we report that various 1,2-dioxines **1a**–**c** react under mild conditions with stabilised phosphorus ylides **2a**–**e** to afford novel diastereomerically pure cyclopropanes [reaction (1)]. To



the best of our knowledge, the reactions of stabilised phosphorus ylides with 1,2-dioxines have not been reported until now. A typical reaction involved treatment of **1a**[3] with **2a** (1.1 equiv.) in an appropriate solvent (usually CH_2Cl_2) at ambient temperature. The major product formed was identified as the cyclopropane **3a** along with a trace of diketone **9a**[4]. Similar reactions afforded a variety of di- and tri-substituted cyclopropanes in excellent yields and are collated in Table 1. Compounds **1a** and **c** afforded essentially diastereomerically pure *trans*-cyclopropanes whilst **1b** afforded the *trans*-cyclopropane as the major diastereomer along with a minor amount of the *cis*-cyclopropane. Typically the isolated yields were within 10% of those quoted whilst the diastereomers were easily separated by column chromatography. The structure and relative stereochemistry of the cyclopropanes were unambiguously elucidated from a combination of ^{1}H, ^{13}C, DEPT, NOESY (^{1}H-COSY and HMQC with gradient coherence selection)

Table 1 Reaction of 1,2-dioxines **1a**–**c** with various stabilised phosphorus ylides **2a**–**e** at 25 °C[a]

1,2-Dioxine	Ylide	Yield of cyclopropane (%)		Yield of **9** (%)
1a	**2a**	**3a** (95)	**6a** (⩽2)	**9a** (3)
	2b	**3b** (96)	**6b** (⩽2)	**9a** (2)
	2c	**3c** (48)	**6c** (nd)	**9a** (52)
	2d	**3d** (nd)	**6d** (nd)	**9a** (100)
1b	**2a**	**4a** (84)	**7a** (15)	**9b** (⩽1)
	2d	**4d** (75)	**7d** (15)	**9b** (10)
	2e	**4e** (82)	**7e** (18)	**9b** (nd)
1c	**2a**	**5a** (100)	**8a** (nd)	**9c** (nd)
	2c	**5c** (80)	**8c** (nd)	**9c** (nd)[b]

[a] All reactions performed in CH_2Cl_2; yields were determined from the ^{1}H NMR spectra (600 MHz) of the crude reaction mixtures; nd denotes not detectable. [b] Another unidentified minor product present.

NMR techniques.† X-Ray analysis‡ of **4a** (Fig. 1) unambiguously confirmed the general structural and stereochemical assignments elucidated by NMR spectroscopy.

The effect of solvent and additives on the rate of reaction between **1a** and **2a** and the cyclopropane : diketone ratio **3a** : **9a** was evaluated. Our initial findings indicate that the overall rate of reaction increases only slightly with increasing solvent polarity. The small rate increase is inconsistent with a mechanism involving zwitterionic intermediates in the rate-determining step. The relative rate and product ratio was unaffected by the addition of TEMPO suggesting that free radicals are not involved. Additionally, the formation of 'free' carbenes can be excluded on the basis that addition of excess cyclohexene failed to compete in cyclopropane formation. This

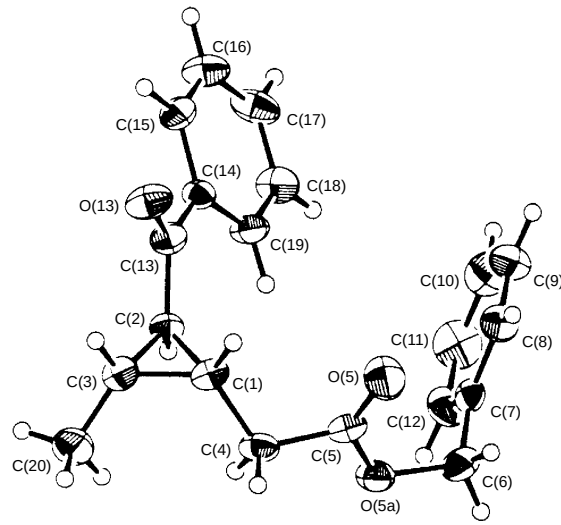


Fig. 1 Molecular structure of **4a** showing the crystallographic numbering scheme employed: O(5)–C(5)–C(4)–C(1) 34(1)°, C(5)–O(5a)–C(6)–C(7) −82.6(8)°, C(2)–C(13)–C(14)–C(15) 159.5(7)°

conclusion was further supported by the observation that only a trace of the carbene dimer (< 1%) could be detected by ^{1}H NMR analysis of the crude reaction mixtures. Finally, performing the reaction at 80 °C simply lead to an increased rate without a change in product outcome or ratio.

The reaction of equimolar amounts of **1a** and **2a** in C_6D_6 was monitored by ^{31}P NMR spectroscopy. At no time could any 'free' triphenylphosphine or zwitterionic intermediates be detected. Careful ^{1}H NMR analysis of the crude mixture after cessation of the reaction revealed the presence of **3a**, **9a**, Ph_3PO and unreacted **2a**. All **1a** had been consumed affording **3a** and **9a** in a 77 : 22 ratio. The remaining 1% constituted the *cis*-cyclopropane. Formation of Ph_3PO (75%) parallels the yield of the cyclopropane as expected. Most important was the observation that 22% unreacted **2a** remained and parallels **9a** formation (22%). This observation suggests that formation of **9a** is catalytic in ylide. Indeed, analysis of all crude reaction mixtures by ^{31}P and ^{1}H NMR spectroscopies showed the same trend. Blank reactions showed that formation of **9a**–**c** was not promoted by Ph_3PO. We have evidence that the rearrangement **1a** → **9a** is not promoted by 'free' Ph_3P liberated during the ylide reaction, *e.g.* addition of excess Ph_3P to the reaction mixture containing **1a** and **2a** failed to dramatically change product outcome. Based on these initial findings we suggest that formation of **9a** in the reaction of **1a** with **2a** is promoted by the ylide acting as a weak base[5] in a catalytic manner. Base catalysed rearrangement (Kornblum–De La Mare decomposition) of cyclic peroxides has been reported previously and is initiated by removal of a proton from the carbon adjacent to the O–O linkage.[6] Finally, the observation that the more sterically hindered **2c** affords less cyclopropane **3c** when compared to that for **2b** in identical solvents suggests that there is a steric component to the two competing processes.

A significant mechanistic finding was the observation of the *trans*-alcohol **10** intermediate during ^{1}H NMR monitoring of these reactions. Indeed, we were able to isolate a quantity of **10** from the reaction mixture and demonstrate that it lead to the observed cyclopropanes and no 1,2-diketone upon addition of ylid. Although the reaction manifold is complicated by many factors, Scheme 1 depicts a general mechanistic overview. Interaction of **1** and **2** leads in a rate-limiting step to the formation of the key intermediate **10**. Michael addition of the ylide to **10**, followed by cyclisation, proton transfer and extrusion of triphenylphosphine oxide from **11** affords the observed cyclopropanes. In competition with this process is the known cyclisation[6] of (*Z*)-**10** *via* the hemi-acetal and rearrangement leading to formation of **9**.

Synthetically, this novel reaction has several advantages over existing methods[7] for cyclopropane formation involving phosphorus ylides, as functionalised cyclopropanes are formed in a highly diastereoselective manner in excellent yields. We are currently evaluating the reactions of various 1,2-dioxines, alkyl hydroperoxides and disulfides with a variety of stabilised and non-stabilised ylides (phosphorus, sulfur *etc.*) and full mechanistic details will be presented in due course.

New route to organoaluminium sulfides: synthesis of $(Mes^*AlS)_2$ (Mes^* = -$C_6H_2Bu^t_3$-2,4,6) and its dimethyl sulfoxide adduct $[Mes^*AlS(OSMe_2)]_2$

Rudolf J. Wehmschulte and Philip P. Power*

Department of Chemistry, University of California, Davis, California 95616, USA

Treatment of the alane $(Mes^*AlH_2)_2$ (Mes^* = -$C_6H_2Bu^t_3$-2,4,6) with $S(SiMe_3)_2$ in refluxing toluene affords the novel organoaluminium sulfide $(Mes^*AlS)_2$ 1 which has a previously unobserved dimeric structure; treatment of 1 with 2 equiv. of Me_2SO furnishes the complex $[Mes^*AlS(OSMe_2)]_2$ 2 in which a dimeric configuration is retained, and which shows weak intermolecular interactions between neighboring dimers.

Group 13 organometallic chalcogenide species of formula $(RME)_n$ (R = alkyl, aryl; M = Al, Ga, In; E = O–Te) are usually synthesized with use of the organometallic precursors MR_3.[1] For the heavier chalcogenide derivatives, direct interaction of the elements themselves (*i.e.* S, Se, Te) with the metal trialkyls has afforded several new compounds which have three-dimensional cage structures.[2] For the lighter oxide derivatives, however, the reaction between water (or water complexed in metal salts)[3] remains the preferred method of synthesis of $(RMO)_n$ compounds.† Recently, it has been shown that aluminium hydride compounds are also useful precursors for the synthesis of organoalumoxanes.[4] Thus, the reaction of the hydride $(Mes^*AlH_2)_2$[5] (Mes^* = -$C_6H_2Bu^t_3$-2,4,6) with $(Me_2SiO)_3$ affords the unique tetramer $(Mes^*AlO)_4$ with elimination of SiH_2Me_2. We now report that the reaction of $(Mes^*AlH_2)_2$ with $S(SiMe_3)_2$‡ affords the unique, dimeric, heavier chalcogenide derivative $(Mes^*AlS)_2$ **1** and that treatment of **1** with Me_2SO does not effect dissociation of the dimeric structure but affords the adduct $[Mes^*AlS(OSMe_2)]_2$, **2**.

Compound **1**, which displays high thermal stability (mp > 200 °C), can be synthesized§ in almost quantitative yield by refluxing $(Mes^*AlH_2)_2$[5] with 2 equiv. of $S(SiMe_3)_2$ in either toluene or *n*-octane. X-Ray crystallographic data¶ for **1** show that it crystallizes as dimeric units (Fig. 1) which have a crystallographically required inversion center. The planar Al_2S_2 core is characterized by almost equal Al–S distances of 2.2083(9) and 2.2107(14) Å and internal ring angles of 78.09(3)° at S and 101.91(3)° at Al. The external S–Al–C angles, 127.94(7) and 130.14(7)°, are quite similar, so that the sum of the angles at Al is 359.99° indicating strictly planar coordination at Al. However, there are also short (2.26–2.33 Å) interactions between a number of *ortho*-Bu^t H atoms and Al. The angle between the normals to the $(AlS)_2$ and aromatic ring planes is 89.3°.

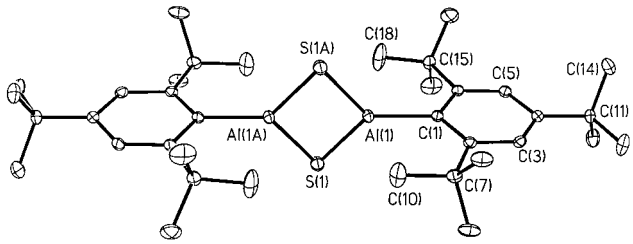

Fig. 1 Thermal ellipsoidal (30%) plot of **1** with H atoms not shown. Some important bond distances (Å) and angles (°): Al(1)–S(1) 2.2083(9), Al(1)–S(1A) 2.2107(14), Al–C(1) 1.956(2), Al(1)···Al(1A) 2.7835(13); Al(1)–S(1)–Al(1A) 78.09(3), S(1)–Al(1)–S(1A) 101.91(3), S(1)–Al(1)–C(1) 127.94(7), S(1A)–Al(1)–C(1) 130.14(7).

The dimeric structure of **1** may be contrasted with the tetrameric structure of the corresponding oxide species $(Mes^*AlO)_4$[4] which features an almost planar, eight-membered Al_4O_4 ring with wide (*ca.* 151°) Al–O–Al angles. The lower aggregation in **1** thus, may be a consequence of the reluctance of the S atoms to hybridize which imposes a narrower interbond angle. This leads to greater steric congestion in the molecule which results in the lower degree of aggregation observed for **1**. Apparently, **1** is only the second example of a mono-organoaluminium sulfide to be fully structurally characterized. The only previous example is the tetrameric species $[(Me_2EtC)AlS]_4$[2d] which has an Al_4S_4 cubane structure with Al–S distances in the range 2.295(8)–2.319(9) Å. The longer Al–S distances in that compound are due to the higher coordination numbers of both Al (four) and S (three). The short Al–S distances in **1** are similar to those observed in the low-coordinate compounds $Al(SMes^*)_3$[6] [Al–S 2.172(2)–2.191(2) Å], $S[Al\{CH(SiMe_3)_2\}]_2$[7] [Al–S 2.187(4) Å] and $Al_4I_4S_2(SMe)_4$[8] [Al–S (two-coordinate) 2.16(1)–2.20(1) Å].

The dimethyl sulfoxide adduct **2** was prepared by the addition of 2 equiv. of Me_2SO to **1** in benzene. Complex **2** was formed essentially instantaneously and it is precipitated from benzene at room temperature. Heating the solution to reflux temperature resulted in redissolution of the precipitate and cooling slowly resulted in crystals suitable for X-ray crystallography. The X-ray data for **2** show that the dimeric Al_2S_2 core structure (Fig. 2) remains intact and that the metals are each complexed by one dimethyl sulfoxide molecule which are disposed on opposite sides of the Al_2S_2 core. This results in an increase of *ca.* 0.05 Å in the Al–S bond lengths which span the narrow range 2.243(2)–2.259(2) Å. The Al–C distances are lengthened by about the same amount; from 1.956(2) Å in **1** to an average of 2.022(8) Å in **2**. The average Al–O distance is 1.86(1) Å, which is within the range found in related complexes.[9] Also, the Al_2S_2 core is folded slightly (fold angle 167.5°) along the S(1)···S(2) axis. Although each Al is complexed by one Me_2SO, it can be seen from Fig. 2 that the relative orientation of each donor molecule is different. Thus, the Me_2SO containing O(1) is oriented such that the SMe_2 moiety lies above the Al_2S_2 core whereas the O(2) containing Me_2SO is oriented away from the core. These different orientations are reflected in different Al–O–S angles of 114.2(2)° at O(1) and 130.0(2) at O(2). It seems that this unusual arrangement is a result of some weak intermolecular interactions involving the Me_2SO donor containing O(2). These interactions involve relatively short O···H distances [*e.g.* O(2)···H(40E) 2.89 Å, O(2)···H(39F) 2.63 Å], and S···H distances [*e.g.* S(1)···H(39C) 3.04 Å, S(2)···H(40E) 3.02 Å]. Another notable feature of the structure of **2** is the distorted geometry at the *ipso*-C atoms of the Mes* ligands. The averaged aromatic ring planes are bent by *ca.* 25° from the Al–C vector lines. Similar distortions have been observed in other Mes* group 13 derivatives.[10]

Finally, although no dissociation of the dimeric **1** was effected by the addition of Me_2SO, attempted redissolution of isolated **2** results in its partial decomposition and production of

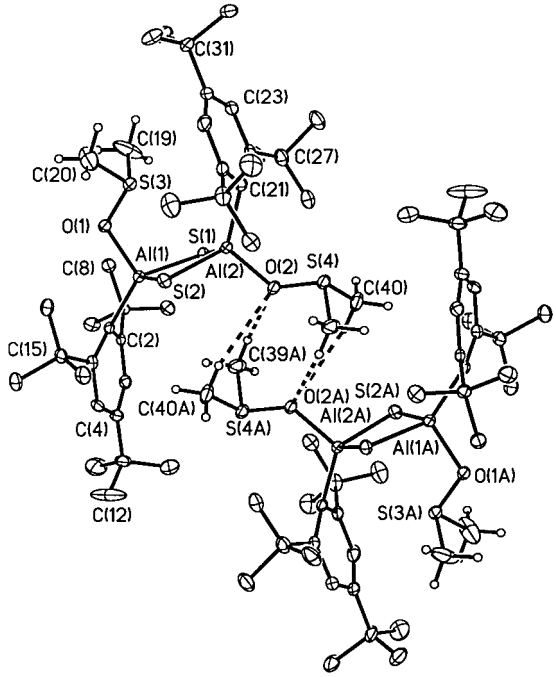

Fig. 2 Computer generated drawing of **2**. H atoms, except those involved in intermolecular interactions, are not shown. † Alumoxanes of formula $R_2AlOAlR_2$ can be synthesized by the reaction of triorganoaluminium compounds with species containing reactive oxygen such as CO_2, $RC(O)NR_2$, $MeCO_2H$ and Me_2SO. See: H. Sinn and W. Kaminsky, *Adv. Organomet. Chem.*, 1980, **18**, 99; W. Uhl, M. Koch, W. Hiller and M. Heckel, *Angew. Chem., Int. Ed. Engl.*, 1995, **34**, 989.

‡ The compound $S(SiMe_3)_2$ has been extensively used recently in the synthesis of several transition metal sulfide cluster compounds. See: D. Fenske and S. Dehnen, *Chem. Eur. J.*, 1996, **2**, 1407.

§ All manipulations were carried out under anaerobic and anhydrous conditions. The compound $(Mes^*AlH_2)_2$[5] was synthesized as described in the literature and $S(SiMe_3)_2$ was purchased from Aldrich and used as received.

1 or **1**·PhMe: A solution of $(Mes^*AlH_2)_2$[5] (1.05 g, 1.91 mmol) in toluene (25 ml) was heated with $(Me_3Si)_2S$ (0.81 ml, 3.82 mmol, 0.68 g) at room temp. The clear, colorless solution was heated to 100–105 °C for *ca.* 21 h during which time large colorless plates of **1**·PhMe formed. Yield: 1.25 g, 93%. Mp: turns opaque at 120–140 °C (desolvation), melts at 305–310 °C. Crystals of unsolvated **1** suitable for X-ray diffraction studies were obtained *via* a similar procedure by the reaction of $(Mes^*AlH_2)_2$ with $(Me_3Si)_2S$ in *n*-octane at 115–120 °C for 38 h. Yield: 42%. Mp: turns slowly opaque at 250–280 °C, melts at 310–312 °C. ^{1}H NMR (C_6D_6, 85 °C): δ 7.51 (s, *m*-H, 4 H), 1.81 (s, *o*-CH_3, 36 H), 1.36 (s, *p*-CH_3, 18 H).

2: Dimethyl sulfoxide (0.06 ml, 0.8 mmol, 0.062 g) was added to a slurry of finely ground **1**·PhMe (0.16 g, 0.23 mmol) in benzene (25 ml) at room temp. to give an almost clear solution from which after a few seconds a fine, colorless solid precipitates. This was dissolved by heating to reflux for *ca.* 1 min to afford a clear colorless solution from which, after 3 days at room temp. *ca.* 0.04 g of colorless plates could be isolated. Yield: 23%. Mp: turns red at 235 °C, gradually darkens to almost black at 300 °C, does not melt below 300 °C.

It is noteworthy that **1** is practically insoluble in hydrocarbon solvents. It can be solubilized by the addition of Me_2SO or HMPA at elevated temperatures (the range 60–80 °C works best). From these solutions crystals are usually obtained upon cooling to room temp. These crystals do not redissolve without decomposition.

¶ Crystal data at T = 130 K with Mo-Kα, (λ = 0.710 73 Å) radiation for **1** and Cu-Kα, (λ = 1.541 78 Å) radiation for **2**: **1**, $C_{36}H_{58}Al_2S_2$, M = 608.9, monoclinic, space group $C2/c$, a = 26.924(5), b = 9.845(2), c = 16.780(3) Å, β = 125.86(3)°, U = 3064(1) Å^3, μ = 0.219 mm^{-1}, Z = 4 (8/2), wR_2 = 0.119 for all 4149 data, R_1 = 0.047 for 3164 [$I > 2\sigma(I)$] data; **2**, $C_{40}H_{70}Al_2O_2S_4$, M = 765.2 monoclinic, space group $P2_1/n$, a = 18.374(5), b = 9.883(2), c = 24.587(3) Å, β = 91.16(2)°, U = 4464(2) Å^3, μ = 2.560 mm^{-1}, Z = 4, wR_2 = 0.143 for all 5830 data, R_1 = 0.053 for 4550 [$I > 2\sigma(I)$] data. Electrochemical oxidation of [5,15-bis(3,5-di-*tert*-butylphenyl)porphyrinato]zinc(II) 1, [5,15-bis(4-methoxycarbonylphenyl)porphyrinato]zinc(II), [5,15-bis(pentafluorophenyl)porphyrinato]zinc(II) or [10-bromo-5,15-diphenylporphyrinato]zinc(II) in benzonitrile using a platinum net as the working electrode afforded the corresponding *meso,meso*-linked oligomer porphyrin arrays, and up to the octamer porphyrin array could be isolated for 1.

Polynuclear porphyrins have been attracting considerable attention as biomimetic models of photosynthetic systems as well as photonic materials and functional molecular devices.[1–7]

In a previous communication we reported the oxidative coupling reaction of [5,15-bis(3,5-di-*tert*-butylphenyl)-porphyrinato]zinc(II) **1** with silver(I) salts to give the porphyrin dimer **2**, the porphyrin trimer **3** and the porphyrin tetramer **4**.[8] The possible mechanism proposed is an initial one-electron oxidation of zinc porphyrin with Ag^{I} followed by nucleophilic attack of a neutral zinc porphyrin. This mechanism suggests that electrochemical oxidation also may lead to the formation of the *meso,meso*-coupled porphyrin arrays. Here we report an electrochemical preparation of the porphyrin arrays, by which the usage of expensive silver salts is not required, the oxidizing potentials can be best tuned to the porphyrin used, and the long porphyrin arrays can be prepared in a one-step procedure through prolonged electrolysis.

Porphyrin **1** (n = 1) (219 mg, 0.293 mmol) was electrolyzed in dry benzonitrile (210 ml) in a single cell with NBu_4ClO_4 (0.1 M) as the electrolyte, a platinum net (1.8 × 2.4 cm) as the counter electrode, and a platinum net (3 × 4 cm) as the working electrode; the electricity used was 0.732 mF. The porphyrin products were purified by being passed through an alumina and then a silica gel chromatography column, and isolated by preparative scale HPLC using a gel permeation column (GPC–HPLC). The structures were identified through comparison with the authentic samples:[8] **1** (44.0%), **2** (n = 2) (20.7%), **3** (n = 3) (2.9%) and **4** (n = 4) (0.9%). When porphyrin **1** (211 mg, 0.282 mmol) was electrolyzed under similar conditions using electricity of 1.65 mF, the higher homologous pentamer **5** (n = 5), hexamer **6** (n = 6), heptamer **7** (n = 7) and octamer **8** (n = 8) could be isolated at yields of 0.5, 0.4, 0.2 and 0.05%, respectively, together with **1** (6.7%), **2** (10.2%), **3** (3.2%) and **4** (1.6%) by GPC–HPLC. The new product was characterized by ^{1}H NMR spectroscopy (500 or 600 MHz) and FAB mass spectrometry or MALDI-TOF mass spectrometry.†

Treatment of [5,15-bis(4-methoxycarbonylphenyl)porphyrinato]zinc(II) **9** at higher oxidation potential (+0.68 V *vs.* Ag/$AgNO_3$) than **1** (+0.54 V *vs.* Ag/$AgNO_3$) with $AgClO_4$ under the conditions reported previously[8] did not afford the corresponding *meso,meso*-linked porphyrin arrays, although an unidentified complex mixture together with *ca.* 60% of the recovered starting material were obtained. However, when **9** (51 mg, 79 μmol) was electrolyzed using electricity of 134 μF, it afforded the *meso,meso*-linked porphyrin dimer **10** (34.3%), porphyrin trimer **11** (6.9%) and the starting porphyrin **9** (47.4%). Similarly, [5,15-bis(pentafluorophenyl)porphyrinato]zinc(II) **12** (+0.77 V *vs.* Ag/$AgNO_3$) and (10-bromo-5,15-diphenylporphyrinato)zinc(II) **13** (+0.56 V *vs.* Ag/$AgNO_3$), which did not give the corresponding *meso,meso*-linked porphyrin arrays by the silver salt method, afforded the corresponding dimers **14** and **15** under similar conditions by electrolysis in isolated yields of 11.6 and 47.5%, respectively. Thus the electrochemical method has a wider scope for the substrates than the silver salt method.

These *meso,meso*-linked porphyrin arrays so far isolated were quite soluble in $CHCl_3$. Of particular note is the fact that even the arrays of porphyrin **9**, **12** and **13**, which have little sterical hindrance to prevent π–π stacking of the porphyrin planes, also had high solubility. This is probably because the porphyrin planes connect nearly perpendicular to each other due to their sterical requirement, and hence their intermolecular π–π stacking was largely prevented.

These results indicate that the present electrochemical method is a convenient way of preparing *meso,meso*-linked porphyrin arrays which should be good candidates for long 'molecular wires'[9,10] having a linear rigid structure and high solubility.

Synthesis and characterization of $Ag_2C_2·2AgClO_4·2H_2O$: a novel layer-type structure with the acetylide dianion functioning in a μ_6-$\eta^1,\eta^1:\eta^2,\eta^2:\eta^2,\eta^2$ bonding mode inside an octahedral silver cage

Guo-Cong Guo, Qi-Guang Wang, Gong-Du Zhou and Thomas C. W. Mak*†

The Chinese University of Hong Kong, Shatin, New Territories, Hong Kong, PR China

In the novel double salt $Ag_2C_2·2AgClO_4·2H_2O$, the C_2^{2-} dianion [bond length 1.217(7) Å] is encapsulated inside an octahedral Ag_6 cage, and the resulting cationic $[C_2@Ag_6]$ units share corners to generate metallic layers between which the perchlorate anions and aqua ligands are accommodated.

The literature contains scant information on the ligand behaviour of C_2^{2-} (acetylide dianion), in contrast to the rich coordination chemistry of its isoelectronic analogues N_2 (dinitrogen) and CN^- (acting in either cyanide or isocyanide mode). The salt-like alkali and alkaline-earth metal acetylides are readily decomposed by water, the best known example being calcium carbide, CaC_2, which exists in at least four different crystalline modifications.[1] Of the group 11 metal acetylides, silver acetylide (Ag_2C_2, also known as silver carbide) was first prepared as an impure yellowish powder by Berthelot in 1866.[2] A linear polymeric structure for silver acetylide has been inferred from its chemical properties, which are consistent with those of a molecular compound; for example, it does not react with water and is highly explosive and sensitive to shock when completely dried.[3] However, the existence of the 'naked' acetylide dianion, C_2^{2-}, as a fully encapsulated species within rhombohedral Ag_8 and monocapped square-antiprismatic Ag_9 cages in the double salts $Ag_2C_2·6AgNO_3$[4,5] and $Ag_2C_2·8AgF$,[6] respectively, suggests that the coordination mode of the C_2^{2-} entity in silver acetylide is much more complex than hitherto imagined.

Recently we have initiated a research project to synthesize and elucidate the X-ray crystal structures of novel compounds containing silver acetylide as a component, so as to shed some light on the nature of the interaction between the acetylide dianion and silver(I) ions. We report here the synthesis and crystal structure of a new double salt of silver acetylide with silver perchlorate, in which the acetylide dianion acts in a μ_6-$\eta^1,\eta^1:\eta^2,\eta^2:\eta^2,\eta^2$ bonding mode that binds the silver cations into an unprecedented two-dimensional planar array.‡

In the crystal structure of $Ag_2C_2·2AgClO_4·2H_2O$, the atoms C(1), C(2), Ag(2) and Ag(3) all lie on the same crystallographic mirror plane. The measured C(1)–C(2) bond distance of 1.212(7) Å is comparable to that found in acetylene (1.205 Å), showing that the acetylide dianion retains its triple bond character inherited from the parent silver acetylide, as confirmed by its laser Raman stretching frequency. The C_2^{2-} dianion is σ-bonded to atoms Ag(2) and Ag(2^i) in the *c* direction, and π-bonded to Ag(3) and Ag(3^{ii}) in the *a* direction and to Ag(1) and Ag(1^{iii}) in the *b* direction (Fig. 1). Thus this dumbbell-like species is encapsulated inside an Ag_6 cage, and the resulting $[C_2@Ag_6]$ octahedra share vertices along the *a* and *c* directions to generate a layer structure. The distances of bridging atom Ag(2) to the C(1) and C(2^{iv}) atoms of its adjacent acetylide dianions are 2.087(3) and 2.108(6) Å, respectively, which are comparable to those (average 2.057 Å) of Ag atoms σ-bonded to the C≡CR groups in the alkynyl complexes $[Ph_3PAgC{\equiv}CPh]_4·3.5thf$ and $[Me_3PAgC{\equiv}CSiMe_3]_\infty$.[7] The C(2)–C(1)–Ag(2) and C(1)–Ag(2)–C(2^{iv}) bond angles are 179.9(3) and 178.5(2)°, respectively. Therefore the coordination mode of the acetylide dianion to two metal atom of type Ag(2) can be regarded as typical linear σ-bonding, as found in the discrete complexes $[\{Ru(CO)_2(Cp)\}_2(\mu\text{-}C{\equiv}C)]$,[8] $[\{Re(CO)_5\}_2(\mu\text{-}C{\equiv}C)]$[9] and $[Cu_4(\mu\text{-dppm})_4(C{\equiv}C)][BF_4]_2$.[10] However, to our knowledge the infinite linear chain resulting from an alternate arrangement of σ-bonded acetylide dianions and type Ag(2) silver atoms in the present compound is unprecedented.

The orthogonal pair of filled π orbitals of the acetylide dianion interact unsymmetrically with Ag(1) and Ag(3) and their symmetry equivalents, such that silver atoms of type Ag(3) serve as bridges to link adjacent infinite chains to form a metallic layer (Fig. 1). The distances of atom Ag(3) to C(1) and C(2) are 2.554(4) and 2.382(6) Å, and the C(1)–C(2)–Ag(3) and C(2)–C(1)–Ag(3) angles are 83.9(3) and 68.0(3)°, respectively. Thus the coordination mode of the acetylide dianion to silver atoms of type Ag(3) can be regarded as unsymmetrical π-bridging, which differs from the symmetrical acetylide–copper interaction observed in $[Cu_4(\mu\text{-dppm})_4(C{\equiv}C)][BF_4]_2$.[10] Similar unsymmetrical π-bonding also occurs between the acetylide dianion and silver atoms of type Ag(1), which are

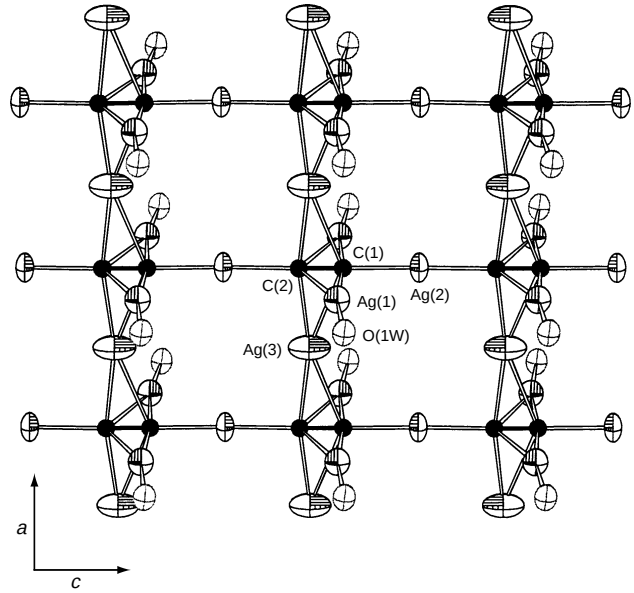

Fig. 1 Cationic layer composed of C_2^{2-} and Ag^+ ions in the crystal structure of $Ag_2C_2·2AgClO_4·2H_2O$ viewed along the *b* axis. The thermal ellipsoids are drawn at the 35% probability level. Selected bond lengths (Å) and angles (°): C(1)–C(2) 1.212(7), Ag(1)–C(1) 2.3448(4), Ag(1)–C(2) 2.579(2), Ag(2)–C(1) 2.087(3), Ag(2)–C(2^i) 2.108(6), Ag(3)–C(1) 2.554(1), Ag(3)–C(2) 2.382(6), Ag(3^{ii})–C(1) 2.596(4), Ag(3^{ii})–C(2) 2.448(6), Ag(1)–O(1W) 2.304(2); Ag(1)–C(1)–Ag(1^{iii}) 173.5(2), C(1)–Ag(1)–O(1W) 171.4(1), C(2)–C(1)–Ag(2) 179.9(3), C(1)–Ag(2)–C(2^{iv}) 178.5(2), C(2)–Ag(3)–C(2^v) 166.8(3), C(1)–C(2)–Ag(3) 83.0(3), C(2)–C(1)–Ag(3) 69.4(3). Symmetry codes: i, *x*, *y*, −1 + *z*, ii, 1 + *x*, *y*, *z*, iii, *x*, ½ − *y*, *z*, iv, *x*, *y*, 1 + *z*, v, −1 + *x*, *y*, *z*.

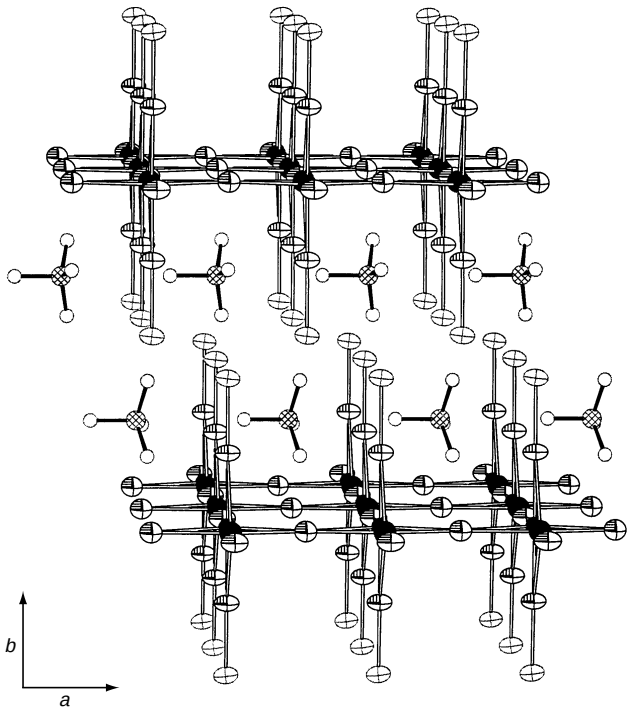

Fig. 2 Crystal structure of $Ag_2C_2·2AgClO_4·2H_2O$ viewed along the *c* axis. For clarity the disordered perchlorate ion is shown in only one of its two orientations, and the hydrogen bonds between the aqua ligands and the perchlorate ions have been omitted.

linked to C(1), C(2) and terminal aqua ligand O(1W) at distances of 2.3448(4), 2.579(2) and 2.304(2) Å, respectively. The dihedral angle between the planes defined by C(1)–C(2)–Ag(3) and C(1)–C(2)–Ag(1) is 90.7°.

The ClO_4^- ion exhibits twofold disorder with two equally populated, opposite orientations that share a common set of three basal oxygen atoms. The terminal aqua ligands that are coordinated to type Ag(1) silver atoms form donor hydrogen bonds to the ClO_4^- ions, thereby contributing to the stability of the structure. Fig. 2 shows that the cationic layers are completely separated by ClO_4^- anions, so that the crystal structure of the present compound may be considered as a stack of alternate conducting and insulating layers. This potential anisotropic conducting property of the metallic layer will be further studied.

Solution injection laser pyrolysis: a novel technique for gas phase pyrolysis of involatile compounds

Janet E. Everett, Noel D. Renner and Douglas K. Russell*

Department of Chemistry, University of Auckland, Private Bag 92019, Auckland, New Zealand

The gas phase pyrolysis of involatile species has been studied by injection of solutions in inert solvents into SF_6 gas heated by CO_2 laser radiation; the gas phase chemistry reflects the distribution of species present in solution, and may potentially be controlled through parameters such as solution pH.

IR laser powered homogeneous pyrolysis (LPHP) has been successfully exploited for over 20 years in the investigation of the mechanisms of thermal decomposition of volatile organic and organometallic compounds.[1,2] The advantages of the technique are well known; very small quantities of materials are needed, initiation of reaction is unambiguously homogeneous, and intermediates are readily trapped.[3,4] Among its shortcomings are difficulties in defining and measuring effective temperatures, although this may be overcome through the use of compounds of well known kinetic parameters. In addition, previous work has been restricted to compounds of at least moderate volatility (> 1 Pa). Here, we show that the latter limitation may be removed by a simple adaptation of the technique, and report some preliminary results.

The modification of IR LPHP described in this study is referred to as solution injection laser pyrolysis, SILP. Saturated solutions of target species in suitable solvents were introduced directly into the SF_6 gas heated by the CO_2 IR laser by means of a Hamilton syringe inserted through a rubber septum. In order to ensure rapid vaporisation of the solvent, the needle orifice was mechanically modified to produce a fine spray, and the needle tip heated to somewhat below red heat by positioning at the perimeter of the heated zone. Effective temperatures were not otherwise monitored in the present work although these are clearly needed in quantitative studies. Gaseous pyrolysis products were identified after injection by FTIR, and quantified with the aid of commercial software. For very soluble species, solution volumes of 10–50 μl yielded strong product IR spectra. In some experiments, additional gaseous reagents were introduced into the pyrolysis cell before solution injection in order to trap reactive intermediates, or the solution pH varied to modify the dominant solute species.

The volumes of solution injected are such that the vapour pressure of the solvent is usually exceeded in the pyrolysis cell; as a result, interpretation of observations might conceivably involve the partial dissolution of gaseous pyrolysis products in residual liquid solvent. In cases where evaluation of this complicating feature was possible, it proved to play no significant role, and has therefore been discounted. It is also possible that partial pyrolysis of solute might take place in solution within the heated needle tip before ejection. Again, investigations correlating product yield with needle tip location indicated that this was not the case; this conclusion is consistent with those from the early development of thermospray mass spectrometry, where orifice temperatures as high as 1000 °C were employed.[5]

The physical processes that occur as solution emerges from the needle tip into the heated gas zone are a matter of vigorous debate in the literature. In the most widely accepted model proposed by Iribarne and Thomson,[6] the majority of the solvent is vaporised into a fine spray as the solution leaves the capillary; the droplets that result may be charged, positively or negatively, in a statistical manner reflecting the distribution of ionic species in solution. As further solvent evaporates from the droplets, the charge density increases and eventually results in a series of 'Coulomb explosions' in which ions, either naked or solvated, are ejected into the gas phase. However, in contrast with electrospray or thermospray mass spectrometry, the principal focus of the present work is the subsequent thermal chemistry of solute species. This process also differs substantially from the suite of 'spray pyrolysis' methods developed for the generation of ceramic materials, where the major pyrolysis processes involve micro-aggregates of solute at heated surfaces.[7] The preliminary results described below confirm the viability of the technique, and illustrate its potential in mechanistic investigations.

Zinc oxoacetate and zinc acetate in toluene. The covalent zinc oxoacetate {hexakis[μ-(acetato-*O*:*O*′)]-μ_4-oxotetrazinc}, $Zn_4O(MeCO_2)_6$, provides a convenient reference point for the investigation of the gas phase pyrolysis chemistry of metal acetates; although little is known of the vapour of this compound, pyrolysis of the solid is known to produce largely CO_2 and acetone.[8] Its very slight volatility, and its stable tetrahedral Zn_4O unit, have also attracted interest in the parent compound as a potential precursor in the chemical vapour deposition of zinc oxide films.[9] In the present work, toluene was selected as the solvent, as it proved thermally inert at the temperatures employed. FTIR spectra (Fig. 1) of the gaseous products of SILP of saturated toluene solutions of $Zn_4O(MeCO_2)_6$ were dominated by solvent vapour and ketene, with smaller amounts of CO_2 and CH_4, and traces of CO, C_2H_4 and C_2H_2; no trace of acetone was detected. Clearly, pyrolysis pathways for isolated molecules in the vapour are very different from those in the bulk solid. Very similar results were found for the less soluble zinc acetate, although the yield of ketene was lower, and that of methane higher. In fully deuterated toluene, CH_3D was produced as well as CH_4, indicating the involvement of methyl radicals. These results concur with the known routes for decomposition of isolated acetate groups on oxide surfaces, and indicate that analogues of zinc oxoacetate may serve as molecular mimics for surface chemistry.[10]

Aqueous alkali metal acetates. There have been several reports on the dominant ionic species observed in the electro-

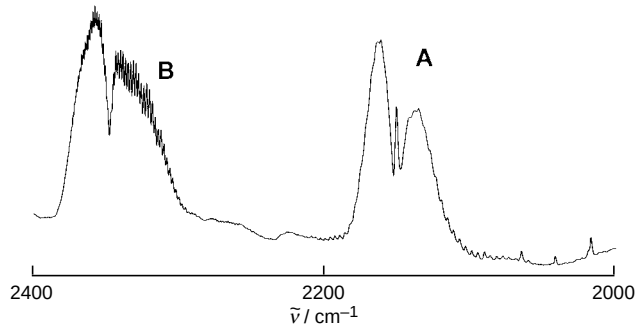

Fig. 1 Partial FTIR spectrum of the products of SILP of zinc oxoacetate in toluene, indicating the production of ketene (A) and CO_2 (B)

spray mass spectra of alkali metal acetates;[11] these include clusters of the form $[M_n(OAc)_{n\mp1}]^{\pm}$. In the SILP system, at high laser powers, the SF_6 photosensitiser was attacked, presumably by metal atoms or ions, resulting in the production of large quantities of SO_2 and extensive etching of the cell walls and windows. This reaction route was not explored in any detail; however, the observation of a blue chemiluminescence within the heated gas zone (presumably electronically excited SO_2) did provide clear visual confirmation of the homogeneous nature of reaction. At lower powers, all the alkali metal acetates behaved identically, and most experiments were conducted with saturated solutions of the potassium salt. In H_2O, the major products were CO_2 and CH_4, together with small amounts of CO and C_2H_2; no ketene was observed, in line with the known ready hydrolysis of ketenes.[12] In D_2O solution, extensive deuteration of C_2H_2 (as both C_2HD and C_2D_2) was observed, suggestive perhaps of ion–molecule reactions, but none of CH_4. Copyrolysis with H_2 resulted in almost complete suppression of CO_2 and CO, and a marked increase in CH_4 production; copyrolysis with D_2 resulted in some CH_3D, but no deuterated acetylenes. Conversely, copyrolysis with O_2 suppressed both hydrocarbons and increased the yield of oxides. Pyrolysis of a saturated solution of potassium acetate in 2 mol l^{-1} NaOH yielded no CO_2, and a marked increase in both CH_4 and C_2H_2.

Aqueous glycine. Many electrospray studies have focussed on systems of biological interest such as amino acids; in particular, the gas-phase chemistry of glycine-related anions and cations has been the subject of a number of experimental and theoretical investigations.[13] The IR-detectable gas phase products of SILP of aqueous solutions of glycine were CO_2, CO, NH_3, HCN, CH_4 and traces of C_2H_2. From 2 mol l^{-1} NaOH solution, no HCN was observed; from acidified solutions, no traces of CH_4, C_2H_2 or NH_3 were detected. With the ^{13}C-labelled $H_2N^{13}CH_2CO_2H$, only $H^{13}CN$ was observed, and both $^{13}CO_2$ and ^{13}CO were also detected at levels dependent on solution pH. From acidic solution, the ratio of $^{13}CO_2:{}^{12}CO_2$ was 1:5, and that of $^{13}CO:{}^{12}CO$ 1:1; from basic solutions, no labelled carbon oxides were generated. Unlike the alkali metal acetates, none of the solute species present in glycine solution are appreciably volatile, and we may conclude that these variations in pyrolysis products reflect changes in the major species appearing in the gas phase.

The above preliminary results indicate that the SILP technique provides the potential for the investigation of pyrolysis of isolated involatile species in the gas phase, most significantly of cations and anions, which are not readily produced by other methods.

We thank the University of Auckland for assistance with the purchase of equipment, the University of Auckland, Faculty of Science, for a Summer Studentship, and the New Zealand Federation of University Women for the Harriet Jenkins Award (to J. E. E.). We also are grateful to Professor Einar Uggerud (University of Oslo) for invaluable correspondence concerning the gas phase ion chemistry of glycine, and Leong Mar (University of New South Wales) for the sample of zinc oxoacetate.

Formation and co-coordination of lithium azide *via* lithium triazasulfite

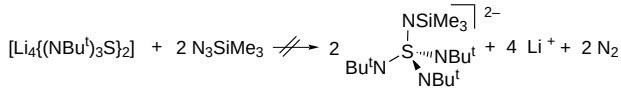
Roland Fleischer and Dietmar Stalke*

Institut für Anorganische Chemie der Universität Würzburg, Am Hubland, D-97074 Würzburg, Germany

The triazasulfite $[Li_4\{(NBu^t)_3S\}_2]$ (the analogue of Li_2SO_3) provides the opportunity to complex *in situ* formed lithium azide and converts this inorganic solid into soluble monomeric residues.

Recently, we described the synthesis and structures of some nitrogen analogues of simple sulfur oxygen compounds. In these derivatives the oxygen atoms are substituted by isoelectronic NR groups to yield the dilithium triazasulfite dimer[1] $[(thf)Li_4\{(NBu^t)_3S\}_2]$ (the analogue of Li_2SO_3) and the dilithium tetraazasulfate monomer[2] $[(thf)_4Li_2(NBu^t)_4S]$ (analogue to Li_2SO_4). Polyimido polyanions containing p-block element bridgeheads like $[RSi(NSiMe_3)_3]_2^{3-}$,[3] $RE(E'R'_2NR'')_3^{3-}$ (R,R′ = H, alkyl; R″ = alkyl, aryl; E,E′ = C, Si),[4] $[Sb(NR)_3]^{3-}$,[5a] $[Sb_2(NR)_4]^{2-}$,[5b] and $[E(NBu^t)_3]^{2-}$ (E = Se, Te)[6] furnish a new family of ligand systems to construct macromolecular architectures of mixed metal cages and clusters.[7] While the alkali metal salts of these polyanions are mostly employed in metal metathesis reactions little is known of their anion solvation behaviour to metal salts. The flexible electronic structure of their alkali metal derivatives, *i.e.* the ability to localise or delocalise the charge in the anion core backbone, should provide the opportunity to complex neutral metal salts.

We report here the reaction of dilithium *N*,*N*′,*N*″-tris(*tert*-butyl)azasulfite $[(thf)Li_4\{(NBu^t)_3S\}_2]$ and trimethylsilyl azide to give the lithium azide adduct $[(thf)_2Li_3(\mu_4N_3)\{(NBu^t)_3S\}]_\infty$ **1**. Organo azides are mainly employed as oxidants in Staudinger type reactions.[8] In an attempt to obtain the aza analogue $Me_3SiNS(NBu^t)_3^{2-}$ of sulfate we added trimethylsilyl azide to a hexane solution of $[(thf)Li_4\{(NBu^t)_3S\}_2]$. During the reaction at room temperature a slight rise in temperature was detected, although no evolution of gas (N_2) was observed (Scheme 1). In addition, silicon could not be detected in the ^{29}Si NMR spectrum of the product and the ^7Li NMR spectrum displayed two different lithium sites in the ratio 1:2. To further investigate the actual composition of the product, an X-ray structure analysis of the air-sensitive crystals (the compound turned dark blue when exposed to oxygen) was performed which established the formation of a polymeric lithium azide adduct **1** of monomeric $[Li_2(NBu^t)_3S]$ (Scheme 2).



Scheme 1

Obviously the trimethylsilyl azide acts as an acid rather than an oxidant in this reaction. That the byproduct $Bu^tNS(Bu^tN\text{-}SiMe_3)_2$ could not be isolated is presumably owing to its instability with respect to decomposition to $S(NBu^t)_2$ and $Bu^tN(SiMe_3)_2$ which were isolated from the reaction mixture† and identified by ^1H and ^{13}C NMR spectroscopy.

Compound **1** crystallises from thf–hexane within a few hours storage at room temperature to give colourless needles.‡ Within the monomeric units (Fig. 1), three lithium atoms are coordinated by the dianionic $S(NBu^t)_3^{2-}$ ligand. The dianion shows almost ideal local C_3 symmetry at sulfur. The three S–N distances are identical within e.s.d.s and are of typical length (av. 163.7 pm).[1] Li(1) and Li(1a) are tetrahedrally coordinated by two nitrogen atoms of the dianionic $S(NBu^t)_3^{2-}$ ligand, one azide nitrogen atom, and a single thf donor molecule. In addition to the two nitrogen atoms of the $S(NBu^t)_3^{2-}$ ligand Li(2) is coordinated by two azide nitrogen atoms [N(5) and N(5a)] of different N_3^- anions completing the tetrahedral coordination sphere of Li(2). Each azide anion μ_4 bridges the three lithium atoms of one $Li_3(NBu^t)_3S$ unit [av. Li–N 220(1) pm] and one lithium atom of a neighbouring monomeric residue

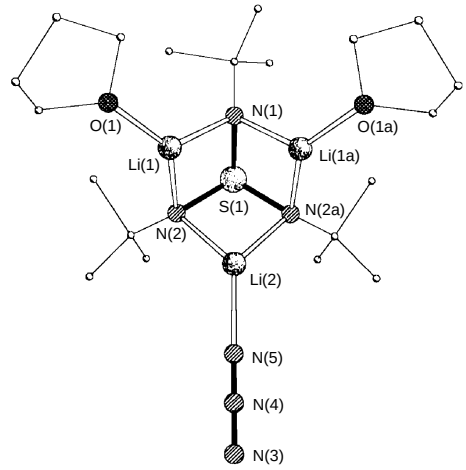


Fig. 1 Solid state structure of a monomeric unit of $[(thf)_2Li_3(\mu_4N_3)\{(NBu^t)_3S\}]_\infty$ **1**. Selected bond lengths (pm) and angles (°): S(1)–N(1) 163.3(5), S(1)–N(2) 164.2(4), Li(1)–N(1) 203.0(9), Li(1)–N(2) 200.3(8), Li(2)–N(2a) 203.3(8), Li(1)–N(5) 219.9(9), Li(2a)–N(5) 221.1(13), Li(2)–N(3) 195.9(12), Li(1)–O(1) 192.1(8), N(3)–N(4) 117.7(8), N(4)–N(5) 117.4(7); N(1)–S(1)–N(2) 100.5(2), N(2)–S(1)–N(2a) 100.8(3), N(3)–N(4)–N(5) 180.0(6), Li(2)–N(5)–N(4) 146.4(5).

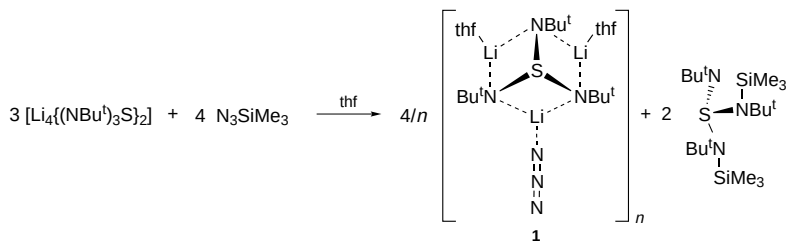

Scheme 2

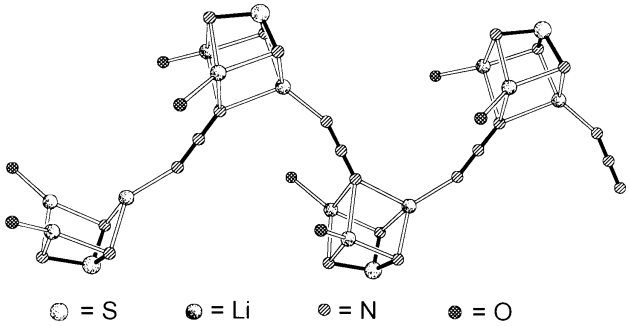

Fig. 2 Arrangement of monomeric **1** to give polymeric wave shaped ribbons; carbon atoms omitted for clarity

[N(5)–Li(2) 196(1) pm] with both terminal nitrogen atoms, such that a polymeric solid state structure is generated (Fig. 2).

In the solid state structure of LiN_3 every lithium atom is octahedrally coordinated by eight nitrogen atoms.[9] Every terminal nitrogen atom of an azide anion μ_3 bridges three lithium atoms with one short (221.4 pm) and two longer (228.9 pm) Li–N distances. In contrast, the Li–N distances of the terminal azide nitrogen atoms [N(3) and N(5)] in **1** are equal within e.s.d.s.

The *in situ* generated lithium azide is incorporated in a metal salt cocoordination complex owing to the capability of the $S(NBu^t)_3^{2-}$ triazasulfite anion to coordinate more than two metal centres.[10] Although balanced in terms of charge the Li_2N_3S framework can accommodate another lithium atom to form a LiN_3 monomer. The polyimido polyanions in general seem to provide access to soluble mixed metal aggregates[11] *via* incorporation of *in situ* generated inorganic solids into complex residues.

We are grateful to the Deutsche Forschungsgemeinschaft, the Stiftung Volkswagenwerk and the Fond der Chemischen Industrie. D. S. kindly acknowledges support of the Bruker axs-Analytical X-ray Systems, Karlsruhe.

‡ *Crystal data* for $[(thf)_2Li_3\{\mu_4N_3\}\{(NBu^t)_3S\}]\cdot 0.5$ thf **1**: $C_{20}H_{43}Li_3N_6O_2S\cdot 0.5C_4H_8O$, M = 488.54, orthorhombic space group *Pnma*, a = 965.60(14), b = 1593.2(4), c = 2079.3(5) pm, U = 3.1988(12) nm^3, Z = 4, D_c = 1.014 Mg m^{-3}, $F(000)$ = 1064, λ = 71.073 pm, μ(Mo-Kα) = 0.128 mm^{-1}, T = 153(2) K, data were collected on a Stoe-Siemens AED. Intensities of a 0.5 × 0.2 × 0.2 mm rapidly cooled crystal in an oil drop[12] were collected by the 2θ–ω method in the range of $4.33 \leqslant \theta \leqslant 22.55°$. Of a total of 3931 reflections, 2179 were independent and together with 608 restraints, were used to refine 322 parameters, largest difference peak and hole: 509 and −255 e nm^{-3}, $R1[F > 4\sigma(F)]$ = 0.0760 and $wR2$ = 0.2369 (all data) with $R1 = \Sigma\|F_o| - |F_c\|/\Sigma|F_o|$ and $wR2 = \{\Sigma w(F_o^2 - F_c^2)^2/\Sigma w(F_o^2)^2\}^{\frac{1}{2}}$; $w = 1/\{\sigma^2(F_o^2) + (0.153P)^2 + 1.81P\}$; $P = (F_o^2 + 2F_c^2)/3$. The structure was solved by direct methods with SHELXS-96[13] and refined by full-matrix least squares on F^2.[14] The Bu^t moiety [C(21)–C(23)] exhibits a rotational disorder. It was refined to a split occupancy of 0.72/0.28. The twist disorder of the coordinated thf molecule [O(1), C(40)–C(43)] was modelled to a split occupancy of 0.61/0.39. Additionally, half an uncoordinated thf was found in the difference Fourier map. It is disordered over a special position and was refined to a split occupancy of 0.52/0.48. In the refinement of the Bu^t moiety [C(10)–C(13)], the symmetry (mirror plane) was suppressed. For the refinement of the disorder bond length and similarity restraints were applied. A riding model was applied in the refinement of the hydrogen atom positions. CCDC 182/720.

Intermolecular hydrogen···metal interactions. The crystal structure of {*cis*-$[PdCl_2(TPA)_2]$}$_2$·H_2O, a water-soluble palladium(II) tertiary phosphine complex

Elmer C. Alyea,* George Ferguson and Shanmugaperumal Kannan

Department of Chemistry and Biochemistry, University of Guelph, Guelph, Ontario, Canada, N1G 2W1

The single-crystal X-ray structural determination of {*cis*-$[PdCl_2(TPA)_2]$}$_2$·H_2O (TPA = 1,3,5-triaza-7-phosphaadamantane) establishes that pairs of *cis*-$[PdCl_2(TPA)_2]$ molecules are linked about inversion centres by intermolecular Pd···H···C three-centre–four-electron interactions (2.86, 3.00 Å for the two independent dimers); the water molecule links these dimers *via* O–H···N hydrogen bonds to form infinite chains extending in the *c*-direction in the crystal lattice.

Attention has focused recently on complexes of the air-stable water-soluble phosphine 1,3,5-triaza-7-phosphaadamantane (TPA) with transition metal ions.[1,2] Darensbourg and co-workers have shown the high catalytic activity of certain ruthenium and rhodium complexes towards the hydrogenation of alkenes and the conversion of unsaturated aldehydes to saturated aldehydes or unsaturated alcohols.[1b,c,f] Given the potential for applications of water-soluble palladium and platinum complexes in catalysis, *e.g.* $[Pd(TPPTS)_4]$ [TPPTS = $P(m\text{-}C_6H_4SO_3Na)_3$] is used for the telomerization of dienes[3] and *cis*-$[PtCl_2(TPPTS)_2]$ for the functionalization of dienes,[4] we are currently extending our preliminary investigations of group 10 complexes of TPA.[2a,c] We report here our discovery that the crystal structure of the square-planar water-soluble palladium(II) complex of TPA, {*cis*-$[PdCl_2(TPA)_2]$}$_2$·H_2O **1** contains rare intermolecular C···H···Pd interactions; such C···H···M interactions, originally postulated in the literature as possible examples of agostic bonding, are best described as three-centre–four-electron (3c–4e) hydrogen bonds.[5]

The analytically pure compound was synthesized by the reaction of solid $PdCl_2$ with an excess of TPA in water.[6] The analytical, ^1H and ^{31}P NMR spectral data† of the isolated greenish–yellow product **1** show that the TPA ligand is bonded through its phosphorus atom to the metal ion in a 2 : 1 ratio. In contrast, a similar reaction employing $PtCl_2$ gave a product having the formula $[Pt(TPA)_3Cl]Cl$.[2c] Crystals of **1** suitable for X-ray diffraction analysis were obtained from a H_2O–MeCN–MeOH mixture by slow evaporation.‡ Our preliminary studies show that this complex is unstable in water, giving TPA oxide, but it is relatively stable in the presence of an excess of TPA. The mechanism of decomposition, which also occurs for the analogous Ni and Pt complexes, is under further investigation.[6]

Compound **1** crystallised in the triclinic space group $P\bar{1}$ and the asymmetric unit contains two molecules of *cis*-$[PdCl_2(TPA)_2]$ and a water molecule which links the two Pd complexes *via* O–H···N hydrogen bonds [O(1)–H(1)···N(13), O···N 2.916(6); O(1)–H(2)···N(33), O···N 2.914(6) Å]. A view of this hydrogen-bonded complex is in Fig. 1. The two independent Pd complexes have essentially identical stereochemistry and conformation; each palladium atom is surrounded by two chlorine and two TPA ligands, giving the expected square-planar geometry. It is well established that *cis*- and *trans*-isomerization in palladium(II) trialkylphosphine complexes of the type $[PdX_2L_2]$ (X = halogen, L = trialkylphosphine) is mainly determined by the phosphine size.[7–9] Thus, the PMe_3 (cone angle θ = 118°) complex is *cis*,[7] whereas larger phosphines such as PEt_3, PPr_3, PMe_2Ph, *etc.*, form isomeric mixtures[8] and the PCy_3 (θ = 170°) complex is *trans*.[9] Since the cone angle of TPA is only 102°,[1a] not surprisingly, in the present complex the two TPA ligands are arranged in a *cis*-orientation, and indeed the P–Pd–P bond angles [93.25(5), 93.58(5)°] are the smallest found for any *cis*-$[Pd(PR_3)_2X_2]$ complexes.[7–10] The P–Pd–P angle for the PMe_3 analogue is reported as 94.7(1) Å in the solid state.[7] Comparable values for *trans*-P–Pd–Cl bond angles also show that less distortion is present in the TPA complex, mean 176.8(4)° compared with a mean value of 172.5(1)° in the PMe_3 complex.[7] The observed Pd–P [2.2392(13)–2.2551(13) Å] and Pd–Cl bond distances [2.3467(14)–2.3777(13) Å] are similar to those in *cis*-$[Pd(PMe_3)_2Cl_2]$ [av. 2.257(2) and 2.368(3) Å respectively] and other analogous complexes.[7–10]

Although bridging hydrogen–palladium interactions are known for a few palladium–phosphine complexes,[5] {*e.g.* Pd···H 2.8 Å in $[Pd(PPhMe_2)_2I_2]$ and 2.92 Å in $[Pd(PEt_3)_2Cl(C_6H_4C\text{-}MeN_2HPh)]$} in most cases the interaction is purely an intramolecular one. Examination of the crystal structure of **1** with PLATON[11] shows that each Pd complex lies close to an

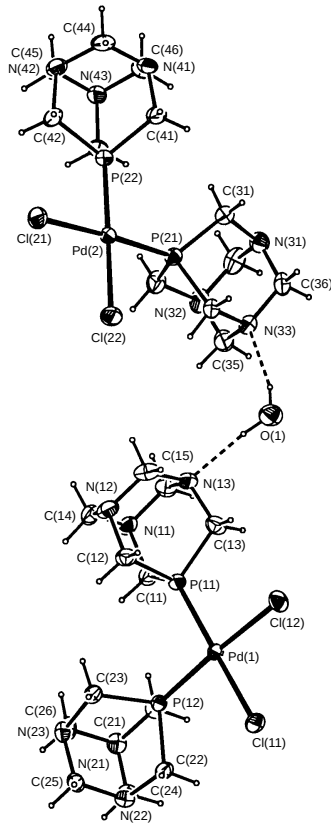

Fig. 1 A view of the asymmetric unit of **1** with our numbering scheme. Anisotropic displacement ellipsoids are drawn at the 40% probability level.

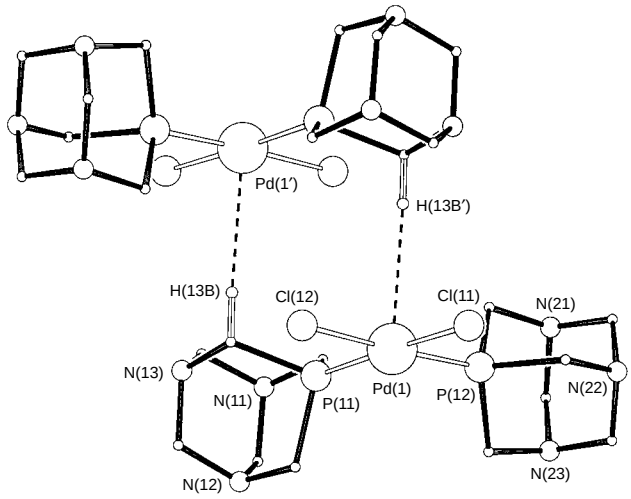

Fig. 2 A view of one of the 'hydrogen-bridged dimers' of *cis*-[$PdCl_2(TPA)_2$] [atom Pd(1′) is related to Pd(1) by the symmetry transformation $-x, -y, 1 - z$]

inversion centre and this leads to a short intermolecular Pd···H···C interaction with an H atom of a TPA ligand of a molecule related by the inversion centre. Each Pd complex forms essentially identical dimers in this way with Pd···H distances of 2.86 [Pd(1)···H(13B′) (at $-x, -y, -z$)] and 3.00 Å [Pd(2)···H(33B′) (at $-x, -y, 1 - z$)] some 0.5–0.6 Å less than the sum of the van der Waals radii. A view of the hydrogen-bridged dimer involving Pd(1) is in Fig. 2; a view of the dimer with Pd(2) is given in supplementary material available from the authors. The orientation of the bridging H atoms above the PdP_2Cl_2 planes is given by *e.g.* the angles P(12)–Pd(1)···H(13B′) (99°) and P(22)–Pd(2)···H(33B) (95°). In the crystal structure, the effect of these Pd···H···C interactions together with the O–H···N hydrogen bonds noted above is to generate infinite chains in the *c*-direction which have 'H-bridged dimers' linked *via* water molecules. These linear C–H···Pd interactions are best described as 3c–4e hydrogen bonds rather than 3c–2e agostic bonds (*i.e.* the out-of-plane Pd d orbital is filled), as has been well documented by Brammer.[5b]

The opening and filling of single walled carbon nanotubes (SWTs)

Jeremy Sloan,[a,b] Jens Hammer,[a] Marek Zwiefka-Sibley[a] and Malcolm L. H. Green*[a]

[a] *Inorganic Chemistry Laboratory, University of Oxford, South Parks Road, Oxford, UK OX1 3QR*
[b] *Department of Materials, University of Oxford, Parks Road, Oxford, UK OX1 3PH*

Single walled nanotubes (SWTs) can be selectively opened and filled using wet chemistry techniques; treatment of the carbon nanomaterials with concentrated HCl apparently leads to the selective opening of the SWTs at their tips; foreign materials can then be deposited inside the resulting cavities in a similar fashion to multi-walled carbon nanotubes (MWTs); the filling of SWTs with small spherical crystals and, additionally, preferentially orientated and elongated single crystals of Ru metal is described; the selective opening of SWTs was inferred from these observations.

Multi-walled carbon nanotubes (MWTs) have attracted much interest since their discovery owing to their high mechanical strength and electrical properties.[1,2] They have already proved to be valuable in their application as tips for scanning probe microscopy and also as field emission devices.[3,4] The discovery and large scale synthesis of single-walled nanotubes (SWTs)[5,6] has given further impetus to this research as they similarly exhibit useful physical and electronic properties. SWTs can be generated by co-evaporating carbon and certain metals in arc-evaporation[5–9] or laser-vaporisation of metal-doped graphite[10,11] although they have also been produced by thinning of MWTs using CO_2.[12] SWTs display a higher degree of uniformity with respect to their physical dimensions compared to MWTs as they consist only of a single cylindrical graphitic layer and exhibit both a smaller range of diameters and far fewer defects than their multi-walled counterparts. Similarly, therefore, a greater degree of uniformity may be anticipated from their physical properties. Theoretical studies suggest that the introduction of foreign material into the inner cavities of MWTs or SWTs may enhance or modify the properties of the resulting composite materials.[13–15] Therefore, following similar work with MWTs,[16,17] we have employed wet chemistry techniques to open and fill SWTs. Here, however, a milder process has been used to selectively open SWTs since the oxidation methodology employed for opening MWTs[16] (*i.e.* refluxing concentrated HNO_3) was found to be too harsh for SWTs and resulted in their destruction.

The SWTs used in these experiments were produced in a modified arc-discharge chamber also employed to make MWTs.[14] Cobalt doped graphite rods were evaporated under a dynamic vacuum with helium (500 Torr) using an electric arc generated from a potential of 30 V and a dc current of 200 A. The external environment of the electrodes was confined by a 10 cm id steel cylinder 20 cm in length. The SWTs were found in the highest yield (*ca.* 30%) in the web-like material deposited on the walls of the cylinder. The diameters of the SWTs were found by high-resolution transmission electron microscopy (HRTEM) to be in the range 1–3 nm. For the filling experiments, samples of SWTs were suspended in concentrated HCl and stirred for 8 h. After centrifuging for 5 min, a light blue solution containing $CoCl_2$ was removed and the specimen was dried at 70 °C for 8 h and then washed with deionised water. A saturated solution of $RuCl_3$ (*ca.* 5 ml) was then added to the SWT-containing specimen and the mixture stirred for 5 h at 35 °C after which the black residue was dried at 60 °C overnight. The sample was then heated in a stream of H_2 at a rate of 5 °C min^{-1} to 45 °C and kept at this temperature for 3 h. After washing with distilled water and drying at 60 °C the residue was prepared for HTREM.

Electron micrographs revealed that a small proportion (*ca.* 5%) of the opened SWT contained foreign material. Fig. 1(*a*) shows a group of three SWTs, two of which apparently are filled with Ru crystals (arrowed). By slightly altering the defocus of the microscope, these crystals were observed to stay at the same focus with the SWTs and therefore we conclude that they are encapsulated inside the SWTs. As with studies carried out with MWTs,[17] individual crystallites were observed to fill the entire width of the hollow core of the SWTs as is seen in Fig. 1(*a*). Energy dispersive X-ray (EDX) microanalyses, utilising a 3 nm probe, performed on clusters of encapsulated crystallites similar to those in Fig. 1(*a*), confirmed their chemical identity as Ru metal [Fig. 1(*b*)], although some slight oxidation is apparent. Encapsulated and elongated crystallites were also frequently observed and these were again identified by EDX to be Ru metal. Fig. 2(*a*) shows an elongated Ru crystallite encapsulated near the elbow of a bent or damaged SWT. Fig. 2(*b*) shows an elongated Ru crystallite growing along the bore of one SWT at

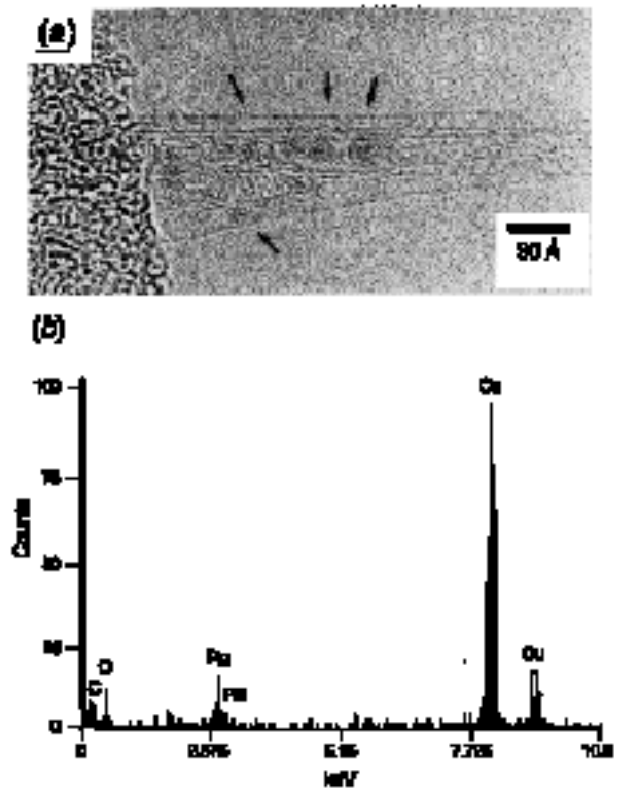

Fig. 1 (*a*) Individual Ru crystals encapsulated inside SWTs (arrowed). The diameter of the crystallites is apparently the same as that of the id of the SWT. (*b*) EDX microanalysis obtained from encapsulated Ru crystals similar to those observed in (*a*). O peak indicates that the crystallites are slightly oxidised. The Cu peak is from the copper TEM support grid.

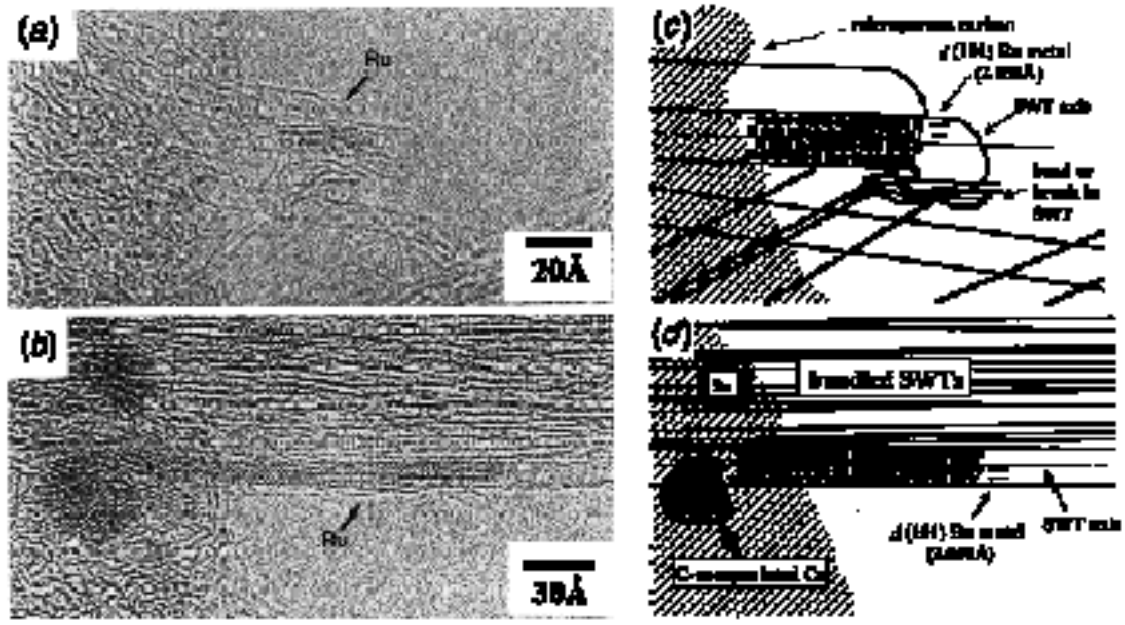

Fig. 2 (*a*) Elongated Ru crystallite encapsulated near the elbow of a bent or damaged SWT. The lattice fringes aligned parallel to the SWT axis corresponding to the *d*(101) lattice fringes of Ru metal. (*b*) Elongated Ru crystallite encapsulated inside a single SWT at the edge of a bundle of SWTs. As with the crystallite in Fig. 1(*a*), the *d*(101) Ru lattice fringes are orientated parallel to the SWT axis. (*c*) Schematic representation of (*a*). (*d*) Schematic representation of (*b*).

the edge of a bundle of SWTs (bundling of SWTs into 'ropes' is very common[10,11]). Both crystallites exhibit preferred orientations, with their *d*(101) lattice fringes[18] aligning parallel to the SWT axes. This phenomenon is represented schematically for Figs. 2(*a*) and (*b*) in Figs. 2(*c*) and (*d*), respectively. The phenomenon of preferred orientation inside SWTs is consistent with the observation of preferred crystallite orientation inside MWTs[19,20] and is most probably the result of the morphological influence of nanotube capillaries over crystallite growth during formation.[21] Other particles were also observed on the exterior of SWTs [Figs. 2(*b*) and (*d*)] and these were found by EDX to be either 'loose' Ru particles or carbon encapsulated Co particles which were presumably protected from acid attack by their carbon shells. It was not possible for us to conclusively image the opened tips of the SWTs by HRTEM because of their very low contrast compared to opened MWTs.[12] The selective opening of the SWTs was therefore inferred indirectly from the observation of their filling with Ru metal from solution which must have occurred in order for filling to occur. A further point is that we have not attempted to estimate the percentage of SWT opening in our experiments, partly for the above reason and also partly because the very high aspect ratio of SWTs would make this an extremely difficult proposition.

Experiments are currently under way in our laboratory to repeat this experiment with both ruthenium and other metals using a higher yield SWT method, similar to that recently reported by Journet *et al.*[22] We are also investigating methods for increasing the yield of the encapsulated product and are also trying to establish the mechanism by which opening occurs.

A novel 'build-bottle-around-ship' method to encapsulate metalloporphyrins in zeolite-Y. An efficient biomimetic catalyst

Bi-Zeng Zhan and Xiao-Yuan Li*

Department of Chemistry, The Hong Kong University of Science and Technology, Clear Water Bay, Kowloon, Hong Kong, PR China

Electrostatic interaction is introduced between the host and guest in the synthesis of faujasite-Y confined metallotetrakis(*N*,*N*,*N*-trimethylanilinium) porphyrin cations ($MTMAnP^{4+}$); the synthesized composites display high catalytic activity in the oxidation of cyclohexene.

One of the most attractive properties of zeolites are their well organized nanopores and nanochannels which serve readily as supporting hosts for various molecules. Encapsulation of catalytically active transition metal complexes inside the nanopores of zeolites, often referred to as 'ship-in-a-bottle' systems,[1] has been believed to be one of the most promising strategies in the development of viable industrial catalysts.[1–6] Extensive effort has been devoted to the synthesis and catalytic properties of zeolite entrapped metallocomplexes with such ligands as bipyridine, salen, polyamines and phthalocyanines.[1–6] In most of these syntheses, a so-called 'assemble-ship-inside-bottle' approach has usually been adopted in which the desired catalytic metallocomplex is synthesized inside the nanopores/channels of the zeolite in the presence of an excess of ligand or its synthetic precursors. As a consequence, what was usually obtained is a mixture of the desired complex with unreacted free ligand as well as side-products. For example, the synthesis of metalloporphyrin (MP) inside zeolites often leads to a significant portion of undesired polymerization product and the unmetallated free base porphyrin ligand.[7–9]

We report here a novel, efficient and quantitative method to synthesize high purity MPs incorporated in faujasite-Y at a controllable loading concentration. The novel aspect of this method is that an electrostatic interaction was introduced between the host (anionic aluminosilicate species) and the guest (cationic peripheral substituents on MPs) in a 'build-bottle-around-ship' approach, namely to synthesize the nanocages of zeolite around the high purity cationic MPs. The selected guest molecules have excellent solubility in aluminosilicate gel. In a typical synthesis, 240 mg of $MTMAnPCl_5$ was added into an aluminosilicate gel, freshly prepared by mixing silicate and aluminate solutions containing 4.6 g of silica, 6.2 g of NaOH, 3.2 g of $NaAlO_2$ and 80 ml of H_2O. The gel was then crystallized at 95 ± 2 °C under static and autogeneous conditions in a stainless steel bomb (250 ml) for 48 h. After cooling to room temp., a solid product was recovered by filtration. The complexes adsorbed on the exterior surfaces were removed by a thorough extraction with distilled water, methanol, pyridine (2%)–methanol, and methanol again, respectively. The removed complexes can be fully recovered for the next round of synthesis. The crystals were then dried at 60 °C for 24 h. Thermogravimetry (TG) of the composite indicates that 1.51 mass% is attributable to the confined guest, corresponding to *ca.* one MP complex for every forty supercages or a supercage occupancy of 2.5%.

The loading concentration of $MTMAnP^{4+}$ is adjustable by controlling its concentration in the aluminosilicate gel before crystallization. The largest loading of *ca.* 5 mass% of the guest molecule can be achieved if 800 mg of $MTMAnPCl_5$ is added to *ca.* 94 g of aluminosilicate gel. We speculate that the main driving force for the very successful nanoinclusion of $MTMAnP^{4+}$ cations in the zeolitic supercages in such a readily controllable manner is the electrostatic interaction between the anionic aluminosilicate species and the cationic peripheral substituents on the porphyrin macrocycle. The excellent aqueous solubility of the cationic MP may contribute to the enhanced loading concentration in the zeolite, but this factor alone does not guarantee successful encapsulation. This assertion is supported by the following experimental facts: (*a*) in addition to $MTMAnP^{4+}$, we have also successfully encapsulated other metalloporphyrins with cationic peripheral substituents into zeolitic cages such as metallo–tetrakis(*N*-methyl-4-pyridyl)porphyrins (M = transition metal ion); (*b*) metalloporphyrins with anionic peripheral substituents, such as metallo–tetra(4-sulfonatophenyl)porphyrin ($MTPPS^{4-}$), could not be entrapped into the supercages of zeolite by this method; and (*c*) metalloporphyrins with neutral peripheral substituents, such as metallo–tetraphenylporphyrin (MTPP), could only be incorporated into the zeolite in trace amounts independent of the initial concentration of the porphyrin in the gel. On the other hand, it is believed that the first step in the construction of the zeolitic framework is the formation of anionic aluminosilicate species.

X-Ray powder diffraction (XRD) patterns of the unloaded zeolite and zeolite entrapped $FeTMAnP^{4+}$ and $MnTMAnP^{4+}$ are in excellent agreement with the calculated simulation of the XRD pattern for faujasite zeolite.[10] The excellent signal to noise ratio in the XRD indicates that our synthesized faujasite crystals are of high quality. X-Ray induced fluorescence (XIF) analysis indicates that all the samples have a Si/Al ratio of *ca.* 1.6. This suggests that the framework around the guest molecule $MTMAnP^{4+}$ is faujasite-Y (denoted MTMAnP@NaY) (M = Fe^{III}, Mn^{III} *etc.*). The encapsulation of the cationic MP inside the zeolite nanopores is also supported by TG, UV–VIS DRS, surface area measurements, and resonance microRaman spectroscopy (μRR, *vide infra*). This observation suggests that the occluded $MTMAnP^{4+}$ cations fit well into the supercages of faujasite-Y. In view of the 13 Å diameter of supercage of faujasite, *ca.* 18 Å $MTMAnP^{4+}$ cation [across two opposite trimethylanilinium (TMAn) substituents assuming a planar macrocycle] must distort itself somewhat in order to fit into a supercage. The most plausible distortion is that each of the four peripheral TMAn groups swings toward one of the four channel windows (*ca.* 7 Å in diameter) tetrahedrally located in a supercage, leading to an overall ruffling of the macrocycle, a distortion commonly observed in the X-ray structures of similar MPs.[11]

Resonance Raman techniques are very powerful in the study of hemeproteins and zeolite confined molecules.[12,13] Here, we applied μRR to study the synthesized zeolite–porphyrin composites. Laser excitation at 632.8 nm, in close resonance with the Q_0 absorption band of $MTMAnPCl_5$, was used. Fig. 1 shows the μRR spectra of $MnTMAnPCl_5$ and its faujasite-Y confined composite MnTMAnP@NaY. The normal modes of $MnTMAnPCl_5$ and other similar compounds have been thoroughly studied and assigned.[13] Fig. 1 clearly shows that the basic RR features of $MnTMAnPCl_5$ are all retained in the spectrum of MnTMAnP@NaY, indicating that neither decom-

Table 1 Catalytic oxidation of cyclohexene with *t*-BHP over MnTMANP@NaY

No	Catalyst	Product distribution (%)				t^a/h	Conv. (%)	TOF^b/h^{-1}

^{a} Reaction time. ^{b} Based on the efficiency of the inserted 'oxygen' into substrate. ^{c} 30 mg of pyridine was added into the reaction mixture (see text).

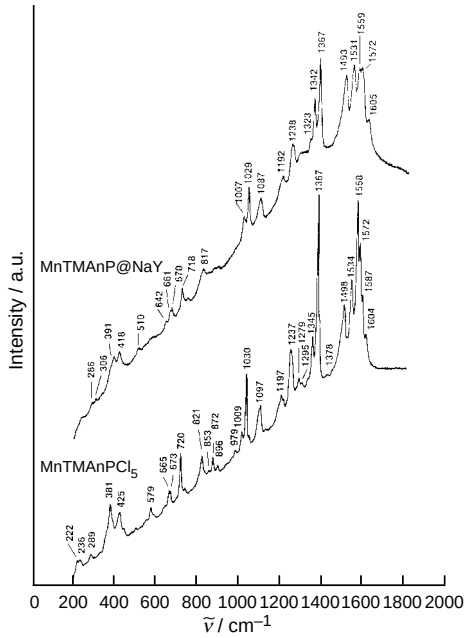

Fig. 1 Resonance microRaman spectra of $MnTMAnPCl_5$ (blank) and MnTMAnP@NaY; 632.8 nm excitation

position nor dimerization occurred during the process of hydrothermal crystallization. It is noticeable that (*a*) several structure sensitive bands located in the region 1300–1600 cm^{-1}, corresponding to the vibrations of $\nu(C_\alpha–N)$, $\nu(C_\alpha–C_\beta)$, $\nu(C_\beta–C_\beta)$, and $\nu(C_\alpha–C_m)$ of the MP macrocycle,[11–13] display some changes in their relative intensity but their frequencies remain more or less the same as that in the spectrum of $MnTMAnPCl_5$; (*b*) the anilinium distortion modes located at 810–900 cm^{-1} become broader and weaker in the spectrum of entrapped MP; and (*c*) the frequency of the Mn–N stretching mode at *ca.* 400 cm^{-1} shifted markedly by *ca.* 10 cm^{-1}. All these changes of vibrational signatures of the entrapped MP indicate that the entrapped complex is indeed distorted in the cavity of faujasite-Y.

The catalytic oxidation of cyclohexene over zeolite confined metalloporphyrins (MnAnP@NaY) with *tert*-butyl hydroperoxide (*t*-BHP) was performed in a glass tube with a stopper in a standard manner. At 50 °C, using a ratio of 1 : 1.5 for cyclohexene to *t*-BHP, and a mole ratio of 12 000 : 1000 : 1 for solvent : reactant : catalyst, we obtained a 28.6% conversion of cyclohexene with an average of 6.1 h^{-1} turnover frequency (TOF) in 48 h when MnTMAnP@NaY was used as the catalyst. Of particular interest is that the catalytic activity of MnTMAnP-@NaY is enhanced *ca.* fivefold in the presence of pyridine in the first 24 h (Table 1, entries 1 and 3). Everything else being the same as above, a blank experiment using H_2TMPyP@NaY gave a conversion of 3.5%, much lower than that of 24.5% for MnTMAnP@NaY (entries 3 and 5). This shows clearly that the encapsulated MP is indeed involved in the oxidation process. Longer reaction time leads to > 90% conversion of cyclohexene and gives adipic acid as the main product. To the best of our knowledge, this is the highest catalytic activity ever achieved in cyclohexene oxidation using a zeolite confined transition metallocomplex as catalyst. No significant loss of activity was detected in the reaction process. The mixture of the final products is colourless and no leaching of MPs into the reaction solution was detected according to atomic absorption spectroscopy. The catalytic activity of our catalyst was completely recovered by filtration of the reaction solution and washing of the catalyst with acetone at room temperature.

In conclusion, we have developed a novel, efficient and quantitative method to synthesize high purity metallo–tetrakis(*N*,*N*,*N*-trimethylanilinium) porphyrin encapsulated in the supercages of faujasite-Y. This method introduced an electrostatic interaction between the host (zeolite) and the guest (cationic MPs) in a 'built-bottle-around-ship' approach. The loading of the guest molecules can be adjusted easily by controlling the initial concentration of cationic MPs in aluminosilicate gel. In our preliminary study of the catalytic oxidation of cyclohexene by *t*-BHP, MnTMAnP@NaY gives very high activity and epoxidation selectivity. Its activity was enhanced *ca.* fivefold when pyridine was added to the reaction mixture.

This project was supported by the Research Grant Council (HK) and Hong Kong University of Science and Technology.

Novel nanostructures of gold–polypyrrole composites

S. Tamil Selvan*

Organic Chemistry III/Macromolecular Chemistry, University of Ulm, D-89069 Ulm, Germany

Different novel nanostructures of gold–polypyrrole composites are observed by the transmission electron microscopy, for the first time, with the advent of block copolymer micelles.
