Usually, DNA cleavage occurs selectively at guanine (G) residues, but without differentiation among the various G sites.[4] Specific G residues can be recognised utilizing more complex conjugates. A [60]fullerene derivative, conjugated with 14 deoxynucleotides, was synthesised and found to possess high affinity for both single and double stranded DNA.[74] The observed increased reactivity at specific G sites was tentatively attributed to the action of singlet oxygen. A similar study by Rubin, Foote and collaborators was also reported.[75] A comparison between two identical deoxyoligonucleotide residues linked to [60]fullerene and eosin, respectively, showed a clear difference in that the latter was much less selective, cleaving a number of different G sites. The fullerene derivative gave a marked preference for the cleavage of a specific G site, namely that closest to the fullerene spheroid. The authors concluded that the cleavage cannot be attributed to the activity of singlet oxygen, an easily diffusing species whose action should be wider, but most probably is to be ascribed to a direct electron-transfer between guanosine and excited fullerene.

A direct consequence of DNA cleavage is the observed cytotoxicity of fullerene derivatives. *In vitro* tests performed on tumoral HeLa S3 cells using compound **13** confirmed that cytotoxic activity is present only in the case of irradiation.[4]

Another case of antitumoral activity was observed by Tabata *et al*.[23] Local irradiation of mice affected by fibrosarcoma and treated with a functionalised [60]fullerene derivative gave not only reduction of the tumor mass but also tumor necrosis without skin damage. It was noted that [60]fullerene accumulates in tumoral tissues not for a specific tropism, but, essentially, because of the excellent vascular permeability and the relatively immature lymphatic system of the tumoral tissues.[23]

It has also been shown that [60]fullerene deactivated enveloped viruses (Togaviridae and Rhabdoviridae) owing to the production of singlet oxygen. The deactivation was oxygen-dependent and the efficacy was maintained even in the presence of proteins.[76]

Enzymatic inhibition and anti-HIV activity

Fullerene derivatives (**13** and **14**) exhibited inhibition of cysteine (papain and cathepsin) and serine (trypsin, plasmin, trombine) proteinases.[4,9] The mechanism of action is not yet well understood, but the hydrophobicity and the electrophilicity of the fullerene spheroid seem to be responsible for inhibition.

The active site of the HIV-1 Protease (HIVP) is a quasi-spherical hydrophobic cavity, whose diameter is about 10 Å. On its surface, two amino acid residues, aspartate 25 and aspartate 125, catalyse the hydrolysis of the substrate. On the basis of molecular modeling, Friedman *et al*. were the first to recognise that the [60]fullerene spheroid can be almost perfectly accommodated inside the hydrophobic site.[5] If the interactions are sufficiently strong, inhibition of the catalytic activity of HIVP is to be expected. *In vitro* studies, performed using a 'first generation' water soluble fullerene derivative (**2**), confirmed that inhibition of acutely and cronically affected peripheral blood mononuclear cells (PBMC) indeed occurred with an EC_{50} of 7 μM.[6,77] In addition, no cytotoxic effect was recorded on non-infected PBMC. Although HIVP inhibitors currently considered for therapy are active at nanomolar or even subnanomolar concentrations, the potential use of fullerene derivatives in this field should not be disregarded, because the recent advancements in the functionalisation chemistry of fullerenes can produce novel interesting candidates. For instance, derivatisation of the fullerene at specific positions with groups that may give electrostatic interactions with Asp 25 and 125 should increase the binding constant by up to three orders of magnitude.[5] A guideline for the preparation of more active fullerene derivatives was suggested based on an increase of desolvation of the hydrophobic cavity of the enzyme and the formation of stronger hydrophobic interactions. Inside the cavity, in fact, two symmetric hydrophobic channels are not occupied by **2** because of steric hindrance. The incorporation of appropriate apolar groups on the fullerene derivative might lead to occupancy of those channels with an increase of binding constants. Calculations carried out on derivatives **16** and **17** confirmed this hypothesis, with a binding constant for **16** about fifty times higher than for **2**.[78]

Other fullerene derivatives that have been solubilised and tested as HIVP inhibitors include **15**, **14** and water soluble peptide **3**.[53] Compound **15** showed an EC_{50} of 2.5 μM without any toxicity,[79] whereas the more active derivative **14** displayed a K_i value of 0.32 μM.[9]

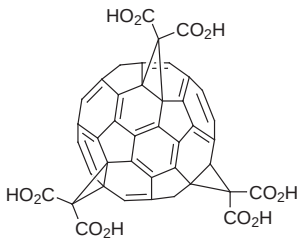
An extensive study of anti-HIVP activity was performed using a variety of functionalised [60]fullerene derivatives. For three of these compounds, an EC_{50} in the range of 0. 9–2.9 μM was observed.[80]

Neuroprotective properties

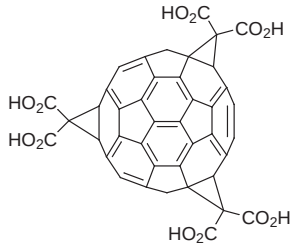
Many neurodegenerative diseases originate from excess production of superoxide and nitric oxide radicals, whose origin may be due to overexcitation of glutamic acid receptors. It has been shown that compounds that act as radical sponges reduce, though not completely, neuronal death. [60]Fullerene, owing to its antioxidant properties and high reactivity toward free radicals, shows promising behavior in this field.[81] Two derivatives of trisaddition of malonic units to [60]fullerene, **18** and **19**,[82] are highly soluble in water and are excellent radical scavengers. *In vitro* experiments using cultures of neocortical cells showed a dose-dependent decrease of neuronal death, with

derivative **18** being more active than **19**.[83] Compound **18** increases also the lifetime of cells deprived of oxygen and glucose, without antagonism between **18** and NMDA (*N*-methyl-D-aspartate) receptors. Daily administration of **18** (15 mg kg^{-1}) to G93A SOD1 G_1 mice, used as models of amyotrophic lateral sclerosis, led to an increase of lifetime of about ten days with respect to control animals.[83]

Superoxide radical quenching was also observed in a bis-malonic acid derivative of [60]fullerene.[84]



18



19

Antiapoptotic activity

Serum depletion induces apoptosis associated with an increase of production of free radicals. The same isomers **18** and **19** have been shown to possess antiapoptotic activity. Apoptosis due to amyloyl peptide $A\beta_{1\text{-}42}$ was also inhibited by the same fullerene derivatives.[83] In a strictly connected work, the effects of trisadducts **18** and **19** on apoptosis induced by ceramide were evaluated. In this case isomer **19** is more active.[85]

A study carried out again utilizing derivatives **18** and **19** among other antioxidant agents showed that only the fullerene derivatives inhibit apoptosis of human hepatoma Hep3B cells, induced by transforming growth factor β (TGF-β).[86] The mechanism of action is supposed to be indirect because all other actions induced by TGF-β remain unaltered.

Antibacterial activity

In preliminary tests, water soluble fullerene derivative **4** was found to be active against a variety of microorganisms. Different species of bacteria and different fungal strains were killed in a slightly modified agar diffusion test: two strains, clinical isolates CA1 and Z11, of *Candida albicans*, a fastidious pathogenic eukariote; strain ATCC 6633 of *Bacillus subtilis*, a spore-forming, Gram positive bacterium; strain AB1153 of *Escherichia coli*, a Gram negative enteric bacterium; a clinical isolate, strain 261/6 of *Mycobacterium avium*, an acid fast, emerging pathogen resistant to most antimicrobial drugs. In the latter case, 70% inhibition was observed with a concentration of 26 μg ml^{-1}, whereas complete inhibition was achieved with concentrations 10 times higher.[24]

Miscellaneous uses

Broncoconstriction induced by exsanguination in guinea-pigs was limited by fullerenols, without significant alteration of respiratory functions.[87] Fullerenols could be used in the perfusion of kidneys before transplantation, as they decreased infiltration of inflammatory cells and inhibited tubular swelling and necrosis.[88] Fullerenols were also investigated as anti-proliferative agents in arteriosclerosis, because they inhibited transduction signals.[89]

Macroscopic quantities of endohedral metallofullerenes containing Gd, Ho, Y, Ce were synthesised, in which, upon neutron activation, the inside metals become radioactive, but are still isolated from the outside world by the presence of the carbon cage. As a matter of fact, this novel class of fullerenes might be useful in nuclear medicine, with potential use as radiotracers or radiopharmaceuticals.[90]

Fullerenes can also be used for analytical purposes. Modelling studies have shown that it is possible to form a salt in which the anion is a DNA phosphate and the cation is a pyrrolidinium salt of [60]fullerene. This hybrid nanoarchitecture would be easily detected with transmission electron microscopy, since the fullerene moiety confers the necessary electron density to these complexes.[91]

Conclusions and perspectives

The impact of fullerenes and fullerene derivatives in biology will be substantiated only if their toxicity is found to be sufficiently low. Preliminary toxicological studies have shown that these novel compounds are not carcinogenic when applied on skin. Although [60]fullerene is incorporated inside cells, it does not seem to affect the proliferation rate of keratinocytes, fibroblasts or leucocytes. Studies of acute, subacute and chronic toxicity at reasonable dosing have so far given negative results. However, dose-dependent toxicity has been observed, whereas administration to pregnant mice gave rise to genetic malformations. Different toxicity levels have also been found for different derivatives.

On the other hand, once the problems of solubilisation and clustering are completely solved, and their toxicity fully tested, the fullerenes will probably find extended use in biology. In fact, owing to their ability of cleaving DNA, these carbon spheres appear promising candidates for use in diagnostics, photodynamic therapy, and as useful photoprobes in the study of genetic transcription. As radical scavengers, the fullerenes are to be considered neuroprotectors in neurodegenerative diseases and in the inhibition of apoptosis. The peculiar geometrical shape makes [60]fullerene an ideal inhibitor of HIV protease, especially if additional stabilising interactions, besides hydrophobic affinity, can be obtained.[5]

Maybe the phrase 'medicinal chemistry' used for the title of this Article is a bit premature for this young field. But we hope that this work will attract organic and medicinal chemists, as well as pharmacologists and biologists. Only their combined efforts will help create the new field of the medicinal chemistry of fullerenes.

First example of opening and hydrogenation of 2,3-dihydrobenzo[*b*]thiophene to 2-ethylthiophenol assisted by a soluble metal complex

Claudio Bianchini,* Andrea Meli, Werner Oberhauser and Francesco Vizza

Istituto per lo Studio della Stereochimica ed Energetica dei Composti di Coordinazione, ISSECC-CNR, 50132 Firenze, Italy. E-mail: bianchin@fi.cnr.it

Received (in Cambridge, UK) 4th February 1999, Accepted 8th March 1999

Displacement of THF by dihydrobenzo[*b*]thiophene (DHBT) in [(triphos)Ir(H)$_2$(THF)]BPh$_4$ yields the η^1-*S*-DHBT adduct [(triphos)Ir(H)$_2$(η^1-DHBT)]BPh$_4$ which reacts in THF at room temperature with KOBu^t to give the neutral 2-vinylthiophenolate derivative (triphos)Ir(H)$_2${η^1-*o*-S(C$_6$H$_4$)CH=CH$_2$} *via* C$_2$–S bond cleavage; the latter compound is hydrogenated under mild conditions (2 bar H$_2$, 80 °C) to the 2-ethylthiophenolate derivative (triphos)-Ir(H)$_2${*o*-S(C$_6$H$_4$)Et} and under harsh conditions (30 bar H$_2$, 160 °C) to free 2-ethylthiophenol and (triphos)IrH$_3$.

The hydrodesulfurization (HDS) of thiophenic molecules occurring in the course of the hydrotreating catalysis of petroleum feedstocks is a complex process whose mechanism is still quite speculative.[1] As is outlined in Scheme 1 for the model substrate benzo[*b*]thiophene (BT), the hydrogenation of thiophenes over heterogeneous catalysts may lead to the formation of hydrocarbons and H_2S *via* two principal mechanisms.

Kinetic studies at elevated H_2 pressures suggest that the reactions go through hydrogenated intermediates (Scheme 1, path a), especially with higher analogs of thiophene such as BT in which the electron density is less localized on the sulfur atom.[2] The prehydrogenation path has never been confirmed by the homogeneous modeling studies which are all consistent with the alternative hydrogenolysis route (Scheme 1, path b).[3]

The present paper constitutes a preliminary account of the first example of opening and hydrogenation of 2,3-dihydrobenzo[*b*]thiophene (DHBT) to 2-ethylthiophenol (ETP) assisted by a transition metal complex. C–S bond cleavage of tetrahydrothiophene (THT) has previously been found to occur on polymetallic species.[4,5] Notably, the C–S bond cleavage of THT in $Cl_3W(\mu\text{-THT})WCl_3$ was obtained by reaction with a nucleophile that remains attached to the C_2 carbon atom.[4]

The iridium complex [(triphos)Ir(H)$_2$(η^1-DHBT)]BPh$_4$ **2** has been synthesized by adding a slight excess of DHBT to a tetrahydrofuran (THF) solution of [(triphos)Ir(H)$_2$(THF)]BPh$_4$[6] **1** [triphos = MeC(CH$_2$PPh$_2$)$_3$].† At room temperature, the reaction is quantitative even in THF as DHBT is a much better ligand than THF. Very few η^1-DHBT complexes have been reported,[7] but their existence has frequently been claimed in homogeneous and heterogeneous catalytic hydrogenation cycles of BT.[1,2,3,7]

As shown in Scheme 2, the reaction of the η^1-S-DHBT adduct **2** in THF with an equivalent amount of KOBu^t at room temperature,[8] followed by treatment with a high pressure of H_2 at 160 °C yields the hydrogenolysis product ETP and converts all the iridium precursor to the trihydride (triphos)IrH$_3$ **3**.[9] The overall process was studied *in situ* by multinuclear NMR spectroscopy in THF-d$_8$ using a sapphire high-pressure NMR tube, initially under nitrogen and then under H_2.[3] The strong base has been found to transform the DHBT ligand in **2** into a 2-vinylthiophenolate group yielding the neutral complex (triphos)Ir(H)$_2${η^1-*o*-S(C$_6$H$_4$)CH=CH$_2$} **4**.† The tube was then pressurized with 2 bar of H_2. No reaction occurred at room temperature. Only at 80 °C, the ^{1}H NMR spectrum showed the signals of the vinyl hydrogens of **4** to decrease in intensity and the ^{31}P NMR spectrum showed the appearance of a new AM_2 spin system. Within 15 h at 80 °C, all **4** converted to the known 2-ethylthiophenolate derivative (triphos)Ir(H)$_2${*o*-S(C$_6$H$_4$)Et} **5**.[10] Both **4** and **5** were isolated in the solid state by simply scaling up the NMR conditions. The hydrogen pressure in the tube was increased to 30 bar and the temperature was raised to 160 °C to observe a further chemical transformation: free 2-ethylthiophenol was formed quantitatively (^{1}H NMR, GCMS)[3d] together with the known trihydride (triphos)IrH$_3$ **3**.[9]

The opening of the DHBT ligand by KOBu^t most likely occurs *via* an E_2 elimination as shown in Scheme 3(a).[11] Indeed, an E_2 elimination mechanism has been proposed to account for the hydrodesulfurization (HDS) of DHBT over the surface of real heterogeneous catalysts [Scheme 3(b)].[12]

The Ministero dell'Ambiente of Italy (contract PR1/C) is gratefully acknowledged for financial support.

Nanosized zeolite crystals—convenient control of crystal size distribution by confined space synthesis

Claus Madsen[a,b] and Claus J. H. Jacobsen*[b]

Received (in Cambridge, UK) 15th February 1999, Accepted 2nd March 1999

Confined space synthesis is a novel method in zeolite synthesis, which allows preparation of nanosized ZSM-5 crystals with a controlled crystal size distribution.

Traditional methods of zeolite synthesis typically involve crystallization from a gel or a clear solution under hydrothermal conditions.[1] Much work has been focused on preparation of large zeolite crystals suitable, *e.g.* for single crystal X-ray diffraction studies. Key factors in controlling the crystal size and morphology have been systematically studied.[2] In shape-selective zeolite catalysis improved selectivity is often found with larger crystals.[3] However, in many other catalytic reactions it appears favourable to use very small zeolite crystals since mass transfer limitations are of less importance. Furthermore, deactivation has in several cases been shown to proceed slower on small crystals due to their larger specific external area.[4] In the literature, some synthesis methods yielding small zeolite crystals have been reported.[5] However, none of these methods allow an easy control of the crystal size and the resulting crystal size distributions appear to be very dependent on the exact experimental conditions. Furthermore, isolation of the small zeolite crystals is not simple due to the colloidal properties of these materials. Therefore, we have attempted a novel method for the preparation of nanosized zeolite crystals. In contrast to other methods, it is possible to tailor-make zeolite crystal size distribution and recovery of the zeolite is simple. The synthesis method involves crystallization of the zeolite within the mesopore system of an inert support material. By use of carbon as the inert support material easy recovery of the zeolite is possible by controlled pyrolysis of the carbon.

Two different carbon black materials, Black Pearls 700 (BP700) and Black Pearls 2000 (BP2000) (supplied by Carbot Corp.) were used in the experiments. The carbon black was dried at 150 °C for 24 h prior to use. All other reagents, tetraethylorthosilicate (TEOS, 98 wt%), tetrapropylammonium hydroxide (TPAOH, 40 wt%), ethanol (EtOH, 99 wt%), sodium hydroxide (NaOH, 97 wt%), aluminium isopropoxide [Al(OPr^i)$_3$, 98 wt%] and distilled water, were used as received.

In a typical recipe, 20 g of carbon black was impregnated to incipient wetness with a clear solution of TPAOH, H_2O, NaOH, EtOH and optionally aluminium isopropoxide. Ethanol was evaporated at room-temperature and subsequently the carbon black was impregnated with TEOS yielding *ca.* 10 and 38 wt% SiO_2 in BP700 and BP2000, respectively. The composition of the synthesis gel (molar basis) was

$$x\ Al_2O_3 : 9\ TPA_2O : 0.15\ Na_2O : 50\ SiO_2 : 390\ H_2O : 200\ EtOH,$$
$$0 \leqslant x \leqslant \tfrac{1}{2}$$

After ageing for 3 h at room temperature the impregnated carbon black was transferred to a porcelain cup, introduced into a stainless steel autoclave containing enough water to produce saturated steam and heated in an oven at 180 °C for 48 h.

After cooling the autoclave to room temperature the product was suspended in water, filtered by suction, resuspended in water, and filtered again. This was repeated four times and finally the product was washed with 99% ethanol and dried at 110 °C for 3 h. The carbon black was removed by pyrolysis in a muffle furnace at 550 °C for 6 h. Three different zeolite samples were prepared using the reported method.

X-Ray powder diagrams were recorded by slow scanning on a Phillips vertical goniometer equipped with a θ-compensating divergence slit and a diffracted beam graphite monochromator utilizing Cu-Kα radiation. Crystal sizes were calculated from the two most intense diffraction peaks (2θ at 23.1 and 23.72° corresponding to the 501 and 151 reflections, respectively) by XRPD line broadening using the Scherrer equation. Transmission electron micrographs were obtained with a Philips EM430 (300 kV).

The ZSM-5 crystals are grown inside the pore structure of the carbon black support materials. Table 1 gives details of the pore structure of the two carbon blacks obtained from N_2 adsorption and desorption isotherms. The significantly larger pore volume of BP2000 compared with BP700 accounts for the higher SiO_2 content after impregnation. It is also seen that the average pore radius of the BP2000 is about twice as large as for BP700.

Fig. 1 illustrates the X-ray powder diagrams obtained after the zeolite synthesis and pyrolysis of the carbon black. It is seen that the sample contains highly crystalline ZSM-5 with an apparently small crystal size as judged from the diffraction line width. Table 2 gives details of crystal sizes determined using the Scherrer equation where crystal sizes of the ZSM-5 prior to and after removal of the carbon support by pyrolysis are provided. Apparently, some growth results from the removal of the carbon black, but this is within within the experimental uncertainty of the crystal size determination using the Scherrer equation.

The transmission electron micrograph of SZ† shown in Fig. 2 provides independent support for the formation of very small

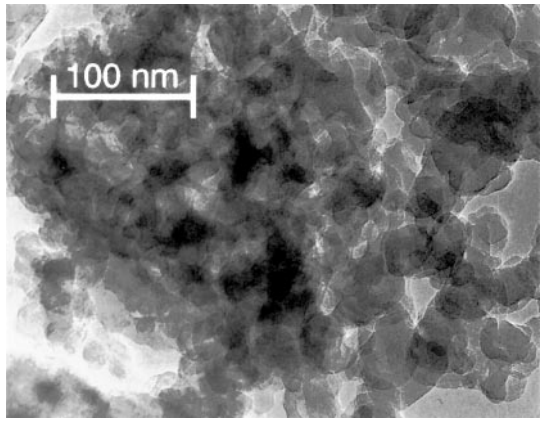

Fig. 2 Transmission electron micrograph of ZSM-5 crystals (SZ†) prepared by confined space synthesis.

zeolite crystals. From this figure it can also be seen that most crystals are in the range 8–30 nm and very little intergrowth is observed.

Sample SZ† has a total BET surface area of 412.4 $m^2\ g^{-1}$ with an external surface area of 185.0 $m^2\ g^{-1}$. The t-plot method (de Boer) of the SZ material revealed a bimodal pore size distribution. In addition to the pore volume inside the ZSM-5 crystals the material had an additional pore volume of 0.58 ml g^{-1} with an average pore radius of 15 nm. This mesopore system resulting from the packing of nanosized ZSM-5 crystals seems to provide excellent possibilities for diffusion of reactants and products, which is of significant importance in heterogeneous catalysis.

The ZSM-5 crystals synthesised using the confined space synthesis have sizes as low as 8 nm. To our knowledge this is the smallest crystal size of highly crystalline ZSM-5 reported so far. Jacobs *et al*.[8] reported the existence of X-ray amorphous ZSM-5, which contained crystals of <8 nm size in an amorphous matrix of silica. Camblor *et al*.[9] were able to synthesize zeolite beta with a crystal size as low as 10 nm determined by TEM. However, the crystal sizes depended strongly on the content of aluminium in the synthesis gel.

By use of the confined space synthesis it is possible to tailor-make zeolites with a given crystal size distribution and also to prepare very small zeolite crystals. Currently, studies are in progress to determine the minimum size of crystalline ZSM-5 crystals that can be prepared by the reported method. Furthermore, other zeolites and zeotypes are being prepared by confined space synthesis.

We would like to thank Iver Schmidt for helpful discussions and Poul Lenvig for obtaining the transmission electron micrographs.

Anion pore structure through packing of molecular triangles

Ralf-Dieter Schnebeck, Eva Freisinger and Bernhard Lippert*

Fachbereich Chemie, Universität Dortmund, D-44221 Dortmund, Germany. E-mail: lippert@pop.uni-dortmund.de

Received (in Basel, Switzerland) 4th February 1999, Accepted 24th February 1999

A molecular triangle, generated from [(en)Pd(2,2′-bpz-N^1,$N^{1'}$)]$^{2+}$ and *trans*-$(NH_3)_2Pt^{II}$, encapsulates a ClO_4^- and aggregates in the solid state in such a way as to form long channels containing a string of anions.

The thermodynamically preferred product of the reaction between $[(en)Pd(H_2O)_2]^{2+}$ and 2,2′-bipyrazine (2,2′-bpz) is the mononuclear chelate [(en)Pd(2,2′-bpz-N^1,$N^{1'}$)]$^{2+}$ **1**.[1] By contrast, $[(en)Pt(H_2O)_2]^{2+}$ forms the kinetic product, triangular [{(en)Pt(2,2′-bpz-N^4,$N^{4'}$)}$_3$]$^{6+}$ **2** (Scheme 1).[1] Both **1** and **2** bind additional metal electrophiles *via* the still available N^4 (**1**) and N^1 (**2**) sites, respectively, to give hexanuclear molecular cups [after reacting **1** with additional $(en)Pd^{II}$ or **2** with $(en)M^{II}$ (M = Pt or Pd)[2,3]], or a flat triangle upon reaction of **1** with *trans*-$(NH_3)_2Pt^{II}$, as demonstrated here.

The compound isolated† and structurally characterised‡ proved to be [{(en)Pd}$_{2.5}$(2,2′-bpz)$_3$]{$(NH_3)_2$Pt}$_3$]$(ClO_4)_6$-$(NO_3)_5$·5H_2O **3** (Fig. 1), a molecular triangle of C_2 symmetry with one of the Pd corners [enPd(2)] having a 50% occupancy only.

Both the Pd_3 and Pt_3 triangles are close to equilateral, with Pd–Pd distances of 13.5 Å and Pt–Pt distances of 7.6–7.7 Å. As a consequence of the incompatibility of the bite angle at Pd (*ca.* 80°) and the 60° angles of the triangle, the Pt atoms are not centred on the sides of Pd_3 but lie outside the sides of these by *ca.* 0.5 Å, with Pt–Pd–Pt angles of *ca.* 69°. Triangle **3** differs from **2** in that the bpz ligands in **3** are, unlike in **2**, essentially coplanar with all metal ions. A single ClO_4^- anion is encapsulated in the centre of the cation, bearing some similarity with the situation in a recently described Co_8 compound.[4] Pairs of triangles approach each other *via* the half-occupied Pd(2) positions [ideally separated by 4.363(8) Å] and are propeller-twisted by *ca.* 50°.

The packing of the cations of **3** is such that they are approximately parallel oriented, yet by 180° rotation the triangles form a stair, which is inclined by *ca.* 60° and has treads separated by *ca.* 6.1 Å (Fig. 2). In the interior of this stair, a channel is formed (Fig. 3), which hosts one ClO_4^- per subunit. This situation is in a way reminiscent of self-assembling ion channels that generate pore structures,[5] however, there are also differences: the interaction between the layered triangles is

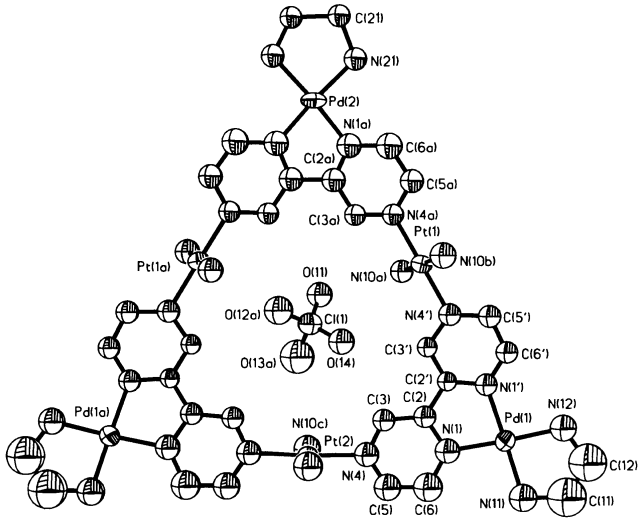

Fig. 1 Crystal structure of cation **3** with encapsulated ClO_4^-. Note that (en)Pd(2) has a 50% occupancy only. Relevant distances (Å) and angles (°): Pt(1)–N(4′) 1.97(2), Pt(1)–N(10b) 1.98(2), Pt(1)–N(10a) 2.00(2), Pt(1)–N(4a) 2.00(2), Pt(2)–N(10c) 2.02(2), Pt(2)–N(10c)#1 2.02(2), Pt(2)–N(4) 2.01(2), Pt(2)–N(4)#1 2.01(2), Pd(1)–N(1) 2.02(2), Pd(1)–N(1′) 2.03(2), Pd(2)–N(1a) 2.00(2), Pd(2)–N(1a)#1 2.00(2), N(10b)–Pt(1)–N(10a) 179.0(7), N(4′)–Pt(1)–N(4a) 178.7(6), N(10c)–Pt(2)–N(10c)#1 179.7(10), N(4)–Pt(2)–N(4)#1 177.1(11), N(1)–Pd(1)–N(1′) 80.5(7), N(1a)–Pd(2)–N(1a)#1 80.4(11).

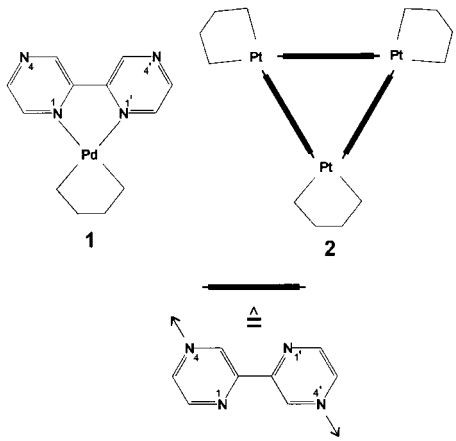
neither *via* direct stacking, the NH_3 ligands of the three Pt^{II} ions are roughly perpendicular to the triangle plane, thereby preventing stacking of the bpz rings, nor by direct H bonding between the layers, as seen in nanotubes generated by cyclic peptides, for example.[6] Rather NO_3^- anions and water molecules, sandwiched between adjacent triangles, act as a 'glue' between the positively charged triangles, reinforced by ClO_4^- anions at the periphery of the triangles, all of which are involved in multiple H bonding interactions with NH_3 and en ligands.

The inner cavity within **3**, across diagonal C(3)H proton sites, is 6.24–6.42 Å wide. The ClO_4^- is located in such a



Scheme 1

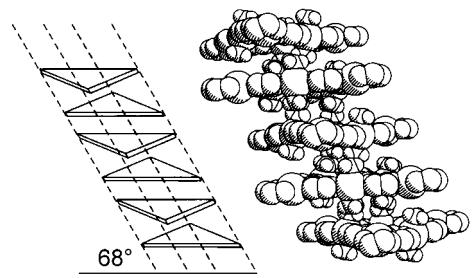


Fig. 2 Schematic representation and space filling of the layered triangles forming a 'stair'. Two NO_3^- anions and two H_2O molecules are layered between adjacent triangles and form multiple H bonds between each other and the Pt-NH_3 groups (not shown). At the periphery ClO_4^- anions interact *via* H bonds with NH_2 groups of Pd(en) entities as well as Pt–NH_3 groups (not shown), thereby generating a very compact structure that resembles a pipe rather than a stair.

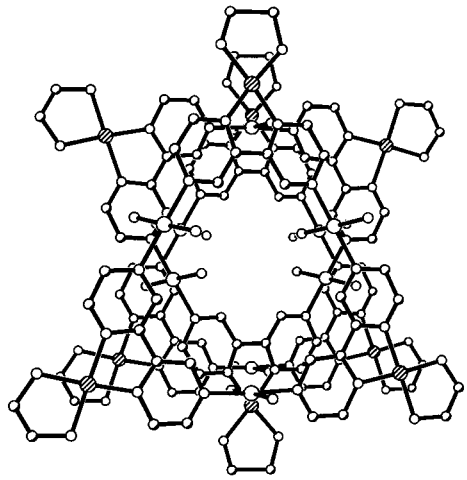

Fig. 3 View along the central channel formed by cations of **3** with ClO_4^- anions omitted. The molecular triangles are not perpendicular to the view but rather inclined by *ca*. 68°.

manner that Cl resides in the plane of the triangle, whereas the oxygen atoms lie pairwise above and below this plane and are clearly disordered. It appears that the oxygen atoms can weakly H bond to both the heterocyclic C(3)H protons [distances: $O_3ClO\cdots C(3)$ 3.02(4)–3.40(4) Å; angles: $O_3Cl–O\cdots H(3)$ 100.8(17)–128.4(19)°] and to the NH_3 protons of the Pt ions (distances: $O_3ClO\cdots H$ 2.6(1)–2.8(1) Å; angles: $O_3Cl–O\cdots H$ 168.8(21)–168.81(21)°], hence simultaneously to both hydrophobic and hydrophilic areas within the channel.

The ^1H NMR spectrum of **3** in D_2O, (pH* = 3.3) confirms the presence of more than a single species in solution. Spectra recorded within 2 h after dissolving crystals of **3** are dominated by three intense resonances in the aromatic region, namely at δ 10.62 (s, H3,H3′), 9.70 (s, w = 14 Hz, H5,H5′), and 8.99 (d, ^3J 3.7 Hz, H6,H6′) which are assigned to the Pd_3Pt_3 species. In addition, there is a large number (> 15) of minor resonances. For the Pd_2Pt_3 species nine sets of aromatic proton resonances are to be expected, each having an intensity of one third of the intensity of the resonances of Pd_3Pt_3. The ^{195}Pt NMR spectrum confirms also the presence of at least two species with PtN_4 coordination (δ −2449 and −2500, *ca*. 3 : 1). The larger number of observable resonances and also the time-dependent changes in the spectrum (resonances due to Pd_3Pt_3 decrease with time) strongly point toward the existence of more species than just Pd_3Pt_3 and Pd_2Pt_3 in solution, possibly $PdPt_3$ is present. There are two ways to simplify the spectrum: first, addition of $[(en)Pd(D_2O)_2]^{2+}$ to a solution of **3** leads to an increase in the intensities of the three resonances assigned to Pd_3Pt_3 with some of the minor resonances, however, still detectable. The relative intensities of the ^{195}Pt NMR resonances are now *ca*. 10 : 1. Second, addition of excess NaCl to an aqueous solution of **3** causes rapid precipitation of yellow $(en)PdCl_2$ and formation of a new major species with three intense sets of resonances at δ 10.20 (s), 9.28 (d, ^3J 3.2 Hz) and 9.18 (br, d), with some additional minor resonances still observable. The major component is tentatively assigned as a Pt_3 species. We have been as yet unable to isolate this compound and to prepare it directly from 2,2′-bpz and *trans*-$(NH_3)_2Pt^{II}$.

In summary, compound **3** is unique in that it (i) combines structural features of 'molecular triangles' which commonly have metal entities either at the corners[1,9] or at the centres of the sides[10] and in addition (ii) crystallises in a fashion that is reminiscent of an anion channel comprised of identical subunits.

This work was supported by the Fonds der Chemischen Industrie.

A novel screening method for combinatorial chemistry for low affinity interactions

Naoki Sugimoto,* Hideki Kazuta, Jin Zou and Daisuke Miyoshi

Department of Chemistry, Faculty of Science, Konan University, 8-9-1 Okamoto, Higashinada-ku, Kobe 658-8501, Japan. E-mail: sugimoto@konan-u.ac.jp

Received (in Cambridge, UK) 20th November 1998, Accepted 4th March 1999

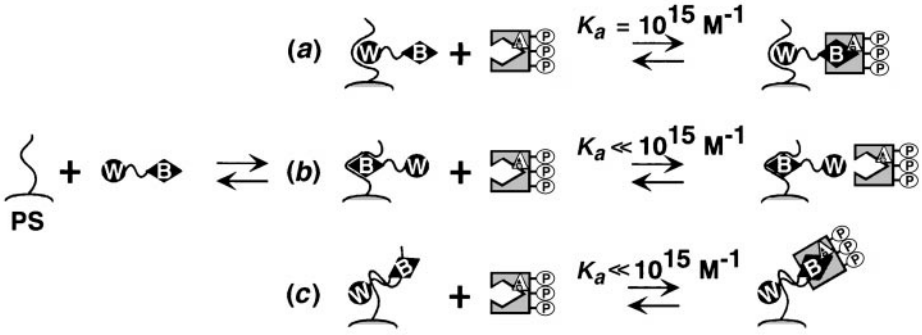
A novel screening method for combinatorial chemistry was developed by utilizing the high binding affinity of the avidin–biotin complex (K_a = 10^{15} M^{-1}), making possible the efficient detection of low affinity interactions between tryptophan and pentapeptides.

Combinatorial chemistry has attracted enormous attention because it can greatly facilitate the drug discovery process.[1,2] It is also an extremely powerful tool in the biotechnology of peptides[3,4] and nucleic acids. In nucleic acid research, this technology (*in vitro* selection) has been employed for finding small ribozymes and recently its reaction mechanism has been elucidated.[5,6] In the field of peptides, several screening methods have been employed using labeled target compounds such as colored dyes,[7] fluorescent dyes,[8] magnetic beads[9] and radioisotopes such as [γ-^{32}P].[10] However, many difficulties have been encountered in the selection of short peptides for a small target with low affinity. In particular, the above screening methods were not successful in extracting tryptophan (Trp) selective peptides from the pentapeptide library.

In this study, we developed a novel screening method utilizing the formation of the avidin–biotin complex, which has a large binding constant of 10^{15} M^{-1}. This screening method made possible the effective detection of low affinity interactions between tryptophan and pentapeptides. Trp was chosen as a target molecule since it is known to play a key role in biological processes, such as the functional peptide that recognizes porphyrin *via* a sandwiching interaction[11] and the *Trp* repressor in which binding Trp enhances DNA affinity as an allosteric effector.[12] Therefore, we have attempted the selection of short peptides that would recognize Trp from a combinatorial library to establish a general model system of low affinity interactions.

The random synthetic pentapeptide library was constructed by the 'split synthesis approach' as previously described.[1,2]† Nineteen natural L-amino acids were used, excluding cysteine to avoid intramolecular cyclization or intermolecular disulfide formation. The library theoretically contains about 2.5 million pentapeptide sequences. Biotin and a hydrophilic linker {biotinyl-ε-aminocaproic acid *N*-hydroxysuccinimide and [2-(2-*tert*-butoxycarbonylaminoethoxy)ethoxy]acetic acid (Boc-AEEA-OH)} were covalently attached to Trp. The introduction of a hydrophilic linker was performed to avoid aggregation of target molecules and such a linker is also effective in raising the activity of the avidin–biotin interaction because its affinity increases with linker length.‡ Moreover, the interactions of individual compounds on both sides of the linker can be treated independently by its introduction.

Our new approach is a novel screening method utilizing the avidin–biotin interaction in two steps. The first step of this screening method is mixing of the pentapeptide library and biotinylated Trp with the hydrophilic linker (BTHL) in an empty column, by gently shaking for 16 h and then washing the library beads.§ There may exist three binding modes between the pentapeptide library and BTHL during this step. These are between the pentapeptide library and the Trp site (W) [Scheme 1(*a*)], the biotin site (B) [Scheme 1(*b*)], and the linker site (L) [Scheme 1(*c*)] of BTHL, respectively. It is also possible that there may be no interaction between pentapeptide library and BTHL. The only desirable binding mode is between the pentapeptide library and W; the other cases must be eliminated. The second step is the addition of fluorescein labeled streptoavidin (FLS) to the library containing BTHL. The solution was gently shaken for 30 min and the library beads were washed with buffer solution to eliminate nonspecific interactions.¶ The concentration of added FLS was evaluated according to the amount of interacting target molecule, whose concentration was determined by UV absorbance of tryptophan in aqueous solution, using an extinction coefficient of 5500 cm^{-1} M^{-1}. Only the desirable interaction in the first step (formation of the W–library complex) will be able to form the avidin–biotin complex preferentially upon FLS addition. The other undesirable interactions, the B–library or L–library complexes, were eliminated since the binding constant of avidin–biotin complex formation (10^{15} M^{-1}) is much larger than those with other sites of BTHL, including W. Furthermore, the activity of the avidin–biotin interaction increases with the linker length of biotin. By regulating the concentration of added FLS, the case of no interaction in the first step can also be eliminated.



Scheme 1 Schematic drawing of the new selection method using the avidin–biotin interaction: Trp, biotin, avidin (streptoavidin), and the probe (fluorescein) are designated by W, B, A and P, respectively. Schemes (*a*), (*b*) and (*c*) show interactions of the pentapeptide library with W, B and L (linker), respectively. The pentapeptide library theoretically contains 2 480 000 pentapeptide sequences. PS designates PEG-PS resin which contains poly(ethylene glycol)-grafted polystyrene.

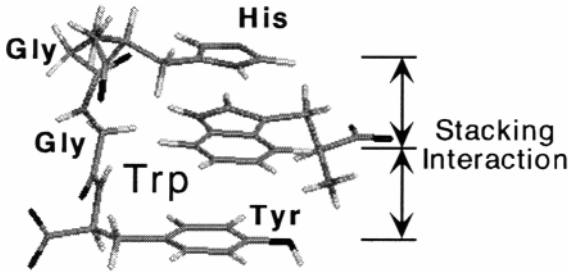


Fig. 1 Structure of the (His-Gly-Gly-Tyr) + Trp complex drawn *via* molecular modeling calculation using QUANTA 96/CHARMm 23.2. The energy of the complex was minimized by the Newton–Raphson method with an adopted basis set. Dynamic simulation of the energy-minimized structure was performed to obtain various conformations as initial coordinates for the calculation. The VERLET algorithm with a time step of 1 fs was used in the dynamic simulation. The system was heated from 0 to 1000 K for the conformational search in the MD simulation. All calculations were performed by running IRIX 5.3 on a Silicon Graphics Indigo2 workstation.

The library beads were subsequently poured carefully onto a plate. By exposing the pentapeptide library beads on the plate to UV light, only the beads which contain the avidin–biotin complex between FLS and TLB are able to generate fluorescence light. As a result, fluorescent beads (positive for the target molecule) were observed in the 2.5 million pentapeptide library. The fluorescent beads which contain the pentapeptide selective for Trp (target molecule) were physically removed from the library and subsequently microsequenced by protein sequencer. A total of ten pentapeptide sequences from the library were determined.

A consensus sequence of the selected peptides is Tyr/His-Gly-Gly-Tyr or His-Pro-Gly-His. The binding behavior of tryptophan with the peptide (Glu-His-Gly-Gly-Tyr) immobilized on the resin was analysed by a Langmuir isotherm. The binding constant was approximately 1.2×10^3 M^{-1} at room temperature. The consensus sequence has aromatic residues (His and Tyr) at the *i* and *i* + 3 positions, and a glycine residue at the *i* + 2 position in the motif can induce a β-turn structure.[13,14] When the motif forms the β-turn structure, two aromatic residues may orient in the same side to produce the sandwiching interaction with Trp between the two aromatic residues possible. To estimate the detailed interaction of the motif peptide (His-Gly-Gly-Tyr) with Trp, energy minimization calculations were performed using QUANTA 96/CHARMm 23.2. The result shows that the motif peptide may form a β-turn structure and the (His-Gly-Gly-Tyr) + Trp complex forms a stacking interaction between the two aromatic residues (His and Tyr) and Trp *via* the sandwiching interaction shown in Fig. 1. It was suggested that the motif peptide specifically recognizes Trp *via* the β-turn motif.

We thank Professor Fu-Ming Chen, Tennessee State University, for a critical reading of the manuscript and helpful comments. This work was supported in part by Grants-in-Aid from the Ministry of Education, Science Sports and Culture, Japan, and a Grant from the 'Research for the Future' Program of the Japan Society for the Promotion of Science.

Notes and references

† A split synthesis approach was carried out with standard peptide synthesis methods on solid phase with fluorenylmethoxycarbonyl (Fmoc) chemistry. Coupling was initiated by the addition of four-fold molar excess concentration of HATU and an eight-fold molar excess concentration of Pr^i_2NEt. The coupling reaction was driven to completion with a four-fold molar excess of Fmoc amino acids and monitored by the standard ninhydrin test. Occasionally, double coupling was needed. The resin was first divided into 19 aliquots of poly(ethylene glycol)-grafted polystyrene (PEG-PS) × HCl which has a hydrophilic linker (PEG) and was chosen as a solid phase support.

‡ Biotinyl-ε-aminocaproic acid *N*-hydroxysuccinimide and Boc-AEEA-OH were purchased from Calbiochem-Novabiochem Corporation and PerSeptive Biosystems, respectively. The coupling was carried out with *tert*-butoxycarbonyl (Boc) solid phase synthesis methods.

§ All experiments were conducted in buffer including 100 mM NaCl, 10 mM Na_2HPO_4 and 1 mM Na_2EDTA (pH 7.0) at room temperature in a same empty column.

¶ The composition of fluorescein labeled streptoavidin is F/S (molar) = 4.6 where F and S indicate fluorescein and streptoavidin, respectively. It was purchased from Vector Laboratories.

Received (in Basel, Switzerland) 15th December 1998, Accepted 4th March 1999

The first gold complex, $[Se(AuPPh_3)_4](CF_3SO_3)_2$, with a μ_4-selenido ligand has been prepared; the crystal structure reveals a square pyramidal geometry with short gold–gold interactions.

The chemistry of complexes in which a main-group element is surrounded by several (phosphino)gold fragments was pioneered by Schmidbaur *et al.*,[1] who prepared fascinating hypercoordinated species of the type $[C(AuPR_3)_5]^+$, $[C(AuPR_3)_6]^{2+}$, $[N(AuPR_3)_5]^{2+}$, $[P(AuPR_3)_5]^{2+}$ and $[P(AuPR_3)_6]^{2+}$.[2–6] Many of these heteroatom-centered complexes are electron-deficient, and gold–gold interactions provide a significant contribution to their stability. Such interactions between formally closed-shell (d^{10}) metal centres have been termed 'aurophilic attractions'[1] and their origin is still a matter of controversy;[7] Pyykkö *et al.* have presented theoretical evidence that these attractions are mainly correlation effects, strengthened by relativistic effects.[8–10]

Although the chemistry of the carbon-, nitrogen-, phosphorus- or arsenic-centered complexes was developed rapidly, the corresponding chalcogen-centered derivatives are still being studied. Recently the μ_4-sulfido[11] or μ_4-oxido[12] gold species were reported and shown to possess square pyramidal (apical sulfur) or tetrahedral geometry (central oxygen), respectively. Our previous work in the area of sulfur-centered complexes involved examples of gold(I) or gold(III) derivatives[13–17] with a μ_3- or μ_4-sulfur ligand. Selenium-centered compounds are limited to the species $[Se(AuPPh_3)_2]$ and $[Se(AuPPh_3)_3]PF_6$;[18–20] here we report the synthesis and structural characterisation of the first μ_4-selenido gold derivative.

The reaction of $[Se(AuPPh_3)_2]$ with 2 equiv. of $[Au(CF_3SO_3)(PPh_3)]$ in dichloromethane affords a solution from which the colourless air- and moisture-stable solid $[Se(AuPPh_3)_4](CF_3SO_3)_2$ **1** can be isolated.† Complex **1** behaves as a 1:2 electrolyte in acetone solution. The $^{31}P\{^1H\}$ NMR spectrum shows only one signal corresponding to a unique phosphorus environment, shifted to high field in comparison with the starting material (δ 4) or the trinuclear compound $[Se(AuPPh_3)_3](CF_3SO_3)$ (δ 1.3). In the liquid secondary positive-ion mass spectrum the monocationic peak $[Se(AuPPh_3)_4]^+$ appears at *m/z* 1915 (35%).

Crystals of **1** suitable for X-ray structure analysis were obtained from dichloromethane–heptane.‡ Compound **1** crystallises with two molecules of dichloromethane and is isostructural with the analogous sulfido compound $[S(AuPPh_3)_4](SO_3F_3)_2$[11] and its cation (Fig. 1) is also similar to that of $[As(AuPPh_3)_4]BF_4$.[21] It possesses a tetragonal pyramidal framework, with the selenium atom occupying the apical position. The Au atoms are not exactly coplanar, but arranged in a flattened butterfly form with a hinge angle of 27° about the Au1···Au2 diagonal; their deviations from the best Au_4 plane are ±0.27 Å, and that of the Se atom is 1.4 Å. The $SeAu_4$ core should be regarded as electron-deficient, considering the selenido ligand to serve as a six-electron donor. Therefore it still possesses a lone pair of electrons in the apical position, which means that further coordination of gold around the selenium atom is conceivable.

Complex **1** may be compared with the above-mentioned trinuclear selenide or the tetranuclear sulfide derivatives; observed differences are essentially as expected. The Au–Se–Au angles, which range from 70.45(4) to 72.59(4)° in **1**, are smaller than those in $[Se(AuPPh_3)_3]PF_6$ [77.7(1)–80.0(1)°][19] or the corresponding S–Au–S angles in the isostructural $[S(AuPPh_3)_4](CF_3SO_3)_2$ [73.5(2)–75.6(2)°]. This difference may be associated with the presence of more diffuse 3p orbitals in the selenium derivative, allowing smaller angles, and/or a

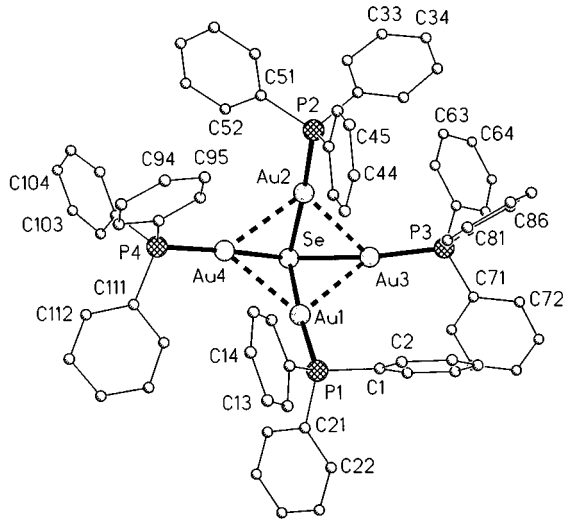

Fig. 1 The structure of the cation of complex **1** in the crystal. Hydrogen atoms have been omitted for clarity; radii are arbitrary.

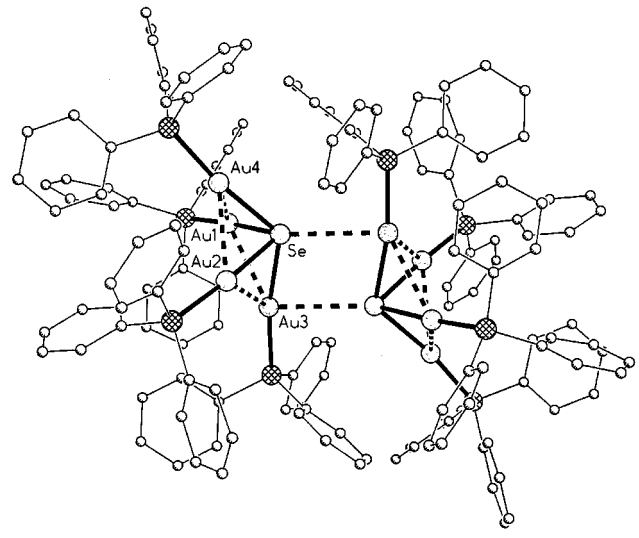

Fig. 2 Association of two cations of **1** in the crystal. The $CF_3SO_3^-$ ions and the CH_2Cl_2 molecules have been omitted.

greater electron repulsion of the lone pair of electrons. The Au–Se distances, 2.4654(13)–2.5347(14) Å, in **1** are longer than in $[Se(AuPPh_3)_3]^+$ [2.425(2)–2.451(2) Å] or (than Au–S) in $[S(AuPPh_3)_4]^{2+}$ [2.362(5)–2.429(5) Å]. Gold–gold distances between adjacent gold atoms in the pyramid base are short, 2.8959(8) to 2.9605(8) Å [the diagonal distances are 3.6 Å for Au(1)···Au(2) and 4.5 Å for Au(3)···Au(4)]. These contacts are longer than those found in the tetranuclear sulfide derivative, 2.883(2)–2.938(2) Å. The Au–P bond lengths in **1** [2.265(3)–2.282(3) Å] lie in the expected range for two-coordinate gold(I) complexes and are very similar to those found in $[Se(AuPPh_3)_3]PF_6$ [2.257(6)–2.283(5) Å].

The cations of **1** are paired across symmetry centres to form loose dimers (Fig. 2), the shorter intermolecular distances being Se···Au3′ 3.248 Å and Au3···Au3′ 4.45 Å.

Conformationally flexible calix[4]arene chromoionophores: optical transduction of soft metal ion complexation by cation–π interactions

Niels J. van der Veen, Richard J. M. Egberink, Johan F. J. Engbersen, Frank J. C. M. van Veggel and David N. Reinhoudt*

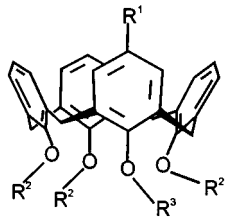
Laboratory of Supramolecular Chemistry and Technology and MESA Research Institute, Faculty of Chemical Technology, University of Twente, 7500 AE, Enschede, The Netherlands. E-mail: d.n.reinhoudt@ct.utwente.nl

Received (in Liverpool, UK) 4th January 1999, Accepted 8th March 1999

Soft metal ions like Pb^{2+}, Cd^{2+}, and Cu^{2+} form partial-cone complexes with a flexible calix[4]arene chromoionophore in which cation–π interactions cause a bathochromic shift of the UV/Vis absorption maximum.

Calix[4]arenes have been extensively used as selective ligands for a wide range of metal ions in selective transport,[1] potentiometric[2] and optical[3] sensors. Recently, they are also being used as building blocks for chromoionophores.[4] The conformation of the calix[4]arene moiety determines the size and geometry of the ligand and therefore has a significant influence on the selectivity.[5] In the partial-cone and 1,3-alternate conformations cation–π interactions between metal ion and the ligand's benzene rings play an important role.[6] Usually, the conformation of these ligands is *fixed* in the synthesis.[7] However, Bartsch *et al.* have shown that conformationally *flexible* calix[4]arene ionophores are selective for heavy metal ions like Pb^{2+} and Hg^{2+}.[8] We are currently studying the application of chromoionophores in integrated optical waveguide sensors selective for heavy metal ions. For this application it is desirable that the chromoionophores have a high selectivity for heavy metal ions over alkali metal ions and that complexation leads to a bathochromic shift of the absorption maximum. The calix[4]arene-based chromoionophores with substantial changes in their absorption spectra published thus far respond to alkali metal ions or Ca^{2+} and are based on the interaction of the complexed ion with a hard donor heteroatom of the chromophore.[9]

Here we report that conformationally flexible chromoionophore **1** is highly selective for Pb^{2+} over Na^+ and shows a



1 $R^1 = N_2C_6H_4NO_2$, $R^2 = OCH_2C(O)N(CH_3)_2$, $R^3 = OCH_3$
2 $R^1 = N_2C_6H_4NO_2$, $R^2 = OCH_2C(O)N(CH_3)_2$, $R^3 = OC_3H_7$
3 $R^1 = H$, $R^2 = OCH_2C(O)N(CH_3)_2$, $R^3 = OH$
4 $R^1 = H$, $R^2 = OCH_2C(O)N(CH_3)_2$, $R^3 = OCH_3$

bathochromic shift of λ_{max} upon complexation of *soft* metal ions. The bathochromic shift does *not* occur when alkali metal ions are complexed. Complexation of either Pb^{2+} or Na^+ by the conformationally fixed analogue **2** leads to a *hypsochromic* shift. Chromoionophores **1** and **2** were synthesized† from calix[4]arene **3**[10] by diazonium coupling with *p*-nitroaniline, followed by alkylation at the lower rim with MeI or PrI, respectively. Reference compound **4** was prepared in two steps from the parent calix[4]arene, *viz.* monomethylation at the lower rim followed by introduction of the (*N*,*N*-dimethylaminocarbonyl)methoxy functionalities on the three remaining hydroxy groups.

It is well known that a methoxy substituent at the lower rim is not sufficiently bulky to fix the conformation of chromoionophore **1**, which can attain both the cone and the partial-cone conformation.[11] When a metal ion is complexed, the ligand will occupy the conformation optimal for the complexation of that particular metal ion. The UV/Vis absorption spectra in Fig. 1 show that complexation of Pb^{2+} ions by either **1** or **2** leads to shifts of λ_{max} in opposite directions. This is caused by the different conformations of the two complexes, involving two principally different modes of metal–chromophore interaction.

Compound **1** binds Pb^{2+} in the partial-cone conformation because in this geometry the metal ion interacts favorably with the π-surface of the chromophore,[12] leading to a 14 nm bathochromic shift of λ_{max} (Fig. 1). A Pb^{2+} ion complexed in chromoionophore **2**, fixed in the cone conformation, interacts with the methoxy oxygen atom lone-pair rather than with the chromophores' π-surface, resulting in a 22 nm hypsochromic shift. Na^+ prefers hard donor atoms, *i.e.* oxygen, and is therefore complexed by chromoionophore **1** in the cone conformation, causing a 4 nm hypsochromic shift of λ_{max}. This shift is small compared to the 22 nm hypsochromic shift of **2** upon Na^+ complexation, because **1** binds Na^+ only weakly.

^{13}C NMR spectroscopy proved that ionophore **4** complexes Na^+ and Pb^{2+} in different conformations.‡ These studies could

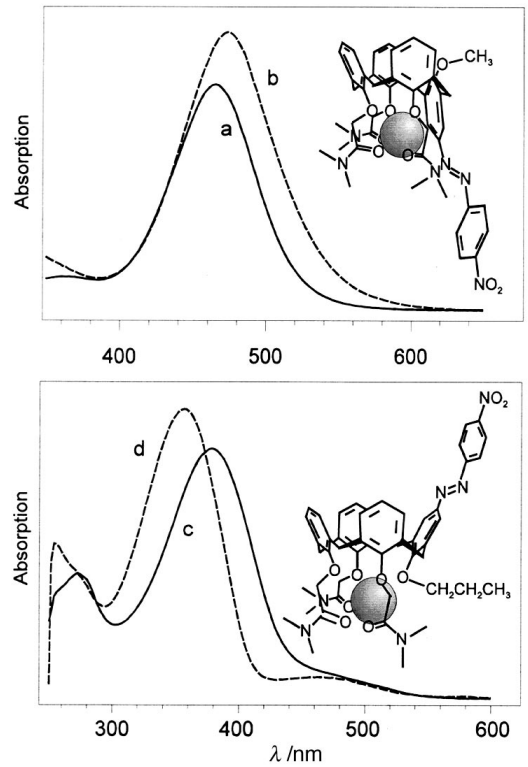


Fig. 1 UV/Vis absorption spectra of (a) **1**, (b) **1**·Pb^{2+}, (c) **2** and (d) **2**·Pb in CH_2Cl_2, with the proposed structures of the complexes.

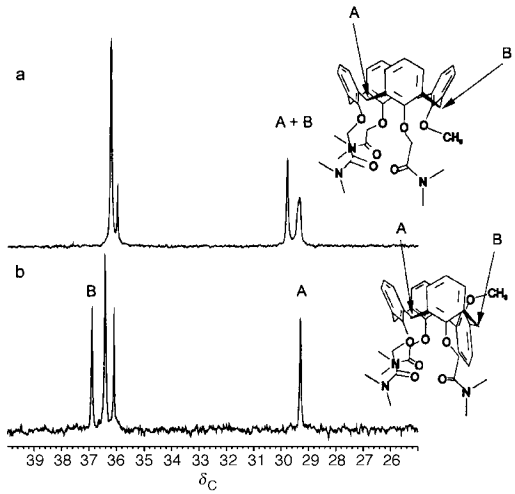

Fig. 2 ^{13}C NMR spectra (δ 40–25) of the complexes (a) **4**·Na^+ and (b) **4**·Pb^{2+}.

not be performed with **1** because of the low solubilities of its complexes. In the absence of metal ions, the NMR spectra of ionophore **4** show broad signals because of the equilibrium between cone and partial-cone conformation. When metal perchlorate salts are added, the signals sharpen into one set that can be attributed to a single conformation. For Na^+ this is the cone conformation, which can be determined from the ^{13}C NMR spectrum of the complex shown in Fig. 2: the methylene carbon atoms bridging the aromatic rings appear at δ 29.30 and 29.11, typical resonances for cone calix[4]arenes.[13] The Pb^{2+} complex has the partial-cone conformation, which can be determined from the two different chemical shifts of the bridging methylene carbon atoms at δ 36.90 and 29.31. The aromatic region of the ^{1}H NMR spectrum is consistent with a quasi-C_{4v} symmetry axis of the Na^+ complex, since all protons *para* with respect to the lower rim oxygen coincide, as do all *meta* protons. The more complex spectrum of the Pb^{2+} complex is typical for the partial-cone conformation.

The results of solution experiments in MeCN (Table 1) show that chromoionophore **1** exhibits bathochromic shifts upon complexation of different metal ions. Soft metal ions with high charges cause the largest shifts, with a maximum shift of 20 nm for Cu^{2+}. Under the same conditions, the alkali metal ions cause no, and alkaline-earth metal ions small, optical responses.

The complexation behavior of **1** shows that conformational flexibility can bias the selectivity of calix[4]arene chromoionophores towards soft heavy metal ions. Addition of 10 equiv. of $Pb(ClO_4)_2$ to a solution of **1** and a *thousand-fold excess* of $NaClO_4$ in MeCN leads to complete formation of the Pb^{2+} complex. This selectivity for Pb^{2+} over Na^+ should find its origin in the conformational flexibility, since ligating amides are generally used in Na^+-selective receptors. In fixed cone ligands, soft donating thioamide groups are necessary to obtain selectivity for Pb^{2+}.[14]

In conclusion, we have found a new type of optical transduction of soft metal ion complexation *via* a bathochromic shift of the absorption maximum due to side-on metal–chromophore interactions, unique to the partial-cone conformation of chromoionophore **1**. The selectivity for Pb^{2+} over Na^+ is due to the different preferential conformations of complexation by **1**. Our current research is aimed at improving the selectivity and sensitivity of flexible chromoionophores.

We thank the Technology Foundation (STW), the Technical Science Branch of the Netherlands Organization for Scientific Research (NWO), for financial support.

Table 1 Optical response of **1** (10^{-5} M) to different metal perchlorate salts (10^{-4} M) in MeCN. The samples were prepared by mixing equal volumes of stock solutions of **1** and the metal perchlorate salts. Reported values signify bathochromic shifts

Metal ion	$\Delta\lambda_{max}$/nm	Metal ion	$\Delta\lambda_{max}$/nm	Metal ion	$\Delta\lambda_{max}$/nm
Li^+	0	Ca^{2+}	8	Cd^{2+}	12
Na^+	0	Sr^{2+}	6	Pb^{2+}	14
Cs^+	0	Ba^{2+}	4	Ga^{3+}	2
Ag^+	0	Cu^{2+}	20	Ce^{3+}	16

The synthesis of α-amino-γ-substituted adipic acids: stereoelectronic effects during the 1,4-addition of organocuprates to methyl *N-tert*-butoxy-6-oxo-1,2,3,6-tetrahydropyridine-2-carboxylate

Mireille Muller, Angèle Schoenfelder, Bruno Didier, André Mann* and Camille-Georges Wermuth

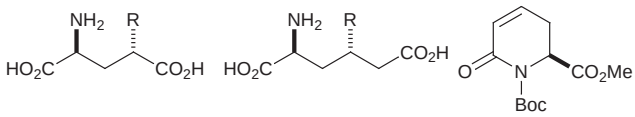
Received (in Liverpool, UK) 26th November 1998, Accepted 4th March 1999

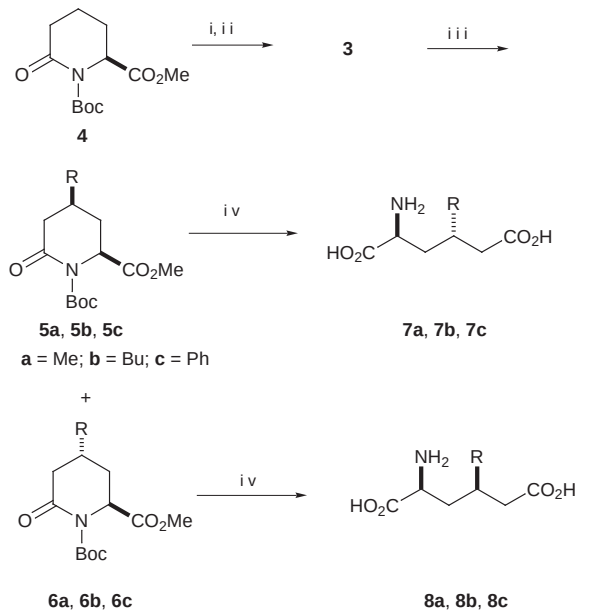
The α,β-unsaturated lactam 3 was submitted to 1,4-addition of organocuprate reagents R_2CuLiI_2 (R = Me, Bu or Ph) to provide the 4-substituted compounds 5a–c, 6a–c as a mixture of diastereomers; these intermediates were then transformed into the corresponding α-amino-γ-substituted adipic acids 7a–c, 8a–c.

The synthesis of modified and unnatural amino acids is a source of constant inspiration in organic chemistry.[1–3] In recent years glutamic acid, a major neurotransmitter in the mammalian brain, has received considerable attention from chemists involved in neurosciences.[4,5] During earlier studies on modified glutamates, we and others have found that the γ-substituted analogues of structure **1** are invaluable tools for the pharmacological exploration of excitatory amino acid receptors.[6,7] Interestingly it was found that the biological activity of such derivatives was largely confined to the 2*S*,4*S* diastereomers. For structure–activity studies devoted to this class of amino acids, we decided to synthesize compounds of type **2** in which the distal carboxylate is moved an additional methylene unit away from the α-amino acid group compared with **1**, generating γ-substituted α-amino adipic acids (Adi). As earlier observations have already demonstrated that Adi itself possesses good affinity for the glutamate receptors,[8] the introduction of different substituents on the Adi backbone may contribute to a better knowledge of steric demands at the receptor level.[9] Our goal was to employ an enantiospecific and diastereoselective synthesis which would provide analogues **2** in which the C-2 and C-4 substituents have the correct configuration for high biological activity. Since we have previously prepared modified glutamic acids using a conjugate addition of organocopper reagents,[10] we therefore proposed to submit compound **3** to a similar sequence, in the expectation that the presence of the C-2 carboxylate would provide facial selectivity.[11,12] We report herein our observations on the diastereoselectivity obtained in the 1,4-addition of organocuprate reagents to the α,β-unsaturated lactam **3**.



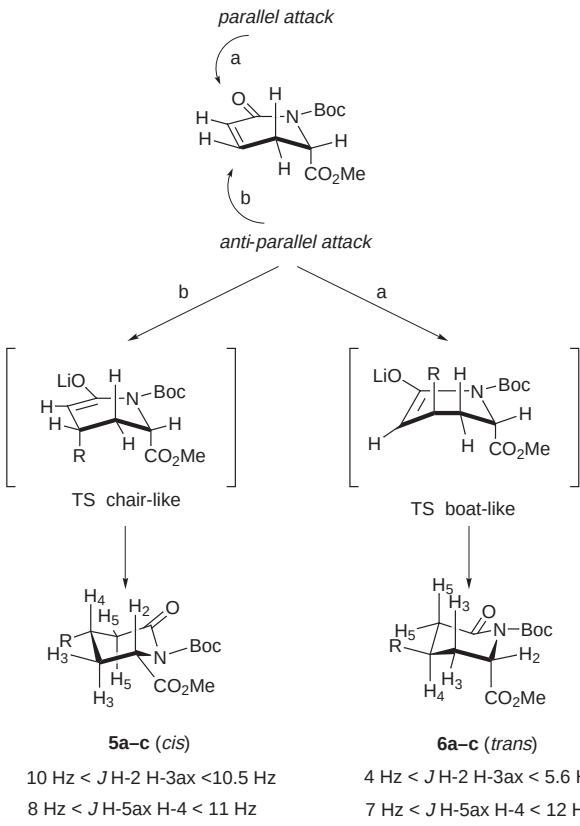
1 **2** **3**

The starting compound **3** was obtained from (*S*)-lysine in enantiomerically pure form *via* piperidone **4**, following literature reports.[13–15] The unsaturation was introduced by a sequence involving selenation and oxidative elimination, as decribed for the preparation of the corresponding benzyl ester (Scheme 1).[15] Since lactam **3** is potentially prone to nucleophilic attack, we were pleased to find that the reaction of this substrate in Et_2O with different organocuprates gave the expected adducts as mixtures of *cis/trans* diastereomers (**5a–c** and **6a–c**) in acceptable yields, and in moderate to good stereoselectivity.† Examination of the ^1H NMR (200 MHz) spectra of the crude mixtures revealed that each diastereomer has a well resolved signal (dd) between δ 4.5–4.8 for the hydrogen attached at C-2. Surprisingly, in analyzing these signals for the **5a**/**6a**, **5b**/**6b** and **5c**/**6c** mixtures, we observed that the intensity for the upfield signal (*trans* diastereomer) increases at the expense of the corresponding downfield one (*cis* diastereomer). These results indicate a change in the *cis* : *trans* ratio related to the structure of the transfered substituent. After purification, the pattern of the H-5ax proton was identified in each diastereomer as a doublet of doublets (B part of an ABX spin sytem) in which largest *J* value (around 17 Hz), corresponds to the geminal coupling H-5ax/H5eq. The smaller *J* value (around 11 Hz) arises from to the coupling between H-5ax and H-4, and these were of comparable value in all the compounds (**5a–c** and **6a–c**), consistent with an axial disposition of the proton at C-4. As a consequence the Me, Bu or Ph substituents attached at C-4 have an equatorial disposition in each diastereomer. For the protons attached at C-2 in **5a** and **6a** two sets of coupling constants were measured: J = 10 and 6 Hz, and J = 4 and 2 Hz, repectively. From these data it was clear that in the analogues **5a–c** the carboxylate adopts an equatorial disposition (large J values = axial orientation of the proton at C-2) whilst in contrast for derivatives **6a–c** the carboxylate has



Scheme 1 *Reagents and conditions*: i, LiHMDS (1.1 equiv.), PhSeCl (1. 2 equiv.), THF −78 °C, 2 h (78%); ii, MCPBA (2 equiv.), CH_2Cl_2, 25 °C, 12 h (72%); iii, for **5a**/**6a**: MeLi (2 equiv.), CuI (1 equiv.), Et_2O, −78 °C, 2 h, **5a** (68%) and **6a** (9%); for **5b**/**6b**: BuLi (2 equiv.), CuI (1 equiv.), −78 °C, 2 h , **5b** (35%) and **6b** (33%); for **5c**/**6c**: PhLi (2 equiv.), CuI (1 equiv.), Et_2O, −78 °C, 2 h , **6c** (48%); HCl in AcOH, reflux, 3 h (from 45 to 80%).

an axial orientation (small *J* values = equatorial orientation of the proton at C-2). These data are consistent with a chair conformation for all of the isolated compounds, in which the products **5a–c** have the substituents in a 1,3-*cis* arrangement, and **6a**–**c** in a 1,3-*trans* arrangement. In order to explain these findings, we performed calculations on lactam **3** (MOPAC out of SYBYL 6.3) which demonstrated that the conformer having the carboxylate at C-2 in an axial disposition is, by far, more stable (5 kcal mol^{-1}) than the corresponding equatorial conformer‡ (Scheme 1). This result is the obvious consequence of a strong $A^{1,3}$ strain between the carboxylate at C-2 and the Boc group on the nitrogen atom.[16] Based on these calculations and several literature reports on the stereoelectronic effects during conjugated addition in related α,β-unsaturated cyclohexanones or 2,3-dihydro-4-pyridones,[17,18] a strong axial bias was expected to operate during the addition of nucleophilic reagents to lactam **3**. Therefore one should observe the preferential formation of the *cis* adducts (**5a**–**c**) at the expense of the corresponding *trans* epimers (**6a**–**c**). Indeed for the smallest substituent (R = Me) an appreciable diastereoselectivity in favor of the *cis* adduct was observed (**5a** : **6a** = 5 : 1). However when the steric demand of the organocuprate was increased (R = Bu), the facial selectivity was lost (**5b** : **6b** = 1 : 1) or, for still bulkier groups (R = Ph) the facial steroselectivity was reversed, and the *trans* diastereomer was the only one detected (**5c** : **6c** = 1 : 30). Allinger has discussed a closely related example involving the 1,4-addition of Grignard reagents to 5-methylcyclohex-2-enone,[19] in which the importance of the conformation of the conjugated enolate (chair or boat) produced by parallel or anti-parallel attack was considered. As the carboxylate function in **3** is assumed to be axial, the major pathway for the reaction with Me_2CuLi_2I was *via* an anti-parallel attack to give the transient enolate of **5a.** This intermediate possesses a low energy chair-like conformation (TS chair), in spite of the 1,3-diaxial interaction between the carboxylate and the incoming methyl group. When the nucleophile is larger, such as in Bu_2CuLi_2I (**5b**/**6b**) or Ph_2CuLi_2I (**5c**/**6c**), the reaction pathway *via* parallel attack takes place preferentially due to a competing strong 1,3-diaxial interaction between the carboxylate and the bulky incoming nucleophile. This gives a transient, boat-like (TS boat) enolate, which collapses to the *trans* chair conformer. The final transformation of **5a**–**c** and **6a–c** into the desired substituted adipic acids was realized under hydrolytic conditions and the amino acids **7a,b** and **8a**–**c** were obtained as crystalline hydrochlorides.§



Scheme 2 Possible transition states and recorded values for coupling constants.

In conclusion, the diastereoselectivity observed for the conjugate addition of organocuprates to cyclic enamide **3** could be controlled by an appropriate choice of the transferable nucleophilic reagent. The significant $A^{1,3}$ strain inherent to the ring system and the size of the nucleophile are probably the key factors responsible for the diastereoselectivity observed in this conjugate addition reaction. Our findings demonstrate that α,β-unsaturated species **3** is an excellent substrate for the preparation of enantiomerically pure (2*S*,4*S*)- or (2*S*,4*R*)-2-amino-4-substituted adipic acids.

We thank Dr Jacques Royer (Gif sur Yvette, France) and Professor Maurizio Taddei (Sassari, Italy) for valuable discussions.

Magnesium fluoride as a catalytic support in hydrodechlorination of CCl_2F_2 (CFC-12)

A. Malinowski,[a] W. Juszczyk,[a] J. Pielaszek,[a] M. Bonarowska,[a] M. Wojciechowska[b] and Z. Karpiński*[a]

Received (in Liverpool, UK) 26th January 1999, Accepted 9th March 1999

Magnesium fluoride-supported palladium and ruthenium appear to be useful catalysts in the reaction of CCl_2F_2 (CFC-12) hydrodechlorination; after doping Pd/MgF_2 with gold the selectivity for CH_2F_2 increased from ~70 to almost 90%.

The need to replace environmentally detrimental chlorofluorocarbons (CFCs) by benign hydrochlorofluorocarbons (HCFCs) and hydrofluorocarbons (HFCs) has resulted in considerable interest in catalytic hydrodechlorination of CFCs.[1] It is obvious from the patent literature that there is much activity in the development of new catalysts capable of very selective chlorine removal from a CFC molecule, *i.e.* avoiding undesired hydrodefluorination. Although this can be achieved with the use of heterogeneous catalysts containing such transition metals as iridium, ruthenium and, especially, palladium,[2] nevertheless the formation of over-dehalogenated products still presents a major concern. The role of a support (active carbon[3] and AlF_3[4] are reported most often in the patent literature) appears important; however, for this class of reaction one must also consider modifying the catalyst by doping the active phase (preferably palladium) with other elements.[5,6]

This report presents preliminary results obtained for MgF_2-supported Pd and Ru catalysts. Several metal fluorides have exhibited interesting properties as carriers for palladium (AlF_3, ZrF_4, TiF_3[4,7,8]), but MgF_2 has not been tested yet. In addition, MgO, as a support in hydrodechlorination,[9] is not resistant to the highly corrosive conditions of this reaction which results from considerable evolution of HCl, which can transform the support into $MgCl_2$. Similarly, by analogy to the catalytic behaviour of alumina-supported catalysts,[7,8] due to inevitable (albeit undesired) formation of HF during CFCs hydrodehalogenation, MgO is (at least partly) transformed into magnesium fluoride, which when located at a metal/support interface might favorably modify the electronic state of the metal particles.[7,8] All these facts and speculations have encouraged us to investigate this area.

The MgF_2-supported Pd, Pd–Au, Ru and Ru–Au catalysts were prepared by impregnation of MgF_2 (obtained in the reaction of $MgCO_3$ with aqueous solution of HF[10]) with appropriate metal salts. X-Ray diffraction (XRD) examination of MgF_2 (BET surface area 43 $m^2\ g^{-1}$, Barrett–Joyner–Halenda average pore size 20 nm, micropore volume 0.22 $cm^3\ g^{-1}$) showed a rutile structure. The reaction of CF_2Cl_2 with dihydrogen was conducted in a glass flow system. The experimental procedure and reaction conditions have been reported elsewhere.[11] Turnover frequencies (TOFs) were calculated on the basis of metal loadings and dispersions (from chemisorption measurements) and are shown in Table 1.

Our results indicate that MgF_2-supported palladium-based catalysts exhibit interesting properties in CCl_2F_2 hydrodechlorination. The first positive point is that CHF_3 is not produced by these catalysts, as often happens on catalysts capable of Cl/F exchange. Secondly, the time-on-stream behaviour (Fig. 1) shows an initial increase in activity, which appears to be stable during the next 17 hours. Thirdly, the selectivity towards CH_2F_2 production is reasonably high (> 70%), resembling the catalytic behaviour of AlF_3-supported palladium catalysts.[7] It can be speculated as others[7,8] have done, that the Lewis acidity of MgF_2, as in the case of AlF_3, decreases electron density in neighbouring Pd sites. In effect, electron-deficient Pd species bind :CF_2 carbene radicals (commonly accepted intermediate species[2,7,8,12]) less strongly, so a hydrogenative desorption of these radicals distinctly prevails over

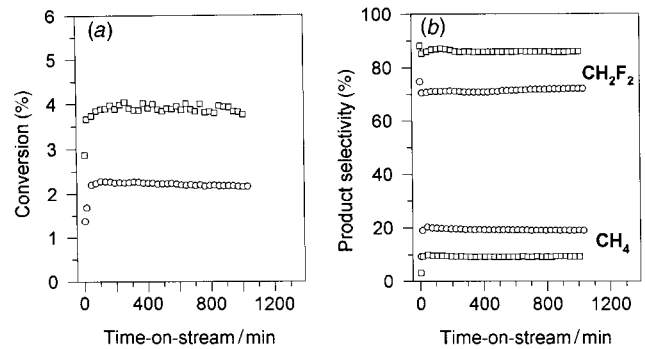

Fig. 1 Time-on-stream behaviour of 2 wt% Pd/MgF_2 (0.121 g, circles) and Pd–Au/MgF_2 (0.201 g, squares) catalysts in CCl_2F_2 hydrodechlorination. (*a*) Overall conversion, (*b*) selectivities to CH_4 and CH_2F_2.

Pd–Au/MgF_2[b]	9.3	86.0	0.4	3.8	0.1	—	0.0820	61.8 ± 1.0
Ru/MgF_2[b]	67.5	7.0	—	19.2	3.8	2.5	0.0053	60.3 ± 0.3
Ru–Au/MgF_2[b]	56.4	12.9	3.4	21.7	3.2	1.9	0.0160	54.1 ± 2.5

[a] Minor products (*e.g.* CH_3Cl, Σ% < 0.5%). [b] 2 wt% Pd/MgF_2 (metal dispersion, H/Pd = 0.02_3); 3.5 wt% $Pd_{0.7}Au_{0.3}/MgF_2$ (H/Pd = 0.02); 2.4 wt% Ru/MgF_2 (CO/Ru = 0.20); 2 wt% $Ru_{0.75}Au_{0.25}/MgF_2$ (CO/Ru = 0.03_2). Subscripts in chemical formulae denote atomic fractions.

hydrodefluorination. Interestingly enough, the selectivity for CH_2F_2 increases with Au doping: from ~72% for the Pd/MgF_2 to 86% for the $Pd–Au/MgF_2$ (Fig. 1 and Table 1).

As expected, preliminary XRD data manifest a substantial degree of Pd–Au mixing in the MgF_2-supported catalyst after reduction. Two Pd–Au solid solutions are present: $Pd_{0.81}Au_{0.19}$ and $Pd_{0.4}Au_{0.6}$ (indexes denote atomic fractions). This significant alloying concerns both reduced as well as spent $Pd–Au/MgF_2$ catalyst. XRD profiles obtained with used Pd–Au catalyst are somewhat complicated because large amounts of carbon (originating from CCl_2F_2) are incorporated into the Pd-based phase.[11,12] Since a Pd–C solution has a lattice parameter ($a_{PdC_{0.13}}$ = 0.399 nm[13,14]) larger than Pd (a_{Pd} = 0.3890 nm), it is difficult to assess whether an increase in the lattice parameter of Pd is due to Au (a_{Au} = 0.4078 nm) or C incorporation. In order to estimate to what extent Pd diffraction lines are affected by carbon dissolution and alloying with Au further studies are underway in our laboratory. This issue seems important, because, as is expected, a close contact between Pd and Au is essential for obtaining higher selectivity towards CH_2F_2. The Pd–Ag/graphite catalyst tested in CFC-12 hydrodechlorination by Coq *et al.*[15] showed selectivity for CH_2F_2 to be similar to that of the Pd/graphite catalyst. Such a result can be interpreted by an apparent absence of Pd–Ag interaction in the catalyst and, indeed, their XRD study of Pd–Ag/graphite showed no formation of Pd–Ag solid solution.

The Ru/MgF_2 catalyst showed rather low selectivity to CH_2F_2 (Table 1), but the selectivity to $CHClF_2$ was higher than in the case of Pd/MgF_2, in a qualitative agreement with Wiersma *et al.*[2] Again, doping with gold increased the selectivity towards partial hydrodechlorination (CH_2F_2 + $CHClF_2$) at the cost of CH_4 formation.

In conclusion, we have shown fair to respectable selectivities towards partial hydrodehalogenation of CCl_2F_2 over Pd, Pd–Au, Ru and Ru–Au catalysts supported on MgF_2. Our results indicate that the presence of gold in the catalyst is beneficial for selectivity variations. Studies are in progress to prepare new Pd–Au and Ru–Au catalysts (with different gold contents), supported on MgF_2 and active carbon.

Flexibility of the Cu(110)–O structure in the presence of pyridine

A. F. Carley, P. R. Davies,* R. V. Jones, G. U. Kulkarni† and M. W. Roberts

Department of Chemistry, Cardiff University, PO Box 912, Cardiff, UK CF1 3TB. E-mail: daviespr@cf.ac.uk

Received (in Cambridge, UK) 15th February 1999, Accepted 9th March 1999

The presence of pyridine is shown by STM to have a profound effect on the structure of a Cu(110)–O surface; the spacing within the < 100 > directed Cu–O chains is unchanged at 3.6 Å but there is an increase in the spacing between the chains from 5.1 to 7.7 Å; the flexibility of the Cu(110)–O structure is emphasised by the observation that the change in structure is reversible when the pyridine is thermally desorbed.

Surface reactions are often discussed in the context of stable structures. However, work in Cardiff over the last 15 years has shown[1–4] that this neglects much of the interesting chemistry that goes on before the stable structures are formed. Furthermore, even when stable structures have been formed they can still be sensitive to weakly adsorbed species and this may have consequences for the chemistry that can occur at the surface.

Here, we return to the adsorption of pyridine at preoxidised copper surfaces, a system which we have previously studied[5] with XPS and HREELS. We reported that at clean Cu(111) surfaces pyridine desorbs completely below 240 K but that at preoxidised surfaces it is stable to 380 K. The HREELS data indicated that in the absence of preadsorbed oxygen, pyridine physisorbs with its ring plane parallel to the surface whereas in the presence of oxygen the orientation is different, with the ring plane perpendicular to the surface. There was also strong evidence for the formation of an N–O bond. The direct interaction between the oxygen and the nitrogen was confirmed by the XPS spectra which showed a shift of the O1s peak upwards in binding energy. The XPS also showed that the maximum concentration of pyridine adsorbed at the Cu(111)-O surface corresponded to approximately one-fifth of the pre-adsorbed oxygen concentration.

Here, we investigate the pyridine–oxygen interaction at the Cu(110) plane where in contrast to Cu(111)[6] there is extensive surface reconstruction[7,8] with the oxygen being incorporated into added copper–oxygen chains orientated in the < 100 > direction.

XPS and STM data were acquired on a combined STM/XPS instrument designed and built by Omicron Vacuum Physik. The sample was sputtered clean using argon at an energy of 0.6 kV and subsequently annealed at *ca.* 750 K for 30 min. Surface cleanliness was confirmed by XPS and the purity of the gases tested with *in situ* mass spectrometry.

Initial oxidation of the Cu(110) surface leads to the formation of copper–oxygen added rows, orientated in the < 100 > direction. The O–O spacing along the row is *ca.* 3.6 Å whilst the inter-row spacing is 5.1 Å giving an overall (2 × 1) unit cell. This well known structure was used to check the calibration of the STM measurements. Fig. 1(a) shows a section of a Cu(110) surface with several small islands of added oxygen–copper rows after exposure of the surface to dioxygen giving a surface coverage of approximately one-third of saturation. The (2 × 1) unit cell can be clearly made out in the image and more faintly the substrate rows that run in the $< 1\bar{1}0 >$ direction. The islands in Fig. 1(a) were stable over several scans and our experience from all of our work on this surface is that oxygen islands of this size are completely stable at room temperature and in the *absence*[9] of any other adsorbates.

Exposure of this surface to 1 L‡ of pyridine results in an increase in the spacing between the Cu–O chains to *ca.* 7.7 Å (three times the copper lattice dimensions), Fig. 1(b), but it is clear from the STM images that the structure within the chains maintains its original spacing. Quantification of the XPS data shows a ratio of 1:0.8 between the surface oxygen concentration and the pyridine molecule concentration. The copper substrate

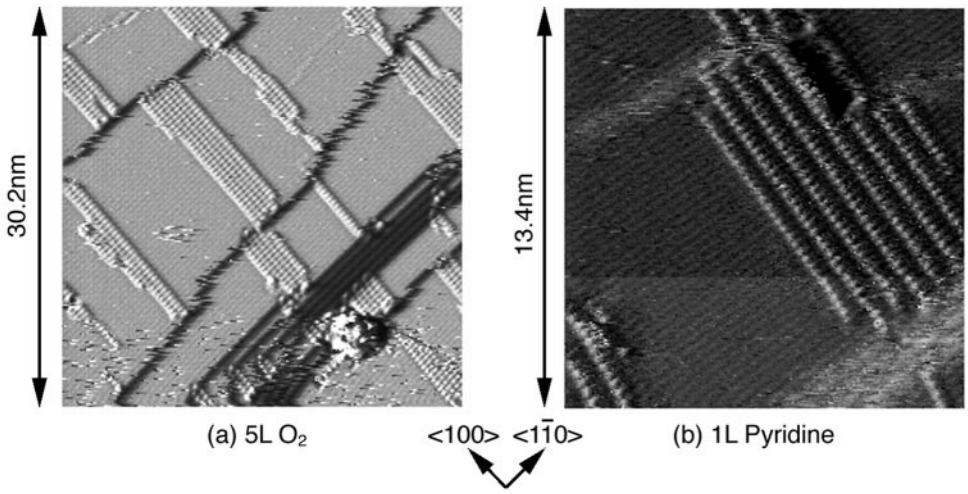

Fig. 1 The effect of pyridine on preadsorbed oxygen at a Cu(110) surface. (a) Cu(110) surface after exposure to 5 L O_2 at 290 K. The added Cu–O rows are *ca.* 5.1 Å apart and are orientated in the < 100 > direction giving a (2 × 1) structure. Imaging conditions: sample bias = −0.94 V, current = 3.1 nA. (b) Close up view of a section from (a) after exposure to pyridine at room temperature, the inter-row spacing is now 7.7 Å but the maxima within the rows are still spaced at 3.6 Å. Imaging conditions: sample bias = −0.12 V, current = 3.1 nA.

structure is very clearly resolved in STM images taken under these conditions, possibly because of the adsorption of pyridine molecules on to the imaging tip. One can see that the brightest features in the restructured chains are exactly in line with the bright rows visible on the substrate. In the original (2 × 1)O structure, the copper rows line up with the positions of the oxygen atoms in the copper–oxygen chains,[7,8] Fig. 2(a). We would expect these features in the restructured chains to be the sites where pyridine is adsorbed and therefore the image adds further weight to the earlier XPS and HREELS evidence from Cu(111) that the pyridine interacts directly with the oxygen atoms within the chains. This is also consistent with the structure of pyridine *N*-oxide.

On heating the surface to *ca*. 380 K for 40 minutes the structures orientated in the <100> direction revert to the interchain separation of 5.1 Å typical of the (2 × 1) oxygen structure.

We deduce that the pyridine molecules adsorb on the Cu–O chains at the oxygen sites and are responsible for forcing the rows apart. The reason for the increase in the inter-row spacing can be understood when one considers that the internal structure along the rows retains its 3.6 Å spacing. The pyridine molecule is *ca*. 5 Å in diameter and the XPS shows close to a 1 : 1 pyridine/oxygen ratio. This implies that the pyridine ring must be orientated perpendicular to the surface with its plane lying in the $<1\bar{1}0>$ direction, in other words at right angles to the direction of the Cu–O chain, Fig. 2(b). Because of the diameter of the ring, steric hindrance would prevent pyridine adsorption on adjacent rows. It seems however, that the formation of the pyridine–oxygen complex provides sufficient energy to break up the existing structure forcing the chains apart and thereby enabling further pyridine adsorption.

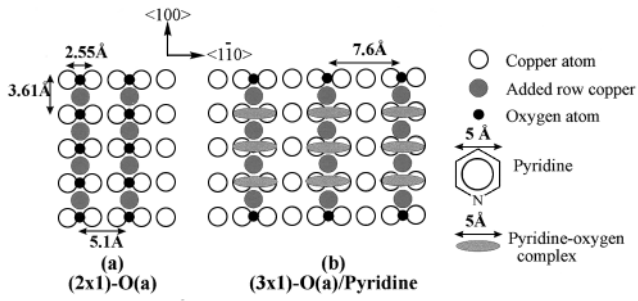

Fig. 2 (a) Structure of the (2 × 1)O(a) added row reconstruction on Cu(110); (b) proposed structure for pyridine adsorbed at the preoxidised Cu(110) surface.

Comparing the adsorption of the pyridine at the (111) and (110) surfaces we note that five times as much pyridine will adsorb onto the surface of the latter. We believe this is due to the flexibility of the particular structure formed by oxygen on Cu(110) in which the oxygen atoms are present in the added chains which are capable of moving over the surface with a low energy cost.[9] In contrast, the adsorbed state of oxygen on Cu(111) involves no large scale reconstruction[6] and the oxygen atoms are embedded within the substrate lattice effectively immobilising them.

The relevance of the observations here to the reactivity of a surface in the presence of a 'co-adsorbate' is obvious. They show that even weakly adsorbed species may influence the structure of the surface in such a way as to increase (or decrease) the availability of adsorption and reaction sites at the surface. Clearly, this must cast doubt on conclusions reached about reaction mechanisms based on structures observed in the absence of other reactants.

We are grateful to EPSRC for their generous support of this research.

The facile synthesis of α-aryl-α-hydroxy esters *via* one-pot vicarious nucleophilic substitution and oxidation

Nicholas J. Lawrence,* Olivier Lamarche† and Nabil Thurrab‡

Department of Chemistry, UMIST, PO Box 88, Manchester, UK M60 1QD. E-mail: n.lawrence@umist.ac.uk

Received (in Liverpool, UK) 4th February 1999, Accepted 1st March 1999

The anion produced by the vicarious nucleophilic substitution reaction of nitroarenes and α-chloro esters is hydroxylated by the action of air and benzaldehyde, thereby producing α-hydroxy esters.

The recently developed process of vicarious nucleophilic substitution (VNS), pioneered by Makosza and co-workers,[1,2] offers a selective mild method for the controlled substitution of hydrogen atoms of aromatic systems. As part of our contribution to the study of the VNS reaction we have developed[3] a one-pot coupling reaction of three components (a nitroarene, a stabilised carbanion derived from **1** and an electrophilic species E^+) for the construction of nitroarenes **4** bearing an adjacent quaternary chiral centre, as illustrated in Scheme 1.[4,5] This process first involves a VNS reaction between the nitroarene and the carbanion to give the intermediate anion **3** *via* loss of HX from the σ-adduct **2**. This post-VNS anion is sufficiently nucleophilic to be quenched *in situ* with a variety of electrophiles E^+ to give the *para*-functionalised nitroarene **4**.

During the study of the reaction of the post-VNS anion **3** with aldehydes, we serendipitously discovered a process for the synthesis of α-aryl-α-hydroxy esters. When the anion **3a** (R = Me), derived from ethyl 2-chloropropionate **1a**, was reacted with benzaldehyde we did not observe the formation of an aldol product. However on one occasion, when air was inadvertently introduced into the reaction flask, we obtained the hydroxy ester **5a** in approximately 50% yield. A careful study of the reaction revealed that the yield could be increased to 66% when 3 equiv. of the ester is used with respect to nitrobenzene (Scheme 2).§ In most of these reactions a small amount (5–10%) of *p*-nitroacetophenone was also produced. It was clear that both benzaldehyde and air were required in the reaction. In the absence of air, the only product obtained upon work up (**4**, R = Me, *E* = H) arose from protonation of the anion **3**. The reaction of the post-VNS anion **3a** with air in the absence of benzaldehyde gave a mixture of α-hydroxy ester **5a** and ketone *p*-nitroacetophenone in near equal proportions. We then applied this intriguing one-pot VNS–hydroxylation process to the reaction of ethyl 2-chlorobutanoate **1b** with nitrobenzene and obtained the ester **5b**. This ester was also obtained in 40% yield when the post-VNS anion was prepared *via* direct deprotonation (NaH, DMF) of ethyl 2-(*p*-nitrophenyl)butanoate followed by oxidation with air and benzaldehyde. In this case the ester was accompanied by 2-(*p*-nitrophenyl)propiophenone (8%) and the diester **6b** (10% as 1 : 1 mixture of *racemic* : *meso* stereoisomers). As confirmation of its structure, the diester **6b** was obtained in 89% yield (*racemic* : *meso* 1 : 1) by treatment of the post-VNS anion **3b** with iodine (Scheme 2).[6] Since such an oxidative coupling is thought to occur *via* a mechanism involving single electron transfer,[5] this reaction also sheds light on the mechanism of the hydroxylation reaction (*vide supra*). Reaction of ethyl α-chlorophenylacetate with nitrobenzene gave ethyl benzoylformate in 35% yield when the VNS reaction was performed at 0 °C for 1 h and 25 °C for 1.5 h; the product presumably arising from direct oxidation of the anion of **1c**. The hydroxy ester **5c** was obtained, albeit in low yield, when nitrobenzene was used in excess (1.5 equiv.) and a longer period of time was used for the VNS reaction (0 °C for 1 h and 25 °C for 3 h). It seems that the enolate derived from **1c** is insufficiently nucleophilic to react efficiently with nitrobenzene. We then applied the hydroxylation reaction to other nitroarenes (Table 1).

Reaction of ethyl 2-chlorobutanoate **1b** with *o*- and *m*-chloronitrobenzenes (entries 1 and 2) and two nitro-substituted pyridines (entries 3 and 4) gave the hydroxy ester products in which the VNS nucleophile has added *para* to the nitro group, as determined from their ^{1}H NMR spectra.¶ The product from 2-nitrothiophene with ethyl 2-chloropropionate **1a** (entry 5) is the 5-substituted hydroxy ester **5e**, as determined from its ^{1}H nmr spectrum.¶ A pair of doublets were observed at δ 7.05 and 7.80 with a coupling constant of 4.3 Hz corresponding to signals from H-3 and H-4 (expected coupling constants:[7] $J_{3,4}$ 3.45–4.35 Hz and $J_{4,5}$ 4.90–5.80 Hz). At low temperature (−33 °C, NH_3, KOH), 2-nitrothiophene is attacked by a variety VNS nucleophiles predominantly at the 3-position.[8] However, as the nucleophile **1a** provides a tertiary anion, it is not surprising that at room temperature the 5-substituted isomer is the exclusive product. It should be noted that oxidation of nitrobenzylic carbanions (made by deprotonation of products of VNS reaction) to aldehydes and ketones has been reported.[9]

The oxidation of enolates by oxygen is, of course, not without precedent. For example, Wasserman and Lipshutz have shown

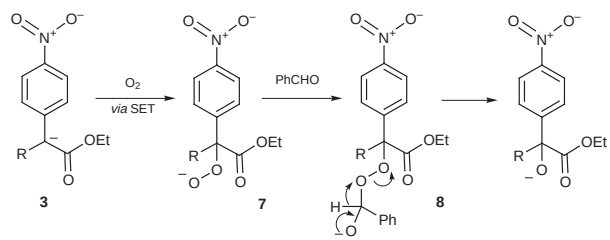
that lithium enolates of esters react with molecular oxygen to give α-hydroxy esters (after reduction of the first formed peroxide with sodium sulfite).[10] A similar procedure lacking the reductive work-up gives the α-hydroperoxy acids from carboxylic acids.[11] The post-VNS hydroxylation we observe is possibly occurring *via* initial oxidation of the anion **3**, *via* single electron transfer, to a radical which combines with an oxygen radical anion to give peroxide **7** which is trapped by benzaldehyde to give species **8** (Scheme 3). Finally a 1,3-hydride shift gives the alkoxide **8**.[12] Clearly the formation of products such as **6** indicate a mechanism involving radicals. We found that the enolate of **1c**, generated by reaction of sodium hydride, in the absence of nitrobenzene, does not react with oxygen. This suggests that the nitro group also plays a role in the oxidation process, in addition to activating the arene to attack by the VNS nucleophile and stabilising the anion **3**. This is in agreement with the finding of Russel and Bemis[13] that nitrobenzene acts as a single eletron transfer catalyst in the oxidation of stabilised



Scheme 3

benzylic anions to peroxides. In summary, we have developed an intriguing one-pot VNS–hydroxylation reaction using inexpensive reagents that lead to novel α-aryl-α-hydroxy esters.

§ To a stirred slurry of NaH (0.74 g of a 60% dispersion in oil, 18.5 mmol) in dry DMF (10 cm^3) at 0 °C was added dropwise solution of ethyl 2-chloropropionate **1a** (1.68 g, 12.33 mmol) and nitrobenzene (0.76 g, 6.16 mmol) in dry DMF (10 cm^3). The deep blue–purple reaction mixture was stirred at 0 °C for 60 min and room temperature for 2 h. Benzaldehyde (0.98 g, 9.25 mmol) was added and the reaction mixture stirred at room temperature under an atmosphere of dry air for 24 h. The resulting brown mixture was poured onto a slurry of ice and hydrochloric acid (1 M, 20 cm^3) and extracted with $CHCl_3$ (3 × 20 cm^3). The solvent (DMF and $CHCl_3$) was removed from the combined extracts *in vacuo*. $CHCl_3$ (75 cm^3) was added to the residue. This solution was washed with water (5 × 75 cm^3) and aq. $NaHCO_3$ (5 × 75 cm^3), dried ($MgSO_4$) and evaporated *in vacuo*. The residue was purified by chromatography to give the hydroxy ester **5a**.

Montmorillonite-mediated hetero-Diels–Alder reaction of alkenes and *o*-quinomethanes generated *in situ* by dehydration of *o*-hydroxybenzyl alcohols

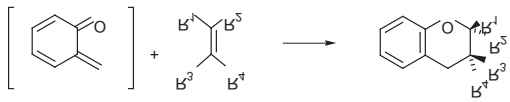
Kazuhiro Chiba,* Tetsuya Hirano, Yoshikazu Kitano and Masahiro Tada

Laboratory of Bio-organic Chemistry, Tokyo University of Agriculture and Technology, 3-5-8 Saiwai-cho, Fuchu, Tokyo 183-8503, Japan. E-mail: chiba@cc.tuat.ac.jp

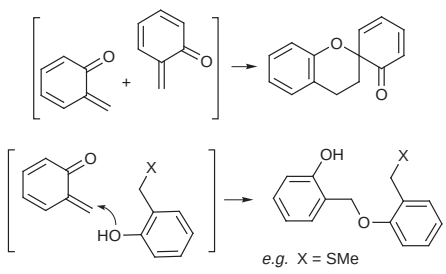
Received (in Cambridge, UK) 25th January 1999, Accepted 9th March 1999

The intermolecular hetero-Diels–Alder reaction of *in situ*-generated *o*-quinomethanes and unactivated alkenes has been accomplished through a wet montmorillonite catalyst in a $LiClO_4$–$MeNO_2$ solution to give good yields of varied chromane skeletons.

o-Quinomethanes play an important role as the heterodiene in the construction of a wide variety of chromane skeletons *via* hetero-Diels–Alder reaction with alkenes (Scheme 1). The generation and cycloaddition of *o*-quinomethanes has been extensively investigated, including pyrolysis of *o*-hydroxybenzyl alcohols,[1] one-electron oxidation of *o*-substituted phenols,[2] desilylation of an *o*-hydroxybenzyl alcohol disilyl ether,[3] and dehydrogenation of allylphenols with DDQ.[4] However, as the *o*-quinomethanes are generally very unstable, they must be trapped by highly active, electron-rich alkenes, by intramolecular reactions, or under high-temperature conditions. Furthermore, by-products of the homo-Diels–Alder reaction, Michael addition, or Friedel–Crafts reaction of *o*-quinomethanes have also often been obtained with desired products (Scheme 2).[5] On the other hand, it has been proposed that many natural products can be generated *via* the intermolecular cycloaddition of *o*-quinomethanes and aliphatic alkenes.[6] Biogenetically, it has been proposed that *o*-quinomethanes are produced by the dehydration of the corresponding *o*-hydroxybenzyl alcohols or benzylic oxidation of the corresponding *o*-cresol derivatives.[7] Biomimetic mild reaction media in which *o*-quinomethanes are generated and trapped efficiently by unactivated aliphatic alkenes have therefore been sought. Recently, we performed the intermolecular hetero-Diels–Alder reaction of electrochemically generated electon-rich *o*-quinomethanes and unactivated aliphatic alkenes to construct some natural product skeletons, but the *o*-quinomethanes were limited to stable ones possessing electron-donating groups (Scheme 3). Accordingly we have further investigated the biomimetic facile method for the generation and cycloaddition reaction of *o*-quinomethanes, and found that a catalytic amount of wet montmorillonite in a $LiClO_4$–$MeNO_2$ solution efficiently

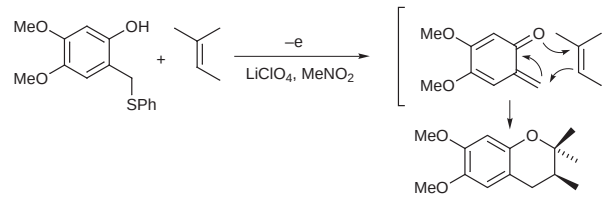


Scheme 1



Scheme 2

generated *o*-quinomethanes by the dehydration of the corresponding *o*-hydroxybenzyl alcohol. The reaction media showed a remarkable acceleration property in the generation and intermolecular cycloaddition of the unstable *o*-quinomethanes with varies unactivated alkenes.



Scheme 3

Under the usual dehydration conditions of benzyl alcohols using Lewis acids or Brønsted acids, salicyl alcohol and 2-methylbut-2-ene **3** gave the corresponding cycloadducts **10** and **11** in very low yields (Table 1). On the other hand, a catalytic amount of dry montmorillonite K 10 in $MeNO_2$ gave the desired cycloadducts in 26.8%, and the addition of $LiClO_4$ effectively increased the yield to 54.8%. Furthermore, the reaction proceeded to give **10** and **11** (6 : 1) almost quantitatively by using wet montmorillonite K 10 in the presence of $LiClO_4$ in $MeNO_2$ at ambient temperature. The wet montmorillonite did not work well in other solvents, even in the presence of $LiClO_4$. Accordingly, the targeted reactions with varied alkenes were performed in $MeNO_2$ in the presence of an *o*-hydroxybenzyl alcohol, wet montmorillonite, and $LiClO_4$ at ambient temperature.† Styrenes gave excellent yields of the corresponding flavanes, while unactivated aliphatic alkenes simply gave chromanes and spirochromanes in good yields (Table 2). Some products were obtained due to skeleton rearrangement of the alkene moieties (Scheme 4).

In the present reaction media, the dehydration reaction may be accelerated on the wide surface of montmorillonite, and the

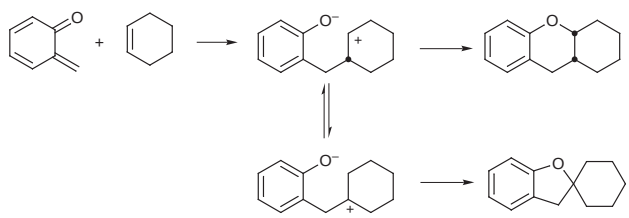
[a] 2-Hydroxybenzyl alcohol (20 mg) and 3 equiv. of alkene were dispersed in 2.0 ml of 0.1 M $LiClO_4$–$MeNO_2$ in the presence of 20 mg of montmorillonite and 36 mg of water. The reaction mixture was allowed to stand at ambient temperature for 48 h.



Scheme 4

addition of water might regulate the acidic decomposition and polymerization of starting materials. $LiClO_4$ is expected to stabilize the *in situ*-generated zwitterion, which is an equivalent of the *o*-quinomethane (Scheme 5). Furthermore, the products are easily extracted from the reaction media with *n*-hexane, and the catalytic solvent system can be reused many times. Employing the hetero-Diels–Alder reaction of *o*-quinomethanes in $LiClO_4$–$MeNO_2$ mediated by wet montmorillonite K 10 is applicable to the formation of a variety of chromanes. In these cases involving unsubstituted, unstable *o*-quinomethanes, the cycloaddition reactions with unactivated alkenes proceeded smoothly to give cycloadducts, including those which are difficult to obtain in high yields *via* other methods.

This work was supported by a Grant-in-Aid for Scientific Research on Priority Areas (No. 283, 'Innovative Synthetic Reactions') from the Ministry of Education, Science, Sports and Culture, Japan.

Covalently attached multilayer assemblies of diazo-resins and porphyrins

Junqi Sun, Zhiqiang Wang, Yipeng Sun, Xi Zhang* and Jiacong Shen

Key Lab of Supramolecular Structure and Spectroscopy, Department of Chemistry, Jilin University, Changchun, 130023, PR China. E-mail: xi@mail.jlu.edu.cn

Received (in Cambridge, UK) 2nd December 1998, Accepted 10th March 1999

Construction of highly stable covalently attached multilayer films containing porphyrins was achieved by UV irradiation of ionic self-assembled multilayer films of diazo-resins (DAR) and tetrasodium 5,10,15,20-tetraphenyl-21H,23H-porphine-P,P′,P″,P‴-tetrasulfonic acid ($tpps_4$).

Layered construction of porphyrins into organized systems has increasingly gained in importance due to its potential application in various disciplines ranging from voltaics, electrochromics to nonlinear optics. Many strategies have been exploited to fulfill this purpose, including Langmuir–Blodgett,[1] self-assembly[2] and electropolymerization techniques.[3] Recently, ourselves and others have developed a new method to fabricate porphyrin multilayer films based on electrostatic interactions as the driving force.[4] This technique has proven to be a rapid and experimentally very simple way to fabricate porphyrin containing films. However, porphyrin films fabricated by this technique are not robust enough and can be etched by solvents which limits applications in an extended range. Here we introduce a new method to fabricate covalently attached multilayer films containing porphyrins by UV photoreacting diazonium and sulfonate groups at the interface. This method combines the simplicity of the ionic self-assembly technique and the high stability of the covalently attached multilayer films. Thus it promises to be a very efficient method to prepare highly stable multilayer films containing porphyrins.

Diazo-resin (DAR) was kindly provided by Prof. Weixiao Cao (College of Chemistry and Molecular Engineering, Peking University, Beijing), and its synthesis has been reported previously.[5] The porphyrin $tpps_4$ was synthesized according to the literature.[6] A freshly cleaned quartz slide was first modified with a layer of (3-mercaptopropyl)trimethoxysilane (MPTS) from benzene, after which terminal –SH functional groups at the exposed surface were oxidized by 30% H_2O_2–HOAc *in situ* into sulfonic acid groups.[7] The sulfonic acid covered quartz slide was then alternately immersed in aqueous solutions of DAR (1.5 mg ml^{-1}) and $tpps_4$ (0.2 mg ml^{-1}) for 20 min, with an intermediate water washing and N_2 drying. Multilayer films can be formed by repeating the above step in a cyclic fashion. The above deposition process was conducted in the dark. Finally, irradiating the multilayer films with UV light for a given time is required to convert the ionic interaction of neighboring layers into covalent bonds.

UV–VIS spectroscopy was used to follow the fabrication process. Fig. 1(a) shows the UV–VIS absorption spectra of eight bilayers of DAR/$tpps_4$ assembled on a quartz slide. The absorbance at 380 nm is attributed to the π–π* transition of the diazonium group, while the absorbance at 426 nm corresponds to the Soret band of porphyrin. It was found that the absorbances at 380 and 426 nm increase linearly with the number of layers, which demonstrates a progressive deposition process. UV–VIS spectroscopy also indicates that the Soret band of the porphyrin in the DAR/$tpps_4$ multilayer films is red-shifted by *ca*. 12 nm compared with that in solution, which is a consequence of formation of aggregates of chromophores in the films.

Owing to the well known photoreaction of diazonium and sulfonate groups, the above assembled films containing eight bilayers of DAR/$tpps_4$ were irradiated with a 30 W medium power mercury lamp at a distance of 20 cm. Fig. 1 shows the changes in UV–VIS spectra of the films with different irradiation times, from which, we can clearly see that the absorbance at 380 nm decreases dramatically due to the decomposition of the diazonium group, concomitantly, the absorbance at 290 nm increases gradually. Throughout the experiment, we found that the decomposition proceeded completely within 30 min. It was also found that at the same time the absorbance of the Soret band of $tpps_4$ decreases gradually with no change in peak position or shape. This decrease is caused by the decrease of the contribution of diazonium groups at this wavelength. The fact that the peak position and shape of the Soret band of $tpps_4$ did not change shows that no or few conformational changes took place during the reaction, which was consistent with the result of polarized UV–VIS spectroscopy.

We compared the stability of the multilayer films before and after UV irradiation by immersing the corresponding films into a ternary mixture of H_2O–DMF–$ZnCl_2$ (3 : 5 : 2, w/w/w). This ternary system was chosen because of the high solubility of the DAR/$tpps_4$ complex in it compared to other solutions, such as aqueous $ZnCl_2$ DMF, chloroform, *etc*. The UV–VIS spectra showed that before UV irradiation treatment, almost all the porphyrin and most of DAR can be dissolved after 5 min of immersion as seen the large decrease of the absorbance at 426 and 380 nm. However, for the UV irradiated films, the spectrum after immersion scarcely decreased showing that < 10% of the films dissolved. Thus the stability of the irradiated films was substantially improved.

From the change of the stability of the multilayer films before and after UV irradiation, it is proposed that a photoreaction takes place between the diazonium groups of DAR and sulfonate groups of $tpps_4$. As for the general reaction mechanism,[8] it is thought that DAR is first converted into its phenyl cationic form after release N_2 upon UV irradiation. Then an S_N1 type of nuclear displacement by sulfonate occurs as shown in Scheme 1. The fact that the photoreaction changes the

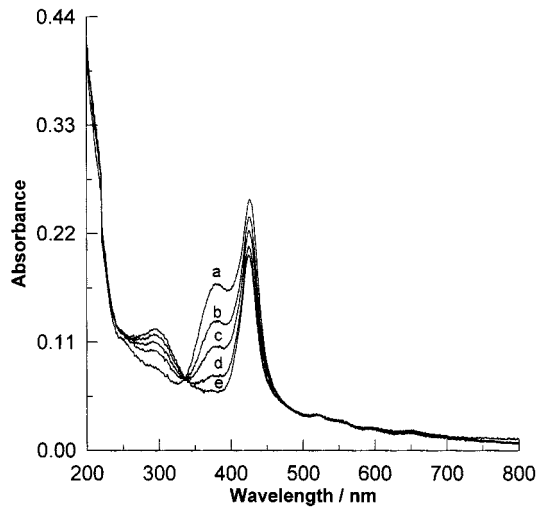

Fig. 1 UV–VIS absorption spectra of eight bilayers of DAR/$tpps_4$ upon irradiation with UV light for (a) 0, (b) 2, (c) 4, (d) 8 and (e) 15 min.

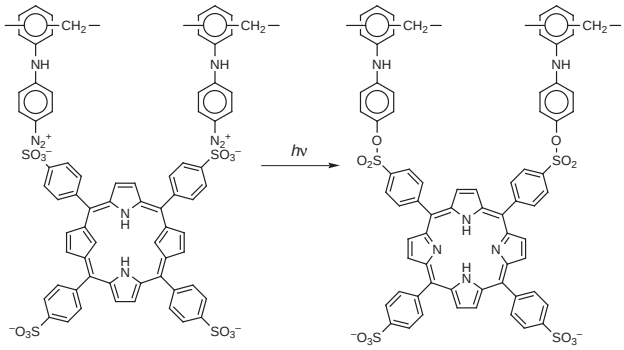

Scheme 1 Photoreaction of DAR and $tpps_4$ in one bilayer.

interactions not only between the neighboring layers, but also the first layer of DAR and the modified substrate from ionic to covalent is likely to be responsible for the improvement of the stability of the irradiated films.

The photoreaction of diazonium and sulfonate groups in multilayer films was further confirmed by IR spectroscopy. Three absorption peaks at 2220, 2163 and 1177 cm^{-1} are observed in the IR spectra of an 18-bilayer film of DAR/$tpps_4$ assembled on CaF_2 substrate [modified by cationic poly-(diallyldimethyl ammonium chloride)] before UV irradiation. The first two originate from the stretching of $-CN_2$ and that at 1177 cm^{-1} from symmetric stretching of $-SO_3^-$. After UV irradiation, the absorptions at 2220 and 2163 cm^{-1} disappeared completely, indicating decomposition of the diazonium group. Meanwhile, a new absorption at 1170 cm^{-1} appeared which corresponds to the symmetric stretching of the sulfonate coupled with the phenyl group. In layer-by-layer multilayer films, the photoreaction should be facilitated to some extent by the close proximity of the diazonium and sulfonate groups. However, it is very difficult to determine the extent of reaction of diazonium with sulfonate groups. Further efforts to solve this problem are in progress.

Polarized UV–VIS spectroscopy was used to study the orientation of the planar porphyrin in the multilayer films before and after photoreaction. In both cases, no detectable changes were found when the multilayer films were examined at normal incidence using polarized light with its electric vector parallel or perpendicular to the plane of incidence, indicating that no in-plane anisotropy exists. When the film was examined at 30° incidence under the similar process, an obvious change of the spectra could be observed both before and after UV irradiation as shown in Fig. 2. We can calculate the orientation angle of the porphyrin plane by using the method described previously by us.[4] Herein, we presume the optical indices of the films before and after UV irradiation are the same and have a value of 1.5. The angle between the normal line of plane *x* and the substrate, *i.e.* θ, calculated before and after UV irradiation films is 53 and 49°. In other words, the oriented angle between the plane and horizon of the substrate are 53 and 49°, respectively, which

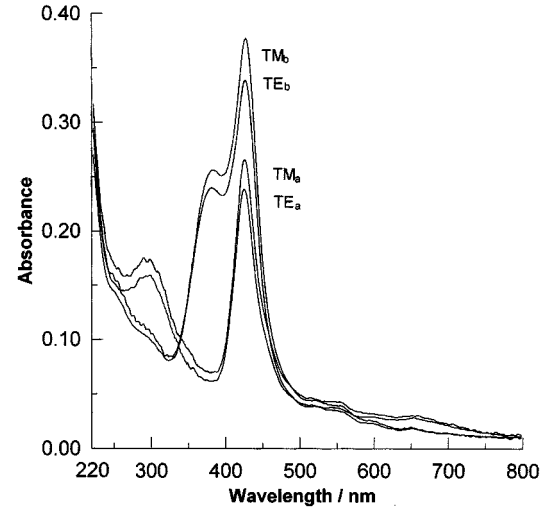

Fig. 2 Polarized UV–VIS spectra of a 12-bilayer DAR/$tpps_4$ film before (TE_b and TM_b) and after (TE_a and TM_a) UV irradiation for TE and TM polarisations. Incident angle = 30°.

show little conformational change of the porphyrin in multilayer films before and after UV irradiation.

In conclusion, a new method to fabricate covalently attached multilayers of porphyrin has been developed exploiting the ionic self-assembly technique and post UV-irradiation photoreaction of the diazonium and sulfonate groups in the multilayer assemblies. This technique is a simple but efficient method to prepare highly stable porphyrin-containing multilayer films.

Received (in Cambridge, UK) 22nd February 1999, Accepted 10th March 1999

Reaction of *cis*-$[Co^{III}(NH_3)_4(H_2O)_2](ClO_4)_3$ with 2,2′-dithiodipyridine (2,2′-DTDP) in nearly equimolar proportion generates $[Co^{III}L_2]ClO_4$ where HL (H = dissociable proton) is di(2-pyridylthio)amine, resulting in an unprecedented insertion of a coordinated ammine N into the S–S bond of 2,2′-DTDP.

Reactions of a disulfide bond (S–S) are of much biological importance.[1] This bond usually undergoes reductive cleavage giving rise to sulfur radicals, thiols/thioethers or thiolate anions.[1] Herein we describe a novel reaction of the disulfide bond.

Reaction of *cis*-$[Co^{III}(NH_3)_4(H_2O)_2](ClO_4)_3$ with 2,2′-dithiodipyridine (2,2′-DTDP) leads to the isolation of diamagnetic $[Co^{III}L_2]ClO_4$ **1** [HL = di(2-pyridylthio)amine ≡ HN{(2-C_5H_4N)S}$_2$] [eqn. (1)].

cis-$[Co^{III}(NH_3)_4(H_2O)_2](ClO_4)_3$ + 2 (2,2′-DTDP)

↓

$Co^{III}[N\{(2\text{-}C_5H_4N)S\}_2]_2 \bullet ClO_4$ + 2 NH_4ClO_4 (1)

1

In this reaction, two coordinated ammine N atoms are inserted into the S–S bonds of two molecules of 2,2′-DTDP, *i.e.* two of the three hydrogen atoms of two coordinated ammine nitrogens are replaced by the sulfur atoms of 2,2′-DTDP and the remaining hydrogen atom of each of the two disulfur substituted amino nitrogens dissociate as protons resulting in two L^- units. Though eqn. (1) suggests a 1 : 2 reaction stoichiometry between the metal and 2,2′-DTDP, the optimum yield of **1** is obtained by reacting almost equimolar amounts of the cobalt tetraammine complex and 2,2′-DTDP.†

The structure of **1** as determined by X-ray crystallography‡ is shown in Fig. 1. The cobalt atom lies at the center of a distorted but centric octahedron of six N (four pyridyl and two amide) atoms. Interestingly, each L^- fragment does not span a meridian but caps a face of the octahedron. If a Co–N(amide) bond is placed along the *y*-axis, then the two pyridyl rings of the L^- moiety lie quite close to the *xy* and *yz* planes, and one of the two sulfur atoms lies in the *xy* plane and the other in the *yz* plane. The average bond length of Co–N(pyridyl) is 1.963 Å and that of Co–N(amide) is 1.951 Å. The amide N is pyramidal with valence angles in the range 111.5(2)–112.0(2)° which are slightly larger than the ideal tetrahedral angle of 109.5°.

X-Ray photoelectron spectra of **1** show normal[2] binding energies: 62 (Co 3p), 164 (S 2p), 227 (S 2s), 284 (C 1s), 398 (N 1s), 533 (O 1s), 782 (Co 2p) and 929 eV (Co 2s). The absence of the spin multiplicity splitting in Co 3p confirms diamagnetism of the complex.[2] A broadening of the linewidth was observed at the lower binding energy side in the N 1s signal. This is possibly due to the difference in the binding energies of pyridyl N (401 eV) and dithioamide N (399 eV).

^{1}H and ^{13}C NMR spectral data for **1** in $(CD_3)_2SO$ are given in Table 1 together with their assignments. The two pyridyl rings become equivalent in solution, though they are not so in the crystal. The doublet signals are assigned to H4 and H1, while triplet signals are assigned to H2 and H3; these assignments are confirmed by 2D NMR. The ^{13}C signals are assigned considering the ^{1}H signals and the electron withdrawing effect of S on the C1 (or C6) atom. For ready comparison, ^{1}H and ^{13}C NMR data for 2,2′-DTDP are also given in Table 1.[3]

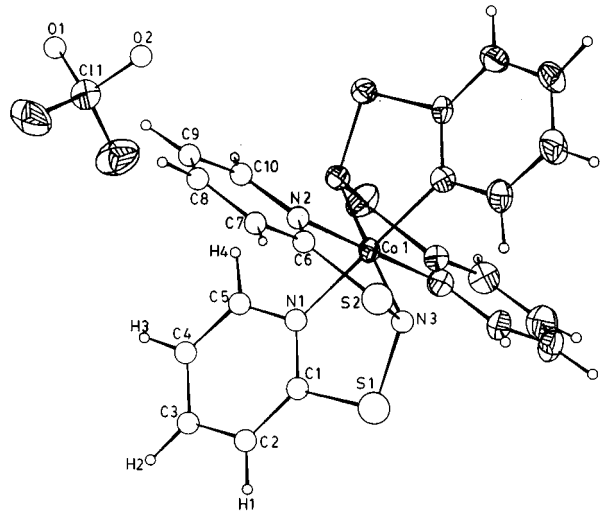

Fig. 1 X-Ray crystal structure of **1**. Selected bond distances (Å) and angles (°): Co1–N1 1.960(3), Co1–N2 1.966(3), Co1–N3 1.951(3), S1–N3 1.711(3), S2–N3 1.718(3), S1–C1 1.747(4), S2–C6 1.742(4); N1–Co1–N2 86.1(1), N1–Co1–N3 88.2(1), N2–Co1–N3 87.9(1), S1–N3–S2 111.5(2), Co1–N3–S1 111.6(2), Co1–N3–S2 112.0(2), N3–S1–C1 100.6(2), N3–S2–C6 101.0(2).

The known complexes of 2,2′-DTDP can be divided into two classes. In one class, metal complexes are formed after reductive cleavage of the S–S bond of 2,2′-DTDP. In such cases, 2-pyridylthiolato complexes are generated with four membered M–N–C–S chelate rings[4] or unidentate thiolato moieties.[4,5] The other class consists of metal complexes of 2,2′-DTDP itself in which the ligand can act in an N,N-bidentate,[6,7]

Table 1 ^{1}H and ^{13}C NMR spectral data for **1** and 2,2′-DTDP in $(CD_3)_2SO$ (δ in ppm from TMS)[a]

	H4	H2	H3	H1	
1	9.13	7.68	7.28	7.47	
2,2′-DTDP	8.4	7.6	7.1	7.2	
	C1	C5	C3	C4	C2
1	177.31	153.24	138.73	118.47	122.04
2,2′-DTDP	158.85	149.45	137.26	119.62	121.02

[a] The atom labelling scheme for **1** is shown in Fig. 1 and similar labelling applies to 2,2′-DTDP; Spectral data for 2,2′-DTDP are taken from ref. 3.

N,S-bidentate[7] or N-unidentate[7] mode. In the N,N-bidentate mode, it can act as a bridging ligand giving rise to polymeric species.[8] Our present complex belongs to a new class of complex of 2,2′-DTDP where a donor atom is inserted into the S–S bond. Such insertion of an atom into an S–S bond in the absence or presence of a metal is, to our knowledge, hitherto unknown.

H. N. thanks the Kagawa Nutrition College, Japan and the Japan Private School Promotion Foundation for support on an outside studies program. Thanks are also due to Dr M. Koizumi, Central Research Laboratory of Mitsubishi Materials Co., Omiya, Saitama, Japan for helping with the X-ray photoelectron spectra and to Dr T. Ekita, Tosoh Co., Ayase, Kanagawa, Japan for helping with the NMR spectra.

† 4.6 g (10 mmol) of *cis*-[$Co^{III}(NH_3)_4(H_2O)_2$](ClO_4)$_3$, synthesised by a reported procedure,[9] and 2.8 g (13 mmol) of 2,2′-DTDP was dissolved in 12 ml of DMF and heated at 100 °C for 1 h. Within 30 min of heating, a shiny dark compound started to separate. The reaction mixture was cooled to room temp. and 6 ml of ethyl acetate was added dropwise with stirring. The precipitate was allowed to settle for 15 min. It was filtered, washed first with 15 ml of DMF–ethylacetate (1 : 2) and then with ethyl acetate, and was dried in air. The crude product was recrystallised from DMF–ethyl acetate. Yield, 1.2 g (20%). Colour: shining brown. Anal. Found (calc.): Co, 9.33(9.41); C, 38.14(38.29); H, 2.42(2.57); N, 13.50(13.40)%. Diamagnetic. Single crystals were grown by direct diffusion of ethyl acetate into a dilute DMF solution of **1**.

‡ *Crystal data* for $CoC_{20}N_6S_4H_{16}O_4Cl$ **1**: M_w = 626.86, monoclinic, space group *C*2/*c*, a = 21.049(3), b = 12.603(2), c = 9.523(2) Å, β = 97.39(4)°, U = 2505.3 Å^3, Z = 4, D_c = 1.662 g cm^{-3}. The data were collected on a CAD-4 diffractometer with Cu-Kα radiation (λ = 1.54178 Å) at 295 K. Absorption correction: empirical T_{min} = 0.7082, T_{max} = 1.6595. The crystal structure was solved by direct methods (SHELXS) and refined by full matrix least squares methods with first isotropic then anisotropic displacement parameters. The hydrogen atoms were located from difference electron density function after the isotropic refinement and placed geometrically, and their isotropic displacement parameters were refined. Formation of 2-phenylethanol from styrene in the presence of zeolites and UV irradiation

Markus Steilemann,[a] John N. Armor[b] and Wolfgang F. Hölderich*[a]

Received (in Cambridge, UK) 14th December 1998, Accepted 9th March 1999

2-Phenylethanol is formed *via* an *in situ* multistep reaction by irradiation of styrene in the presence of silica–alumina compounds such as zeolites in aqueous and methanolic systems; the first step is presumably an oxidation.

The formation of anti-Markovnikov compounds by direct functionalization of olefins is of great interest for technical and synthetic applications. The Brown hydroboration–oxidation provides a useful tool to obtain the interesting products, but unfortunately this method is accompanied by disadvantages for its commercial application.[1–3] It is known that anti-Markovnikov addition can be achieved by the use of photosensitizers under photochemical reaction conditions, involving radical cations as intermediates.[4,5] It is also well known that zeolites are excellent hosts for photochemical reactions.[6–8] We tried to replace these photosensitizers by zeolites due to their known properties for the generation and stabilization of organic radicals adsorbed on their surface. Here we present some unexpected results pointing to an unusual combination of photochemical and thermal processes.

With regard to the work of Yates and Arnold we choose styrene as a model substance for our investigation.[9] By using EPR and UV spectroscopy we were able to show the formation of styrene radical cations on an H-ZSM-5 zeolite. The formation of this radical cation occurs, either in non-irradiated or in irradiated samples, equally as well in aqueous as in organic slurries of the zeolite with styrene. For the reaction we used the following reaction conditions: a 450 W mercury medium pressure lamp from Ace Glass, Inc., and quartz tube reactors with a magnetic stirrer placed beside the immersion lamp, while the reaction mixture is cooled by a centered cooling finger. In this reactor a mixture of typically 15 g water, 2 mmol styrene and 3 g of the zeolite was placed and irradiated for a period of 24 h at room temperature. After the reaction the mixture was centrifuged, the zeolite was separated and the fluid phase was extracted with Et_2O, then dried with Na_2SO_4 and, after evaporation of the solvent, analysed by gas chromatography. Instead of the zeolite a commercially available silica–alumina, Aldrich 34, 335–8 and CdS, ZnS and ZnO were used in other experiments. A 30 W D_2 lamp from Heraeus was also used as the irradiation source. In all cases the conversion was higher than 99%. In water the selectivity for 2-phenylethanol was 0.06% for H-ZSM-5 and 0.04% for SiO_2–Al_2O_3; for CdS, ZnS, ZnO or SiO_2 it was not detectable. But for H-ZSM-5 in MeOH the selectivity for 2-phenylethanol rises to 19.4%; methoxystyrene was not detected. Therefore we do not believe MeOH participates directly in this reaction and we regard this result as a proof for our proposed reaction mechanism (discussed below). Other by-products such as olefins, oligomers or alkylated styrene compounds were also not observed.

Although in the case of water as reaction medium the selectivity is negligible and more than 90% of the styrene reacts to form polymeric products, we tried to determine if direct addition of water in the anti-Markovnikov direction is the reason for the formation of 2-phenylethanol. By mass spectroscopy and cross checking experiments with the identified products, we identified the substances acting as intermediates in the reaction. Styrene is oxidized. This step is proved to be made possible by light below $\lambda \leqslant 290$ nm and we suspect the formation of superoxide radical anions and their reaction with styrene or the styrene radical cations. In the absence of the zeolite or silica–alumina under otherwise identical conditions no styrene oxide is found, but benzaldehyde is formed because of singlet oxygen formation. In the following step phenylacetaldehyde is formed *via* thermally or photochemically induced rearrangement of styrene oxide. The next steps are not clearly identified: possibly a decarbonylation and the formation of benzyl radicals take place, followed by a further reaction with formaldehyde or MeOH to give the corresponding alcohol. This could explain the drastically increased selectivity in the presence of MeOH. Nevertheless, the MeOH could act as an electron-donating reductant adsorbed on the surface. In this case the zeolite and the silica–alumina would show photo-semiconducting properties. A two-electron reduction of the phenylacetaldehyde would take place leading to 2-phenylethanol by *in situ* protonation. The assumed reaction steps are shown in Fig. 1.

The use of the deuterium lamp in our experiments increased the selectivity for 2-phenylethanol to 0.5% in aqueous systems. Due to the shorter reaction time of 6 h instead of 24 h in these experiments, the much lower overall irradiation energy, the specific spectra of both lamps and the absorption spectra of the organic and inorganic compounds, we assume the required wavelength to run the reaction to be *ca.* 210 nm. Although the spectra of styrene adsorbed on the zeolite shows a new broad absorption at $\lambda \approx 550$ nm, this absorption is not required for the reaction, as experiments with Pyrex reactors show. Other spectra with MeOH- or water-loaded zeolites showed no differences in the range $\lambda \leqslant 290$ nm that could be assigned to the creation of special electronic states too. Therefore we expect

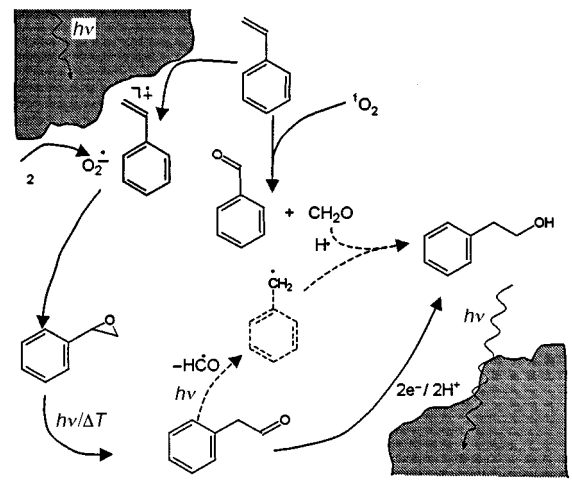

Fig. 1 Assumed reaction scheme for the formation of 2-phenylethanol from styrene.

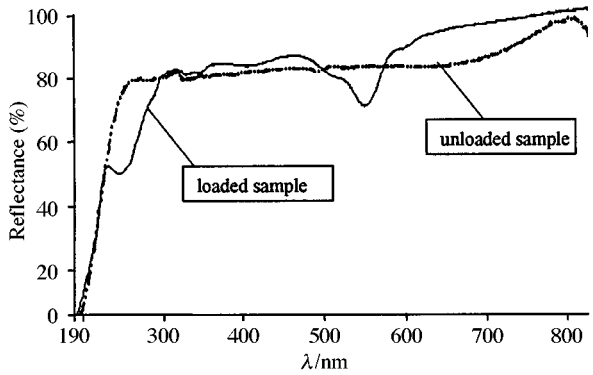

Fig. 2 UV–VIS reflectance spectra of the styrene loaded and unloaded zeolite H-ZSM-5.

the reaction to take place by direct excitation of the zeolite or the silica–alumina. Judging from the recorded spectra this is only possible by irradiation at $\lambda \leqslant 210$ nm. The spectra of preadsorbed styrene and without preadsorbtion of styrene are shown in Fig. 2. Experiments to obtain more reliable information and to run the reaction more selectively using UV lasers are planned. These would also enable us to carry out the kinetic studies which are currently lacking.

In conclusion, this is the first time, to the best of our knowledge, that the formation of 2-phenylethanol has occurred *via* the assumed reaction scheme, *i.e.* by a combination of the assumed thermal and photochemical steps *via* irradiation of styrene in the presence of silica–alumina and H-ZSM-5.

Furthermore, the substantial selectivity for the anti-Markovnikov product 2-phenylethanol under irradiation in the presence of H-ZSM-5 and MeOH is reported here for the first time.

Capillarity and silver nanowire formation observed in single walled carbon nanotubes

Jeremy Sloan,[ab] David M. Wright,[ab] Hee-Gweon Woo,[c] Sam Bailey,[a] Gareth Brown,[a] Andrew P. E. York,[a] Karl S. Coleman,[a] John L. Hutchison[b] and Malcolm L. H. Green[a]

Received (in Cambridge, UK) 26th February 1999, Accepted 10th March 1999

Single walled carbon nanotubes (SWNTs) exhibit similar capillarity properties to those exhibited by multiple walled carbon nanotubes (MWNTs); SWNTs, previously filled in low yield (*ca.* 2%) by solution chemistry techniques, can be filled in high yield (up to *ca.* 50%) by the liquid phase method; compositions from the KCl–UCl_4 and AgCl–AgBr systems were used to fill SWNTs without causing them significant chemical or thermal damage; in the case of the latter, exposure to light or an electron beam resulted in the partial photolytic reduction of SWNT incorporated silver halides to continuous metallic silver 'nanowires' within the capillaries.

It has been demonstrated that molten media such as PbO_x, V_2O_5 and MoO_3 can fill MWNTs by capillary action.[1–3] This ability of such materials to be so incorporated depends on three characteristics of the filling materials: (i) they must 'wet' the capillaries and have surface tensions below a threshold value in the range 100–200 mN m^{-1};[4] (ii) their overall melting temperature must be low enough to preclude thermal damage to the MWNT capillaries; and (iii) they must not attack MWNTs chemically. A modification to the capillary method has extended both the range and complexity of materials available for filling of MWNTs by capillarity.[5] This technique is based on the deposition of either eutectic or non-eutectic components from a mixed metal salt system. Here, we show how the melting properties of the KCl–UCl_4[6] eutectic melting system [Fig. 1(a)] and also those of the AgCl–AgBr[7] solid solution [Fig. 1(b)] system can be used to introduce continuous fillings of solid phase materials into SWNTs. The filling yield obtained from these liquid phases and mixtures greatly exceeds that obtained previously by the solution-deposition filling technique.[8]

The conditions for preparing SWNTs filled with compositions from the KCl-UCl_4 and AgCl–AgBr systems were established from surface tension/composition data (Tables 1 and 2)[9] and the phase relations depicted in Fig. 1(a) and (b). The SWNTs used in this study were prepared according to the high yield catalytic arc synthesis method reported by Journet *et al.*[10] A structural representation and HRTEM lattice image of an empty 'kinked' unfilled SWNT obtained by the catalytic method are shown in Fig. 2(a) and (b), respectively. All of the halide mixtures were ground and weighed under dry box conditions, and in the case of the silver halide mixtures, exposure to light was minimised. The halide samples were ground together with SWNTs and sealed under vacuum in silica quartz ampoules. The ampoules were passed at 3 cm min^{-1} through a 30 cm three-zone tube furnace with a temperature gradient spanning 300 °C and held for 30 min. at a maximum temperature of *ca.* 100 °C higher than the liquidus or melting temperature of the filling material [see Fig. 1(a) and (b)]. The resultant mixture was then furnace cooled for 3 h to room temperature. The filled specimens were characterised by high resolution transmission electron microscopy (HRTEM) and energy dispersive X-ray spectroscopy (EDX).

In the case of the KCl–UCl_4 system, the pure end component UCl_4 apparently attacked the SWNTs and no filling was observed. In addition, the KCl end member was found to be too

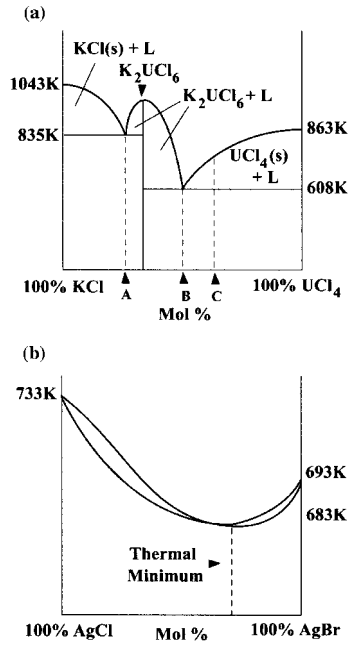

Fig. 1 (a) KCl–UCl_4 pseudobinary eutectic melting system. Compositions A, B and C were used to fill SWNTs. (b) Diagram showing the melting properties of the AgCl–AgBr solid solution system. AgCl, AgBr and the thermal minimum ($AgCl_{0.2}Br_{0.8}$) were used to fill SWNTs.

Table 1 Melting temperatures and surface tensions of compositions used to fill SWNTs in the KCl-UCl_4 system [see also Fig. 1(a)]

Composition [see Fig. (1b)]	KCl–UCl_4 (mol %)	Filling temperature/K	Surface tension/mN m^{-1}
KCl	100	1143	93.13
A	73.2 : 26.8	935	64.98
B	50 : 50	700	54.00
C	39.33 : 60.67	842	50.54
UCl_4	0 : 100	963	26.8

Table 2 Melting temperatures and surface tensions of compositions used to fill SWNTs in the AgCl–AgBr system [see also Fig. 1(b)]

Composition	Filling temperature/K	Surface tension/mN m^{-1}
AgCl	833	173.08
AgBr	800	151.3
$AgBr_{0.2}Cl_{0.8}$	783	154.4

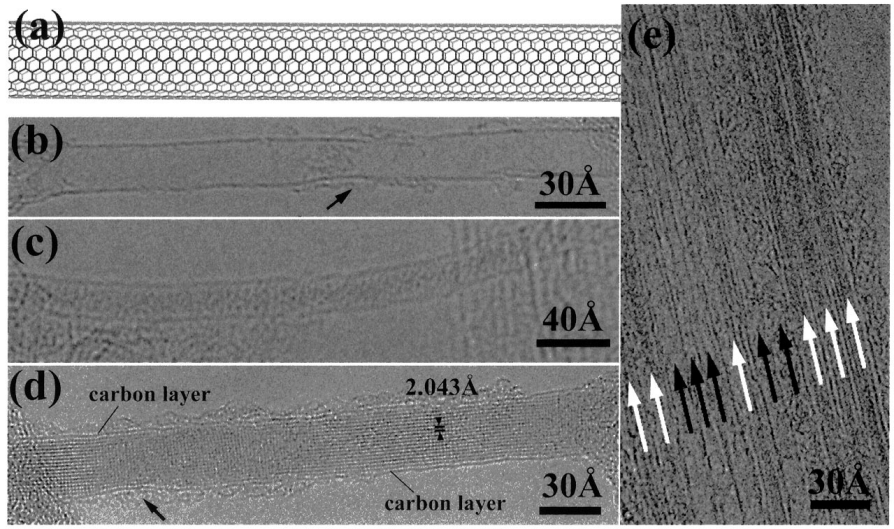

Fig. 2 (a) Schematic structural representation of a SWNT. (b) HRTEM image showing an empty SWNT. The defect region near the centre (arrowed) is possibly caused by the incorporation of non-six-membered rings into the graphene wall. (c) SWNT continuously filled with a KCl–UCl_4 eutectic mixture [composition A, Fig. 1(a)]. (d) Wide capillary SWNT continuously filled with Ag metal formed by capillary insertion of AgCl followed by photolytic decomposition. The indicated *d*-spacings correspond to the (020) lattice planes of Ag metal. Note 'kink' causing distortion in the Ag microstructure [*cf.* Fig. (b)]. (e) Showing high yield incorporation of AgBr into an SWNT bundle. Filled SWNTs are indicated by light arrows; unfilled SWNTs by dark arrows.

beam sensitive to be directly observed at room temperature *via* HRTEM. However, the three lower melting compositions A, B and C [Fig. 1(a)] were able to wet and fill the SWNTs without causing them significant damage. For composition A, corresponding to one of two eutectics in the KCl-UCl_4 system [see Fig. 1(a)], an amorphous homogenous product of composition $(KCl)_x(UCl_4)_y$ (with $x/y \approx 3:1$) was obtained inside SWNTs. Fig. 2(c), shows a HRTEM micrograph of a discrete (10,10) SWNT continuously filled with the $(KCl)_x(UCl_4)_y$ eutectic mixture. Fillings obtained with compositions B and C (not shown) were found to be either crystalline or polycrystalline.

For the AgCl–AgBr system, the melting range was both lower and narrower than for the KCl–UCl_4 system [see Fig. 1(b)]. An important difference was that both end components were able to fill SWNTs without damaging them. The filling yields for the various compositions were found to be $AgCl_{0.2}Br_{0.8} \geqslant AgBr > AgCl$ with approaching 50% filling for the highest yield specimen and *ca.* 20% for the lowest. A difficulty with directly observing the SWNT incorporated products in these kinds of experiments by HRTEM was that the silver halides are both light and electron beam sensitive. However, in the case of SWNTs with lower diameters, phototolytic reduction was apparently retarded and EDX showed that SWNT bundles incorporated with either of the two silver halides still contained both the metal and the respective halogen. For wide bore SWNTs, this was not the case and several were observed with pure Ag filling. Figure 2(d) shows a HRTEM image of a large diameter [≈ 38 Å; *ca.* (28,28) nanotube] SWNT completely filled with 17 layers of silver metal. The initial filling medium in this case was AgCl. A noticeable 'kink' in the SWNT (arrowed), possibly originating from defects present in the original SWNT [*cf.* Fig. 2(b)], causes a corresponding distortion in the incorporated crystal. The *d*-spacing of the material, measured relative to nearby 3.4 Å (0002) graphene fringes (not shown) was measured to be 2.04 ± 0.05 Å, which corresponds to the (200) *d*-spacing of Ag metal and not to the corresponding (020) *d*-spacing in AgCl (2.775 Å), which has a similar $Fm\bar{3}m$ cubic unit cell.[11] Fast Fourier transforms (FFTs) calculated from the lattice image of the incorporated crystal (not shown) also indicated that the Ag wire was veiwed close to a [100] projection and that the (020) lattice fringes belonged to this projection. Fig. 2(e) shows a HRTEM micrograph of the product of a high yield SWNT filling with AgBr within a bundle of (10,10) SWNTs. The paths of empty and filled SWNTs are indicated by dark and light arrows, respectively, and the difference in contrast between the empty and filled SWNTs is clearly visible. Several bundles similar to those illustrated in Fig. 2(e). were observed in this specimen with up to 50% of similarly filled SWNTs.

An important aspect of this work concerns the mechanism of opening of the SWNTs. Previously, we stated that SWNTs could be opened by gently refluxing in HCl.[8] However, none of the filling experiments described in this communication required a separate opening step which indicates that either one is unnecessary (*i.e.* the SWNTs are already open at at least one end) or that the fullerenic end caps of SWNTs are selectively attacked by the molten media during the filling process.

In conclusion, we have demonstrated a simple and reproducible method for the continuous filling of the capillaries of SWNTs in high yield with a variety of materials, thereby showing that these types of nanotubes exhibit similar wetting and capillarity properties to MWNTs. The advantages of using SWNTs over MWNTs in these types of filling experiments is that the former are relatively much more uniform and defect free structures in comparison to the latter and their composite properties will be correspondingly more uniform. The physical properties of the composite materials formed by the methods decribed here are expected to be considerably modified with respect to those of unfilled SWNTs.

Diastereo- and enantioselective synthesis of 2,8-dioxabicyclo[3.3.0]octan-3-one derivatives

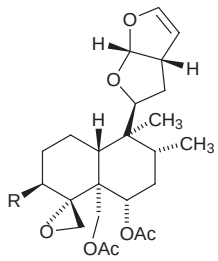
Dieter Enders,* Juan Vázquez and Gerhard Raabe

Institut für Organische Chemie, Rheinisch-Westfälische Technische Hochschule, Professor-Pirlet-Straße 1, D-52074 Aachen, Germany. E-mail: enders@rwth-aachen.de

Received (in Liverpool, UK) 8th December 1998, Accepted 11th March 1999

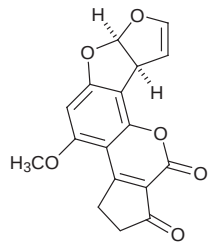
An efficient asymmetric synthesis of 4-substituted (1*S*,4*S*,5*R*)-2,8-dioxabicyclo[3.3.0]octan-3-one derivatives (de ⩾98%, ee = 80– > 98%) in good overall yields is reported by a stepwise Michael addition–α-alkylation and subsequent hydrolytic domino reaction protocol employing formaldehyde SAMP-hydrazone as a neutral formyl anion equivalent and 5,6-dihydro-2*H*-pyran-2-one as a Michael acceptor.

Many insect antifeedant clerodanes, such as clerodin (R = H) and caryoptin (R = OAc) **A** or mycotoxins like aflatoxin B_1 **B**,



A

clerodin (R = H)
caryoptin (R = OAc)



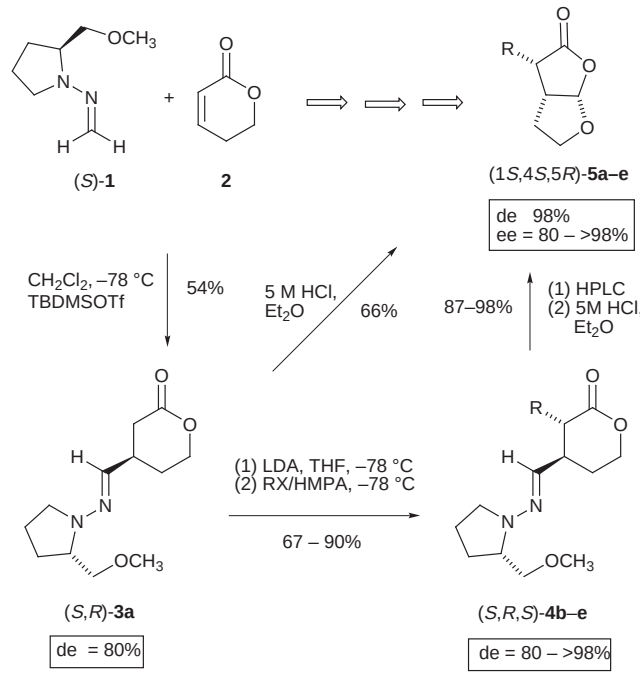
B

aflatoxin B_1

contain furo[2,3-*b*]furan moieties in various oxidation levels.[1] Although many synthetic methods for accessing such furofurans have been reported during the last decade,[2] there is still a need for enantioselective procedures suitable for structural variations and, for instance, their incorporation into the clerodane framework. Since it has been reported that this and other clerodane subunits may be crucial for insect antifeedant activity,[3,4] the development of novel asymmetric syntheses is an important goal in this context.

We describe here the asymmetric synthesis of diastereomerically pure and highly enantiomerically enriched derivates of the title perhydrofuro[2,3-*b*]furan lactone system based on the Michael addition of formaldehyde SAMP-hydrazone[5] **1** to 5,6-dihydro-2*H*-pyran-2-one **2** as the key step (Scheme 1).[6] The 1,4-adduct **3** was obtained under Lewis acid activation with TBDMSOTf (1.2 equiv.) in acceptable yield (54%) and good diastereomeric excess (de = 80%). Because the mixture of diastereoisomers of **3** was only separable by HPLC on chiral stationary phase, this mixture was directly used in the subsequent deprotonation–α-alkylations. The use of LDA at −78 °C, followed by addition of HMPA and finally the requisite alkylating agent afforded the 4-substituted lactone hydrazones **4** in good to excellent yields (67–90%) and diastereomeric excesses (de = 80– > 98%). The *trans* configuration of the disubstituted lactones **4** was determined by ^{1}H NMR spectroscopy through the *trans*-diaxial coupling constants (9.5–10.7 Hz) of the protons at the new stereogenic centres. This was confirmed by NOE experiments on compound **4b** (R = Me).† The absolute configuration of the minor diastereoisomer (*R*,*R*)-**4b** was determined by X-ray structure analysis,‡ the absolute configuration of the major diastereoisomer therefore being (3*S*,4*R*). Fortunately, in some cases the diastereoisomers of the lactone hydrazones **4** are separable by flash chromatography (**4b**) or by HPLC (**4c**,**d**) and it was possible to use the diastereomerically enriched hydrazones in the following key step.

Thus, the asymmetric Michael addition of **1** to pent-2-enolide **2** and subsequent α-alkylations enabled us to synthesize the appropriate precursors with the desired carbon skeleton for the formation of the title compounds. Finally, a domino reaction was initiated by acidic hydrolysis in a two-phase system and afforded the desired furofuran lactones derivatives **5**[7] in excellent yields (87–98%) and stereoisomeric purity (de ⩾ 98%, ee = 80–98%) (Table 1). Only in the case of the unsubstituted compound **5a** is the yield lower probably due to its sensitivity under the reaction conditions. The final cascade



Scheme 1

Table 1 Asymmetric synthesis of (1*S*,5*R*)-2,8-dioxabicyclo[3.3.0]octan-3-one derivatives

5	R	Yield[a] (%)	Mp[b]/°C	$[\alpha]_D^{RT}$ (*c*, $CHCl_3$)	Ee[c] (%)
a	H	66	oil	+29.5 (0.96)	85
b	Me	98 (75)[d]	78–80	+49.8 (0.95)	80 (> 98)[d]
c	Pr^n	97	oil	+76.8 (0.80)	88
d	Allyl	87	52–54	+75.6 (0.80)	> 98
e	Bn	90	oil	+104.4 (0.91)	80

[a] Yield after flash chromatography. [b] Uncorrected, measured on a Büchi apparatus. [c] Determined by GC on chiral stationary phases. [d] Figures in parentheses indicate values after recrystallization of the final product.

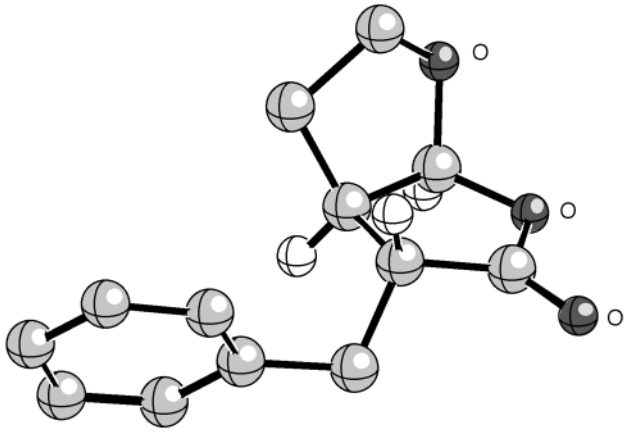


Fig. 1 X-Ray structure of furofuran lactone (1*S*,4*R*,5*R*)-**5e**.

steps involve the cleavage of the hydrazone moiety, opening of the lactone ring and, finally, formation of the furofuran lactone system through the corresponding hemiacetal intermediate.

The relative configuration of the perhydrofurofuran lactones **5** was confirmed by NOE experiments on (1*S*,4*S*,5*R*)-**5e**§ and the absolute configuration of this compound was determined by X-ray structure analysis of its minor diastereoisomer (1*S*,4*R*,5*R*)-**5e**, which was separable from the major one by HPLC (Fig. 1).¶ Assuming uniform reactions pathways, the absolute configuration of **5a**–**d** were assigned by analogy with **5e**.

The enantiomeric purity of all compounds was determined by GC on chiral stationary phases indicating the absence of racemization during our procedure. Some of the substituted derivatives of (1*S*,5*R*)-2,8-dioxabicyclo[3.3.0]octan-3-one **5a** were solids and enabled us to increase the ee of the final furofuran lactones by simple recrystallization.

The bicyclic lactone acetal **5a**, which constitutes a valuable chiral building block for the synthesis of clerodane derivatives, could be easily transformed to the alcohol and to the 2,3-dihydrofurofuran[8] derivatives widely encountered in the clerodane family.

In conclusion, our new procedure *via* asymmetric Michael addition of formaldehyde SAMP-hydrazone to pent-2-enolide followed by α-alkylations, and subsequent cleavage of the hydrazones using acidic hydrolysis in a two-phase system affords the desired 4-substituted furofuran lactone derivatives in acceptable overall yields (32–47%) and high diastereo- and enantiomeric purity (de ⩾98%, ee = 80–98%). In addition, pentenolides with different substituents in position 6 could allow access to a library of potential insect antifeedants. The extension of this methodology is currently under study in our laboratory.

Decapitation of dihydroporphyrazinediol derivatives: synthesis and X-ray structure of a novel seco-porphyrazine

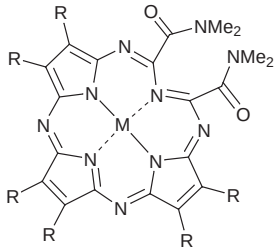
Hanlin Nie,[a] Charlotte L. Stern,[a] Anthony G. M. Barrett*[b] and Brian M. Hoffman[a]

[a] *Department of Chemistry, Northwestern University, Evanston, Illinois 60208, USA. E-mail: bmh@nwu.edu*
[b] *Department of Chemistry, Imperial College of Science, Technology and Medicine, London, UK SW7 2AY*

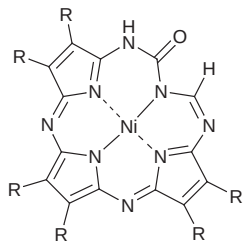
Received (in Cambridge, UK) 20th January 1999, Accepted 4th March 1999

The dihydroporphyrazinediol 8, which was prepared by Linstead macrocyclisation of 2,5-diiminopyrrolidine with 3,4-bis(4-*tert*-butylphenyl)pyrroline-2,5-diimine, followed by TFA demetallation and OsO_4 tetroxide mediated dihydroxylation, underwent reaction with $Ni(OAc)_2$ at 100 °C in the presence of air to give the novel seco-porphyrazine 10, the structure of which was established by an X-ray crystallographic study.

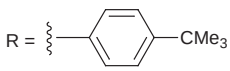
Recently, we described the synthesis of seco-porphyrazines **1a**–**d** by the peripheral oxidations of porphyrazines. Subsequent to our report, several related seco-chlorins have been described, and we have shown that porphyrazine **1d** (M = Zn) sensitises the formation of singlet oxygen with the remarkable overall quantum yield of $\phi_\Delta = 0.54$. In a continuation of our efforts to develop porphyrazines peripherally functionalised for metal bindings and porphyrazines with strong absorptions at wavelengths above 700 nm for biomedical applications, we have prepared porphyrazine *cis*-diols **8** *and* **9** *via* the OsO_4 mediated dihydroxylation of porphyrazines **6** and **7**, respectively. Surprisingly, reaction of diol **8** with $Ni(OAc)_2$ in air at 100 °C did not give any nickel(II) porphyrazinediol **9**. Instead, this procedure gave a mixture of products including a red pigment with much lower polarity than the porphyrazine diols **8** or **9**. Herein, we report the full characterisation of novel compound **10** a new type of seco-porphyrazine ring system generated by the loss of the two β-carbons of a pyrrole.



1a M = 2H, R = -NMe_2
b M = Zn, R = -NMe_2
c M = 2H, R = Pr
d M = Zn, R = Pr



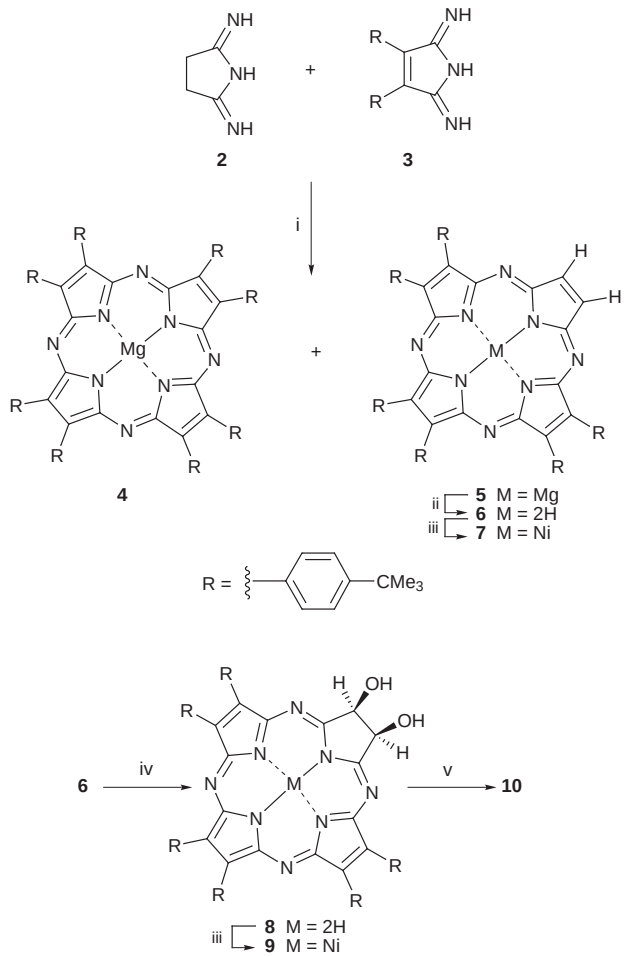
10



2,5-Diiminopyrrolidine **2** was co-macrocyclised with 3,4-bis(4-*tert*-butylphenyl)pyrroline-2,5-diimine **3** using $Mg(OBu)_2$ in BuOH at reflux (Scheme 1). The products contained both the unsymmetrical porphyrazine **5**† and symmetrical porphyrazine **4**, which were separated by chromatography. Demetallation of **5** by treatment with TFA gave the free base porphyrazine **6**. In a typical cyclisation, reaction of **2** with 3.5 equiv. of **3** ultimately led to porphyrazine **6** with an overall yield of 17% following demetallation. Subsequent reaction of **6** with $Ni(OAc)_2$ at 100 °C in PhCl–DMF (3 : 1) under N_2 resulted in the formation of nickel complex **7** (98% yield). Finally, OsO_4 mediated dihydroxylation of **6** and **7** gave dihydroporphyrazinediol **8** (69% yield) and the nickel(II) dihydroporphyrazinediol **9** (65% yield), respectively. Subsequent reflux of a solution of diol **8** with $Ni(OAc)_2$ in $CHCl_3$–MeOH (3 : 1) under nitrogen also gave the nickel diol **9** (90%).

The parent porphyrazine **6** showed a UV-visible absorption spectrum with two well separated Q-bands at λ_{max} 587 and 655 nm; porphyrazine 7 showed a typical metalloporphyrazine absorption spectrum, with a strong Q-band at 615 nm (Fig. 1) whereas the *cis*-diols **8** and **9** displayed different optical spectra from those observed for the related chlorins, 2,3-*vic*-dihydroxy *meso*-tetraphenylchlorins, with strong absorptions at λ_{max} 730 and 702 nm for porphyrazines **8** and **9**, respectively.

Reaction of porphyrazine **8** with 10 equiv. of $Ni(OAc)_2$ at 100 °C in PhCl–DMF (3 : 1) that had been only partially deaerated gave a mixture of products, including a new red pigment, denoted **10**, which was obtained with higher yields when porphyrazinediol **9** was reacted in air under similar conditions (Scheme 1). This pigment,‡ which was less polar



Scheme 1 *Reagents and conditions*: i, $Mg(OBu)_2$, BuOH, reflux; ii, TFA, then NH_4OH (17% from **2**); iii, $Ni(OAc)_2$, MeOH–$CHCl_3$, N_2, reflux (98%); iv, OsO_4, CH_2Cl_2–pyridine, then H_2S (69%); v, $Ni(OAc)_2$, DMF–PhCl, air, 100 °C (40%).

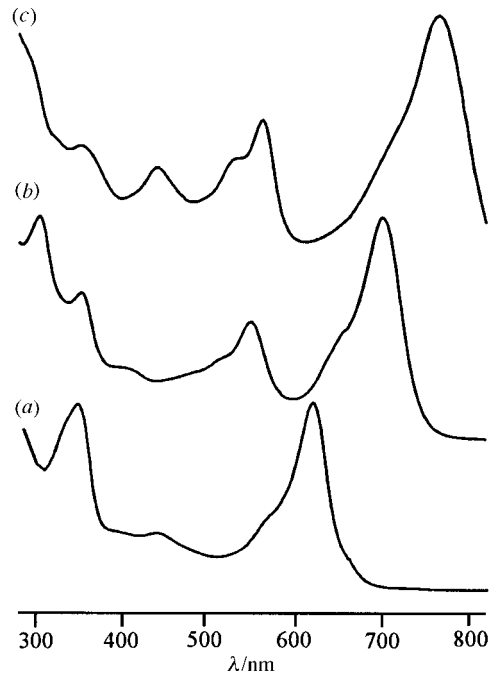


Fig. 1 UV-visible spectra of porphyrazines (*a*) **7** and (*b*) **9**, and (*c*) seco-porphyrazine **10**.

than the diols, was obtained in 40% yield after chromatography (silica, CH_2Cl_2–hexanes 4 : 1). Its UV-visible spectrum (Fig. 1) showed an unusual strong absorption band at λ_{max} 768 nm, which is red shifted by 66 nm compared to that of porphyrazinediol **9**.

Slow diffusion of MeOH into a $CHCl_3$ solution of **10** yielded single crystals suitable for X-ray crystallographic study,§ which (Fig. 2) unequivocally established the structure of the red pigment as seco-porphyrazine **10**. Spectroscopic measurements confirm the tautomeric form shown for **10**. Both ^{1}H and ^{13}C NMR spectra showed that the compound lacks the C_{2v} symmetry of the porphyrazine diols, and FAB$^+$ MS measurement was consistent with the composition of $C_{74}H_{80}N_8NiO$. The IR spectrum displayed a medium intensity band at ν_{max} 3380 cm^{-1} and a strong band at ν_{max} 1674 cm^{-1} which are consistent with the urea-like functionality on the ring of **10**, and ^{1}H NMR analysis showed the expected exchangeable proton signal at δ 9.45.

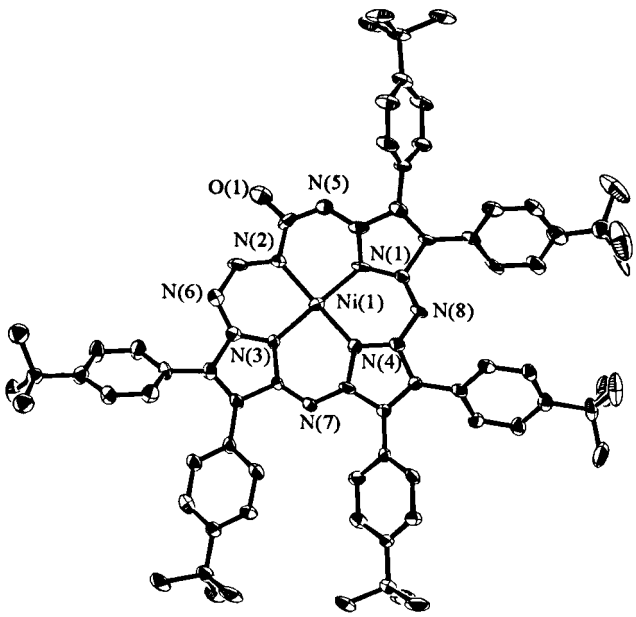

Fig. 2 X-Ray crystal structure of seco-porphyrazine **10**.

Compound **10** represents a novel macrocyclic ring system, which may result from the nickel-mediated air oxidation of the *cis*-diol unit and subsequent double loss of CO_2. Alternatively the mechanism may involve dehydration and subsequent cycloaddition of singlet oxygen, decarboxylation and deformylation. The methodology described above offers the opportunity for synthesis of the same type of heterocycles with other internal metal ions and different peripheral substituents for biomedical applications, and this investigation is in progress.

Synthesis and structures of neutral and cationic β-diketiminatoaluminium methyls†

Frédéric Coslédan, Peter B. Hitchcock and Michael F. Lappert*

The Chemistry Laboratory, University of Sussex, Brighton, UK BN1 9QJ. E-mail: m.f.lappert@sussex.ac.uk

Received (in Basel, Switzerland) 4th January 1999, Accepted 25th February 1999

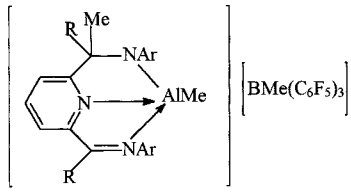
Trimethylaluminium with the β-diketimine H(LL) yields the aluminium complex [Al(LL)Me$_2$], from which the salts [Al(LL)Me(thf)][BMe(C$_6$F$_5$)$_3$]·0.5thf and [Al(LL)Me(OEt$_2$)][B(C$_6$F$_5$)$_4$]·0.5Et$_2$O have been prepared, and crystallographically characterised.

There is much current interest in bi- or tri-dentate nitrogen-centered spectator ligands, which often are a component of electrophilic metal alkyl catalysts for olefin polymerisation or related reactions. Emphasis has been on Ti^{IV}, Zr^{IV}, Fe^{II}, Co^{II}, Ni^{II} or Pd^{II} complexes.[1] Attention is also now turning to Al compounds, triggered by the disclosure of Coles and Jordan in 1997 that certain cationic amidinatoaluminium methyls **A**–**C** are active catalysts for polymerisation of ethylene [**A** > **B** or **C**; LL = Bu^{t}C(NPr^i)$_2$ in **A** or **B**, but MeC(NPr^i)$_2$ in **C**];[2] as are compounds **D** (R = H, Ar = C$_6$H$_3$Pr$^i_2$-2,6 or C$_6$H$_2$Me$_3$-2,4,6; or, the least active, R = Me, Ar = C$_6$H$_3$Pr$^i_2$-2,6)[3] and **E** (LL = **G**),[4] while the X-ray-characterised **F** only showed only trace activity.[4]

[Al(LL)Me][B(C$_6$F$_5$)$_4$] **A**

[{Al(LL)Me}$_2$(μ-Me)][BMe(C$_6$F$_5$)$_3$] **B**

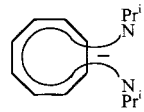
[$^+$Al(LL)(Me)…MeB$^-$(C$_6$F$_5$)$_3$] **C**



D

[Al(LL)R][B(C$_6$F$_5$)$_4$] **E** (R = Et or Bu^t)

[{Al(LL)Me}$_2$(μ-Pr^i)][B(C$_6$F$_5$)$_4$] **F**



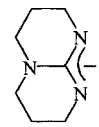
G

Nitrogen-centered, bidentate, monoanionic, four-electron spectator ligands [LL]$^-$ which form four-coordinate aluminium dimethyls [Al(LL)Me$_2$] are the amidinates [LL = RC(NR′)$_2$],[2,5] guanidinates [LL = R$_2$NC(NR′)$_2$ or **H**],[6] aminotroponimate **G**[4,7] and the β-diketinimates **I**;[8] the thioureido complex [Al{N(Ad)C(Me)S}Me$_2$] is a close relative (Ad = adamantyl).[9]

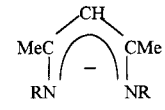
Tridentate, monoanionic ligands, such as those in **D**[2] or [R(H)N(CH$_2$)$_2$N(Me)(CH$_2$)$_2$NR] (R = Me or SiMe$_3$)[10] have yielded five-coordinate AlMe$_2$ complexes. The diketiminatoaluminium compounds [Al(LL)Me$_2$] (LL = **I**, R = C$_6$H$_4$Me-4) failed to furnish an isolable cationic complex with B(C$_6$F$_5$)$_3$.[8] The related compounds [Al(LL)R′$_2$] (LL = **I** with R = C$_6$H$_3$Pr$^i_2$-2,6 and R′ = Et or Bu^i) with [Ph$_3$C][B(C$_6$F$_5$)$_4$] and (for R′ = Et) then PhNMe$_2$ gave [Al(LL)Et(NMe$_2$Ph)][B(C$_6$F$_5$)$_4$] or [Al(LL)Bu^i][B(C$_6$F$_5$)$_4$] (structures based on ^{1}H and ^{13}C NMR spectral data).[11]

† No reprints available.

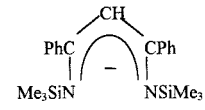
We now report the synthesis and structures of the crystalline β-diketiminatoaluminium compounds [Al(LL)Me$_2$] **1**, [Al(LL)Me(thf)][BMe(C$_6$F$_5$)$_3$] **2** and [Al(LL)Me(OEt$_2$)][B(C$_6$F$_5$)$_4$] **3**, and of some related complexes based on the spectator ligand **J**.[12] Compounds **2** and **3** are the first X-ray-characterised, mononuclear, four-coordinate, cationic aluminium methyls. Preliminary experiments, to be reported in details elsewhere, show that **3** catalyses the conversion of MMA to syndiotactic PMMA of low polydispersity.



H



I (R = C$_6$H$_3$Pr$^i_2$ or C$_6$H$_4$Me-4)



J

The β-diketiminatoaluminium dimethyl **1** was obtained (Scheme 1, step i) by addition of trimethylaluminium to an equivalent portion of the β-diketimine H(LL) (LL = **J**).[12] Treatment of **1** in diethyl ether with tris(pentafluorophenyl)borane in pentane and addition of thf yielded (Scheme 1, step ii) the cationic methylaluminium tris(pentafluorophenyl)methylborate **2**. When the same procedure was carried out, but omitting addition of thf, a sticky orange product, tentatively formulated as impure **4** (on the basis of the ^{11}B NMR spectral signal at δ −16.85; *cf.* δ −16.7 (**2**), −19.1 (**3**) and −19.0 (**4**), was obtained (Scheme 1, step iv). From equivalent portions of **1** and *N*,*N*-dimethylanilinium tetrakis(pentafluorophenyl)borate in toluene at ambient temperature and successive removal of toluene, washing with pentane, dissolution of the residue in diethyl ether and crystallisation the cationic methylaluminium salt **3** (Scheme 1, step iii) was isolated. In a similar NMR spectroscopic experiment in C$_6$D$_6$ rather than toluene, but without addition of Et$_2$O, quantitative formation of the related salt **5** is inferred (step v of Scheme 1).

The new, pale yellow, highly air-sensitive, readily benzene-soluble, crystalline compounds **1**–**3** gave satisfactory analyses, NMR solution spectra (to be reported in the full paper) and single crystal X-ray diffraction data. The EI-MS data showed the highest *m/z* peak corresponded to [M − Me]$^+$ for **1** and [B(C$_6$F$_5$)$_3$]$^+$ for **2**.

The molecular geometry of crystalline **1** (details to be published in the full paper) and the two compounds [Al(LL)Me$_2$] (LL = **I**)[8] are closely similar, Table 1. The AlNCCCN fragment in **1** has the boat conformation, as previously found *inter alia* in [Li(LL)]$_2$ and Sn(LL)Me$_3$,[12] although sometimes this β-diketiminatometal moiety is planar, as in [Co(LL)$_2$][13] (LL = **J**).

The molecular structures of the cations of the crystalline salts **2** and **3** are illustrated in Fig. 1 (**2**) and 2 (**3**); the anions will be described in the full paper. The four-coordinate aluminium atom in each cation has a distorted monopyramidal (TMP) geometry, with a similar distortion from tetrahedral to TMP. The Al–C distances are significantly shorter in each cation than in the neutral precursor **1**, but the Al–N bonds are slightly longer due to the widening of the N–Al–N′ angle in **2** or **3** compared with **1**, Table 1. The remaining geometric parameters of the β-diketiminato ligand are very similar in **1**–**3**. The sum of the angles at each nitrogen atom (of **1**–**3**) is close to 360°. There is no evidence of significant cation–anion interaction; the anion structures are unexceptional.[14]

The NMR spectra of compounds **1**–**3** in C$_6$D$_6$ (**1** and **3**) or CDCl$_3$ (**2**) indicate that the solution structures of **1**–**3** are identical to those in the crystal, except that in **1** there is only one ^{1}H or ^{13}C(^{1}H) signal for the two methyl groups, indicating that they undergo fast exchange.

The present results demonstrate once again [*e.g.*[15] the monomeric [Ce(LL)$_2$Cl] (LL = **J**)] that the β-diketiminato ligand **J** is exceptionally sterically demanding, having allowed us to prepare the well separated ion pairs in **2** and **3**; reactivity and catalytic studies are in hand. This ligand can be fine-tuned by varying the substituents in its skeleton.

We thank EPSRC for support.

Phase transitions in disordered solids *via* hybrid Monte Carlo: the orthorhombic to cubic phase transition in $(Mg,Mn)SiO_3$ perovskite

John A. Purton,[ab]† Neil L. Allan*[a] and Jon D. Blundy[b]

[a] *School of Chemistry, University of Bristol, Cantock's Close, Bristol, UK BS8 1TS. E-mail: n.l.allan@bristol.ac.uk*
[b] *CETSEI, Department of Geology, University of Bristol, Wills Memorial Building, Bristol, UK BS8 1RJ*

Received (in Cambridge, UK) 11th January 1999, Accepted 9th March 1999

We show how a novel hybrid Monte Carlo simulation technique can be used to investigate the influence of high impurity or defect concentrations on phase transitions; impurity cations can have a much larger effect than that expected from a mean-field treatment or linear interpolation between end-member compounds.

We report a novel computational methodology for determining the phase stability of disordered inorganic materials and solid solutions. The motivation for this work is twofold. Firstly, although calculations have provided considerable insight into the thermodynamic and structural aspects of materials,[1] most have been limited to the study of solids with periodic, ordered structures. Secondly, a detailed understanding of the thermodynamics and phase stability of disordered solids is crucial for many areas of mineralogy and solid-state chemistry. For example, minerals often contain a large number of minor and trace element impurities, possibly disordered over several crystallographic sites, which may have dramatic effects on physical and chemical behavior and phase stability.

Supercell or *point* defect calculations have traditionally been used to investigate impurities in solid state materials. The clear limitations of these methods for systems with an appreciable impurity or defect content exclude studies of many naturally occurring minerals and ceramics of industrial importance. Accordingly, the principal objective of this work is to show how a modified hybrid Monte Carlo (HMC) technique can be used to study the effect of disorder on phase transitions in ionic solids and minerals. The HMC technique permits an efficient sampling of different configurations, takes explicit account both of ionic relaxation near impurity ions and thermal effects, and is readily extended to different ensembles. Our methods do not involve the use of an approximate parameterised Hamiltonian since the parameterisation of, for example, an Ising-type Hamiltonian becomes increasingly difficult beyond binary or pseudobinary mixtures and can average out local effects due to ion clustering and association. Moreover, such methods cannot readily be extended to include the effects of lattice vibrations and pressure.

Most Earth materials are solid solutions rather than pure end-members and an understanding of the effect of trace components is essential. Many properties of the deep Earth, such as electrical conductivity,[2] phase changes[3] and rheology are profoundly altered by the presence of impurities at concentrations of a few wt%, or less. The magnesium-rich silicate perovskite is thought to be the major constituent of the Earth's lower mantle and an understanding of its thermodynamic and physical behaviour is crucial for a wide range of geophysical and geochemical problems such as the convection and chemical differentiation of the mantle. Previous work[4] used constant-pressure molecular dynamics (MD) to demonstrate that at pressures above 10 GPa, orthorhombic $MgSiO_3$ undergoes a temperature induced phase transition to a cubic phase prior to melting, whereas at lower pressures the orthorhombic phase melts without any change of solid phase. The size difference between Mn^{2+} and Mg^{2+} is such that Mn–Mg mixing in silicates is expected to be quite non-ideal[5] and so here we investigate the effect of Mn, a minor element constituent of the Earth's mantle, on the high pressure orthorhombic–cubic phase transition. The potential model used within this study has been discussed previously;[6] we have employed the ionic model assigning charges of +1.2 for Mg and Mn, –1.2 for O and +2.4 for Si, and used the set of short-range potential parameters discussed in ref. 3.

The HMC approach we have developed is related to that used in the modelling of polymers and biomolecules.[7–9] The technique has been applied recently to such problems as the enthalpies of mixing of binary oxides[10] and non-convergent ordering of cations in olivine,[11] but not thus far to phase transitions. During one HMC cycle, one of three options is chosen at random, with equal probability. The first of these is a short NVE molecular dynamics (MD) simulation consisting of 15 steps and with a timestep of 1.5 fs. The length and timestep were chosen so as to allow efficient sampling of the different configurations. The last configuration is accepted or rejected by comparing its energy with the energy of the starting configuration and using the standard Metropolis algorithm.[12] If the last configuration is rejected, the original configuration is included in the statistical averaging of thermodynamic properties. In the second, which is only applicable to the solid solution, a short MD run follows a random exchange of Mg and Mn ions. Again, the difference in energy between the previous configuration and that immediately after the MD simulation is used in the Metropolis algorithm. At the start of each MD run, velocities are chosen anew at random from a Maxwellian distribution. The third option is a random change of the volume/shape of the box,[13] which again is accepted or rejected using the Metropolis algorithm. Enthalpy and structural data were averaged over a period of 50 000 cycles, prior to which an equilibration period of 50 000 cycles was undertaken. Results presented here are for a simulation cell containing 540 ions ($3 \times 3 \times 3$ unit cells).

For $MgSiO_3$ we obtain very similar results using HMC to those of the MD study of Matsui and Price[4] with a calculated transition temperature of 3900 K at 20 GPa from the orthorhombic to the cubic phase. Fig. 1 shows the calculated variation of the lattice parameters for $Mg_{0.6}Mn_{0.4}SiO_3$ which shows that this compound also undergoes a similar phase transition at this pressure. From the calculated transition temperatures at 20 GPa for $Mg_xMn_{1-x}SiO_3$ (Fig. 2) as a function of composition *x*, it is clear that a linear extrapolation between the two end members, is a very poor approximation. For example, the phase transition for $Mg_{0.6}Mn_{0.4}SiO_3$ is at a much lower temperature (2500 ± 50 K) than the value of almost 3000 K predicted by a simple linear interpolation of transition temperature *vs.* composition. In this context it is worth noting that, unlike the transition temperature, the calculated volume as a function of composition displays only a small positive deviation from Vegards' law, since the *a* lattice parameter itself has a positive and the *b* and *c* lattice parameters a negative deviation. We have been unable to find any experimental data for comparison. An orthorhombic–cubic transition at high

† Present address: CLRC, Daresbury Laboratory, Warrington, Cheshire WA4 4AD, UK.

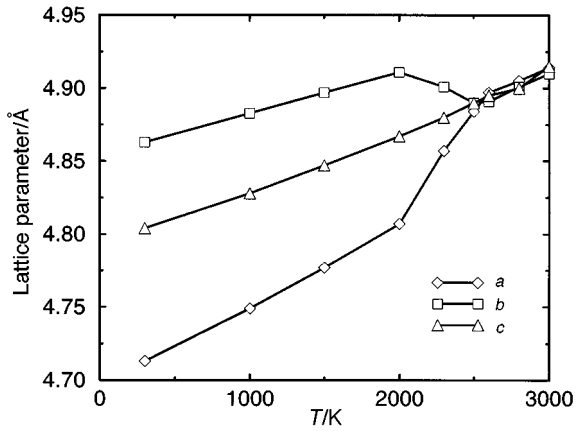

Fig. 1 Lattice parameters (Å) *vs.* T(K) at 20 GPa for $Mg_{0.6}Mn_{0.4}SiO_3$.

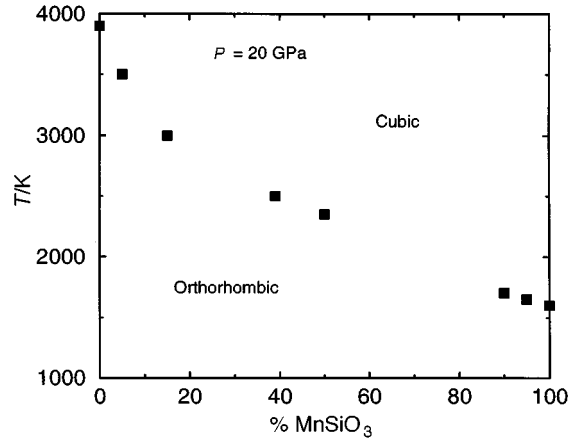

Fig. 2 Calculated orthorhombic–cubic transition temperature (K) at 20 GPa *vs.* composition.

pressure by the analogous compound (Mg,Fe)SiO_3, for which experimental evidence is currently contradictory,[14] would have important implications for the thermodynamic and compositional modelling of the Earth's mantle since thermodynamic data is often extrapolated from low pressures and temperatures and from the end-member compositions.

In summary, the HMC technique removes major limitations of the existing methods for the simulation of phase transitions in disordered solids, which restrict considerably the contact between experiment and theory. The methodology is general and readily applicable to a wide range of real rather than model, undefective systems. It is essential to take explicit account of ionic relaxation in each of the configurations without any averaging out of local effects. We envisage that that our new approach will add significantly to our understanding of the behaviour of complex systems at the atomic level, providing an important link between the microscopic and macroscopic behaviour of ceramics and minerals, and hope the present study will prompt new experimental investigations of the effects of trace impurities on high-pressure phase transitions.

Catalytic reaction of methane with $CBrF_3$

Kai Li,[a] Eric Kennedy,*[a] Bogdan Dlugogorski[a] and Russell Howe[b]

[a] *Department of Chemical Engineering, University of Newcastle, Callaghan, NSW 2308, Australia. E-mail: cgek@cc.newcastle.edu.au*
[b] *School of Chemistry, University of New South Wales, Sydney, NSW 2052, Australia*

Received (in Cambridge, UK) 4th February 1999, Accepted 10th March 1999

The catalytic reaction of CH_4 with $CBrF_3$ over Co, Cu and Mn ZSM-5 zeolites is described; major products (at low temperatures) are those expected for simple hydrodebromination: CH_3Br and CHF_3.

The hydrodehalogenation reaction of chlorofluorocarbons (CFCs) and bromofluorocarbons or bromochlorofluorocarbons (halons) are potentially important reactions for both disposal of ozone depleting chemicals and production of hydrofluorocarbon replacements. Previous work in this area has focussed on reactions of CFCs with hydrogen over supported palladium catalysts.[1–12] Little attention has been paid to the corresponding hydrodebromination of halons. Here we describe for the first time the catalytic reaction of halon 1301 ($CBrF_3$) with methane over transition metal exchanged ZSM-5 zeolites. This novel catalytic reaction offers potential new routes to hydrofluorocarbons using methane as the hydrogen source.

Cobalt, copper and manganese exchanged ZSM-5 zeolites were prepared from a commercial ZSM-5 (PQ, Si/Al = 25), and charged into an alumina plug flow microreactor. Reactant gas stream (CH_4–$CBrF_3$–N_2 = 1 : 1 : 10) was flowed over the catalyst at a GHSV of 3500 h^{-1}, and products were analyzed by on-line gas chromatography after passing through a caustic scrubber.

Fig. 1 shows typical $CBrF_3$ conversions *versus* time on stream over four different zeolite catalysts at 873 K. Also shown is the corresponding conversion in the homogeneous reaction, as reported elsewhere.[13] The gas phase reaction between CH_4 and $CBrF_3$ begins at *ca.* 800 K, and increases dramatically above 900 K. A striking feature of the reaction in the presence of zeolite catalysts is the initial high conversion of $CBrF_3$ which then falls to a steady state value. Our preliminary investigations of this breakthrough period suggest reaction of $CBrF_3$ with the zeolite which generates the active phase for the hydrodehalogenation reaction. ^{27}Al MAS NMR measurements show that framework tetrahedral aluminium in the zeolite is completely transformed into an as yet unidentified form, although XRD analysis shows no change in the zeolite structure. In the case of HZSM-5, the steady state conversion approaches that found in the absence of catalyst. For the transition metal exchanged zeolites, however, there is a very evident influence of catalyst on the steady state conversion. It is important to note that zeolite crystallinity is fully retained during this reaction, even after 36 h on stream.

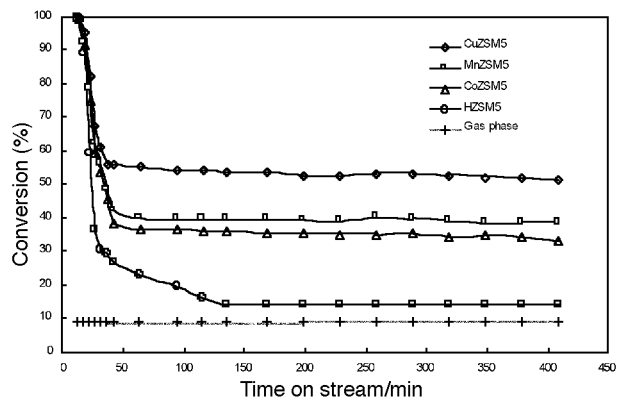

Fig. 1 Conversion of $CBrF_3$ *versus* time on stream at 873 K over various catalysts.

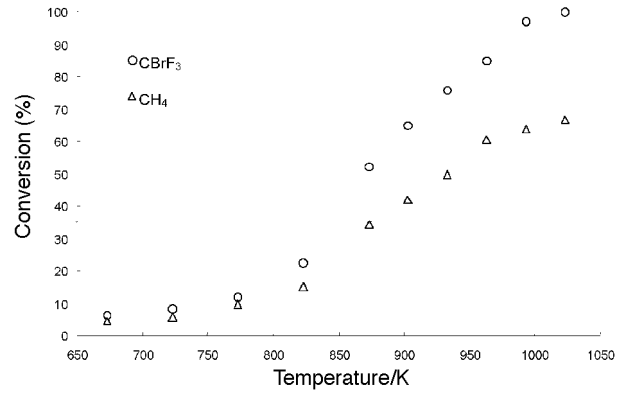

Fig. 2 Steady state conversion of $CBrF_3$ and CH_4 *versus* temperature over MnZSM-5.

Fig. 2 plots the steady state $CBrF_3$ and CH_4 conversions *versus* reaction temperature over MnZSM-5; similar profiles were measured for the other transition metal zeolites. The $CBrF_3$ conversion exceeds that of CH_4 at all temperatures, suggesting that the reaction pathway is more complex than that predicted for the simple 1:1 stoichiometry of reaction (1):

$$CBrF_3 + CH_4 \rightarrow CH_3Br + CHF_3 \quad (1)$$

In separate experiments, we have noted that $CBrF_3$ undergoes pyrolysis reactions over the same catalysts, producing C_2F_6 and Br_2,[14] and C_2F_6 was detected as a minor product also in the reactions with methane. The major reaction products detected in the reactions with methane at lower temperatures are those expected from reaction (1), as illustrated in Fig. 3. Above 873 K, however, the yield of CH_3Br declines, and other reaction products appear, (notably hydrocarbons C_2H_4 and C_2H_2), due to further reaction of CH_3Br. Other products identified include $C_2H_2F_2$, C_2H_3Br, CH_2BrF, and trace (less than 5 ppm) quantities of $C_2HBr_2F_3$, CH_2Br_2, C_2F_6, $C_2H_3F_3$, C_6H_5Br and H_2. Mass balances for all reactions were generally better than ±

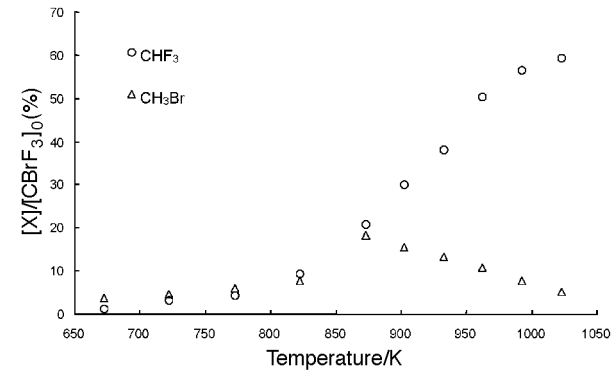

Fig. 3 Steady state conversion of $CBrF_3$ to major products CHF_3 and CH_3Br *versus* temperature over MnZSM-5.

3% and usually ± 1%, and suggest any as-yet unidentified species represent only a small fraction of reaction products.

The reaction mechanisms involved in this intriguing chemistry are not yet clear. The high initial conversions of $CBrF_3$, and the results of preliminary characterization experiments on catalysts exposed to $CBrF_3$ plus CH_4 or $CBrF_3$ alone for short periods[14] suggest that initial reaction of $CBrF_3$ with fresh catalysts generates the catalytically active species. The high reaction selectivity (at low temperatures) may result from the selective cleavage of C–Br bonds in preference to C–F bonds in $CBrF_3$, and reflects the lower relative strength of the C–Br bond (295 kJ mol^{-1})[15] compared with C–F bonds (*ca*. 460 kJ mol^{-1}, estimated from analogous F–CF_2Cl bond strength) in CF_3Br. Low temperature cleavage of C–Br would occur before evidence of C–F bond cleavage, leaving the CF_3 moiety intact.

Further work is needed to optimize catalysts, identify active sites and determine reaction pathways. At present we are also investigating the reactions of CFCs and other halocarbons with methane. The results presented here offer a new route for methane utilization in the disposal and upgrading of ozone depleting materials.

This work has been supported by the Australian Research Council.

Syntheses of mixed-metal $M_2Ti_2S_4$ cubane-type sulfido clusters (M = Ru, Rh, Ir, Cu) from a dinuclear organometallic thiotitanate anion

Takashi Amemiya, Shigeki Kuwata and Masanobu Hidai*

Department of Chemistry and Biotechnology, Graduate School of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113-8656, Japan. E-mail: hidai@chembio.t.u-tokyo.ac.jp

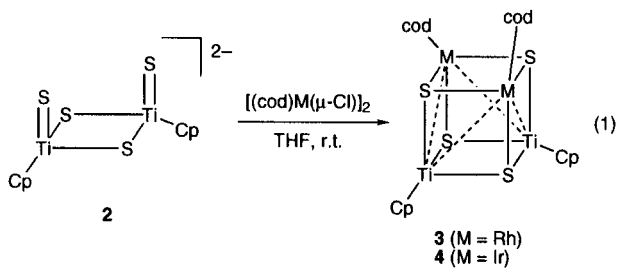
Received (in Cambridge, UK) 5th February 1999, Accepted 8th March 1999

The dinuclear organometallic thiotitanate anion $[(CpTiS)_2(\mu\text{-}S)_2]^{2-}$ reacted with $[Cp^*Ru(\mu_3\text{-}Cl)]_4$, $[(cod)M(\mu\text{-}Cl)]_2$ (M = Rh, Ir) and $[Cu(\mu_3\text{-}Cl)(PPh_3)]_4$ to afford the early–late heterobimetallic cubane-type sulfido clusters $[(CpTi)_2(Cp^*Ru)_2(\mu_3\text{-}S)_4]$, $[(CpTi)_2\{M(cod)\}_2(\mu_3\text{-}S)_4]$ and $[(CpTi)_2\{Cu(PPh_3)\}_2(\mu_3\text{-}S)_4]$, respectively.

Mixed-metal sulfido clusters have been the subject of much attention owing to their possible relevance to biological and industrial catalysis.[1] Thiometalate anions such as $[MS_4]^{2-}$ (M = Mo, W) are now recognized as versatile building blocks for the syntheses of such clusters.[2] Recently organometallic thiometalates, which contain both hydrocarbyl and sulfido ligands, have often been employed to this end because of their solublity in organic solvents and facility for the NMR study.[3] However, employment of polynuclear organometallic thiometalates as precursors for syntheses of heterometallic clusters remains undeveloped[4] compared with uncharged metal–sulfur aggregates with hydrocarbyl ligands.[5] As to group 4 metals, thiometalate species themselves are quite rare.[6] Kubas and coworkers have recently prepared the organometallic thiotitanate salt $[Na_4(thf)_8][\{(CpTiS)_2(\mu\text{-}S)_2\}_2]$ **2** from $[Cp_2Ti(SH)_2]$ **1** and an equimolar amount of sodium hydride.[7] Since the Ti_2S_4 framework in **2** may be regarded as a part of the cubane-type metal–sulfur core, it is expected to incorporate heterometals into the two missing vertices to afford mixed-metal cubane-type sulfido clusters. Indeed, more prevalent group 6 metal–sulfur aggregates with similar M_2S_4 frameworks are known to form a variety of mixed-metal cubane-type clusters in such a manner.[8,9] In our ongoing effort to develop the syntheses and reactivities of cubane-type sulfido clusters,[9–11] we have found that **2** reacts with late transition metal complexes to give a series of mixed-metal cubane-type sulfido clusters containing titanium.

Because of the low stability of **2**, we used **2** for further reactions without its isolation. To the dark green solution of **2** in THF was added $[(cod)M(\mu\text{-}Cl)]_2$ (M = Rh, Ir) in a Ti : M ratio of 1 : 1, and the mixture was stirred for 3 h at room temperature. The resultant dark brown suspension was evaporated *in vacuo* and extracted with benzene. Subsequent recrystallization from dichloromethane–ethanol afforded the mixed-metal cubane-type sulfido clusters $[(CpTi)_2\{M(cod)\}_2(\mu_3\text{-}S)_4]$ (**3**, M = Rh; **4**, M = Ir) in moderate yield [eqn. (1)].† The ^1H NMR spectra of **3** and **4** show the presence of both Cp and cod ligands in a ratio of 1 : 1. The heterobimetallic cubane type structure has further been confirmed by the X-ray analysis for **3** (Fig. 1).‡ The structure of **3** closely resembles that of the related ruthenium cluster $[(CpTi)_2(Cp^*Ru)_2(\mu_3\text{-}S)_4]$ **5**, which we have recently prepared through a different synthetic route.[11] The Ti–Ti distance of 3.051(2) Å is comparable to that in **5** [3.060(1) Å].[11] The four Ti–Rh distances [2.927(1)–3.056(1) Å] are consistent with the Rh→Ti dative bond, which is observed in the thiolato-bridged heterobimetallic complex $[CpTi(\mu\text{-}SCH_2CH_2CH_2S)_2Rh(nbd)]$ (nbd = norbornadiene) with a Ti–Rh distance of 2.915(2) Å.[12] The long Rh–Rh distance in **3** [3.575(1) Å] precludes the presence of the metal–metal bond. Very recently, Oro and coworkers have prepared the related titanium–rhodium sulfido clusters $[CpTi(\mu_3\text{-}S)_3\{Rh(tfbb)\}_3]$[13] (tfbb = tetrafluorobenzobarrelene) and $[(CpTi)_2\{Rh(CO)\}_2\{Rh(CO)[P(OPh)_3]\}_2(\mu_4\text{-}O)(\mu_3\text{-}S)_4]$[14] by the reaction of **1** with $[(diene)Rh(\mu\text{-}OMe)]_2$.

To delineate the synthetic versatility of the dinuclear organometallic thiotitanate **2** we have further investigated the reaction of **2** with various heterometal complexes. As expected, treatment of **2** with $[Cp^*Ru(\mu_3\text{-}Cl)]_4$ resulted in the formation of the known titanium–ruthenium heterobimetallic cubane-type sulfido cluster **5** in 49% yield; furthermore, **2** also reacted with $[Cu(\mu_3\text{-}Cl)(PPh_3)]_4$ to give the novel titanium–copper cluster $[(CpTi)_2\{Cu(PPh_3)\}_2(\mu_3\text{-}S)_4]$ **6** (Scheme 1). The molecular structure of **6** has unequivocally been determined by the X-ray analysis (Fig. 2).‡ Each Ti atom adopts a three-legged piano stool geometry, whilst each Cu atom has a tetrahedral geometry. The short Ti–Cu distances of 2.8093(9)–2.833(1) Å suggest the dative interaction between the d^{10} copper centre and the d^0 titanium centre. Related Cu→Ti dative bonds are found in thiolato-bridged heterobimetallic complexes such as $[Cp_2Ti(\mu\text{-}SMe)_2Cu(NCMe)_2][PF_6]$ [2.847(2) Å].[15] In contrast, the Cu–Cu



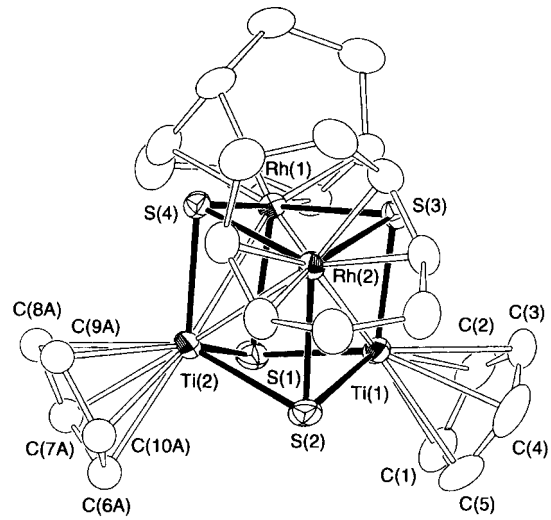


Fig. 1 Molecular structure of **3**. One of the cyclopentadienyl groups [C(6)–C(10)] was found in two disordered positions and refined as rigid groups with the occupancies of 60 and 40%. The minor component as well as all hydrogen atoms is omitted for clarity. Selected interatomic distances (Å): Ti(1)–Ti(2) 3.051(2), Ti(1)–Rh(1) 2.927(1), Ti(1)–Rh(2) 3.056(1), Ti(2)–Rh(1) 3.007(1), Ti(2)–Rh(2) 2.940(1), Rh(1)–Rh(2) 3.575(1).

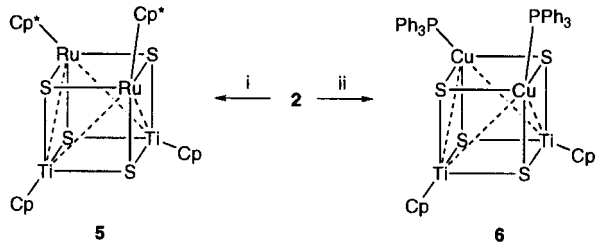

Scheme 1 *Reagents*: i, $[Cp^*Ru(\mu_3\text{-}Cl)]_4$; ii, $[Cu(\mu_3\text{-}Cl)(PPh_3)]_4$.

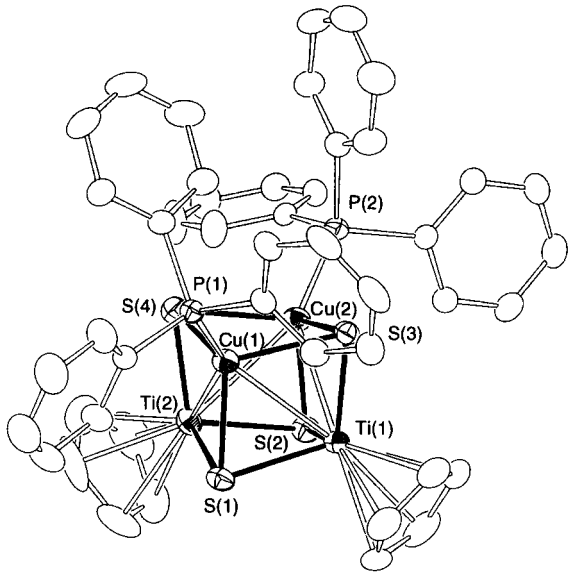

Fig. 2 Molecular structure of **6**. Hydrogen atoms are omitted for clarity. Selected interatomic distances (Å): Ti(1)–Ti(2) 3.178(1), Ti(1)–Cu(1) 2.8093(9), Ti(1)–Cu(2) 2.8306(9), Ti(2)–Cu(1) 2.8155(9), Ti(2)–Cu(2) 2.833(1), Cu(1)–Cu(2) 2.878(1).

distance in **6** [2.878(1) Å] falls in the range of those observed in Cu^I clusters which contain little direct metal–metal interaction according to theoretical calculations (2.60–3.26 Å);[16] however, the closed-shell interactions between the d^{10} metal centres remain debatable.[17] The Ti–Ti distance [3.178(1) Å] is comparable to the nonbonding Ti^{IV}–Ti^{IV} contact in the parent complex **2** [3.174(1) Å].[7]

Mixed-metal sulfido clusters containing group 4 metals are still scarce compared with those of group 6 and 8 metals.[18] The present study has demonstrated that the dinuclear organometallic thiotitanate **2** serves as a useful precursor to early–late heterobimetallic cubane-type sulfido clusters containing titanium. Further studies on syntheses of heterobimetallic clusters from **2** as well as the reactivities of **3**–**6** are now under way.

One-pot stereoselective synthesis of tricyclic γ-lactones from 2-methoxyfuran and 2-methoxyphenols

Polisetti Dharma Rao, Chien-Hsing Chen and Chun-Chen Liao*

Department of Chemistry, National Tsing Hua University, Hsinchu, Taiwan 300. E-mail: ccliao@faculty.nthu.edu.tw

Received (in Cambridge, UK) 16th February 1999, Accepted 10th March 1999

A one-pot synthesis of the title compounds is achieved *via* highly facile Diels–Alder reactions of 2-methoxyfuran with masked *o*-benzoquinones.

The butyrolactone moiety features in a large number of natural products which exhibit interesting and useful biological activities.[1] Moreover, the butyrolactone moiety is an immediate precursor of the α-methylene-γ-butyrolactone substructure which also features in many pharmacologically important natural products.[1,2] During the synthesis of natural products, construction of a β,γ-fused butyrolactone skeleton is generally achieved in a linear fashion using various precursors that contribute at least two carbons to the butyrolactone moiety.[2,3] In contrast, there are no efficient methods that can directly and stereoselectively introduce a β,γ-fused butyrolactone unit into a carbocycle in an intermolecular reaction using a four-carbon unit.[4] In this regard, the intermolecular Diels–Alder reactions of 5-alk-1-enylfuran-2(3*H*)-one with maleic anhydride, vinyl sulfones and α-chloroacrylonitrile and intramolecular cycloaddition reactions of 5-alkadienylfuran-2(5*H*)-one are noteworthy.[5]

Masked *o*-benzoquinones (MOBs) are a type of cyclohexa-2,4-dienones with a high propensity to dimerize.[6] Our laboratory has succeeded in developing efficient procedures for their generation and in identifying their immense synthetic potential especially as dienes in Diels–Alder reactions. Their inter- and intra-molecular Diels–Alder reactions have been shown to be quite useful in the synthesis of various polysubstituted cyclohexanes, *cis*-decalins, bicyclo[2.2.2]octenones, bicyclo[4.2.2]-decenones, linear and angular triquinanes.[7,8] Although furans have been widely used as dienes in Diels–Alder reactions,[9] their dienophilic behavior was observed only in a few specially activated cases.[10] Recently we have clearly shown that furan as well as some of its derivatives can function efficiently as dienophiles in their Diels–Alder reactions with selected MOBs.[11] It occurred to us that if 2-alkoxyfurans can also function as dienophiles, the reactions would provide an easy means for the direct and stereoselective synthesis of β,γ-fused butyrolactones. Accordingly, Diels–Alder reactions of 2-methoxyfuran with several MOBs were examined. We herein report that 2-methoxyfuran reacts as a dienophile with MOBs **1a–l** generated from 2-methoxyphenols **2a–l** to provide an easy access to highly functionalized tricyclic γ-lactones **3a–l** in excellent yields (Scheme 1, Table 1).

Addition of 2-methoxyfuran to a freshly prepared MOB **1** in MeOH at 0 °C (Method A) or gradual addition of (diacetoxy)-iodobenzene (DAIB) to a mixture of 2-methoxyphenol **2** and 2-methoxyfuran in MeOH at room temperature (Method B) affords ortho esters of the type **5**. These cyclic ortho esters, which should have resulted from the addition of MeOH to the initially formed cyclic ketene acetals **4**, are not stable to purification by column chromatography and are not characterized. Instead they were hydrolyzed to afford the tricyclic lactones **3a–l** in excellent yields.[12] The reactions of MOBs **1a–c** produced considerable amounts of dimers when they were generated in the absence of 2-methoxyfuran. Consequently, phenols **2a–c** were oxidized in the presence of 2-methoxyfuran to suppress dimerization.

The gross structures of all the lactones were determined by their IR, ^{1}H and ^{13}C NMR, DEPT, low- and high-resolution mass spectral analyses. All these lactones provided satisfactory elemental analyses. The ^{1}H NMR (400 MHz) spectra of the crude reaction mixtures showed the formation of a single lactone in every case indicating the high regio- and stereoselectivity of the initial cycloaddition reactions. The regiochemistry of these cycloaddition reactions was determined by ^{1}H–^{1}H decoupling NMR experiments on the corresponding lactones in each case and is in agreement with our earlier results.[11]

The assigned stereochemistry of the lactones was deduced from the observed long-range coupling between vinylic hydrogens and the nearest ring junction hydrogens in all the cases where vinylic hydrogens exist. In the cases of **3h** and **3j**, it was assigned as shown by analogy with our earlier results where the

[a] See ref. 12. [b] Yields are of isolated lactones and are not optimized. [c] DAIB was added during 80 min. [d] Dimer of **1b** was also produced in 30% yield.

anti configuration of furan moiety to the keto group was confirmed by X-ray diffraction analysis.[11] The fact that in all the cases the *endo* adducts were produced exclusively shows that these cycloaddition reactions obey all the ground rules of Diels–Alder reactions.[13]

It is important to mention that 2-methoxyfuran was earlier shown to act as dienophile in its high pressure cycloaddition reactions with tropone albeit with moderate efficiency and poor stereoselectivity.[14] On the other hand, 2-alkoxy- and 2-silyloxyfurans have been often used as dienes and nucleophiles.[9,15] Interestingly, 2-methoxyfuran underwent facile cycloaddition with MOBs bearing electron-withdrawing as well as electron-donating substituents unlike other furan derivatives which reacted with only MOBs bearing electron-withdrawing substituents in our earlier studies.[11]

In conclusion, the present reactions make use of readily available 2-methoxyfuran and 2-methoxyphenols and produce highly complex and potentially useful multifunctional molecules in excellent yields *via* a simple one-pot process. Most importantly, these reactions resulted in the development of a novel and efficient methodology for the direct and stereoselective introduction of a β,γ-fused γ-butyrolactone moiety using 2-methoxyfuran as a masked but-3-enolide.

We thank National Science Council (NSC) of the Republic of China for financial support to our research. P. D. R. thanks NSC for a postdoctoral fellowship.

12 Method A: *General procedure for 2-methoxyphenols* **2d-l**: A solution of phenol **2** (1 mM) in MeOH (10 mL) was cooled to 0 °C and DAIB (1.1 mM) was added as solid in one portion. After 10 min of stirring at 0 °C, 2-methoxyfuran (5 mM) was added and the cooling bath was removed. The reaction mixture was stirred at room temperature for 2–4 h (2 h for **2d–f** and 4 h for **2g–l**) and then MeOH and other volatile materials were removed under reduced pressure. The residue was dissolved in THF and *p*-TsOH (100 mg) and water (3 drops) were added. The resulting solution was stirred for 4 h at room temperature and the volatiles were then removed under reduced pressure. The residue was purified by column chromatography on silica gel using 40% ethyl acetate in hexanes as eluent to obtain lactone **3** as a colorless solid. Method B: *General procedure for 2-methoxyphenols* **2a-c**: To a mixture of 2-methoxyphenol (1 mM) and 2-methoxyfuran (5 mM) in MeOH (4 mL) was added a solution of DAIB (1.2 mM) in MeOH (6 mL) during a period of time (10 min for **2a** and **2c** and 80 min for **2b**) using a syringe pump at room temperature. After stirring for a further 1 h, MeOH and other volatile materials were removed under reduced pressure and the residue was subjected to hydrolysis as described in method A.

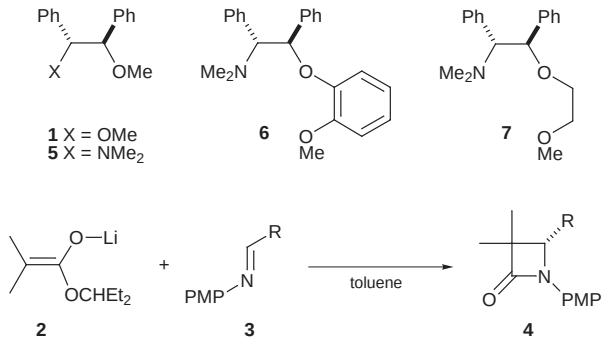
Received (in Cambridge, UK) 22nd February 1999, Accepted 11th March 1999

An external chiral tridentate amino diether ligand 7 catalyzed the condensation reaction of a lithium ester enolate 2 with an imine 3 to give the enantiomerically enriched β-lactam 4 in high yield.

Condensation of a lithium ester enolate with an imine is the established synthetic methodology for β-lactams.[1] Although the asymmetric reaction has been developed using chiral enolates or chiral imines,[2] the asymmetric reaction of achiral lithium ester enolates with prochiral imines in the presence of an external chiral controller is undeveloped.[3,4] We have reported that a ternary complex reagent, constituted from a lithium enolate, chiral diether **1** and an achiral lithium amide, enables the asymmetric condensation of the lithium ester enolate with the imine.[5] However, this methodology lacks generality because strong lithium amides cause undesirable side reactions such as deprotonation and nucleophilic attack. During continuing efforts directed towards the development of simple catalytic reactions which use lithium enolates and catalytic amounts of chiral ligands as a nucleophile and a catalyst, we found that 5–20 mol% of a tridentate amino diether ligand catalyzed asymmetric condensation of lithium ester enolates with imines to afford β-lactams in high ee. The efficiency of the reaction is crucially governed by the structural features of the ligand.

At the beginning of studies, we examined the catalytic activity of chiral diether **1** and found that condensation of 2.2 equiv. of lithium ester enolate **2**, generated from pentan-3-yl 2-methylpropanoate and LDA, with imine **3a** (R = Ph, PMP = 4-$MeOC_6H_4$) in the presence of 5 mol% of **1** in toluene at 0 °C for 7 h gave (*S*)-**4a** (R = Ph) quantitatively in 40% ee (Scheme 1).[6] It was a logical extension to examine the catalytic activity of amino ether ligand **5** because the dimethylamino group of **5** would coordinate to lithium and enhance the reactivity of the lithium enolate more efficiently than the methoxy group of **1** does.[7] As expected, the reaction was catalyzed by 5 mol% of **5** more efficiently at −20 °C for 3 h to afford **4a** quantitatively in 49% ee. Encouraged by these results, we examined the reaction in the presence of a tridentate amino diether ligand **6** which had been found to be a good ligand for the asymmetric Michael reaction of lithium thiophenoxide.[8] Although the reaction was completed within 1 h at −20 °C, the selectivity was not satisfactory, affording **4a** in only 47% ee even if 2.6 equiv. of **6** were used. However, we were pleased to find that a stoichiometric amount of amino diether **7**,[8] bearing a methoxyethoxy group in place of the methoxyphenoxy group of **6**, gave **4a** quantitatively in 91% ee after 1 h at −20 °C. Catalytic reactions using 10 and 5 mol% of **7** at −20 °C for 1.5 h gave **4a** quantitatively in 88 and 84% ees, respectively. Recrystallization of **4a** of 84% ee from Pr^i_2O gave optically pure **4a** in 75% overall yield. The chiral ligand **1** was recovered quantitatively for reuse.



Scheme 1

The efficiency of the catalytic reaction was examined in the presence of 20 mol% of **7** using imines **3a-f** having aryl, vinyl and alkyl groups as shown in Table 1. The arylimines were converted to **4a-d** in 90–84% ee. The imine **3e** bearing a vinyl group also gave **4e** in 82% ee, whereas alkylimine **3f** was converted to **4f** in a lower 65% ee.

Table 1 The asymmetric condensation of **2** with **3** giving **4** catalyzed by **7**[a]

Entry	3	R	*t*/h	Yield (%)	Ee (%)[b]
1	**a**	Ph	1.5	99	89
2	**b**	PMP	3.5	99	90
3	**c**	1-Naphthyl	1.5	99	84
4	**d**	2-Naphthyl	2.5	99	88
5	**e**	CMe=CHPh	5	90	82
6	**f**	CH_2CH_2Ph	0.5	99	65

[a] Reaction was carried out using 20 mol% of **1** in toluene at −20 °C. [b] The ee was determined *via* chiral stationary phase HPLC using Daicel Chiralcel OD or OD-H, Pr^iOH–hexane (1 : 100). The absolute configuration was determined according to the reported procedure (ref. 5).

Although the enantioselectivity is not extremely high, we believe that the catalytic asymmetric reaction demonstrated here provides a promising approach to efficient catalytic carbon–carbon bond forming reactions.

Biosynthesis of isoprenoids in *Escherichia coli*: stereochemistry of the reaction catalyzed by isopentenyl diphosphate : dimethylallyl diphosphate isomerase

Aquiles E. Leyes, Jonathan A. Baker, Frederick M. Hahn and C. Dale Poulter*

Department of Chemistry, 300 South 1400 East, Henry Eyring Building, University of Utah, Salt Lake City, UT 84112, USA. E-mail: poulter@chemistry.chem.utah.edu

Received (in Corvallis, OR, USA) 22nd January 1999, Accepted 25th February 1999

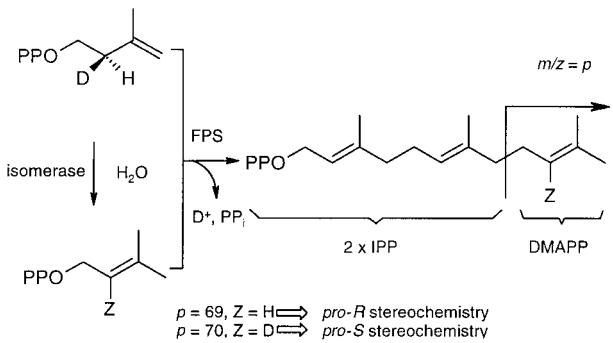
The interconversion of isopentenyl diphosphate (IPP) and dimethylallyl diphosphate (DMAPP) catalyzed by *E. coli* and *S. pombe* IPP isomerase proceeds with removal of the *pro-R* proton at C2 of IPP and addition of a water-derived proton to the *re* face of the C2–C3 double bond in DMAPP; this is the same stereochemistry observed for *S. cerevisiae* and rat liver enzymes.

The isomerization of isopentenyl diphosphate (IPP)† to dimethylallyl diphosphate (DMAPP) is a key activation step in the biosynthesis of isoprenoid compounds by the mevalonate pathway.[1] In eukaryotes and yeast, IPP isomerase catalyzes an antarafacial [1.3] transposition of hydrogen by a proton addition–elimination mechanism. For IPP→DMAPP, the *pro-R* proton at C2 of IPP is removed, while for DMAPP→IPP a proton from water is delivered to the *re* face of the C2–C3 double bond.

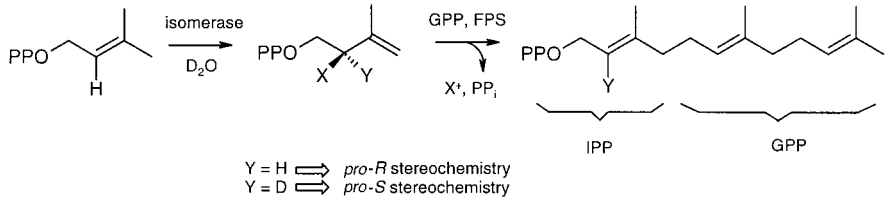
Many bacteria, including *E. coli*, and plant chloroplasts synthesize isoprenoids from 1-deoxy-D-xylulose by a non-mevalonate pathway.[2] In experiments where 3-deutero-1-deoxy-D-xylulose was fed to *E. coli* cultures, deuterium was found exclusively at the C2 position of the ω-isoprene unit of the ubiquinone-8 side chain.[3] These results are in contrast to the biosynthesis of isoprenoids in yeast and rat liver by the mevalonate pathway, where the *pro-R* proton is removed both in the isomerization and chain elongation reactions.[1] In an attempt to reconcile these observations we have determined the stereochemistry at C2 for IPP→DMAPP and DMAPP→IPP using recombinant *E. coli* enzyme.[4]

The experiment to determine the stereochemistry for IPP→DMAPP is outlined in Scheme 1. A 2 mg (6.7 μmol) sample of (*R*)-2-deuteroisopentenyl diphosphate {(*R*)-[2-^{2}H]-IPP} was incubated with 0.02 units of recombinant *E. coli* IPP isomerase and 1 unit of avian FPP synthase (FPS)[5] in a 20 mM BHDA buffer (pH 7.0) containing 1 mM $MgCl_2$, 50 mM KCl, and 0.5 mM DTT, at 37 °C. After 5 h, diethanolamine buffer (0.5 M), pH 10.5, 0.5 mM $ZnCl_2$, and 100 units of calf intestinal alkaline phosphatase were added. Incubation was continued for 8 h, after which time the samples were extracted with *tert*-butyl methyl ether. Farnesol, synthesized enzymatically from (*R*)-[2-^{2}H]-IPP, was analyzed by GC/MS. A parallel set of reactions was run using recombinant *Schizosaccharomyces pombe* IPP isomerase[6] as a control. Electron impact mass spectra for the enzymatically synthesized farnesol samples were similar to that from an authentic sample of unlabeled alcohol. An intense peak was seen at *m/z* 69 (100%) for the $C_5H_9^+$ fragment from the ω-isoprene unit. Thus, little of the deuterium originally at C2 in [2-^{2}H]-IPP was incorporated into the portion of farnesol arising from DMAPP. Chemical ionization (CH_4) mass spectra for enzymatic and unlabeled farnesol gave peaks at *m/z* 223 (1–3%, $[M + 1]^+$) and 205 (18%, $[M + 1 - H_2O]^+$). In addition, the enzymatic samples had small peaks at *m/z* 224 ([224]/[223] = 0.3) and 206 ([206]/[205] = 0.4), consistent with a small amount (~10%) of (*S*)-[2-^{2}H]-IPP in the sample. As shown in Scheme 1, the lack of deuterium incorporation in the ω-isoprene unit of farnesol indicates that the *pro-R* methylene hydrogen is preferentially removed from IPP by both *E. coli* and *S. pombe* IPP isomerases during isomerization to DMAPP.

Scheme 2 outlines a complementary set of experiments to determine the stereochemistry at C2 in the DMAPP→IPP direction. DMAPP (6 mg, 20 μmol) was incubated for 4 h with 0.6 units of IPP isomerase in a deuterated buffer[7] (pD 7.0).‡ The isomerization was rendered irreversible by adding geranyl diphosphate (GPP) (18 mg, 42 μmol) and FPP synthase (6.4 units) to the mixture so that newly formed [2-^{2}H]-IPP was immediately converted to FPP. FPP synthesized from the coupled reactions was purified by reversed phase HPLC on a C18 Magellan column§ and analyzed by ^{1}H NMR spectroscopy. As illustrated in Fig. 1, the low field region of the spectrum showed peaks at δ 4.52, 5.24 and 5.52 corresponding to protons at C1, C6/C10 and C2, respectively. The ratio of the intensities for the resonances at δ 4.52 and 5.52 (5.52/4.52 = 2.1) demonstrates that deuterium from the buffer was not incorporated at C2 of FPP. A portion of the sample was hydrolyzed with alkaline phosphatase as described previously, and analyzed by GC/MS (CI, CH_4). Samples of enzymatic and authentic unlabeled farnesol gave identical spectra. Eukaryotic FPP synthases remove the *pro-R* hydrogen from IPP during



Scheme 1



Scheme 2

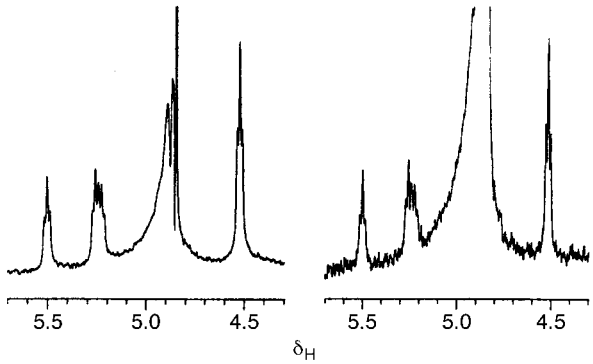


Fig. 1 500 MHz ^{1}H NMR spectra of enzymatically produced FPP in D_2O, low field region. Left: *S. pombe* isomerase reaction. Right: *E. coli* isomerase reaction. Signal at δ 5.52 corresponds to vinylic proton at C2. Solvent peak (δ 4.85) was presaturated before pulsing.

chain elongation. The absence of label in FPP therefore requires synthesis of (*R*)-2-deuteroisopentenyl diphosphate by addition of a deuterium to the *re* face of DMAPP and subsequent loss of deuterium during chain elongation.

Our data show that the stereochemistry at C2 for the reactions catalyzed by *E. coli* IPP isomerase is the same as the eukaryotic isomerases—the *pro-R* proton is removed during IPP→DMAPP and a proton is added to the *re* face of the double bond during DMAPP→IPP. These findings have interesting implications in light of the recently reported labeling studies in *E. coli* with deoxy-D-xylulose.[3] If (*S*)-[2-^{2}H]-IPP is produced from 3-deutero-1-deoxy-D-xylulose, the stereochemistry of chain elongation by *E. coli* FPP synthase must be different than its eukaryotic relatives. However, if the (*R*)-enantiomer of [2-^{2}H]-IPP is formed, the molecule of DMAPP incorporated into the ω-position of the ubiquinone side chain cannot be synthesized from IPP by the action of the *E. coli* isomerase we have characterized. Perhaps *E. coli* has another as yet unidentified IPP isomerase with the opposite stereospecificity. Alternatively, there is no *a priori* requirement that IPP be synthesized before DMAPP by the non-mevalonate pathway, and both diphosphates might be synthesized simultaneously from a common precursor. In this scenario, the *E. coli* isomerase would not be a required enzyme for isoprenoid biosynthesis but it would allow the cell to balance the concentrations of IPP and DMAPP during periods of active metabolism to optimize their utilization.

This work was supported by NIH grant GM 25521.

The self-assembly and spontaneous resolution of a hydrogen-bonded helix

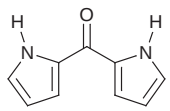
Tyler B. Norsten, Robert McDonald and Neil R. Branda*

Department of Chemistry, University of Alberta, Edmonton, Alberta, Canada T6G 2G2. E-mail: neil.branda@ualberta.ca

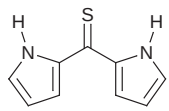
Received (in Columbia, MO, USA) 2nd November 1998, Accepted 9th February 1999

Although geometrically similar at the single-molecule level, the crystal structures of 2,2′-dipyrrolyl ketone and its synthetic precursor, 2,2′-dipyrrolyl thioketone, vary greatly at the supramolecular level: the ketone self-assembles *via* hydrogen bonding into supramolecular helices accompanied by a spontaneous resolution process to generate homochiral crystals, whereas the thioketone assembles into non-helical and racemic crystals composed of layers of alternating enantiomers held together by weak interactions.

The ability to encode molecules with well-defined non-covalent binding motifs, such as hydrogen bond sites, is critical in order to create predictable and useful solid-state supramolecular architectures of nanoscale dimensions.[1] During the synthesis of C_2-symmetric porphyrins, we prepared 2,2′-dipyrrolyl ketone **1**



1



2

as previously described.[2] This simple molecule contains a high degree of encoded molecular recognition functionality. Of the twelve non-hydrogen atoms, three possess complementary hydrogen bond sites: two amine (N–H) donors and two carbonyl (C=O) lone pair acceptors. Additionally, the steric crowding of the C3 and C7 hydrogen atoms† on the two pyrrole rings forces the molecule into a twisted conformation. It was anticipated that the combination of these molecular features would translate into a helical supramolecular array held together by intermolecular N–H···O=C hydrogen bonds.[3]

We present here the crystal structures‡ of ketone **1** and its synthetic precursor, thioketone **2**. Single crystals of the ketone were obtained by layering a $CHCl_3$ solution of **1** with hexane. Ketone **1** self-assembles *via* hydrogen bonding into supramolecular helices, accompanied by a spontaneous resolution process to generate homochiral crystals. Interestingly, the sulfur analogue thioketone **2** crystallizes, under the same conditions, into a non-helical racemate.

Crystalline 2,2′-dipyrrolyl ketone **1** adopts a conformation in which both amine (N–H) groups point in the same direction as the ketone's carbonyl group [Fig. 1(*a*)]. Solution-state studies of the electric dipole moment of **1** attribute this conformational preference to the existence of intramolecular hydrogen bonding between the two N–H hydrogen atoms and the lone pair electrons of the carbonyl oxygen.[4] As expected, the crystal structure shows that the steric crowding of the C3 and C7 hydrogen atoms on the pyrrole rings does force the molecule to adopt a slightly twisted conformation. The result of these two effects is a convergent but non-coplanar self-complementary hydrogen bond surface. It is this spatial positioning of the molecular recognition sites that influences the self-assembly process in terms of the resulting supramolecular topology.

Ketone **1** crystal packs into supramolecular hydrogen bonded helices that extend indefinitely throughout the crystal lattice (Fig. 2). It is this extended network of strong N–H···O

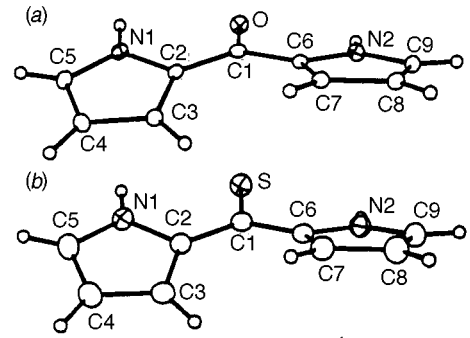


Fig. 1 Perspective view of (*a*) ketone **1** and (*b*) thioketone **2** showing the atom labeling schemes.

intermolecular hydrogen bonds (2.86 Å in length)§ that drives the formation of the helix between adjacent stacked columns of the ketone (Fig. 3). The dipyrrole building blocks are compressed within each of these columns so as to maximize favorable intermolecular π–π stacking interactions.¶ The path of the helix can easily be traced by following the hydrogen bonds counterclockwise around the two-fold screw axis of the helix (dashed lines in Fig. 3). Only one of the N–H groups is involved in intermolecular hydrogen bonding while the other N–H acts as a spectator. Two units of the ketone combine to make up a single turn of the helix generating a helical pitch of 5.9 Å.

At the molecular level, the crystal contains a single enantiomer of the ketone. This local chirality translates throughout the crystal into the formation of only left-handed (*Λ*)

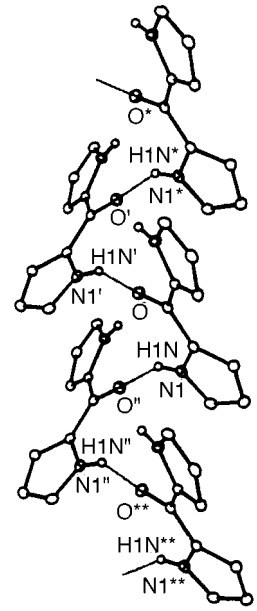

Fig. 2 View illustrating intermolecular hydrogen-bonded interactions between adjacent molecules within the helix. Carbon-bound hydrogen atoms have been omitted for clarity.

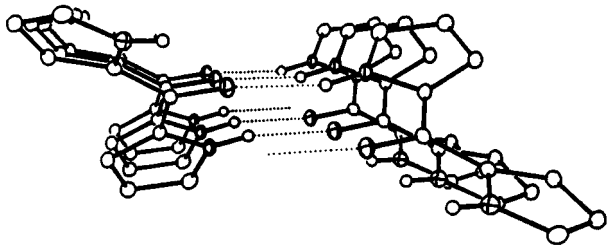

Fig. 3 Crystal packing diagram of ketone **1** viewed down the screw axis of an isolated helix. Intermolecular hydrogen bonds between stacked columns of molecular units are illustrated as dashed lines.

helices at the supramolecular level. There clearly must exist an auto-resolution process that is in effect during crystallization, whereby the pre-assembled helices *communicate* with the neighboring helices during the packing of the crystal lattice. Such chiral resolution processes are of interest because of their implications in the origin of homochirality.[5] Although only one crystal was sampled, we are assuming there exists an equal amount of crystals of both handedness in the bulk solid-state mixture.

At the molecular level, the geometry of thioketone **2** is virtually identical to that of the ketone. The only difference is a slightly increased interplanar angle (31.9°) presumably due to the larger sulfur atom, which forces the N–H groups slightly further out of coplanarity [Fig. 1(*b*)]. A significant difference is seen, however, at the supramolecular level, where a non-helical racemic crystal is generated falling into the achiral space group *Pbca*. The thioketone packs into antiparallel layers of opposing enantiomers. These layers appear to be held together by very weak interactions between the amine hydrogen and the sulfur atom of adjacent but offset enantiomers (dashed lines in Fig. 4) about which an inversion center is created. It is not clear whether these interactions can be rigidly defined as hydrogen bonds as the NH···S distance is close to the sum of the van der Waal's radii of these atoms.‖ It is clear that the replacement of the strong hydrogen bond acceptor (the carbonyl oxygen atom) with a weaker acceptor (the sulfur atom)[6] has a great effect on the supramolecular architecture. We attribute this to the change in the driving force for crystal packing from strong hydrogen bonds in the case of ketone **1** to weaker van der Waal's interactions in the case of thioketone **2**.

We have shown here that although the geometries of both ketone **1** and thioketone **2** are virtually identical at the molecular level, they vary greatly in their supramolecular topologies.[7] Where ketone **1** packs primarily *via* strong hydrogen-bonding interactions into helical arrays, the crystal packing of the thioketone **2** seems to be driven mainly by weaker interactions. The hydrogen-bonded network of ketone **1** results in a helical architecture that may play a role in the resulting auto-resolution. The effects of varying recrystallization conditions such as solvent, temperature and the presence of seed crystals are currently being investigated. This body of work demonstrates how the appropriate tailoring of prefabricated molecular components can lead to interesting supramolecular structures. Great care must be taken when choosing the molecular recognition constituents as the solid-state architecture is clearly governed by their attributes.

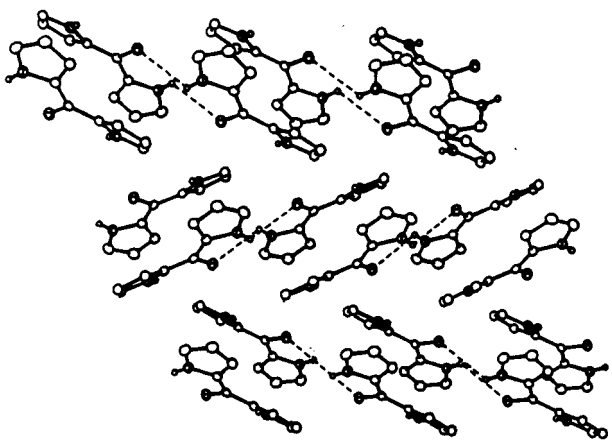

Fig. 4 Cross-section of the crystal packing diagram of thioketone **2** illustrating the herringbone arrangement of stacked antiparallel layers. Carbon-bound hydrogen atoms have been omitted for clarity. Dashed lines represent weak N–H···S contacts between offset enantiomers.

We are grateful to Dr Daniel Frankel (Nonius Co., Bohemia, New York 11716) and Scott Lovell (University of Washington, Seattle, Washington 98195-1700) for the X-ray crystallographic data collection of ketone **1**. Financial support for this work was provided by the Natural Sciences and Engineering Research Council of Canada.

Esterase catalysed enantioselective ring closure

C. Vivienne Barker,[a] Stewart R. Korn,[b] Michael Monteith[b] and Michael I. Page*[a]

Received (in Liverpool, UK) 11th February 1999, Accepted 9th March 1999

Porcine liver esterase catalyses the reaction of γ-amino esters in water to give a mixture of the corresponding γ-lactam and the hydrolysis product, deacylation of the acyl enzyme intermediate by ring closure occurs with a high enantioselectivity giving an ee of 90% for the formation of (*S*)-5-phenyl-2-pyrrolidone from racemic ethyl 4-phenyl-4-aminobutanoate.

Enzymes which catalyse reactions in discrete steps by, for example, the formation of a covalently modified enzyme intermediate, have the potential to exhibit their chirality in at least two steps—formation and breakdown of the intermediate. Esterase enzymes catalyse the hydrolysis of esters through the intermediate formation of an acyl enzyme[1] but generally exhibit little significant enantioselectivity with racemic esters with chiral centres in either the alcohol or carboxylic acid residues.[2] Acyl enzyme intermediates potentially can be trapped not only by external nucleophiles but also intramolecularly to form cyclic products. This ring closure may be favoured over hydrolysis either because of the entropy effect[3] and/or because it is enzyme catalysed.

In the absence of enzymes, the intermolecular aminolysis of esters occurs readily only with reactive amines or with activated esters with good leaving groups,[3] or those with electron-withdrawing substituents in the acyl group.[4] Intramolecular lactam formation from amino esters occurs more easily but is normally hydroxide ion catalysed and requires high pH.[5] In aqueous solution, amide or lactam formation occurs in competition with hydrolysis which is also usually hydroxide ion catalysed and so the ratio of aminolysis to hydrolysis is dependent on the pK_a of the amino ester and the pH. By contrast, enzyme catalysed hydrolysis of esters can occur under mild conditions near neutrality. The esterase catalysed reaction of γ-amino esters generates an acyl–enzyme intermediate which could be trapped by the amino group to form a γ-lactam rather than the hydrolysis product (Scheme 1).[6]

Although the stereoselective enzymatic acylation of alcohols is well established, the enzymatic resolution of amines is less common.[7] The ring closure reaction offers a potential method of enantioselective cyclisation as it occurs at the enzyme surface, even though the first acylation step shows little or no selectivity.[2] A problem with such reactions is that it may be expected that the amino group would be protonated at neutral pH and therefore the enzyme reaction would be sensitive to pH and the pK_a of the aminium ion of the amino ester.

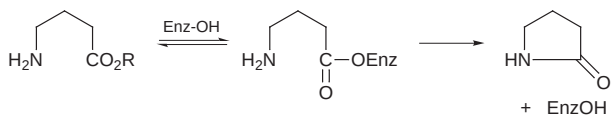
In the absence of enzyme, the reaction of ethyl 4-aminobutanoate in aqueous solution gives both hydrolysis and ring closed products. The ratio of 4-aminobutanoic acid to 2-pyrrolidone depends on the pH, buffer type and buffer concentration. For example, at pH 9.0 and 30 °C, no γ-lactam is formed, whereas at pH 10.0 and 12.0, 16 and 100% of the product is 2-pyrrolidone, respectively. At pHs above the pK_a of 9.9, the amount of lactam formed increases because the rate of lactamisation is given by eqn. (1), where RNH_2 and RN^+H_3 are the unprotonated and protonated forms of the γ-amino ester,

$$\text{Rate} = k_{OH}(RNH_2)(OH^-) = \frac{k_{OH}K_a}{K_w}(RNH_3^+)(OH^-)^2 \quad (1)$$

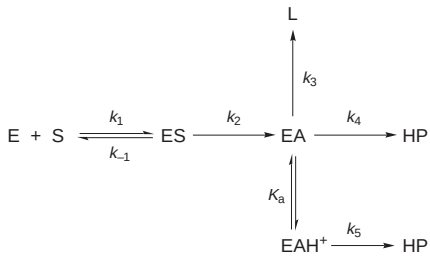
respectively, and K_a is its dissociation constant. Consequently, the rate of lactamisation is second-order in hydroxide ion at pHs below its pK_a and the rate of ring closure falls off rapidly with decreasing pH.

Likewise it was anticipated that the amount of lactam formed in the enzyme catalysed reaction and the extent of catalysis would be critically dependent on the pH and the pK_a of the amino ester. The degradation of ethyl 4-aminobutanoate in water is catalysed very effectively by pig liver esterase, with an apparent first order rate constant which shows a first order dependence on enzyme concentration. At pH 9.0, 30 °C and an enzyme concentration of 1.2×10^{-7} mol dm^{-3}, the rate of reaction is increased 360-fold over the non-enzyme catalysed reaction under the same conditions. Whereas there is no γ-lactam formed at this pH in the absence of enzyme, in its presence 48% of the product is 2-pyrrolidone. The amount of γ-lactam formed is independent of enzyme concentration, as expected for the ring closure reaction taking place within the acyl–enzyme intermediate. The amount of ring closed product formed increases with pH ranging from 20% at pH 7 to 80% at pH 10.5. The logarithm of the second order rate constant for enzyme catalysed reaction (k_{cat}/K_m) has a unit positive slope with respect to pH from pH 7.0 to 9.5, but becomes pH independent above the pK_a of the substrate with a maximal value of k_{cat}/K_m of 1.33×10^6 dm^3 mol^{-1} s^{-1}. This suggests that the substrate for the esterase catalysed reaction of the amino esters is the unprotonated form of the substrate. Below pH 7 the rate of hydrolysis of *neutral* esters falls off very fast because enzyme activity is dependent on an unknown ionising group of pK_a 7 in its basic form.[8] Above pH 7, the rate of the esterase catalysed hydrolysis of *neutral* esters is pH independent.

Similar catalytic behaviour is seen with the degradation of racemic ethyl 4-phenyl-4-aminobutanoate **1** (Scheme 3, Nu = NH) but because the pK_a is reduced to 8.90 maximal catalytic activity is reached at a lower pH and very effective catalysis occurs with an enzyme concentration of 1.0×10^{-8} mol dm^{-3}. The second order rate constant, k_{cat}/K_m, is 1.78×10^6 dm^3 mol^{-1} s^{-1} at 30 °C. Not only is the γ-lactam formed in the presence of the enzyme but it is predominantly (> 95%) the *S* enantiomer as determined by GC on a β-cyclodextrin column. The enantiomeric excess for 5-phenyl-2-pyrrolidone is independent of pH and enzyme concentration. The enantiomeric excess of the hydrolysis product agrees with that predicted from the assumption that hydrolysis is not stereoselective, as found for the hydrolysis of substituted acyclic esters.[2] For example, at pH 9.0, 38% of the γ-lactam is formed from racemic ethyl 4-phenyl-4-aminobutanoate with 90% ee for the *S* enantiomer, which gives a calculated ee for the *R* amino acid of 56%. This agrees perfectly with the observed ratio of 22% (*S*) and 78% (*R*) for 4-phenyl-4-aminobutanoic acid as determined by chiral



Scheme 1



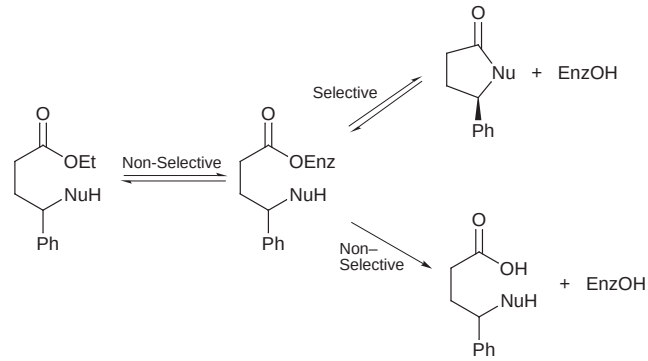
Scheme 2

HPLC (CHIROBIOTIC T250X 4.6 mm, teichoplanin coating eluting with 60 : 40 v/v EtOH–H_2O, t_R 11.5 and 13.2 min).

It is interesting to note that hydrolysis of the acyl enzyme appears to be non-selective whereas the intramolecular aminolysis to give the lactam is enantioselective. Deacylation of the acyl–enzyme is rate-limiting[2] and although the substrate for acylation of the esterase by amino esters is the neutral unprotonated amine, the same may not hold for deacylation. The dominant species at pHs below the pK_a of the amino acyl enzyme should be the protonated amine if the system is at thermodynamic equilibrium. However, the rate of hydrolysis–lactamisation could be faster than proton transfer to allow equilibrium with the pH environment. The unprotonated amino acyl enzyme (EA) must be the substrate for ring closure but not necessarily for hydrolysis (Scheme 2, where L and HP are the lactam and hydrolysis products, respectively). If the mechanism for hydrolysis and lactamisation occur through the same intermediate using the same catalytic apparatus of the enzyme then the ratio of lactam to amino acid product would be pH independent. If hydrolysis can occur through the protonated amine then the ratio of products should change with pH according to eqn. (2). The amount of lactam formed does increase with pH, as predicted by eqn. (2).

$$\frac{[\text{lactam}]}{[\text{hydrolysis}]} = \frac{k_3}{k_4 + k_5(\text{H}^+/K_a)} \qquad (2)$$

Previous work from our laboratory[2,9,10] has shown that the hydrolysis of γ-lactones catalysed by pig liver esterase occurs enantioselectively and the ring opening acylation step is selective (Scheme 3, Nu = O) whereas acylation of the acyclic hydroxy ester does not show selectivity during the hydrolysis mechanism.[9] The present results show that ring closure of γ-amino esters occurs enantioselectively (Scheme 3, Nu = NH)



Scheme 3

and is therefore compatible with intramolecular attack of the amino group occurring from only one face of the acyl enzyme with some form of recognition for the amino group—perhaps involving the enzyme catalytic machinery used for deacylation—and a binding pocket for the phenyl group.

Chiral ring closure is less effective for other γ-substituted amino esters but pig liver esterase does also catalyse the formation of δ-lactams but not β- or ε-lactams, from their respective amino esters.

Hybrid organic–inorganic materials. Preparation and properties of dibenzo-18-crown-6 ether-bridged polysilsesquioxanes

Claude Chuit, Robert J. P. Corriu,* Géraud Dubois and Catherine Reyé

Laboratoire de Chimie Moleculaire et Organisation du Solide, UMR 5637 CNRS, Université de Montpellier II, Sciences et Techniques du Languedoc, Place E. Bataillon, F-34095 Montpellier Cedex 5, France.

Received (in Cambridge, UK) 28th January 1999, Accepted 15th March 1999

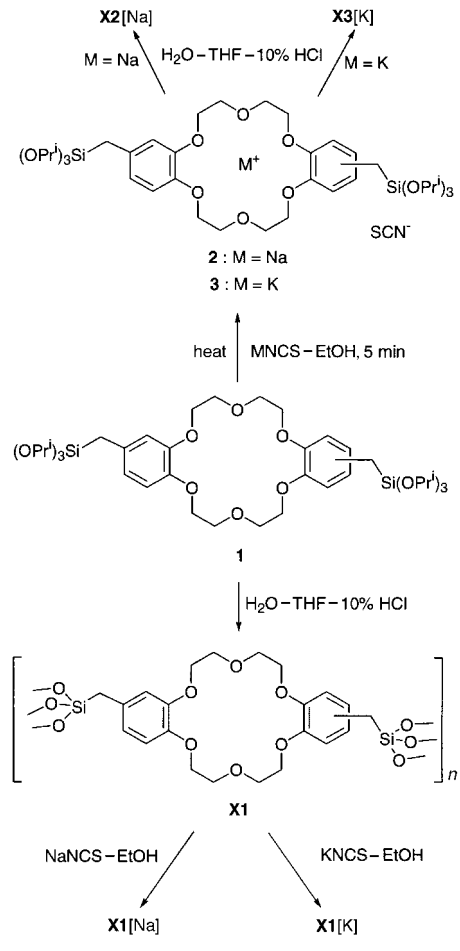
The complexation of alkali metal cations (Na^+ and/or K^+) by organic–inorganic hybrid materials incorporating dibenzo-18-crown-6 ether moieties covalently linked to silica by two Si–C bonds is explained in terms of deformations of the crown ether moiety during the sol–gel process

Crown ethers[1] immobilised on organic or inorganic polymers,[2] have been widely used for the separation of alkali or alkaline earth metal ions. The use of silica as an inorganic polymer is interesting especially for ion chromatography[2] and as an ion transport membrane.[3,4] Crown ethers can be linked to the stationary phase either dynamically[5] (physically absorbed) or through a covalent bond. Up to now two methods have been used to chemically bond the crown ether to the silica framework. The first consists of anchoring either a crown ether to a chemically modified silica[6] or a silylated crown ether to silica.[7,8] The second method is the co-hydrolysis and co-polymerisation of a mixture of a crown ether bearing one hydrolysable $Si(OR)_3$ group with a tetraalkoxysilane[9] or an organotriethoxysilane[9–11] by using the sol–gel process.[12] In both cases, the crown ether is co-valently bound to the matrix by only one Si–C bond and it is located at the surface.[13,14] Recently, the sol–gel process has been used to prepare hybrid organic–inorganic materials by hydrolysis and polycondensation of organic molecules substituted by more than one hydrolysable $Si(OR)_3$ group.[15–17] It has been shown that in this case the organic units can be incorporated into the silica matrix. Furthermore, a short-range organisation has been found by means of chemical reactivity studies.[16,17]

We report here the preparation of the 4,4′(5′) mixture of the bisilylated 18-crown-6-ethers **1**, as well as its hydrolysis and polycondensation by the sol–gel process and the study of the binding ability of the resulting solid towards Na^+ and/or K^+.

Bisilylated crown ether **1** was prepared by reaction of triisopropyloxysilylmethylmagnesium chloride[18] with the commercial mixture of 4,4′(5′)-dibromo-18-crown-6.† Treatment of **1** with 1 equiv. of NaSCN or KSCN in EtOH gave the corresponding complexes **2** and **3** respectively in high yield (Scheme 1). Sol–gel polycondensation of **1**, **2** and **3** was performed at room temperature in THF solution (1 M for **1** and 0.5 M for **2** and **3**) in the presence of a stoichiometric amount of water (3 equiv.) and 10% of HCl as catalyst. The gel formation is very fast (< 5 min) for **2** and **3** but takes nearly 12 h for **1**. This large difference in gel times could be attributed to an increased rigidity for **2** and **3** compared to that of **1** and most probably to a partial protonation of the free oxygen atoms of the crown ether **1**, thus decreasing the catalytic activity of HCl. The gels were allowed to age for five days at room temperature and were powdered and washed twice with ethanol followed by diethyl ether and dried at 120 °C under vacuum (20 mm Hg) for 12 h. From ^{29}Si CP MAS NMR spectroscopy it was shown that the xerogels **X1**, **X2**[Na] and **X3**[K} all display one major resonance centred at δ −62 (substructure T^2 [C–Si(OR)-$(OSi)_2$]). Thus, in spite of different gel times the degrees of polycondensation lie in the same range. The specific surface areas of these three xerogels, determined by adsorption–desorption of N_2 (BET), were found to be very low (< 10 m^2 g^{-1}). Furthermore, during the sol–gel polymerisation of **2** and **3**, 95% of Na^+ cations and 96% of K^+ cations were retained within the xerogel (as measured by elemental analysis) which indicates that the conformation of the crown-ether moiety was not distorted during the sol–gel process.

The xerogel **X1** was treated with 1 equiv. of NaSCN or KSCN in EtOH for 12 h at room temperature or under reflux. The amount of non-complexed cations was measured by flame spectrophotometry after filtration of the solid followed by washing with EtOH until no more salt was recovered, and then evaporation of the solvent, and solubilisation of the remaining alkali metal salt in water. From these data the amount of cations incorporated into **X1** was inferred (Table 1). Further confirmation of the complexation of Na^+ and K^+ cations into **X1** was given by IR spectroscopy (DRIFT). Indeed, ν(C≡N) frequencies of NaSCN and KSCN incorporated into **X1** appear respectively



Scheme 1

Table 1 Yield (%) of alkali metal cations incorporated into xerogel **X1**

NaSCN–KSCN (1 : 1)[c]	78	10[b]	74[a], 76[b]

[a] Measured by flame spectrophotometry. [b] Measured by microanalysis. [c] Competitive experiments.

at 2068 and 2059 cm^{-1} (2073 and 2024 cm^{-1} for NaSCN and at 2042 and 2004 cm^{-1} for KSCN). The formation of the Na^+ complex was also shown by solid state ^{23}Na NMR spectroscopy. The ^{23}Na NMR spectrum of **X1**[Na] displays one broad signal centred at δ −25 (δ −10.6 for NaSCN under the same conditions). The poor yield (43–47%) of complexation of Na^+ cations into **X1** could be due to the rigidity of the crown ether moiety bound to the inorganic matrix, rigidity which did not allow the crown ether to adopt the more favorable conformation for the Na^+ complexation.

Competition experiments from a 1 : 1 mixture of NaSCN and KSCN in EtOH were likewise investigated using the same method of titration by flame spectrophotometry (Table 1). About 10% of the crown-ether moieties are able to complex Na^+ in the presence of K^+. As about 45% of the crown-ether moieties are able to complex Na^+ in the absence of K^+, we can conclude that about 35% of the complexing sites are able to complex both ions but should be more specific for K^+. If we compare the results of the competition experiments with those for the complexation of K^+, we can infer that about 40% (75 − 35) of the crown ether moieties are specific for K^+. Thus from the overall results it appears that the crown-ether sites are of three types: (1) specific for Na^+ (*ca.* 10%), (2) able to complex both ions but more specifically K^+ (*ca.* 35%) and (3) specific for K^+ (*ca.* 40%). One explanation could be that during the sol–gel process the crown ether undergoes steric constraints which distort the rings giving rise, in the xerogel, to sites which are specific for the complexation of Na^+ and/or K^+. Furthermore from the competition experiments, it appears that 85–90% of the crown ether moieties are accessible to the salts, though the crown-ether moieties are most probably located in the core of the solid in contrast to the case of crown-ether grafted to silica.[6–8] In order to analyse the surface composition of these materials, TOF-SIMS investigations[14] are currently in progress.

Notes and references

† *Experimental procedure*. A mixture of 80.4 ml (579 mmol) of a THF solution of $(Pr^iO)_3SiCH_2MgCl$,[18] 10 g (19.2 mmol) of 4,4′(5′)-dibromo-18-crown-6, and 630 mg (1.16 mmol) of $(PPh_3)_2NiCl_2$ in THF (200 ml) was heated under reflux for 48 h. The THF was removed under vacuum and 150 ml of ether was added to precipitate the salts. After filtration and removal of ether under vacuum, 35.4 g of the $MgCl_2$–crown ether complex was obtained as a brown oil. Decomplexation was accomplished by heating the complex in 200 ml of MeOH under reflux overnight. MeOH was removed under vacuum and 150 ml of pentane was added. A precipitate was formed which was filtered and washed with pentane (3 × 50 ml). Evaporation of pentane gave 17.6 g of a yellow oil which was purified by chromatography to give 6 g (7.52 mmol, 39%) of **1** as a white oil.

NMR ($CDCl_3$): ^1H, δ 1.07 (d, 36H, d, CH_3), 2.02 (s, 4H, CH_2Si), 3.93 (m, 8H CH_2O), 4.07 (m, 14H, CH_2O + CH), 6.66–7.02 (m, 6H, aryl); ^{13}C, δ 21.15 (CH_2Si), 25.9 (CH_3), 65.6 (CH), 69.2, 69.7, 70.45, 70.52, 70.63 (CH_2O), 114.55, 114.67, 115.38, 115.49, 121.96 (CH aryl), 131.8, 146.4, 148.96 (C aryl); ^{29}Si, δ −54.8. Satisfactory elemental analyses (C, H, Si) were obtained.

Received (in Oxford, UK) 29th January 1999, Accepted 10th March 1999

The catalytic reduction of NO has been studied over novel supported uranium oxide catalysts which exhibit comparable activity and selectivity to that of conventional supported Pt catalysts and for which *in situ* XRD identifies the active phase to be UO_x ($2 < x < 2.25$).

Emissions of NO and higher nitrogen oxides (NO_x) are the subject of stringent legislation as a result of their adverse environmental impact.[1] An effective method of reducing such emissions is to employ catalytic systems such as the three-way catalyst, currently installed in automotive vehicles, and selective catalytic reduction (SCR) of NO_x by ammonia in stationary sources. Selectivity is a key issue since catalysts can reduce NO_x to undesirable nitrous oxide (N_2O) instead of nitrogen. Nitrous oxide is now recognised as a contributor to the destruction of ozone in the stratosphere and has a high Greenhouse coefficient. Despite intensive research over many years few catalyst systems have been developed which exhibit both the desired levels of activity, selectivity and stability, together with high poison tolerances.

The potential of uranium oxides as catalytic materials has been reviewed by Collette *et al.*[2] Uranium is an actinide element and, with six valence electrons, is similar to chromium, molybdenum and tungsten. The ability to attain high coordination numbers makes for a promising catalytic material and indeed uranium has been used in applications such as Fischer–Tropsch synthesis, dehydrogenation and oxidation (ref. 2 and references therein). More recently, uranium oxides have been identified as candidates for the destruction of volatile organic compounds.[3,4] Uranium is reported to be a uniquely effective promoter of rhodium and platinum in three-way catalysts in the presence of high sulfur levels.[5–7] This study identifies uranium oxide derived catalysts for the selective reduction of nitric oxide.

Reactions were performed in a single-pass, fixed-bed microreactor. The reactor comprised a 10 mm i.d. silica tube located inside a Carbolite MTF furnace. Gas-flow rates were independently regulated by three mass-flow controllers (Hastings and MKS). An in-line filter (2 μm) was located downstream of the reactor to contain UO_x dust particles. On-line analysis of reactant and product gas streams was performed using a Perkin-Elmer 8410 TCD gas chromatograph with a Carboxen 1000 (60/80 mesh) column. Quoted conversions are ±3% and selectivities are ±5%. The catalyst charge, of between 0.5 and 4 g (250–500 μm particle size), was supported inside the reactor on a silica wool bed. The catalyst temperature was read from an external thermocouple located adjacent to the catalyst bed. The feed gases used in this study included NO (99%), CO (99.99%) and He (99%). A constant GHSV of 2300 h^{-1} (total gas flow rate of 70 ml min^{-1}) was employed in all experiments, using a 4% NO and 4% CO mixture with He balance. Before reaction, samples were heated to temperature under He (30 ml min^{-1}) before introducing reactants. *In situ* XRD spectra were acquired at BNFL Springfields using a Philips Expert MPD diffractometer and Cu-Kα radiation in conjunction with an Antonparr XRK cell equipped with Brooks mass-flow controllers. The scan range was 2θ = 5–50° in increments of 0.05°. Single point BET (N_2) surface areas were determined by standard N_2 adsorption for samples degassed at 200 °C.

Alumina supported catalysts were synthesised from solutions of uranium(VI) dinitrate hexahydrate, $UO_2(NO_3)_2{\cdot}6H_2O$ (Strem Chemicals 99.8%) as follows. First, $UO_2(NO_3)_2{\cdot}6H_2O$ (containing *ca.* 0.2% ^{235}U) was dissolved in water to produce a 1.1 M solution (pH = 2). A known quantity of the support was dried and subsequently impregnated with the $UO_2(NO_3)_2{\cdot}6H_2O$ solution by the incipient wetness method. Finally, samples were dried for 24 h at 100 °C prior to calcination under flowing air for 3 h at either 450 or 800 °C. The support used was γ-Al_2O_3 (Alumina C, Degussa), with catalysts designated as UO_x(450 or 800). A third catalytic formulation, $UO_x(H_2)$, was obtained by reducing the 800 °C calcined sample under flowing hydrogen for 10 h at 523 °C as described by Madhavaram *et al.*[8] The nominal uranium oxide loadings (based on oxide stoichiometries discussed below) ranged between 26 and 29 wt%. Comparative experiments were also conducted with uranium(V,VI) oxide (U_3O_8 99.8%), and a conventional 5 wt% Pt/Al_2O_3 Type 94 catalyst from Johnson Matthey. Before reaction, samples were heated under He (30 ml min^{-1}) to 450 °C for 1 h and cooled to reaction temperature. Steady-state was achieved and results obtained after > 1 h reaction.

In the absence of a reductant, the uranium-oxide catalysts, and the alumina support, were each inactive for direct NO decomposition at temperatures below 1000 °C. In contrast, following the introduction of CO the light-off curves shown in Fig. 1 were obtained. For simplicity, only results for the most active bulk UO_x phase, which we have identified as U_3O_8, are included. The catalytic performance of the $UO_x(H_2)$ and UO_x(800) samples was indistinguishable, and hence only results for the UO_x(800) catalyst are shown.

The most striking aspect of the light-off curves is the substantial promotional effect of supporting uranium oxides on high surface area oxide supports. The temperature for 50% NO conversion (T_{50}) is decreased by up to 300 °C following UO_x

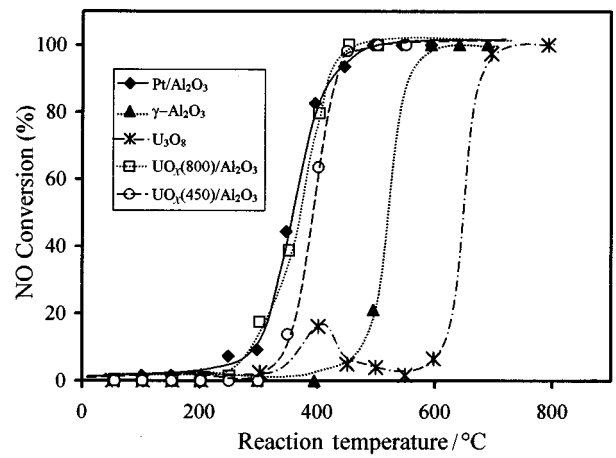

Fig. 1 Effect of temperature on catalyst activity for NO reduction.

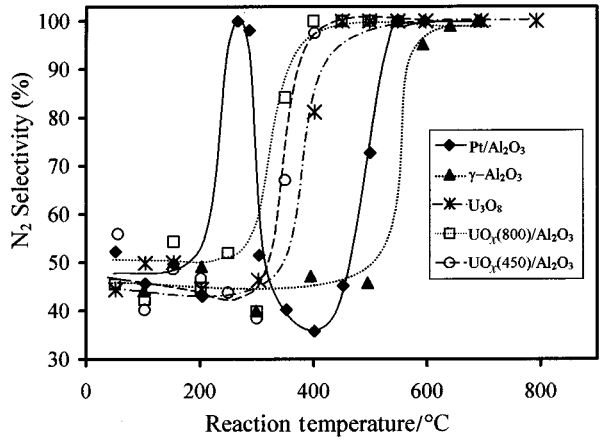

Fig. 2 Effect of temperature on catalyst selectivity towards N_2.

Table 1 BET surface areas for fresh and post light-off catalyst samples[a]

Sample	Surface area[b]/m^2 g^{-1} (±5 %)
5% Pt/Al_2O_3 (fresh)	144
5% Pt/Al_2O_3 (post reaction)	137
UO_x(800) (fresh)	52
UO_x(800) (post reaction)	54
UO_x(450) (fresh)	57
UO_x(450) (post reaction)	57

[a] *Reaction conditions*: 4% NO + 4% CO, balance He; T_{react} = 25–1000 °C. [b] ±5%.

dispersion on alumina; indeed bulk U_3O_8 is less active for NO reduction than the alumina support. T_{50} values for the supported UO_x/Al_2O_3 catalysts appear relatively insensitive to precalcination temperature, although higher temperature calcination does produce the most active uranium catalyst. Remarkably these supported catalysts exhibit T_{50} values essentially identical to those of a commercial Pt/Al_2O_3 NO_x-reduction catalyst. The best uranium-derived catalyst, UO_x(800) lights off at *ca.* 250 °C, attaining 100% NO conversion above 400 °C. Light-off was accompanied in all cases by small, sustained exotherms of *ca.* 5–10 °C.

Over all the uranium catalysts the initial low temperature reduction of NO produced predominantly N_2O as the major product. With increasing reaction temperature and thus NO conversion, the selectivities of all bulk and supported uranium catalysts rise rapidly, with 100% selectivity towards N_2 achieved above 400 °C (Fig. 2). The temperature-dependent selectivity of the Pt/Al_2O_3 catalyst differs markedly from those of the uranium catalysts. Selectivity towards N_2 rises to a sharp maximum just before catalyst light off, albeit at low conversions, before gradually returning to zero at at *ca.* 400 °C. The selectivity recovers at higher temperatures with only N_2 formed above 500 °C, although at these temperatures the alumina support is itself active and selective for NO reduction to N_2.

Preliminary lifetime studies (> 24 h on-stream) show that the supported UO_x catalysts exhibit both high thermal stability and high sulfur tolerance. Indeed steady state NO conversion remains *ca.* 60% after 140 h reaction at 375 °C in the absence of SO_2, and at similar levels for > 17 h after the introduction of 1000 ppm SO_2 into the reaction stream at 550 °C, conditions which strongly poison the commercial Pt/Al_2O_3 catalyst. The N_2 BET surface areas of the fresh and spent supported UO_x catalysts are *ca.* 50 m^2 g^{-1} for reaction temperatures up to 1000 °C, above which the alumina support itself begins to sinter (Table 1).

The supported UO_x catalysts underwent colour changes during use in the reactor. The UO_x(800) sample turned from green to brown, while the UO_x(450) sample changed from orange to brown. Comparison with the colours of bulk uranium oxides suggests that these changes are associated with catalyst reduction from U_3O_8-like and UO_3-like phases respectively to a UO_2-like phase under reaction conditions. This interpretation is supported by *in situ* XRD measurements (Fig. 3) on the UO_x(450) and UO_x(800) sample. For both catalysts a phase transformation occurs between 375 and 400 °C associated with the disappearance of reflections at 2θ 21.4, 26.02 and 33.94° characteristic of stoichiometric U_3O_8, and the emergence of new peaks at 2θ 28.37 and 32.9° characteristic of stoichiometric UO_2. This transformation is complete above 400 °C for the UO_x(800) catalyst; however, for the UO_x(450) catalyst calcined at lower temperature a mixture of U_3O_8 and UO_2 phases coexists even after reaction at 525 °C. The $UO_x(H_2)$ sample remained brown for the duration of the experiments and the *in situ* XRD data exhibited diffraction lines at 2θ 28.37 and 32.9°, characteristic of stoichiometric U_4O_9, which did not change for the duration of the experiment. No such colour or phase changes are observed following identical thermal treatments under inert atmospheres for any sample. These results suggest the existence of a common active phase of stoichiometry UO_x ($2 < x < 2.25$) within the supported UO_x catalysts.

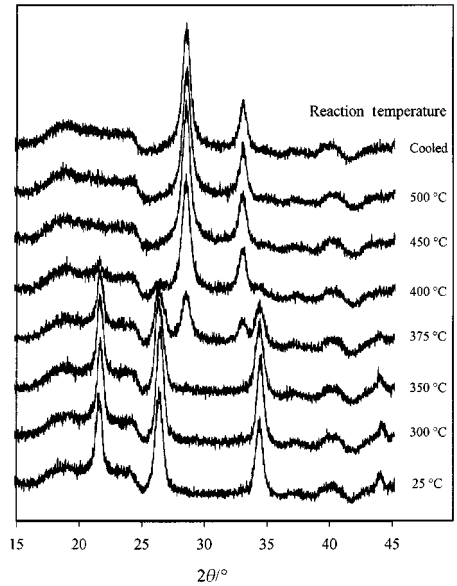

Fig. 3 *In situ* X-ray diffractograms for UO_x(800) as a function of temperature under standard reaction conditions.

Epoxidation of alkenes using dioxygen in the presence of an alcohol catalyzed by *N*-hydroxyphthalimide and hexafluoroacetone without any metal catalyst

Takahiro Iwahama, Satoshi Sakaguchi and Yasutaka Ishii*

Department of Applied Chemistry, Faculty of Engineering & High Technology Research Center, Kansai University, Suita, Osaka 564-8680, Japan. E-mail: ishii@ipcku.kansai-u.ac.jp

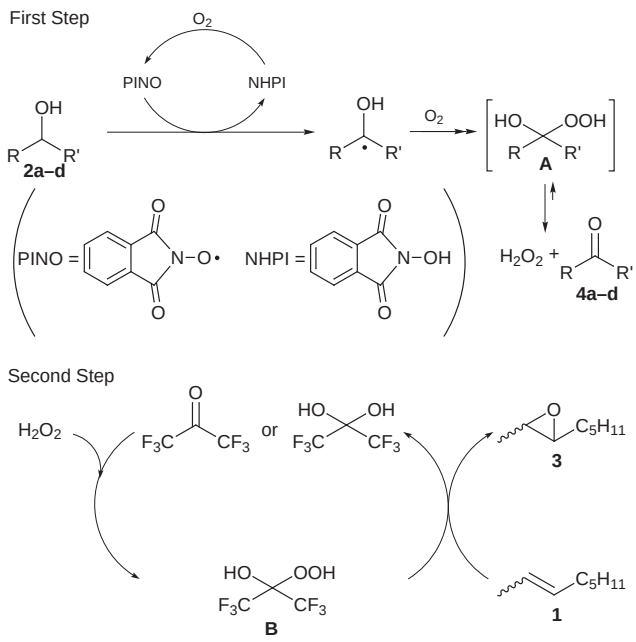
Received (in Cambridge, UK) 1st March 1999, Accepted 12th March 1999

A new approach for the epoxidation of alkenes using O_2 without any metal catalyst was developed; a variety of alkenes were epoxidized in a regio- and stereoselective manner with O_2 in the presence of benzhydrol catalyzed by *N*-hydroxyphthalimide and hexafluoroacetone.

From an economic and environmental viewpoint, the epoxidation of olefins with O_2 is valuable and particularly attractive. Therefore, much effort has been made to utilize O_2 for the epoxidation of olefins, especially using transition metals as catalysts.[1] However, few efficient catalytic aerobic oxidation systems are known that proceed under mild conditions and are amenable to the production of bulk and fine chemicals.[2] We have recently found a novel aerobic oxidation system of hydrocarbons *via* a radical process which employs *N*-hydroxyphthalimide (NHPI) as the catalyst under mild conditions.[3,4] Using this method, alcohols are also able to be oxidized with O_2 to ketones or carboxylic acids *via* the formation of α-hydroxy hydroperoxides.[5] To highlight the importance of this radical catalyst for aerobic oxidation, our efforts are now directed to a new approach for the epoxidation of alkenes using O_2 without any metal catalyst.

Our epoxidation involves a new strategy consisting of radical and ionic processes as key reactions, *i.e.* (i) *in situ* generation of H_2O_2 *via* α-hydroxy hydroperoxide **A** from an alcohol and O_2 assisted by NHPI, and (ii) the epoxidation of olefins by 2-hydroperoxyhexafluoropropan-2-ol **B** derived from the formed H_2O_2 and hexafluoroacetone (HFA) (Scheme 1).†

To optimize reaction conditions for the epoxidation of alkenes, oct-2-ene **1** was chosen as a model substrate and allowed to react under O_2 (1 atm) in the presence of alcohol **2** under the influence of catalytic amounts of NHPI and HFA (Table 1).‡



Scheme 1

The first variable examined was the alcohol used as the source of hydroperoxide (entries 1–4). It was proved that benzhydrol **2b** is the best source of hydroperoxide in the present epoxidation system. The use of propan-2-ol **2c** reduced the conversion and selectivity of **1** to **3**. It is believed that abstraction of the α-hydrogen from **2c** by phthalimide-*N*-oxyl (PINO), generated from NHPI and O_2, takes place in competition with abstraction of the allylic hydrogen of the olefin **1**.§ In an electrochemical oxidation using NHPI as the mediator, Masui *et al.* reported that the allylic oxidation of olefins occurs more easily than the dehydrogenation of alcohols, such as propan-2-ol and cyclohexanol, to ketones.[6] Hence, in epoxidations using an alcohol whose α-hydrogen is more easily abstracted than the allylic hydrogen of **1**, the epoxidation was expected to proceed more easily. Thus, the reaction of **1** using benzyl alcohol **2d** led to **3** with higher selectivity and conversion. HFA was also important to complete the epoxidation (entries 1, 5 and 6). An α-hydroxy hydroperoxide derived from 1,1,1-trifluoroacetone was inadequate to epoxidize **1** in satisfactory yield.

On the basis of these results, the aerobic epoxidation of various olefins using **2b** in the presence of catalytic amounts of NHPI and HFA was examined under selected reaction conditions (Table 2).

The epoxidation of *cis*- and *trans*-oct-2-enes proceeded smoothly in a stereospecific manner to form *cis*- and *trans*-2,3-epoxyoctanes, respectively, in high yields. It is noteworthy that the present system provides a stereospecific epoxidation route with O_2, since in the epoxidation of *cis* olefins using O_2 no such selectivity has been previously observed. Geranyl acetate and neryl acetate afforded the corresponding epoxides in which the double bonds remote from their acetoxy groups were epoxidized with high regioselectivities. Even terminal olefins, which are difficult to epoxidize compared with internal olefins, could be epoxidized by the present method. However, the epoxidation of cyclohexene led to cyclohexene oxide in

Table 1 Epoxidation of oct-2-ene **1** to 2,3-epoxyoctane **3** with O_2 in the presence of alcohols **2a–d** by NHPI and HFA[a]

		Conversion (%)		Yield (%)[b]	
Run	Alcohol	**1**	**2a–d**	**3**	**4a–d**
1	MePhCHOH **2a**	90	30	66 (73)	29 (97)

3[d]	Pr^iOH **2c**	58	—	24 (42)	—
4	BnOH **2d**	84	27	60 (71)	20 (74)
5[e]	**2a**	7	34	3	32 (94)
6[f]	**2a**	8	34	4	33 (98)

[a] **1** (3 mmol) was allowed to react with O_2 (1 atm) in the presence of NHPI (10 mol%), HFA (HFA•$3H_2O$) (10 mol%) and **2** (15 mmol) in PhCN (6 ml) for 24 h. [b] Product yields were determined by GC analysis. Selectivity is in parentheses. [c] 18 h. [d] Conversion of **2c** and yield of **4c** were not determined. [e] In the absence of HFA. [f] 1,1,1-Trifluoroacetone was used instead of HFA.

Table 2 Epoxidation of various alkenes with O_2 catalyzed by NPHI and HFA in the presence of benzhydrol **2b**[a]

Entry	Substrate	*t*/h	Conversion (%)	Product	Yield (%)	Selectivity (%) (*trans* : *cis*)
1		18	93		87	93 (>99:<1)
2 [b]		24	90		72	80 (>99:<1)
3		16	94		81	86 (98:2)
4		16	96		80	83 (99:1)
5		15	90		74	82
6		20	88		71	81
7		20	89		74	83
8 [c,d]		24	80		72	90
9 [d,e]		24	83		70	84
10 [d,f]		24	78		63	80
11 [d,e]		20	72		60	83 (75:25)

[a] Substrate (3 mmol) was allowed to react under dioxygen (1 atm) in the presence of NHPI (0.3 mmol), HFA (0.3 mmol) and **2b** (15 mmol) in PhCN (6 ml) at 80 °C. [b] **2a** was used in place of **2b**. [c] Reaction was carried out at 90 °C. [d] α,α,α-Trifluorotoluene was used as solvent. [e] NHPI (0.6 mmol) was used. [f] Cyclohex-2-en-1-one (8%), cyclohex-2-en-1-ol (2%) and cyclohexane-1,2-diol (1%) were obtained. [g] Ratio α : β.

somewhat lower yield because of concomitant formation of allylic oxidation products such as cyclohexenone (8%) and cyclohexenol (2%). Cholesteryl benzoate produced the 5,6-α-epoxide in preference to the 5,6-β-epoxide (α : β = 75 : 25), which is comparable to epoxidation by MCPBA.[7] In contrast, the same epoxidation using the aldehyde–O_2 system with an Ni complex is reported to give α : β = 31 : 69.[8]

We believe that the actual epoxidizing reagent **B** arises from HFA and H_2O_2 liberated from α-hydroxy hydroperoxides **A**.[9] In fact, ^{1}H NMR experiments show that treatment of **2a** with O_2 in the presence of NHPI in CD_3CN at 70 °C produced H_2O_2, but not α-hydroxy hydroperoxide.¶

In conclusion, we have developed the epoxidation of olefins by *in situ* generation of H_2O_2 from alcohols and O_2 under the influence of NHPI and HFA without any metal catalyst. This method provides an alternative route to the epoxidation of olefins by molecular oxygen in a stereospecific manner.

This work was partly supported by the Research for the Future program.

Notes and references

† 2-Hydroperoxyhexafluoropropan-2-ol is reported to be easily derived from HFA (or HFA hydrate) and H_2O_2: see R. P. Heggs and B. Ganem, *J. Am. Chem. Soc.*, 1979, **101**, 2484.

‡ *Typical procedure* for the epoxidation of **1**: A PhCN (6 ml) solution of **1** (3 mmol), NHPI (49 mg, 10 mol%), HFA•$3H_2O$ (66 mg, 10 mol%) and **2b** (15 mmol) was placed in a two–necked flask equipped with a balloon filled with O_2. The mixture was stirred at 80 °C for 18 h, and then extracted with Et_2O. The organic layer was dried over $MgSO_4$ and analyzed by GLC with an internal standard. The products were separated from the solvent under reduced pressure and purified by column chromatography on silica gel (*n*-hexane–AcOEt = 20 : 1) to give the corresponding epoxides.

§ In a previous paper, we reported that phthalimide-*N*-oxyl (PINO) is produced by exposing NHPI to O_2 at 80 °C in PhCN, see ref. 4.

¶ ^{1}H NMR analysis of the resulting reaction mixture indicates a broad peak at δ 8.8 attributed to the proton of H_2O_2 and protons assigned to the methyl groups of alcohol **2a** and ketone at δ 1.4 and δ 2.6, respectively, but no peaks corresponding to the α-hydroxy hydroperoxide were observed. In addition, an independent reaction of **2a** (5 mmol) with O_2 (1 atm) in the presence of NHPI (10 mol%) at 70 °C in MeCN (5 ml) gave H_2O_2 (1.6 mmol) and acetophenone (**4a**) (1.8 mmol).

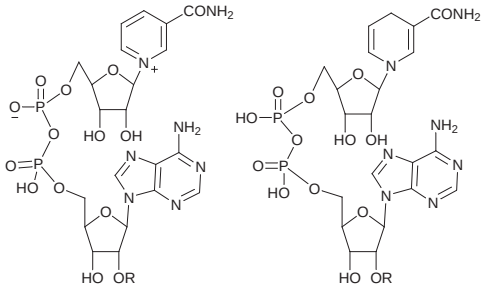
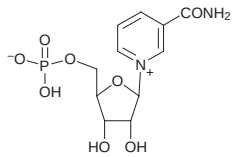
Received (in Cambridge, UK) 18th February 1999, Accepted 10th March 1999

A practical synthesis of nicotinamide mononucleotide (β-NMN) and a high yield coupling with AMP-morpholidate that also provides NAD^+ in an efficient manner are reported.

The nicotinamide cofactors, NAD^+, $NADP^+$, NADH and NADPH, are useful in a variety of enzyme-catalyzed oxidation and reduction reactions in organic synthesis. In the course of bioconversion research in our laboratories, there was need for a reliable, practical synthesis of these cofactors. NAD^+ **1**, also known as Coenzyme 1, is currently manufactured by a yeast based fermentation process.[1] An early chemical synthesis of NAD^+ was reported by Todd *et al*.[2] In their approach, dicyclohexylcarbodiimide (DCC) was used for the coupling of adenosine monophosphate (AMP) and β-nicotinamide mononucleotide (β-NMN, **5**). In a semi-synthetic approach to NAD^+



1 NAD^+, R = H
2 $NADP^+$, R = $PO(OH)_2$
3 NADH, R = H
4 NADPH, R = $PO(OH)_2$

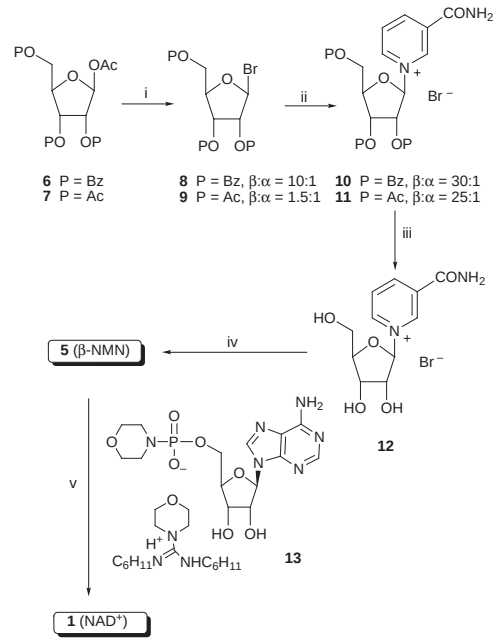


5 β-NMN

by Whitesides *et al*., β-NMN was reacted with adenosine triphosphate (ATP) using NAD pyrophosphorylase (NADPP) immobilized in a polyacrylamide gel.[3b] Since this condensation required a stoichiometric amount of ATP, a costly reagent, a method to generate ATP from AMP was developed. This required the use of several enzymes and associated reagents, such as acetyl phosphate, acetyl kinase, adenyl kinase, and NAD-pyrophosphorylase.[3b] We envisioned that AMP could be activated as a phosphoroamidate and would react with β-NMN or *vice versa*. For this purpose we first examined the existing methods for preparing β-NMN. The β-NMN synthesis reported by Todd *et al.*,[2,3] was improved by Mikhailopulo and co-workers in terms of β-selectivity in the *N*-glycosylation step using SO_2 as a solvent.[4]

We found, however, that the deprotection of tribenzoate **10** under the literature conditions (NH_3, MeOH) was not easily repeated on a large scale (Scheme 1). We observed substantial epimerization giving a *ca.* 2 : 1 β : α mixture of anomeric nucleosides **12**. After considerable effort to improve the deprotection of the tribenzoate, we decided to define a more suitable protecting group with the following requirements: (i) readily removable in the presence of the reactive anomeric pyridinium group; (ii) stable to the bromination conditions; and (iii) able to provide neighboring group participation during the glycosylation step. Nicotinamide triacetate **11** was identified as a potential candidate and was prepared as follows. Bromination of commercial tetra-*O*-acetyl-β-D-ribofuranose **7** with HBr in CH_2Cl_2 gave a 1.5 : 1 β : α mixture of anomeric bromides **9**. Condensation of **9** with nicotinamide in SO_2 at −10 °C followed by a crystallization from 5 : 1 acetone–Bu^{t}OMe afforded the desired β-nicotinamide mononucleoside **11** in 90% overall yield from **7**. We examined other solvents for the glycosylation step. Although a 3.3 : 1 (β : α) anomeric mixture was obtained in MeCN, the pure β-anomer was selectively crystallized in 65% yield from the reaction mixture (−15 °C). Although lower yielding, this procedure provides an alternative to SO_2.

Clean deprotection of tri-*O*-acetate **11** was elusive. A substantial amount of nucleoside cleavage at the glycosidic linkage was observed on treatment with methanolic ammonia. After several attempts, it was learned that the extent of cleavage was largely dependent on the initial concentration and the total amount of ammonia in the reaction mixture. Under the optimized conditions (3 equiv. of NH_3, 1 M in MeOH, −3 to −5 °C for 20 h), deacetylation followed by a crystallization (1 : 5 MeOH–acetone), gave a single β-nicotinamide nucleoside



6 P = Bz
7 P = Ac
8 P = Bz, β:α = 10:1
9 P = Ac, β:α = 1.5:1
10 P = Bz, β:α = 30:1
11 P = Ac, β:α = 25:1

Scheme 1 *Reagents and conditions*: i, HBr (g), CH_2Cl_2; ii, nicotinamide, SO_2, −10 °C, 90% from **7**; iii, NH_3, MeOH, −5 °C, 20 h, 80%; iv, $POCl_3$ (4 equiv.), $PO(OMe)_3$, −5 to 0 °C, 7 h, 80%; v, $MnCl_2$–$MgSO_4$, $HCONH_2$, room temp., 16 h, 78% (58% isolated yield, > 99% purity).

bromide salt **12** as a crystalline solid in 80% isolated yield. It is noteworthy that, contrary to the previous report,[4] we found both **11** and **12** to be air-stable and non-hygroscopic solids.

The phosphorylation of the nicotinamide triol **12** has been reported in the literature using 1 equiv. of $POCl_3$ in $PO(OMe)_3$ with variable yield (35–64%).[4,5] Accordingly, we reexamined the reaction conditions and observed that reaction was very slow below −5 °C, while at > 5 °C a chlorination reaction was the favored pathway.[6,7] Thus the triol **12** was treated with 4.0 equiv. of $POCl_3$ in $PO(OMe)_3$ between −5 and 0 °C for 7 h to give the desired phosphorylated product in 90–92% yield (Scheme 1). Upon neutralization of the reaction mixture, the crude β-NMN **5** was separated from the reaction mixture by addition of MeCN–Et_2O (1 : 3). This crude product was further purified using resin chromatography to give the β-NMN in > 97% purity in 80% isolated yield.[8,9] Use of excess of $POCl_3$ (4 equiv.) at controlled temperature proved far superior to the more conventional stoichiometric amount of the reagent.

With β-NMN in hand, our attention turned to development of a practical method for pyrophosphate bond formation *en route* to NAD^+.[10] Conventional ways to make the pyrophosphate bonds include carbodiimide coupling,[2,11] the Michelson procedure,[12] and the Khorana–Moffatt procedure.[13] This last method, involving the coupling of a suitable salt of a sugar phosphate and a nucleotide phosphoromorpholidate, has been widely used for the synthesis of various sugar nucleotides.[13] However, the reaction between β-NMN and AMP-morpholidate[13*b*] (**13**) was attempted and gave NAD^+ in < 5% yield.[14] Our initial attempts using the AMP-imidazolidate,[15] triazolidate, or tetrazolidate, or to react AMP with β-NMN-imidazolidate[16] under the modified Khorana–Moffat conditions gave only low conversion to NAD^+ (formamide, 16 h to 6 days). We reasoned that this low reactivity of AMP-amidates might be due to the fact that β-NMN is an inner salt and is thus less nucleophilic. Under these conditions, a second dissociation of the phosphoric acid in the β-NMN, pK_a ~ 7, is probably not occurring to any significant extent. Accordingly, we attempted to activate the reaction using Lewis acid additives. The coupling between β-NMN and AMP-imidazolidate in the presence of $MnCl_2$–$4H_2O$ in formamide gave the desired NAD^+ in 25% yield after 16 h.[16] Further fine-tuning of the reaction conditions improved conversion up to 78% (HPLC assay yield). Typically, the reaction was carried out using 1.0 equiv. of AMP-morpholidate (**13**) with 1.1 equiv. of β-NMN (**5**) in 0.2 M solution of $MnCl_2$ (1.5 equiv.)[17] and $MgSO_4$ (2 equiv.) in formamide at room temperature for 16 h. Upon completion, the crude NAD^+ was precipitated from the reaction mixture with MeCN, and further purified by resin chromatography (Sephadex QAE A-25, elution with 0.25 M aq. $(NH_4)HCO_3$ solution; then Amberite XAD-16 with water–MeOH gradient at 5 °C)[18] followed by freeze-drying to give the NAD^+ as its ammonium salt with > 99% purity in 58% isolated yield.

The practical synthesis of NAD^+ outlined above has a number of noteworthy steps. The mild deacetylization procedure allowed isolation of the crystalline air stable nicotinamide nucleoside. Phosphorylation conditions were developed to provide β-NMN in 80% isolated yield. A new catalyzed pyrophosphate formation between β-NMN and AMP-morpholidate using a combination of $MnCl_2$ and $MgSO_4$ gave NAD^+ in 78% yield. An improved resin isolation process provided NAD^+ in 58% isolated yield.

We are grateful to Dr R. Czaja, Mr J. Bergan and Mr Bob Reamer for technical assistance.

3 While β-NMN is commercially available, its high price ($508 per gram, Sigma 1997 catalog) and a lack of supply made large scale preparation of NAD^+ difficult. For other preparations of β-NMN, see D. R. Walt, V. M. Rios-Mercadillo, J. Auge and G. M. Whitesides, *J. Am. Chem. Soc*., 1980, **102**, 7806; D. R. Walt, M. A. Findeis, V. M. Rois-Mercadillo, J. Auge and G. M. Whitesides, *J. Am. Chem. Soc*., 1984, **106**, 234; G. M. Whitesides and D. R. Walt, US Pat. 4,411,995-A, 1983; R. Jeck, P. Heik and C. Woenckhaus, *FEBS Lett*., 1974, **42**, 161.

6 In considering an efficient method for the synthesis of the pyrophosphate, we attempted to prepare the intermediate dichlorophosphate (phosphorodichloridate). Dichloridate was then treated *in situ* with AMP monosodium salt and triazole. However, no pyrophosphate bond formation was observed by ^{31}P NMR spectroscopy.

7 In an attempt to eliminate the bis-adduct formation, the reaction was also carried out using a 1 : 1 mixture of $POCl_3$–H_2O [*in situ* generation of $(HO)POCl_2$]; see M. Yoshikawa, T. Kato and T. Takenishi, *Bull. Chem. Soc. Jpn.*, 1969, 3505.

8 Chromatography on Dowex resin (two successive columns, 1X2 formate, 50WX8 H^+ form) followed by subsequent lyophilization of the aqueous fractions provided β-NMN in 80% yield, 97% purity (120 g scale). The two resin column isolation process proved to be operationally simple and the Dowex 50WX8 resin (H^+ form) served the dual purpose of purification and, more importantly, pH adjustment to provide the desired inner salt form of β-NMN.

9 The crude β-NMN was initially purified by a resin-free isolation [*i.e.* precipitation followed by treatment with activated carbon (Ecorsob-C, P-502-H)]. Although the process is simple, the yield for the next coupling reaction with AMP-morpholidate under the optimized condition was only moderate (it still required pH adjustment using H^+ cation resin). Alternatively, a direct resin chromatography using Dowex (50W X 8-100) resin column was developed (97% purity, eluted with 5% formic acid in water). However, this procedure required high resin loads with the product eluting in a large volume of water.

17 For a successful high yielding coupling reaction, reagents and the solvents were dried. A $MnCl_2$ solution was prepared by dissolution of the commercial tetrahydrate in formamide to give a 0.2 M stock solution. The solution was dried over 4 Å molecular sieves for several days prior to use. Typically the solution had 0.5 M H_2O content and was used for the reaction successfully. Use of commercial anhydrous $MnCl_2$ proved inferior.

18 Purification of NAD^+ using resin chromatography at room temperature resulted in partial decomposition of purified NAD^+ (5% purity loss). Therefore, the chromatography was carried out at 5 °C (110 g scale, > 99% purity).

The cyclization mechanism of squalene in hopene biosynthesis: the terminal methyl groups are critical to the correct folding of this substrate both for the formation of the five-membered E-ring and for the initiation of the polycyclization reaction†

Tsutomu Hoshino,*[ab] and Tomohiro Kondo[b]

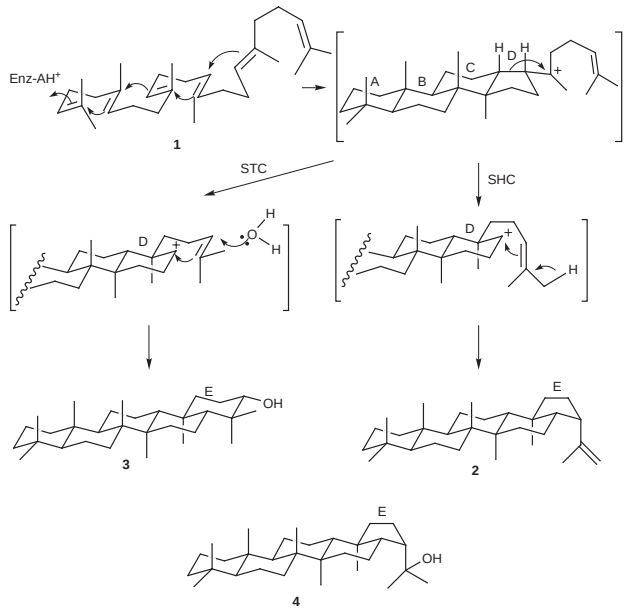
Received (in Cambridge, UK) 18th February 1999, Accepted 10th March 1999

Incubations of C(23)-norsqualenes 5 and 6, lacking one of the two terminal methyl groups, with squalene-hopene cyclase gave unprecedented products 7 and 8 having a tetrahymanol skeleton together with a neohopane skeleton 12, strongly suggesting that the two geminal methyls of squalene 1 are critical to the formation of the five-membered E-ring in hopene biosynthesis and also are required to initiate the cyclization reactions of 1 into the pentacyclic triterpenes 2 and **3**.

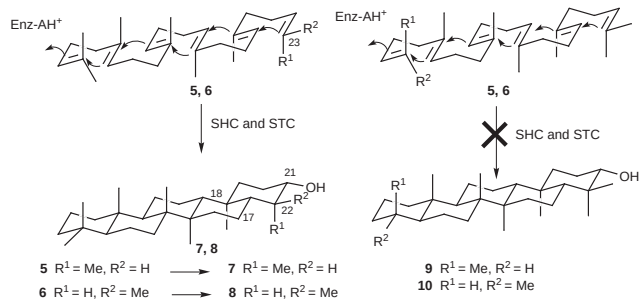
The biocyclization of squalene **1** into hop-22(29)-ene **2** catalyzed by squalene-hopene cyclase [EC 5.4.99.-] (SHC) or into tetrahymanol **3**, by squalene-tetrahymanol cyclase [EC 5.4.99.-] (STC), is one of the most intricate biochemical reactions (Scheme 1).[1] Compound **4**, hopan-22-ol, is a minor by-product. The cyclization proceeds *via* precise enzymatic control to form the fused 6/6/6/6/5- or 6/6/6/6/6-ring system and nine new stereocenters. The polyene cyclization reaction of **1** is analogous to that of 2,3-oxidosqualene into lanosterol catalyzed by lanosterol synthase.[1] Recently, it has been proposed that a ring expansion process from the five- to the six-membered ring is involved in the D-ring formation of hopene biosynthesis, prior to the further cyclization (Scheme 1).[2a,b] Formation of the five-membered intermediate D-ring is consistent with the Markovnikov rule. The expansion process of the D-ring may also be responsible for tetrahymanol biosynthesis.[2c] Such a ring expansion reaction was also demonstrated for the oxidosqualene cyclization.[3] Computational energy calculations of the five- and six-membered intermediates have supported the feasibility of such a ring expansion process.[4] The structure of **2** differs from that of **3** only in the terminal E-ring, *i.e.* five- and six-membered rings for **2** and **3**, respectively. To gain insight into the different cyclization mechanism between SHC and STC, the substrate analogues **5** and **6**, lacking one of the two terminal methyls in squalene backbone **1**, were separately incubated with SHC or STC, resulting in the formation of **7**, **8** and **12** as SHC enzyme products, and **7** and **8** as STC products; SHC, despite responsibility for the formation of the five-membered E-ring, did produce a tetrahymanol skeleton having a six-membered E-ring. We show herein that the terminal methyl groups play a critical role for the determination of either five- or six-membered E-ring formation.



Scheme 1

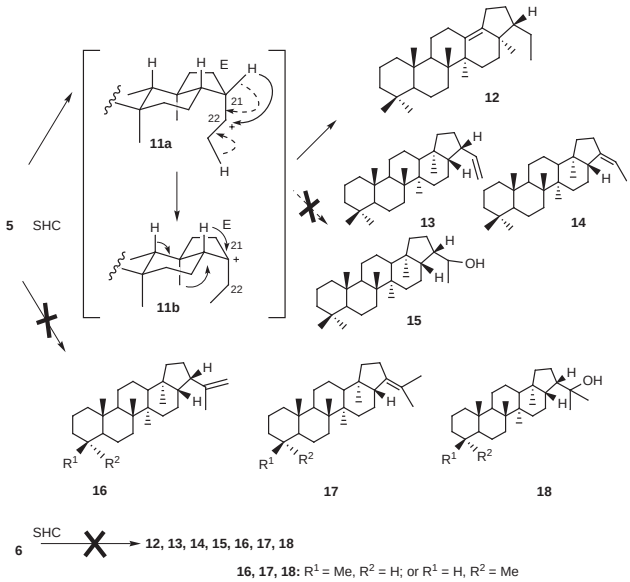
The analogues **5** and **6** were synthesized as follows: (±)-2,3-oxidosqualene was treated with HIO_4 to give the C_{27}-aldehyde, which was then subjected to a Wittig reaction with $EtPPh_3Br$ in the presence of Bu^nLi in THF. The C(23)-norsqualenes **5** and **6** thus obtained were separated with a SiO_2 column (10% $AgNO_3$) with hexane; **6** followed by **5.** The 7 methyl signals of **5** in $CDCl_3$ were as follows: δ_H 1.66 [3H, s, (*E*)-CH_3C=] and 1.58 [18H, (*Z*)-CH_3C=], while those of **6** were: δ_H 1.66 [3H, s, (*E*)-CH_3C=], 1.61[3H, brd, *J* 5.8, (*E*)-CH_3C=], 1.58 [12H, s, (*Z*)-CH_3C=] and 1.57 [3H, s, (*Z*)-CH_3C=].[5]

Separate incubations of **5** and **6** with cell-free homogenates from the cloned *E. coli* harboring SHC under catalytic optimal conditions[6] afforded highly polar products **7** and **8**, respectively (Scheme 2). From the incubation mixtures of **5**, another product **12** was found together with some minor products, both of which had lower polarities than **7** on TLC. Separation of each product was performed using a SiO_2 column with hexane–EtOAc, but the minor products, present in negligible amounts, were inseparable even on $AgNO_3$–SiO_2 TLC. Isolation yields of **7** and **12** from **5** were 17 and 12%, respectively, while that of **8** from **6** was 16%; neither **12** nor the minor products were detected from **6** (Scheme 3), using the same quantities of the substrate and the cell-free extracts as for **5**.



Scheme 2

† Details of orbital interactions and 2D NMR analyses for **7**, **8** and **12** are available from the RSC website, see: http://www.rsc.org/suppdata/cc/1999/731/



Scheme 3

Independent incubations of **5** and **6** with cell-free extracts from *Tetrahymena pyriformis* STC[7] also gave **7** and **8** (1 : 2.5 ratio), respectively. No other products were detected. The products with STC were indistinguishable from those with SHC *via* GC-MS.

The structures of highly polar compounds **7**[5] ($C_{29}H_{50}O$, EI-HRMS: *m/z* 414.3834; requires 414.3862) and **8**[5] ($C_{29}H_{50}O$, *m/z* 414.3854) were determined *via* NMR analysis. The signals at δ_C 74.1 and 76.7 in **7** and **8**, respectively, proved the involvement of a hydroxy group. Detailed analyses using 2D NMR revealed that **7** and **8** had a pentacyclic tetrahymanol skeleton possessing a chair conformation of the E-ring.[5] The hydroxy groups of both **7** and **8** were in the same equatorial orientation at the 21-position, but the arrangements of the methyl at the 22-position were different; axial for **7** by taking account of the coupling constants of H-21 [δ_H 3.69 (*ddd*, J = 11.2, 5.2, 5.2 Hz)] and equatorial for **8** owing to the *ddd* splitting of H-21 [δ_H 3.05 (J = 11.0, 11.0, 4.8 Hz)]. Product **12**[5] ($C_{29}H_{48}$, EI-HRMS: *m/z* 396.3722; requires 396.3756) did not have a hydroxy group. One of the 7 methyl groups appeared as a triplet (J = 7.6 Hz) and the other 6 methyls as singlets in the ^{1}H NMR spectrum, showing the presence of one ethyl group in **12**, and detailed analysis revealed a neohopene skeleton,[2a] but with a carbon skeleton of C_{29}.

Formation of the tetrahymanol skeleton by SHC has never been reported before, and also is quite interesting from the evolutionary aspect of squalene cyclases. The E-ring formation proceeded with complete stereoselectivity; the (23*Z*)-methyl group of **5** was axial, while the corresponding *E*-methyl of **6** was equatorial during the E-ring formation. The methyl orientations of each product from SHC agreed with those from STC (Scheme 2), and were consistent with the previous report that the (23*E*)-methyl of natural **1** was arranged in an equatorial orientation during the E-ring formation.[7a] The hydroxy groups of both **7** and **8** were introduced in the same equatorial disposition as a result of nucleophilic attack of a water molecule in an equatorial direction on the C-21 cation. The cyclization of the six-membered E-ring formation would be a concerted reaction under stereoelectronic control and explained in terms of HOMO–LUMO interactions.[8]

It is noticeable that **12** was produced only from **5**, and not from **6** (Scheme 3). This fact implicates that the (23*Z*)-methyl of **1** is more important than the (23*E*)-methyl for the formation of the hopanyl cation **11** with the 5-membered E-ring. However, the two terminal methyls would be necessary for the complete building of the five-membered E-ring, since the six-membered species **7** and **8** were produced in significant amounts when one of the two methyls was absent. Why was the tetrahymanol skeleton produced by the incubations of the norsqualene **5** and **6** with SHC? One plausible answer may be that the two geminal methyls strongly bind to SHC to acquire the desired conformation, shown in Scheme 1, during the formation of the five-membered E-ring, and the substrate affinity would become looser when one of the terminal methyls is absent, which would have led to the formation of a tetrahymanol skeleton under stereoelectronic control. The binding force of the *Z*-methyl to the SHC would be stronger than the corresponding *E*-methyl, because **12** was produced only from **5**, and not from **6**. The absence of **13** from **5**, although the hopanyl cation **11** has been produced, suggests that the migration of the hydride (1, 2-shift) must be fast compared with the two deprotonation reactions for the formations of **13** and **14**. This would be due to a greater stability of the tertiary C21-carbocation intermediate **11b** compared to the secondary C22-cation **11a**. The hopanol analogue **15** was also not found. At the present time, we cannot propose which terminal methyl of either the *Z*- or *E*-isomers of the natural **1** is responsible for the proton elimination when the double bond in **2** is introduced. Compounds **9**, **10**, **16**, **17** and **18** were also not detected in any reaction mixture from either SHC or STC, all of which are the presumed enzymic products based on the idea that the polycyclization could be initiated from the methyl-deficient part (Scheme 2 and 3). This finding strongly suggested that the two geminal methyls are indispensable for the initiation of polycyclizations by both STC and SHC, which is in contrast to the report that 2,3-*trans*-1′-norsqualene 2,3-oxide, lacking one methyl on the epoxide ring, was cyclized by the lanosterol synthase.[1,9]

This work was partly supported by a Grant-in-Aid to T.H. (No.0966011) from the Ministry of Education, Science and Culture, Japan.We are also indebted to Dr M. Takahashi, Tsukuba University, for the gift of *Tetrahymena pyriformis* (GL strain).

Received (in Cambridge, UK) 4th January 1999, Accepted 17th March 1999

Separation of methylalumoxane (MAO) by adsorption on siliceous porous materials with different average pore diameters has been carried out; polymerization of ethylene was conducted with Cp_2ZrCl_2 using the separated MAO as cocatalyst, it was found that the MAO adsorbed on MCM-41 with average pore size of *ca*. 25 Å is very effective for ethylene polymerization.

Methylalumoxane (MAO) generated by controlled hydrolysis of trimethylaluminium (TMA) is known to be a changeable mixture of oligomers owing to the coexistence of TMA. Although several structures have been proposed for MAO such as rings, clathrates and linear or branched chains, the detailed structure of active MAO remains ambiguous because of the multiple equilibria being present in the solution.[1–3]

Recently, heterogenization of the alumoxane structure has been widely studied by using a variety of porous materials such as amorphous silica gel, zeolite or siliceous mesoporous materials MCM-41 as carriers.[4] However, no report concerning the adsorptive separation of MAO by such porous materials has been published. From such a viewpoint, we have attempted to separate MAO with the use of typical porous inorganic materials having different pore sizes and tested them towards ethylene polymerization. From those results, we propose here the potential use of mesoporous molecular sieve MCM-41 for the separation of active MAO.

MCM-41 has a regular array of uniform unidimensional pores where diameter can be controlled by altering the alkyl chain length of the surfactant.[5] Siliceous MCM-41(*n*) [*n*; chain length of 10, 16 and 22] were prepared from surfactants of decyltrimethylammonium bromide, hexadecyltrimethylammonium bromide and docosyltrimethylammonium chloride.[6,7] A silicalite of a MFI type was prepared under conventional hydrothermal synthesis conditions. Amorphous silica gels (average pore diameter : grade P6 = 137 Å, P10 = 293 Å) were donated by Fuji Silysia Co. To prevent the reaction between MAO and the surface hydroxy groups in the carriers, these materials were silylated by refluxing for 8 h with trimethylchlorosilane as a silylating agent. Characterization of these materials was conducted by X-ray diffraction (Rigaku RINT 2000), FTIR (JEOL JIR-7000) and nitrogen adsorption (Belsorp 28SA).

MAO was purified by drying the commercial MAO (from Tosoh Akuzo Co.) *in vacuo* in order to remove the free TMA. The amount of TMA left in the purified MAO was estimated to be *ca*. 8 wt% by ^{1}H NMR (Varian Gemini 300).[8] Separation of MAO from the silylated porous materials was conducted as follows : 0.7 g of each carrier was added to 10 mmol (based on Al) of MAO in toluene (10 ml) and the mixture was left to stand at room temperature for 5 h. The solid fraction was separated by filtration and washed 3 times with 20 ml toluene, followed by drying at room temperature under vacuum. The concentrations of Al in both solution and solid fractions were analyzed by inductively coupled plasma atomic emission spectroscopy (ICP, Seiko SPS7700) after decomposition of MAO with nitric acid. The concentrations of Zr were also analyzed by ICP.

Polymerization of ethylene was conducted at 40 °C for 10 min with Cp_2ZrCl_2 using the separated MAO as cocatalyst. The Al/Zr ratio in the feed was kept constant. Measured amounts of toluene and the separated MAO were introduced into a 300 ml glass reactor equipped with a mechanical stirrer at room temperature. After the reactor was heated to the polymerization temperature (40 °C), the MAO solution was saturated with ethylene. A given amount of Cp_2ZrCl_2 was then injected to initiate the polymerization reaction. Ethylene was continuously fed to the reactor to keep the pressure constant during polymerization. The polymerization reaction was terminated by adding acidified methanol (5 wt% HCl). The precipitated polymers were washed with fresh methanol and dried under vacuum at 60 °C for 6 h. The number-average molecular weight ($\overline{M}_n$) and molar mass distribution (MMD; $\overline{M}_w/\overline{M}_n$) of the polymers were measured at 145 °C by gel permeation chromatography (GPC; Senshu Scientific SSC7100) using *o*-dichlorobenzene as the solvent. The GPC was calibrated using polystyrene standards and the method of universal calibration.

The synthesized MCM-41(*n*) (specific BET surface area *ca*. 1000 $m^2\ g^{-1}$) and silicalite (382 $m^2\ g^{-1}$) had well defined structures, as demonstrated by their X-ray diffraction patterns. The loss of the 3740 cm^{-1} peak assigned to the isolated OH groups was observed in the FTIR spectra of the silylated materials. Although a slight reduction in the specific BET surface area and the pore size calculated by the Dollimore–Heal (D–H) method was observed for silylated materials, no structural degradation occurred. The amount of MAO adsorbed in the carrier strongly depended upon its pore diameter. MCM-41(10), MCM-41(16) and MCM-41(22) showed higher adsorption ability, while MAO was scarcely adsorbed by silicalite probably due to an insufficient pore size. The pore volume of the MAO-containing MCM-41(16) (0.495 $cm^3\ g^{-1}$) was reduced to *ca*. three fifths of its original value.

Fig. 1 shows the correlation between the pore size of porous materials and the activity of ethylene polymerization when MAO left in the liquid phase was used as cocatalyst. Activity is defined as the yield of polyethylene (PE) calculated from the

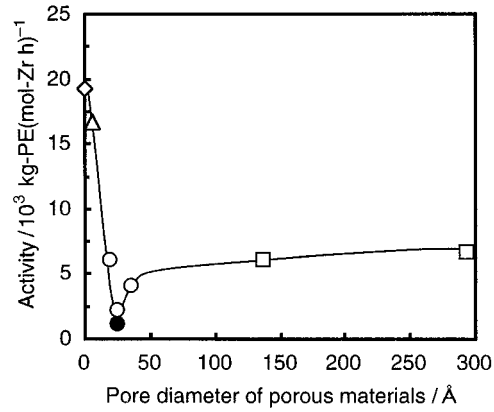

Fig. 1 Effect of pore diameter of porous materials on the initial activity of ethylene polymerization using the solution fraction. *Polymerization conditions*: T = 40 °C, Cp_2ZrCl_2 = 0.001 mmol, Al/Zr = 1000: (◇) ordinary MAO, (△) Silicalite, (○) MCM-41, (●) addition of TMA (1 mmol), (□) Silica gel.

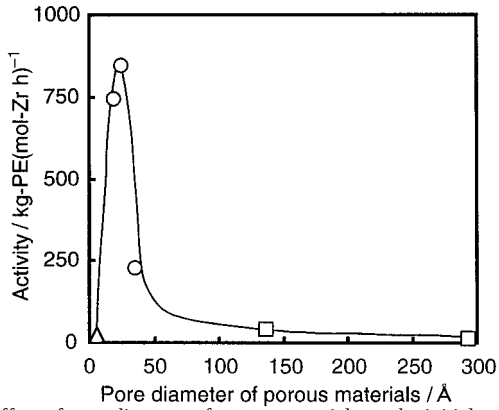

Fig. 2 Effect of pore diameter of porous materials on the initial activity of ethylene polymerization using the solid fraction. *Polymerization conditions*: T = 40 °C, Cp_2ZrCl_2 = 0.02 mmol, Al/Zr = 40: (△) Silicalite, (○) MCM-41, (□) Silica gel.

ethylene consumption at 10 min of the polymerization time. It was confirmed that the ethylene consumption measured by the flow meter agrees well with the polymer yield. The polymerization activity decreased drastically with increase in the pore diameter, and the minimum value was obtained at *ca*. 25 Å, suggesting that the MAO adsorbed on MCM-41 with an average pore size of *ca*. 25 Å is very effective for ethylene polymerization. Of course, we can not rule out a possibility that some factors other than the size of MAO affect the polymerization activity.

It is reported that some free TMA remains unremoved even when the MAO solution is dried under vacuum.[9,10] The residual TMA is considered to play an important role in the activation of metallocenes. Accordingly, it may be plausible to assume that such a marked decrease in the polymerization activity as observed in Fig. 1 is attributable to the reduction of free TMA. To clarify this point, ethylene polymerization was conducted by injecting additional TMA (1 mmol). The activity decreased slightly as shown in Fig. 1, indicating that the decrease in the activity is caused by some other factors.

Ethylene polymerization was then carried out using the solid fraction as cocatalyst. Prior to the polymerization, it was confirmed from the following experiments that the MAO once adsorbed in MCM-41(10), does not elute into the liquid phase during polymerization. The mixture of MAO-containing MCM-41(10) and Cp_2ZrCl_2 was brought into contact in toluene, and ethylene polymerization was conducted using the solution fraction as cocatalyst. However, only a trace amount of polymer was obtained. The degree of Al elution measured by elemental analysis of the solution fraction was *ca*. 1%. Fig. 2 shows the correlation between the pore size of porous materials and the polymerization activity, where the activity was evaluated on the basis of the amount of Cp_2ZrCl_2 occluded in the pores. The Al/Zr ratios in the solid were 70–90. In contrast to the results obtained by using the solution fraction (Fig. 1), the polymerization activity of the solid fraction was initially low and increased markedly, followed by a drastic decrease passing through a maximum value at *ca*. 25 Å. The result again supports the above assumption that the MAO adsorbed on MCM-41 with average pore size of *ca*. 25 Å is very effective for ethylene polymerization. Similar results have recently been reported by Van Looveren *et al*.[11] They studied the *in-situ* synthesis of MAO in the pores of MCM-41, and found that the $\{C_2H_4(1\text{-indenyl})_2\}Zr(CH_3)_2$ catalyst combined with the resulting MAO displays activity as high as the corresponding ordinary homogeneous catalyst system for ethylene–propylene co-oligomerization.

Table 1 Number-average molecular weight ($\overline{M}_n$) and molar mass distribution (MMD: $\overline{M}_w/\overline{M}_n$) of polyethylene obtained with various MAO materials.

Cocatalyst	Carrier	$10^{-3}\,\overline{M}_n$	$\overline{M}_w/\overline{M}_n$
MAO (solution fraction)	Silicalite	160	2.3
	MCM-41(10)	156	2.3
	MCM-41(16)	116	2.4
	MCM-41(22)	149	2.3
	Silica gel P6	178	2.1
	Silica gel P10	145	2.2
MAO (solid fraction)	MCM-41(10)	46	2.9
	MCM-41(16)	22	3.7
	MCM-41(22)	34	3.7
	Silica gel P6	7	6.6
Ordinary MAO		245	1.9

For reference, some analytical data of polyethylene obtained here are summarized in Table 1. The number-average molecular weights ($\overline{M}_n$) of polyethylene produced by the solution fraction are much higher as compared with those produced by the solid fraction. On the other hand, the molar mass distributions (MMD) of polyethylene produced by the solid fraction seem to be slightly broader. These results may suggest that the polymerization in MCM-41 is controlled by monomer (ethylene) diffusion through the pores which are sterically very crowded by MAO, Cp_2ZrCl_2 and produced polyethylene. A further study is now in progress to isolate the active MAO using the modified separation technology.

We thank Dr E. Kaji (Tosoh Akuzo Co.) for helpful discussions.

Received (in Cambridge, UK) 4th February 1999, Accepted 11th March 1999

Grafting an ethynylated-pyrene moiety to a Ru(II) or Os(II) polypyridine complex perturbs the photophysical properties of the metal fragment and, when the relevant energy levels are properly balanced, provides a 115-fold prolongation of the triplet lifetime.

Ford and Rodgers[1] have described reversible triplet energy transfer between pyrene and a ruthenium(II) polypyridine complex attached *via* a flexible hydrocarbon chain. This strategy prolonged the triplet lifetime of the metal complex by a factor of *ca*. 11-fold; a feat confirmed by Sasse and coworkers[2,3] who achieved a 5-fold extension in triplet lifetime with a similar dyad. In seeking to design improved luminophores for specific analytical applications we note the following points: (i) conformational heterogeneity introduced by the flexible connector, or by direct attachment of the reactants,[4] would be avoided with a rigid spacer. (ii) The rates of forward and reverse triplet energy transfer would be increased with an acetylene group as connector.[5] Consequently, photoactive dyads have been synthesized (Scheme 1) wherein an ethynylated pyrene moiety is grafted onto an Ru(II) or Os(II) polypyridine complex† and the photophysical properties recorded.

The emission spectrum recorded for pyr-bpy-Os (Fig. 1) is characteristic[5] of an 'Os(bpy)' molecular fragment (bpy = 2,2′-bipyridine), allowing[6] the triplet energy (E_T) to be derived (Table 1). The emission quantum yield (Φ_L), peak maximum (λ_L) and lifetime (τ_L) remain as expected for an 'Os(bpy)' fragment while the transient absorption spectrum recorded after laser excitation (FWHM = 20 ps, λ = 532 nm) is entirely consistent[7] with the excited triplet state being localized on the metal complex (Fig. 2). Decay of the triplet absorption signal follows first-order kinetics, giving a lifetime (τ_T) similar to that measured by emission spectroscopy (Table 1). Laser spectroscopy shows that the pyrene triplet is not populated but, since the corrected emission excitation spectrum closely matches the absorption spectrum, photons absorbed by pyrene must be channelled quantitatively to the 'Os(bpy)' fragment. It appears, therefore, that the triplet state of the 'Os(bpy)' fragment lies at lower energy than the pyrene-like triplet state.[8]

Under identical conditions, the emission spectrum of pyr-bpy-Ru is characteristic of the 'Ru(bpy)' fragment (Fig. 1) but emission is exceptionally long-lived for such a species (Table 1). Both λ_L and Φ_L remain typical of a 'Ru(bpy)' fragment bearing an ethynylene group while the corrected excitation spectrum agrees well with the absorption spectrum. Control studies show the free ligand (*i.e.*, pyr-bpy) to be non-phosphorescent at rt. Analysis of the emission spectral profile[6] shows that the triplet energy of the 'Ru(bpy)' fragment greatly exceeds that of the corresponding 'Os(bpy)' fragment (Table 1). However, the transient absorption spectral profile (Fig. 2) is remarkably similar to that recorded for the pyrene unit in pyr-bpy and is unlike that of any 'Ru(bpy)'-based triplet. This pyrene-like triplet decays with the same lifetime as found for the 'Ru(bpy)'-like luminescence. These observations can be satis-

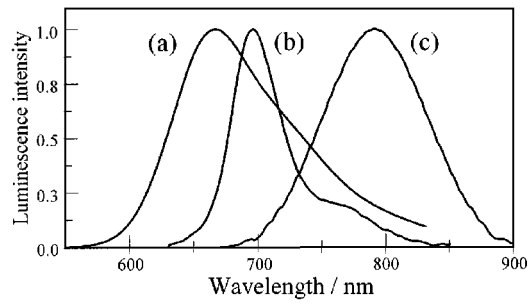

Fig. 1 Corrected luminescence spectra recorded for (a) pyr-bpy-Ru, (b) pyr-terpy-Ru and (c) pyr-bpy-Os in deoxygenated acetonitrile at 20 °C.

Table 1 Photophysical properties measured for the various pyrene-containing molecular dyads in deoxygenated acetonitrile at 20 °C

Compound	λ_L/nm	Φ_L	τ_L/ns	τ_T/ns	E_T/kJ mol^{-1}	ΔE_{TT}/cm^{-1}	α	K	S
pyr-bpy-Ru	670	0.026	42 000	43 000	195	930	0.98	49	35
pyr-terpy-Ru	698	0.005	580	560	179	−390	0.13	0.15	1.2
pyr-bpy-Os	790	0.001	12	14	162	−1865	0	0	1.0

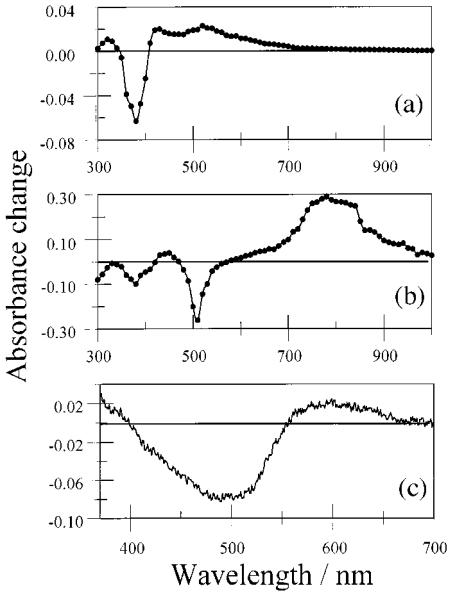

Fig. 2 Transient differential absorption spectra recorded for (a) pyr-bpy-Ru after 500 ns, (b) pyr-terpy-Ru after 100 ns, and (c) pyr-bpy-Os after 1 ns in deoxygenated acetonitrile at 20 °C following excitation with a 20-ps laser pulse at 532 nm.

factorily explained[1] in terms of the two triplet states being in thermal equilibrium at rt, with the balance favouring the pyrene-like triplet. In fact, comparing Φ_L measured for pyr-bpy-Ru with appropriate 'Ru(bpy)'-based reference compounds[5] lacking the pyrene substituent but possessing a similar radiative rate constant, allows the fraction (α) of pyrene-like triplets in the equilibrium distribution to be established at 0.98. On this basis, the energy of the pyrene-like triplet state must be *ca*. 184 kJ mol^{-1} since the equilibrium constant [K = $\alpha/(1-\alpha)$] is calculated to be *ca*. 49.

Confirmation of these energy gaps was sought by measuring the photophysical properties of pyr-terpy-Ru for which r.t. emission (Fig. 1) is characteristic[9] of the 'Ru(terpy)' fragment (terpy = 2,2′:6′,2″-terpyridine). The emission lifetime recorded for pyr-terpy-Ru is long for an ethynylated mononuclear 'Ru(terpy)' fragment (Table 1) whilst the transient absorption spectrum clearly contains important contributions associated with triplet-triplet transitions localized on the metal complex (Fig. 2). Spectral analysis indicates that the triplet energy of the 'Ru(terpy)' fragment in pyr-terpy-Ru is slightly lower than that derived for the pyrene-like triplet with the result that the triplet equilibrium distribution (K = 0.15; α = 0.13) lies in favour of the metal complex. Reversible energy transfer, therefore, provides only a minor stabilization for the triplet localized on the 'Ru(terpy)' fragment. It should be noted, however, that relative to the parent $[Ru(terpy)_2]^{2+}$ complex (Φ_L < 0.0002; τ_L = 0.56 ns), pyr-terpy-Ru is strongly luminescent at r.t.

Reversible triplet energy transfer[1–3] between the terminals in pyr-bpy-Ru serves to extend the triplet lifetime of the 'Ru(bpy)' fragment to 42 μs, which is well beyond the range of any related system. The equilibrium distribution is established within the 20 ps excitation pulse, indicating that both forward and reverse energy-transfer steps are rapid. The observed triplet lifetime is set by the inherent decay rate constants for individual triplets localized on pyrene (k_P) and 'Ru(bpy)' (k_R) and by the fractional contribution of each component [eqn. (1)]:

$$k_D = 1/\tau_T = \alpha k_P + (1 - \alpha)k_R \quad (1)$$

Here, α is determined by the energy gap (ΔE_{TT}) between the two triplets (Table 1) while k_P (= 7770 s^{-1}) is obtained by monitoring the triplet state of pyr-bpy under appropriate conditions. This allows k_R to be estimated from the experimental data and the derived value ($k_R = 8.4 \times 10^5$ s^{-1}) is seen to be comparable to decay rates measured for other ethynylated 'Ru(bpy)' fragments, where inherent triplet lifetimes tend to be slightly > 1 μs.[5] Furthermore, it now becomes possible to quantify the effect of the pyrene unit in terms of a stabilization factor ($S = k_R\tau_T$), which for pyr-bpy-Ru has a value of *ca*. 35 and is marginally greater than unity for pyr-terpy-Ru. For both compounds, however, S increases markedly when due allowance is made for the additional stabilization imposed by the ethynylene group. Thus, using k_R values appropriate[10] for simple 'Ru(bpy)' or 'Ru(terpy)' units having the same triplet energy as the metallo-fragments in pyr-bpy-Ru and pyr-terpy-Ru, respectively, gives revised S values of 115 and 10.‡ It is anticipated that this prolongation of the triplet lifetime will advance opportunities for employing the unique luminescence properties of 'Ru(bpy)'-based systems in sophisticated analytical or electro-chemiluminescent applications.

Notes and references

† Full synthetic details will be given elsewhere. All new compounds were authenticated by NMR, FTIR, MS and elemental analyses. *Selected data*: pyr-bpy-Ru, IR (KBr disc): 2195 cm^{-1} [ν(C≡C)];^{13}C{^{1}H} NMR ($CDCl_3$): δ 96.4 (C≡C), 90.7 (C≡C), MS (FAB$^+$, *m*-NBA): 939.0 $(M-PF_6)^+$; UV-VIS (MeCN) λ_{max}/nm (ε/dm^3 mol^{-1} cm^{-1}): 416 (45 200), 280 (118 300). pyr-bpy-Os, IR(KBr disc): 2195 cm^{-1} [ν (C≡C)] MS (FAB$^+$, *m*-NBA): 1029.0 (M − PF_6 + H)$^+$; UV-VIS (MeCN) λ_{max}/nm (ε/dm^3 mol^{-1} cm^{-1}): 408 (23 900), 284 (72 600). pyr-terpy-Ru, IR(KBr disc): 2192 cm^{-1} [ν(C≡C)]; ^{13}C{^{1}H} NMR (CD_3CN): δ 97.2 (C≡C), 93.1 (C≡C), MS (FAB$^+$, *m*-NBA): 937.2 $(M - PF_6)^+$; UV-VIS (MeCN) λ_{max}/nm, ε/dm^3 mol^{-1} cm^{-1}): 511 (44 800), 281 (53 200).

‡ For example, Cook *et al*.[10] list four $[Ru(bpy)_3]^{2+}$ analogues with emission maxima at 670 nm and for which the triplet lifetime is (0.36 ± 0.04) μs. Similarly, examination of the photophysical properties of $[Ru(terpy)_2]^{2+}$ complexes indicates that the triplet lifetime of a compound having an emission maximum at 698 nm should be (60 ± 15) ns.

Alkane-tetrathiol induced formation of remarkably stable self-assembled monolayer and polymer films containing electroactive tetrathiafulvalene moieties on metal electrodes

Hisashi Fujihara,* Hidetaka Nakai, Masakuni Yoshihara and Toshihisa Maeshima

Department of Applied Chemistry, Kinki University, Kowakae, Higashi-Osaka 577-8502, Japan.

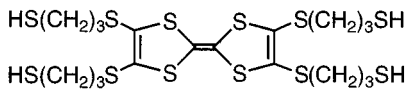
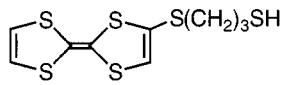
Received (in Cambridge, UK) 4th February 1999, Accepted 16th March 1999

Remarkably stable self-assembled monolayer and polymer films composed of a new tetrathiafulvalenyl-tetrathiol have been formed on metal electrodes: this is a new class of surface modification by self-assembly and electrochemical polymerization using the same alkane-tetrathiol.

Self-assembled monolayer and polymer films on metal surfaces are the focus of intense investigation, because these films constitute an important strategy in the surface modification of electrodes.[1–4] The majority of self-assembled organosulfur monolayers studied consist of adsorbates which contain an alkyl chain with a surface-active sulfur group, such as alkane-*monothiols* and *n*-alkyl disulfides, however, such surface modification using alkane-*polythiols* has received much less attention. Meanwhile, the modification of electrodes with electroactive polymer films has been performed from the electrochemical polymerization of pyrrole and thiophene-based monomers which are the most commonly used materials.[4] We have now found that a new class of surface-modification reagent, tetrathiafulvalenyl alkane-tetrathiol **1**, gives remarkably stable self-assembled monolayers on a gold (Au) electrode and polymer films on a glassy carbon (GC) electrode. To our knowledge, this is the first example for the surface modification of metallic electrodes with the same adsorbate molecule by the self-assembly method and electropolymerization using the same starting material.



1



2

The immersion of a clean polycrystalline gold electrode in a solution of the new tetrathiol **1**[5] (1.0 mM in CH_2Cl_2, 40 °C, 24 h) resulted in the formation of a monolayer of tetrathiol **1**, which chemisorbed on the gold surface *via* thiolate–Au bonds. After extensive rinsing of the modified electrode, the voltammetric response in CH_2Cl_2 clearly exhibited anodic and cathodic waves characteristic of the reversible two-electron oxidation of the immobilized tetrathiafulvalene (TTF)-groups [Fig. 1(a)]. The potential ($E_{1/2}$) for the oxidation process was +0.35 and +0.66 V (*vs.* Ag/0.1 M $AgNO_3$). The potential difference between the anodic and cathodic peaks was 20 mV at v = 100 mV s^{-1}, and the peak current increased linearly with the scan rate. These two voltammetric features unequivocally indicate the surface-confined nature of the electroactive TTF groups. The surface coverage (Γ) of **1** on the Au electrode was found to be 1.6×10^{-10} mol cm^{-2}.

Tetrathiol-monolayer modified Au electrode allowed to stand at 0 V in CH_2Cl_2 or MeCN showed no diminution of the anodic peak current response over more than several weeks, showing that the molecular film is not readily stripped by non-aqueous solvents. The electrochemical stability of the monolayer of **1** on an Au electrode in CH_2Cl_2 was investigated by continuously cycling the potential. After 10 scans between −0.05 and +0.95 V, only 5% of the electroactivity is lost [Fig. 1(b)]. This finding indicates that the monolayer of tetrathiol **1** is stable in non-aqueous solvents.[6] Interestingly, the monolayer of the *tetrathiol* **1** was remarkably stable compared to the monolayer of the *monothiol* **2** on an Au electrode as evidenced from the repeated electrochemical cycling of those monolayers.

Normally, alkane-monothiols can not be polymerized by repeated anodic oxidations and none of the polymer film from monothiol **2** was formed upon repeated cyclic scanning of the potential.[7] However, tetrathiol **1** on repeated electrochemical oxidation showed intriguing results. The first scan of the cyclic voltammogram of tetrathiol **1** in CH_2Cl_2 + 0.1 M NBu_4PF_6 at a glassy carbon electrode exhibited the regular reversible waves corresponding to the TTF–$TTF^{\cdot+}$–TTF^{2+} system at $E_{1/2}$ = +0.34 and +0.67 V [Fig. 2(a)]. These two waves are followed by an irreversible oxidation peak at +0.90 V (E_p) which seems to correspond to oxidation of thiol groups. Surprisingly, repeated

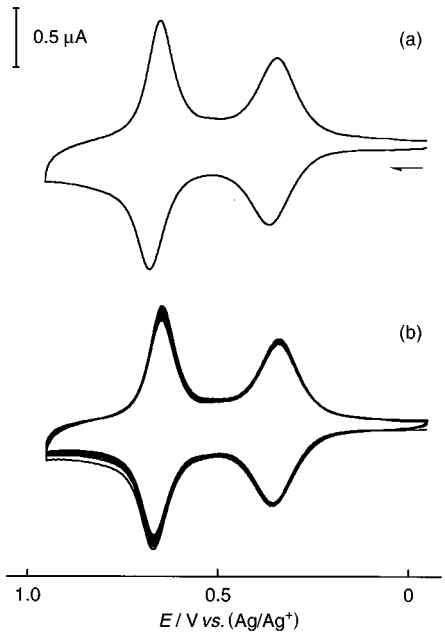


Fig. 1 Cyclic voltammograms for a monolayer of **1** adsorbed onto an Au electrode in 0.1 M NBu_4PF_6–CH_2Cl_2: (a) first scan; (b) multiple scans. Scan rate 100 mV s^{-1}.

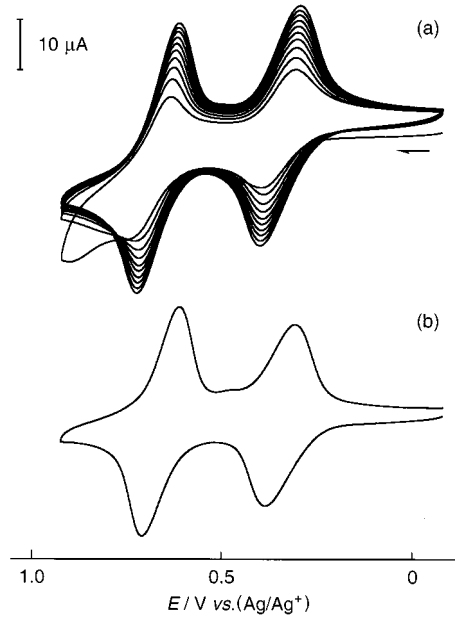

Fig. 2 (a) Oxidative electropolymerization of **1** (1 mM) by repeated potential scans on a GC electrode in 0.1 M NBu_4PF_6–CH_2Cl_2; scan rate 100 mV s^{-1}. (b) Cyclic voltammogram of a poly-TTF modified GC electrode in 0.1 M NBu_4PF_6–CH_2Cl_2; scan rate 100 mV s^{-1}.

scans over the −0.08 to +0.92 V range led to the growth of a polymer film on the electrode.[8] Evidence for this is given by the continuous increase in the peak intensity of the TTF–$TTF^{\cdot+}$–TTF^{2+} system. After 10 scans, the electrode was rinsed copiously with solvent and dipped into fresh CH_2Cl_2 solution. The cyclic voltammogram of the polymer–TTF modified electrode ($\Gamma = 1.0 \times 10^{-9}$ mol cm^{-2} after 10 cycles) is shown in Fig. 2(b).[9] The cyclic voltammogram of the polymer modified GC electrode displayed only two redox peaks corresponding to the TTF–$TTF^{\cdot+}$–TTF^{2+} system at $E_{1/2}$ = +0.34 and +0.66 V. This contrasts with the electropolymerization of pyrrole-substituted electroactive compounds which showed oxidation waves of both the pyrrole and the electroactive groups in the cyclic voltammogram. Many scans of the poly-TTF modified electrode can be performed without any change of the voltammetric wave. Thus, poly-TTF is readily formed as stable films on a GC electrode surface. This is a new type of controlled polymerization using alkane-polythiols.[10]

In summary, a monolayer of a new TTF-derivatized tetrathiol **1** on a gold electrode is more stable than that of monothiol **2** under electrochemical recycling. Tetrathiol **1** can be easily electropolymerized at moderate potential into highly stable poly-TTF films. Thus, alkane-tetrathiol **1** provides both remarkably stable monolayers and multilayers containing electroactive TTF moieties. Further work is currently in progress in this and related areas.

This work was supported in part by the Grant-in-Aid for Scientific Research No. 09239252 and No. 10133255 from the Ministry of Education, Science and Culture, Japan.

Received (in Cambridge, UK) 15th February 1999, Accepted 10th March 1999

The syntheses of $[Bu^tPAs(NMe_2)_2K{\cdot}pmedta]_2$ 1 and $[\{CyNAs(NMe_2)_2K\}_2]_\infty$ 2 from the reactions of $[As(NMe_2)_3]$ with Bu^tPH_2 and $CyNH_2$, respectively, in the presence of potassiated bases exemplify a general approach to multifunctional secondary phosphide and amide anions containing variable sets of group 15 donor centres.

Studies of alkali metal phosphoramide (containing $[R_2PNR]^-$)[1] and related hydrazide (containing $[R_2NNR]^-$)[2] complexes have revealed a diverse range of structural types in the solid state for this important class of ligands, in which both the anionic and neutral N and P centres can coordinate the cations. However, to our knowledge the only analogous ligands containing other combinations of group 15 elements to be structurally characterised are $[Bu^t(H)PPBu^t]^{-3}$ and $[Bu^t_2AsAsBu^t]^-$.[4] We have recently synthesised new polydentate imido and phosphinidene anion ligand systems containing other group 15 elements, such as $[Sb(ER)_3]^{3-}$ (E = N, P),[5] and now report that a related methodology involving dimethylamido group 15 reagents gives the anions $[REAs(NMe_2)_2]^-$. These secondary phosphide and amide anions (related to simple phosphoramides and hydrazides) are a new class of highly functionalised donor ligands.

The reaction of $[As(NMe_2)_3]$ (1 equiv.) with Bu^tPH_2/$[Bu^tPHK]$ (1:1 equiv.) can be controlled, giving the stable complex $[\{Bu^tPAs(NMe_2)_2\}K{\cdot}pmdeta]_2$ **1** in the presence of pmdeta [= $(Me_2NCH_2CH_2)_2NMe$].† This outcome contrasts with the prolonged reactions between $[As(NMe_2)_3]$ and [Bu^t-PHLi] (1:3 equiv.) or $[Bu^tPHLi]/Bu^tPH_2$ (1:1:1 equiv.), which yield species containing the cyclic $[(Bu^tP\}_3As)^-$ anion.[6] The reaction producing **1** appears to involve an acid-catalysed process (Scheme 1), as is suggested by the isolation of the related amide complex $[\{CyNAs(NMe_2)_2K\}_2]_\infty$ **2** from the reaction of $[As(NMe_2)_3]$ with $CyNH_2$ in the presence of $[Pr^i_2NK]$ (1:1:1 equiv.) as the base.†

The X-ray structures of **1** (Fig. 1) and **2** (Fig. 2)‡ reveal that both species are composed of similar centrosymmetric K_2P_2 and K_2N_2 dimeric units in the solid state, in which two K^+ cations are bridged by the anionic P and N centres of their respective $[Bu^tPAs(NMe_2)_2]^-$ and $[CyNAs(NMe_2)_2]^-$ ligands. The K–P bond lengths in **1** [K(1)–P(1) 3.315(4), K(1)–P(1a) 3.462(3)Å] and K–N distances in **2** [K(1)–N(1) 2.893(6) to K(1)–N(1A) 2.780(7) Å] within these dimer units are similar to those found in the few structurally characterised K phosphide[3,7] and amide[8] complexes. The K^+ cation in each complex further interacts with one of the Me_2N groups [K(1)–N(5) 2.991(8) in **1**, K(1)–N(3) 2.852(7)Å in **2**] to form a four-membered chelate ring. Further aggregation of the dimeric units of **1** is prevented by coordination of the K^+ cations by pmdeta, resulting in a distorted octahedral geometry at the metal centres. However, the absence of Lewis base solvation in **2** leads to the association of the dimers, *via* the second Me_2N group of each [CyN-$As(NMe_2)_2]^-$ anion [K(1)–N(2B) 3.071(7) Å], giving a novel poymeric chain structure. This arrangement results in a distorted-tetrahedral geometry for the K^+ centres and in the formation of puckered centrosymmetric $[KNAsN]_2$ rings which link the K_2N_2 dimer units of **2** together. The low coordination number of the K^+ cations of **2** appears to be compensated for by extensive, relatively short[9] Cy α-C···K and Me C···K contacts [K(1)···C 3.26–3.48Å].

Comparison with other As–P[10] and As–N[11] bonded compounds reveals that the As–P and As–N bonds in **1** [As(1)–P(1) 2.260(3) Å] and **2** [As(1)–N(1) 1.782(7) Å] are at the lower end of the range of values observed for single bonds, and in **2** this bond is significantly shorter than the two As–NMe_2 bonds (mean 1.914 Å). It seems most likely that the relatively short As–P bond in **1** largely stems from the effect of polarisation, with the geometry about the anionic P centre in this complex giving no indication of any partial multiple bonding [*e.g.* C(14)–P(1)–As(1) 98.1(3)°]. However, the bond angle at the

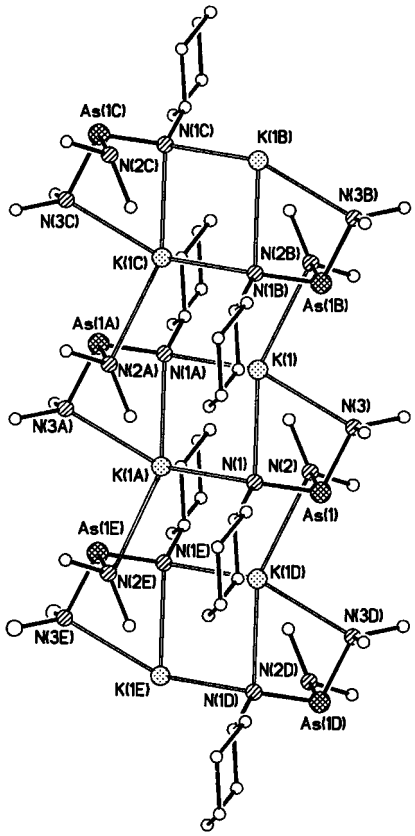

Fig. 2 Part of the infinite polymeric structure of **2** which runs along the *a*-axis of the unit cell. H atoms have been omitted for clarity. Selected bond lengths (Å) and angles (°): K(1)–N(1) 2.893(6), K(1)–N(1A) 2.780(7), K(1)–N(3) 2.852(7), K(1)–N(2B) 3.071(7), Cy α-C(–H) and Me C(–H) K(1)···C 3.26-3.48, As(1)–N(1) 1.782(7), As(1)–N(2) 1.894(7), As(1)–N(3) 1.935(6), K(1)–N(1)–K(1A) 87.9(2), N(1)–K(1)–N(1A) 92.1(2), C(1)–N(1)–As(1) 117.4(6), N(1)–As(1)–N(2) 98.9(3), N(1)–As(1)–N(3) 99.8(3), N(2)–As(1)–N(3), 97.5(3), As(1)–N(3)–K(1) 97.3(3).

anionic N centre in **2** [C(1)–N(1)–As(1) 117.4(6)°] may indicate that there is some contribution from p_π–d_π interaction, an effect which may be exacerbated by the elongation of the As–N bond involved in the chelate ring [As(1)–N(3) 1.935(6); *cf.* As(1)–N(2) 1.894(7)].

In conclusion, the synthetic route used in the preparation of **1** and **2** is potentially applicable to an extensive series of related group 15 anions. The $[Bu^tPAs(NMe_2)_2]^-$ and $[CyN\text{-}As(NMe_2)_2]^-$ anions **1** and **2** represent a unique set of readily accessible new ligands, containing combinations of group 15 elements within their frameworks (all of which being capable potentially of coordinating a metal centre). The structural studies of **1** and **2** provide the first indication of the coordination chemistry and structural trends in these species. The structure of **2** is particularly noteworthy, being composed of a polymer of dimers rather than having a more conventional ladder arrangment.[12]

† *Syntheses* **1**: [Bu^tPHK] was prepared by the reaction of $PhCH_2K$ (0.78 g, 6.0 mmol) with Bu^tPH_2 (0.4 ml, 6.0 mmol) in hexane (10 ml)/thf (5 ml) under argon. After stirring the reaction at room temp. (30 min.) it was cooled (−78 °C) and a mixture of $[As(NMe_2)_3]$ (6.0 mmol, 2.4 ml, 2.5 mol dm^{-3} in hexane) and Bu^tPH_2 (0.4 ml, 6.0 mmol) in hexane (10 ml) [which had previously been stirred at room temp. (30 min.)] was added. Excess pmdeta (7.1 mmol, 1.5 ml) was added and the reaction was allowed to warm to room temperature. Removal of the solvent under vacuum and addition of hexane (17 ml) gave a precipitate. Addition of thf (5 ml) and gentle heating dissolved the solid. Storage at −30 °C gave colourless crystals of **1**. First batch yield 0.30g (11%). mp 121 °C (decomp. to a brown solid). ^{31}P NMR (MHz, +25 °C, d_8-thf, rel. to 80% H_3PO_4–D_2O), δ−5.91(s). Satisfactory elemental analyses (C,H,N,P) were obtained for **1**.

2: [Pr^i_2NK] (6.0 mmol) was prepared by the reaction of $PhCH_2K$ (0.78 g, 6.0 mmol) with Pr^i_2NH (0.85 ml, 6 mmol) in hexane (20 ml)–toluene (10 ml). After heating to reflux and stirring at room temp. (30 min.), a mixture of $[As(NMe_2)_3]$ (3.9 ml, 1.55 mmol dm^{-3} in hexane, 6.0 mmol) and $CyNH_2$ (0.69 ml, 6.0 mmol) in hexane (10 ml) [which had previously been heated to reflux and stirred at room temperature (30 min.)] was added. After stirring at room temperature (10 min.) a green solution was formed with a small amount of precipitate. Gentle heating dissolved the solid and storage at −30 °C (24 h) gave yellow crystals of **2**. First batch yield 0.14 g (8%). ^1H NMR (250 MHz, +25 °C, d_8-thf), δ 2.60 (s., 12H, Me_2N), *ca.* 3.3–1.0 (collection of overlapping mult., 11 H, Cy). Satisfactory elemental analyses (C,H,N) were obtained for **2**.

Ir-catalysed allylic substitution: mechanistic aspects and asymmetric synthesis with phosphorus amidites as ligands

Björn Bartels and Günter Helmchen*

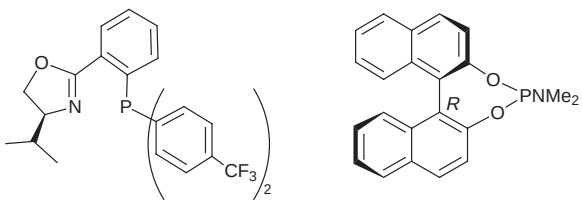
Organisch-Chemisches Institut der Universität, Im Neuenheimer Feld 270, D-69120 Heidelberg, Germany. E-mail: en4@ix.urz.uni-heidelberg.de

Received (in Liverpool, UK) 29th January 1999, Accepted 16th March 1999

Ir-catalysed allylic alkylations of enantiomerically enriched monosubstituted allylic acetates proceed with up to 79% retention of configuration using $P(OPh)_3$ as ligand; further evidence supports the assumption of σ-allyl complexes as intermediates, and high regio- and enantioselectivity in asymmetric allylic alkylations of achiral or racemic substrates is achieved with phosphorus amidites as ligands.

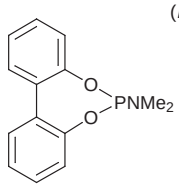
The transition metal catalysed asymmetric allylic alkylation is a useful reaction in organic synthesis.[1] Over the last few years, research has been focused on finding catalysts which favour the formation of branched, chiral products **3** in the substitution of monosubstituted allylic substrates **1** or **2** (Scheme 1). With palladium complexes this is so far only possible for special cases.[2] With Mo- or W-based catalysts, so far only substrates with R = aryl gave high levels of both regio- and enantioselectivity.[3] Reactions with all these catalysts proceed *via* π-allyl complexes as intermediates which display fast π–σ–π-rearrangement. However, the substitutions catalysed by Fe- or Rh-complexes probably proceed *via* σ-allyl complexes which isomerise slowly so that almost complete chirality transfer occurs. As a consequence, even with achiral ligands, enantiomerically enriched products **3** are obtained in a double inversion process from enantiomerically enriched substrates **1**.[4]

Ir-catalysed allylic substitutions have so far been rarely studied. It was recently found that catalysts prepared by combining $[Ir(COD)Cl]_2$ with a strong π-acceptor ligand, *e.g.* triphenyl phosphite, *in situ* give rise to excellent regioselectivities in favour of the branched product **3** for both aryl and alkyl substituted allylic substrates.[5] We were able to achieve regioselectivity of 95 : 5 and enantioselectivity of 96:4 for aryl substituted substrate **2b** with phosphinooxazoline **5** as chiral ligand.[6]



5

(*R*)-**6**



7

Extending this work, we have investigated the application of our catalyst to alkyl substituted allylic acetates. The reaction with substrate *rac*-**1a** using an *in situ* catalyst $[Ir(COD)Cl]_2$–**5** (24 h at 65°C) was found to be significantly slower than the reaction catalysed by $[Ir(COD)Cl]_2$–$P(OPh)_3$ or $[Ir(COD)Cl]_2$ without an additional ligand (*ca.* 3 h at room temperature) (*cf.* Table 1, entries 1,2,4). This observation led us to search for a suitable monodentate chiral ligand. Furthermore, the re-

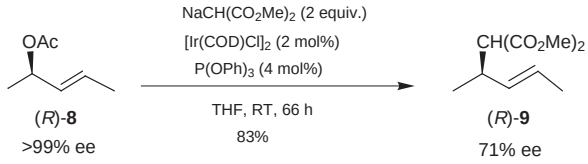


Scheme 2

gioselectivity (ratio of **3**:**4**) starting from achiral **2a** was low (**3**:**4** = 62:38) and the enantioselectivity high [(*R*)-**3a** of 78% ee], whereas with the regioisomeric racemic substrate **1a** it was just the opposite: the regioselectivity was high (**3**:**4** = 95:5) and the enantioselectivity low [(*S*)-**3a** of 8% ee] (entries 4–7). These results demonstrate that properties of allyl–Ir intermediates differ from those of allyl–Pd intermediates. As a rule, in Pd-catalysed allylic substitutions regioisomeric starting materials give rise to the same products; memory effects are known, but are small for bidentate ligands.[7]

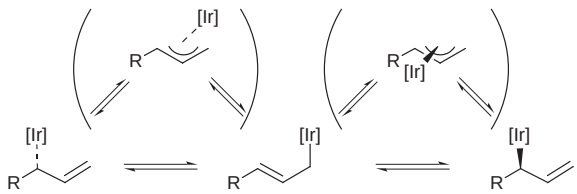
For further clarification, the configurational stability of intermediary allyl–Ir complexes and the configurative course of the substitution were investigated. First, enantiomerically enriched **1a** and **1b** were alkylated using $P(OPh)_3$ as ligand.† Starting from (*R*)-**1a** of 91% ee the product (*R*)-**3a** was obtained with 51% ee with retention of configuration, *i.e.* 79% of the substrate had reacted with retention of configuration (entry 9). Similar results were achieved with the phenyl substituted substrate **1b** (entry 8).‡ Second, enantiomerically pure pent-3-en-2-yl acetate† [(*R*)-**8**] was reacted with dimethyl 2-sodiomalonate (Scheme 2); alkylation product (*R*)-**9** with 71% ee was formed.

As of now we cannot offer a conclusive explanation of our results. As a working hypothesis we assume that the Ir-catalysed reactions proceed, similar to the mechanism proposed for Rh-catalysed reactions,[4] by substitution of acetate to give σ-allyl–Ir complexes which further react with malonate again with inversion; the σ-complexes undergo slow racemisation (or epimerisation) *via* σ–π–σ-rearrangement or sigmatropic 1,3-rearrangement (Scheme 3).

The easily accessible phosphorus amidite **6**[8] was used as a monodentate chiral ligand (ratio Ir:**6** = 1:1). For all substrates this ligand is equivalent to $P(OPh)_3$ with respect to catalytic efficiency and regioselectivity (entries 11–14). Surprisingly, and in contrast to the results obtained with the bidentate ligand **5**, enantioselectivity induced by **6** was higher for the branched substrate *rac*-**1a** than for the linear substrate **2a**.

Reactions with added halide salts were investigated (entries 15-17) because a marked influence of halide ions on allylic substitution has been reported.[9] LiCl or LiBr indeed caused a marked increase of regio- and enantioselectivity, although also a small decrease of reactivity (entry 10). The effect of chloride was further studied for alkylations of (*R*)- and (*S*)-**1a** (entries 18–23). The reaction with the substrate–ligand combination (*R*)-**1a**–(*R*)-**6** was faster and more enantioselective (matched case) than with the combination (*S*)-**1a**–(*R*)-**6** (mismatched), yielding (*R*)-**3a** in both cases, *i.e.* control by the ligand is stronger than that by the substrate. The influence of the ligand is enhanced by addition of LiCl.

As the acetates **1** and **2** do not isomerise under the usual reaction conditions,§ it was of interest to explore a kinetic resolution. The result for the reaction of *rac*-**1a** with NaHC$(CO_2CH_3)_2$, catalysed by $[Ir(COD)Cl]_2$–(*R*)-**6,** is shown in Fig. 1. According to this plot, (*R*)-**1a** is consumed *ca.* 12 times faster than (*S*)-**1a**.[10] Consequently, the slower reacting acetate is



Scheme 3

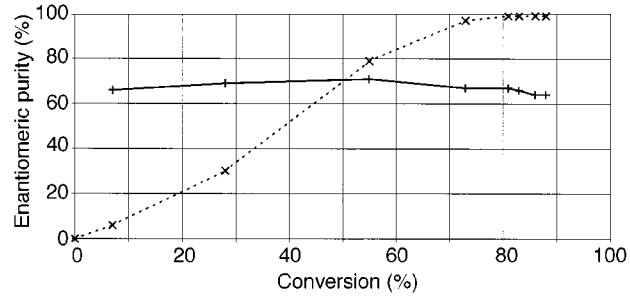


Fig. 1 Enantiomeric purity of (×) **1a** and (+) **3a** vs. conversion¶ for the reaction of (±)-**1a** with dimethyl 2-sodiomalonate catalysed by $[Ir(COD)Cl]_2$–(*R*)-**6**.

obtained in enantiomerically pure form beyond conversion of *ca*. 80%.

In conclusion, our results demonstrate that it is possible to achieve high levels of enantioselectivity in Ir-catalysed alkylations of monoalkylallyl acetates. Presently it is necessary to use racemic, branched substrates. Further progress will be achieved on the basis of detailed mechanistic investigations. It appears of particular importance to investigate the structure and dynamic properties of allyl–Ir complexes.

This work was supported by the Deutsche Forschungsgemeinschaft (SFB 247) and the Fonds der Chemischen Industrie. We thank Degussa AG for iridium salts.

Notes and references

† Enantiomerically enriched **1a** and **8** were prepared by enzyme (Novozym 435) catalysed esterification in vinyl acetate. (*R*)-**1b** was prepared from (*R*)-1-phenylprop-2-en-1-ol which was purchased from Fluka.

‡ Change of the descriptors in the starting material and product is a consequence of CIP priorities of substituents.

§ Isomerisation between **1a** and **2a** was not observed starting either from **1a** or from **2a** (reaction conditions: 2 mol% $[Ir(COD)Cl]_2$, 4 mol% $P(OPh)_3$, 2 equiv. NaOAc, 18 h, room temperature). For enantiomerically enriched **1a** (83% ee) a low degree of racemisation was obtained when the same reaction conditions were employed (70% ee).

¶ The degree of conversion was determined by HPLC.

Why is the antiviral nucleotide analogue 9-[2-(phosphonomethoxy)ethyl]adenine in its diphosphorylated form ($PMEApp^{4-}$) initially a better substrate for polymerases than (2′-deoxy)adenosine 5′-triphosphate ($dATP^{4-}$/ATP^{4-})? Considerations on the mechanism of nucleic acid polymerases

Received (in Basel, Switzerland) 15th February 1999, Accepted 4th March 1999

The observation that the antivirally active PMEA in its diphosphorylated form ($PMEApp^{4-}$) is initially a better substrate for polymerases than $dATP^{4-}$ (ATP^{4-}) can be rationalized by (i) the increased basicity of the phosphonyl group (compared to a phosphoryl group) and (ii) the participation of the ether O atom of $PMEApp^{4-}$ in metal ion binding; both effects together favor M^{2+} binding at the α group and thus its nucleophilic attack.

Since adenosine 5′-triphosphate is at the crossroad of many metabolic processes, the search for analogues which can be employed as therapeutic agents is long-standing.[1] A promising attempt is presently focusing on 9-[2-(phosphonomethoxy)-ethyl]adenine (PMEA) and related derivatives,[1,2] which can be considered as acyclic analogues of adenosine 5′-monophosphate (AMP^{2-}; Fig. 1)[3] as well as of its 2′-deoxy or 2′,3′-dideoxy derivatives. PMEA shows antiviral properties and is active, after its diphosphorylation by kinases,[4] against a variety of DNA viruses and retroviruses (*e.g.* human immunodeficiency viruses; HIV).[1,4]

The triphosphate analogue ($PMEApp^{4-}$) is recognized by nucleic acid polymerases as substrate and incorporated in the growing nucleic acid chain, which is then terminated due to the lack of a 3′-hydroxy group, which is present in the parent adenosine 5′-triphosphate (ATP^{4-}) and 2′-deoxyadenosine 5′-triphosphate ($dATP^{4-}$) nucleotides.[4,5] Indeed, $PMEApp^{4-}$ is initially an excellent substrate, *e.g.* for reverse transcriptases, which are effectively inhibited even in the presence of a 20-fold excess of $dATP^{4-}$; similar observations have been made for other DNA polymerases.[6] Why are $PMEApp^{4-}$ and its relatives excellent substrates for polymerases? We are suggesting below that this is due to the special metal ion-binding properties of these nucleoside 5′-triphosphate (NTP) analogues.

Kinetic studies of the M^{2+}-promoted dephosphorylation of ATP^{4-} and other triphosphates have shown[7] that in the most reactive species one metal ion is coordinated to the α,β-phosphate groups and one to the terminal γ-phosphate group. This transphosphorylation mechanism was recently confirmed in biological systems by an X-ray structural study of *Escherichia coli* phosphoenolpyruvate carboxykinase.[8] The mentioned

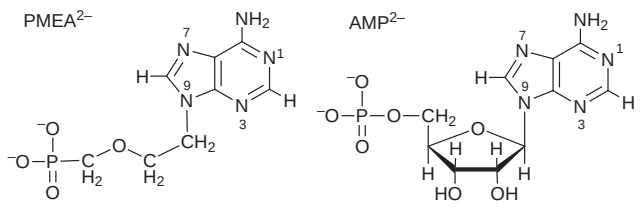

Fig. 1 $PMEA^{2-}$ in comparison to AMP^{2-} which is depicted in its dominating *anti* conformation; the structure of $PMEA^{2-}$ is analogous.[3]

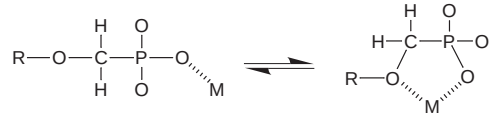
kinetic studies[7] have also led to the conclusion that the two activating metal ions 'may interact not only in a M(α,β)–M(γ)-like way but that a M(α)–M(β,γ) coordination can also be enforced (by an enzyme) and this would then lead to a reactive species ready for the transfer of . . . a nucleoside monophosphate' unit.[7a] Indeed, X-ray studies of nucleic acid polymerases have confirmed that two metal ions are involved in this process and corresponding mechanisms were proposed.[9]

The crucial step in the polymerase mechanism indicated above is to force a metal ion into the α position of the triphosphate chain[7] of an NTP^{4-}. Hence, one might suspect that $PMEApp^{4-}$, being initially an excellent substrate, has in this respect an advantage over $dATP^{4-}$ or ATP^{4-}. Indeed, methylphosphonate is somewhat more basic than methyl phosphate; this follows from the release of the primary proton from the twofold protonated species which occurs with $pK^{H}_{CH_3P(O)(OH)_2}$ = 2.10 ± 0.03 (ref. 10) and $pK^{H}_{CH_3OP(O)(OH)_2}$ = 1.1 ± 0.2,[11] respectively. This increased basicity of a phosphonyl compared to a phosphoryl group should favor metal ion binding.

To verify the above assumption, we compared for Mg^{2+}, Mn^{2+} and Zn^{2+} (M^{2+}) the metal ion-binding properties of methyl phosphonylphosphate, $CH_3–P(O)_2^{-}–O–PO_3^{2-}$ ($MePP^{3-}$),[12,13] with those of methyl diphosphate and other diphosphate monoesters, $R–OP(O)_2^{-}–O–PO_3^{2-}$ ($R–DP^{3-}$), where R is a noncoordinating residue. The results summarized in Fig. 2, where the logarithms of the measured stability constants are plotted in dependence on the pK_a values of $H(R–DP)^{2-}$ or $H(MePP)^{2-}$, show that the $Mg(MePP)^{-}$ and $Mn(MePP)^{-}$ complexes are somewhat more stable than is expected on the basis of the basicity of the terminal phosphate group of $MePP^{3-}$. The stability increases, which correspond to the vertical broken lines seen in Fig. 2, are $\log \Delta_{Mg(MePP)}$ = 0.08 ± 0.04 and $\log \Delta_{Mn(MePP)}$ = 0.16 ± 0.04; not shown in Fig. 2 is $\log \Delta_{Zn(MePP)}$ = 0.16 ± 0.04.[14] Hence, the higher basicity of a phosphonyl unit, compared to that of a phosphoryl group, leads to an increased complex stability!

In the present context one must also mention that the ether oxygen of $PMEA^{2-}$ (see Fig. 1) participates in M^{2+} binding[15,16] which gives rise to the following intramolecular equilibrium:



Of course, the formation of the indicated five-membered chelate is also reflected in an increased complex stability (based on log *K versus* pK_a correlation lines)[16] which amounts for the M(PMEA) complexes[15a] of Mg^{2+}, Mn^{2+} and Zn^{2+} to $\log \Delta_{Mg(PMEA)}$ = 0.16 ± 0.05, $\log \Delta_{Mn(PMEA)}$ = 0.21±0.08, and log

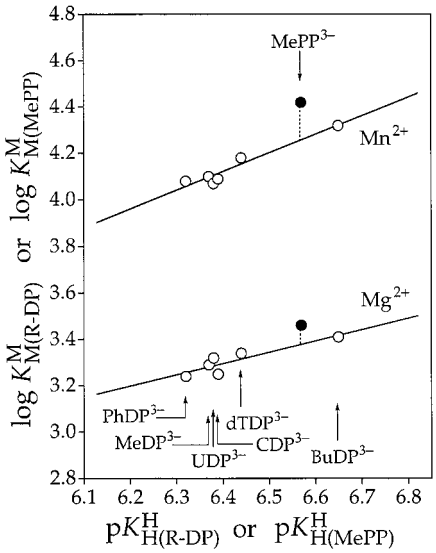


Fig. 2 Comparison of the stabilities of the Mg(MePP)$^{-}$ and Mn(MePP)$^{-}$ complexes (●) with those of the corresponding M^{2+} complexes formed with diphosphate monoesters (R–DP^{3-}) (○) based on the relationship between log $K^{M}_{M(R-DP)}$ and p$K^{H}_{H(R-DP)}$, for the Mg^{2+} and Mn^{2+} 1:1 complexes of phenyl diphosphate (PhDP^{3-}), methyl diphosphate (MeDP^{3-}), uridine 5′-diphosphate (UDP^{3-}), cytidine 5′-diphosphate (CDP^{3-}), thymidine [= 1-(2′-deoxy-β-D-ribofuranosyl)thymine] 5′-diphosphate (dTDP^{3-}), and *n*-butyl diphosphate (BuDP^{3-}) (from left to right). The least-squares lines are drawn through the indicated six data sets; the corresponding straight-line equations are listed in Table 4 of ref. 13(*b*). The equilibrium constants for the M^{2+}–MePP systems are given in footnote 13(*a*). All plotted values refer to aqueous solution at 25 °C and I = 0.1 M ($NaNO_3$).

$\Delta_{Zn(PMEA)}$ = 0.30 ± 0.10,[17] respectively; the corresponding formation degrees of the five-membered chelates are 31(±8), 38(±11), and 50(±12)%, respectively.[15a]

The above mentioned two effects, *i.e.* the increased basicity of the phosphonyl group and the participation[15c] of the ether oxygen in metal ion binding, favor the coordination of a second metal ion at the α group which occurs under the 'guidance' of the enzyme.[7,9] The binding of both metal ions to PMEApp^{4-} is depicted in Fig. 3 in comparison to the situation in ATP^{4-}. Of course, a higher formation degree of the structurally correct M_2(PMEApp) species will also facilitate the nucleophilic attack

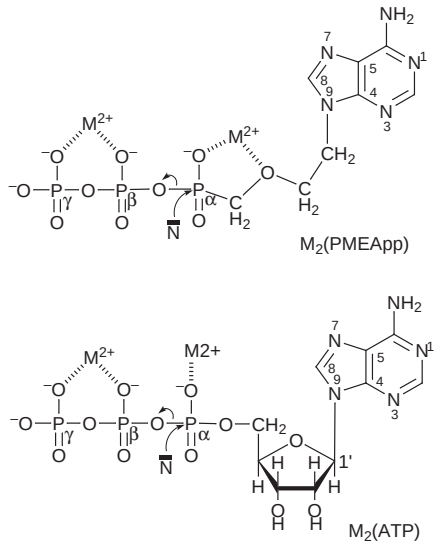

Fig. 3 Structures of the M_2(PMEApp) and M_2(ATP) intermediates ready for the attack of a nucleophile (N) and on their way to the transition state in nucleic acid polymerases. Metal ion binding to the α group is favored with PMEApp^{4-} (top) due to the formation of the five-membered chelate involving the ether oxygen atom as well as by the enhanced basicity of the α-phosphonyl group. Both divalent metal ions (usually Mg^{2+}) are anchored to amino acid-side chains (see, *e.g.* ref. 9) of the protein. Of course, the adenine residue can also be replaced by other nucleobase moieties.

at the α group and thus favor the transfer of the phosphonyl unit with its nucleobase residue in the polymerase-catalyzed reaction and its incorporation into the growing nucleic acid chain and thus, the termination of the latter. The above given mechanistic considerations are further confirmed by the repeated observation that the ether oxygen of PMEA^{2-} and of its (phosphonomethoxy)ethyl relatives is important for obtaining a biological effect:[1,6] its omission or replacement leads to a reduction or even loss of the antiviral activity.[18]

To conclude, in the search for new antivirally active nucleotide analogues the above gained insight should be kept in mind that favored metal ion-binding properties of the α-group are important for obtaining a high biological activity of the nucleotide analogues.

17 Estimated value; see ref. 15*a*.
18 It may be added that PMEApp is a *poorer* substrate than ATP for ATPases[4] and this agrees with the above conclusions because for ATPases, like for kinases,[7,8] a M(α,β)–M(γ)-like coordination is desirable. Clearly, M(α,β) binding of M^{2+} will be somewhat inhibited by the five-membered chelate formed with the α group and the ether O atom.

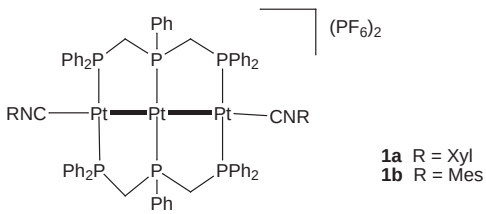
Received (in Cambridge, UK) 11th January 1999, Accepted 22nd March 1999

Reaction of linear triplatinum complexes, *linear*-$[Pt_3(\mu\text{-dpmp})_2(RNC)_2](PF_6)_2$ 1, with an excess of $[NO][BF_4]$ afforded an unprecedented nitrosyl-bridged double-A-frame triplatinum complexes, $[Pt_3(\mu\text{-dpmp})_2(\mu\text{-NO})_2(RNC)_2](BF_4)_4$ [2a: R = 2,6-xylyl; 2b: R = 2,4,6-mesityl, dpmp = bis(diphenylphosphinomethyl)phenylphosphine], which were characterized by X-ray crystallographic analysis and extended Hückel MO calculations.

Metal–metal bonded small-size transition-metal clusters have attracted increasing attention, since they could be minimal models for the surface of heterogeneous catalysts and have the potential to promote new homogeneous reactions which are not established by mononuclear centers.[1] We have recently reported a new strategic synthetic route to homo- and hetero-trimetallic clusters with Pt_2M cluster cores by using a tridentate phosphine ligand, bis(diphenylphosphinomethyl)phenylphosphine (dpmp).[2–5] In particular, we have demonstrated the synthesis and characterization of linearly ordered, side-by-side triplatinum complex, *linear*-$[Pt_3(\mu\text{-dpmp})_2(RNC)_2](PF_6)_2$ [**1a**: R = xylyl (Xyl)], which could be regarded as an indispensably important expansion of the well known chemistry on dppm-bridged diplatinum complexes, where dppm = bis(diphenylphosphino)methane. Complex **1a** was also shown to react with H^+, electron-deficient alkynes, and *p*-nitrophenyl isocyanide, affording asymmetrical A-frame triplatinum clusters bridged by hydride and the organic molecules, where only one Pt–Pt bond breaking took place even treated with an excess amount of reagents.[6] In the present report, we have examined the reaction of **1** [R = Xyl, mesityl (Mes)] with $[NO][BF_4]$ and have successfully isolated and characterized unprecedented nitrosyl-bridged double-A-frame triplantinum complexes, $[Pt_3(\mu\text{-dpmp})_2(\mu\text{-NO})_2(RNC)_2](BF_4)_4$. The reaction involves a novel, simultaneous three-center oxidative addition on linearly ordered triplatinum core supported by the tridentate phosphine ligands.



1a R = Xyl
1b R = Mes

Reaction of **1a** with an excess of $[NO][BF_4]$ yielded pale green crystals formulated as $[Pt_3(\mu\text{-dpmp})_2(\mu\text{-NO})_2(XylNC)_2](BF_4)_4$ **2a** (yield 66%).† Similar reaction of **1b** also gave $[Pt_3(\mu\text{-dpmp})_2(\mu\text{-NO})_2(MesNC)_2](BF_4)_4$ **2b** in 68% yield. The IR spectra of **2** indicated the presence of terminal isocyanide ligands at 2206 (**2a**), 2205 cm^{-1} (**2b**) and nitrosyl units at 1514 (**2a**), 1513 cm^{-1} (**2b**), the latter corresponding to the values for N–O triple bond rather than double bond. The detailed structure of **2a** was determined by an X-ray crystallographic analysis and an ORTEP plot for the complex cation is illustrated in Fig. 1.‡ The complex cation has a crystallographically imposed inversion center on the central platinum (Pt2) and consists of three platinum atoms linearly supported by two dpmp ligands. The Pt–Pt separation of 3.0962(4) Å, indicating the absence of a Pt–Pt bond, is shorter than those for the A-frame diplatinum complexes with dppm ligands, *e.g.* $[Pt_2Cl_2(\mu\text{-NO})(\mu\text{-dppm})_2]BPh_4$ **3a** (3.246 Å),[7a] $[Pt_2Cl_2(\mu\text{-NO})(\mu\text{-dppm})_2]BF_4$ **3b** (3.186 Å),[7b] $[Pt_2Cl_2(\mu\text{-CH}_2)(\mu\text{-dppm})_2]$ (3.151 Å),[8] and is comparable to that of $[Pt_2Cl_2(\mu\text{-CS}_2)(\mu\text{-dppm})_2]$ (3.094 Å).[9] Two nitrosyl groups are inserted into the two Pt–Pt bonds of **2a** with an almost symmetrical manner, Pt1–N1 2.020(6) Å, Pt2–N1 2.019(6) Å, Pt1–N1–Pt2 100.1(3)°, Pt1–N1–O1 125.9(6)°, Pt2–N1–O1 133.2(6)°, resulted in a double-A-frame trimetallic structure. This is the first structurally characterized example of nitrosyl-bridged double-A-frame trinuclear clusters on the basis of analysis of the Cambridge Crystallographic Structure Database. The N–O bond lengths is 1.09(1) Å,§ which corresponds to values for a neutral N–O triple bond rather than an N–O double bond,[10] and is in accord with the IR data. This nitrosyl-bridging structure is quite different from that of **3** which involves an NO^- unit with an N–O bond length of 1.20(2) Å.[7,8] From the X-ray crystal structure, the present reaction can be regarded as a novel three-center oxidative addition proceeding on a linear triplatinum center, which involves an apparent two electron transfer from the triplatinum core to two NO^+ ions.

Structurally characterized nitrosyl-bridged diplatinum complexes are extremely rare, with the two complexes **3** being the sole example, probably owing to the low-lying LUMO and small HOMO–LUMO gap as Hoffmann predicted theoretically on the basis of extended Hückel MO calculations.[11] In order to elucidate the electronic structure of **2**, we have carried out EHMO calculations on a model compound $[Pt_3(\mu\text{-}$

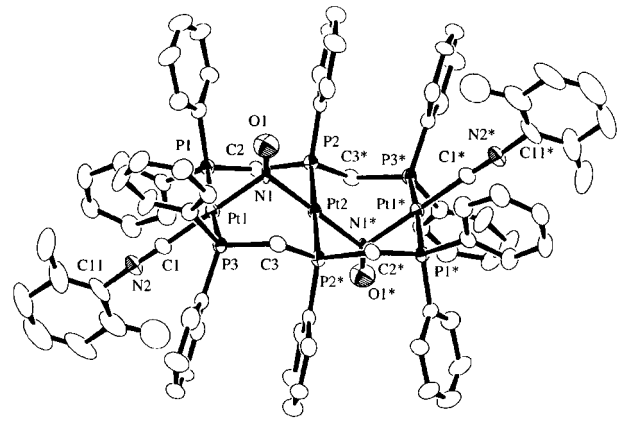


Fig. 1 ORTEP diagram for the complex cation of **2a**. Selected distances (Å) and angles (°): Pt1···Pt2 3.0962(4), Pt1–P1 2.358(2), Pt1–P3 2.343(2), Pt1–N1 2.020(6), Pt1–C1 1.923(8), Pt2–P2 2.321(2), Pt2–N1 2.019(6), O1–N1 1.09(1), N2–C1 1.14(1); N1–Pt1–C1 176.1(2), N1–Pt2–N1* 180.0, Pt1–N1–Pt2 100.1(3), Pt1–N1–O1 125.9(6), Pt2–N1–O1 133.2(6), Pt1–C1–N2 175.7(7).

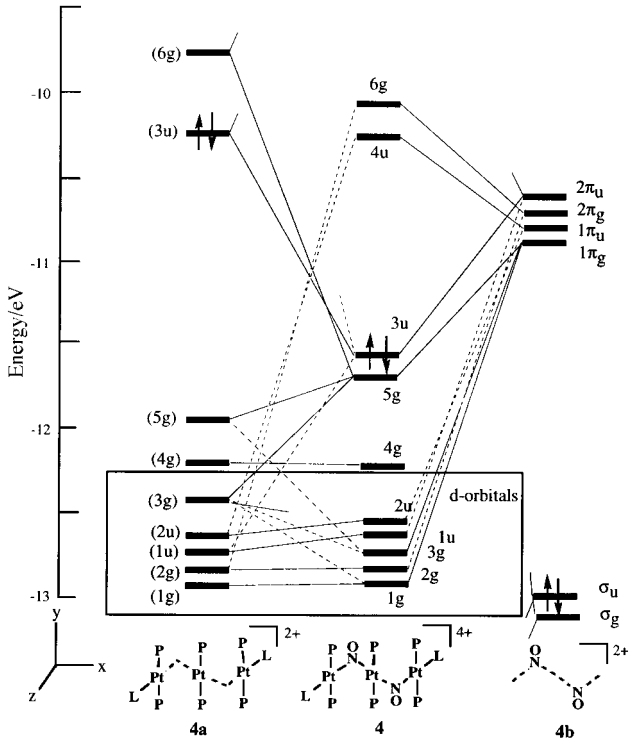

Fig. 2 MO interaction diagram for $[Pt_3(\mu\text{-}NO)_2(PH_3)_6(CNH)_2]^{4+}$ **4** (C_i), in terms of the fragments $[Pt_3(PH_3)_6(CNH)_2]^{2+}$ **4a** and $[NO)_2]^{2+}$ **4b**; P = PH_3, L = CNH.

$NO)_2(PH_3)_6(CNH)_2]^{4+}$ **4** (C_i), the ideal coordinates being derived from simplification of the crystal structure of **2a**.[12–15] An interaction diagram for **4** in terms of the fragments $[Pt_3(PH_3)_6(CNH)_2]^{2+}$ **4a** and $[(NO)_2]^{2+}$ **4b** is shown in Fig. 2.[16] The triplatinum system of **1** has a Pt–Pt σ-bonding orbital (HOMO) and σ-antibonding orbital (LUMO) at higher and lower energy levels, respectively, than the corresponding σ_{Pt-Pt} and σ^*_{Pt-Pt} orbitals of the diplatinum model.[2] The decrease of the σ–σ* energy gap causes the HOMO (3u) and LUMO (6g) of **4a** to match well with the low-laying π* orbitals of **4b** ($2\pi_u$ and $1\pi_g$), generating two significant bonding interactions, 3u (−11.61 eV) and 5g (−11.62 eV) orbitals of **4**. These two bonding orbitals should be responsible for partial electron transfer from the Pt_3^{2+} core to the two bridging NO^+ groups and stabilize the double-A-frame structure. There is no bonding overlap between the central and terminal Pt atoms as expected from the crystal structure. When CO groups are used instead of NO^+, the high-lying π* orbitals of CO groups do not match with the σ and σ* orbitals of the Pt_3^{2+} core and the corresponding 3u (−10.62 eV) and 5g (−11.34 eV) orbitals are destabilized at higher energy levels, consistent with our failure to obtain $[Pt_3(\mu\text{-dpmp})_2(\mu\text{-CO})_2(RNC)_2]^{2+}$ from the reaction of **1** with CO.

The present results could provide useful information in relation to metal-surface mimetic chemistry or fine organometallic cluster chemistry. We are now attempting to explore the reactivity of complex **2**, involving transformation of bridging NO groups to nitrogen-containing organic compounds.

† To a 20 ml dichloromethane solution containing 100 mg of *linear*-$[Pt_3(\mu\text{-dpmp})_2(XylNC)_2](PF_6)_2$ was added 27 mg of $[NO][BF_4]$. The reaction solution was stirred at room temp. for 3 h during which it changed from orange to pale green. The solution was concentrated to *ca.* 3 ml and was kept in a refrigerator to afford block-shaped plae green crystals of $[Pt_3(\mu\text{-dpmp})_2(\mu\text{-NO})_2(XylNC)_2](BF_4)_4\cdot CH_2Cl_2$ (**2a**$\cdot CH_2Cl_2$) in 66% yield. Anal. Calc. for $C_{83}H_{78}O_2N_4P_6B_4F_{16}Cl_2Pt_3$: C, 42.51; H, 3.83; N, 1.84. Found: C, 42.37; H, 3.34; N, 2.38%. A similar procedure using *linear*-$[Pt_3(\mu\text{-dpmp})_2(MesNC)_2](PF_6)_2$ **1b** (43 mg) afforded pale green crystals of $[Pt_3(\mu\text{-dpmp})_2(\mu\text{-NO})_2(MesNC)_2](BF_4)_4\cdot 2CH_2Cl_2$ (**2b**$\cdot 2CH_2Cl_2$) in 68% yield. Anal. Calc. for $C_{86}H_{84}O_2N_4P_6B_4F_{16}Cl_4Pt_3$: C, 41.89; H, 3.43; N, 2.27. Found: C, 42.02; H, 3.45; N, 1.80%. Complex **1b** was prepared by the reaction of **1a** with MesNC and was characterized by X-ray crystallography, which will be reported elsewhere.

‡ *Crystal data*: **2a**$\cdot CH_2Cl_2\cdot 3H_2O$ ($C_{83}H_{84}N_4O_5P_6B_4F_{16}Cl_2Pt_3$, M_r = 2406.83, T = −116 °C, monoclinic, space group $P2_1/c$, a = 12.873(4), b = 29.350(6), c = 14.826(4) Å, β = 110.49(3)°, V = 5246(2) Å^3, Z = 2. A pale green block-shaped crystal was fixed on the top of a glass fiber with Paraton N oil. 9211 reflections ($4 < 2\theta < 50°$) were measured on a Rigaku AFC7R diffractometer with graphite monochromated Mo-Kα radiation. The structure was solved by direct methods using the program SIR92 and was refined to R = 0.058, R_w = 0.072, and GOF = 2.53 for 6842 independent reflections with $I > 3\sigma(I)$. CCDC 182/1201. See http://www.rsc.org/suppdata/cc/1999/745/ for crystallographic files in .cif format.

§ It should be noted that the Pt–N and N–O bond lengths derived from the X-ray crystallography might involve relatively large errors on the basis of flat (N1) and large (O1) thermal motions of the NO unit, the former seemingly resulting from the influence of highly scattering Pt Atoms.

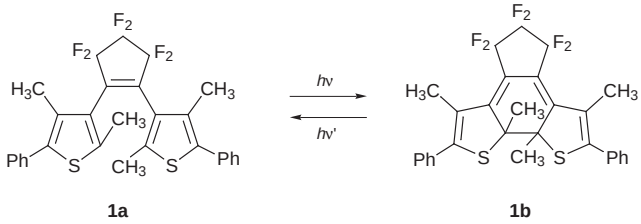
Received (in Cambridge, UK) 2nd December 1998, Accepted 12th March 1999

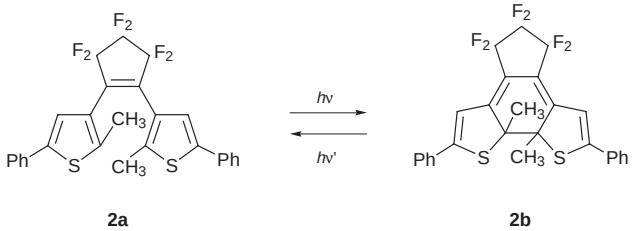
Beside normal cyclization/ring-opening photochromic reactions, a side reaction to produce a photostable by-product took place when 1,2-bis(2-methyl-5-phenyl-3-thienyl)perfluorocyclopentene was irradiated in deaerated hexane with ultraviolet light.

Light-induced reversible isomerization between two forms having different absorption spectra is referred to photochromism, and compounds capable of these reactions are called photochromic compounds. Various types of photochromic compounds, such as spiropyrans, spirooxazines, fulgides and diarylethenes, have been so far developed[1] in an attempt to apply the compounds to optoelectronic devices,[2,3] such as optical memory, photo-optical switching and displays. Among the compounds, diarylethenes with heterocyclic aryl groups are the most promising photochromic compounds for these applications, because of their fatigue-resistant and thermally-irreversible properties.[4] Although diarylethenes with benzothiophene aryl groups undergo fatigue-resistant photochromic reactions (more than 10 000 coloration/decoloration cycles)[5–7] without any destruction of their structures, some diarylethenes with thiophene rings cease their photochromic cycles in less than several hundred cycles even in the absence of oxygen.[6–9] To know the reason why the thiophene derivatives are easily damaged by photoirradiation, we compared the fatigue-resistant properties of dithienylethenes **1** and **2**.[10,11]

Compound **1**[10] has methyl groups at the 4 and 4′ positions of the thiophene rings, while compound **2**[11]† has no methyl groups at these positions. The cyclization quantum yield of **2a** (Φ = 0.68) is larger than that of **1a** (Φ = 0.46),[10] while the ring-opening quantum yields are similar (Φ = 0.013 and 0.015, respectively).



1a **1b**



2a **2b**

Fig. 1 shows the fatigue resistant behavior of the two compounds in hexane in the absence of oxygen. The absorbance of the two compounds at 313 nm was normalised. In each cycle **1a** and **2a** were converted to **1b** and **2b**, respectively, to give 80% of the photostationary states by irradiation with 313 nm light, and both closed-ring forms, **1b** and **2b**, were completely bleached by irradiation with > 440 nm light. The absorbances of the bleached samples were plotted in Fig. 1. The absorbance of **1a** (λ_{max} 268 nm) remained almost constant even after 800 cycles, while the absorbance of **2a** (λ_{max} 276 nm) gradually declined. At the same time a photostable violet product with an absorption maximum at 547 nm was formed. As can be seen in Fig. 1 the formation process of the by-product coincides with a decrease of the open-ring form **2a**. The saturation tendency after 200 cycles is ascribed to the overlapping of the strong absorption of the by-product at 313 nm (see Fig. 2). In the case of **1** no such colored photoproduct was detected. In the presence of oxygen both **1** and **2** readily decomposed in less than 500 cycles. The decomposition is due to the formation of oxidized products.[7]

The stable photoproduct could be isolated by HPLC (silica gel column, hexane) and was found by elementary analysis and molecular mass determination to be isomeric with compound **2a**. Fig. 2 shows the absorption spectrum of the by-product **3** along with those of **2a** and **2b**. The absorption maximum of the by-product slightly shifted to shorter wavelength and its ε value

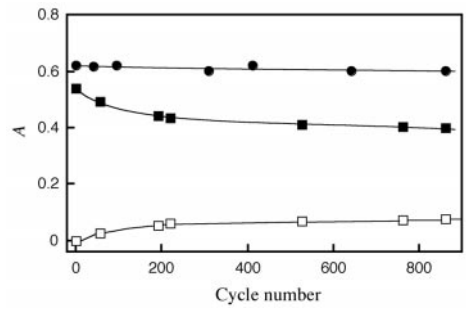


Fig. 1 Fatigue resistant properties of **1** and **2** in deaerated hexane. Absorbances of **1a** (●) and **2a** (■) were plotted after irradiation with visible light. The visible absorbance at 547 nm (□), which still remained after visible irradiation of a hexane solution containing **2**, was also plotted.

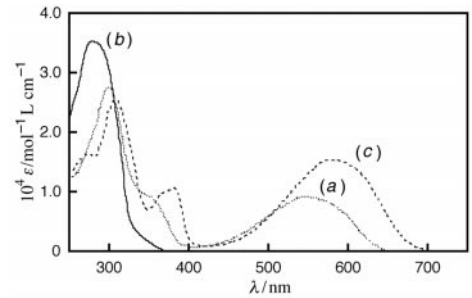

Fig. 2 Absorption spectrum of the (*a*) by-product **3** along with those of (*b*) **2a** and (*c*) **2b** in hexane.

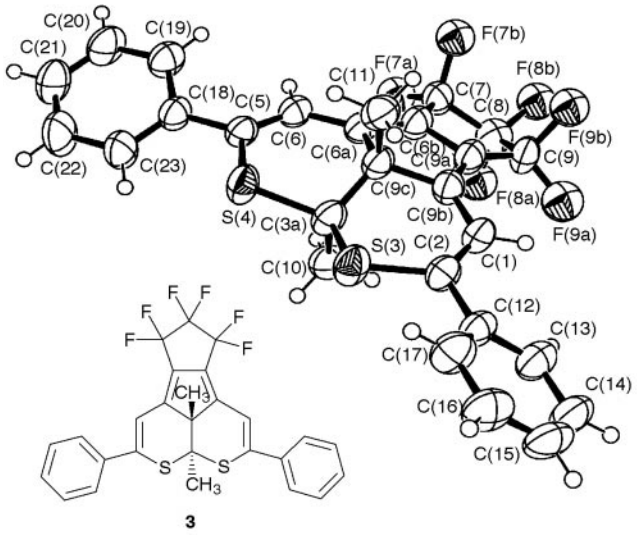

Fig. 3 ORTEP view of by-product **3** (50% probability thermal ellipsoids) and its chemical structure. The fluorinated cyclopentane ring was disordered. Only the major structure is illustrated for clarity.

in the visible region was 60% of the closed-ring form.The structure of the by-product could not be determined conclusively by NMR spectroscopy,‡ but was established by X-ray crystallographic analysis of a single crystal (mp 131 °C) from MeOH–hexane.§

Fig. 3 shows the molecular structure of by-product **3**. The thiophene rings no longer exist, having formed a condensed system with two six-membered heterocyclic rings. The polyene structure is similar to the closed-ring form **2b**. This is the reason why the by-product has a similar absorption spectrum. Although the formation mechanism of the by-product has not yet been revealed, the by-product was more efficiently produced from **2b** by ultraviolet irradiation.

Compound **2** underwent photochromism even in the crystalline phase. It is worthwhile to note that the by-product **3** formation was not observed in the crystalline phase. The fatigue resistant characteristics of crystalline **2a** were examined by alternate irradiation with ultraviolet (313 nm) and visible ($\lambda > 440$ nm) light. Any appreciable increase in the visible absorption was not observed for the crystal even after 2000 coloration–decoloration cycles. The transmittance of the crystal decreased to around 80% of the fresh crystal after 10 000 cycles, but the decrease is mainly due to an increasing roughness of the crystal surface and not due to by-product formation.

Synthesis of the functionalised core of neoliacinic acid

J. Stephen Clark,*[a] Alexander G. Dossetter,[a] Alexander J. Blake,[a] Wan-Sheung Li[a] and William G. Whittingham[b]

[a] *School of Chemistry, University of Nottingham, University Park, Nottingham, UK NG7 2RD. E-mail: j.s.clark@nottingham.ac.uk*

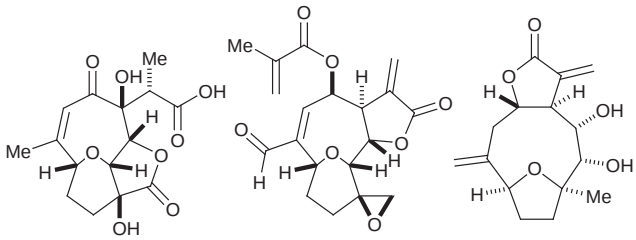
Received (in Cambridge, UK) 3rd March 1999, Accepted 18th March 1999

An advanced intermediate in the synthesis of neoliacinic acid has been prepared, and the structure and relative stereochemistry have been confirmed by X-ray crystallography.

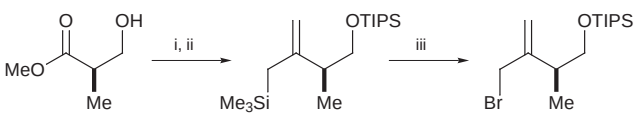
The highly oxidised sesquiterpene neoliacinic acid **1** was isolated from leaves of the plant *Neolitsea acciculata* Koidz in 1987,[1] and is a member of a burgeoning family of bioactive ether-bridged germacranolides. These compounds have been isolated from a variety of plants worldwide; other representative examples are the lactone **2**[2] and the anti-bacterial compound tanargyrolide **3**.[3] Neoliacinic acid **1**[1] is thought to possess cytotoxic activity in common with a structurally related compound, neoliacine, which was isolated from the same plant.[4]



1 neoliacinic acid **2** **3** tanargyrolide

The unusual ether-bridged tricyclic framework of neoliacinic acid **1** coupled with the dense array of oxygen-containing functionality and the number of contiguous stereogenic centres present a formidable challenge to contemporary methods for ring construction and stereocontrol. Recently, we disclosed a powerful new strategy for the synthesis of neoliacinic acid, in which the required ring system was constructed using a carbenoid C–H insertion reaction in conjunction with tandem oxonium ylide generation and rearrangement.[5] We now report the exploitation of this reaction sequence for the construction of an advanced precursor of neoliacinic acid, the structure of which has been confirmed by X-ray crystallography.

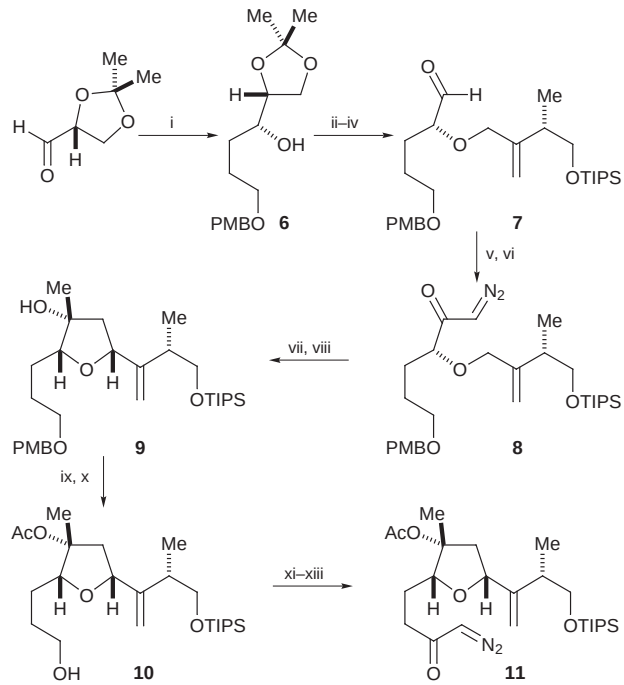
Preparation of the required side chain from commercially available methyl (*R*)-3-hydroxy-2-methylpropionate was undertaken first (Scheme 1). Protection of the hydroxy group as the TIPS ether and reaction of the ester with an excess of the organocerium reagent prepared from $TMSCH_2MgCl$ and $CeCl_3$[6] afforded the allylic silane **4** resulting from double Grignard addition and *in situ* Peterson elimination of the intermediate β-hydroxy disilane.[6,7] The allylic silane **4** was then converted to the allylic bromide **5** by treatment with pyrrolidone hydrotribromide.[8,9] This reagent was used to deliver the precise amount of bromine required, circumventing the problem of over-bromination that was encountered when molecular bromine was employed for the transformation.



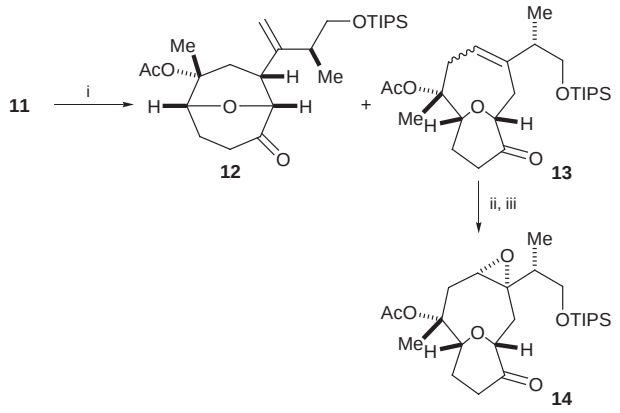
4 **5**

Scheme 1 *Reagents and conditions*: i, Pr^i_3SiCl (1 equiv.), imidazole (2 equiv.), DMF, rt (99%); ii, $TMSCH_2MgCl$ (3 equiv.), $CeCl_3$ (3 equiv.), THF, −70 °C→rt (98%); iii, pyrrolidone hydrotribromide (1 equiv.), pyridine, THF, –10 °C→rt (97%).

Assembly of the cyclisation precursor **11** commenced with (*R*)-isopropylideneglyceraldehyde, which was readily prepared from D-mannitol in two steps using standard literature methods (Scheme 2).[10] Chelation-controlled addition of the organocopper reagent prepared from reaction of CuI with *p*-$MeOC_6H_4CH_2O(CH_2)_3MgBr$ afforded the alcohol **6** in good yield as a 10:1 mixture of diastereoisomers.[11] Alkylation of the alcohol **6** with the allylic bromide **5** under standard ether coupling conditions, followed by acid-promoted removal of the acetonide and periodate cleavage of the resulting 1,2-diol provided the aldehyde **7** in good yield. Subsequent oxidation of



Scheme 2 *Reagents and conditions*: i, *p*-$MeOC_6H_4CH_2O(CH_2)_3MgBr$, CuI, DMS, THF, −78 °C→rt (81%, 10:1 mixture of diastereoisomers); ii,NaH, THF, rt→reflux, then **5**, THF, rt→reflux (90%); iii, PPTS (0.2 equiv.), $HO(CH_2)_2OH$–THF–CH_2Cl_2 (2 : 1 : 1), reflux; iv, $NaIO_4$ (4 equiv.), THF–H_2O (95%, 2 steps); v, PDC (3.5 equiv.), DMF, rt; vi, Bu^iOCOCl (1 equiv.), Et_3N, Et_2O, rt then CH_2N_2, Et_2O, rt (82%, 2 steps); vii, $Rh_2(HNCOCF_3)_4$ (1 mol%), CH_2Cl_2, rt; viii, $AlMe_3$ (3 equiv.), CH_2Cl_2, −78→5 °C (60%, 2 steps); ix, Ac_2O (3 equiv.), DMAP (3 equiv.), CH_2Cl_2, reflux (74%); x, DDQ (1.5 equiv.), CH_2Cl_2–H_2O, rt (94%); xi, PDC (3.5 equiv.), DMF, rt; xii, NaOMe (1 equiv.), MeOH, rt; xiii $(COCl)_2$, C_6H_6, rt, then CH_2N_2, Et_2O, rt (47%, 3 steps).



Scheme 3 *Reagents and conditions*: i, $Cu(hfacac)_2$ (2 mol%), CH_2Cl_2, reflux (**12** 7%, **13** 61%); ii,AIBN, EtSH, C_6H_6, reflux (81%); iii, MCPBA (1.5 equiv.), CH_2Cl_2, reflux (95%).

the aldehyde to afford the carboxylic acid was effected using PDC. The acid was then converted into a mixed anhydride, and this was treated with an excess of CH_2N_2 to give the α-diazo ketone **8**. Exposure of this α-diazo ketone to $Rh_2(HNCOCF_3)_4$[12] in CH_2Cl_2 resulted in formation of a reactive carbenoid that underwent intramolecular C–H insertion adjacent to the ether oxygen[13] to give the required cyclic ether, as a diastereomeric mixture (~7:1, *cis*:*trans*), along with some of the product arising from competitive intramolecular alkene cyclopropanation. Separation of the products was not performed at this stage, and the mixture was treated directly with $AlMe_3$.[5,14] This delivered the required alcohol **9** (60% yield from the α-diazo ketone **8**), which was easily separated from all other products and stereoisomers by chromatography. Standard protocols were then used to acetylate the tertiary hydroxy group and remove the *p*-methoxybenzyl protecting group, and oxidation of the free primary hydroxy group to the carboxylic acid was then performed using PDC. The synthesis of the α-diazo ketone **11** was completed by conversion of the sodium salt of the carboxylic acid to the corresponding acid chloride and treatment of this compound with an excess of CH_2N_2.

The pivotal cyclisation reaction was effected using analogous conditions to those employed in our model study (Scheme 3).[5] Treatment of the α-diazo ketone **11** with copper(II) hexafluoroacetylacetonate [Cu(hfacac)$_2$] in CH_2Cl_2 at reflux afforded the bridged bicyclic ether **13** in 61% yield as a 3:2 mixture of *Z* and *E* isomers along with the compound **12** (7% yield) arising from a [1,2]-shift of the intermediate oxonium ylide.[15] It is noteworthy that a mixture of alkene isomers was obtained upon rearrangement of the putative oxonium ylide intermediate, in contrast with the model reaction which provided the *E* isomer exclusively.[5] Isolation of the [1,2]-shift product[15] was also significant because analogous products were not isolated from model cyclisation reactions.[5]

The mixture of isomers was then subjected to isomerisation under radical conditions[16] to give the thermodynamically favoured *Z* alkene, which was then treated with MCPBA to afford the solid epoxide **14**.† Recrystallisation provided crystals that were suitable for X-ray analysis (Fig. 1),‡ and the structure and relative stereochemistry of the epoxide **14** were confirmed by this method.

We have prepared an advanced intermediate **14** in the synthesis of neoliacinic acid **1**, which possesses the skeleton found in the natural product and most of the oxygen-containing functionality. Completion of the synthesis by elaboration of this highly functionalised intermediate is in progress, and the results of this work will be reported in due course.

We thank the EPSRC for support, and the award of a CASE studentship (to A. G. D.) and a postdoctoral fellowship (to W.-S. L.).

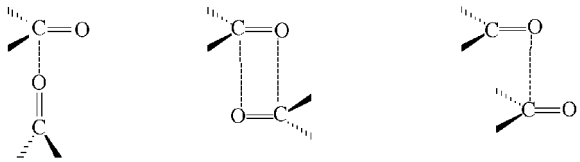
Received (in Cambridge, UK) 20th January 1999, Accepted 16th March 1999

Dipolar carbonyl–carbonyl contacts generally occur in one of three motifs, and all are exhibited in the X-ray crystal structures of two phases of acetone derived at 15 kBar and at 150 K; a neutron powder-diffraction study at 5 K and an X-ray diffraction study at 110 K reveal strengthened CH···O as well as CO···CO electrostatic contacts which appear to explain the unusual thermodynamic properties of acetone, the nature of which have remained a mystery since 1929.

One motive for performing crystallographic studies on very simple systems is that they can reveal structural motifs that are applicable to whole classes of compound. Though there are few compounds so familiar in the laboratory as acetone, little is known about its structure in the solid state. We now describe five crystal structures of acetone determined at high pressure and at low temperature. The two distinct phases characterised in this study exhibit all three of the archetypal packing motifs identified in an important recent survey of dipolar carbonyl–



carbonyl interactions.[1] The identification of more than eighty 'highly unsatisfied' main-chain H-bond acceptors in protein structures[2] reflects the likely structural significance of dipolar interactions in biological macromolecules,[3] and the results described here are relevant to identifying and modelling these contacts. We have also been able to suggest a solution to a long-standing question about the thermodynamic properties of crystalline acetone.[4,5]

A sample of acetone was solidified at room temperature under pressure and a single crystal obtained by the methods described in ref. 6. X-Ray diffraction data were collected at 15 kBar (at room temperature), and structure solution† revealed a C-centred orthorhombic phase composed of layers of acetone molecules disposed along the *c*-axis. The layers consist of molecules stacked along the [010] direction, in which each molecule is involved in four C···O contacts formed in a sheared-parallel motif (Type III, Fig. 1) with a C=O···C=O distance of 3.365(2) Å, which is slightly shorter than the median for this type of interaction (3.45 Å).[1]

An orthorhombic C-centred phase can also be obtained by cooling the liquid slowly through the melting point at ambient pressure. A data set acquired at 165 K showed this to be essentially isostructural with the high pressure phase, except that the cell dimensions increase by between 4 and 7%.‡ This phase is metastable and decomposes after a few hours to the primitive phase described below. The shortest 'Type III' C=O···C=O distance is 3.587(3) Å, and in the context of other, similar, interactions examined in ref. 1 this contact is of marginal significance. Since there do not appear to be any other notable contacts, this may explain the instability of this phase.

During the course of this study this metastable phase was observed only twice, and the precise conditions which promote its formation are as yet unclear, although it seems to decompose more quickly the lower the temperature. All other low-temperature crystallisations yielded a stable, primitive orthorhombic phase.§ Once again, the crystal structure (determined at 150 K) consists of layers of molecules stacked along the *c*-axis, which is approximately twice as long as in the high pressure phase because neighbouring layers are crystallographically independent. The arrangement of molecules in the layers is quite different from that observed at high pressure. In one layer [Fig. 2(*a*)] pairs of molecules interact in antiparallel fashion ['Type II', C···O 3.300(3) Å], with each pair forming perpendicular 'Type I' contacts to neighbouring molecules [C···O 3.491(3) Å]. The other layers [Fig. 2(b)] consist of chains of molecules interacting only *via* the perpendicular motif [C···O 3.458(3) Å]; the closest C to O distance between the chains is 3.74 Å.

Calorimetric studies on crystalline acetone show a broad peak in the heat capacity *vs*. temperature curve centred around 127 K. The origin of this behaviour has remained an unresolved issue since it was first observed in 1929,[4] although the entropy change suggested that it was not associated with an order–disorder transition or rotations of the methyl groups.[5] Neutron powder diffraction patterns were measured for acetone between 5 and 140 K, and at all temperatures these patterns could be indexed on primitive orthorhombic unit cells similar to that given in

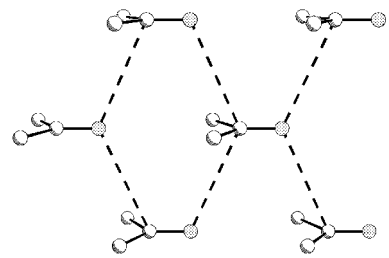


Fig. 1 Skew-parallel (Type III) C=O···C=O intermolecular interactions in the crystal structure of acetone at 15 kBar. H-atoms are disordered and omitted for clarity.

footnote §, although the cell dimensions changed rapidly and anisotropically with temperature. The crystal structure could not be resolved in the original neutron study, and so a firm statement regarding the structural nature of the heat capacity behaviour was not possible.[5]

We have refined the structure of acetone against the neutron powder data set collected at 5 K¶ to reveal C–H···O contacts of 2.336(6) and 2.479(5) Å respectively formed between and within the chains of molecules shown in Fig. 2(*b*); the angles at the donor H-atoms are 154.9(3) and 133.4(3)°. The dipolar contacts are also shorter at 5 K, and details are given in the figure captions. Although O···H distances derived from X-ray and neutron diffraction experiments are difficult to compare directly, at 150 K only one C–H···O contact (2.51 Å, where the C–H distance has been 'normalised' to 1.08 Å) falls within the sum of the van der Waals radii of O and H (2.60 Å).

It seemed plausible that the variation of heat capacity with temperature is associated with the strengthening of electrostatic C=O···C=O and CH···O contacts. This was confirmed in a variable-temperature X-ray structure determination study which at 110 K§ shows three contacts 'locking-in' with significantly shortened distances: the CH···O contact between the chains in Fig. 2(*b*) has an X-ray CH···O distance of 2.511(12) Å, compared to 2.618(13) Å at 150 K; the CH···O contact within the chains shortens from 2.71(2) to 2.604(18) Å, and the Type I (perpendicular) C=O···C=O interaction between the molecules in Fig. 2(*a*) shortens from 3.491(4) to 3.417(4) Å. The cell dimensions derived in this single crystal study are somewhat different from those obtained in the variable temperature neutron powder-diffraction study. It is important to emphasise that the heat capacity transition is very broad, occurring over a range of some 60 K, and varies with the thermal history of the sample.[5] Structural parameters observed in a particular run of experiments may well therefore exhibit effects which are sample-specific.

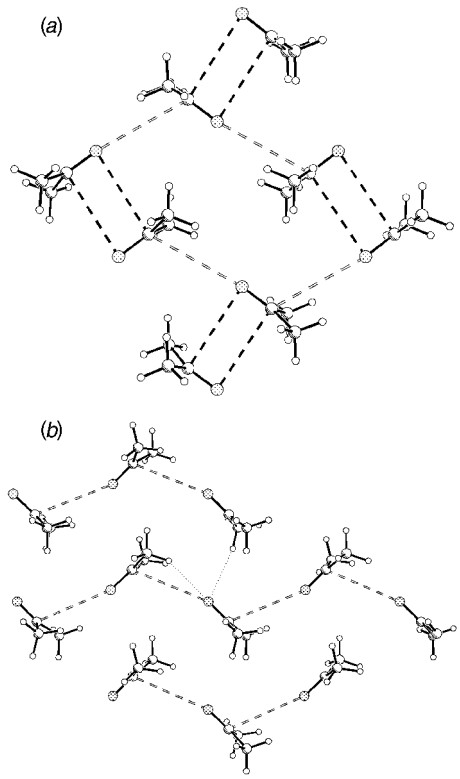

Fig. 2 The stable primitive orthorhombic phase of acetone at 150 K. (*a*) Layers containing perpendicular and antiparallel carbonyl interactions. The C···O distances at 5 K were 3.368(4) and 3.231(5) Å, respectively. (*b*) Layers comprised of strands of acetone molecules interacting *via* the perpendicular motif [Type I, 3.391(4) Å at 5 K]. Also shown (dotted lines) are C–H···O contacts that assume importance at 5 K.

A series of *ab initio* density functional calculations was performed with the aim of modelling the enthapy derived experimentally for this phase transition (259 J mol^{-1}).‖ Since the systems are periodic, an unbiased plane wave basis set was used to express the electronic wavefunction to alleviate the convergence problems of traditional quantum chemistry basis sets.[7] On minimising the total energy of the systems, the energy difference between the phases is 215 J mol^{-1}. This is below the experimental value because total energy calculations measure the absolute difference in the local energy minima of the two phases, and do not take dynamics into account.

We thank Mr Hugh Vass for technical assistance and the EPSRC for support.

All structures were solved by direct methods (ref. 8) and refined with Shelxl (ref. 9); *R* factors were between 5 and 6%.

† *Crystal data* for acetone at 15 kBar: C_2H_6O, M = 58.04, orthorhombic, a = 6.1219(11), b = 5.2029(10), c = 10.244(3) Å, *Cmcm*, Z = 4. The methyl groups are rotationally disordered about the C–C axis.

‡ *Crystal data* for the metastable C-centred orthorhombic low-temperature phase of acetone: a = 6.514(4) , b = 5.4159(18), c = 10.756(5) Å, U = 379.5(3) Å^3, T = 165 K, *Cmcm*. The H-atoms are ordered and were located in a difference map and refined freely.

§ *Crystal data* for the stable orthorhombic low-temperature phase of acetone: a = 8.873(3), b = 8.000(4), c = 22.027(7) Å, U = 1563.5(10) Å^{-3}, T = 150 K, *Pbca*, Z = 16, H-atom positional parameters were refined subject C–H and H–H similarity restraints. Cell dimensions at 110 K: a = 9.172(8), b = 7.761(8), c = 21.66(2) Å, U = 1542(3) Å^3.

¶ Time-of-flight diffraction data were recorded on the High Resolution Powder Diffractometer (ref. 10) at the ISIS spallation neutron source at 5 K over a time-of-flight range of 30 to 230 ms corresponding to a *d*-spacing range of 0.6 to 4.6 Å. a = 9.16686(1), b = 7.53231(1), c = 21.24861(5) Å. The structure was refined without constraints using the Rietveld method (ref. 11, 12) and using the 150 K structure as the starting model (space group *Pbca*). Only the D atoms were refined anisotropically. R_E = 1.64%, R_P = 3.03%, R_{wP} = 3.84%, χ^2 = 5.48 for 5948 observations and 162 basic variables. CCDC 182/1197. Crystallographic data are available in CIF format from the RSC web site, see: http://www.rsc.org/suppdata/cc/1999/751/

‖ The calculations were performed using the CASTEP density functional code (ref. 13). A generalised gradient approximation (ref. 14) was used to describe the exchange and correlation energy, requiring a plane wave basis set of 1.5 million functions for convergence. The *ab initio* forces on the atoms and stresses on the unit cell were used to perform an energy minimisation of the structure using a pre-conditioned conjugate gradients routine (note that these calculations refer to systems at zero-pressure and so the quantity minimised was the total energy of the system U). During the relaxation no symmetry constraints were applied; symmetry-breaking was not observed.

Structural distortions and the insulator to metal transition in $NiCr_{2-x}V_xS_4$

Anthony V. Powell* and Paz Vaqueiro

Department of Chemistry, Heriot-Watt University, Edinburgh, UK EH14 4AS. E-mail: a.v.powell@hw.ac.uk

Received (in Oxford, UK) 20th January 1999, Accepted 18th March 1999

The insulator to metal transition in $NiCr_{2-x}V_xS_4$ is accompanied by a structural distortion which results in the formation of zigzag chains of cations within the $(Cr,V)S_2$ layer.

The insulator to metal (ITM) transition[1,2] is of fundamental importance in condensed-matter science and encompasses phenomena as diverse as metallization processes in stars and size-induced transitions in microscopic metal particles.[3] From a chemical perspective, materials which lie close to the metal–insulator divide are of immense interest owing to the unique properties which they frequently exhibit and the opportunities afforded to tailor such properties using chemical control. For example, high temperature superconductivity in the cuprates[4] and the exceptional magnetotransport properties of mixed-manganese oxides[5] are two phenomena which appear to be linked to the proximity of these materials to the metal–insulator boundary.

Our investigations have been directed towards mixed-metal sulfides which lie in this important region of the electronic phase diagram, and have focused on materials which adopt the monoclinic Cr_3S_4 structure. This consists[6] of hexagonally close-packed sulfide layers, between alternate pairs of which, all of the octahedral sites are occupied by cations, giving rise to a unit of stoichiometry CrS_2. Half-occupancy, in an ordered manner, of the remaining octahedral sites between CrS_2 units, leads to a two-dimensional superstructure, with dimensions related to those of the primitive hexagonal unit cell (a_h) by $\sqrt{3}a_h \times a_h$. Progressive substitution of chromium by either divalent vanadium[7] or nickel[8] has been used to effect changes to the physical properties of metallic Cr_3S_4 and the contrasting electronic and magnetic properties of the two resulting non-stoichiometric series, $A_xCr_{3-x}S_4$ (A = V, Ni; $0 \leqslant x \leqslant 1$), may be correlated with differing cation distributions.[8,9]

This investigation has recently been extended to study the effect of chemical substitution within the MS_2 layers, through preparation of mixed-metal sulfides of general formula $NiCr_{2-x}V_xS_4$ ($0 \leqslant x \leqslant 2$). As the end-member phase $NiCr_2S_4$ is a semiconducting ferrimagnet[10] (T_c = 180 K) whilst NiV_2S_4 appears to be a metallic paramagnet,[11] an ITM transition would be expected in the non-stoichiometric series $NiCr_{2-x}V_xS_4$. The rigid-band model, which successfully accounts for the electronic properties of the stoichiometric end-member phases,[12] predicts all non-stoichiometric materials to be metallic, owing to holes in the t_{2g}-derived band. Here, we report that a critical level of substitution is required before the ITM transition occurs, and that this transition is accompanied by a structural distortion of the MS_2 unit which results in zigzag chains of octahedrally coordinated cations in the fully occupied layer.

All materials were prepared by conventional high temperature techniques. Initial characterisation by analytical electron microscopy, thermogravimetry and powder X-ray diffraction demonstrated that single-phase Cr_3S_4-type materials, with compositions in good agreement with nominal stoichiometries, were produced across the entire series. Transport properties, determined by the four-probe DC technique, clearly indicate semiconducting behaviour in the compositional range $0 \leqslant x \leqslant 0.5$ and metallic behaviour in the range $0.8 \leqslant x \leqslant 2.0$. However, for $NiCr_{1.4}V_{0.6}S_4$, $\rho(T)$ is almost temperature independent down to *ca*. 40 K, below which a slight increase in resistivity is observed leading to ambiguity over the sign of $d\rho/dT$ for materials in the composition range $0.5 < x < 0.8$. This may be the result of the influence of grain boundary resistances arising from the polycrystalline nature of the materials. Nevertheless, it leads to an uncertainty of no more than ±0.15 in the location of the ITM transition. Magnetic susceptibility data suggest that materials with $0 \leqslant x \leqslant 0.6$ exhibit long-range magnetic order. This has been confirmed by low temperature neutron diffraction. Conversely, materials with $0.6 < x \leqslant 2.0$ are paramagnetic, with evidence for spin-glass behaviour at low temperatures. Representative transport and magnetic data for materials in the semiconducting and metallic regions are presented in Fig 1.

Detailed structural studies were carried out by Rietveld analysis using a combination of powder X-ray diffraction and powder neutron diffraction, undertaken at the high-flux reactor, ILL Grenoble. Structural refinements, full details of which will be presented in due course, proceeded smoothly with weighted residuals of 4–7%. In addition to confirming solid-solution behaviour across the whole series, data demonstrate that in the

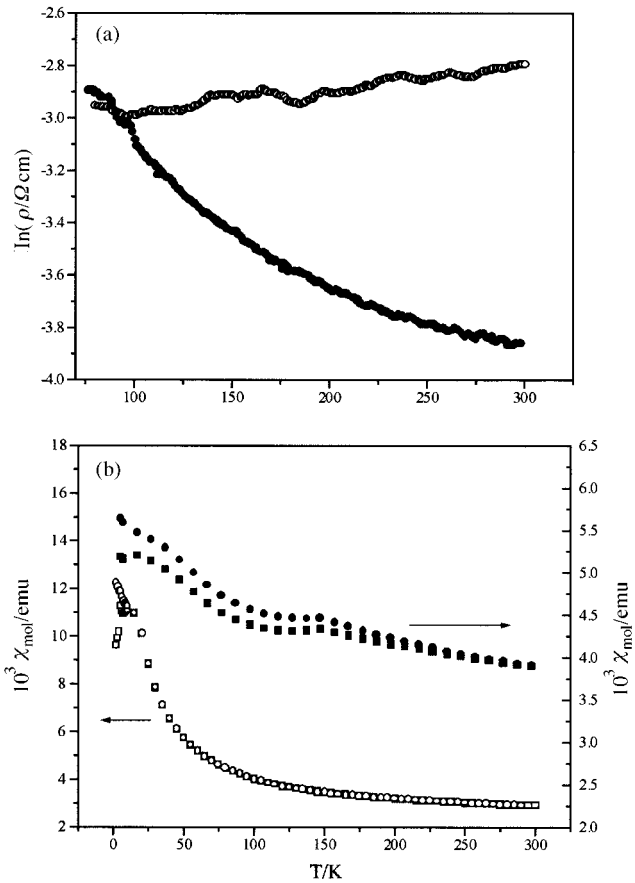

Fig. 1 (a) Resistivity data and (b) magnetic susceptibility data for $NiCrVS_4$ (open points) and $NiCr_{1.6}V_{0.4}S_4$ (solid points). Zero-field-cooled and field-cooled magnetic susceptibilities are denoted by squares and circles respectively.

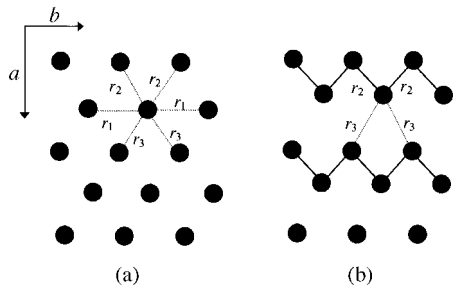

Fig. 2 (a) The pseudo hexagonal arrangement of cations in the MS_2 layer in materials with $x \leqslant 0.4$ and (b) the zigzag chains of cations in materials with $x > 0.4$.

non-stoichiometric materials, vanadium substitution occurs exclusively at sites in the fully occupied (MS_2) layer. There was no evidence of ordering of vanadium and chromium cations in the MS_2 layer.

Examination of cation–cation separations reveals that despite the solid-solution behaviour of $NiCr_{2-x}V_xS_4$, vanadium doping induces structural changes in the fully occupied layer, in the region of composition where the change from a magnetically ordered semiconductor to a paramagnetic metal is observed. The geometry of this layer in $NiCr_2S_4$ is shown in Fig. 2(a). Each cation has two neighbours at *ca.* 3.4 Å (r_1) resulting from lattice translation along the *b*-axis, two at a comparatively short distance (r_2) of *ca.* 3.2 Å and two at a slightly greater separation (r_3) of *ca.* 3.6 Å, giving six nearest neighbours in a pseudo-hexagonal arrangement within the layer. Although at low levels of vanadium doping this geometry is little perturbed, above x = 0.4, r_2 begins to decrease and r_3 increase whilst r_1 shows little change across the entire compositional range. Significantly, between x = 0.6 and 0.8, the decrease in r_2 is sufficient to bring it below the critical distance (R_c = 3.09–3.12 Å) proposed by Goodenough[13] for itinerant electron behaviour as a result of direct cation–cation interaction. These changes in cation–cation separations are manifested in an abrupt increase in the ratio r_3/r_2 at compositions with $x > 0.4$ (Fig. 3). This increase corresponds to a change from the pseudo-hexagonal symmetry of the fully occupied layer in $NiCr_2S_4$ to an arrangement in which there are zigzag chains of cations directed parallel to the *b*-axis [Fig. 2(b)]. The separation between cations within the chains (r_2) is considerably shorter than the shortest inter-chain (r_3) distance. These distances are *ca.* 2.9 and *ca.* 3.8 Å respectively, in NiV_2S_4.

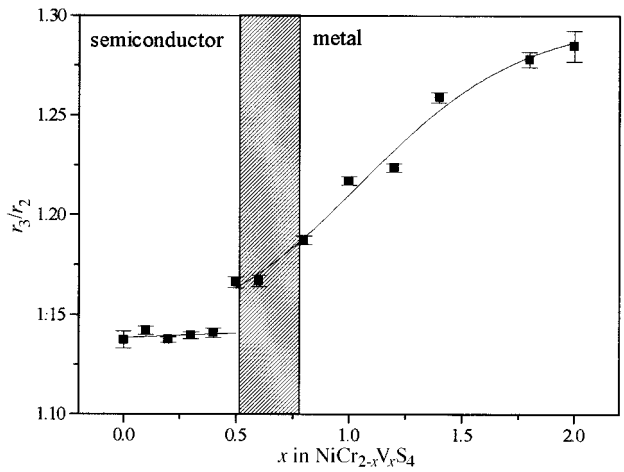

Fig. 3 Correlation between the compositional dependence of the degree of structural distortion within the MS_2 layer and electronic properties. Compositions for which there is ambiguity over the sign of $d\rho/dT$ are indicated by the shaded region.

The data presented here suggest that, contrary to predictions based on changing electron populations, the substitution of Cr^{III} d^3 by V^{III} d^2 is itself insufficient to induce metallization through the introduction of holes into the t_{2g}-derived band. This is a limitation of the approximations of the rigid-band model which ignores the effect of distortions on band structure or changes to band width as substitution proceeds. Using the extended Hückel method, Canadell *et al.*[14] have performed band structure calculations for a series of stoichiometric mixed-metal sulfides containing the MS_2 structural unit. Describing the MS_2 unit in terms of edge-sharing M_2S_6 double octahedral chains, the effect on band structure of distortions which give rise to metal clustering within the MS_2 layer, was investigated. The results demonstrate that when d^2 ions are present in this layer, strong cation–cation interactions within M_2X_6 chains lead to pronounced dispersion of one component of the t_{2g}-derived band and metallic behaviour pertains. The accompanying distortion of the ideal hexagonal array of cations corresponds to a structure in which zigzag clustering of the type depicted in Fig. 2(b) is present. Conversely, calculations reveal that when the t_{2g} manifold is half-filled as in AMo_2S_4, a Peierls distortion within individual M_2S_6 chains gives rise to a diamond clustering within the MS_2 layer and opens a band gap, resulting in semiconducting behaviour. Interestingly, despite the half-filled t_{2g} band, no metal clustering has been observed in materials of the form ACr_2S_4 (A = V, Cr, Ni). This has been attributed to the effects of electron localisation,[14] consistent with the more contracted orbitals of chromium compared to those of molybdenum [R_c(Mo) = 3.97 Å]. With increasing vanadium content in the series, $NiCr_{2-x}V_xS_4$, semiconducting behaviour persists until above some critical composition ($x \approx 0.4$), the MS_2 layer begins to distort resulting in the formation of chains of cations in which the intrachain cation–cation separation becomes lower than the critical distance for direct cation–cation orbital interaction. Of the three components of the t_{2g}-derived band, that in the chain direction, which is predominantly of $d_{x^2-y^2}$ character, shows pronounced dispersion, resulting in metallic behaviour.

The authors wish to thank The Leverhulme Trust for a research fellowship for P. V. The assistance of Dr C. Ritter, ILL, Grenoble, with the collection of neutron diffraction data is gratefully acknowledged.

A crystalline carbene–silylene adduct 1,2-$C_6H_4[N(R)]_2C$-$Si[N(R)]_2C_6H_4$-1,2 (R = CH_2Bu^t); synthesis, structure and bonding in model compounds†

Received (in Basel, Switzerland) 28th January 1999, Accepted 17th March 1999

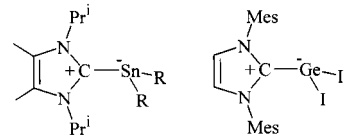
The red–brown, crystalline carbene–silylene adduct, 1,2-$C_6H_4[N(R)]_2C$-$Si[N(R)]_2C_6H_4$-1,2 (R = CH_2Bu^t) 4, was obtained from its factors, the carbene 3 and silylene 1, or from $Ni\{C[N(R)]_2C_6H_4$-1,2$\}_2$ and 1; the X-ray structure of 4 shows a long C–Si bond [2.162(5) Å] and NMR spectral data indicate significant C^+–Si^- bond polarity, features consistent with DFT calculations at the B3LYP/6-311+G level on $[(CH)_2(NH)_2]C$–$Si[(NH)_2(CH)_2]$, $(H_2N)_2C$–$Si(NH_2)_2$ or even $[(CH)_2(NH)_2]C$–SiH_2 and $(H_2N)_2C$–SiH_2, but not H_2C=$Si(NH_2)_2$ or H_2C=$Si[(NH)_2(CH)_2]$.**

Recently we reported on the coordination chemistry of the stable silylene $Si[N(CH_2Bu^t)]_2C_6H_4$-1,2 **1** [abbreviated as Si(NN)]. The crystalline, diamagnetic complexes [Ni(PPh$_3$)-{Si(NN)}$_3$], [Ni{Si(NN)}$_4$] or *trans*-[Pt{Si(NN)Cl}$_2$-{Si(NN)}$_2$] were obtained from **1** and [$NiCl_2(PPh_3)_2$], [Ni(cod)$_2$] or [$PtCl_2(PPh_3)_2$].[1] An attempt to synthesise a mixed carbene(silylene)–nickel complex was the starting point of the present investigation.

The new bis(carbene)nickel(0) complex **2** {obtained from [Ni(cod)$_2$] and the carbene **3** (*cf.* ref. 2)} afforded the crystalline carbene-silylene adduct **4** in good yield, accompanied by a deposit of Ni; an intermediate may have been a transient Ni{C(NN)}{Si(NN)} complex. Compound **4** was also prepared directly from its factors **1** and **3**. Compound **3** was synthesised from the thiourea **5** and C_8K at ambient temperature (*cf.* ref. 3). These data are summarised in Scheme 1.

Each of the new compounds **2**–**5** gave satisfactory microanalytical and NMR spectroscopic data. The $^{13}C\{^1H\}$ and $^{29}Si\{^1H\}$ NMR spectral signals for **4** in [$^2H]_8$toluene or [$^2H]_6$benzene at ambient temperature were at *ca.* 15 ppm lower frequency compared to the values in the free carbene **3**, δ_C 231.6, or silylene **1**, δ_{Si} 96.9.[4] However, these chemical shifts for **4** rose in frequency with increasing temperature, steadily approaching those for **3** and **1**, indicative of a dissociative equilibrium: **4** ⇄ **1** + **3**. Nonetheless, the EI mass spectrum of **4** at 70 eV showed the molecular ion $[\mathbf{4}]^+$ at *m/z* 532 as the highest peak present in substantial abundance (46%).

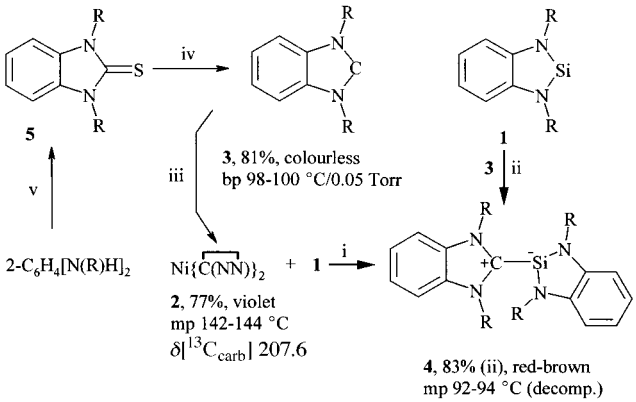
Crystalline **4** is a monomer, Fig. 1.‡ There is a long central bond of 2.162(5) Å between the three-coordinate C and Si atoms, the carbon atom being in an almost planar but the silicon in a pyramidal environment: the sum of the angles at C(1) being 351.4° and at Si 291.6°. This may be compared with the C=Si bond length in the silenes $Ad(Me_3SiO)C{=}Si(SiMe_3)_2$ [1.764(3) Å, twist angle 14.6°][5] and $Bu^t_2(Me)Si(Me_3Si)C{=}SiMe_2$ [1.702(5) Å, twist angle 1.6°][6] having the essentially planar double bond geometry; the sum of the three angles at Si or C is 360°. In **4**, the fold angles are 28° at C(1) and 77° at Si. There is significant torsion of the N_2CSiN_2 skeleton as evident by the dihedral angles N(1)–C(1)–Si–N(4) of 75° and N(2)–C(1)–Si–N(3) of 128.1°. We infer that the CSi bond in **4** is dipolar, with the silicon being the negative end of the dipole, a C=Si double bond being ruled out. This conclusion is supported by DFT calculations on model compounds (see below), as well as by analogy with suggestions on the nature of the di(amino)-carbene–tin(II) and –germanium(II) complexes **6**,[7] **7**,[8] and **8**.[9]



6 R = $C_6H_2Pr^i_3$-2,4,6 **8**
7 R = Cl

The silylene M[N(Bu^t)(CH$_2$)$_2$NBu^t] (M = Si) failed to react with the carbene (M = C), germylene (M = Ge) or CO.[10] By contrast, **1** not only forms the adduct **4** with **3**, but also reacts with the heavier group 14 carbene analogues M′[$N(SiMe_3)_2]_2$ (M′ = Ge, Sn or Pb),[11] although we now report that it did not react with CO in supercritical xenon at > 20 atm at 25 °C.[12]

Density functional calculations[13] were performed on the parent silene $H_2C{=}SiH_2$ **9** and derivatives X_2CSiY_2 **10**–**15** (X_2



Scheme 1 Synthesis of the carbene-silylene adduct **4** and compounds **2**, **3** and **5** (R = CH_2Bu^t). *Reagents and conditions* (at *ca.* 20 °C): i or ii, C_6H_6; iii, [Ni(cod)$_2$], C_6H_6; iv, 2 C_8K, thf; v, $C(S)Cl_2$, 2 NEt_3.

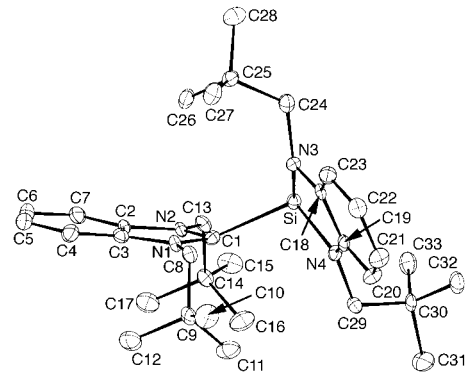


Fig. 1 Molecular structure of **4**. Selected bond lengths (Å) and angles (°): Si–C(1) 2.162(5), C(1)–N(1) 1.362(5), C(1)–N(2) 1.362(5), Si–N(3) 1.791(4), Si–N(4) 1.790(4), N(1)–C(1)–N(2) 105.6(4), N(3)–Si–N(4) 87.5(2).

and Y_2 are hydrogens or nitrogen functions, Table 1). The structures, illustrated by **9**, **10**, **12** and **15** in Fig. 2, separate into two distinct groups. The model compounds $H_2C{=}SiY_2$ **9**–**11** all have CSi double bonds with distances near 1.70 Å, planar or nearly planar geometries and large association energies. The second group, **12**–**15**, like **4**, have longer SiC distances (1.93–2.02 Å, compared with 1.885 Å in $H_3C{-}SiH_3$),[14] strongly pyramidal geometries at silicon, and weaker association energies.

The dramatic structural changes produced by substituting the hydrogens at carbon by amino groups are clarified by natural bond order analysis. The N–C–N unit delocalises the positive charge on carbon. The polarities of **12**–**15** are reversed (*cf.* **9** and **10**) and the SiY_2 moieties are negative (Fig. 2). The π-delocalisation causes amino groups on carbon, but not on silicon, to be co-planar (or nearly so). The silicon substituents bond through the silicon p orbitals at angles approaching 90°.

The association energies for the model compounds **9**–**15** (Table 1) are highly revealing. These are based on the energies of the process $X_2C{:} + {:}SiY_2 \rightarrow X_2CSiY_2$ [using the $:CH_2$ ($^1A_1$) energy for uniformity as the other carbenes and silylenes are ground state singlets]. The association energies vary remarkably, from 116.5 kcal mol^{-1} for the parent silene **9** to only 3.2 kcal mol^{-1} for **15**, the model closest to **4**. These energies reflect the changes in carbene and silylene stability due to their substituents. The C=Si bond in the parent silene **9** is weakened markedly by NH_2 substitution, much more on C than on Si. The effects on C and Si are roughly additive. The aromaticity conferred by the five-membered Si[$(NH)_2(CH)_2$] ring in **11** (*vs.* **10**) has a much greater effect on lowering the association energy than that due to the C[$(NH)_2(CH)_2$] ring in **13** (*vs.* **12**).[15]

The structures of **4** and **12**–**15** can best be considered as donor–acceptor complexes in which the carbene lone pair interacts with the formally vacant silicon p orbital, as suggested for the H_2Si–CO complex which also has pronounced pyramidalisation at silicon.[16] The polarisation of the parent silene **9** is reversed by amino substitution at the carbon and the SiY_2 moiety assumes anionic character. The lowering of the association energy in **12**–**15** also results in longer CSi separations. The difference between the CSi distance in **15** (2.02 Å) from that in **4** (2.16 Å) is not significant in view of the weakness of these complexes. The computed torsion barrier for **15** is only 1 kcal mol^{-1} and, like **4**, has a significantly twisted energy minimum.

In a full paper, we shall report on the synthesis and structures of the heavier group 14 analogues of the carbene–silylene complex **4**.

We thank EPSRC, the European Union, [especially for fellowships for B. G. (EPSRC) and W. M. B. (HCM, category 20)] and the Fonds der Chemischen Industrie for support.

MOVPE Mechanisms from studies of specially designed and labelled precursors

David J. Cole-Hamilton

School of Chemistry, University of St. Andrews, St. Andrews, Fife, Scotland, UK KY16 9ST. E-mail: djc@st-and.ac.uk

Received (in Cambridge, UK) 5th January 1999, Accepted 5th February 1999

Studies of the reaction or decomposition products of precursors for metal organic vapour phase epitaxy (MOVPE) do not always give enough information to allow the unequivocal determination of decomposition or growth mechanisms. By studying deuterium labelled precursors in the presence or absence of their protio analogues, other precursors and/or He, H_2, D_2 or by studying precursors carrying substituents that are designed to give different products if different mechanisms operate, it is possible to draw more definitive conclusions.

Using these studies coupled with semi-empirical molecular orbital calculations, it is shown that primary arsines decompose by reductive elimination of H_2 followed by β-abstraction (Bu^tAsH_2) or reaction with the parent arsine to form RAsH·, which undergoes reductive elimination (PhAsH·), β-abstraction (Bu^tAsH·) or As–C bond cleavage (Bu^tAsH·). Hex-5-enylarsine has been used to show that adduct formation is not important during growth of GaAs.

For group 16 dialkyls (R_2E, E = S, Se or Te), the predominant decomposition mechanism is homolytic E–C bond cleavage. Subsequent reactions involve abstraction of H from the β-position of the intact R_2E to give alkane, two molecules of alkene E and H· (E = Te or Se). For E = Te, H· does not react significantly with Pr^i_2Te, but for Bu^t_2Se a short chain-reaction is initiated by H·. The importance of free radicals is confirmed by studies of (but-2-enyl)$_2$Te, (hex-5-enyl)$_2$E (E = S, Se, Te), (pent-5-enyl)$_2$Te and (hex-5-enyl)SH, as well as of secondary and tertiary analogues. Reactions of the labelled and designed group 16 precursors with Me_2M (M = Cd or Zn) are also discussed.

Introduction

Semiconductors are the major components of the computer age. Elemental semiconductors such as silicon from Group 14 have found use in applications from transistors and computers through to solar energy converters, but they have the limitation that the band-gap is fixed so that the wavelengths they can absorb or emit cannot be varied over a wide range. Compound semiconductors, which are made up from elements of Groups 13 and 15, 12 and 16 or sometimes 13 and 16, on the other hand, have a variety of different band gaps which cover the whole electromagnetic spectrum from the IR (InSb) through to the UV (ZnS).[1] Using three or four of these elements, *e.g.* $Cd_xHg_{1-x}Te$ or $Ga_xIn_{1-x}As_yP_{1-y}$, the band gap within one materials system can be varied over a wide range. In addition, the mobility of electrons within some of these materials can be an order of magnitude higher than in silicon.

For the elemental semiconductors, large single crystals can be grown and cleaved to make the required electronic devices, but the growth of large single crystals of the compound materials has proved highly problematical. Since only a thin film of the semiconductor is usually required for the fabrication of devices, the most important methods to have been developed to surmount this problem involve the growth of thin layers of the desired semiconductor on a single crystal of another, using the ordered array of the substrate atoms to align those of the growing layer. A variety of methods has been devised for doing this, but one of the most important is metal organic vapour phase epitaxy (MOVPE).[1,2] In this approach, highly purified volatile compounds of the elements to be incorporated into the semiconductor are passed over the heated substrate where they decompose to give the thin film. The composition of the growing layer can be controlled by regulation of the gas phase composition and dopants can be included by incorporating extra precursor streams. The technique has proved highly versatile and is now production technology for a variety of semiconductor devices, many of which contain up to 100 layers of different but controlled composition.[2]

The earliest examples of semiconductor growth by MOVPE involved metal alkyls (usually MMe_n) for the Group 12 or 13 precursors and hydrides (EH_n) for the Group 15 or 16 elements.[3,4] In most cases these systems worked well and in some they continue to be used in production.[1] These compounds are, however, highly reactive and often toxic materials[5] so there have been developments in recent years particularly towards the use of different precursors for the Group 15 and 16 precursors. Most of these involve the replacement of the hydrides by compounds that contain one or more alkyl or amide groups and hence the chemistry leading to the semiconductor film becomes more complex and has the potential to incorporate extraneous elements into the growing layer such as carbon or nitrogen, which have detrimental effects on the electronic properties.[6] There is thus a considerable interest in understanding the processes that occur during the growth of layers from these precursors so as to be able to improve on their design.

Various groups have used surface science techniques to study the species present on the surface during growth,[7,8] but often these studies have been carried out under high vacuum and there can be no certainty that the interesting results obtained correlate with what occurs under growth conditions (generally *ca.* 1 atm).

David Cole-Hamilton received his training in Organometallic Chemistry with Dr T. A. Stephenson (Edinburgh) and Professor Sir Geoffrey Wilkinson (Imperial College). He was on the staff at Liverpool, where Professor A. K. Holliday introduced him to Dr J. B. Mullin (MOD) and the design of MOVPE precursors, before taking up the Irvine Chair of Chemistry in St. Andrews. His work is in the area of organometallic compounds applied to homogeneous catalysis and problems in Materials Chemistry. Some of his work on the production of highly purified metal alkyls has been commercialised through Epichem Ltd (Founded 1983). He was the first Sir Edward Frankland Fellow of the RSC (1984–5) and won the Corday Morgan medal and prize in 1983. In 1998 he won the RSC Industrial award for Organometallic Chemistry sponsored by Monsanto.

Furthermore, in addition to reactions on the surface, gas phase processes may be occurring of which surface techniques remain ignorant. Gas phase reactions may also determine the nature of the surface species. Kinetic studies have been carried out under real growth conditions and certain conclusions have been drawn on the basis of product analyses (usually using mass spectrometry, gas chromatography–mass spectrometry (GCMS)[9] or FTIR[10] studies). These have given valuable insight, although without quantitative calibration, they are of limited value and, as will be demonstrated, they do not always lead to the appropriate conclusions.

Our approach has been to design precursors which are as similar as possible to those that are used in the growth process, but which, as a result of the products they form, give definitive information about the way in which they decomposed or reacted. We have used two main approaches. The first involves the use of deuterium labelling whilst the second involves the design of special 'reporter ligands', whose reaction products give information on the mechanisms involved in their formation. Product analyses are carried out using multinuclear NMR spectroscopy or GCMS and in some cases these experimental studies are backed up by theoretical calculations. In this article, we discuss our work on gallium arsenide and on II–VI (12–16) semiconductors involving Zn, Cd, Hg, S, Se or Te.

Gallium arsenide

Gallium arsenide was originally grown from Me_3Ga and AsH_3[3] and some commercial processes still use these precursors extensively.[2] However, AsH_3 is a highly toxic gas and is usually supplied in high pressure cylinders diluted with hydrogen. The risks associated with the possible rupture of one of these cylinders or their ancilliary equipment, either in use or during transport, led to a search for alternative arsenic precursors. The main ones to be introduced were the primary arsines, Bu^tAsH_2 and $PhAsH_2$, of which Bu^tAsH_2 is now the precursor of choice. These compounds are not intrinsically very much less toxic than AsH_3,[5] but being liquids, they are generally supplied in small metal containers and a spillage is not catastrophic—it simply requires evacuation of the area until the arsenic compound has evaporated and dissipated.

The various first steps in the decomposition mechanisms for Bu^tAsH_2 are shown in Fig. 1. They are, reductive elimination of Bu^tH or H_2, β-H abstraction to give AsH_3 and 2-methylpropane or homolytic cleavage of the As–C or As–H bond. At the time when we started to work in this area, some elegant studies had been performed that showed that both 2-methylpropene and 2-methylpropane were products.[11,12] All of these only considered that mechanisms that involved loss of the As–C bond, by reductive elimination of 2-methylpropane, by homolytic fission of the As–C bond or by β-H abstraction, were likely to be important since literature values of the bond enthalpies are much higher for As–H than for As–C.[13]

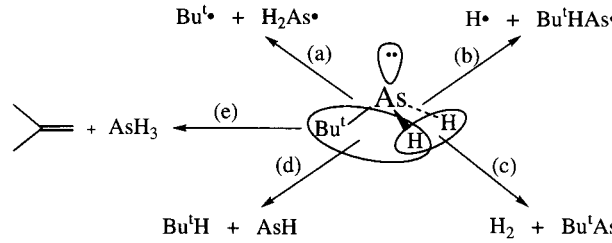

Fig. 1 Possible first steps in the decomposition of Bu^tAsH_2. (a) As–C bond cleavage; (b) As–H bond cleavage; (c) reductive elimination of H_2; (d) reductive elimination of Bu^tH; (e) β-elimination.

We opted to study[13–15] $PhAsH_2$ since one of the pathways (β-H abstraction) is not available. The organic product from its decomposition is benzene and this could arise from As–C bond cleavage or from reductive elimination. To test which of these was operative, we studied the decomposition of (*o*-tolyl)AsD_2, reasoning that reductive elimination would only give toluene deuteriated in the *ortho* position, whereas homolytic fission would give the *o*-tolyl radical which would either abstract D to give toluene deuteriated in the *ortho*-position or would isomerise to the allylic stabilised benzyl radical which would abstract D to give toluene deuteriated in the methyl group.

Decomposition of *o*-tolylAsD_2 produced toluene with D in the *ortho*-position, but also in the methyl group. Surprisingly, however, we observed that the methyl group contained 0, 1, 2 or 3 D atoms. This could not easily be explained by any of the mechanisms that had previously been suggested so we carried out calculations in the PM3 system on the various possible first steps in the decomposition, including those which involved As–H bond cleavage. These showed that, at the temperatures involved, loss of H_2 was both kinetically and thermodynamically the most favoured option.[15] We also showed that reductive elimination of toluene from (*o*-toly)AsH· had a very similar free energy of activation to tautomerism to give the stabilised benzyl radical, $H_2AsC_6CH_2$·; a pathway that could account for multiple D incorporation into the methyl group. This led us to propose that the decomposition of (*o*-tolyl)AsH_2 occurred as shown in Fig. 2, with (*o*-tolyl)As reacting with (*o*-tolyl)AsH_2 to give (*o*-tolyl)AsH· from which the final products were generated. Calculations suggested that a very similar sequence of reactions accounted for the decomposition of Bu^tAsH_2 except that β-H abstraction in Bu^tAs, formed by loss of H_2, competed with the bimolecular reaction to produce Bu^tAsH·.[15]

One of the other controversies surrounding the growth of GaAs by MOVPE concerned whether or not adducts of the form [Me_3Ga·AsR_3] (R = H, alkyl or aryl) were involved in the growth process. There is no doubt that these form at room temperature and below, but at 600–700 °C entropy may ensure that their existence is at best fleeting. We probed this by studying the model primary alkyl arsine, (hex-5-enyl)-AsH_2.[15–18] We selected the hex-5-enyl group originally as a

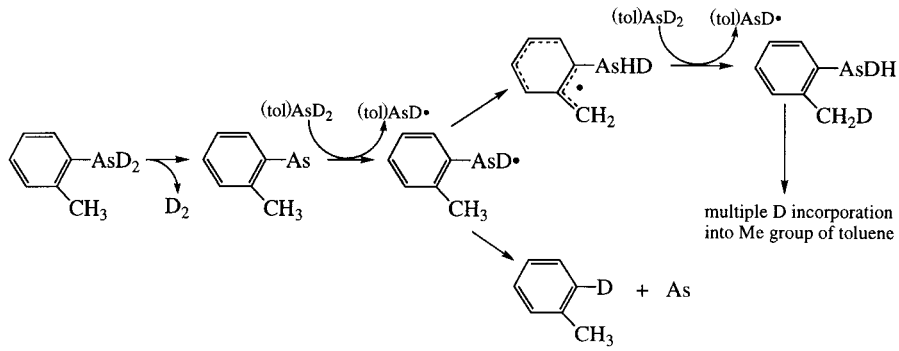

Fig. 2 Proposed mechanism for the decomposition of (*o*-tolyl)AsD_2.

probe for the decomposition mechanism of primary arsines since, if hex-5-enyl radicals are formed at any stage by As–C cleavage, they will cyclise to cyclopentylmethyl or cyclohexyl radicals.[19,20] Non-radical processes will, on the other hand, give straight chain products. The decomposition of (hex-5-enyl)-AsH_2 on its own produces hex-1-ene as the major hydrocarbon product,[16,17] showing that free alkyl radicals are not produced, as confirmed by the decomposition of (*o*-tolyl)AsD_2 and the calculations on Bu^tAsH_2 (see above). When (hex-5-enyl)arsine was reacted with Me_3Ga in the liquid phase at low temperature, we were able to identify the adduct, [$Me_3Ga{\cdot}As(hex)H_2$] which decomposed on heating, giving off methane, to produce [$Me_2GaAs(hex)H]_3$ then [$MeGaAs(hex)]_n$. Heating the polymer produced GaAs together with methane and methylene-cyclopentene. The last product shows that the final step involves As–C and Ga–C bond cleavage to give Me· and hex-5-enyl radicals, which cyclise to cyclopentylmethyl radicals and react with Me· to give the observed products (see Fig. 3). The different products obtained from the decomposition of [(hex-5-enyl)AsH_2] in the presence or absence of Me_3Ga allow us to determine whether the gas phase reaction involved adduct formation or not, by analysing the products from the gas-phase reaction of Me_3Ga with [(hex-5-enyl)AsH_2]. In practice, we obtained[16,17] a product distribution that is extremely similar to that obtained from [(hex-5-enyl)AsH_2] alone along with methane and unreacted Me_3Ga, confirming that adduct formation is not significant in the gas-phase—at least in this system.

II–VI Compounds

$Cd_xHg_{1-x}Te$, ZnSe, ZnS

Cadmium mercury telluride is the main semiconductor used for IR detectors and emitters. It is also of importance for long range transmission over fibre optic cables made from fluoride glasses. Hydrogen telluride is not sufficiently stable for use in MOVPE[4] so dialkyl- or diallyl-tellurium compounds have generally been employed together with Me_2Cd and elemental mercury.

Diallyltellurium [bis(prop-2-enyl)tellurium] decomposes to give hexa-1,5-diene and tellurium.[21] These products could be produced by reductive elimination or by Te–C bond cleavage to give prop-2-enyl radicals which combine to give the observed product. In order to test which of these mechanisms is operating, we studied[22] the decomposition of [bis(but-2-enyl)tellurium] since reductive elimination should give only octa-2,6-diene (as *Z,Z, E,Z* and *Z,E* isomers) whilst formation of butenyl radicals followed by radical coupling should give these products together with 2,4-dimethylhexa-1,5-diene and *Z*- and *E*-3-methylhepta-1,5-diene. In practice, we observed that all the products were observed (Fig. 4) in similar ratios to those obtained from bis(but-2-enyl)zinc, which is known to decompose by a free radical mechanism.[23] Furthermore, at partial conversion there was no evidence for isomerisation of the starting material to bis(1-methylpropenyl)tellurium, ruling out the reductive elimination mechanism.

The main tellurium precursors that have been employed are dialkyltelluriums, especially Pr^i_2Te. To probe the decomposition mechanisms of this kind of alkyl in the presence or absence of Me_2Cd and/or Hg, we have studied the decomposition of bis(hex-5-enyl)tellurium,[24,25] bis(pent-4-enyl)tellurium[24] and of Pr^i_2Te labelled with deuterium.[26]

The model studies in the gas phase showed that a mixture of straight chain and cyclic products was obtained from bis(hex-5-enyl)tellurium indicating that Te–C bond cleavage was certainly important (Fig. 5), but not giving detailed information about subsequent steps in the decomposition. In the liquid phase, bis(hex-5-enyl)tellurium produced linear and cyclic hydrocarbons, but also (cyclopentylmethyl)(hex-5-enyl)tellurium and bis(cyclopentylmethyl)tellurium. Both of these products suggest that the dialkyltellurium undergoes homolytic fission of the Te–C bond and that the free carbon based radical (after cyclisation in this case) reacts back with intact bis(hex-5-enyl)tellurium, eliminating a further hex-5-enyl radical.[24,25] Using bis(pent-5-enyl)tellurium in the liquid or gas phase, we obtain pent-1-ene and penta-1,4-diene together with 2-methyltelluracyclopentane. The last product shows that once Te–C bond cleavage has occurred, the RTe· formed in this case is sufficiently stable to undergo internal cyclisation to the telluracyclopentylmethyl radical which then picks up H·.

These reactions clearly show that Te–C bond cleavage is important, but they involve primary alkyls which differ from those generally employed in growth. We, therefore, studied d[14]-

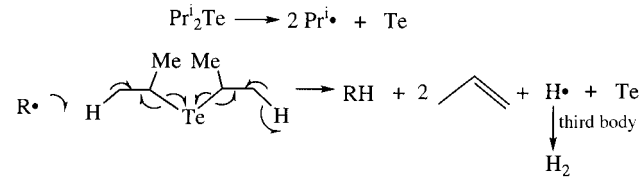

Fig. 6 Proposed major pathway for the decomposition of Pr$^i_2$Te [R = Pr^i or Me (from Me_2Cd)].

labelled Pr$^i_2$Te to investigate the pathways open to a real precursor.[26] The organic products from decomposition of unlabelled Pr$^i_2$Te are propene and propane (2 : 1) together with small amounts of 2,3-dimethylbutane, much less than would be expected from gas phase reactions of Pr^i· with one another.[27] The various possible processes for decomposition of a compound of this type are similar to those shown in Fig. 1 but involve reductive elimination to give 2,3-dimethylbutane, β-H abstraction or Te–C bond cleavage.

Codecomposition of d^0- and d^{14}-Pr$^i_2$Te gives a mixture of d^0, d^1, d^7 and d^8 propane (1.7 : 1 : 1.5 : 1) together with d^0 and d^6-propene. This strongly suggests that Te–C bond cleavage occurs rather than β-H abstraction followed by competing β-H abstraction and reductive elimination, which might be expected to give only d^0- and d^8-propane together with d^0- and d^6-propene. Care must be exercised here, however, since exchange of [C_3H_7TeH] with [C_3D_7TeD] is expected to occur to give [C_3H_7TeD] and [C_3D_7TeH] from which reductive elimination would give d^1- and d^7-propane. Careful analysis of the product ratios does allow us to distinguish between the two pathways, however, since it can be shown that the expected ratio for the β-H elimination-scrambling-reduction elimination process should be approximately 1 : 1 : 1 : 1 for d^0, d^1, d^7 and d^8-propane (given the *ca.* 1 : 1 ratio of C_3H_7 : C_3D_7 observed in the products) whereas kinetic isotope effects should make d^0 and d^7 the major products from a free radical process, as is observed. The fact that the d^0 : d^1 ratio (1.7) is very similar to d^7 : d^8 (1.5) is consistent with a free radical mechanism with k_H/k_D for H abstraction being *ca.* 1.6. Further support for the free radical processes arises from the fact that we have trapped free alkyl radicals and observed them by EPR spectroscopy during the liquid phase decomposition of simple tellurium alkyls such as Pr$^i_2$Te.[28,29]

For Pr$^i_2$Te, carrying out the decomposition in hydrogen increases the amount of propane relative to propene formed and decomposition of d^{14}-Pr$^i_2$Te in hydrogen produces some C_3D_7H (d^7 : d^8 ≈ 1 : 1) confirming that Pr^i· is formed and reacts with H_2. To explain the 2 : 1 ratio of propane : propene obtained in the decomposition of Pr$^i_2$Te in helium, we have proposed that Pr^i· formed from homolytic fission of the Te–C bond abstracts H· from intact Pr$^i_2$Te initiating a 'cascade' reaction that leads to 2-methylpropane, 2 × 2-methylpropene, Te and H· (Fig. 6).

Recently we have obtained further support for mechanisms of this kind from studies of Bu^{t}Se,[30–32] a precursor that has recently found favour because H_2Se leads to severe problems associated with prereactions if used with R_2M (R = Me or Et, M = Zn or Cd) to grow MSe,[33] as well as to passivation of N dopants, probably as N–H.[34] We have shown that the prereactions involve cluster growth in the gas phase leading to nucleation as nanoparticles[35–37] and have developed this chemistry into a method for synthesising polymer–nanoparticle composites of these important materials.[38–40] The replacement of H_2E (E = S or Se) by Bu^{t}EH has been partially successful in eliminating the prereaction,[41,42] although we have recently shown that a different prereaction occurs to give [Bu^{t}EMR]$_5$ which, in turn decompose on heating to give nanoparticles of ME.[43]

Bu$^t_2$Se completely removes the problem of prereaction and may reduce the problem of N–H passivation. Previous studies had suggested, on rather limited evidence, that β-H elimination might be important.[10,44] We have used both deuterium labelling and designed precursors to study the decomposition of bis-(tertiaryalkyl)selenium compounds and find that a radical mechanism is the only one that explains all of the data. The key observations from the gas phase pyrolysis of Bu$^t_2$Se in He, H_2 or D_2 in the presence or absence of d^{18}-Bu$^t_2$Se are: (i) 2-methylpropene and 2-methylpropane are formed in a 10 : 1 ratio; (ii) neither Bu^{t}SeH nor H_2S are observed, although they would be stable under the decomposition conditions; (iii) the temperature profiles of the decomposition and the 2-methylpropene : 2-methylpropane ratio are essentially the same in H_2 or He; (iv) decomposition of d^{18}-Bu$^t_2$Se in H_2 produces C_4D_9H and C_4D_{10} (ratio 2.6 : 1); (v) co-decomposition of d^0- and d^{18}-Bu$^t_2$Se produces d^0, d^1, d^9 and d^{10} 2-methylpropane in the ratio 2.29 : 1 : 2.86 : 1.2.[31,32] The failure to observe 2,2,3,3-tetramethylbutane, Bu^{t}SeH or H_2Se effectively rules out reductive elimination or β-H abstraction.

The failure to observe 2,2,3,3-tetramethylbutane together with the observation that the 2-methylpropane : 2-methylpropene ratio ≠ 1 might also indicate that the products cannot be formed from reactions of Bu^t·. However, at temperatures above 290 °C, the loss of H· from Bu^t· becomes competitive with disproportionation and combination and the proportions of both 2-methylpropane and 2,2,3,3-tetramethylbutane fall as the temperature rises.[45] This complication does not arise in the studies of Pr$^i_2$Te since these were carried out at 370 °C, whilst the loss of H· from Pr^i· is not significant below 400 °C.[27] Although the close similarity of the 2-methylpropene : 2-methylpropane ratio formed from Bu$^t_2$Se in He and H_2 suggests no involvement of the carrier gas, the formation of C_4D_9H from the decomposition of d^{18}-Bu$^t_2$Se in H_2 shows that the carrier gas can be involved.

A mechanism that would rationalise all of these observations is similar to that shown in Fig. 6 for Pr$^i_2$Te, with R· being Bu^t· or H·. In helium Se–C bond cleavage leads to Bu^t· and Bu^{t}Se· which immediately decomposes Se and a second Bu^t·. Bu^t· then abstracts H· from Bu$^t_2$Se (the highest concentration species available) to give 2-methylpropane, 2 × 2-methylpropene, Se and H· (as for Pr$^i_2$Te, see above). H· then starts a chain reaction by abstracting H· from Bu$^t_2$Se. In H_2, Bu^t· can abstract H· from intact Bu$^t_2$Se or from H_2. Either way, the product ratio will be unaffected since H· continues the chain. For Pr$^i_2$Te, the 2 : 1 ratio of 2-methylpropene : 2-methylpropane and the increase in the proportion of 2-methylpropane in hydrogen over that obtained in helium suggests that H· does not abstract H· from intact Pr$^i_2$Te in this case. Calculations have shown, however that the concerted reaction similar to that shown in Fig. 6 may not occur for Bu$^t_2$Se, at least in the gas phase, because both $Se_{(g)}$ and H· are high energy species, but rather that it occurs in a

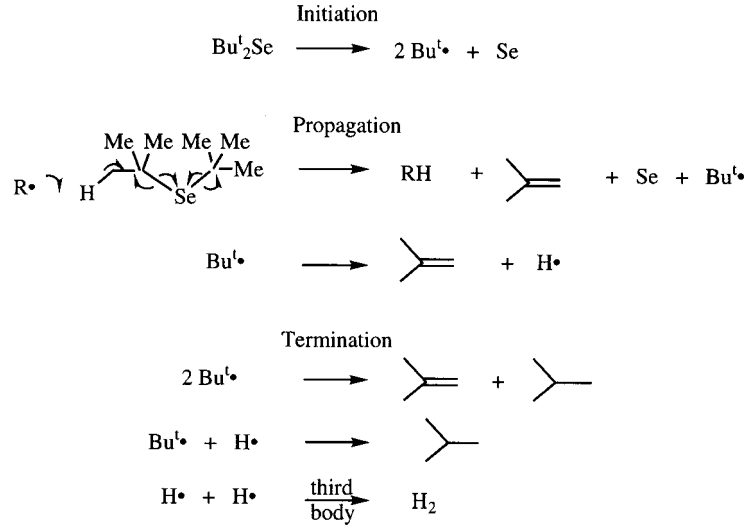

Fig. 7 Proposed mechanism for the decomposition or reaction of Bu^t_2Se [R = Bu^t·, Me· (from Me_2Zn) or H· (from decomposition of Bu^t· or from Bu^t· + H_2)].

stepwise manner (Fig. 7). This is very likely because H· loss from Bu^t· is important at these temperatures.[45] Using published and calculated activation parameters, it is possible to model all the observed results using this sequential mechanism.[32]

A sequence of reactions similar to that shown in Fig. 7, but with HS· as the chain carrier, accounts for the decomposition of Bu^tSH and it is sobering to note that this mechanism was first proposed nearly 50 years ago on the basis of careful kinetic measurements![46]

Me_2M (M = Cd or Zn) both undergo homolytic cleavage of the M–C bond, but in the absence of any other reagent the radicals recombine and the decomposition temperature is very high. In the presence of Bu^t_2Se[31,32] or Pr^i_2Te,[26] the methyl radicals abstract H·, in the case of Me_2Zn and Bu^t_2Se to initiate a chain reaction similar to that shown in Fig. 6, but with all the species except the hydrocarbons adsorbed on the surface of ZnSe. This reaction becomes accessible if surface bound, rather than free, Se and H· are formed. Surface bound H· carries the chain so that methane and 2-methylpropene are the major products. For Me_2Cd and Pr^i_2Te, similar reactions occur but radical coupling to give 2-methylpropene (Me· + Pr^i·), ethane (Me· + Me·) and 2,3-dimethylbutane (Pr^i· + Pr^i·) are also important. In this case, it is believed that Me· reacts with Pr^i_2Te by H abstraction, but also by addition to give $MeTePr^i_2$· from which Pr^i· is released, enhancing the flux of Pr^i· and forming $MeTePr^i$, which is an observed product and leads on to Me_2Te *via* Me_2Te_2.[26] Similar reactions have led us to show that $MeTe^tBu$[47] and MeTe(allyl)[48] are not good tellurium precursors because, although Te–C bond cleavage occurs at low temperature, Me_2Te is very stable so that their ability to release tellurium at low temperature is limited. Interestingly, we do not see evidence for addition of Me· to Bu^t_2E' (E′ = S or Se), presumably for steric reasons (bigger alkyl group, smaller chalcogenide). We do, however, observe small amounts of 2-methylpropane if the Me_2Zn and Bu^t_2Se are copyrolysed in hydrogen. In D_2, the 2-methylpropane is predominantly $C_4H_8D_2$ whereas Me_2Zn and d^{18}-Bu^tSe in H_2 give $C_4D_9H_2$, showing that the 2-methylpropane is a secondary product formed from the hydrogenation of 2-methylpropene, presumably catalysed by ZnSe.[31,32]

Photochemically at room temperature, Bu^t_2Se decomposes to give 2-methylpropene and 2-methylpropane (1 : 1) together with small amounts of 3,4-dimethylbutane and $Bu^t_2Se_2$. Co-photolysis of d^0- and d^{18}-Bu^t_2Se gives the same products (2-methylpropane is d^0, d^1, d^9 and d^{10}) together with d^9-Bu^t_2Se, suggesting that Bu^tSe· is stable at this temperature and that radical–radical reactions dominate. The $Bu^t_2Se_2$ is d^0 and d^{18} (no d^9 is formed) so it is formed by a concerted reaction between Bu^t_2Se and Se.[31,32]

We have also used 'reporter groups' to probe the decomposition of R_2E' and RE′H (E′ = S or Se), based on the ideas elaborated above for hex-5-enyl groups[25] but extending them to include secondary (1-methylhex-5-enyl) and tertiary (1,1-dimethylhex-5-enyl) groups.[49]

For $(hex\text{-}5\text{-}enyl)_2E'$, 50% of the products are cyclic whilst the other 50% are hexa-1,3- or -2,4-dienes. As shown in Fig. 5, the cyclic products arise from E′–C bond cleavage followed by cyclisation of the formed hex-5-enyl radicals and we have concluded that the hexadienes arise from cyclisation of (hex-5-enyl)E′· to give a six- or seven-membered ring from which the dienes are produced by an unknown mechanism.[25] Abstraction of H from intact $(hex\text{-}5\text{-}enyl)_2E'$ by cyclohexyl or cyclopentyl methyl radicals, analogous to the reactions proposed for the decomposition of Bu^t_2Se or Pr^i_2Te, does not appear to be important since we largely see cyclohexene and methylenecyclopentene from *loss* of H· from the radicals. This may be rationalised because the primary alkyl groups have only a small number of β-H atoms available for abstraction. The presence of primary alkyl groups and/or the ability of (hex-5-enyl)E′· to cyclise might also explain the stability of (hex-5-enyl)E·, the similarity in the product distribution for E′ = S or Se and the high decomposition temperature of these alkyls. Reducing the number of β-H atoms reduces the probability of reaction between (hex-5-enyl)E′· and $(hex\text{-}5\text{-}enyl)_2E'$ and radical radical reactions must then become more important, thus also contributing to the higher decomposition temperatures. For (hex-5-enyl)SH, the majority of the products are the hexa-2,3- and -3,4-dienes suggesting that, in this case, S–H bond cleavage is important.

Using a similar approach but designing the hexenyl group so that it has a tertiary C atom attached to the chalcogenide, *i.e.* 1,1-dimethyhex-5-enyl (hex′), the dialkyl compounds are too involatile for gas phase studies, but we have studied the decomposition of MeE(hex′) (E = Se or Te).[49] In both cases the major hydrocarbon products are unsaturated cyclic hydrocarbons, with smaller amounts of 2-methylhepta-1,6- and -1,5-diene. (These products are more important for E = Se.) The cyclic hydrocarbons mainly contain six-membered rings, but some of them do not contain the expected geminal dimethyl group. We assume that these are secondary products caused by rearrangements at the high temperatures involved in this study. For the tellurium compound, products in which the cyclised radicals add back to MeTe· are also observed together with Me_2Te_2 and Me_2Te. The Se containing products are Me_2Se_2, Me_2Se and MeSeH. All the hydrocarbon products can be rationalised by a decomposition mechanism involving E–C

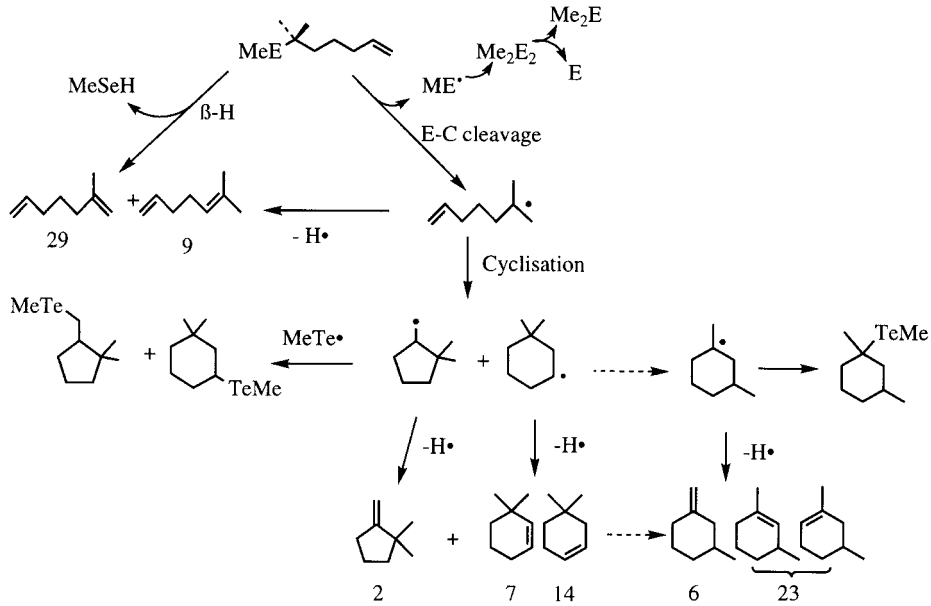

Fig. 8 Proposed mechanism for the decomposition of (1,1-dimethylhex-5-enyl)MeE (E = Se or Te). The dashed arrows indicate tentative rearrangements. Numbers shown are % of hydrocarbon products for E = Se at 450 °C in He (10% of an unknown product was also observed). For E = Te, the ratios are similar, except that much less of the straight chain products are observed indicating that β-H elimination is not important for E = Te.

cleavage followed by loss of H· from the 2-methylhept-6-en-2-yl radical before or after cyclisation (Fig. 8). However, the larger amounts of straight chain products obtained when E = Se and the observation of MeSeH show that in this case, β-H abstraction is a competing process, although its importance decreases as the temperature is raised. There is no evidence for abstraction of H from intact MeE(hex′) by any of the radicals since this would lead to saturated cyclic or monounsaturated straight chain products. None are observed. This is presumably because H· loss from these bulky radicals is expected to be dominant at the high temperatures of this study, by analogy with the reactivity of Bu^{t}·.[45]

Conclusions

Labelled and specially designed analogues of precursors are capable of giving high quality information about the processes that occur during MOVPE reactions. For primary arsines, these studies together with semi-empirical calculations show that reductive elimination of H_2 is the first step and that gas-phase adducts are not important in the reaction chemistry. For Group 16 precursors, homolytic cleavage of the C–E bond (E = S, Se or Te) occurs and detailed product analyses, especially when using labelled precursors give mechanistic details about susbequent steps in the reactions. These types of studies allow new precursors with better properties for *e.g.* low temperature growth to be designed.[50]

Acknowledgements

I thank all the authors whose names appear in the list of references, but especially Doug Foster, a fine experimentalist and constant source of ideas; Brian Mullin and Janet Hails (DERA) with whom I have had countless fruitful discussions and who (Janet Hails) did many painstaking GCMS studies and Chris Glidewell and Nick Maung who have underpinned our wilder speculations by careful calculations. I am also indebted to the funding agencies, DERA and EPSRC and their pregenitors without whose help this work would not have been possible.

Received (in Cambridge, UK) 23rd February 1999, Accepted 23rd March 1999

Silicate macroskeletons which have both templated mesoporosity and open-cell macrovoid structures have been prepared in monolithic form at near ambient temperatures from continuous metastable foams of non-ionic alkylpolyethylene oxide surfactants under aqueous, neutral pH reaction conditions.

The controlled synthesis of inorganic frameworks exhibiting very large pores and complex macroscale forms is an area of intense scientific and technological effort for potential applications in catalysis, molecular sieving and biomaterials.[1] Assemblies of both charged and uncharged amphiphilic molecules are known to interact with inorganic precursors to form complex architectures in the inorganic phase.[2,3] However, void size control of such porous compositions has generally been restricted to the micro- and meso-scales between 0.3 and 30 nm diameter.[4,5] Recent work by the groups of Ozin, Stucky and Mann have produced materials that display porosity and morphology on the supermeso- and macro-scales.[6–8] Ozin reported the morphosynthesis of SBA-2 materials into complex rod, disc, swirl and top shapes,[6] while Stucky described the templating and shaping of supermesoporous oxides.[7] The morphosynthesis of silica and calciferous materials displaying open skeletal frameworks have been reported by Mann and coworkers.[8] The voids created by the amorphous silica, calcium phosphate or carbonate skeletons are of the order of micrometres and thus begin to approach structures with void dimensions and compositions desirable for bioceramic applications.[9] Possible technological drawbacks of these materials are that they are obtained as precipitated particles, the solid phases are non-porous and that they are synthesised in frozen, complex bicontinuous microemulsions over long reaction times. The use of biliquid foam structures to prepare transition metal oxide films from super-saturated precursor solutions has also been reported.[10] Ceramic foams of various metal oxide compositions are well known in industrial applications and are generally prepared by slurry coating a ceramic powder, for example alumina and zirconia, onto the surface of a fibrous polymer support which is then removed through calcination.

In an effort to simplify the microemulsion synthesis system and to produce materials with larger macrovoids, we replaced the unstable biliquid microemulsion with a metastable surfactant foam system. This was with the goal of replicating, in an inorganic silica phase, the three dimensional macrostructured foam under ambient and benign reaction conditions. Here we describe the sol–gel synthesis of novel silica and metallosilicate materials that exhibit both open macroporous skeletal networks of amorphous silica and templated mesoporosity within the solid skeleton. These novel macrostructured mesoporous silica foam materials, which we label MMSF, are formed directly from tetraethoxyorthosilicate (TEOS) or TEOS plus a basic metal salt, solubilised within the water-rich film of an alkylpolyethylene oxide (PEO) based nonionic surfactant foam.[11] The reaction conditions are almost identical to those previously reported for [Si]- and [M]-MSU-X mesostructure syntheses.†[12,13] The appearance of these products suggests that void size control over length scales[14] of differing orders of magnitude can be achieved in a single, simple synthesis medium. The MMSFs have added novelty over most existing macrostructured materials in that they can be formed in monolithic shapes with, in principle, no limit to their dimensions.

X-Ray diffraction (XRD) patterns‡ of the hydrothermally treated and calcined MMSFs (Fig. 1) exhibit single peak d_{100} reflections at low angle. No higher angle reflections and hence long-range symmetry were indicated, suggesting that the solid part of the MMSF material is amorphous with a regular repeating pore motif. The single reflection XRD patterns are identical to those obtained from [M]-MSU-X mesostructures and thus suggest that a pore structure exists that is similar to the three dimensional disordered worm-like pore arrays exhibited by [M]-MSU-X materials.[13–15] Nitrogen sorption isotherms‡ of hydrothermally treated/calcined monolithic samples indicate the presence of well defined large mesopores. The adsorption branch displays a strong capillary condensation step indicative of mesopores with well defined diameters (Fig. 2) while the desorption branch exhibits some hysteresis as a result of the high partial pressure of adsorption. We therefore conclude that the solid silicate phase that makes up the MMSF material, is itself mesoporous and furthermore, the analytical data indicate that the solid skeleton of MMSF is at the mesoscopic level, identical to hydrothermally treated [M]-MSU-X powders[15] exhibiting surface areas between 800 and 900 $m^2\ g^{-1}$, pore volumes of *ca.* 1.0 mL g^{-1} and pore diameters between 20 and 40 nm depending upon template dimensions, synthesis temperatures and length of hydrothermal treatment. Optical photographs‡ of sections of MMSF monoliths display the macrovoid nature of the MMSF materials that distinguish them from exisiting [M]-MSU-X materials which are produced only as powders. These images suggest that a true macrostructured skeletal material is assembled from both skeleton-like silica filaments or struts [Fig. 3] and surface-like structures and not agglomerations of silica particles. The open-cell nature of the MMSF was demonstrated by the absorption of a brightly

coloured aqueous dye solution into a monolithic sample *via* capillary action. The photographs presented indicate that the macrovoids range in diameter from hundreds of microns to 1–2 mm, the smaller end of this scale being ideal for application in artificial bioceramic bone implant technologies.[9] Currently the MMSF materials are brittle and exhibit only limited fracture resistance. Improvement of the compressive and tensile strengths is being pursued.

A perhaps surprisingly simple mechanism of formation of the MMSFs is proposed. Minimum surface spherical bubbles make up the surfactant foam, their diameters being determined by the rate and mode of agitation of the surfactant emulsion. Upon TEOS addition, the water immiscible $Si(OC_2H_4)_4$ monomers are progressively solubilised through hydrogen bonding between the surfactant PEO head-group of micelle structures and the alkoxide species. The PEO micellar corona solvates the TEOS monomers, transports them throughout the foam film and the strong H-bonding therein induces polarisation of the Si–OR bond and subsequent hydrolysis and condensation.[12] In the initial stages of reaction the rate of film drainage is high and no stable foam results. As hydrolysis and condensation of the TEOS proceed, the viscosity within the foam film increases and drainage from the film slows, allowing a stable, interconnected open cell foam to be maintained.[16]

The synthesis route described here is very simple, low cost, environmentally benign and able to be modified in many ways so that varied product engineering is possible. Development of the MMSF structures, compositions and physical properties is continuing. The author thanks Industrial Research Ltd. for funding through the Non-Specific Output Fund as part of a contract with the New Zealand Foundation for Research, Science and Technology.

Notes and references

† *Experimental*: in a typical MMSF synthesis, TEOS is added to a dilute 5–10 wt% solution of a non-toxic, inexpensive non-ionic surfactant (*e.g.* Triton N-101 nonyl-PEO_{10}), at 24–30 °C and at neutral pH. Metallosilicate analogues may be prepared by adding a basic metal salt solution [*e.g.* $Al_2(SO_4)_3$, $TiOSO_4$, $ZrOCl_2$, $VOSO_4$] to the TEOS, before addition to the surfactant emulsion. This causes pre-hydrolysis of the TEOS and formation of water soluble Si–O–M units.[14] In the step that separates [M]-MSU-X synthesis from MMSF synthesis, the surfactant/TEOS emulsion is then stirred rapidly at 750–1000 rpm with a magnetic stirrer whose length is 60–75% of the width of the reaction vessel thereby creating turbulence within the vessel. Hydrolysis of the TEOS is catalysed by hydrogen bonding with the PEO[13] surfactant headgroup. As this hydrolysis proceeds spherical bubbles aggregate to form an organic/inorganic composite foam which adopts the dimensions of the reaction vessel. After 16–24 h, stirring is arrested and the foam composite is allowed to age under static conditions for 24–48 h. The solid foam monolith that results may then be removed from the vessel and dried, taking care to avoid cracking caused by drying too quickly. The as-prepared MMSFs may then be hydrothermally treated at 100–150 °C and/or calcined at 450 °C for 4 h in air to yield an inorganic silicate foam. Calcination without hydrothermal treatment invariably induces cracking in the MMSF monoliths. Hydrothermal treatment[15] improves the cross-linking within the amorphous silica, the mesopore diameters and also the fracture resisitance. MMSF yields are typically 80–90% in Si while the remainder of the SiO_2 is retrieved as precipitated templated [M]-MSU-X. Foam bubble sizes and hence final macrovoid dimensions may be modified by changing the turbulence within the reaction vessel. This can be achieved by moderation of the stirring speed or by substituting different shaped magnetic stirrer followers and is the subject of continued investigation.

‡ *Characterisation*: XRD patterns were measured on a Philips PW 1700 series APD diffractometer equipped with an automatic variable divergence slit and Co-Kα radiation (λ = 0.179026 nm). Nitrogen sorption isotherms were obtained with a Micromeritics ASAP 2010 sorptometer at −196 °C. Surface areas were calculated using the BET model while pore size distributions were calculated using the BJH model. Optical photographs were obtained with a Nikon Multiphot type A camera equipped with a 65 mm Macro Nikkor lens using incident lighting and T-Max 100 black and white film.

Received (in Cambridge, UK) 4th Febuary 1999, Accepted 16th March 1999

The first heterodinuclear macrocyclic Schiff base complex containing both first- and second row transition metal ions, $[NiPdL](ClO_4)_2\cdot 3MeCN$ has been synthesised and characterised by spectroscopic methods; the X-ray structure of this complex and its mononuclear precursor are reported.

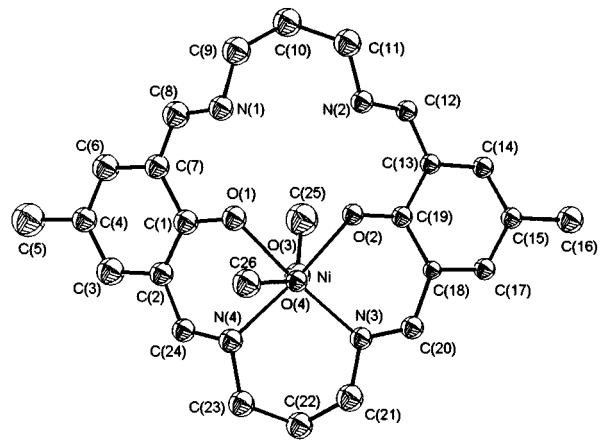
The first macrocyclic dinuclear complexes $[M_2L]^{2+}$ {where H_2L is the macrocyclic Schiff base ligand (Fig. 1) 11,23-dimethyl-3,7,15,19-tetraazatricyclo[19.3.1.1^{19,13}]hexacosa-2,7,9,11,13(26),14,19,21(25),22,24-decaene-25,26-diol and $M^1 = M^2 = Mn^{2+}$, Fe^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+} ord Zn^{2+}} were synthesised in a direct template 2+2 condensation of 2,6-diformyl-4-methylphenol and 1,3-diaminopropane by Robson and Pilkington[1] and by Okawa and Kida[2] in a stepwise synthesis. More recently, the first examples of homodinuclear complexes of the ligand L^{2-} with second- and third-row transition metal ions have been reported.[3]

Apart from homodinuclear complexes, the analogous heterodinuclear ($M^1 \neq M^2$) complexes have also been synthesised in stepwise syntheses starting from non-cyclic precursors.[4] This synthetic strategy often utilises the difference in the coordination preferences of the two metal ions by using two different diamine fragments in the left and right side of the macrocyclic system. Both homo- and hetero-dinuclear complexes of L^{2-} and related ligands have proved to be very useful in studying magnetic coupling phenomena, mimicking bimetalic metalloenzymes, investigating mixed-valence systems *etc.*,[4–6]

Here, we report the synthesis, spectroscopic characterisation and X-ray crystal structure of the mixed nickel(II)–palladium(II) complex $[NiPdL](ClO_4)_2\cdot 3MeCN$. To the best of our knowledge this is the first example of a heterodinuclear macrocyclic complex containing both first- and second-row transition metal ions. We present also the X-ray crystal structure of the mononuclear complex $[Ni(H_2L](ClO_4)_2\cdot 2MeOH$[1] which is the precursor in the synthesis of the mixed $Ni^{II}Pd^{II}$ complex and other heterodinuclear complexes.[7]

The starting complex $[Ni(H_2L)](ClO_4)_2\cdot H_2O$ was obtained as described in ref. 1. $[NiPdL](ClO_4)_2\cdot 3MeCN$† was obtained by reacting $[NiH_2L](ClO_4)_2\cdot H_2O$ with palladium(II) acetate in acetonitrile, in a similar fashion to related heterodinuclear complexes containing two first row metal ions[7]. This synthetic strategy is remarkably simple compared to the stepwise syntheses of related heterodinuclear macrocyclic complexes. Moreover, our attempts to obtain the $[NiPdL]^{2+}$ complex in alternative stepwise syntheses starting from the non-cyclic *N*,*N*′-propylenebis(3-formyl-5-methylsalicylideneaminato)-nickel(II) or -palladium(II) complexes, although while leading to the desired heterodinuclear systems as judged from spectroscopic data, have not yielded pure products so far.

^{1}H NMR and electrospray MS spectra confirm the heterodinuclear nature of the obtained complex and show that no scrambling of metal ions takes place during the synthesis. The ESMS of $[NiPdL](ClO_4)_2\cdot 3MeCN$ shows signals with a maximum at *m/z* 667.3 corresponding to $[NiPdL](ClO_4)^+$ and at *m/z* 282.9 corresponding to $[NiPdL]^{2+}$. The large isotropic shifts observed for the ^{1}H NMR spectra of $[NiPdL](ClO_4)_2\cdot 3MeCN$ in D_2O or CD_3OD solutions are in accord with the presence of high-spin Ni^{II}. The signal assignment was based on the intensity, expected shift values, linewidth analysis and comparison with the spectra[7] of $[Ni(H_2L)](ClO_4)_2\cdot H_2O$ and $[Ni_2L]Cl_2\cdot 2H_2O$. Protons **a**, **b**, **d**, **e**, **h** and **i** resonate at δ −6.17, 119.2, 9.77, 3.06, 6.32 and 2.75, respectively (see Fig. 1 for labelling scheme). The signals at δ 24.34 and 11.55 correspond to positions **f** and **g** or *vice versa*, while the signal of proton **c**, expected in the region δ 250–450 region, is too broad to be



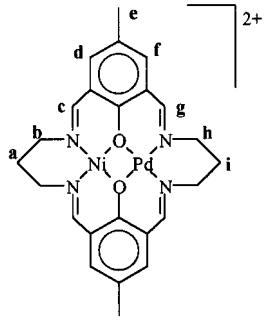


Fig. 1 The labelling scheme of the ligand L^{2-} in the $[NiPdL]^{2+}$ complex (axial ligands omitted).

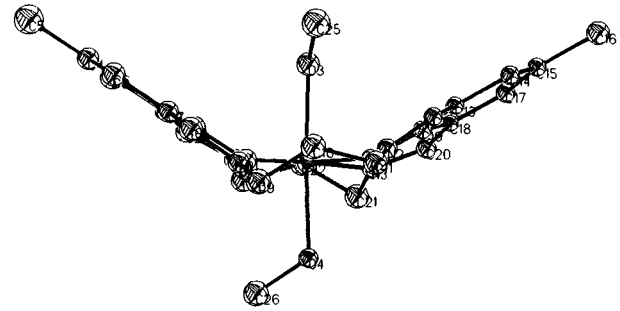

Fig. 2 Top and side view of the $[Ni(H_2L)(MeOH)_2]^{2+}$ complex cation together with atom labels.

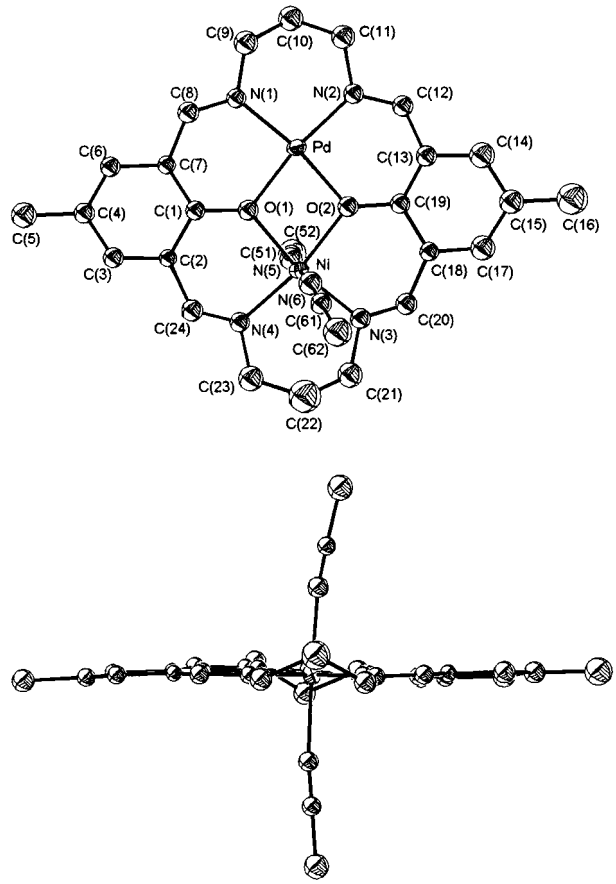

Fig. 3 Top and side view of the $[NiPdL(MeCN)_2]^{2+}$ complex cation together with atom labels.

detected. As expected, the protons that are three or four bonds away from the paramagnetic Ni^{II} ion exhibit relatively large isotropic shifts. On the other hand the protons that belong to the methyl group and the Pd^{II}-complexed side of the ligand experience smaller isotropic shifts due to less effective spin delocalisation.

Crystals of $[Ni(H_2L)](ClO_4)_2\cdot 2MeOH$ were obtained by diffusion of diethyl ether into methanol solution of $[Ni(H_2L)](ClO_4)_2\cdot H_2O$ and crystals of $[NiPdL](ClO_4)_2\cdot 3MeCN$ were grown from acetonitrile.‡ The complex cation in $[Ni(H_2L)](ClO_4)_2\cdot 2MeOH$ (Fig. 2) is composed of the macrocyclic ligand bonded to Ni^{II} with four of its ligating atoms [two O and two N atoms; Ni–O(1) 2.013(11), Ni–N(3) 2.017(13), Ni–O(2) 2.022(10), Ni–N(4) 2.040(13) Å]. The two remaining coordination sites of Ni^{II} are occupied by two methanol molecules [Ni–O(4) 2.101(10), Ni–O(3) 2.156(11) Å], leading to a slightly distorted octahedron around the metal ion. In $[NiPdL](ClO_4)_2\cdot 3MeCN$ the macrocyclic ligand binds two metal ions, Ni^{II} and Pd^{II} (Fig. 3). Both phenyl oxygen atoms, unlike in the case of $[Ni(H_2L)](ClO_4)_2\cdot 2MeOH$, are deprotonated. The octahedral coordination of Ni^{II} cation is completed by two acetonitrile molecules [Ni–N(4) 2.002(15), Ni–N(3) 2.003(14), Ni–O(2) 2.035(12), Ni–O(1) 2.037(11), Ni–N(5) 2.09(2), Ni–N(6) 2.10(2) Å], whereas the Pd^{II}) environment forms a slightly distorted square [Pd-N(1) 1.990(14), Pd-O(2) 1.997(11), Pd-N(2) 2.000(13), Pd-O(1) 2.012(11) Å]. The presence of Pd^{II} changes the overall conformation of the macrocycle. In $[NiPdL](ClO_4)_2\cdot 3MeCN$ the ligand adopts a planar conformation similar to that observed in other crystallographically characterised $[M_2L]^{n+}$ complexes.[3a,6] The angle between two flat fragments of the ligand [C(1)C(2)C(3)C(4)C(5)C(6)C(7)C(8)C(24)O(1)N(1)N(4) and C(12)C(13)C(14)C(15)C(16)C(17)C(18)C(19)C(20)O(2)N(2)-N(3)] is 177.4°. In contrast, in $Ni(H_2L)](ClO_4)_2\cdot 2MeH$ (Fig. 3) the ligand is considerably bent with the above mentioned planes forming the angle of 115.9°. However, this bending of the ligand is not as profound as that observed in the completely bent conformation of the protonated free ligand[3a] (phenyl rings almost parallel).

In principle, the unique combination of macrocyclic environment and different reactivities of the first- and second-row metal complexes may lead to new catalytic systems. Presently we are investigating the catalytic properties of $[NiPdL](ClO_4)_2\cdot 3MeCN$ and related complexes.

This work was supported by KBN grant 3 T09A 071 12.

Notes and references

† The complex has been characterised by elemental analysis, IR and UV-VIS spectroscopy

‡ *Crystal data:* the crystals chosen for the data collection were placed in Lindemann glass capillaries and then mounted on a Kuma KM4 diffractometer. The intensities of three standards were monitored every 100 reflections. During measurement both crystals partially decomposed. The final loss of intensity was 57% for $[NiPdL](ClO_4)_2\cdot 3MeCN$ and 79% for $[Ni(H_2L)](ClO_4)_2\cdot 2MeOH$. The structures were solved using Patterson methods with SHELXS-86, and then refined with SHELXL-93. The C-bonded hydrogen atoms were placed in geometrically calculated positions. As both crystals were poor scatterers, and the data/parameters ratios were unfavourable, the anisotropic thermal vibration parameters were applied to metal and chlorine atoms only, the other atoms being refined isotropically. The temperature factors for H atoms were set as 1.2 times the factors of the C atoms to which the relevant H atoms were bonded. For $[NiPdL](ClO_4)_2\cdot 3MeCN$ it was found that the oxygen atoms of the perchlorate anions and a part of the solvent (acetonitrile) molecules were disordered. The respective site occupation factors were assumed to be 0.5. a)

The insertion of alkylgallium(I) groups [Ga–C(SiMe$_3$)$_3$] into P–P bonds of P$_4$: formation of a P$_4$(GaR)$_3$ cage

Werner Uhl* and Maike Benter

Fachbereich Chemie, Universität, Postfach 2503, D-26111 Oldenburg, Germany.

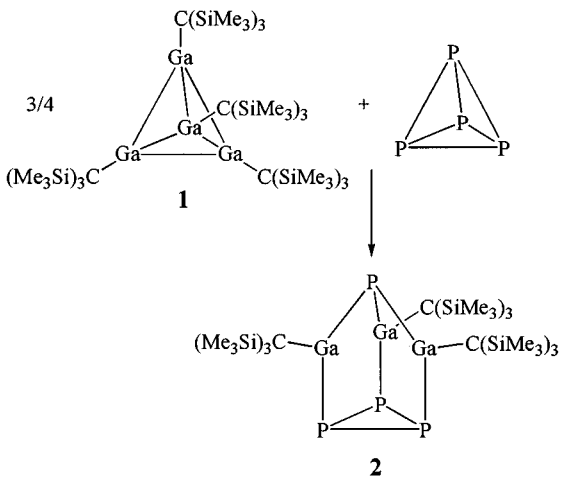
Received (in Basel, Switzerland) 25th January 1999, Accepted 8th March 1999

The tetrahedral gallium(I) compound Ga$_4$[C(SiMe$_3$)$_3$]$_4$ 1 reacted with white phosphorus by the threefold insertion of its monovalent gallium atoms into P–P bonds of the P$_4$ tetrahedron with formation of a novel P$_4$(GaR)$_3$ cage possessing a structure similar to P$_4$S$_3$.

Recently, we succeeded in synthesizing the first known alkylgallium(I) compound (**1**), which in the solid state adopted the tetrahedral structure Ga$_4$[C(SiMe$_3$)$_3$]$_4$, but dissociated into monomeric GaR fragments in dilute solutions.[1] Compound **1** is available now in a high yield by the reduction of the corresponding alkyltrichlorogallate with Rieke magnesium,[2] and shows a remarkable and unprecedented chemical reactivity similar to the up to now more intensively investigated indium analogue In$_4$[C(SiMe$_3$)$_3$]$_4$.[3] The chalcogens sulfur, selenium and tellurium gave heterocubane type molecules,[4] the insertion of a GaR fragment into one P–P bond of tri(*tert*-butyl)cyclotriphosphane was observed,[5] and the monomers are able to replace carbonyl groups in transition metal carbonyl complexes to yield novel transition metal gallium compounds.[5] The reaction of **1** with white phosphorus is reported here.

Tetragallane(4) **1** and P$_4$ reacted slowly in boiling *n*-hexane to yield yellow crystals of the novel trigallium tetraphosphorus compound **2** in a yield of 52%. The formation of **2** can be described by the insertion of three monomeric GaR fragments into three of the six P–P bonds of the P$_4$ tetrahedron. A similar reaction has not been observed before. The cyclopentadienylaluminium(I) derivative (AlCp*)$_4$ gave the electron deficient cage compound (AlCp*)$_6$P$_4$, which consists of two face-sharing heterocubanes with two opposite corners unoccupied.[6] The indium analogue of **1** yielded another product probably containing four indium atoms and only one phosphorus atom, which, however, could not, as yet, be characterized completely. As expected, singlets were observed for the SiMe$_3$ groups in the ^{1}H and ^{13}C NMR spectra of **2**, and the resonance of the α carbon atoms attached to gallium (δ 27.8) was in the characteristic range of compounds containing coordinatively unsaturated tricoordinated gallium atoms. Two resonances were detected in the ^{31}P NMR spectrum at δ −202.8 and −521.9. The first is in the expected range and splits into a doublet due to the coupling with the phosphorus atom at the apex of the cage. It was assigned to the P$_3$ group, of which each member is further coordinated by only one gallium atom. The apical phosphorus atom attached to three gallium atoms showed a quite unusual chemical shift to a very high field and gave a quartet caused by the coupling to the equivalent phosphorus atoms of the P$_3$ ring. To the best of our knowledge, similar high field shifts have been observed for only very few compounds such as P$_4$ itself (δ −488), tin(II) derivatives (SnPR)$_x$ and BaSn$_3$P$_4$R$_4$ (up to δ −529).[7]

The molecular structure of the Ga$_3$P$_4$ cage (Fig. 1) contains a homocycle of three phosphorus atoms, of which each is further attached to one gallium atom. The fourth phosphorus atom resides at the apex of the cage and is pyramidally coordinated by three gallium atoms, which are coordinatively unsaturated and bind to one carbon atom and two phosphorus atoms in an ideal planar arrangement (Ga2 due to its special position on a crystallographic mirror plane, Ga1: sum of angles 360.0°). The structure is, thus, quite similar to the structures of [P$_7$]$^{3-}$ or P$_4$S$_3$,[8] which have, however, electronically saturated atoms in the bridging positions. The Ga–P distances to the single phosphorus atom P1 (234.2 pm) are little shorter than those to the P$_3$ ring (237.2 pm), which may be caused by the higher negative charge at P1 and a stronger ionic contribution to its bonds. All Ga–P bonds are in the lower range usually observed for organogallium phosphides, in which generally the phosphorus atoms are further attached to alkyl groups as in heterocubane type molecules (RGaPR)$_4$.[9] The P–P distances (218.1 pm, average) are in the usual range and only a little shorter than in



Scheme 1

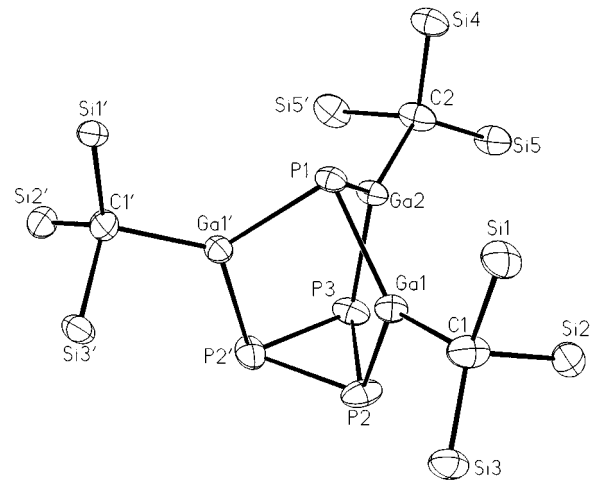


Fig. 1 Molecular structure of **2**. Selected bond lengths (pm) and angles (°): P1–Ga1 234.2(1), P1–Ga2 234.2(2), P2–Ga1 236.9(2), P3–Ga2 237.8(2), P2–P2′ 217.8(3), P2–P3 218.3(2), Ga1–C1 197.5(5), Ga2–C2 198.1(7); Ga1–P1–Ga1′ 86.43(6), Ga1–P1–Ga2 85.91(5), Ga1–P2–P2′ 102.54(4), Ga1–P2–P3 102.20(8), Ga2–P3–P2 102.33(7), P2′–P2–P3 60.08(5), P2–P3–P2′ 59.8(1), P1–Ga1–P2 113.76(5), P1–Ga2–P3 113.53(7).

P_4. The cage geometry forces the Ga atoms to approach to a distance of 319.7 pm on average, which is much shorter than the sum of the van der Waals radii (380 pm),[10] but longer than the Ga–Ga separation in the Ga_4 tetrahedron of **1** (268.8 pm).[1] These structural parameters suggest the treatment of **2** with a strong reducing agent in order to transfer electron density to the unsaturated gallium atoms and to obtain a delocalized σ bond in the cage. The Ga–C bonds (197.7 pm) are much shortened compared to those of the starting compound **1** (208 pm). The shortening is more pronounced than observed previously, and even in heterocubanes with the more electronegative chalcogen atoms longer distances were observed.[4] Several reasons may account for this observation such as the increase of oxidation state of the Ga atoms from +1 in **1** to +3 in compound **2**, the lower steric strain in the molecule and the low coordination number of the Ga atoms with an increased s character of the Ga–C bond.

We are grateful to the Deutschen Forschungsgemeinschaft and the Fonds der Chemischen Industrie for generous financial support.

The isolated iron–molybdenum cofactor of nitrogenase catalyses hydrogen evolution at high potential

Thierry Le Gall, Saad K. Ibrahim, Carol A. Gormal, Barry E. Smith and Christopher J. Pickett*

Nitrogen Fixation Laboratory, John Innes Centre, Norwich Research Park, Norwich, UK NR4 7UH. E-mail: chris.pickett@bbsrc.ac.uk

Received (in Cambridge, UK) 1st March 1999, Accepted 23rd March 1999

The isolated cofactor of nitrogenase FeMoco catalyses hydrogen evolution at the high potential associated with the FeMoco$^{ox/semi\text{-}red}$ couple ($E°$ = −280 mV *vs.* NHE , $C_6F_5S^-$ ligated form); analysis of the current–potential dependence of the catalysis suggests a mechanism involving rate-determining loss of H_2 from an FeMoco(H)$_2$ ^{red} intermediate (k = 3 s^{-1}); the relatively slow kinetics of this step may be related to an obligatory role for hydridic intermediates in substrate reductions by nitrogenase.

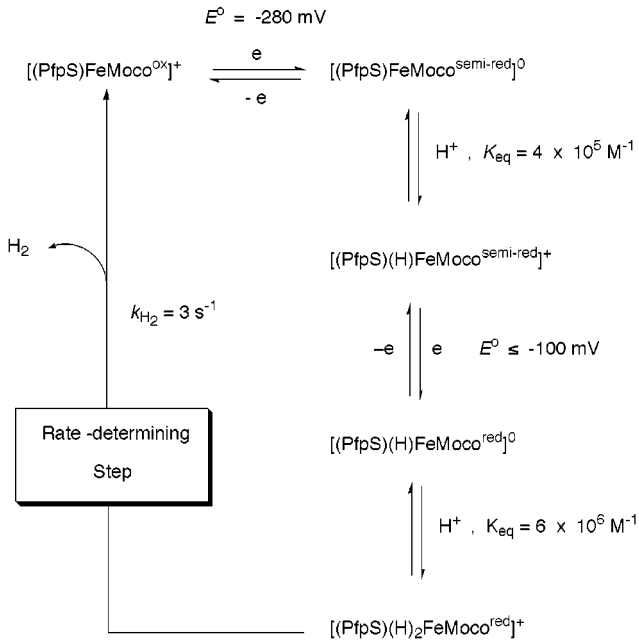
Catalysis of proton reduction to dihydrogen is an intrinsic property of the nitrogenase system. In the absence of molecular nitrogen (or other reducible substrates) turnover of the enzyme results in hydrogen evolution which is believed to be associated with successive 1e/1H$^+$ transfers to the resting-state redox level of the molybdenum–iron protein.[1] The centre within this protein at which proton reduction takes place is almost certainly[2] the {$MoFe_7S_9$}-cluster which has been shown to have the structure depicted in Scheme 1 when the protein is in the resting-state.[3] Disruption of the protein ligation of the cluster allows extraction into *N*-methylformamide (NMF) of a cofactor (FeMoco) which reactivates mutant apo-protein.[4] Spectroscopic, analytical and other evidence indicate that FeMoco retains the structure of the protein bound {$MoFe_7S_9$}-cluster but with the histidine ligand replaced by coordination of a solvent molecule to Mo and the cysteinyl ligand at the capping Fe replaced by an anion, probably *N*-methylformamidate.[5] Herein we show that FeMoco is capable of electrocatalysing the reduction of protons to dihydrogen at high potential, a process which may directly relate to the enzymic catalysis.

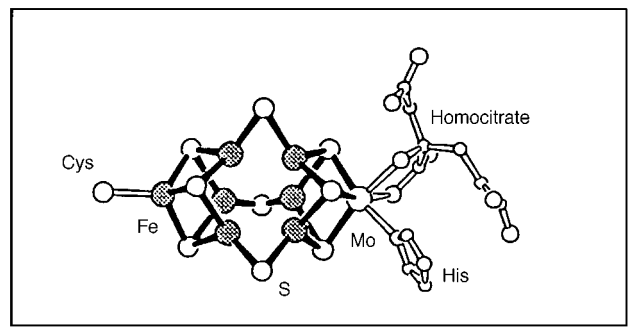
FeMoco was extracted into an NMF–phosphate buffer solution from molybdenum–iron protein that had been isolated from *Klebsiella pneumoniae* using minor modifications of the method described earlier.[6] It was derivatised by pentafluorothiophenolate (PfpS$^-$) ligation at the capping tetrahedral Fe atom,[7] and studied in the oxidised, EPR-silent, form which we shall refer to as {(PfpS)FeMoco}^{ox}. Cyclic voltammetry of {(PfpS)FeMoco}^{ox} showed that the cofactor undergoes a well defined, reversible, diffusion-controlled, single-electron reduction to give {(PfpS)FeMoco}$^{semi\text{-}red}$. This directly parallels earlier observations by Schultz, Newton and coworkers on the thiophenolate derivatised form of the cofactor.[8]

However, pentafluorothiophenol can function both as a ligand to FeMoco and as a source of protons. The pK_a(H_2O) for PfpSH (2.68) is considerably lower than that for PhSH (6.43) and we would expect that this greater acidity of PfpSH also pertains in the NMF system. Fig. 1 shows the effect of increasing [PfpSH]$_{total}$ on the cyclic voltammetry of the {(PfpS)FeMoco}$^{ox/semi\text{-}red}$ couple.† The peak current, I_p^{red}, is enhanced and the reversibility of the system decreased as the concentration of the acid is increased. Fast potential scan-rates (v) restore some reversibility to the system whereas at low v, the current response approaches that expected for a catalytic substrate reduction with the magnitude of I_p^{red} independent of v.

Controlled potential electrolysis of the cofactor (0.5 μmol) was performed at $E_{applied}$ = −550 mV *vs.* SCE (*ca.* −320 mV *vs.* NHE) in a sealed electrochemical cell in the presence of 60 mM of [PfpSH]$_{total}$. The gas-space was sampled after the passage of 4.3 μmol of electrons. Gas chromatographic analysis confirmed the formation of dihydrogen (1.84 μmol, 85%, *ca.* 9 turnovers). An enzyme reconstitution assay[4] of a sample of the catholyte after electrolysis showed that the cofactor was still fully active, *i.e.* the structural integrity of the cofactor was retained.

Fig. 2 shows a plot of I_p^{red} *vs.* [PfpSH]$_{total}$ together with the calculated response based on the mechanism proposed in Scheme 1. At low [PfpSH]$_{total}$ the phosphate buffer neutralises protons and there is little enhancement of I_p^{red}; above [PfpSH]$_{total}$ *ca.* 40 mM the current increases as the semi-





Scheme 1 Mechanism and key constants for hydrogen evolution catalysed by extracted FeMoco. [PfpSFeMoco^{ox}] is assigned an *arbitrary* net charge of 1+ to clarify proton/electron counting. The potentials are quoted *vs.* NHE which is taken to be 242 mV positive of SCE in the NMF electrolyte.[8] The box shows the structure of Femoco bound within the protein in the semi-reduced resting state.[3]

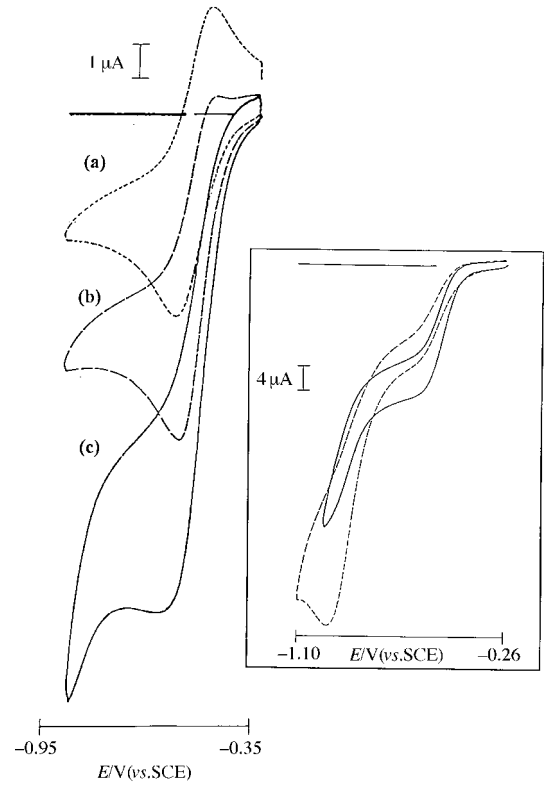


Fig. 1 Effect of adding PfpSH on the cyclic voltammetry of the {(PfpS)FeMoco}$^{ox/semi\text{-}red}$ system. *Conditions*: 1.3 mM FeMoco extract in NMF containing sodium hydrogen phosphate, *ca.* 40 mM; potential scan-rate = 20 mV s^{-1} at a vitreous carbon working electrode of area 0.0707 cm^2; SCE reference and platinum secondary electrodes were employed. Nominal concentration of PfpSH (a) 30 mM (b) 60 mM and (c) 75 mM. Inset: effect of cyanide ($[Et_4N]CN$, 2 equiv.) on the catalytic wave, $[PfpSH]_{total}$ = 135 mM; (—) before addition of cyanide; (- - -) after addition of 2 equiv. CN^-. Note the enhanced reduction of free proton at the more negative potential in the presence of cyanide.

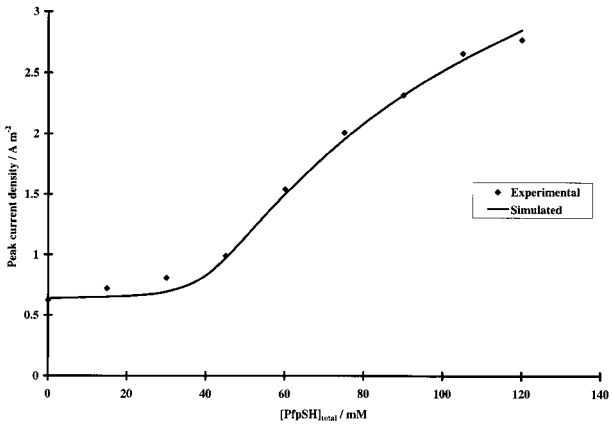

Fig. 2 Plot of I_p^{red} *vs.* $[PfpSH]_{total}$. The points are experimental data, the solid line is the simulated response based upon the mechanism shown in Scheme 1. For the simulation all protonation steps were assumed to be diffusion-controlled; the acid dissociation constant of PfpSH in NMF was taken as 2×10^{-7}; the diffusion coefficient of FeMoco^{ox} used in the simulation was independently measured as 1.65×10^{-6} cm^2 s^{-1} at 293 K; full details of the simulation are supplied as supplementary material (http://www.rsc.org/suppdata/1999/cc/773).

reduced cofactor protonates and is engaged in the catalytic cycle.‡ The rate-determining step in the mechanism involves the irreversible loss of dihydrogen from an hydridic intermediate, {(PfpS)FeMoco$(H)_2$}^{red}; the first-order rate constant (k_{H_2}) for this step is estimated to be 3 s^{-1} at 293 K (Scheme 1).

Accessing reduced states of the cofactor at high potential by protonation may well be essential for the binding of molecular nitrogen, or other substrates, within the enzyme.[1,9] Oxidation by fast release of molecular hydrogen from such states cannot be conducive to efficient catalysis, *viz.* nitrogenase is a 'poor' hydrogenase. The observation that reduced states of isolated FeMoco can be accessed at high potential and that re-oxidation by dihydrogen loss involves a kinetically slow step may be closely linked to the behaviour of the enzyme.

A key feature of hydrogen evolution by nitrogenase is its inhibition by cyanide which is presumed to bind to the iron–molybdenum cluster and decreases electron flux to this centre.[1] Remarkably we also find that cyanide decreases catalytic reduction of protons by isolated cofactor. Fig. 1 (inset) shows the effect of cyanide (2 equiv.) on the catalytic wave. This wave is suppressed and that for direct reduction of proton at the electrode is enhanced. Detailed studies of the electrochemistry of FeMoco in the presence of cyanide, which will be reported elsewhere, show that ligation of this inhibitor to the cofactor shifts the potential of the FeMoco$^{ox/semi\text{-}red}$ couple to a more negative value. This presumably accounts for suppression of electron flux at high potential in both the isolated cofactor and the enzyme system.

In conclusion, we are now beginning to see that the extracted cofactor can engage in electron-transfer chemistry which has some of the attributes of the whole enzyme system : catalytic hydrogen evolution which is kinetically slow and cyanide inhibition of the catalysis. Other parallels are also emerging, for example we have observed the capacity of the cofactor to bind carbon monoxide when the system turns over.[10] In addition, there are reports that acetylene can be catalytically reduced by amalgam reductants in the presence of FeMoco.[11] It is not excessively speculative to suggest that, by suitable modification, it may be possible to achieve the binding and reduction of molecular nitrogen by isolated FeMoco.

We thank the BBSRC and the John Innes Foundation for supporting this work and Dr R. A. Henderson for helpful comments.

Notes and references

† $[PfpSH]_{total}$ is the concentration of the added thiol if it were undissociated. It corresponds to $[PfpSH]_{total}$ = {[PfpSH] + [$PfpS^-$]}.
‡ The equilibrium constant for protonation of {(PfpS)FeMoco}$^{semi\text{-}red}$ is very similar to that determined for the unmodified cofactor in a related system.[12]

Communication 9/01608B

A new multicomponent reaction of nitro compounds with isocyanides

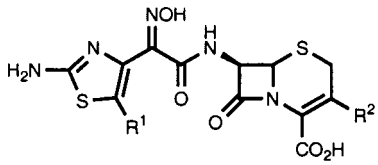
Paul Dumestre, Laurent El Kaim* and Ariane Grégoire

Laboratoire Réacteur et Processus, Ecole Nationale Superieure de Techniques Avancées, 75015 Paris, France. E-mail: elkaim@ensta.fr

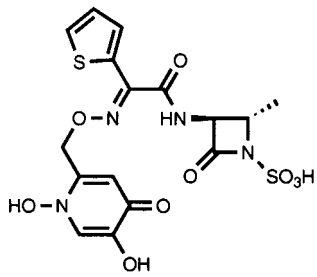
Received (in Liverpool, UK) 4th February 1999, Accepted 16th March 1999

The first multicomponent reaction between nitro compounds, isocyanides and acylating agents is described, providing an original route to α-oximinoamides.

α-Oximinoamides form a class of compounds with useful pharmaceutical applications as shown by the structures of cephalosporin **1** and β-lactamase inhibitor **2**.[1] Following our efforts towards finding new applications of isocyanides in synthesis,[2] we wish to report a straightforward synthesis of α-oximinoamides by the interaction of isocyanides with nitro compounds.



1



2

Most applications of nitro compounds in synthesis take advantage of easy proton abstraction under basic conditions to form nitronate anions followed by coupling with an electrophile.[3] Nucleophilic attack by carbon nucleophiles on the carbon of the nitro group are more rare. Water adds to nitro compounds following their conversion into the tautomeric nitronic acids, leading to their efficient transformation into ketones and aldehydes (Nef reaction).[4] The extension of the Nef reaction to carbon nucleophiles has probably been hampered by the reported instability of nitronic acid derivatives.[5] Besides some useful [3 + 2] cycloaddition of nitronates under acid catalysis,[6] this approach has been mainly exploited by Seebach *et al.*, giving average to good yields of ketoximes from primary nitro compounds and alkyllithiums.[7]

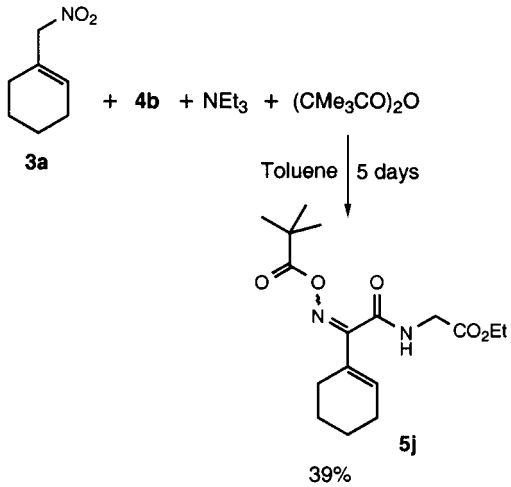


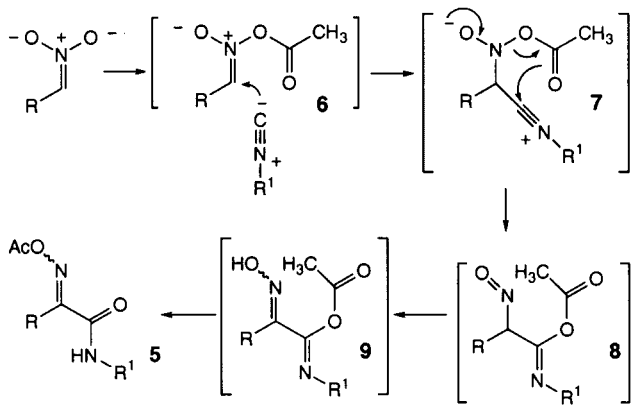
Scheme 3 Addition of isocyanide **4a** to nitro derivative **3a** under pivalic anhydride activation.

The Ugi–Passerini reactions[8] exploit the nucleophilic properties of isocyanides towards carbonyl derivatives; a similar reaction can be envisaged with nitronic acids as shown in Scheme 1.

Keeping in mind the sensitivity of nitronic acid derivatives and their ability to form nitrile oxides,[5] we first examined and reported[9] the behaviour of isocyanides in the presence of NEt_3, primary nitro compounds and butyl isocyanate under conditions propicious for nitrile oxide formation. Under such conditions, the primary nitro compound is cleanly converted into a nitrile by oxygen transfer to the isocyanide.

To avoid nitrile oxide formation, we decided to generate the *O*-acyl nitronate at low temperatures in the presence of the isocyanide by analogy to the addition of organometallics to silyl and acyl nitronate.[7,10] Preliminary experiments were encouraging as a 30% yield of the α-oximinoamide **5a** was obtained after reaction of nitro derivative **3a** with butyllithium, acetic acid anhydride and *tert*-butyl isocyanide **4a** (Scheme 2). However all our attempts to raise this yield through changes in reactants, temperature and order of addition did not meet with success.

Our problems may stem from the ambiphilic nature of nitronic acid derivatives which may compete as nucleophiles with the isocyanide; a slow generation of the reactive *O*-acyl nitronate in the presence of the isocyanide could alleviate this problem. In our conversion of nitro compounds into nitriles,[9] fast dimerisation of nitrile oxide was suppressed under such conditions: slow generation of nitrile oxide through nitronate formation using a tertiary amine in toluene. Indeed, a remarkable increase in yield (63%) was observed when a solution of nitro compound **3a** (1 M), NEt_3 (1.1 equiv.), acetic acid anhydride (1.1 equiv.) and isocyanide **4a** was left to react at room temperature for a few hours. Various nitro compounds **3** and isocyanides **4** were tested in this new multicomponent reaction, giving moderate to good yields of α-acyloximinoamide **5** (Table 1).



Scheme 4 Possible mechanism for the formation of amides **5**.

As observed for nitrile formation, best yields were obtained with allylic nitro derivatives prone to easy base deprotonation. For aliphatic nitro compounds, the yield can however be raised by a proper selection of the reagents, the formation of **5f** was thus enhanced up to 60% yield by changing from NEt_3 to the more basic DBU. The synthetic potential of this reaction can easily be extended by a change in the starting carboxylic acid (Scheme 3). A significant decrease in yield was observed with isocyanides possessing electron withdrawing groups. Even though yields are modest, it represents nevertheless a very straightforward preparation of complex dipeptide analogues **5g**, **5i** and **5j**. A possible mechanism for this new reaction is depicted in Scheme 4. The acid-base equilibrium between the nitro compound and its nitronate conjugate base is slowly displaced with acetic acid anhydride to give the *O*-acyl nitronate **6**. The latter, though highly unstable at room temperature, is trapped by the isocyanide to give the putative species **7**–**9** through nitroso formation and acylation of the tautomeric oxime.

In conclusion, we have disclosed in this study, the first three-component reaction involving the addition of isocyanides to nitro compounds. This reaction enables a fast preparation of complex peptide analogues from readily available nitro derivatives; it could find application in total synthesis as well as in combinatorial chemistry. Efforts to increase the yield by a proper selection of reagents and solvents are under way in our group.

11 A typical experimental procedure is as follows: to a solution of nitro compound (2 mmol) in toluene (2 ml) were added NEt_3 (2.2 mmol), acetic anhydride (2.2 mmol) and isocyanide (3 mmol). The reaction was stirred at room temperature under an inert atmosphere until completion (a few hours to a few days for aliphatic nitro compounds); evaporation of the solvent and chromatography on silica finally furnished the desired product.

1,4-Dithiin annelated with bicyclo[2.2.2]octene units: experimental and theoretical evidence for the aromaticity in 1,4-dithiin dication

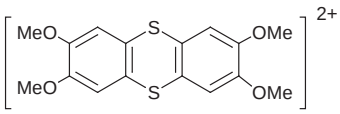
Tohru Nishinaga, Atsushi Wakamiya and Koichi Komatsu*

Institute for Chemical Research, Kyoto University, Uji, Kyoto 611-0011, Japan. E-mail: komatsu@scl.kyoto-u.ac.jp

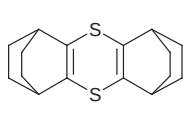
Received (in Cambridge, UK) 15th February 1999, Accepted 16th March 1999

1,4-Dithiin dication annelated with bicyclo[2.2.2]octene units was generated by the two-electron oxidation of the neutral dithiin and found to be aromatic based on the results of NMR measurements and theoretical calculations.

Although there have been a considerable number of studies on cationic π-conjugated systems containing sulfur atom(s), surprisingly little is known on the dicationic species of 1,4-dithiin,[1] and the spectroscopically characterized derivative is limited only to the expanded π-system of 2,3,7,8-tetramethoxythianthrene dication (**1**$^{2+}$). The ^{1}H NMR spectra of this dication showed broad signals at room temperature[2] while the $\Delta m = 2$ transition was observed by EPR at low temperature.[3] From the EPR experiments, it was concluded that this dication is ground state triplet and the energy gap between the singlet and triplet states is < 1 kcal mol^{-1}.[3] These results are consistent with the X-ray structure of **1**$^{2+}$($SbCl_6^-$)$_2$, in which it was interpreted that this dication is divided into two cyanine subunits with each π-delocalization more favored than the cyclic π-conjugation as a whole.[4]



1^{2+}



2

Is the triplet state of non-expanded 1,4-dithiin dication itself also more stable than the singlet state which might have an aromatic stabilization? Here, is given the first experimental and theoretical evidence for the presence of aromaticity in a derivative of 1,4-dithiin dication, *i.e.* 1,4-dithiin dication **2**$^{2+}$ annelated with bicyclo[2.2.2]octene units. The annelation of this bicyclic unit has been shown to be quite effective for the stabilization of the radical cation[5] and dication[6] of cyclooctatetraene, which is isoelectronic to 1,4-dithiin. Also the electronic structures of the singlet and triplet states are compared between the dications of parent 1,4-dithiin **3** and thianthrene **4** for better understanding of the electronic properties of these species.

For the synthesis of 1,4-dithiin derivative **2**,† the method of Nakayama *et al.*[7] was employed. Thus, 3-bromobicyclo[2.2.2]octan-2-one, synthesized from 2-bromobicyclo[2.2.2]octene by the same method for the chloro derivative,[8] was allowed to react with Na_2S to give bis(3-oxobicyclo[2.2.2]oct-2-yl) sulfide (63%). The reaction of this sulfide with Lawesson's reagent[9] afforded **2** in 63% yield.

Cyclic voltammetry of **2** in CH_2Cl_2 at −78 °C under vacuum using a Pt wire as a pseudo-reference electrode showed two reversible oxidation waves at +0.00‡ and +0.82 V§ *vs.* Fc/Fc^+ (Fig. 1), indicating that both the radical cation and dication of **2** are stable under these conditions. In comparison with the oxidation potential of tetramethoxythianthrene **1** (E^1 = +0.58, E^2 = +0.83 V *vs.* Fc/Fc^+, calibrated from the potential *vs.* Ag/Ag^+ in acetonitrile),[2]¶ the first oxidation potential of **2** is remarkably lowered owing to the inductive and σ–π conjugative effects of bicyclo[2.2.2]octene units. On the other hand, the difference between the first and second oxidation potentials of

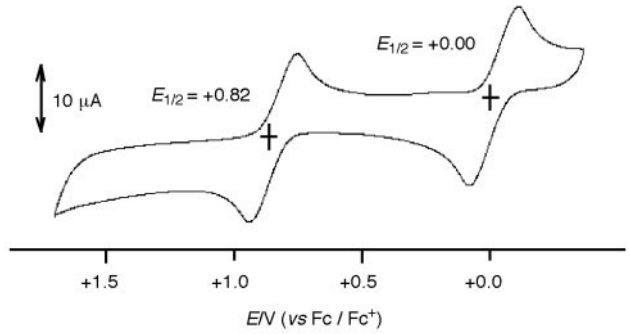


Fig. 1 Cyclic voltammogram of **2** in CH_2Cl_2 containing NBu_4ClO_4 (0.1 M) at −78 °C under vacuum; scan rate, 0.1 V s^{-1}.

2 is larger than that of **1**, suggesting that there is a larger Coulombic repulsion in dication **2**$^{2+}$ than in **1**$^{2+}$.

The reaction of **2** with an excess of SbF_5 in CD_2Cl_2 at ambient temperature gave an orange solution, which exhibited ^{1}H and ^{13}C NMR signals at considerably low field compared with the neutral dithiin (Table 1). The observed chemical shifts for this orange solution were in fair agreement with the calculated values for **2**$^{2+}$ (GIAO/HF/6-31+G*//B3LYP/6-31G*), giving a strong support to the formation of dication **2**$^{2+}$. The signal of bridgehead protons which are located in the plane of the dithiin's π-system exhibited a marked downfield shift of 2 ppm as compared with that of neutral **2**. This clearly indicates the presence of a diamagnetic ring current in the dicationic dithiin ring and the aromatic character in this 6π-electronic system. The value of nucleus independent chemical shift (NICS)[10] of **2**$^{2+}$ was calculated to be −8.8 (GIAO/HF/6-31+G*//B3LYP/6-31G*), which also supports the aromaticity in this dication.

The optimized structures obtained theoretically at the B3LYP/6-31G* level for neutral and dicationic species **2** and **2**$^{2+}$ are shown in Fig. 2. As two electrons are removed from **2**, the C–S single bonds in the dithiin ring are shortened and the C=C double bonds elongated, with the conformational change from boat to planar structures. Such changes in the bond length and conformation can be rationalized by the enhanced cyclic π delocalization for **2**$^{2+}$ again supporting the presence of the aromaticity in the 1,4-dithiin dication.

Table 1 ^{1}H and ^{13}C NMR chemical shifts for **2** and **2**$^{2+}$

	δ_H			δ_C		
Compound		CH	CH_2	C=C	CH	CH_2
2	Obs.[a]	2.46	1.53 (8H) 1.33 (8H)	128.4	38.1	26.2
2^{2+}	Obs.[a]	4.48	2.47 (8H) 1.86 (8H)	180.0	43.0	25.1
	Calc.[b]	4.18	2.84 (*anti*) 1.66 (syn)	197.0	38.7	22.2

[a] In CD_2Cl_2. [b] GIAO/HF/6-31+G*//B3LYP/6-31G*.

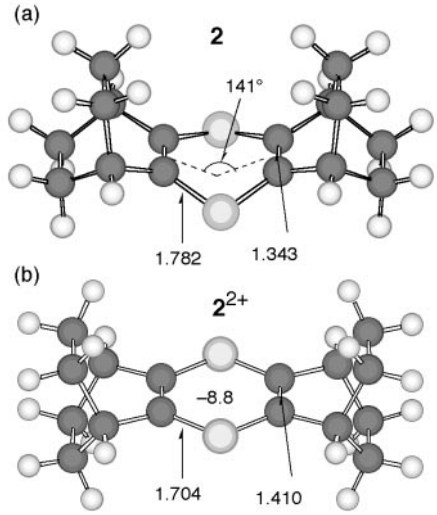

Fig. 2 Calculated structures of (a) **2** and (b) $\mathbf{2}^{2+}$ at the B3LYP/6-31G* level. Selected bond lengths (Å), a bending angle of **2**, and a NICS value (ppm) of $\mathbf{2}^{2+}$ are included.

The ^{1}H NMR spectrum of dication $\mathbf{2}^{2+}$ showed no line broadening and the triplet state did not seem to mix to the singlet state in contrast to the case of $\mathbf{1}^{2+}$. In order to gain further insight with regard to these results, the difference in energy between the singlet (s) and triplet (t) states for the parent 1,4-dithiin dication $\mathbf{3}^{2+}$ and for the thianthrene dication $\mathbf{4}^{2+}$ were calculated (B3LYP/6-31G*), together with their NICS values (GIAO/HF/6-31+G*//B3LYP/6-31G*). The calculated results are shown in Fig. 3, together with the resonance formulae for $\mathbf{4}^{2+}$. As to the dication $\mathbf{3}^{2+}$, the singlet state $\mathbf{3}^{2+}$(s) was shown to be more stable than the triplet state $\mathbf{3}^{2+}$(t) by 54.1 kcal mol^{-1}, with a significant difference in the NICS value, *i.e.* −8.5 for $\mathbf{3}^{2+}$(s) and 5.1 for $\mathbf{3}^{2+}$(t). Similarly the singlet state $\mathbf{4}^{2+}$(s) was found to be more stable than the triplet state $\mathbf{4}^{2+}$(t), with the NICS value in the dithiin ring calculated to be −9.6 for $\mathbf{4}^{2+}$(s) and 1.8 for $\mathbf{4}^{2+}$(t), but the energy gap between the singlet and triplet states was smaller (11.2 kcal mol^{-1}). In the resonance structures, the canonical formulae of $\mathbf{4}^{2+}$(t) involve the extended π-conjugation for each of the radical cation parts as compared with $\mathbf{3}^{2+}$(t) and the retention of some aromaticity in the benzene ring (NICS value, −5.2). Thus it is concluded that, owing to further substitution with methoxy groups at appropriate positions, the triplet ground state has been attained for $\mathbf{1}^{2+}$ while $\mathbf{2}^{2+}$ with electron-donating σ-frameworks is exhibiting the singlet-state aromaticity.

The present work is supported by a Grant-in-Aid for Scientific Research on Priority Areas (A) (No. 10146101) from the Ministry of Education, Science, Sports and Culture, Japan. Computation time was provided by the Super Computer Laboratory, Institute for Chemical Research, Kyoto University.

Ti/ITQ-2, a new material highly active and selective for the epoxidation of olefins with organic hydroperoxides

Avelino Corma,* Urbano Díaz, Vicente Fornés, José L. Jordá, Marcelo Domine and Fernando Rey

Instituto de Tecnología Química, UPV-CSIC, Universidad Politécnica de Valencia, Avda. de los Naranjos s/n, 46022 Valencia, Spain. E-mail: acorma@itq.upv.es

Received (in Cambridge, UK) 28th January 1999, Accepted 23rd March 1999

Materials containing highly accessible and well ordered titanium sites prepared by grafting titanocene on ITQ-2 material are excellent catalysts for epoxidation of olefins, yielding high conversions and selectivities to the desired epoxides.

In recent years Ti containing molecular sieves, which are able to catalyze the selective oxidation of hydrocarbons using peroxides as oxidants, have been developed.[1] In this way, Ti-silicalite and Ti-beta are able to carry out successfully the epoxidation of olefins using H_2O_2,[2,3] while Ti-MCM-41 materials, incorporating the Ti, either by one-step synthesis or by post-synthesis, are active and selective catalysts to perform the epoxidation of olefins using organic hydroperoxides.[4–7] A successful Ti/MCM-41 catalyst was obtained when a titanocene was grafted on the surface of a MCM-41,[7] opening the possibility for preparing highly accessible and isolated Ti sites on a very high surface area silica. However, this material still presents some drawbacks related with the stability of the material and the formation of Ti–O–Ti linkages owing to the closeness of the silanol groups. Then, in order to design new Ti grafted solid catalysts, it would be highly desirable to start with a highly stable material with a high surface area accessible to reactants, and containing a well defined distribution of silanol groups on which Ti species can be grafted. Such characteristics coincide with those of the large or extralarge pore Ti-zeolites. Unfortunately, the Ti-zeolites prepared up to now are not successful epoxidation catalysts when reactants with large molecular diameters are involved.[5] Looking for new structures which combine the benefits of the mesoporous and zeolitic materials, we have recently obtained a new material denoted as ITQ-2,[8] which is prepared by delaminating the precursor of the pure siliceous MWW polymorph (ITQ-1).[9] ITQ-2, consists of very thin silica layers of 2.5 nm height with an extremely high and well defined (> 700 m^2 g^{-1}) external surface. As shown in Fig. 1, an hexagonal array of 'cups' of 0.7×0.7 nm penetrate into these layers from each side of the sheet. The structure of this layer is completed by a double 6-ring window which connects the bottom of the cup to the bottom of another cup located at the other side of the layer. In between the cups, *i.e.* inside the sheet, runs a smooth 10-membered ring (10 MR) channel system. Moreover the external surface formed by the array of cups has an important population of silanol groups which are located in specific positions as corresponding to the lamellar precursor of the MWW structure.[10] Such highly accessible well defined silanols are clear candidates to anchor Ti precursors, which can lead to highly dispersed and stable Ti catalytic active sites. This approach has been pursued by first preparing the pure silica layered precursor as follows: 6.164 g of hexamethyleneimine (HMI) and 1.88 g of NaCl were dissolved in 131.40 g of a 0.38 M solution of trimethyladamantamonium hydroxide (TMAdaOH). 37.56 g of H_2O and 12.02 g of SiO_2 (Aerosil 200) were added to the above solution, and a gel was obtained with the following composition: $1SiO_2 : 0.25$ TMAdaOH : 0.31 HMI : 0.1 NaCl : 44 H_2O

The resultant gel was mechanically stirred for 90 min at room temperature. Crystallisation of the lamellar precursor was performed at 150 °C over 5 days at 60 rpm. The material which was filtered off and dried at 100 °C for 12 hours, shows an XRD pattern characteristic of the laminar precursor of the MWW structure.[9,10]

The purely siliceous ITQ-2 was prepared from the lamellar precursor following a previously described procedure[8] and the resultant material shows a BET surface area of 800 m^2 g^{-1}.

Ti was grafted on the surface of the pure silica ITQ-2, by the procedure illustrated in Fig. 1:[7] 10 g of ITQ-2 was dehydrated at 300 °C at 10^{-3} Torr over 2 h. Then, a solution containing an appropriate amount of titanocene dichloride in 90.0 g of $CHCl_3$ was added. The suspension was stirred for 1 h at room temperature under an inert atmosphere. Subsequently, triethylamine dissolved in 10 g of $CHCl_3$ giving a ratio $NEt_3/TiCp_2Cl_2 = 1$ was added and the suspension changed from orange–red to yellow–orange indicating a change of coordination around the Ti atoms. The solids were recovered by filtration and after prolonged washing with CH_2Cl_2, calcination at 540 °C for 1 h

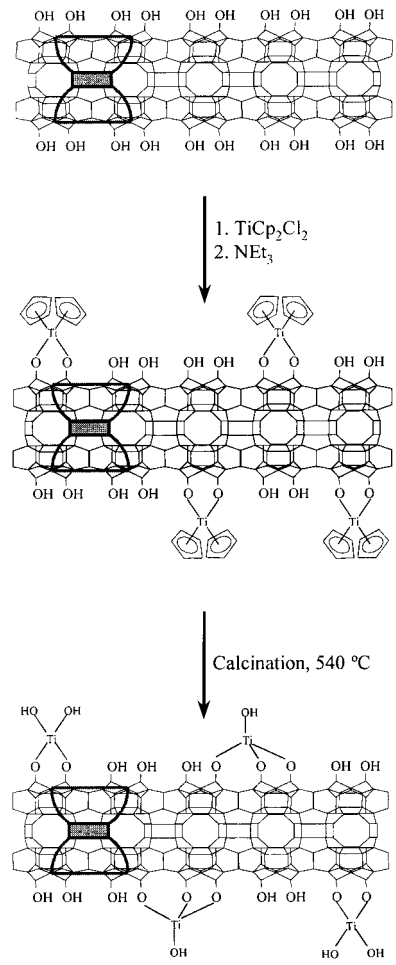

Fig. 1 Schematic grafting of titanocene on the ITQ-2 surface.

Table 1 Cyclohexene conversion and selectivity after 120 min reaction time, and initial rate of reaction for Ti containing samples

Sample	Conversion (%)	Selectivity (%)	r_c/mol g_{cat}^{-1} h^{-1}	r_c/mol mol_{Ti}^{-1} min^{-1}
0.125%TiO_2/ITQ-2	71.7	98.3	0.044	46.9
0.25%TiO_2/ITQ-2	75.1	97.8	0.047	25.0

1%TiO_2/ITQ-2	68.2	91.6	0.045	7.5
0.125%TiO_2/ITQ-2/sil.	73.4	99.4	0.049	64.7
1%TiO_2/ITQ-2/sil.	85.3	99.0	0.070	11.7
Ti/MCM-41[a,7]			0.18	2.1
TiO_2-SiO_2 co-gel[b,18]			0.50	3.3

[a] TBHP/cyclohexene = 1.2, 8 wt% cyclohexene in $CHCl_3$; reaction temperature = 40 °C. [b] Using cumene hydroperoxide (CHP) as oxidant (12 wt% in cumene). Cyclohexene/CHP = 4, 4 wt% of catalyst, reaction temperature = 60 °C.

in N_2 and then 6 h in air was carried out in order to remove all the organics. The resultant materials (Ti/ITQ-2) have the same textural and structural characteristics as ITQ-2, and present in their UV–VIS spectrum only a narrow band located below 220 nm assigned to the formation of monomeric Ti^{IV} species.[11,12] The presence of monomeric Ti species has been further established by the presence of a very intense pre-edge peak in the XANES spectrum of the dehydrated Ti/ITQ-2 sample with an intensity of 0.74, close to the intensities found for Ti-zeolites possessing Ti isomorphically substituted in the framework,[13,14] and higher than those reported for Ti-MCM-41[15,16] and Ti grafted on MCM-41.[15,16,7] This is clear evidence for the presence of Ti linked through O bridges to the siliceous ITQ-2 framework, in the absence of polymeric species of titanium.

Ti/ITQ-2 (295 mg) was used as a catalyst for epoxidation of cyclohexene (4.648 g) with *tert*-butyl hydroperoxide (TBHP) (cyclohexene/TBHP = 4.0) at 60 °C. Results are given in Table 1 where it is evident that the activity and selectivity of all the Ti/ITQ-2 materials to the epoxide are excellent. It is clear that the selectivity to the epoxide decreases as the Ti content increases. This is an indication of the presence of some weak acid sites which are responsible for the opening of the epoxide ring to form the corresponding glycols. Recently, we have reported that the presence of glycols in the reaction medium deactivates the catalysts.[17] The selectivity to the epoxide can be improved, and therefore the formation of glycols reduced, by modifying the adsorption properties of the Ti/ITQ-2 catalysts by silylation. This can be done by contacting 10 g of dehydrated Ti/ITQ-2 with a solution of 6.33 g of $SiMe_3Cl$ in 90 g of $CHCl_3$, and subsequently with a solution of 4.27 g of NEt_3 in 10 g of $CHCl_3$. The catalytic performance of two silylated Ti/ITQ-2 catalysts containing different loadings of Ti is also given in Table 1 where a strong improvement in the activity and selectivity is observed. Also, it is noticeable that Ti/ITQ-2 containing 1 wt% TiO_2 shows a higher activity and similar selectivity to a 0.125 wt% TiO_2 catalyst, indicating that when no deactivation occurs, the higher the Ti content, the higher the catalytic activity.

In order to obtain comparative estimates of the catalytic performances of the different Ti/ITQ-2 catalysts, Table 1 lists catalytic conversion of cyclohexene and the selectivity to the corresponding peroxide. Also, the turnover number and the kinetic rate obtained on Ti/ITQ-2 is compared to literature values for other Ti-containing catalysts (Ti grafted on MCM-41 and Ti mesoporous materials obtained by a co-gel procedure).[18] Ti/ITQ-2 shows the best performance per Ti atom.

However, as important as the activity and selectivity of the catalysts are their stability towards Ti leaching. In order to study this, we have recycled the Ti-ITQ-2 silylated catalysts (METIQ-2) (1wt% TiO_2) three times, and the conversion obtained remained practically the same indicating the good stability of this catalyst.

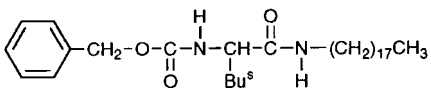
Received (in Cambridge, UK) 8th February 1999, Accepted 23rd March 1999

Smectic liquid-crystalline states have been successfully gelled by low molecular weight hydrogen-bonded molecules and anisotropic fibrous aggregates of the gelling agents are obtained when the sol–gel transition occurs within the smectic temperature range.

In recent years, a number of low molecular weight compounds have been found to gel various organic solvents.[1] The self-aggregation of the gelling agents through intermolecular interactions, such as hydrogen bonding, leads to the formation of solid fibrous networks in organic solvents. Recently, we have shown that nematic liquid crystals can be gelled by these hydrogen-bonded compounds.[2] Faster electro-optic responses of nematic materials induced by this physical gelation have been achieved in twisted nematic cells.[3] These mixtures of liquid crystals and gelling agents show three thermoreversible states: isotropic liquid, isotropic gel, and liquid-crystalline gel.[2,3] In these cases, the aggregation of the gelling agent occurs in the isotropic state of mesogenic molecules on cooling the sample from the isotropic liquid, which results in the formation of random networks of dispersed fibres. The liquid-crystalline gel is obtained at the transition of the isotropic state to the liquid-crystalline state of mesogenic solvents.

Smectic liquid crystals have higher molecular order which leads to potential applications in functional devices.[4] We expect that the molecular self-organization in smectic mesomorphic order leads to the fabrication of smectic gels, which are a new type of anisotropic material.

Here, we report the anisotropic aggregation of a hydrogen-bonded compound in a smectic molecular structure and the gelation of a smectic liquid crystal. A commercially available ferroelectric liquid crystal, SCE8 (Hoechst), which is a mixture of low molecular weight compounds, was used as a smectic material. On cooling, SCE8 exhibits isotropic–nematic, nematic–smectic A, smectic A–chiral smectic C phase transitions at 102, 78 and 58 °C, respectively. Amino acid derivative **1**, which is able to gel various organic solvents and nematic liquid crystals by the formation of intermolecular hydrogen bonds,[5] was chosen as the gelling agent.



1

When the gelling agent was added to SCE8 and then cooled to room temperature, **1** effectively gelled the smectic liquid-crystalline state. Fig. 1 shows the phase transition behavior of a mixture of SCE8 and **1** as a function of the concentration (wt%) of **1** on cooling. In this system, the sol–gel transition occurs within the range of smectic A and chiral smectic C phases. In the gelation process of SCE8 with **1**, the growth of fibrous network aggregates of **1** and the microphase separation in the polydomain of the smectic liquid-crystalline state have been observed under a polarizing optical microscope.

In order to control the aggregation process of **1** in the smectic liquid-crystalline state, a mixture of SCE8 and **1** was placed between polyimide-coated glass substrates, which had been rubbed in the parallel direction. The mixture was then heated to an isotropic state, and slowly cooled to the required temperature. The formation of fibrous solids ordered in one direction was formed in the smectic liquid-crystalline medium. A polarized photomicrograph of the mixture of SCE8 and **1** containing 1.0 wt% of **1** in a parallel rubbed cell is shown in Fig. 2(*a*). Interestingly, the growing direction of the fibres is perpendicular to the rubbing direction, *i.e.* to the direction of the long axis of the liquid-crystalline molecular order. The scanning electron micrograph (SEM) in Fig. 2(*b*) represents the directional ordering of the bundles of the fibres.† FTIR measurements of the mixture of SCE8 and the anisotropic fibre of **1** in the parallel rubbed cell showed that the absorbance of the amide bond of **1** at 3294 cm^{-1} (N–H stretch) and 1647 cm^{-1} (C=O stretch) was at a maximum value when the polarized light was perpendicular to the molecular orientation of liquid-crystalline molecules, whereas the minimum absorbance was observed when the polarized light was parallel to the long axis of the liquid crystal.‡ These results suggest that compound **1** forms an anisotropic aggregation structure as shown schematically in Fig. 3.

In contrast to the results of the SCE8 mixture, for covalently bonded polymers that are formed in liquid crystals,[6] the direction of the fibre is parallel to the molecular axis of the anisotropic solvents. For the formation of hydrogen-bonded aggregates of compound **1**, the compound is also aligned in the direction of the molecular axis of SCE8 and thereby the hydrogen bonding chains develop in the direction perpendicular to the molecular long axis between the smectic molecular layers.

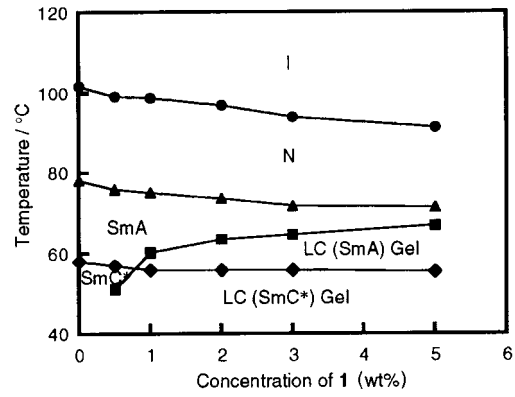


Fig. 1 Phase behavior of a mixture of SCE8 and **1** on cooling. I: isotropic; N: nematic; SmA: smectic A; SmC*: chiral smectic C; LC: liquid-crystalline.

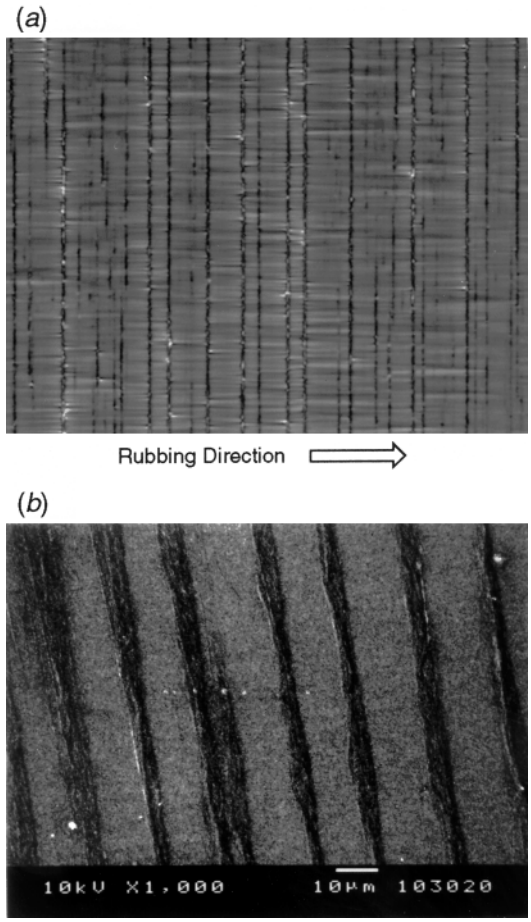

Fig. 2 (*a*) Optical polarized photomicrograph of a mixture of SCE8 and **1** (1.0 wt%) at 60 °C in a parallel rubbed cell; (*b*) SEM image of oriented fibres made of **1** after the extraction of SCE8.

Up until now, although molecular self-aggregation in isotropic solvents has been extensively studied, no attention had been paid to molecular assembly in anisotropic solvents. The present results show a controlled molecular aggregation in anisotropic solvents, which is a new class of self-assembly.

The composite materials of covalently bonded polymers and ferroelectric liquid crystals are studied for potential electro-optic systems.[7] The smectic liquid-crystalline gel reported here is a new material, which is a molecular composite consisting of a molecular aggregate and a smectic solvent. It offers potential applications in dynamically functional molecular materials.

Notes and references

† For SEM observation, samples in the cells were prepared by immersing the liquid-crystalline materials in hexane for two days to remove the liquid-crystalline solvent and finally drying at room temperature.

‡ For polarized FTIR measurements, sample cells were prepared by using BaF_2 substrates instead of glass cells.

Received (in Cambridge, UK) 9th February 1999, Accepted 25th March 1999

The reaction of pyridine-2,6-dimethanol (H_2pdm) with $[Mn_3O(O_2CMe)_6(py)_3][ClO_4]$ gives the $2Mn^{II}$, $2Mn^{III}$ title compound 1, which has an $S = 8$ ground state and displays strong out-of-phase signals in ac susceptibility studies that establish 1 as a new class of single-molecule magnet.

The study of molecules with unusually large numbers of unpaired electrons has taken on added impetus in recent years as this area has been identified as the source of a new magnetic phenomenon of relevance to the magnetic materials arena, *i.e.* the ability of molecules below a critical temperature to function as magnetizable magnets.[1–10] Samples of such molecules thus function as collections of extremely small magnetic particles and ones that are of a uniform size distribution in contrast to metal oxide particles (or other magnetic materials) of nanoscale dimensions, which are prepared as a range of particle sizes. To date, $[Mn_{12}O_{12}(O_2CR)_{16}(H_2O)_4]$ ($S = 10$),[1–5] $[Mn_{12}O_{12}(O_2CR)_{16}(H_2O)_4]^-$ salts ($S = 19/2$),[6] $[Mn_4O_3X(O_2CMe)_3(dbm)_3]$ ($S = 9/2$; dbm is the anion of dibenzoylmethane),[7,8] $[Fe_8O_2(OH)_{12}(tacn)_6]^{8+}$ (tacn = 1,4,7-triazacyclononane) salts ($S = 10$)[9] and $[V_4O_2(O_2CR)_7(L–L)_2]^z$ ($S = 3$; L–L = 2,2′-bipyridine, pyridine-2-carboxylate anion)[10] are the most well studied examples. A convenient way of detecting the slow magnetic relaxation (reorientation of the magnetic moment or magnetization vector) of a single-molecule magnet (SMM) is by the appearance of an out-of-phase signal (χ_M'') in ac susceptibility studies showing that the relaxation is too slow to keep up with the oscillating field. We herein report access to a new class of Mn-based SMMs with an $S = 8$ ground state and a strong χ_M'' signal, representing an important new addition to this small family of molecules.

The potentially tridentate chelating ligand pyridine-2,6-dimethanol(H_2pdm), or 2,6-bis(hydroxymethyl)pyridine has been little employed[11,12] in metal chemistry but offers interesting possibilities for transition metal cluster chemistry. Reaction of H_2pdm with $[Mn_3O(O_2CMe)_6(py)_3][ClO_4]$ in a 3 : 1 molar ratio in CH_2Cl_2 gives a red–brown solution from which $[Mn_4(O_2CMe)_2(Hpdm)_6][ClO_4]_2$ **1** precipitates within 24 h. The solid can be recrystallized in *ca.* 50% total yield after three days from a MeCN/Et_2O layering. Diffusion of Et_2O directly into an MeCN reaction solution also gives **1** but in only 15% yield after one week. The centrosymmetric cation of **1**†‡ (Fig. 1) consists of a planar, mixed-valence Mn_4 rhombus with Mn(1) and Mn(2) assigned as being Mn^{III} and Mn^{II}, respectively, on the basis of bond valence sum calculations and the presence at Mn(1) of a Jahn–Teller elongation axis [O(17)–Mn(1)–N(30)], as expected for high-spin Mn^{III}. All ligands are thus only mono-deprotonated (*i.e.* Hpdm) as found for this group previously.[11] Two Mn_3 triangular faces are each bridged by a μ_3-oxygen [O(17)] from a bidentate, chelating Hpdm whose protonated [O(23)] is unbound. Two of the remaining groups are also bidentate, with O(27) bridging Mn(1) and Mn(2′) and O(33) not ligated, but the remaining two Hpdm groups are tridentate with protonated O(13) terminally coordinated and O(7) bridging Mn(1) and Mn(2). Two bridging $MeCO_2^-$ groups complete the ligation. The Mn^{II} metal atoms Mn(2) are thus seven-coordinate with distorted pentagonal bipyramidal geometry, whereas Mn(1) is distorted octahedral. There is an intramolecular hydrogen bond between O(13) and O(23) [2.852(9) Å]. The cation of **1** is the first example of the (H)pdm ligand in a bridging mode and suggests that other clusters might be accessible with this versatile ligand.

Solid-state dc magnetization measurements were performed on **1** in the range 5.0–300 K. The effective magnetic moment (μ_{eff}) slowly increases from 10.5 μ_B at 300 K to 12.8 μ_B at 15.0 K, and then decreases to 11.3 μ_B at 5.0 K, suggesting the complex to have a high spin ground state; the low-temperature decrease is assigned to zero-field splitting (ZFS) and Zeeman effects. Owing to the low symmetry of the cation of **1**, it is not possible to use the Kambe approach to fit the μ_{eff} *vs.* T data with the three requisite J values. In order to determine the ground state, therefore, magnetization data were collected in the temperature and magnetic field ranges 2.00–4.00 K and 20.0–50.0 kG (2–5 T) (Fig. 2). Fitting of these data, assuming only the ground state is populated at $T \leqslant 4.00$ K, gave $S = 8$, $g = 1.85(3)$ and $D = -0.25(3)$ cm^{-1}, where D is the axial ZFS parameter. Thus, **1** is a new example of a species with an unusually large spin.

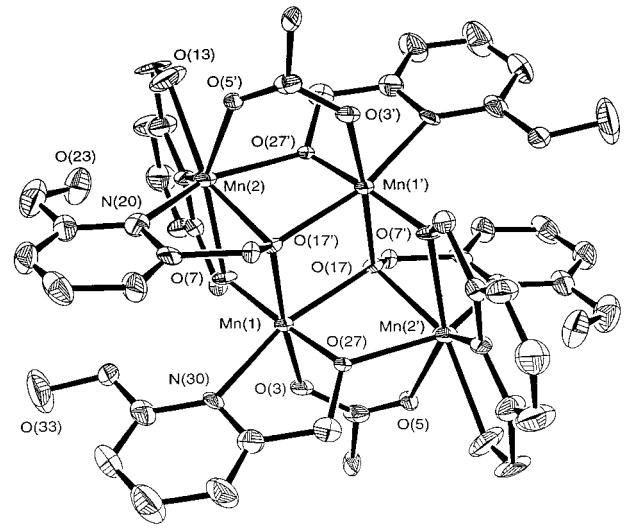

Fig. 1 ORTEP plot with 50% probability ellipsoids of the cation of **1**. Selected interatomic distances (Å) and angles (°): Mn(1)···Mn(1′) 3.253(2), Mn(1)···Mn(2) 3.351(2), Mn(1)···Mn(2′) 3.284(2), Mn(1)–O(7) 1.879(5), Mn(1)–O(17′) 1.967(4), Mn(1)–O(17) 2.264(4), Mn(1)–O(27) 1.873(5), Mn(2)–O(7) 2.271(4), Mn(2)–O(17) 2.300(5), Mn(2)–O(27′) 2.227(4); Mn(1)–O(17)–Mn(1′) 100.27(17), Mn(1)–O(17′)–Mn(2) 103.24(20), Mn(1′)–O(17′)–Mn(2) 92.03(16), Mn(1)–O(7)–Mn(2) 107.30(23), Mn(1′)–O(27′)–Mn(2) 106.13(22).

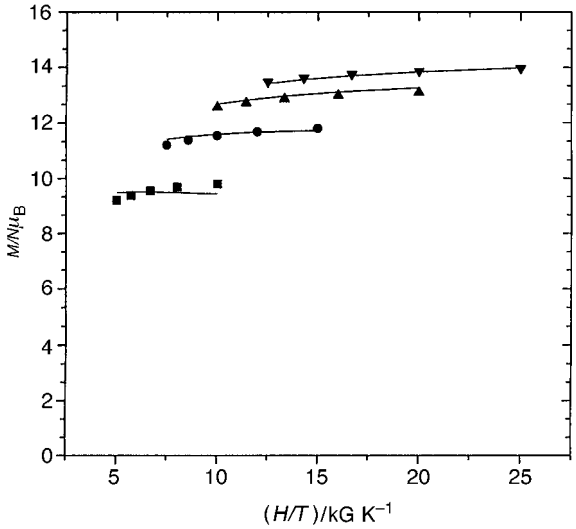

Fig. 2 Plot of reduced magnetization *vs.* *H/T* for complex **1**. The solid lines are fits of the data to an $S = 8$ state with $g = 1.85$ and $D = -0.25$ cm^{-1}. Data were measured at 20 (■), 30 (●), 40 (▲) and 50 kG (▼).

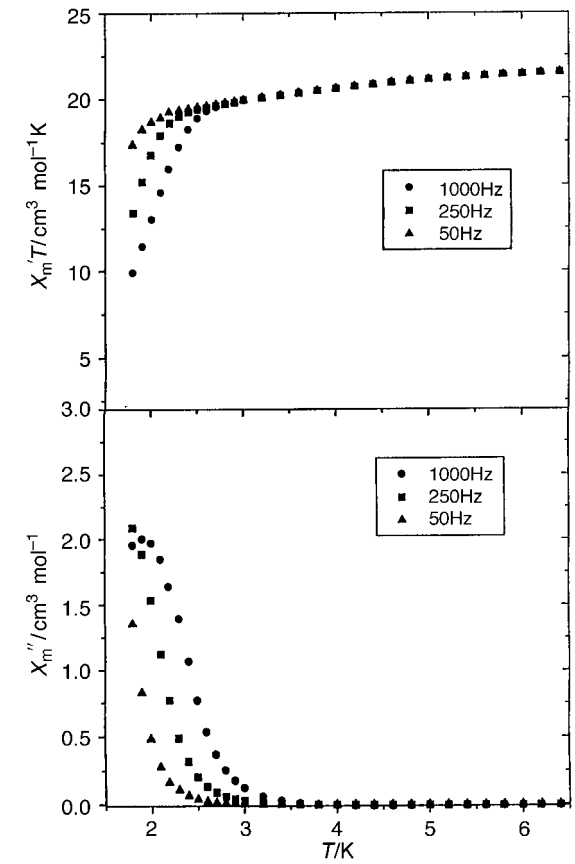

Fig. 3 Plots of the in-phase (χ_M') signal as $\chi_M'T$ and out-of-phase (χ_M'') signal in ac susceptibility studies *vs.* temperature in a 1 G field oscillating at the indicated frequencies.

Complex **1** appeared a good candidate for ac susceptibility studies to determine if it displays the slow magnetization relaxation characteristic of a single-molecule magnet; data were thus collected in the range 1.8–6.4 K range in a 1 G ac field oscillating at 50–1000 Hz. The barrier to thermally activated magnetization relaxation is $S^2|D|$ for an integer spin system, which is 16 cm^{-1} for $S = 8$ and $D = -0.25$ cm^{-1}, a value that is significant compared with thermal energy at low temperature. Indeed, the in-phase $\chi_M'T$ signal (Fig. 3) shows a frequency-dependent decrease at $T < 3.5$ K indicative of the onset of slow relaxation, and this was confirmed by the appearance of an out-of-phase (χ_M'') signal showing that **1** cannot relax fast enough at these temperatures to keep in phase with the oscillating field. The χ_M'' signal is strong, with a peak evident at *ca.* 2 K at a 1000 Hz ac frequency; the peak position corresponds to the temperature at which the relaxation rate is equal to the ac oscillation frequency. A preliminary analysis of the χ_M'' data indicates that the barrier for magnetization relaxation is 12(2) cm^{-1}, in keeping with the presence of magnetization tunnelling. Complex **1** is only the third structural type to show such a strong χ_M'' signal with a peak at $T \geqslant 2$ K, the others being the complexes $[Mn_{12}O_{12}(O_2CR)_{16}(H_2O)_4]^{0,-}$ and $[Mn_4O_3X(O_2C\text{-}Me)_3(dbm)_3]$, and this indicates **1** to be a particularly welcome new addition to this small but growing class of molecules. It also emphasizes that oxide (O^{2-}) bridged clusters are not the sole source of the SMM family of complexes. Efforts are in progress to fit the μ_{eff} *vs.* T data for **1** by a matrix diagonalization approach to determine the individual pairwise exchange interactions, as well as extending studies to $T < 1.8$ K to investigate the degree of hysteresis exhibited by **1**.

This work was supported by the National Science Foundation.

The amphiphilic and solvochromatic characteristics of flavins are utilized as a non-invasive polarity sensor for silica-based media.

Zeolites, molecular sieves and other porous media are crucial components in catalysis and separation technology.[1,2] In these systems, surface structure is a key determinant of performance. To determine surface and pore polarities, both silicas[3] and sol–gels[4] have been doped with various dyes. These dyes have generally relied upon large hydrophobic aromatic groups, with charged functionality as the sensing element. This creates the potential for perturbation of local environments through both dopant size and functionality.[5]

N^{10}-isobutyl flavin **1** (Fig. 1) and flavin mononucleotide (FMN) **2** possess isoalloxazine units with highly solvochromic S_0–S_2 transitions: λ_{max} (FMN) **2** occurs at 374 nm in aqueous media and 358 nm in ethanolic solution,[6] while λ_{max} (**1**) occurs at 349 nm in chloroform and 335 nm in carbon tetrachloride.[7] The amphiphilicity of the heterocyclic flavin nucleus plays two key roles in microenvironment sensing. First, it allows solubilization without aggregation[8] in virtually any solvent using non-interfering sidechains at the N^{10} position. Second, it provides a non-invasive probe for the characterization of dynamic media. We report here the application of flavins **1** and **2** as solvochromic probes of silicate microenvironments.

In initial investigations, we explored the environment of silica gel environment. Flavin **1** in chloroform has a λ_{max} of 349 nm (Fig. 2). When commercial grade silica gel[9] was soaked with a chloroform solution of **1** (providing an approximate matching of refractive index), the λ_{max} shifted to 374 nm, indicating the flavin was responding as expected to the polar surface of the silica gel.

In further studies, we used flavin to probe the polarity of 'MCM-type' silicates. The final preparation of these porous silica materials involves calcination at high temperatures in which the polar Si–OH functionalities on the interior silica surface revert to Si–O–Si *via* dehydration.[10] When a non-calcined, templated silica material[11] was soaked with a chloroform solution of **1**, the λ_{max} (S_0–S_2) was 374 nm. This indicates that the surface was highly polar with surface functionality consisting primarily of Si–OH groups. However, the λ_{max} occurred at 349 nm with a calcined MCM-41 type material,[12] confirming no interaction between the flavin and the interior surface (Fig. 2). This is consistent with the low surface density (8–27%) of silanols present in calcined MCM-41.[13]

With the ability of flavin to sense polarity in preformed, static environments established, we next explored the application of this sensing methodology to dynamic systems. Previous studies had seen relatively minor changes in polarity in silicate matrices during their formation *via* the sol–gel process, a result that could arise from 'templating' effects by the sensing molecule. To explore polarity changes in these systems, flavin silicate sols were prepared by the addition of aqueous solutions of flavin **2** to tetramethylorthosilicate. After sonication, homogeneous and transparent yellow sols were obtained which subsequently solidified yielding the flavin **2** functionalized sol–gels. In these gels, the flavin provides a direct probe the polarity of the microenvironment within the developing sol–gel silicate. In the sol phase, the λ_{max} of flavin **2** occurred at 374 nm, confirming the essentially aqueous nature of the sol–gel at preparation. Polarity changes indicative of a two-step transformation were observed. During the initial stages of gelation a large decrease in polarity was observed, arising from release of methanol during orthosilicate hydrolysis. After this initial phase, the λ_{max} moved steadily to shorter wavelengths, reaching a limiting value of 360 nm (Fig. 3). This slower process can be attributed to the decrease in silanol concentration during the formation of the silicate matrix.

When these methanol-rich sol–gels were allowed to dry under ambient conditions, the λ_{max} shifted to longer wavelengths, reaching a final value of 370 nm (Fig. 3). This red shift arises from the diffusion of methanol out of the silicate matrix, resulting in shrinkage of the silicate structure.[14] Constricting the region surrounding the flavin. In consequence, the polar Si–OH functionalities of the silicate matrices interact with the immobilized flavin, creating a microenvironment slightly less polar than water.[15]

In conclusion, we have shown flavins nucleus to be extremely capable microenvironmental probes of silicate-based media. The amphiphilicity and solvochromicity of the isoalloxazine nucleus, coupled with its non-invasive nature, make these

Received (in Cambridge, UK) 3rd February 1999, Accepted 24th March 1999

The new mixed Mo/V heteropoly compound $[Ni(C_2N_2H_8)_3]_2Na[Mo^{V}_{2}Mo^{VI}_{6}V^{IV}_{8}O_{40}(PO_4)]\cdot H_2O$ with a tetra-capping Keggin structure has been synthesized hydrothermally and its structure determined by X-ray diffraction

There is considerable current interest in polyoxometalates containing Keggin moieties from both fundamental and practical points of view.[1,2] They are capable of being fine-tuned at the molecular level to promote a variety of applications ranging from catalysis to medicinal use.[3–7] To our knowledge, in contrast to an extensive literature on Keggin and transition metal substituted Keggin species, structural information relating to capped Keggin structures is very limited due to the lack of good quality single crystals, and only bi- and mono-capped Keggin derivatives are structurally known.[8–18] It has been recently demonstrated that the hydrothermal technique is well suited for the preparation and crystal growth of mixed Mo/V heteropoly compounds.[16–18] Here, we report the application of this technique to an Mo/V system which has resulted in the formation of $[Ni(C_2N_2H_8)_3]_2Na[Mo^{V}_{2}Mo^{VI}_{6}V^{IV}_{8}O_{40}(PO)_4].H_2O$ **1**, the first mixed Mo/V tetra-capped Keggin structure heteropoly compound to be structurally characterised.

Compound **1** was prepared hydrothermally from a mixture of NH_4VO_3, $Ni(OAc)_2$, Na_2MoO_4, en, H_3PO_3 and H_2O heated to 160 °C for six days.† The IR spectrum of **1** exhibited a complex pattern of bands at 1060, 940, 920, 720 and 650 cm^{-1}, ascribed to ν(P–O), ν(M=O), ν(M–O–M) (M = V or Mo), respectively. A novel discrete polyanion $[Mo^{V}_{2}Mo^{VI}_{6}V^{IV}_{8}O_{40}(PO)_4]^{5-}$, counter ions Na^+, $[Ni(C_2N_2H_8)_3]^{2+}$ and lattice water molecules were revealed by X-ray analysis.‡ The polyanion $[Mo^{V}_{2}Mo^{VI}_{6}V^{IV}_{8}O_{40}(PO_4)]^{5-}$ (Fig. 1) is based on the well known Keggin structure of $[XM_{12}O_{40}]^{n-}$ with four additional five-coordinated terminal VO^{2+} units, which include V(3) and its symmetry-related partner V(4) and V(5). The polyanion lies on a crystallographic twofold axis at *x*, 0, 0.25 which passes through P, V(4) and V(5), and it is disordered. The cluster anion contains a central P^{5+} in an almost regular tetrahedral environment of PO_4 with P–O distances in the range 1.514(7)–1.518(6) Å, and bond angles of 108.5(4)–110.3(4)°.

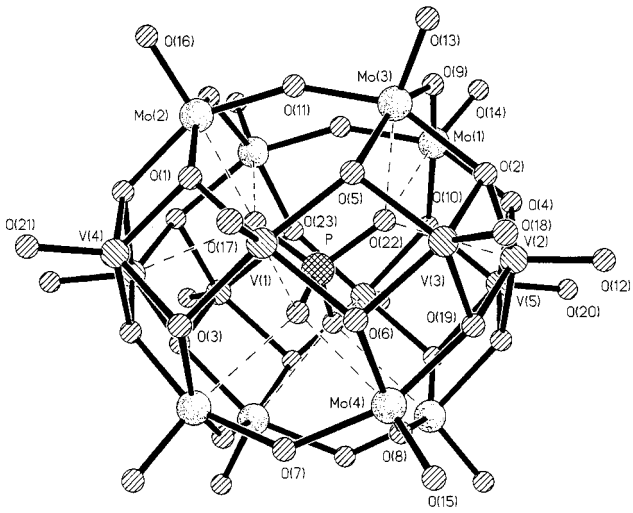

Fig. 1 Ball-and-stick representation of the structure of the polyanion $[Mo^{V}_{2}Mo^{VI}_{6}V^{IV}_{8}O_{40}(PO_4)]^{5-}$ in **1**

The number of Mo sites revealed by X-ray analysis is consistent with the result of elemental analysis§ which gave an average ratio Mo/V of 1.0. While all the Mo atoms have a distorted octahedral environment, vanadium displays two different coordination environments square pyramidal and distorted octahedral. The Mo–O and V–O bond lengths are in the range 1.661(9)–2.543(5) and 1.589(8)–2.562(7) Å, respectively, comparable to those found in capping-Keggin structures. As shown in Fig. 1, the unusual feature of compound **1** is that the V=O units cap four of the six available four coordinate sites on the surface of the $[Mo^{V}_{2}Mo^{VI}_{6}V^{IV}_{4}O_{40}(PO_4)]^{13-}$ Keggin anion so as to produce a structure in which the vanadium atoms form a central belt, and each trimetallic group of $[Mo^{V}_{2}Mo^{VI}_{6}V^{IV}_{4}O_{40}(PO_4)]^{13-}$ (Keggin part) contains one V and two Mo atoms. The Mo_4 rings (each one-electron-reduced) are bonded above and below this V_8 belt. To the best of our knowledge, such a tetra-capped Keggin structural polyanion has not been previously observed in other heteropoly compounds. Only a Ni^{2+} signal was evident (g = 2.07) in the room temperature EPR spectra, the lack of signals for Mo^{5+} and V^{4+} indicating that the 10 electrons of the polyanion are delocalised. The assignment of oxidation states for the vanadium and molybdenum atoms are consistent with their coordination geometries and are confirmed by valence sum calculations[19] which gives the values for Mo(1), Mo(2), Mo(3) and Mo(4) of 5.45, 6.007, 5.656 and 5.870, while the calculated valence sum for V(1), V(2), V(3), V(4) and V(5) are 3.901, 4.180, 4.103, 4.501 and 3.685, respectively. The average value for calculated oxidation state of Mo and V are 5.746 and 4.074, consistent with the formula of **1**. The Ni^{2+} cations are coordinated by three ethylene diamine ligands with Ni–N distances in the range 1.999(4)–2.208(7) Å.

This research was supported by the National Foundation of China and Key Project of the Ministry of Science and Technology.

Notes and references

† A mixture of NH_4VO_3 (0.40 g), $Ni(OAc)_2$(0.40 g), Na_2MoO_4 (0.8 g), en (2 ml) and H_2O (10 ml) ratio was neutralized to pH = 6.0 with 50% phosphorous acid. It was then sealed in a 15 cm^{-3} Teflon-lined reactor, which was heated to 160 °C for six days. After cooling to room temperture, black needle crystals were isolated (0.4 g, 48% based on Mo).

‡ *Crystal data* for **1**: tetragonal, space group $P4_322$, $a = b$ = 15.829(2) c = 28.712(6) Å, v = 7194(2) $Å^3$, Z = 4. A black needle crystal with dimension of 0.22 × 0.16 × 0.14 mm was mounted on a glass fiber. Data were collected on Siemens P4 four-circle diffractometer at 20 °C in the range $3.64 < 2\theta < 23.05°$ using the ω scan technique. A total of 12486 reflections was collected of which 8353 with $I > 2\sigma(I_0)$ were used. An empirical absorption correction was applied. The structure was solved by direct methods and refined using SHELX86 and SHELXL93 programs. The occupancy factor of major conformation [Mo(1)–Mo(4), V(1)–V(3),

O(91)–O(19)] is 0.8564(6). The metal atoms and P atom were refined anisotropically, and the remaining non-metal atoms were refined isotropically. Structure solution and refinement based on 5046 reflections with $I > 2\sigma(I_0)$ and 382 parameters gave $R(R_w) = 0.0765$ (0.1987). CCDC 182/1204. Stabilities of cooperatively formed cyclic pseudorotaxane dimers

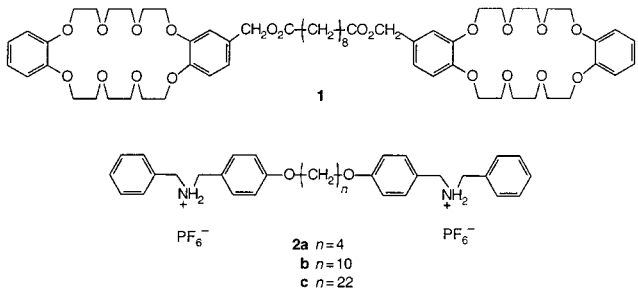
Nori Yamaguchi and Harry W. Gibson*

Department of Chemistry, Virginia Polytechnic Institute and State University, Blacksburg, Virginia, USA. E-mail: hwgibson@vt.edu

Received (in Cambridge, UK) 8th February 1999, Accepted 24th March 1999

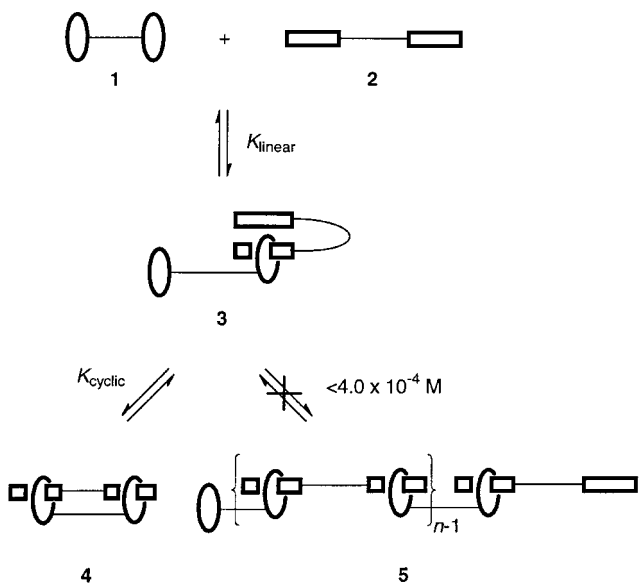
Systematic analysis of the stabilities of cyclic pseudorotaxane dimers formed between complimentary homoditopic molecules demonstrates that cooperative cyclic dimerization can be minimized by increasing the length of one component *via* an aliphatic spacer.

Recently, we reported preparation of supramolecular linear polymer **5b** (Scheme 1) with up to 9.1 repeat units in which monomeric homoditopic molecules **1** and **2b** containing



dibenzo-24-crown-8 (DB24C8) and dibenzylammonium hexafluorophosphate moieties, respectively, are linked non-covalently *via* pseudorotaxane complexes in equimolar concentrated solutions (> 1.0 M in CD_3COCD_3–$CDCl_3$, 1 : 1 v/v at 295 K).[1]

Unsurprisingly, cyclic dimer **4b** (Scheme 1) was preferentially formed in equimolar dilute solutions ($< 1.0 \times 10^{-3}$ M in CD_3COCD_3–$CDCl_3$, 1 : 1 v/v at 295 K) as observed in other cases.[2–6] In pursuit of more efficient construction of supramolecular polymers **5**, we speculated that by mismatching the lengths of the aliphatic spacer units in the homoditopic molecules (*e.g.* **1** and **2**),† the equilibrium process may be reversed to favor linear extension (*e.g.* **3** and then to **5**) even in dilute conditions largely due to a greater steric penalty associated with the corresponding cyclic dimer complex (*e.g.* **4**).‡ Here, we investigate the stabilities of cyclic and linear dimer complexes based on complementary homoditopic molecules whose spacer segments were varied systematically.



Scheme 1 Cartoon illustrations of formation of the linear dimer complex **3** and cyclic dimer complex **4** from homoditopic molecules **1** and **2** in substantially dilute conditions.

The ^{1}H NMR spectra of dilute equimolar solutions of **1** and **2** [Fig. 1(*a*)–(*c*)] revealed four sets of N-CH_2 signals corresponding to (i) uncomplexed moieties of the ditopic guest molecule [H(**2**)$_u$], (ii) complexed moieties in cyclic dimer [H(**4**)], and (iii) complexed and (iv) uncomplexed moieties in the linear dimer [H(**3**)$_c$ and H(**3**)$_u$, respectively] on the basis of slow exchange on the NMR time scale.§ Integration of H(**3**)$_c$ and H(**3**)$_u$ gave a ratio of 1:1 for each solution,¶ indicating that the signals assigned to H(**3**)$_c$ and H(**3**)$_u$ arise from the same species.

The signal assignments were properly made based on our previous investigation[1] and the ^{1}H NMR spectrum [Fig. 1(*d*)] of a dilute solution of DB24C8 and **2b** which exhibited three sets of N-CH_2 signals corresponding to uncomplexed ammonium salt moieties of **2b** [H(**2b**)$_u$]‖ and complexed and uncomplexed ammonium salt moieties of **6b** [H(**6b**)$_c$ and H(**6b**)$_u$, respectively].** The signals for H(**6b**)$_c$ and H(**6b**)$_u$ were integrated to be 1 : 1; thus complex **6b** was exclusively formed, confirming that the two signals assigned to **6b** (and to **3**) arise from the same species. The considerable downfield chemical shift observed for H(**6b**)$_u$ with respect to H(**2b**)$_u$ in Fig.1(*d*) ($\Delta\delta$ = 0.17 ppm) is presumably a consequence of interaction(s) between the pseudorotaxane and free ammonium salt moieties in **6b** (and by analogy in **3**); *e.g.* 'intramolecular' π-stacking between a benzo ring of complexed DB24C8 and the terminal phenyl ring of the free ammonium salt moiety achieved by folding of the flexible aliphatic spacer, as illustrated in Scheme 2.†† These spectroscopic observations allowed us to conclude that the signals in the region of δ 4.35 to 4.45 in Fig. 1(*a*)–(*c*) correspond to H(**3**)$_u$, and that only **3** and **4** exist and cyclic or linear oligomers **5** are not present in detectable amounts in these dilute solutions.

Since the concentrations of each species (**1**, **2**, **3** and **4**) at equilibrium are readily known, one can estimate the association

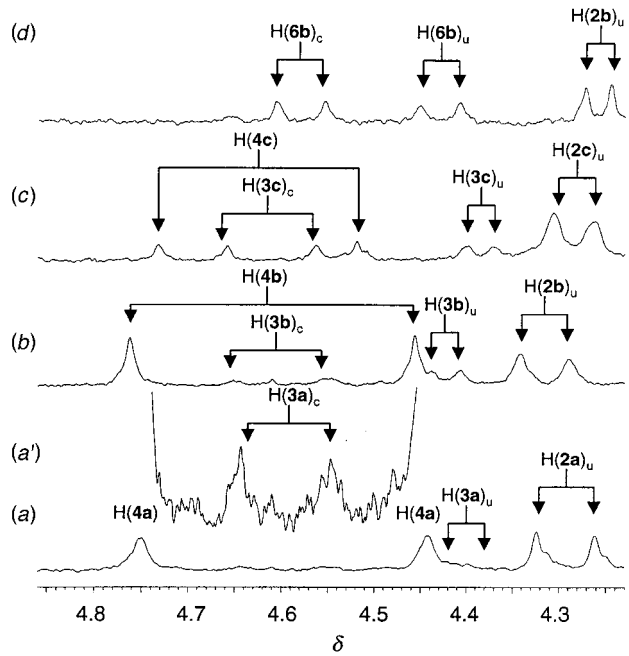

Fig. 1 The stacked ^{1}H NMR spectra of equimolar solutions of (*a*) **1** and **2a**, (*b*) **1** and **2b**, and (*c*) **1** and **2c** (4.0 × 10^{-4} M each) and (*d*) a solution of DB24C8 and **2b** (8.0 × 10^{-4}/4.0 × 10^{-4} M) at 295 K (400 MHz, CD_3COCD_3–$CDCl_3$, 1 : 1, v/v). A vertically enlarged version of the spectrum in Fig. 1(*a*) (δ 4.45-4.75) is shown in Fig. 1(*a*′). In Fig. 1(*a*)–(*c*) the four sets of signals are assigned for the benzylic protons of the ammonium salt units in **2** (uncomplexed, u), **3** (complexed end, c, and uncomplexed end, u) and **4**. In Fig. 1(*d*) the three sets of signals are assigned for the benzylic protons of the ammonium salt units in **2b** (uncomplexed, u) and **6b** (complexed end, c, and uncomplexed end, u).

constants (K_{linear} and K_{cyclic}); the results at 295 K are summarized in Tables 1 and 2 with ΔH and ΔS values.‡‡

K_{linear} (Table 1) varies systematically, increasing as the length of the aliphatic spacer increases (from **3a** to **3c**). Note that ΔH_1 and ΔS_1 become more negative from **3a** to **3b**, but the values for **3b** and **3c** are essentially identical. This observation is consistent with more effective stabilization of **3b** and **3c** relative to **3a** by 'intracomplex' interaction between the threaded crown ether and the non-threaded ammonium salt moiety; as shown by CPK models the longer spacers in the latter two species allow more effective interaction.

Similarly, K_{cyclic} (Table 2) varies systematically, decreasing as the length of the aliphatic spacer increases (from **4a** to **4c**). ΔH_c and ΔS_c also become less negative as the spacer length increases, the most dramatic change taking place from **4a** to **4b**. These observations are consistent with two factors: (i) limited stabilization of precursor **3a** by intracomplex interaction and (ii) the increasing end-to-end distance of the linear precursors **3**.

As we anticipated, K_{cyclic} for **4c** was reduced, almost three-fold, compared to that for **4b**. Most importantly, the K_{linear}/K_{cyclic} value, which should be regarded as a critical parameter for the efficiency of linear extension to **5**, obtained for **3c**/**4c** (8.4 × 10^3 M^{-1}) clearly stands out, showing nearly a 16-fold improvement with respect to that of **3a**/**4a** (5.2 × 10^2 M^{-1}).

Our present results, contrary to our initial speculation, indicate that the steric penalty associated with **4** may not be as important as the end-to-end distance of **3** in terms of shifting the equilibrium over to the linear dimer complex. Nevertheless, purposely increasing the length of the spacer in one component successfully reversed the equilibrium of **3** and **4** toward **3**. Our preliminary investigation of construction of a supramolecular polymer using **1** and **2c** as building components has revealed an improved linear extension in **5c** at lower concentrations relative to using **1** and **2b**. We will report these results in detail in a forthcoming publication.

Footnotes and references

† All compounds were characterized by ^{1}H NMR spectroscopy, FAB mass spectrometry, and elemental analysis.

‡ Similar observations, though qualitative in nature, were reported for complexation of ditopic aromatic guests with biscyclophanes in water (ref. 6).

§ Slow exchange was also reported for the complexation of Bn-NH_2^+–Bn·PF_6^- and DB24C8 in solution (ref. 7).

¶ The ^{1}H NMR spectra of three sets of each solution were recorded with at least 50 min of acquisition time for determination of ratios of the H(**3**)$_c$ and H(**3**)$_u$ signals. Each spectrum was enlarged vertically (thus the signals of interest were detectable from the baselines; *e.g.* Fig. 1(*a*′) shows a vertically enlarged version of the spectrum in Fig. 1(*a*) from δ 4.45 to 4.75) and the signals were integrated using a deconvolution technique. Ratios of the H(**3**)$_c$ and H(**3**)$_u$ signals were determined within experimental errors (*ca.* 5%).

‖ The downfield chemical shift ($\Delta\delta$ = 0.05 ppm) observed for H(**2b**)$_u$ in Fig. 1(*b*) compared to that in Fig. 1(*d*) is attributed to the increased ratio of PF_6^- relative to uncomplexed ammonium salt moieties of **2b**. To demonstrate this phenomenon experimentally, a solution of DB24C8 and **2b** (8.0 × 10^{-4}/4.0 × 10^{-4} M in CD_3COCD_3–$CDCl_3$, 1 : 1 v/v) was mixed with solutions of $Bu_4N^+PF_6^-$ (from 4.0 × 10^{-4} to 16 × 10^{-4} M in the same solvent system) and the ^{1}H NMR spectra were taken at 295 K. A gradual downfield chemical shift for H(**2b**)$_u$ was observed as the PF_6^- concentration was increased, validating the hypothesis.

** Many different conformations existing at the pseudorotaxane complexation site of **6b** contribute to the broadening of the H(**6b**)$_c$ and H(**6b**)$_u$ signals since the signals are time averaged.

†† In the crystal structure of the pseudorotaxane from DB24C8 and Bn–NH_2^+–Bn·PF_6^- (ref. 7) one of the benzo rings π-stacks with one of the phenyl rings. The other electron rich benzo ring is uncomplexed.

‡‡ Variable-temperature ^{1}H NMR spectroscopy was performed in the range 285–313 K. Plots of $R\ln K_{linear}$ and $R\ln K_{cyclic}$ *versus* 1/*T* yielded straight lines (R > 0.97) from which ΔH and ΔS values for linear and cyclic dimerization were obtained.

Odd–even effect in optically active poly(3,4-dialkoxythiophene)

Elena Ramos Lermo, Bea M. W. Langeveld-Voss, René A. J. Janssen and E. W. Meijer*

Received (in Cambridge, UK) 12th March 1999, Accepted 23rd March 1999

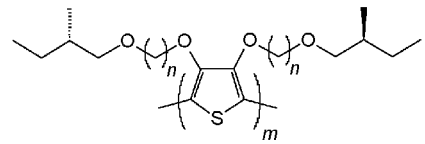
An odd–even effect is observed in the CD spectra of a homologous series of aggregated optically active poly(3,4-dialkoxythiophene)s, suggesting a helical packing of polymer chains into chiral superstructures, similar to that of the cholesteric liquid crystalline phase.

Polythiophenes attract considerable interest for their incorporation as active elements into electronic and electro-optical devices.[1] The optical and electronic properties of polythiophenes are dependent on the chemical structure[2] as well as on the intrachain and interchain structural organisation.[3] Control over the chemical structure has improved dramatically since synthetic routes towards well-defined substituted polythiophenes have become available.[2] The three-dimensional structure of the macromolecules in solution and the morphology in the solid state are influenced to a great extent by solvent and temperature.[4]

Novel insights into the organisation process of substituted polythiophenes have been obtained from well-defined polymers carrying optically active β-substituents.[5] Although in solution or in the melt no optical activity is observed for the π–π* transition of these chiral polythiophenes, they exhibit a strong bisignate circular dichroism (CD) effect associated with the main-chain absorption in the aggregated or solid state, consisting of a positive and a negative signal of comparable intensity. The presence of a CD effect shows that the chirality of the side chains induces optical activity in the polythiophene main chains. The parallel occurrence of aggregation and optical activity, as well as studies on bis(oligothiophene) model compounds,[6] indicate that the bisignate CD effect originates *via* exciton coupling from adjacent polythiophene chains in chiral superstructures. The sign of the experimental CD effects in the model compounds is in accordance with the prediction from exciton theory for the relative orientation of the two oligothiophene moieties in these models.[6] This suggests that in optically active polythiophenes, chiral packing of polythiophene chains occurs, comparable to the organisation processes in cholesteric liquid crystals. However, a complete understanding of the organisation process and the induction of chirality is lacking.

For some cholesteric liquid crystalline compounds an empirical relation between the helical ordering of the constituent molecules in the mesophase and the chirality in the flexible chain has been established by Gray and McDonnell.[7] According to these Sol-Rel, Sed-Rod alternation rules, the rotation of plane polarised light through a helical mesophase, clockwise (+, dextro) or counterclockwise (–, laevo), depends on the absolute configuration of the chiral centre (*S* or *R*) and its distance to the rigid mesogenic core (odd or even number of atoms). By definition the dextro-rotation is produced from a left handed helix, while the laevo-rotation originates from a right handed helical organisation. The rules are also applicable to other liquid crystalline mesophases, like helicoidal smectics,[8] and a similar odd–even alternation effect has even been observed for helical poly(isocyanides) with mesogenic substituents.[9] Here we show that the alternation rules are applicable to aggregated optically active poly(3,4-dialkoxythiophene)s.

In order to investigate the effect of distance between the stereocentre in the side chain and the polymer main chain, a series of poly(3,4-dialkoxythiophene)s **2**–**7** (Fig. 1) containing



2 (*n*=2) – **7** (*n*=7)

Fig. 1 Optically active poly(3,4-dialkoxythiophene)s **2**–**7**.

increasing lengths of alkoxy spacers has been synthesised. For the synthesis the tosylate of commercially available (*S*)-2-methylbutanol is coupled once to the spacers ethane-1,2-diol through to heptane-1,7-diol. The resulting optically active alcohols are introduced at the β-positions of thiophene by transetherification of 3,4-dimethoxythiophene.[10] Polymerisation is accomplished by chemical oxidation using anhydrous iron(III) chloride.[11] The crude poly(3,4-dialkoxythiophene)s are dedoped by precipitation in MeOH–25% ammonia (v/v, 5/1). Further purification *via* Soxhlet extractions using MeOH–25% ammonia (v/v, 5/1) and hexane, and isolation *via* Soxhlet extraction with $CHCl_3$ gives pristine **2**–**7**. ^1H and ^{13}C NMR spectroscopy reveal the desired 2,5-polymerization without any observable irregularities.†

Microcrystalline aggregates of **2**–**7** are readily formed in poor solvents, *e.g.* decan-1-ol and pentan-1-ol.‡ The UV–Vis spectra of the microaggregates of **2**–**7** exhibit vibronic fine structure, indicative of intrachain and interchain order, with a 0–0 transition at *ca.* 610 nm, *i.e.* considerably red-shifted compared to the spectra of the polymers in good solvents (*e.g.* $CHCl_3$).[5b,c] The CD spectra of these ordered aggregates alternate in sign with an odd or even number of atoms in the spacer (Fig. 2).§

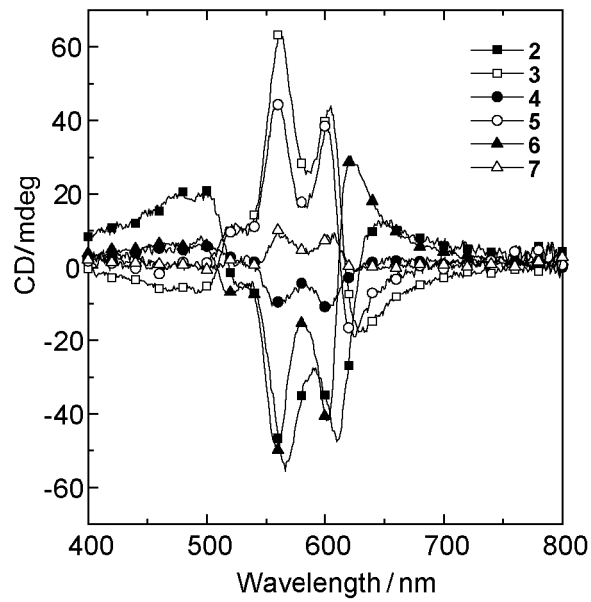


Fig. 2 CD spectra of **2**–**7** in decan-1-ol at room temperature. The spectra are normalised to unit absorbance at λ_{max}.

It is tempting to interpret the sign of the CD effect of these poly(3,4-dialkoxythiophene)s in terms of supermolecular helicity. Exciton theory and model studies predict that, for the π–π* transition of helically ordered aggregates of poly(3,4-dialkoxythiophene)s, a positive CD signal at the high wavelength implies a right-handed organisation of the chains in the aggregates, *i.e.* laevo in liquid crystal terminology. When the CD signal at the 0-0 transition (*ca*. 610 nm) is taken to represent the sign of the low-energy component of the couplet, it is found that **2**–**7** follow the Sol-Rel, Sed-Rod alternation rules that were originally developed for cholesteric liquid crystals. Polymer **6**, for example, has an *S* configuration at the stereocentre, 10 atoms (even) from the rigid part to the stereocentre, and is organised according to a left-handed helix (dextro) because of a negative CD signal at 605 nm.

While the CD spectra of **2**–**7** are indeed reminiscent of exciton coupling, the spectra fail to represent the characteristic exciton couplet, consisting of two peaks of equal intensity and opposite sign,[6] and integration of the CD spectrum over the π–π* band does not yield zero. These are clear indications that the CD spectra do not represent simple exciton couplets. Therefore, the explanation of the CD effect in terms of an interaction between chains in a helical fashion, providing the exciton coupled CD (bisignate), has to be augmented with a helical conformation for the individual polymer chains resulting in an intrinsic CD (monosignate).

The CD spectra of **2**–**7** in Fig. 2 are normalised to unit absorbance and clearly differ in intensity. Similar to a decreasing pitch observed in liquid crystals with increasing distance between the stereocentre and mesogenic core,[7] it can be expected that the influence of the optical activity in the side chain on the chiral organisation within the aggregates decreases with the number of atoms in the spacer. However it was extremely difficult to verify this expectation, because the magnitude of the CD effect is influenced by batch-dependent characteristics like the molecular weight and polydispersity,[12] and on subtle changes in sample preparation conditions, *i.e.* polymer concentration, temperature, and time of aggregation.¶

In conclusion, we have shown that in a homologous series of poly(3,4-dialkoxythiophene)s **2**–**7** with increasing lengths of spacers in β-substituents, the sign of the induced optical activity in the π–π* transition alternates with the parity of the number of atoms in the spacer when the polymers are in an aggregated phase. This effect is similar to alternation effects observed in helical liquid crystals and suggests that the CD effect associated with the π–π* transition arises from a similar chiral organisation of the polythiophene main chains. When the CD signal at the first vibronic transition is used to predict the sense of helicity *via* exciton theory, it is found that the alternation of CD signal in polythiophenes is consistent with the Sol-Rel, Sed-Rod alternation rules that were originally developed for cholesteric liquid crystals.‖

Notes and references

† The polymerisation conditions were varied for the amount of oxidising agent (2–4 equiv.) and the reaction time (4–16 h) but have not been optimised for each monomer. The final polymers differ significantly in molecular weight M_n and polydispersity D as determined by SEC measurements in THF, relative to polystyrene standards. M_n (D) varies between 10 kg mol^{-1} (3.3) for **2** and 62 kg mol^{-1} (4.7) for **5**. The work-up procedure of **4** repeatedly gave problems in the dedoping step and results presented for **4** should be regarded as tentative.

‡ Microaggregate formation in decan-1-ol was achieved by adding a small quantity of the polymer to decan-1-ol, warming until the polymers dissolved completely, and slow cooling to room temperature. Solutions in pentan-1-ol were prepared by adding a drop of a concentrated solution of **2**–**7** in $CHCl_3$ to pentan-1-ol.

§ Similar CD spectra with alternating sign have been obtained for thin films of polymers **3** and **5**–**7** on glass substrates when spin coated from $CHCl_3$ solution. For polymer **3** this involved an annealing step at 150 ºC for 2 h to reach the thermodynamically most stable form of aggregation, while **4** did not show good film formation.

¶ The shape and sign of the CD spectra are usually not affected by these parameters.

‖ Poly{3,4-bis[(*S*)-2-methylbutoxy]thiophene}[5b,c] also follows the Sol-Rel, Sed-Rod alternation rules (*S*, odd, CD at 610 nm is positive and hence laevo), whereas poly{2,5-bis[(*S*)-2-methylbutoxy]-1,4-phenylenevinylene} shows an opposite behaviour (*S*, odd, CD at 575 nm is negative and hence dextro).[13]

Double intramolecular Diels–Alder reaction of α,β-unsaturated hydrazones: a new route to 2,2′-bipyridines

Nicholas Bushby,[a] Christopher J. Moody,*[ab] David A. Riddick[b] and Ian R. Waldron[c]

[a] *School of Chemistry, University of Exeter, Stocker Road, Exeter, UK EX4 4QD. E-mail: c.j.moody@ex.ac.uk*

Received (in Liverpool, UK) 26th February 1999, Accepted 15th March 1999

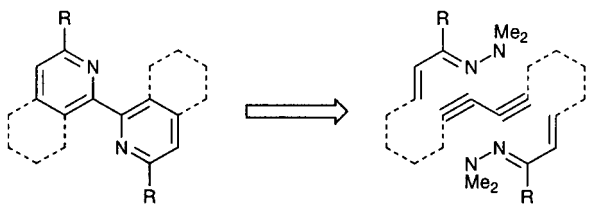
Heating the 1,3-diynyl bis-α,β-unsaturated hydrazones 3, 6 and 10 results in double intramolecular Diels–Alder reaction of the 1-azadienes, and after aromatisation by loss of dimethylamine, the formation of bipyridines 11–14.

In the 110 years since its first preparation, 2,2′-bipyridine has been extensively used as a ligand in organometallic chemistry.[1] Indeed 2,2′-bipyridine is one of the best known, and most effective bidentate ligands for a range of metals, and in recent years chiral bipyridine ligands have found wide use in asymmetric synthesis.[2] We now report a new route to 2,2′-bipyridines based on the double intramolecular Diels–Alder reaction of 1,3-diynyl bis-α,β-unsaturated hydrazones (Scheme 1).

The preparation of 6-membered ring heterocyclic compounds by the hetero Diels–Alder reaction is now a common tactic in organic synthesis,[3] and the use of azadienes as components in such reactions is established.[4] One useful route to pyridine derivatives is the Diels–Alder reaction of α,β-unsaturated hydrazones with various dienophiles, and since the pioneering work of Ghosez,[5] these 1-azadienes have been used in both inter- and intra-molecular Diels–Alder approaches to pyridine derivatives.[6–8] The intramolecular Diels–Alder (IMDA) reaction of α,β-unsaturated hydrazones with alkynes, first reported in 1988,[8] is a particularly attractive route to annelated pyridines since the initial Diels–Alder adduct readily aromatises by loss of dimethylamine. Therefore we decided to adapt this procedure to the direct synthesis of annelated bipyridines by the simple incorporation of an oxidative homocoupling step giving a 1,3-diyne which would then undergo the desired double IMDA reaction (Scheme 1).

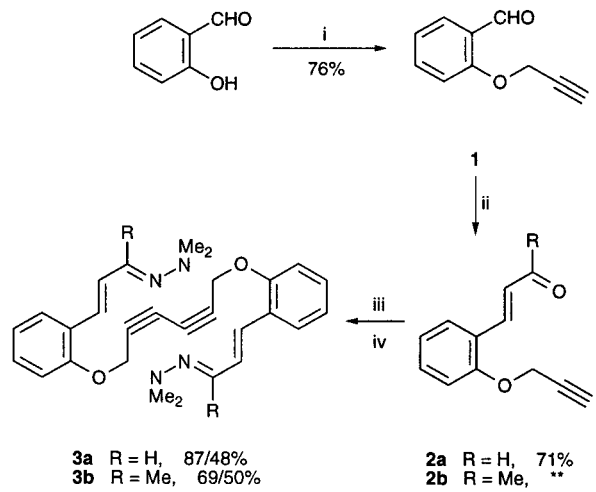
The substrates for the double IMDA reactions were prepared by straightforward routes (Schemes 2–4). The first route involved the alkylation of salicylaldehyde with propargyl chloride (prop-2-ynyl chloride) to give the corresponding aldehyde **1**. Subsequent homologation of the aldehyde with either α,α-bis(trimethylsilyl)-*N*-*tert*-butylacetaldimine,[9] or with acetylmethylenetriphenylphosphorane gave the α,β-unsaturated aldehydes and ketones **2**. Hydrazone formation followed by Glaser–Eglinton coupling with copper(II) acetate[10] then gave the first substrates **3** for the double IMDA reaction (Scheme 2).

The IMDA substrate **6** was prepared from the known hydrazone **4**[11] by propargylation, and oxidative homocoupling of the alkyne (Scheme 3).

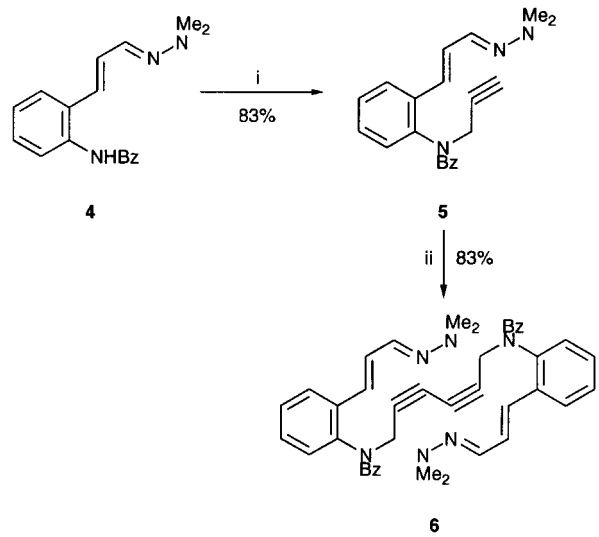


Scheme 1 (Alkynes drawn non-linear for clarity.)

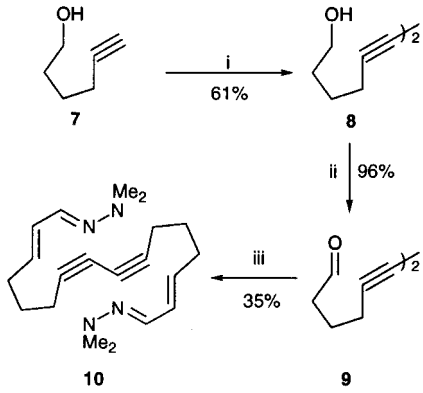
The final substrate investigated was derived from hex-5-ynol **7**, the homocoupling of the terminal acetylene being carried out first (Scheme 4). Thus Glaser–Eglinton coupling of the alkyne gave the corresponding 1,3-diyne **8**; oxidation to the corresponding aldehyde **9** was achieved using *o*-iodylbenzoic acid (IBX) in DMSO.[12] The hydrazone **10** was prepared directly by reaction of **9** with diethoxyphosphonoethanal *N*,*N*-dimethylhydrazone.[8]



Scheme 2 *Reagents and conditions*: i, $HC{\equiv}CCH_2Cl$, K_2CO_3, EtOH; ii, (R = H) *t*-BuN=CHCH(TMS)$_2$, $ZnBr_2$, THF, followed by aq. $ZnCl_2$; ** (R = Me) prepared from salicylaldehyde by reaction with $Ph_3P{=}CHCOMe$ (91%), followed by $HC{\equiv}CCH_2Cl$, K_2CO_3, EtOH (76%); iii, Me_2NNH_2, $MgSO_4$, CH_2Cl_2; iv, Cu(OAc)$_2$, pyridine, MeOH, ether.

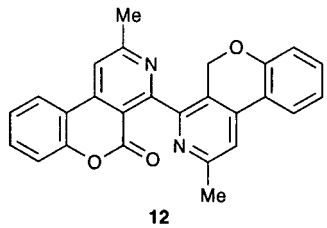


Scheme 3 *Reagents and conditions*: i, $HC{\equiv}CCH_2Cl$, KH, DMF; ii, Cu(OAc)$_2$, pyridine, MeOH, ether.



Scheme 4 *Reagents and conditions*: i, $Cu(OAc)_2$, pyridine, MeOH, ether; ii, IBX, DMSO; iii, $(EtO)_2POCH_2CH{=}NNMe_2$, BuLi, THF.

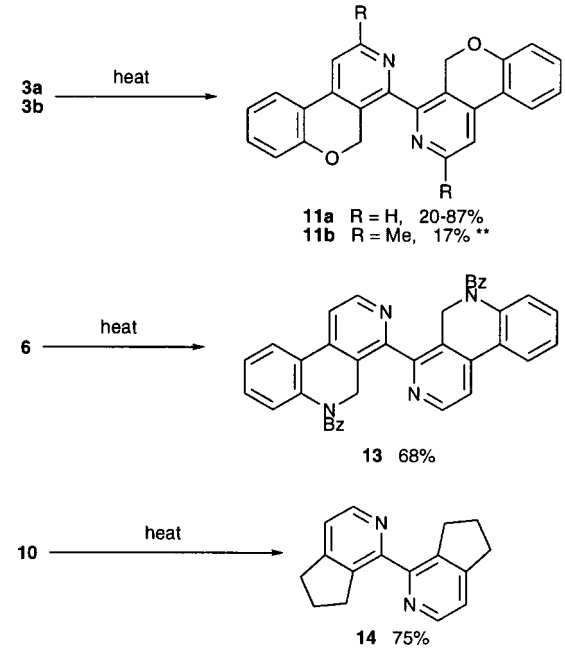
With a range of substrates in hand, the key double IMDA reactions were carried out. Heating the 1,3-diyne bis-hydrazone **3a** in boiling xylene gave the desired annelated 2,2′-bipyridine as the only isolable product (yield of crude material 60–87%), though considerable losses occurred in purification. The substrate **3b** derived from the α,β-unsaturated ketone was much less satisfactory in the double IMDA reaction; azadiene **3b** gave only 17% of a bipyridine after prolonged heating in mesitylene, though the product was isolated as the mono-oxidation product, the monolactone **12** formed by oxidation at the 5-position of one



12

of the benzopyrano[3,4-*c*]pyridine rings. The *N*-benzoyl compound **6**, a nitrogen analogue of **3a**, underwent smooth double IMDA on heating in xylene to give, after loss of dimethylamine, the 4,4′-bi(benzo[*c*][2,7]naphthyridine) **13** in 68% yield. Finally in the series where the azadiene fragment is connected to the alkyne dienophile by a simple alkyl chain, substrate **10** readily underwent the desired double IMDA reaction in boiling xylene to give the 1,1′-bi(cyclopenta[*c*]pyridine) **14** in good yield (Scheme 5).

We thank the EPSRC for support of this work, and the EPSRC and Zeneca Pharmaceuticals for a CASE Award (D. A. R.).



Scheme 5 (** Isolated as an oxidation product, the monolactone **12** formed by oxidation at the 5-position of one of the benzopyrano[3,4-*c*]pyridine rings.)

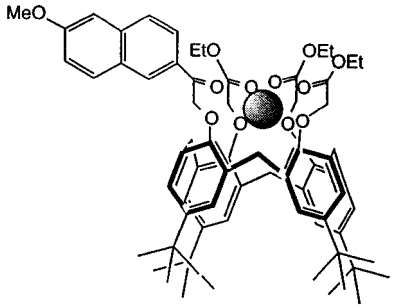
Received (in Basel, Switzerland) 4th January 1999, Accepted 8th March 1999

A new calix[4]arene with three ester groups and an appended naphthalenic fluorophore has been synthesized; investigation of its photophysical and complexing properties towards alkali and alkaline-earth metal ions reveals a high selectivity for Na^+ in water–ethanol mixtures.

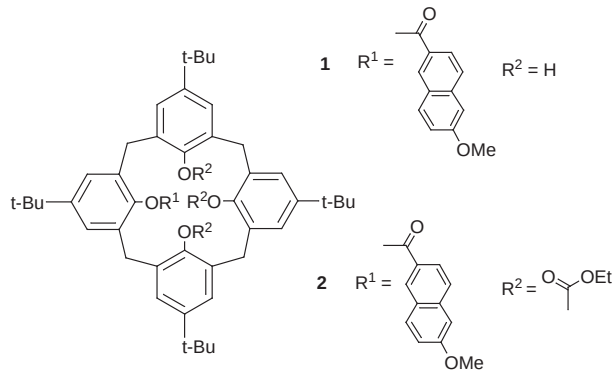
Considerable effort is being devoted to the design of a fluorescent sensor for metal ions.[1–4] Progress has still to be made in relation to the selectivity exhibited towards a given ion. Calixarenes with appropriate appended groups are good candidates because they have been shown to be highly specific ligands[5] and their potential applications as sensing agents have received increasing interest.[6] In particular, several calixarene-based fluorescent sensors have already been designed.[7]

In the present work, a novel calix[4]arene containing three ester groups and an appended naphthalenic fluorophore is described. Calix[4]arene tetraesters have been previously shown to be of interest as complexing agents of alkali metal ions.[8] In view of our previous studies on crowned-coumarin sensors, based on cation-enhancement of photoinduced charge transfer,[9] we have chosen as a fluorophore 6-acyl-2-methoxynaphthalene (AMN) which includes an electron-donating substituent (methoxy group) conjugated to an electron-withdrawing substituent (carbonyl group). It undergoes intramolecular charge transfer upon excitation and is thus expected to be environmentally sensitive. As for crowned coumarins, the fluorophore is linked to calix[4]arene so that the carbonyl group participates in the complexation process (Scheme 1). Consequently, cation binding results in the enhancement of photoinduced charge transfer with concomitant marked changes of photophysical characteristics.

Calix[4]arene **2**‡ was prepared in three steps. 6-Choroacyl-2-methoxynaphthalene was obtained by Friedel–Craft acylation between methoxynaphthalene and chloroacetyl chloride in nitrobenzene.[10] 4-*tert*-Butylcalix[4]arene was mono-alkylated using 2 equiv. of 6-chloroacyl-2-methoxynaphthalene and 2 equiv. of $KHCO_3$ in acetone. The remaining three phenolic groups were later functionnalized using 4 equiv. of ethyl bromoacetate and 2 equiv. of K_2CO_3 in acetone.[8] The cone conformation was confirmed by NMR.[11]



Scheme 1



The effects upon addition of Li^+, Na^+, K^+, Mg^{2+} and Ca^{2+} perchlorates to **2** were first examined in acetonitrile solution. The absorption and fluorescence spectra of **2** and its complexes with Li^+, Na^+, K^+ and Ca^{2+} are shown in Fig. 1 and 2, respectively. The spectra of the Mg^{2+} complex are not shown because full complexation was still not achieved upon addition of $Mg(ClO_4)_2$ at a concentration of 0.04 M. An increase in the molar absorption coefficients together with red shifts of the absorption and emission spectra are observed upon cation binding, as expected from the cation-induced enhancement of the electron-withdrawing character of the carbonyl; the higher the charge density of the cation, the larger the observed effects. The red shifts of the emission spectrum are 45 and 61 nm upon complexation of Na^+ and Ca^{2+}, respectively.

Moreover, the fluorescence quantum yield, which is very low for **2** (1.24×10^{-3}), drastically increases upon cation binding (*e.g.* 0.68 for Ca^{2+}). The enhancement factors are 16, 35, 250, 550, for K^+, Na^+, Li^+, Ca^{2+}, respectively, again following the trend in charge density. Such an enhancement can be tentatively explained in terms of the relative locations of the singlet $\pi\pi^*$ and $n\pi^*$ states. For a ketone like **2**, some $n\pi^*$ character is expected for the lowest excited singlet state.[12] This results in an efficient intersystem crossing to the triplet state and consequently a low fluorescence quantum yield. In the presence of cation which strongly interacts with the lone pair of the carbonyl group, the $n\pi^*$ state is likely to be shifted to higher energy so that the lowest excited state becomes $\pi\pi^*$.

In ethanol, we first note that the fluorescence quantum yield of **2** is 2.5×10^{-3}, *i.e.* 2 times larger than in acetonitrile. This solvent dependency of the quantum yield, which increases with increasing solvent polarity, supports the existence of a low lying $n\pi^*$ state in the absence of a cation. The cation-induced photophysical changes in ethanol follow the same trends as in acetonitrile, but they were found to be weaker upon addition of Li^+, Mg^{2+} and Ca^{2+} and subsequently it was impossible to measure the spectral characteristics and the fluorescence quantum yields of the relevant complexes in this solvent. The fluorescence quantum yield increases by a factor of 15 and 38 upon binding of K^+ and Na^+, respectively.

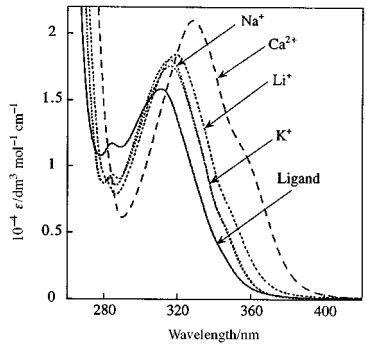


Fig. 1 Absorption spectra of ligand **2** and its complexes in acetonitrile.

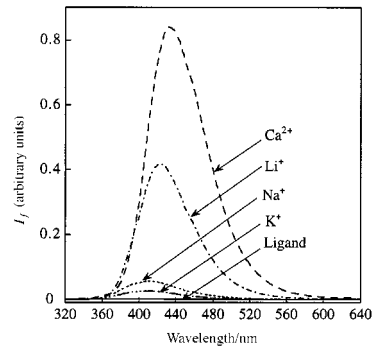

Fig. 2 Corrected fluorescence spectra of ligand **2** and its complexes in acetonitrile. Excitation wavelength 320 nm.

Table 1 Stability constants of the complexes of **3** in acetonitrile, ethanol and ethanol–water mixtures

Solvent	Cation	logβ
MeCN	Li^+	6.32 ± 0.07[a]
	Na^+	6.28 ± 0.06[a]
	K^+	4.74 ± 0.03[a]
	Mg^{2+}	2.06 ± 0.04[a]
	Ca^{2+}	5.30 ± 0.06[a]
EtOH	Li^+	0.9 ± 0.08[a]
	Na^+	14.3[b]
	K^+	2.87 ± 0.03[a]
	Mg^{2+}	1.82 ± 0.06[a]
	Ca^{2+}	1.25 ± 0.03[a]
EtOH–H_2O (80 : 20 v/v)	Na^+	3.87 ± 0.05[a]
	K^+	1.17 ± 0.05[a]
EtOH–H_2O (60 : 40 v/v)	Na^+	3.04 ± 0.07[a]
	K^+	0[a] (β = 0.75 ± 0.3)

[a] 1 : 1 stoichiometry for the complex. [b] 1.2 stoichiometry, log K_{11} = 4.6 ± 0.1 (M + L ⇌ ML), log K_{12} = 9.7 ± 0.1 (ML + L ⇌ ML_2), β = $K_{11}K_{12}$.

We then examined the stability of the complexes and their selectivity. The stability constants of the complexes in acetonitrile, ethanol and water/ethanol mixtures are reported in Table 1. In acetonitrile, the values of the stability constants are consistent with those previously reported for the analogous tetraethyl *p-tert*-butylcalix[4]arene tetraacetate and tetraphenyl *p-tert*-butylcalix[4]arene tetraketone.[8] As expected, the stability of the complexes is lower in ethanol. In the case of Na^+, the titration curve could not be satisfactorily fitted under the assumption of a 1 : 1 complex. Careful analysis of the evolution of the absorption spectra revealed that a 2 : 1 complex and a 1 : 1 complex with sodium were successively formed upon addition of Na^+.§

We then studied the ion-response of **2** in the presence of water since in most applications the metal ions to be detected are in aqueous solutions. Although, **2** is not soluble in water, this is not considered to be a drawback as our eventual aim is to design an optical-fibre device in which **2** will be immobilized in a polymer or sol–gel film. Furthermore, insolubility in water is preferable so as to minimize leakage. Meanwhile, in order to test the response of **2** in aqueous environments, we measured the stability constants in ethanol–water mixtures. The maximum water content which facilitates sufficient solubility of **2** is 40% by volume. Values are reported in Table 1. It is worth noting, that, in the presence of water, the 2 : 1 complex with Na^+ is no longer observed. The stability constant decreases as the water content increases, as expected, but it appears to level off. It is remarkable that the stability constant of the Na^+ complex in ethanol–water (60 : 40 v/v) is *ca.* 1300; this is suitable for measuring sodium ion concentrations in the mmolar range. In the same ethanol–water mixture, the stability constant of the K^+ complex is *ca.* 1. Therefore, selectivity Na^+/K^+ (expressed by the ratio of the stability constants) is *ca.* 1300. Moreover, it should be emphasized that the other cations used in this study (Li^+, Mg^{2+} and Ca^{2+}) have negligible effects. Finally, it is remarkable that the fluorescence quantum yield of the sodium complex in ethanol–water (60 : 40 v/v) is 0.11, *i.e.* 30 times larger than that of the free ligand.

The next step of this investigation will be the synthesis of calix[4]arenes with four appended chromophores along the same design principles. The molar absorption coefficient will therefore be four times larger and additional cation-induced photophysical effects are expected.

We acknowledge Ania Chaouanne for assistance with the spectroscopy measurements. The Belgian FNRS and French CNRS institutions are thanked for financial support. J. L. H. J. is a 'Chercheur qualifie' from the FNRS.

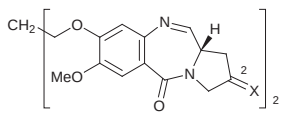
Received (in Liverpool, UK) 16th December 1998, Accepted 1st March 1999

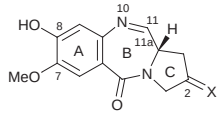
A C2/C2′-*exo* unsaturated pyrrolobenzodiazepine dimer 1 has been synthesised which is cytotoxic at the picomolar level and has remarkable covalent DNA binding affinity, raising the melting temperature of duplex-form calf thymus DNA by 34 °C after 18 h incubation.

There is presently interest in low molecular weight ligands that can interact with nucleic acids in a sequence-selective manner. Such agents have potential use in the validation of DNA sequences as potential therapeutic targets, in the therapy of genetic-based diseases (*e.g.* cancer[1,2]), and in the development of diagnostic agents. The pyrrolo[2,1-*c*][1,4]benzodiazepines (PBDs) are a family of antitumour antibiotics derived from various *Streptomyces* species that exert their biological activity by interacting with DNA in a sequence-selective fashion, forming a covalent bond between their electrophilic C11-position and the exocyclic C2-NH_2 group of a guanine base in the minor groove of DNA.[3] Recently, it has been demonstrated that PBDs can inhibit both endonuclease activity[4] and *in vitro* transcription[5] in a highly sequence-selective manner.

Although the parent PBDs span approximately three base pairs with a preference for purine–guanine–purine (*e.g.* AGA) sequences, a series of C-ring-unsubstituted C8-diyldioxy ether-linked PBD dimers have been synthesised (*e.g.* DSB-120 **4**) that



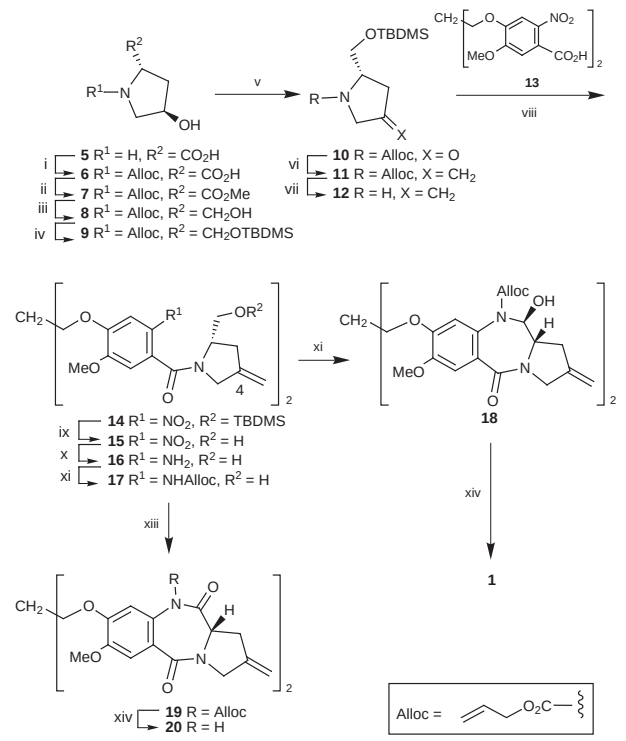
1 X = CH_2
4 X = H,H



2 X = H, H
3 X = CHMe

span approximately six base pairs of DNA and have enhanced sequence selectivity (*e.g.* purine-GATC-pyrimidine for DSB-120).[6,7] The sub-micromolar cytotoxicity of DSB-120 has been attributed to its ability to irreversibly cross-link DNA *via* guanine residues on opposite strands.[8] In an attempt to further extend base-pair span and recognition behaviour, we have investigated the inclusion of C2/C2′ substituents that should follow the contour of the host minor groove. Here, we report a novel synthesis of SJG-136 **1**, a C2/C2′*exo*-methylene analogue of DSB-120. This molecule has exquisite cytotoxicity in the picomolar region (*i.e.* IC_{50} = 0.000024 μM) in the cisplatin-resistant A2780cis human ovarian carcinoma cell line, some 9000-fold more potent than DSB-120 (IC_{50} = 0.21 μM). Furthermore, SJG-136 raises the melting temperature of calf thymus (CT) DNA by a record value of 33.6 °C after 18 h incubation at a [PBD] : [DNA] ratio of 1 : 5.

Synthesis of the target molecule was initially approached using the thioacetal method of Thurston and co-workers.[9,10] However, this had to be abandoned due to the unwanted addition of EtSH across the C4-*exo*-methylene of intermediates of type **11** during attempted thioacetal formation. Instead, synthesis of **1** was achieved by employing the B-ring cyclisation strategy first reported by Fukuyama and co-workers[11] (Scheme 1). Commercially available *trans*-4-hydroxy-L-proline **5** was initially *N*-protected as carbamate **6** in 87% yield.[12] Following esterification in disappointing yield (43%) using catalytic H_2SO_4 in refluxing MeOH, the resulting ester **7** was reduced with $LiBH_4$ to give diol **8** in quantitative yield. Selective silylation of the primary alcohol (**8** → **9**) was achieved using DBU as a silyl transfer agent. Disilylated product and unreacted diol were removed by column chromatography to provide the TBDMS ether **9** in 52% yield. Oxidation to the ketone **10** was achieved using either the Swern reaction or tetrapropylammonium perruthenate (TPAP) in the presence of NMO and 4 Å molecular sieves, both methods producing **10** in almost quantitative yield. The key C4 (*pro*-C2/C2′) unsaturation was introduced by performing a Wittig reaction on **10** to afford the olefin **11** in 87% yield. Initial attempts to deprotect **11** using



Scheme 1 *Reagents and conditions*: i, Alloc-Cl, aq. NaOH, THF, 0 °C, 87%; ii, MeOH, H_2SO_4, Δ, 43%; iii, $LiBH_4$, THF, 0 °C, 99%; iv, TBDMS-Cl, Et_3N, DBU, CH_2Cl_2, 52%; v, TPAP, NMO, 4 Å molecular sieves, CH_2Cl_2, MeCN, 92% or $(COCl)_2$, DMSO, Et_3N, CH_2Cl_2, −70 °C, 95%; vi, Ph_3PCH_3Br, $KOBu^t$, THF, 0 °C, 87%; vii, Bu_3SnH, $Pd(PPh_3)_2Cl_2$, H_2O, CH_2Cl_2, 77%; viii, $(COCl)_2$, DMF, THF, then **12**, Et_3N, H_2O, 0 °C, 74%; ix, TBAF, THF, 0 °C, 94%; x, $SnCl_2.2H_2O$, MeOH, Δ, 61%; xi, Alloc-Cl, pyridine, CH_2Cl_2, 0 °C, 50%; xii, TPAP, NMO, 4 Å molecular sieves, CH_2Cl_2, MeCN, 32%; xiii, $(COCl)_2$, DMSO, Et_3N, CH_2Cl_2, −45 °C, 51%; xiv, $Pd(PPh_3)_4$, PPh_3, pyrrolidine, CH_2Cl_2, MeCN, 0 °C, 77% for **1** and 43% for **20**.

$PPh_3/Pd(PPh_3)_4$ in the presence of a suitable allyl scavenger (*e.g.* pyrrolidine, dimedone, 2-ethylhexanoic acid)[13,14] were unsuccessful. Eventually, the Alloc group was cleaved by palladium-catalysed hydrostannolysis[15] with Bu_3SnH to provide the amine **12** in 77% yield.

The known PBD dimer core **13**[6,7] was converted to the corresponding acid chloride, and coupled to **12** to furnish the bis(nitro amide) **14** in 74% yield. The TBDMS protecting groups were removed rapidly and selectively under mild conditions using TBAF in THF to produce the bis(nitro alcohol) **15** in 94% yield. Reduction of the nitro groups while retaining the C4/C4′ unsaturation intact was achieved in 61% yield by employing $SnCl_2 \cdot 2H_2O$ in refluxing MeOH. The resulting *bis*-aniline **16** was Alloc-protected at the *pro*-N10/N10′ positions (**17**), before subjecting it to Swern conditions in order to bring about oxidative cyclisation to give the bis-N10-protected product **18**. Unfortunately, **18** was prone to over-oxidation and only the tetralactam **19** was obtained under these conditions. However, oxidation with TPAP, NMO and 4 Å molecular sieves afforded the required **18** in 32% yield with no contaminating tetralactam. Deprotection of **18** with $Pd(PPh_3)_4$, PPh_3 and pyrrolidine[13] afforded the novel PBD dimer **1** in 77% yield. Treatment of **19** under identical conditions afforded **20**, the first example of a PBD dimer tetralactam, in 43% yield.

The C2/C2′-methylene groups of **1** were clearly visible in the ^{1}H NMR (broad singlets at δ 5.17 and 5.20) and ^{13}C NMR (δ 109.4) spectra.† Similarly, the diagnostic N10-C11/N10′-C11′ imine signals could be observed at δ 7.68 (d, J 4.4 Hz) and δ 162.6, respectively. FAB MS gave parent ions at 665 and 773, corresponding to single and double thioglycerol addition adducts, respectively. In addition, the observed $[\alpha]_D^{21}$ value of +357.7 (*c* 0.07, $CHCl_3$) compared favourably with that for DSB-120[7] ($[\alpha]_D^{23}$ +330 (*c* = 0.6, $CHCl_3$)], confirming that the C11a/C11a′ stereochemistry crucial for DNA interaction had been maintained throughout the synthesis.

The data presented in Table 1 show that SJG-136 **1** is the most potent DNA-stabilising agent known to date according to this particular assay.[16] For a 1 : 5 molar ratio of [PBD] : [DNA], the PBD dimer elevates the helix melting temperature of CT DNA by an unprecedented 33.6 °C after incubation for 18 h at 37 °C. Under identical conditions, the C-ring-unsubstituted dimer DSB-120 **4** provides a ΔT_m of 15.1 °C, demonstrating the extraordinary effect of introducing C2/C2′-unsaturation. In common with other PBD dimers, **1** exerts most of its effect upon the GC-rich or high temperature regions of the DNA melting curves. In a similar fashion to DSB-120, it provides some 60–80% of its stabilising effect without prior incubation, suggesting a kinetic effect in the reactivity profile. However, the comparative ΔT_m curves show that, on a concentration basis alone, SJG-136 is ≥10-fold more effective than DSB-120. Even at a [PBD] : [DNA] molar ratio of 1 : 100, SJG-136 effects significantly better DNA binding affinity than the monomer tomaymycin **3** at a 1 : 5 molar ratio (see Table 1).

Table 1 Thermal denaturation with calf thymus DNA[a] at a [PBD] : [DNA] molar ratio of 1 : 5[b] and *in vitro*[c] cytotoxicity data in the A2780 and A2780cisR cell lines for SJG-136 **1** and DSB-120 **4**

	Induced ΔT_m/°C[a,b,d] after incubation at 37 °C for			IC_{50}/μM[c]		
Compound	0 h	4 h	18 h	A2780	A2780cisR	RF[e]
SJG-136 **1**	25.7	31.9	33.6	0.0000225	0.000024	1.1
DSB-120 **4**	10.2	13.1	15.1	0.0072	0.21	29.2
Cisplatin	—	—	—	0.265	8.4	32

[a] For CT-DNA at pH 7.00 ± 0.01, T_m = 67.83 ± 0.06 °C (mean value from 30 separate determinations). All ΔT_m values ± 0.1–0.2 °C. [b] For a 1 : 5 molar ratio of [ligand] : [DNA], where CT DNA concentration = 100 μM in aqueous buffer [10 mM sodium phosphate + 1 mM EDTA, pH 7.00 ± 0.01]. [c] Dose of PBD required to inhibit cell growth by 50% compared with PBD-free controls. The cells were incubated with the compounds for 96 h at 37 °C. [d] For comparative purposes: ΔT_m of tomaymycin **3** = 0.97, 2.38 and 2.56 °C at 0, 4 and 18 h, respectively. [e] RF is the resistance factor (IC_{50} resistant/parent).

Representative cytotoxicity data for SJG-136 in the human ovarian carcinoma cell line A2780 and its cisplatin-resistant subline A2780cisR are shown in Table 1, together with data for DSB-120 and cisplatin for comparison. Relative to the parental line, the A2780cisR subline is known to have elevated GSH levels, an increased level of repair of DNA–cisplatin adducts, and a decreased ability to uptake cisplatin.[17] The IC_{50} value for **1** in the A2780 cell line is only 23 pM, representing a 320-fold increase in cytotoxicity compared to DSB-120 (IC_{50} = 7.2 nM). Interestingly, whereas DSB-120 has a reduced potency towards A2780cisR (IC_{50} = 0.21 μM), SJG-136 is almost 9000-fold more potent in this cell line with a similar IC_{50} value (24 μM) to that in the parent cells, giving a Resistance Factor of 1.1. The fact that DSB-120 and cisplatin give RF values of 29.2 and 32, respectively, for this pair of cell lines suggests that SJG-136 may have potential in cisplatin-refractory disease.

In summary, the synthesis of SJG-136 **1** reported here demonstrates the importance of C2/C2′-*exo*-unsaturation in enhancing the DNA-binding affinity and cytotoxicity of the PBD dimers, and in overcoming cisplatin resistance. The sequence selectivity and cross-linking ability of **1** will be reported elsewhere.

We thank the CRC for providing financial support (Programme Grant SP1938/0401 to DET) and Jane Rimington for help with manuscript preparation.

Bathochromicity of Michler's ketone upon coordination with lanthanide(III) β-diketonates enables efficient sensitisation of Eu^{3+} for luminescence under visible light excitation†

Received (in Exeter, UK) 15th March 1999, Accepted 23rd March 1999

The electronic absorption of Michler's ketone (MK) and related push–pull sensitisers undergoes a strong red shift upon coordination with lanthanide(III) β-diketonates, which enables unprecedently efficient sensitisation of Eu^{3+} luminescence for excitation at long wavelengths extending well into the visible region to above 450 nm.

The design of photoluminescent lanthanide complexes continues to be an active area of research,[1,2] mainly because such complexes may be useful for application in fluorescent probes, and for the conversion and amplification of light. The long lifetimes of the excited states of the lanthanide ions are an advantage in these applications, and so is the spectral purity of their light emission. The ligands in luminescent lanthanide complexes contain, besides chelating groups, one or more sensitising chromophores ('antennae') which are needed to overcome the excitation bottleneck formed by the inherently small absorption cross sections of the lanthanide ions. The chromophores absorb the light and consecutively transfer the energy to the lanthanide ion.[3] Bearing in mind possible applications, it would be most advantageous to have antenna chromophores that absorb significantly at wavelengths longer than 400 nm and then transfer the excitation energy efficiently and irreversibly to the ion. However, for luminescent Eu^{3+} and Tb^{3+} complexes, the excitation window appears to be limited to the near-UV due to the energetic constraints posed by the photophysics of sensitised lanthanide luminescence.[4] Eu^{3+} complexes containing chromophores that absorb at wavelengths longer than 400 nm have been reported, but the overall luminescence quantum yields of these systems are generally low, because energy transfer is inefficient due to back energy transfer processes. For example, mixed complexes of certain β-diketonates and *o*-phenanthroline display absorption bands in the region 380–400 nm, but show luminescence quantum yields upon ligand excitation of 10^{-4} to 2×10^{-3}.[5] Also in a series of Eu^{3+} Schiff base complexes studied recently,[6] the quantum yield drops dramatically as the absorption maximum of the ligand approaches the visible region. In our ongoing search for improved antenna chromophores for lanthanide ions, experiments aimed at observing intermolecular energy transfer between organic chromophores and lanthanide chelates in organic solvents yielded surprising results.

When colourless solutions of Michler's ketone [4,4′-bis(*N*,*N*-dimethylamino)benzophenone] and $Eu(fod)_3$ [europium tris(6,6,7,7,8,8,8-heptafluoro-2,2-dimethyloctane-3,5-dione)] in benzene (both 1 mM) are mixed, a yellow colour develops instantaneously. Moreover, a red glow emerges from the solution under daylight illumination. The emission spectrum (Fig. 1) demonstrates that this red glow is europium(III) luminescence: the sharp peaks are characteristic of lanthanide ion emission, Eu^{3+} usually having its most intense emission around 615 nm.[7] The corresponding excitation spectrum is in accordance with the observation that this luminescence can be excited by visible light. It extends well beyond 450 nm (λ_{max} 414 nm). The quantum yield was found to be 0.17 in aerated solution and 0.20 after deoxygenation by four freeze-pump-thaw cycles (excitation at 420 nm, using quinine bisulfate in 1 M H_2SO_4 as a reference[8]).

Michler's ketone and $Eu(fod)_3$ apparently form a ground-state complex under the experimental conditions, most likely by interaction of the electron rich carbonyl group with the positively charged Eu^{3+} ion. Such interactions are already well known from the use of lanthanide diketonates as NMR shift reagents,[9,10] and in fact coordination of certain aliphatic substrates to $Eu(fod)_3$ have been found to enhance its luminescence quantum yield.[11] Never before, however, has it been reported that complexation of chromophores to lanthanide β-diketonates yields efficient luminescent Eu^{3+} complexes that absorb visible light. The new absorption band is probably due to a bathochromic shift of the first singlet–singlet transition of Michler's ketone occurring upon complexation. This π–π* transition possesses charge-transfer character: in the process of excitation, electron density is moved towards the carbonyl group making the transition solvatochromic.[12] Thus, it is quite likely that the transition energy is largely affected by the presence of the lanthanide ion.

Upon closer inspection, the coordination of MK to lanthanide β-diketonates was found to occur only in non-coordinating solvents. Also, water molecules can compete with MK for free coordination sites on the lanthanide ion. Therefore, all reagents and solvents were dried before use. MK was purified according to a literature procedure.[13]

The complex formation of MK with $Eu(fod)_3$ in benzene can be monitored using UV-VIS absorption spectroscopy. The absorption band of the complex resides at longer wavelengths, where MK and $Eu(fod)_3$ themselves do not absorb. Fig. 2 shows a titration experiment, in which small amounts of a $Eu(fod)_3$ stock solution are added to a solution of MK. It clearly shows 1 : 1 complex formation of MK with $Eu(fod)_3$. Analysis of the titration data yields the formation constant for the MK–$Eu(fod)_3$ complex in benzene, $\log K = 4.85$. The extinction coefficient at 414 nm, the absorption maximum, was found to be 3.04×10^4 M^{-1} cm^{-1}.

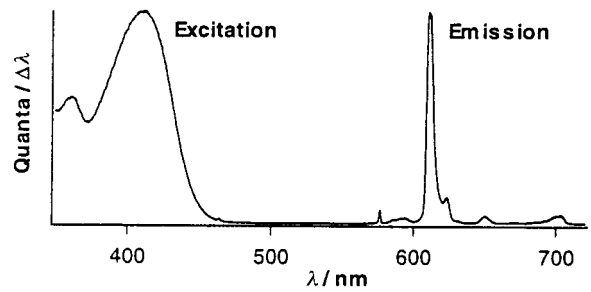

Fig. 1 Corrected luminescence excitation (λ_{em} = 612 nm) and emission (λ_{exc} = 450 nm) spectra of a solution of 10^{-5} M Michler's ketone and 10^{-4} M $Eu(fod)_3$ in benzene.

† Supplementary data outlining the analysis methodology used and giving additional spectra are available from the RSC web site, see: http://www.rsc.org/suppdata/cc/1999/799/

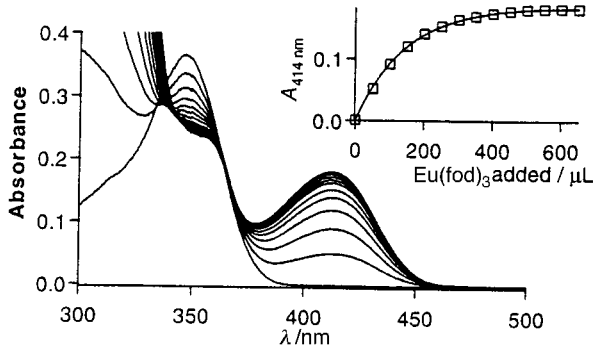

Fig. 2 UV–VIS titration of a solution of Michler's ketone in benzene with $Eu(fod)_3$. To 2.5 ml of a 10^{-5}M solution of MK in benzene, a $Eu(fod)_3$ solution (5×10^{-4} M in benzene) is added in steps of 50 μl. The inset shows formation of the complex by means of its absorption at 414nm as a function of the amount of $Eu(fod)_3$ solution added. The solid line is the theoretical curve for a 1 : 1 complex with log K = 4.85 and $\varepsilon_{max} = 3.04 \times 10^4$ M^{-1} cm^{-1}. The dilution has been taken into account.

The same bathochromic shift of the MK absorption as the one induced by $Eu(fod)_3$ is also observed with other lanthanides. Addition of $Yb(fod)_3$, $Er(fod)_3$, $Gd(fod)_3$ or $Pr(fod)_3$ to MK in benzene produces in all cases the same 414 nm absorption band. This reflects the electrostatic nature of the interaction: all lanthanide ions carry a 3+ charge and the distance between the ion and the MK is equal in all complexes. They will therefore have the same effect on the electronic energy levels of the chromophore. Obviously, the red glow is only observed with $Eu(fod)_3$.

Although the induced 'optical shifts' are the same for different $Ln(fod)_3$ species, the shifts of the MK ^{1}H nuclear magnetic resonances induced by these complexes are entirely different, which clearly shows that the effects have different origins (electrostatic *vs.* magnetic). For example, $Eu(fod)_3$ causes a downfield shift whereas $Pr(fod)_3$ shifts the resonances upfield. The protons closest to the carbonyl group are affected most, and the protons on the dimethylamino groups are relatively unaffected. This supports our view that the MK interacts with the lanthanide diketonate through its carbonyl group.

The sensitisation pathway in luminescent lanthanide complexes generally consists of excitation of the antenna chromophore into its singlet state, subsequent intersystem crossing of the antenna to its triplet state and energy transfer from the antenna triplet to the lanthanide ion,[14] implying that the triplet energy must be sufficiently high. In view of the unprecedented observation of efficiently sensitised Eu^{3+} luminescence upon excitation with visible light the singlet–triplet gap of the coordinated MK must be exceptionally small compared to other organic chromophores used until now as sensitisers or (less likely) another mechanism such as the electron transfer mechanism proposed by Horrocks *et al.*[15] must be involved.

The Gd^{3+} β-diketonates provide a way to study the triplet state energy of the coordinated MK. Having no electronic energy levels below 32000 cm^{-1} (310 nm), Gd^{3+} can not accept any energy from MK, but as mentioned above, it induces the same optical shift and eventually enhances singlet–triplet and triplet–singlet transitions in MK by its heavy atom effect. As a result in deoxygenated benzene, even at room temperature, phosphorescence of MK–$Gd(fod)_3$ is observed (excitation at 410 nm), as a broad band peaking at 540 nm. From the emission spectrum of MK–$Gd(fod)_3$ in methylcyclohexane glass at 77 K, the triplet energy of the coordinated MK is estimated to be 19600 cm^{-1}, which is indeed sufficient to efficiently populate the $^5D_0$ luminescent state of Eu^{3+} (17500 cm^{-1}), possibly *via* energy transfer to the $^5D_1$ state (19000 cm^{-1}) and subsequent relaxation to $^5D_0$.[16] The triplet energy of free MK is around 23000 cm^{-1}.[13] These results clearly point to the occurrence of the 'usual' triplet pathway in the sensitisation of Eu^{3+} by MK without resort to more exotic mechanisms. The crucial point is that the very small singlet–triplet gap of MK is fully retained upon coordination *via* its carbonyl oxygen to the lanthanide but that at the same time these energy levels are significantly lowered because the coordination stabilises the very polar excited states involved.

The effect of variation of β-diketonates was investigated as well. In benzene, the maximum of the absorption band varies from 398 nm for MK–$Eu(dpm)_3$ (dpm = 2,2,6,6-tetramethylheptane-3,5-dionate) *via* 414 nm for MK–$Eu(fod)_3$ to 430 nm for MK–$Eu(hfa)_3$ (hfa = 1,1,1,5,5,5-hexafluoropentane-2,4-dionate). We tentatively attribute this to a variation of the distance between the MK chromophore and the lanthanide ion in the complexes due to steric hindrance by the β-diketonate ligand. Unlike MK–$Eu(dpm)_3$ and MK–$Eu(fod)_3$ (both having 0.20 quantum yield in deoxygenated benzene), the sensitised luminescence quantum yield of MK–$Eu(hfa)_3$ is very low (6.2×10^{-5} in deoxygenated benzene). This is probably a result of too low a triplet energy of the antenna chromophore. The phosphorescence spectrum of MK–$Gd(hfa)_3$ (methylcyclohexane, 77 K) reveals a triplet energy of about 18800 cm^{-1}, which means that back energy transfer processes from Eu^{3+} to the coordinated MK might readily occur at room temperature.

In conclusion, lanthanide β-diketonates have been found to form complexes with the carbonyl containing 'push–pull' chromophore Michler's ketone. This interaction brings about a bathochromic shift in the optical absorption spectum of this chromophore. We note that this 'optical shift' effect is more general. In preliminary experiments, we also found bathochromic shifts in the dyes Nile Red and Phenol Blue induced by $Ln(fod)_3$.[17] A remarkable feature of the 'optically shifted', visible light absorbing MK chromophore is that it efficiently sensitises Eu^{3+} luminescence, which is an interesting property, *e.g.* for application as a luminescent label in time-resolved fluorescence microscopy, since visible light is less harmful to biological tissue than ultraviolet. A challenge in this respect is the development of more stable, water soluble complexes. This aspect and more details of the interesting photophysics of MK–$Eu(fod)_3$ and related complexes are currently under investigation.

Photochemistry of bicyclo[2.2.2]octenones: an uncommon oxidative decarbonylation

Tsung-Ho Lee, Polisetti Dharma Rao and Chun-Chen Liao*

Department of Chemistry, National Tsing Hua Univesity, Hsinchu, Taiwan 30043. E-mail: ccliao@faculty.nthu.edu.tw

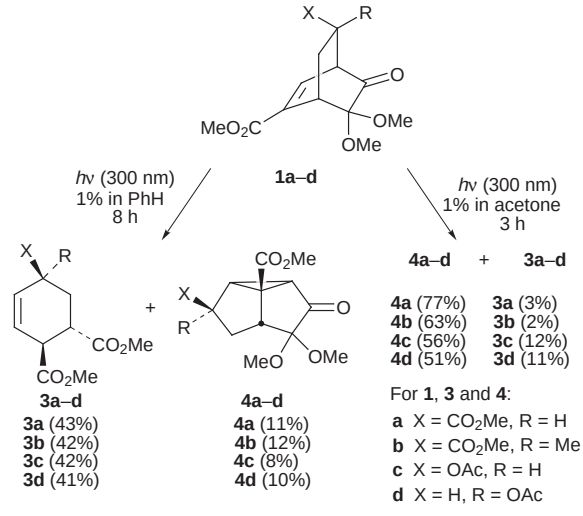
Received (in Cambridge, UK) 11th February 1999, Accepted 16th March 1999

Several substituted 3,3-dialkoxy-5-methoxycarbonylbicyclo[2.2.2]oct-5-en-2-ones underwent unusual oxidative decarbonylation to produce polysubstituted cyclohexenes upon direct irradiation and usual ODPM rearrangement under sensitized conditions. A plausible mechanism for the oxidative decarbonylation is also given.

Bicyclo[2.2.2]octenones, with an embedded β,γ-unsaturated carbonyl chromophore, are rich with photochemistry.[1] They are known to undergo a variety of photochemical reactions such as decarbonylation, ketene extrusion, 1,3-acyl shift and most importantly the 1,2-acyl shift, also known as oxa-di-π-methane (ODPM) rearrangement, depending on reaction conditions, substrate structure and the wavelength of the incident light.[1] Apart from the ODPM rearrangement, and the 1,3-acyl shift,[2–4] other reactions of bicyclo[2.2.2]octenones or β,γ-unsaturated ketones in general have been considered as undesirable side reactions and received little attention.[5] This may be due to the fact that these fragmentation reactions were observed only when the desired ODPM rearrangement or 1,3-acyl shift are inefficient processes for the given substrate or when the substrate undergoes reactions in indescrete modes. Furthermore, these reactions appear to be more structure dependent and selectively affecting them may not always be possible. Apparently, the synthetic potential of decarbonylation has remained unexplored apart from a few cases.

We have been interested in this area of research for sometime and we have already employed the ODPM rearrangement reactions of bicyclo[2.2.2]octenones in the synthesis of iridoids and both angular and linear triquinanes.[6,7] In continuation of our efforts towards exploitation of the synthetic potential of bicyclo[2.2.2]octenones,[8] a study of the photochemical reactions of compounds **1** and **2** was contemplated. We now report that direct irradiation of bicyclo[2.2.2]octenones **1** and **2** in benzene results in the production of stereochemically pure polysubstituted cyclohexenes and under sensitized conditions **1** and **2** yield the usual ODPM rearrangement products in fair yields as one of the major isolable products (Schemes 1 and 2). To the best of our knowledge such formation of cyclohexenes *via* photochemical oxidative decarbonylation of bicyclo[2.2.2]octenones is unprecedented.

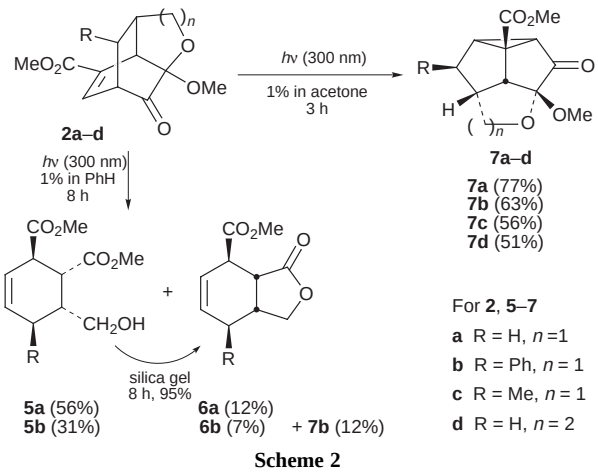
Accordingly the required bicyclo[2.2.2]octenones **1a–d** were prepared *via* intermolecular Diels–Alder reactions of methyl acrylate, methyl methacrylate and vinyl acetate with masked *o*-benzoquinone generated *in situ* by the oxidation of methyl vanillate using diacetoxyiodobenzene in MeOH. Compounds **2a-d** were prepared *via* intramolecular Diels–Alder reactions of masked *o*-benzoquinones generated by the oxidation of methyl vanillate in presence of allyl alcohol, crotyl alcohol, cinnamyl alcohol and homoallyl alcohol in CH_2Cl_2 using the procedure developed in our laboratory.[9] Direct irradiation of compounds **1a–d** in benzene (1% w/v) using light of wavelength centered at 300 nm in a Rayonet reactor for about 8 h furnished cyclohexenes **3a–d** in 41–43% yield along with ODPM rearrangement products **4a–d** in about 8–12% yield. However, irradiation of **1a–d** in acetone for 3 h produced the expected ODPM rearrangement products **4a–d** in 51–77% yield along with 2–12% of **3a–d** (Scheme 1).



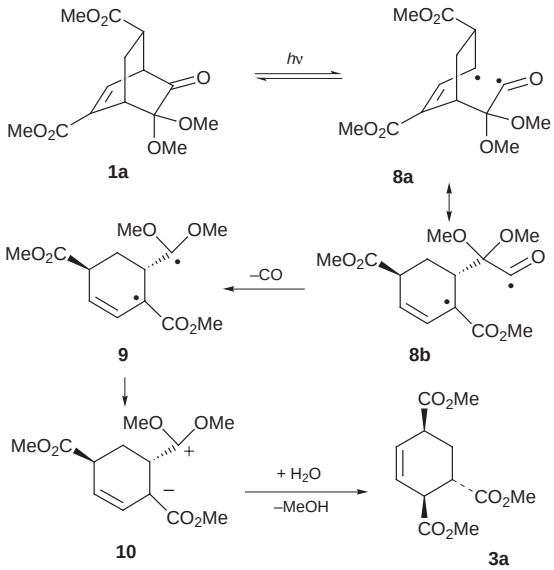
Scheme 1

On the other hand, irradiation of **2a** in benzene provided the expected cyclohexene **5a** and the corresponding lactone **6a** in a total yield of 68%. No ODPM rearrangement product could be observed. In contrast, **2b** provided both decarbonylated products **5b** and **6b** as well as ODPM rearrangement product **7b**. Both **5a** and **5b** could be transformed into **6a** and **6b** respectively by treatment with silica gel in EtOAc. The reaction mixtures obtained upon irradiation of **2c** and **2d** in benzene could not be separated into individual compounds. However, irradiation of **2a–d** in acetone furnished the expected ODPM rearrangement products **7a–d** in good yields (Scheme 2).

All the new compounds were thoroughly charecterized *via* their IR, ^{1}H (400 MHz) and ^{13}C NMR, DEPT, low and high resolution mass spectral analyses. The relative stereochemistry of compounds **3a**, **4b**, **6b** and **7c** was unambiguosly established with the aid of ^{1}H-^{1}H COSY and NOESY spectra. The stereochemical assignments of their analogues were based on analogy and coupling constants.

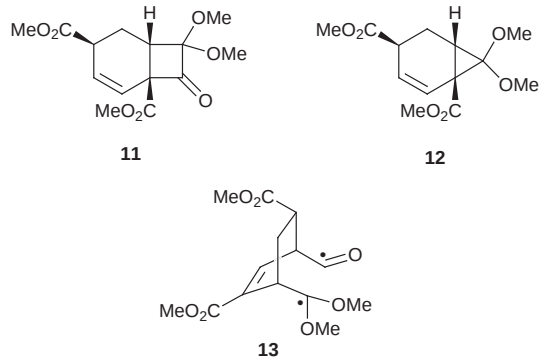


Scheme 2



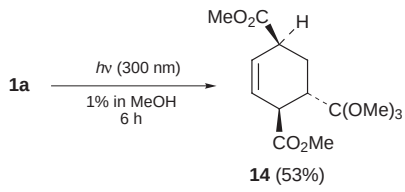
Scheme 3

The following mechanism is believed to be responsible for the formation of cyclohexenes upon direct irradiation of compounds **1** and **2** (Scheme 3). The initial Norrish type I α-cleavage of the C_1-C_2 bond results in the diradical species **8**.[10] The diradical **8**, instead of undergoing 1,3-acyl shift to provide the cyclobutanone derivative **11**, undergoes decarbonylation to

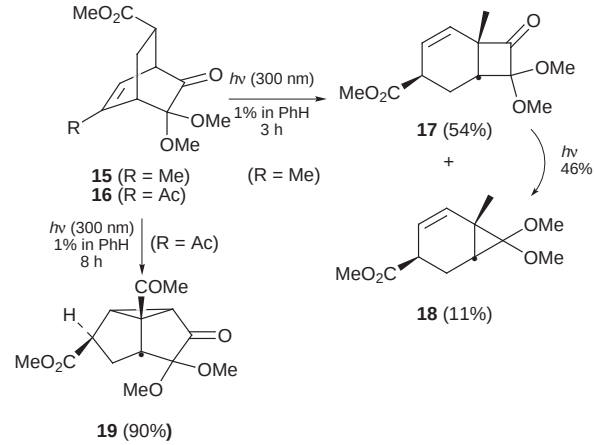


result in the relatively more stable diradical **9**. The diradical **9** fails to cyclize to provide the cyclopropane derivative **12**, and instead results in the zwitterion **10**, which upon stereoselective abstraction of a proton from the traces of water present in benzene followed by hydrolysis provides **3a**. An alternative pathway for the formation of **11** *via* the diradical **13**, which in turn could result from C_2–C_3 bond cleavage, cannot be ruled out. The intermediacy of the zwitterion gained support from the formation of the orthoester **14** as the sole isolable product when compound **1a** was irradiated in MeOH at 300 nm (Scheme 4).

The fact that both **11** and **12** were not observed indicates that the recyclization, prior to decarbonylation (1,3-shift) or fol-



Scheme 4



Scheme 5

lowed by decarbonylation, is constrained probably by electronic factors. The stability of the zwitterion **10** appears to be the driving force for the preferential decarbonylation against formation of strained cyclobutanone **11** or cyclopropane **12**. In order to verify this hypothesis, compound **15** (R = Me) was irradiated under identical conditions to obtain both 1,3-acyl shift product **17** and cyclopropane **18**. On the other hand, irradiation of **16** in benzene at 300 nm furnished ODPM rearrangement product **19** in 90% yield (Scheme 5). Obviously, the C-5 ester group is responsible for prevention of 1,3-acyl shift and formation of cyclopropane.

Nevertheless, these reactions provide an easy access to stereochemically defined polysubstituted cyclohexenes and tricyclo[3.3.0.$0^{2,8}$]octanones of established synthetic potential. Furthermore the starting materials are obtained from inexpensive aromatic compounds in excellent yields. In conclusion the present study has unravelled previously unknown photochemical behavior of a type of bicyclo[2.2.2]octenones.

We thank the National Science Council (NSC) of the Republic of China for financial support. P. D. R. thanks NSC for a post-doctoral fellowship.

Received (in Cambridge, UK) 22nd February 1999, Accepted 26th March 1999

A porphyrin with a β-fused 3-sulfolene on one of the pyrroles acts as a porphodimethylidene precusor which can be used for a variety of Diels–Alder cycloaddition reactions.

The need for molecular assemblies that will match the increasingly sophisticated design demands of supramolecular chemistry has been the motive for the production of modular components that can be assembled readily and predictably. This is especially so for custom-designed porphyrins which can be utilised in an impressive variety of systems.[1]

For some applications it has been necessary to constrain rotational freedom of the porphyrin nucleus within the assembly, and this has most effectively been achieved by a 1,2-linkage at adjacent β-pyrrole positions. Hence the construction of many rigid porphyrin-containing systems has commonly utilised Schiff base formation with preformed porphyrin diamines or diones.[2] However, the Diels–Alder reaction is a classic cycloaddition reaction which leads to fused ring systems and is ideally suited to the construction of well-defined molecular assemblies with limited flexibilities.

There have been few reports of Diels–Alder chemistry involving porphyrins and related macrocycles. Of these, several have used β-vinyl porphyrins as the diene,[3] and a related tetramethine-bridged porphyrin has also been shown to undergo cycloaddition reactions.[4] Alternatively, tetraaryl porphyrins have been used as dienophiles, giving a mixture of products with reactive dienes under forcing conditions,[5] and Diels-Alder methodology has been used in the construction of benzoporphyrins.[6] More recently, *N*-substituted β-fused pyrroloporphyrins have been used as dienes for certain cycloaddition reactions.[7] We have shown that cycloaddition reactions provide an excellent method for geometric control in certain made-to-order rigid assemblies which incorporate porphyrins.[8]

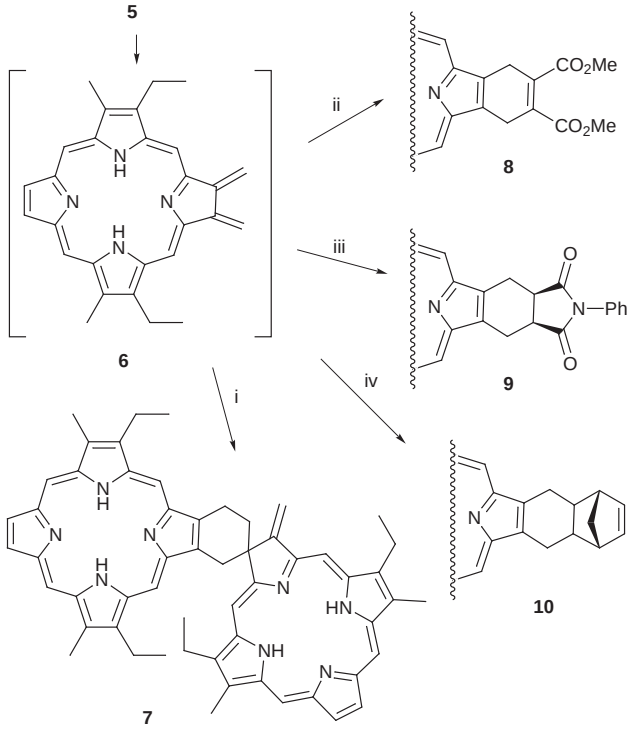
Aromatic fused 3-sulfolenes have been used as precursors for highly reactive *o*-quinodimethanes.[9] Thermal extrusion of sulfur dioxide from the sulfolenes is usually performed in the presence of a dienophile so that the quinodimethane is trapped as a Diels–Alder adduct.[10] While *N*-substituted pyrrole-fused 3-sulfolenes have been used as a source of annelated pyrroles,[11] some of which have been subsequently used in the synthesis of pyrroloporphyrins[12] and symmetrical tetra-substituted porphyrins,[6] reported here is the first example to the best of our knowledge of a porphyrin with a β-fused sulfolene that allows subsequent chemistry at only *one* of the pyrroles. This is a key precusor for a range of cycloadducts resulting from Diels–Alder reaction of the intermediate porphodimethylidene which is formed by elimination of sulfur dioxide under mild conditions.

The pyrrole-fused 3-sulfolene **1** was prepared by a modification of the Barton–Zard reaction[13] using benzyl isocyanoacetate and 3-phenylsulfonyl-2,5-dihydrothiophene 1,1-dioxide (Scheme 1),[14] in an analogous manner to that for the corresponding ethyl ester reported by Vicente *et al*.[6] Hydrogenolysis (H_2, 10% Pd–C) and oxidative iodination (I_3^-, room temperature, 2 h) to give **2** followed by reduction (H_2, 10% Pd–C, NaOAc, 3 atm) produced **3**. Condensation (Montmorillonite clay, CH_2Cl_2, room temperature, 10 h) with benzyl 5-acetoxymethyl-4-ethyl-3-methylpyrrole-2-carboxylate resulted in the tripyrrane **4**, which was subsequently hydrogenolysed and subjected to a '3 + 1' porphyrin synthesis[15] with pyrrole-2,5-dicarbaldehyde (TFA, CH_2Cl_2, room temperature, 2 h, followed by DDQ, 1 h) to form the desired porphyrin **5**.†

While **5** is indefinitely stable at ambient temperatures, on heating above 80 °C it readily loses SO_2 to form the reactive porphodimethylidene **6**. Although it was not possible to isolate **6**, it could be trapped as Diels–Alder adducts in the presence of suitable dienophiles. In the absence of a dienophile and at moderate temperatures (80–110 °C, toluene) it cleanly produced the dimer **7**.

Compound **7** is analogous to the previously identified dimeric product formed from *o*-quinodimethane itself,[9] and its structure was established from its ^{1}H NMR spectrum and mass spectrum [*m/z* 841.5 $(M + H)^+$]. In particular the NMR spectrum (C_6D_6) showed a clear lack of simple symmetry, and individual

EtOH), 5 h, room temp.; iii H_2, Pd–C (10%), NaOAc, 3 atm, 22 h, room temp.; iv, Montmorillonite clay K-10, CH_2Cl_2, N_2, 10 h, room temp.; v, H_2, Pd–C (10%), 3 atm, 3 h, then pyrrole-2,5-dicarbaldehyde, TFA, CH_2Cl_2, 2 h, then DDQ, 1 h, room temp.



Scheme 2 *Reagents and conditions*: i, Δ, toluene, 80–110 °C, 2 h; ii, $MeO_2CC{\equiv}CCO_2Me$, Δ, toluene, 110 °C, 4.5 h; iii, *N*-phenylmaleimide, Δ, 85 °C, 3 h; iv, norbornadiene, Δ, 80 °C, 2 h.

resonances for each of the substituents on the porphyrin and chlorin rings.† For example, there are four distinct ethyl and methyl resonances, two AB quartets for the β-pyrrole protons, eight singlets for the *meso*-protons, and two NH singlets at high field. The exocyclic methylene is defined by two singlets (δ 6.16 and 6.95) significantly deshielded by the neighbouring porphyrin while the deshielded single bridging methylene is a clear AB quartet at δ 5.18 and 5.56. The remaining ethylene of the spiro-linked cyclohexene bridge is a series of complex multiplets at δ 3.05, 3.34 and 4.68. The UV-visible spectrum of **7** is a composite of both porphyrin and chlorin-type rings and not surprisingly shows little evidence of electronic communication between the linked macrocycles.

On heating **5** in toluene at 80–110 °C in the presence of various dienophiles shown in Scheme 2, the corresponding Diels–Alder adducts were isolated in good yields (65–95%).† The C_{2_v} symmetry of each is clear from the ^{1}H NMR spectra. In the case of **10**, only a single stereoisomer was isolated, and both a lack of vicinal H, H-coupling and no significant shielding of the ethylenic protons indicates it to be the *exo*-product (molecular modelling indicates a close proximity of the ethylenic protons to the shielding region of the porphyrin in the *endo*-isomer, although the environments of the bridge methylenes are little different in either isomer). Each of these suggests considerable potential as building blocks for higher level structures. For example **8** can be utilised in further cycloaddition reactions using its activated double bond, **9** *via* a variety of associated *N*-substituted derivatives can provide a single attachment point on a *meso*-unsubstituted porphyrin, and the formation of **10** indicates the possibility for more elaborate architectures. Although these few reactions demonstrate the utility of **5**, its potential is clearly much more extensive and can now be explored.

This research was supported by the Australian Research Council.

The iron-mediated intramolecular addition of carboxylates to conjugated dienes

Ming-Chang P. Yeh,* Li-Wen Chuang, Ya-Sheng Hsieh and Ming-Shan Tsai

Department of Chemistry, National Taiwan Normal University, 88 Sec. 4, Ding-Jou Road, Taipei, Taiwan, Republic of China. E-mail: cheyeh@scc.ntnu.edu.tw

Received (in Cambridge, UK) 1st March 1999, Accepted 25th March 1999

Treatment of carboxylic acid functionalized (η^4-diene)-$Fe(CO)_3$ complexes with 3.0 equiv. of $NOBF_4$ in the presence of Et_3N generates γ- and δ-lactones containing an α,β-unsaturated aldehyde or oxime functionality after NO^+ insertion.

Nucleophilic additions to conjugated dienes coordinated to a transition metal have attracted considerable interest in organic synthesis.[1] Transition metals, such as molybdenum, palladium or iron, have been used to activate dienes towards nucleophilic additions. The (η^4-cyclohexa-1,3-diene)$MoCp(CO)_2$ cations underwent reaction with a variety of carbon nucleophiles at the terminal position of the diene ligand to produce neutral (π-allyl)molybdenum complexes. Hydride abstractions from these complexes regenerated cationic diene complexes which again underwent intermolecular nucleophilic attack from the face opposite the metal, resulting in overall 1,3-stereocontrol in the six-membered ring.[2] With a pendant carboxylic acid group, neutral (π-allyl)molybdenum complexes underwent intramolecular addition with carboxylates by conversion of the neutral species to the cationic nitrosyl intermediates (exchange of neutral CO for NO^+) to afford γ- and δ-lactone derivatives.[3] In the palladium-catalyzed oxidation of conjugated dienes, two nucleophiles were added in a regio- and stereoselective manner across the diene. Nucleophiles that could be used in the overall 1,4-addition included carboxylates, amides, alcohols, and halides.[4] Conjugated dienes could also be activated towards nucleophilic additions by the $Fe(CO)_3$ moiety. The intermolecular addition of reactive ester or cyano stabilized carbanions to diene–iron complexes under CO afforded cyclopentanoids after acid quenching.[5] Recently, we have extended this chemistry into an intramolecular variant. Thus, sequential additions of carboester functionalized zinc–copper organometallics to (η^5-pentadienyl)$Fe(CO)_3$ cations furnished bicyclo[3.3.0]octanones or trisubstituted cyclopentanecarboxylic acid derivatives depending on the quenching process.[6] However, nucleophiles that could be used to add at the diene ligand of $Fe(CO)_3$ complexes have been restricted to stabilized carbanions. It would be of great synthetic interest to extend these regio- and stereoselective additions to other nucleophiles, such as oxygen and nitrogen nucleophiles. Here we report, for the first time, on the intramolecular addition of carboxylates to conjugated dienes by conversion of neutral (η^4-diene)$Fe(CO)_3$ complexes to the cationic nitrosyl intermediates (exchange of neutral CO and NO^+). The addition proceeded regiospecifically to form γ- and δ-lactones with an α,β-unsaturated aldehyde or oxime functionality after NO^+ insertion.

The starting acid complexes **1**–**3** were prepared in two steps according to literature procedures.[6,7] Addition of carboester functionalized zinc–copper reagents to the corresponding (η^5-dienyl)$Fe(CO)_3$ cationic salts followed by hydrolysis of the residue with KOH in MeOH–THF–H_2O at 30 °C produced complexes **1**–**3** as the major products in good yields (70–90%). Finally, our intramolecular addition involved the addition of an MeCN solution of $NOBF_4$ (3.0 equiv.) to **1a** in MeCN at 0 °C under nitrogen and then addition of Et_3N (2.0 equiv.). The addition was carried out for 30 min at 0 °C followed by workup with saturated aqueous NH_4Cl and CH_2Cl_2 extraction. After purification by flash column chromatography on silica gel and distillation under reduced pressure, γ-lactone **4**† bearing an α,β-unsaturated aldehyde at the γ-position of the ring was obtained as the major product in 60% yield (entry 1, Table 1). Under the same reaction conditions, intramolecular cyclization of **1b** with an additional methyl group at the terminal position of the diene ligand afforded γ-lactone **5** with an α,β-unsaturated oxime at the γ-position of the ring in 64% yield (entry 2, Table 1). The formation of **4** and **5** may result from NO^+ insertion. However, it is important to mention that the intramolecular addition of carboxylates to (η^3-allyl)$MoCp(CO)(NO)$ cations to give γ and δ-lactones did not involve NO^+ insertion.[3] A mechanism for generation of **4** and **5** is suggested in Scheme 1. Addition of $NOBF_4$ to complexes **1a**,**b** may produce the cationic species **10**. Deprotonation of **10** with Et_3N gave carboxylate **11**, with attack exclusively at the terminal position of the diene ligand to

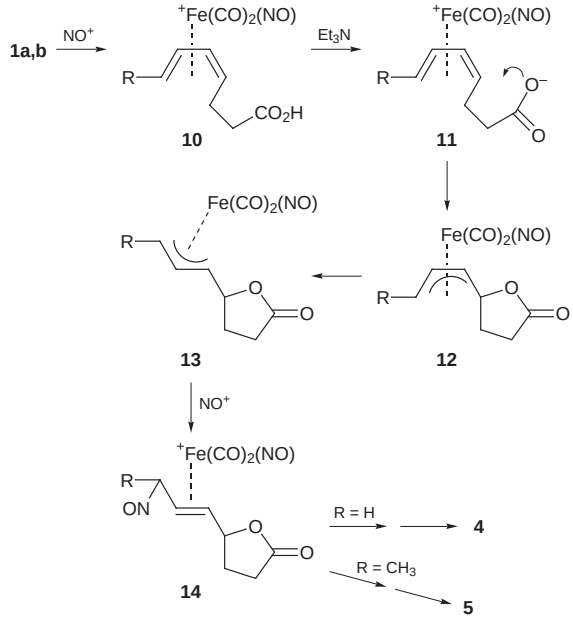
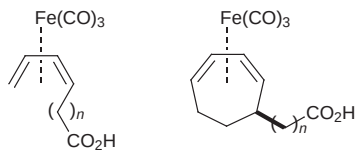


Scheme 1 Proposed reaction pathway for the formation of lactones **4** and **5**.

produce the postulated neutral (π-allyl)$Fe(CO)_2(NO)$ intermediate **12**. *Syn/anti* isomerization of **12** *via* π-allyl/σ-allyl interconversion of the allyl ligand produced **13**.[8] Intermediate **13** may undergo nitrosyl migration with an additional NO^+ to give **14**. However, neutral complexes, such as (η^3-allyl)$Fe(CO)_2NO$, underwent internal CO (rather than NO^+) insertion upon treatment with 1,2-bis(diphenylphosphino)ethane to give an iron acyl intermediate. Quenching the iron acyl intermediate with I_2/EtOH produced a β,γ-unsaturated carboxylic ester.[9] Thus, it is reasonable to suggest that complex (η^3-allyl)$Fe(CO)_2NO$ **13** may undergo nitrosyl insertion with an excess of $NOBF_4$ (3.0 equiv. of NO^+) to produce **14**. The primary nitroso compound (R = H) hydrolyzed to **4**, while the secondary nitroso derivative (R = CH_3) underwent nitroso–oxime tautomerization to produce **5** after aqueous workup and flash column chromatograph of the residue.

Increasing the tether length by one with complexes **2a** and **2b** (entries 3 and 4, Table 1) also allowed intramolecular cyclisation to provide δ-lactones **6** (55%) and **7** (53%), respectively, as the only product in each case. The results are consistent with complexes **1a** and **1b**. Thus, the substrate with an additional methyl group at the diene ligand, **2b**, produced lactone **7** with an α,β-unsaturated oxime functionality at the δ-position of the ring, while complex **2a** generated δ-lactone **6** bearing an α,β-unsaturated aldehyde functionality. However, preliminary attempts to prepare β- and ω-lactones were unsuccessful. No cyclization has been observed for acid complexes **15** and **16**.



15 $n = 1$ **16** $n = 4$ **17** $n = 1$ **18** $n = 2$

Using the same methodology, we are able to construct fused bicyclic lactones **8** and **9** *via* intramolecular addition of carboxylates to cyclic diene–iron complexes **3a** and **3b**, respectively. Fused bicyclic lactones **8**† (50%) and **9** (64%) bearing an α,β-unsaturated oxime functionality were obtained as the only diastereoisomer in each case. The *cis*-stereochemistry at the ring juncture in lactones **8** and **9** was fixed by *anti* addition of carboxylates at the terminal position of the diene ligands and ^1H NMR studies provided evidence supporting the structure assignments. The coupling constants of 5.3 and 4.8 Hz, respectively, of the adjacent fused protons in **8** and **9** demand *cis*-fused bicyclic skeletons. These values are consistent with the couling constants observed for the *cis* fused bicyclo γ- and δ-lactones reported in the literature.[8] Rigorous proof of the structure of **8** was further accomplished by X-ray diffraction analysis.‡ Although the iron-mediated intramolecular cyclisation works well for the formation of fused bicyclic lactones **8** and **9** from (η^4-cyclohexa-1,3-diene)-$Fe(CO)_3$ acid complexes, attempts to obtain fused bicyclo γ- and δ-lactones from intramolecular cyclisation of (η^4-cyclohepta-1,3-diene)$Fe(CO)_3$ acid complexes **17** and **18** have thus far failed.

We thank the National Science Council of the Republic of China for the financial support.

Realisation of highly stereoselective dihydroxylation of a cyclopentene in the synthesis of (−)-aristeromycin

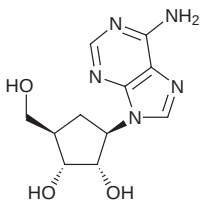
Yuko Tokoro and Yuichi Kobayashi*

Department of Biomolecular Engineering, Tokyo Institute of Technology, 4259 Nagatsuta-cho, Midori-ku, Yokohama 226-8501, Japan. E-mail: ykobayas@bio.titech.ac.jp

Received (in Cambridge, UK) 8th March 1999, Accepted 23rd March 1999

A 2-furyl group was used as a synthetic equivalent of the CH_2OH at the 4′ position of aristeromycin, and dihydroxylation of the cyclopentene possessing the furyl group proceeded highly stereoselectively to produce the key diol for the synthesis of (−)-aristeromycin.

Aristeromycin **1** is a carbocyclic analogue of adenosine and its unique biological properties and structure have attracted considerable interest among organic chemists. Total syntheses of **1** have been reported and are summarised in several reviews.[1] In order to improve or use the biological properties of **1**, analogues of **1** have also been synthesised. Among these syntheses, the strategy of utilizing the monoacetate of *cis* cyclopent-4-ene-1,3-diol (*i.e.* **2**)† as the starting material, which

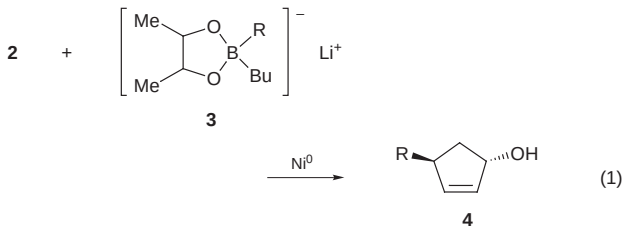


1

2

was originally reported by Deardorff,[2] is attractive especially in that (i) both enantiomers are readily available[3] and (ii) installation of the substituents onto the cyclopentene ring of **2** simply accomplishes a synthesis of **1**. Several groups have published syntheses of **1** along this line, and the efficiency in installing the nitrogen-containing moiety and "CH_2OH" group has also been improved.[4] The stereoselectivity of the dihydroxylation, however, still remains at low levels.[2,4,5] Recently, an explanation for the low selectivity of the dihydroxylation was proposed by Katagiri.[6] Namely, the cyclopentene possessing the requisite 'CH_2OR' group at the 4′ position (aristeromycin numbering) and a heteroatom at the 1′ position adopts minor and major conformers, and the dihydroxylation of the latter inevitably produces a mixture of stereoisomeric diols. Therefore, a new approach, whereby dihydroxylation would take place stereoselectively, is required in order to use the convenient monoacetate **2** as a starting material for **1**.

Recently, we reported a nickel-catalysed coupling reaction of **2** and lithium borates **3**, where aryl, furyl and alkenyl groups (R) on the borates can be transferred onto **2** (eqn. 1).[7] This reaction proceeds stereo- and regio-selectively to furnish *trans* 1,4-products **4**, for the first time, as the major products. These groups (R) are all candidates for 'CH_2OR' and are bigger than 'CH_2OR'. Consequently, even in the *undesired* conformer of the cyclopentene possessing such a group (R) and a nitrogen atom at the 4′ and 1′ positions, respectively, the approach from the β-face would be prevented more effectively than that with CH_2OR as the R group. Our proposal is illustrated in Fig. 1. To examine the above idea, we chose the furyl group (R = 2-furyl) as a 'CH_2OR' precursor and succeeded in the stereoselective synthesis of acetonide **11**. Hydrolysis of **11** to aristeromycin has already been established.[4b,8] In addition, **11** is an important starting compound for the synthesis of analogues and supermolecules containing aristeromycin.[9]



The synthetic route is summarised in Scheme 1. The cyclopentenol **4a** was prepared from (1*R*)-acetate **2** (> 95% ee)[3c] and lithium 2-furylborate **3** (R = 2-furyl). Reaction of **4a** with $(PhO)_2P(O)N_3$[10] proceeded selectively to afford **5**‡ as the sole product. The key dihydroxylation was examined under various conditions and the results are summarised in Table 1. A 4 : 1 ratio of the desired product **6** and the stereoisomer **12** was obtained in good yield when the reaction was carried out at room temperature (entry 1). Although the ratio was definitely higher than previously reported ones, it was still low from a synthetic point of view. Fortunately, reaction at lower temperature (0 °C) resulted in a substantially higher ratio of 14 : 1 (entry 2). Since the observed coupling constant between Ha and Hc of **5** (J_{ac} = 5.4 Hz) indicates that **5** does take both the desired and undesired conformers according to Katagiri,[6] it is clear that the observed high stereoselectivity is provided by the furyl group. Use of acetone as solvent slightly decreased the ratio (entry 3). Double diastereoselectivity between chiral **5** and the Sharpless reagent (AD-mix-α or –β),[11] was also examined. Unfortunately, better selectivity (*i.e.* ratio of **6** to **12**) was not attained (entries 4 and 5). A reagent lacking the chiral ligand for AD-mix resulted in a similar ratio (entry 6).[12]

Since separation of the diols **6** and **12** by chromatography was not an easy task due to their similar mobility on TLC, the mixture was transformed into the corresponding acetonides **7** and **13**, which were easily separated by chromatography. The furyl group of **7** was then transformed into a CO_2Me group by oxidation using $NaIO_4$ and $RuCl_3$ catalyst followed by esterification with CH_2N_2 to afford **8** in 80% yield. Treatment of **8** with $LiAlH_4$ effected reduction of the ester and the azide

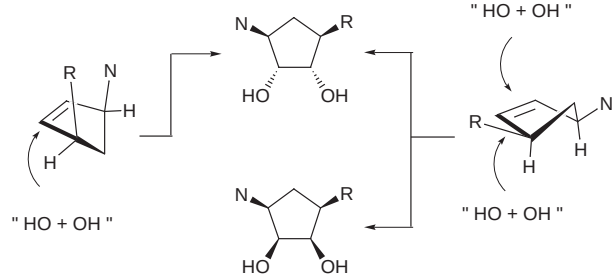


Fig. 1 Desired (left) and undesired (right) conformers for dihydroxylation.

12 R = H
13 R = C(Me)$_2$

groups to afford **9**. The amino group of **9** was converted to a chloropurine moiety using the standard procedure. Finally, reaction of **10** with NH_3 gave the acetonide of aristeromycin **11**, whose ^{1}H NMR (300 MHz) spectrum was fully coincident with the reported data.[13] Use of EtOH for this transformation proved to be better than the standard solvent of MeOH since NH_3–MeOH gave the corresponding methoxide as a by-product. The deprotection of **11** to aristeromycin has already been published.[8]

Since high stereoselection in the dihydroxylation was achieved using the furyl group, it is possible that an aryl or alkenyl group may control the dihydroxylation and that such a group, after being installed onto the cyclopentene ring, can be transformed by taking advantage of their reactivity into various polyoxygenated side chains at the 4' position. These modifications are important for the next generation of carbocyclic sugars.

We thank to Toyo Kasei Kogyo Co. Ltd. for a generous supply of $(PhO)_2P(O)N_3$.

E-mail: kcn@scripps.edu

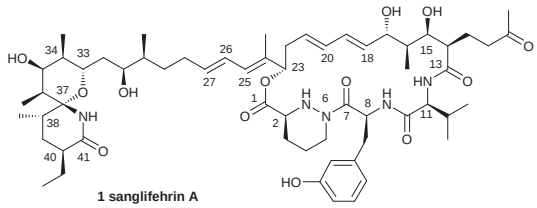
Received (in Cambridge, UK) 5th February 1999, Accepted 24th March 1999

The synthesis of the macrocyclic core of sanglifehrin A, a newly discovered natural product, is described.

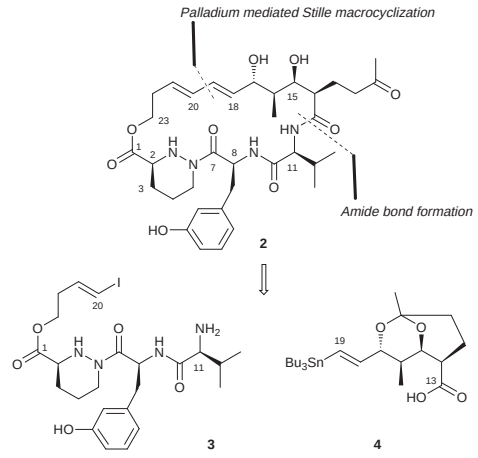
Sanglifehrin A[1] **1** is a newly discovered natural product with impressive biological properties, including cyclophilin binding,



immunosuppressive activity and inhibition of both B-cell and T-cell proliferation.[1] Isolated from the fermentation broths of an unidentified species of Actinomycetes by a team of scientists at Novartis, this substance possesses a novel molecular architecture whose main domains are a [5.5] spirolactam moiety and a 22-membered macrocycle featuring a number of novel functionalities. Here we report construction of the macrocyclic system of sanglifehrin A in which the diene segment at C23 has been judiciously replaced by a hydrogen substituent for the purpose of this model study (compound **2**, Scheme 1).

From the many disconnections one can envision for the construction of macrocycle **2**, we chose the strategy based on the intramolecular Stille coupling,[2] (Scheme 1). This approach requires the preparation of a precursor carrying the C21–C20 vinyl iodide and C18–C19 vinyl stannane functionalities for the cyclization process under the catalytic influence of palladium(0). Disconnection of the indicated NH–CO linkage led to building blocks **3** and **4**, which became our first subtargets.

The synthesis of the C13–C19 vinyl stannane fragment **4** is summarized in Scheme 2. Thus, the α,β-unsaturated ester **5**[3] was converted to its TIPS ether **6** (95% yield) and thence reduced with DIBAL-H (87% yield) to afford allylic alcohol **7**. The MCPBA-mediated epoxidation of **7** proceeded stereoselectively to afford epoxide **8** in 100% yield (β:α epoxide ratio *ca.* 6:1). Regioselective epoxide opening[4] of **8** by



Scheme 1 Retrosynthetic analysis of sanglifehrin model system **2**.

CH_2=$CHCH_2CH_2MgBr$[5] in the presence of CuI furnished diol **9** (80% yield), whose selective protection as a pivaloate ester proceeded smoothly (95% yield) to afford monopivaloate **10**. Desilylation of **10** with TBAF provided **11** (81% yield) which was subjected to Wacker oxidation[6] and internal ketalization to furnish **12** in 88% overall yield *via* the corresponding dihydroxy ketone. Sequential hydrogenolysis of the benzyl ether group from **12**, tetrapropylammonium perruthenate (TPAP)–NMO[7] oxidation of the resulting alcohol (83% for two steps), and reaction with $(MeCO)C(=N_2)PO(OMe)_2$[8] in the presence of K_2CO_3 led to terminal alkyne **14** (98%) *via* aldehyde **13**. Regio- and stereoselective addition of Bu_3SnH to acetylenic compound **14** proceeded in the presence of catalytic amounts of $PdCl_2(PhCN)_2$, P(*o*-Tol)$_3$ and Pr^i_2NEt to afford vinyl stannane **15** in 79% yield (regioselectivity > 20:1). The latter (**15**) was oxidised in high yield to carboxylic acid **4** by sequential treatment with TPAP–NMO and $NaClO_2$ (NaH_2PO_4, 2-methylbut-2-ene) and was judged to be of sufficient purity after work-up to be used as such in the subsequent coupling with amide **3**.

The second required fragment, compound **3**, was synthesized according to Scheme 3. Thus, coupling of *m*-hydroxybenzaldehyde **16** with phosphonate **17**[9] in the presence of DBU proceeded smoothly to afford olefinic product **18** in geometrically pure form (90% yield). The asymmetric hydrogenation of **18** was carried out in the presence of [SS-Et-DuP-Rh]$^+$TfO$^-$ catalyst[10] and was followed by hydrogenolysis of the Cbz group

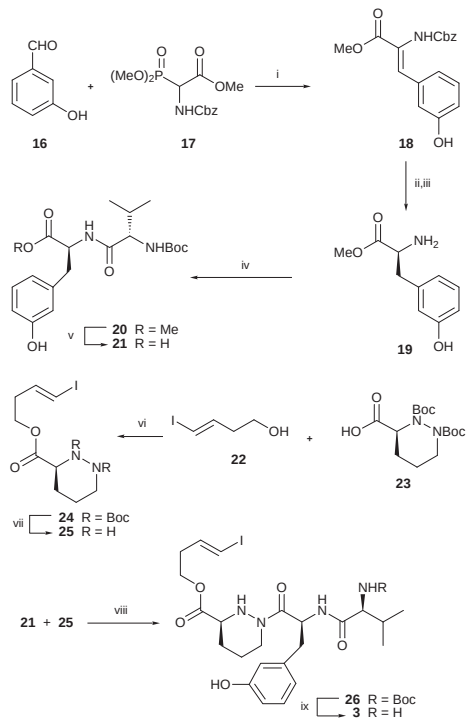
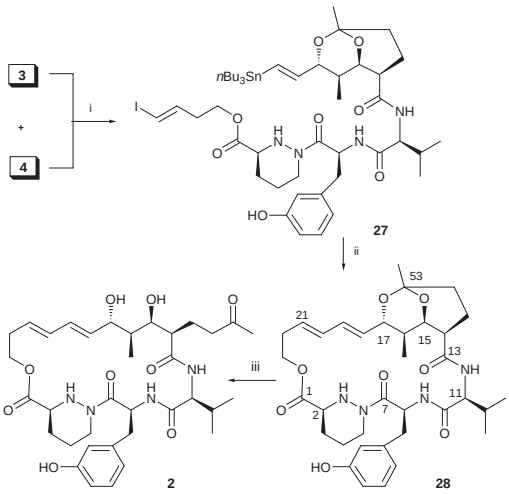


Scheme 3 *Reagents and conditions:* i, DBU (2 equiv.), CH_2Cl_2, 25 °C, 2 h, 90%; ii, [(*S*,*S*)-Et-DuP-Rh]$^+$TfO$^-$ (0.7 mol%), 60 psi, 96 h, 98% ee, 90%; iii, H_2, 10% Pd/C, MeOH, 25 °C, 12 h, 96%; iv EDC (3 equiv.), HOAt (3 equiv.), CH_2Cl_2, 0 → 25 °C, 3 h, 78%; v, LiOH (2 equiv.), THF–H_2O (3 : 1), 0 → 25 °C, 1.5 h, 89%; vi, EDC (2 equiv.), 4-pyrolidinopyridine (0.1 equiv.), Pr$^i_2$NEt (1 equiv.), CH_2Cl_2, 0 → 25 °C, 80%; vii, TFA–CH_2Cl_2 (1 : 1), 0 → 25 °C, 2 h, viii, HOAt (1 equiv.), Pr$^i_2$NEt (3 equiv.), EDC (1.2 equiv.), CH_2Cl_2, 0 → 25 °C, 3.5 h, 66% for two steps; ix, TFA–CH_2Cl_2 (1 : 1), 0 → 25 °C, 2 h.



Scheme 4 *Reagents and conditions:* i, HATU (1 equiv.) Pr$^i_2$NEt (4 equiv.) DMF, 0 → 25 °C, 10 h, 51% over three steps from **15**; ii, $Pd_2(dba)_3$·$CHCl_3$ (0.15 equiv.), $AsPh_3$ (0.6 equiv.), Pr$^i_2$NEt (10 equiv.), DMF, 25 °C, 3 h, 40%; iii, 0.8 M H_2SO_4, THF–H_2O (4 : 1), 25 °C, 10 h.

(H_2, 10% Pd/C), furnishing amino acid derivative **19** in 98% *ee* and 96% yield. Coupling of **19** with the Boc derivative of valine, facilitated by 1-(3-dimethylaminopropyl)-3-ethylcarbodümide hydrochloride (EDC) and 1-hydroxy-7-azabenzotriazole (HOAt)[11] gave peptide **20** in 78% yield. The next step involved mild hydrolysis of the methyl ester group of **20** (LiOH, THF : H_2O) to afford the carboxylic acid **21** (89% yield), whose coupling with piperazic acid derivative **25** (EDC, HOAt) led to product **26** (66% yield from **25**). Compound **25** was prepared by coupling of fragments **22**[12] and **23**[13] (80% yield), followed by TFA-induced removal of the Boc groups. Liberation of the amino group from **26** furnished segment **3** in high yield which was used directly in the coupling with acid **4**.

Union of fragments **3** and **4** proceeded smoothly in the presence of *o*-(7-azabenzotriazol-1-yl)-*N*,*N*,*N*′,*N*′-tetramethyluronium hexofluorophosphate (HATU),[11] furnishing the cyclisation precursor **27** (51% over three steps from **15** *vs*. 58% over two steps from **3**), whose cyclisation was realized upon exposure to $Pd_2(dba)_3$ and $AsPh_3$[14] in DMF at room temperature affording compound **28**† (40% yield). Acidic rupture of the internal ketal **3** furnished the sanglifehrin model system **2** as part of a three component mixture presumably due to the formation of two diastereomeric six-membered ring lactols[1a] [HMRS (FAB) calc. for $C_{35}H_{50}N_4O_9$ (M+Cs): 803.2632, found 803.2606].

The described chemistry demonstrates the feasibility of an intramolecular Stille coupling approach to sanglifehrin's macrocyclic skeleton and paves the way for a total synthesis of this novel natural product. A solid phase version of this strategy may also be envisioned, as can the application of the developed technology to combinatorial sanglifehrin libraries for biological screening.

We thank Dr D. H. Huang and Dr G. Siuzdak for NMR and mass spectroscopic assistance. This work was financially supported by the NIH (USA), The Skaggs Institute for Chemical Biology, and grants from Pfizer, Schering Plough, Hoffmann La Roche, Merck, Dupont, and Parke-Davis.

Received (in Cambridge, UK) 17th February 1999, Accepted 11th March 1999

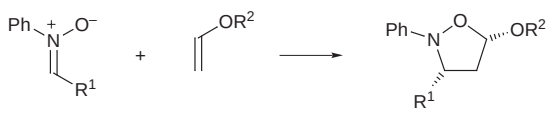
A highly diastereo- and enantioselective 1,3-dipolar cycloaddition reaction of nitrones with alkenes catalyzed by chiral polybinaphthyl Lewis acids has been developed giving isoxazolidines with up to 99% ee; the chiral polymer ligand shows almost identical stereoselectivity to its monomeric version but has the advantage of easy recovery and reuse, and this work further demonstrates that a rigid and sterically regular polymer chain can be used to preserve the catalytic properties of monomeric catalysts.

The potential of polymer-based catalysts, compared to the traditional monomeric catalysts, has stimulated the development of new polymeric chiral Lewis acid catalysts for asymmetric catalysis.[1] Easy recovery of the reusable catalyst/ligand and an often simplified purification procedure are among the obvious advantages of this class of catalysts. Furthermore, these catalysts may lead to the development of enantioselective continuous reactions by means of flow reactors or flow membrane reactors.

Two entries have been used to prepare chiral polymeric catalysts: (i) the traditional approach, where a chiral monomeric ligand is attached to a polymer support, often resulting in a marked decrease in selectivity when compared to the monomeric ligand,[1] and (ii) systems in which the optically active monomer is a part of a polymer backbone. Recently, optically active polymeric ligands of the latter type, based on a binaphthol (BINOL) backbone, have been developed,[1c,2] and shown the ability, in combination with a Lewis acid, to catalyse the addition of Et_2Zn to aldehydes[3] and a hetero-Diels–Alder reaction with high enantioselectivity.[4]

The asymmetric 1,3-dipolar cycloaddition (1,3-DC) reaction between nitrones and alkenes has been studied extensively recently because of the importance of the isoxazolidines formed.[5] The development of catalytic enantioselective 1,3-DC reactions has mainly involved electron-deficient alkenes reacting with various types of nitrones,[6] whereas only a few examples of catalytic enantioselective cycloaddition reaction of nitrones, activated by chiral Lewis acid complexes, with electron-rich alkenes are known.[7]

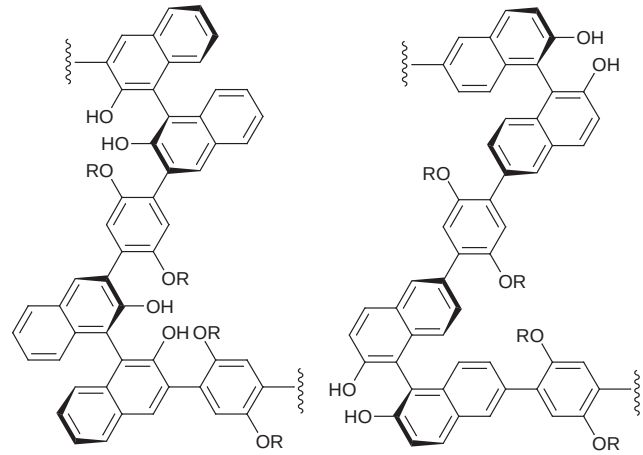
Here we report the first example of a polymer-catalyzed highly diastereo- and enantioselective 1,3-DC reaction. In this study, the reaction of *N*-phenyl nitrones **1** with vinyl ethers **2** gives the *exo*-diastereomer of the isoxazolidines **3** catalyzed by the polymeric ligand (*R*)-**4**, as well as the monomeric counterpart-ligands (*R*)-**6**, in combination with $AlMe_3$ as the Lewis acid [(eqn. (1)]. To the best of our knowledge only one example of a



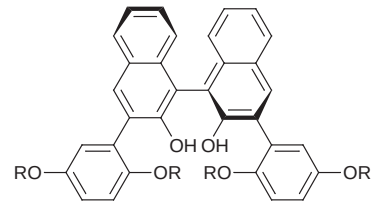
1 **2** *exo*-**3** (1)

1,3-DC reaction for nitrones with electron-deficient alkenes catalyzed by a polymeric catalyst, based on solid supported Ti-TADDOLates, has been reported and with varying diastereoselectivity (52–86% de), but with only modest enantioselectivity (< 56% ee).[8]

The active polymeric chiral aluminium catalysts were prepared *in situ* by addition of a solution of $AlMe_3$ in hexane to



(*R*)-**4** R = C_6H_{13} (*R*)-**5** R = C_6H_{13}



(*R*)-**6** R = C_6H_{13}

a solution of the polymer (*R*)-**4** (20 mol%) in CH_2Cl_2 (1 mL). The solution was allowed to stand for 1 h before diphenyl nitrone **1a** and ethyl vinyl ether **2a** were added in an 1:2.5 ratio. Complete conversion of **1a** was observed after 2 h whereupon the catalysts were hydrolyzed and precipitated by addition of MeOH (1–2 mL).[9] The polymeric ligand was precipitated and isolated by centrifugation and the clear solution was removed by decantation and evaporated to give isoxazolidine *exo*-**3a** in nearly quantitative isolated yield (97%) as an enantiopure compound (99% ee) and with very high diastereoselectivity (> 96% de). The purity of the reaction without any form of purification is notable as a ^1H NMR spectrum of the crude product after evaporation only gives signals consistant with *exo*-**3a**. When the reaction was tested with 10 mol% catalyst, a slight decrease in enantioselectivity was observed, but due to the fact that the polymeric ligand can be recycled (*vide infra*) with only moderate degeneration the use of 20 mol% is reasonable.

The use of the 6,6′ linked polymeric catalyst (*S*)-**5**–AlMe (20 mol%) on the same substrates resulted in a 75 : 25 *exo* : *endo* ratio of **3a** and a significant decrease in enantioselectivity (23%

ee). Despite this low selectivity, this result is better than the reaction using the (*S*)-1,1′-bi-2-naphthol-derived catalyst which gives the same diastereoselectivity, but less than 5% ee.[7c] The catalytically active species for the (S)-1,1′-bi-2-naphthol-based aluminium catalyst may not be monomeric, but rather may be an aggregate.

The polymeric catalyst (*R*)-**4**–AlMe was applied to the 1,3-DC reaction of different nitrones **1a**,**b** with vinyl ethers **2a**–**c**. Generally, *exo*-**3a**–**d** were isolated in very high yield, diastereoselectivity and ee (Table 1, entries 1–5).

The polymeric ligand (*R*)-**4** has been isolated and reused successfully in at least four consecutive reactions of nitrone **1a** with ethyl vinyl ether **2a**, as shown in Fig. 1. Both the yield and ee of *exo*-**3a** showed only slight decreases after the catalyst had been reused four times. The reason for the slight decrease is probably that the reactions are performed on a small scale and that a small part of the catalyst is lost when recovered. However, after four cycles the catalyst still gives *exo*-**3a** in 88% yield and with 90% ee.

It is often observed that the traditional polymeric catalysts give lower ee's than their monomeric counterparts. Therefore, the reaction was carried out with the monomeric 3,3'-bis(2,5-dihexyloxyphenyl)-BINOL (*R*)-**6** as the ligand. When (*R*)-**6**, in combination with $AlMe_3$ (10 mol%) was used as the catalyst, the 1,3-DC reaction between nitrone **1a** and ethyl vinyl ether **2a** showed complete conversion after 1 h with the same high selectivities as found using the polymeric catalyst (Table 2, entry 1). Similar selectivities were also found when the reaction was carried out in the presence of 10 mol% of the catalyst at 0 °C (entry 2) and in toluene (entry 3). This ligand system proved to be quite general. When the same conditions were used for reaction of the nitrones **1a**–**c** with the vinyl ethers **2a**,**b**, the isoxazolidines exo-**3a**–**g** were isolated in good yield (76–93%), very high *endo* : *exo* ratio (96% de) and chiral induction (93% ee) (Table 2, entries 4–8).

The present work on the use of the poly-BINOL–AlMe catalyst represents the first chiral polymer catalyzed highly regio-, diastereo- and enantioselective 1,3-dipolar cycloaddition reaction of nitrones with alkenes. The chiral polymeric ligand can be easily recovered, and after multiple recycling, the

polybinaphthyl ligand still maintains most of its original catalytic properties. Unlike many traditional polymer catalysts, the rigid and sterically regular binaphthyl polymer (*R*)-**4** shows almost the same high stereoselectivity as its monomeric version. This demonstrates that a rigid and sterically constrained polymer backbone can be used to preserve the steric and electronic environment of monomeric catalysts, and thus to preserve their catalytic properties.

This work was made possible by a grant from The Danish National Research Foundation. Q. S. H. and L. P. acknowledge the partial support of the US National Science Foundation (DMR-9529805).

9 Experimental procedure. The appropriate ligand (0.02 mmol) was placed in a 5 mL Schlenk flask flushed three times with N_2, and CH_2Cl_2 (1 mL) was added with a syringe. To this solution was added a 2 M solution of $AlMe_3$ in heptane (10 mL, 0.02 mmol). The solution was stirred for 1 h and the nitrone (0.2 mmol) and vinyl ether (0.5 mmol) were added. After the appropriate reaction time, the reaction was quenched with MeOH (1 mL) and the ligand was isolated by centrifugation. The clear solution was evaporated to give the single diasteromer of *exo*-**3** as a pure product (TLC, ^{1}H and ^{13}C NMR).

Unprecedented μ-1,2,3κ*S*:4,5κ*N* coordination mode of the thiocyanate anion in two new double salts of silver(I), $AgSCN·2AgNO_3$ and $AgSCN·AgClO_4$

Guo-Cong Guo and Thomas C. W. Mak*

Department of Chemistry, The Chinese University of Hong Kong, Shatin, New Territories, Hong Kong, China. E-mail: tcwmak@cuhk.edu.hk

Received (in Cambridge, UK) 9th March 1999, Accepted 31st March 1999

The double salts $AgSCN·2AgNO_3$ and $AgSCN·AgClO_4$ both feature an unprecedented μ_5-1,2,3κ*S*:4,5κ*N* coordination mode of the thiocyanate ligand, which generates a two- or three-dimensional network according to the relative coordinating capability of the co-existing nitrate or perchlorate anion.

With the advent of supramolecular chemistry, the coordination concept as applied to metal ions has been extended to polyatomic species such as neutral molecules, organic cations, and anions of various types.[1] In the design of polynuclear metal complexes[2] and the crystal engineering of coordination networks,[3] the possible coordination modes of anionic ligands have to be considered in the synthetic strategy. In this context, it is of interest to determine the highest ligation number[4] (HLN) of simple inorganic polyatomic anions, namely the largest number of coordination bonds that a particular anion can form with neighboring metal centers in its complexes. For example, the HLN of the μ_6-carbonato group in the hexanuclear oxovanadium(IV) cluster $[(VO)_6(CO_3)_4(OH)_9]^{5+}$ is six.[5]

The group 11 metal(I) ions, each having a spherical d^{10} electronic configuration, can in principle serve as ideal probes for obtaining the HLN of small inorganic anions. The synthesis of suitable complexes for such investigations is favored by the tendency of the monovalent coinage metal ions to form aggregates through homoatomic d^{10}–d^{10} interactions.[6,7] Furthermore, silver(I) has distinct advantages over the other members of the coinage triad, as copper (I) is easily oxidized to the +2 oxidation state, and gold(I) has a strong tendency to adopt linear digonal coordination geometry and is also susceptible to disproportionation into Au(III) and Au(0). Our recent studies on the crystal structures of double salts of silver have shown that the cyanide ion has a HLN of four in $3AgCN·2AgF·3H_2O$,[8] and the azide ion has a HLN of six in $AgN_3·2AgNO_3$.[9]

The coordination modes of the ambident thiocyanate ligand[10] in their metal complexes exhibit considerable diversity (Fig. 1), and modes **F**, **H** and **K** are hitherto unknown.[11] Thus far the maximum coordinating capacity of SCN^- involves the formation of two coordination bonds by its nitrogen atom, or three coordination bonds by its sulfur atom, but not simultaneously. Here, we report two novel double salts $AgSCN·2AgNO_3$ **1** and $AgSCN·AgClO_4$ **2**† in which the thiocyanate group exhibits an unprecedented μ_5-1,2,3κ*S*:4,5κ*N* coordination mode **K** with a HLN of five.

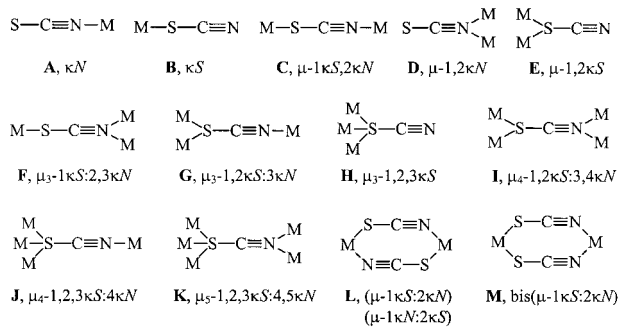

Fig. 1 Possible coordination modes of the thiocyanate ligand.

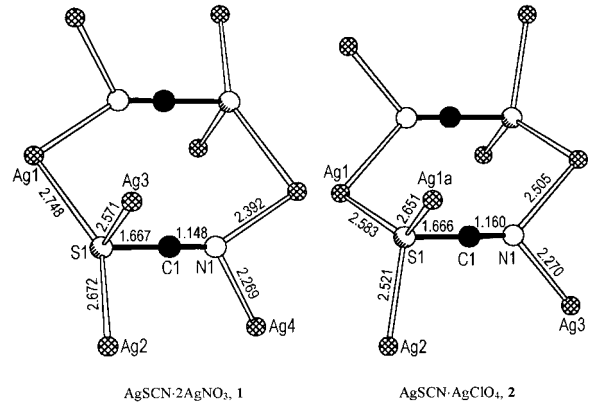
The crystal structures‡ of both **1** and **2** feature a common centrosymmetric, nearly planar eight-membered $(AgSCN)_2$ ring that has angularly distorted hexagonal geometry, which can be regarded as a basic architectural unit for constructing the coordination network. In each planar heterocycle, there are two 'substituent' silver atoms bonded to each sulfur atom and one 'substituent' silver atom bonded to each nitrogen atom, as shown in Fig. 2. To our knowledge the nearly planar $(AgSCN)_2$ ring moiety with six additional silver atoms attached to it and the resulting μ_5-1,2,3κ*S*:4,5κ*N* coordination mode of the thiocyanate ligand are both unprecedented.

In the crystal structure of **1**, the basic architectural units share the S-bonded 'substituent' silver atoms of type Ag2 and Ag3 along the $[1\bar{1}0]$ and [110] directions to generate a corrugated layer (Fig. 3), with the nitrate anions located between adjacent layers. One of the two independent NO_3^- anions functions as a tightly bridged ligand to silver atoms of type Ag1 and Ag4 [average Ag–O 2.445(3) Å], and the other as a loosely bridged one to silver atoms of type Ag2 and Ag4 [average Ag–O



$AgSCN·2AgNO_3$, **1** $AgSCN·AgClO_4$, **2**

Fig. 2 Basic architectural units in **1** and **2**, each consisting of a nearly planar eight-membered $(AgSCN)_2$ ring with six 'substituent' silver atoms.

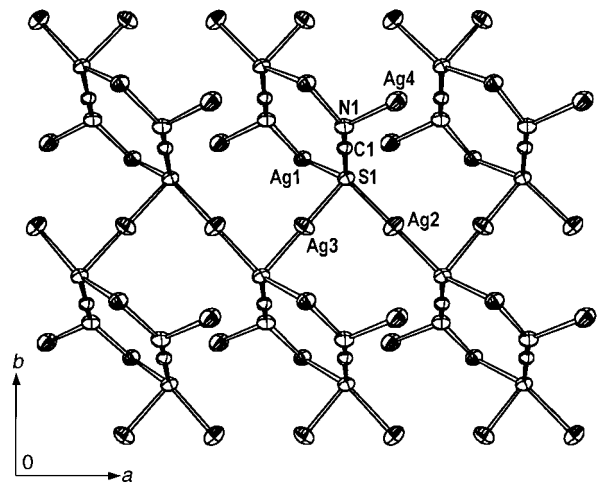


Fig. 3 Corrugated layer formed by linkage of basic architectural units in **1**. The interlayer NO_3^- ligands have been omitted for clarity.

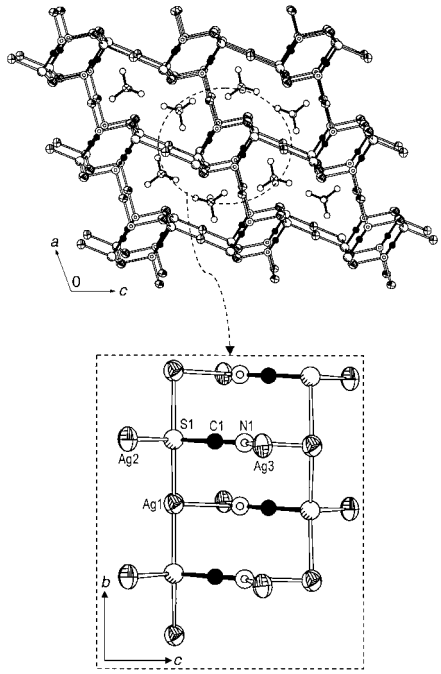

Fig. 4 Crystal structure of **2** viewed along the *b* direction (top), and a hexagonal channel viewed along the *a* direction showing it as a ladder-like chain of fused $(SCN)_2$ rings.

2.579(4) Å], thus linking adjacent layers along the *c* direction into a three-dimensional framework. Interestingly, there co-exist four kinds of coordination modes of silver atoms in **1**, namely linear coordination for type Ag3 atoms at $\bar{1}$ [Ag3–S1 2.571(1) Å], nearly coplanar triangular coordination for type Ag1 atoms [Ag1–N1 2.392(4), Ag1–O2 2.479(3), Ag1–S1 2.748(2) Å, sum of bond angles at Ag1 358.5°], distorted square coordination for type Ag2 atoms at $\bar{1}$ [Ag2–O6 2.566(4), Ag2–S1 2.672(1) Å] and distorted tetrahedral coordination for type Ag4 atoms [Ag4–N1 2.269(4), Ag4–O3 2.411(3) Ag4–O5 2.591(4), Ag4–S1 2.861(2) Å].

In the crystal structure of **2**, fusion of the basic architectural units along the *b* direction generates a ladder-like chain, which takes the appearance of a hexagonal column when viewed in the *b* direction (Fig. 4). The hexagonal columns are connected by sharing the S-bonded Ag2 atoms (site symmetry 2) along the *c* direction and the N-bonded Ag3 atoms (site symmetry $\bar{1}$) along the *a* direction to form a three-dimensional channel-type network, as shown in Fig. 4. The perchlorate anions are stacked as a double column within each channel. In contrast to the nitrate anions in **1**, the perchlorate anions in **2** do not directly bond to silver atoms, leading to lower coordination numbers, namely linear coordination for type Ag2 [Ag2–S1 2.521(2) Å] and Ag3 [Ag3–N1 2.270(6) Å] atoms, and trigonal pyramidal coordination for the type Ag1 atom [Ag1–S1 2.583(2) and 2.651(2), Ag1–N1 2.505(6) Å].

The sulfur and nitrogen atoms of the thiocyanate unit in both **1** and **2** are asymmetrically bonded to silver atoms. The Ag–S and Ag–N distances are significantly longer than those found in AgSCN [Ag–S 2.428(11), Ag–N 2.223(28) Å],[12] respectively, but still fall within the range found in many transition metal thiocyanate complexes.[13] The thiocyanate units in both **1** and **2** are essentially linear. The S–C and C≡N distances of the thiocyanate ligands in **1** [S–C 1.669(4), C–N 1.148(5) Å] and **2** [S–C 1.666(2), C–N 1.160(3) Å] are in good agreement with those found in AgSCN [S–C 1.64(3), C–N 1.19(7) Å][12] and many transition metal thiocyanates.[11] In contrast to AgSCN, in which the cations and anions are arranged alternately to form an infinite zigzag chain such that each silver atom is only bound to one nitrogen and one sulfur atom,[12] the thiocyanate unit bridges five silver atoms in both double salts **1** and **2** to form two- and three-dimensional networks, respectively, resulting in a variety of coordination environments around individual silver atoms.

Notes and references

† *Synthesis*: AgSCN was prepared by mixing aqueous solutions of ammonium thiocyanate and silver nitrate at room temperature. The white precipitate was filtered, washed several times with de-ionized water, and temporarily stored in wet form in the dark.

Synthesis of $AgSCN{\cdot}2AgNO_3$ **1**: wet AgSCN was added to 2 mL of a concentrated MeCN solution of $AgNO_3$ (*ca.* 40%) with stirring until saturated at 40 °C. The excess amount of AgSCN was filtered off, and the solution was placed into a desiccator charged with P_2O_5. In the course of two days colorless crystals of $AgSCN{\cdot}2AgNO_3$ were obtained in nearly quantitative yield. The compound is stable when immersed in its mother liquor; it is hygroscopic and slowly decomposes in air.

Synthesis of $AgSCN{\cdot}AgClO_4$ **2**: the above procedure was repeated using EtOH and silver perchlorate instead of MeCN and silver nitrate, respectively. The distinct difference between the two preparations is that the filtrate of **2** turned from colorless to pale purple and the cyrstals of **2** are pale purple.

‡ *Crystal data*: **1**: colorless prism, Siemens P4/PC diffractometer, Mo-Kα radiation (λ = 0.71073 Å), 2275 unique reflections (R_{int} = 0.0247), 1423 of which with $I > 2\sigma(I)$ were considered as observed, triclinic, space group $P\bar{1}$ (no. 2), Z = 2, D_c = 4.256 g cm^{-3}, a = 6.569(5), b = 7.732(1), c = 8.031(2) Å, α = 104.09(1), β = 93.94(4), γ = 90.04(3)°, V = 394.6(3) Å^3, μ = 76.41 cm^{-1}, $R1$ = 0.0394, GOF = 0.990.

2: pale purple plate, Rigaku RAXIS IIC diffractometer, Mo-Kα radiation (λ = 0.710 73 Å), 1086 unique reflections (R_{int} = 0.0862), 1032 of which with $I > 2\sigma(I)$ were considered as observed, Monoclinic, space group $C2/c$ (No. 15), Z = 8, D_c = 3.958 g cm^{-3}, a = 15.294(4), b = 4.766(1), c = 18.278(4) Å,β = 109.89(2)°, V = 1252.7(5) Å^3, μ = 69.55 cm^{-1}, $R1$ = 0.0642, GOF = 1.116. The structures of **1** and **2** were solved by the direct method (SHELXS-86) and refined by full-matrix least squares on F^2 using the Siemens SHELXTL-93 (PC Version) package of crystallographic software. All non-hydrogen atoms were refined with anisotropic thermal parameters. Results of the crystal structure determination (CSD-410622 and 410623) have been deposited at the Fachinformationszentrum Karlsruhe, D-76344, Eggenstein-Leopoldshafen, Germany (fax: (+49)7247-808-666; e-mail: crysdata@fiz-karlsruhe.de). Possible intermediates in the selective catalytic reduction of NO_x: differences in the reactivity of nitro-compounds and *tert*-butyl nitrite over γ-Al_2O_3

Virginie Zuzaniuk,* Frederic C. Meunier*† and Julian R. H. Ross

Centre for Environmental Research, University of Limerick, National Technological Park, Limerick, Ireland. E-mail: virginie.zuzaniuk@ul.ie

Received (in Liverpool, UK) 19th January 1999, Accepted 24th March 1999

Nitromethane decomposes over alumina to give various surface species such as isocyanates and its oxidation by O_2 yields significant amounts of ammonia; on the other hand, *tert*-butyl nitrite decomposes to give only surface nitrate species and mostly oxides of nitrogen are formed by reaction with O_2.

Several authors have suggested that the selective catalytic reduction (SCR) of nitrogen oxides by hydrocarbons proceeds *via* organic nitro or nitrite intermediates over various catalysts such as promoted ZSM5[1–3] or Pt/SiO_2.[4] For the latter material, Tanaka *et al.* reported that the oxidation of both nitromethane and *n*-butyl nitrite gave products similar to those of the SCR of NO_x.[4] The gas phase decomposition and oxidation of nitromethane and its reactivity have previously been studied in connection with the NO_x-SCR over different catalysts such as Co-ZSM5, H-ZSM5, Na-ZSM5, SiO_2 or Al_2O_3.[5,6] The adsorption of this molecule on Al_2O_3, one of the most active single metal oxides for SCR reactions, has also been studied by Yamaguchi.[7] While organic nitro or nitrite species have not usually been differentiated in their involvement in the SCR reaction, our present work reports significant differences in the adsorption and reaction/oxidation of nitromethane and *tert*-butyl nitrite over Al_2O_3. These differences stress the need to consider differently the role of these compounds in the modelling of SCR reactions over alumina.

The catalytic experiments were carried out in a quartz flow microreactor (4 mm internal diameter) using 200 mg of Al_2O_3 (Alcan AA400, 150 $m^2\ g^{-1}$) previously calcined for 6 h at 973 K . The reactant gases used were O_2 (BOC 99%) and Ar (Air Products, high purity grade). Nitromethane (Fluka, puriss $\geqslant$ 99.0%) and *tert*-butyl nitrite (Fluka, assay $\geqslant$ 90%) were fed using a saturator flushed by the O_2 stream, which was then added to the Ar stream. The total rate of flow was 100 $cm^3\ min^{-1}$ with 1.5% O_2 in the gas mixture. The saturator was kept at room temperature and at 273 K for the experiments using nitromethane and *tert*-butyl nitrite, respectively. The products of reaction were analysed using a gas-cell (Foxboro®) fitted in a FTIR spectrophotometer (Nicolet 550®), 64 scans with a resolution of 1 cm^{-1} were usually collected. The diffuse reflectance FTIR measurements (DRIFTS) were carried out *in situ* using a finely ground sample (*ca.* 30 mg) of Al_2O_3 and the spectra were recorded after 128 scans at a resolution of 2 cm^{-1}. The catalytic experiments and the *in situ* measurements were both carried out at 573 K under steady state conditions. The nitromethane and *tert*-butyl nitrite were pre-adsorbed on the Al_2O_3 at room temperature for the *in situ* DRIFTS experiments.

Fig. 1(a) shows the DRIFT spectrum of the species formed from the adsorption of nitromethane on Al_2O_3 at room temperature and subsequently heated to 573 K in argon alone. The bands at 1376 cm^{-1} ($\nu^{sym}{}_{OCO}$), 1393 cm^{-1} (δ_{CH}), 1598 cm^{-1} ($\nu^{a}{}_{OCO}$), 2902 cm^{-1} (ν_{CH}) and 3003 cm^{-1} (combination band $\nu^{a}{}_{OCO} + \delta_{CH}$) can be assigned to a formate species; the vibration mode to which each band corresponds is given in parentheses.[8,9] The small band at 2092 cm^{-1} could be characteristic of a linearly adsorbed cyanide whereas the major band at 2228 cm^{-1} could be characteristic of an (inorganic) isocyanate group, a bridged cyanide or a nitrile species.[9,10] The adsorption of HCN on our Al_2O_3 showed in the spectral region 2000–2300 cm^{-1}, only a band at 2092 cm^{-1} whereas a band at 2228 cm^{-1} was observed when cyclohexyl isocyanate was adsorbed. Additional experiments have shown that the band at 2228 cm^{-1} derived from nitromethane was readily displaced by water at 573 K and NH_3 was observed in the gas phase. This high reactivity with water suggests that this band should be assigned to an isocyanate species rather than to a cyanide/nitrile species which are significantly less reactive towards water.[11,12] Other peaks were detected at 1447, 1681 and 3390 cm^{-1} which could tentatively be assigned to the ν_{NCO}, ν_{CO} and ν_{NH} of carbamic acid (NH_2CO_2H), respectively. Similar DRIFTS spectra to that observed with nitromethane were obtained with several other nitro compounds: nitroethane, 2-nitropropane and nitrobutane.

The DRIFT spectrum obtained from the adsorption of *tert*-butyl nitrite on Al_2O_3 at room temperature followed by heating to 573 K in Ar alone [Fig. 1(b)] was markedly different from that obtained using nitromethane. Only nitrate species, with characteristic bands at 1258, 1306 and 1554 cm^{-1}, were detected. Separate adsorption experiments over the same Al_2O_3 sample using NO, NO_2 and O_2 showed that the bands at 1258 and 1554 cm^{-1} were coupled, whereas the band at 1306 cm^{-1} was coupled with a band at 1580 cm^{-1}. This latter could not be observed here because it overlapped with the band at 1554 cm^{-1}. According to the literature, these bands correspond to two different types of bidentate nitrate species.[9] Some CH vibrations were also observed following the pre-adsorption of

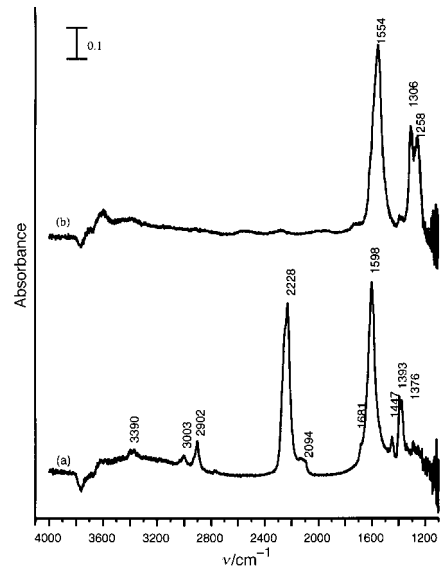

Fig. 1 DRIFT spectra at 573 K in argon of Al_2O_3 following pre-adsorption of (a) nitromethane and (b) *tert*-butyl nitrite at room temperature.

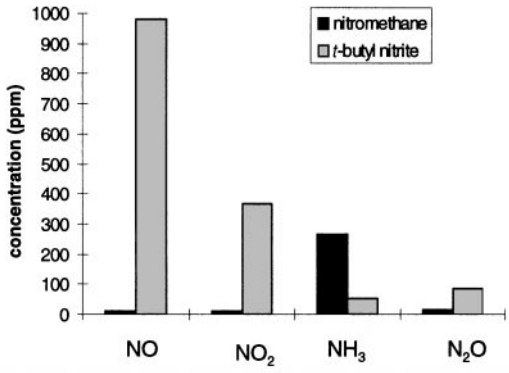

Fig. 2 Distribution of the products of reaction in the oxidation of nitromethane and *tert*-butyl nitrite at 573 K over Al_2O_3. Feed: 1.5% O_2 + 405 ppm nitromethane or 1700 ppm *tert*-butyl nitrite in Ar. Total flow 100 $cm^3\ min^{-1}$.

the *tert*-butyl nitrite at room temperature. However, these CH bands were readily displaced with increasing temperature (under argon) and only the ad-NO_x species bands remained on the sample surface at 573 K. Details of these experiments will be given in a subsequent paper.

Fig. 2 shows the distributions of the main products of the oxidation of nitromethane and *tert*-butyl nitrite over alumina: NO, NO_2, N_2O and NH_3 were detected in both cases. Traces of HCN (not quantified) were also detected during oxidation of nitromethane and *tert*-butyl nitrite. Any N_2 formed could not be detected as it is inactive in the IR. The oxidation of nitromethane yielded a significant proportion (267 ppm) of NH_3, but NO (12 ppm), NO_2 (10 ppm) and N_2O (14 ppm) were formed only in much lower concentrations. In contrast, the oxidation of *tert*-butyl nitrite yielded oxides of nitrogen (*i.e.* NO: 983 ppm, NO_2: 366 ppm and N_2O: 87 ppm) as the main products of reaction whereas only traces of NH_3 (51 ppm) were observed.

The formation of NH_3 from the oxidation of nitromethane can be explained by the following reaction mechanism [eqn. (1)]:[5,6,12,13]

$$MeNO_2 \longrightarrow HNCO_{(ads)} + H_2O \longrightarrow NH_2CO_2H_{(ads)} \longrightarrow CO_2 + NH_3 \quad (1)$$

The formation of the isocyanate species from the nitro-compound is believed to occur through the dehydration of the enol tautomer of nitromethane followed by isomerisation of the corresponding nitrile *N*-oxide. The intermediacy of carbamic acid in eqn. (1) is supported by the observation by DRIFTS of IR bands at 1448, 1681 and 3390 cm^{-1} which are compatible with its molecular structure. The reaction between the surface isocyanate species ($HNCO_{ads}$) and H_2O is probably fast enough on the Al_2O_3 surface to prevent the release of isocyanic acid (HNCO) to the gas phase, as no HNCO was detected during the catalytic oxidation experiment.

As described above, the adsorption of *tert*-butyl nitrite on Al_2O_3 gave rise to nitrate surface species [Fig. 1(b)], and so the formation of NO and NO_2 during the oxidation of this molecule was easily understandable. It has previously been reported that NO and NO_2 were formed in TPD experiments of nitrate species adsorbed on various catalysts.[14]

As has been often suggested,[1–3] organic nitro and organic nitrite compounds might both be intermediate species in the SCR of NO_x by hydrocarbons since their oxidation products were similar to those obtained in this reaction. However, the present work shows that their reactivity was quite different on alumina and hence that any reaction scheme for the SCR reaction must associate with them a specific role. This is of particular importance with regards to some recent results from our laboratory[15] which indicate that the formation of organo-nitrogen compounds may be a crucial step in the C_3H_6-SCR of NO over alumina. Among other reactions, it would be quite understandable if any ammonia (or, for that matter, any primary amine from which ammonia could be derived) formed from the decomposition of a nitro-type compound were to react with the NO_2 formed from the decomposition of a nitrite-type compound to yield N_2 as in a typical ammonia-SCR process.

Short and efficient enantioselective total synthesis of angucyclinone type antibiotics (+)-rubiginone B_2 and (+)-ochromycinone

M. Carmen Carreño,* Antonio Urbano and Claudio Di Vitta†

Departamento de Química Orgánica (C-I), Universidad Autónoma, Cantoblanco, 28049-Madrid, Spain. E-mail: carmen.carrenno@uam.es

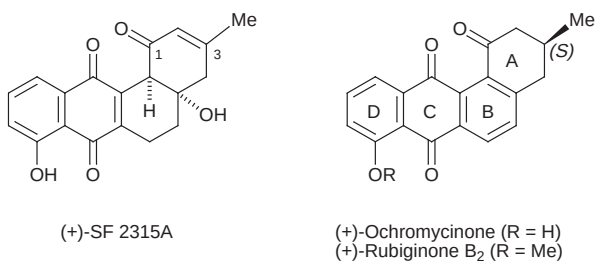
Received (in Liverpool, UK) 26th February 1999, Accepted 15th March 1999

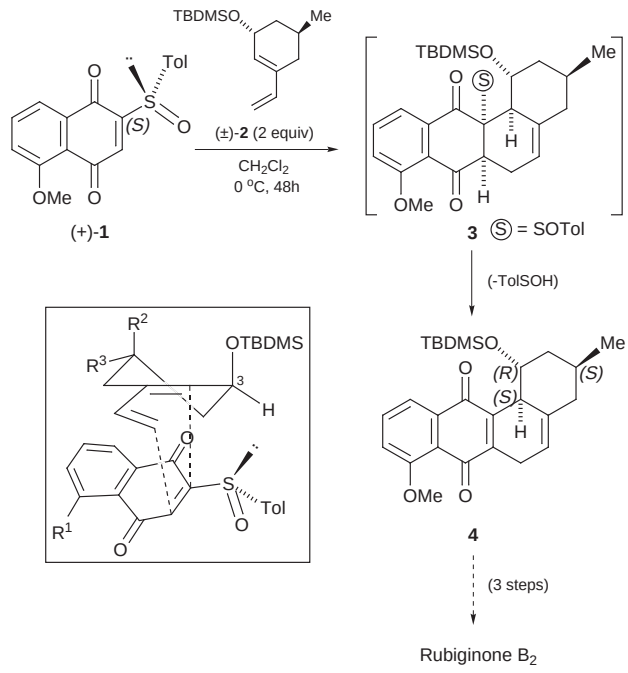
The enantioselective total synthesis of antibiotics rubiginone B_2 and ochromycinone is achieved from enantiopure (*S*)-5-methoxy-2-(*p*-tolylsulfinyl)-1,4-naphthoquinone and a racemic vinylcyclohexene through a short sequence involving a tandem Diels–Alder reaction–sulfoxide elimination process with simultaneous kinetic resolution of the racemic diene, followed by controlled aromatization and functional group deprotection.

Ochromycinone and rubiginone B_2, first isolated respectively by Bowie[1] and Oka,[2] are components of the anguciclinone family, a growing class of natural products with remarkable antibiotic activity and cytotoxicity.[3] The major components of this family show a benz[*a*]anthracene framework of decaketide origin[4] bearing a methyl group at C-3 and an oxygen function at C-1. The 3*S* absolute configuration is also a common characteristic of C-3 non-oxygenated angucyclinones. The main structural differences are found in the aromatic or hydroaromatic nature of the A and/or B rings. The regioselective construction of the angularly fused tetracyclic skeleton has been achieved applying several methods which are summarized in a recent review article.[5] The most general strategy employed is based on the Diels–Alder reaction between a substituted naphthoquinone and a vinylcyclohexene. While several efficient total syntheses have focused on the racemic forms, access to the isolated optically active species remains a problem. The asymmetric syntheses of antibiotics (+)-SF 2315A and urdamycinone B were reported by Sulikowski[6] who used an asymmetric Diels–Alder reaction with an appropriately functionalized chiral diene obtained from (−)-quinic acid as the key step. A second Diels–Alder approach was described by Larsen[7] who achieved the total syntheses of antibiotics (+)-emycin A and (+)-ochromycinone by using a chiral catalyst in the cycloaddition step which allowed the kinetic resolution of the diene partner in a single operation. Finally, chromatographic separation of the diastereoisomeric mixture resulting in the cycloaddition between a *C*-glycosyl juglone and a racemic vinylcyclohexene has also allowed the asymmetric synthesis of urdamycinone B.[8,9] In spite of the structural similarities between (+)-ochromycinone and (+)-rubiginone B_2 (ochromycinone methyl ether), to the best of our knowledge, the latter has never been synthesized in an optically active form.

Our previous work devoted to the use of enantiopure (*S*)-2-(*p*-tolylsulfinyl)-1,4-quinones as dienophiles[10] had shown a high ability of the sulfoxide to control the regiochemistry, *endo*-selectivity and π-facial diastereoselectivity of their Diels–Alder cycloadditions with a wide range of cyclic and acyclic dienes. We established the tandem Diels–Alder reaction–pyrolytic sulfoxide elimination as a general one-pot strategy to enantiomerically pure polycyclic dihydroquinones. More recently,[11,12] we envisaged the ability of the sulfinyl group to promote a double induction in the cycloaddition process leading to the efficient kinetic resolution of differently substituted chiral racemic vinylcyclohexenes.[11] The high facial selectivity achieved was explained by invoking the favored transition state indicated in Scheme 1. This strategy provided a diastereoselective entry into the tetracyclic framework of angucyclinones.[12] To account for this, we reasoned that cycloaddition of a methoxy substituted sulfinylnaphthoquinone such as **1** would provide a short and convergent asymmetric entry into the angucyclinone family. Here we report the application of this novel methodology for the total synthesis of natural antibiotics (+)-rubiginone B_2 and (+)-ochromycinone.

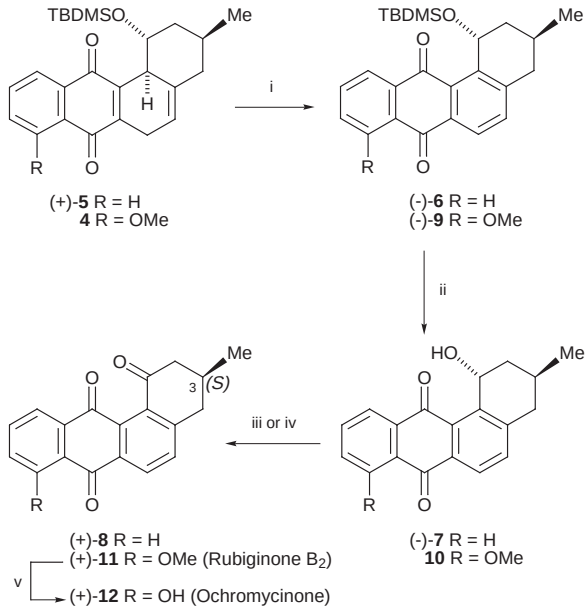
Our approach to an immediate tetracyclic precursor to both natural products is outlined in Scheme 1. We selected the TBDMS protected derivative of *trans*-3-hydroxy-5-methyl-1-vinylcyclohexene **2** as starting material since our previous studies had shown that free OH was less efficient in the *anti/syn* discrimination of the cycloaddition transition states.[11,12] Diene **2** was synthesized from *cis*-3-hydroxy-5-methyl-1-vinylcyclohexene through a Mitsunobu inversion of C-3 followed by protection of the OH group.[11] Thus, cycloaddition of enantiopure (*S*)-5-methoxy-2-(*p*-tolylsulfinyl)-1,4-naphthoquinone (+)-**1**[13] with two equivalents of chiral racemic *trans*-3-[(*tert*-butyldimethylsilyl)oxy]-5-methyl-1-vinylcyclohexene **2** af-





Scheme 1

† On leave from Instituto de Química da Universidade de São Paulo, Brazil.



Scheme 2 *Reagents and conditions*: i, DBU, CH_2Cl_2, 0 °C, 2 h, 81% from **5**, 58% from **1** for two steps; ii, 40% aq. HF, CH_3CN, rt, 1 h, 52% from **6**; iii, air, *hv*, CH_2Cl_2, rt, 2 h, 70% from **7**, 48% from **9** for two steps; iv, PCC, CH_2Cl_2, rt, 8 h, 74% from **7**; v, $AlCl_3$, CH_2Cl_2, rt, 20 h, 86%.

forded the 1,4-dihydroquinone derivative **4**, after pyrolytic elimination of the sulfoxide in the initially formed adduct **3** which occurred spontaneously even at 0 °C. The formation of **4** as a single regioisomer and *anti* diastereoisomer revealed a high efficiency of the sulfinylquinone **1** in controlling both the regioselectivity and diastereoselectivity of the cycloaddition step. Transformation of **4** into rubiginone B_2 only required three steps: aromatization of the B ring, deprotection of the OTBDMS group and further oxidation of the benzylic alcohol function. Unfortunately, compound **4** was not stable enough to be isolated pure due to its easy decomposition. We thus turned our attention to the more stable demethoxy analogue (+)-**5** (Scheme 2), which had been obtained in the reaction between (*S*)-2-(*p*-tolylsulfinyl)-1,4-naphthoquinone and diene (±)-**2**.[11]

Upon treatment with DBU,[14] partial aromatization of compound **5** proceeded rapidly to give the benz[*a*]anthraquinone (−)-**6** in 81% yield (Scheme 2). The OTBDMS protecting group of **6** was removed by treatment with 40% aqueous HF in CH_3CN[15] to provide alcohol (−)-**7** in 52% yield. The oxidation of **7** into the 8-deoxyangucyclinone (+)-**8** was carried out in 70% yield following a photooxygenation process,[16] in which a CH_2Cl_2 solution of **7** was exposed to daylight. This transformation could also be achieved by using a PCC oxidation (74% yield). The optical rotation of **8** was $[\alpha]_D^{20}$ +97 (*c* 0.5, $CHCl_3$), in accordance with those of natural angucyclinones rubiginone B_2[2] and ochromycinone,[1] suggesting the correct *S* absolute configuration at C-3, the only stereocenter present in the molecule. From a ^{1}H-NMR study an 80% ee was determined for (+)-**8** using $Pr(hfc)_3$ as chiral lanthanide shift reagent,‡ showing that no racemization had occurred during the reaction sequence outlined in Scheme 2, which started from derivative (+)-**5** (ee = 80%).

The natural products **11** and **12** were then synthesized following a similar reaction sequence (Scheme 2). Thus, after cycloaddition between (+)-**1** and (±)-**2** (Scheme 1), the crude reaction mixture containing compound **4** was aromatized into benz[*a*]anthraquinone (−)-**9** by treatment with DBU at 0 °C. Derivative **9** could thus be obtained in 58% yield for the one-pot three steps cycloaddition–sulfoxide elimination–aromatization process from (+)-**1**. Further deprotective treatment of OTBDMS derivative **9** with 40% aqueous HF in CH_3CN gave rise to the very unstable alcohol **10** which, without isolation, was oxidized in the presence of air and daylight to the corresponding ketone **11** in 48% yield from **9** for the one-pot two step desilylation–oxydation sequence. Synthetic **11** {$[\alpha]_D^{20}$ +62 (*c* 0.5, $CHCl_3$), 80% ee} was shown to be identical in all physical and spectroscopic properties to the natural (+)-rubiginone B_2 {$[\alpha]_D^{20}$ +78 (*c* 0.5, $CHCl_3$)}.[2] Finally, demethylation of rubiginone B_2 (+)-**11** was achieved in 86% yield by using $AlCl_3$ in CH_2Cl_2 at room temperature, to afford the hydroxy derivative **12** {$[\alpha]_D^{20}$ +163 (*c* 0.05, CH_2Cl_2), 80% ee} which was identical in all physical and spectroscopic data[14] to the natural (+)-ochromycinone {$[\alpha]_D^{20}$ +204.5 (*c* 0.05, CH_2Cl_2)}.[1] The analoguous rotary power of synthetic and natural products confirmed the (3*S*) configuration of the former as well as the (1*R*,3*S*,12b*S*) configuration for intermediate **5** which resulted in the cycloaddition process shown in Scheme 1. On this basis, a transition state similar to that indicated in Scheme 1 explains the major formation of the observed diastereoisomer.

In summary, we have reported a short enantioselective synthesis of the angucyclinone antibiotics rubiginone B_2 and ochromycinone, based on the asymmetric Diels–Alder reaction between the enantiopure methoxy substituted 2-(*p*-tolylsulfinyl)-1,4-naphthoquinone (+)-**1** and the racemic chiral vinylcyclohexene (±)-**2**, through the efficient kinetic resolution of the diene partner and the spontaneous sulfoxide elimination which recovers the quinone skeleton in a single step. The total synthesis of natural derivative (+)-**11** was thus achieved in a two-pot four step procedure starting from (+)-**1** with 80% ee and 28% overall yield. Ochromycinone (+)-**12** was obtained from (+)-**11** after an additional demethylation step with the same optical purity and 25% overall yield.

We thank DGICYT (PB95-0174) for financial support and FAPESP for a post-doctoral fellowship to C. D. V.

Towards hydrocarbon analogues of the porphyrins: synthesis and spectroscopic characterization of the first dicarbaporphyrin†

Timothy D. Lash,* Jennifer L. Romanic, Michael J. Hayes and John D. Spence

Department of Chemistry, Illinois State University, Normal, Illinois 61790-4160, U.S.A. E-mail: tdlash@ilstu.edu

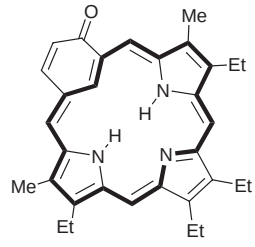
Received (in Corvallis, OR, USA) 8th December 1999, Accepted 5th March 1999

Condensation of 3,4-diethylpyrrole with 1,3-diformylindane in the presence of catalytic HBr afforded, following oxidation with $FeCl_3$, the first example of a dicarbaporphyrin in moderate yield; this novel bridged annulene system retains a strong diamagnetic ring current in ^{1}H NMR spectroscopy as well as a porphyrin-like UV–VIS spectrum.

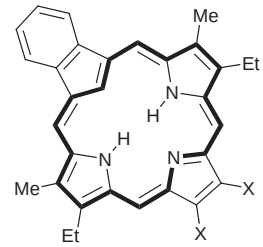
The nature of aromaticity in porphyrins and related structures has been the subject of much debate,[1] although these systems are commonly described as bridged diaza[18]annulenes.[2] This description also helps to explain the properties of synthetic porphyrinoids such as porphyrin isomers[3] and expanded porphyrins.[4] Nonetheless, the nitrogen atoms clearly play an important role in the spectroscopic and chemical properties of Nature's [18]annulenes. In earlier studies, the replacement of pyrrole subunits with furan and/or thiophene rings was explored.[3,5] While the resulting porphyrin analogues had substantially modified properties they retained the aromatic characteristics that are associated with the tetrapyrrolic structures. However, it has only been very recently that porphyrin analogues with carbocyclic rings replacing one of the pyrrolic moieties have been reported.[6–9] These include oxybenziporphyrin (**1**),[6] tropiporphyrin,[7] carbaporphyrins (*e.g.* **2**)[8] and carbachlorins.[9] It is noteworthy that all of these structures show powerful diamagnetic ring currents by ^{1}H NMR where the internal CHs resonate near $\delta -7$ and the external *meso*-protons mostly appear downfield between δ 9 and 10.[6–9] Although the substitution of one nitrogen by a carbon atom does not significantly disrupt the aromaticity of these macrocycles, it remains less than clear whether hydrocarbon porphyrinoids such as **3** would similarly retain porphyrin-like aromatic properties. While at the present time the characteristics of the tetracarbaporphyrin system **3** remain open to speculation, we now report the next step towards this hypothetical system.

During our earlier work on the synthesis of carbaporphyrins **2**,[8] we reacted the diformylindene intermediate **4** with diethylpyrrole **5** in the presence of TFA in CH_2Cl_2 (Scheme 1). Following neutralization, a nonpolar orange–brown band was collected from column chromatography on alumina that appeared to correspond to the dicarbaporphyrin **6**. The yield for this chemistry was very low (< 0.1%), but this is perhaps not surprising as the relatively high oxidation level of **4** must require that some type of reduction takes place in order to generate the aromatic porphyrinoid **6**. While these observations demonstrated that syntheses of dicarbaporphyrins are achievable, the methodology was not suitable for synthesizing more than trace amounts of material.

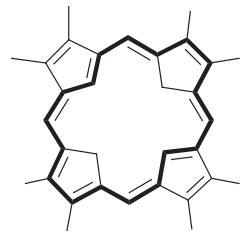
Given our recent successes in utilizing aliphatic dialdehydes in the synthesis of carbachlorins,[9] diformylindane **7** was considered to be a better choice for these investigations. This previously unknown compound was synthesized in two steps from norbornadiene derivative **8**[10] (Scheme 2). Oxidation of **8** with $KMnO_4$ afforded the diol **9** in 45% yield, and subsequent



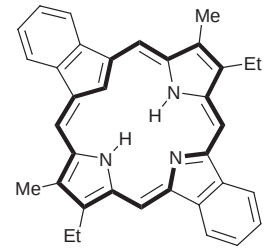
1



2a X = Et
b X–X = $(CH_2)_4$



3



10

reaction with $NaIO_4$ afforded the required dialdehyde **7** as a pale yellow oil (quantitative). Condensation of **7** with diethylpyrrole **5** in the presence of TFA in CH_2Cl_2, followed by oxidation with 0.52 equiv. of DDQ, afforded the dicarbaporphyrin in low yields. Some improvement was observed when HBr was used as the acid catalyst, although the yields were still generally only approximately 1–2%. However, superior results (4.0–7.8%) were obtained when the DDQ oxidation was replaced by a brief treatment with aqueous $FeCl_3$. In this procedure, the acidic CH_2Cl_2 solution was washed successively with water, 0.1% $FeCl_3$ solution, water and saturated $NaHCO_3$. The crude material was chromatographed on Grade III neutral alumina eluting with CH_2Cl_2, and the colored fractions combined and further chromatographed on Grade I alumina. The first orange–brown band was evaporated and recrystallized from $CHCl_3$–MeOH to give the new porphyrinoid as dull purple crystals.‡

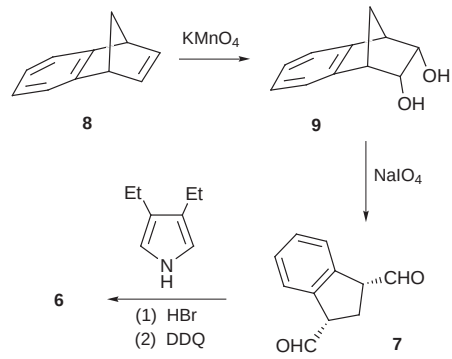

Scheme 2

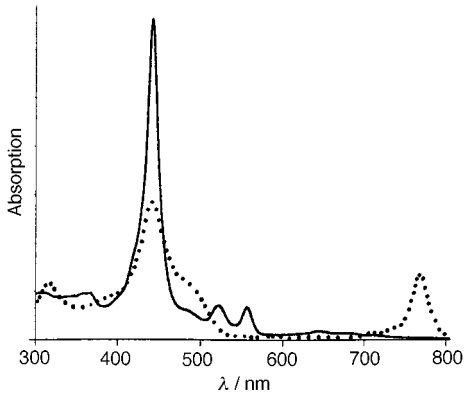

Fig. 1 UV–VIS spectra of dicarbaporphyrin **6**: free base in $CHCl_3$ (bold line); monocation **11** in 0.1% TFA–$CHCl_3$ (dotted line).

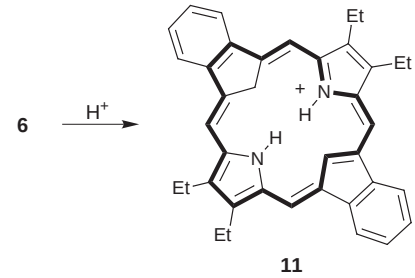
Solutions of the dicarbaporphyrin proved to be unstable, even in the absence of light, producing unidentified green materials. As a precaution, all manipulations were carried out with low ambient lighting and the columns, flasks and separatory funnels were covered with aluminium foil to limit photodegradation. In crystalline form, dicarbaporphyrin **6** appears to be reasonably stable and can be stored indefinitely.

Dicarbaporphyrin **6** was only sparingly soluble in $CDCl_3$, and this led to some problems in obtaining quality proton NMR spectra for this species. Trace impurities, together with the instability problems, led to the presence of small impurity peaks but otherwise the data were in full agreement with the proposed structure. Owing to the high level of symmetry in **6**, all four *meso*-protons are equivalent and resonate at δ 9.8. In addition, the internal CH protons appeared upfield at δ −5.7, while the NHs were noted at δ −4.8. It is evident that this species possesses a strong diamagnetic ring current and this supports the formulation of **6** as a bridged annulene structure with porphyrinoid aromaticity. A dibenzomonocarbaporphyrin **10** has also been prepared by dehydrogenation of **2b** with DDQ in refluxing toluene, and this structurally similar compound provides some useful comparisons. For the ^{1}H NMR spectra of carbaporphyrin **10** in $CDCl_3$, the external *meso*-protons appeared at δ 10.04 and 10.06, while the internal CH resonated at δ −6.6 and the NHs were observed near δ −4. These data indicate that the macrocyclic ring current is slightly greater in **10** compared to **6**, possibly due to the more crowded cavity in the latter which contains four hydrogens, compared to three in the former, and this factor may perturb that planarity of the structure. Further evidence for the porphyrin-like nature of **6** comes from the UV–VIS spectrum in $CHCl_3$ (Fig. 1) which shows a strong Soret band at 442 nm, together with a series of Q absorptions between 500 and 700 nm. EI mass spectrometry shows a strong molecular ion at *m/z* 520 and a small amount of benzylic fragmentation together with doubly charged ions of 25–30% the intensity of the base peak.

When small amounts of TFA were added, the brown solution turned green due to C-protonation to give the related cation **11**



Scheme 3

(Scheme 3). Although 0.1% TFA–$CHCl_3$ was sufficient to fully protonate the dicarbaporphyrin, further protonation to a dication was not observed even in 50% TFA–$CHCl_3$. The UV–VIS spectrum for **11** was radically altered (Fig. 1), showing a broadened Soret band of much lower intensity together with a strong absorption in the far red near 760 nm (Fig. 1). The proton NMR spectrum for **6** in TFA-$CDCl_3$ confirmed the presence of a strong aromatic ring current, although the lower symmetry of structure **11** resulted in a larger number of resonances; two 2H singlets were noted for the *meso*-protons near δ 10, while the upfield region showed the internal CH_2 at δ −4.3, the remaining CH at δ −3.3 and the two NHs near δ −1. The two benzo units also displayed surprisingly different chemical shifts and one of the 2H multiplets was shifted downfield to δ 9.7. These data are consistent with a benzo[18]annulene formulation for **11** where the C-protonated indene unit directs 18π-electron delocalization through one of the fused benzene rings.

The synthesis of the first dicarbaporphyrin represents an important step forward and allows us to set our sights on still further modified porphyrin analogs such as the tetracarbaporphyrin system **3**, a structure that must now be considered to be the Holy Grail in this research area. However, the marked decrease in stability of the dicarbaporphyrin system may not bode well for these investigations.

Methyltrioxorhenium-catalysed epoxidation of alkenes in trifluoroethanol

Michiel C. A. van Vliet, Isabel W. C. E. Arends and R. A. Sheldon*

Laboratory for Organic Chemistry and Catalysis, Delft University of Technology, Julianalaan 136, 2628 BL Delft, The Netherlands. E-mail: secretariat-ock@stm.tudelft.nl

Received (in Cambridge, UK) 17th March 1999, Accepted 30th March 1999

The well known methyltrioxorhenium-catalysed epoxidation of alkenes with aqueous H_2O_2 is significantly improved by conducting the epoxidation in trifluoroethanol; excellent reaction rates and yields can be obtained for a variety of (terminal) alkenes with only 0.1 mol% of catalyst.

Catalytic epoxidation of alkenes with aqueous H_2O_2 has been extensively studied in the last two decades.[1] Rhenium-based systems are especially interesting because rhenium, in contrast to many other transition metals, does not catalyse the facile decomposition of H_2O_2.[2]

The discovery of the catalytic activity of methyltrioxorhenium ($MeReO_3$; MTO) by Herrmann and co-workers[3] marks a turning point in the use of rhenium compounds as catalysts for epoxidations with H_2O_2. This catalyst proved to be very active in epoxidation with anhydrous H_2O_2 in Bu^{t}OH. The main disadvantage, however, was the low selectivity when acid sensitive epoxides were formed. The high acidity of MTO–H_2O_2 caused hydrolysis and further degradation of the epoxide. This drawback could be partly circumvented by adding basic ligands (*e.g.* bipyridine) to the catalyst, but not without decreasing the activity of the catalyst.[4]

A major improvement in the MTO catalysed epoxidation was achieved by Sharpless and co-workers.[5] They discovered that a large excess of pyridine relative to the catalyst ($>10:1$) actually improved the activity of the catalyst while maintaining the high selectivity. An important feature of this new system was the possibility of using commercially available aqueous H_2O_2 as the oxidant. This discovery boosted interest in MTO research and shortly afterwards new improvements were achieved by the Sharpless and Herrmann groups.[6,7] The best results up to now were reported with pyrazole (pyrazole : MTO ratio of 24 : 1) as the basic ligand and CH_2Cl_2 as solvent.[7]

During our research on catalytic epoxidation with inorganic rhenium compounds as the catalyst, we found that trifluoroethanol was an excellent solvent for epoxidations with aqueous H_2O_2.[8] We subsequently found that a major improvement could be achieved when this solvent was used in the MTO system.

Fig. 1 shows the catalytic epoxidation of hex-1-ene. The results using 0.5 mol% MTO, 10 mol% pyrazole and 2 equiv. 30% H_2O_2 in CH_2Cl_2 are comparable to those reported by Herrmann and co-workers (95% conversion in 8 h; curve A). The use of 0.1 mol% MTO resulted in a much slower reaction and complete conversion of the alkene could not be reached in 24 h (curve B). The use of 60% H_2O_2 showed a slightly increased rate, but again complete conversion was not reached in 24 h (curve C).

A marked increase in the rate was observed, however, when the same catalyst and ligand were used in trifluoroethanol. This increase was observed both with 30% H_2O_2 (curve D) and more pronounced with 60% H_2O_2 (curve E). The rate was comparable to that observed with five times as much MTO in CH_2Cl_2 and complete conversion of the alkene with high selectivity to the epoxide could be reached within 24 h. With 5 mol% of pyrazole the rate was even slightly higher and a 95% yield of epoxide could be obtained in 5 h (curve F). The use of pyridine or 3-cyanopyridine resulted in slower rates, in analogy with the CH_2Cl_2 based system.

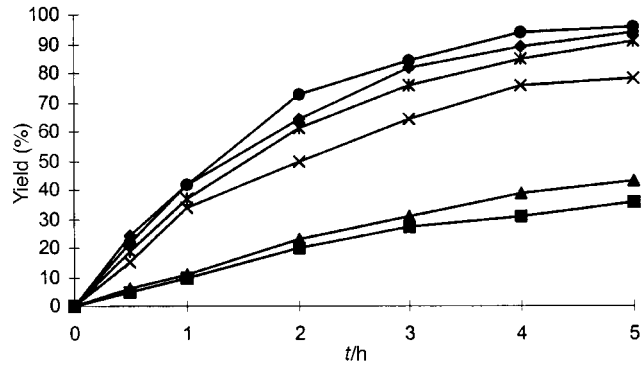

Fig. 1 Epoxidation of hex-1-ene by various catalytic systems. Conditions: 10 mmol hex-1-ene, 1 mmol Bu_2O (internal standard), $MeReO_3$, pyrazole, 20 mmol H_2O_2 and 5 ml of solvent. Reaction at room temperature. Analysis by GC. (◆) Curve A: 0.5 mol% MTO, 10 mol% pyrazole, 30% H_2O_2 in CH_2Cl_2. (■) Curve B: 0.1 mol% MTO, 10 mol% pyrazole, 30% H_2O_2 in CH_2Cl_2. (▲ Curve C: 0.1 mol% MTO, 10 mol% pyrazole, 60% H_2O_2 in CH_2Cl_2. (×) Curve D: 0.1 mol% MTO, 10 mol% pyrazole, 30% H_2O_2 in trifluoroethanol. (*) Curve E: 0.1 mol% MTO, 10 mol% pyrazole, 60% H_2O_2 in trifluoroethanol. (●) Curve F: 0.1 mol% MTO, 5 mol% pyrazole, 60% H_2O_2 in trifluoroethanol.

The high rates in trifluoroethanol are in agreement with earlier observation by Sharpless and co-workers, who found that polar, non-coordinating solvents showed the highest rates.[5] Despite its alcoholic nature, trifluoroethanol is a non-coordinating solvent owing to the strong electron-withdrawing effect of the trifluoromethyl group. The trifluoromethyl group also prevents the oxidation of the alcohol group, rendering this primary alcohol relatively stable towards oxidation.

Based on these results we tested a number of terminal alkenes in the MTO catalysed epoxidation in trifluoroethanol (Table 1). In most cases complete conversion was observed within 24 h

Table 1 Epoxidation of terminal alkenes catalysed by MTO in trifluoroethanol[a]

Alkene	*t*/h	Yield (%)
Hex-1-ene	6	95
	21	>99
Hept-1-ene	21	>99
Oct-1-ene	21	>99
Non-1-ene	21	>99
Dec-1-ene	21	97
Vinylcyclohexane	21	>99
Styrene	2	82[b]
3-Phenylpropene	21	97
4-Phenylbut-1-ene	21	>99

[a] Conditions: 10 mmol alkene, 1 mmol Bu_2O (internal standard), 0.010 mmol $MeReO_3$ (0.1 mol%), 0.5 mmol pyrazole, 20 mmol 60% H_2O_2 and 5 ml trifluoroethanol. Stirring at room temperature, analysis by GC. [b] Phenylethane-1,2-diol and benzaldehyde were also detected.

Table 2 Epoxidation of internal alkenes catalysed by MTO in trifluoroethanol[a]

Alkene	*t*/h	Yield (%)
Cyclohexene	0.5	> 99
Cycloheptene	1	> 99
Cyclooctene	1	> 99
1-Methylcyclohexene	0.5	> 99
Methylenecyclohexane	1	99
Indene	1	65[b]
2-Methylhept-1-ene	1.5	98
2-Methylhept-2-ene	1	99

[a] Conditions:1 mmol Bu_2O (internal standard), 0.010 mmol $MeReO_3$ (0.1 mol%), 1 mmol pyrazole and 20 mmol 60% H_2O_2 were dissolved in 5 ml trifluoroethanol. The stirred mixture was cooled in an ice bath to *ca.* 5 °C. The alkene (10 mmol) was then added dropwise in 20–30 min. The mixture was warmed to room temperature and analysed by GC. [b] Several hydrolysis products were also detected.

with 0.1 mol% of catalyst. The epoxide was formed with high selectivity and no noticeable by-products were observed. The only notable exception was styrene. Its very sensitive epoxide was partly decomposed to phenylethane-1,2-diol and benzaldehyde. The yield, however, is comparable to the best results claimed by Sharpless and co-workers.[6] These high turnovers obtained for terminal alkenes are unprecedented and can only be approached by the recently improved manganese triazonane catalyst.[9]

The high turnovers could also be obtained in the oxidation of the more reactive internal alkenes. However, the reaction was in several cases too fast, resulting in the decomposition of the catalyst and incomplete conversion of the alkene. When appropriate cooling was applied, no catalyst decomposition was observed. A better procedure was to add the substrate slowly (*ca.* 20 to 30 min) to the ice-cooled reaction mixture. In most cases the reaction was complete within minutes after the addition of the last portion of alkene. The presence of the active catalyst, even after 1000 turnovers, was indicated by the intense yellow colour of the peroxo complex. The results for some internal alkenes are shown in Table 2. Most epoxides give > 99% yield of epoxide, except indene. Indene oxide is known to be very sensitive towards hydrolysis. The homogeneous reaction mixture with water present in the same phase as the epoxide results in decomposition of the product. The two-phase system with CH_2Cl_2 generally gives higher yields, because the water and epoxide are present in separate phases. This behaviour is known for other catalytic systems as well.[10] Most other epoxides, however, are stable enough to resist hydrolysis in a monophasic system.

The catalyst is still active after 1000 turnovers, and 2500 turnovers could be obtained by slow addition of alkene to the reaction mixture. At a substrate to catalyst ratio of 2000 complete conversion was reached within 1 h with cyclohexene. At a substrate to catalyst ratio of 3000 the catalyst decomposed and only 90% conversion could be reached. These high turnovers require very careful addition of the alkene. A slightly faster addition of the alkene than the optimum addition rate causes the reaction mixture to warm up, resulting in complete loss of catalytic activity.

One disadvantage of the present catalytic system is the high polarity of the reaction medium. Very apolar alkenes (C_{12} or higher alkenes and stilbenes) do not dissolve in the reaction medium, and are therefore not epoxidised. In other cases (the experiments of Table 1 and 2) the alkene does not dissolve completely at the beginning of the reaction. During the course of the reaction the medium becomes homogeneous due to the formation of polar, soluble epoxide. The time required for a homogeneous reaction mixture depends on the polarity of the alkene and ranges from 1 h for hex-1-ene to 6 h for dec-1-ene. The more reactive internal alkenes give a homogeneous reaction mixture within minutes after the addition.

In summary, the use of MTO–pyrazole in trifluoroethanol allows for the highly selective epoxidation of a variety of olefins with 30–60% aqueous H_2O_2 at low (0.1 mol%) catalyst loading. The methodology should have wide applicability in organic synthesis.

Received (in Cambridge, UK) 22nd February 1999, Accepted 19th March 1999

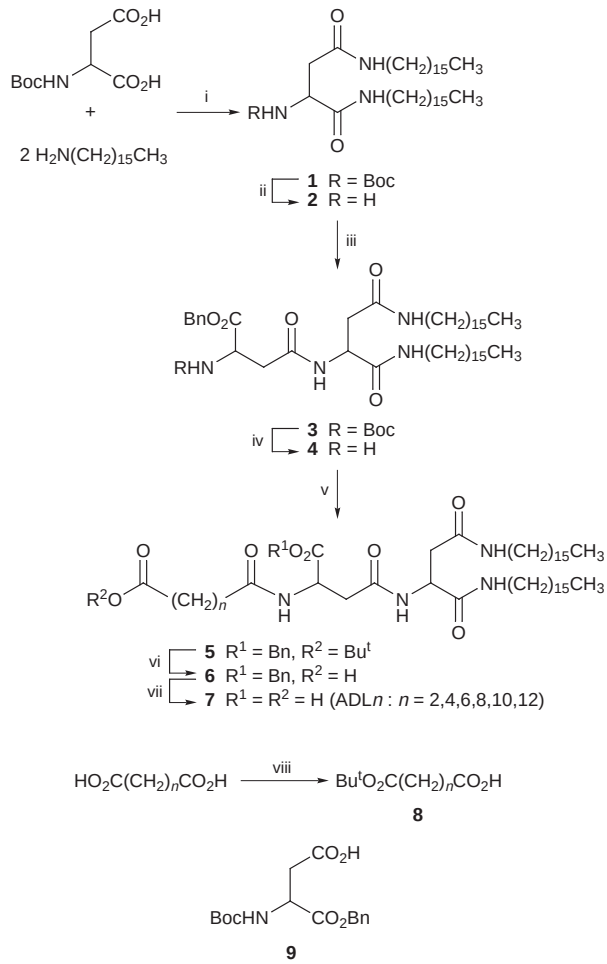
Liposomes including aspartic acid-derived artificial lipids (ADL) with various carboxy alkyl chains as head groups (ADL*n*; *n* indicates the number of the methylene groups, *n* = 2,4,6,8,10,12) are prepared, in which ADL6 and ADL8 liposomes induce remarkably high lipid-mixing in the acidic region.

For the last decade, liposomes have been exploited predominantly as potent carriers of various polar materials into cells.[1–4] We show here that artificial lipids with simple structures can induce pH-dependent membrane fusion in a manner similar to authentic fusion inducers such as the Spike protein of the influenza virus.[5–7] Homologous artificial lipids (ADL*n*; *n* = 2, 4, 6, 8, 10, 12) were designed and synthesized according to Scheme 1.† These lipids are composed of three fundamental parts: (A) two long alkyl chains in the tail part, which can be anchored to the hydrophobic region of lipid bilayer, (B) a polar moiety composed of two aspartic acid residues in the central part, (C) a terminal carboxylic acid group as a pH-dependent trigger for liposome fusion. Part (C) composed of the carboxy group and the alkyl chain was designed so that its polarity could be controlled by pH, depending upon whether the carboxy group is protonated or deprotonated. Since the pK_a was expected to be 4.6–4.8, in view of the pK_a of an ordinary carboxy group, part (C) was expected to behave as a hydrophobic protrusion on the lipid membrane like fusion peptides[8] at acidic pH. The time course of fusion % of liposomes composed of ADL*n* (5–20 mol%) and egg phosphatidylcholine (Egg PC, Avanti Polar Lipids, Inc., special grade) was measured from the efficiency of the fluorescence resonance energy transfer (FRET) between *N*-(7-nitro-2,1,3-benzoxadiazol-4-yl)phosphatidylethanolamine (NBD-PE) and lissamine rhodamine B sulfonyl phosphatidylethanolamine (Rh-PE).[9,10]‡ The fusion % was calculated from eqn. (1),

$$\text{Fusion \%} = 100[F(t)-F(0)]/[F(\text{Triton})-F(0)] \qquad (1)$$

where $F(0)$, $F(t)$ and F(Triton) signify the fluorescence intensity at 530 nm (λ_{ex} = 480 nm) before adding citric acid, at time t, and after the collapsing of liposomes by Triton X-100, respectively. Fusion % after 5 min reaction at pH 4 is depicted in Fig. 1 ([ADL*n*] = 5, 10, 15, 20 mol%). As expected, very high liposome fusion was observed in some liposomes, which suggests that the carboxy group in the head part can act as a trigger in the fusion. It should be noted here that there are optimal lengths of the methylene group in the head group between 6 and 10, with ADL6 (20 mol%) showing especially high fusion % (*ca.* 40%). It was also confirmed that at neutral pH the liposome fusion was scarcely observed for any of the lipids, at least within 1 h. The pH dependence of the fusion % for ADL6 and ADL8 is shown in Fig. 2 together with the control experiment where liposomes are composed of only Egg PC without ADL*n*. The fusion in the presence of ADL6 or ADL8 was significantly accelerated below *ca.* pH 5 due to the protonation of the carboxy group, while that of the control liposome gave low fusion % between pH 3.6 and 7.2. In contrast to ADL6, ADL8 and ADL10, the lipids with shorter or longer chains, ADL2, ADL4 and ADL12, did not induce remarkable fusion even at acidic pH.

In most fusion inducers such as the Spike protein of the influenza virus, the hydrophobic fusion peptide is hidden at neutral pH. At acidic pH, however, it protrudes from the membrane surface and is incorporated into another membrane. Consequently these membranes are close together, resulting in membrane fusion. The carboxylic acid with a long alkyl chain, which is protonated at low pH, seems an appropriate hydrophobic group to mimic fusion peptides as a simple fusion inducer. Fig. 2 clearly suggests that the protonation of the terminal carboxylate of ADL*n* is the trigger of liposome fusion and Fig. 1 suggests that there is an optimal hydrophobicity



Scheme 1 Synthetic route to ADL*n*: i, HOBt, TBTU, DMAP; ii, TFA; iii, **9**, HOBt, EDC, DMAP; iv, TFA; v, **8**, HOBt, TBTU, DMAP; vi, TFA; vii, H_2/Pd-C; viii, Bu^{t}OH, EDC, DMAP. EDC = 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride, HOBt = 1-hydroxybenzotriazole, TBTU = *O*-(1*H*-benzotriazol-1-yl)-*N*,*N*,*N*′,*N*′-tetramethyluronium tetrafluoroborate.

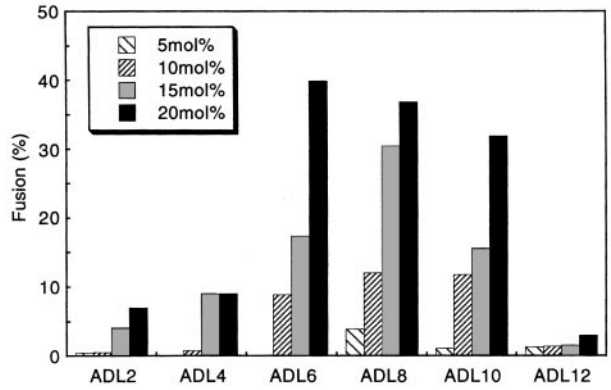


Fig. 1 Dependence of fusion % after 5 min reaction upon alkyl chain lengths of head groups of ADL*n*; pH 4.0, 37 °C; composition (mol%) of ADL*n* in liposomes is described inside the figure.

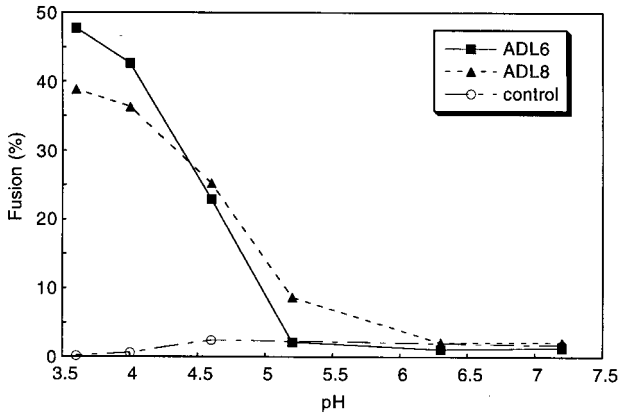

Fig. 2 pH profile of fusion % after 5 min reaction at 37 °C; [ADL*n*] = 20 mol%.

between ADL6 and ADL10. The reason for the very poor ability of ADL12 to induce liposome fusion may be that its alkyl chain in the head part is too long and too hydrophobic to remain in an outer aqueous phase and, consequently, ADL12 may be embedded in the membrane even at neutral pH. In contrast, the head alkyl chains of ADL2 and ADL4 are considered too short and too hydrophilic to migrate to another membrane, which may also result in low fusion %.

‡ Egg PC was dissolved in $CHCl_3$–MeOH (3 : 1, v/v) with various amounts of ADL*n* for fusion liposome (Fusion-Lip), and with 0.5 mol% of NBD-PE and 0.5 mol% of Rh-PE for fluorescence-labeled liposome (Label-Lip). Lipid solutions were dried under a N_2 gas stream followed by the removal of residual solvent under high vacuum for 3 h. The resulting lipid films were hydrated by vortex-mixing with HEPES buffer (10 mM HEPES, 100 mM NaCl, pH 7.2) to make multilamellar vesicles (MLVs). MLVs were sonicated at 65 °C for 5 min by a probe-type sonicator and the resulting clear suspension (SUVs) was used in the experiments. After Fusion-Lip and Label-Lip (10:1, v/v) were mixed at 37 °C the lipid mixing assay was started by adding the necessary amount of citric acid (0.4 M) to adjust the pH.

Highly *trans*-selective intramolecular pinacol coupling of dials catalyzed by bulky Cp_2TiPh

Yoshihiko Yamamoto, Reiko Hattori and Kenji Itoh*

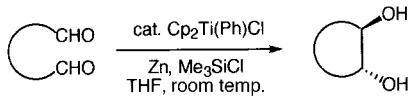
Department of Applied Chemistry and Department of Molecular Design and Engineering, Graduate School of Engineering, Nagoya University, Chikusa, Nagoya 464-8603, Japan. E-mail: itohk@apchem.nagoya-u.ac.jp

Received (in Cambridge, UK) 18th March 1999, Accepted 29th March 1999

$Cp_2Ti(Ph)Cl$ in the presence of Me_3SiCl and Zn provides an effective pinacol coupling catalyst for aromatic and aliphatic aldehydes.

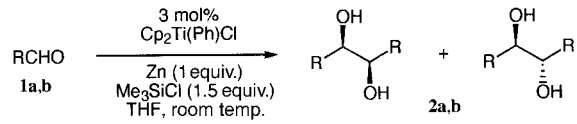
Chiral 1,2-diols have found extensive use as asymmetric ligands for catalytic asymmetric reactions[1] and as chiral auxiliaries for diastereoselective transformation of carbonyl substrates.[2] Such valuable diols are commonly obtained by the resolution of racemic products prepared from a wide variety of aldehydes *via threo*-selective pinacol coupling.[3] Pinacol coupling has also been employed as a key step in the construction of highly important natural and artificial compounds.[3] For these purposes, stoichiometric reactions have so far been employed, however, catalytic methods are highly desirable as a metal-atom-economical and practical entry to the above 1,2-diols. From this point of view, some catalytic methods have been developed,[4] but few of them have been applied to the intramolecular coupling of dials.[4g] This is partly because the intramolecular pinacol coupling of dials is often accompanied by side reactions such as intramolecular aldol condensation. With this in mind, we developed the $Cp_2Ti(Ph)Cl$-catalyzed intramolecular pinacol coupling of dials, which gave cyclic 1,2-diols in moderate to good yields with excellent *trans*-selectivity under mild conditions (Scheme 1).

Cp_2TiCl has received much attention as an excellent single-electron reductant in organic synthesis.[5] In this context, Teuben *et al.* have reported the Cp_2TiPh-mediated reductive coupling of benzonitrile leading to benzil,[6] and recently we have found that the same titanium(III) reagent reacted with γ- and δ-ketonitriles to give α-hydroxycycloalkanones as reductive cyclization products in good yield.[7] The importance of the Ti^{III}–Ph σ-bond is obvious from the fact that the parent Cp_2TiCl was not effective for the above two reductive transformations. The phenyltitanium(III) reagent was readily prepared *in situ via* reduction of Cp_2TiCl_2 with Pr^iMgCl followed by the addition of PhMgBr.[6,7] The same reactive species may alternatively be generated by reducing $Cp_2Ti(Ph)Cl$[8] with Zn powder.[9] Given this fact, $Cp_2Ti(Ph)Cl$ should catalyze pinacol coupling reactions in the presence of a stoichiometric amount of Zn. In fact, stoichiometric reaction using equimolar amounts of $Cp_2Ti(Ph)Cl$ and Zn promoted the desired reductive coupling of benzaldehyde **1a** to give hydrobenzoin **2a** in 99% yield with a diastereoselectivity of *threo* : *erythoro* = 84 : 16. We carried out the catalyzed reaction as follows; a THF (5 ml) solution of **1a** (3 mmol) and Me_3SiCl (1.5 equiv.) was added to a mixture of 3 mol% $Cp_2Ti(Ph)Cl$ and Zn (1 equiv.) in THF (20 ml) and the mixture was stirred for 70 min at ambient temperature. Usual work-up gave **2a** in 88% yield with a diastereomeric ratio of *threo* : *erythro* = 71 : 29 (Scheme 2). In the absence of the titanium catalyst, **2a** was obtained in only 7% yield (*threo* : *erythro* = 50 : 50) along with the reduced product benzyl alcohol (13%).[10] The complete loss of diastereoselectivity demonstrated the importance of the titanocene catalyst. In addition to the aromatic aldehyde, less reactive aliphatic aldehyde **1b** was converted into the corresponding diol **2b** in good yield, although its *threo*-selectivity was lower than **2a**. These results demonstrate that $Cp_2Ti(Ph)Cl$ is an efficient catalyst for the pinacol coupling of both aromatic and aliphatic aldehydes.



Scheme 1

On the basis of the above results, we applied our new catalytic system to the intramolecular reductive coupling of dials (Table 1). In the presence of 6 mol% $Cp_2Ti(Ph)Cl$, the acid sensitive 1,5-dial **3a** was reduced at ambient temperature over 38 h to afford the desired diol **4a** in 40% yield with excellent *trans*-selectivity (*trans* : *cis* = 99 : 1). It is noteworthy that this high diastereoselectivity is in striking contrast to the *cis*-selectivity observed in the known methods using stoichiometric amounts of SmI_2[11] or $TiCl_3(THF)_3$–Bu^tOH catalyst.[4g] In a similar manner, 10 mol% of the catalyst transformed 1,6-diol **3b** into *trans*-cyclohexanediol **4b** in a higher yield (65%). Moreover, 1,6-dial **3c** having a bulky Bu^t group at the 3-position gave only a single stereoisomer **4c** in 52% yield. The relative



2a R = Ph, 0.12 M, 70 min, 88% (*threo* : *erythro* = 71 : 29)
2b R = CH_2CH_2Ph, 0.2 M, 18 h, 80% (*threo* : *erythro* = 64 : 36)

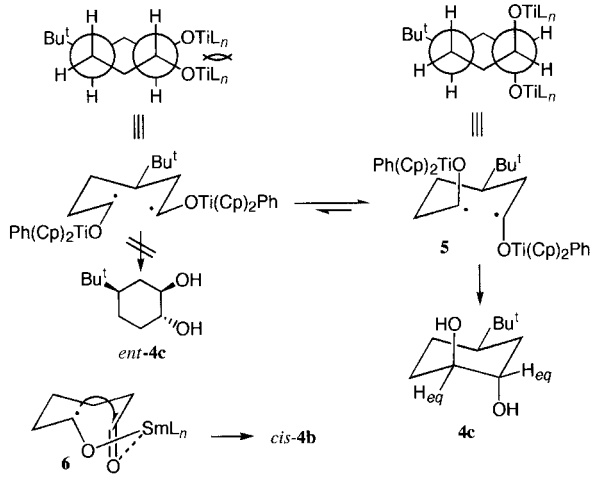

Fig. 1 Mechanism of stereoselection.

configurations of all three stereogenic centers in **4c** were completely controlled. The stereochemistry of **4c** was determined by comparison of its spectral data with those previously reported.[12] In the ^{1}H NMR spectrum, the methyne protons α to the hydroxy groups have no H_{ax}–H_{ax} or H_{ax}–H_{eq} coupling with coupling constants over 10 Hz, indicating that both are constrained to occupy the equatorial positions. Among the four isomers, **4c** is the only one having no axial methyne proton α to the hydroxy groups, as shown in Fig. 1. In addition, the ^{13}C NMR spectrum of **4c** and its melting point are in good agreement with reported data.[12]

These results clearly indicate that the bulky Ti^{IV} fragment surrounded by two cyclopentadienyl and one phenyl ligands cannot coordinate to the other carbonyl terminus, and cyclization must proceed *via* diradical intermediates such as **5**, in which two bulky Cp_2(Ph)TiO moieties occupy axial positions in order to reduce steric repulsion (Fig. 1). This is in contrast to the intramolecular coupling of **3b** promoted by SmI_2 affording *cis*-products *via* chelated intermediates such as **6**.[11]

In addition to the aliphatic dials, a biphenylic dial **3d** was converted into a tricyclic diol **4d**[13] in good yield (70%) with high *trans*-selectivity (*trans* : *cis* = 91 : 9).

In conclusion, we have demonstrated that Cp_2Ti(Ph)Cl is an effective pinacol coupling catalyst for both aromatic and aliphatic aldehydes in the presence of Me_3SiCl and Zn. The catalytic intramolecular pinacol coupling of dials afforded cyclic *trans*-1,2-diols with excellent *trans*-selectivities of *trans* : *cis* = > 90 : 10, indicative of non-chelation intermediates being involved in the present reductive cyclization. These results are in striking contrast to reported *cis*-selective methods.

Unusual redox-type addition of nitroalkanes on the C_{60} surface

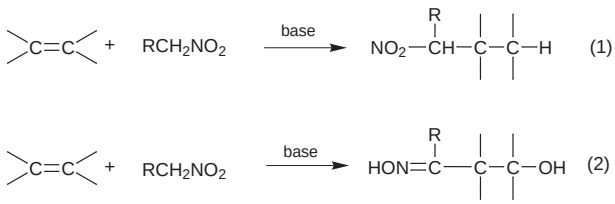
Masatomi Ohno,* Arihiro Yashiro, Yohei Tsunenishi and Shoji Eguchi

Department of Molecular Design and Engineering, Graduate School of Engineering, Nagoya University, Chikusa, Nagoya 464-8603, Japan. E-mail: ohno@apchem.nagoya-u.ac.jp

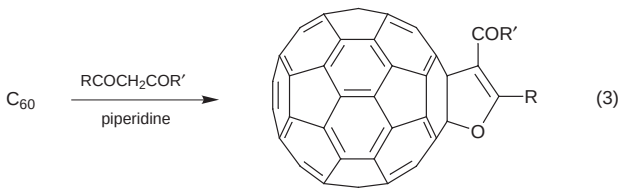
Received (in Cambridge, UK) 2nd March 1999, Accepted 30th March 1999

Nitroethanes underwent base-catalyzed addition to C_{60} to give 2-hydroxy-1,2-dihydrofulleryl ketoximes by way of a unique intramolecular redox process, which is not observed in normal alkenes.

Usual base-catalyzed reaction of nitroalkanes with electron-deficient alkenes is known to proceed in a 1,4-addition manner to give γ-nitro-functionalized products [eqn. (1)].[1] While fullerenes possess similar reactivity with nucleophilic reagents because of their low LUMO level,[2] this reaction with C_{60} was found to proceed with a different addition pattern to give β-hydroxy oxime products [eqn. (2)].

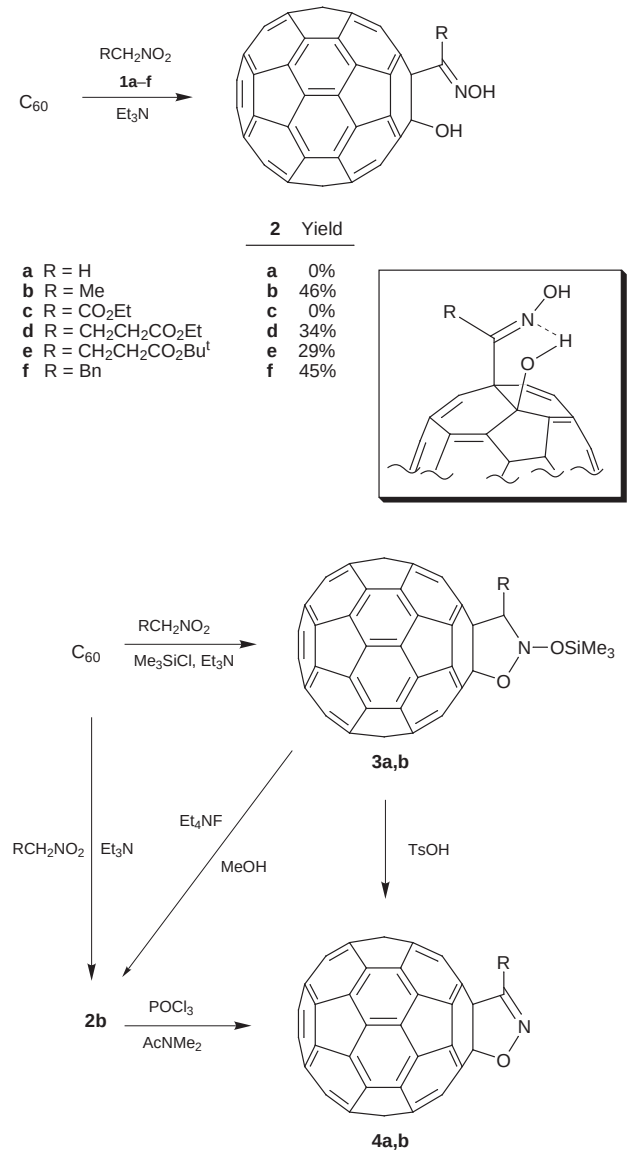


This result is not observed with standard alkenes and is ascribable to the specific nature of the double bonds on the C_{60} surface. So far, remarkable oxidative (cyclo)additions of C_{60} have been recorded in nucleophilic cyclization of 1,2-diamines,[3] photoinduced cyclization of Et_3N,[4] F-promoted cyclopropanation of a silyl enol ether,[5] 1,4-bisaddition of Grignard reagents,[6,7] and 1,2-bisaddition of alkoxy anions.[8] In our studies on heterocyclization of C_{60}, base-catalyzed oxidative [3+2]cycloaddition of β-dicarbonyl compounds has also been shown to give dihydrofuran-fused C_{60} derivatives [eqn. (3)].[9] Likewise,



ambiphilic nitroalkanes could undergo an analogous addition but instead lead to the formation of a 1,2-bifunctionalized hydroxy oxime derivative as a result of an intramolecular redox process, which is reported here with a proposed mechanism.

Previously, nitromethane **1a** was demonstrated to react with C_{60} in the presence of Et_3N and TMSCl to give the parent *N*-silyloxyisoxazolidine **3a** as the result of 1,3-dipolar cycloaddition of the *in situ* formed *N*-silyloxynitrone; a following acid-catalyzed elimination reaction gave isoxazoline **4a** (Scheme 1).[10] The same reaction conditions in the absence of the silylating reagent were anticipated to allow the oxidative [3+2]cycloaddition as observed in β-dicarbonyl compounds, but this did not take place. Despite this failure, homologous nitroethane **1b** could be reacted smoothly with C_{60} at room temperature for 2 h by employing excess reagents (20 equiv.), and a brown product was obtained after silica gel chromatography (toluene). Unexpectedly, the FAB mass spectrum included a molecular ion peak at *m/z* 795 (exact sum of molecular weights of C_{60} + $C_2H_5NO_2$), which revealed that the product was certainly a 1 : 1 adduct but not an oxidative cycloadduct (M^+ must be reduced by 2 amu). Nevertheless, the IR (KBr) and UV–VIS (dioxane) spectra showed absorptions at 527 cm^{-1} and 428 nm, respectively, which are characteristics of a C_{60} derivative arising from 1 : 1 addition at a 6,6 junction. The ^1H NMR signals were observed at δ 2.83 (3 H), 4.20 (1 H), and 6.45 (1 H), all as singlet peaks, with the integrations of the last two decreased by addition of D_2O, implying the existence of OH groups but no methylene or methine groups in the molecule. The ^{13}C NMR signals were observed at δ 14.95, 83.58, 99.59, 135.65–149.86 (52 lines),† and 156.53. The first three peaks and next low field aromatic peaks were assignable to sp^3



Scheme 1

carbons due to methyl and junction carbons and spherical sp^2 carbons, respectively; the total 52 lines due to C_{60}, seemingly, suggested no molecular symmetry. The last peak might be due to a C=N moiety. These data were difficult to completely assign. Consequently, the suggestion that an intramolecular redox process may split the nitro group to give nitroso (tautomeric oxime) and hydroxy groups, as shown below, prompted us to determine the structure *via* an independent synthesis. Recently, Hassner reported that β-hydroxy ketoximes were obtained by the fluoride-induced ring cleavage of *N*-silyloxyisoxazolidines derived from 1,3-dipolar cycloaddition reaction of *N*-silyloxy-nitrones.[11] This method was applied to the chemistry of C_{60}. Thus, C_{60} was allowed to react with **1b** in the presence of Et_3N and TMSCl,[10] and the prepared **3b** was successively treated with Et_4NF in MeOH at −20 °C for 1 h to give the ring-cleaved product, 2-hydroxy-1,2-dihydrofulleryl methyl ketoxime **2b**. As a result, the HPLC retention time and spectral data of this authentic sample were consistent with those of the addition product obtained from the base-catalyzed reaction with **1b**. This identification was supported by chemical conversion of the product into isoxazoline **4b** by cyclodehydration with $POCl_3$ and $AcNMe_2$. Intuitively, the confirmed β-hydroxy oxime structure might have C_s symmetricity, but this was not supported by the ^{13}C NMR data; however, the spectrally observed lack of symmetry could be explained by considering a boat-like form (as shown in Scheme 1) composed of an intramolecular hydrogen-bond between the oxime and hydroxy groups. In fact PM3 calculations suggested that a coplanar hydrogen-bonded structure was much less stable than the boat-like one. From a synthetic point of view, the above new 1,2-bifunctionalization of C_{60} can be applied to nitroethanes but not to nitromethanes. Whereas the similar reaction with ethyl nitroacetate **1c** was unsuccessful, those with ethyl and *tert*-butyl 4-nitrobutanoates **1d**,**e** and β-nitroethylbenzene **1f** under the same conditions lead to the formation of the corresponding bifunctionalized **4d**–**f** in moderate yields (Scheme 1).

As a clue to understanding the mechanism of the above unusual addition reaction, it is considered likely that a nitro group can essentially serve as an oxygen donor (*i.e.* reduction to a nitroso group), a β-hydrogen to this group being necessary for the reaction to occur. Since the use of active methylene compounds in oxidative [3+2]cycloadditions has precedent from our previous work,[9a] a formal intramolecular redox process is proposed as follows (Scheme 2). First, addition of a nitronate anion at the carbon site to a double bond on C_{60} is followed by 1,5-hydrogen shift and subsequent addition at the oxygen site to give an isoxazoline *N*-oxide intermediate (**i** → **ii** → **iii**; this resembles the foregoing reaction with β-dicarbonyl compounds[9]). Second, two hydrogens migrate to a fused isoxazoline ring *via* tautomerization from a nitrone form to a *N*-hydroxyenamine species (this step requires the β-H); abstraction of an acidic hydrogen on the core by the enamine is followed by a 1,4-hydrogen shift and subsequent hydride attack on an iminium cation (**iii** → **iv** → **v** → **vi**). This sequence is regarded as an intramolecular redox process. Finally, eliminative ring cleavage to a nitroso alcohol intermediate and subsequent tautomerization gives the product β-hydroxy ketoxime (**vi** → **vii** → **viii**).

In conclusion, nitroethanes were shown to undergo redox-type addition to a double bond of C_{60} under base-catalyzed conditions to give 2-hydroxy-1,2-dihydrofulleryl ketoximes. The mode of addition as seen in this reaction is quite unique, compared with normal electron-deficient alkenes which simply act as a Michael acceptor in the common nucleophilic reaction of nitroalkanes. While some previous oxidative additions to C_{60} were reported to occur with C_{60} itself as an oxidant,[4b,8a] in this case, a nitro group played such a part intramolecularly. This pattern is peculiar in fullerene chemistry and provides a new methodology for its bifunctionalization.

This work was partly supported by a Grant-in-Aid for Scientific Research on Priority Area (A) (No. 10146101) from the Ministry of Education, Science, Sports and Culture, Japan.

New catalysts for the aerobic selective oxidation of hydrocarbons: Mn(III)- and Co(III)-containing molecular sieves for the epoxidation of alkenes

Robert Raja, Gopinathan Sankar and John Meurig Thomas

Davy Faraday Laboratory, The Royal Institution of Great Britain, 21 Albemarle Street, London, UK W1X 4BS. E-mail: robert@ri.ac.uk

Received (in Liverpool, UK) 9th February 1999, Accepted 16th March 1999

Co(III) or Mn(III) ions that replace some 4 atom% of Al(III) sites in microporous aluminophosphate number 36 (AlPO-36) function as catalytically active centres for the production from benzaldehyde of acylperoxy radicals: these, in turn, in dry air (30 bar) convert cyclohexene, pinene, limonene and styrene to their corresponding epoxides and diols.

Replacing stoichiometric oxidants such as $KMnO_4$, Ag_2O and CrO_3 by less environmentally damaging ones is self-evidently a sensible chemical strategy. Doing so catalytically, with alkyl-hydroperoxides or hydrogen peroxide as the oxidants, is an even better one: but best of all would be to develop[1] catalysts that selectively oxidise hydrocarbons using either dioxygen or air under mild conditions. In this communication we describe two related heterogeneous catalysts that efficiently epoxidise alkenes using molecular oxygen and sacrificial aldehydes, under conditions that mirror those of Mukaiyama *et al*.,[2] who used homogeneous (transition-metal-based) catalysts.

By extending our earlier work on the design of redox molecular sieve catalysts for the aerobic terminal oxidation of linear alkanes,[3] for the selective oxidation of cyclohexane[4] (to cyclohexanone and cyclohexanol) and for the Baeyer–Villiger oxidation of ketones to lactones,[5] we have achieved good conversions and selectivities for the epoxidation of cyclohexene and other alkenes using framework-substituted metal ions (M) in microporous aluminium phosphate, MAlPO-36 (M = Mn or Co), catalysts.

Details of the synthesis (and structure) of the Mn(II)- and Co(II)-containing AlPO-36 molecular sieves have been reported previously.[4,6] Briefly, the Mn(II) (or Co(II)) ion is introduced to the template-containing precursor gel from which small crystals of phase-pure product appear. Upon calcination in O_2 at *ca.* 550 °C, the organic template (tripropylamine) is entirely gasified, leaving the oval-shaped cages (6.5 × 7.5 Å) of the resulting catalyst empty. X-Ray absorption spectroscopy shows[7] that after calcination in O_2, some 50% of the Mn(II) (or Co(II)) originally present (isomorphously substituting for Al(III)) are converted to the Mn(III) (Co(III)) oxidation state, but that all these transition-metal ions remain securely in tetrahedral co-ordination within the microporous AlPO framework.[8] Others[9–12] have also shown that Co(II) ions in framework sites may be raised to the Co(III) state without loss of structural integrity of the AlPO framework.

In a typical experiment, 0.25 g of catalyst, 35 g of the alkene and an alkene–benzaldehyde (mole) ratio of 1 : 3 are used. The reaction mixture is loaded into a stainless steel, high-pressure catalytic reactor (Cambridge Reactor Design), lined with polyether ether ketone (PEEK), and equipped with a mechanical stirrer and liquid sampling value. Dry air is pressurised into the reaction vessel (30 bar), and the reactor heated typically for 8 h at a temperature of 323 K. The results are summarised in Table 1, and Fig. 1 shows a typical kinetic plot. Results obtained with comparable larger-pore (MAlPO-5) and smaller-pore (MAlPO-18) redox molecular sieve catalysts, the shapes of which are 7.3 × 7.3 Å and 3.8 × 3.8 Å respectively, are also tabulated. Note that conversions are consistently higher for both the MnAlPO-36 and CoAlPO-36 catalysts compared with those of their larger-pore (AlPO-5) analogues. Almost certainly, the reasons for the superior performance of the MAlPO-36 catalyst is because a greater fraction (*ca.* 0.5 compared with 0.25) of the Mn (or Co) can be raised to the +3 oxidation state,[7] which (see below) is the root cause of catalytic activity. Significantly MgAlPO-36 is totally inactive: there is no redox ion in the framework of the micropores in this case, and hence there is no

Table 1 Catalytic aerobic partial oxidation of alkenes[a]

Scheme 1

means of initiating the free-radical reactions leading to epoxidation.

Benzaldehyde molecules may freely enter the large (*ca.* 650 $m^2\ g^{-1}$) internal surfaces of both MAlPO-36 and MAlPO-5 catalysts, thereby generating[11,13] first PhCO· and then the PhCOOO· radicals which, from the sequence of steps shown in Scheme 1, lead to the formation of benzoic acid and cyclohexene oxide. In this sequence, reaction (5) is known[14] to proceed much faster than reaction (6). This free-radical based epoxidation of cyclohexene (and the other alkenes listed in Table 1) is mechanistically quite distinct from the radical-free epoxidation of alkenes[15–17] using alkyl hydroperoxides and titanosilicate catalysts.

Other aldehydes may also be used as sacrificial oxidants provided they are small enough to gain access to the active sites situated at the inner surface of the molecular sieve catalyst. Benzaldehyde is itself too large to enter Mn (or Co)-AlPO-18, but hexanal is not. Although it diffuses less rapidly into the MAlPO-18 structure than benzaldehyde does in AlPO-36, it nevertheless functions efficiently in epoxidising hex-1-ene.

The experimental conditions chosen for this study—the concentration of catalytically active redox ions at the inner surface of the molecular sieve (arbitrarily set at 4 atom%), the ratio of reactants, the amount of catalyst, temperature, pressure, *etc.*—have not been optimised for maximal conversion and selectivity. There is considerable scope for achieving improvements in catalytic performance. Note also that under the reaction conditions employed here, the framework-substituted transition-metal-ions are not leached out during use. When the solid catalyst is removed by filtration and the reactants returned into the reactor no epoxidation ensues under the conditions given in Table 1.

We thank the EPSRC, UK for financial support (rolling grant to J. M. T.), the Royal Commission for the Exhibition of 1851 for a Research Fellowship to R. R., and Professors J. M. van Hooff and R. A. van Santen for sending us a copy of H. F. W. J. van Breukelen's Eindhoven thesis, 1998.

Photolytic induction of the asymmetric catalytic complexation of prochiral cyclohexa-1,3-dienes by the tricarbonyliron fragment[1]

Received (in Liverpool, UK) 11th March 1999, Accepted 24th March 1999

Photolytic induction of the asymmetric catalytic complexation of prochiral cyclohexa-1,3-dienes by the tricarbonyliron fragment using a camphor-derived azadiene catalyst provides the corresponding tricarbonyliron complexes quantitatively in up to 86% ee.

Asymmetric catalysis provides the most efficient access to enantiopure compounds for organic synthesis starting from achiral precursors because only catalytic amounts of the chiral auxiliary are required.[2] We recently reported a novel method of asymmetric catalysis which transforms prochiral dienes into their planar-chiral tricarbonyl(η⁴-diene)iron complexes. Tricarbonyl(η⁴-diene)iron complexes have found numerous applications to stereoselective organic synthesis.[3] Therefore, a simple and versatile access to the chiral complexes in enantiomerically pure form would open up new routes for enantioselective synthesis. We now report that the asymmetric catalytic complexation of prochiral cyclohexa-1,3-dienes proceeds much more efficiently by photolytic induction.

The reaction of dienes with tricarbonyliron transfer reagents provides a much better access to the corresponding iron complexes than direct complexation with pentacarbonyliron.[4] Enantioselective complexations of prochiral 1,3-dienes were achieved with moderate enantioselectivity using chiral tricarbonyl(η⁴-1-oxadiene)iron complexes as transfer reagents.[5] Recently we introduced (η⁴-1-azadiene)tricarbonyliron complexes as a novel class of tricarbonyliron transfer reagents.[6] Moreover, the 1-azadienes represent highly efficient catalysts for the catalytic complexation of dienes with pentacarbonyliron.[7] Most noteworthy using chiral 1-azadienes an asymmetric catalytic complexation of prochiral cyclohexa-1,3-dienes was achieved.[8] The highest asymmetric inductions were obtained by using chiral catalysts which have a fixed s-*cis* conformation of the 1-azadiene moiety. These 1-azadiene catalysts are easily prepared by aldol condensation of a chiral cyclic ketone with *p*-methoxybenzaldehyde and subsequent imine formation with *p*-anisidine. Thus, (1*R*)-(+)- and (1*S*)-(−)-camphor were transformed to (*R*)-**1** and (*S*)-**1**, (1*R*)-(+)-nopinone to (*R*)-**2**, and (+)-estrone methyl ether to (−)-**3** [$[\alpha]_D^{20}$ −318.1 (*c* 0.53, $CHCl_3$)]. The catalyst (*R*)-**4** was prepared by imine condensation of *o*-anisidine with (1*R*)-(−)-myrtenal.

Catalyst **1** showed the highest enantioselectivity in the asymmetric catalytic complexation of 1-methoxycyclohexa-1,3-diene **5a** which was performed in benzene at reflux with exposure to daylight. An extensive reinvestigation of the asymmetric catalytic complexation of **5a** using catalyst (*R*)-**1** revealed two important aspects (Table 1). First, the result is strongly dependent on the amount of catalyst applied. Higher turnovers and asymmetric inductions are obtained at higher concentrations of the catalyst (*R*)-**1**. Second, the asymmetric catalysis is influenced by light, perhaps due to a photolytically induced loss of a carbon monoxide ligand (compare our proposed mechanism).[7b,8c] In the dark the reaction proceeds much more slowly and using catalytic amounts of (*R*)-**1** also the ee of the product is lower in the absence of light. After reaction for 7 d with exclusion of light in the presence of 4 equiv. of (*R*)-**1** the asymmetric complexation of **5a** provides a result (99% yield, 88% ee of the *S* enantiomer) which is comparable with respect to yield and ee to the corresponding outcome obtained in the presence of daylight after 2 d.

Based on the experimental observations described above, we hoped to exploit the photolytic induction of the asymmetric complexation in order to achieve a quantitative reaction with high asymmetric induction (> 85% ee) by using only catalytic amounts of the chiral 1-azadienes with shorter reaction times. Therefore, we investigated the asymmetric catalytic complexation of **5a** with pentacarbonyliron in benzene at reflux on irradiation with a 10 W halogen lamp using the catalysts (*R*)-**1** to (*R*)-**4** (Scheme 1, Table 2). The ee values were determined accurately *via* separation of the two enantiomers by chiral HPLC on a cyclodextrin column.[9] To avoid the formation of hexacarbonyldiiron clusters,[7b,8c] the excess of pentacarbonyliron was reduced to 1.5 equiv. based on the diene. A blank experiment (complexation without catalyst) demonstrated that photolytic induction in contrast to the solely thermal conditions promotes also the uncatalyzed complexation, which leads to the formation of racemic product (compare also the two blank experiments in Table 1). However, the catalytic complexation proceeds much faster and therefore, this pathway predominates. The camphor-derived catalyst **1** proved to be the best for the photolytically induced asymmetric catalytic complexation and

[a] All reactions were performed using 0.25 equiv. of catalyst, 1.5 equiv. of $Fe(CO)_5$ and a 10 W halogen lamp (12 V) in benzene at 80 °C. [b] Ee determined by chiral HPLC (absolute configuration) (ref. 9). [c] Specific rotation in $CHCl_3$ (concentration).

led to a quantitative complexation within only one day. Using the 1-azadiene (*R*)-**1** complex (*S*)-**6a** was obtained in 86% ee (Fig. 1) and (*S*)-**1** provided complex (*R*)-**6a** in 85% ee.† The previous procedure for asymmetric catalytic complexation using the same catalyst afforded complex **6a** quantitatively after a reaction time of 12 days and with 73% ee of either enantiomer.[8c] Also for the other catalysts application of the photolytic induction led to a significant increase of the asymmetric induction compared to the result of the thermally induced catalytic complexation.

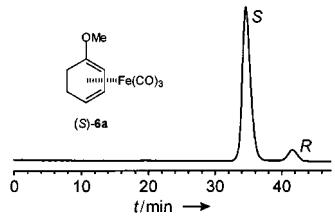

Fig. 1 Chiral HPLC on a permethylated β-cyclodextrin column of complex **6a** with 86% ee of the (*S*)-(+) enantiomer.

We investigated the photolytic induction of the asymmetric catalytic complexation for a series of prochiral cyclohexa-1,3-dienes **5** using the chiral catalysts (*R*)-**1** and (*S*)-**1** (Scheme 2, Table 3). Quantitative yields should be available in all cases simply by extension of the reaction time. However, further optimization was not executed because at this stage of our studies we were primarily interested in the enantioselectivity of the reaction. The asymmetric induction for the catalytic complexation of **5b**,**c** and **e** was in the range of 70–80% ee. Complex **6d**, a potential precursor for discorhabdin alkaloids,[10] was obtained in 50% ee for either enantiomer. The photolytically induced asymmetric catalytic complexation of **5f** with pentacarbonyliron using the catalysts (*R*)-**1** and (*S*)-**1** provided only 42% ee for either enantiomer of the corresponding tricarbonyliron complex. In this case however, the estrone-

Received (in Cambridge, UK) 4th January 1999, Accepted 26th March 1999

A variety of alcohols are oxidized to the corresponding carbonyl compounds in excellent yields by zeofen under classical heating and microwave irradiation in solventless system.

Oxidation of alcohols to carbonyl compounds is a fundamental transformation in organic synthesis and, because of its significant role, the development of newer methods is attracting much current interest[1–4] in spite of the availability of numerous methods reported in the literature.[5,6] The use of heavy metals and peracids is very common.[7,8] However, a drawback of such oxidants and their use in multistage organic synthesis in spite of their power is their lack of selectivity. For instance, over-oxidation of aldehydes to carboxylic acids[9] and degradation of unsaturated substrates are often unavoidable side reactions.[10] In addition to their lack of selectivity, oxidants based on chromium[11] and manganese[12] are corrosive, irritants and toxic.[13]

In view of economic, practical and recent environmental demands,[14] we saw significant advantage in using a non-toxic and inexpensive metal salts such as iron(III) nitrate. Some early success in the use of clayfen for oxidation of alcohols[15] supported this idea.

Reagents impregnated on mineral supports have gained popularity in organic synthesis because of their selectivity and ease of manipulation.[16,17] Recently we reported the use of zeolite catalyzed[18] and microwave enhanced chemical reactions[19] on organic solid supports.[20] We report here a facile oxidation of alcohols to carbonyl compounds using zeofen [short for zeolite HZSM-5 supported iron(III) nitrate] in CH_2Cl_2 at room temperature and under microwave irradiation in a solventless system.

To prepare zeofen, $Fe(NO_3)_3.9H_2O$ (0.80 g, 2 mmol) and a weight equivalent of HZSM-5 zeolite[21] were crushed together so as to form an intimate mixture (zeofen). This new reagent can be stored in a dark brown bottle and is stable without suffering from the problem of slow decomposition that clayfen does.[22] In a typical reaction 1–1.2 equiv. of zeofen was added to a stirring solution of an alcohol in dry CH_2Cl_2 at room temperature. After the completion of the reactions (monitored by TLC) the reagent was filtered off and washed with CH_2Cl_2. Evaporation of solvent gave the corresponding carbonyl compounds. It should be pointed out that in the absence of zeolite, the reaction was sluggish and even at reflux temperature a considerable amount of starting material was recovered unchanged. Different types of alcohols were converted to their corresponding carbonyl compounds by this procedure in high yields. The results are presented in Table 1.

Although there has been growing interest in applying microwave dielecteric heating to accelerate organic reactions,[23] oxidation reactions are less often considered as candidates for microwave irradiation due to their unsafe and uncontrollable experimental conditions.[24] It has been shown that polar reactants adsorbed on the surface of solid supports absorb microwaves.[25] In connection with our interest in using microwaves to increase the rates of reactions,[19] we have investigated the above oxidation under microwave irradiation. The oxidation reactions were carried out simply by mixing 1–1.2 equiv. of zeofen with 1 equiv. of an alcohol in a beaker under microwave irradiation (900 W) for 2 min. For example, benzyl alcohol was oxidized to benzaldehyde in almost quantitative yields after 10 s. It is noteworthy to mention that in the absence of zeolite, the reaction was slow and, more seriously, molten ferric nitrate and/or its degradation product(s) adhered to the walls of the reaction vessel, forming an intractable solid mass which made the isolation of carbonyl compounds difficult and led to erratic results. Indeed when iron(III) nitrate was used without zeolite the conversion of benzyl alcohol to benzaldehyde was only 50% under conditions otherwise similar to those described above. Clearly zeolite aided the reproducibility and high activity of iron(III) nitrate. To assess the generality of this oxidation a variety of alcohols were reacted under these conditions, which yielded the corresponding carbonyl compounds in excellent yields. Table 2 summarizes the data for oxidation of alcohols under microwave irradiation in a solventless system.

In conclusion, zeofen can be easily prepared from inexpensive and non-toxic materials and serves as an excellent oxidizing agent for various types of alcohols at room tem-

perature in solvent and under solvent-free conditions using a house-hold microwave oven. Solvent-free microwave irradiation has an advantage over conventional heating, offering a practical and environmentally benign protocol, decreasing reaction time and in some cases giving cleaner reactions and easier work up.

ChemComm

A new germanium based linker for solid phase synthesis of aromatic compounds

Alan C. Spivey,*[a] Christopher M. Diaper[a] and Andrew J. Rudge[b]

[a] *University of Sheffield, Brook Hill, Sheffield, Yorkshire, UK S3 7HF. E-mail: a.c.spivey@sheffield.ac.uk*

Received (in Liverpool, UK) 2nd February 1999, Accepted 22nd March 1999

An efficient three-step synthesis of germyl linker precursor 4 is described which enables a simple two step immobilisation of lithiated aromatics to Argogel™ polymer; cleavage from the polymer support *via ipso*-degermylation with TFA, ICl, Br_2 and NCS provides protio-, iodo-, bromo- and chloroaryls, respectively.

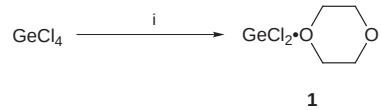
The development of new linkers for the immobilisation of organic compounds on functionalised polymer supports is an area of current interest.[1] The immobilisation of aromatics has commanded particular importance as compounds of this type are pervasive constituents of pharmaceuticals. Protecting-group linker strategies are suitable for this purpose provided that the functional group unmasked on cleavage is required in the target molecules. If not, then a traceless linker (*e.g.* arylsilane based) can be employed.[2] Arylsilane cleavage is generally achieved *via* acidolytic or basic fluoridolytic *ipso*-protodesilylation,[3] or by electrophilic *ipso*-halodesilylation using Br_2 or ICl to release aryl bromides and iodides respectively.[4] The ability to employ a range of electrophiles for cleavage is desirable for library preparation as diversity is introduced on release into solution.

We were interested in devising a new aryl linker susceptible to cleavage by an increased range of electrophiles and to this end the work of Vasella[5] on trimethylgermane protection of alkynes drew our attention. Vasella has noted that relative to the corresponding alkynylsilanes, alkynylgermanes are more readily cleaved by electrophiles (due to the more powerful β-effect of germanium)[6] and additionally display enhanced stability towards bases and nucleophiles. These properties combined with the low toxicity of aryl- and alkylgermane compounds suggested to us that an arylgermane-based linker might provide a useful addition to the current repertoire of traceless linkers.

During the course of our studies Ellman,[7] in response to the low reactivity of an electron deficient arylsilane bound benzodiazepine library towards acidolytic cleavage, reported the first arylgermane linker. Ellman demonstrated that his arylgermane linker was more readily cleaved by electrophiles (TFA, Br_2) than the corresponding arylsilane linker and that his linker was compatible with a range of transformations associated with the introduction and manipulation of a diverse array of functional groups. In the light of this pioneering 'proof of concept' our efforts focussed on the development of a more economic arylgermane linker as Ellman's linker synthesis relied on Me_2GeCl_2 for introduction of the germanium. This compound is expensive and is difficult to prepare from $GeCl_4$ (the cheapest commercial source of germanium).

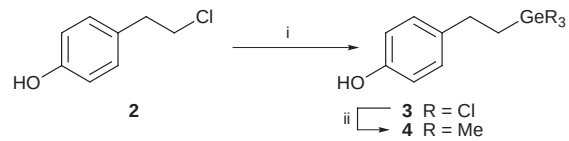
One interesting facet of germanium chemistry is the coordination and insertion reactions associated with dihalogermylenes.[8] We opted to exploit this chemistry in the preparation of our arylgermane linker. Thus, known dichlorogermylene–1,4-dioxane complex, $GeCl_2.C_4H_8O_2$ **1**, was synthesised in one step from $GeCl_4$ by reduction with tetramethyldisiloxane (TMDS) in refluxing dioxane (Scheme 1). This reaction routinely provides 70–90% isolated yields of this stable crystalline complex on a preparative scale.[9]

Various dichlorogermylene complexes have been reported to undergo thermally induced insertion into C–Cl bonds.[10] We found that the dioxane complex **1** inserts cleanly into the homobenzylic C–Cl bond of 4-(2-chloroethyl)phenol **2**.† Simply heating the two components in a Carius tube with a minimum amount of dioxane furnished trichlorogermane **3** in 91% yield. Exhaustive methylation by refluxing with an excess of MeMgBr then furnished trimethylgermane linker precursor **4**‡ in 82% yield[11] (Scheme 2).



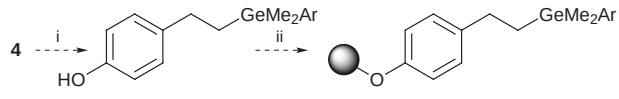
1

Scheme 1 *Reagents and conditions*: i, TMDS, 1,4-dioxane, 3 h, 100 °C.



Scheme 2 *Reagents and conditions*: i, $GeCl_2.C_4H_8O_2$ **1**, 1,4-dioxane, 16 h, 140 °C (91%); ii, MeMgBr, Et_2O, toluene, 16 h, 110 °C (82%).

We envisaged that immobilisation of an aromatic compound onto a hydroxy functionalised polymer support could be achieved in a simple two step procedure using trimethylgermane linker precursor **4**. This would involve selective monohalodemethylation and *in situ* arylation with the appropriate aryl organometallic species (→ **I**, Scheme 3) followed by Mitsunobu coupling of the resulting phenolic dimethylarylgermane to the polymer support (→ **II**, Scheme 3).



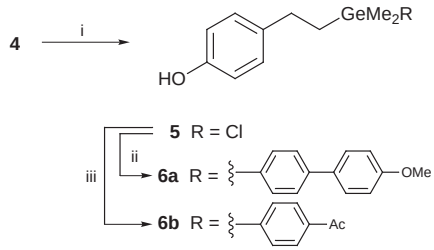
I **II**

Scheme 3 Two step immobilisation strategy: i, mono-halodemethylation and *in situ* arylation with aryl organometallic; ii, Mitsunobu coupling to resin.

To exemplify this protocol we report here the immobilisation of two aromatic systems: 4-(4′-methoxy)biphenyl and 4-acetophenone. The former was chosen as this biphenyl would provide a stringent test system on which to assess electrophilic cleavage by virtue of having an electron rich aryl group susceptible itself to competitive electrophilic aromatic substitution. The latter was chosen as acetophenone provides a versatile functional handle for library construction.

Butyltrimethylgermane (Me_3BuGe) has been shown to undergo selective mono-chlorodemethylation to give chlorobutyldimethylgermane ($Me_2BuGeCl$) upon treatment with $SnCl_4$.[12] We were able to replicate this exquisite chemoselectivity with our linker precursor **4**. Thus treatment with $SnCl_4$ in $MeNO_2$ gave chlorodimethylgermane **5** quantitatively (Scheme 4).

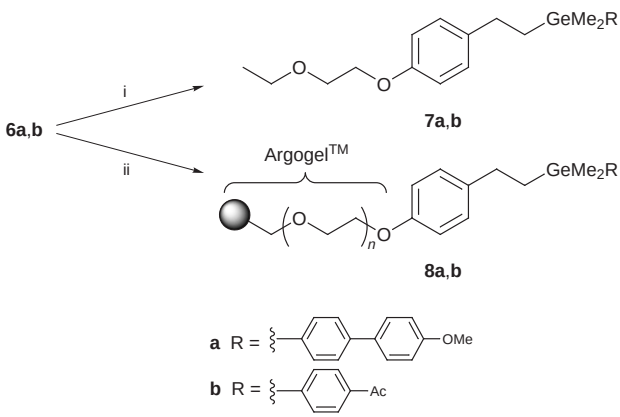
Arylation of **5** was accomplished by refluxing overnight in toluene–THF with the appropriate aryllithium reagent.[13] The 4-litho-4′methoxybiphenyl and dioxolane protected 4-lithioacetophenone, used to prepare arylgermanes **6a** and **6b**



Scheme 4 *Reagents and conditions*: i, $SnCl_4$, $MeNO_2$, 16 h, 50 °C (100%); ii, 4-bromo-4′-methoxybiphenyl, BuLi, hexane, THF, toluene, 16 h, 110 °C [**6a** (82%)]; iii, (a) 2-(4-bromophenyl)-2-methyl-1,3-dioxolane, BuLi, THF, toluene, 16 h, 110 °C, (b) PPTS, acetone, H_2O, 48 h, 67 °C [**6b** (84% from **5**)].

respectively, were made from the corresponding bromides by standard lithium–halogen exchange at −78 °C. Dioxolane deprotection was accomplished using PPTS in acetone–H_2O (Scheme 4).

Tsunoda's modified Mitsunobu redox system of *N*,*N*,*N*′,*N*′-tetramethylazodicarboxamide (TMAD)–PBu_3 was found to effect efficient coupling of arylgermanes **6a** and **6b** to ethoxyethanol to give model systems **7a** and **7b** respectively.[14] Ethoxyethanol was selected as a solution phase 'surrogate' for PEG based Argogel™.§ Use of a solution phase model for development of appropriate Mitsunobu coupling conditions was vindicated when these optimised conditions were employed without modification for the efficient loading of arylgermanes **6a** and **6b** to Argogel™. Thus following successive washing of the polymer with DMF, EtOH, THF, Et_2O and CH_2Cl_2 the aryl functionalised polymers **8a** and **8b** were obtained with loading levels of 0.47 and 0.43 mmol g^{-1}¶ respectively (Scheme 5).



Scheme 5 *Reagents and conditions*: i, $EtOCH_2CH_2OH$, TMAD, PBu_3, PhH, room temp. 16 h [**7a** (98%), **7b** (87%)]; ii, Argogel™, TMAD, PBu_3, PhH, room temp., 16 h (**8a**, **8b**, see text).

Electrophilic cleavage conditions were optimised initially using solution phase biarylgermane model system **7a**. It was pleasing to find that treatment with TFA, ICl and Br_2 at room temperature led to quantitative cleavage of the aryl–germanium bond, yielding the protio-, iodo- and bromobiaryl products **9**, **10** and **11** respectively. Furthermore, chlorobiaryl **12** could also be obtained cleanly using NCS (or Dichloramine-T) in refluxing THF. There were no traces of products resulting from competitive electrophilic substitution in the anisole ring. Minimal optimisation was required to translate this success to cleavage from Argogel™. Thus when employing functionalised resin **8a**, monitoring release of the biaryl products into solution by analytical HPLC of the *crude* washings revealed all these protocols to proceed cleanly and quantitatively (Fig. 1). The identity of the released biaryls **9**, **10**, **11** and **12** were confirmed in each case by co-injection with authentic samples.

To conclude, we have developed an efficient three step synthesis of germyl linker precursor **4** (from inexpensive $GeCl_4$) and demonstrated that this compound can be employed in a simple two step immobilisation of lithiated aromatics to Argogel™ polymer. Clean release from the polymer by electrophilic *ipso*-degermylation affords either protio-, iodo-, bromo- or chloroaryls, depending on the electrophile employed.

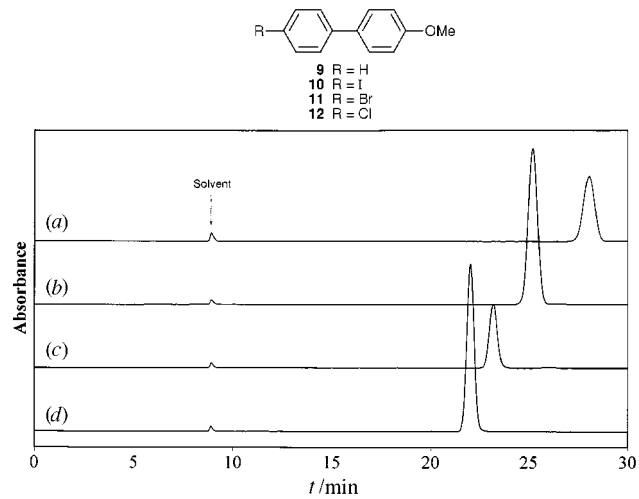


Fig. 1 HPLC traces of biaryls cleaved from Argogel™. [Column: Hichrom spherisorb-S5W (25 × 0.8 cm), eluting with 80 : 20 hexane–$CHCl_3$, 1.0 ml min^{-1}]. *Reagents and conditions*: (*a*) TFA room temp., 16 h (→ **9**); (*b*) ICl, CH_2Cl_2, room temp., 30 min (→ **10**); (*c*) NCS, THF, 67 °C, 14 h (→ **12**); (*d*) Br_2, CH_2Cl_2, room temp., 2 h (→ **11**).

We are currently preparing a library of aryl containing compounds using functionalised polymer **8b** and extending the range of electrophiles able to effect cleavage of the aryl–germanium bond.

Grateful acknowledgement is made to Pfizer for financial support of this work.

Notes and references

† 4-(2-Chloroethyl)phenol is readily prepared in 90% yield from commercially available 4-(2-hydroxyethyl)phenol by heating in concentrated HCl (ref. 15).

‡ Now commercially available from AFChemPharm Ltd., Unit B31-14, Manor Development Centre, 40 Alison Crescent, Sheffield, UK S2 1AS.

§ Commercial Argogel™ (nominal loading level 0.49 mmol g^{-1}) was selected as the polymer support due to its non-benzylic hydroxy functionalisation and favourable characteristics for high resolution MAS ^1H NMR.

¶ As determined by mass balance (of introduction and subsequent cleavage). Polymers **8a** and **8b** were also characterised by solid state MAS ^1H NMR.

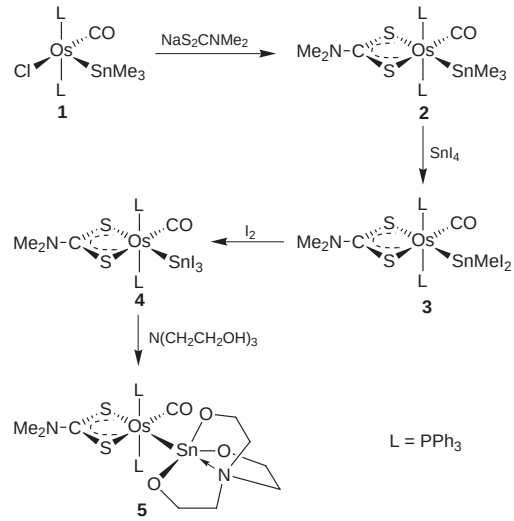
Received (in Cambridge, UK) 22nd February 1999, Accepted 29th March 1999

The first metal substituted stannatrane, $Os(Sn[OCH_2CH_2]_3N)(\eta^2\text{-}S_2CNMe_2)(CO)(PPh_3)_2$, has been synthesised by reaction between triethanolamine and the triiodostannyl osmium complex $Os(SnI_3)(\eta^2\text{-}S_2CNMe_2)(CO)(PPh_3)_2$: the transannular Sn–N distance of 2.422(4) Å indicates a bonding interaction which is not seen in the corresponding silatranyl complex $Os(Si[OCH_2CH_2]_3N)(\eta^2\text{-}S_2CNMe_2)(CO)(PPh_3)_2$ which has an Si–N distance of 3.176(6) Å.

Silatranes, cyclic organosilicon ethers of tris(2-oxyalkyl)amine, have been the subject of intense study since their discovery in 1961.[1] Perhaps the most intriguing aspect of these hypervalent silicon compounds is the nature of the silicon–nitrogen interaction and the variation in the transannular Si–N distance as a function of change in the axial silicon substituent.[2–5] Although many structurally characterised examples of silatranes have been reported,[6] only two bear metal atoms as axial substituents, and both of these feature strikingly long Si–N distances.[7,8] In contrast to silatranes, reports of the analogous tin compounds, stannatranes, are sparse, with only two crystallographically characterised examples.[9,10] Our recent work has focused on the synthesis of trihalostannyl osmium complexes because these complexes are amenable to further derivatisation at the tin centre. Here, we report the synthesis and structural characterisation of the first metal-substituted stannatrane, $Os(Sn[OCH_2CH_2]_3N)(\eta^2\text{-}S_2CNMe_2)(CO)(PPh_3)_2$, which is formed by a ligand reaction of the triiodostannyl osmium complex, $Os(SnI_3)(\eta^2\text{-}S_2CNMe_2)(CO)(PPh_3)_2$, with triethanolamine. In order to compare the properties of stannatranyl and silatranyl ligands, particularly with respect to the transannular interaction, the structure of the analagous silatranyl complex, $Os(Si[OCH_2CH_2]_3N)(\eta^2\text{-}S_2CNMe_2)(CO)(PPh_3)_2$, has also been determined.

The coordinatively unsaturated complex, $Os(SnMe_3)Cl(CO)(PPh_3)_2$ **1**,[11] may be converted easily to the six coordinate dithiocarbamate complex, $Os(SnMe_3)(\eta^2\text{-}S_2CNMe_2)(CO)(PPh_3)_2$ **2**, by treatment with NaS_2CNMe_2 at 0 °C (Scheme 1). Reaction of **2** with an excess of tin(IV) iodide in benzene provides $Os(SnMeI_2)(\eta^2\text{-}S_2CNMe_2)(CO)(PPh_3)_2$ **3** in high yield. Although such redistribution reactions are common for R_xSnX_{4-x} systems we believe this represents the first example of such a reaction for a metal stannyl complex. All attempts to remove the last methyl substituent with an excess of SnI_4 failed, even at elevated temperatures. However, treatment of **3** with one equivalent of I_2 in dichloromethane smoothly cleaves the remaining Sn–Me bond to yield yellow $Os(SnI_3)(\eta^2\text{-}S_2CNMe_2)(CO)(PPh_3)_2$ **4**. It should be noted here that direct addition of I_2 to **2** results mainly in the cleavage of the osmium–tin bond.

Treatment of **4** with an excess of triethanolamine in benzene over 30 min provides the colourless, air stable, stannatranyl compound, $Os(Sn[OCH_2CH_2]_3N)(\eta^2\text{-}S_2CNMe_2)(CO)(PPh_3)_2$ **5**, in good yield.† A single crystal X-ray structure determination of this product has been carried out‡ and the molecular structure is depicted in Fig. 1.



Scheme 1

The geometry about the osmium centre can be best described as distorted octahedral with the main cause of distortion arising from the necessarily constricted bite angle of the dithiocarbamate ligand. The Os–Sn bond distance of 2.6119(3) Å is at the low end of the range of previously reported values the mean of which is 2.721 Å.[12] The most arresting aspect of the structure lies in the stannatranyl moiety where the Sn–N distance of 2.422(4)Å is only slightly longer than those found in

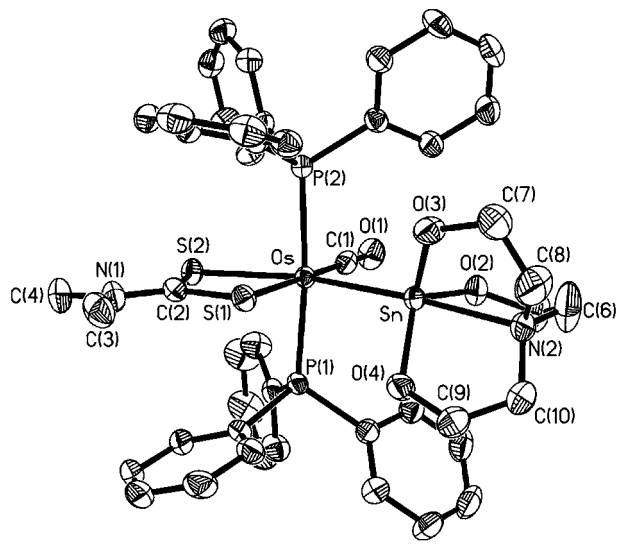


Fig. 1 Crystal structure of **5**. Selected bond lengths (Å) and angles (°): Os–Sn 2.6119(3), Sn–N(2) 2.422(4), C(8)–N(2)–C(6) 110.8(6), C(10)–N(2)–C(6) 114.4(5), C(10)–N(2)–C(8) 114.0(5), Sn–Os–S(2) 160.62(3).

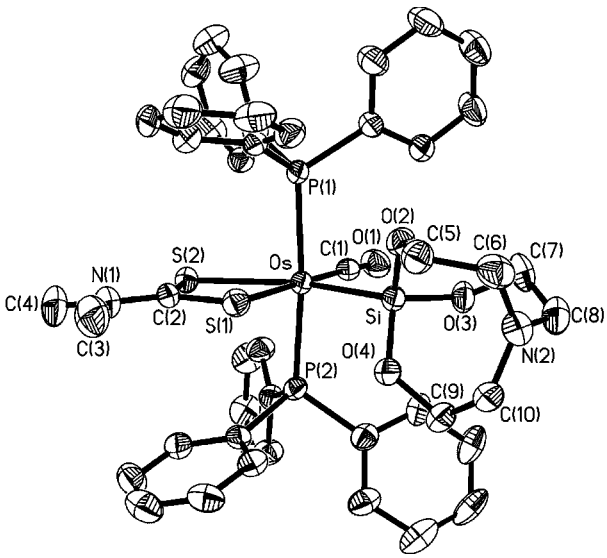

Fig. 2 Crystal structure of **6**. Selected bond lengths (Å) and angles (°): Os–Si 2.3783(17), Si–N(2) 3.176(6), C(8)–N(2)–C(6) 120.3(6), C(10)–N(2)–C(6) 120.0(6), C(10)–N(2)–C(8) 118.6(7), Si–Os–S(2) 154.98(6).

$[MeSn(OCH_2CH_2)_3N]_3$ [2.28(1) Å][9] or $Bu^tSn(OCH_2CH_2)_3N$ (2.324 Å).[10] However, is still considerably shorter than the sum of the van der Waals radii, and must surely constitute a significant interaction. The tin atom displays a very distorted trigonal bipyramidal arrangement, with the osmium and nitrogen atoms axial, and the oxygen atoms equatorial. The tin lies out of a plane taken through O(2), O(3) and O(4) by 0.533(2) Å in the direction of the osmium atom. The geometry at the nitrogen can be seen as tetrahedral, with the nitrogen atom lying out of the plane defined by C(8), C(6) and C(10) by 0.388(5) Å towards osmium.

In order to compare the structural features of this stannatrane with the corresponding silatrane, $Os(Si[OCH_2CH_2]_3N)(\eta^2\text{-}S_2CNMe_2)(CO)(PPh_3)_2$ **6** was prepared in high yield by the addition of NaS_2CNMe_2 to $Os(Si[OCH_2CH_2]_3N)Cl(CO)(PPh_3)_2$.[8] Crystals were grown from dichloromethane–ethanol and a single crystal diffraction study performed.‡ The structure of **6** is shown in Fig. 2, along with selected bond lengths and angles. It is immediately apparent that the silatrane moiety has a very different cage geometry. In this case the Si–N distance is 3.176(6) Å, whereas typical silatrane structures feature values in the range 2.00–2.26 Å. The Si–N distance in **6** is even longer than the distances found in either $Os(Si[OCH_2CH_2]_3N)Cl(CO)(PPh_3)_2$ [3.000(7) Å][8] or *trans*-$Pt(Si\{OCH_2CH_2\}_3N)Cl(CO)(PMe_2Ph)_2$ [2.89(1) Å].[7] The bonds about the nitrogen atom are almost perfectly trigonal planar with the sum of angles at N being 358.9°. The nitrogen atom is displaced 0.088(7) Å from the plane defined by C(6), C(8) and C(10) in the direction away from the metal atom. The silicon atom has approximately tetrahedral geometry. The geometry about the osmium atom does not differ markedly from that found in compound **5**, except that the Os–S(2) distance is significantly longer for **6** [2.5431(15) Å] compared to the corresponding distance in compound **5** [2.4805(10) Å]. This disparity is presumably a reflection of a greater *trans* influence exerted by the silicon atom over that of the tin atom.

The structural comparison of these two analogous metal substituted atrane systems reveals marked differences. Whereas the stannatrane retains the Sn–N interaction to a large extent, in the silatrane the Si–N interaction is almost totally absent. This is most likely a reflection on the greater ability of tin to form hypervalent compounds when compared to silicon.

T. J. W. is grateful to the Royal Society for the award of a Post Doctoral Fellowship.

Notes and references

† *Synthesis and selected data for* $Os(Sn[OCH_2CH_2]_3N)(\eta^2\text{-}S_2CNMe_2)(CO)(PPh_3)_2$ **5**: triethanolamine (1.10 g, 1.09 mmol) was added dropwise to a chilled (0 °C) and stirred solution of $Os(SnI_3)(\eta^2\text{-}S_2CNMe_2)(CO)(PPh_3)_2$ (0.195 g, 0.143 mmol) in deoxygenated dichloromethane (40 cm³). The solution was stirred for 1 h, during which time the yellow colour faded completely. The organic layer was washed with water (3 × 25 cm³) and filtered. Addition of ethanol (20 cm³) and reduction of solvent volume *in vacuo* to 5 cm³ produced a white precipitate which was collected by filtration. Recrystallisation from dichloromethane–ethanol provided **5** in 76% yield. ν_{max}(KBr)/cm^{-1}: 1896 (CO), 1535, 1155 (dithiocarbamate); δ_H($CDCl_3$, 400.133 MHz, 300 K) 1.89 (s, 3H, NCH_3), 2.23 (t, 6H, *J* 5.34 Hz, NCH_2), 2.31 (s, 3H, NCH_3), 3.28 (t, *J* 5.34 Hz, 6H, OCH_2), 7.25–7.95 (m, 30H, PhH); δ_C($CDCl_3$, 100.623 MHz, 300 K) 35.80 (S_2CNMe_2), 36.42 (S_2CNMe_2), 53.30 [$Sn(OCH_2CH_2)_3N$, ^3J(SnC) 34.2 Hz), 57.39 [$Sn(OCH_2CH_2)_3N$, ^2J(SnC) 42.4 Hz], 126.76 (*o*-PPh_3), 128.67 (*p*-PPh_3), 129.78 (*ipso*-PPh_3), 135.27 (*m*-PPh_3), 185.61 [t, *C*O, ^2J(PC) 22.0 Hz], 210.59 (S_2CNMe_2); $\delta_{^{119}Sn}$[$CDCl_3$–$CHCl_3$ (1 : 3) 149.144 MHz, 300 K] −513.4 [t, ^2J(SnP) 193.86 Hz]; Calc. for $C_{46}H_{48}N_2O_4P_2S_2OsSn\cdot 2CH_2Cl_2$: C, 47.72; H, 4.22; N, 2.39. α-Diazo ketone self-assembled monolayer modified electrode: a proposed photoreactive template for electrode derivatisation

Glorija J. Jocys and Mark S. Workentin*

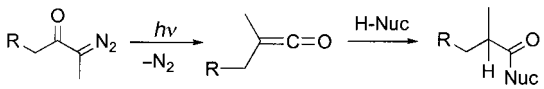
Department of Chemistry, The University of Western Ontario, London, Ontario Canada N6A 5B7. E-mail: mworkent@julian.uwo.ca

Received (in Corvallis, OR, USA) 14th January 1999, Accepted 22nd March 1999

A gold electrode modified with an α-diazo ketone has been prepared and its photo-Wolff chemistry investigated in the presence of MeOH as a ketene trap; results suggest that these modified electrodes are a potential photoreactive template for surface modifications.

Modification of electrode surfaces with monolayers of organic substrates *via* self-assembly continues to be an area of active investigation. In particular, there are a great number of studies whose goals are to prepare electrode surfaces modified with the appropriate organic functionality at the interface to provide the site for molecular recognition or modulation of electronic factors for a sensing action.[1,2] Despite the power of photochemistry to provide careful control of surface modifications of organic functionality through photo-patterning techniques, this approach remains relatively unexplored considering the enormous amount of work in the area of self-assembly of organic substrates on metals. Examples of the types of photoreactions of substrates on gold surfaces that have been reported include photoextrusion of nitrogen from aryl azide,[3] *E–Z* photoisomerisation of stilbenes[4] and azo compounds[5] and other photochromic materials,[5] and photodimerization reactions.[6]

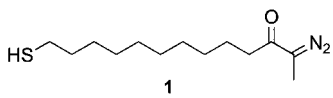
Our approach is to employ the photochemistry of α-diazocarbonyl compounds to serve as a photoreactive template for further surface modifications. Compounds containing an α-diazo ketone functionality are known to produce a ketene intermediate, *via* the photo-Wolff rearrangement, upon photoexcitation and loss of nitrogen [eqn. (1)]. The resulting ketenes



(1)

are known to react with a wide range of nucleophiles to form a variety of functional groups. Simple examples include water, alcohol and amine nucleophiles to form carboxylic acids, esters and amides, respectively. Owing to their wide-ranging reactivity, α-diazocarbonyl compounds[7] and ketenes[8] have been extensively used in solution phase synthetic strategies. Of particular interest to us is extending this chemistry to provide a template for ways to derivatize selectively the monolayer surface with a variety of nucleophile substrates. Here we report the first example of an α-diazo ketone functionality incorporated into the interface of a self-assembled monolayer on a gold electrode. As proof of concept that this modified surface has potential as a template for photo-Wolff chemistry, we have photolysed this novel surface in the presence of MeOH as the nucleophile to form an ester derivatized surface.

The α-diazo ketone monolayer precursor, 2-diazo-13-mercaptotridecan-3-one **1**, was synthesized in four steps



1

from 11-bromoundecanoic acid. First, the acid was converted into its acid chloride by refluxing in $SOCl_2$. This was followed by diazotisation of the acid chloride using $MeCHN_2$ to form 13-bromo-2-diazotridecan-3-one. The latter was thioesterified with AcSK to form $AcS(CH_2)_{10}C(O)C(N_2)Me$. Finally, the thioester was hydrolysed to the thiol with methanolic K_2CO_3 and then purified by repeated column chromatography to yield analytically pure **1**, in 10% overall yield. The structure of **1** was confirmed by ^1H and ^{13}C NMR, infrared and mass spectroscopy.[9] For latter comparison the transmission IR of **1** taken as a thin film on a NaCl plate is shown in Fig. 1(*c*).

Monolayers of **1** on gold (Au-**1**) were prepared by immersion of clean Au[10] in a 50 mM deareated EtOH solution of **1** for 1–96 h. The homogeneity of the monolayer was examined qualitatively using cyclic voltammetry, by monitoring the reversible $Fe^{2+/3+}$ redox chemistry of $Fe(CN)_6^{3-}$ in aqueous solution above the Au-**1** derivatized electrodes. On average soaking times of 16 h resulted in a overall current decrease of greater than 10^3 [*i.e.* no detectable $Fe(CN)_6^{3-}/Fe(CN)_6^{4-}$ redox activity] compared to the bare gold electrode (no further current reduction was observed on samples soaked for up to 4 days). This overall current decrease and the observed cyclic voltammograms of the blocked gold electrodes are similar to those published for other organic thiol self-assembled monolayer systems on Au using the same redox probe.[6,10] A grazing angle infrared spectrum of an Au-**1** substrate prepared in a similar manner is shown in Fig. 1(*a*). Note that the spectral features compare well to the transmission IR spectrum of the same compound measured as a thin film on NaCl [Fig. 1(*c*)]. Diagnostic absorptions are listed in Table 1; also listed for comparison are the absorptions for a thin film of **1**. In particular we note that the characteristic methylene symmetric and asymmetric stretching frequencies and intensities are similar to other densely packed, well-ordered Au-alkyl monolayers of similar length.[11] Also diagnostic are the C=N=N asymmetric and C=O stretching absorptions at 2086 and 1698/1646 cm^{-1}, respectively.[12] The C=O absorption appears to be split into two in Au-**1**. This may be due to (i) a solid state correlation effect,[13]

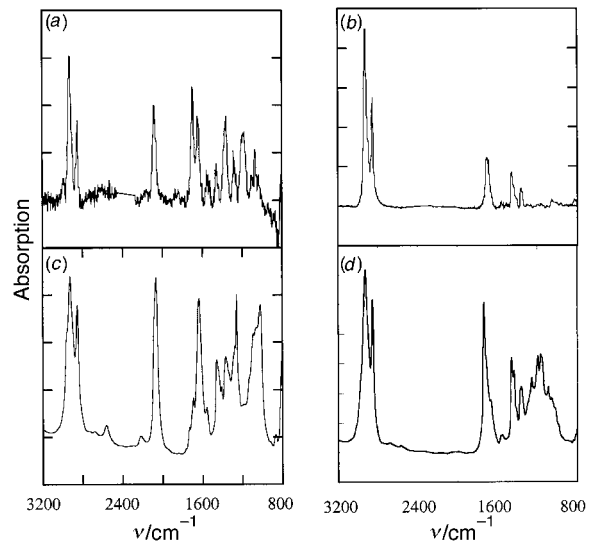


Fig. 1 Grazing angle fourier transform infrared spectra of (*a*) Au-**1** and (*b*) Au-**2** on gold and absorption FTIR of (*c*) **1** and (*d*) **2** as neat thin film samples on NaCl plates. Note: in the spectrum of Au-**1** the absorptions due to CO_2 have been deleted for clarity.

Table 1 Diagnostic infrared assignments for Au-**1** and **1** prior to and after irradiation in MeOH (Au-**2** and **2**)

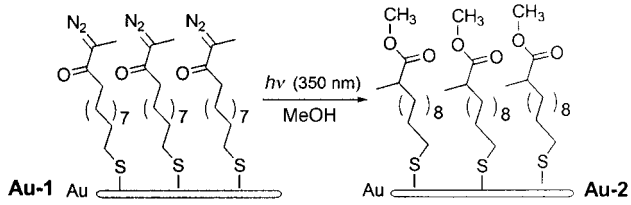
[a] Assignments are based on similar systems and from ref. 12. [b] Tentative assignment, since multiple modes are possible in this region. [c] See text.



Scheme 1

suggesting that even the groups at the interface are well ordered, (ii) different rotational isomers of the O=C–C(N2) (*i.e.* s-*cis* and s-*trans*) that become more prevalent in the densely packed monolayer compared to **1**, or (iii) the rotational restrictions may lead to some decrease in the conjugation due to steric interactions in the densely packed monolayer.

Au-**1** samples above were irradiated in a nitrogen saturated MeOH solution at 350 nm using a medium pressure Hg-lamp with appropriate filters. A grazing angle IR spectrum of the Au-substrate after complete photolysis is shown in Fig. 1(*b*) and characteristic absorptions are listed in Table 1. Note the complete absence of the C=N=N asymmetric stretch; the appearance of the IR spectrum measured at intermediate times shows gradual loss of the characteristic C=N=N absorption concomitant with a change in the spectral region of the carbonyl absorption. The new C=O absorption is shifted to slightly higher energy consistent with that for a CH_2–C(O)–OMe ester.[13] The intensity of the C=O absorption of the ester is somewhat reduced compared to the thin film; we assign this tentatively to an orientation effect, where the C=O mode is aligned roughly parallel to the metal surface. The relative intensities of the absorptions due to the methylene groups of the long chain tether in the irradiated sample compared to those of Au-**1** before irradiation do not vary, indicating that under the photolysis conditions the monolayer remains intact and relatively ordered. After irradiation the same extent of electrochemical blocking of the $Fe(CN)_6^{3-}/Fe(CN)_6^{4-}$ redox probe also remained.

Fig. 1(*d*) shows an infrared spectrum of the corresponding thiol ester, methyl 12-mercapto-2-methyldodecanoate **2** synthesized from solution phase photochemical trapping of the ketene derived from photolysis of **1** in MeOH. Its spectrum compares favorably with the spectrum of photolysed Au-**1** [Fig. 1(*b*)]. In the solution phase photochemistry of **1** in MeOH using 350 nm irradiation, over 98% of the product isolated after complete photolysis was **2**, formed from MeOH trapping of the ketene intermediate. Based on this, we propose the photochemical modification of Au-**1** to Au-**2** as shown in Scheme 1. Under the conditions outlined no evidence was found for 'intra'-monolayer reactivity between a ketene and a neighbouring C=O or between two ketene moieties.[14]

These results suggest that Au-**1** is a potential photoreactive template for derivatisation of the self-assembled monolayer. Because of the absorption characteristics of the C(=N_2)C=O moiety, the photoinitiated Wolff rearrangement and ketene chemistry can be activated with comparatively long wavelengths of light in the presence of a large number of organic trapping agents that absorb at much higher energy and are transparent in the region where we irradiate. We believe that this particular feature makes the use of the photo-Wolff a powerful technology for synthetic modifications. The generality of this photochemistry for surface modifications, and photopatterning, and the limitations of this important technology are currently being investigated by extending the studies to other ketene trapping nucleophilic reagents.

Received (in Bloomington, IN, USA) 10th March 1999, Accepted 15th March 1999

Reaction of 1,3,5-tricarboxylatobenzene (trimesic acid) with $[Mo_2(DAniF)_2(MeCN)_4][BF_4]_2$ (DAniF = *N*,*N*′-di-*p*-anisylformamidinate) leads to the quantitative formation of a large tetrahedral molecule containing four triply-bridging $C_6H_3(CO_2)_3$ (trimesic acid trianion) groups and six $Mo_2(DAniF)_2$ units; the structure has been determined by X-ray crystallography.

Since the early 1990s there has been a lot of research activity directed toward the synthesis of nanosize polynuclear coordination compounds having two or more metal atoms assembled by suitable ligands into dinuclear (linear), trinuclear (triangular), and tetranuclear (square) molecules. Until very recently all of the reported work was done with building blocks consisting of single metal atoms associated with a few ligands (*e.g.* $[Pd(en)]^{2+}$, $[Pt(Ph_2PCH_2CH_2CH_2PPh_2)]^{2+}$, *etc.*) and these were linked by linear bidentate ligands such as 4,4′-dipyridine.[1]

Recently, in keeping with Chisholm's assertion[2] ('Anything one can do, two can do, too—and it's more interesting'), we have been developing this kind of chemistry with dimetal units, M_2^{n+}, where M = Mo, Rh, W, Ir, and others.[3] The metal-containing building blocks that we use are entities such as $[Mo_2(DAniF)_3]^+$ and $[Rh_2(DAniF)_2]^{2+}$, in which the remaining coordination sites are occupied by the easily displaced ligand, acetonitrile. In this way we have created molecules of the types shown in Scheme 1, where the dinuclear metal units are symbolized by the nicked circles and the linkers are dicarboxylate dianions, symbolized by the heavy double arrows. These linkers can be enormously varied; a few examples are shown in Scheme 2. In this way we have achieved results topologically equivalent to many of those obtained by using single metal centers. All these results, however, have been in the realm of one- or two-dimensional arrays. What about three-dimensional assemblages?

In the realm of single-metal compounds, although imaginative projections of what might be doable in three dimensions have not been lacking,[1a,b] relatively few actual syntheses have been reported,[4–9] and only a few three-dimensional assemblages have been confirmed by X-ray crystallography. Two[4] contain a tetrahedral array of four iron atoms, two others a set of six copper or silver atoms.[5] Fujita *et al.* have characterized an assembly of six metal atoms (Pd) connected by four trifunctional linkers[6] and another Pd compound has also been characterized crystallographically.

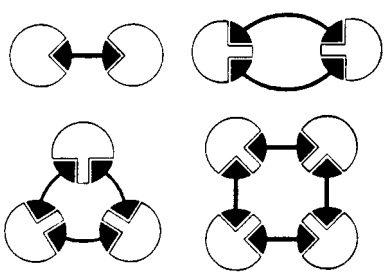
The molecule reported here was obtained in the so-called 'self-assembly' manner, but by design.† The key to this synthesis was, as in other cases,[6–9] the use of a trifunctional linker that imparts threefold symmetry to the assemblage.

The molecular structure is shown in Fig. 1.‡ The centroids of the four six-membered rings define a tetrahedron and the centroids of the six Mo_2^{4+} units define an octahedron. The overall idealized symmetry is T_d, but crystallographically there is only a single twofold axis that bisects the bonds between the atoms Mo(4), Mo(4A) and Mo(3), Mo(3A). The ^1H NMR spectrum is consistent with this high symmetry; it shows only one resonance for all of the 12 aromatic protons on the $C_6H_3(CO_2)_3^{3-}$ linkers and the signals for the twelve *N*,*N*′-di-*p*-anisylformamidinate ligands show them to be equivalent. Refinement of the structure presented some challenge, due to disorder in many of the peripheral anisyl groups and some disorder of the dimetal units spanning the two-fold axis. Disorder was also present at several of the 20 different sites containing interstitial acetonitrile and dichloromethane. The most prominent instance of CH_2Cl_2 is a disordered 'ball' of the solvent located directly in the center of the metal-complex cage. Careful modeling and judicious use of restraints allowed successful refinement of the whole model.

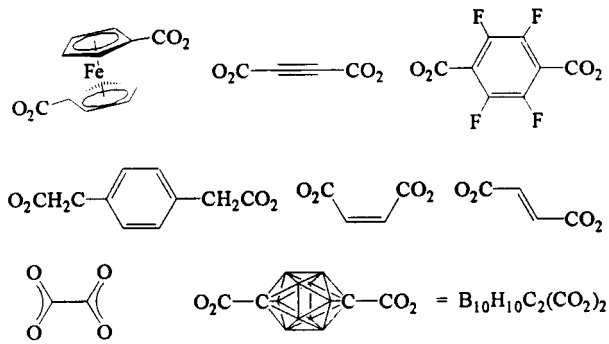
Cyclic and differential pulse voltammetries show three distinct reversible oxidation steps at $E_{1/2}$ of 268, 330 and 370 mV *vs.* the Ag/AgCl couple.§ Based on DPV, the ratio of the number of electrons involved in these steps is 1:1:1, respectively. Using $Mo_2[(m\text{-}CF_3C_6H_4N)_2CH]_4$ as a standard, these have been assigned as one-electron oxidation steps.

In closing, we make two observations. In the preparation of several of the previously reported three-dimensional assemblages, the use of a template or guest was said to be essential[8] or at least preferred. In the present case this is not so. We are not unmindful, however that the cavity in our molecule is well suited to being occupied by a variety of medium size entities, *inter alia*, N_2 and the noble gases.

We also note that while this type of chemistry has often been characterized[7] as using 'metal atoms to control self-assembly of



Scheme 1



Scheme 2

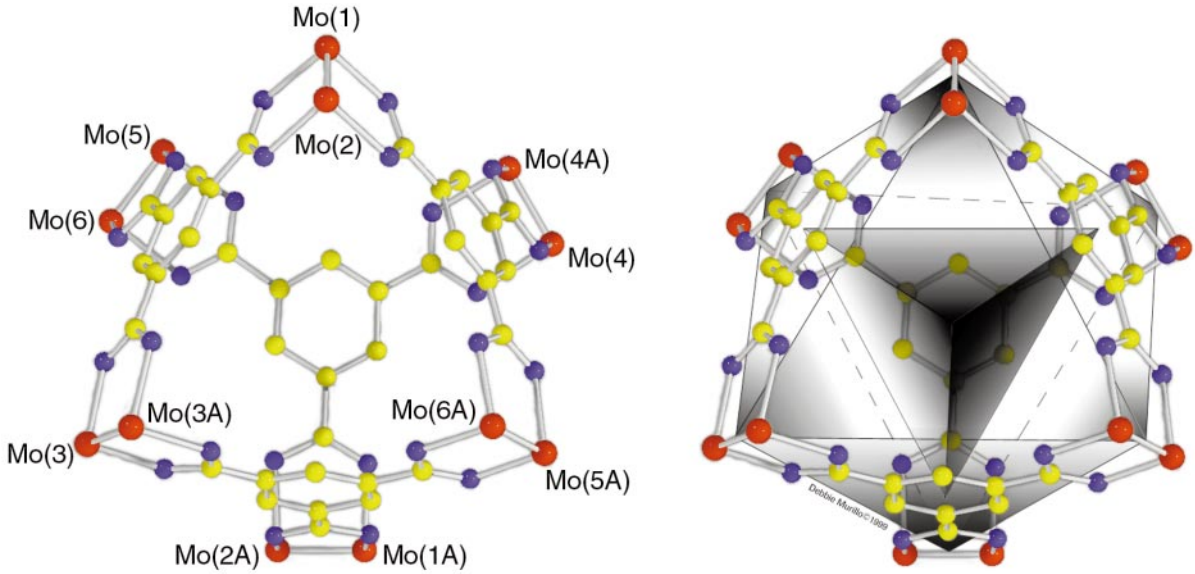


Fig. 1 The core of the molecular structure of $[Mo_2(DAniF)_2]_6[\mu_3\text{-}C_6H_3(CO_2)_3]_4$. The two DAniF anions attached to each quadruply bonded Mo_2^{4+} units and the interstitial solvent molecules have been omitted for clarity. The left view shows the atom labelling scheme. Selected bond distances (Å) are Mo(1)–Mo(2) 2.099(2), Mo(3)–Mo(3A) 2.098(2), Mo(4)–Mo(4A) 2.104(5), Mo(5)–Mo(6) 2.098[4]; Mo–N (av) 2.10[1]; Mo–O (av) 2.20[2]. The right drawing emphasizes the pseudo-octahedral distribution of the Mo_2^{4+} units. A cut of the octahedron shows the tetrahedral cavity; the apices are located at the center of the rings of the trimesate anions.

multicomponent supramolecular structures' this seems to us a one-sided view of the matter. The synthesis reported here, as well as several by Fujita and others, seem better characterized as using a suitably chosen linker to control the 'self-assembly'.

We thank the National Science Foundation for financial support and Debbie Murillo for the artwork in Fig. 1.

Notes and references

Note added in proof: The use of trimesic acid to form a similar structure was very recently reported by others: S. S.-Y. Chui, S. M.-F. Lo, J. P. H. Charmant, A. G. Orpen and I. D. Williams, *Science*, 1999, **283**, 1148.

† To a stirred solution of $[Mo_2(DAniF)_2(MeCN)_4][BF_4]_2$ (312 mg, 0.30 mmol) in 30 mL of MeCN was added $[NBu_4]_3[1,3,5\text{-}C_6H_3(CO_2)_3]$ (187 mg, 0.20 mmol) in 20 mL of MeCN. An immediate reaction took place with the formation of a bright red precipitate, which was collected, washed several times with MeCN, and dried. The crude product was extracted with CH_2Cl_2 (3 × 5 mL). Acetonitrile was then carefully layered on top. Bright red crystals were collected after about two weeks. The yield was essentially quantitative. ^{1}H NMR δ (ppm, in CD_2Cl_2) 9.39 (s, 12H, aromatic of trimesate), 8.52 (s, 12H, –NC*H*N–), 6.62 (dd, 96H, aromatic of formamidinate), 3.67 (s, 72H, –OCH_3).

‡ *Crystal data* for $[Mo_2(DAniF)_2]_6[C_6H_3(CO_2)_3]_4\cdot 22.1MeCN\cdot 2.3CH_2Cl_2$: $C_{262.5}H_{262.9}Cl_{4.6}Mo_{12}N_{46.1}O_{48}$, M = 6145.84, monoclinic, space group $C2/c$, a = 29.825(3), b = 27.377(2), c = 38.248(3), β = 112.71(1)°, V = 28809(4) Å^3, Z = 4, μ(Mo-Kα) = 0.622 mm^{-1}. Data were collected at 173(2) K. The structure, refined on F^2, converged for 13285 unique reflections and 1190 parameters to give $R1(F)$ = 0.098 and $wR2(F^2)$ = 0.217 with a goodness-of-fit of 1.073. CCDC 182/1205. Side chain selective binding of *N*-acetyl-α-amino acid carboxylates by a 2-(guanidiniocarbonyl)pyrrole receptor in aqueous solvents

Carsten Schmuck

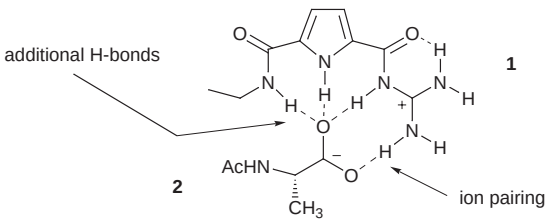
Institute of Organic Chemistry, University of Cologne, Greinstrasse 4, 50939 Cologne, Germany. E-mail: carsten.schmuck@uni-koeln.de

Received (in Liverpool, UK) 9th February 1999, Accepted 23rd March 1999

2-(Guanidiniocarbonyl)pyrrole 1 binds *N*-acetyl-α-amino acid carboxylates in 40% H_2O–DMSO with binding constants ranging from K = 360 to 1700 mol^{-1} depending on the structure of the amino acid side chain.

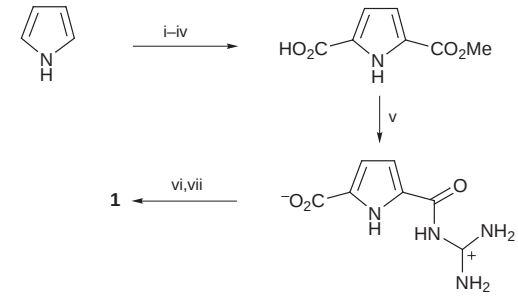
The development of artificial receptors for the selective molecular recognition of a given substrate is still a challenging task, especially in polar solvents.[1] A large number of host systems for hydrophobic solvents (mostly $CHCl_3$) have been described.[2] However, for the design of biosensors or the targeting of cellular molecules, like peptide hormones, neurotransmitters or carbohydrates, $CHCl_3$ is not the solvent of choice. There are only very few examples of artificial receptors that function in more 'natural' solvents like DMSO, MeOH or even water.[3] As the polarity of the surrounding solvent increases, the strength of hydrogen bonds and electrostatic interactions, mainly used for molecular recognition, decreases rapidly, due to the competitive solvation of donor and acceptor sites by the solvent.

Herein we describe a new class of receptor molecules for the binding of carboxylates in aqueous media. Our idea was to improve the binding affinity of guanidinium cations, well known for the complexation of oxo anions in organic solvents such as $CHCl_3$ or MeCN,[4] by adding additional binding sites. To serve this purpose, we chose substituted 2-(guanidiniocarbonyl)-1*H*-pyrroles. The pyrrole NH as well as suitable donor sites in the side chain should be able to hydrogen bond to the bound carboxylate in addition to ion pairing with the guanidinium unit. For the selective binding of *N*-acetyl-α-amino acid or peptide carboxylates[3,5] these primary interactions to the backbone can



provide the necessary binding energy even in polar solvents. Additonal interactions of the amino acid side chain with the receptor could then be used to achieve selectivity of the recognition process.[1b,6] By variation of this general theme (*e.g.* by combinatorial methods), a new class of receptor molecules should be accessible whose binding properties and selectivity can be tuned deliberately. We wish to demonstrate the usefulness of this general design by reporting the binding properties of a first example: the [5-(*N*-ethylcarbamoyl)-1*H*-pyrrol-2-ylcarbonyl]guanidinium cation **1**. The synthesis of **1** is shown in Scheme 1.

As anticipated, addition of **1** to a solution of *N*-acetyl-L-alanine carboxylate **2** in DMSO caused significant complexation induced shifts of the various protons of **2** in the ^{1}H NMR spectrum. Actually, at millimolar concentrations, the binding is so strong that a NMR titration in [$^2H_6$]DMSO just showed a linear increase of the shift changes until a molar ratio of 1 : 1 was



Scheme 1 *Reagents and conditions*: i, Cl_3CCOCl, Et_2O, reflux, 30 min, 85%; ii, NaOMe (0.1 equiv.), MeOH, room temp. 30 min, 63%; iii, $POCl_3$, DMF, CH_2Cl_2, 0 °C → reflux, 63%; iv, $KMnO_4$, acetone–H_2O (1 : 1), 40 °C, 30 min, 75%; v, guanidinium chloride (5 equiv.), NaOMe (5 equiv.), MeOH, reflux, 12 h, 72%; vi, $(COCl)_2$ (1.1 equiv.), DMF (cat.), CH_2Cl_2, reflux 2 h; vii, $EtNH_3Cl$, Et_3N, 68% over both steps.

reached, clearly proving the 1 : 1 binding stoichiometry.[7] Therefore NMR binding studies with various *N*-acetyl-α-amino acid carboxylates were performed in 40% water in DMSO (at higher concentrations of water the solubility of the receptor was too limited). The binding constants were calculated from the observed shift changes of the amide NH of the carboxylates (or of the α-CH in the case of acetate) using nonlinear least-squares fitting with a 1 : 1 association model (Fig. 1).[8]

As shown in Table 1, receptor **1** strongly binds carboxylates with binding constants up to $K \approx 2800$ mol^{-1}. These association constants are much larger than with the parent *N*-acetyl guanidinium cation, which, for example, binds **2** with K = 50 mol^{-1} (compared to K = 770 mol^{-1} for the binding of **2** by **1**). Obviously, as hoped for, the binding affinity of guanidinium cations for carboxylates can be significantly improved by additional hydrogen bonding donors in the receptor. Furthermore, the recognition process is selective for the amino acid side chain: phenylalanine is bound much stronger than alanine or lysine.

According to molecular modelling calculations† the general binding scheme for all carboxylates is the same: the guanidin-

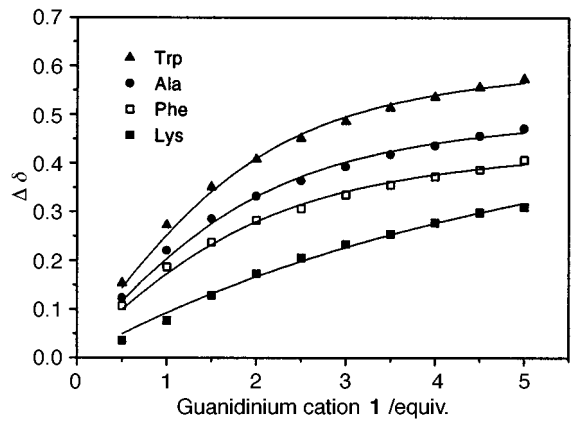


Fig. 1 NMR titration curves of **1** with various carboxylates in 40% water–[$^2H_6$]DMSO.

Table 1 Binding constants of **1** with various carboxylates[a]

Carboxylate	Solvent	K^b/mol^{-1}	$-\Delta G$/kJ mol^{-1}
Ac-L-Ala	DMSO	$>10^6$	
Ac-L-Ala	H_2O–DMSO	770	16.5
Ac-L-Phe	H_2O–DMSO	1700	18.4
Ac-L-Trp	H_2O–DMSO	810	16.6
Ac-L-Lys	H_2O–DMSO	360	14.6
Acetate	H_2O–DMSO	2790	19.7

[a] Measured by NMR titration, each one with 10 measurements at 25 °C; [carboxylate] = 1 mM in [$^2H_6$]DMSO or 40% H_2O–[$^2H_6$]DMSO. [b] Error limit in K < ± 5%.

ium cation forms an ion pair with the carboxylate which is simultaneously hydrogen bonded by both the pyrrole and the amide NH.[9] Acetate shows the highest binding constant with **1** because there are no unfavorable steric interactions with the receptor. The carboxylate group and the receptor binding sites are completely coplanar allowing maximum interaction. In the case of the amino acid carboxylates, the steric bulk of the *N*-acetyl group forces the carboxylate out of the plane of the receptor, thereby decreasing the binding affinity. The differences in complex stability among the various amino acids result from secondary interactions of the side chains with the receptor. The methyl group of alanine points away from the receptor molecule so that there are neither any stabilizing nor destabilizing interactions. In the case of phenylalanine the aromatic ring π-stacks with the acylguanidinium unit of **1** (Fig. 2). This cation–π interaction further stabilizes the complex.[10] Hence, the association constant for the binding of phenylalanine is more than two times larger than for the binding of alanine.

The indole ring of tryptophan is probably too large to effectively π-stack with the acylguanidinium unit. The positively charged ammonium group in lysine decreases the binding affinity relative to alanine due to unfavorable electrostatic interactions with the positively charged guanidinium group.

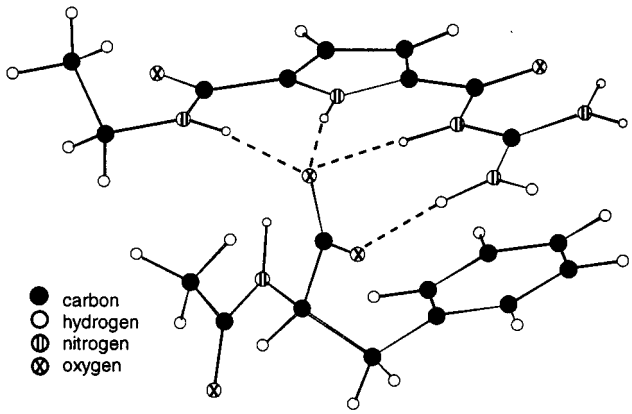

Fig. 2 Structure of **1** with *N*-acetylphenylalanine in water derived from molecular modelling. Intermolecular hydrogen bonds are shown as broken lines.

It is noteworthy that, even in 40% water–DMSO, this simple receptor **1** already shows a level of amino acid selectivity which is in the same range as described for other much more complex receptors in $CHCl_3$.[1b,2a,6] We hope that even greater selectivity including enantioselectivity can be achieved by variation of the substituent at the pyrrole ring.

Financial support for this work by the Fonds der Chemischen Industrie is gratefully acknowledged. The author thanks Professor Albrecht Berkessel (Cologne) for his generous support and helpful discussions.

Catalytic dechlorination of aromatic chlorides using Grignard reagents in the presence of $(C_5H_5)_2TiCl_2$

Ryuichiro Hara, Kimihiko Sato, Wen-Hua Sun and Tamotsu Takahashi*

Catalysis Research Center and Graduate School of Pharmaceutical Sciences, Hokkaido University, Sapporo 060-0811, Japan and CREST, Science and Technology Corporation (JST), Sapporo 060-0811, Japan. E-mail: tamotsu@cat.hokudai.ac.jp

Received (in Cambridge, UK) 3rd March 1999, Accepted 30th March 1999

Dechlorination of aromatic chlorides was efficiently performed with alkyl Grignard reagents in the presence of a catalytic amount of $(C_5H_5)_2TiCl_2$.

Dehalogenation of organic halides is a fundamental subject in organic chemistry.[1] Therefore, diverse methods and a variety of reagents have been developed. The reactivity order of halogens is, in most cases, I > Br > Cl ⩾ F, and that of halogen-containing substrates is allylic ≈ benzylic > aliphatic > aromatic. It is thus suggested that dechlorination of aromatic chlorides cannot readily be achieved,[2] and the development of methodology for such remains to be studied. In addition to the synthetic usefulness of the reaction, recently evolving ecological demands for dechlorination of pollutant perchlorinated compounds[3] strongly motivated us toward this subject.[4]

We have recently published a report that $(C_5H_5)_2ZrCl_2$ catalyzed the efficient and selective debromination or deiodination reactions of aromatic halides using alkylmagnesium reagents.[5] However, this reaction did not proceed at a significant level for chloro derivatives. During the course of our study on the dechlorination reactions of aromatic chlorides, we found that titanocene dichloride catalyzed the reduction of aromatic chlorides when used with appropriate alkylmagnesium reagents [eqn. (1)].

$$\mathrm{Ar{-}Cl} \xrightarrow[\text{THF, room temp.}]{\text{RMgBr, } Cp_2TiCl_2 \text{ (cat.)}} \mathrm{Ar{-}H} \qquad (1)$$

Colomer and Corriu reported early in 1974 that Pr^iMgBr–$(C_5H_5)_2TiCl_2$ reacted with various organic bromides and iodides in Et_2O to give the dehalogenated products.[6] They suggested, however, that their system was not applicable to aromatic chlorides.

The use of THF as a solvent was found to dramatically improve the reactivity of the titanium-catalyzed dehalogenation reaction. A typical reaction procedure is as follows: To a solution of an aromatic chloride (1.0 mmol) and $(C_5H_5)_2TiCl_2$ (0.1 mmol, 0.1 equiv. with respect to the substrate) in THF (2.5 ml) was added BuMgCl (1.0 M solution in THF, 3.0 mmol, 3 equiv. at −78 °C. The reaction mixture was stirred at ambient temperature for several hours and the products were detected by GC and NMR.

Dechlorination of 4-chloroanisole was carried out using various Grignard reagents (Table 1). As expected, MeMgBr did not reduce 4-chloroanisole. The reaction with PhMgBr, which has an aromatic β-hydrogen, did not proceed. Bu^tCH_2MgBr which has γ- rather than β-hydrogens, gave a yield which did not exceed the amount of catalyst used. The reaction with Bu^tMgBr or EtMgBr gave moderate yields while the reactions with PrMgBr, Pr^iMgBr, Bu^iMgBr or BuMgCl gave high yields. Thus, the difference in reactivity may be due to both the β- and γ-hydrogens and their steric factors.

Table 2 shows the results of dechlorination of various aromatic chlorides. Chloroanisoles were reduced to anisole over varied reaction times (entries 2–4). Chloronaphthalenes were reduced within 30 min (entries 5 and 6). The hydroxy group of 4-chlorophenol was deprotonated by an additional equimolar amount of Grignard reagent and the reaction then proceeded (entry 7).

When 2,4-dichloroanisole was treated with a catalytic amount of $(C_5H_5)_2TiCl_2$ (0.2 mmol) and 6 equiv. of BuMgCl, the 2,4-dichloroanisole was completely consumed within 1 h. Anisole was obtained in 66% yield after 24 h, and 24% of 4-chloroanisole and 10% of 2-chloroanisole remained. Addition of 9 equiv. of BuMgCl did not significantly improve this situation.

Interestingly, when a combination of 1.0 equiv. of $(C_5H_5)_2TiCl_2$ and 2.0 equiv. of BuMgCl was used for the

[d] BuMgCl (4 equiv.). [e] BuMgCl (6 equiv.), $(C_5H_5)_2TiCl_2$ (0.2 equiv.). [f] Yield of anisole: 66%; 2-ClC_6H_4OMe: 10%; 4-ClC_6H_4OMe: 24%; 2,4-$Cl_2C_6H_3OMe$: 0%.

stoichiometric reaction of 1-chloronaphthalene, we obtained only 10% of naphthalene after 1 h and 11% after 3 h. This is in sharp contrast to the fast reaction under catalytic conditions (see Table 2, entry 5) and the stoichiometric reduction of bromobenzene by $(C_5H_5)_2ZrBu_2$.[5] Addition of an additional 1.0 equiv. of BuMgCl promoted the reaction to afford 43% of the reduction product after 1 h. This suggests that the actual catalyst in the reaction is formed only when an excess of Grignard reagent is present, and the species is not solely $(C_5H_5)_2TiBu$ or $(C_5H_5)_2Ti–H$, which are thought to be formed in various hydrogenation reactions.[7]

The reduction of alkyl chlorides was also attempted under similar conditions. However, for example, 1-chlorooctane was reduced to octane in a moderate yield of 64% where isomers of octenes as by-products were detected. This may be due to the formation of an octyltitanium species followed by β-hydrogen elimination.

The reaction mechanism is not clear yet for our specific case although several possibilities in similar reactions have been discussed.[6] The plausible intermediates are (i) $(C_5H_5)_2Ti^{III}–H$,[8] which may transfer hydride through a four-membered transition state, (ii) a hydridomagnesium species,[9] and (iii) direct β-hydride transfer from an alkyl substituent on titanium metal.

In conclusion, aromatic chlorides were successfully dechlorinated by alkylmagnesium reagents in the presence of a catalytic amount of $(C_5H_5)_2TiCl_2$, where the corresponding bromides and iodides were also dehalogenated. The choice of solvent was found to be important. Our investigation on this subject is still progressing to widen the scope and to clarify the mechanism.

Synthesis and base-induced epimerization of *cis,cis,cis,trans*-tribenzo[5.5.5.6]fenestranes

Björn Bredenkötter,[a] Dieter Barth[a] and Dietmar Kuck*[ab]

[a] *Fakultät für Chemie, Universität Bielefeld, Universitätsstraße 25, D-33615 Bielefeld, Germany. E-mail: dietmar.kuck@uni-bielefeld.de*

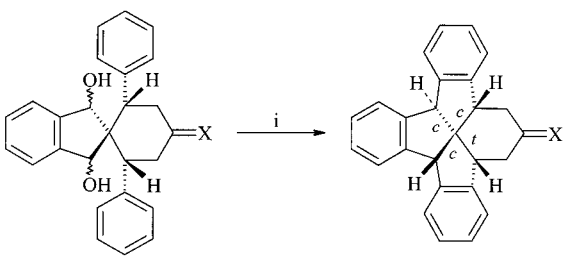
[b] *Fachbereich Chemie und Chemietechnik, Universität-Gesamthochschule Paderborn, Warburger Straße 100, D-33098 Paderborn, Germany*

Received (in Liverpool, UK) 11th March 1999, Accepted 26th March 1999

Strained *cis,cis,cis,trans*-tribenzo[5.5.5.6]fenestranes are accessible in good yield by two-fold cyclodehydration of *cis*-2,6-diphenylspiro[cyclohexane-1,2′-indane]-1′,3′-diols and the particularly high acidity of their 'inverted' benzylic bridgehead C–H bonds, causing facile epimerization to the more stable all-*cis*-tribenzo[5.5.5.6]fenestranes, is shown.

Strained stereoisomers of all-*cis*-[*m.n.o.p*]fenestranes have been of particular interest with respect to the quest for planar tetracoordinate carbon.[1–3] While extensive computational work has been published on strain and geometry of stereoisomeric fenestranes,[3a–c,4–6] only a few small-ring congeners bearing a single *trans*-fused pair of rings together with three *cis*-annelated ones, *i.e.* the *cis,cis,cis,trans*-fenestranes, are known by experiment.[7–9] Fenestranes bearing more than one *trans* junction have remained unknown to-date,[3,10] and even normal-ring fenestranes containing the *cis,cis,cis,trans* skeleton have only recently been realized in a single case.[11] Herein we report the first synthesis of a *cis,cis,cis,trans*-tribenzo[5.5.5.6]fenestrane **2** and some of its derivatives, and demonstrate the ease and some mechanistic details of its epimerization to the corresponding all-*cis* stabilomers.

Benzoannelated all-*cis*-[5.5.5.6]- and all-*cis*-[5.5.5.5]-fenestranes have been synthesized by two-fold cyclodehydration of the stereochemically suitable *trans*-2,6-diarylspiro[cyclohexane-1,2′-indane]-1′,3′-diols.[12,13] In these tandem cyclization reactions, the *trans* orientation of the two aryl groups translates directly into the all-*cis* stereochemistry of the fenestrane nucleus. Surprisingly, and contra-intuitively, we found that, under similar conditions, isomeric *cis*-diarylspirodiols such as **1** and **3**,[14] which are readily accessible from the corresponding spirotriketones,[15,16] undergo two-fold cyclization as well, giving the corresponding *cis,cis,cis,trans*-[5.5.5.6]fenestranes, such as **2** and **4**,† in good yields (Scheme 1). Force-field and semi-empirical MO calculations (MM+ and PM3, respectively) suggest that *cis,cis,cis,trans*-[5.5.5.6]fenestranes are, by *ca*. 10 kcalmol^{-1}, more strained than the all-*cis* isomers,[3a] in agreement with previous estimates on alicyclic analogues,[4,6] and that one of the unbridged bond angles of the fenestrane nucleus is also considerably increased.‡ Moreover, the cyclohexane ring adopts a boat conformation in the most stable conformer of **2** and **4**.[14]

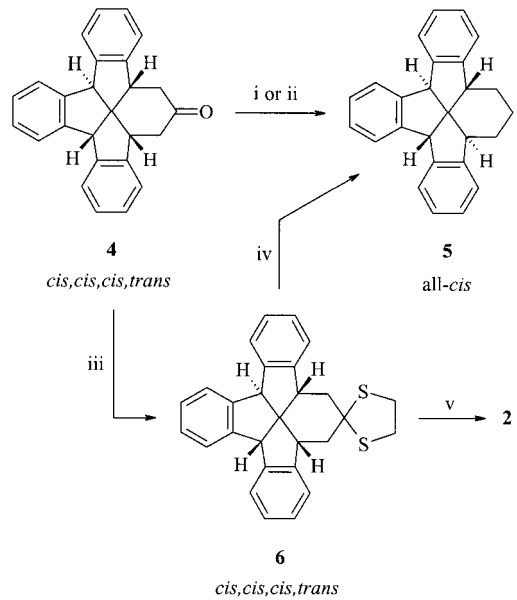


1 X = H, H
3 X = OCH_2CH_2O
2 X = H, H
4 X = O

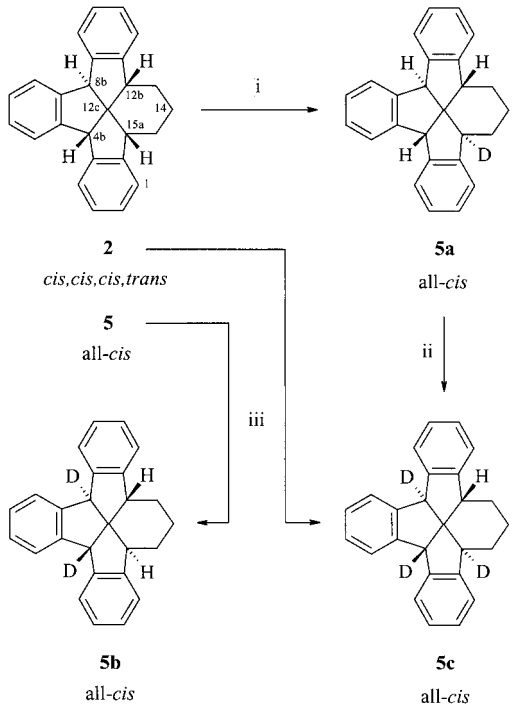
Scheme 1 *Reagents and conditions*: i, H_3PO_4, toluene, Δ; **1** → **2**, 24 h, 82%; **3** → **4**, 15 h, 87%.

Reduction of fenestranone **4** under Wolff–Kishner–Huang–Minlon conditions, as well as reduction of its hydrazone with KOBu^t in DMSO at 20 °C and even Raney nickel-catalyzed hydrogenolysis of thioacetal **6**,[14] all resulted in the formation of the all-*cis* hydrocarbon **5** instead of **2** (Scheme 2). Obviously, the basic conditions used are sufficiently harsh to induce epimerization by a deprotonation–reprotonation sequence. In contrast, radical-induced desulfurization of **6** using Bu_3SnH and AIBN afforded retention of configuration at the 'inverted' bridgehead during reduction, giving the *cis,cis,cis,trans*-tribenzo[5.5.5.6]fenestrane **2** in good yield. These results suggest that C–H acidity at the strained fenestrane nucleus is the origin of epimerization, irrespective of the presence of a functional group at C(14).

In fact, independent experiments carried out with fenestranes **2** and **5** under essentially the same conditions used for reduction of **4** and its hydrazone revealed that base-induced epimerization occurs with high selectivity by deprotonation at the 'inverted' bridgehead (C-15a). Thus, treatment of all-*cis*-fenestrane **5** with KOBu^t in [$^2H_6$]DMSO gave rise to complete H/D exchange at the benzhydrylic bridgeheads to generate **5b**, whereas the *cis,cis,cis,trans* isomer **2** underwent complete epimerization with concomitant incorporation of three deuterium atoms at the benzhydrylic and one of the benzylic positions to yield **5c**



Scheme 2 *Reagents and conditions*: i, $N_2H_4{\cdot}H_2O$, KOH, diethylene glycol, 120 → 180 °C, 73%; ii, (a) $N_2H_4{\cdot}H_2O$, EtOH, Δ, 92%, (b) KOBu^t, DMSO, 20 °C, 80%; iii, $(CH_2SH)_2$, $BF_3{\cdot}Et_2O$, AcOH, 20 °C, 95%; iv, Raney-Ni (W2, 'neutral'), 1,4-dioxane, Δ, 80%; v, Bu_3SnH, AIBN, benzene, Δ, 87%.



Scheme 3 *Reagents and conditions*: i, KOD, [*O*,*O*′-$^2H_2$]diethylene glycol, 180 °C, 3 h; ii, KOD, [*O*,*O*′-$^2H_2$]diethylene glycol, 240 °C, > 4 h; iii, KOBu^t, [$^2H_6$]DMSO, 20 °C, 15 h; > 90% in both cases.

(Scheme 3, paths iii). Moreover, use of KOD in *O*,*O*′-dideuterated diethylene glycol revealed that the C(15a)–H bond of **2** is far more acidic than the benzhydrylic C–H bonds in both **2** and **5**. When heated to 180 °C for 3 h, the *cis*,*cis*,*cis*,*trans* isomer **2** was partially epimerized (path i) to give a mixture consisting exclusively of monodeuterated all-*cis*-fenestrane **5a** and unlabelled starting material ([**5a**]:[**2**] ≈ 46:54 by ^{1}H NMR). Only prolongated heating at 240 °C effected relatively slow incorporation of deuterium into the benzhydrylic bridgeheads of **5a** to eventually give **5c** (path ii).

The results clearly show that benzoannelated *cis*,*cis*,*cis*,*trans*-[5.5.5.6]fenestranes are easily accessible by directed synthesis, in spite of the considerable increase of strain in the tetracyclic framework, but that the additional strain also induces facile base-induced epimerization of the 'inverted' bridgehead to give the more stable all-*cis* isomers. This sheds some light on the extraordinary challenge to synthesize benzoannelated *cis*,*cis*,*cis*,*trans*-[5.5.5.5]fenestranes.[3a]

We are grateful to the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie for financial support.

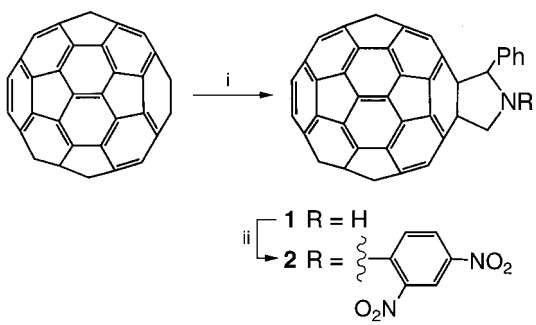
Received (in Corvallis, OR, USA) 12th February 1999, Accepted 22nd March 1999

Using Sanger's method, an electroactive organofullerene dyad, *N*-(2,4-dinitrophenyl)-2-phenylfulleropyrrolidine, is synthesized and its spectral and electrochemical characterization is reported.

Studies on C_{60}-based electroactive organofullerene dyads[1] are of current interest due to the interesting electronic and optical properties they display. Such electroactive fullerenes are considered to be useful in the development of molecular electronic devices[2] and non-linear optical materials[3] as well as in the design of artificial photosynthetic systems.[4,5] Two types of electroactive organofullerene dyads are known, namely, (i) C_{60} covalently linked to a donor entity (C_{60}–Donor type dyads) and (ii) C_{60} bearing an electron-deficient entity (C_{60}–Acceptor type dyads). A number of studies have reported electroactive fullerene dyads of the former type, while only a few systems of the latter type are known in the literature,[1] even though the potential for such double electron acceptor systems as precursors for the formation of multichromophoric systems with well-defined gradient of redox potentials has been realized.[5]

Among the different types of electron deficient compounds that could be utilized to form C_{60}–Acceptor dyads, nitroaromatic compounds are one of the attractive candidates. This is because the reduction potential of this acceptor molecule can be easily tuned by choosing appropriate numbers of nitro groups and other substituents on the aromatic ring.[6] However, no nitroaromatic acceptor molecule-linked fullerene dyad is known to date, although several donor–acceptor type molecules involving nitroaromatic compounds are known in the literature.[7] This has been achieved in the present study where we report the first synthesis and electrochemical characterization of a nitroarene appended fullerene dyad.

The strategy adopted for the synthesis of nitroarene appended fullerene is shown in Scheme 1. This involves the initial synthesis of 2-phenylfulleropyrrolidine **1**[8] followed by treatment with 1-fluoro-2,4-dinitrobenzene in the presence of NaH according to Sanger's reaction.[9] The secondary nitrogen on the pyrrolidine ring reacts with 1-fluoro-2,4-dinitrobenzene to yield the desired *N*-(2,4-dinitrophenyl)-2-phenylfulleropyrrolidine **2**.† The molecular integrity of the newly synthesized compound is established from mass, UV–visible and ^{1}H NMR spectroscopy. In addition to the fullerene absorption bands, the UV–visible spectrum of the product in hexane exhibited an absorption band at 274 nm indicating the presence of the dinitrophenyl entity.[6] It is also observed that the proton resonance peaks of the *N*-dinitrophenyl entity are shielded by *ca.* 0.5 ppm as compared to the peaks of the starting material, 1-fluoro-2,4-dinitrobenzene, while the protons of the 2-phenylpyrrolidine group experienced a small deshielding upon forming the *N*-(2,4-dinitrophenyl)-2-phenylfulleropyrrolidine (Fig. 1).



Scheme 1

The redox behavior of the newly synthesized compound has been investigated using cyclic voltammetry.‡ Fig. 2 shows the cyclic voltammograms of 2-phenylfulleropyrrolidine and *N*-(2,4-dinitrophenyl)-2-phenylfulleropyrrolidine in PhCN with 0.1 M Bu_4NPF_6. In the investigated solvent, the first three reductions of 2-phenylfulleropyrrolidine are found to be reversible one-electron processes with an anodic to cathodic peak separation, ΔE of *ca.* 80 mV. These processes are located at $E_{1/2}$ = −1.05, −1.48 and −2.01 V *vs.* Fc/Fc$^+$, respectively, and are negatively shifted by 120 to 190 mV compared to the corresponding electroreductions of C_{60} (Table 1). The redox behavior of *N*-(2,4-dinitrophenyl)-2-phenylfulleropyrrolidine is found to be more complicated due to the overlapping reductions of the dinitrophenyl entity [Fig. 2(*b*)]. Only the first reduction process is reversible and is located at $E_{1/2}$ = −1.01 V *vs.* Fc/Fc$^+$. Spectroelectrochemical studies have indicated that this reduction occurs at the C_{60} macrocycle resulting in the formation of a C_{60} anion radical. The observed positive shift of 40 mV for the first reduction of *N*-(2,4-dinitrophenyl)-2-phenylfulleropyrrolidine as compared to the first reduction of the starting material, 2-phenylfulleropyrrolidine, indicates small electronic interactions between the C_{60} and dinitrobenzene entities, consistent with the ^{1}H NMR results discussed above.

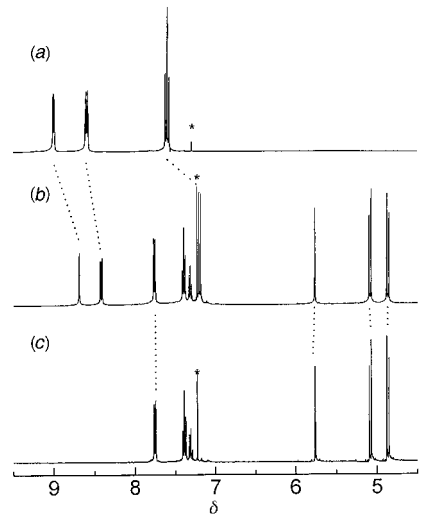


Fig. 1 ^{1}H NMR spectrum of (*a*) 1-fluoro-2,4-dinitrobenzene, (*b*) *N*-(2,4-dinitrophenyl)-2-phenylfulleropyrrolidine and (*c*) 2-phenylfulleropyrrolidine, in CS_2–$CDCl_3$ (1 : 1).

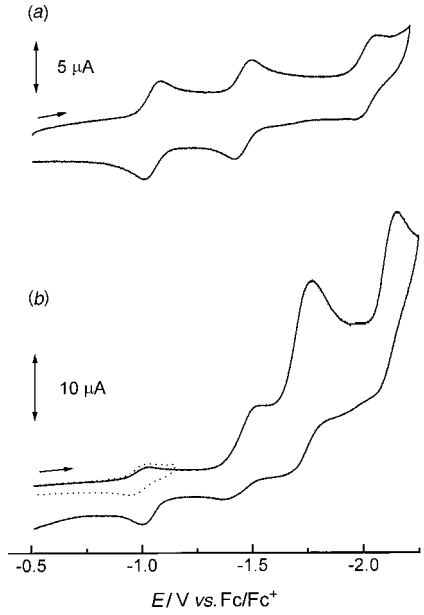

Fig. 2 Cyclic voltammogram of (*a*) 2-phenylfulleropyrrolidine and (*b*) *N*-(2,4-dinitrophenyl)-2-phenylfulleropyrrolidine in PhCN with 0.1 M Bu_4NPF_6. Scan rate = 100 mV s^{-1}.

Table 1 Half-wave potentials for the reduction of C_{60} and fulleropyrrolidine derivatives in PhCN with 0.1 M Bu_4NPF_6

	E/V *vs.* Fc/Fc^+		
Compound	1st	2nd	3rd
C_{60}	−0.92	−1.34	−1.83
2-phenylfulleropyrrolidine	−1.05	−1.48	−2.01
N-Dinitrophenyl-2-phenylfulleropyrrolidine[a]	−1.01		

[a] Additional peaks corresponding to the reduction of C_{60} and the dinitrobenzene entities are observed. See Fig. 2 and text for details.

The first reduction of the appended dinitrophenyl entity is found to be irreversible and is located at E_{pc} = −1.56 V *vs.* Fc/Fc^+, that is, the potential where the second reduction of C_{60} occurs. Control experiments performed by using a model compound, 1-morpholino-2,4-dinitrobenzene, synthesized by reacting morpholine and 1-fluoro-2,4-dinitrobenzene, confirmed the reduction of the dinitrophenyl entity in this potential range. When the potential is scanned to more negative potentials, additional reductions of the C_{60} and the dinitrophenyl entities are also observed. A comparison between the potentials corresponding to the first reduction of C_{60} and the first reduction of dinitrophenyl entities in the synthesized compound reveal a large potential separation of nearly 500 mV.

In summary, we are able to synthesize an *N*-dinitrobenzene-appended fulleropyrrolidine *via* Sanger's reaction using a simple one step procedure. The electrochemical and spectroelectrochemical results indicate that the reduction of C_{60} in the newly synthesized compound is easier by 40 mV than the starting fulleropyrrolidine. Both ^1H NMR and the cyclic voltammetric results indicate the existence of weak interactions between the C_{60} and dinitrophenyl entities in the synthesized compound. Owing to a potential separation of nearly 500 mV between the first reductions of the C_{60} and dinitrobenzene entities in the synthesized compound, utilization of this dyad as a precursor for developing multichromophoric supramolecular systems is envisioned.

The authors thank the donors of the Petroleum Research Fund, administered by the American Chemical Society, for support of this work.

Notes and references

† To a solution of 2-phenylfulleropyrrolidine (22.5 mg) in dry THF (15 ml), NaH (2 mg) was added and the resulting suspension was stirred. After the evolution of hydrogen had ceased, 1-fluoro-2,4-dinitrobenzene (20 μl) was added and the solution was stirred for another 6 h. At the end, water (1 ml) was added and the solution was evaporated under reduced pressure. The crude product was adsorbed on silica and separated on a silica gel column using 1 : 1 toluene–hexane as eluent (68% yield). Negative ion electrospray mass spectrum of the product in either a toluene or MeOH matrix revealed peaks at *m*/*z* 963.7 and 838.2 corresponding to the molecular ion minus nitro and dinitrobenzene units respectively. A control experiment performed using ^{19}F NMR of the product revealed the complete absence of the fluorine resonance peak that was present in the starting material, 1-fluoro-2,4-dinitrobenzene, at δ 221.5 (C_6F_6 at δ 166); $\delta_H[CS_2$–$CDCl_3$ (1 : 1) 8.69 (s, 1H, dinitrophenyl-H), 8.42 (m, 1H, dinitrophenyl-H), 7.76 (d, 1H, phenyl-H), 7.39 (m, 2H, phenyl-H), 7.31 (m, 2H, phenyl-H), 7.19 (d, 1H, dinitrophenyl-H), 5.77 (s, 1H, pyrrolidine-H), 5.09 (d, 1H, pyrrolidine-H), 4.87 (d, 1H, pyrrolidine-H); λ_{max}(hexane)/nm 429, 307(sh), 274, 252, 213.

‡ Cyclic voltammograms were obtained on a EG & G Model 263 A potentiostat using a three-electrode system. A glassy carbon electrode was used as the working electrode. A platinum wire served as the counter electrode, while a Ag/AgCl electrode was used as the reference electrode. All the potentials are referenced against an internal Fc/Fc^+ redox couple. Analysis of the peak current and peak potentials from the voltammetric data was carried out using EG&G M270 electrochemical software. All the experiments were carried at 22 ± 1 °C.

In situ energy dispersive EXAFS (EDE) of low loaded $Pt(acac)_2/H_I\ SiO_2$ catalyst precursors on a timescale of seconds and below

Steven G. Fiddy,[a] Mark A. Newton,[a] Andrew J. Dent,[b] Guiseppe Salvini,[b] Judith M. Corker,[a] Sandra Turin,[a] Tom Campbell[a] and John Evans[a]

[a] *Department of Chemistry, The University of Southampton, Highfield, Southampton, UK SO17 1BJ*

Received (in Cambridge, UK) 3rd February 1999, Accepted 29th March 1999

We demonstrate second and sub-second time resolved energy dispersive EXAFS (EDE) for *in situ* interrogation of phase changes in a supported metal catalyst precursor [(≤5 wt%) $Pt(acac)_2/H_I\ SiO_2$] during thermal decomposition and reduction; the formation of Pt particles is radically altered by the presence H_2, in both kinetic and structural senses.

Extended X-ray absorbtion fine structure (EXAFS) has long been a frontline technique in the determination of local structure and has found widespread application. However, the predominant *modus operandi* is rooted in the interrogation of the steady state, due to the stepwise progression of the monochromator through the energy window of interest. Quick EXAFS (QuEXAFS)[1] allows relatively rapid data acquisition *via* the optimisation of this monochromator movement: EXAFS spectra from supported metal catalysts can be collected on a timescale of > 20–30 s though timescales of > 1 min are more common,[2–5] in one case Cu K-edge XANES has been collected in *ca.* 3 s.[6]

EDE (or DEXAFS) utilises an (ideally) elliptically bent monochromator to produce a focused beam containing the required spread of X-ray energies. The EXAFS experiment may therefore be achieved with *no* subsequent monochromator movement.[7] In the present case a four point bending mechanism[8] is used to minimise aberations and produce an extremely small spot size. The speed of data acquisition is therefore limited only by the time required to achieve acceptable statistics. However, simultaneous illumination of the sample with a range of X-ray energies requires extreme spatial homogeneity of the sample. In the case of heterogeneous catalysts, these uniformity requirements have resulted in the predominate use of QuEXAFS[1–6] or pressed disk samples.[7,8b,9] Using this latter approach, EDE has been used on heterogeneous systems on a time scale of (at best) 30 s.[8b,9] Pressed disks present problems in terms of non-uniform gas distribution within the disk,[10a] and possible degradation of the support material structure.[10b,11] We present a methodology that allows fast, high quality, EDE measurements to be made with a sample presentation much more in keeping with catalytic testing.

The mesoporous silicas ($H_I\ SiO_2$), prepared following the procedure previously described,[12] were impregnated with $Pt(acac)_2$ from dry toluene. The $Pt(acac)_2/(H_I\ SiO_2)$ catalyst precursors were then sieved to a particle size of *ca.* 100 μm and packed into a flow microreactor based upon thin walled quartz tubes (*ca.* 2 mm o.d; 0.1 mm wall thickness). A second tube, the reference for the EDE experiment, was packed in the same manner with unloaded mesoporous silica ($H_I\ SiO_2$). This approach is similar to that demonstrated by Clausen *et al.*[2] although the increased diameter of the quartz tube used, allows the insertion of a 0.25 mm, mineral insulated, type K thermocouple directly into the sample. The samples were reacted under flowing N_2 or 10% H_2–90% N_2 gas using a linear sample heating ramp of 4 K min^{-1}. Gases are passed over the catalyst beds under mass flow control.

Fig. 1 shows Pt L_{III} edge EXAFS spectra obtained from $Pt(acac)_2/(H_I\ SiO_2)$ catalyst precursors. Spectrum (a) was obtained from a standard EXAFS experiment (*ca.* 1 h). Spectra (b)–(f) are EDE† obtained for a range of collection times (as indicated). Spectrum (f) is that derived from a 1 wt% $Pt/H_I\ SiO_2$ sample in 21 s. The Pt L_{III}-edge EXAFS-derived‡ structural parameters are summarised in Table 1.

Clearly, good quality EXAFS analysis (one or two coordination shells) can be obtained using this approach down to sub-second acquisition times (at 5 wt%). Analysis of the data obtained in 0.05 s leads to inconsistent structural parameters making it unsuitable for detailed EXAFS analysis. This data is suitable for determination of spectral change in the XANES region. The 1 wt% Pt case represents the current dilution limit of this approach and a reasonable quality of data can be achieved in *ca.* 21 s.

Fig. 2 shows phase corrected Fourier transforms derived from temperature dependent EDE spectra recorded at 8 s acquisition time (scan time 80 ms; 100 scans) for the reduction of a 5 wt% Pt sample under 8 ml min^{-1} 10% H_2–90% N_2 gas. The $Pt(acac)_2$ collapses to form Pt particles over an extremely narrow temperature region (*ca.* 15 K) indicative of some form of autocatalytic kinetics. In the temperature region shown these particles show little evidence of any subsequent increase in size.

Fig. 3 shows the variation in Pt–O and Pt–Pt coordination obtained from such EDE experiments for the following cases: 5 wt% Pt sample thermally decomposed as above in H_2–N_2 (a) and N_2 (c) mixtures; and a 1 wt% Pt sample reduced in H_2–N_2 (b). The particles resulting from the thermal decomposition of this catalyst precursor in pure N_2, and the kinetics of their production, are radically different to those produced *via* reduction in the H_2–N_2 mixture. The degree of particle agglomeration attained after the low *Z* coordination has been removed is significantly different between the case where H_2 is present and where only N_2 is used: with the latter case resulting in significantly smaller Pt particles. The persistence of low *Z* (C/O) coordination in the decomposition of this catalyst precursor therefore has considerable ramifications for the size of the particulate Pt formed.

In summary we have demonstrated that good quality, *in situ*, Pt L_{III} edge EDE can be obtained from low loaded heterogeneous samples on a time scale of seconds and below. The

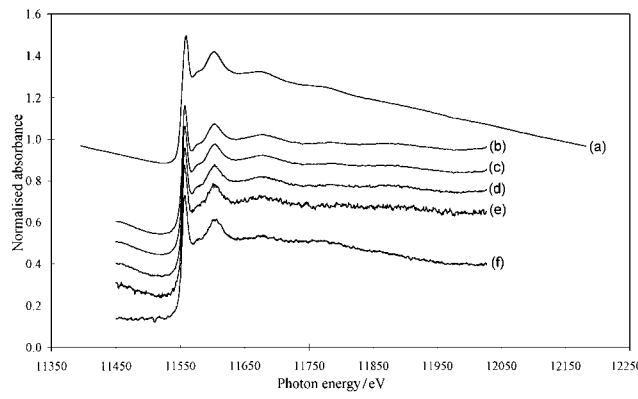

Fig 1 The Pt L_{III}-edge absorption spectra of as-synthesised 5wt%$Pt(acac)_2/H_I\ SiO_2$ catalysts showing (a) the conventional EXAFS data obtained over 1 h. Also shown is the equivalent EDE data obtained in (b) 50 s, (c) 5 s, (d) 0.5 s and (e) 0.05 s on Station 9.3. Spectra (f) shows the EDE data obtained in 21 s for a 1 wt% Pt $Pt(acac)_2/H_I\ SiO_2$ catalyst.

Table 1 Structural and statistical parameters derived from the analysis of the EDE and EXAFS spectra shown in Fig. 1. (a) Δk = 2–12 Å^{-1}, (b)–(f) Δk = 2–10 Å^{-1}. The *R* factors = $(\int [\chi^T - \chi^E]k^3dk/[\chi^E]k^3dk) \times 100\%$ where χ^T and χ^E are the theoretical and experimental EXAFS and *k* is the photoelectron wave vector; the Debye–Waller factor = $2\sigma^2$, where σ is the root mean square internuclear separation. Values in parentheses are statistical errors generated in EXCURVE (see footnote [b])

Sample	Shell	CN[a]	*r*/Å[b]	1.5% error in *r*[b]	$2\sigma^2$/Å^2 [b]	*R*-factor (%)

Metallation-induced migration of phosphorus from nitrogen to carbon in 1-oxo-2,8-diphenyl-2,5,8-triaza-1λ^5-phosphabicyclo[3.3.0]octane: unusual bonding parameters of the double migration product

Susan A. Bourne,[c] Zhengjie He,[a] Tomasz A. Modro*[a] and Petrus H. Van Rooyen[b]

Received (in Cambridge, UK) 9th March 1999, Accepted 31st March 1999

The title compound undergoes lithiation-induced rearrangement, first to a bicyclic phosphonic diamide, and next to a bicyclic phosphinic amide; for the latter product an unusually long phosphoryl bond was observed.

Recently we reported the regioselective cleavage of one P–N bond in the title compound **1** leading to either the eight-membered (2,5,8-triaza-1λ^5-phosphacyclooctane) or the five-membered (1,3,2λ^5-diazaphospholidine) monocyclic product.[1] We present here another transformation of substrate **1** induced by treatment with BuLi. We reported before the LDA-induced migration of phosphorus from nitrogen to aromatic carbon for simple phosphoric *N*-phenylamides,[2] but for **1** the reaction, involving a bicyclic substrate, leads to the formation of new bicyclic systems. Because of the presence of two N–Ph groups in **1**, lithiation can induce single or double N → C migration of the P atom, leading to the bicyclic phosphonic diamide **2** or the bicyclic, symmetrical phosphinic amide **3**, depending on the excess of BuLi.† The product of single migration **2** can be also converted to **3** upon further treatment with BuLi (Scheme 1). The structures of products **2** and **3** were deduced from their NMR (^{31}P, ^{1}H, ^{13}C) spectra, but the unambiguous structural evidence was obtained from the crystal structures of both products (Figs. 1 and 2).‡ Since the crystal structure of **1** was determined before,[3] we could compare the molecular parameters of all three bicyclic compounds. The comparison revealed some interesting structural changes that take place at the phosphorus centre during the transformation **1** → **2** → **3** leading to some unusual bonding parameters of the phosphoryl function in the final product **3** (Table 1). The P–C bond distance in **2** has a typical value,§ but for **3** the differences in the P–C distances within each of the crystallographically independent molecules are worth noting as they lead to the effective loss of the molecular symmetry for **3**. The P–N bond distances in all three compounds are typical for the amides of P^{IV} acids,[5] with the possible exception of the unusually long bond in one of the two molecules of **3**. Dramatic variations have however been

3	1.641(3)[d] 1.578(3)[d]	1.785(4)[d] 1.664(4)[d]	1.608(4)[e] 1.750(4)[e] 1.607(4)[e] 1.959(5)[e]

[a] Taken from ref. 3. [b] P–N(Ph) bond. [c] P–N(CH$_2$)$_2$ bond. [d] For two crystallographically independent molecules. [e] Each pair for one of the two crystallographically independent molecules.

observed within the series **1**, **2**, **3** for the distance parameter of the phosphoryl group. It is well known that the P–O bond distance in the phosphoryl function is insensitive to its molecular environment or external effects; for example, although the P=O group can accept up to three hydrogen bonds, its length seems to be little affected.[6] The average P=O bond length in phosphates is given as 1.462 Å, with the extreme range of 1.38–1.56 Å observed for 82 compounds studied.[7] The phosphoryl group in **1** represents a typical, average case of the P=O bond distance. The rearrangement to the structure **2** results in some increase of the P=O bond length, but still within the typical range. It is, however, the 7/7-membered fused ring system **3**, in which a dramatic elongation of the P=O bond takes place. In fact, the values of 1.578 and 1.641 Å locate the function within the typical range for a *single* P–O bond (1.56–1.64 Å[7]), thus indicate the dipolar resonance notation, P^{+}–O^{-}. Since **3** belongs to the class of *N*,*N*-disubstituted diarylphosphinic amides, it could be compared with the simplest analogue $Ph_2P(O)NMe_2$. The P=O bond distance in the latter was determined as 1.47 Å;[8] for **3** the average value is 0.14 Å greater, indicating *ca.* 10% elongation of the phosphoryl bond. A Cambridge Crystallographic Data File search revealed the distribution of the P=O bond distances for phosphinic amides [C(C)P(O)N structural unit, 44 structures], as shown in Fig. 3, showing that the P=O distance in **3** lies beyond the usual range, particularly in view of the fact that the few cases with the P=O distance greater than 1.49 Å concern complexes with Lewis acids, *i.e.* when a decrease in the P=O bond order is expected. The elongation of the P–O distance in **3** is not a consequence of any unusual 'back donation' effect of the amide nitrogen, as there is not only no shortening of the P–N bond in **3**, but the amide bond is slightly longer than the typical value for the related systems. The change in the nature of the P=O bond in **3** was confirmed by IR spectroscopy. The characteristic bands for the P=O stretching vibrations occur in the range of 1200–1400 cm^{-1}.[9] For **1** the ν_{PO} = 1234 cm^{-1}, similar to that of 1209 cm^{-1} reported for HMPA.[9] The change of **1** to **2** is followed by a bathochromic shift to ν_{PO} = 1185 cm^{-1}; for **3** the absorption occurs at 1162 cm^{-1}, beyond the usual range for the phosphoryl compounds and approaching the range typical for a single P–O bond stretching vibration.

In the solid state the molecules of **3** are interconnected *via* a network of hydrogen bonds between the phosphoryl oxygens and the N–H amine functions. Because of the packing pattern, there are three types of N–H···O=P bonds, each characterized by the following values of the N···O distance and the N–H···O angle: (i) 2.495(6) Å, 163(4)°; (ii) 3.478(6) Å, 167(3)°; (iii) 2.866(5) Å, 175(5)°. Those values are similar to the parameters observed for other phosphoric amides,[5] and do not indicate any particularly strong bonding that might be responsible for the unusually long P–O distance. It seems therefore that the observed bonding parameters are a consequence of the specific steric effects operating in the highly rigid skeleton of the molecule. This in turn suggested that the reactivity of the amide bond in **3** should differ from that observed for simple phosphinic amides, as well as from the reactivity of the precursors **2** and **1**. The reactivity of **3** is currently being studied in our laboratory.

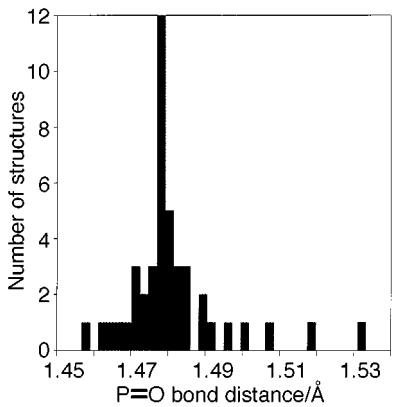

Fig. 3 Distribution of the P=O bond distances in phosphinic amides.[12]

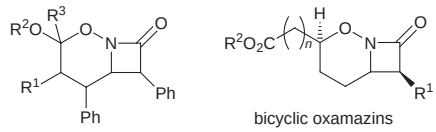
Received (in Liverpool, UK) 23rd February 1999, Accepted 11th March 1999

A high pressure promoted tandem [4 + 2]/[3 + 2] cycloaddition of β-nitrostyrene with a variety of enol ethers followed by a base catalysed rearrangement provided a novel class of di- and tricyclic *N*-oxy-β-lactam compounds.

Since the discovery of heteroatom activated β-lactams several reports mention the unique properties of this class of compound which show potential antibacterial activity. The biological activity of *N*-oxy-β-lactams has been attributed to electronic activation of the azetidinone ring. The oxygen atom directly attached to the ring makes the β-lactam more susceptible to nucleophilic attack than the corresponding *N*-alkyl-β-lactams.[1] Although polycyclic *N*-oxy-β-lactams can be considered as attractive targets in the search for new antibiotics only a few articles describing their synthesis have been reported.[2,3]

Here we describe a stereoselective route towards novel di- and tricyclic heteroatom activated β-lactams **1** from easily accessible building blocks such as enol ethers and β-nitrostyrene. The bi- and tricyclic *N*-oxo-β-lactams described are new compounds strongly resembling the biologically active bicyclic oxamazins.[2,4]



1a R^1 = H, R^2 = Et, R^3 = H
b R^1 = H, R^2 = PMB, R^3 = H

d R^1–R^2 = $(CH_2)_2$, R^3 = H

Recently, we reported the one-pot three-component tandem [4 + 2]/[3 + 2] cycloaddition of nitroalkenes, enol ethers and mono-substituted electron-poor alkenes (Scheme 1).[5] The powerful effect of high pressure resulted in the formation of the nitroso-acetals **2** without the need of stoichiometric amounts of Lewis acid catalysts as reported by Denmark and Seebach.[6,7] Furthermore it is reported that 1,2-disubstituted olefins are unreactive under Lewis acid conditions at ambient pressure in this type of tandem [4 + 2]/[3 + 2] cycloaddition.[7] This stimulated us to study the reactivity of 1,2-disubstituted olefins under high pressure conditions.

Here we report the high pressure promoted tandem cycloaddition of enol ethers and β-nitrostyrene in which β-nitrostyrene reacts both as heterodiene and 1,2-disubstituted dipolarophile. In general, the tandem cycloaddition of the enol ether with an excess of β-nitrostyrene (4 equiv.) resulted in the formation of regioisomers **3** and **4** (Scheme 2). β-Nitrostyrene first reacts as an electron-poor diene in an inverse electron demand Diels–Alder reaction with an electron-rich enol ether and thereafter as an electron-poor dipolarophile with the *in situ* formed mono-adduct in a 1,3-dipolar cycloaddition. The reaction was studied with mono-substituted and cyclic enol ethers.

Surprisingly the main regioisomer **3** was converted in one step into β-lactam **1** during purification on silica gel using an eluent containing Et_3N, pointing to a base catalysed rearrangement (Scheme 2). This was further confirmed by stirring the crude reaction mixture in CH_2Cl_2 with a catalytic amount of Et_3N. In this way the same mixture of products was obtained. In agreement with these results it is suggested that first the acidic proton adjacent to the nitro group is removed by the base followed by N–O bond cleavage and elimination of nitrite (Scheme 2).[8] Table 1 shows the regioisomeric ratios of cycloadducts **1a**–**d** in the crude reaction mixture (measured by ^{1}H NMR).

The stereochemistry of the cycloadducts has been elucidated by high field 2D-NOESY ^{1}H NMR experiments. It was found that the [4 + 2] cycloaddition proceeded with complete regio- and *endo*-selectivity while the [3 + 2] cycloaddition proceeded with variable regioselectivity and with moderate *exo*-selectivity. However β-lactam **1** was formed after a completely *endo*-selective [4 + 2] and *exo*-selective [3 + 2] cycloaddition.

The stereochemistry of the cycloadducts is discussed on the basis of a representative example (entry 2, Table 1). The main product **7** and regioisomers **5a**† and **6** (Scheme 3) were detected by NMR analysis of the crude reaction mixture in a 7 : 2 : 1 ratio. After purification, β-lactam **1b**‡ and nitroso-acetals **5b** and **6** were isolated in a 7 : 2 : 1 ratio, indicating a complete conversion of **7** to **1b** and **5a** to **5b**. Product **5b** is the NO_2 epimer of the *endo*[4 + 2]-*anti-endo*[3 + 2]-isomer **5a** and product **6** is the

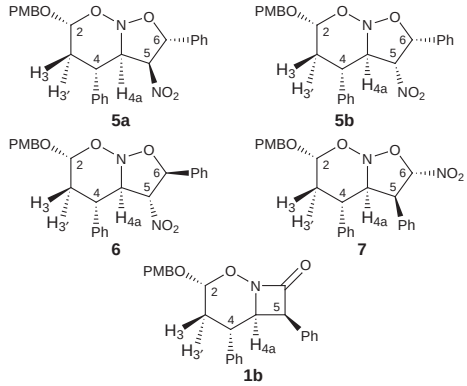
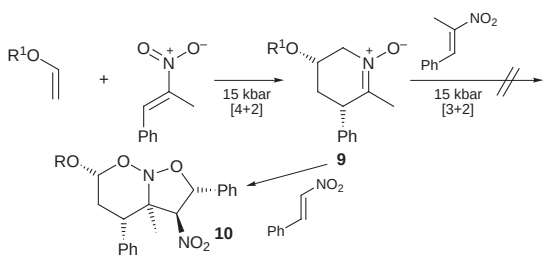


Scheme 3

endo[4 + 2]-*anti*-*exo*[3 + 2]-isomer.[9] Some crystals of compound **7** were obtained from the crude reaction mixture and the structure of **7** was assigned by 2D-NMR as depicted in Scheme 3. The C-5 epimer of β-lactam **1b** was not detected. NOE contact between H-4a and H-5 of **1b** indicate a *cis* configuration for these protons. The formation of regioisomers **5b** and **6** however proceeded with less selectivity (**5b** : **6** = 2 : 1). NOE-contacts between H-2 and H-3, H-3 and H-4, and H-2 and H-4 indicate a chair-like conformation of the 6-membered ring formed after the *endo*-selective hetero Diels–Alder reaction. These NOE contacts were observed for both regioisomers **5b**, **6** and β-lactam **1b**. X-Ray analysis of compound **1b** confirmed the configuration of the 6-membered ring. In all cases the attack of β-nitrostyrene in the [3 + 2] dipolar cycloaddition was *anti* (with respect to the phenyl group) since a *trans* relationship between H-4a and H-4 was found in the cycloadducts.

The formation of regioisomer **7** is rather unexpected since literature data concerning the 1,3-dipolar cycloaddition of nitrones and olefins with unequally electron-withdrawing groups such as nitro and phenyl substituents predict opposite regioselectivity (*e.g.* **5** and **6**).[10] AM1 calculations predict a HOMO-dipole controlled formation of regioisomers **5** and **6**.[11] The experimental regioisomeric outcome could be explained on the basis of charge distribution between dipole and dipolarophile obtained through AM1 calculations which is in agreement with calculations reported by Baskaran *et al.*[12,13]

1-Phenyl-2-nitropropene and *p*-methoxybenzyl vinyl ether reacted stereoselectively to give *endo* [4 + 2] adduct **9**. This mono-adduct failed to react with another molecule of 1-phenyl-2-nitropropene (15 kbar, 50 °C, 48 h) probably because of steric hindrance but it reacted completely regio- and stereoselectively with β-nitrostyrene in accordance with the predicted regioselectivity towards bicyclic nitroso-acetal **10**[13] (Scheme 4).



Scheme 4

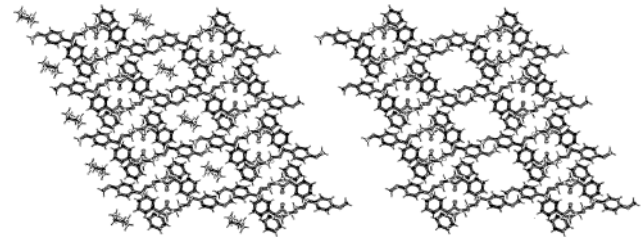


Fig. 1 2D depiction of the X-ray structure of β-lactam **1b** with (left) and without (right) cyclohexane.

Interestingly the X-ray structure of **1b** showed parallel oriented channels with aromatic walls holding cyclohexane molecules present in the solvent from which the compound was crystallised (Fig. 1). It seems that **1b** acts as an organic zeolite since complete selectivity for the inclusion of cyclohexane was found after crystallisation from *n*-hexane–CH_2Cl_2 (*n*-hexane contains 3–10% cyclohexane by GC analysis). The zeolite properties of this compound are under investigation (*e.g.* inclusion of other solvents or chiral compounds).

We gratefully acknowledge the support of NWO-CW and Solvay Pharmaceuticals.

Received (in Cambridge, UK) 24th December 1998, Accepted 5th February 1999

Poly(ferrocenylsilanes) are a novel class of transition metal-containing macromolecules with a backbone that consists of alternating ferrocene and organosilane units. High molecular weight examples of these interesting materials were first prepared several years ago by thermal ring-opening polymerization (ROP) of silicon-bridged [1]ferrocenophanes ([1]silaferrocenophanes). This Feature Article discusses current knowledge of the properties of these readily available and processable organometallic polymers together with recent developments made possible by the discovery of living anionic and transition metal-catalyzed ROP routes. These methodologies have provided ambient temperature access to poly(ferrocenylsilanes) with molecular weight control and also to well defined architectures such as block copolymers. The latter materials self-assemble in the solid state to form ordered arrays of nanoscale redox-active organometallic domains and in solution form well defined supramolecular organometallic polymer aggregates such as spheres, cylinders, and more complex architectures.

Introduction

Whereas the synthetic scope and technological achievements of organic polymer science are remarkably impressive, the corresponding macromolecular chemistry of inorganic elements is at a much more primitive stage of development.[1] This is particularly the case for transition metal-based polymers which would be expected to possess a range of interesting and potentially useful physical and/or catalytic properties.[1,2] Nevertheless, synthetic breakthroughs, which have occurred sporadically over the last 10–15 years and at a more rapid pace recently, have provided access to a range of fascinating new materials.[1–5] Rigid rod poly(metallaynes) such as **1** and **2** provide an excellent illustration of the potential of this area.[4] These polymers, of which the first examples were reported at the end of the 1970s, possess novel conjugated backbones, and in several cases interesting physical properties such as lyotropic liquid crystallinity and third-order non-linear optical properties have been established.[1,4,6]

Much of the early pioneering work in transition metal-based polymer science in the 1950s and 1960s targeted poly(metallocenes).[7] Such efforts were encouraged by the remarkable stability and unusual properties of monomeric and dimeric metallocenes which were discovered by the fundamental, exploratory chemistry conducted during this period.[8] However, most of the attempted polymer syntheses utilized polycondensation reactions where either the difunctional monomeric precursors were impure or the coupling chemistry was not clean. For such step growth processes this guaranteed the generation of poorly defined, low molecular weight oligomeric materials (M_n < *ca.* 3000) of correspondingly low processability.[9] In addition, many of the resulting products were insoluble and poorly characterized.[9]

In 1992 our group reported the discovery of a thermal ring-opening polymerization (ROP) route to high molecular weight poly(ferrocenylsilanes) **4**, a novel class of poly(ferrocenes), from strained cyclic, silicon-bridged [1]ferrocenophane ([1]-silaferrocenophane) precursors (**3**).[10] This chain growth synthetic approach permitted access to very high molecular weight polymers with weight average molecular weights (M_w) and number average molecular weights (M_n) of the order of M_w = 10^5–10^6 and M_n > 10^5.[10–15] We have subsequently expanded this ROP methodology to a range of analogous strained monomers which contain other bridging elements and transition metals or different π-hydrocarbon rings.[15,16] In this article we

Professor Ian Manners is Professor of Chemistry in the Department of Chemistry, University of Toronto, Canada. He was born in London, England, in 1961 and received his BSc and PhD (with Professor Neil Connelly) from the University of Bristol in 1982 and 1985, respectively. From 1986–87 he was a Royal Society European Postdoctoral Fellow at the RWTH, Aachen (with Professor Peter Paetzold) and from 1988–90 he worked as a Research Associate (with Professor Harry R. Allcock) at the Pennsylvania State University, USA. He joined the Faculty at Toronto as an Assistant Professor in 1990. Manners' research interests focus on both the fundamental and applied aspects of the chemistry of rings, chains, and macromolecules based on main group or transition elements. He has received several awards and these include an E. W. R. Steacie Fellowship from Canada (1997–99), a Corday-Morgan Medal from the Royal Society (1997), an Alfred P. Sloan Fellowship from the USA (1994–98), and a University of Toronto Faculty of Arts and Science Outstanding Teaching Award (1993).

review progress specifically made on poly(ferrocenylsilanes) which have been particularly well studied since the initial ROP discovery. In particular we discuss some new directions arising from the development of more controlled polymerization methods which allow access to block copolymers. These have provided avenues to self-assembled, supramolecular organometallic polymer architectures.

Synthesis and properties of poly(ferrocenylsilanes)

[1]Silaferrocenophane monomers **3** are readily available on a substantial (>100 g) laboratory scale from the reaction of dilithioferrocene–tetramethylethylenediamine ($fcLi_2$·TMEDA) with dichloroorganosilanes $RR'SiCl_2$.[17] The first example of these species, the phenylated derivative **3** (R = R′ = Ph), was prepared by Osborn and Whiteley at the University of Exeter in the mid 1970s.[18] The cyclopentadienyl ligands present in [1]silaferrocenophanes are appreciably tilted with respect to one another by 16–21° which is indicative of the presence of appreciable ring strain which has been estimated to be *ca.* 60–80 kJ mol^{-1}.[16,19] Spirocyclic [1]silaferrocenophanes such as **5** are

5

also readily accessible.[18,20] The molecular structures of two typical [1]silaferrocenophanes polymerised in our group are shown in Fig. 1.[20,21]

Since the initial ROP discovery a wide range of silicon-bridge [1]ferrocenophanes **3** with either symmetrically or unsymmetrically alkyl- or aryl-substituted silicon atoms have been prepared and polymerized to afford high molecular weight poly(ferrocenylsilanes) **4**.[15] Substituents such as hydrogen, chlorine, trifluoropropyl, norbornenyl and ferrocenyl groups have also been introduced (Table 1).[15,22,23] Very recently, we have found a facile route to the first poly(ferrocenylsilanes)

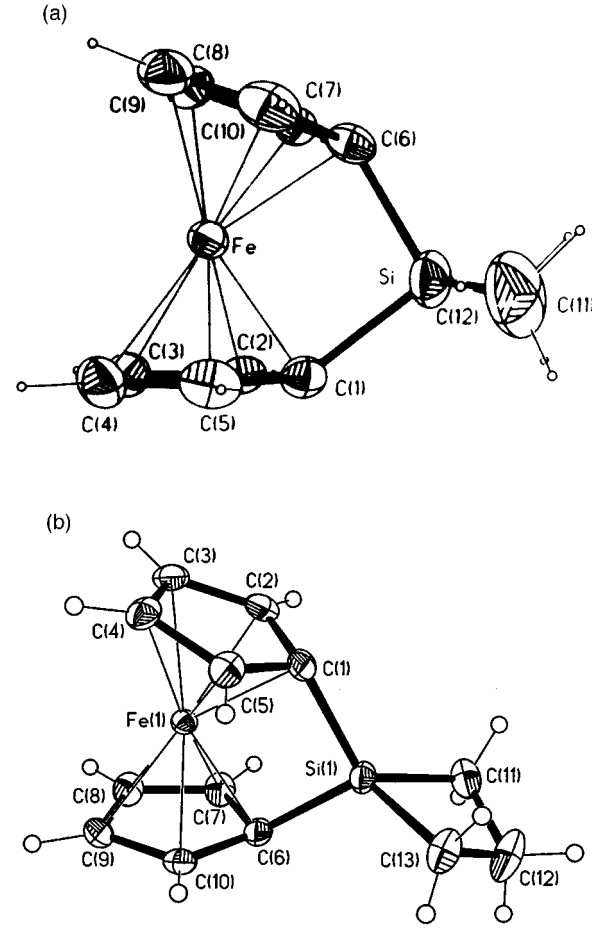

Fig. 1 Molecular structure of (a) silicon-bridged [1]ferrocenophane **3** (R = R′ = Me) and (b) spirocyclic [1]silaferrocenophane **5** determined by X-ray diffraction.

with alkoxy, aryloxy, and amino substituents at silicon.[24] These stable materials (**8** and **10**, respectively) are accessible *via* the ROP of similarly substituted [1]silaferrocenophane precursors (**7** and **9**) which can be accessed *via* nucleophilic substitution

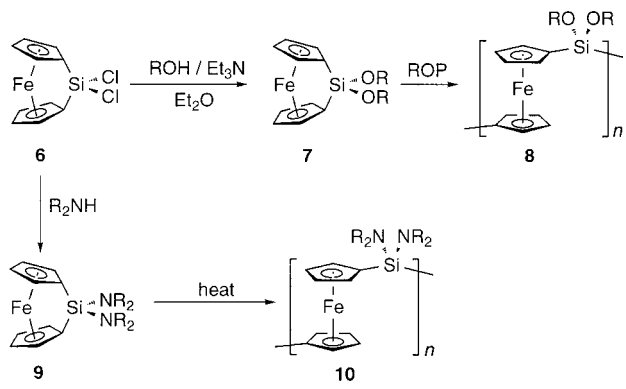
[a] GPC data obtained from the analysis of THF polymer solutions which contained 0.1% $[Bu_4N][Br]$ and molecular weight values are relative to polystyrene standards. Although in this case GPC provides only molecular weight estimates absolute determinations of M_w by static light scattering for several polymers have indicated that GPC underestimates the real values by a factor of two (see ref. 15) [b] DSC data collected at a heating rate of at 10 °C min^{-1}. [c] PDI = M_w/M_n. [d] Fc = $(\eta\text{-}C_5H_4)Fe(\eta\text{-}C_5H_5)$. [e] Insoluble polymer.



Scheme 1

reactions on the $SiCl_2$-bridged [1]ferrocenophane **6** (Scheme 1). The latter species is easily prepared in high yield *via* the reaction of $fcLi_2$·TMEDA with $SiCl_4$.

Because of their novel backbone of alternating ferrocene and organosilane units it is interesting to consider how the poly(ferrocenylsilane) chains pack together in the solid state and the possible chain conformations that might exist.[25] Another important feature of these polymers is their glass transition temperature (T_g) which reflects, at least to a certain degree, the conformational flexibility present. Regular packing in the solid state (*i.e.* crystallization) is possible for many symmetrically substituted derivatives.[15,25] For example, the prototypical poly(ferrocenylsilane), the dimethyl derivative **4** (R = R′ = Me), is an amber, film-forming thermoplastic [Fig. 2(a)] which possesses melt transitions (T_m) in the range 122–143 °C.[15,25,26] Crystals on the surface of aged polymer films can be observed by atomic force microscopy [Fig. 2(b)].[27] This material possesses a T_g at 33 °C, which is remarkably low for a polymer with a bulky unit such as ferrocene in the main chain. The ability of the iron atom in ferrocene to act as a freely rotating 'molecular ball-bearing' probably plays a key role in generating the observed conformational flexibility. The manner in which these polymer chains pack in the solid state for this polymer has attracted significant interest and has been examined by detailed conformational calculations and X-ray structural studies of well defined oligomers by O'Hare and coworkers and ourselves, respectively.[28,29]

Poly(ferrocenyldimethylsilane) [**4** (R = R′ = Me)] can be melt-processed into shapes above 150 °C [Fig. 2(c)] and can be used to prepare crystalline, nanoscale fibers (diameter < 1.5 μm) by electrospinning in which an electric potential is used to produce an ejected jet from a solution of the polymer in THF which subsequently stretches, splays, and dries. The nanofibers of different thickness show different colours due to interference effects similar to those in soap bubbles [Fig. 2(d)].[30]

Like the dimethyl material, other symmetrically substituted poly(ferrocenylsilanes) with short (C_2–C_5) alkyl chains at silicon will also crystallize and similar melting behavior is observed (Table 1). In contrast to the poly(ferrocenylsilanes) with shorter C_2–C_5 alkyl chains, the *n*-hexyl analogue **4** (R = R′ = *n*-hexyl) is an amber, gummy amorphous material with a T_g of −26 °C. Alkoxy-substituted poly(ferrocenylsilanes) such as **8** (OR = *n*-hexyloxy) are also amorphous and possess T_g values down to −51 °C. Poly(ferrocenylsilanes) with longer alkoxy side chains [*e.g.* **8** (OR = *n*-octadecyloxy)] have been found to crystallize and form lamellar structures with interdigitated side groups.[24]

In addition to their morphological behavior, considerable effort has also been directed towards investigating and understanding the physical properties of the resulting poly(ferrocenylsilane) materials the vast majority of which are soluble in organic solvents despite their very high molecular weights. Cyclic voltammetric studies of poly(ferrocenylsilanes) generally show the presence of two reversible oxidation waves spaced by *ca.* 0.25 V in a 1 : 1 ratio providing clear evidence for the existence of interactions between the iron atoms.[15] The proposal that initial oxidation occurs at alternating iron sites along the main chain followed by oxidation of those remaining at a higher potential has been supported by recent detailed work on individual members of a series of model oligomers with between two and nine ferrocene units.[29] Comparisons of the behavior of poly(ferrocenylsilanes) with analogous polymers suggest that the metal–metal interactions are mediated by the silicon spacer.[31] Poly(ferrocenylsilanes) also possess interesting hole transport properties and partial oxidation leads to a 10^{10} increase in electrical conductivity up to semiconductor values (*ca.* 10^{-3}–10^{-4} S cm^{-1}).[32] Thin films of the polymers are attracting attention as, for example, chemomechanical sensors, electrochromic materials, electrode mediators, and variable refractive-index materials.[33–36] The polymers also have interesting potential as precursors to ceramic materials. Thus, heating to 500–1000 °C can yield magnetic ceramics containing α-Fe crystallites. In several cases the ceramic yield is > 90% and allows the formation of ceramic monoliths with shapes defined by that of the processable polymeric precursor.[37] Oxidation of poly(ferrocenylsilanes) has been reported[38] to yield materials which display spin alignment, albeit at low temperatures although other studies have not reproduced these results.[39]

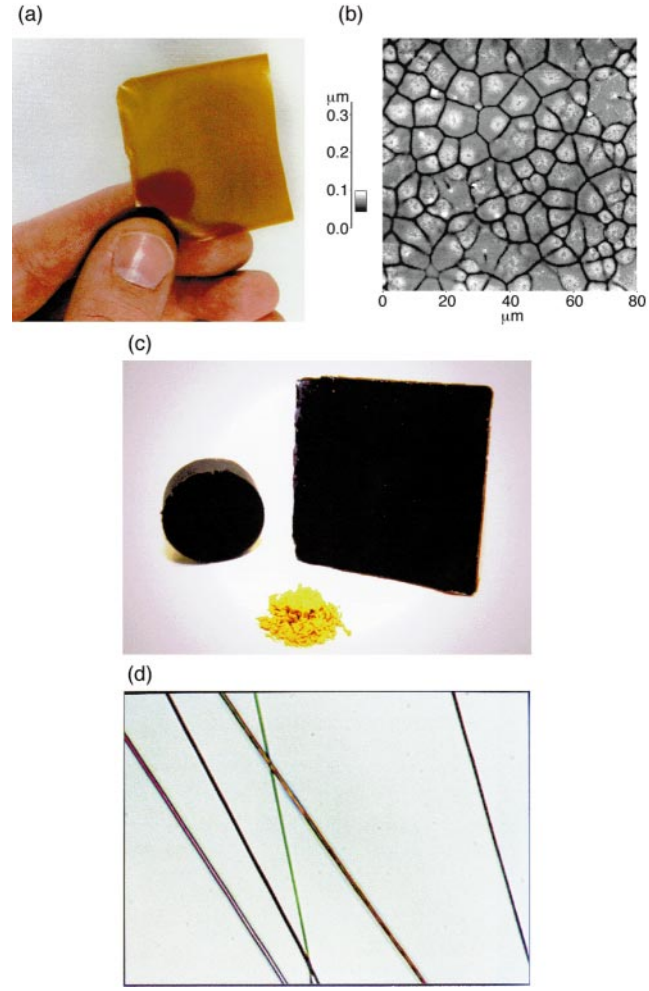


Fig. 2 Poly(ferrocenyldimethylsilane) **4** (R = R′ = Me): (a) a solvent-cast film, (b) surface crystals grown on a thin film after 3 months observed by atomic force microscopy, (c) melt-processed fabricated shapes, (d) electrospun fibers. Figures (b) and (d) are courtesy of Nina Sheller and Mark D. Foster and Zhihao Chen, Hao Fong, Darrell H. Reneker, and Mark D. Foster, respectively, of the Institute of Polymer Science at the University of Akron, USA.

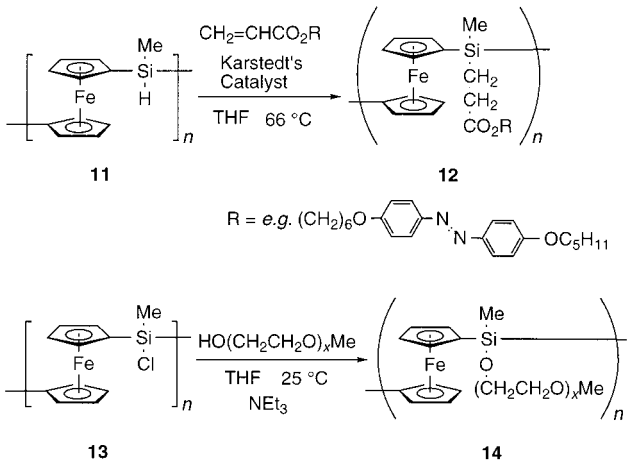
Very recently, controlled crosslinking of poly(ferrocenylsilanes) has been achieved to yield solvent swellable, redox-active gels. The crosslinking can be controlled by using specific amounts of the spirocyclic [1]ferrocenophane **5** (Fig. 1) in the polymerization mixtures.[20]

Functionalization of poly(ferrocenylsilanes) has been achieved by several methods (Scheme 2).[23,40] For example,



11 **12** **13** **14**

Scheme 2

ROP of [1]silaferrocenophane **4** (R = Me, R′ = H) with a Si–H functionality affords **11** which undergoes metal-catalyzed hydrosilylation reactions. This methodology has been recently used to prepare thermotropic liquid crystalline poly(ferrocenylsilanes) such as **12**. To illustrate another approach, ROP of **4** (R = Me, R′ = Cl) followed by substitution of Si–Cl bonds present in poly(ferrocenylsilane) **13**, permits access to water soluble poly(ferrocenylsilanes) such as **14** ($x \sim 7$).

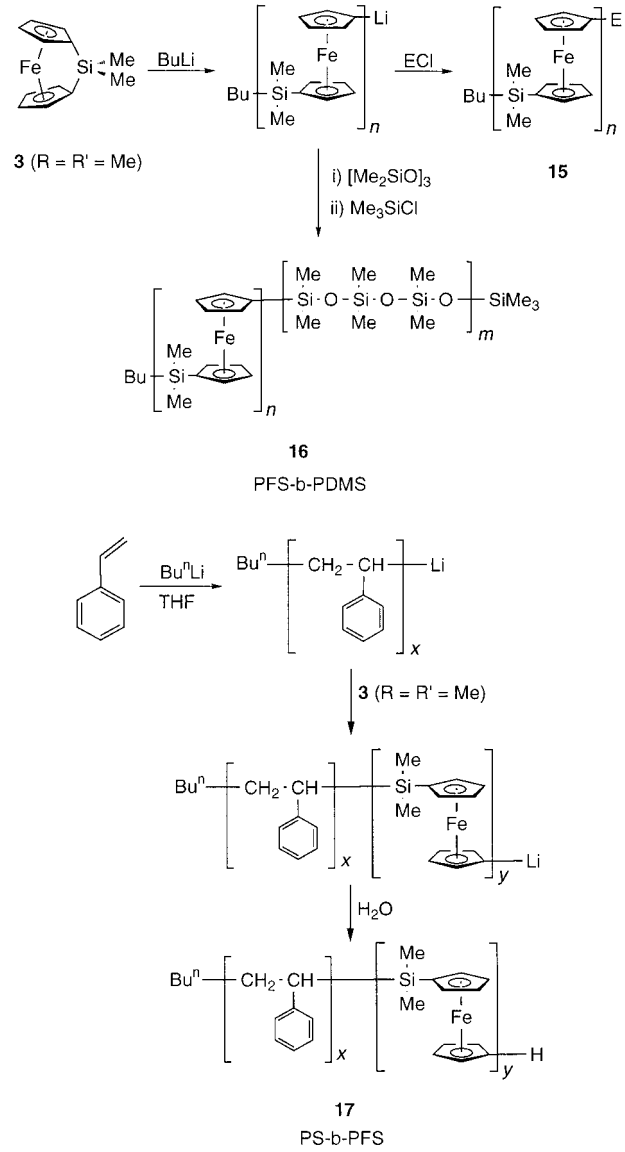
Living anionic ROP of silicon-bridged [1]ferrocenophanes

Thermal copolymerization can be used to prepare random copolymers from mixtures of different silicon-bridged [1]ferrocenophanes and also copolymers of ferrocenophanes with other monomers such as cyclic silanes and silicon-bridged bis(benzene)chromium complexes.[32,41] However, thermal ROP of metallocenophanes at elevated temperatures leads to virtually no control over molecular weight and the molecular weight distribution is broad with polydispersity indices (PDI = M_w/M_n) of *ca.* 1.5–2.5. In 1994 we showed that highly purified silicon-bridged [1]ferrocenophanes undergo living anionic ROP at 25 °C using initiators such as Bu^nLi in THF.[42] This has permitted the synthesis of poly(ferrocenylsilanes) **15** (E = H) with controlled molecular weights and narrow molecular weight distributions (polydispersities < 1.3) and has also allowed the preparation of end-functionalized polymers **15** (E ≠ H) and the first block copolymers (*e.g.* **16** and **17**) containing skeletal transition metal atoms (Scheme 3).[43]

Logical further developments of this chemistry include the extension to other organic (and inorganic) monomers to access other poly(ferrocene) multiblock systems. Moreover, the ability to functionalize chain ends should allow the development of end-functionalized, redox-active polymers for surface (*e.g.* electrode) attachment, *etc.*[11,43]

Transition metal catalyzed ROP of [1]ferrocenophanes

Transition metal-catalyzed ROP of silicon-bridged [1]ferrocenophanes, which also occurs in solution at room temperature,



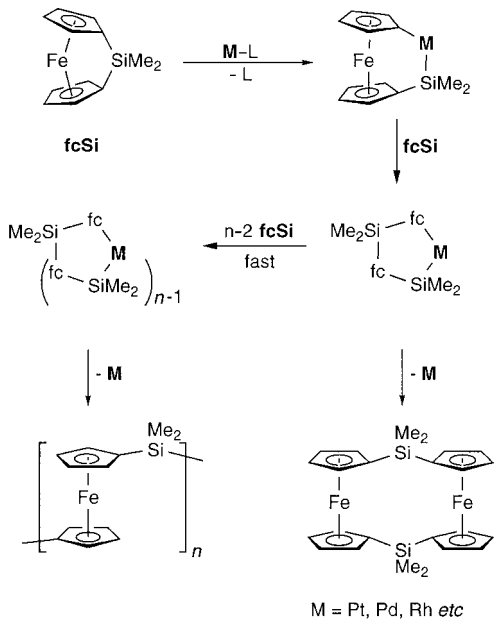
Scheme 3

has also been reported using Pt^{II}, Pt^0, Rh^I, and Pd^{II} pre-catalysts.[44,45] Significant understanding of the mechanism of these transition metal-catalyzed reactions has also been forthcoming and a possible mechanism is shown in Scheme 4.[9]

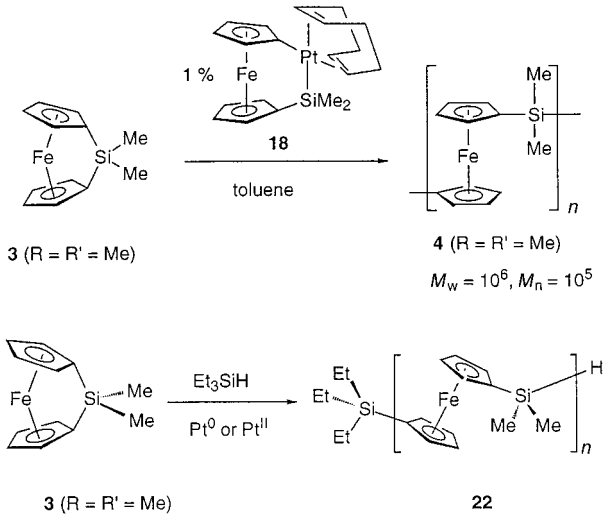
The initial step is believed to be insertion of the transition metal into the strained Cp–Si bond. Indeed, species such as **18** have been prepared from exactly this type of reaction [in the case of **18** from **3** (R = R′ = Me) and Pt(1,5-cod)$_2$] and function as ROP precatalysts.[46]

Transition metal catalyzed ROP is a mild method which does not require monomer with an exceptional degree of purity and has now been developed to the stage where considerable control over poly(metallocene) architectures is possible.[47,48] For example, [1]silaferrocenophanes with different cyclopentadienyl rings (**19**) undergo transition metal catalyzed ROP to yield the regioregular, crystalline poly(ferrocenylsilane) **20** whereas thermal ROP affords a regioirregular amorphous material **21** (Scheme 5).

Addition of sources of Si–H bonds such as Et_3SiH to the polymerization mixture allows molecular weight control (Fig. 3). The process is believed to occur *via* competition of the Si–H bond and the strained Si–C bond of the [1]ferrocenophane for oxidative addition at the metal center. Addition of the Si–H bond followed by reductive elimination affords the Et_3Si–fc and Si–H terminated product (**22**).



Scheme 4



If polysiloxanes with Si–H groups as substituents or as terminii are used in place of Et_3SiH then graft (**23**) or block (**24**) copolymers can be prepared. Moreover, the use of cyclic tetrasiloxanes as sources of the Si–H functionalities allows the preparation of novel poly(ferrocenes) (**25**) with star architectures with a cyclosiloxane core (Scheme 6). The remarkable convenience by which complex organometallic polymer architectures can be constructed compensates for the broader polydispersities (M_w/M_n = 1.4–1.8) compared to materials prepared *via* anionic polymerization (M_w/M_n < 1.3).

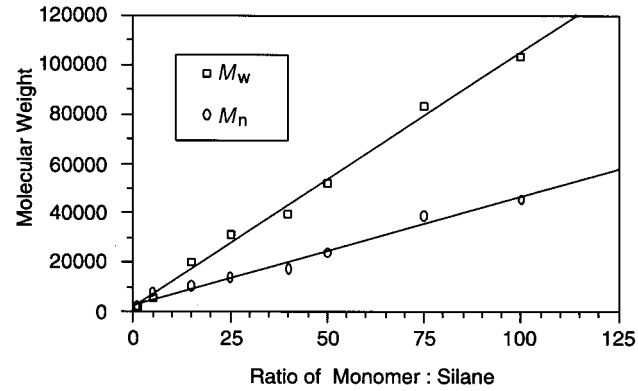


Fig. 3 Plot of M_w and M_n *vs.* ratio of monomer **3** (R = R′ = Me): Et_3SiH demonstrating molecular weight control (using Karstedt's catalyst in toluene).

Applications of ring-opened poly(ferrocenes) in the preparation of magnetic nanostructures

As mentioned above, poly(ferrocenylsilanes) function as preceramic polymers and have been shown to yield interesting ferromagnetic ceramic composites at 500–1000 °C which contain Fe particles in a SiC/C matrix.[37] The use of such involatile but processable polymeric precursors to ceramics is potentially an attractive way of circumventing the difficulty of processing ceramic materials into desired shapes. In collaboration with the group of Ozin at Toronto we have recently explored the pyrolysis of poly(ferrocenylsilanes) within the channels of the mesoporous silica MCM-41 with the aim of accessing nanostructured magnetic ceramic materials (Fig. 4).[49]

The monomer **3** (R = R′ = Me) can be sublimed into the hexagonal mesopores at room temperature. The resulting intercalated material was characterized by solid state ^{13}C and ^{29}Si NMR and by X-ray powder diffraction. ROP can then be induced by heating the resulting material at 200 °C, a process that was followed similarly and also by DSC which showed a ROP exotherm. Heating to 900 °C generates black, nanostructured magnetic ceramic products which can be visualized in the 30 Å channels by transmission electron microscopy (TEM) (Fig. 5). These materials were also characterized by X-ray diffraction, which showed the presence of small α-Fe nanoclusters with dimensions 20 ± 5 Å.[49] Studies of the

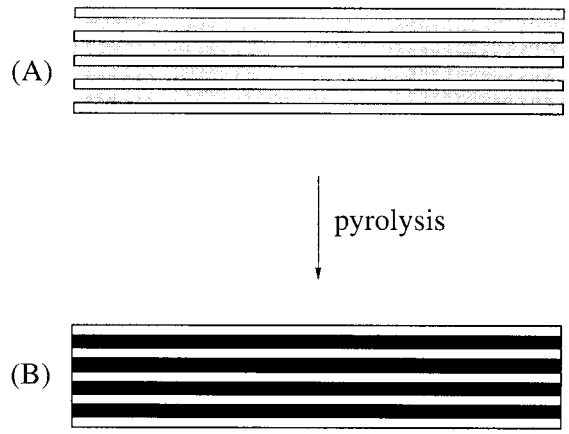

Fig. 4 Formation of nanostructured magnetic composites (B) *via* the pyrolysis of nanoscale cylinders of a poly(ferrocenylsilane) within the pores of mesoporous silica (MCM-41) (A).

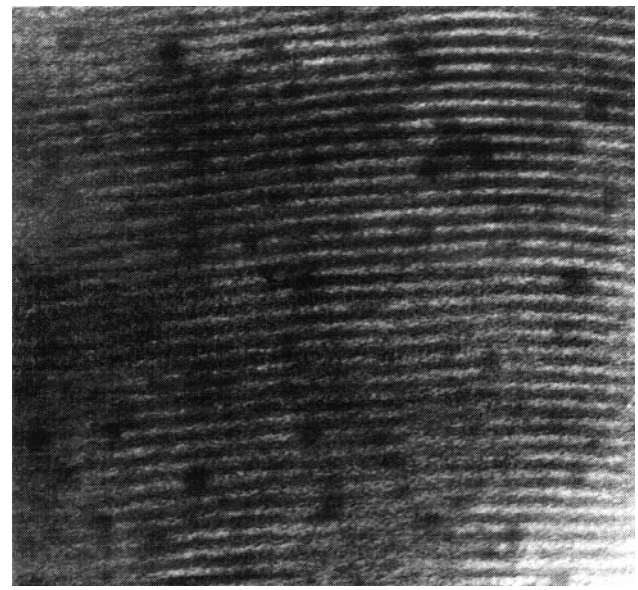

Fig. 5 Transmission electron micrograph perpendicular to the 30 Å channels of MCM-41 showing the incorporation of ceramics derived from the pyrolysis of poly(ferrocenylsilane) **4** (R = R′ = Me) in the mesopores at 900 °C.

magnetic properties of the composites confirmed that the materials are superparamagnetic rather than ferromagnetic which is consistent with the small sizes of the iron particles and the consequent, facile thermally induced reorientation of the magnetic domains at room temperature.

Self-assembly of poly(ferrocene) block copolymers: supramolecular organometallic polymer chemistry

Poly(ferrocene) block copolymers in which the blocks are immiscible (which is generally the case) would be expected to self-assemble to form phase separated domains in the solid state or to form micellar aggregates in selective solvents for one of the blocks.[50] This would allow the generation of unique supramolecular organometallic polymer architectures.

Based on the classical behavior of organic block copolymers, in the solid state poly(ferrocene) diblock copolymers should

form domains such as spheres, cylinders (or their anti-structures), double diamonds or gyroids, or lamellae. The preferred domain structure would be expected to be controlled by the ratio of the blocks, their degree of incompatibility (as defined by the Flory–Huggins interaction parameter χ), and the overall molecular weight of the block copolymer.[50] We reported the first studies in this area using differential scanning calorimetry (DSC) and TEM in 1996.[43] In the case of PS-b-PFS (**17**) detailed studies confirm that spherical, cylindrical, and lamellar domains are formed by using the expected block ratio variations [see, for example, Fig. 6(a) and (b)[27,51]] and also indicate that the PS-b-PFS materials possess phase behavior

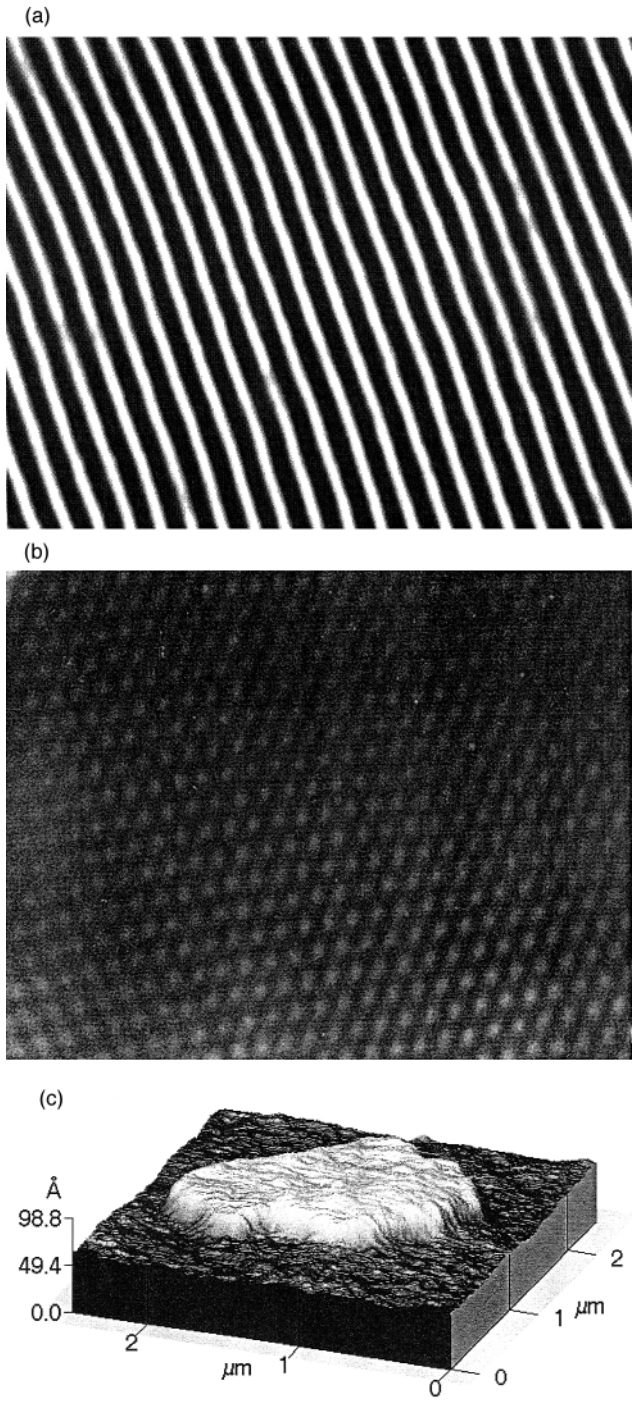

Fig. 6 Transmission electron micrographs of thin films of PS-b-PFS showing (a) lamellar morphology formed by a block copolymer with approximately equal block lengths, (b) ordered cylinders (end-on) of PS in a PFS matrix formed by a block copolymer with a 0.74 : 1.00 block ratio, (c) an AFM image showing crystals protruding from the surface of an annealed film. In TEM images (a) and (b) no staining agent was used and the PFS domains are dark and the PS domains light.

which is complicated by the presence of the crystallizable PFS block.[27,43,51–53] The crystallization is illustrated by the observation of 3D topological features on films of PS–b–PFS using atomic force microscopy (AFM) which shows elevated PFS crystallites [Fig. 6(c)].[27]

The self-assembly of poly(ferrocene) block copolymers in selective solvents for one block would also be anticipated based on studies of organic block copolymers. In the case of organic materials most studies have led to the identification of spherical structures with a core of the more insoluble polymer within a corona formed by the more soluble block. Only comparatively recently have non-spherical structures become more common.[54]

In collaboration with the group of Winnik at Toronto we have studied, for example, PS-b-PFS materials with a short PFS block (PS : PFS ratio 9 : 1). Films of these materials phase separate into spheres of PFS in a PS matrix and, in acetone, which is a selective solvent for low molecular weight PS, spherical micelles with an organometallic PFS core within a PS corona have been characterized.[51]

Recently, we have shown that interesting architectures can be generated *via* the solution aggregation of PFS-b-PDMS block copolymers (**16**) with long polysiloxane blocks (PFS : PDMS ratio = 1 : 6). Simply dissolving the amber, tacky block copolymer in warm hexanes leads to the formation of cylindrical, wormlike micelles with a PFS core and a corona of PDMS (Fig. 7).[55]

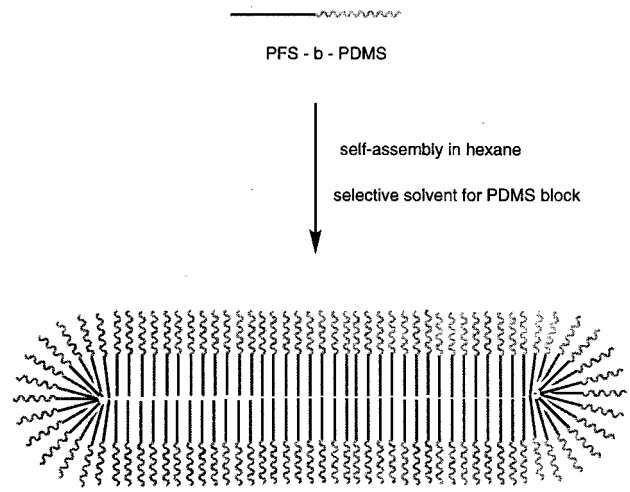

Fig. 7 Self-assembly of PFS-b-PDMS into cylindrical micelles in hexane.

These structures maintain their structural integrity in the solid state and the 20 nm iron-rich cores can be readily visualized by TEM which uses electron density differences to obtain contrast [see Fig. 8(a)]. AFM, on the other hand, allows both the core and corona to be imaged. The cylinders show considerable stability in solution and are unchanged in size after heating to 80 °C, However, ultrasonication of samples of the cylindrical micelles leads to a shortening as indicated by light scattering studies and by TEM [Fig. 8(b)].[55]

These cylinders formed in hexane consist of a wire-like core of semiconducting poly(ferrocenylsilane) surrounded by a sheath or corona of insulating poly(dimethylsiloxane) and are of interest as semiconducting nanowires (Fig. 9). Pyrolysis of such structures, particularly if crosslinked, offers the possibility of generating magnetic wire-like structures with a silica coating.

Recently we have prepared amphiphilic poly(ferrocenylsilane) diblock copolymers with N-methylated poly(vinylpyridine) (PVP) and poly(ethylene oxide) (PEO) and these materials, PVP-b-PFS and PFS-b-PEO, are soluble in water as long as the organic block is sufficiently long. Transition metal catalyzed ROP also provides very convenient access to block copolymers. The PFS-b-PDMS-b-PFS triblock materials (**24**) self-assemble in hexanes to yield a variety of remarkable

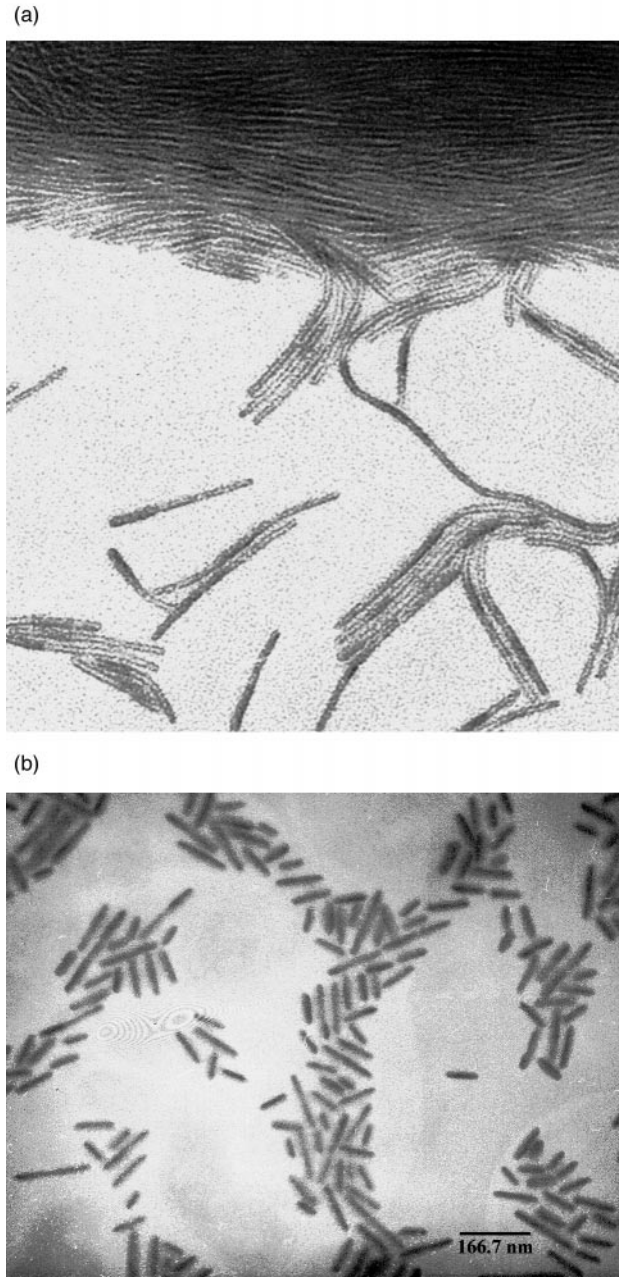

Fig. 8 Transmission electron micrograph of PFS-b-PDMS micelles aerosol-sprayed from a dilute solution in hexanes onto a thin carbon film supported on mica (no staining agent was used); (a) shows a region where the individual cylinders are starting to pack to form a 2D film as well as isolated cylinders; (b) shows the smaller cylinders that are formed after ultrasonication for 2 h (60 W).

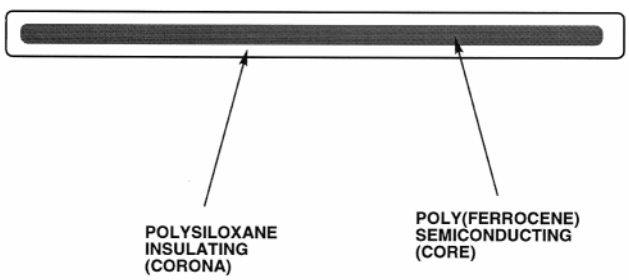

Fig. 9 Structure of cylindrical micelles of PFS-b-PDMS in hexanes.

architectures. In several systems morphologies such as vesicles and compound micelles in addition to spheres and cylinders have been identified.

Future opportunities exist for the generation of highly ordered, periodic structures which could be selectively oxidized (chemically or electrochemically, *e.g.* by using scanning probe microscope tips) to give materials with interesting properties. For example, the controlled orientation of nanoscale block copolymer cylindrical, or lamellar domains (*e.g.* at surfaces) might allow charge transport in certain directions. Of particular interest is an extension of the ideas that have been previously developed (and described above) for the synthesis of magnetic nanostructures *via* the pyrolysis of poly(ferrocene)/MCM-41 composites to ordered, phase-separated block copolymer structures. Thus, nanoscale poly(ferrocene) domains may allow the generation of ordered arrays of magnetic spheres, magnetic multilayers *etc*, *via* oxidation or pyrolysis (*e.g.* using lasers). Selective ablation of blocks (*e.g.* using plasmas) may also provide a methodology for defining patterns.[56] Research work on many of these ideas and others is ongoing in our group, in many cases in collaboration with other researchers.[11,43,51]

Summary

ROP of [1]silaferrocenophanes has permitted facile access to poly(ferrocenylsilane) homopolymers, a novel class of processable organometallic materials which have been found to possess a range of interesting physical properties. Living anionic and transition metal catalyzed ROP have allowed the preparation of materials with controlled molecular weights and architectures, *e.g.* block copolymers. Self-assembly of poly(ferrocenylsilane) block copolymers in the solid state or in solution yields well defined supramolecular, nanoscale organometallic architectures. Future work will be directed in particular towards further exploration of the properties of poly(ferrocenylsilane) homopolymers and understanding the self-assembly of block copolymers. In addition, applications in a variety of intriguing areas such as, for example, nanostructured magnetic materials, sensors, and charge-transport materials, and redox-active gels, will also be explored.

Acknowledgements

I would like to thank my exceptionally motivated and talented students who have performed most of the research described in this article and whose names are cited in the references. I also thank the funding agencies that have supported our research. I have had the privilege to collaborate with a variety of scientists with respect to some of the work described in this article, namely Mark Foster (Akron, USA) and Julius Vancso (initially at Toronto and now at Twente, the Netherlands) (morphology of homopolymers and block copolymers), John Sheridan (Rutgers University) (Transition Metal Catalyzed ROP), and Geoffrey Ozin and Mitchell A. Winnik of our Department (organometallic and magnetic nanostructures). I am also extremely grateful to the Alfred P. Sloan Foundation for a Research Fellowship (1994–98), the Natural Science and Engineering Research Council of Canada (NSERC) for an E. W. R. Steacie Fellowship (1997–1999), and the University of Toronto for a McLean Fellowship (1997–2003).

Received (in Cambridge, UK) 1st March 1999, Accepted 7th March 1999

Langmuir–Blodgett films have been fabricated from a regioregular poly(thiophene) derivative by the vertical dipping method while still maintaining the high self-organization associated with the regioregularity of the polymer.

A great deal of progress has been made towards the molecular engineering of conducting polymers that allow us to control nanoscopic structure and that possess exceptional properties. Many of the important advances in this area have centered on the synthesis of structurally homogeneous materials.[1,2] Most notably, the recent development of regioregular conducting polymers based on 3-substituted poly(thiophenes) has heralded a new direction for molecular engineering research.[3–6] These regiochemical arrangements provide an opportunity to understand structure–property relationships in conducting polymers with enhanced electrical and optical properties. It has been recognized that electrical and optical properties based on conjugated systems strongly depend on their nano-structural organization, which can be controlled by the introduction of functional groups and regioregularity. To date, however, only conventional solution casting and spin-coating methods, which offer very little control over molecular order and organization of the polymer, have been utilized to process the novel regioregular polymers. We have recently shown that it is possible to fabricate Langmuir–Blodgett (LB) thin films from mixed monolayers containing stearic acid and regioregular poly(3-alkylthiophenes).[7–9] This novel approach results in well-defined and controllable molecular architectures with desirable optical and electrical properties. We now report further work aimed at fabricating highly ordered LB films of regioregular poly(3-{2-[(*S*)-2-methylbutoxy]ethyl}thiophene) [P(S)MBET] without stearic acid as an amphiphilic molecule. The influence of regioregularity on LB manipulation and solid state structure is also discussed by comparing the monolayers of regioregular and regiorandom P(S)MBET.

The regioregular poly(thiophene) derivative, head-to-tail poly(3-{2-[(*S*)-2-methylbutoxy]ethyl}thiophene) [*HT*-P(S)MBET], was synthesized according to the modified Rieke method.[3] *HT*-P(S)MBET was an optically active polymer with > 93%e head-to-tail linkages, as determined from NMR data.[10] Regiorandom P(S)MBET [*R*-P(S)MBET] with 54% head-to-tail linkages was also prepared by the same catalytic polymerization with $Pd(PPh_3)_4$. *HT*-P(S)MBET used in this study had $M_w = 2.15 \times 10^4$, $M_n = 1.56 \times 10^4$ and $M_w/M_n = 1.38$, while *R*-P(S)MBET had $M_w = 2.05 \times 10^4$, $M_n = 1.02 \times 10^4$, and $M_w/M_n = 2.02$. Since the transfer ratios and the collapse pressures of the monolayer increased with decreasing temperature, LB monolayer and multilayer thin films were fabricated using a Lauda film balance at 10 °C. Monolayers were spread from $CHCl_3$ solutions on a purified aqueous subphase.[11,12]

In order to manipulate soluble conducting polymers into LB films, it is normally necessary to utilize amphiphilic molecules that are capable of forming monolayers at the air–water interface of an LB trough. Thus, poly(3-alkylthiophenes) cannot be formed directly into monolayers owing to the lack of a strong dipole. For example, the spreading of a $CHCl_3$ solution containing poly(3-hexylthiophene) onto the air–water interface of an LB trough simply results in the formation of aggregated islands of the polymer which only exhibit a surface pressure when they are forced together into a very small molecular area. Regioregular poly(3-hexylthiophene) also shows similar phenomena even if the higher regioregularity provides a more coplanar structure of thiophene rings and leads to higher rigidity in the monolayers. Highly ordered LB films of regioregular and regiorandom poly(3-alkylthiophenes) can be easily fabricated by mixing the polymer with suitable portions of an amphiphilic molecule such as stearic acid.[7–9]

HT-P(S)MBET and *R*-P(S)MBET were spread from a $CHCl_3$ solution on the water surface to measure the π–*A* isotherms at 10 °C. (Fig. 1). *HT*-P(S)MBET monolayers exhibit a stable condensed solid phase with a phase transition at about 18 mN m^{-1}. It is of interest that both the π-*A* isotherms show a relatively steep rise at a large molecular area. The area per molecule of *HT*-P(S)MBET was estimated to be 17 Å^2 per polymer repeat unit, which was larger than that for head-to-tail poly(3-hexylthiophene) (*HT*-PHT) (about 8 Å^2).[7–9] According to the CPK model, 17 Å^2 corresponds with the cross section of the thiophene ring of *HT*-P(S)MBET. As the most probable molecular orientation, the coplanar poly(thiophene) backbones float on the water surface and the side chains on one side of the zigzag formation orient toward the water phase. In contrast, the monolayer of *R*-(S)MBET shows a larger molecular area (19 Å^2) and lower collapsed pressure (10 mN m^{-1}), indicating that *R*-P(S)MBET molecules randomly orient and the monolayer is relatively unstable compared with *HT*-P(S)MBET. These results clearly demonstrate that the methylbutoxyethyl groups of P(S)MBET provide suitable dipoles for forming monolayers

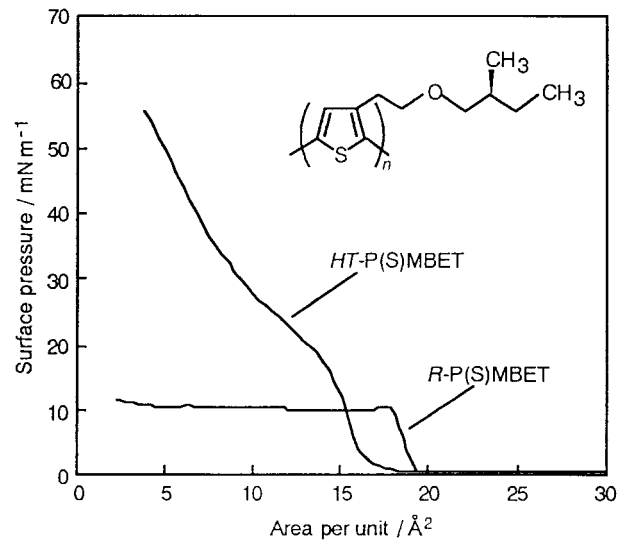

Fig. 1 Surface pressure–area isotherms of *HT*-P(S)MBET and *R*-P(S)MBET monolayers at 10 °C.

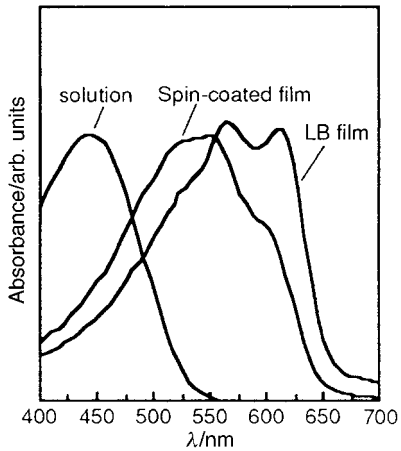

Fig. 2 UV–VIS spectra of *HT*-P(S)MBET in $CHCl_3$, an *HT*-P(S)MBET spin-coated film, and an *HT*-P(S)MBET LB film.

on the air–water interface. We further found that the higher regioregularity gives self-organized structures and induces rigid and coplanar main-chain structures that are capable of forming stable condensed solid monolayers at the air–water interface.

The *HT*-P(S)MBET LB films can be produced by the standard Langmuir–Blodgett vertical dipping method. Optical absorption measurements made on stepped films as a function of the number of layers deposited indicate that the *HT*-P(S)MBET is transferred reproducibly into the multilayer films, while multilayer thin films could not fabricated from *R*-P(S)MBET monolayers on the air–water interface due to the instability of the condensed monolayers. As shown in Fig. 2, the maximal absorption of the *HT*-P(S)MBET LB film shows lower π–π^* transition energy than that of the spin-coated film, while the intensity of the shoulder for the LB film at the longer wavelength around 610 nm is relatively stronger than that of the spin-coated film. These spectra also indicate that *HT*-P(S)MBET molecules in the LB films have a more planar conformation with longer conjugation length compared with the spin-coated films of *HT*-P(S)MBET. Further, it is found from the polarized UV-VIS absorption spectra that *HT*-P(S)MBET molecules in the LB films are oriented parallel to the plane of the substrate and have a tendency to orient along the dipping direction. In practice E_p/E_s was about 1.5, where E_p and E_s were the absorbances of light polarized with the electric vector parallel and perpendicular respectively to the direction of dipping of the substrate. Thus, the LB technique provides molecular control over the regioregular polymers to form better-organized structures that exhibit more planar conformations with low band-gaps and with anisotropic orientations of polymer chains.

The X-ray diffraction pattern of an *HT*-P(S)MBET LB film is shown in Fig. 3. The presence of at least three Bragg diffraction peaks clearly demonstrates that we have formed a well-defined layered structure with a repeat distance of around 18 Å, which is identical to the interlayer *d*-spacing of well-organized lamellar structure for *HT*-P(S)MBET spin-coated films. These results suggest that *HT*-P(S)MBET molecules in the LB films maintain the high self-organization associated with the regio-regularity and adopting a crystalline, self-organized lamellar morphology with three dimensional ordering of the polymer chains such as is observed for regioregular poly(3-alkyl-thiophene) cast films. Ultrathin films with lamellar morphology artificially built up were produced for the first time.

3-Substituted poly(thiophenes) with regioregular structures are expected to be highly ordered and therefore to exhibit improved electrical and optical properties. These highly-

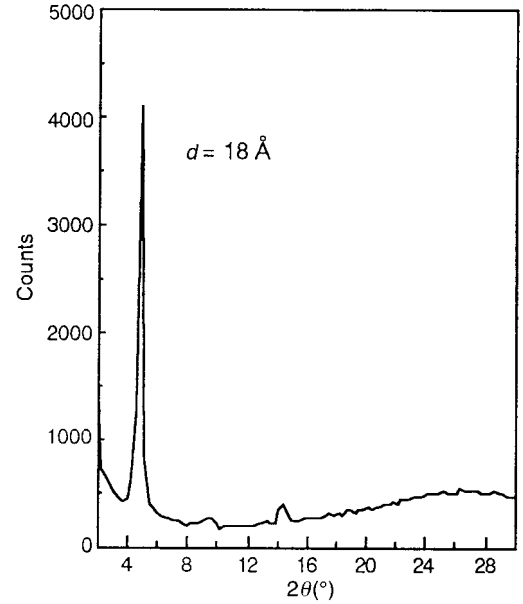

Fig. 3 X-Ray diffraction pattern of an LB film (10 layers) of *HT*-P(S)MBET.

ordered LB films are readily doped with oxidizing agents such as nitrosyl hexafluorophosphate and ferric chloride to produce electrically conductive multilayer thin films. To date, we have been able to reach in-plane conductivity of about 1-5 S cm^{-1}, which is 10^4- to 10^5-fold higher than *R*-P(S)MBET spin-coated films. Our films also exhibit highly anisotropic behavior in electrical conductivity to the dipping direction. In addition, preliminary results have shown that these LB films exhibit enhanced optical nonlinear susceptibility $\chi^{(3)}$.

In summary, we have presented a method for the synthesis and thin film formation of regioregular P(S)MBET, which results in a large improvement in electrical and optical properties. We believe that the introduction of regioregularity and suitable functional groups results in better molecular organization and this in turn results in the excellent optical and electrical properties of these interesting materials.

Received (in Cambridge, UK) 22nd January 1999, Accepted 7th April 1999

Whereas {Ru(terpy)$_2$}$^{2+}$ salts are essentially non-luminescent in fluid solution luminescent molecular wires with {Ru(bpy)$_3$}$^{2+}$-like activity result when these units are connected by 2,5-thiophenediyl spacers.

Multinuclear oligopyridine complexes are important in metallosupramolecular chemistry and species such as rods or wires,[1] helicates[2] and dendrimers[3] are well established.[4,5] The investigation of photoinduced energy- and electron-transfer in geometrically well defined polynuclear systems allows the electronic and nuclear factors governing these processes to be investigated.[6–8] The exploitation of the spectroscopic (particularly luminescence) properties of transition metal–oligopyridine complexes for ion-sensing,[4,5,9] light-harvesting or energy-collection using high-nuclearity dendrimers is of intense current interest.[6] The {Ru(terpy)$_2$}$^{2+}$ chromophore is often employed in such assemblies[10] even though its luminescence properties are poor (room temperature, MeCN solution: $\phi \approx 10^{-5}$, $\tau \leqslant 0.3 \times 10^{-9}$ s[10,11]) in comparison to {Ru(bpy)$_3$}$^{2+}$. Substituents on the terpy ligand significantly improve the luminescence properties[6,8,10,12] and we now describe a new ligand in which a 2,5-thiophenediyl spacer[13] connecting {Ru(terpy)$_2$}-chromophores modifies the properties such that di- and tri-nuclear complexes exhibit {Ru(bpy)$_3$}$^{2+}$-like luminescence.

The new dinucleating ligand **1** was prepared in a two step process from 2-acetylpyridine and thiophene-2,5-dicarbaldehyde in *ca.* 30% yield as a white solid.† The reaction of [Ru(terpy)Cl$_3$] with a stoichiometric amount of **1** in EtOH containing *N*-ethylmorpholine (NEM) gave the mononuclear *ligand-complex* [(terpy)Ru(**1**)]$^{2+}$ isolated as a red PF_6^- salt in 60% yield [MALDI-TOF MS: *m/z* 1024 (M − PF_6), 879 (M − 2PF_6)]. All ruthenium complexes were purified by chromatography over SiO_2 using MeCN–H_2O–saturated aqueous KNO_3 mixtures as the mobile phase. The direct reaction of 3 equivalents of [Ru(terpy)Cl$_3$] with **1** in ethanol containing NEM gave the dinuclear complex [(terpy)Ru(**1**)Ru(terpy)][PF_6]$_4$ [95%, MALDI-TOF MS: *m/z* 1362 (M − 3PF_6), 1212 (M − 4PF_6)] together with [(terpy)Ru(**1**)][PF_6]$_2$ (39%). The trinuclear complex [(terpy)Ru(**1**)Ru(**1**)Ru(terpy)][PF_6]$_6$ was obtained in 48% yield from the reaction of the ligand-complex [(terpy)Ru(**1**)][PF_6]$_2$ with $RuCl_3 \cdot 3H_2O$ in $HOCH_2CH_2OH$ containing NEM in a 600 W microwave oven. All of the complexes are electrochemically active, but in their cyclic voltammograms (MeCN, Fc/Fc$^+$ reference) exhibit only a single Ru(II)/Ru(III) process {[(terpy)Ru(**1**)][PF_6]$_2$ and [(terpy)Ru(**1**)Ru(**1**)Ru(terpy)][PF_6]$_6$ +0.87 V, [(terpy)Ru(**1**)Ru(terpy)][PF_6]$_4$ +0.88 V}. Preliminary structural data for the complex [(terpy)Ru(**1**)Ru(terpy)][PF_6]$_2$[NO_3]$_2$ indicate a planar bridging ligand and a Ru···Ru distance of 14.4 Å.[14]

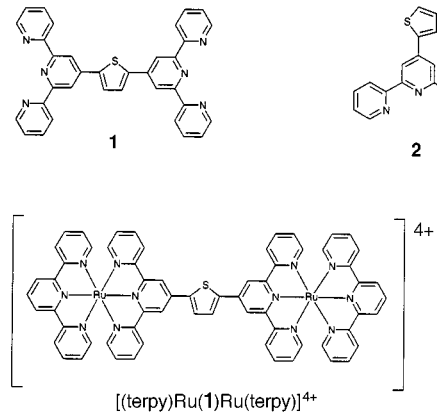

Table 1 lists room temperature absorption and luminescence data for MeCN solutions of the dinuclear and trinuclear complexes, together with those for mononuclear reference

complexes;‡ absorption and luminescence spectra of the complexes are presented in Fig. 1.§ All of the complexes display intense UV absorption bands (306–316 nm, ε = 5–15 10^4 dm^3 mol^{-1} cm^{-1}) and less intense bands in the visible region (485–532 nm, ε = 2.4–11 10^4 dm^3 mol^{-1} cm^{-1}). The former bands are due to ligand centered (^{1}LC) transitions and those in the visible are due to metal-to-ligand charge-transfer (^{1}MLCT).[6,10] For the mononuclear model complexes [(terpy)-Ru(**2**)][PF_6]$_2$ and [Ru(**2**)$_2$][PF_6]$_2$ the 2-thienyl group causes significant changes in the band maximum and minor changes of the band intensity with respect to [Ru(terpy)$_2$][PF_6]$_2$ (Table 1). In contrast, on passing from mononuclear [(terpy)Ru(**2**)][PF_6]$_2$ to the di- and tri-nuclear species, the band associated with the lowest lying ^{1}MLCT transition moves sequentially to longer wavelengths with a concomitant increase in ε (Table 1). This behaviour is consistent with the increasing numbers of {Ru-(terpy)$_2$}$^{2+}$ chromophores and may indicate that the 2,5-thiophenediyl spacer allows some intermetal electronic communication, allowing a stablisation of the MLCT levels through electronic and electrostatic effects.[8,15] The polynuclear complexes also exhibit a band at *ca.* 360 nm not present in the mononuclear compound; we are currently investigating the origin of this band which could arise from CT or LF states.

The excited states responsible for the luminescence are formally triplet Ru → terpy CT levels[10] and the luminescence maxima in Table 1 are consistent with their sequential stabilisation on passing from the mono- to the di- and tri-nuclear complexes (Table 1). What is remarkable is that for the polynuclear species the luminescence lifetime and efficiency increase by two and one order of magnitude, respectively, with respect to the mononuclear complexes. This effect is presumably related to the stabilisation of the cluster of ^{3}MLCT levels responsible for the luminescence leading to a large energy gap between these and the upper lying ^{3}MC levels which offer very effective pathways for non-radiative processes.[15]

The 2,5-thiophenediyl linker is chemically inert, in contrast to polyalkyne spacers, and offers new possibilities for building up high-nuclearity luminescent {Ru(terpy)$_2$}$^{2+}$-based molecular wires with photochemical properties akin to those of {Ru(bpy)$_3$} derivatives. Work is in progress to prepare and study mixed Ru(II)/Os(II) heteropolynuclear species where photoinduced RuOs energy transfer may allow a detailed understanding of the properties of the 2,5-thiophenediyl spacers.

‡ Full details of ligand **2** and its complexes will be reported later.

§ Absorption and luminescence spectra of dilute solutions (10^{-5} M) in MeCN were recorded with a PE Lambda 5 spectrophotometer and with a Spex Fluorolog II spectrofluorimeter (λ_{exc} = 480 nm) respectively. Uncorrected luminescence band maxima (±2 nm) are quoted. Corrected band maxima and luminescence quantum efficiencies (±20%) were determined using the procedure described in ref. 15. Luminescence lifetimes (±8%) were obtained with IBH single-photon counting equipment or with a picosecond fluorescence spectrometer based on a ND : YAG laser (Continuum PY62-10) and a Hamamatsu C1587 streak camera.[15]

Tetrahedral bipyridyl copper(I) complexes: a new class of non-dipolar chromophore for nonlinear optics

Thierry Renouard,[a] Hubert Le Bozec,*[a] Sophie Brasselet,[b] Isabelle Ledoux[b] and Joseph Zyss[b]

[a] *Laboratoire de Chimie de Coordination et Catalyse, UMR 6509 CNRS-Université de Rennes 1, Campus de Beaulieu, 35042 Rennes Cedex, France. E-mail: lebozec@univ-rennes.fr*

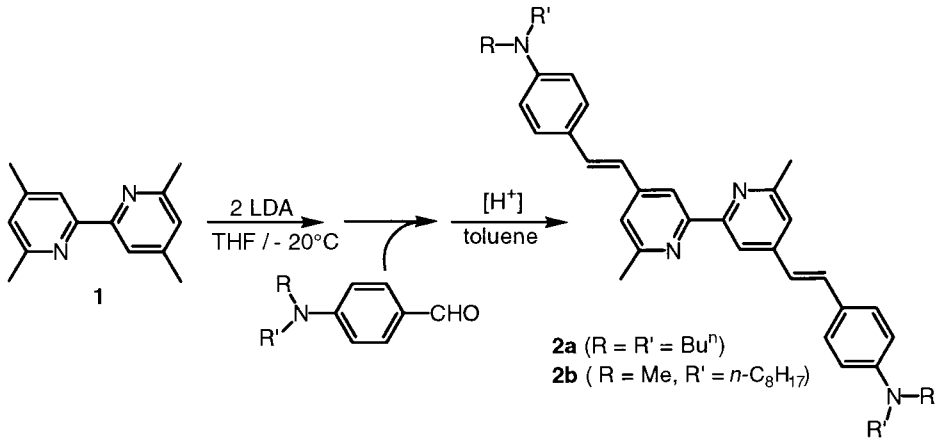
Received (in Oxford, UK) 12th March 1999, Accepted 9th April 1999

The synthesis of 4,4′-bis(dialkylaminostyryl)-6,6′-dimethyl-2,2′-bipyridine ligands is described; the corresponding tetrahedral bis(bipyridyl) copper(I) complexes have been prepared, and their second-order nonlinear optical properties determined by harmonic light scattering (HLS) at 1.34 μm; these new octupolar complexes exhibit large molecular hyperpolarisabilities *β*.

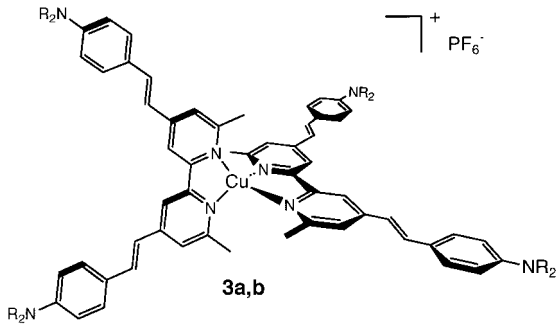
A new concept of octupolar non-linearities of two- and three-dimensional (2D and 3D) molecules has recently been proposed and has opened new perspectives in elaboration of efficient nonlinear optical materials.[1] Research on octupolar structures has mainly focused on organic chromophores with threefold symmetry such as 1,3,5-triamino-2,4,6-trinitrobenzene and related derivatives,[2] crystal violet,[3] trisubstituted amines[2,4] and cyanine salts.[2,5] The first examples of nondipolar tetrahedral organotin,[6] phosphonium[7] and biphenyl[8] chromophores have recently been investigated. Organotransition metal complexes also offer many possibilities for the design of 3D non-centrosymmetric octupolar molecules owing to the large diversity of metals, ligands and geometries. Thus, nonlinearities of tris(bipyridine) ruthenium(II) complexes has been demonstrated[9,10] and we have recently reported the enhanced molecular hyperpolarisability β of octahedral ruthenium(II) complexes possessing three bipyridine ligands substituted in 4,4′-positions by *p*-dialkylaminostyryl groups.[11] In the course of our study of nondipolar complexes for NLO, we have been interested in the generation of metal complexes displaying tetrahedral coordination geometries. Copper(I)–bipyridine or –phenanthroline complexes with substituents α to the nitrogen atoms are known to give stable tetrahedral molecules of D_{2d} symmetry[12] and such complexes have been widely used to prepare molecular architectures such as catenates and knots,[13] helicates[14] and polymers.[15] Using this approach, we sought to design 4,4′-dialkenyl-6,6′-dimethyl-2,2′-bipyridines in which the alkenyl fragments bear π-donor groups. Here we describe the synthesis of such ligands and we show that the corresponding copper(I) complexes represent a new class of nondipolar NLO organometallic chromophore combining good transparency and large nonlinearity.

The new ligands **2a** and **2b** were prepared by a controlled functionalisation of the 4,4′-positions of 4,4′,6,6′-tetramethyl-2,2′-bipyridine **1**: dilithiation of **1** with LDA at −20 °C followed by reaction with 2 equiv. of *p*-dibutylaminobenzaldehyde afforded the corresponding dialcohol, and subsequent dehydration with pyridinium toluene-*p*-sulfonate (PTPS) in boiling toluene yielded exclusively **2a** in 75% overall yield. Ligand **2b** was prepared analogously as described for **2a** (Scheme 1). The observation of a strong NOE (10%) between the methyl groups at $C^{6,6'}$ and the $H^{5,5'}$ protons clearly established the regioselectivity of the reaction. In their UV–VIS spectra, **2a**,**b** show typical bands at *ca.* 390 nm ($\varepsilon \approx 50\,000$ dm^3 mol^{-1} cm^{-1}) which are assigned to intramolecular charge-transfer transitions.[16]

Copper(I) complexes were obtained upon treatment of the ligands **2a**,**b** (2 equiv.) with $[Cu(MeCN)_4]PF_6$ (1 equiv.) in dichloromethane solution (Fig. 1). The red complexes **3a**,**b** were isolated in nearly quantitative yield and their structures were demonstrated by FAB-MS and ^{1}H NMR spectroscopy. In the ^{1}H NMR spectra, the methyl groups in the 6,6′ positions are characteristically shifted upfield by 0.45 ppm with respect to the free ligands, and according to the strong vicinal coupling constants of the olefinic protons ($J_{HH} \approx 16$ Hz) no detectable *E/Z* isomerization of the alkenyl fragments is observed. The UV–VIS spectra recorded in dichloromethane are dominated by intense intraligand charge-transfer bands ($\lambda_{ILCT} \approx 420$ nm, $\varepsilon \approx$ 80 000 dm^3 mol^{-1} cm^{-1}) which are 30–40 nm red-shifted upon complexation. It is noteworthy that the bis(bipyridyl)copper(I) derivatives **3a**,**b** have a considerably blue-shifted ILCT band when compared to the corresponding tris(bipyridyl)ruthenium(II) complexes ($\lambda_{ILCT} \approx 515$ nm),[11] which is of crucial importance for second-harmonic generation. The MLCT transi-



Scheme 1



3a,b

Fig. 1

tion [$Cu^{I} \rightarrow \pi^*$(bpy)] is typically observed at *ca.* 480 nm with relatively smaller absorption coefficients and can be discerned in the spectra as a shoulder of the more intense ILCT band.

As EFISH experiment is precluded for nondipolar and/or ionic molecules like **3**, the molecular hyperpolarisability β was measured by means of the harmonic light scattering technique (HLS).[17] The experiments were performed in chloroform at a fundamental wavelength of 1.34 μm, generated by a Q-switched, mode-locked Nd:YAG laser providing subnanosecond pulse train at 10 Hz repetition rate. The T_d (or D_2) symmetry reduces the nonlinear microscopic coefficient to only one non-vanishing term, β_{xyz}, which can be easily deduced from the following relation: $<\beta^2_{HLS}> = 4/7\ \beta^2_{xyz}$. The experimentally determined $<\beta^2>^{1/2}$, the static $<\beta_0>^{1/2}$, deduced from $<\beta^2>$ using a degenerate three-level dispersion model valid in the case of purely octupolar molecules,[18] and the corresponding β_{xyz} coefficients for **3a**,**b** are given in Table 1.

Table 1 Linear[a] and nonlinear[b] optical data

Complex	λ/nm (ε/dm^3 mol^{-1} cm^{-1})	10^{30} β_{HLS}/esu	10^{30} β_{HLS}^0/esu	10^{30} β_{xyz}/esu	10^{30} β_{xyz}^0/esu
3a	424(83300) 484(sh)	144	78	190	103
3b	420(73800) 475(sh)	128	70	169	93

[a] In CH_2Cl_2. [b] HLS measurements in $CHCl_3$ at 1.34 μm. The error in the measurements is estimated to be ±10%.

Results show that chromophores **3a** and **3b** exhibit microscopic optical nonlinearities which are larger than those of recently reported tetrahedral molecules such as the tetrakis(dibutylaminoazobenzenephosphonium)chromophore [λ_{max} = 511 nm; $\beta_{HLS}^0 = 56.7 \times 10^{-30}$ esu].[7] Dibutylaminophenyl is slightly more efficient than the methyl(octyl)aminophenyl donor group, a trend that have already been observed for octahedral trisbipyridyl ruthenium(II) complexes bearing the same dialkylaminophenyl groups.[11] Compared to these latter complexes, the copper(I) derivatives **3** have lower β_{HLS} values. At first glance, this may be due to the presence of four *vs.* six donor groups and to the less efficient acceptor strength of Cu^+ *vs.* Ru^{2+} metallic ion. A more pronounced blue-shift of the absorption maximum is observed in the copper complexes, and the higher energy of the ILCT excited state also contributes to this observed decrease of β as compared to the octupolar ruthenium species.

To summarize, we have synthesized and investigated a new class of nondipolar NLO complexes showing good transparency/efficiency trade-off. Work towards the incorporation of such chromophores into macromolecular architectures are under progress.

Supramolecular templated synthesis of platinum-supported silica

María Ángeles Aramendía, Victoriano Borau, César Jiménez,* José María Marinas and Francisco José Romero*

Department of Organic Chemistry, Faculty of Sciences, University of Córdoba, Avda. San Alberto Magno s/n, E-14004 Córdoba, Spain. E-mail: qo2rosaf@uco.es

Received (in Cambridge, UK) 10th March 1999, Accepted 7th April 1999

The incorporation of Pt onto MSU-1 mesoporous silica by direct inclusion of various precursors in a synthesis gel containing a structure-directing non-ionic surfactant was studied.

The M41S family of mesoporous molecular sieves has aroused enormous interest ever since these materials started to be used as sorbents, catalysts and supports[1] of high thermal stability, pore size uniformity and surface area. Individual noble metals including Pd[2] and Pt,[3,4] and combinations such as Cu–Ru,[5] have been supported on MCM-41 to prepare catalysts that are active in various processes. The metal is incorporated onto the support either by incipient wetness impregnation, ion exchange or direct introduction of platinum during the synthesis of MCM-41. This last procedure ensures uniform dispersion of platinum on the support, with particle sizes in the region of 6 nm that vary with the particular precursor used.[4]

Mesoporous metal oxides, designated MSU-X, can be obtained by assembling electrically neutral polyethylene oxide surfactants and neutral inorganic precursors.[6,7] These surfactants promote framework assembly through hydrogen bonding between the hydrophilic $(EO)_n$ segments and the silanol groups of the neutral inorganic precursor. These materials exhibit wormhole structures that lack regular channel packing order; however, they possess uniform channel diameters over a range comparable to M41S materials. The low cost and ready biodegradation of the surfactant are two major advantages of this synthetic procedure.

Controlled synthesis of colloidal platinum nanoparticles has been accomplished by altering the ratio of the concentration of a capping material (sodium polyacrylate) to that of Pt^{2+} ions.[8] Also, nanostructured mesoporous platinum has been synthesized by using a lyotropic liquid-crystalline phase as reaction medium.[9] This porous material possesses a high surface area, which is of great interest with a view to its catalytic application.

This paper reports the synthesis of platinum nanoparticles supported on mesoporous silica by use of the surfactant Tergitol 15-S-12 $[Me(CH_2)_{14}O(OCH_2CH_2)_{12}OH]$ as structure-directing agent.

Unsupported mesostructured silica (solid MSU-1) was synthesized following procedures similar to those reported elsewhere.[6] Platinum-supported silicas were obtained by supplying the starting mixture with 1 mol % Pt (relative to Si), using $(NH_4)_2PtCl_4$, H_2PtCl_6 and $(NH_3)_4PtCl_2$ as precursor salts, which produced the solids denoted MSU-1-1, MSU-1-2 and MSU-1-3, respectively.† A Tergitol 15-S-12 solution (0.1 mol l^{-1}), under stirring, was supplied with the platinum salt at 298 K. Then, TEOS was added and stirring was continued for a further 24 h. The TEOS–Pt–surfactant–H_2O mole proportion in the mixture was 10 : 0.1 : 1 : 560. The mixture was allowed to age for 72 h and the resulting powder was filtered, washed with distilled water and air-dried. Finally, the solid was calcined at 873 K in the air for 3 h.

Solids were characterized by powder X-ray diffraction (XRD), thermogravimetric analysis (TGA), N_2 sorptometry, elemental analysis (for Pt), transmission electron microscopy (TEM), temperature programmed reduction (TPR) and hydrogen chemisorption.

As a rule, the XRD patterns obtained (Fig. 1) exhibited a low angle peak (d_{100}), with a *d*-spacing between 37 and 66 Å (Table 1). The second-order peaks obtained at higher incidence angles were broad and short. These are typical of mesostructured materials with a sponge-like or worm-like pore channel structure, which are devoid of any regular long-range order, as expected for materials assembled using neutral or non-ionic surfactants. All the solids studied were calcined at 873 K in order to ensure removal of the surfactant, which was confirmed by TGA (*e.g.* solid MSU-1-1 exhibited a total weight loss of 52% as a result). In every case, the low angle d_{100} peak was

shifted to a higher angle upon calcination, thus indicating gradual contraction of *d*-spacings in the lattice upon removal of the surfactant.

Table 1 also gives the surface areas, pore diameters and pore volumes of the solids. As can be seen, all possess a high specific surface area (>600 m^2 g^{-1}). The N_2 adsorption–desorption isotherms are of type IV (*i.e.* typical of mesoporous solids) for MSU-1 and MSU-1-3 (Fig. 2), pore size in which varies over narrow ranges (35–50 and 32–42 Å), with type H2 and type H4 hysteresis cycles, respectively.[10] Also, MSU-1-1 and MSU-1-2 exhibit a type I isotherm, with the step at a relative pressure around 0.2. Nitrogen isotherms of this kind are typical of pores with sizes in between the micro and meso ranges.[11] The micropore distribution in solid MSU-1-1 as determined by the Horvath–Kawazoe method[12] confirms the presence of pores in this size range, most of size about 7 Å (Fig. 2).

Table 1 lists the Pt content in each solid. As can be seen, the amount of Pt incorporated into the silica was only significant (50% of the amount added) when $(NH_4)_2PtCl_4$ was used as precursor. A temperature programmed reduction (TPR) run for solid MSU-1-1 revealed that virtually the whole deposited metal was present as Pt^0, so the metal ion was reduced during the solid synthesis and calcination, which is consistent with previous findings in MCM-41 as support.[4] Chemisorption tests revealed solid MSU-1-1 to be able to adsorb 60 and 19 μl of H_2 at room temperature and 673 K, respectively; this results in a metal dispersion of 32%, with a metal surface area of 80 m^2 g_{metal}^{-1} and an average particle diameter of 43 Å, all consistent with the TEM results. Fig. 3 shows the particle size distribution as

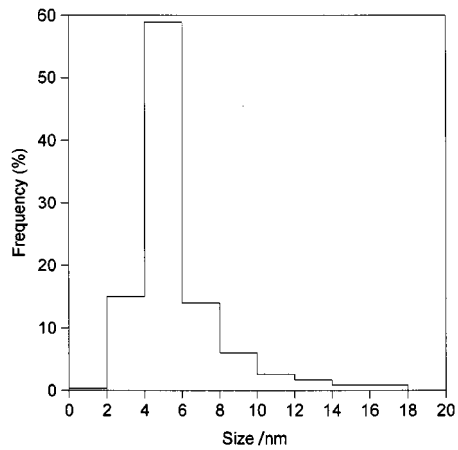

Fig. 3 Size distribution of platinum particles in solid MSU-1-1.

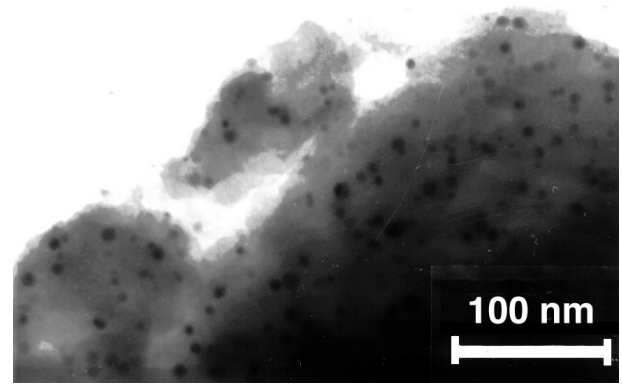

Fig. 4 TEM image of calcined MSU-1-1.

determined by this technique and Fig. 4 shows a typical TEM image.

In summary, our results suggest that platinum nanoparticles can be supported onto mesostructured silica by using a non-ionic surfactant assembly involving direct incorporation *via* the synthesis gel. Other experimental variables such as the surfactant used, temperature, concentrations, solvent extraction of the surfactant, *etc.*, can be altered as required. One of the most salient advantages of this procedure is that it allows the incorporation of metal nanoparticles into other mesoporous metal oxides that are inaccessible by electrostatic templating routes, simply by hydrolysing the corresponding alkoxides (*e.g.* titania or tin oxide). These materials can be used as, for example, catalysts, and also in optical, electronic and magnetic devices.

The authors would like to thank Spain's DGES, Ministry of Education and Culture, for funding this research within the framework of Project PB97-0446, and Junta de Andalucía for additional financial support.

Notes and references

† *Typical procedure:* solid MSU-1-1 was obtained by adding 10 ml of tetraethylorthosilicate (TEOS) over a solution containing 0.171 g of $(NH_4)_2PtCl_4$ in 46 mL of 0.1 mol l^{-1} Tergitol 15-S-12 at room temperature. After 24 h under stirring, the suspension was allowed to stand for 3 days and the solid was filtered off, air-dried and calcined at 873 K for 3 h.

Isolation and crystal structure of a novel dinuclear nickel(II) O-bound sulfinate from the oxidation of 2,2′-bipyridine-1,2-benzenedithiolatonickel(II)

T. Matthew Cocker and Robert E. Bachman*

Department of Chemistry, Box 571227, Georgetown University, Washington, D.C., 20057-1227, USA. E-mail: bachman@gusun.georgetown.edu.

Received (in Bloomington, IN, USA) 22nd January 1999, Accepted 30th March 1999

The first example of an O-bound sulfinate diimine nickel(II) complex has been isolated from the partial oxidation of Ni(bpy)(bdt) 1 (bpy = 2,2′-bipyridine, bdt = 1,2-benzenedithiolate), and characterized by X-ray crystallography and ESI-MS.

Since the first report by Miller and Dance in 1973, mixed dithiolene-α-diimine complexes of group 10 metals have received considerable attention because of their many unique physical properties, which include multiple accessible redox states, intense colors and non-linear optical behavior.[1] While complexes of this type have been reported for all three metals, particular attention has been focused on the heaviest (Pt^{II}) and the lightest (Ni^{II}) members of the group. In the former case this attention is the result of the unique optoelectronic properties of the systems.[2] In the latter case, the interest has been focused on the potential of these complexes to act as models for biological systems such as nickel-containing CO-dehydrogenase.[3,4] Investigations into the oxidation chemistry of nickel(II) diamine dithiolates have produced several compounds including monosulfenates [RS–M–SOR], disulfenates [M–$(SOR)_2$], monosulfinates [RS–M–SO_2R], disulfinates [M–$(SO_2R)_2$], and mixed sulfinate–sulfenate [ROS–M–SO_2R] complexes.[5] Recently, Henderson *et al*. reported the first process in which a Ni–S bond is oxidatively cleaved to yield an O-bound disulfonate [M–$(SO_3R)_2$].[6] However, to date no examples of O-bound sulfinates have been reported. We report herein the isolation and X-ray structure of an unusual dinuclear nickel(II) complex which contains the first example of an O-bound sulfinate diimine nickel(II) complex (**2**), as well as an additional example of a disulfonate diimine nickel(II) complex **3**.

During a UV–VIS study of Ni(bpy)(bdt) **1** (bpy = 2,2′-bipyridine, bdt = 1,2-benzenedithiolate) in DMF, we observed that solutions of **1** slowly changed color from purple to orange. While the initial spectrum contains a broad absorption between 500 and 600 nm, characteristic of complexes such as **1**, this band disappears and is replaced by a new absorption peak at 874 nm. Slow evaporation of this solution yielded a small amount of orange X-ray quality crystals. The X-ray crystal structure of these crystals was determined and is shown in Fig. 1.†

The solid material was found to be a co-crystal of both the monosulfinate $(bpy)_2$Ni(bdtO_2)Ni(bdt) **2a** and the disulfinate $(bpy)_2$Ni(bdtO_4)Ni(bdt) **2b** in an approximate 60:40 ratio. ESI-MS of the crystalline material yielded molecular ions for both **2a** and **2b** with appropriate relative intensities.[7] All attempts to prepare **2** in a rational fashion using a chemical oxidant, such as H_2O_2, produced only **3** (Fig. 2) regardless of the stoichiometry.†

The Ni–N distances in **2** and **3** (2.05–2.08 Å) are both similar to those observed for the related compound $(bpy)_2(PhS)_2$-Ni^{II}·D_2O (2.08–2.10 Å).[8] As expected, the Ni(1)–O bond distance in **2** (2.104(5) Å) is longer than the Ni–O bonds in complex **3** (2.05-2.06 Å) and is also longer than the Ni–O bonds in [(3-thia-1,5-diaminopentane *S*-oxide)$_2$Ni]$^{2+}$ (2.07–2.09 Å)[9] and the Ni–OH_2 bond [2.084(1) Å] in [Ni(dsodm)-$(H_2O)_2$]·$2H_2O$ (dsodm = [$(O_3SCH_2CH_2)MeNCH_2CH_2N$-$Me(CH_2CH_2SO_3)$]).[6] This difference is most likely the result of the stronger donor ability of the bpy ligands in **2**. The Ni–O bonds in **3** [2.060(3) Å and 2.054(3) Å]) are also slightly longer than the Ni–sulfonato bonds in [Ni(dsodm)$(H_2O)_2$]·$2H_2O$ [2.044(1) Å], again probably due to the more electron-rich nickel in **3**.[6] The Ni–S bond lengths observed for **2** are 2.13–2.17 Å for the square planar Ni(2) and 2.499(3) Å for the octahedral Ni(1). The former are similar to those observed for other four-coordinate systems such as **1** (2.14–2.15 Å) and Ni(bdt)$_2^{2-}$ (2.17–2.18 Å).[10,11] Interestingly the Ni–S bond length in **2** and other four-coordinate Ni-sulfinates are not significantly affected by the oxidation state of the sulfur.[5] The Ni–S bond length for the octahedral Ni in **2** is similar to that in $(bpy)_2(PhS)_2Ni^{II}$·D_2O [2.445(2) Å].[8]

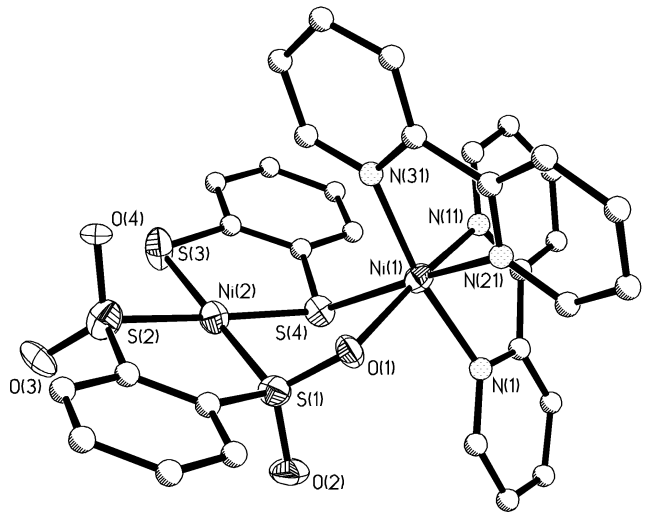

Fig. 1 Diagram showing the sulfinate complex **2a,b** with the significant atoms shown with displacement ellipsoids at 50% probability and the remaining atoms shown as spheres of arbitrary radius. The hydrogen atoms have been omitted for clarity. Selected bond distances (Å) and angles (°): Ni(1)-N 2.05-2.07, Ni(1)-O(1) 2.104(5), Ni(1)-S(4) 2.499(3), Ni(2)-S(1) 2.127(3), Ni(2)-S(2) 2.156(3), Ni(2)-S(3) 2.166(3), Ni(2)-S(4) 2.154(3), S(1)-O(1) 1.490(6), S(1)-O(2) 1.472(6); O(1)-S(1)-Ni(2) 111.8(3), Ni(2)-S(4)-Ni(1) 101.85(10), S(1)-O(1)-Ni(1) 122.8(4).

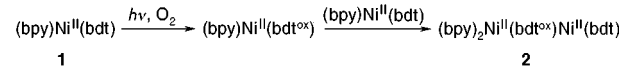
While the exact origin of **2** is still uncertain, it can be seen from **3** that the complete oxidation of **1** to **3** involves both rupture of the Ni–S bonds and the exchange of ligands. While the fate of the other nickel thiolate fragment in conversion of **1** to **3** remains unknown, the observed ligand disproportionation allows for a rationalization for the formation of **2** (Scheme 1).



Scheme 1 A rationalization of the formation of **2** from **1** *via* a 'partial' disproportionation.

Under the ambient conditions present in the spectrometer, a small amount of **1** was converted into the mono or disulfinate form (**1^{ox}**) which then begins to undergo a disproportionation process with an unoxidized molecule of **1**. The decreased solubility of **2**, in relation to **1** or **1^{ox}**, leads to this 'intermediate'

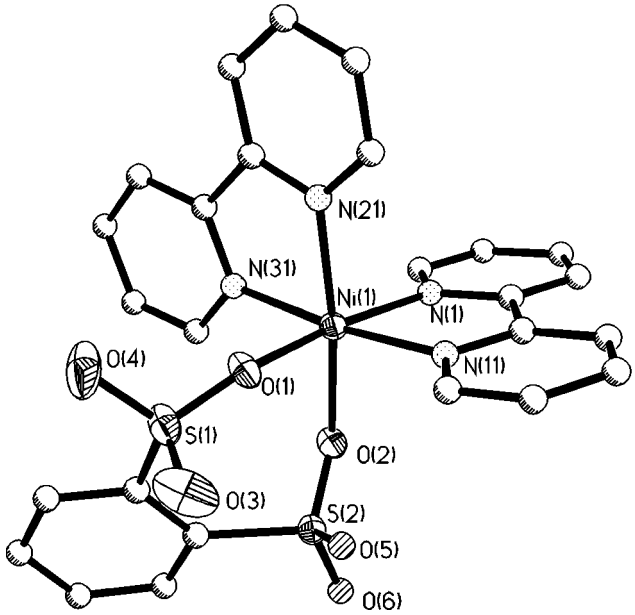


Fig. 2 Diagram showing the sulfonate complex **3**·0.5dmf with the significant atoms shown with displacement ellipsoids at 50% probability and the remaining atoms shown as spheres of arbitrary radius. The DMF molecule and the hydrogen atoms have been omitted for clarity. Selected bond distances (Å) and angles (°): Ni(1)–O(1) 2.060(3), Ni(1)–O(2) 2.054(3), Ni(1)–N 2.06–2.08, S(1)–O(1) 1.452(3), S(1)–O(3) 1.452(4), S(1)–O(4) 1.420(4), S(2)–O(2) 1.485(3), S(2)–O(5) 1.436(3), S(2)–O(6) 1.446(3); O(2)–Ni(1)–O(1) 90.97(12), S(1)–O(1)–Ni(1) 151.98(19), S(2)–O(2)–Ni(1) 128.38(16).

in the disproportionation process being 'trapped' by precipitation, producing the observed result. We are currently pursuing a rationale synthesis of **2a,b** and attempting to resolve the outstanding mechanistic questions related to the formation of both **2** and **3**.

This work was supported by Georgetown University and the donors of the Petroleum Research Fund, administered by the ACS. The purchase of the X-ray diffractometer was made possible by a grant from the National Science Foundation (CHE-9115394). The authors wish to acknowledge Professor J. T. Davis at University of Maryland, College Park for ESI-MS analysis.

Notes and references

† *Crystal data*: **2**: crystals of **2** were obtained by evaporation of a DMF solution used in a UV–VIS study at room temperature. $C_{32}H_{24}N_4Ni_2O_{2.83}S_4$, M = 755.45; monoclinic, $P2_1/n$, a = 11.5407(3), b = 16.9821(4), c = 16.7013(4) Å, β = 106.9880(10)°, V = 3130.39(13) Å^3, Z = 4, D_c = 1.603 g cm^{-3}, μ = 1.511 mm^{-1}. All data were collected on a Bruker-AXS SMART CCD system at −100 °C. A small orange plate of **2** (0.04 × 0.16 × 0.16 mm) was mounted on a glass fiber using epoxy. The data were collected as described elsewhere[12] to provide a complete sphere of data to 0.75 Å ($2\theta_{max}$ = 56.62°) yielding 25633 data. Final unit cell parameters were calculated using 5720 reflections culled from the entire data set. The data were corrected for Lorentz and polarization effects and an absorption correction was applied on the basis of equivalent reflection measurements using Blessing's method as incorporated into the program SADABS.[13]

Owing to their poor quality, the data were truncated on the basis of intensity statistics at a resolution of 0.85 Å ($2\theta_{max}$ = 49.42°) to yield a final data set of 19526 reflections (5340 unique, R_{int} = 0.2091). The structure was solved using direct methods and refined against F^2 by full-matrix least-squares methods using the programs in SHELXTL and SHELX-97.[14] All non-hydrogen atoms were refined anisotropically, while hydrogen atoms were refined isotropically. The oxygen atoms O(3) and O(4) were refined to 40% site occupancy and then held fixed at this value. The final refinement converged with residuals of wR_2 = 0.2125 (all data), $R_1(F)$ = 0.0785 [$I > 2\sigma(I)$], and GOF = 0.998. Significant bond lengths and angles are given in Fig 1.

3·0.5 dmf; crystals of **3**·0.5 dmf were obtained by treatment of **1** with H_2O_2 in DMF followed by slow evaporation of the solution at room temperature. $C_{27.50}H_{20}N_{4.50}NiO_{6.50}S_2$, M = 640.31; triclinic, $P\bar{1}$, a = 9.31350(10), b = 12.5526(2), c = 12.7451(2) Å, α = 96.0170(10), β = 101.8868(3), γ = 110.0760(10)°, V = 1344.26(3) Å^3, Z = 2, D_c = 1.582 g cm^{-3}, μ = 0.932 mm^{-1}. A small colorless plate of **3**·0.5 dmf (0.02 × 0.10 × 0.16 mm) was mounted on a glass fiber using epoxy and the data were collected as above to yield 11300 reflections (6302 unique, R_{int} = 0.0599). Final unit cell parameters were calculated using 5378 reflections culled from the entire data set. The dmf molecule was found to be disordered over the inversion center and was modeled as three separately oriented molecules with a total combined occupancy of 0.5. The final refinement converged with residuals of wR_2 = 0.1340 (all data), $R_1(F)$ = 0.0691 [$I > 2\sigma(I)$], and GOF = 1.066. Significant bond lengths and angles are given in Fig 2.

Received (in Bloomington, IN, USA) 25th February 1999, Accepted 6th April 1999

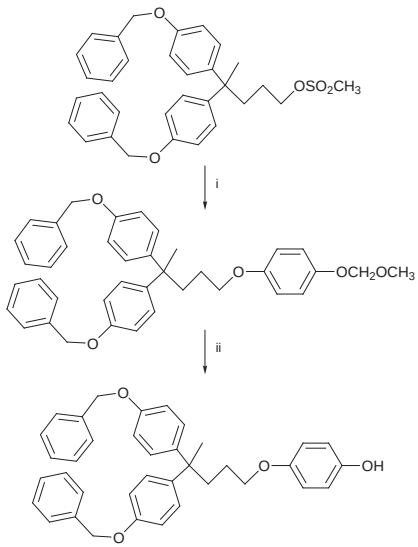
Dendrons with focal phenoxide groups were shown to substitute for triflate or methoxide ligands around an Mo_6Cl_8 core to form molecules of the form $Mo_6(\mu_3\text{-}Cl)_8(OR)_6$ where R = dendrons with zero to two hyperbranches, respectively; these molecules represent a new type of metal cluster core dendrimer with six arms and high symmetry.

Metals and inorganic clusters have served several roles in the construction of dendrimer structures.[1] These include acting as the linking elements, the peripheral elements and as the core element of dendrimers. When used as cores, metals and inorganic clusters have several documented functions.[1] They can be used as reporters of the interior environment of these molecules by virtue of their luminescent, electrochemical or magnetic properties. They can take advantage of the microenvironment of the dendrimer in catalysis applications. Moreover, they can utilize the dendrimer to control electron transfer.[2,3]

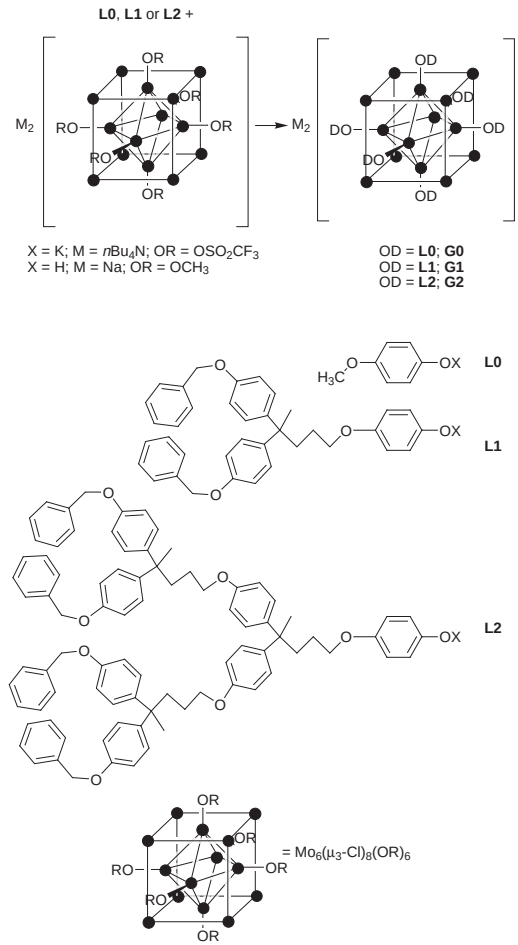
To these ends and others, a variety of metal and metal cluster core dendrimers have been prepared. These include dendrimers with porphyrin,[4–8] iron–sulfur,[2] metal tris-bipyridine[9] and octasilsesquioxane[10,11] cores. All of these syntheses rely on either a core that is tolerant of organic coupling reactions or a core that can undergo some type of ligand exchange to substitute dendritic ligands for smaller ligands. The ligand exchange route to dendrimers can be particularly attractive. In the iron–sulfur core dendrimers discussed above, ligand exchange of a bulky aliphatic thiol for a focally substituted aromatic thiol dendron resulted in virtually quantitative synthesis of molecules with molecular weights of up to 22 kD.[2]

Here we report that ligand exchange reactions around a metal cluster core of the form Mo_6Cl_8 can be employed to form molecules of the form $Mo_6(\mu_3\text{-}Cl)_8(OR)_6$ (R = dendrons with 0–2 hyperbranches), respectively. These six arm, pseudo-octahedral core dendrimers represent one of the first examples of this type.[12] The replacement of both methoxy by other alkoxy ligands[13–16] and of triflate by other alkoxy or carboxy ligands[17,18] at the corner positions of these clusters have been reported. Here, the use of such reactions in the synthesis of new hybrid organic–inorganic macromolecules is illustrated.

The first and second generation ligands (**L1** and **L2**) used to prepare the six-arm dendrimers were prepared by reacting the previously reported[19] focally substituted dendron mesylates (mesylate = OSO_2CH_3) with mono-methoxymethyl hydroquinone followed by deprotection of the methoxymethyl group (Scheme 1). Molecules **G0**, **G1** and **G2** (named corresponding to the generation of dendrimer they represent) were prepared by ligand exchange with either triflate-capped $[n\text{Bu}_4\text{N}]_2[\text{Mo}_6$-



Scheme 1 Preparation of focally-substituted phenol dendrons. Sequence is shown for the preparation of **L1**. Preparation of **L2** is performed in an identical fashion. *Reagents and conditions*: i, HOC_6H_4OMOM (1 equiv.), K_2CO_3 (6 equiv.), 18-crown-6 (0.2 equiv.), dry acetone, reflux 60 h; ii, MeOH–THF–HCl, reflux overnight.



Scheme 2 Preparation of dendrimers. *Reagents and conditions* for $[n\text{Bu}_4\text{N}]_2\mathbf{G}x$ (x = 0, 1, 2): 10 equiv. $\mathbf{L}x$ (x = 0, 1 2), excess KH, THF, r.t., N_2, 30 min then $[n\text{Bu}_4\text{N}]_2\text{Mo}_6\text{Cl}_8(\text{OSO}_2\text{CF}_3)_6$, THF, r.t., N_2 overnight, ppt $KOSO_2CF_3$, washing with toluene, filter and ppt product washed with Et_2O. *Reagents and conditions for* $\text{Na}_2\mathbf{G}x$ (x = 0, 1, 2): 10 equiv. $\mathbf{L}x$ (x = 0, 1, 2), $\text{Na}_2\text{Mo}_6\text{Cl}_8(\text{OMe})_6$, MeOH–toluene or MeOH–1,2-dichlorobenzene, 80–90 °C, overnight, N_2, Et_2O ppt.

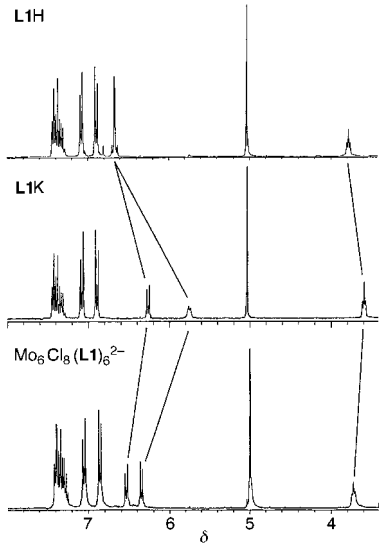


Fig. 1 Series of ^{1}H NMR spectra illustrating the distinct shifts in the resonances of the focal aromatic ring protons upon deprotonation and attachment to the cluster. Rapid exchange was ruled out by adding excess ligand and observing two distinct sets of peaks.

$Cl_8(OSO_2CF_3)_6]$[17] or methoxy-capped $Na_2[Mo_6Cl_8(OMe)_6]$[20] clusters (Scheme 2).

Deprotonation and subsequent reaction of a slight excess of ligand with the triflate-capped cluster resulted in complete exchange in the case of the $[n\text{Bu}_4\text{N}]_2$**G0** and $[n\text{Bu}_4\text{N}]_2$**G1** molecules.[21] This series of reactions is nicely illustrated by the series of ^{1}H NMR spectra shown in Fig. 1. Complete precipitation of potassium triflate coproduct was found to be essential as this reaction was determined to be reversible. NMR samples of pure **G1** in THF-d^8 were found to undergo ligand loss when a few equivalents of potassium triflate were added to this solution. Moreover, only partial exchange was observed when **L2** was employed as evidenced by broad ^{1}H NMR signals of the multiple, overlapping, partially substituted species. These two latter features limited the utility of this reaction in our hands.

Using a modification of conditions reported in the literature,[13–16,22] reaction of the ligands **L0**, **L1** and **L2** with $Na_2[Mo_6Cl_8(OCH_3)_6]$ resulted in complete exchange for all molecules prepared. In the case of Na_2**G0**, a 98% yield of an analytically pure product was obtained, and crystals suitable for X-ray structure determination were obtained (Fig. 2).[23] Bond lengths and angles similar to those reported for related Mo_6Cl_8-core structures were found (*e.g.* Mo–Cl 2.48–2.50 Å, Mo–O 2.04–2.09 Å).[13,16,24]

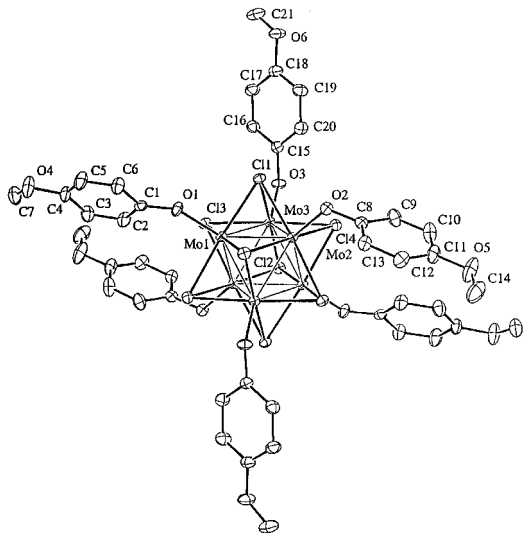

Fig. 2 The molecular structure of Na_2**G0.**

Dendrimers were characterized by NMR and mass spectrometry (MS). We found electrospray MS to be most convenient as a strong parent ion signal could be obtained. The charge on the clusters as well as perhaps their hydrophobicity[25] were probably beneficial factors in the success of these characterization experiments.

In conclusion, it has been shown that high-symmetry metal cluster cores can be used in the preparation of hybrid organic–inorganic dendrimers. In the case of an Mo_6Cl_8 core, the choice of ligand exchange reaction was found to be important to the success of making higher molecular weight dendrimers.

This research was supported by the Air Force Office of Scientific Research MURI program in Nanoscale Chemistry and by the National Science Foundation (CAREER Award, DMR-9600138). Mass spectra were obtained at the Mass Spectrometry Laboratory for Biotechnology. Partial funding for the Facility is from NSF grant 94-2.

22 To a suspension of $Na_2[Mo_6Cl_8(OMe)_6]$ (80 mg, 0.073 mmol) in a solution of **L***x* (x = 1, 2) (0.47 mmol) in 1,2-dichlorobenzene (3 ml), 3 ml of anhydrous methanol was added with stirring. The resulting mixture became clear immediately, and was further stirred overnight under a partial vacuum of 100 mTorr. This allowed solvents and by-product methanol to be removed slowly, and a yellow solid remained. The residue was dissolved into 4 ml of toluene, and filtered under nitrogen to remove the unreacted starting cluster, and then 10 ml of Et_2O was added to the filtrate. The precipitate was collected and washed with Et_2O. The product was further purified by precipitation from toluene–Et_2O several times (yield: 92% for **G1**). Molecule **G0** was prepared similarly except that DMF was substituted for 1.2-dichlorobenzene.

Synthesis and X-ray structure of the first 1,3,2,4-diazaphosphaaluminetidine

Stephan Schulz,* Tillmann Bauer and Martin Nieger

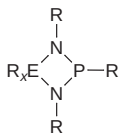
Institut für Anorganische Chemie der Universität Bonn, Gerhard-Domagk-Str. 1, D-53121 Bonn, Germany. E-mail: stephan@ac4010se.chemie.uni-bonn.de

Received (in Basel, Switzerland) 3rd March 1999, Accepted 2nd April 1999

Dehydrogenation reaction between $AlH_3{\leftarrow}NMe_3$ and $Bu^tP[N(H)Bu^t]_2$ leads to $Bu^tP(NBu^t)_2AlH{\leftarrow}NMe_3$, the first neutral 1,3,2,4-diazaphosphaaluminetidine.

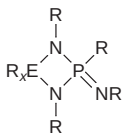
Four-membered heterocycles $RP(\mu\text{-}NR')_2ER''_x$ (E = main group element) have been studied extensively during the last two decades. Several neutral 1,3,2σ³λ³-diazaphosphatedines (type 1)[1] and 1,3,2σ⁴λ⁵-diazaphosphonatatedines (type 2)[2] have been synthesised and structurally characterised.

Type 1



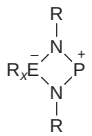
R_xE = RB,[1a] CO,[1b] R_2Si,[1c] RP,[1d] RAs,[1e] SO_2[1f]

Type 2



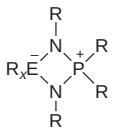
R_xE = RB,[2a] R_2Si,[1c, 2b] RP[2c]

Type 3



R_xE = R_2Al,[2b, 3a] R_2Ga[3b]

Type 4



R_xE = R_2Al,[3a, 4a, 4b] R_2Ga,[4a, 4c] R_2In[4a]

We became interested in the synthesis of neutral 1,3,2σ³λ³-diazaphosphatedines containing an element of group 13 due to the lack of structural information. Although 1,3,2,4-diazaphosphaboretidines $RP(\mu\text{-}NR')_2BR''$, synthesised by reactions of (a) aminoiminophosphanes $RN{=}P{-}NR_2'$ with BX_3 (X = Cl, Br),[1a,4] (b) dilithiated bis(amino)phosphanes $RP(NR'Li)_2$ with dichloroboranes $RBCl_2$,[1a] (c) iminoboranes $RN{=}BR'$ with dichlorophosphanes $RPCl_2$,[1a,3] (d) iminoboranes with aminoiminophosphanes,[1a,2] (e) aminoiminoboranes with PCl_3,[1a,3] and (f) aminoiminoboranes with aminoiminophosphanes,[1a,5] have been known for several years, to our knowledge, their solid state structures have not been determined. Investigations concerning the synthesis of 1,3,2,4-diazaphosphatidines of higher homologues of group 13 were not successful, because reactions (a) and (b) using Al, Ga or In compounds lead to zwitterionic complexes (type 3,[3] or 4[4]) and the analogous starting compounds for reactions (c)–(f), imino-alanes, -gallanes and -indanes $RN{=}ER'$ (E = Al, Ga, In), are, as yet, unknown.

We now report the synthesis and structural characterisation of the first neutral 1,3,2,4- diazaphosphaaluminatidine by a dehydrogenation reaction. $Bu^tP[N(H)Bu^t]_2$ was added to $AlH_3{\leftarrow}NMe_3$, which immediately led to gas evolution. The resulting viscous solid was subsequently heated to 115 °C until the gas evolution stopped. Cooling to room temperature led to a light yellow solid, which was dissolved in pentane and stored at −30 °C. Colourless crystalline **1** was obtained and characterised by ^1H, ^{13}C and ^{31}P NMR, IR and mass spectroscopy as well as single crystal X-ray analysis.‡

The ^1H NMR spectrum shows a doublet for the Bu^tP group and a singlet for the Bu^tN moieties, indicating that the two Bu^tN groups are equivalent. The ^{31}P NMR spectrum shows a singlet at δ 121.2, comparable to that (δ 126.6) found in $MeP(\mu\text{-}NBu^t)_2BMe$.[1a] The Al–H resonance was not observed in the ^1H NMR spectrum probably owing to broadening,[5] but the IR spectrum displays a typical Al–H stretching absorption band at 1793 cm^{-1}.

Crystals of **1** suitable for a single crystal X-ray structure determination were grown in pentane at −30 °C. The geometry at the P atom is pyramidal with an endocyclic N1–P1–N2 bond angle of 89.6° (Fig. 1). The average P–N bond length [1.732(2) Å] is comparable to those found in $(Bu^tN)Bu^tP(\mu\text{-}NBu^t)_2BBu^t$ [171.0(2) Å],[2a] $RP(\mu\text{-}NBu^t)_2SiMe_2$ [174.1(3) Å][1c] and $(Me_3Si)_2NP(\mu\text{-}NR')_2SiBu^t_2$ [176.9(2) Å][6] and reveals the absence of any double-bond character within the PN_2 fragment. The Al atom shows a distorted tetrahedral environment with an endocyclic N1–Al1–N2 bond angle of 83.3°. The average Al–N bond length within the non-planar ring [1.836(2) Å] is comparable to Al–N compounds with four-coordinate Al centers bound to three-coordinate N atoms.[7] The zwitterionic complexes $P(\mu\text{-}NAr)_2AlMe_2$ (Ar = $C_6H_2Bu^t_3$-2,4,6),[3a,4] $P(\mu\text{-}NSiMe_3)AlCl_2$[3a] (type 3) and $[(Ph_2P)NPPh_2N(SiMe_3)AlMe_2]$[4b] (type 4) show significantly shorter P–N [average of 1.617(4), 1.614(6) and 1.613(1) Å, respectively] and longer Al–N bond lengths [average of 1.977(4), 1.890(6) and 1.947(2) Å,

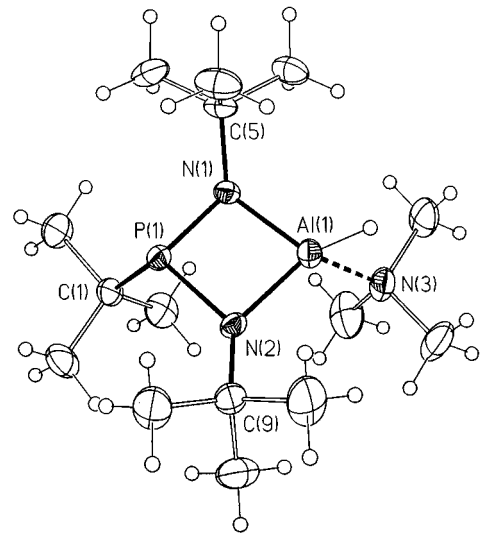


Fig. 1 The molecular structure of **1** (50% thermal ellipsoids). Selected bond lengths (Å) and angles (°): C(1)–P(1) 1.902(2), P(1)–N(1) 1.732(2), P(1)–N(2) 1.732(1), Al(1)–N(1) 1.846(2), Al(1)–N(2) 1.826(2), Al(1)–N(3) 2.028(2), Al(1)–H(1) 1.478(5); N(1)–P(1)–N(2) 89.6(1), C(1)–P(1)–N(1) 105.0(1), C(1)–P(1)–N(2) 106.3(1), N(1)–Al(1)–N(2) 83.3(1), N(1)–Al(1)–N(3) 118.2(1), N(2)–Al(1)–N(3) 116.2(1), C(5)–N(1)–Al(1) 123.3(1), C(5)–N(1)–P(1) 120.7(1), C(9)–N(2)–P(1) 126.4(1), C(9)–N(2)–Al(1) 131.8(1), H(1)–Al(1)–N(1) 122.9(7), H(1)–Al(1)–N(2) 121.3(7), H(1)–Al(1)–N(3) 96.8(8).

respectively], while coordination of a Lewis base to a complex of type 3 as shown in $P(\mu\text{-}NSiMe_3)_2AlCl_2\cdot$quinuclidine[8] leads to comparable Al–N [average 1.855(10) Å] and less shortened P–N bond lengths [average of 1.673(10) Å]. The Al–H bond length [1.478(5) Å] and the terminal Al–N bond length [2.028(2) Å] in **1** are within the expected range.[5]

Received (in Cambridge, UK) 26th February 1999, Accepted 6th April 1999

The glycylglycine and glycine complexes of *cis,cis*-1,3,5-triaminocyclohexane–copper(II), model reaction intermediates of peptide hydrolysis by Cu^{II}–triamine complexes, have been synthesized and characterized by X-ray crystallography.

There has been great interest in designing artificial metallopeptidases that hydrolyze unactivated amides under mild conditions.[1,2] Up to now a variety of metal complexes of Cu^{II},[1,3] Zn^{II},[3c,d] Ni^{II},[3c,d] Pd^{II},[4] Co^{III}[2,5] and Ce^{IV}[6] have been used to study the hydrolysis of amides. Recently Burstyn and coworker[1] reported the discovery that a macrocyclic copper(II) complex, Cu[9]aneN_3, can hydrolyze both the unactivated dipeptide glycylglycine and proteins at near physiological pH. Although no reaction mechanism has been shown for Cu[9]aneN_3, in such a reaction, the activation of the carbonyl group of the amide by the metal centre seems to play an important role, and it is necessary to get information about the reaction intermediate to advance the hydrolysis reaction. We have been studying some copper(II)–triamine complexes which effectively promote the hydrolytic cleavage of phage DNA,[7] as well as peptide bonds. To understand the mechanism of the hydrolytic reaction of peptides by Cu^{II}–triamine complexes, we present here the crystal structures of glycylglycine and glycine complexes of *cis,cis*-1,3,5-triaminocyclohexane–copper(II) as model reaction intermediates.

We have investigated the hydrolysis of peptide with *cis,cis*-1,3,5-triaminocyclohexane–copper(II) complex[7] **1** by HPLC and found that glycylglycine is hydrolyzed to glycine when incubated with **1**.† The hydrolysis of glycylglycine (Gly-Gly) (2 mM) to glycine (Gly) with **1** (2 mM) at 70 °C and pH 8.1 ± 0.1 (50 mM HEPES) is *ca.* 18% for 24 h, which is similar to that of Cu[9]aneN_3, and the conversion is dependent on metal complex concentration, reaction time and solution pH.

The tetraphenylborate salts of $[Cu(tach)(gly\text{-}gly)]^+$ **2** and $[Cu(tach)(gly)]^+$ **3** (tach = *cis,cis*-1,3,5-triaminocyclohexane, gly = glycine anion, gly-gly = glycylglycine anion) were synthesized by stirring a mixture of $CuSO_4.5H_2O$ (1 mmol), tach (1 mmol) and Gly-Gly (1 mmol) for **2** or Gly (1 mmol) for **3** in MeOH–water at pH 8 (in the presence of $NaBPh_4$) in 40% yield for **2** and 60% yield for **3**, respectively. Blue crystals of the two complexes were grown by slow evaporation of a MeOH–water solution and the structures were characterized by X-ray crystallography.‡

The crystal structures (Figs. 1 and 2) of complexes **2** and **3** both show a five co-ordinate copper centre ligated to the three face capping nitrogens of the tach ligand. In each case the copper co-ordination geometry is square pyramidal distorted along the apical Cu(1)–N(3) bond with a distance of 2.232(3) Å in **2** and 2.152(6) Å in **3**. The other Cu–N distances, Cu(1)–N(1) and Cu(1)–N(2), are 1.990(3) and 2.015(2) Å in **2** and 2.019(6) and 2.042(6) Å in **3**, respectively, as in other copper-tach complexes.[8] The peptide (gly-gly) is coordinated through the terminal NH_2 group and the carbonyl oxygen atom from the same glycine residue. The carbonyl oxygen atom O(1) is here prefered to the peptide nitrogen N(5) as a metal binding site at pHs where the amide proton is not dissociated, as in the tripeptide complexes of $Cu(gly\text{-}gly\text{-}gly)^+$,[9] $Cu(gly\text{-}leu\text{-}tyr)^+$,[10] and $Zn(gly\text{-}gly\text{-}gly)^+$,[11] or the Co^{III}–tetraamine complex of the glycylglycine *O*-ethyl ester.[12] This mode of co-ordination accounts for the ease of hydrolysis of the dipeptide. The positively charged copper(II) ion renders the carbonyl carbon atom C(8) more susceptible to nucleophilic reagents (OH^-) and the peptide chelate ring is not required to break for hydrolysis to occur, so the NH_2-terminal glycine remains attached to the Cu(tach) residue to form [glycinato–copper(II)–tach] complex

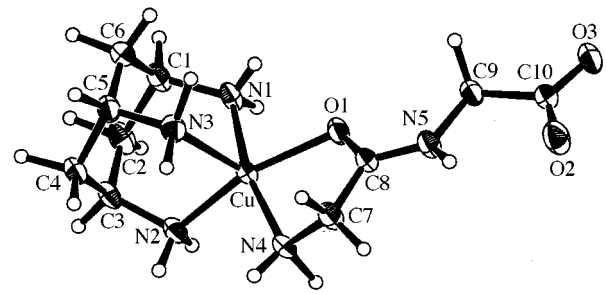

Fig. 1 ORTEP plot with 30% probability thermal ellipsoids showing the structure of the cation of **2**. Fig. 2 ORTEP plot with 30% probability thermal ellipsoids showing the structure of the cation of **3**. Selected bond distances (Å) and angles (°): Cu–O(1) 1.974(4), Cu–N(1) 2.019(6), Cu–N(2) 2.042(6), Cu–N(3) 2.152(6), Cu–N(4) 2.007(6), O(1)–Cu–N(1) 173.6(2), O(1)–Cu–N(2) 87.5(2), O(1)–Cu–N(3) 97.0(2), O(1)–Cu–N(4) 82.6(2), N(1)–Cu–N(2), 92.8(3), N(1)–Cu–N(3) 89.4(2), N(1)–Cu–N(4) 93.2(2), N(2)–Cu–N(3) 92.7(2), N(2)–Cu–N(4) 141.4(2), N(3)–Cu–N(4) 125.5(2).

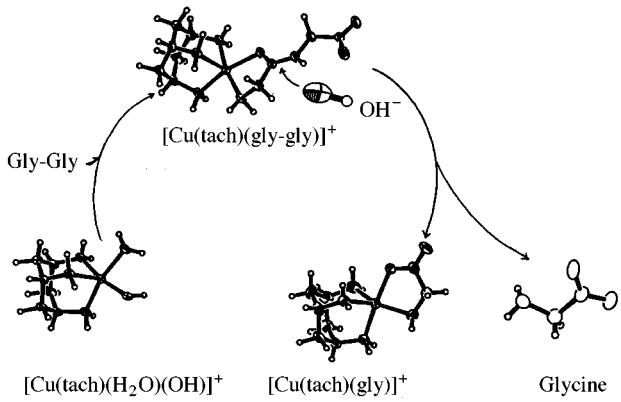

Scheme 1

ion, as shown in Fig. 2. Thus the complex cation of **2**, $[Cu(tach)(gly\text{-}gly)]^+$, is an intermediate of the hydrolysis of the N-terminal peptide bond promoted by Cu^{II}–triamine complex, and is clear evidence for the activation of the C=O group by the metal centre.

On the basis of the intermediate structure a reasonable mechanism may be postulated for the peptide hydrolysis at near physiological pH, as shown in Scheme 1. The initial step involves the rapid replacement of the water molecule by the N-terminal amino group of the peptide, which becomes chelated to the copper(II) ion. The carbonyl group is then activated to attack by external OH^-. The mechanism is supported by the fact that the rate of hydrolysis increases with increasing hydroxide concentration.§

Experiments to prove this mechanism *via* solution chemistry studies and kinetic measurements of the hydrolysis of peptides by Cu^{II}–triamine complexes are presently being conducted.

The support of this work by a JSPS postdoctoral fellowship to X. S. T. from the Japan Society for the Promotion of Science (No. P97370) and by a Grant-in-Aid for Science Research (No. 09440224) from the Ministry of Education, Science, Sports and Culture of Japan is gratefully acknowledged.

Microreactors for elemental fluorine

Richard D. Chambers and Robert C. H. Spink

University of Durham, Department of Chemistry, South Road, Durham, UK DH1 3LE.
E-mail: r.d.chambers@durham.ac.uk.

Received (in Liverpool, UK) 18th January 1999, Accepted 29th March 1999

A microreactor has been designed for use with elemental fluorine, both for selective fluorination and for perfluorination of organic compounds.

Interest in the use of elemental fluorine directly, for the synthesis of fluorine-containing organic compounds, has increased dramatically in the last few years,[1–3] but scale-up will always present problems of safe handling and temperature control, for some of the most exothermic reactions in organic chemistry.

There is currently much interest in the development of microreactors for chemical processing,[4] because the benefits would include arithmetic scale-up from the performance of a single reactor to a theoretically unlimited number. Also, in principle, this scale-up could be achieved by the techniques of the electronics industry.

Microreactors have considerable attraction for application to direct fluorination processes because there is (i) a small inventory of fluorine in the reaction zone, (ii) opportunity for good mixing and temperature control, and (iii) simple scale-up. However, prior to this work, there was little knowledge available on the practicability of this approach.

After much development, we have now designed a simple micro-reactor, fabricated from a block of nickel (or copper), from which we have cut a groove as the micro-reactor; the design is indicated in Fig. 1, where the seal is provided by a block of polychlorotrifluoroethene, which also enables direct viewing of the reaction zone. Reactants and solvent were injected *via* a syringe and syringe-pump, while fluorine in nitrogen was introduced directly from a small cylinder *via* a mass-flow controller. Using this technique, all of the liquid–gas mixing that we carried out proceeded *via cylindrical flow* (the term is intended to indicate that the liquid forms an outer cylinder, coating the reactor surface, with the gas flowing through the centre) as opposed to *slug flow* (alternate slugs of liquid and gas), which might have been anticipated. Indeed, the former provides enormous advantages in that it provides very large surface to volume ratios for the liquid phase, which is highly beneficial for efficient reaction over a short distance in the reactor. There is also excellent mixing and very effective opportunities for heat control, through the cooling channels indicated. Furthermore, a surprisingly large through-put for such a small channel is possible, *e.g.* 0.5–5 ml h^{-1} have been used routinely.

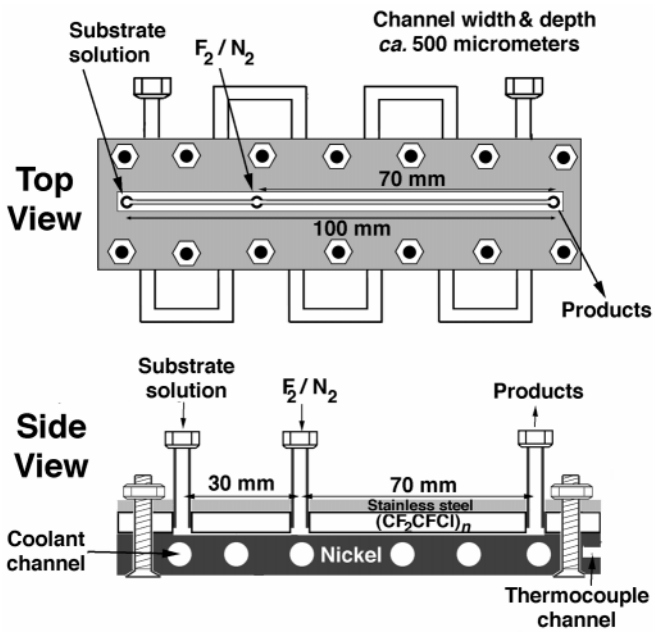

Fig. 1 Microreactor top and side view.

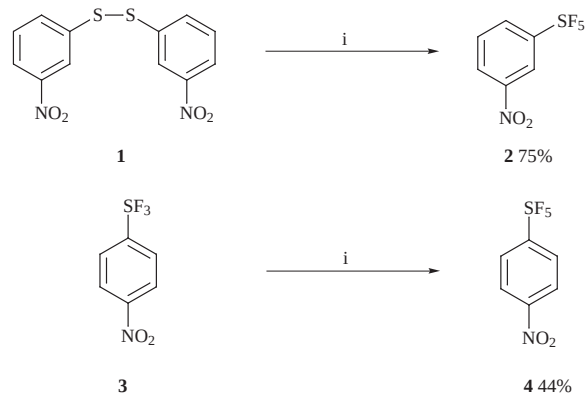
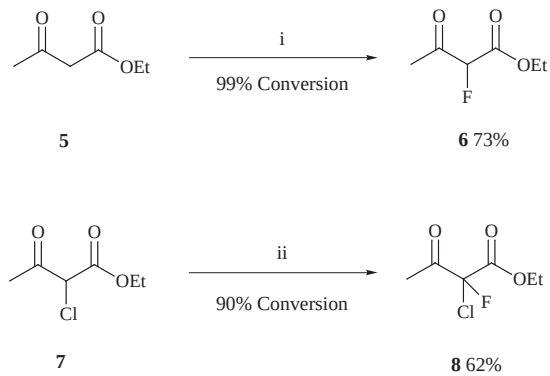
Products were trapped out in a half inch diameter FEP tube, cooled by either a salt–ice bath or an acetone–carbon dioxide slush bath. Residual gases were scrubbed in a soda-lime tower and any dissolved hydrogen fluoride was removed by either adding sodium fluoride to the product mixture or washing with water.

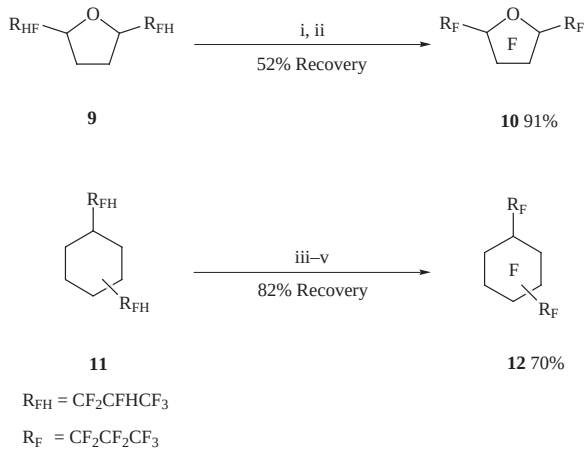
Using this system, we have successfully carried out various selective fluorinations, as shown in Schemes 1 and 2. Sulfur pentafluoride derivatives are of considerable interest[5] and



Scheme 1 *Reagents and conditions*: i, MeCN (5 ml h^{-1}), 10% F_2 in N_2 (10 ml min^{-1}), room temp.



Scheme 2 *Reagents and conditions*: i, 10% F_2 in N_2 (10 ml min^{-1}), 5 °C, HCO_2H (0.5 ml h^{-1}); ii, 10% F_2 in N_2 (10 ml min^{-1}), 5 °C, HCO_2H (0.25 ml h^{-1}).



Scheme 3 *Reagents and conditions*: i, 0.5 ml h^{-1}, 50% F_2 in N_2 (15 ml min^{-1}), room temp.; ii, 0.5 ml h^{-1}, 50% F_2 in N_2 (15 ml min^{-1}), room temp. then 280 °C; iii, 0.5 ml h^{-1}, 20% F_2 in N_2 (20 ml min^{-1}), room temp.; iv, 0.5 ml h^{-1}, 50% F_2 in N_2 (10 ml min^{-1}), room temp. then 50 °C; v, 0.5 ml h^{-1}, 50% F_2 in N_2 (15 ml min^{-1}) room temp. then 280 °C.

fluorination can be achieved directly from the di(*m*-nitrophenyl) disluphide **1**. However, for the *p*-nitro system **3**, due to its very low solubility in MeCN, preliminary fluorination (in bulk) to produce soluble trifluorides was performed and then the more difficult fluorination to pentafluorides was carried out in the microreactor.

Fluorination of β-dicarbonyl compounds proceeded with high efficiency and, moreover, these reactions demonstrated clearly a catalytic effect by the fluorinated metal surface. Fluorination is usually limited by either the concentration of enol, at equilibrium, or the rate constant for forming the enol. However, while bulk fluorination of ethyl 2-chloroacetoacetate **7** gives only low conversion to **8**,[6] the flow system is clearly efficient and the fluorinated metal surface obviously promotes the formation of enol.

We have also demonstrated that the technique can be used for *perfluorination*. In this case, however, we need an additional heated stage to complete the reaction and this is connected simply to the outlet of the reactor. Results are shown in Scheme 3 and there is no reason why these otherwise hazardous procedures could not be scaled up with safety. Traditionally, cobalt trifluoride (obtained using elemental fluorine) is used in industry to perfluorinate hydrocarbons, but for some of the examples shown here, the temperature required for perfluorination with elemental fluorine is significantly lower than that required for perfluorination using cobalt trifluoride.[7]

These experiments illustrate the significant potential for this approach to the use of elemental fluorine, both in the laboratory and at the industrial scale.

We acknowledge financial support from BNFL.

Transition metal labels on peptide nucleic acid (PNA) monomers

Alexandra Hess and Nils Metzler-Nolte*

Max-Planck-Institut für Strahlenchemie, Stiftstraße 34–36, D-45470 Mülheim/Ruhr, Germany.
E-mail: nils@mpi-muelheim.mpg.de

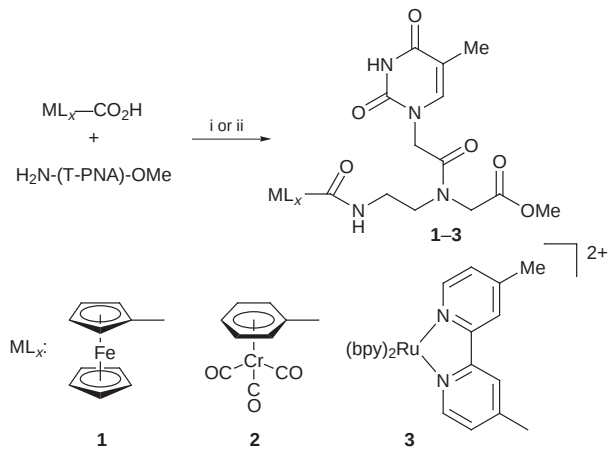
Received (in Basel, Switzerland) 25th February 1999, Accepted 2nd April 1999

The synthesis, spectroscopic properties (including Mössbauer and electrochemistry) and self-association characteristics of thymine peptide nucleic acid (T–PNA) monomers with covalently linked transition metal markers are described.

Peptide nucleic acids (PNA) constitute a relatively young class of DNA analogues[1] for studies in structural biology[2–5] and applications in antisense-antigene technology.[6] PNA consists of a pseudopeptide backbone, to which the nucleobases are attached through a methylene-carbonyl spacer.[7,8] Among the favourable properties of PNA in the form introduced by Nielsen and Burchardt are high binding affinity to single- and double-stranded DNA with the formation of duplex and triplex helices and an increased hydrolytic stability compared to analogous DNA strands. For analytical purposes in molecular biology, however, PNA lacks a unique spectroscopic handle. Consequently, it would be highly desirable to have PNA attached to an independent and sensitive spectroscopic probe. To this end we have synthesized two organometallic PNA hybrids, namely ferrocene–PNA for electrochemical detection and (benzene)-chromiumtricarbonyl–PNA in which the carbonyl groups provide a sensitive probe for IR detection. Also, we present here the first synthesis and spectroscopic properties of a bipyridyl–ruthenium PNA derivative. Ruthenium derivatives of oligonucleotides have become invaluable tools for the study of electron transfer in DNA.

Ferrocene carboxylic acid thymine-PNA methyl ester (Fc–(T–PNA)–OMe, **1**) was originally prepared by the reaction of ferrocene carboxylic acid chloride, prepared *in situ* from ferrocene carboxylic acid and oxalylic chloride in CH_2Cl_2 solution, with thymine–PNA methyl ester H_2N–(T–PNA)–OMe (Scheme 1). For the synthesis of benzoic acid chromium-tricarbonyl thymine–PNA methyl ester (Cr–(T–PNA)–OMe, **2**), a HBTU (*O*-(1*H*-benzotriazol-1-yl)-*N*,*N*,*N*′,*N*′-tetramethyluronium hexafluorophosphate) mediated coupling between benzoic acid chromium tricarbonyl and H_2N–(T–PNA)–OMe was used.† After work-up, both compounds are obtained in 80 and 60% yield, respectively, as analytically pure yellow solids. Deeply orange–red coloured bis(bipyridyl) (4-methyl-4′-carboxylic acid bipyridyl) ruthenium(II) thymine–PNA methyl ester (Ru–(T–PNA)–OMe, **3**) was obtained by reaction of HBTU-activated $[(bpy)_2Ru(4\text{-Me-bpy-}4'\text{-}CO_2H)]^{2+}$ with H_2N–(T–PNA)–OMe and purified by chromatography on silica.

All metal–PNA hybrids exhibit characteristic NMR spectra which are essentially a combination of their components.‡ As an indication of a successful coupling, however, the signal of the newly introduced amide proton can be observed in aprotic solvents. There is a distinct solvent dependence of this resonance [for **1**: δ 7.24 in $CDCl_3$, δ 7.9 in $(CD_3)_2SO$] which is attributed to the formation of hydrogen bonds with the $(CD_3)_2SO$ solvent. On the other hand, the ^{15}N NMR resonance of the attached nitrogen atom, which can be detected by 2D indirect detection techniques [**1**: δ_N −276 in $CDCl_3$, δ_N −274 in $(CD_3)_2SO$ $^1J_{NH}$ = 90 Hz], remains almost unperturbed.[9] The existence of two isomers denoted major (ma) and minor (mi) in PNA monomers[7,10] and oligomers[11] is well documented. These isomers are also observed in **1**–**3** and we have used the good solubility and stability of the ferrocene derivative **1** in different solvents to shed further light on the nature of the two conformers. First, there is a distinct solvent dependence of the ma/mi ratio as shown in the ^1H NMR spectra of **1**. If all intermolecular hydrogen bonds are broken in CD_3OD solvent in favor of PNA–solvent interactions, the ma/mi ratio is 65 : 35. Changing to an aprotic solvent infers a further stabilisation of the ma isomer, possibly due to hydrogen bonding [ma/mi = 71 : 29 in $(CD_3)_2SO$, ma/mi = 79 : 21 in $CDCl_3$). Coalescence of all ma/mi signal pairs was observed by ^1H NMR spectroscopy in $(CD_3)_2SO$ between 40 and 100 °C. From these data a rotation barrier of 75 ± 0.5 kJ mol^{-1} is calculated, consistent with rotation about the tertiary amide bond.[7,10] There is also a distinct concentration dependence of some ^1H NMR signals of **1** in $CDCl_3$ (Fig. 1). Over a concentration range of 0.375–0.0027 mol l^{-1} the NH proton of the pyrimidine ring (a) shifts 1.5 ppm to higher field, consistent with the accepted model of T–T self association.[12,13] However, while the positions of most other signals remain almost constant and the



Scheme 1 Synthesis metal–PNA conjugates. *Reagents and conditions*: i, $(COCl)_2$, CH_2Cl_2 then NEt_3, THF (**1**), (ii) HBTU, MeCN (**2** and **3**, see Experimental).

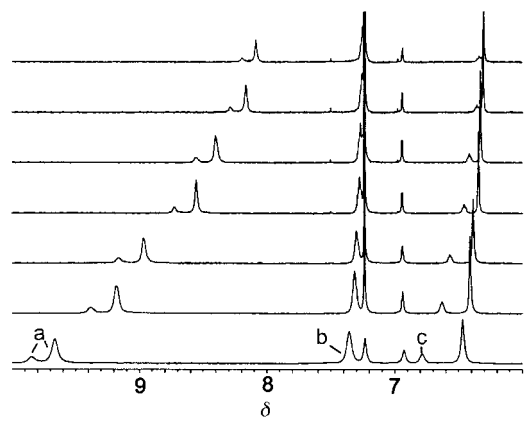


Fig. 1 ^1H NMR spectra of **1** at different concentrations between 375 mmol l^{-1} (bottom trace) and 2.7 mmol l^{-1} (top trace) in $CDCl_3$ at 27 °C. Marked signals are thymine NH(both isomers, a), amide NH (ma, b) and amide NH (mi, c).

FcCON*H* proton of the ma isomer (b) moves < 0.1 ppm, the amide proton signal of the mi isomer (c) shifts also by 0.5 ppm. This suggests that an additional intermolecular interaction, which may be impossible in the ma isomer on steric grounds, might stabilize the mi isomer.§

In the chromium derivative **2**, which is generally less soluble in organic solvents than **1**, the ma/mi ration is 25 : 10 in $(CD_3)_2SO$. In the IR spectrum of **2**, the two strongest bands occur at 1973 and 1898 cm^{-1} and can be assigned to the A and E modes of the $Cr(CO)_3$ moiety. Jaouen and coworkers have used the very strong bands of organometallic carbonyl compounds for the detection of biogenic amines with excellent sensitivity.[14,15] In an elegant application, this carbonyl metallo immuno assays (CMIA), has been applied to study the binding of polyclonal antibodies to cortisol and testosterone.[16]

To confirm the possibility of electrochemical detection of metal–PNA hybrids the ferrocene and ruthenium derivatives **1** and **3** were investigated by cyclic voltammetry. **1** can be reversibly oxidized at a potential of +169 mV *vs.* Fc/Fc^+ (CH_2Cl_2 solution with 0.1 mol l^{-1} NBu_4PF_6) a potential which can be easily achieved in a biological environment without destruction of the biological matrix.[17,18] For **3**, a reversible one-electron oxidation occurs at 897 mV *vs.* Fc/Fc^+, consistent with a Ru^{II}/Ru^{III} redox couple. Ligand centred redox waves were observed at −1.63, −1.90 and −2.15 V. The optical spectrum of **3** exhibits several overlapping bands around 450–430 nm which are assigned to metal-to-ligand charge transfer transitions (MLCT),[19] while two weak bands at 359 and 327 nm result from metal centred transitions and mostly ligand centred π–π* transitions are observed around 290 nm.[20] We have also recorded a ^{57}Fe Mössbauer spectrum for **1**. The isomer shift (0.52 mm s^{-1}) and quadrupole splitting (2.32 mm s^{-1}) are very similar to the value for ferrocene (0.53 mm s^{-1} and 2.37 mm s^{-1}),21 suggesting that there is little influence of the overall solid state structure of **1** on the electric field gradient of the iron nucleus.

We have reported the straightforward synthesis and full characterization of transition metal derivatives of T–PNA monomers and we are confident that this chemistry can be extended to PNA oligomers. As shown in this communication, these new compounds show unique spectroscopic features which in principle permit their sensitive detection even in complex biological matrices such as intact cells. Encouraged by these results, we are further developing the chemistry of metal–PNA hybrids towards applications in structural biology and antisense / antigene technology.

The authors are grateful to Professor. K. Wieghardt for his support of our work.

Notes and references

† *Typical experimental procedure using* HBTU: to a solution of 1 mmol of the transition metal complex in MeCN was added 1 equiv. of HBTU and NEt_3. After stirring for 15 min. (15 h for **3**) brine was added, the solution extracted with EtOAc ($MeNO_2$ for **3**), and the organic phase washed with 2 M HCl, water, aq. $NaHCO_3$, and water, dried over $MgSO_4$ and the solvent removed to yield the desired metal–PNA hybrid.

The *ansa*-effect in permethyltantalocene chemistry: a [Me_2Si] *ansa* bridge promotes olefin-insertion and reductive-elimination reactions for [$Me_2Si(C_5Me_4)_2$]Ta(η^2-C_2H_4)H and [$Me_2Si(C_5Me_4)_2$]TaH_3

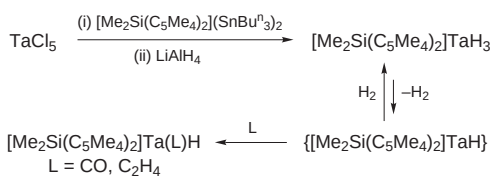
Received (in Bloomington, IN, USA) 1st February 1999, Accepted 31st March 1999

The *ansa*-effect, as it applies to tantalocene chemistry, has been investigated by a comparison of the chemistry of [$Me_2Si(C_5Me_4)_2$]TaH_3 and [$Me_2Si(C_5Me_4)_2$]Ta(η^2-C_2H_4)H with their permethyltantalocene counterparts; these studies demonstrate that incorporation of the [Me_2Si] *ansa* bridge substantially enhances the rates of both reductive elimination of H_2 and ethylene-insertion into a Ta–H bond.

The ability of an *ansa* bridge to modify the chemistry of a metallocene system has recently found important applications. For example, the stereoregularity of polymers obtained using metallocene catalysts is influenced considerably by the presence of such bridges.[1] The majority of studies on *ansa*-metallocene complexes, however, has principally been concerned with identifying the manner in which the *ansa*-bridge effects a product distribution, with relatively little attention having been given to defining, and quantifying, its effect on fundamental organometallic transformations.[2] Here, we describe quantitative aspects of the *ansa*-effect as it applies to two of the most important reactions in organometallic chemistry, namely olefin-insertion and reductive-elimination.

By comparison with unsubstituted tantalocene complexes, Cp_2TaX_n, their permethylated counterparts $Cp^*_2TaX_n$ (Cp^* = η^5-C_5Me_5) have provided a most valuable system for studying a variety of elementary organometallic transformations.[3] An investigation of the chemistry of the corresponding permethylated *ansa*-tantalocene complexes [$Me_2Si(C_5Me_4)_2$]TaX_n should, therefore, allow for a quantitative evaluation of the influence of an *ansa* bridge on elementary transformations at a tantalum center. Single atom bridged *ansa*-tantalocene complexes are, however, most uncommon. For example, the only structurally characterized *ansa*-tantalocene complexes with η^5,η^5-coordination listed in the Cambridge Structural Database[4] are the imido derivatives, [$Me_2C(C_5H_4)_2$]Ta(NBu^t)Cl[5] and [$Me_2C(C_5H_4)_2$]Ta[$N(C_6H_3Pr^i_2)$]Cl.[6,7] In view of the large number of *ansa*-metallocene complexes of Ti, Zr, and Hf, the paucity of studies in *ansa*-tantalocene chemistry may be a reflection of synthetic difficulties in obtaining the requisite compounds; indeed, even the literature synthesis of $Cp^*_2TaCl_2$[8] is considerably more complicated than those of the Group 4 analogues, $Cp^*_2MCl_2$ (M = Ti, Zr, Hf). It is, therefore, noteworthy that we have been able to access the *ansa* bridged {[$Me_2Si(C_5Me_4)_2$]Ta} system. Specifically, the trihydride complex [$Me_2Si(C_5Me_4)_2$]TaH_3 may be obtained *via* reaction of $TaCl_5$ with [$Me_2Si(C_5Me_4)_2$]$(SnBu^n_3)_2$,[9] followed by treatment with $LiAlH_4$ (Scheme 1).

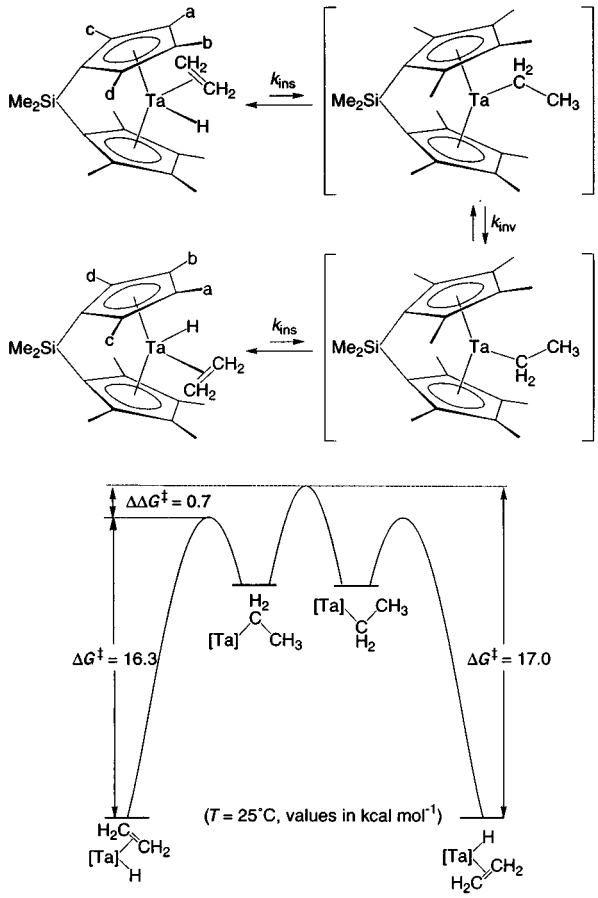
[$Me_2Si(C_5Me_4)_2$]TaH_3 is a convenient precursor to other derivatives, including the ethylene and carbonyl complexes, [$Me_2Si(C_5Me_4)_2$]Ta(η^2-C_2H_4)H and [$Me_2Si(C_5Me_4)_2$]Ta(CO)H (Scheme 1). While the pentamethylcyclopentadienyl analogues, $Cp^*_2Ta(\eta^2$-$C_2H_4)H$ and $Cp^*_2Ta(CO)H$, have likewise been prepared from $Cp^*_2TaH_3$,[8] an important distinction between the two systems resides with the conditions required to effect reaction. For example, [$Me_2Si(C_5Me_4)_2$]Ta(η^2-C_2H_4)H is readily obtained over a period of hours at 80 °C, whereas the literature synthesis of the pentamethylcyclopentadienyl analogue requires prolonged heating for 10 days at 140 °C.[8] A more detailed comparison indicates that the *ansa* complex [$Me_2Si(C_5Me_4)_2$]TaH_3 reacts with C_2H_4 *ca.* 4000 times faster than does $Cp^*_2TaH_3$ under identical conditions.[10] Likewise, (i) the reaction of [$Me_2Si(C_5Me_4)_2$]TaH_3 with CO and (ii) H/D exchange with D_2 are also enhanced over the corresponding reactions of $Cp^*_2TaH_3$. These comparisons clearly demonstrate that the [Me_2Si] *ansa* bridge strongly promotes reductive elimination of H_2 in this system, a most notable result because a completely opposite effect is observed in a related tungsten system. Specifically, Green and coworkers demonstrated that the [Me_2C] *ansa* bridge in [$Me_2C(C_5H_4)_2$]W(R)H totally inhibits reductive elimination of alkane, an observation that was rationalized in terms of the *ansa* bridge preventing adoption of the parallel ring geometry favored for a tungstenocene intermediate.[11] The tantalum systems, however, do not require a parallel ring geometry since both monohydride intermediates, {[$Me_2Si(C_5Me_4)_2$]TaH} and [Cp^*_2TaH], are expected to have a bent sandwich structure.[12] Other factors are, therefore, responsible for dictating the influence of the [Me_2Si] *ansa* bridge on reductive elimination reactions in tantalocene complexes. One possible explanation is associated with the notion that the [Me_2Si] *ansa* bridge reduces the electron donating capability of the attached cyclopentadienyl groups (*vide infra*).[2b,13] As such, the Ta(V) trihydride would be stabilized with respect to the Ta(III) monohydride intermediate to a lesser degree for the *ansa* system than that for the unbridged system and so their interconversion would be more facile.



Scheme 1

Dynamic NMR spectroscopic studies (line broadening and magnetization transfer) indicate that the ethylene hydride complex [$Me_2Si(C_5Me_4)_2$]Ta(η^2-C_2H_4)H is in rapid equilibrium with its ethyl tautomer {[$Me_2Si(C_5Me_4)_2$]$TaCH_2CH_3$} (Scheme 2).[14] Significantly, the [Me_2Si] *ansa* bridge also enhances the rate of ethylene insertion in [$Me_2Si(C_5Me_4)_2$]-Ta(η^2-C_2H_4)H by a factor of *ca.* 760 (at 100 °C)[15] over that for its non-bridged counterpart, $Cp^*_2Ta(\eta^2$-$C_2H_4)H$.[16] As with the reductive elimination reactions described above, it is likely that the origin of the effect on the olefin insertion reaction is also attributable to an electronic influence resulting from the reduced electron donating properties of the *ansa* bridged ligand. Indeed, a similar argument has been made by Bercaw to rationalize the observation that olefin insertion within $Cp_2M(\eta^2$-$C_2H_4)H$ is more facile than that within $Cp^*_2M(\eta^2$-$C_2H_4)H$ (M = Nb, Ta).[3b]

In addition to olefin insertion, the barrier to 'inversion',[17] *i.e.* the combined barrier to cleaving any potential agostic interaction, passing the alkyl group through the center of the wedge, and rotating about a M–C bond (Scheme 2), is of most relevance



Scheme 2

to the use of metallocene derivatives as polymerization catalysts. Specifically, depending on the catalyst system, the polymer stereochemistry will depend critically on the relative rates of such 'inversion' and olefin insertion.[18] While it is not possible to study inversion within $Cp^*_2Ta(\eta^2\text{-}C_2H_4)H$ because of the lack of a suitable diagnostic technique, it is possible to detect the occurrence of this process for the *ansa* analogue $[Me_2Si(C_5Me_4)_2]Ta(\eta^2\text{-}C_2H_4)H$ by virtue of the diasterotopic methyl substituents of the $[Me_2Si(C_5Me_4)_2]$ ligand. In particular, the barrier for ethylene–hydride site interchange within $[Me_2Si(C_5Me_4)_2]Ta(\eta^2\text{-}C_2H_4)H$ may be conveniently measured by monitoring exchange of the aforementioned diasterotopic methyl substituents (a ↔ b and c ↔ d) by using ^{1}H NMR spectroscopy. These experiments indicate that there is indeed an additional barrier required to effect 'inversion' in this system. The additional barrier ($\triangle\triangle G^{\ddagger}$) is, however, modest, with a value of only *ca.* 0.7 kcal mol^{-1} at 25 °C (Scheme 2), corresponding to a factor of *ca.* 4 in rate constant.[15]

Spectroscopic studies are in accord with the notion that the $[Me_2Si]$ *ansa* bridge causes a reduction in the electron density at the tantalum centers in $\{[Me_2Si(C_5Me_4)_2]Ta\}$ complexes as compared with their $[Cp^*_2Ta]$ counterparts. Thus, the ν(CO) stretch of $[Me_2Si(C_5Me_4)_2]Ta(CO)H$ (1887 cm^{-1}) in pentane is substantially greater than that of $Cp^*_2Ta(CO)H$ (1868 cm^{-1}). X-Ray diffraction studies[19] suggest that these spectroscopic differences are a result of the $[Me_2Si]$ *ansa* bridge displacing the cyclopentadienyl groups from their preferred positions with respect to tantalum. For example, the Cp_{cent}–Ta–Cp_{cent} angle in $[Me_2Si(C_5Me_4)_2]Ta(CO)H$ [139.7°] is significantly reduced from that in $Cp^*_2TaH_3$ [148.3°].[20] More importantly, the angle between the ring normals in $[Me_2Si(C_5Me_4)_2]Ta(CO)H$ [131.3°] is reduced to an even greater extent, so that the ring normals lose coincidence with the Ta–Cp_{cent} vectors and there is an increase in the asymmetry of the Ta–Cp interactions.[21] The binding mode thus approaches η^3,η^3-coordination and thereby reduces the electron density transferred to the metal center.

We thank the U.S. Department of Energy, Office of Basic Energy Sciences (#DE-FG02-93ER14339) for support of this research and Dr Peter Desrosiers (Symyx Technologies) for valuable technical assistance.

14 As has been noted previously, exchange processes of this type do not require the participation of a 16-electron alkyl complexes, but may occur *via* an 18-electron agostic alkyl species.

15 For ethylene insertion, $\Delta H^{\ddagger}$ = 15.49(33) kcal mol^{-1} and $\Delta S^{\ddagger}$ = −2.60(10) cal mol^{-1} K^{-1} corresponding to k_{ins} = 1.83 × 10^3 s^{-1} and $\Delta G^{\ddagger}$ = 16.44 kcal mol^{-1} at 100 °C. For inversion, $\Delta H^{\ddagger}$ = 17.96(24) kcal mol^{-1} and $\Delta S^{\ddagger}$ = 3.3(8) cal mol^{-1} K^{-1}.

16 Data for $Cp^*_2Ta(\eta^2\text{-}C_2H_4)H$ at 100 °C: k_{ins} = 2.4 s^{-1}; $\Delta G^{\ddagger}$ = 21.3 kcal mol^{-1}. See ref. 3(*b*).

17 The term 'inversion' in this sense is being used to refer to ethylene–hydride site (or alkyl–vacancy) interchange. Since the molecule is not chiral, it is not intended to refer to enantiomer interconversion.

18 See, for example: C. P. Casey, M. A. Fagan and S. L. Hallenbeck, *Organometallics*, 1998, **17**, 287 and references therein.

19 See supplementary data for the structures of $[Me_2Si(C_5Me_4)_2]Ta(CO)H$, $[Me_2Si(C_5Me_4)_2]Ta(\eta^2\text{-}C_2H_4)H$, and $Cp^*_2TaH_3$. The C_2H_4 and hydride ligands of $[Me_2Si(C_5Me_4)_2]Ta(\eta^2\text{-}C_2H_4)H$ are statistically disordered about a crystallographic mirror plane that lies in the Cp_{cent}–Ta–Cp_{cent} plane. CCDC 182/1209. See http://www.rsc.org/suppdata/cc/1999/887/ for crystallographic files in .cif format.

20 Cp_{cent}–Ta–Cp_{cent} = 148.3°; Cp_{norm}/Cp_{norm} = 148.2°.

21 Individual Ta–C_{Cp} bond lengths for $[Me_2Si(C_5Me_4)_2]Ta(CO)H$ range from 2.32 Å to 2.45 Å. The difference between the Cp_{cent}–Ta–Cp_{cent} angle and the angle between the ring normals is 8.2° for $[Me_2Si(C_5Me_4)_2]Ta(CO)H$, but only 0.1° for $Cp^*_2TaH_3$.

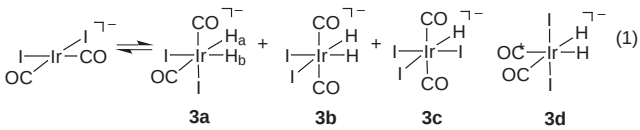
Received (in Cambridge, UK) 4th February 1999, Accepted 12th April 1999

***para*-Hydrogen enhanced NMR signals are used to show that $NBu_4[M(CO)_2I_2]$ (M = Rh, Ir) add hydrogen to form NBu_4-{*all-cis*-$[M(H)_2(CO)_2I_2]$} which for M = Ir undergoes H_2 elimination in a step where $\Delta H^{\ddagger}$ 106 ± 10 kJ mol^{-1} and $\Delta S^{\ddagger}$ 60 ± 6 J K^{-1} mol^{-1} while showing a rich substitution chemistry with PPh_3 that leads to both charged and neutral products *via* square pyramidal $Ir(H)_2(CO)_2I$.**

When transition metal complexes are reacted with *para*-hydrogen (*p*-H_2) the size of the detectable NMR signatures of many hydride reaction products are dramatically enhanced owing to the generation of non-Boltzmann spin populations.[1–4] This phenomenon provides sufficient sensitivity to facilitate the observation of intermediates in catalytic reactions, species in minor reaction pathways such as $RhH_2(PMe_3)_2I_2Rh(PMe_3)(CO)$ and minor constituents in equilibria, for example *all-cis*-$[Ru(PMe_3)_2(CO)_2(H)_2]$.[5] Here we examine the reactivity of $NBu_4[M(CO)_2I_2]$ (M = Ir, Rh) towards hydrogen. While these complexes are known to react with MeI to form $NBu_4[MI_3Me(CO)_2]$, and play a substantial role in acetic acid generation, their reactivity towards hydrogen, a substrate also present in this process, is far less well understood.[6] We show that two isomers of $NBu_4[IrH_2(CO)_2I_2]$ are formed upon H_2 addition to $NBu_4[Ir(CO)_2I_2]$, and report for the first time kinetic and thermodynamic parameters for H_2 elimination from a *p*-H_2 enhanced dihydride. The lability of the ligand sphere of the *all-cis* isomer is further explored by employing PPh_3 as a vacant coordination site scavenger.

When a 0.1 mM solution of $NBu_4[Ir(CO)_2I_2]$ **1** in benzene-d_6 is monitored by ^{1}H NMR spectroscopy at 295 K while under 3 atm of *p*-H_2 substantial signals arise from a previously undetected complex at δ −9.13 and −13.30 [Fig. 1(a)].† These resonances are assigned to the hydride ligands H_a and H_b of **3a**, and their chemical shifts indicate they are *trans* to carbonyl and iodide respectively.† The two carbonyl resonances of **3a** were detected at δ 167.2 and 160.9 by a ^{1}H–^{13}C HMQC experiment, and when a sample containing **1** and *p*-H_2 was monitored with an excess of NBu_4I present the product signal intensities were unchanged. This information suggests that **3a** corresponds to the *all-cis* isomer of $NBu_4[Ir(H)_2(CO)_2I_2]$ **3a** as shown in eqn. (1).



(1)

Weak hydride resonances attributable to species **3b** and **3c** of eqn. (1) were also observed in the ^{1}H NMR spectra.[7] Resonances attributable to **3a** are also observable in methanol-d_4 and acetic acid-d_4. We further note, that **3a** is only visible with *p*-H_2, and that isomer **3d** is not seen even when ^{13}CO labelled **1** is employed. Additionally, when the sample is left under H_2 at room temperature, the resonance for **3c** disappears leaving **3b** as the only detectable hydride containing species.

The mechanism of generation of these species requires further comment since concerted H_2 addition to NBu_4*{cis*-$[Ir(CO)_2I_2]$} should only yield **3a**. We therefore investigated the dynamic behaviour of **3a** using gradient-assisted EXSY spectroscopy. This revealed that at 323 K **3a** undergoes simple reductive elimination to form free H_2, which at temperatures beyond 350 K is complicated by both *intermolecular* hydride interchange and *intramolecular* exchange into **3b**. Under these conditions, addition of an excess of free NBu_4I, such that the solution is saturated, results in a 5% increase in the rate of H_2 loss and suppression of the intermolecular and intramolecular exchange peaks. In view of this we can state that H_2 loss occurs from **3a** rather than the 16-electron complex $[Ir(H)_2(CO)_2I]$. Analysis of the exchange peak intensity as a function of mixing time allowed the rate of H_2 elimination from **3a** to be determined; at 325 K this corresponds to 0.17 s^{-1}. Monitoring this process as a function of reaction temperature enabled the activation parameters $\Delta H^{\ddagger}$ 106 ± 10 kJ mol^{-1} and $\Delta S^{\ddagger}$ 60 ± 6 J K^{-1}mol^{-1} to be calculated.

Importantly, when a 0.1 mM solution of the rhodium analogue **2** is warmed with *p*-H_2 to 350 K and monitored by ^{1}H NMR spectroscopy [Fig 1(b)] two rhodium coupled hydride resonances are observed at δ −9.75 (J_{RhH} 17.3, J_{HH} −4 Hz) and −14.15 (J_{RhH} 16.5 Hz) which are consistent with the formation of the previously unseen species NBu_4*{all-cis*-$[RhH_2(CO)_2(I)_2]$}. Clearly the extent to which NBu_4*{all-*

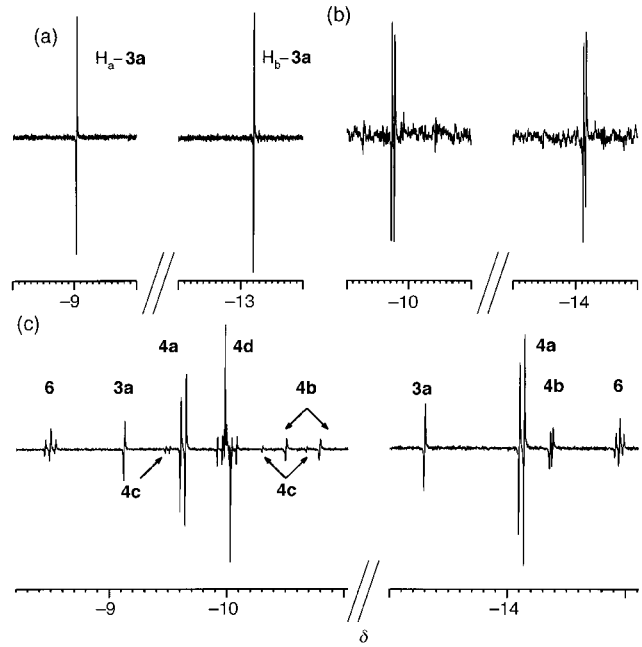


Fig. 1 (a) ^{1}H NMR spectrum (400 MHz, 295 K) of a 0.1 mM solution of **1** in benzene-d_6 under 3 atm of *p*-H_2. The antiphase resonances arise from the parahydrogen enhanced hydride resonances in the *all-cis* isomer of $NBu_4[Ir(H)_2(CO)_2I_2]$, **3a**. (b) ^{1}H NMR spectrum (400 MHz, 350 K) of a 0.1 mM solution of **2** in benzene-d_6 under 3 atm of *p*-H_2 showing resonances due to the *all-cis* isomer of $[Rh(H)_2I_2(CO)_2]$. (c) ^{1}H NMR spectrum (400 MHz, 295 K) of a 0.1 mM solution of **1** in benzene-d_6 under 3 atm of *p*-H_2, in the presence of 0.1 mM of PPh_3 with resonance assignments indicated.

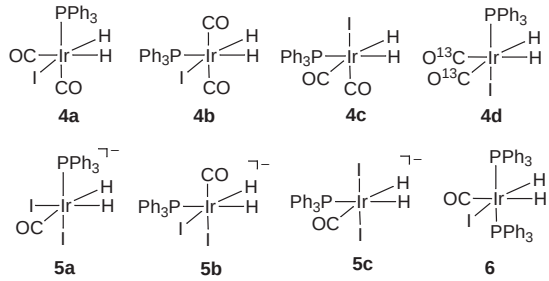
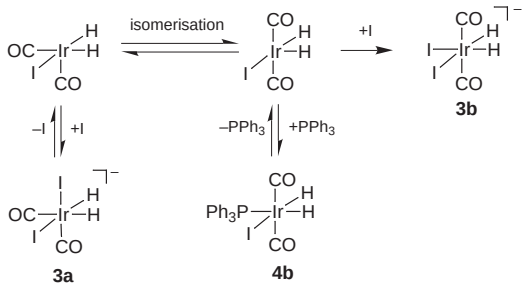
cis[$RhH_2(CO)_2(I)_2$]} forms is much lower than that of **3a**, and the temperatures required to observe it are at least 60 K higher.

The observation of intramolecular and intermolecular exchange pathways indicated that the substitution reactivity of **3a** was worthy of examination. We therefore monitored benzene-d_6 solutions containing **1**, *p*-H_2 and PPh_3 (< 2 equivalents). A typical ^1H spectrum is shown in [Fig. 1(c)]. The new mononuclear products, identified by ^1H–^1H COSY, ^1H–^{31}P and ^1H–^{13}C HMQC techniques, correspond to four isomeric forms of $IrH_2(CO)_2(PPh_3)I$, three isomers of $NBu_4[IrH_2(CO)(PPh_3)I_2]$, and $IrH_2(CO)(PPh_3)_2I$ with *trans* phosphines are shown below.† Surprisingly, when $NBu_4[Rh(CO)_2I_2]$ **2**, *p*-H_2 and PPh_3 were examined at 350 K no new dihydride products were detected.



When samples containing **1**, PPh_3 and H_2 were monitored by EXSY spectroscopy at 295 K the signals observed for each hydride of **3a** connected to both hydride resonances of **4b** *via* cross peaks arising from chemical exchange. Examination of the intensity of these peaks indicated that interconversion of **3a** to **4b** places **3a**-H_a *trans* to phosphine in **4b** more often than *trans* to iodide; this process is suppressed upon addition of NBu_4I. As expected, the reverse situation is true when cross peaks from H_b-**3a** are considered and the difference in intensity between the corresponding hydride cross peaks falls as the temperature rises. This information suggests that **4b** forms from **3a** *via* a process involving iodide loss to yield an intermediate with inequivalent hydrides which undergoes rearrangement to form the square pyramidal intermediate $IrH_2(I)(CO)_2$ with *trans* carbonyls. Coordination of phosphine then generates **4b**, or iodide **3b**, as shown in Scheme 1. Furthermore, while the two hydride ligands of $IrH_2(I)(CO)_2$ are inequivalent they must be able to interchange their positions on the same time scale as phosphine coordination. Significantly, weaker cross peaks, connect the hydride resonances of **4b** to **3a** which indicates that they are in equilibrium.

The only other exchange peaks visible in the hydride region of the spectrum at 350 K connect the hydride resonances of **4c** to those of **4b**. This interconversion process occurs with a twofold preference for placing the hydride ligand of **4c** that was *trans* to phosphine *trans* to iodide in the product, **4b**. While both phosphine and CO loss from **4c** are possible in the first step, the data suggests CO loss is more likely since different intermediates to those shown in Scheme 1 are required to account for the dramatically different hydride exchange preferences seen in the two interconversion processes. This second reaction therefore most likely involves square pyramidal $Ir(H)_2(I)(CO)(PPh_3)$.



Scheme 1

Here, we have shown that *p*-H_2 derived spectral amplification can be used to examine the hydrogen addition chemistry of both $NBu_4[IrI_2(CO)_2]$ and $NBu_4[RhI_2(CO)_2]$. Products not previously observed have been characterised, and for the first time activation parameters have been determined for H_2 elimination from a *p*-H_2 enhanced product. Additionally, a new series of iridium dihydrides containing phosphine and carbonyl ligands have been characterised, and the intermediates, $IrH_2(I)(CO)_2$ and $Ir(H)_2(I)(CO)(PPh_3)$, involved in their formation shown to be square pyramidal.

A new mineralomimetic $Cd(CN)_2$ host framework which is intermediate between H- and L-cristobalite-like frameworks

Takafumi Kitazawa*

Department of Chemistry, Faculty of Science, Toho University, Miyama, Funabashi, Chiba 274-8510, Japan.
E-mail:kitazawa@chem.sci.toho-u.ac.jp

Received (in Cambridge, UK) 1st March 1999, Accepted 7th April 1999

The three-dimensional $Cd(CN)_2$ clathrate enclathrating the CH_2BrCH_2Br molecule produces a new mineralomimetic $Cd(CN)_2$ host framework (space group $I4_1/amd$) which is intermediate between H-cristobalite- (space group Fd-3m) and L-cristobalite-like species (space group $P4_12_12$).

In natural crystalline SiO_2 minerals, the SiO_4^{4-} tetrahedra are linked so that every oxygen atom is shared between two tetrahedra, giving the composition SiO_2. Likewise, the mineralomimetic $Cd(CN)_2$ host frameworks in the $Cd(CN)_2{\cdot}n$G clathrates are topologically similar to the polymorphic forms of SiO_2.[1–5] The nature of the $Cd(CN)_2$ host frameworks depends on guest molecules. The H-cristobalite, L-cristobalite and H-tridymite-like hosts of $Cd(CN)_2$ were obtained using guest molecules of different properties, sizes, shapes and symmetries. For example, $CHCl_2CHCl_2$,[2,3] $CHCl_2CH_2Cl$[4] and Bu_2O[4] produce an H-cristobalite-like $Cd(CN)_2$ host framework (Fd-3m), an L-cristobalite-like species ($P4_12_12$) and an H-tridymite-like species ($P6_3/mmc$), respectively. Selecting guest molecules provides new mineralomimetic $Cd(CN)_2$ host frameworks with a body-centered tetragonal $I4_1/amd$ lattice which is intermediate between the H-cristobalite-like species (space group Fd-3m) and the L-cristobalite-like species (space group $P4_12_12$).

In nature, H-cristobalite is the high-temperature polymorph of SiO_2, existing above 1743 K. However, H-cristobalite (cubic space group Fd-3m) metastably exists up to above 540 K, where it experiences a rapid and reversible inversion to L-cristobalite (tetragonal space group $P4_12_12$).[6] A crystallograhic comparison between the two structures has been reported.[7] To the best of my knowlege, the cristobalite structure which is intermediate between H-cristobalite (Fd-3m) and L-cristobalite ($P4_12_12$) has not previously been obtained and/or found. From a crystallographic view point, an intermediate structure with a tetragonal space group $I4_1/amd$ is possible.

The new mineralomimetic framework of $Cd(CN)_2$ between the H and L-cristobalite-like types has been obtained using CH_2BrCH_2Br as guest. Treating an equimolar aqueous solution of $CdCl_2{\cdot}2.5H_2O$ and $K_2[Cd(CN)_4]$ with 1,2-dibromoethane gives colourless tetragonal crystals of $Cd(CN)_2{\cdot}CH_2BrCH_2Br$. The IR spectrum indicates that the conformation of CH_2BrCH_2Br in $Cd(CN)_2$ is *trans* (1184, 594 cm^{-1}), based on the neat CH_2BrCH_2Br data.[8]

The X-ray single crystal determination† (Fig. 1) shows that the topological properties of the host framework in $Cd(CN)_2{\cdot}CH_2BrCH_2Br$ are intermediate between those of H- and L-cristobalite. For example, $Cd(CN)_2{\cdot}CMe_4$[3] and $Cd(CN)_2{\cdot}Pr^iBr$[4] contain mineralomimetic $Cd(CN)_2$ frameworks analogous to H- and L-cristobalite SiO_2, respectively: $Cd(CN)_2{\cdot}CMe_4$, space group Fd-3m, a = 12.757(2) Å, Z = 8; $Cd(CN)_2{\cdot}Pr^iBr$, $P4_12_12$, a = 9.124(1), c = 11.335(3) Å, Z = 4, while the new mineralomimetic $Cd(CN)_2{\cdot}CH_2BrCH_2Br$ crystalizes in the body-center tetragonal $I4_1/amd$ with lattice parameters, a = 8.116(5), c = 14.721(5) Å, Z = 4. Like the H- and L-cristobalite-like $Cd(CN)_2$ framework structures, the host framework of the present inclusion compound is composed of individual tetrahedral units linked to four neighboring tetrahedra by Cd–CN–Cd linkages. However, the new mineralominetic $Cd(CN)_2$ host framework in $Cd(CN)_2{\cdot}CH_2BrCH_2Br$ does not topologically correspond to natural SiO_2 structures. Clearly, there is a large difference in the scale and orientation of the tetrahedra between the $Cd(CN)_2$ and SiO_2 structures, since organic guest species must be accommodated in the adamantane-like cavity. The Cd–CN–Cd distance is *ca.* 5.5 Å and the Cd–CN–Cd angle is 180°, whereas the Si–O–Si distance is *ca.* 3.2 Å and the Si–O–Si bond angle is more flexible.

As shown in Fig. 2, the adamantane-like cavity in the new $Cd(CN)_2{\cdot}CH_2BrCH_2Br$ clathrate is occupied by the guest CH_2BrCH_2Br molecule, like the H- and L-cristobalite-like cadmium cyanide clathrates. However, the accommodation mode of CH_2BrCH_2Br is completely different from that of the guest molecules in the H- and L-cristobalike-like clathrates. The shape, size and conformation of CH_2BrCH_2Br is associated with forming the $I4_1/amd$ $Cd(CN)_2$ host framework. The orientation of the guest CH_2BrCH_2Br molecules is along the c axis. The Br atom projects toward a branch consisting of one Cd atom and two cyanide groups in the adamantane-like cavity, while each methyl group of CMe_4 in H-cristobalite-like $Cd(CN)_2{\cdot}CMe_4$ projects toward a tripod consisting of one Cd atom and three cyano groups,[3] and the two methyl groups of Pr^iBr in the L-cristobalite-like $Cd(CN)_2{\cdot}Pr^iBr$ project towards two tripods.[4] The guest CH_2BrCH_2Br as a template allows the new mineralomimetic $Cd(CN)_2$ host framework, which can be obtained by expanding the c axis and depressing the a and b axes in the H-cristobalite-like Fd-3m host framework. The insertion into the branch induces an expansion of the host framework along the c axis. The affinity of the guest molecules in the polymeric host framework varies depending on the

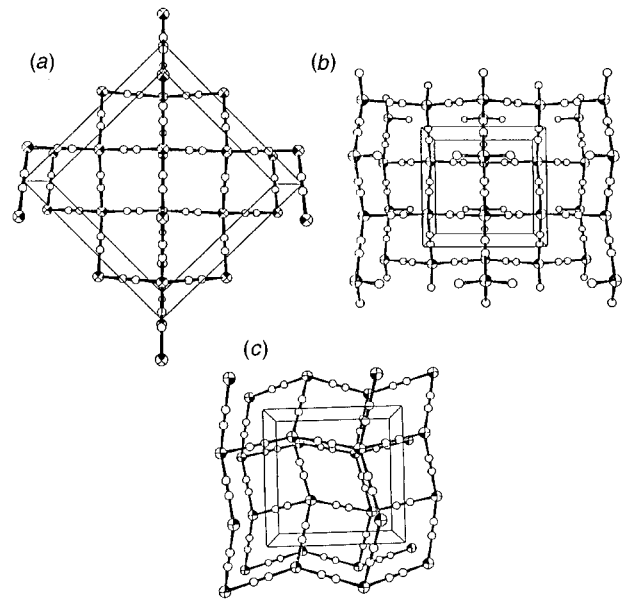

Fig. 1 The cristobalite-like $Cd(CN)_2$ host framework structures along the c axis. Guest molecules are omitted. (*a*) The H-cristobalite-like Fd-3m type, *e.g.* $Cd(CN)_2{\cdot}CMe_4$. (*b*) The new mineralomimetic $I4_1/amd$ type, $Cd(CN)_2{\cdot}CH_2BrCH_2Br$. (*c*) The L-cristobalite-like $P4_12_12$ type, *e.g.* $Cd(CN)_2{\cdot}Pr^iBr$.

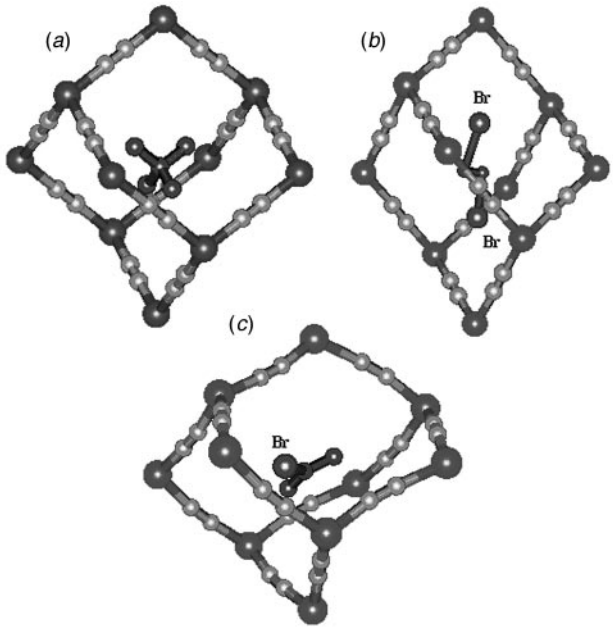

Fig. 2 The adamantane-like cavities of the $Cd(CN)_2$·G clathrates. (*a*) The cavity of the H-cristobalite-like $Cd(CN)_2$·CMe_4 clathrate. (*b*) The cavity of the new mineralomimetic $I4_1/amd$ type, $Cd(CN)_2$·CH_2BrCH_2Br clathrate. Since the C atoms of the CH_2BrCH_2Br are highly disordered, one possible conformation is shown. proprieties of the guest molecules. The guest structure serves as a template for the solid host lattice.

These results indicate that the cadmium cyanide host is flexible depending on the guest molecules. To the best of my knowledge, a SiO_2 structure topologically similar to the host in $Cd(CN)_2$·CH_2BrCH_2Br has not been previously found. The new mineralomimetic $Cd(CN)_2$ host framework with a $I4_1/amd$ space group has implications for the natural and/or synthetic SiO_2 systems. The formation of the mineralomimetic $I4_1/amd$ $Cd(CN)_2$ host structure suggests the formation of $I4_1/amd$ type SiO_2 under special conditions. This new cadmium cyanide clathrate may be of significant interest as a crystalline model compound for studies of the transformation of SiO_2 and nanoscale control of host frameworks.

† *Crystal data*: $Cd(CN)_2$·CH_2BrCH_2Br, M = 352.31, $I4_1/amd$ (No. 141), a = 8.116(5), c = 14.721(5) Å, U = 969.7(9) Å^3, Z = 4, D_x = 2.41 g cm^{-3}, μ(Mo-Kα) = 10.423 mm^{-1}; 322 reflections observed, 2 restrains and 18 parameters refined: R = 0.0629 [$I > 2\sigma(I)$], goodness of fit (gof) = 1.056. The collection of X-ray diffraction intensity data was carried out on a Rigaku AFC5S diffractometer (Mo-Kα: λ = 0.71069 Å) at 180 K. The structure was solved using the TEXSAN software package installed on the diffractometer system and refined by full-matrix least-squares methods with the program SHELXL-93. After refinement of the host lattice $Cd(CN)_2$, the difference map suggested that the guest CH_2BrCH_2Br molecules displayed considerable positional disorder due to the large thermal motion and pseudo-symmetry associated with the space group. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms have not been located. Since disorder in the orientation of the cyanide group between tetrahedral Cd atoms has been found by solid state ^{113}Cd NMR spectroscopy in $Cd(CN)_2$ host–guest materials (ref. 9), all the relevant C and N atoms were assumed to have 50% probability of being C and N. Novel concise ring closure leading to bridged ten-membered ring compounds

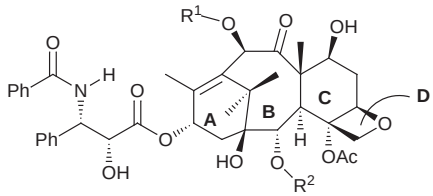
Hiroshi Fujishima, Hiroshi Takeshita, Masahiro Toyota and Masataka Ihara*

Graduate School of Pharmaceutical Sciences, Tohoku University, Aobayama, Sendai, 980–8578, Japan. E–mail: mihara@mail.pharm.tohoku.ac.jp

Received (in Cambridge, UK) 19th February 1999, Accepted 12th April 1999

An unusual TBAF-mediated intramolecular cyclisation of diallylsilane derivatives 3 and 12 provided bicyclo[6.2.2]-dodecanes 5 and 13 in good yields.

The taxol derivatives have attracted the attention of synthetic chemists due to their novel mode of action and the complexity of their structures.[1] So far, several groups have achieved the total synthesis of taxol[2] and numerous synthetic methods have

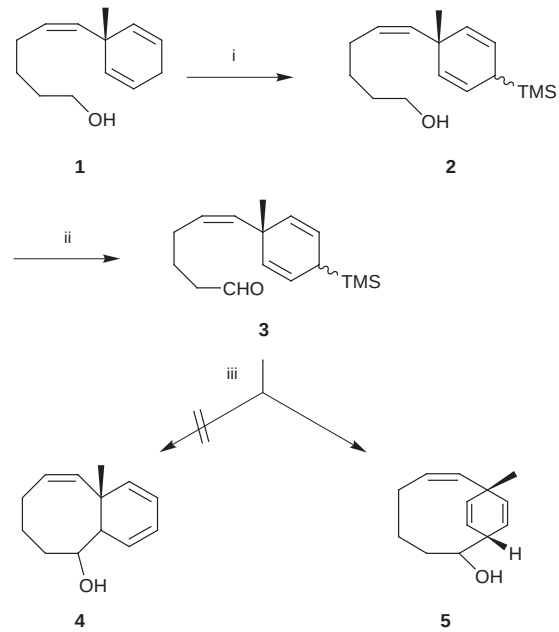


Taxol R^1 = Ac, R^2 = Bz
Taxotere R^1 = H, R^2 = Boc

been developed for the construction of the key bicyclic (BC ring) system. However, assembly of the eight-membered ring (B ring) needs multiple steps owing to its highly oxygenated structural features and, therefore, the establishment of a novel and concise route is highly desirable. In order to achieve an efficient construction of the B ring framework, we have been studying various intramolecular cyclisations.[3] In particular, cyclisation reactions employing allylsilanes[4,5] attracted our attention. During our investigations, we found that an unusual cyclisation took place when the diallylsilanes **3** and **12** were treated with TBAF, leading to the formation of the bridged ten-membered ring compounds **5** and **13**, respectively. Herein we describe the outcome of this novel TBAF-promoted cyclisation and the structural determination of the cyclised products.

The synthesis of substrate **3** is summarized in Scheme 1. The alcohol **1**[3a] was treated with BuLi and TMSCl in the presence of TMEDA to give the *C*- and *O*-silylated product, which was reacted with 2 M H_2SO_4 to furnish the diallylsilane **2** as a mixture of diastereoisomers (diastereoselection 3 : 1). Oxidation of **2** with a catalytic amount of tetrapropylammonium perruthenate (TPAP) and NMO[6] in CH_2Cl_2 afforded the desired aldehyde **3**.

First of all, **3** was subjected to the Hosomi–Sakurai reaction[4] in the presence of Lewis acids,[7] that is, the solution of material in solvent was treated with 1.1–3.0 equiv. of Lewis acid. Contrary to our expectations, reactions with $TiCl_4$ or $BF_3{\cdot}OEt_2$ did not provide the cyclised compound **4**, but brought about rapid decomposition of **3** (Table 1; entries 1 and 2); with $LiBF_4$ and HF·Py, compound **3** was recovered (entries 3 and 4). However, the α-carbon of the allylsilane moiety of **3** added as a nucleophile to the aldehyde in the presence of TBAF yielding the bicyclic products **5**[8] in fair to good yield (entries 5–8). It is important to note that this reaction proceeds with a catalytic amount of TBAF (0.05 equiv.) at room temperature for 1 h to afford **5** in 47% yield (entry 5). Moreover, the addition of 4 Å molecular sieves gave the best result and **4** was obtained in 79% yield (entry 7). The ten-membered structure (the so-called dihydro[6]paracyclophane) of **5**, obtained as a single isomer,



Scheme 1 *Reagents and conditions*: i, BuLi, TMSCl, TMEDA, THF, 0 °C, then 2 M H_2SO_4 (93%); ii, 20 mol% TPAP, NMO, 4 Å molecular sieves, CH_2Cl_2, rt (71%); iii, see Table 1.

was suggested by the absence of absorptions due to the conjugated diene in the UV spectrum.

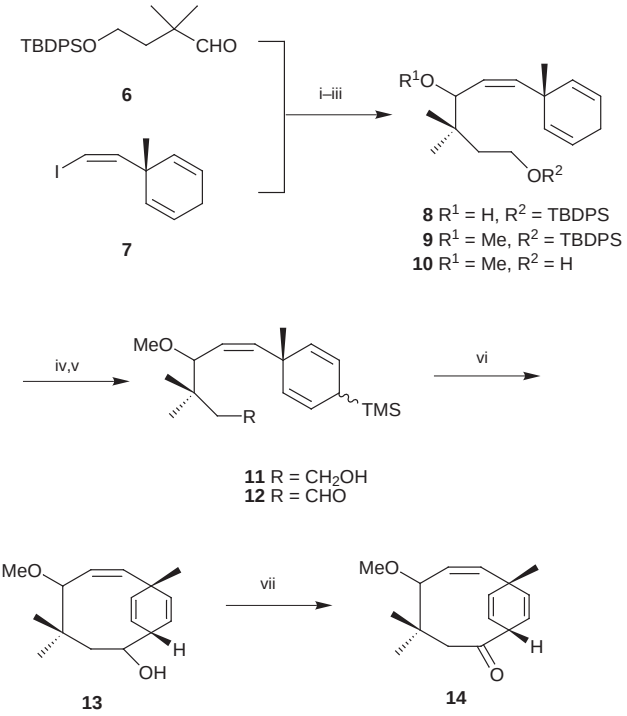
The cyclisation of the substituted material **12** was next investigated under the same conditions as above. The assembly of **12** is depicted in Scheme 2. The coupling reaction of the aldehyde **6**[9] and the vinyl iodide **7**[10] with 2.2 equiv. of Bu^{t}Li afforded the alcohol **8** in 84% yield. Methylation of **8** followed by desilylation of **9** gave the alcohol **10**. Upon treatment of **10** as above, the diallylsilanes **11** were obtained as a mixture of diastereoisomers (diastereoselection 13 : 1). Oxidation of **11** with TPAP as above afforded the aldehyde **12**, which was converted into the bridged ten-membered ring products **13**[11] as a 14 : 1 mixture of two diastereoisomers with 1.1 equiv. of TBAF at room temperature in 66% yield.

The structure of the product **13** was determined by X-ray analysis (Fig. 1), after its conversion into the ketone **14**[12]

Table 1 Reactions of **3** with various Lewis acids or TBAF

Entry	Reagent (equiv.)	Solvent	*T*/°C	*t*/h	Yield(%)[a]
1	$TiCl_4$ (1.1)	CH_2Cl_2	−78	1.0	0
2	$BF_3{\cdot}OEt_2$ (1.5)	CH_2Cl_2	−78 → 0	4.0	0
3	$LiBF_4$ (1.1)	THF	0 → rt	7.0	0
4	HF·Py (1.1)	THF	0 → rt	7.0	0
5	TBAF[b] (0.05)	THF	rt	1.0	47
6	TBAF[b] (1.0)	THF	rt	0.7	44
7	TBAF[b,c] (3.0)	THF	rt	0.3	79
8	TBAF[b,c] (3.0)	MeCN	rt	1.0	38

[a] Isolated yield. [b] 1.0 M THF solution was used. [c] 4 Å molecular sieves were added.



Scheme 2 *Reagents and conditions*: i, Bu^t Li, THF, −78 °C (84%); ii, MeI, NaH, DMF, 0 °C → rt (96%); iii, TBAF, THF, rt (94%); iv, BuLi, TMSCl, TMEDA, THF, 0 °C, then 10% $KHSO_4$ (94%); v, 20 mol% TPAP, NMO, 4 Å molecular sieves, CH_2Cl_2, rt (77%), vi, TBAF, THF, rt (66%); vii, 20 mol% TPAP, NMO, 4 Å molecular sieves, CH_2Cl_2, rt (95%).

obtained as a single stereoisomer. It is well documented by Birch that cyclopentadienyl anions react in the middle position.[13]

In summary, the Hosomi–Sakurai type reaction of **3** and **12** possessing the diallylsilane moiety afforded the bicyclic compounds **5** and **13** under mild conditions. We thank Dr C. Kabuto, Instrumental Analysis Center, Faculty of Science, Tohoku University, for the X-ray analysis of **14**.

Photocatalytic oxidation of trichloroethylene using TiO_2 coated optical microfibers

Charles V. Rice and Daniel Raftery*

Department of Chemistry, H.C. Brown Laboratory, Purdue University, West Lafayette, Indiana 47907, USA. E-mail: raftery@chem.purdue.edu

Received (in Bloomington, IN, USA) 21st December 1998, Accepted 9th April 1999

TiO_2 particles have been attached to optical microfibers to allow the irradiation of the interior of a powdered photocatalyst, and the UV initiated photocatalytic oxidation of trichloroethylene was followed using ^{13}C solid-state NMR.

The photocatalytic activity and surface chemistry of TiO_2 is currently of significant interest owing to its use in light harvesting[1] and pollutant remediation applications.[2] Much is known about TiO_2 photocatalysis at the liquid/solid interface whereas the gas/solid interface is less well understood.[3] A variety of experimental techniques have been applied to study the surface photochemistry of TiO_2, including GC–MS,[4] IR[5] and XPS.[6] We have shown that solid-state nuclear magnetic resonance (SSNMR) spectroscopy can provide information about the identity and nature of surface-bound and gas-phase species during *in situ* photocatalytic reactions.[7] Owing to the light scattering characteristics of TiO_2, it is best to disperse the catalyst as a thin film to expose the particles in a homogeneous fashion. However, the outer portions of TiO_2 powders packed inside the SSNMR rotor will either scatter or absorb most of the incoming photons and create dark regions within the interior of the sample. Reactants in these dark regions will not participate in the photochemical reaction, producing long-lived species and complicating the interpretation of results. Our laboratory has previously circumvented this problem by supporting monolayer TiO_2 films on porous Vycor glass. This reduces scattering and can be successfully used to follow the photoreactions with SSNMR.[7] Here, we report a different approach which allows UV light to penetrate the interior of a powdered sample and creates an opportunity to use SSNMR to study the photocatalytic surface chemistry on TiO_2 powders.

TiO_2 powders can be supported on glass plates,[8] rods,[9] beads,[10] meshes[11] and large diameter optical fibers.[12] However, these supports are impractical for use in SSNMR experiments. Thus, we utilized microscopic quartz optical fibers to deliver the UV photons to the interior of the sample. The optical microfibers can be tightly packed inside the SSNMR rotor and the incident photons can be directed towards either the ends of the fibers or perpendicular to their long axis. The photochemical behavior of the coated fibers was evaluated by monitoring the conversion of trichloroethylene (TCE), an important environmental contaminant, into several intermediates and final products.

The quartz microfibers (Quartzel Fiber®, 9 μm diameter, Quartz Products Company) were supplied as a roving with each strand composed of 4800 individual fibers. Approximately 20 sections of the roving (each 15 cm long) were placed in a test tube (2.5 cm OD, 30 cm long) and calcined at 400 °C to remove the polyimide cladding. The fibers were allowed to cool, bound together at one end with copper wire and dipped into an aqueous suspension of TiO_2 similar to that used by Nazeeruddin *et al.*[13] The suspension was prepared by adding 4 ml of water to 10 g of TiO_2 powder (Degussa P-25, surface area 55 $m^2\ g^{-1}$, 70% anatase) in a ceramic mortar. A thick paste was formed by grinding the mixture and adding 800 μl of pentane-2,4-dione to promote dispersion of the particles. The paste was diluted by the slow addition of 16 ml of water while grinding. To allow the suspension to cover the fibers evenly, 200 μl of a detergent (Triton X-100, Aldrich) was added.

After dipping the fibers, they were heated at 500 °C for 30 min, cooled to room temperature and rinsed under flowing water to remove excess TiO_2. The dipcoating, heating, and rinsing procedure was repeated 2 additional times. It was found that the surface area of the coated fibers could be increased further by allowing the coated fibers to dry, then dipping them into a 20% solution of titanium isopropyl alcohol (Aldrich) in anhydrous isopropyl alcohol (Aldrich) and calcining at 500 °C for 3 h. After cooling, the fibers were rinsed a final time and dried. Assuming even coverage of the fibers, gravimetric analysis indicated that the TiO_2 layer is *ca.* 0.5 μm thick.

In a typical experiment, *ca.* 40 000 coated microfibers (estimated by weight) were gathered into a bundle and inserted into a Teflon tube (4.5 mm ID, Small Products Company). A 1 cm section of the fiber-filled tube was cut, held at the opening of a standard 5 mm NMR tube (Norell) and a glass rod used to push the fiber bundle into the bottom of the NMR tube. After attachment to a vacuum manifold, the fibers were calcined at 400 °C to remove any remaining organic material, cooled to room temperature and exposed to humid air for 12 h to rehydrate the surface. The NMR tube was reattached to the manifold and heated at 150 °C under vacuum (10^{-4} Torr) for 2 h to remove excess water. The tube was then cooled to 77 K for the addition of per-^{13}C trichloroethylene (Cambridge Isotopes) and oxygen. The sample was isolated from the manifold by flame sealing. The gas pressure of the reagents in the tube at room temperature is estimated to be 1–2 atm.

NMR analysis was performed on a 300 MHz Varian Unity Plus NMR spectrometer with a home built, double resonance optical magic angle spinning (MAS) probe which has been described previously.[7] A 300 W Xe arc lamp (ILC Technology) was used as the light source and a dichroic mirror (Oriel Corp.) was used to limit the light to 350–450 nm. Irradiation of the sample in the end-on configuration was performed outside the magnet while the side irradiation experiments were performed *in situ* as described previously.[7]

The proton decoupled ^{13}C MAS NMR spectra collected during the photocatalysis of 48 μmol of TCE in the presence of 96 μmol of O_2 are shown in Fig. 1. The sample was irradiated in the end-on configuration. Each spectrum represents an average of 256 transients obtained with a recycle time of 4 s. Spectra taken after various irradiation times show the formation and decomposition of reaction intermediates which have been identified by comparison with reported ^{13}C chemical shift data. As can be seen in the Fig. 1, dichloroacetyl chloride (DCAC, $Cl_2CHCOCl$, doublets at δ 70 and 167), dichloroacetic acid (Cl_2CHCO_2H, doublets at δ 63 and 167) oxalyl chloride (ClCOCOCl, δ159), phosgene (CCl_2O, adsorbed, δ143 and gas phase, δ 139), trichloroacetaldehyde (CCl_3CHO, doublets at δ 93 and 177) and carbon dioxide (δ 123) are formed during the reaction. The major products are phosgene and CO_2 with small quantities dichloroacetic acid and trichloroacetaldehyde remaining at the end of the reaction.

Although these results demonstrate the photocatalytic behavior of the coated optical fibers, the question as to whether the

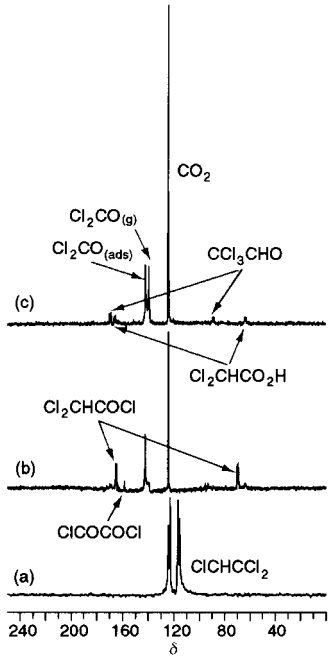

Fig. 1 Proton-decoupled ^{13}C MAS NMR spectra obtained during the photooxidation of 48 μmol of TCE and 96 μmol of O_2 on the TiO_2 coated optical fibers irradiated in the end-on configuration for (a) 0, (b) 30 and (c) 150 min. The spinning rate was 3 kHz.

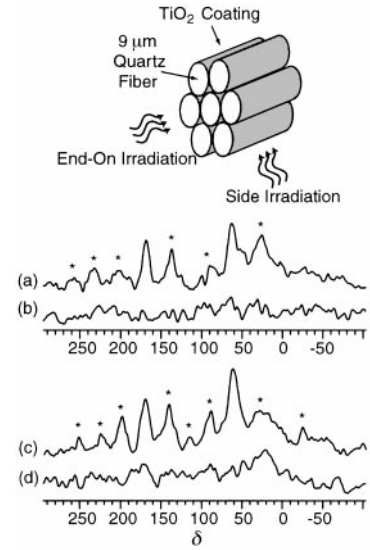

Fig. 2 ^{13}C proton-decoupled CP MAS spectra of chemisorbed dichloroacetate collected with ^{1}H–^{13}C cross polarization (contact time = 3 ms): (a) before end-on irradiation; (b) after end-on irradiation for 120 min; (c) before side irradiation; (d) after side irradiation for 150 min. The spinning rate was 3.0 kHz and asterisks denote spinning sidebands.

light is penetrating to the interior of the sample remained. This issue was explored by monitoring the formation and degradation of DCAC, which is known to chemisorb to the TiO_2 surface by reaction with hydroxyl groups to form dichloroacetate. The degradation of dichloroacetate requires additional UV photons, and thus its persistance under continued irradiation indicates the presence of dark regions within the sample.[7] In the case of the TiO_2-coated optical fibers, the concentration of dichloroacetate was maximized by stopping the photocatalysis of TCE after 30 min (when the DCAC concentration was highest) and storing the sample in the dark for several days to allow the DCAC to react with the surface hydroxyl groups. The sample was then broken open and evacuated to remove all non-surface bound species. Oxygen was reintroduced and the sample flame sealed. Fig. 2 shows the ^{13}C NMR spectrum taken using cross polarization (CP) and MAS conditions. Surface bound dichloroacetate has two isotropic peaks (δ 64 and 177) as well as a number of spinning sidebands. Subsequent irradiation of this sample in the end-on configuration shows the loss of the acetate signal [Fig. 2(b)] indicating that light is indeed reaching the interior of the sample. The experiment was repeated with the light directed towards the side of the sample and the degradation of the acetate [Fig. 2(c), (d)] was also observed, although the rate was slower. At this time, the mechanism for light transmission to the interior of the sample is not known. It is likely that the photons propagate down the microfibers, and that side irradiation is successful because the TiO_2 layer is not thick enough to absorb all of the photons.[14] Alternatively, it may be that the coated microfibers are able to create void spaces within the powder allowing the light to propagate between the particles which may also explain the success of side irradiation. Future experiments are planned to explore this issue further.

In summary, we have demonstrated that supporting TiO_2 powders on optical microfibers decreases light scattering, permitting study of the surface photochemistry with SSNMR. Efforts are currently underway to expand this methodology to other photochemical systems where light scattering is problematic, such as zeolite photochemistry.[15]

Received (in Cambridge, UK) 15th March 1999, Accepted 12th April 1999

Biologically important planar five-ring aromatic bases as their imidazolium and pyrazolium cations form crystalline 2 : 2 complexes with dibenzo-18-crown-6, creating one-dimensional arrays in a polar crystal lattice.

Supramolecular complexation, where the main binding force is π-stacking or charge-transfer interaction between two aromatic units, has recently attracted increasing attention.[1] These interactions have been utilised for example in the preparation of catenanes and rotaxanes and their precursor complexes.[2] Carbocations such as tropylium ion also form supramolecular complexes, where the charge-transfer interaction is the dominant binding force.[3] The biologically important nitrogen-containing heterocycle imidazole and its isomer pyrazole form planar five-membered organic cations when treated with the proper acid. The cations are bis-functional and can interact with crown ether type host structures both by hydrogen bonding to the ether oxygen atoms and/or by charge-transfer interactions to the electron rich phenyl rings of the crown ether.[4] In this work we have prepared and characterised such complexes and found out that dibenzo-18-crown-6 (DB18C6) complexes form polar crystal lattices with very interesting structural features.

The DB18C6·imidazolium complex **6**† is much more stable (NMR titration in CD_3CN solution, Table 1) than the corresponding π–π tropylium complex (5.6 dm^3 mol^{-1}),[3] indicating additional H-bonding in the former compound. For the imidazolium perchlorate the highest stability constant was measured for 18-crown-6 (18C6) owing to the H-bonding to the ether oxygen atoms. The stability constants for the benzo and dibenzo crown ethers were, however, nearly 50% lower. This implies a competing complexation behaviour between H-bonding and π-stacking/charge-transfer interactions for the imidazolium complex. The stability constant of DB24C8 was close to the corresponding value of tropylium cation[3] (10.2 dm^3 mol^{-1}) and manifests complexation predominantly *via* π–π interactions. The aromatic ring in the crown ether decreases electron density in the adjacent oxygen atoms, which seems to result in higher stability of the 18C6·imidazolium complex. The stability constant of the DB18C6·pyrazolium complex **7** is much higher than that for the DB18C6·imidazolium complex. This can be rationalised by the suitable stereochemistry of two simultaneously-acting intracomplex (Scheme 1) hydrogen bonds.

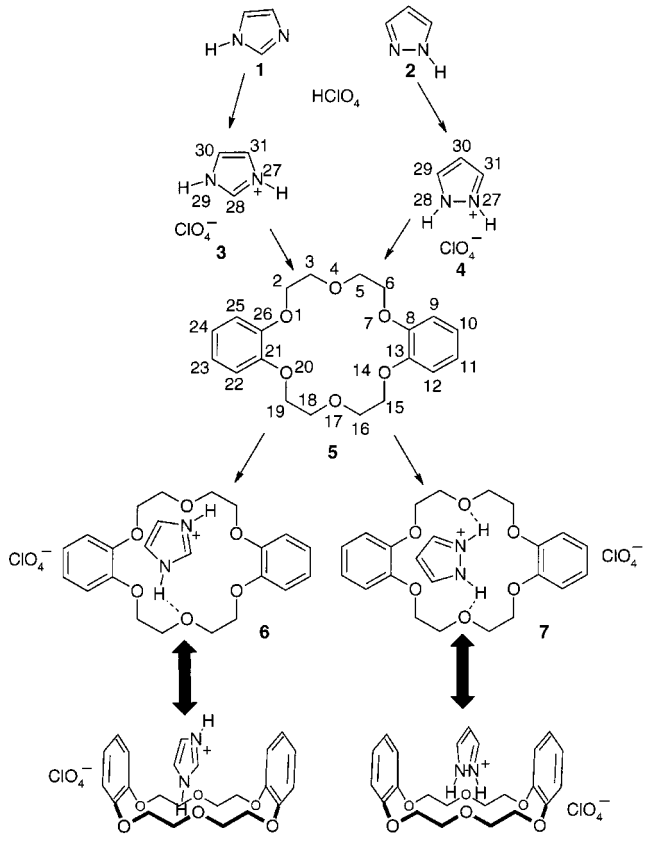
Table 1 Stability constants and limiting shifts for the interaction of crown ethers with imidazolium and pyrazolium ions in CD_3CN at 303 K

Host	K_a/dm^3 mol^{-1}	$\Delta\delta_C$/ppm	$r^{2\,a}$
Imidazolium perchlorate			
DB24C8	8 ± 1	0.36 ± 0.04	0.993
DB18C6	27 ± 5	0.50 ± 0.06	0.977
B18C6	25 ± 1	0.62 ± 0.01	0.999
18C6	40 ± 1	0.563 ± 0.004	0.999
Pyrazolium perchlorate			
DB18C6	113 ± 6	0.197 ± 0.003 (H-3,5)	0.995
	65 ± 1	0.463 ± 0.004 (H-4)	0.999

[a] Regression correlation for Benesi–Hildebrandt plot.

In the crystalline state,‡ however, the structures of **6** and **7** are surprisingly similar. In both cases the complexes crystallised out in an acentric monoclinic space group (*Cc*) due to a spontaneous resolution. The crown ether offers two interaction sites, a structurally minor site that is formed by the OCH_2CH_2O chains of the crown and a structurally major site situated between the phenyl rings. These two sites, both capable of inclusion of a planar guest, have a 90° angle towards each other and are facing opposite directions (Fig. 1). The simultaneous inclusion of a guest into the both sites during the packing creates a one-dimensional array of host–guest complexes with a 90° turn between the adjacent DB18C6 molecules.

Although formally complexes are 1 : 1 complexes in solution, the crystal packing can only be described as a 2 : 2 complex. The



Scheme 1

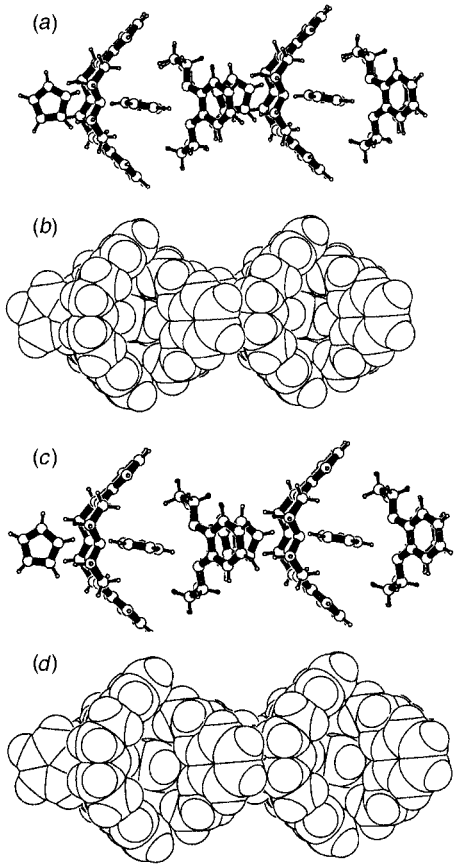


Fig. 1 PLATON (ref. 8) plot for the packing of complexes **6** and **7** into one-dimensional arrays. Four adjacent complexes are shown as ball-and-stick and VDW presentations: (*a*) and (*b*) for **6** and (*c*) and (*d*) for **7**.

polarity of the crystal is caused by the interaction of the adjacent one-dimensional arrays. The arrays all pack in the same direction, thus creating a polar axis in the crystal lattice. The existence of the H-bonding and the weak charge transfer interaction is evident for both structures. The imidazolium cation in **6** has one intracomplex H-bond to the major site of its host [N27···O4 = 2.823(7), H27···O4 = 1.99(9) Å and angle 148(7)°] and two weaker intercomplex H-bonds to the minor site of the adjacent host [N29···O1′ = 3.022(7), H27···O1′ = 2.28(8) Å and angle 132(6)°; N29···O20′ = 3.048(7), H27···O20′ = 2.19(8) Å and angle 144(6)°]. The distance between the centroids of the cation and the nearest phenyl ring is 4.12(1) Å, indicating a weak charge-transfer interaction. The pyrazolium cation in **7** is more strongly bound into the major site of its host by two H-bonds [N27···O17 = 2.71(1), H27···O17 = 1.88 Å and angle 155(1)°; N28···O4 = 2.79(1), H28···O14 = 1.91(12) Å and angle 174(1)°]. The charge-transfer interaction is similar to that in complex **6** [distance between closest centroids is 4.04(1) Å]. The interaction in complex **7** to the minor site of the adjacent host is much weaker (H···O′ distances vary from 2.59 to 3.45 Å) than in the case of complex **6**. The adjacent guests inside the arrays of **6** and **7** are surprising close to each other, the non-bonded contact distance between the closest adjacent H-atoms are 2.82 Å for **6** (H31···H29′) and 2.83 and 2.96 Å for **7** (H30···H27′ and H30···H28′, respectively).

The structures presented here are interesting from the crystal engineering[5] and supramolecular technology[6] points of view. This type of tightly packed one-dimensional molecular arry could form a matrix for (photo)chemical reactions leading to advanced molecular wires and similar new materials. The close proximity of the guests inside the array is a feature not frequently encountered in crystal lattices and could, with the use of larger crown ethers and functionalised guests, lead to new tailor-made polymers or polyrotaxanes.

Notes and references

† *Synthesis and characterisation*: The imidazolium and pyrazolium salts were prepared according to a published procedure (ref. 7). The complexes were prepared by mixing equimolar amounts of the above salt and DB18C6 MeCN solutions. The complexes **6** and **7** precipitated soon after mixing of the components or after addition of anhydrous Et_2O.

Selected data for **6**: 54%, mp 215–220 °C; *m/z* (FAB, NBA matrix) 429 [DB18C6·$C_3N_2H_5$ − ClO_4]$^+$; δ_H(200 MHz, CD_3CN, 25 °C) 3.8 (m, OCH_2, 8H), 4.1 (m, OCH_2, 8H), 6.9 (s, aryl, 8H) 7.4 (d, imidazolium, 2H), 8.8 (t, imidazolium, 1H) ($C_{23}N_2H_{29}ClO_{10}$ (528.93): calc. Solid-state electrogenerated chemiluminescence in sol–gel derived monoliths

Maryanne M. Collinson* and Skylar A. Martin†

Department of Chemistry, 111 Willard Hall, Kansas State University, Manhattan, KS 66506-3701, USA. E-mail: mmc@ksu.edu

Received (in Bloomington, IN, USA) 11th February 1999, Accepted 29th March 1999

Stable solid-state electrogenerated chemiluminescence has been achieved by trapping the chemiluminescent precursors, ruthenium(II) tris(bipyridine) and tripropylamine, in a porous silicate host matrix prepared by the sol–gel process and exciting them electrochemically *via* an immobilized microelectrode assembly.

The development of new technology and methods for the fabrication of large area emissive panels and displays with low operating voltages is important in the electro-optics industry. Conjugated polymers (*i.e.* the organic semiconductors) have received considerable attention due to the ease at which they can be prepared, processed, and modified.[1–2] To a lesser extent, electrogenerated chemiluminescence[3] (ECL) based materials have also been investigated. These materials hold considerable promise because the ECL can be generated with relatively low voltage bias and with reasonably high efficiency.

To date, several approaches to solid-state ECL have been investigated. Abruna and Bard initially showed in the 1980s that ECL can be observed from electropolymerized films of $Ru(vbpy)_3^{2+}$ (vbpy = 4-vinyl-4′-methyl-2,2′ bipyridyl) on platinum electrodes in acetonitrile *via* sequential oxidation and reduction of the immobilized redox centers.[4] Similar results have also since been observed with chemiluminescence or conjugated polymers prepared from diphenylanthracene and polyphenylenevinylene derivatives.[5,6] More recently, solid-state ECL has been observed from poly$[RuL_3]^{2+}$ (L = vbpy or ester substituted bipyridine) films prepared on interdigitated array electrodes or in a sandwich type arrangement.[7,8] Light emission results from the reaction between RuL_3^{+} and the RuL_3^{3+} states formed *via* independent control of the potentials of the closely spaced electrodes.[7,8] When fixed concentration gradients are established in the film, the system gives rise to ECL in the *absence of solvent*.[7,8] In related work, Rubner and coworkers have also noted solid-state ECL from ruthenium derivatives trapped in an ionic polymer or bound to the polymer framework and sandwiched between two electrodes.[9]

In this work, an entirely different approach has been taken to generate ECL in the absence of solution. Ruthenium(II) tris(bipyridine) [$Ru(bpy)_3^{2+}$] and tripropylamine (TPA) have been encapsulated, along with a microelectrode assembly, in a porous, solid host prepared *via* the sol–gel approach.[10,11] This ECL system was chosen because it allows the luminescence to be generated at a relatively *low* potential bias in an *aqueous* environment.[12,13] The known immunity of the $Ru(bpy)_3^{2+}$–TPA system to water will likely improve the long term stability of the ECL. In this system, emission results when the TPA amine radical formed upon reduction of $Ru(bpy)_3^{3+}$ or *via* direct electrode oxidation reacts with another $Ru(bpy)_3^{2+}$ or additional $Ru(bpy)_3^{3+}$ to form $[Ru(bpy)_3^{2+}]^*$ which then decays to produce orange emission centered at 610 nm.[12,13] The original $Ru(bpy)_3^{2+}$ species is regenerated during the reaction, albeit with consumption of TPA.[12,13] In contrast to previous studies[4–7,9] where the ECL decayed on the timescale of seconds to tens of minutes and often required an inert atmosphere, this approach yields stable emission for over *two hours* under room conditions.

† Current address: Department of Chemistry, Truman State University, Kirksville, Missouri 63501, USA.

In these experiments, the silica sol was prepared by mixing tetramethoxysilane (Aldrich, 98%) with water and 0.1 M hydrochloric acid followed by rapid stirring for at least 2 h. The hydrolyzed sol was doped with $[Ru(bpy)_3]Cl_2$ (Aldrich) and stirred for 45–90 min. A 2 mL aliquot of the doped sol was pipetted in a silanized glass vial[14] housing the microelectrode assembly.[15] 1 mL of TPA (Aldrich, 99%) in pH 7.0, 0.1 M phosphate buffer was then added to the sol and the resultant solution quickly mixed. The gel was aged for 2–3 days and dried for 1–2 days at a relative humidity of 60–70% by exposing a small hole (*ca.* 2 mm diameter.) in the cap to the atmosphere. Very little shrinkage ($< 10\%$) in volume was observed. The solid-state electrochemical cell was placed in a dark box *ca.* 3.5 cm from the photocathode of a Hammamatsu 4632 photomultiplier tube and the data collected with a multichannel scaler (photon counter, EGG Ortec T-914). Either a Pine AFRDE5 bipotentiostat or a BAS 100 potentiostat was used to apply the excitation waveform (linear sweep or potential step).

Fig. 1(a) shows cyclic voltammograms (CVs) of gel-encapsulated $Ru(bpy)_3^{2+}$ at a 13 μm radius Pt ultramicroelectrode acquired at 10 mV s^{-1} (solid line). In the absence of TPA, the voltammograms are steady state in nature and superimposed on a relatively large rising background from solvent oxidation. As the sweep rate is increased (up to 10 V s^{-1}), the

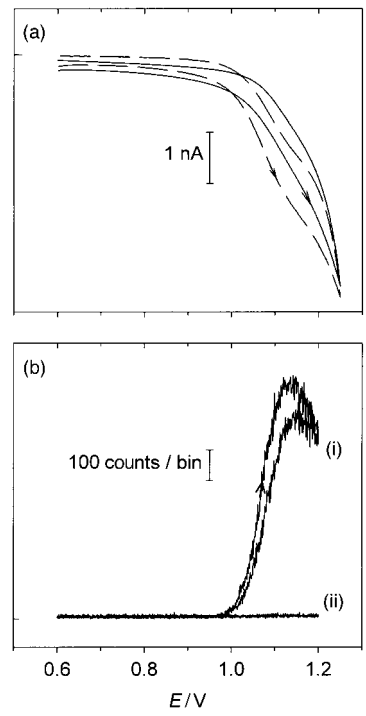

Fig. 1 (a) Cyclic voltammograms of gel-encapsulated $Ru(bpy)_3^{2+}$ (solid line) and gel encapsulated $Ru(bpy)_3^{2+}$ and TPA (dashed line) at a 13 μm radius Pt microdisk electrode. Scan rate: 10 mV s^{-1}. (b) Corresponding intensity–potential curves for gel-encapsulated $Ru(bpy)_3^{2+}$ (i) and gel-encapsulated $Ru(bpy)_3^{2+}$ + TPA (ii). Precursor concentrations in the sol: 10 mM $Ru(bpy)_3^{2+}$ or 10 mM $Ru(bpy)_3^{2+}$ + 10 mM TPA. Bin size = 100 ms.

voltammograms become more peak shaped in appearance due to the onset of planar diffusion (data not shown).[16,17] A half-wave potential ($E_{1/2}$) of *ca.* 1.1 V was estimated from the voltammograms acquired at 100–1000 mV s^{-1}. This value is consistent with that previously measured for both solution and gel-encapsulated $Ru(bpy)_3^{2+}$.[18] In the presence of TPA, the oxidation current for gel-entrapped $Ru(bpy)_3^{2+}$ increases consistent with the oxidative–reduction mechanism for $Ru(bpy)_3^{2+}$ ECL [Fig. 1(a)], dashed line). The relatively facile nature at which gel-entrapped $Ru(bpy)_3^{2+}$ and TPA can diffuse in the gel and be oxidized at the electrode surface is evident in the shapes of the voltammograms acquired at 10–1000 mV s^{-1} and the resultant luminescence. Although the gel is macroscopically rigid, it is microscopically porous and hydrated.[19,20] Prior work has shown the diffusion coefficients of redox molecules trapped with these solids during the initial stages of drying to be nearly identical to values measured in solution (10^{-6} cm^2 s^{-1}).[19,20]

Corresponding ECL-potential curves for these materials are shown in Fig. 1(b). In the absence of either TPA or $Ru(bpy)_3^{2+}$, no significant ECL emission can be observed at the Pt microdisk electrode. Only when both reagents are present can the ECL be observed. The onset of luminescence is contiguous with the oxidation of gel-encapsulated $Ru(bpy)_3^{2+}$ and TPA and peaks near 1.15 V. It is not fully understood at the present time why the ECL intensity becomes lower as the electrode potential is scanned significantly past $E_{1/2}$, but it may be related to quenching, solvent oxidation products or concentration polarization.

The long term stability of the ECL at the ultramicroelectrode was evaluated by repetitively cycling the electrode potential for > 30 min and also by stepping the electrode potential to a near diffusion controlled value for 2 h. The results are shown in Fig. 2. As can be seen, the light intensity is remarkably stable upon repetitive potential cycling at 10 mV s^{-1}. The ECL is typically *ca.* 5–20% lower on the first potential scan relative to subsequent cycles where near constant emission is observed. Fig. 2(b) shows the ECL emission at a 13-μm Pt microdisk electrode following a potential step from 0.6 to 1.15 V. The luminescence increases nearly immediately upon application of the potential step where it then remains at a near constant level for the duration of the experiment. Typically, < 15% drop in intensity is observed over 2 h.

The enhanced stability of the ECL can be attributed not only to the small size of the electrode which results in a decreased consumption of TPA, but also to the steady state or quasi-steady state flux of reagents to the electrode surface.[16,17] For an ultramicroelectrode, the dimensions of the diffusion layer greatly exceed that of the electrode in a relatively short period of time (*e.g.* seconds).[16,17] Because a greater population of TPA molecules are then able to diffuse to the electrode from the increased volume around the electrode, steady state is reached quickly.[16,17] Since the electrode area is very small (10^{-6} cm^2), very little TPA is consumed during the experiment (*i.e.* theoretically calculated to be ≪0.01% for a 2 h time period). Similar results were also observed using microband electrodes.

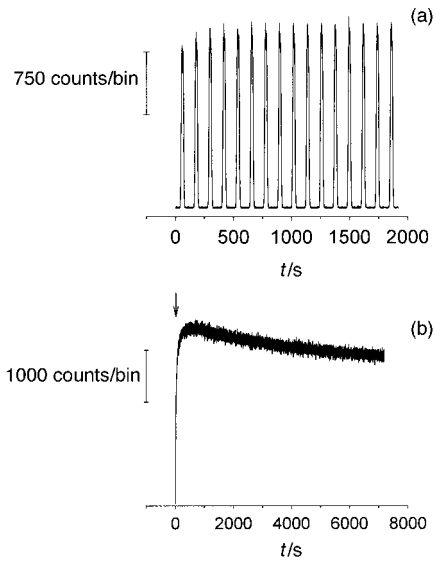

Fig. 2 Intensity–time transients during 16 repetitive potential cycles from 0.6 to 1.2 V at 10 mV s^{-1} (a) and following a potential step from 0.6 to 1.15 V (b) for gel-encapsulated $Ru(bpy)_3^{2+}$ + tripropylamine at a 13-μm radius Pt microdisk electrode. Precursor concentration in the sol: 10 mM $Ru(bpy)_3^{2+}$ + 5 mM tripropylamine. Bin size: 0.2 s (a) and 1 s (b).

In summary, the use of ultramicroelectrodes for the generation of ECL reagents in a solid host results in remarkably stable light emission under room conditions. At a microdisk electrode, the ECL remains at a near constant level upon application of a relatively low potential for time periods in excess of 2 h. One of the most promising aspects of this work is that it provides a relatively simple approach for the generation of light without the use of excess solvent, flowing streams, stringent solution conditions, or inert atmosphere. Different emission wavelengths can likely be achieved through variations in the gel-encapsulated precursor molecules. Likewise, optimization of precursor concentrations, the porosity of the host, and the electrode geometry and size, should result in greater emission intensities. Future work will be directed toward these investigations.

We gratefully acknowledge support of this work by the National Science Foundation through the NSF CAREER Award Program (CHE-9624813) and the Research Experiences for Undergraduates Program (CHE-9732103). We also like to thank Dr Rajendra Makote for useful discussions concerning the experiments and Dr Jon Howell from BAS for the trigger output modification to the BAS 100.

Bis(phospha-adamantyl)alkanes: a new class of very bulky diphosphines

Victoria Gee, A. Guy Orpen, Hirihattaya Phetmung, Paul G. Pringle* and Robert I. Pugh

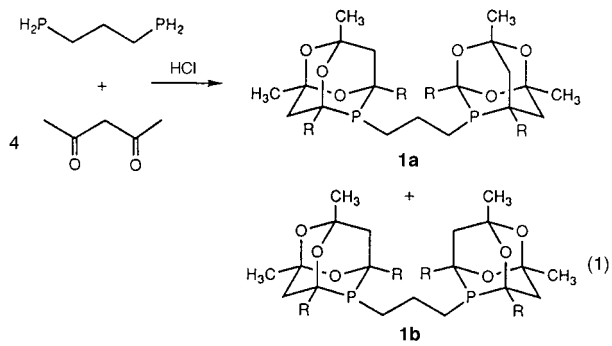
School of Chemistry, University of Bristol, Cantock's Close, Bristol, UK BS8 1TS. E-mail: paul.pringle@bristol.ac.uk

Received (in Cambridge, UK) 26th March 1999, Accepted 12th April 1999

Adamantane-like cages are formed when $H_2P(CH_2)_nPH_2$ (n = 2 or 3) react with acetylacetone or trifluoroacetylacetone and the crystal structures of the dichloropalladium(II) complexes of the C_3-diphosphine ligands show that their cone angles are much larger than $Bu^t_2P(CH_2)_3PBu^t_2$; a diphospha-adamantane derived from o-$C_6H_4(PH_2)_2$ is also described.

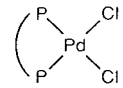
Bulky alkyl diphosphines of the type $R_2P(CH_2)_nPR_2$, (n = 1–5, R = Bu^t, Pr^i or Cy) have been at the heart of many key developments in transition metal chemistry over the last 25 years[1–7] including the stabilisation of unusual oxidation states and low coordination numbers,[1,2] formation of agostic alkyls, activation of C–H and C–C bonds,[3,4] and preparation of polyhydride complexes.[1,3,5] Recently bulky alkyl diphosphine complexes of palladium have attracted attention as carbonylation catalysts[6] and as catalysts for the Heck reaction.[7] We report here a simple route to a new class of very bulky alkyl diphosphines which are air-stable.

It has been reported that PH_3 reacts with acetylacetone[8] or trifluoroacetylacetone[9] to give adamantane-like cage secondary phosphines although no coordination chemistry of these ligands has been reported. This prompted us to attempt the synthesis of bis(phospha-adamantyl)alkanes from diprimary phosphines. Thus $H_2P(CH_2)_3PH_2$ was reacted with acetylacetone in the presence of HCl and this gave an air-stable, crystalline product which was identified as a mixture of the diastereomeric phospha-adamantane diphosphines **1a** and **1b** [eqn. (1)] on the



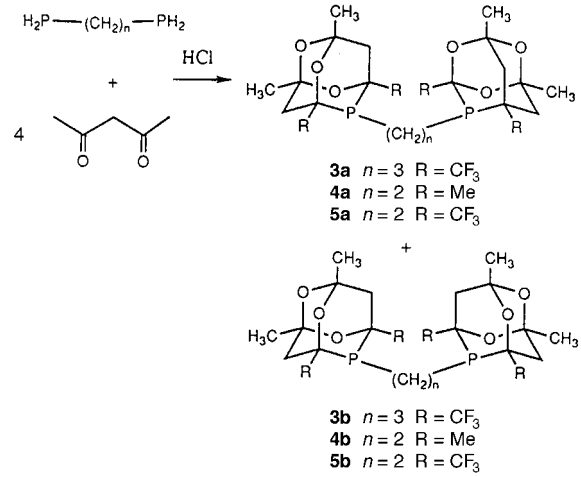
(1)

basis of elemental analysis, mass spectrometry, ^{31}P and ^{1}H NMR spectroscopy. The $^{31}P\{^{1}H\}$ NMR spectrum of the product in $CDCl_3$ showed two singlets at −31.0 and −30.2 ppm in the ratio of *ca.* 1 : 1, consistent with the presence of *rac* (**1a**) and *meso* (**1b**) diastereoisomers. Addition of MeOH to a CH_2Cl_2 solution of the mixture of ligands **1a** and **1b** leads to selective crystallisation of the *rac* isomer **1a**; in this way samples of **1a** and **1b** in purity of > 95% are readily obtained.



2a diphosphine = **1a** **2b** diphosphine = **1b**
6a diphosphine = **3a** **6b** diphosphine = **3b**
7a diphosphine = **4a** **7b** diphosphine = **4b**
8a diphosphine = **5a** **8b** diphosphine = **5b**

The dichloropalladium(II) chelates **2a** and **2b** were made by treatment of $[PdCl_2(NCPh)_2]$ with **1a** and **1b** respectively and the crystal structure of **2a**, as determined by X-ray crystallography,† is illustrated in Fig. 1. The bulk of the phospha-adamantane diphosphines is evident and the estimated cone angle[10] is 173° (*cf.* 155° for $Bu^t_2PCH_2CH_2CH_2PBu^t_2$ in its $PtCl_2$ complex[11]); furthermore there is no possibility of



(2)

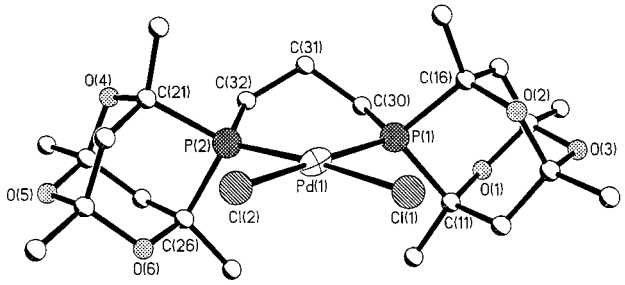


Fig. 1 Molecular structure of **2a** with all hydrogen atoms omitted for clarity.

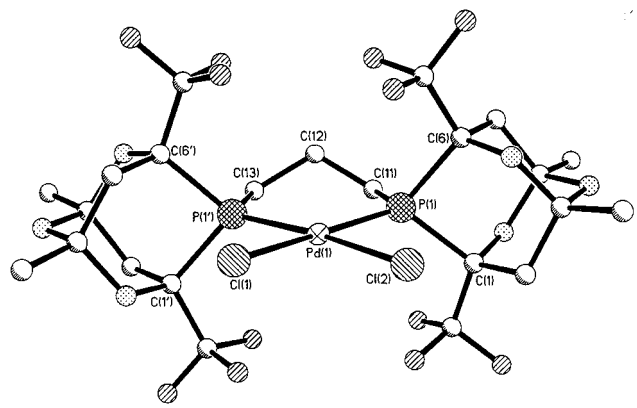

Fig. 2 Molecular structure of **6a** with all hydrogen atoms omitted for clarity. Primed atoms are related by non-crystallographic mirror symmetry.

reduction of the bulk of this ligand by intermeshing. The most unusual aspect of the geometry is the long intra-cage P–C distances and small C–P–C angles (Fig. 1). The electronic consequences of this geometric distortion at phosphorus on the metal–phosphine bond and its chemistry is currently under investigation. Methoxycarbonylation of alkenes catalysed by derivatives of **2a** and **2b** has recently been reported.[12]

The condensation reaction shown in eqn. (1) can be generalised to other diphosphines and other acetylacetones [eqn. (2)]. Hence the ligands **3**–**5a**,**b** have been made in high yield as mixtures of diastereoisomers using the appropriate $H_2P(CH_2)_nPH_2$ and 1,3-diketone. Preliminary results show that the corresponding dichloropalladium chelates **6**–**8a**,**b** can be made and the crystal structure of **6a** (Fig. 2)† reveals the great steric bulk of the coordinated diphosphine **3a**, with an estimated cone angle of 192°.

A different type of product was obtained when 1,2-diphosphinobenzene was added to acetylacetone in the presence of HCl. The structure of the product was assigned to the diphospha-adamantane **9** on the basis of the symmetry of its ^{1}H, ^{13}C{^{1}H} and ^{31}P{^{1}H} NMR spectra and the structure was confirmed by X-ray crystallography.† The diphosphine **9** reacts with [AuCl(tht)] to give the binuclear gold(I) complex **10** which has also been characterised by X-ray crystallography (Fig. 3).†

The mechanism for the formation of the monophospha-adamantanes has been previously discussed[9] and a mechanism for the formation of the diphospha-adamantane cage **9** is suggested in Scheme 1. The rigidity of the phenylene backbone promotes the formation of **9** because the pendant PH_2 group in **A** is held in close proximity to the electrophilic carbon thus facilitating the ring closure step ii.

We have shown that diphosphines featuring very bulky, rigid, phospha-adamantane cages are readily accessible in one step from primary diphosphines. The extension of this work to other diprimary phosphines and other 1,3-diketones is being explored alongside investigation of the coordination chemistry and applications of these remarkable ligands. We thank EPSRC, Albright and Wilson and Shell International for supporting this work and Johnson Matthey for a loan of palladium compounds.

Theoretical evidence of a feasible concerted *antara–antara* cycloaddition

José I. García*, José A. Mayoral and Luis Salvatella*

Departamento de Química Orgánica, Instituto de Ciencia de Materiales de Aragón, Facultad de Ciencias, Universidad de Zaragoza-C.S.I.C. Pedro Cerbuna, 12, E-50009 Zaragoza, Spain. E-mail: jig@posta.unizar.es

Received (in Liverpool, UK) 8th March 1999, Accepted 7th April 1999

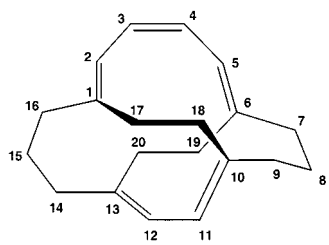
For the first time it is demonstrated, based on theoretical considerations, that concerted *antara–antara* cycloadditions are chemically possible, and even easy to observe for molecules with the appropriate geometry.

Since the discovery of the Diels–Alder reaction in 1928,[1] cycloadditions[2] have become very useful tools in organic synthesis.[3] One of the main features of these reactions is that they frequently follow concerted mechanisms, which accounts for the stereospecificities observed. Many aspects of cycloaddition reactions have been explained by means of the Woodward–Hoffmann rules.[4] According to these rules, two types of reactivity can be considered for each of the reactants involved: *supra* (if newly forming sigma bonds are situated on the same face of the π-system) and *antara* (if these bonds are situated on opposite faces). Since concerted cycloadditions involving more than two reactive systems seem to be very unlikely,[5] cycloadditions can thus be classified as *supra–supra*, *supra–antara* and *antara–antara*. It is worth mentioning that each of these possibilities would lead to compounds with different stereochemistries.

The *supra–supra* mechanism is involved in most of these reactions, for example Diels–Alder[6] and 1,3-dipolar cycloaddition reactions.[7] On the other hand, the *supra–antara* pathway is much less common[8] and it has recently been disregarded for the ketene + cyclopentadiene reaction,[9] which was, up until then, considered a typical example from theoretical considerations. Theoretical calculations on the ethylene dimerization reaction indicate that the concerted mechanism is not favoured.[10] Finally, to the best of our knowledge, the concerted *antara–antara* cycloaddition mechanism has never been invoked for any chemical reaction to date.

The Woodward–Hoffmann rules predict that *antara–antara* cycloadditions are allowed in the same cases as the *supra–supra* ones, *i.e.* thermal reactions involving $2n + 2$ π electrons and photochemical reactions involving $2n$ π electrons. Competition with the *supra–supra* mechanism could explain the lack of experimental evidence for the occurrence of *antara–antara* cycloadditions, the latter being generally disfavoured because of the molecular distortion necessary to obtain the adequate geometrical requirements in the transition states (TSs). However, the question remains; are concerted *antara–antara* cycloadditions really impossible from an experiment point of view?

In our search for chemical systems for which this kind of mechanism was plausible, we considered the [6 + 4] cycloadditions as a good starting point, given that the combination of triene + diene may offer the flexibility required for an *antara–antara* approach. Thus, the reaction between *cis* hexa-1,3,5-triene and buta-1,3-diene was chosen as a model example, and, using Density Functional Theory calculations,[11] we were able to build a template for the corresponding *antara–antara* TS. Examination of this structure suggested to us that the simplest way to obtain a chemical system able to give a cycloaddition through a concerted *antara–antara* mechanism would consist of freezing the spatial arrangement of the atoms in the corresponding transition structure. This action would diminish the contribution of the reactive distortion to the activation barrier. With this aim in mind we designed the molecule



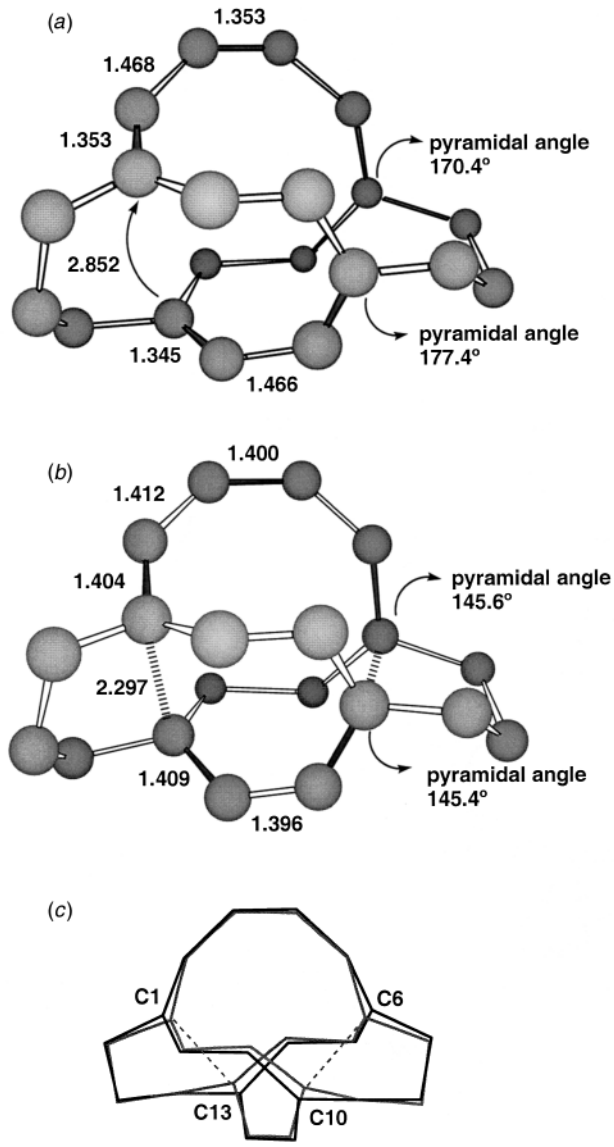


Fig. 1 Some calculated [at the B3LYP/6-31G(d) level] geometrical features of (*a*) antarene and (*b*) the corresponding TS for the *antara–antara* [6 + 4] cycloaddition, and (*c*) a superimposition of the two structures. Hydrogen atoms are omitted for clarity.

Table 1 Relative energies, enthalpies, free energies and entropies of the structures involved in the *antara–antara* [6 + 4] cycloaddition of antarene, calculated at the HF/6-31G(d) and B3LYP/6-31G(d)[a] theoretical levels

Level	Structures	ΔE_0/kcal mol^{-1}	ΔH_{298}/kcal mol^{-1}	ΔG_{298}/kcal mol^{-1}	ΔS_{298}/cal mol^{-1} K^{-1}
HF/6-31G(d)	Reactant	0.0	0.0	0.0	0.0
	TS	49.7	47.4	48.5	−3.8
	Adduct	−29.0	−27.9	−26.1	−6.2
B3LYP/6-31G(d)	Reactant	0.0	0.0	0.0	—
	TS	16.0	13.7	14.9	—
	Adduct	−23.6	−22.6	−20.7	—

[a] Using the frequencies HF/6-31G(d) for thermochemical data.

(1*Z*,3*Z*,5*Z*,10*Z*,12*Z*)-tricyclo[8.6.2.2^{6,13}]icosa-1,3,5,10,12-pentaene, hereafter referred to as 'antarene'.

Fig. 1(*a*) shows some geometrical parameters of this molecule, calculated at the B3LYP/6-31G(d) theory level. As can be seen, antarene consists of the hexatriene and butadiene moieties, linked by two trimethylene and two ethylene bridges in such a manner that the *antara–antara* disposition of the reactive parts of the molecule are strongly enforced. The transition structure of the intramolecular [$_\pi 6_a + {}_\pi 4_a$] cycloaddition of antarene could be found at the B3LYP/6-31G(d) level[16] [Fig. 1(*b*)]. This transition structure shows C_2 symmetry, corresponding to a concerted and synchronous process with newly forming bond lengths of 2.297 Å.

Relative energies for the structures involved (Table 1) show that the reaction is exothermic (22.6 kcal mol^{-1}) and presents a low barrier of activation (16.0 kcal mol^{-1}). Since the geometrical constraints of antarene are assumed to make other competitive reactions very difficult, one can deduce that antarene must react through a concerted *antara–antara* cycloaddition mechanism. Fig. 1(*c*) also illustrates this point, showing that the only noticeable geometrical difference between antarene and the transition structure is the displacement of the carbon atoms involved in the formation of the new signma bonds, caused by the change of hybridization from sp^2 to sp^3. As a consequence of the rigidity of the structure, and of the small degree of atomic reorganization along the reaction path, the activation entropy is as low as −3.8 cal mol^{-1} K^{-1}. In fact, the free activation energy is so low (*ca.* 15 kcal mol^{-1}) that one can deduce that antarene should not be very stable in solution at room temperature!

Antara–antara cycloadditions, whose feasibility we have demonstrated for the first time from theoretical considerations, open the door to the synthesis of medium-sized and macropolycycles with unique stereochemical features, and hence to new compounds with different properties.

11 Calculations were carried out by means of the Gaussian 94 package (ref. 12) using the Hartree–Fock and Density Functional Theory [through the B3LYP hybrid functional (ref. 13)] levels and the 6-31G(d) basis set (ref. 14). B3LYP/6-31G(d) calculations are known to perform well as regards cycloaddition reactions (ref. 15). The nature of all stationary points (reactants, transition structures and adducts) was tested by means of frequency calculations, which also served to calculate the thermodynamic parameters of the reactions considered.

16 The transition structure search was performed without any geometrical constraint at the HF/6-31G(d) and B3LYP/6-31G(d) levels, leading to very similar geometries. The nature of the transition structure was fully characterized by the presence of only one imaginary frequency, correponding to the symmetric stretching of the four atoms involved in the formation of the sigma bonds. Frequency calculations were only carried out at the HF/6-31G(d) level, due to the size of the system.

Cyclic alkynes–electronic behaviour as a function of ring strain

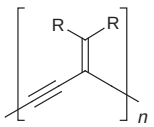
Rik R. Tykwinski

Department of Chemistry, University of Alberta, Edmonton, Alberta, Canada T6G 2G2. E-mail: rik.tykwinski@ualberta.ca

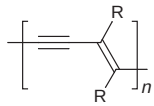
Received (in Corvallis, OR, USA) 2nd February 1999, Accepted 2nd April 1999

UV/Vis spectroscopic analysis of a series of cross-conjugated enediyne macrocycles as a function of increasing ring strain and planarity shows little effect on the electronic absorptions of the macrocycles, despite an obvious rehybridization of the alkylidene carbon atoms as evidenced by ^{13}C NMR spectroscopy.

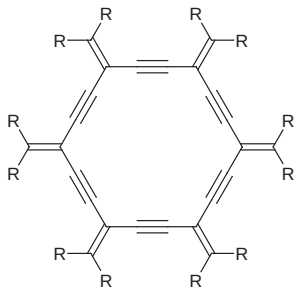
Conjugated organic compounds have considerable potential as materials for electronics and photonics.[1] We are interested in the electronic characteristics of cross-conjugated oligomers



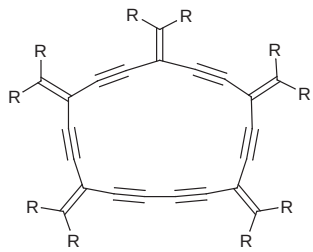
1



2



3



4

such as *iso*-polydiacetylenes (*iso*-PDAs, **1**)[2] and the comparison of their properties to the more prevalently studied compounds, *e.g*. polydiacetylenes **2**, that contain linear conjugation.[3] In the course of investigating the effects of cross conjugation in the cyclic analogues of **1**, namely radialenes **3** and **4**,[4] it became necessary to evaluate the influence of ring strain on the electronic absorption behavior of these molecules.[5–11] Reported herein is the synthesis of a novel series of cross-conjugated, enyne macrocycles[4,12–14] (cyclic expanded dendralenes)[15] and their UV/Vis absorption characteristics as a function of ring strain and planarity.

The macrocyclic enynes **8a**–**c** were constructed as outlined in Scheme 1. Vinyl triflate **5** (2.2 equiv.)[16] was coupled with the commercially available diynes **6a**,**b** and **6c**[17] in DMF in the presence of Et_2NH, CuI and $Pd(PPh_3)_4$.[2] The coupling process proceeded rapidly at room temperature as monitored by TLC, and column chromatography (silica gel, hexanes–CH_2Cl_2 20:1) afforded fair yields of tethered enediynes **7a**–**c**.† Compounds **7a-c** were protodesilylated with K_2CO_3 in MeOH–THF (1 : 1) for 2–3 h to afford the terminal alkynes. The desilylation was essentially quantitative, and (following aqueous work-up) the products were immediately carried on to the next step. Oxidative acetylenic coupling of the respective terminal alkynes of **7a**–**c** was conducted in CH_2Cl_2 (*ca*. 0.001 M) in the presence of CuI and TMEDA.[18] Under these relatively dilute conditions, the coupling reactions were complete in *ca*. 4–5 h. Macrocycles **8a**–**c** were isolated in modest yields as white solids by column chromatography (SiO_2, hexanes–CH_2Cl_2 4:1).‡ Oligomers resulting from intermolecular oxidative coupling of the acetylenic precursors were observed as the major side-products. Unfortunately, this intermolecular coupling process effectively competed with intramolecular cyclization despite the use of increasingly dilute reaction conditions. The isolated macrocycles are thermally stable, and even the highly strained **8a** was stable as a crystalline solid to well above 100 °C. Under ambient conditions in the presence of oxygen, all cycles slowly decompose over a period of days. They can, however, be stored under refrigeration for months with minimal decomposition.

The structure of the most strained cyclic dendralene **8a** was confirmed by X-ray crystallographic analysis of a single crystal grown by diffusion of MeOH into a $CHCl_3$ solution at 4 °C.§ An ORTEP drawing of **8a** is shown in Fig. 1, and, interestingly, it shows that in the solid state this molecule is not C_2 symmetrical as might be expected. Whereas all of the alkyne moieties are strained, with angles much smaller than an ideal 180°, the angles of enediyne segment C(4)–C(5)–C(6)–C(7)–C(8) bear the majority of this strain with C(4)–C(5)–C(6) bent to just over 160°. The conjugated enyne portion of macrocycle **8a** is only slightly twisted from planarity, with a torsion angle between C(14)–C(13) • • • C(7)–C(8) of 3°. The enediyne bond angles C(14)–C(1)–C(2) and C(5)–C(6)–C(7) at *ca*. 111 and 108° are both smaller than the analogous angles of an acyclic *iso*-PDA at *ca*. 115°.[2] Despite the strained nature of macrocycle **8a**, there are no anomalous bond lengths when compared to the *iso*-PDA. The crystal structure of **8a** provides a quite remarkable example of the significant ability of packing forces to distort molecular structure in the solid state as compared to solution.¶

The ^{1}H and ^{13}C NMR spectra of macrocycles **8a-c** are completely consistent with their macrocyclic structures. Particularly interesting are the shifts of the alkylidene carbons. As the size of the macrocycle is decreased from 17 to 15 to 14 carbons in **8c**, **8b** and **8a**, respectively, a consistent shift is observed for the ^{13}C resonances of the olefinic carbons. The ^{13}C resonance of the endocyclic vinylidene carbon of **8c**, representing that of an unstrained system, is found at δ 82, whereas the analogous ^{13}C resonances of **8b** and **8a** are deshielded to δ 88 and 90, respectively. These shifts likely result from rehybridization effects as bond angle deformation imparts greater p character to the σ-bonds of the ring and, consequently, more s character to the olefin. The chemical shifts of the exocyclic vinylidene carbons, affected to a lesser extent, are consistently shifted upfield from δ 151 in **8c** to δ 149 and 147 for **8b** and **8a**, respectively. These ^{13}C resonances clearly reflect the expected rehybridization of the ring carbons as a function of decreased bond angles and increased ring strain.[12,19]

The UV/Vis spectra of the new macrocycles **8a-c** were examined to determine if the varied hybridization of the ring carbons affected the electronic absorption characteristics. In addition, the increased rigidity and enforced planarity as the ring size is decreased could also influence the respective electronic absorptions as observed previously for radialenes.[20] Unexpectedly, the electronic absorption spectra for **8a-c** (Fig. 2) show no variation in energy of the lowest energy electronic absorptions. These absorptions, presumably arising from the linearly conjugated dienediyne segment of each macrocycle, are observed at virtually identical values of 290, 309 and 329 nm. The absorption peaks do, however, gradually broaden as the ring size, and hence flexibility, is increased from 14 to 15 to 17 carbons. The absence of electronic absorption changes between *e.g.* **8a** and **8c** also suggests little or no contribution to π-electron delocalization *via* homoconjugation, as might be

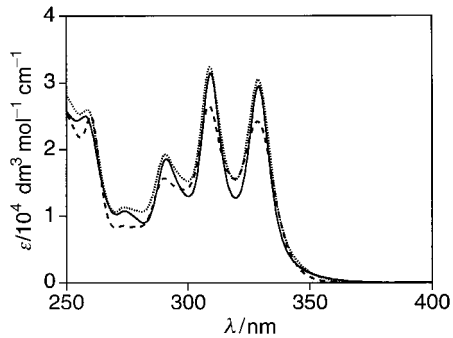

Fig. 2 Electronic absorption spectra in $CHCl_3$ comparing cyclic alkynes **8a** (———), **8b** (• • • • •) and **8c** (– – – – –).

anticipated from the constricted ring size that forces the in-plane acetylenic sp orbitals to closer spatial proximity.[21]

The syntheses of more strained derivatives of **8** (n = 2, 3) are currently being pursued, as is the analogous series of macrocycles containing the ene-yne-ene segment of **3**. Together, these additional analogues will further detail the influence of ring strain on π-electron delocalization.

This work was supported by a Gen-Science Endowment from the University of Alberta and by NSERC of Canada. I thank Dr R. McDonald for the X-ray structural determination of **8a**.

21 A change in absorption energy as a result of angle deformation would also be expected for the in-plane π-system of the central butadiyne moiety of **8a-c**, as has been previously shown for cycloalkynes (ref. 8). Whereas absorptions are observed in the expected region of the butadiyne segment (*ca.* 250–275 nm) of **8a-c**, interpretation of shifts is, at this point, inconclusive. The expected absorption range of 250–275 nm is based on the lowest energy absorptions of known butadiyne derivatives, see: J. B. Armitage and M. C. Whiting, *J. Chem. Soc.*, 1952, 2005. I thank one of the reviewers for helpful suggestions.

Porphyrin derivatives as water-soluble receptors for peptides†

Mallena Sirish and Hans-Jörg Schneider*

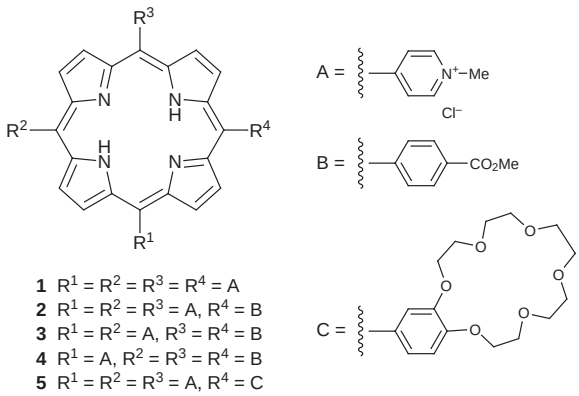
FR 11.2 Organische Chemie der Universität des Saarlandes, D-66041 Saarbrücken, Germany. E-mail: ch12hs@rz.uni-sb.de

Received (in Cambridge, UK) 17th February 1999, Accepted 13th April 1999

The porphyrin–crown ether derivatives described here exhibit affinities to unprotected peptides of hitherto unknown magnitude in aqueous solution; the optical signal built-in to porphyrin receptors makes these applicable also to sensor techniques; the results can also form the basis of new catalytic systems, *e.g.* for the catalytic oxidation of peptides (such as tyrosinase models).

Porphyrins and their non-covalent interactions are of interest in view of their role in biological systems. They also can provide new artificial host compounds with a built-in optical sensor by their Soret bands, which are sensitive towards binding of many ligands. Porphyrin derivatives with positively charged substituents in the *meso*-position were shown earlier to interact with nucleotides and with DNA[1] as well as with many aromatic substrates[2] primarily *via* stacking between the aromatic units. We wanted to explore the use of modified porphyrins as peptide receptors, which unlike most artificial host compounds in this important class of compounds[3] work in protic solvents. The goal of selective peptide complexation in aqueous solution was approached only recently,[4] and still needs considerable progress until artificial receptors come close to the efficiency of biological systems. The present paper reports a new step in this direction, with binding constants of hitherto unkown magnitude for natural, unprotected peptides.[5]

We first carried out UV-visible titrations using the commercially available 5,10,15,20-tetrakis(4-methylpyridinium)porphyrin **1** with several *N*-benzyloxycarbonyl-protected amino acids and peptides, as unprotected amino acids and peptides showed no detectable binding. Addition of the Z derivatives (Z = benzyloxycarbonyl) resulted in a intensity reduction of the Soret band with a concomitant red shift of the band maximum. The change in absorbance values (ΔA), varied from 0.2 to 0.4, and the change in wavelength ($\Delta\lambda$) from 5 to 10 nm. Non-linear least-squares fitting of the observed absorbance changes obtained at several different wavelengths in the region 400–430 nm showed satisfactory fitting with a 1 : 1 association model. Similar behaviour was observed with a new porphyrin derivative **2** with one methyl benzoate and three 4-pyridinium substituents in the *meso* positions. This as well as two other derivatives with only two or one 4-pyridinium substituents (**3** and **4**) were synthesized analogous to literature procedures,[6] as it was hoped that partial displacement of the charged units might lead to more selective binding. Dilution experiments, however, made evident the fact that **3** and **4** aggregate severely in water in spite of the charges even at 10^{-6} M concentration, and were therefore unsuitable for binding studies.



1 $R^1 = R^2 = R^3 = R^4 = A$
2 $R^1 = R^2 = R^3 = A$, $R^4 = B$
3 $R^1 = R^2 = A$, $R^3 = R^4 = B$
4 $R^1 = A$, $R^2 = R^3 = R^4 = B$
5 $R^1 = R^2 = R^3 = A$, $R^4 = C$

With host compounds **1** and **2** the log*K* values (2.9–3.7 M^{-1}, Table 1) show rather high affinities, in particular if a geometric fit is to be expected from the models. It is obvious that the binding strength with the protected peptides is generally larger for aromatic ligands, except in the case of Z-Asp, in line with previous findings.[1,2]

Considering the aqueous medium the affinities observed with **1** and **2** are promising, but unprotected peptides did not show any binding. The positive charge at the peptide NH_3 terminus will always destabilize complexes with **1** or **2**, which suggests the introduction of an additional binding site at the porphyrin ring in order to complex natural peptides. This was achieved by inserting a crown ether unit, which is known to complex primary ammonium groups. The synthesis of this porphyrin derivative **5** was carried out in acid medium using the classical Adler–Longo method.[7] Reaction of 4-formylbenzo-18-crown-6, pyridine-4-carbaldehyde and pyrrole in the presence of Ac_2O and refluxing propionic acid for 1.5 h gave a mixture of porphyrins which after purification on an alumina column and subsequent methylation yielded **5** in an overall yield of about 3%.

UV titrations with the new crown ether receptor **5** indeed showed with *unprotected* peptides binding constants (Table 2) which are even higher than those observed with the protected peptides necessary for the use of **1** and **2**. The fit to a 1 : 1 model was again satisfactory (Fig. 1), as long as the molar ratio of [peptide]/[**5**] did not exceed 200. At higher concentrations of the

added peptide one observes a biphasic behaviour of the isotherm, indicating other binding modes. The complexation-induced absorption and wavelength changes were smaller than those with **1** and **2**, but in most cases sufficient for evaluation of *K*. Computer aided molecular modelling of the complex between **5** and Gly-Gly-Phe using energy minimization with the CHARMm force field established an essentially strain-free fit between the crown and $^+NH_3$ at one end, and between an adjacent 4-pyridinium unit and the COO^- groups at the other end, as well as stacking between the terminal phenyl ring and the porphyrin, with retention of most stable extended conformation of the peptide (Fig. 2). The two carboxylate oxygens of Gly–Gly–Phe are in van der Waals contact with the neighbouring pyridyl *ortho*-Hs [PheCO(1)···HC(pyridyl-*ortho*) = 2.52 Å] and the β-pyrrole carbon atom [PheCO(2)···C(β-pyrrole) 3.03 Å].

The data in Table 2 illustrate that the binding strength increases as a function of the peptide length and with the number of aromatic units in the amino acid side chains, as expected from stacking contributions. A force field-minimised structure of the complex between **5** and Phe–Gly–Gly did show stacking interactions between the porphyrin pyridyl group and the peptide phenyl ring, in addition to other non-covalent interactions. However, the extremely large association constants, such as $K = 10^5$ M^{-1} with tetraglycine, are obviously due to additional binding effects. Preliminary measurements with aliphatic amides, hampered by very small spectral changes,

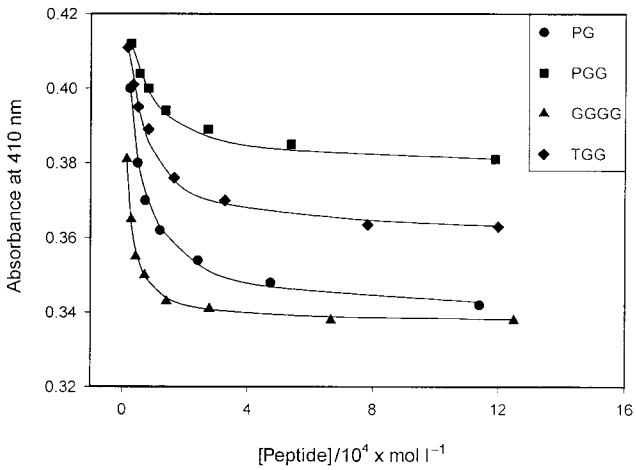

Fig. 1 UV-visible titration curves of porphyrin **5** with peptides (PG = Phe–Gly, PGG = Phe–Gly–Gly, GGGG = Gly–Gly–Gly–Gly, TGG = Trp–Gly–Gly).

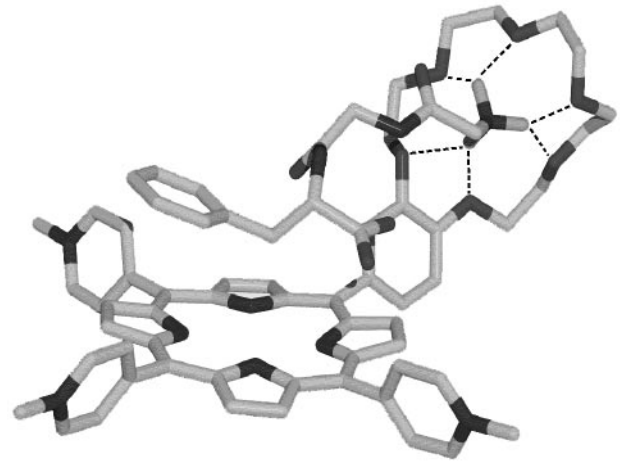

Fig. 2 A force field (CHARMm) optimized structure of porphyrin **5** with the peptide Gly–Gly–Phe. Hydrogens are omitted for clarity except those of peptide NH_3 . The phenyl group of Phe is not far from van der Waals contacts to the pyrrole (d_{av} = 3.95 Å); the NH_3 protons have distances of 1.90–2.05 Å to the crown ether oxygen; the carboxylate group comes close to neighbouring pyridyl protons with d_{av} = 3.0 Å.

suggest the amide function itself contributes significantly to the associations.

In conclusion, we have shown that porphyrins can associate with peptides with high affinities, if the charges are accommodated in a complementary fashion. The findings suggest new approaches to the design of peptide receptors and potentially also to supramolecular catalysts for peptide modification; they also shed light on possible interaction mechanisms in protein–porphyrin aggregations.[8]

Our work is supported by the Deutsche Forschungsgemeinschaft, Bonn, and the Fonds der Chemischen Industrie, Frankfurt. M. S. thanks the A. v. Humboldt foundation for a stipend.

Received (in Cambridge, UK) 3rd March 1999, Accepted 12th March 1999

The photo-reactions of 2,4,6-tris(phenylthio)hepta-2,4,6-trienal 1 and its 2,4-dinitrophenylhydrazone 5 gave the 2-oxa- or 2-azabicyclo[3.3.0]octa-3,7-dienes 2 and 9, respectively, *via* a photo-induced intramolecular tandem cyclization reaction.

The Paterno–Büchi reaction has become increasingly familiar to chemists engaged in investigation of its mechanism or synthetic applications.[1] The widespread advances in this area of synthetic organic chemistry have led to convenient methodology for the preparation of the oxetane-containing biologically active materials.[2] Intramolecular photo-reactions of the vinyloxy ω-carbonyl compounds and their furan derivatives usually provides the fused oxetane ring compounds,[3] which lead to other useful compounds by successive transformations.[4]

Recently, we reported the tandem α-(thio)- or α-(seleno)-formylolefination reactions of the aldehydes.[5] Three cycles of the olefination process with pivalaldehyde stereoselectively afforded (2*E*, 4*E*, 6*E*)-8,8-dimethyl-2,4,6-tris(phenylthio)nona-2,4,6-trienal **1**, which contains three conjugated vinyl sufide moieties. This trienal **1** was found to be light-sensitive like the retinal chromophores.[6] This result prompted us to investigate the reactivities of the trienal under photo-irradiation conditions; surprisingly, a new ring system, oxabicyclo[3.3.0]octa-3,7-diene, was formed *via* an unusual photo-cyclization. Here we report the unprecedented intramolecular tandem cyclization reaction of trienal **1**.

Irradiation of an Ar saturated solution of **1** in MeCN (1.0×10^{-3} mol l^{-1}) using a 40 W fluorescent daylight lamp afforded (1*R**, 5*R**, 6*S**)-6-*tert*-butyl-1,4,7-tris(phenylthio)-2-oxabicyclo[3.3.0]octa-3,7-diene **2**[7] in 54% yield as shown in Scheme 1. The structure of **2** followed from the fact that the IR spectrum showed no carbonyl absorption, while the ^{1}H NMR spectrum showed two methine protons at δ 2.82 (t, *J* 2) and 3.40 (t, *J* 2) and two olefinic protons at δ 5.07 (s) and 6.50 (d, *J* 2). The stereochemistry of oxabicyclo compound **2** was determined as (1*R**, 5*R**, 6*S**) by single crystal X-ray analysis; the ORTEP drawing of **2** is shown in Fig. 1.[8] Furthermore, a few fundamental reactions of **2** were examined using oxidizing agents. MCPBA oxidation of **2** gave the corresponding sulfone **3** in 78% yield (Scheme 2). The reaction with Pd–C in toluene under reflux conditions afforded the ring-opened cyclopentadiene **4** in 40% yield. The structure of **4** was determined from the IR spectrum, which showed the carbonyl absorption at ν 1650 cm^{-1}, the ^{1}H NMR spectrum, which exhibited two doublets at δ 6.54 (d, *J* 7) (due to the olefinic proton) and 11.13 (d, *J* 7) (due to the aldehyde proton), and the mass spectrum, which showed a molecular ion peak ($C_{28}H_{22}OS$) at *m/z* 378. The stereochemistry of **4** was determined as *Z* by an NOE experiment. Irradiation of the *tert*-butyl protons at δ 1.22 increased the intensity of the olefinic proton at δ 6.54 (4%).

Next, we examined the photo-reaction of the trienal hydrazone **5**, irradiating at 400–500 nm in benzene to give 2-azabicyclo[3.3.0]octa-3,7-diene **6** in 41% yield (Scheme 3).[9]

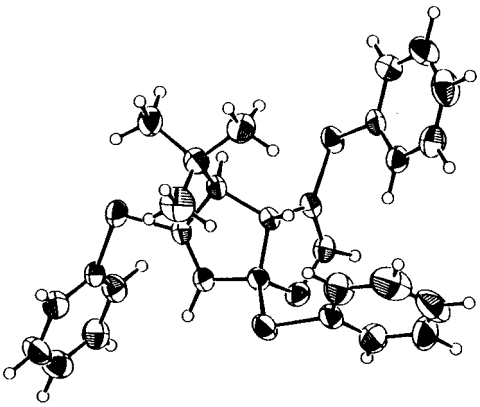
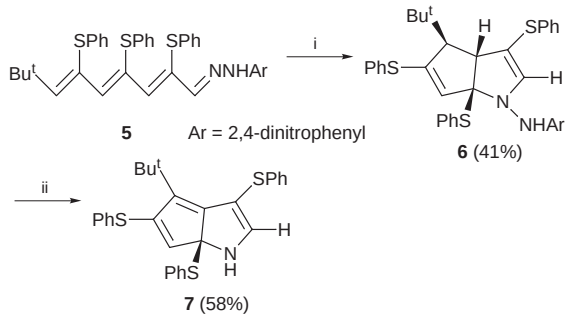
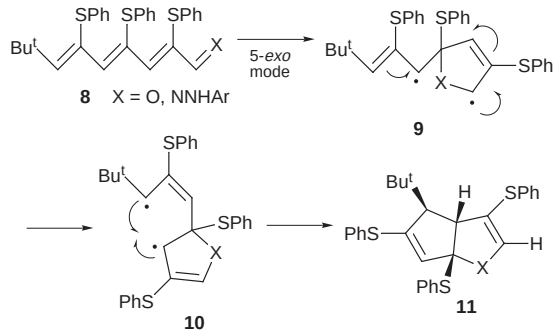
Scheme 1 *Reagents and conditions*: i, *hν* (500–600 nm), MeCN.



Scheme 2 *Reagents and conditions*: i, MCPBA, $ClCH_2CH_2Cl$; ii, Pd–C, toluene.



Scheme 3 *Reagents and conditions*: i, *hν* (400–500 nm), benzene; ii, AIBN, benzene, reflux.



Scheme 4

Recently, we reported that the 2,4-dinitrophenylhydrazones reacted with AIBN and underwent dearylamination.[10] Treatment of the hydrazone **6** with AIBN in benzene afforded 2-azabicyclo[3.3.0]octa-3,5,7-triene **7** in good yield.

A plausible mechanism for formation of the photo-reaction products is shown in Scheme 4. Intermolecular [2 + 2] photocycloadditions have been intensively investigated and have indicated that the reaction intermediate is a flexible 1,4-biradical.[11] Our intramolecular cyclization would also proceed *via* triplet biradical intermediates and cyclize in 5-*exo* mode to give the 1,4-biradical **9**. Isomerization of **9** affords a 1,5-biradical **10**. Tandem cyclization leads to the bicyclo-[3.3.0]octa-3,7-diene **11**.

In conclusion, 2,4,6-tris(phenylthio)hepta-2,4,6-trienal derivatives are highly sensitive to light and their photo-reactions were found to afford the 2-oxa- or 2-azabicyclic compounds *via* a unique tandem cyclization reaction.

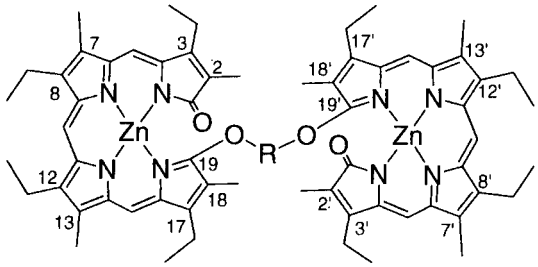
Received (in Cambridge, UK) 19th March 1999, Accepted 16th April 1999

Helical chirality of zinc bilinone is completely regulated by dimerizing bilinone units through a chiral cyclohexane spacer.

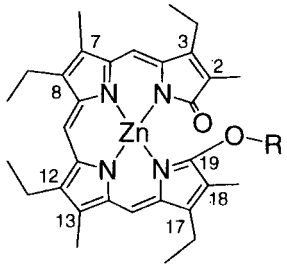
Zinc bilinone (ZnBL) is a helical molecule[1,2] with the low energetic barrier between the *P*- and *M*-helix conformers leading to rapid racemisation at room temperature.[3] Upon complexation with chiral amino acid esters and amines, the racemisation equilibrium is driven to a preferred enantiomer, implying the possible use of zinc bilinones as a framework for a chiral receptor.[4] For this purpose, however, the conformational flexibility of zinc bilinones should be limited. As an approach to rigidly fix the helical chiral conformation, we report here the synthesis of ZnBL dimers and complete control of the chirality by use of a rigid chiral spacer. Two ZnBL frameworks that are assembled *via* a chiral *trans*-cyclohexane-1,2-dioxy spacer gave a homochiral structure exclusively.

The bilinone dimer **1** was synthesized by a nucleophilic ring-opening reaction of oxoniaporphyrin by an alkoxide generated *in situ* from optically active *trans*-(*R*,*R*)- or (*S*,*S*)-1,2-cyclohexanediol, followed by zinc insertion using zinc(II) acetate.[5–7] The total yield of **1** from the oxoniaporphyrin was 35–46%. The



1a ; R =  **1b** ; R = 

2 ; R = 



3 ; R = 

4 ; R = Me

structure of dimer **1** was confirmed by ^{1}H and ^{13}C NMR, UV–VIS, high resolution mass spectrometry and elemental analysis. Full assignments of all the protons and carbons were achieved by ^{1}H–^{1}H COSY, ROESY, and ^{1}H–^{13}C HSQC spectra. In the ^{1}H NMR spectrum of **1**, each bilinone moiety is magnetically equivalent, indicating that **1** adopts a C_2 symmetric conformation.

Circular dichroism spectra of **1**, **2** and **3** are shown in Fig. 1. The signs of the Cotton effects show that the *P*-helix conformation is more abundant than that of the *M*-helix in **1a**, and *vice versa* in **1b**.[8–11] The Cotton effects observed for **2** were much smaller than those for **1** or for the ZnBL monomer **3** bearing a chiral auxiliary. Previously we found that the magnitude of Cotton effects of ZnBL derivatives is directly in proportion to the efficiency of helical chirality induction.[4,12,13] Therefore, these CD spectral studies revealed that the helical chirality induction in **1** is much more effective than in **2** and **3**.

Variable-temperature ^{1}H NMR and CD studies offered more conclusive evidence for chiral induction in **1**: one set of the signals [Fig. 2(a)] was observed in the ^{1}H NMR spectrum over the temperature range 288–198 K. UV–VIS and CD spectra showed small changes upon cooling from 288 to 198 K: a 2 nm blue shift and a 9 nm red shift in the higher energy band and the lower energy band respectively, in the UV–VIS while CD spectra suggested a minor conformational equilibrium, but indicative of no changes in distribution among (*P*,*P*)-, (*P*,*M*)- and (*M*,*M*)-conformers. In contrast to this observation, monomeric ZnBL **3**, exhibited a drastic change in the CD intensity upon cooling from 288 to 223 K ($\Delta\varepsilon_{405}$ = −65.2 dm^3 mol^{-1} cm^{-1} at 288 K, $\Delta\varepsilon_{402}$ = −88.2 dm^3 mol^{-1} cm^{-1} at 223 K), where the diastereomeric excesses of the helical structure were 51 and 72%, respectively. All these results indicate that both ZnBL moieties of **1a** exclusively adopt the (*P*)-conformation.

In the ^{1}H NMR spectra of a more flexible dimer **2**, three sets of signals were observed in the region of the methine protons and the methylene protons adjacent to the oxygens, which were

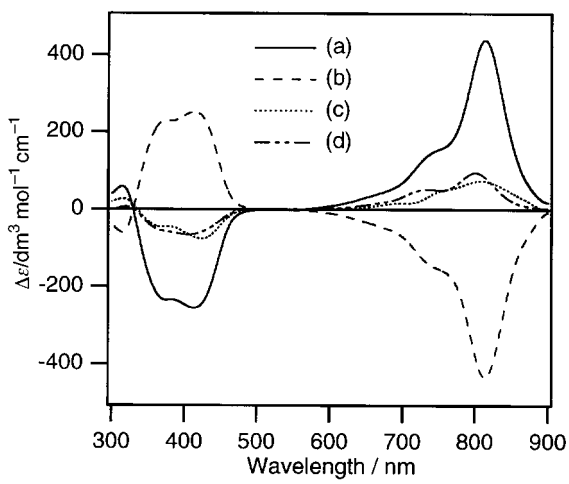


Fig. 1 Circular dichroism (CD) spectra of (a) **1a** (1.97×10^{-5} M), (b) **1b** (1.53×10^{-5} M), (c) **2** (1.99×10^{-5} M) and (d) **3** (3.68×10^{-5} M) in CH_2Cl_2 at 288 K.

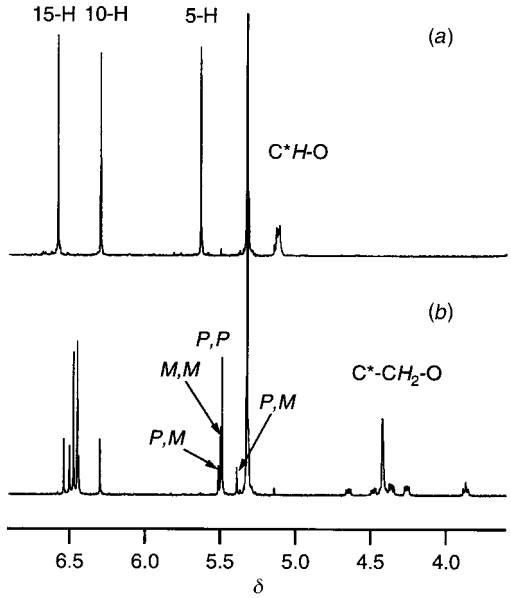

Fig. 2 Expanded region of ^{1}H NMR spectra of (a) **1a** and (b) **2** in CD_2Cl_2 at 288 K. [**1a**] = 2.57 mM and [**2**] = 2.50 mM.

ascribed to (*P*,*P*)-, (*P*,*M*)- and (*M*,*M*)-conformers, respectively [Fig. 2(b)]. The ratio of these three isomers determined by the signal integrations of the 5-H proton was (*PP*) : (*MM*) : (*PM*) = 51 : 27 : 22, indicating that homochiral conformers are preferred over *M*-helix, with a 24% excess of the *P*-helix of ZnBL. Therefore, extra methylene groups in **2** led to larger rotational freedom and less efficient helical chirality induction. It is noteworthy that, even in the flexible dimer **2**, homochiral conformers were preferred over the heterochiral one.

A further remarkable feature of **1** is that an anomalous upfield shift of one of the peripheral methyl groups was found in the ^{1}H NMR spectrum: the chemical shift of the 18-Me protons of **4** was observed at δ 1.72, whereas that of **1** was at δ 1.01. Other methyl protons appeared in a narrow region (δ 1.75, 2.01 and 2.07 for 2-, 7- and 13-methyl protons in **4**). This upfield shift is most likely caused by the proximity of the 18-methyl group of **1** to the ring current anisotropy of the other ZnBL. These NMR results and conformational search by force field/molecular orbital calculations afforded one of the possible conformers as shown in Fig. 3. In this conformation, the distance between the 18-Me carbon of ZnBL and the C-2′ carbon of the other ZnBL was 3.51 Å, indicating the van der Waals contact between the methyl group at the 18-Me and the A-ring pyrrole moiety of the other ZnBL. These van der Waals forces effectively fix the homochiral conformation.

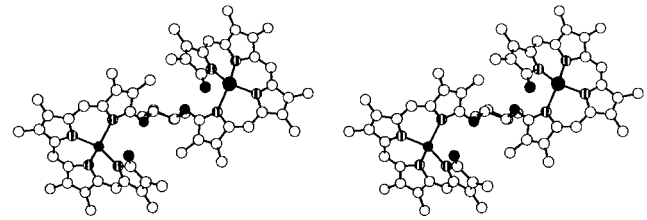

Fig. 3 Stereoview of one of the possible conformers of a model compound of **1a**, in which all the peripheral ethyl groups were replaced by methyl groups. All hydrogen atoms are omitted for clarify. The C_2 symmetric conformer was found by use of the grid conformational search program of Sybyl and the geometry was further optimized by MO calculations at the PM3 level (Spartan version 3).

Preliminary experiments showed that the (*P*,*P*)-conformer of **1a** was stable even in the presence of excess amounts of (*M*)-conformer-inducing L-amino acid esters.[4] Therefore, dimerization of the highly flexible framework of zinc bilinone led to the robust structure of **1**, which should be suitable as a framework of receptors.

First highly enantioselective allylic alkylations catalysed by platinum complexes

Received (in Liverpool, UK) 25th February 1999, Accepted 7th April 1999

Platinum complexes derived from phosphino-oxazolines are highly enantioselective catalysts for allylic alkylation reactions, but show different behaviour from related palladium complexes.

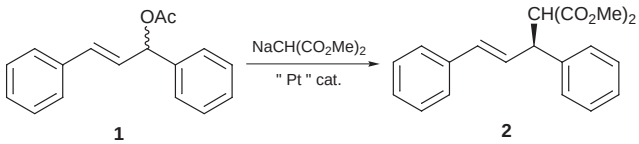
Transition metal catalysed allylic substitution reactions are classically carried out with palladium catalysts.[1] Although palladium often gives excellent results, the use of alternative metal catalysts has expanded the scope of the reaction considerably. Consequently, the study of different transition metals in this type of reaction is currently attracting considerable attention,[1,2] and there are recent reports on enantioselective allylic substitutions catalysed by iridium, [3] tungsten,[4] molybdenum[5] and nickel.[6] Reports on platinum catalysed allylic substitution reactions are extremely rare,[7] so we elected to study whether the different properties of platinum could expand the scope of this reaction still further.

Our initial studies have focused on the alkylation of diphenylpropenyl acetate with dimethyl sodiomalonate (Scheme 1). The chiral ligand **3** was chosen as it has been shown to be particularly suited to the palladium catalysed reaction.[8] As a starting point, we tested some readily available precursors in the presence of the chiral ligand. For example, 5 mol% of $(Ph_3P)_2Pt–(C_2H_4)$ in the presence of 10% of ligand **3** gave complete conversion to product at room temperature, but with low enantioselectivity (90% yield; 28% ee, 16 h, CH_2Cl_2, 20 °C).

We thought it likely that the PPh_3 present was competing with ligand **3**, and hence reducing the ee. We therefore felt that we needed to prepare a catalyst which would contain a single P,N ligand as the only phosphine present.

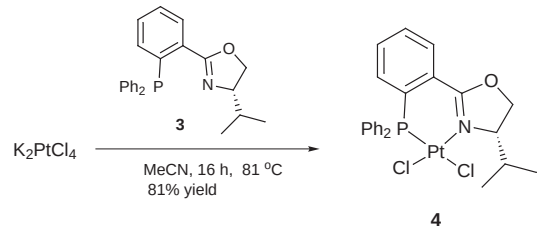
We had previously found that a combination of $(Ph_3P)_2PtCl_2$ and the reducing agent $NaBH(OMe)_3$ generates a Pt^0 complex which is an active catalyst (100% conversion: 16 h, 20 °C). We therefore chose to prepare the related complex **4**. This is readily accomplished by stirring the ligand and K_2PtCl_4 in refluxing MeCN (Scheme 2).

In contrast to the $(Ph_3P)_2PtCl_2/NaBH(OMe)_3$ system, a combination of complex **4** and $NaBH(OMe)_3$ does not catalyse the allylic alkylation of **1** at room temperature (Table 1, entry 1). However, after 30–50 h in refluxing THF, complete conversion into product is observed. It seems that complexes containing a bidentate P,N ligand make much less reactive catalysts when compared with complexes containing two phosphines. The ee of the products was high, but not as high as can be obtained with palladium.[8,9] If **4** is used in conjunction with 5% of ligand **3**, a small increase in ee was observed, whereas 10% added ligand



1 **2**

Scheme 1



Scheme 2

gives significantly lower ee as shown in Table 1 (entries 4 and 5). If 5% PPh_3 is added, a highly reactive (but unselective) catalyst is generated (Table 1, entry 6). These results suggest that the P–Pt–N chelate ring is not stable in the presence of other ligands.

Despite early failures using the readily available tetrameric compound $[(C_3H_5)PtCl]_4$, **5**,[10] it was found that 1.25 mol% of **5** in combination with 5 mol% of ligand **3** catalysed the reaction. This system also requires reflux temperatures to obtain high yields of product. The highest ee (90%) was obtained at room temperature (Table 2, entry 1) and is reduced somewhat (entry 2) when the reaction is carried out at 65 °C. It should be noted that at high conversions, the ee of the starting acetate **1** had

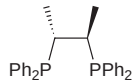
reached significant levels (73% ee). With this catalytic system, the presence of an increased amount of ligand is again detrimental to the enantioselectivity.

It seems clear that enantioselectivity and reactivity in the platinum catalysed reaction are much more sensitive to reaction conditions when compared with palladium. A possible explanation for this is that ligand **3** can be hemilabile when complexed to platinum. If this were the case, even to a small extent, it would be possible for the reaction to go *via* two competing pathways (Fig. 1). It is assumed that intermediate B would fail to give any significant level of enantiocontrol.

The platinum catalysed reaction had one more surprise in store for us, we tested the ligand (*R*,*R*)-chiraphos **6** in the catalytic reactions using tetramer **5** as our platinum source.



6

Bosnich and co-workers had previously found that, in the Pd catalysed reaction, this ligand does not give high enantioselectivity for substrate **1** (100% yield, 22% ee).[11] It was therefore interesting to find that at moderate conversion the product obtained had 95% ee. If the reaction was carried out at higher temperatures, moderate yields and somewhat lower enantioselectivity were obtained (Table 3, entry 2). The reaction was then tested using the palladium catalyst $[(C_3H_5)PdCl]_2$. In this instance we observed substantially higher enantioselectivity than was previously obtained (entry 3).

In conclusion, we have shown that several Pt complexes catalyse allylic alkylation with good enantioselectivity. Carefully controlled conditions are required in order to prevent loss of enantioselectivity by less selective pathways. This suggests that ligand **3** shows different coordination chemistry for platinum (compared with palladium). We are now trying to exploit the different properties of platinum to develop new asymmetric allylation reactions.

Table 3 Enantioselective allylic alkylation of acetate **1** in the presence of (*R*,*R*)-chiraphos[a]

Entry	Catalyst	*T*/°C	*t*/h	Conversion (%)[b]	Ee (%)[b] (config.)
1	5% $[(C_3H_5)PtCl]_4$	20	72	39	95 (S)
2	5% $[(C_3H_5)PtCl]_4$	56	67	57	74 (S)
3	5% $[(C_3H_5)PdCl]_2$	20	16	100	85 (S)

[a] All reactions carried out in THF, using 1.7 equiv. $NaCH(CO_2Me)_2$ as nucleophile. [b] Determined by HPLC using Daicel Chiralcel® OD column (hexane/Pr^{i}OH 99 : 1). Configuration by comparison with known Pd catalysed products (ref. 8).

We are grateful to the LINK asymmetric synthesis programme, Glaxo-Wellcome and Zeneca for financial support.

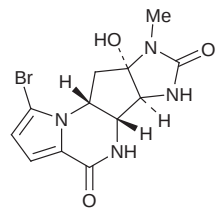
Antineoplastic agents. Part 395.[1] Isolation and structure of agelagalastatin from the Papua New Guinea marine sponge *Agelas* sp.

George R. Pettit,* Jun-ping Xu, Diane E. Gingrich, Michael D. Williams, Dennis L. Doubek, Jean-Charles Chapuis and Jean M. Schmidt

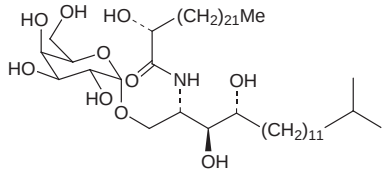
Cancer Research Institute and Department of Chemistry, Arizona State University, Tempe, Arizona 85287-2404, USA

A human cancer cell line bioassay-directed investigation of the Western Pacific marine sponge *Agelas* sp. led to isolation of a trace (7.42×10^{-6}% yield) cancer cell growth inhibitor (lung NCI-H460 GI_{50} 0.77 μg m^{-1} to ovary OVCAR-3 GI_{50} 2.8 μg ml^{-1}) designated agelagalastatin 6; it is the first example of a natural product containing a digalactofuranosyl unit.

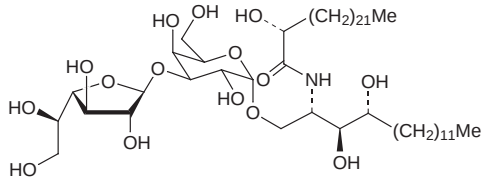
The marine porifera genus *Agelas* (class Demospongae, order Agelasida, family Agelasidae) has proven to be a rich source of new marine alkaloids[2] such as the cytotoxic (L1210 leukemia cell line) agelastatin A **1**[2a] and a series of glycosphingolipids[3]



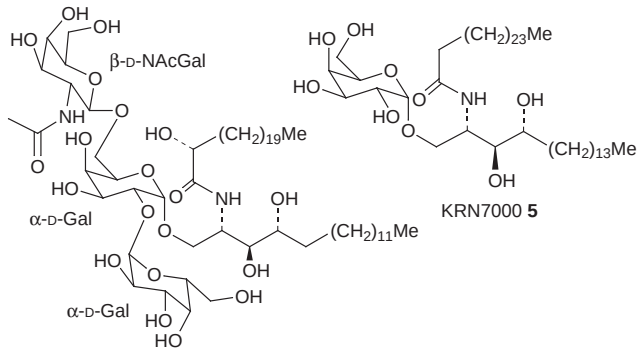
Agelastatin A **1**



Agelasphin-9b **2**



Longiside **3**



4

(*cf.* **2**,[3a], **3**,[3b], **4**[3c], **5**[3d]). Some (*e.g.* **2** and **5**) of these have shown immunomodulating activity,[2a,3d] and a structural modification **5**[3g] has been considered for preclinical development as an anticancer (murine melanoma B16 *in vivo* active) and non-specific immunostimulating agent.[3a,g] Because glycosphingolipids (cerebrosides) are vitally important in a variety of biochemical processes ranging from antigenic specificity to cell–cell signaling and modulation of the immune response, discovery of new naturally occurring cancer cell growth inhibitory compounds is clearly necessary. We now report the isolation and structural elucidation of the new glycosphingolipid agelagalastatin **6** from *Agelas* sp. that was initially evaluated during our 1980 expedition to the southeast coast of Papua New Guinea and recollected in 1983.

Agelas sp. (450 kg wet wt.) was extracted with MeOH and the alcohol-soluble portion was successively partitioned between 1 : 1 CH_2Cl_2–MeOH and water followed by n-hexane and 9 : 1 MeOH–water and finally CH_2Cl_2 and 3 : 2 MeOH–water. The resulting CH_2Cl_2-soluble fraction (630.5 g) was separated (directed by human cancer cell line bioassays) by a series of gel permeation and partition chromatographic procedures on Sephadex LH-20 columns with the series MeOH → n-hexane–CH_2Cl_2–MeOH (8 : 1 : 1) → n-hexane–Pr^iOH–MeOH (8 : 1 : 1) → n-hexane–toluene–acetone (1 : 4 : 4) as eluents to afford a fraction inhibitory to a selection of cancer cells. The bioactive fraction was treated with MeOH to selectively isolate the more soluble active constituent herein named agelagalastatin (**6**, 6.5 mg, 7.42×10^{-6}% yield). The residual fraction was dissolved in CH_2Cl_2–MeOH (1 : 1) and subsequently identified (by NMR spectral analysis) as a mixture of monogalactosyl ceramides[4,5] related to agelasphin-9b **2**.

Agelagalastatin **6** was obtained as a colorless amorphous powder: $[\alpha]_D$ + 59 (*c* 0.65, CH_3OH) which showed a molecular ion peak in the HRFABMS spectrum at *m*/*z* 1192.7859 $[M+Na]^+$ (calc. 1192.7910) corresponding to molecular formula $C_{60}H_{115}NO_{20}$. When a 5.2 mg specimen of agelagalastatin was subjected to acid hydrolysis (15 h at 70 °C) with 1 M HCl–MeOH (8 : 91) followed by acetylation, methyl α,β-D-galactopyranoside tetracetate (identical with an authentic sample) and the sphinganines (2*S*,3*S*,4*R*)-2-amino-15-methyl-1,3,4-trihydroxyhexadecane and (2*S*,3*S*,4*R*)-2-amino-16-methyl-1,3,4-hydroxyheptadecane were identified by physical and spectral data. The FABMS spectrum afforded three fragment ion peaks at *m*/*z* 1030.5 $(M + Na + H - Gal)^+$, 868.5 $(M + Na + H\text{-}2Gal)^+$ and 706.5 $(M + Na + H - 3Gal)^+$, suggesting the trisaccharide unit [Gal-Gal-Gal].

Interpretation of the ^1H–^1H COSY and TOCSY-NMR spectra led to assignment of the proton relay signals corresponding to five spin systems. The HMBC and ROESY 2D NMR experiments supplied definitive structural information regarding connections to the five spin systems and allowed a view of the overall structure. Detailed data from HMQC and HMBC spectra suggested the ceramide unit was composed of two spin systems, namely 4-hydroxysphinganine and an α-hydroxy ester. The latter was shown by mass spectral analysis of the preceding methanolysis products to be primarily a (2*R*)-hydroxypentacosanoate with about 20% of the corresponding homologous (2*R*)-hydroxytetracosanoate. Furthermore, the HMBC correlation peaks of C-1* with NH, H-2 and H-2* indicated that the two segments were linked together through an amide bond and all the chemical shifts shown by the ceramide units were reminiscent of those known for related compounds.[3]

The three anomeric proton signals appeared as doublets at δ 5.47 (H-1′), 5.78 (H-1″) and 5.61 (H-1‴) and were a useful starting point for establishing an additional three spin systems. The heteronuclear chemical shift correlation (HMQC) spectrum was used to assign relationships between protons and carbon in the three carbohydrate units A, B, and C. The ^{13}C NMR chemical shift data and the proton coupling constants measured by 2D *J* resolution experiments revealed the inner galactose (A) unit to be a D-galactopyranoside. From consideration of the *J*

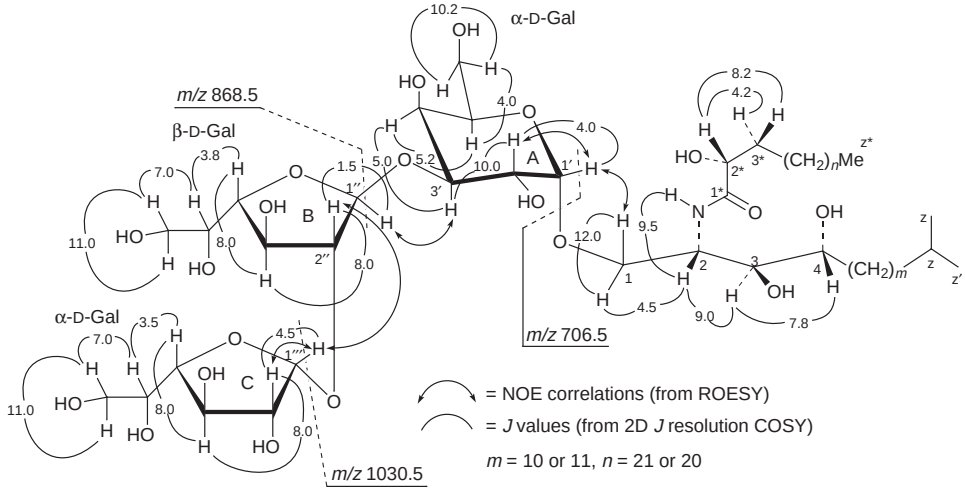


Fig. 1 NOE correlations and *J* values of agelagalastatin **6** (mass fragments include sodium).

value of the anomeric proton (H-1′, *J* 4.0 Hz) as well as the chemical shift of the corresponding carbon (C-1′, δ 101.31), the anomeric α-configuration was assigned. The HMBC correlations of H-1/C-1′ and H-1′/C-1 proved that the inner galactose segment (A) was directly connected with the C-1 ceramide hydroxy group by a glycosyl linkage.

Glycosylation shifts were observed at C-3′ (+8.42 ppm) and C-2′ (−2.36 ppm), along with HMBC correlations involving H-3′/C-1″ and H-1″/C-3′. Both results signified that C-3′ of galactose unit (A) was bonded through a glycoside link to the middle saccharide unit (B). The NOE correlation peaks of H-1/H-1′ and H-3′/H-1″ provided further evidence supporting two glycosyl linkages at two positions of the inner galactose section (A).

The two series of ^{13}C chemical shifts displayed by units B and C were both characteristic of a D-galactofuranoside.[6] Because of the five-membered ring, the ^{13}C chemical shifts of C-2″, C-3″ and C-4″ of unit B as well as those of C-2‴, C-3‴, and C-4‴ of unit C were significantly downfield compared with the corresponding data for D-galactopyranoside. Additional NMR data suggested that the two furanoside units (B and C) corresponded to 1,4-linked five-membered rings. Confirmatory evidence arose from the HMBC correlations of H-1″/C-4″, H-1‴C-4‴ and H-4‴/C-1‴, which exactly defined the furanosyl 1,4-linkages, and from 2D *J* resolution values attesting to the 2,3-diaxial (*J* 8.0 Hz) and 3,4-diaxial (*J* 8.0 Hz) relationships in the D-galactofuranoside (Fig. 1).

The chemical shifts of the anomeric carbons at δ 108.51 (C-1″) and 101.69 (C-1‴) together with the coupling constants of the anomeric protons (H-1″, *J* 1.5 Hz and H-1‴, *J* = 4.5 Hz) allowed the middle (B) and outer D-galactofuranosyl units (C) to be assigned β- and α-configurations,[6] respectively. Furthermore, the NOE relationship from H-1″ to H-3′ together with HMBC correlation between H-1″ and C-3′ showed the presence of a 1″–3′ glycosyl linkage between galactosyl sections A and B. The HMBC correlations of H-1‴/C-2″ and H-2″/C-1‴ combined with the NOE relationship of H-2″/H-1‴ indicated that the outer furanose unit (C) was joined to the C-2″ hydroxy group of the middle furanose (B). Thus, agelagalastatin was assigned structure **6** assuming that the overall stereochemistry and absolute configuration corresponds to that generally found for such glycosphingolipids.[3] To the best of our knowledge, agelagalastatin **6** is the first marine animal constituent found to possess a digalactofuranosyl unit.

Agelagalastatin **6** displayed significant *in vitro* activity against a portion of our minipanel (including brain SF-295, renal A498, colon KM20L2 and melanoma SK-MEL-5) of human cancer cell lines with GI_{50} values ranging from 0.77 μg ml^{-1} for lung NCI-H460 to 2.8 μg ml^{-1} for the ovarian OVCAR-3. Future research based on discovery of agelagalastatin will entail confirmation of the stereochemistry by total synthesis followed by detailed biological evaluation.

We thank the following for necessary financial assistance: Outstanding Investigator Grant CA 44344-01A1-09 and PHS Grant CA-16049-09-12 awarded by the Division of Cancer Treatment, National Cancer Institute, DHHS; the Fannie E. Rippel Foundation; the Arizona Disease Control Research Commission; the Robert B. Dalton Endowment Fund; Virginia Piper; Diane Cummings Halle (The Nathan Cummings Foundation); Lottie Flugel; Polly J. Trautman; John and Edith Reyno; the Fraternal Order of Eagles Art Ehrmann Cancer Fund; and the Ladies Auxiliary, VFW, Department of Arizona. Communication 9/02380A

A concise approach towards the synthesis of steganone analogues

Adrian Bradley,[a] William B. Motherwell*[a] and Feroze Ujjainwalla[b]

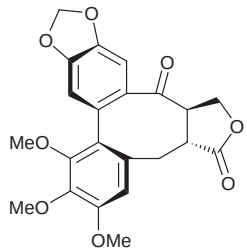
[a] *Department of Chemistry, Christopher Ingold Laboratories, University College London, 20 Gordon Street, London, UK WC1H 0AJ. E-mail: w.b.motherwell@ucl.ac.uk*

[b] *Department of Chemistry, Imperial College of Science, Technology and Medicine, South Kensington, London, UK SW7 2AY*

Received (in Cambridge, UK) 27th January 1999, Accepted 12th April 1999

The cobalt-mediated [2+2+2] cycloaddition of a tethered deca-1,9-diyne is used as a key step in a highly convergent route to steganone analogues.

Steganone **1** is one member of the family of four bisbenzocyclooctadiene lignan lactones isolated from the Ethiopean shrub *Steganotaenia araliciae* Hochst and characterised by Kupchan[1]



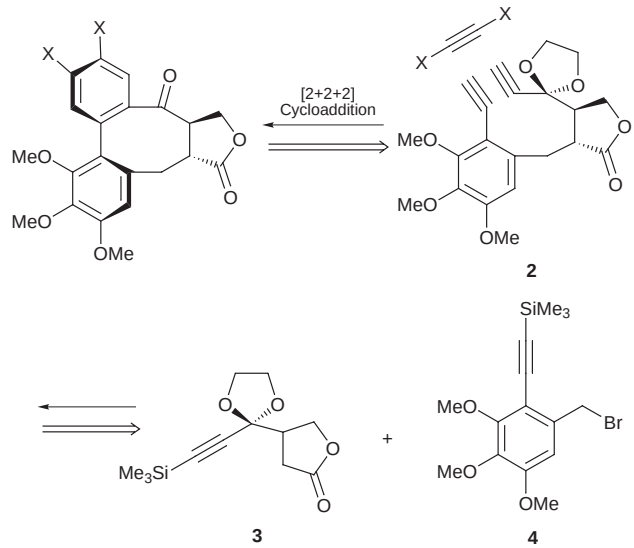
1

in 1973. These compounds have displayed significant activity *in vivo* against P-388 leukemia in mice and *in vitro* against cells derived from human carcinoma of the nasopharynx (KB). They act as spindle poisons and function by stabilising dimeric tubulin and thereby inhibiting formation of microtubules.[2] These intriguing structures, comprising an eight-membered ring fused to a biaryl moiety, are composed of three stereochemical elements, two deriving from the *trans*-fused γ-lactone, whilst the third is the stereogenic axis of the atropisomeric biaryl unit. Since its discovery, steganone **1** has proven to be a favoured target for sustained synthetic effort, and for more than two decades a wide variety of synthetic strategies have culminated in a number of total/formal syntheses.[3] Careful scrutiny of these approaches reveals striking parallels in retrosynthetic analysis, with no less than ten of the syntheses requiring a late stage installation of the *trans*-fused γ-lactone. Moreover, in every single instance to date some variant of a biaryl coupling reaction is used to forge the crucial carbon–carbon bond between the two aromatic rings.

Since the properties of steganone **1** itself are well known, our own objective in this area was to develop a highly convergent route which would be potentially amenable to the syntheses of a wide variety of differentially substituted aromatic analogues for use in structure–activity studies. To the best of our knowledge, only a single analogue of this type has thus far been reported.[4] As shown in Scheme 1, the key element of the present strategy involves the use of the tethered diyne **2** in a cobalt mediated [2+2+2] cycloaddition,[5] thereby enabling closure of the eight-membered carbocyclic ring with concomitant construction of a usefully functionalised northern aryl unit for further elaboration. We also envisaged that the required *trans* stereochemistry round the γ-lactone **2** would be derived by alkylation of the lactone enolate from **3** with the benzylic bromide **4** or congeners thereof which would allow yet further variation in aromatic functionality to be introduced at an antepenultimate stage.

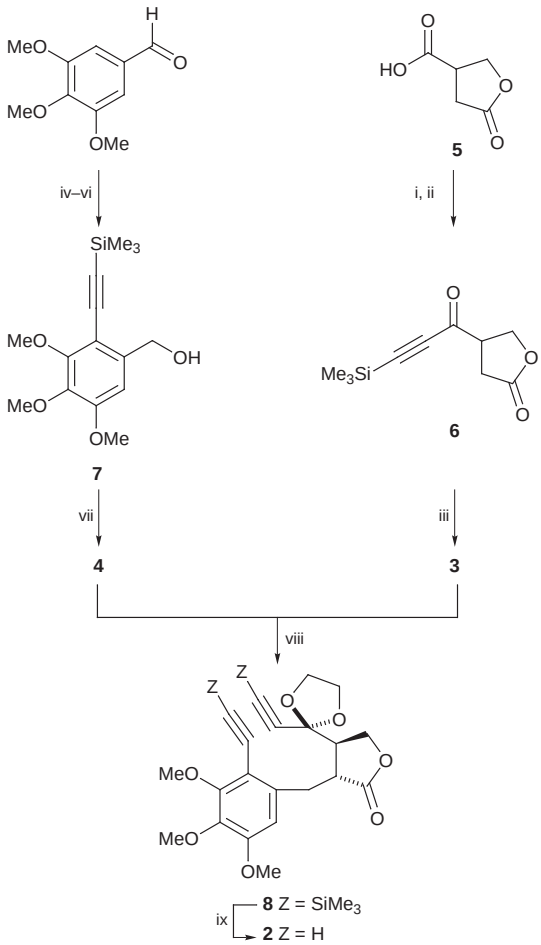
In the event, as outlined in Scheme 2, it was possible to develop a concise and highly efficient route to multigram quantities of the required diyne **2**. Thus, the protected lactone **3** was readily prepared from racemic paraconic acid **5** *via* palladium-catalysed coupling of the derived acid chloride with $Me_3SiC{\equiv}CSnMe_3$ followed by ketalisation of the resultant ynone **6**, whilst the known benzylic alcohol[7] **7** was available from 3,4,5-trimethoxybenzaldehyde *via* a straightforward sequence involving iodination, borohydride reduction, and a second palladium catalysed coupling reaction of the resultant iodoarene with $Me_3SiC{\equiv}CH$. The transformation to the corresponding bromide **4** was then acheived using the PPh_3–CBr_4 protocol. The coupling reaction of the two fragments proceeded smoothly through prior generation of the lithium enolate of lactone **3** with LDA at −78 °C followed by alkylation with the benzylic bromide **4** at −35 °C to give **8** as a single diastereoisomer. Deprotection of the acetylenic groups then furnished the parent diyne **2**.

Our attention then focused on the crucial $CpCo(CO)_2$-mediated [2+2+2] cycloaddition step using diyne **2**, $Me_3SiC{\equiv}CSiMe_3$ as the third acetylenic component, and the standard irradiation conditions developed by Vollhardt.[5] To our consternation, initial experiments failed to yield any significant amounts of the desired biaryl **9**, and the beautifully crystalline orange material which could be isolated as a single diastereoisomer in up to 57% yield was shown by X-ray crystallography to be the cobaltacyclobutadiene complex **10** (Scheme 3). Although the formation of similar complexes has been previously observed[9] and is generally considered to arise when either co-ordination or insertion of the third alkyne component is problematic, it was nevertheless encouraging to note that the structure **10** confirmed both the viability of the eight-membered ring closure and also the *trans* stereochemistry around the γ-lactone. Gratifyingly however, whether *via* the intermediacy of the putative metallocyclopentadiene precursor to **10** or one of the other two possible candidates from reaction with Me_3-



2 **3** **4**

Scheme 1



Scheme 2 *Reagents and conditions*: i, $(COCl)_2$, CH_2Cl_2, DMF (cat), room temp., 1 h; ii, $Me_3SiC{\equiv}CSnMe_3$, $Pd(PPh_3)_2Cl_2$, $ClCH_2CH_2Cl$, 50 °C, 16 h, 67% over 2 steps; iii, $HOCH_2CH_2OH$, PhH, PPTS (cat), reflux, 12 h, 87%; iv, I_2, AgO_2CCF_3, CH_2Cl_2, 20 °C, 12 h, quant.; v, $NaBH_4$, MeOH, −5 °C, 30 min, quant.; vi, $Me_3SiC{\equiv}CH$, $Pd(PPh_3)_2Cl_2$, CuI, Et_2NH, 50 °C, 2 h, 92%; vii, CBr_4, PPh_3, Et_2O, 24 h, 92%; viii, **4**, LDA, THF, −78 °C, 1 h, then add **3**, −35 °C, 1 h, 80%; ix, K_2CO_3, MeOH, 20 °C, 15 h, 95%.

$SiC{\equiv}CSiMe_3$, further variation in experimental conditions gave the desired biaryl **9** possessing the carbocyclic steganone core in 20% yield.

The structure of the indicated atropisomer of the biaryl **9**, which corresponds to the natural series, was established both by NOE experiments and also by deprotection of the ketal using wet formic acid which furnished the parent ketone **11** (ν_{max} 1674 cm^{-1}) in 54% yield (Scheme 3). Deprotection accompanied by selective mono- or di-protodesilylation could also be achieved in a single step by treatment of **9** with TFA either at room temperature or at reflux to afford the further steganone analogues **12** and **13** in 73 and 51% yield, respectively.

In summary, these preliminary results demonstrate the viability of using a tethered deca-1,9-diyne in a cobalt-mediated [2+2+2] cyclobenzannulation strategy for the construction of steganone analogues in a highly convergent manner. Within this framework, current studies are directed towards the use of further 2π addends and additional metal-based cyclotrimerisation reactions both for aromatic and heteroaromatic rings in order to further enhance the flexibility of this approach.

We thank the EPSRC and Zeneca Agrochemicals for the award of a CASE studentship to F. U., and University College London for the provision of a Provosts' studentship to A. B. We are also indebted to Professor D. Williams and Dr A. M. Z. Slawin for X-ray structural determination and the University of London Intercollegiate Research School (ULIRS) for mass spectral measurements. Finally, one of us (W. B. M.) wishes to acknowledge his personal debt of gratitude to the late Professor R. A. Raphael FRS, whose mastery of the Art of Organic Synthesis was matched only by his ability to encourage and to instil his love and enthusiasm for the subject in others.

Trifluorovinylxenon(II) tetrafluoroborate

H.-J. Frohn*[a] and V. V. Bardin[b]

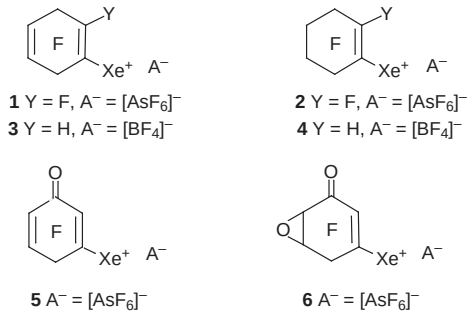
[a] *Fachgebiet Anorganische Chemie, Gerhard-Mercator-Universität Duisburg, Lotharstr. 1, D-47048 Duisburg, Germany. E-mail: frohn@uni-duisburg.de*

[b] *Institute of Organic Chemistry, Lotharstr. 1, 630090 Novosibirsk, Russia*

Received (in Basel, Switzerland) 18th February 1999, Accepted 2nd April 1999

The first acyclic alkenylxenon(II) compound, trifluorovinylxenon(II) tetrafluoroborate, was prepared from XeF_2 and trifluorovinylboron difluoride and characterized by ^{13}C, ^{19}F and ^{129}Xe NMR spectroscopy.

In 1993 we reported the first preparation of the cyclic alkenylxenon(II) compounds, (heptafluorocyclohexa-1,4-dien-1-yl)xenon(II) **1** and (nonafluorocyclohexen-1-yl)xenon(II) **2** hexafluoroarsenates by stepwise fluorine addition to $[C_6F_5Xe]^+[AsF_6]^-$ using XeF_2 in anhydrous HF (aHF).[1] Later (2-H-hexafluorocyclohexa-1,4-dien-1-yl)xenon(II) **3** and (2-H-octafluorocyclohexen-1-yl)xenon(II) **4** tetrafluoroborates[2] were obtained in a similar manner from (2,3,4,5-tetrafluorophenyl)xenon(II) tetrafluoroborate. Electrophilic oxygenation of $[C_6F_5Xe]^+[AsF_6]^-$ with XeF_2 and stoichiometric amounts of H_2O in HF gave (3-oxopentafluorocyclohexa-1,4-dien-1-yl)xenon(II) **5** and (3-oxo-4,5-epoxypentafluorocyclohexen-1-yl)xenon(II) **6** hexafluoroarsenates.[3]

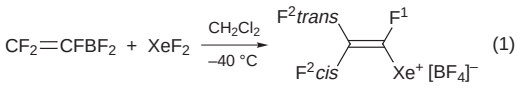


1 Y = F, A^- = $[AsF_6]^-$ **2** Y = F, A^- = $[AsF_6]^-$
3 Y = H, A^- = $[BF_4]^-$ **4** Y = H, A^- = $[BF_4]^-$

5 A^- = $[AsF_6]^-$ **6** A^- = $[AsF_6]^-$

All these synthetic routes to cyclic alkenylxenon(II) salts are based on the functionalization of arylxenon(II) salts and are restricted to the preparation of compounds with cyclohexadienyl- and cyclohexenyl-xenon(II) skeletons.

The topic of this paper is the elaboration of an alternative and new strategy and a more general approach to the synthesis of fluoroalkenylxenon(II) compounds: the reaction of XeF_2 with polyfluoroalkenylboron difluorides. When XeF_2 was reacted with trifluorovinylboron difluoride at −40 °C in CH_2Cl_2 the first acyclic alkenylxenon(II) salt, trifluorovinylxenon(II) tetrafluoroborate **7**,† was obtained in very good yield [eqn. (1)].



(1)

7

Salt **7** is a white solid which decomposes above *ca*. 0 °C. It is insoluble in CH_2Cl_2 but dissolves well in anhydrous HF (aHF), MeCN and EtCN. Its solution in aHF is stable at room temperature for some hours (monitored by ^{19}F NMR), whereas in MeCN (basic medium) **7** decomposes slowly above −20 °C and rapidly at room temperature with formation of xenon and some uncharacterized polyfluoroolefins.

The ^{19}F NMR spectrum[4] of the vinylxenon salt **7** in aHF (−30 °C) consists of resonances at δ −81.91 (F-2 *trans*) [^2J(F-2 *trans*)-(F-2 *cis*) 42 Hz, ^3J(F-2 *trans*)–(F-1) 105 Hz], −100.13 (F-2 *cis*) [^3J(F-2 *cis*)–(F-1) 126 Hz], −126.36 (F-1), −148.22 ($[BF_4]^-$, br) and HF at δ −190.83. All resonances of fluorine atoms bonded to carbon have ^{129}Xe satellites corresponding to the natural abundance of ^{129}Xe (I = 1/2) of 26.4%: ^3J(F-2 *cis*)-(^{129}Xe) 30 Hz, ^3J(F-2 *trans*)–(^{129}Xe) 146 Hz and ^2J(F-1)–(^{129}Xe) 248 Hz.

Resonances[4] of the carbon atoms C-1 and C-2 in the ^{19}F-decoupled ^{13}C NMR spectrum of **7** were located at δ 100.60 and 148.77, respectively and both displayed ^{129}Xe satellites: ^1J(C-1)–(^{129}Xe) 131 Hz and ^2J(C-2)–(^{129}Xe) 18 Hz. For comparison, the resonance of the carbon atom C-1 in the ^{13}C NMR spectrum of (nonafluorocyclohexen-1-yl)xenon(II) hexafluoroarsenate **2** in aHF (−10 °C) occurs at δ 96.28 and ^1J(C-1)–(^{129}Xe) is 114 Hz.[1]

The ^{129}Xe NMR spectrum[4] of compound **7** in aHF (−30 °C) displays a doublet of doublets of doublets at δ −3636.1($\Delta\nu_{1/2}$ = 13 Hz) [^2J(^{129}Xe)–(F-1) 248 Hz, ^3J(^{129}Xe)–(F-2 *cis*) 30 Hz, ^3J(^{129}Xe)–(F-2 *trans*) 146 Hz] (Fig. 1). This deshielding of the xenon atom in **7** is remarkable when compared to δ(^{129}Xe) values of the (polyfluorocycloalken-1-yl)xenon(II) compounds **1**–**6** (δ −3912.3, −3858.4, −3771.8, −3714.0, −3916.2 and −3900.3, respectively)[1–3] and is probably the result of a strong 'through-space' electronic interaction of the xenon atom with the geminal fluorine atom F-1. This consideration is also in agreement with the large value of ^2J(^{129}Xe)–(F-1), which is the largest of the the known coupling constants in organoxenon compounds.

The ^{19}F NMR spectrum of a solution of **7** in EtCN at −40 °C consists of resonances at δ −84.97 (F-2 *trans*) [^2J(F-2 *trans*)–(F-2 *cis*) 46 Hz, ^3J(F-2 *trans*)–(F-1) 90 Hz], −103.36 (F-2 *cis*) [^3J(F-2 *cis*)–(F-1) 124 Hz], −137.81 (F-1) and −149.59 ($[BF_4]^-$) [^3J(F-2 *cis*)–(^{129}Xe) 29 Hz, ^3J(F-2 *trans*)–(^{129}Xe) 139 Hz, ^2J(F-1)–(^{129}Xe) 191 Hz]. The ^{129}Xe NMR signal was located at δ −3510.6 [^2J(^{129}Xe)–(F-1) 197 Hz, ^3J(^{129}Xe)–(F-2

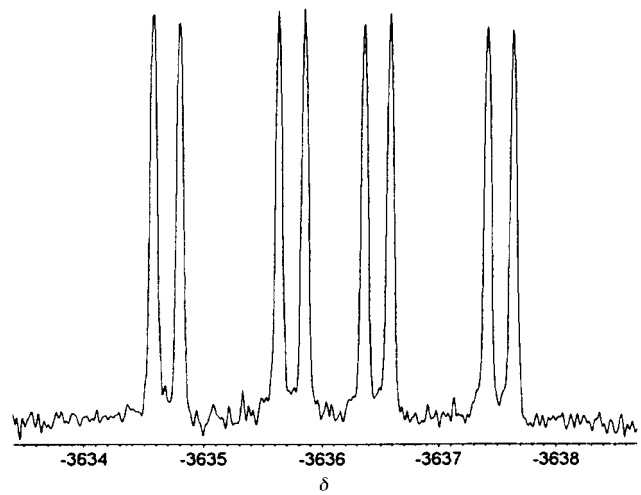


Fig. 1 ^{129}Xe NMR resonance of **7** (aHF, −30 °C, 5 mm glass tube with FEP inliner, measured on a Bruker DRX 500 spectrometer at 138.34 MHz; shift values relative to neat $XeOF_4$ at 24 °C.

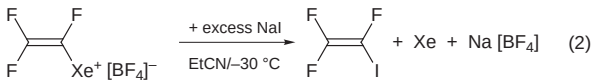
cis) 27 Hz, $^3J(^{129}Xe)$–(F-2 *trans*) 136 Hz]. Cooling to −70 °C led to shielding of the fluorine atom F-1 and a decrease of ^2J(F-1)–(^{129}Xe) to 188 Hz resulting from a favoured cation–anion interaction over the cation–EtCN interaction:[5] δ −84.09 (F-2 *trans*) [^2J(F-2 *trans*)–(F-2 *cis*) 46 Hz, ^3J(F-2 *trans*)–(F-1) 88 Hz], −102.62 (F-2 *cis*) [^3J(F-2 *cis*)–(F-1) 123 Hz], −138.27 (F-1) and −150.31 ([BF_4]$^-$) [^3J(F-2 *cis*)–(^{129}Xe) 28 Hz, ^3J(F-2 *trans*)–(^{129}Xe) 136 Hz].

Chemical proof of the carbon–xenon bond and of the electrophilic nature of the vinylxenon(II) cation in **7** was obtained by conversion into trifluoroiodoethene with loss of Xe^0 when a solution of **7** in EtCN was treated with NaI in excess at ⩽−30 °C [eqn. (2)] (*cf.* ref. 6).



(2)

In summary, the trifluorovinylxenon cation is of great importance for preparative and theoretical chemistry because it is an unique precursor for the trifluorovinyl radical and cation.

We gratefully acknowledge Volkswagen Stiftung and Fonds der Chemischen Industrie for financial support.

Received (in Columbia, MO, USA) 31st December 1998, Accepted 31st March 1999

The synthesis and characterization of an epitaxial growth of zeolite β on SSZ-31 nanofibers is described, and a structural model of the interface between the two zeolites is proposed.

Zeolite crystals in the form of nanofibers have several potential catalytic applications, owing to the short diffusion lengths across these fibers and their low resistance to fluid flow (low pressure drop), as well as other advanced materials applications owing to the possibility of incorporating them in membrane, sensor or electronic devices. A few zeolites with one-dimensional (1-D) pore systems are known to crystallize in a needle-like morphology[1–3] with the channels running along the long axis of the particles. This raises the possibility of epitaxially growing other zeolitic structures on nanofibers of such 1-D pore zeolites. We report here, the first such epitaxial process, involving the growth of zeolite-β on nanofibers of the 1-D zeolite SSZ-31, and we propose a structural model for the interface between the two zeolites.

Zeolite-β is an industrially important large-pore material, widely used in catalytic and adsorption processes.[4,5] Previous syntheses of zeolite-β resulted in equiaxed particles that contain both the β polymorphs A and B. In this study, zeolite-β was synthesized as pure silica polymorph using 1,3,3,6,6-pentamethyl-6-azoniumbicyclo[3.2.1]octane cation as the organic structure-directing agent (SDA). This cation was synthesized by quaternization of the parent amine with an excess of MeI in CCl_3H, and was used in hydroxide form after anion exchange of the iodide.

For the zeolite synthesis, tetraethylorthosilicate (21.89 g) was hydrolysed in 35.02 g of an aqueous solution of the SDA in hydroxide form (1.49 mmol g^{-1}). The mixture was stirred, allowing evaporation of the ethanol produced in the hydrolysis. Further stirring for 3 h at room temperature allowed the evaporation of a total mass of 22.69 g (ethanol plus water). Then, HF (2.18 g, 48% aqueous solution) was added and the mixture was shaken till homogeneous. Hydrothermal crystallization of this mixture (final composition SiO_2 : 0.5 $C_{12}H_{24}NOH$: 0.5 HF : 9.9 H_2O) in rotating (60 rpm) Teflon-lined stainless steel autoclaves at 150 °C for 20 days produced a crystalline solid with an XRD pattern similar to that of zeolite-β.[6,7]

However, there were several facts suggesting that this material was not identical to zeolite-β and that it could also be related to zeolite SSZ-31. First, the XRD pattern shows some differences with the pattern of zeolite-β and some similarities with that of SSZ-31[3,8]. For instance, the shape of the first broad peak at low angle is more like that of the second peak in SSZ-31 rather than the first peak in zeolite-β. Also, the separation of the two main peaks in the range 2θ 20–22.5° of 1.20° is closer to that in SSZ-31 (1.28°) than in β (1.08°). Furthermore, the adsorption capacity of this material (0.13 cm^3 g^{-1}) calculated from the N_2 adsorption isotherm using the *t*-plot method, is intermediate between those of zeolites β (0.19 cm^3 g^{-1}) and SSZ-31 (0.08 cm^3 g^{-1}). Interestingly, when the final water : silica ratio in the above synthesis mixture composition was increased to 15, SSZ-31 was obtained (when the ratio was decreased to 7.5, ITQ-3[9] was the crystallization product). All these suggested that the synthesized solid could actually be an intergrowth of zeolites β and SSZ-31.

To characterize the synthesized crystals, transmission electron microscopy was performed with a JEOL 3010 microscope operating at 300 kV. A low-resolution TEM image shows that a significant number of crystals are nanofibers of length 1–2 μm, with radial outgrowths *ca.* 20 nm in radius [Fig. 1(a)]. A few fibers of length up to 5 μm have also been observed. A high-resolution TEM image [Fig. 1(b)] from the center of such a crystallite reveals that a nanofiber of zeolite SSZ-31 forms a 'backbone' (running along the centerline of the nanofiber) for epitaxial growth of zeolite-β. This is further corroborated by the presence of SSZ-31 nanofibers free of zeolite-β outgrowths. Complete channels of β (polymorph B) lie immediately above the β/SSZ-31 interface. Two SSZ-31 channels are observed, apparently running parallel to the second channel direction of zeolite-β. These observations suggest that the β/SSZ-31 interface contains composite 12-membered channels constructed from β and SSZ-31 'half-channels'. The SSZ-31 'backbone' is observed to be always three unit cells thick.

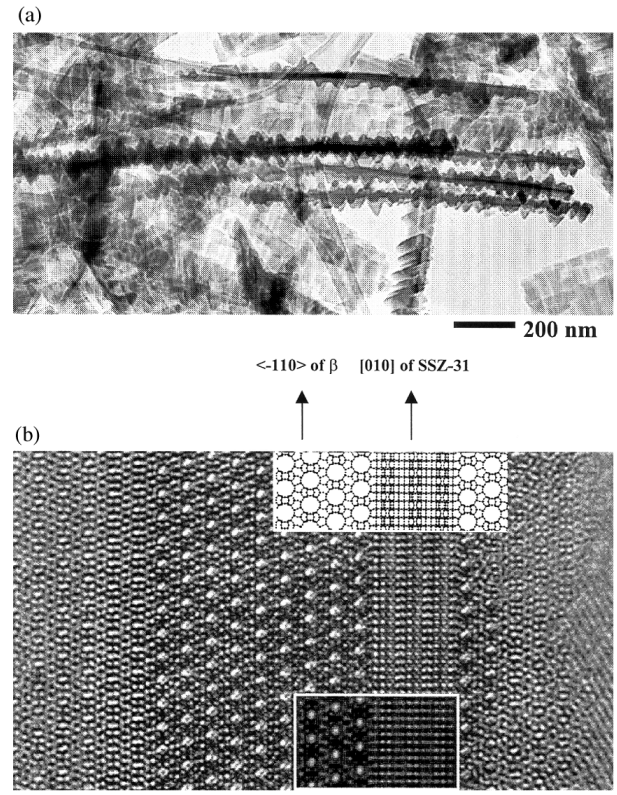

Fig. 1 (a) TEM image of synthesized crystals showing SSZ-31 nanofibers with epitaxial outgrowths of zeolite-β; (b) high-resolution TEM image of the epitaxial growth of zeolite-β on zeolite SSZ-31; model of the intergrowth (inset, upper); and TEM simulation of this model (inset, lower).

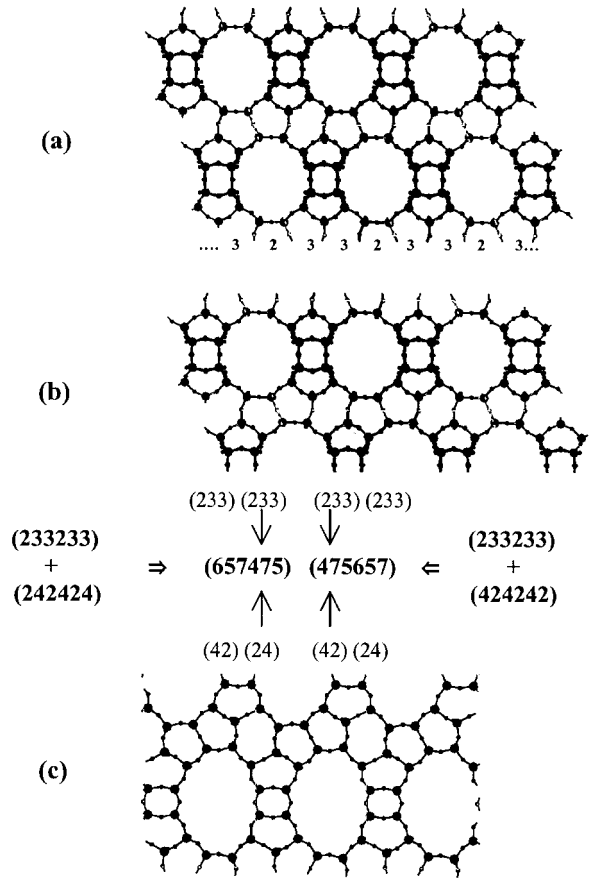

Fig. 2 (a) Projection of β structure along < 110 > showing the two- and three-membered ring fragments in a (233) sequence; (b) projection along < −110 > showing the half-channels. Each of the eight lowermost silicon atoms is a member of a (233) sequence running alongside a half-channel in the < −110 > direction; (c) projection of SSZ-31 polymorph B along [010] showing the half-channels. Each of the uppermost silicon atoms is a member of a (24) sequence running alongside the half-channel. These sequences are laterally shifted with respect to each other. The generation of the (657475) and (475657) sequences at the interface of zeolite-β with SSZ-31 polymorphs A–D is indicated.

To construct possible interfaces, it is first assumed that the 12-membered composite channels are comprised of six silicate tetrahedra derived from a β channel, and the remaining six tetrahedra from an SSZ-31 channel. We terminate the β structure at a plane parallel to the < −110 > channel direction, leaving six-membered half-channels in this direction and complete channels in the < 110 > direction. Fig. 2(a) shows a view of the β polymorph B along the < 110 > direction, and Fig. 2(b) shows a view along the < −110 > direction showing the half-channels. Since the β channels are enclosed by four-, five- and six-membered rings, the termination results in ring 'fragments' of two or three tetrahedra, which are visible at the bottom of Fig. 2(a). These fragments follow a periodic 2–3–3–2–3–3 . . . sequence (abbreviated to 233), as shown in the figure. At the interface plane, a β half-channel is therefore bounded by two identical 233 sequences (one on either side of the half-channel) propagating down the < −110 > channel direction, as indicated in Fig. 2(b). Similar termination of β polymorph A results in the same structure at the interface. Since β polymorph B is observed at the interface in Fig. 1(b), only this polymorph is considered in the following discussion.

There are eight polymorphs (A–H) of SSZ-31 with different connectivities down the [010] channel direction.[8] The SSZ-31 structure is similarly terminated by a plane parallel to the [010] direction, leaving six-membered half-channels. Fig. 2(c) shows the terminated structure of SSZ-31 polymorph B viewed along the [010] direction, indicating the half-channels. Inspection of this structure in the channel direction shows that the interface plane contains ring fragments of two or four tetrahedra, that form periodic (2–4–2–4–) chains (abbreviated to 24) running along the channel direction. However, these chains are laterally shifted with respect to each other, so that a two-membered fragment on one chain has as its neighbor, a four-membered fragment of the adjacent chain. The two sequences running alongside an SSZ-31 half-channel can be represented as (24) □ (42) for polymorphs A–D. The symbol □ indicates the half-channel as viewed down [010], with one sequence running along its left and right. Polymorphs E–H have adjacent (24) □ (26), and (26) □ (24) half-channels.

The epitaxy is achieved by bonding the half-channels of β and SSZ-31 (*via* oxygen atoms) to form 12-membered interfacial composite channels. The combination of the sequences of zeolite-β with the sequences of SSZ-31 polymorphs A–D results in closed rings following the periodic sequences (475657) ■ (657475); where the symbol ■ indicates the composite channel. Interfaces of β with SSZ-31 polymorphs E–H have two types of composite channels when viewed down the channel direction: (475657) ■ (495858), and (495858) ■ (475657). These channels are adjacent to each other at the interface. The interfaces therefore contain seven-membered rings, and even nine-membered rings in the case of epitaxial growths involving SSZ-31 polymorphs E–H. The two polymorphs of β together with the eight polymorphs of SSZ-31 lead to 16 possible epitaxial growths, with only two possible interfacial structures, (475657) and (495858), as shown above. Considering the unit cell dimensions of the two zeolites, the 2-D rectangular epitaxial unit cell at the interface would have dimensions of 25.2 Å in the SSZ-31 channel direction and 12.33 Å in the perpendicular β channel direction. Composite channels comprising unequal numbers of tetrahedra from each zeolite (*e.g.*, eight from β and four from SSZ-31) do not appear to be feasible due to non-matching bond positions on either side of the interface.

The epitaxy of β polymorph B on SSZ-31 polymorph B is simulated as described above, using the *Cerius*[2] Interface Builder. The resulting structure [Fig. 1(b), upper inset] is found to match the TEM image. In the TEM image, the two zeolite-β domains on either side of the SSZ-31 domain appear to be laterally shifted with respect to each other. The structural model proposed above accounts for this observation, since it allows the β structure to be shifted along the channel direction of SSZ-31. This shift is captured in the interface simulation, and appears in the upper inset of Fig. 1(b). A TEM simulation of the interface is also shown (lower inset), and it is seen to match the actual image. However, the information available from the TEM image appears insufficient to identify the SSZ-31 polymorph that is actually involved in the epitaxy. It is also possible that the synthesized sample contains intergrowths of zeolite-β and SSZ-31 in addition to the epitaxial regions that we observe.

Unusual cyclopropanol formation from a β-silyl aldehyde

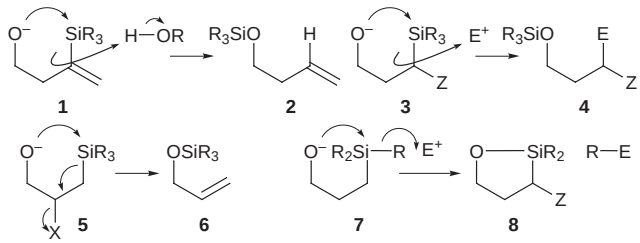
Ian Fleming* and Ajay K. Mandal

Department of Chemistry, Lensfield Road, Cambridge, UK CB2 1EW. E-mail: if10000@cam.ac.uk

Received (in Liverpool, UK) 9th March 1999, Accepted 6th April 1999

The hemiacetals 15 and 18 gave cyclopropanols 17 and 20 when treated with NaH in DMSO, showing that the silyl group has enhanced electrofugal powers because of the participation of the oxyanion.

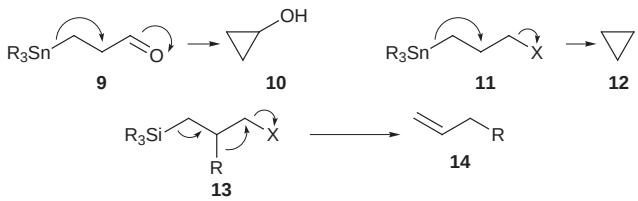
The well known electrofugal power of a silyl group attached to carbon is enhanced when a nucleophilic atom coordinates to it. This unexceptionable statement is supported by much circumstantial evidence (Scheme 1). A silyl group can be removed more easily (**1** → **2**) by protodesilylation from a vinyl, or even an alkyl, carbon when an oxyanion is poised five atoms away.[1] More generally, a variety of electrophiles can be made to react with the incipient or actual carbanion nucleophile (**3** → **4**) if the carbon carrying the silyl group has an anion-stabilising group on it.[2] An oxyanion can also remove a silyl group in a 5-*endo-tet* sense to create a double bond (**5** → **6**).[3] And an oxyanion can push one of the other ligands off a silyl group in the sense (**7** → **8**) to make the R group into a carbon nucleophile.[4] We now report a case where the presence of an oxyanion makes a silyl group behave more like a stannyl group, in a reaction with precedent only with a 1,2-Brook rearrangement from an α-oxyanion rather than a γ-oxyanion.[5]



Scheme 1

β-Stannyl aldehydes and ketones[6] form cyclopropanols on treatment with Lewis acids (**9** → **10**) (Scheme 2), but β-silyl aldehydes and ketones are remarkably robust to acid and base, often being carried through many steps before being used as masked α,β-unsaturated carbonyl compounds,[7] or as masked β-hydroxy carbonyl compounds.[8] When they do react with Lewis or protic acids, they undergo rearrangements,[9] or intramolecular transfer of ligand from the silicon to the carbonyl group,[10] and we know of only one example where a cyclopropanol-forming pathway has been suggested.[11] In parallel with these observations, cyclopropane formation (**11** → **12**) is normal with γ stannyl carbocations and their precursors,[12] but is unusual with the corresponding silyl compounds,[13] for which rearrangement (**13** → **14**) is the normal pathway.[14]

The reaction we have now discovered occurred originally when we had been trying to carry out a Wittig reaction on the racemic hemiacetal **15**, prepared by DIBAL-H reduction of the corresponding lactone.[15] When we treated the hemiacetal **15** with NaH in DMSO at room temperature for 3 h, with or without methyltriphenylphosphonium iodide, we obtained only the cyclopropanol **17** (Scheme 3). We see this tin-like behaviour as having taken place because of the presence in the intermediate aldehyde of an oxyanion, which can coordinate to the silicon **16** (arrows), and make the pentacovalent silyl anion into a better electrofugal group. We were not able to assign the stereochemistry of the cyclopropanol **17** reliably from the ^{1}H NMR spectrum, it is assigned here by analogy, so we repeated the reaction with a marginally more simple analogue **18**, which similarly gave the cyclopropanol **20** (Scheme 3). COSY and NOE difference experiments on this compound allowed us to confirm the stereochemistry, which corresponds to inversion of configuration at the silicon-bearing carbon, exactly analogous to the inversion seen in reactions of the type **11** → **12** in the tin series. The stereochemistry at the C–OH carbon corresponds to that expected if the carbonyl group more or less eclipses the neighbouring hydrogen atom at the time of cyclopropane formation, which seems reasonable.

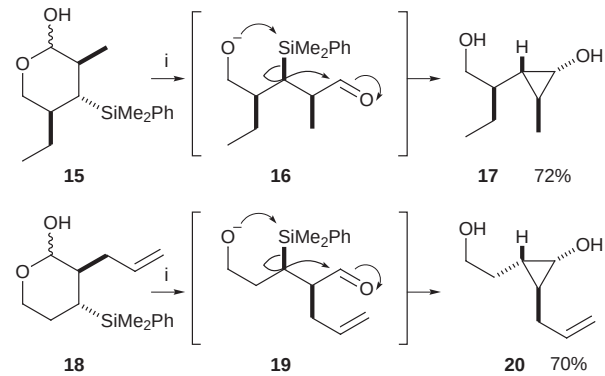


Scheme 2

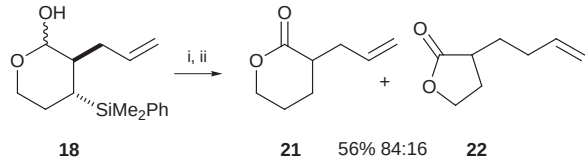
If we left the hemiacetal **18** and NaH/DMSO at room temperature for 10 h instead of 3 h, we obtained a mixture of four hemiacetals, which gave a mixture of two lactones **21** and **22** on oxidation (Scheme 4). The hemiacetal precursor of the lactone **21** looks as though the original hemiacetal **18** had merely undergone a somewhat implausible protodesilylation, but the true pathway, by way of the cyclopropanol **20**, is revealed by the presence of the minor lactone **22**.

This observation may explain our failure to achieve cyclopropanol formation from the even more simple hemiacetal **23**, which gave only the product **24** of protodesilylation (Scheme 5), possibly directly in this case, but also possibly by way of a cyclopropanolate, which can be expected to open regioselectively by way of the benzyl anion.

The cyclopropanol formation is not a general reaction, for we found that the 2-methyl and 2-allyl groups in **15** and **18** appear to be necessary, not only for the determination of the stereochemistry of the reaction, but also for it to take place at all. The hemiacetal **25** gave no sign of a cyclopropanol, but gave instead a diene **26**, which we suggest has taken the course illustrated in Scheme 6, with the possibility that the final elimination step is actually preceded by a Mislow rearrangement.

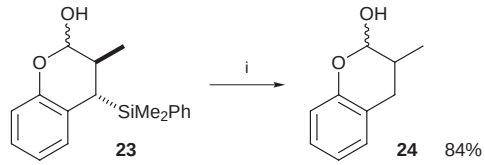


Scheme 3 *Reagents and conditions*: i, NaH, DMSO, rt, 3 h.



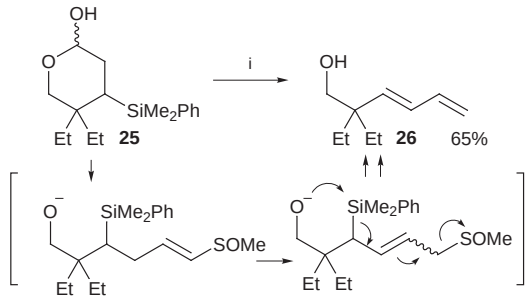
18 **21** 56% 84:16 **22**

Scheme 4 *Reagents and conditions*: i, NaH, DMSO, rt, 10 h; ii, PCC, CH_2Cl_2, rt, 2 h.



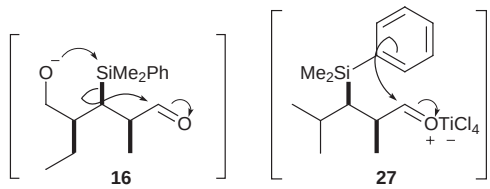
23 **24** 84%

Scheme 5 *Reagents and conditions*: i, NaH, DMSO, rt, 3 h.



Scheme 6 *Reagents and conditions*: i, NaH, DMSO, rt, 3 h.

Perhaps most intriguing is the contrast between the reaction described here, *pushed* forward by nucleophilic activation **16**, and the reaction on a closely similar system **27** *pulled* forward by electrophilic activation.[10] In both cases, our plans for a synthesis of ebelactone-a were thwarted.



We thank the CVCP as managers of the ORS scheme and the managers of the Nehru Trust for support (A. K. M.).

Hydrazinolysis of Fischer-type oxacarbenes made efficient: a new and easy entry to alkyl and aryl hydrazinocarbene complexes

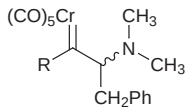
Emanuela Licandro,* Stefano Maiorana,* Antonio Papagni, Dario Perdicchia and Raffaella Manzotti

Dipartimento di Chimica Organica e Industriale, Università degli Studi di Milano, via C.Golgi, 19, I-20133 Milano, Italy. E-mail: maior@icil64.cilea.it

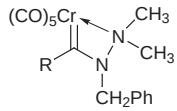
Received (in Liverpool, UK) 14th January 1999, Accepted 16th April 1999

Hydrazinolysis of the pentacarbonyl[alkyl- or aryl-(methoxy)carbene] complexes of W^0 and Cr^0 with both 1,1- and 1,2-disubstituted hydrazines affords the corresponding new hydrazinocarbenes 15–18, 21 and 22, and the presence of LiCl in the reaction medium greatly increases their yields.

We have recently achieved the first synthesis of a number of new pentacarbonyl and chelate hydrazino(alkyl)carbene complexes **1**–**3**.[1]



1 R = Me
2 R = Et, but-3-enyl



3 R = Et, but-3-enyl, Pr^i

The synthesis of **1**–**3** is of general applicability only when applied to 1-substituted hydrazides.[2] The hydrazinolysis of oxacarbenes was a highly appealing procedure, even if Fischer[3] reported that, for the reaction between the 1,1-dimethylhydrazine and the pentacarbonyl[methoxy(methyl)carbene]chromium(0), it was unsuccessful. However, the hydrazinolysis of oxacarbenes has more recently been shown to be possible in a few specific cases.[4,5]

We here report on the reactions between the 1,1-disubstituted hydrazines **5** and **7**–**10** and the methoxy(methyl)carbene tungsten(0) complex **11**, as well as those between the 1,2-dimethylhydrazine **12** and the methoxy(methyl)- and methoxy(phenyl)-carbene chromium(0) complexes **4** and **13**. The results of this study eventually revealed a new and efficient entry to alkyl- and aryl-(hydrazino)carbenes.

We initially reacted under nitrogen the 1,1-dimethylhydrazine **5** (1.1 mmol) with the tungsten complex **11** (1 mmol) in dry THF solution at −78 °C for 30 min, but even the use of tungsten only afforded the $(CO)_5W{\leftarrow}N{\equiv}C{-}Me$ complex **14** (Table 1). However, when we reacted the hydrazines **7**–**10** with **11** under the same conditions, we isolated a reaction mixture containing the (*Z*)-hydrazinocarbenes **15**–**18**† and variable amounts of the acetonitrile complex **14**; the yields are shown in Table 1.

Although the yields of hydrazinocarbenes **15**–**18** were not very high, this first set of results showed us that it was possible to use the simple procedure described above to prepare stable and isolable alkyl hydrazinocarbene complexes of tungsten. We therefore decided to look carefully at the possible mechanism of the hydrazinolysis reaction. The aim was to identify the factors potentially capable of differentiating the pathway leading to the acetonitrile complex **14** from that affording the target hydrazinocarbenes **15**–**18**.

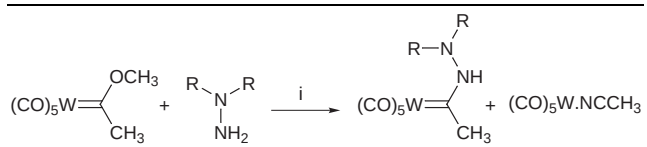
According to Aumann,[4] during the hydrazinolysis of alkoxy(alkynyl)carbenes, the hydrazinocarbenes **15**–**18** are formed through the elimination of MeOH from the tetrahedral intermediate of the reaction, whereas product **14** arises from the breaking of the N–N bond with amine elimination. This latter process is a consequence of the proton shift from the α- to the β-nitrogen.

All of the attempts to prevent this proton shift, *i.e.* (i) by increasing steric hindrance around the β-nitrogen, (ii) by running the reactions in the presence of an excess of Et_3N as an external competing base and, (iii) by reducing the β-nitrogen lone pair availability by means of acylation, failed, and there was no improvement in the yields of the complexes **15**–**18**. Looking for an alternative way to minimize the undesirable β-nitrogen protonation, we considered a Lewis acid as a possible coordinating species capable of engaging the β-nitrogen lone pair without transforming this nitrogen into a good leaving group: Li^+ (as LiCl) appeared to be a suitable reagent for achieving this goal.

The results of the hydrazinolysis of complex **11** with the *N*-aminomorpholine **8** and *N*-amino-*trans*-2,6-dimethylmorpholine **9** in the presence of 2.2 equiv. of LiCl were surprisingly good, with the yields of complexes **16** and **17** being respectively double and eight times of those obtained in the absence of LiCl (Scheme 1).

The presence of LiCl also had a dramatic effect on the reaction times, which increased from 30 min to 5 h. We believe that this effect can be rationalized in terms of the formation of an aggregate in THF between LiCl and the hydrazines **8** and **9**,‡ in which the nucleophilic character of the hydrazines would be

Table 1 Reaction of **11** with various hydrazines[a]

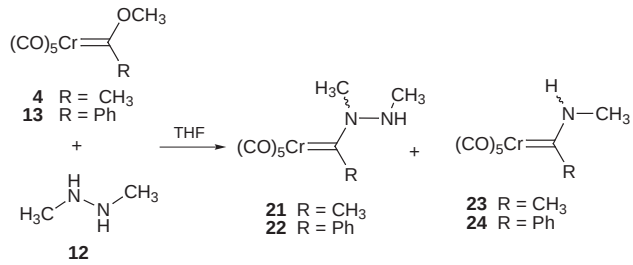


11 **5, 7–10** **15–18** **14**

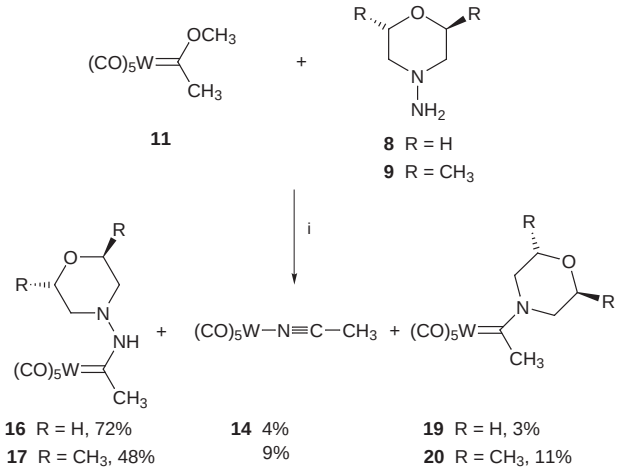
Hydrazine	(*Z*)-Hydrazinocarbene **15**–**18** (% yield)	Yield of **14** (%)
5 	—	52
7 	**15** (34)	42
8 	**16** (34)	50
9 	**17** (6)	74
10 	**18** (28)	41

[a] *Reagents and conditions*: i, THF, −78 °C, 30 min.

Table 2 Hydrazinolysis in the presence of LiCl



Complex	LiCl (equiv.)	*T*/°C	Time	Hydrazinocarbene (% yield, *E* : *Z*)	Aminocarbene (% yield)
4	—	−78	5 min	21 (18, 7 : 3)	23 (40)
4	2	−78 → −20	15 h	21 (73, 4 : 6)	23 (7)
13	—	−78	5 min	22 (30, 1 : 1)	24 (35)
13	2	−78 → −20	15 h	22 (80, 1.3 : 1)	23 (13)



Scheme 1 *Reagents and conditions*: i, LiCl (2 equiv.), THF, −40 °C, 3 h.

reduced. As a result of the decrease in reaction rates, the amines produced in the N–N bond breaking step can compete with the hydrazine in the reaction with **11** affording the aminocarbenes **19** and **20** (Scheme 1).

Even in the presence of LiCl, only the (*Z*)-isomer of the hydrazinocarbenes **16** and **17** was formed. In a typical procedure, LiCl (0.0999 g, 2.47 mmol) was dissolved in anhydrous THF (3 ml) and hydrazine **8** (0.115 ml, 1.19 mmol.) was added under N_2 at the same temperature, thus generating a white slurry to which a 3 ml THF solution of **11** (0.412 g, 1.08 mmol.) was added dropwise over 5 min at −78 °C. After 2 h at −78 °C, the temperature was raised and kept at −40 °C for a further 3 h. Standard work-up followed by purification by flash chromatography [eluent: Et_2O–light petroleum (6 : 4) then Et_2O] gave the hydrazinocarbene **16**.§

The hydrazinolysis reaction was then extended to the 1,2-dimethylhydrazine **12** which was reacted with the chromium(0) carbenes **4** and **13** (Table 2). When the free hydrazine was used, the expected hydrazinocarbenes **21** (*E*/*Z* = 7 : 3) and **22** (*E*/*Z* = 1 : 1) were obtained in 18 and 30% yield respectively, as well as the methyl(amino)carbene complexes **23** and **24** (yields of 40 and 35%, respectively). Also in this case, the presence of 2 equiv. of LiCl in the reaction mixture greatly increased the yields of hydrazinocarbenes **21** and **22** (see Table 2), thus demonstrating a general and important effect of the presence of this salt in the reaction medium. The reaction was carried out starting from a commercially available dihydrochloride salt of the 1,2-dimethylhydrazine (0.328 g, 2.46 mmol) suspended in anhydrous THF (20 ml), and treated under nitrogen at 0 °C with a stoichiometric amount of Bu^nLi (1.4 M *n*-hexane solution, 3.5 ml, 4.92 mmol) (Table 2).

In conclusion, carbene complexes of tungsten(0) and chromium(0) **16**, **17**, **21** and **22** were synthesized in satisfactory to good yields by means of the hydrazinolysis reaction carried out in the presence of 2 equiv. of LiCl. It is likely that hydrazine/LiCl aggregates are involved as the reactive species. To the best of our knowledge, nothing has yet been reported in the literature concerning the use of stable aggregates between hydrazines and LiCl for synthetic purposes.[6]

We gratefully acknowledge joint financial support from M.U.R.S.T., Rome, and the University of Milan (National Project 'Stereoselezione in Sintesi Organica, Metodologie ed Applicazioni'). We also acknowledge the C.N.R. of Rome.

Notes and references

† Only the (*Z*)-rotamers were observed. The lack of isolation of any of the (*E*)-rotamers of **15**–**18** means that they are not formed at all or, if formed, they are unstable and immediately give the $W(CO)_5{\cdot}NCCH_3$ as postulated by Fischer (ref. 3).

‡ To a THF solution of LiCl (2 equiv.), the hydrazine **8** (1 equiv.) was added at room temperature. The resulting white solid was isolated and used for the hydrazinolysis of complex **11**, affording the hydrazino complex **16** in the same yield as that shown in Scheme 1 (72%). The structure of the above lithium aggregate is under investigation.

Received (in Basel, Switzerland) 18th December 1998, Accepted 2nd April 1999

By reacting an aqueous solution of ammonium heptamolybdate with formic acid in the presence of hydrazinium sulfate at pH ≈ 4.2 the compound $(NH_4)_{42}[Mo^{VI}_{72}Mo^{V}_{60}O_{372}(HCO_2)_{30}(H_2O)_{72}]\cdot x HCO_2Na\cdot y H_2O$ 1 ($x \approx 30$, $y \approx 250$) with spherically shaped stable cluster anions is obtained; owing to the spherical shape of the cluster–shell template, the anion 1a (with the small 'nondisturbing' bidentate HCO_2^- ligand) exhibits a remarkable overall 'onion-type' structure, thereby revealing also a novel type of inclusion: a hydrogen-bonded cluster with 'onion-type' structure, which suggests interesting aspects for a new type of supramolecular chemistry.

Linking elementary building blocks in different ways in order to synthesize a large variety of different molecular constructions, in particular those of the nanoworld is still a formidable challenge for the inorganic chemist.[1] Recently we succeeded in developing a synthetic route for an inorganic superfullerene or a giant ball-shaped cluster anion.[2] Here we report on the synthesis of a new related compound **1** which shows a novel structural feature: an unusual hydrogen-bonded cluster of guest molecules encapsulated as a part of the overall 'onion-type' structure.

Compound **1** which crystallizes in the space group $R\bar{3}$ was synthesized by reducing an aqueous molybdate solution with hydrazinium sulfate in the presence of formic acid (pH ≈ 4.2).‡§ The spherical icosahedral cluster shell of the anion **1a** is built up by 12 $\{Mo_{11}\}$ fragments of the type $\{(Mo)Mo_5\}\{Mo^{V}_1\}_5$ with a central bipyramidal pentagonal $\{MoO_7\}$ unit (Fig.1). (Throughout, the oxidation state of the molybdenum center is only given if different from VI.) Each central $\{MoO_7\}$ unit is connected *via* edges to five $\{MoO_6\}$ octahedra which are linked in pairs to the five surrounding Mo^V atoms. Each of the latter is bonded to a Mo^V center of one of the five neighbouring $\{Mo_{11}\}$ fragments thus forming a $\{Mo^{V}_2\}$ unit. All oxygen atoms of the 132 $Mo–O_{term}$ groups lie on the surface of the ball-shaped cluster and accordingly the *trans*-orientated H_2O ligands of the 72 Mo centers as also the carboxylate ligands bonded to the $\{Mo^{V}_2\}$ groups point towards the center of the ball. To give an alternative description, the twelve $\{(Mo)Mo_5\}$ pentagons of **1a** are bridged *via* the 30 well known $\{Mo^{V}_2\}$ groups with Mo–Mo single bonds which themselves are stabilized by the bidentate carboxylate ligands. The corresponding formulation is $[\{(Mo)Mo_5O_{21}(H_2O)_6\}_{12}\{Mo^{V}_2O_4(HCO_2)\}_{30}]^{42-}$.

Most interestingly, the small carboxylate ligand used here allows a special type of organization of the encapsulated H_2O molecules resulting in a hydrogen-bonded cluster as guest system with an 'onion-type' structure[3] (see Fig. 2 with space filling representation). Six H_2O molecules with nearly trigonal antiprismatic ordering (in violet) form the innermost shell with a distance of *ca.* 3.5 Å from the (unoccupied) center of the 'onion'. The second shell (6.2–6.9 Å, highlighted as green spheres) is approximately close packed and contains *ca.* 35 H_2O molecules. The third shell (8.2–8.7 Å, shown as yellow spheres) contains a smaller number of H_2O molecules. This unusual arrangement which is induced by the spherical cluster shell spanned by the 132 molybdenum atoms is obviously only possible in the presence of the comparatively small formate ligands coordinating to the $\{Mo^{V}_2\}$ groups. This allows the H_2O molecules of the third shell to occupy positions between the bidentate ligands in the region of the 'pores'.

To evaluate the influence of the carboxylate ligands on the structure of the encapsulated molecules we also used other carboxylate ligands. The analogous reaction of sodium molybdate with monochloroacetic acid, for instance, led to the formation of a spherically shaped cluster anion and the related compound $(NH_4)_{42}[Mo^{VI}_{72}Mo^{V}_{60}O_{372}(ClCH_2CO_2)_{30}(H_2O)_{72}]\cdot x ClCH_2COONa\cdot y H_2O$ ($x \approx 15$, $y \approx 250$) which crystallizes in the space group $Fm\bar{3}$. However, due to the poor crystal quality and disorder problems we were unable to locate in detail the arrangement of guest molecules inside the cavity.¶ Interestingly, the spherical anion was possibly abundant in a solution investigated by Ostrowetsky in the early 1960s as the UV–VIS spectrum reported there is identical with that obtained by us.[4]

The high stability of **1** is remarkable and allows the development of a chemistry similar to that of the Keggin-ion type, for instance a new type of host–guest chemistry. In the

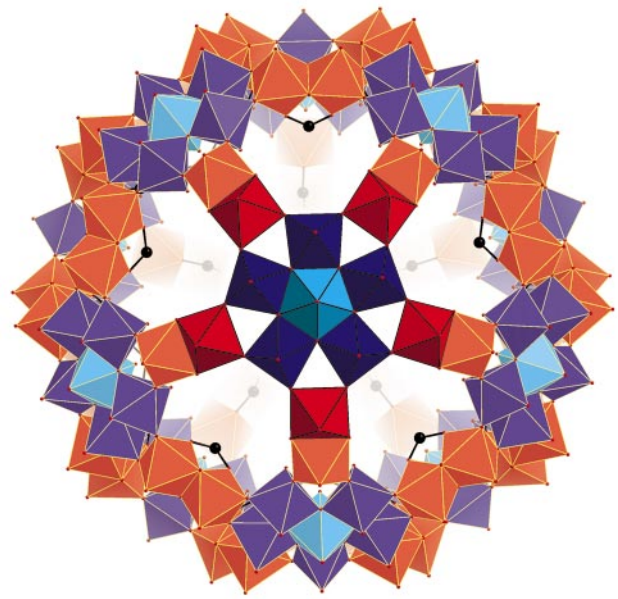

Fig. 1 Illustration of the structure of **1a** with perspective view along a fivefold symmetry axis highlighting a pentagonal $\{Mo_{11}\}$ unit owing to the structural complexity of the spherical shape shown in polyhedral representation. The five peripheral atoms of a $\{Mo_{11}\}$ unit are formed by the Mo centers of the five related $\{Mo^{V}_2O_4\}^{2+} = \{Mo^{V}_2\}$ groups attached to the $\{(Mo)Mo_5\}$ pentagons ($\{(Mo)Mo_5\}$ groups blue with the central MoO_7 bipyramids cyan; $\{Mo^{V}_2\}$ bridge red).

† On leave from the Institute of Inorganic Chemistry, Russian Academy of Sciences, pr. Lavrentjeva 3, Novosibirsk 630090, Russia.

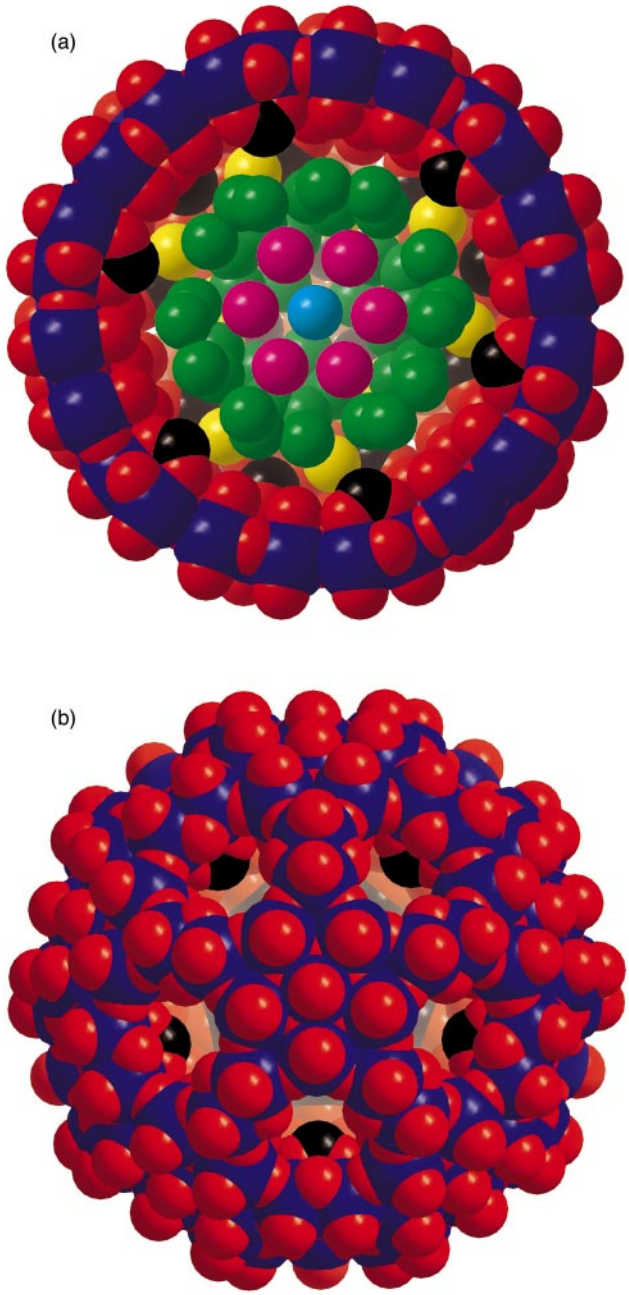

Fig. 2 Cross section through the equator of **1a** (shown in space filling representation) allowing a view into its cavity and highlighting the hydrogen-bonded cluster of the encapsulated H_2O molecules (only oxygen atoms are shown) (*a*). While the empty central region is marked by a light-blue circle, the different shells spanned by encapsulated H_2O molecules are represented by spheres with different colours: violet shell (radius *ca.* 3.5 Å), green shell (6.2–6.9 Å) and yellow shell (8.2–8.7 Å). Interestingly, the onion-like structure of the whole anion is completed by the three successive outer shells consisting of (1) that of the 72 H_2O and 30 formate ligands coordinated to molybdenum atoms and pointing into the cavity (*ca.* 10.5 Å), (2) that of the 132 molybdenum atoms (*ca.*13.1 Å) and (3) that of the terminal 132 oxygen atoms (*ca.* 14.7 Å) (molybdenum atoms blue, oxygen red, carbon black). For comparison, the whole spherical cluster anion is shown in space filling representation (*b*) (molybdenum atoms blue, oxygen red, carbon black).

present case it would be of special interest, theoretically, to study the influence of the outer spherical shell (including that with differently coordinated ligands) on the organization of the complementary inner-shells of hydrogen-bonded-type clusters, such as observed in compound **1**. The structures of the discrete $(H_2O)_n$-type clusters and related hydrogen-bonded aggregates are, of course, also interesting (see for instance ref. 5 and papers cited therein).

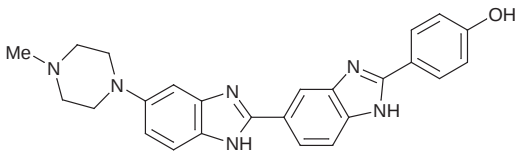
Received (in Liverpool, UK) 8th February 1999, Accepted 30th March 1999

A series of *bis*-benzimidazole compounds with a head-to-head orientation have been designed as sequence-specific DNA binders; crystallographic analysis of oligonucleotide complexes has been combined with DNase I footprinting to confirm that the predicted optimal site for the core bis-benzimidazole motif is the four-base-pair sequence 5′-AATT; this sequence specificity results in inhibition of transcription at A/T sites and may be responsible for the cytotoxic and antitumour effects shown by these head-to-head bis-benzimidazoles.

The minor groove of duplex DNA is the site of non-covalent interaction of a large number of anticancer drugs, antibiotics and antiviral agents,[1] which are believed to exert their action by competing with transcription factors[2] or architectural proteins,[3] such as E2F, TATA-box binding proteins or DNA topoisomerase I/II. The molecular basis of DNA recognition for a number of drugs in this super-family (notably distamycin, netropsin, berenil, pentamidine and Hoechst 33258) has been extensively studied, by crystallographic,[4] NMR[5] and footprinting methods.[6] These studies have shown that their AT preferences are a consequence of, in particular, (i) the sequence-dependent narrow width of the minor groove of B-form DNA, resulting in stabilisation by van der Waals interactions with the walls of the groove,[7] and (ii) their ability to form specific H-bonds with donor and acceptor atoms on the minor groove edge of A : T base pairs. These factors have been utilised in the design of molecules with altered and extended recognition properties, some of which are capable of sequence-specific gene regulation.[8]



Hoechst 33258

We have previously reported crystallographic analyses of a number of oligonucleotide complexes with the head-to-tail bis-benzimidazole compound Hoechst 33258, and several of its derivatives,[9] including a tris-benzimidazole with an extended recognition site.[10] These have shown that each benzimidazole subunit interacts with two A : T base pairs by means of a pair of cross-strand H-bonds. The head-to-tail arrangement forces the site for each successive subunit to overlap the previous one by one base-pair (bp), so that each benzimidazole group in Hoechst 33258 and other head-to-tail analogues effectively recognises 1.5 A : T bps.

Molecular modelling, based on these structural studies, has suggested to us that the novel symmetric head-to-head benzimidazole arrangement could also effectively bind in the minor groove. This arrangement would extend the size of the *bis*-benzimidazole recognition site from three (in Hoechst 33258 and analogues) to four consecutive A:T bps, with distinctive cross-strand H-bonding involving each base pair. This arrangement thus extends the effective recognition of each benzimidazole sub-unit to two A:T bps. The modelling used the structures of the self-complementary duplex sequences d(CGCGAATTCGCG) and d(CGCAAATTTGCG), as found in several relevant drug complexes.[9,10] It suggested that the central 5'-AATT sequence would be an optimal site for the head-to-head motif and for maintenance of helical register with all four consecutive bps without necessitating significant DNA conformational change. An initial range of head-to-head bis-benzimidazoles have now been synthesised, and is reported here.

The highly convergent synthesis of these bis-benzimidazoles (Scheme 1) involves the condensation between the requisite 4-substitituted aryl aldehyde and 3,3′,4,4′-tetraaminobiphenyl **7**. The latter is commercially available, but is of variable quality, and we preferred to prepare it by the route shown. Thus, **1** and **2** were easily obtained from 4-methoxybenzaldehyde and 4-hydroxybenzaldehyde, respectively, while **3** was obtained from 4-(3-dimethylaminopropoxy)benzaldehyde prepared from 4-hydroxybenzaldehyde and 3-dimethylaminopropanol using a Mitsunobu reaction. In each instance the aryl aldehyde and 3,3′,4,4′-tetraaminobiphenyl were heated in nitrobenzene at 150 °C for 8–10 h to effect the condensation, and the yields of bis-benzimidazoles were typically 25–40% on the 10 mmol scale.

Crystallographic analyses have been undertaken on (i) the bis(hydroxyphenyl) compound **2** co-crystallised with the oligonucleotide sequence d(CGCGAATTCGCG), and (ii) its Me_2N derivative **3** with the sequence d(CGCAAATTTGCG). Both crystal structures[11] show a B-form DNA double helix with ligand bound in the A/T region of the minor groove [Fig. 1(*a*)]. They show H-bonding between all four central A : T bps and the benzimidazole subunits [Fig. 1(*b*)], in full accord with the modelling predictions. Each inner-facing ring nitrogen atom of

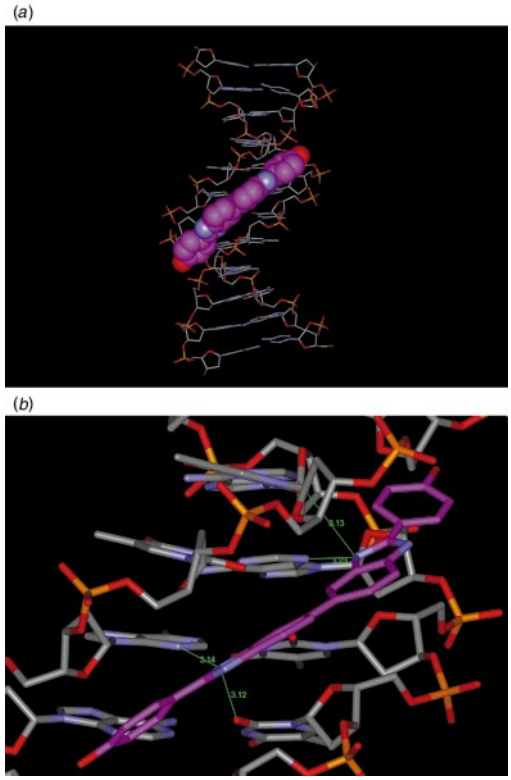

Fig. 1 Computer plots of the crystal structure of the complex of **2** with d(CGCGAATTCGCG): (*a*) shows the ligand, in space-filling mode, centrally bound in the minor groove of the 12-mer double helix, while (*b*) shows a detailed view of **2** and the H-bond contacts to A : T bp edges.

Table 1 Cytotoxicity of *bis*-benzimidazole compounds, for 96 h exposure in a panel of four ovarian cell lines (as $IC_{50}/\mu M$)

Compound	A2780	A2780-Pt^R	CH1	SKOV-3
1	13.5	5.1	3.8	16.5
2	4.3	2.7	1.05	16
3	0.235	0.115	0.24	0.375
Hoechst 33258	12.0	9.5	26.5	> 100

a benzimidazole ring H-bonds to a thymine O2 atom of one bp and an adenine N3 atom on the opposite strand of an adjacent one. It is notable that the absence of formal cationic charge in **2**, does not affect its sequence selectivity, suggesting that the role of charge is to modulate affinity rather than to determine sequence selectivity.

These preferences have also been observed in DNase I footprinting studies with a natural DNA fragment, which have shown that **2** and **3** both interact preferentially with some A/T sites. Compound **3** binds to AT sites between 7–10-fold better than **2**, and has an especially high affinity for the 5′-AATT site (30 nM). Quantitative footprinting data indicated that the order of preference is 5′-AATT > 5′-ATAT > 5′-TAAT > 5′-TATA ~ 5′-TTAA, similar to that previous determined for Hoechst 33258. The increased affinity of **3** relative to **2** does not affect its sequence selectivity. This enhanced binding strength may be a consequence of its cationic charge or its increased DNA site size, since the crystal structure of the complex with $d(CGCAAATTTGCG)_2$ shows it to cover 6 bps. The ability of the head-to-head bis-benzimidazoles to discriminate between the 136 possible tetranucleotide sequences may be further enhanced by flanking sequence preferences. These remain to be systematically explored. Whilst this paper was in preparation, a report has appeared which describes compound **2** and its interactions with tRNA.[12]

These new bis-benzimidazoles have been examined for potential cytotoxic effects in a group of ovarian carcinoma cell lines. Table 1 shows that all compounds are cytotoxic at the μM level, with activity significantly greater than that shown by Hoechst 33258. The Me_2N derivative **3** is over 10-fold more active than the others in three out of the four lines. **3** also shows significant activity in several ovarian lines in the NCI 60-cell line panel (to be published). The compound with least *in vitro* activity, the hydrophobic dimethoxy derivative **1**, has been examined in an *in vivo* tumour model with the ADJ/PC6 plasmacytoma, where it showed 44% tumour inhibition with ip administration. Compound **3** has been examined in an *in vitro* transcription assay. It effectively inhibits transcription at a number of A/T sites, consistent with the above data. In addition, compound **3** inhibited transcription at least 10-fold more efficiently than compound **2**, consistent with its increased cytoxicity. We speculate that the activity of **3** *in vitro* and *in vivo* may be related to its potent ability to specifically inhibit transcription at a small sub-set of A/T sites. The relatively low affinity of compound **3** for 5′-TATA sites suggests that it is less likely to block TATA-box binding proteins at the start of transcription.

This work has been supported by grants from the Cancer Research Campaign, the Royal Society of Chemistry (Adrien Albert Memorial Fund) and the Ghanaian Government.

11 Compound **2** was co-crystallised with d(CGCGAATTCGCG) (from Oswell DNA Service, Southampton) using the hanging-drop method at 286 K. Elongated prismatic crystals were obtained from a 1.5 mM solution of 1 in 50% w/w MPD, in a droplet containing 10 mM $MgCl_2$, 60 mM KCl, 0.75 mM DNA and 6 mM spermine, equilibrated against 30% w/w MPD. The crystals are orthorhombic, space group $P2_12_12_1$, with cell dimensions a = 25.46(2), b = 39.96(4) and c = 65.66(7) Å. Intensity data were collected from a flash-frozen crystal maintained at 100 K with a RAXIS-4 image plate detector, using Cu-Kα radiation from a rotating-anode generator and mirror-focussing optics. A total of 6380 unique reflections were obtained after merging Friedel equivalents (R_{merge} = 0.044) to a resolution of 1.8 Å. The structure was solved using molecular replacement, and refined with the SHELX-97 package. The final model included 174 water molecules, and had an R of 0.229 for 6157 reflections with $F > 4\sigma(F)$, and 23.2% for all data to 1.8 Å. R_{free} was 25.1%. Coordinates and reflection data have been deposited at the Nucleic Acid Database as entry no. dd0013. See http://www.rsc.org/suppdata/cc/1999/929/ for a 3D image in .pdb format.

Phosphonamidothioic acids as thiophosphonylating agents: stereochemistry of reactions of *N*-*tert*-butyl-*P*-phenylphosphonamidothioic acid with alcohols

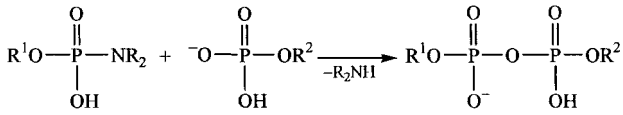
Martin J. P. Harger* and Christopher Pater

Department of Chemistry, The University, Leicester, UK LE1 7RH

Received (in Liverpool, UK) 18th March 1999, Accepted 9th April 1999

Enantiopure PhP(S)(OH)NHBu^t reacts with alcohols in CH_2Cl_2 to give PhP(S)(OH)OR (R = Me, Pr^i, Bu^t); reaction is completely non-stereospecific with Bu^{t}OH and largely so with Pr^{i}OH and very low concentrations of MeOH, pointing to the involvement of a thiometaphosphonate (PhPOS) intermediate.

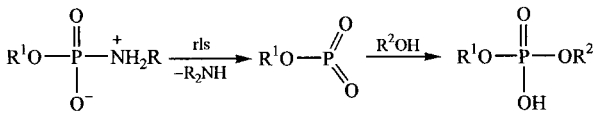
Early work on the synthesis of biologically important pyrophosphates and triphosphates made use of phosphoramidic acid monoesters **1** as phosphorylating agents (Scheme 1).[1] In



1 **2** **3**

Scheme 1

principle the phosphoryl transfer could involve a monomeric metaphosphate intermediate (R^1OPO_2) but the kinetics indicated rather a bimolecular reaction,[1,2] *i.e.* direct nucleophilic attack of the acceptor **2** to give the product **3**. More recently Jankowski and Quin[3] have found that phosphoramidic acid monoesters will also phosphorylate alcohols efficiently, even (or especially) when bimolecular reaction is impeded by steric factors in the donor and acceptor. For these reactions the kinetics,[3] including kinetic isotope effects,[4] appear to indicate the dominance of a unimolecular mechanism (Scheme 2; R^1 = Et, R = 1-adamantyl or mesityl), *i.e.* decomposition of the



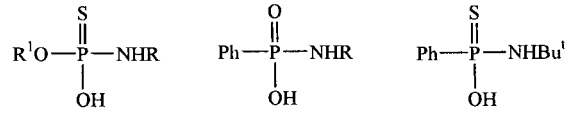
4 **5** **6**

Scheme 2

zwitterionic form **4** of the donor to release the monomeric metaphosphate **5** which is then trapped by the alcohol to give the product **6**. Moreover, the thiophosphorylation[5] of alcohols by phosphoramidothioic monoesters **7** and phosphonylation[6] by phosphonamidic acids **8** seem to be mechanistically similar.

It should be possible to distinguish between bimolecular and unimolecular mechanisms by examining the stereochemistry of reaction. A P=O donor compound (*e.g.* **1** or **8**) will not be chiral at phosphorus unless one of the oxygen (^{16}O) atoms is replaced by an isotope (^{18}O), but a P=S donor compound (*e.g.* **7** or **9**) is inherently chiral. We have therefore sought to obtain the phosphonamidothioic acid **9** as a single enantiomer and ascertain the stereochemistry of its reactions with alcohols.

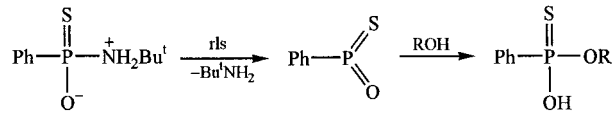
Racemic phosphonamidothioic acid **9** was prepared from $PhPCl_2$ by a published procedure[7] and was resolved using α-methylbenzylamine. From the less soluble (Et_2O) of the diastereoisomeric salts formed with (*R*)-(+)-$PhMeCHNH_2$ the acid **9** was obtained as a single enantiomer (≥99%) after



7 **8** **9**

recrystallisation (Et_2O–light petroleum), mp 82–83 °C (lit.,[7] 81.5–82.5 °C for the racemate); $[\alpha]_D$ + 21.7 (*c* 1.2 in CH_2Cl_2); salt with (*S*)-(−)-$PhMeCHNH_2$, $\delta_P(C_6D_6)$ 54.3; $\delta_H(C_6D_6)$ 1.22 (NBu^t) [addition of racemic **9** introduced new peaks at higher field, $\Delta\delta_P$ 2.1 ppm, $\Delta\delta_H$ 0.11 ppm].†

The reactions of the amidic acid (+)-**9** were examined at 30 °C as dilute solutions (0.02 mol dm^{-3}) in CH_2Cl_2 containing an excess (10 equiv.) of the appropriate alcohol (0.20 mol dm^{-3}). Reaction was halted at 50–60% completion (0.4–0.8 h) and the product **12** (Scheme 3) and unreacted substrate were isolated as a mixture of the free acids. This mixture was treated with (*S*)-(−)-$PhMeCHNH_2$ to form diastereoisomeric salts of the acids. Analysis by $^{31}P\{^1H\}$ NMR spectroscopy (C_6D_6 solution) revealed the diastereoisomer ratios for the salts and by implication the enantiomer ratios of the acids. In every case the unreacted substrate was found to be still a single enantiomer, showing that it is configurationally stable under the conditions of reaction. Any departures from enantiopurity in the products must therefore be a reflection of how they are formed from (+)-**9**.‡



10 **11** **12**

Scheme 3

With MeOH the product **12** (R = Me) was obtained with one enantiomer in large excess (ee 76%) [salt: $\delta_P(C_6D_6)$ 72.8 and 72.5, ratio 88 : 12; $\delta_H(C_6D_6)$ 3.36 (major) and 3.35 (both d, J_{PH} 13.5, OMe)] but with Pr^{i}OH the excess of one of the enantiomers of **12** (R = Pr^i) was modest (ee 15%) [salt: δ_P 68.7 and 68.35, ratio 57.5 : 42.5; δ_H 1.34, 0.88 (major) and 1.32, 0.87 (all d, J_{HH} 6, OCH*Me*$_2$)] and with Bu^{t}OH the product **12** (R = Bu^t) was practically racemic [salt: δ_P 60.3 and 60.2; δ_H 1.47 and 1.46 (both s, OBu^t)].§ A reasonable explanation is that there are competing stereospecific and non-stereospecific pathways and that the relative importance of each is dependent on the identity of the alcohol nucleophile. Also, given the earlier mechanistic evidence, it seems likely that these pathways are bimolecular and unimolecular respectively.¶

The bimolecular pathway would presumably involve in-line attack [$S_N2(P)$] of the alcohol on the zwitterionic form **10** of the substrate, giving the product **12** with inversion of configuration at phosphorus.[8] Steric interactions in the five-coordinate transition state will be more severe with bulky alcohols and reaction by this pathway will be correspondingly less favourable. The unimolecular pathway would involve unassisted decomposition of the zwitterion **10** and liberation of the

thiometaphosphonate **11** (Scheme 3); this, being planar (trigonal) and open to attack at either face by the alcohol, will give the product **12** as the racemate. In this case, the alcohol does not bond to phosphorus in the rate-limiting step; the unimolecular pathway will therefore acquire increasing relative importance as the bimolecular pathway becomes less favourable, *i.e.* as the bulk of the alcohol nucleophile increases.

As a test of mechanistic duality the dependence of the stereochemistry of reaction on the concentration of the nucleophile was examined. With lower concentrations of alcohol the non-stereospecific unimolecular pathway should assume greater importance while higher concentrations should favour the stereospecific bimolecular pathway. In the event, reducing the concentration of MeOH or Pr^iOH to 0.05 mol dm^{-3} gave the product **12** with an enantiomer ratio of 70 : 30 (R = Me) or 51 : 49 (R = Pr^i) and increasing it to 0.80 mol dm^{-3} gave an enantiomer ratio of 98 : 2 (R = Me) or 58.5 : 14.5 (R = Pr^i). With Bu^tOH the product was practically racemic at all alcohol concentrations, implying a negligible contribution from stereospecific bimolecular reaction.§

In one case—the 0.20 mol dm^{-3} MeOH reaction—the dependence of the stereochemistry on the temperature was also examined. Relative to the reaction at 30 °C (enantiomer ratio of product **12**, 88 : 12), reducing the temperature increased the overall stereospecificity of reaction (enantiomer ratio 96 : 4 at 0 °C) and increasing the temperature reduced it (72 : 28 at 60 °C). This implies a more ordered transition state for the stereospecific pathway, consistent with it being of higher molecularity.

That the monomeric thiometaphosphonate **11** plays an important part in the reactions of **9** with alcohols seems certain, but the nature of the competing stereospecific process is less clear. It shows the characteristics expected of an associative $S_N2(P)$ reaction but so might a dissociative reaction if it involves preassociation of the substrate and nucleophile.[9] Then the nucleophile will already be in place when the zwitterion **10** decomposes and the thiometaphosphonate is formed. This may now be trapped stereoselectively, by attack of the alcohol on one face before the leaving group (H_2NBu^t) has diffused away from the other. The reactions of **9** with alcohols may therefore proceed *entirely via* the thiometaphosphonate, in a free (liberated) state or associated with the nucleophile. The stereochemistry observed with **9** does, we think, support the view of Jankowski and Quin that metaphosphate intermediates are involved in the reactions of related amidic acids with alcohols.

Notes and references

† The free amidic acid **9** begins to decompose as soon as it is dissolved in an aprotic solvent. All operations involving solutions of **9** were conducted with cooling and executed as rapidly as possile. The value of $[\alpha]_D$ must be considered approximate.

‡ The products **12** were isolated from reactions allowed to proceed to ⩾90% completion and were purified and characterised as their dicyclohexylammonium salts [^1H and ^{31}P NMR and IR spectroscopy; mass spectrometry (ES and −FAB) including accurate mass measurement].

§ The ^{31}P NMR signals for the diastereoisomeric salts of **12** (R = Bu^t) were not quite fully resolved and in this case the enantiomer ratio is not as precise (±2% in each component) as for **12** (R = Me) or **12** (R = Pr^i).

¶ With Pr^iOH and Bu^tOH the substrate **9** and product **12** (salts with $PhMeCHNH_2$) accounted for only ~90% of the $^{31}P\{^1H\}$ NMR spectrum. The most prominent of the minor peaks were doublets (J_{PP} 39 Hz) at *ca.* $\delta_P(C_6D_6)$ 67 and 62.5, most likely due to the pyrophosphonate $PhP(S)(O^-)OP(S)(NHBu^t)Ph$ [*m/z* (−ES) 384] resulting from reaction of **9** with itself instead of with the alcohol (*cf.* ref. 3, 5 and 6).

Designer clusters: synthesis and characterization of $Cp^*_2Rh_2Co_3(CO)_8B_3HCl$ ($Cp^* = \eta^5$-C_5Me_5)

Xinjian Lei, Maoyu Shang and Thomas P. Fehlner*

Department of Chemistry & Biochemistry, University of Notre Dame, Notre Dame, IN 46556, USA

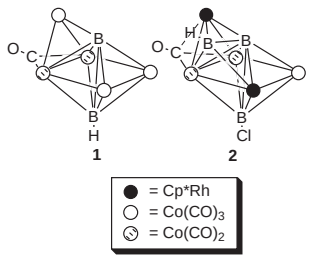
Received (in Bloomington, IN, USA) 19th February 1999, Accepted 13th April 1999

Sigma bond metathesis of B–H in $Cp^*_2Rh_2B_3H_6Cl$ with Co–Co in $Co_2(CO)_8$ leads directly to the title compound.

Both B–H[1,2] and Si–H[3] bonds undergo σ-bond metathesis with the Co–Co bond in $Co_2(CO)_8$ as illustrated in eqns. (1a) and (1b).

$$2\ R_3SiH + Co_2(CO)_8 \rightarrow 2\ (CO)_4CoSiR_3 + H_2 \quad (1a)$$
$$2\ BH_3{\cdot}thf + Co_2(CO)_8 \rightarrow 2\ (CO)_4CoBH_2{\cdot}thf + H_2 \quad (1b)$$

For this reason, the formation of the unusual cluster, $Co_5(CO)_{14}B_2H$ **1**, from the reaction of $BH_3{\cdot}SMe_2$ and $Co_2(CO)_8$ was rationalized using σ-bond metathesis of the B–H bond as an essential feature of the cluster building reaction. [4,5] However, this metallaborane, and an intermediate compound, $Co_2(CO)_6B_2H_4$, were only isolated in low yields partly due to efficient competitive formation of $Co_4(CO)_{12}$. Hence, without confirmation this mechanism remains speculative. For this reason, we have sought support for such a cluster building route in alternative systems. Here, we report the rational synthesis of an analog of **1** formed in good yield from $(Cp^*Rh)_2B_3H_6Cl$ ($Cp^* = \eta^5$-C_5Me_5), which, in turn, is readily accessible from the reaction of $Cp^*_2Rh_2Cl_4$ and $BH_3{\cdot}thf$. [6,7] The postulated cluster building reaction is corroborated and the structure exhibited by **1** is verified as the preferred core geometry for the cluster electron count.



The reaction of $Cp^*_2Rh_2B_3H_6Cl$ and $Co_2(CO)_8$ under mild conditions gives $(Cp^*Rh)_2Co_3(CO)_8B_3HCl$ **2**, in 30% isolated yield.† The spectroscopic data are consistent with the molecular structure shown in Fig. 1 and derived from a solid state structure determination.‡ Comparison of **2** with **1** reveals the close structural relationship of these two clusters. Compound **1** was shown to be an unanticipated isomeric analog of a trigonal prismatic, boron centered M_6 90 cluster valence electron (cve) cluster.[5,8] Converting one M vertex of the M_6 cluster to BH leads to the observed 80 cve and the M *vs* B size mismatch leads to the isomeric structure observed. As shown in Scheme 1, **2** can be derived from a rectangular face-capped trigonal prismatic, boron centered M_7 102 cve cluster, *e.g.* $[HFe_7(CO)_{20}B]^{2-}$.[9] Just as with **1**, conversion of two M vertices to BH and BCl followed by rearrangement leads to the observed geometry. The predicted cve count is 82 as observed. The difference between the radial properties (size) of main group and transition metal fragments with similar frontier angular orbital properties and populations (isolobal) forces the unexpected isomeric structure observed for **1** and **2**.[10]

The origin of **2** from $Cp^*_2Rh_2B_3H_6Cl$ can be described with a small set of reasonable assumptions that allow the stoichiometric and geometric pathway to **2** *via* **3** to be traced out. We assume the B_3 fragment remains intact; the BH cluster bonds react with the cobalt reagent by σ-bond metathesis; CO loss from the cluster bound $Co(CO)_4$ fragment leads to insertion and consequent cluster expansion; and ML_x fragment rearrangement is facile.[11] The result is shown in Scheme 2. Reaction with $Co_2(CO)_8$ at room temperature leads to the formation of $Cp^*_2Rh_2Co(CO)_3B_3H_3Cl$ **3** (80%, Scheme 2) which has been fully characterized. [7] By itself **3** is stable at 60 °C; however, in the presence of $Co_2(CO)_8$ it is rapidly converted to **2**. Three repetitions of σ-bond methathesis plus insertion lead from reactant to product **2**. Of course the detailed nature of the insertion and rearrangement processes remains unclear, but the overall process is straightforward.

The use of $Co_2(CO)_8$ as a metal fragment source is well illustrated in cluster chemistry.[12] Evidence for a radical pathway was found for reactions of $Co_2(CO)_8$ with organome-

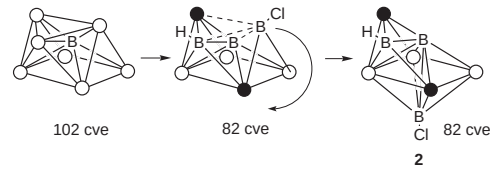
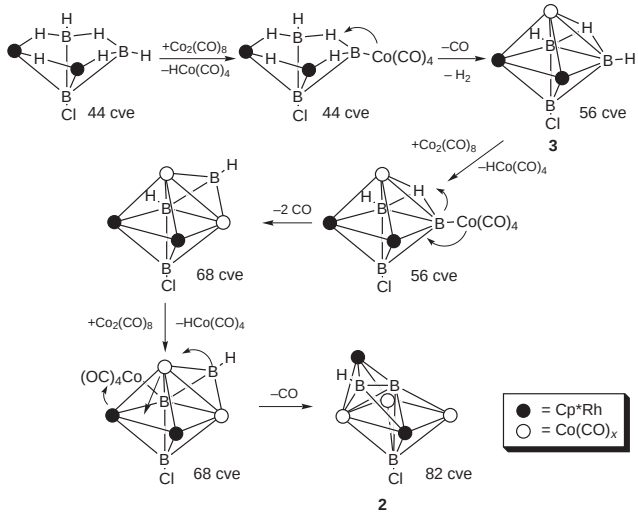


Scheme 1



Scheme 2

tallic clusters resulting in metal fragment substitution or cluster expansion.[13,14] Presumably the cluster metal–metal bonding network is directly involved. The nature of the cluster building pathway observed here appears distinctly different. This is consistent with earlier work which demonstrates that BH bonds can interact directly with transition metal centers.[15–18] For example, the activity of exocluster B–H bonds towards metal addition has been utilized in promoting the addition of unsaturated organic substrates to borane cages.[19] Thus, even though we have no direct evidence for the cluster–$Co(CO)_4$ intermediates proposed in Scheme 2, their existence is reasonable.

The generous support of the National Science Foundation is gratefully acknowledged.

Photophysical properties of osmium(II) complexes with the novel 4′-*p*-phenylterpyridine-triarylpyridinium ligand

Philippe Lainé* and Edmond Amouyal

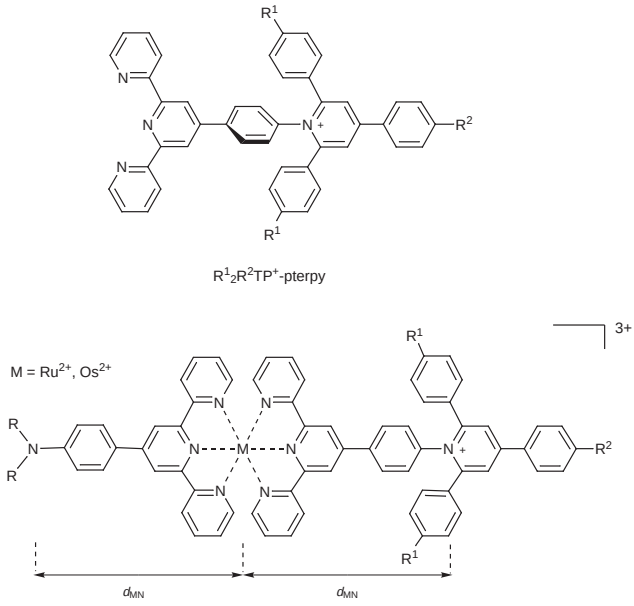
Molecular Photonics Group, Laboratoire de Physico-Chimie des Rayonnements, CNRS UMR 8610, Université Paris-Sud, Bâtiment 350, 91405 Orsay, France. E-mail: philippe.laine@lpcr.u-psud.fr

Received (in Basel, Switzerland) 14th February 1999, Accepted 11th April 1999

A new family of electron acceptor ligands complexed with osmium(II) and associated with appropriate electron donor subunits within heteroleptic compounds, results in multicomponent assemblies of potential interest for both synthetic chemistry and supramolecular photochemistry.

As part of our studies devoted to photochemical conversion of solar energy[1] we are interested in producing long-lived photoinduced charge separation (CS) states within inorganic supramolecular species. Determining criteria that govern intramolecular electron transfers (ET) in multicomponent systems (*i.e.* polyads) have already been addressed in previous work.[2,3] A representative composition for a polyad system devised for CS purposes consists of a linear disposition of peripheral electron donating (D) and withdrawing (A) groups borne by a central photosensitiser P in a *trans* configuration *e.g.* D–P–A (triad).[4] Spacers do play an important role in such constructions by providing the rigidity of the architecture and mediating the electronic coupling between the components. Regarding non-porphyrinic inorganic polyads, widespread strategy is to modulate the efficiency of A (and/or D) *vs.* intramolecular ET by varying the length and nature of saturated spacers; our approach hereby described is to preferably involve *intrinsically weak* electron acceptors *fairly strongly coupled* to P rather than the usual *good* acceptors *almost insulated* from P. The aim remains the same in both cases *i.e.* favour the formation of the CS state D^+–P–A^- by retarding the charge recombination (CR).

Based on hitherto established structural and energetic requirements, we have designed the new 4′-[4-*N*-(2,4,6-triarylpyridinio)phenyl]-2,2′:6′,2″-terpyridine ligand ($R^1{}_2R^2TP^+$-pterpy) depicted in Scheme 1. Related triphenylpyridinium derivatives are known to undergo charge transfer reactions when covalently linked to some donor groups as is the case for solvatochromic Reichardt's dyes like betaine 30,[5,6] the promoted electron being located on the pyridinium moiety. Our proposal is thus to replace the latter donor by a light-triggered electron donor, namely an inorganic chromophore (P) of the Ru/Os-bis(terpyridyl) type.



Scheme 1

It is noteworthy that $R^1{}_2R^2TP^+$-pterpy (A) specifically fits to polyad architectures where the electron-donating part (D) is built from 4′-(4-*N*,*N*-disubstituted-aminophenyl)terpy (R_2N-pterpy, R = alkyl, aryl). In such a structure, both pyridinio and amino nitrogen atoms are located at equal distance d_{MN} from the metal centre and connected to it with identical spacers (Scheme 1). From a topological viewpoint, the CS-state lifetime is expected to be increased in this particular arrangement that allows an optimal competition between the possible reductive quenching reactions of oxidised photosensitiser ($D–P^+–A^- \rightarrow D^+–P–A^-$ *vs.* $D–P^+–A^- \rightarrow D–P–A$). Another advantage of $R^1{}_2R^2TP^+$-pterpy ligands comes from the tuneable redox properties of the pyridinium moiety[5,7] the potential of which can be varied systematically by altering substituents R^1 and R^2.

These acceptor-modified terpyridyl ligands (A) are readily synthesised following a general convergent approach[8] consisting in separately preparing the triarylpyrylium salt and the amino derivative of the chelating polyimine which are subsequently reacted together to afford the target molecule in reasonable yield (*ca.* 60% *vs.* amine). The chemical variability of $R^1{}_2R^2TP^+$-pterpy actually stems from pyrylium precursors, the chemistry of which is very rich and also well documented from the synthetic viewpoint.[9] In addition, this route to pyridinium derivatives can be successfully applied to other oligopyridine molecules.[10] Typically, the first element of the ligand family ($R^1 = R^2 = H$), H_3TP^+-pterpy, is obtained by the reaction of 4′-*p*-aminophenyl-terpy ($Na_2S_2O_4$-reduced 4′-*p*-nitrophenyl-terpy) with a triphenylpyrylium cation (HSO_4^- salt, 1 equiv.) in refluxing EtOH for 6 h in the presence of anhydrous NaOAc. Regarding the electron-donor component, the model ligand used is 4′-*p*-dimethylaminophenyl-terpy (Me_2N-pterpy) synthesised following the classical method for *para*-substituted phenyl terpy.[11] Up to 12 Ru^{II} and Os^{II} complexes were then synthesised corresponding to the different combinations between the following three ligands: H_3TP^+-pterpy, Me_2N-pterpy and 4′-*p*-tolyl-terpy (tterpy); after standard work-up purification these compounds prepared as PF_6^- salts afforded microcrystalline powders which were fully characterised;† experimental details will be given elsewhere.[10*b*] Owing to their better emission properties at room temperature than that of analogous Ru^{II} complexes, preliminary photophysical results are given for the Os^{II} complexes only *i.e.* $[Os(tterpy)_2]^{2+}$ **1**, $[Os(Me_2N\text{-}pterpy)_2]^{2+}$ **2**, $[Os(pterpy\text{-}TPH_3^+)_2]^{4+}$ **3**, $[(Me_2N\text{-}pterpy)Os(tterpy)]^{2+}$ **4**, $[(tterpy)Os(pterpy\text{-}TPH_3^+)]^{3+}$ **5** and $[(Me_2N\text{-}pterpy)Os(pterpy\text{-}TPH_3^+)]^{3+}$ **6**. Properties of two H_3TP^+-pterpy complexes **5** and **6**, compared to that of **1** are more specifically discussed.

As illustrated in Fig. 1 for this series, the luminescence is shown to be gradually weakened when going from **1** to **6**. Compared to the reference chromophore **1** with an emission

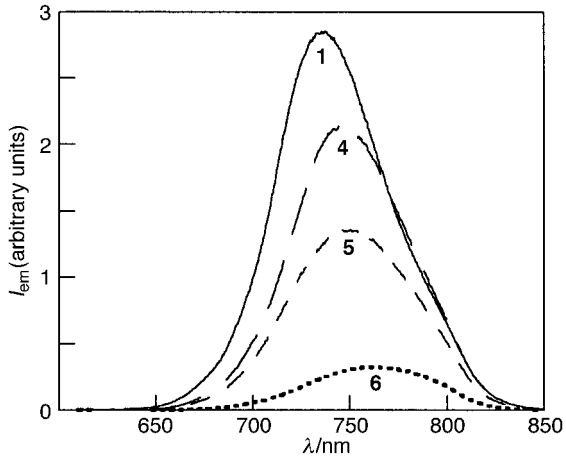


Fig. 1 Emission spectra of Os^{II} complexes in deaerated MeCN solutions at room temperature, measured in identical experimental conditions (in particular, same OD at $\lambda_{exc.}$ = 600 nm).

Table 1 Luminescence properties[a]

	λ_{max}[b]/nm	$10^2\Phi$[c]	I_{rel}[c,d](%)	τ[e]/ns
1	734	2.00	100	247
4	747	1.48	74.3	206
5	750	1.02	50.9	168
6	764	0.24	12.1	57

[a] Room temperature measurements; deaerated MeCN solutions. [b] Emission maxima for uncorrected spectra. [c] Luminescence quantum yields were determined relative to $[Os(bpy)_3]^{2+}$ (Φ_{em} = 5×10^{-3} in MeCN at 298 K).[12] [d] I_{rel} = 100 × [Φ_{em}(species)/Φ_{em}(**1**)]. [e] Determined by laser flash photolysis, λ_{exc} = 308 nm.[13]

quantum yield of 2.0×10^{-2}, ^{3}MLCT emission of the D–P–A triad **6** is *ca.* 90% quenched and lifetime shortened to 57 ns (Table 1).

Note that the contribution of the donor fragment to the quenching phenomenon should not be overestimated as revealed by I_{rel} values for **2** and **4**: 80.5 and 74.3%, respectively. A synergetic effect of electroactive subunits D and A upon emission is, however, clearly identified in the case of **6** when compared with luminescence properties of heteroleptic compounds **4** and **5**.

The rate constant k_Q for the bimolecular quenching reaction (1) of the excited state of the reference chromophore **1** (*P) by the model-acceptor species *N*-phenyl-2,4,6-triphenylpyridinium (p-TPH_3^+) was experimentally determined (Stern–Volmer plot). This k_Q value of *ca.* 6×10^7 dm^3 mol^{-1} s^{-1} (with τ_{em} of **1** = 247 ns) cannot account for the more efficient quenching process observed within the dyads and triad; therefore, the effective contribution of an *inter*-molecular ET to the quenching mechanism is negligible.

$$*[Os(tterpy)_2]^{2+} + p\text{-}TPH_3^+ \rightarrow [Os(tterpy)_2]^{3+} + p\text{-}TPH_3^{\bullet} \quad (1)$$

In addition, owing to photophysical properties of organic colourless D and A electroactive fragments (UV-absorbing) with respect to that of *P (NIR–VIS-emitting ^{3}MLCT state at *ca.* 740 nm), the above reported quenching effect cannot originate from energy transfer.

Further photophysical investigations at low temperature and picosecond time-scale are currently under way in order to elucidate whether the luminescence behaviour of this series results from effective *intra*-molecular ET or an alteration of the electronic properties of the complexes due to their inter-component coupling.[14]

The chemical variability provided by R^1 and R^2 (Scheme 1) allows the modulation of the electron withdrawing ability of the acceptor as well as leading to the opportunity to expand the structure along the C_2-axis (*via* R^2) in polyads such as D–P–A_1–A_2 (redox cascade). Hence, $R^1{}_2R^2TP^+$-pterpy is a promising candidate to perform sequential and vectorial long-range ET over extended rod-like rigid systems engineered for CS.

Helpful discussions with Dr Valérie Marvaud were much appreciated by P. L.

[b] *Department of Chemistry, Via Vienna 2, Universita' di Sassari, 07100 Sassari, Italy. E-mail: grepioni@ssmain.uniss.it*

Received (in Basel, Switzerland) 8th February 1999, Accepted 11th April 1999

The hydrated crystalline material $[(\eta^5\text{-}C_5H_5)_2Co]^+[(\eta^5\text{-}C_5H_4CO_2H)(\eta^5\text{-}C_5H_4CO_2)Fe]^-\cdot H_2O$ 3 is prepared by simply *grinding* either the crystalline powder 1 that precipitates from thf on reacting $[(\eta^5\text{-}C_5H_5)_2Co]$ with $[(\eta^5\text{-}C_5H_4CO_2H)_2Fe]$ or single crystals of $[(\eta^5\text{-}C_5H_5)_2Co]^+[(\eta^5\text{-}C_5H_4CO_2H)(\eta^5\text{-}C_5H_4CO_2)Fe]^-$ 2 obtained by recrystallization of 1 from nitromethane; on heating at 373K 3 loses water and reverts to the starting material 1.

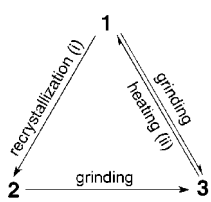
Crystal engineering is a bridge between supramolecular and molecular materials chemistry and constitutes one of the most attractive research fields in modern structural chemistry.[1] Crystal-to-crystal transformations are of obvious interest.

Recently, we have begun to utilize organometallic building blocks to prepare crystalline materials to exploit the variable valence, spin and charge states of coordination complexes.[2] Exciting new results are being obtained, in particular when the crystalline products are investigated by a combination of different solid state techniques.[3]

Here we report the unusual behaviour of the crystalline material[2b] $[(\eta^5\text{-}C_5H_5)_2Co]^+[(\eta^5\text{-}C_5H_4CO_2H)(\eta^5\text{-}C_5H_4CO_2)Fe]^-$ **2**, previously synthesised together with the mixed-metal mixed-spin system $\{[(\eta^6\text{-}C_6H_6)_2Cr]^+\}_2\{[(\eta^5\text{-}C_5H_4CO_2H)(\eta^5\text{-}C_5H_4CO_2)Fe]_2[(\eta^5\text{-}C_5H_4CO_2H)_2Fe]^{2-}\}$.[4]

We have discovered that the hydrated *pseudo*-polymorph $[(\eta^5\text{-}C_5H_5)_2Co]^+[(\eta^5\text{-}C_5H_4CO_2H)(\eta^5\text{-}C_5H_4CO_2)Fe]^-\cdot H_2O$ **3** is obtained by *grinding* either the crystalline powder **1** that precipitates from thf on reacting $[(\eta^5\text{-}C_5H_5)_2Co]$ and $[(\eta^5\text{-}C_5H_4COOH)_2Fe]$ to prepare **2**,† or single crystals of **2** obtained by subsequent recrystallization of **1** from nitromethane or methanol.† Importantly, both **2** and **3** have been characterized by single crystal X-ray-diffraction, while powder diffractograms have been measured for **1** and **3** so that the relationship between reactant and product of this peculiar solid state transformation is known in detail.‡ The process is summarized in Scheme 1. The reverse process proceeds only from **3** → **1** as confirmed by thermal gravimetric analysis, which shows stoichiometric loss of water at *ca.* 373 K, and by powder X-ray diffraction, which shows the conversion into **1** of a sample of **3** heated for 2 h at 383 K under argon. Single crystals of **2** do not absorb water in the air, while crystalline **3**, once formed, behaves like any 'normal' crystalline salt, *i.e.* can be dissolved and recrystallized without further structural change.

The key structural features of **2** and **3** can be summarised as follows:



Scheme 1 *Reagents and conditions* i, from $MeNO_2$ or MeOH; ii, 383 K, 2 h, argon atmosphere.

(i) both **2** and **3** belong to the class of supramolecular salts (*supersalts*[2b]) in which the anions, obtained by deprotonation of the dicarboxylic acid $[(\eta^5\text{-}C_5H_4CO_2H)_2Fe]$, are self-assembled *via* O–H···O and/or O–H···O$^-$ hydrogen bonding interactions and are linked to the cobaltocenium cations $[(\eta^5\text{-}C_5H_5)_2Co]^+$ *via* a profusion of *charge assisted* $C\text{–}H^{\delta+}\cdots O^{\delta-}$ interactions.[5] For sake of clarity only the anionic backbones are compared in Fig. 1. Relevant hydrogen bonding parameters are given in the caption.

(ii) In **2** the $[(\eta^5\text{-}C_5H_4CO_2H)(\eta^5\text{-}C_5H_4CO_2)Fe]^-$ anions form chains with no cross-links, *viz.* a mono-dimensional network,[6] while in **3** the chains are *cross-linked* by water molecules inserted between $–CO_2$ groups, generating a two-dimensional network.

(iii) The ferrocene moieties in **2** and **3** not only show different ring conformations but have also different relative orientations along the chains.

Fig. 2 collects the evidence on the process depicted in Scheme 1 and compares the experimental (exp) X-ray powder diffractograms obtained for **1** and **3** with those calculated (calc) on the basis of the single-crystal structures for **2** and **3**. It can be seen that: (i) **1**(exp) ≠ **3** (exp) and **2** (calc), (ii) **3** (exp) ≠ **2** (calc), and (iii) **3** (exp) ≡ **3** (calc).

Although the effect of grinding samples for powder diffraction, as well as the possibility of monitoring solid state reactions

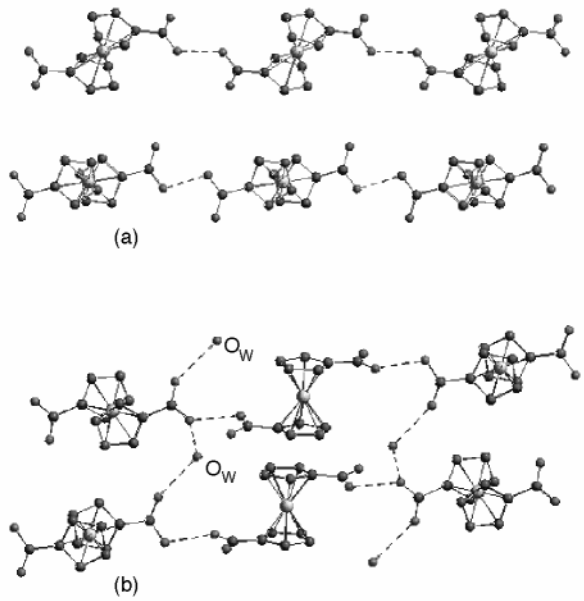


Fig. 1 Chains of O–H···O bonded $[(\eta^5\text{-}C_5H_4CO_2H)(\eta^5\text{-}C_5H_4CO_2)Fe]^-$ anions in **2** (a) and **3** (b). Note how the water molecules in **3** act as *cross-links* between the anionic chains. Hydrogen atoms are omitted for clarity. Relevant O···O separations within the hydrogen bonded systems are: **2** anion–anion 2.45(2), **3** anion–anion 2.49(2) and 2.52(2), anion–water 2.81(2), 2.73(2), 2.83(2) Å.

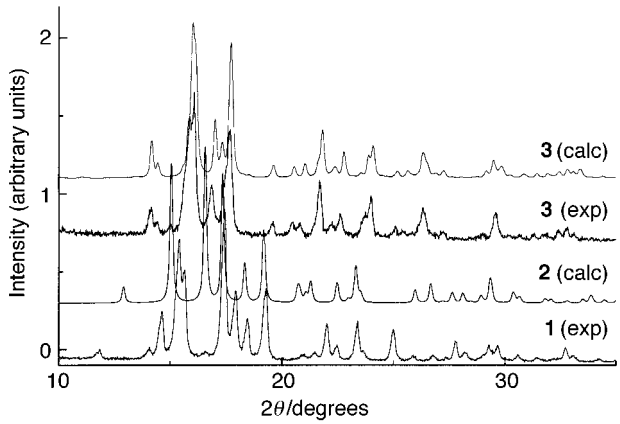

Fig. 2 Comparison between the experimental powder diffractograms of **1** (obtained from the reaction mixture in thf) and **3** (obtained by grinding crystalline **2**) and the diffractograms of **3** and **2** calculated on the basis of the experimental single-crystal structures. A colour version of this figure is shown in electronic form, see http://www.rsc.org/suppdata/cc/1999/937.

via powder diffraction, is well known,[7] what appears to be unprecedented in the case of the **1**, **2** → **3** transformations is the fact that water molecules can be inserted in stoichiometric ratio into a complex and highly organized crystal edifice without loss of crystallinity or (at least in the case of **2**) disruption of the anionic organization. The overall process is fully reproducible. The relationship between the structure of **1** and that of **2** remains unknown, though they are very likely two polymorphic modifications of the same anhydrous material.[8]

Although it is difficult (and somewhat 'unsafe') to model solid-to-solid transformations, *e.g.* between two thermodynamic free energy minima, it is still interesting to observe what is *preserved* and what is *changed* on passing from **2** to the *pseudo*-polymorph **3**. The anionic chain structure is maintained, together with the sequence of O–H···O interactions, while the distribution of cations, hence the distribution of weak C–H···O bonds, and the relative orientation of the ferrocene moieties along the chain change significantly. The former aspect reveals that the hydrogen bonded chain is a *structural determinant* which, together with inter-ion interactions, is responsible for crystal cohesion. Structural flexibility and the diffuse network of weak, less directional, interactions provide instead the necessary ion mobility and permeability to water molecules.

Two remarks to conclude this preliminary communication: (i) since the reaction products in crystal engineering are solids the utilization of powder diffraction is, sometimes, the only way to ascertain whether the whole solid material has the *same structure* as that characterized by single crystal X-ray diffraction.[9] Our findings are a *caveat* since a common method of sample preparation (powder grinding) may lead to dramatic solid state transformations.

(ii) Not less important is the notion that such crystal transformations may be quantitatively achieved by mechanical stress (and consequent thermal effect). Indeed this is something that may be exploited: work is in progress to ascertain whether other molecules with hydrogen bonding capacity similar to that of water may be used in solid state reactions with crystalline **2**.

We thank Dr Gianna Cojazzi for help with the thermal gravimetric analysis. Financial support from the University of Bologna—Project '*Innovative Materials*' and from MURST–Project '*Supramolecular Devices*' is acknowledged.

Notes and references

† [(η^5-C_5H_5)$_2$Co] and [(η^5-$C_5H_4CO_2H$)$_2$Fe] were purchased from Aldrich. For the preparation of crystalline **2** see ref. 4. Upon 1 : 1 reaction between [(η^5-$C_5H_4CO_2H$)$_2$Fe] (84 mg, 0.30 mmol) and [(η^5-C_5H_5)$_2$Co] (57 mg, 0.30 mmol) in 20 ml of anhydrous thf an orange powder precipitate **1** immediately formed. After 1 h, **1** was filtered and a portion was recrystallized overnight from nitromethane (or methanol), yielding air stable orange crystals of **2**. Grinding of the second portion of **1** to prepare a sample for powder diffraction led to formation of crystalline powder **3**, which on recrystallization from nitromethane gave single crystals of **3**. It is important to stress that, in the preparation of powder diffraction samples, we followed a conventional 'open-air' procedure. Grinding was performed manually for few minutes till a fine powder was obtained in order to avoid preferential orientation problems. If the grinding is done in a dry box, only partial hydration is observed and the powder spectrum is a mixture of those of **1** and **3**. This indicates that water for hydration comes both from ambient humidity and from surface wetting, this latter water is very difficult to remove.

‡ Powder X-ray diffraction measurements: Philips PW-1100 automated diffractometer, Cu-Kα radiation, monochromator graphite. Single crystal X-ray diffraction: CAD4 diffractometer, Oxford Cryostream liquid-N2 device, Mo-Kα radiation, monochromator graphite. Data were corrected for absorption by azimuthal scanning of high-χ reflections (min. and max. transmission 0.87 and 1.00). *Crystal data* for **3**: $C_{22}H_{21}CoFeO_5$, T = 223(2) K, M = 480.17, monoclinic, $P2_1/n$, a = 12.251(5), b = 17.276(6), c = 18.083(7) Å, β = 91.56(3), V = 3825.8(25) Å^3, Z = 8, F(000) = 1968, μ = 1.658 mm^{-1}, θ-range 3.0–25 °, 6933 reflections, 6710 independent, refinement on F^2 for 454 parameters, wR (F^2, all reflections) = 0.1495, R_1[I > 2σ(I)] = 0.0455. SHELXS-97[10a] and SHELXL97[10a] were used for structure solution and refinement based on F^2. The asymmetric unit contains two cations, one anion, two 'half' anions located on inversion centres, and two water molecules unit. The hydrogen bond pattern in **3** is more complex than in **2** and will be discussed in a full report. SCHAKAL97[10b] was used for the graphical representation of the results.

Drastic enhancement of the enantioselectivity of lipase-catalysed esterification in organic solvents by the addition of metal ions

Takashi Okamoto[a] and Shinichi Ueji*[b]

[a] *The Graduate School of Science and Technology, Kobe University, Nada, Kobe 657-8501, Japan*
[b] *Division of Natural Environment and Bioorganic Chemistry, Faculty of Human Development and Sciences, Kobe University, Nada, Kobe 657-8501, Japan. E-mail: ueji@natura.h.kobe-u.ac.jp*

Received (in Cambridge, UK) 22nd March 1999, Accepted 12th April 1999

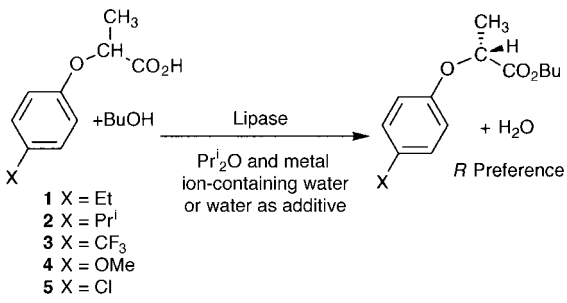
By the addition of metal ion-containing water, a marked enhancement of the enantioselectivity for the lipase-catalysed esterification of 2-(4-substituted-phenoxy)propionic acids in Pr^i_2O was observed, the mechanism of which will be discussed briefly on the basis of the initial rate obtained for each enantiomer of the substrate.

Recently, much attention has been paid to lipase-catalysed enantioselective transformations in organic solvents, because lipases display broad substrate specificities with high enantioselectivities.[1] For this reason, organic chemists often use lipases for the synthesis of useful optically active compounds. One of the most important factors for lipase-catalysed reactions is the control of their enantioselectivites as a function of reaction conditions.[1]

Here, we report a new and a simple method for improving markedly the enantioselectivity of lipase-catalysed esterification of 2-(4-substituted-phenoxy)propionic acids **1**–**5** in Pr^i_2O as a model reaction by the addition of alkaline metal ion (*e.g.* LiCl)-containing water (Scheme 1). This is the first example of an alkaline metal ion enhancing the enantioselectivity of a lipase in organic solvents. Furthermore, the mechanism of the enhanced enantiorecognition will be discussed briefly utilising data on the initial rate obtained for each enantiomer of substrate **1** in the model reaction.

All the substrates used in the model reactions, racemic 2-(4-substituted-phenoxy)propionic acids, were prepared from ethyl 2-bromopropionate and the corresponding 4-substituted-phenols according to the known method.[2]

In a typical enzymatic reaction, the substrates **1**–**5** (0.36 mmol) and a three-fold molar excess of BuOH (1.08 mmol, 80 mg) were dissolved in 2 ml of Pr^i_2O. To the solution, a small amount of 2.4 M metal ion-containing water or water (0–0.75 vol%) was added followed by ultrasonic dispersion, and then powdered lipase MY or lipase AY from *Candida rugosa* (30 mg) was added. The suspension was shaken (170–200 strokes min^{-1}) at 37 °C until *ca.* 40% of the substrate was converted to the corresponding butyl ester. The enantiomeric ratio (*E* value) was calculated from the enantiomeric excess (ee) for the butyl ester produced, according to the literature.[3] The ee was measured by HPLC on a chiral column [Daicel Chiral Cel OK].



Scheme 1

For the model reaction (Scheme 1), the *R* enantiomer of the butyl ester were preferentially produced in all the substrates **1**–**5**. We investigated the behaviour of the lipase's enantioselectivity caused by the addition of a small amount of alkaline metal ion (LiCl, NaCl or KCl)-containing water or a small amount of water to the Pr^i_2O of the reaction medium. Fig. 1 shows the variation of the *E* value for the lipase MY-catalysed esterification of **1** at *ca.* 40% conversion as a function of the amount of each additive. As is seen in Fig. 1, when a small amount of the alkaline metal ion-containing water was added to the reaction medium, the enantioselectivity was found to be dramatically enhanced, as compared with addition of water alone or no additive. In particular, upon addition of 0.5 vol% of LiCl-containing water, lipase MY displayed the highest *E* value (*ca.* 200), which was 5 and 50 times larger than that for water alone or no additive, respectively. A drop in the *E* value, however, was produced by the addition of a large amount of the metal ion-containing water (see the bell-shaped plots in Fig. 1). This can be explained by assuming that an excess of water molecules hydrated to the ion in the reaction medium causes the hydrolysis (the reverse reaction) of the corresponding ester product of **1**, thus leading to the loss of enantioselectivity, probably because the sites of the lipase molecule associated with the water molecule are restricted. The same trend was also observed for water alone (Fig. 1). In fact, the ester product of **1** was subjct to hydrolysis in Pr^i_2O with water or LiCl-containing water of 0.75 vol% or above.†

In order to investigate the scope of this enhancement effect, the other substrate **2**–**5** with a wide variety substituents and the other enzyme lipase AY were submitted to the model reaction. From the data summarized in Table 1, the optimum additive conditions (0.5 vol% of LiCl-containing water) were found to produce dramatically increased enantioselectivity for all the substrates **1**–**5** and both lipases, although lipase AY differs from lipase MY in its catalytic features.[4]

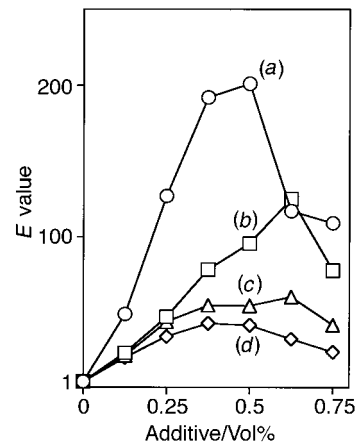


Fig. 1 The variation of the *E* value of lipase MY-catalysed esterification of **1** at *ca.* 40% conversion as a function of the amount of each additive: (*a*) LiCl, (*b*) NaCl, (*c*) KCl and (*d*) water.

			B	62	38.0	80.3	15
			C	168	33.9	87.1	23

[a] A: None; B: 0.5 vol% water; C: 0.5 vol% aq. LiCl (2.4 M).

It is known that a small amount of water improves the lipase's enantioselectivity in organic solvents, the origin of which is due to the enzyme's conformational flexibility arising from multiple hydrogen bond formation with water molecules.[5] This fact was also supported by solid-state NMR measurements as judged by tyrosyl ring motion in α-lytic protease.[6]

In order to gain an insight into the mechanism of the enhancement of the enantioselectivity by the metal ion and water, we investigated the initial rate for each enantiomer of **1** in the presence of the additives (Table 2). For addition of water alone, the initial rates for the *R* enantiomer (correctly reacting substrate) and the *S* enantiomer (incorrectly reacting substrate) were accelerated 37-fold and 12-fold, respectively, as compared with no additive conditions (see the relative ratio of the initial rate listed in Table 2). From the value of (relative ratio of V_R)/(relative ratio of V_S) = *ca.* 3 calculated from Table 2, the enhancement of the enantioselectivity was found to be mainly ascribed to the greater acceleration in the initial rate for the *R* enantiomer compared to that for the *S* enantiomer.

Table 2 The initial rate of the esterification for each enantiomer under the three conditions

Additive	V_R[b]	Relative ratio of V_R	V_S[b]	Relative ratio of V_S
None	9.0	1	0.56	1
Water (0.5 vol%)	340	37	6.9	12
LiCl (0.5 vol%)[a]	140	15	0.51	0.91

[a] The additive concentration was 2.4 M. [b] The V_R and V_S denote the initial rates of the *R* and *S* enantiomers, respectively, in nM s^{-1} (mg of protein)$^{-1}$.

In contrast, the addition of LiCl-containing water was found to bring about a slight inhibition (0.91-fold) of the initial rate for the *S* enantiomer, whereas that for the *R* enantiomer was accelerated (12-fold), as compared with the water alone additive (Table 2). Therefore, the larger value of (relative ratio of V_R)/(relative ratio of V_S) = *ca.* 18, arising from the reverse trend of each initial rate, is responsible for the significant enhancement of the lipase MY's enantioselectivity.

In conclusion, there is a difference in the mechanism of the enhancement of the lipase's enantioselectivity between the alkaline metal ion-containing water and water alone as the additive. Our method forms a useful tool to improve the enantioselectivity in lipase-catalysed reactions in organic solvents.

Stereochemical preference for heterochiral coupling controls selectivity in competitive peptide synthesis

David Birch,[a] Roger R. Hill,*[b] G. E. Jeffs[b] and Michael North[a]

Received (in Cambridge, UK) 4th March 1999, Accepted 13th April 1999

Competitive activated couplings of *N*-phthaloyl amino acids with amino acid dimethylamides show little selectivity among substrates in respect of their sidechains, but a consistent and significant preference for heterochiral outcomes.

Spontaneous abiotic formation of peptides from amino acid derivatives is a topic of considerable interest within prebiotic chemistry,[1] peptide synthesis[2] and combinatorial chemistry.[3] Whilst non-random thermal condensations in amino acid mixtures are seen as routes to incipient informational biopolymers,[4] evidence for selectivity at lower temperatures is equivocal.[2,5] Moreover, we are unaware of any study that addresses the question of stereoselectivity in competitive reactions where epimerizing equilibration is not a factor. We have found that, in DCC/HOBt-mediated coupling of *N*-phthaloyl amino acids and amino acid dimethylamides, stereoselectivity not only is the dominant controlling factor but also favours reaction between substrates of opposite configuration. An explanation of this phenomenon implies that such selectivity could be more widely applicable, with potentially significant consequences.

N-Phthaloyl (Pth) and *N*,*N*-dimethylamido (DMA) derivatives were selected for convenient chromophorically-based detection and as an inert C-terminus, respectively. Competitive couplings were carried out mostly pair-wise, where one type of substrate had the opportunity to react with two of the other type of substrate, the latter usually present in considerable molar excess. In an illustrative procedure, a solution of Pth-L-phenylalanine 1-hydroxybenzotriazole (HOBt) ester (0.1 mmol) in CH_2Cl_2 (10 cm^3), prepared *in situ* from Pth-L-phenylalanine, HOBt (0.12 mmol) and DCC (0.12 mmol), was added to racemic phenylalanine dimethylamide hydrobromide (1.0 mmol) dissolved in CH_2Cl_2 (25 cm^3) and Et_3N (1.2 mmol).[6] The mixture was stirred for two days, the CH_2Cl_2 removed by evaporation, the residue taken up in the initial HPLC eluent (30% aq. MeCN) and a homogeneous sample analysed by the area ratio of peaks identified by standards[7] as the L,L- and D,L-diastereoisomers of the corresponding derivatized dipeptides.

The outcomes of 28 such competition experiments are summarised in Tables 1 and 2, results being averaged in the cases where experiments were repeated. Table 1 shows the consistent and significant preference for heterochiral couplings, irrespective of whether the excess reagent is the Pth component or the DMA component. In order to confirm that products resulted from kinetic rather than thermodynamic control, we allowed one experiment to proceed with 1 equiv. of the racemic DMA and found the ratio of diastereomers to be close to 1 : 1 at completion. Table 2 demonstrates that when a choice of amino acids is presented, selectivity additional to that of stereochemistry is only significant in respect of the preferred coupling with glycyl residues.

The presence of one reactant in significant excess allows the approximation that product ratios in competing reactions correspond with the ratio of rate constants. Thus, the rate of peptide bond formation in these reactions is largely independent of β-substitution but significantly and uniformly faster between amino acid derivatives of opposite configuration. Further confirmation of a substantial preference for heterochiral coupling was found in the outcome of reactions between equimolar racemic reagents. Thus, the percentages of heterochiral diastereoisomer in reactions between racemic Pth-alanine and racemic dimethylamides of alanine, valine and phenylalanine were 75.6, 89.3 and 87.9, respectively. More complex mixtures also behaved consistently. For example, reaction between 1 equiv. of Pth-L-phenylalanine and a mixture of 5 equiv. each of the dimethylamides of L-alanine, L-phenyl-

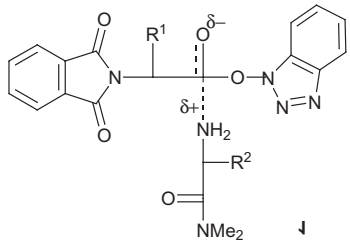
alanine and *racemic* valine gave a product mixture with a ratio 15 : 6 : 4(LL):75(LD), respectively.

The dominance of chirality over sidechain as an influence in these competitive reactions may be explained by considering the probable structure of the activated complex **1**, where it can



be seen that the two α-carbon atoms are separated by only two other atoms, whereas β-carbon atoms are more remote from potentially interacting centres. The consistent preference for a heterocyclic outcome is less readily anticipated, but would follow if **1** gained secondary stabilization by interactions between the terminal groups in a six-membered chair conformation, where the more favoured diequatorial disposition of sidechains would lead to the observed results (**2b**).

L, D
2b

If valid, this interpretation would suggest that the selectivity is largely independent of activating and terminal groups as long as the latter interact positively. (Similar independence has been noted in respect of amino acid selectivity in the reactions of different amino acids with the phosphoanhydrides of alanine and various nucleoside monophosphates; specificity was unaffected by alternative nucleosides.[8]) The results support Dose's contention that rate differences in condensations in amino acid mixtures would generally be too small to direct sidechain sequences,[5] but introduce the prospect that, in the absence of epimerization equilibria, such sequences in extendable systems would entail alternating configurations at C_α until interrupted by a glycyl residue. We are presently exploring the generality of this effect with other systems.

We thank Mrs J Burrage and Mr Eric Williams for technical assistance.

Low temperature selective methane activation to alkenes by a new hydrogen-accumulating system

M. V. Tsodikov,[a] Ye. V. Slivinskii,[a] V. P. Mordovin,[a] O. V. Bukhtenko,[a] G. Colón,[b] M. C. Hidalgo[b] and J. A. Navío*[b]

Received (in Cambridge, UK) 22nd February 1999, Accepted 16th April 1999

A heterogeneous hydrogen-accumulating system containing porous titanium with 0.4 wt% Ni combined with high-purity titanium chips was tested for methane activation; methane conversion to C_1–C_4 hydrocarbons reached a value of *ca.* 20% over this material, working at 450 °C and 10 atm, after methane circulation across the system for 22 h; the split hydrogen was accumulated as TiH_2, being in solid solution with porous metallic titanium.

Methane is the principal constituent of natural gas, landfill gas or coalbed methane. It is also a by-product of oil refining and chemical processing. Many techniques have been developed for improving the industrial processes which convert methane into higher hydrocarbons, gasoline and olefins by both indirect and direct conversion processes.[1,2] However these industrial processes involve expensive separation steps and/or require the use of temperatures higher than 80 °C, with the subsequent consumption of energy.[1,2]

Direct methane conversion eliminates the need (and subsequently reduces the cost) for the syngas preparation step. However, since methane is a very stable molecule[2,3] its reactions generally have high activation energy and, once activated, it is difficult to stop the reaction from going further than desired.

On the other hand, the non-favourable thermodynamic parameters[4] for methane self-interaction reactions led us to predict that, without strong oxidants, it would be difficult to transform methane into higher homologues at moderate temperatures using conventional catalytic approaches. We presumed, however, that it should be possible to shift the equilibrium *via* the introduction of separate stages, including the formation of [CH_3*] and [CH_2*] intermediates using heterogeneous systems with dual activities: a high activity for C–H bond fission and simultaneous hydrogen-accumulating properties. The latter might lead to an increase in the probability of direct self-interactions between generated intermediates, giving higher hydrocarbon molecules by a route which has not been explored until now. The adsorption of H_2 on transition metals has been much studied.[5] At the same time the adsorption/reaction of hydrocarbons on metallic catalysts is a very well known topic,[5] with Ni metal having a capability for hydrogenolysis of C–C and steam reforming of CH_4.

With this goal in mind we used a heterogeneous system containing porous high purity titanium (99.6%) with 0.4 wt% Ni in the form of cylindrical pellets (10 mm long and 5 mm in diameter) (**I**) combined with titanium chips (**II**) also obtained from high purity titanium. The **I**:**II** ratio was 5.3. The composite was thermally activated at 850 °C *in vacuo* (10^{-5} torr) before being placed in a loop reactor with a total volume of 0.42 L in circulation mode with a flow rate of 5 L of gas per hour at 10 atm. It was shown by laser (ML-2) and scanning high temperature mass spectroscopy (VIMS MS-720) that vacuum treatment is sufficient to clean up the surface. Using 19 g of this catalytic material it was found that methane conversion reached around 20% after methane flow-circulation across the catalyst bed at a temperature of 450 °C for 22 h. This degree of conversion was constant even after 28 h of continuous flow-circulation, as experimental controls showed (Fig. 1). It should be mentioned that methane conversion into C_2 hydrocarbons was initiated at 330 °C. Table 1 summarises the composition of the methane conversion products. As can be seen, after methane flow-circulation for 1 h a conversion of about 4.5% was reached, yielding predominantly ethylene and ethane (92.9%). After prolonged reaction time an increase of C_2–C_4 olefins of around 70–75% was observed, 50–55% of which was ethylene. At this point, the level of hydrogen in the reaction volume was not more than 0.01% according to GC (LKhM-8MD and Biokhrom chromatographs) and MS (VIMS MS-7201) analyses.

Analysis by X-ray (DROM-3M, Cu-Kα) diffraction of the composition of the catalyst showed that, in addition to the reflections corresponding to the metal titanium phase [d = 2.24; 2.34; 2.55 A], titanium chips removed from the reactor under anaerobic conditions showed well-resolved intense reflections

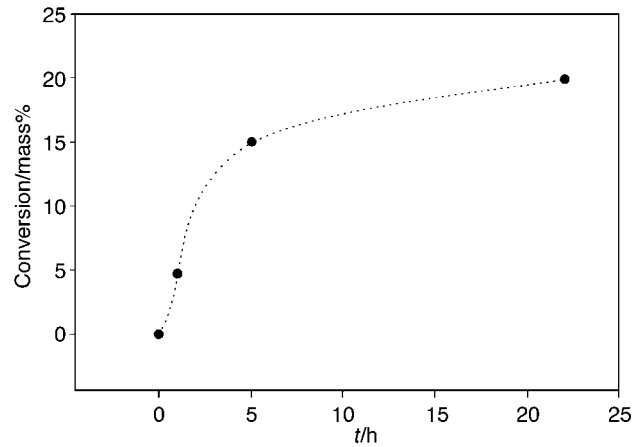

Fig. 1 Conversion of methane into products summarised in Table 1.

Table 1 Methane conversion and the composition of products from its transformation (T = 450 ºC, P = 10 atm)

Composition (% mass)	Composition (mass%)			
	1 h	5 h	22 h	28 h
CH_4	95.3	85.3	79.8	80.1
C_2H_4	2.5	8.2	10.0	10.8
C_2H_6	1.9	3.0	4.8	4.4
C_3H_6	0.1	2.5	3.1	2.1
C_3H_8	0.2	0.4	0.4	0.3
C_4H_8	< 0.1	0.4	1.3	1.7
C_4H_{10}	< 0.1	0.2	0.6	0.6

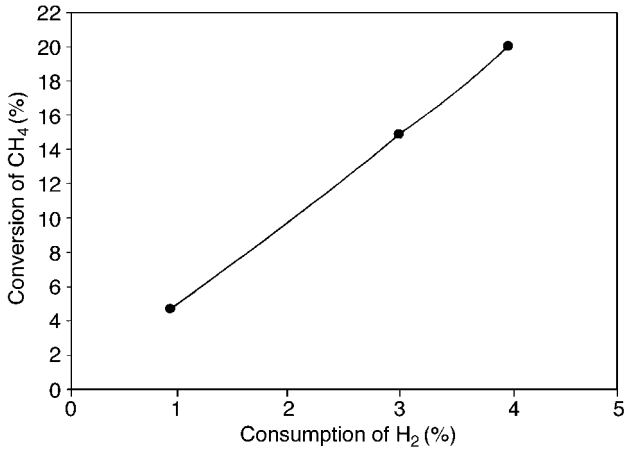

Fig. 2 Dependence of methane conversion on the quantity of hydrogen evolved and sorbed by the heterogeneous system.

due to a hydride phase (TiH_2) [d = 2.22; 2.31; 2.53 A]. At the same time, the reflections associated with the metal titanium phase shifted by only 0.45–0.47° (2θ) with respect to the starting system for the porous titanium. This evidence for the formation of a Ti–H interstitial solid solution during the decomposition of methane.

Fig. 2 shows that the increase in the methane conversion, in the range of operation, is proportional to the amount of hydrogen sorbed by the system, this being calculated on the basis of the stoichiometry of the reaction. This enables us to conclude that the removal of hydrogen from the reaction zone is, as expected, one of the main stages of the transformation of methane into higher products.

On the basis of the balance of the identified products, we may propose the pathways in eqns. (1)–(4) for the self-interaction reactions between the intermediates formed from methane activation.

$$2\ CH_4 \rightarrow 2\ [CH_2^*] - 4\ [H] \rightarrow C_2H_4 \quad (1)$$

$$2\ CH_4 \rightarrow 2\ [CH_3^*] - 2\ [H] \rightarrow C_2H_6 \quad (2)$$

$$3\ CH_4 \rightarrow 3\ [CH_2^*] - 6\ [H] \rightarrow C_3H_6 \quad (3)$$

$$3\ CH_4 \rightarrow [CH_2^*] + 2\ [CH_3^*] - 4\ [H] \rightarrow C_3H_6 \quad (4)$$

The C_4 fraction is probably a result of ethylene dimerization. We also propose that one of the limitations of this process is the coordination of CH_2^* intermediates to the surface metal centres. The interaction between closely coordinated [CH_2–M] species at the catalyst surface could be followed by their elimination leading to ethylene formation. In this way we can explain the high selectivity for C_2 alkene. In fact this tentative mechanism for the formation of olefins is in good accordance with the concepts of metal complex homogeneous catalysis.[6]

In any case our results indicate that C_2–C_3 species can be obtained by a single step, compared with direct or indirect processes which involve multi-steps such as the syngas and steam reactions. Of course, the problem of the hydrogen spillover to the titanium chips requires further study, which is now in progress.

Here we have reported a new finding which opens the way to selective low temperature methane conversion to important products by a new means using bifunctional hydrogen accumulating systems. At the same time the process offers the possibility of simultaneously obtaining high purity dihydrogen.

Received (in Cambridge, UK) 6th January 1999, Accepted 9th March 1999

The goal of this feature article is to introduce the dimension 'magnetic anisotropy' in the field of molecule-based magnets. For that, we have focused on three cyano-bridged $Mn^{II}Mo^{III}$ compounds synthesized from the $[Mo^{III}(CN)_7]^{4-}$ precursor. The pentagonal bipyramid structure of this precursor is not compatible with a cubic lattice, as found in the Prussian blue phases. In this precursor, Mo^{III} has a low-spin configuration, with a local spin $S_{Mo} = 1/2$, and a strongly anisotropic *g* tensor. Two of the compounds have a three-dimensional structure. Their formulas are $Mn_2(H_2O)_5Mo(CN)_7 \cdot nH_2O$, with $n = 4$ for the α phase, and $n = 4.75$ for the β phase. One of the compounds, of formula $K_2Mn_3(H_2O)_6[Mo(CN)_7]_2 \cdot 6H_2O$, has a two-dimensional structure, with K^+ cations and water molecules located between double-sheet layers. The compounds crystallize in the monoclinic system, and the lattice symmetries are very low. For the three compounds, we have succeeded in growing well shaped single crystals suitable for magnetic anisotropy measurements, and we have investigated the magnetic properties as follows: first, we have determined the magnetic axes by looking for the extremes of the magnetization in the three crystallographic planes *ab*, *bc*, and *ac*. Then, we have measured the temperature and field dependences of the magnetization in the dc mode along the three magnetic axes. These measurements have revealed the existence of several magnetically ordered phases for the three-dimensional compounds, and of field-induced spin reorientations for the three compounds. For the very first time in the field of molecular magnetism, we have been able to determine the magnetic phase diagram for each compound. We have obtained additional information from magnetic data recorded in the ac mode, with both zero and non-zero static fields. Finally, we have found that when the non-coordinated water molecules are released, the long-range magnetic ordering temperatures are shifted toward higher temperatures. Irrespective of the structural details, the Mo^{III}–C–N–Mn^{II} interaction has been found to be ferromagnetic. We have discussed this unexpected result, and proposed a mechanism accounting for this. We have also discussed the factors governing the magnetic anisotropy of the compounds.

Introduction

The first two molecular compounds exhibiting a spontaneous magnetization below a certain critical temperature, T_c, were described in 1986.[1,2] These reports have opened a new field of research, that of molecule-based magnets, and in the last decade quite a few new compounds of that kind have been synthesized.[3–19] What characterizes this field of research is its deeply multidisciplinary nature; it brings together synthetic organic, organometallic, and inorganic chemists along with theoreticians and physicists as well as material and life science people.

To a large extent, the field so far has been governed by the race toward high coercivity and/or high critical temperature. High coercivity means that the material has a pronounced memory effect. As a matter of fact, applying a weak magnetic field to a magnet results in a saturation magnetization aligned in the field direction. When the field is switched of, the magnetization does not disappear, but takes a value called remnant magnetization. The coercive field is the field which must be applied in the opposite direction to annul this remnant magnetization, *i.e.* to suppress the information associated with the remnant magnetization. Recently, a very hard molecule-based magnet was discovered. Its coercive field depends on the particle size; it may be as large as 25 kOe at 5 K. This compound contains three kinds of spin carriers, Co^{2+} and Cu^{2+} ions as well as radical cations. It structure is very peculiar; it consists of two perpendicular honeycomb like (or graphite like) networks which interpenetrate in such a way that each hexagon belonging to one of the networks is interlocked with a hexagon belonging to the perpendicular network.[20–22] The key factor of the huge coercivity is the presence of very anisotropic Co^{2+} ions in octahedral surroundings. The interlocking of the two networks also contributes to this coercivity.

High critical temperature obviously means that the magnetically ordered state is easily accessible. In that respect, T_c above room temperature is a must. This goal has been reached with a compound of formula $V^{II}_{0.42}V^{III}_{0.58}[Cr^{III}(CN)_6]_{0.86} \cdot 2.8H_2O$.[23] This compound belongs to the vast family of the Prussian blue like phases with the general formula $A_k[B(CN)_6]_l \cdot nH_2O$ where

Olivier Kahn was born in Paris (France). He received his PhD thesis from the University of Paris in 1969. He became Professor of Chemistry at the University of Paris South in 1975, and moved to the Institut de Chimie de la Matière Condensée de Bordeaux in 1995. He is presently Professor at the University of Bordeaux I, and Member of the Institut Universitaire de France. Olivier Kahn is a Fellow of the (French) Academy of Science and of other academies. His fields of research are molecular materials, molecular electronics, and molecular magnetism.

Joulia Larionova was born in Saint Petersburg (Russia). She received her PhD thesis from the University of Bordeaux I in 1998. She initiated the work on the anisotropy properties of molecule-based magnets and determined the first magnetic phase diagrams for this class of compounds during her PhD.

Lahcène Ouahab was born in Sétif (Algeria). He received his PhD thesis from the University of Rennes I in 1985. He is presently Director of Research at the Laboratoire de Chimie du Solide et Inorganique Moléculaire of the University of Rennes I, and leads the molecular materials group. His fields of research concern the synthesis, and the crystal chemistry of molecular materials, in particular charge transfer complexes, radical ion salts, and organic–inorganic hybrids.

A is a high spin metal ion and B a low spin one. The basic structure is faced-centered cubic with A–N–C–B linear linkages along three perpendicular directions. Alkaline cations may occupy A_4 or B_4 tetrahedral sites. For $k > 1$, some $B(CN)_6$ groups are missing, which creates a local breaking of the three-dimensional periodicity. These vacant sites are usually occupied by water molecules coordinated to the adjacent A site.[24,25] The magnetic interaction between nearest neighbor A and B ions may be antiferro- or ferromagnetic. In the former case, the local spins tend to align in an antiparallel way. When it is so, the compound below T_c is a ferrimagnet, provided that there is no exact cancellation of the A and B spin sublattices. This situation is by far the most frequent. In the latter case, the local spins tend to align in a parallel way, and below T_c the compound is a ferromagnet. One of the appealing aspects of the magnetic studies dealing with Prussian blue phases[26–30] resides in the fact that it is possible to predict the nature, and to estimate *a priori* the value of the critical temperature, using simple theoretical models based on the symmetry of the singly occupied orbitals.[31] This is due to the fact that the symmetry of both the A and B metal sites is strictly octahedral so that the e_g and t_{2g} orbitals do not mix. The design of the room temperature magnet mentioned above does not arise from serendipity, but was achieved in a rational way.[32] The cubic symmetry of the Prussian blue phases, however, has a cost. These compounds are structurally, and hence magnetically isotropic, and many interesting features associated with the structural and magnetic anisotropies cannot be observed. It may be noticed that nobody so far has succeeded in growing single crystals of Prussian blue phases suitable for detailed magnetic measurements. This situation is not too embarrassing as no anisotropy is expected, except perhaps a weak shape anisotropy for thin film samples. On the other hand, the thorough investigation of the properties of molecule-based magnets of low symmetry requires obviously well shaped single crystals.

The goal of this article is to emphasize the beauty and the richness of the phenomena arising from the low symmetry of molecule-based magnets. For that, we will focus on cyano-bridged bimetallic magnets synthesized from the $[Mo(CN)_7]^{4-}$ precursor. The choice of this precursor is motivated by three reasons: (i) as for the Prussian blue phases, the presence of cyano ligands can lead to extended lattices. (ii) These networks should be of low symmetry; as a matter of fact, the heptacoordination of the precursor is not compatible with a cubic symmetry. (iii) In $KNa_2[Mo(CN)_7]\cdot 2H_2O$, the Mo^{III} ion is in a low-spin pentagonal bipyramid environment. The orbitally degenerate ground state, $^2E''_1$, is split into two Kramers doublets by the spin–orbit coupling, and the ground Kramers doublet is strongly anisotropic.[33–35] In other words, the value of the magnetization when applying a magnetic field strongly depends on the orientation of this field with respect to the fivefold axis of the pentagonal bipyramid.

We will try to present this article in a tutorial way; we will report on the magnetic properties of three compounds, but each new concept in molecular magnetism will be introduced and discussed only once.

The three-dimensional compounds $Mn_2(H_2O)_5Mo(CN)_7\cdot nH_2O$, α and β phases

Crystal structure of the α phase

The slow diffusion of two aqueous solutions containing $K_4[Mo(CN)_7]\cdot 2H_2O$ and $[Mn(H_2O)_6](NO_3)_2$, respectively, affords two kinds of single crystals, with elongated plate (α phase) and prism (β phase) shapes.[36,37] The local environments of the metal sites are similar for both phases, but the three-dimensional organizations are different. There is one molybdenum site along with two manganese sites, denoted as Mn1 and Mn2, as shown in Fig. 1. The molybdenum atom is surrounded by seven –C–N–Mn linkages, four of them involving a Mn1 site and three of them a Mn2 site. The geometry may be described as a slightly distorted pentagonal bipyramid. Both Mn1 and Mn2 sites are in distorted octahedral surroundings. Mn1 is surrounded by four –N–C–Mo linkages and two water molecules in *cis* conformation. Mn2 is surrounded by three −N–C–Mo linkages and three water molecules in a *mer* conformation. The three-dimensional organization for the α phase may be described as follows: edge-sharing lozenge motifs $(MoCNMn1NC)_2$ form bent ladders running along the *a* direction. Each ladder is linked to four other ladders of the same kind along the [011] and [01 − 1] directions through cyano bridges. These ladders are further connected by the $Mn2(CN)_3(H_2O)_3$ groups. Mn2 is linked to a Mo site of one of the ladders and to two Mo sites of the adjacent ladder. The structure as a whole viewed along the *a* direction is represented in Fig. 2.

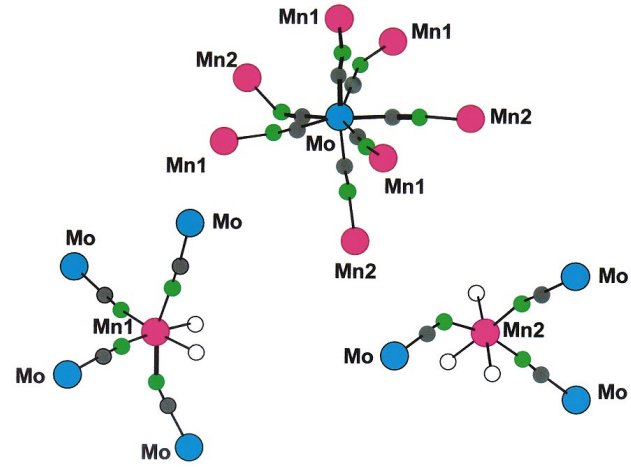

Fig. 1 Local structure of the molybdenum and manganese sites for $Mn_2(H_2O)_5Mo(CN)_7\cdot 4H_2O$ (α phase). The color code is the following: the manganese atoms are in red, the molybdenum atoms in blue, the carbon atoms in black, the nitrogen atoms in green, and the oxygen atoms (of water molecules) in white.

Magnetic properties of the α phase

We first checked that in the three crystallographic planes *ab*, *bc*, and *ac*, the extremes of the magnetization are obtained when the field is aligned along the *a*, *b* and *c** axes. Therefore, these axes are the magnetic axes of the compound. It may be noticed that the twofold axis of the monoclinic lattice, *b*, was necessarily one of the magnetic axes.[38] All the magnetic measurements were carried out on single crystals with the external field successively applied along these three axes. We first measured the temperature dependences of the magnetization, *M*, under a field of 5 Oe. The three curves are shown in Fig. 3. They reveal that the material is anisotropic, the magnetization along the easy magnetization axis, *b*, being about twice as large as along the *a* axis. Moreover, these curves exhibit a break with an inflexion point at $T_{1c} = 51$ K along with another anomaly, more visible along the *a* axis, at $T_{2c} = 43$ K. Very few magnetic anisotropy measurements on molecule-based magnets were performed so far.[3,39]

The most accurate technique to determine transition temperatures is the measure of the heat capacity as a function of temperature. In the present case, the heat capacity curve shows a λ peak at 51 K, but nothing is detected at 43 K (see Fig. 4). It follows that the compound presents two magnetic transitions, and the entropy change associated with that occurring at 51 K is much larger than the entropy change associated with that occurring at 43 K.

In order to obtain more insights on the magnetic anomaly detected at 43 K, visible essentially along the *a* direction, we measured the magnetization along this direction with an external field varying from 1 up to 100 Oe. The results are

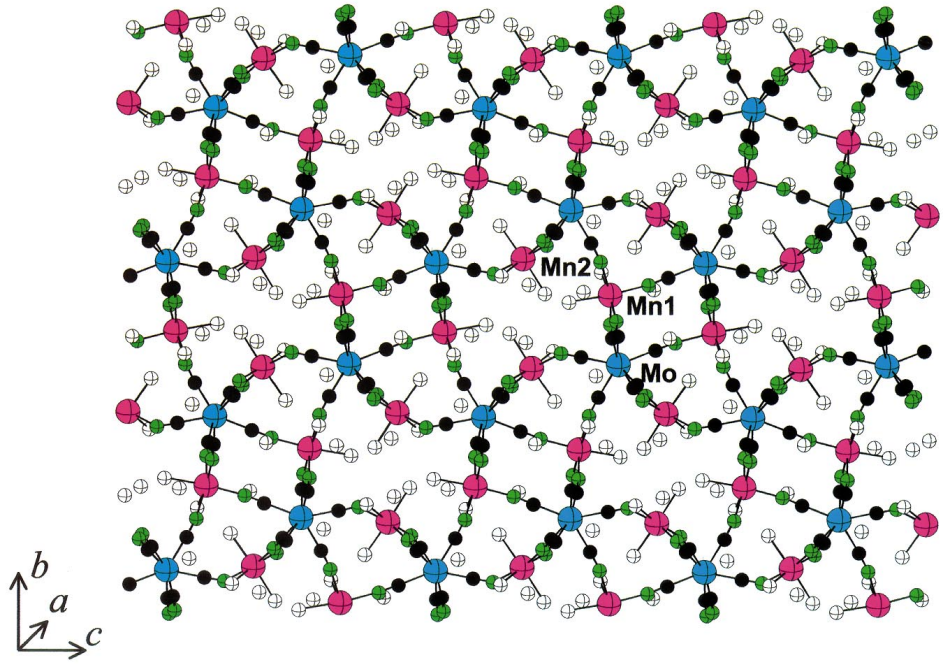

Fig. 2 Structure of the compound $Mn_2(H_2O)_5Mo(CN)_7{\cdot}4H_2O$ (α phase) viewed along the *a* direction.

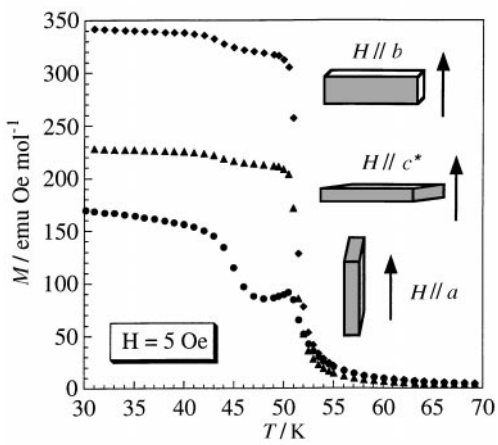

Fig. 3 Temperature dependences of the magnetization along the *a*, *b* and *c** directions, using an external field of 5 Oe, for $Mn_2(H_2O)_5Mo(CN)_7{\cdot}4H_2O$ (α phase).

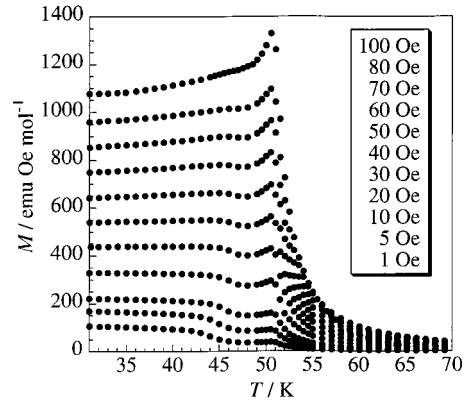

Fig. 5 Temperature dependences of the magnetization along the *a* direction, using different values of the external field, for $Mn_2(H_2O)_5Mo(CN)_7{\cdot}4H_2O$ (α phase).

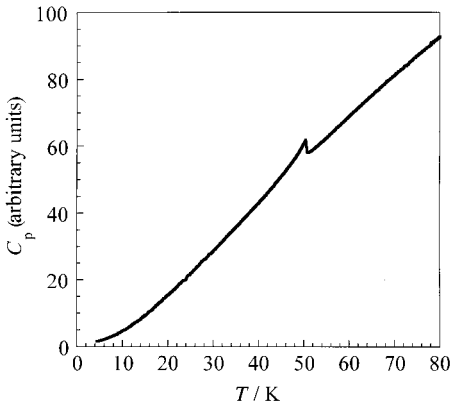

Fig. 4 Temperature dependence of the heat capacity for $Mn_2(H_2O)_5Mo(CN)_7{\cdot}4H_2O$ (α phase).

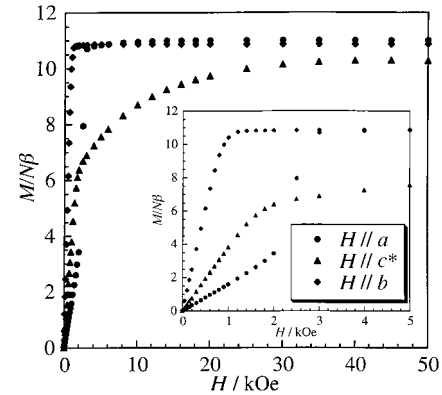

Fig. 6 Field dependences of the magnetization at 5 K along the *a*, *b* and *c** directions for $Mn_2(H_2O)_5Mo(CN)_7{\cdot}4H_2O$ (α phase).

displayed in Fig. 5. T_{2c} is shifted toward higher temperatures as the magnetic field increases, and eventually, for a field of *ca.* 100 Oe, merges with the transition at 51 K. For each field, T_{2c} was determined as the inflexion point of the $M = f(T)$ curve.

We then measured the field dependences of the magnetization at 5 K along the *a*, *b* and *c** directions (see Fig. 6). The curves are strictly identical when increasing and decreasing the field; the compound exhibits no coercivity. Along the easy magnetization direction, *b*, the saturation is reached with *ca.* 1 kOe. The saturation magnetization is found equal to 11 Nβ. This value corresponds exactly to what is expected for one $S_{Mo} = 1/2$ and two $S_{Mn} = 5/2$ local spins aligned along this direction. The interaction between adjacent Mo^{III} and Mn^{II} ions is ferromagnetic. Along the *c** direction, the magnetization increases progressively when applying the field, and even at 50 kOe the

saturation is not totally reached. Along the *a* direction, the *M versus H* curve is peculiar; it shows an inflexion point for a critical field, H_c, of about 2.2 kOe. We are faced with a field-induced spin reorientation phenomenon.[40–44]

Field-induced spin reorientation

Let us examine in more detail what happens when applying the field along the *a* axis. In zero field, the resulting moment of 11 Nβ is essentially aligned along *b*. When applying the field, first this moment hardly rotates from *b* to *a*, then for a critical value of the field the rotation becomes much easier. Finally, for a saturation value of the field, H_{sat}, the moment is aligned along *a*. The spin reorientation is a non-linear phenomenon. It is difficult to unhook the moment from the *b* axis. When the field is large enough, this unhooking is realized, and then a weak increase of the field induces a strong rotation until the moment is collinear with *a*. To determine the H_c and H_{sat} *versus T* curves, we measured the field dependence of the magnetization along *a* every 5 K in the 5–51 K range. The critical field at each temperature was determined as the field for which the d*M*/d*H* derivative is maximum. The saturation field at each temperature was determined as the weakest field for which the saturation is reached. The temperature dependences of H_c and H_{sat} for a field applied along the *a* axis are utilized to determine the magnetic phase diagram of the compound.

Magnetic phase diagram

From the magnetic data presented above, it is possible to plot the magnetic phase diagram of the compound when the field is applied along the *a* axis. This diagram shown in Fig. 7 presents

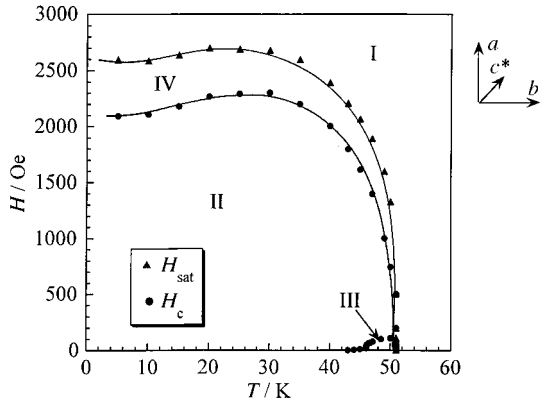

Fig. 7 Magnetic phase diagram for $Mn_2(H_2O)_5Mo(CN)_7{\cdot}4H_2O$ (α phase); the full lines are a guide to the eye.

four domains. Domain I is the paramagnetic domain in which the spins are either randomly oriented, or aligned along the field direction. Domains II and III are ferromagnetic domains in which the spins are essentially aligned along the *b* direction. Domain III is limited to the 43–51 K temperature range and the 0–100 Oe field range. Domain IV, finally, is limited by the $H_c = f(T)$ and $H_{sat} = f(T)$ curves, and corresponds to a mixed domain in which the spins may rotate easily from the *b* to the *a* direction. It is worth mentioning that the boundary between domains II and IV corresponds to a first-order transition, while that between domains I and IV corresponds to a second-order transition.

The question we are faced with is the difference between domains II and III. We have seen that the entropy variation associated with the transition between these two domains is very weak, and not detected in the heat capacity curve of Fig. 4. Therefore, the magnetic structures of these domains are similar to each other. The transition between these two domains, at 43 K in zero field, is more pronounced when applying the field along the *a* axis than along the other two magnetic axes. This strongly suggests that the main difference between domains II and III concerns the component of the resulting moment along *a*. Assuming that the magnetic symmetry of the low-temperature domain II is lower than that of the high-temperature domain III, we may suggest that domain III is a perfectly ferromagnetic domain with the magnetic moments aligned along *b* in zero field, and that a small canting occurs as *T* is lowered below 43 K, with a weak component of the resulting moment along *a*. If it was so, applying a field of 100 Oe along *a* would destabilize the perfectly ferromagnetic domain in favor of the weakly canted domain. Alternatively, the two domains might be weakly canted, with a component of the moment along *a*, the degree of canting being slightly more pronounced in domain II. Neutron diffraction studies should allow us to specify the differences between domains II and III.

A quick look on the β phase

The structure of the β phase is shown in Fig. 8. Each ladder made of edge-sharing lozenge motifs is surrounded only by two instead of four identical ladders. This phase again exhibits a ferromagnetic transition at T_c = 51 K. It is even more anisotropic than the α phase, and the magnetic phase diagram is even more complex, with several ferromagnetically ordered domains, and a spin reorientation domain.[45]

The partial dehydration of the α or β phase leads to the same compound which exhibits a long-range ferromagnetic ordering at 66 K along with a coercive field of 850 Oe at 5 K.

The two-dimensional compound $K_2Mn_3(H_2O)_6[Mo(CN)_7]_2{\cdot}6H_2O$

When the slow diffusion between aqueous solutions containing $K_4[Mo(CN)_7]{\cdot}2H_2O$ and $[Mn(H_2O)_6](NO_3)_2$, respectively, takes place in the presence of an excess of K^+ ions, a two-dimensional compound of formula $K_2Mn_3(H_2O)_6$-$[Mo(CN)_7]_2{\cdot}6H_2O$ is obtained.[46] The structure contains again a unique molybdenum site along with two manganese sites, denoted as Mn1 and Mn2, as shown in Fig. 9. The molybdenum atom is surrounded by six –C–N–Mn linkages and a terminal –C–N ligand. The geometry may be described as a strongly distorted pentagonal bipyramid, and both the Mo–C–N and C–N–Mn bridging angles deviate significantly from 180°. Both the Mn1 and Mn2 sites are surrounded by four –N–C–Mo linkages and two water molecules in *trans* conformation. The two-dimensional structure is made of anionic double-sheet layers parallel to the *bc* plane, and K^+ and non-coordinated water molecules situated between the layers, as shown in Fig. 10. Each sheet is a kind of grid in the *bc* plane made of edge-sharing lozenges $[MoCNMn2NC]_2$. Two parallel sheets of a layer are further connected by $Mn1(CN)_4(H_2O)_2$ units situated between the sheets. The thickness of a double-sheet layer is 8.042 Å, and that of the gap between two layers is 7.263 Å.

Magnetic phase diagram

We first checked that *a*, *b* and *c** were the magnetic axes of the compound, *b* being the easy magnetization axis, then we studied the temperature and field dependences of the magnetization along the three axes. No hysteresis was observed along *a* and *b*, while a narrow hysteresis, of *ca.* 125 Oe, was observed along *c** at 5 K. These measurements revealed that the compound exhibits a long range ferromagnetic ordering at T_c = 39 K, and that below T_c a field induced spin reorientation occurs along the *c** axis. We determined the critical and saturation fields every 5 K below T_c when applying the field along *c**. The H_c and H_{sat} *versus T* curves shown in Fig. 11 define the magnetic phase diagram for the compound when the magnetic field is applied along *c**. This diagram is simpler than that of Fig. 7. It presents only three domains. Domain I corresponds to the paramagnetic, or saturated paramagnetic domain. Domain II corresponds to

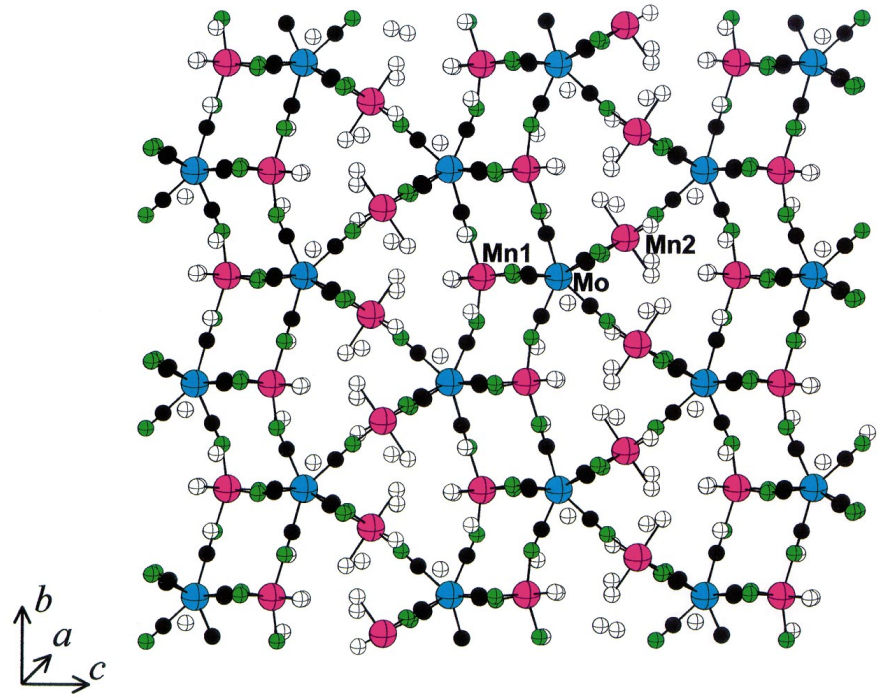

Fig. 8 Structure of the compound $Mn_2(H_2O)_5Mo(CN)_7{\cdot}4.75H_2O$ (β phase) viewed along the *a* direction.

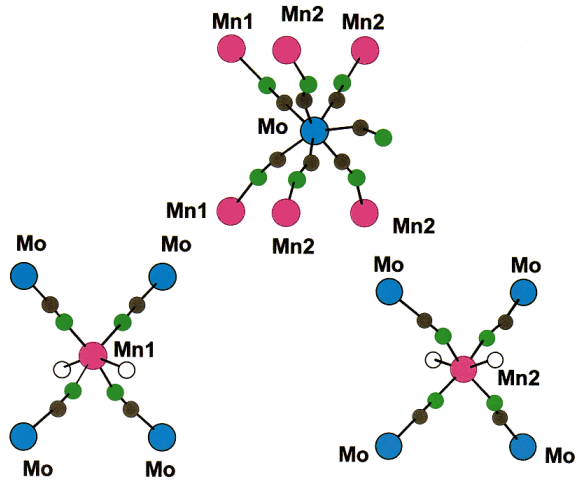

Fig. 9 Local structure of the molybdenum and manganese sites for $K_2Mn_3(H_2O)_6[Mo(CN)_7]_2{\cdot}6H_2O$. The color code is the same as for Fig. 1.

the ferromagnetically ordered domain in which the spins are essentially aligned along the *b* axis. Domain III, finally, is a spin-reorientation domain in which the spins rotate from the *b* to the *c** direction as the field increases from H_c to H_{sat}.

To complete this study, we also determined the temperature dependence of the spontaneous magnetization. For that, we studied the field dependence of the magnetization along the *b* axis every 5 K. Some curves are shown in Fig. 12 (top). At each temperature, the spontaneous magnetization, M_S, can be determined by extrapolating down to zero the $M = f(H)$ data obtained in the field range where the variation is linear. The temperature dependence of the spontaneous magnetization is represented in Fig. 12 (bottom). The spontaneous magnetization is equal to 17 $N\beta$ at absolute zero, decreases as the temperature increases, and vanishes at T_c = 39 K.

ac Magnetic measurements

So far, we only spoke of magnetic measurements recorded in the dc mode; *i.e.* with a static external field. Additional information can be obtained by working in the ac mode.[47] The magnetic field is then expressed as:

$$H = H_0 + h \exp(i\omega t)$$

where H_0 is the static field, which may be taken as zero, h is the amplitude of the oscillating field, ω the frequency, and t the time. The ac susceptibility, χ_{ac}, is then equal to dM/dH. The ac magnetic susceptibility is determined from its two components, the in-phase (or real) component, χ'_{ac}, and the out-of-phase (or imaginary) component, χ''_{ac}. The in-phase susceptibility is an initial susceptibility with the same phase as the oscillating field. The out-of-phase susceptibility characterizes the phase delay of the magnetization with respect to the oscillating field in the magnetically ordered phase.

We report here on two experiments in the ac mode. First, we measured the temperature dependences of the in-phase, χ'_{ac}, and out-of-phase, χ''_{ac}, magnetic susceptibilities under a zero static field. Along the three directions, the in-phase responses exhibit a break at T_c = 39 K. The χ'_{ac} values along the *b* axis below T_c are much higher than along the other two directions. The out-of-phase response along the *b* axis is zero down to 39 K, then presents an abrupt break as T is lowered below this temperature, and reaches a maximum around 34 K. Along the other two directions, χ''_{ac} is negligibly weak down to 2 K.

When the field is applied along the easy magnetization axis, *b*, both the displacement of the domain walls and the rotation of the magnetic moments contribute to the ac magnetic response. On the other hand, when the field is applied along a hard magnetization axis, only the rotation of the magnetic moments contributes to the ac response.[48] In the present case, the very high response along *b* as compared to the responses along *a* and *c** indicates that the domain walls move very easily, which is in line with the quasi absence of hysteresis in the $M = f(H)$ curves.

The second experiment consisted of measuring the field dependence of χ'_{ac} along the *c** axis every 5 K in the magnetically ordered phase. The results are displayed in Fig. 13. At each temperature, χ'_{ac} first increases as the field increases, reaches a maximum, then tends to zero at high field. The maximum of χ'_{ac} determines the critical field, H_c, and the extreme of the derivative $d\chi'_{ac}/dH$ determines the saturation field, H_{sat}. The $H_c = f(T)$ and $H_{sat} = f(T)$ curves deduced from this experiment are strictly similar to those shown in Fig. 11.

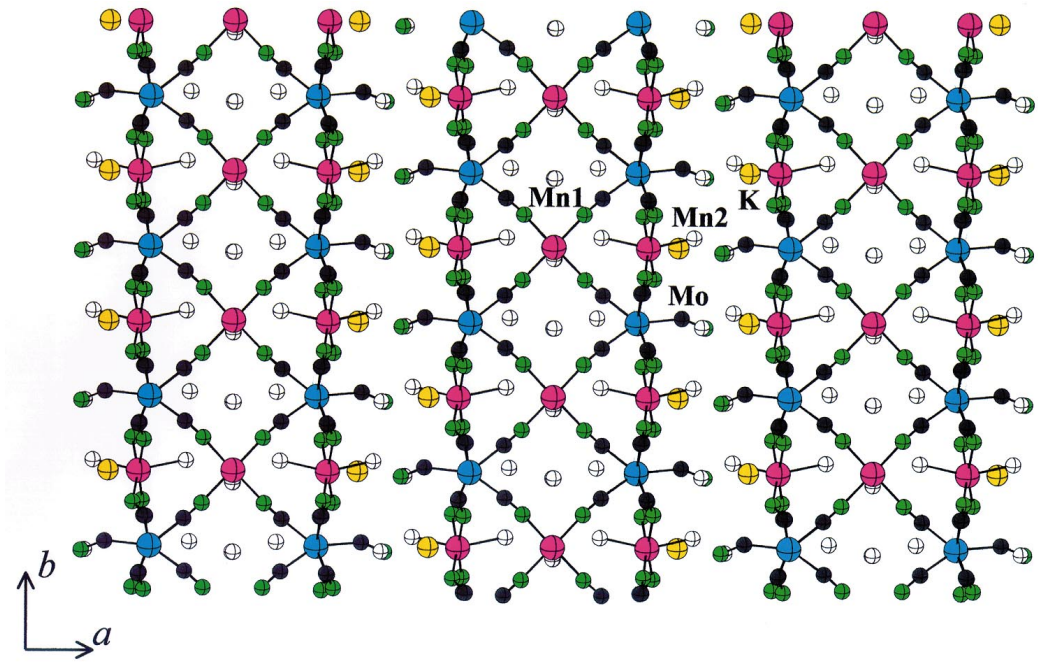

Fig. 10 Structure of the compound $K_2Mn_3(H_2O)_6[Mo(CN)_7]_2{\cdot}6H_2O$ in the *ab* plane. Potassium atoms are in yellow.

Modification of the magnetic properties through partial dehydration

The magnetic properties of $K_2Mn_3(H_2O)_6[Mo(CN)_7]_2{\cdot}6H_2O$ can be dramatically modified through partial dehydration. When the non-coordinated water molecules of a single crystal are released under vacuum, the external shape of the crystal is not modified. Magnetic measurements suggest that the crystallographic directions are retained. We then investigated the temperature dependences of the magnetization along these directions. The $M = f(T)$ curves along *b* and *c** are not distinguishable. After dehydration, the *bc* plane may be considered as an easy magnetization plane, even in low field. The spin reorientation is suppressed. Both in the *bc* plane and perpendicularly to this plane, the magnetization shows a break at T_c = 72 K, while the critical temperature for the non-dehydrated compound is 39 K. We measured the field dependences of the magnetization at 10 K both in the *bc** plane and along the *a* direction. The results are displayed in Fig. 14. In the easy magnetization plane, the saturation value of 17 $N\beta$ corresponding to the parallel alignment of all the spins is obtained under *ca.* 5.0 kOe. On the other hand, along the *a* axis, the saturation is not reached yet under 50 kOe. Magnetic hystereses are observed along both directions, with coercive fields of 1.3 kOe in the *bc* plane, and 0.55 kOe along *a*.

We can notice here that the Prussian blue phases are also hydrated. It would be interesting to see whether their partial dehydration also modifies their magnetic properties.

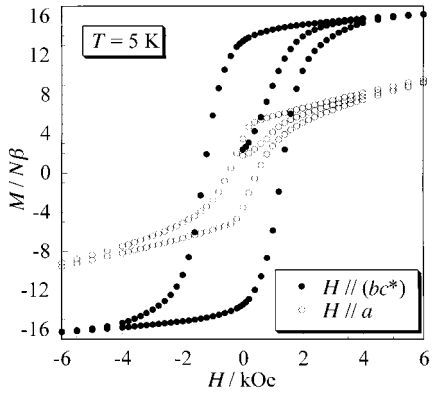

Fig. 14 Hysteresis loops in the *bc** plane and along the *a* axis at 10 K for a partially dehydrated crystal of $K_2Mn_3(H_2O)_6[Mo(CN)_7]_2{\cdot}6H_2O$.

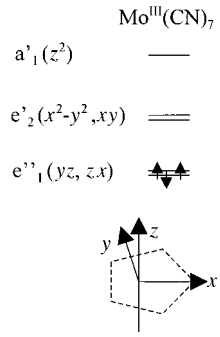
Why is the Mo^{III}–C–N–Mn^{II} interaction ferromagnetic?

One of the striking features concerning the compounds described in this article is the ferromagnetic nature of the interaction between low-spin Mo^{III} and high-spin Mn^{II} ions through the cyano bridge. For several decades, quite a few studies have been devoted to the microscopic mechanisms of the interaction between spin carriers, more particularly to those of the mechanisms favoring a parallel alignment of the electron spins.[31,49] Three situations have been found to stabilize the parallel spin state, namely: (i) *the strict orthogonality of the magnetic orbitals*. Such a situation is achieved when all the singly occupied orbitals centered on a spin carrier (called also magnetic orbitals) are orthogonal (*i.e.* give a zero overlap integral) with all the singly occupied orbitals centered on the adjacent spin carrier. This situation of strict orthogonality of the magnetic orbitals is certainly the most efficient way to achieve a ferromagnetic interaction. (ii) *The electron transfer from a singly-occupied orbital on a site toward an empty orbital on an adjacent site, or from a doubly-occupied orbital on a site toward a singly-occupied orbital on an adjacent site*. This mechanism is probably less efficient than the previous one, and more difficult to control. (iii) *The interaction between a zone of negative spin density on a fragment and a zone of positive spin density on an adjacent fragment*. This mechanism, first suggested in the context of assemblies of organic radicals,[50] may apply for transition metal species as well.

We carefully examined the relevance of each of these mechanisms in the case of Mo^{III}–C–N–Mn^{II}. The strict orthogonality of the magnetic orbitals is not realized, and the absorption spectra of the compounds synthesized from the $[Mo(CN)_7]^{4-}$ precursor do not reveal any metal–metal charge transfer band of relatively low energy. Therefore, we are wondering whether the ferromagnetic interaction could arise from a close contact between negative and positive spin density zones.

The orbital energy diagram for low-spin Mo^{III} in pentagonal bipyramid symmetry (D_{5h}) is represented below.



At the self consistent field (SCF) approximation, the e'_2 ($x^2 - y^2$, xy) and a'_1 (z^2) orbitals with a predominant 4d character are empty. It follows that at this approximation level, there is no spin density along both equatorial and axial Mo–C–N directions. It is now well established that such a view is oversimplified. The $^2E''_1$ SCF ground state may couple with SCF excited states of the same symmetry in which electrons have been promoted from the doubly-occupied and bonding e'_2 and a'_1 orbitals with a predominant cyano character to the empty and antibonding e'_2 and a'_1 orbitals with a predominant metal character. This configuration interaction gives rise to a negative spin density in the σ orbitals of the cyano ligands, along the Mo–C–N directions. This spin polarization effect has been experimentally observed in the hexacyanometallates involving 3d ions, such as $[Cr(CN)_6]^{3-}$ and $[Fe(CN)_6]^{3-}$, from polarized neutron diffraction experiments.[51,52]

The crucial point is that the stronger (*i.e.* the more covalent) the M–(CN) bond is, the more pronounced the spin polarization. Owing to the diffuseness of the 4d orbitals as compared to the 3d orbitals, the Mo^{III}–(CN) bond is significantly stronger than the Cr^{III}–(CN) or Fe^{III}–(CN) bond. It follows that the negative spin density along the Mo–C–N directions of the $Mo(CN)_7$ fragment might be particularly important. If it was so, the interaction between this negative spin density with a σ character and the σ singly occupied orbitals of Mn^{II} might favor the parallel alignment of the S_{Mo} and S_{Mn} spins.

If the interpretation above was correct, this would mean that the Mo^{III}–C–N–M interaction should be ferromagnetic for all M ions with unpaired electrons in σ (*i.e.* e_g in the case where M is in an octahedral environment) orbitals. All the data available so far confirm this idea.

What is the origin of the anisotropy?

Let us list the various factors affording magnetic anisotropy. We begin with the two local factors: the anisotropy of the ***g*** tensors and the zero-field splitting of the local spin states for the magnetic ions with a local spin higher than 1/2. In addition, there are several many-body (or collective) factors. These are: (i) the anisotropic interactions, resulting from the synergistic effect of the local spin–orbit coupling for an ion and the interaction between the excited states of this ion and the ground state of the adjacent ion; (ii) the antisymmetric interaction whose origin is similar to that of the anisotropic interaction, but in addition requires a low lattice symmetry; (iii) the dipolar interactions which may become important for lattices of low symmetry, and/or for high local spins (for instance $S_{Mn} = 5/2$); (iv) the shape anisotropy, finally, depending on the shape and size of the single crystals or particles utilized for the magnetic measurements.[38,53] Applying an external field H along the easy magnetization axis results in an internal field H_i related to H through:

$$H_i = H - NM$$

where N is the demagnetizing factor depending on the shape anisotropy, and NM the demagnetizing field. The field dependences of M shown in Fig. 6 are not corrected for the demagnetizing field.

Except when all the local spins are 1/2, the local zero-field splittings are usually more important than the anisotropic interactions. As for the antisymmetric interaction, it leads to spin canting, which may superimpose to both a ferromagnetic or an antiferromagnetic state. In this latter case, it gives rise to the phenomenon of weak ferromagnetism.[31]

What are the relevant factors in the case of the compounds described in this article? Mn^{II} in octahedral surroundings has a $^6A_1$ ground state, with a very weak zero-field splting. On the other hand, the ***g*** tensor for the $[Mo^{III}(CN)_7]$ chromophore is expected to be strongly anisotropic.[34] In other respects, the lattice symmetries are very low, even for the three-dimensional compounds. It follows that the two main anisotropy factors are the anisotropy of the ***g*** tensor for the $[Mo^{III}(CN)_7]$ chromophore along with the dipolar interactions. The spin reorientation might be due to a competition between these two factors. In zero (or low) external field, the ferromagnetically coupled local spins tend to align along the direction of the Mo–C–N–Mn–C–N

infinite linkages (for instance, the *b* axis for $Mn_2(H_2O)_5$-$Mo(CN)_7{\cdot}4H_2O$, α phase), which minimizes the dipolar energy. When the magnetic field reaches a certain value, the ***g*** anisotropy for Mo^{III} favors the spin alignment along another direction.

Conclusion

One of the peculiarities of molecular chemistry as compared to high-temperature solid state chemistry is that it usually affords species of low symmetry. In the field of molecule-based magnets, this low symmetry may lead to very interesting physical phenomena. Of course, the thorough investigation of these phenomena and their correct interpretation requires work on single crystals, which is time consuming and sometimes not trivial. However, accepting to do so may be very rewarding. To the best of our knowledge, the spin reorientation phenomenon had only been found so far for ferromagnetic intermetallic compounds, and not for insulating ferromagnets. In other respects, the magnetic phase diagrams of Fig. 7 and 11 are the very first for magnetic materials synthesized from molecular precursors.

The field of molecule-based magnets has many fascinating issues, such as strong coercivity, high critical temperature, processability, and photomagnetic effects.[54] The characterization of new phenomena arising from structural and magnetic anisotropies may be also considered as one of these issues.

Paper 9/00180H

Synthesis and reactivity of the osmium methylidene complex $[(C_5Me_5)Os(=CH_2)(dppm)][OTf]$

Julia L. Brumaghim and Gregory S. Girolami*

School of Chemical Sciences, University of Illinois at Urbana-Champaign, 600 South Mathews Avenue, Urbana, Illinois 61801. E-mail: girolami@scs.uiuc.edu

Received (in Bloomington, IN, USA) 26th February 1999, Accepted 12th April 1999

Treatment of the hydride complex $(C_5Me_5)Os(dppm)H$, [dppm = bis(diphenylphosphino)methane] with 2 equivalents of methyl trifluoromethanesulfonate (MeOTf) affords the methylidene complex $[(C_5Me_5)Os(=CH_2)(dppm)][OTf]$; the molecular structure and dynamic NMR behavior of this methylidene complex are described.

Transition metal alkylidenes have been of interest for the last 20 years owing to their role as intermediates in olefin metathesis[1–7] and Fischer–Tropsch[8] reactions. In most cases, the alkylidene ligand is substituted; in contrast, there are relatively few examples of the simplest alkylidene, a terminal methylidene ($=CH_2$) ligand. In 1975, Schrock described the first such complex, $Cp_2Ta(=CH_2)(CH_3)$,[9] and the number of complexes containing a terminal methylidene ligand has slowly grown since.[1,10–19]

Most terminal methylidene complexes have been synthesized by one of two routes: by abstraction of a hydride from a methyl group, or by abstraction of a proton from a cationic methyl compound.[13] We now describe the synthesis of an osmium methylidene complex from the reaction of an osmium hydride with methyl trifluoromethanesulfonate (MeOTf).

Treatment of $(C_5Me_5)Os(dppm)H$[20] with 2 equivalents of MeOTf in pentane at room temperature for 18 h affords a yellow powder, which has been identified as the new methylidene compound $[(C_5Me_5)Os(=CH_2)(dppm)][OTf]$ **1**.† The ^1H NMR spectrum of **1** at −30 °C shows that the two hydrogen atoms of the methylidene ligand are inequivalent. In the ^{13}C NMR spectrum of **1**, the methylidene carbon gives rise to a triplet at δ 261.9 (J_{CH} 144 Hz). The inequivalence of the hydrogen atoms is a result of the preferred orientation of the methylidene ligand, which places one hydrogen atom proximal to, and the other distal from, the C_5Me_5 ligand. The same orientation is seen for the methylidene ligands in other $[(C_5R_5)M(=CH_2)L_2]^{n+}$ complexes.[15,17,18]

As the temperature is raised, the methylidene signals in the ^1H NMR spectrum broaden and finally coalesce at 60 °C as rotation of the methylidene ligand around the Os=C bond becomes fast on the NMR time scale. The variable-temperature ^1H NMR line shapes and the simulations of the spectra are shown in Fig. 1. An Eyring plot showed that the activation parameters for rotation of the methylidene ligand in **1** are $\Delta H^{\ddagger}$ = 16.4 ± 0.5 kcal mol^{-1} and $\Delta S^{\ddagger}$ = 5.7 ± 1.5 cal mol^{-1} K^{-1}; the free energy of activation is 14.7 ± 0.5 kcal mol^{-1} at 25 °C.

The rotation barrier is a measure of how much the π bonding is weakened upon rotating the methylidene ligand by 90° about the M=C axis. Somewhat surprisingly, the activation entropies and enthalpies of rotation have never been measured for any terminal methylidene complex.[15,17,18] For four molecules, however the free energies of activation have been reported: 8.3 ± 0.1 kcal mol^{-1} at −85 °C for $[(C_5Me_5)W(=CH_2)(PPh_3)(CO)_2][AsF_6]$,[15] 9.0 ± 0.1 kcal mol^{-1} at −70 °C for $[(C_5Me_5)W(=CH_2)(PEt_3)(CO)_2][AsF_6]$,[15] 10.7 ± 0.2 kcal mol^{-1} at −28 °C for $[(C_5Me_5)Fe(=CH_2)(dppe)][BF_4]$,[18] and ≥ 19 kcal mol^{-1} at 114 °C for $[(C_5Me_5)Re(=CH_2)(NO)(PPh_3)][PF_6]$.[17]

An X-ray crystallographic study‡ of **1** revealed that the Os–C distance for the methylidene ligand is 1.926(9) Å (Fig. 2). This value is comparable to the M=C bond distances seen for other late transition metal methylidene complexes: 1.87(1) Å in $Ir(=CH_2)[N(SiMe_2CH_2PPh_2)_2]$,[11] 1.90(2) Å in $[(C_5Me_5)Re(=CH_2)(NO)\{P(OPh)_3\}]^+$,[17] and 1.92(1) Å in $Os(=CH_2)(PPh_3)(NO)Cl$.[14]

Like other cationic methylidene complexes,[14] the methylidene complex **1** is susceptible to attack by nucleophiles. Thus, treatment of **1** with $LiBH_4$ yields the corresponding methyl complex, $(C_5Me_5)Os(dppm)CH_3$.§

At least two mechanisms could account for the formation of **1** upon treatment of $(C_5Me_5)Os(dppm)H$ with MeOTf. In one mechanism [eqn. (1)], an osmium methyl/hydride intermediate is generated initially, and dihydrogen is lost to form **1**.

$$L_nOs{-}H \xrightarrow{CH_3^+} L_nOs^{+}(H)(CH_3) \xrightarrow{-H_2} L_nOs{=}CH_2^+ \quad (1)$$

In another mechanism [eqn. (2)], the osmium methyl/hydride intermediate undergoes reductive elimination of methane;

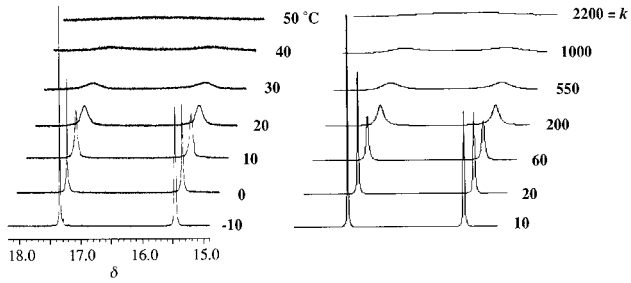

Fig. 1 Variable temperature 500 MHz ^1H NMR line shape for the methylidene protons in **1** (thf-d_8, left) and simulated spectra (right). Rate constants are given in s^{-1}.

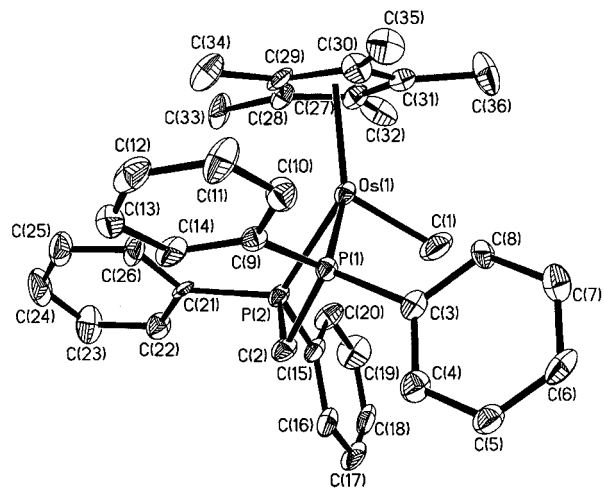

Fig. 2 Crystal structure of $[(C_5Me_5)Os(=CH_2)(dppm)][OTf]$, molecule 1; 35% probability density surfaces are shown. The hydrogen atoms and triflate anion are omitted for clarity.

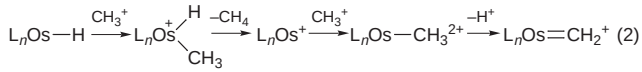
attack by a second equivalent of MeOTf followed by loss of a proton affords **1**.



In both of these mechanisms, the first step is formation of an osmium methyl/hydride cation. This step has precedence in our study of the analogous $(C_5Me_5)Os(dmpm)H$ system [dmpm = bis(dimethylphosphino)methane].[21] The mechanism responsible for the formation of **1** was determined by following the reaction of $(C_5Me_5)Os(dppm)H$ with MeOTf in a sealed NMR tube. As judged by ^1H NMR spectroscopy, no dihydrogen is generated, but a peak attributable to methane (δ 0.11) grows in during the course of the reaction. On a preparatory scale, if $(C_5Me_5)Os(dppm)H$ and MeOTf are allowed to react for only 1 h in pentane, the triflate complex $(C_5Me_5)Os(dppm)OTf$ can be isolated.¶ Subsequent treatment of isolated samples of $(C_5Me_5)Os(dppm)OTf$ with additional MeOTf affords **1** in high yield. These results suggest that **1** is generated by the second of the two mechanisms shown above.

Further studies of these new osmium complexes are in progress.

We thank the Department of Energy (Grant DEFG02-96-ER45439) for support of this work, and the University of Illinois School of Chemical Sciences for a departmental fellowship to J. L. B. NMR spectra were collected on instruments in the Varian Oxford Instrument Center for Excellence at the University of Illinois at Urbana-Champaign; external funding for this instrumentation was obtained from the Keck Foundation, NIH, and NSF.

Communication 9/01644I

Selective synthesis of monohydrosilanes by the reactions of organoytterbium iodides with dihydrosilanes

Wu-Song Jin, Yoshikazu Makioka, Tsugio Kitamura and Yuzo Fujiwara*

Department of Chemistry and Biochemistry, Graduate School of Engineering, Kyushu University, 6-10-1 Hakozaki, Higashiku, Fukuoka 812-8581, Japan. E-mail: yfujitcf@mbox.nc.kyushu-u.ac.jp

Received (in Cambridge, UK) 22nd February 1999, Accepted 12th April 1999

Monohydrosilanes can be prepared selectively in high yields from the reaction of various aryl and alkyl iodides with ytterbium metal followed by the reaction with dihydrosilanes.

Recently, lanthanoid complexes with the pentamethylcyclopentadienyl ligand and its analogues have been reported to catalyze the hydrosilylation reactions of alkenes and alkynes, as well as cyclization/silylation and polymerization of silanes.[1,2] Marks and coworkers and others reported that the reactions of $Cp^*_2LnCH(SiMe_3)_2$ (Cp^* = C_5Me_5, Ln = La, Nd, Sm) with $PhSiH_3$ gave $CH_2(SiMe_3)_2$, while $Cp^*_2YMe(THF)$ converted $PhSiH_3$ to $PhMeSiH_2$.[2] However, applications of lanthanoid complexes to direct alkylation or arylation of silanes are still limited. Evans *et al.* reported the synthesis of divalent organolanthanoid σ-complexes (RLnI) from organic iodides and lanthanoid metals in THF.[3] We have explored the chemistry of RLnI and found some unique reactivity toward various electrophiles.[4] In our continuing study on the organolanthanoid chemistry, we have found that the monohydrosilanes can be prepared selectively from the reaction of excess divalent organoytterbium σ-complexes (RYbI) with dihydrosilanes [eqn. (1)]. Here, we report these results.

$$\mathrm{RI} + \mathrm{Yb} \xrightarrow[\mathrm{THF}]{} \mathrm{RYbI} \xrightarrow{\mathrm{R'R''SiH_2}} \mathrm{R'R''RSiH} \qquad (1)$$

First, we studied the reaction of various arylytterbium σ-complexes (ArYbI) with dihydrosilanes [eqn. (2)] and results are summarized in Table 1.

As shown in entry 1 in Table 1, when the reaction was carried out using an equimolar amount of iodobenzene **1a**, Yb metal and $MePhSiH_2$ **2a**, the monosilane **3a** was formed only in 64% yield. However, when the ratio of **1a** and Yb to **2a** was doubled, **3a** was obtained quantitatively (entry 2). Most of the substrates **1a**–**g** and **1i**–**m** (entries 2–15 and 17–26) reacted smoothly with ytterbium metal to produce arylytterbium iodides, and successive treatment with dihydrosilanes gave selectively monohydrosilanes **3a**–**g**, **3a′**–**g′** and **3i**–**m′** in high yields. For *o*-chloroiodobenzene **1h** (entry 16), many by-products were formed, and the isolation of the desired product **3h** was unsuccessful. Under the present conditions, arylytterbium iodides displayed high reactivity toward not only methylphenylsilane but also diphenylsilane. In addition, dimers of silanes were not formed in this reaction.[5]

On the other hand, different results were obtained in the reaction of aliphatic iodides [eqn. (3)] as shown in Table 2. Primary alkyl iodides such as 1-iodoethane, 1-iodoheptane and isobutyl iodides (**1n**–**p**) proceeded smoothly to afford monohydrosilanes **3n**–**p** in high yields (entries 15–17). By contrast, for bulky **1q**, the yield of **3q** was low (entry 4). In the reactions of secondary and tertiary iodides **1r**–**t**, the reaction proceeded slowly to give small amounts of the monosilanes **3r**–**t**. These results indicate that steric factors of the substrates plays an important role in the reaction. It seems curious that no reaction occurs with α-methoxy-substituted **1u** although Yb metal reacts with **1u** to form $(MeOCH_2)YbI$ (entry 8).

In similar reactions of Grignard reagents and organolithiums, the former give monosubstituted silanes in low yields even

under refluxing conditions,[6] while the latter afford tetra-substituted silanes rather than monosubstituted silanes.[7] By contrast, the present reaction of organoytterbium iodides with dihydrosilanes proceeds smoothly under mild conditions and gives monosubstituted silanes exclusively. Thus this reaction should be a useful method for the synthesis of mono-hydrosilanes.

In conclusion, we have demonstrated that monohydrosilanes can be prepared selectively and conveniently from the reaction of dihydrosilanes with excess divalent organoytterbium σ-complexes under mild conditions.

Notes and references

† *Typical reaction procedure*: Yb metal (173 mg, 1.0 mmol) was placed in a 50 ml Schlenk tube. Then, THF (4.0 ml) and *p*-iodoanisole (234 mg, 1.0 mmol) were successively added at 0 °C under argon and the mixture stirred for 30 min at this temperature to give a red–brown solution of the ArYbI complex. Then, methylphenylsilane (61 mg, 0.5 mmol) was added. The mixture was then heated to room temperature and stirred for 4 h. Usual workup followed by a silica gel column chromatography (*n*-hexane–benzene) gave *p*-anisylmethylphenylsilane **3d** in 79% (90 mg) yield. The GC yields were determined using *n*-tetradecane, *n*-nonadecane and *n*-eicosane for aromatic iodides, 1-iodonaphthalene and aliphatic ioidides, respectively, as an internal standard. Yields are based on dihydrosilanes.

Transparent colloidal solution of 2 nm ceria particles

Masashi Inoue,* Minoru Kimura and Tomoyuki Inui

Department of Energy and Hydrocarbon Chemistry, Graduate School of Engineering, Kyoto University, Yoshida, Kyoto 606-8501 Japan. E-mail: inoue@scl.kyoto-u.ac.jp

Received (in Cambridge, UK) 3rd February 1999, Accepted 20th April 1999

The reaction of cerium metal in 2-methoxyethanol at 200–250 °C yielded a transparent colloidal solution of ultrafine (2 nm size) ceria particles.

Hydrothermal oxidation of metals has been widely examined as a synthesis route for inorganic materials and various compounds having specific properties have been prepared.[1,2] Although it is known that some metals corrode in alcohols, oxidation of metals in alcohols has never been examined from the viewpoint of material synthesis until our recent report that the reaction of aluminium metal in alcohols at 250–300 °C yielded alkoxyalumoxanes.[3] As an extension, we applied this method to cerium metal and found that a transparent colloidal solution of ultrafine ceria particles was directly obtained by the reaction of cerium metal in 2-methoxyethanol at 200–300 °C.

Cerium metal chips [*ca.* 2.40 g; 0.2 mm × 3.5 mm × (3–5) mm] and 2-methoxyethanol (85 mL) were placed in a test tube, which was then set in an autoclave (200 mL). An additional 20 mL of 2-methoxyethanol was placed in the gap between the test tube and the autoclave wall. The autoclave was completely purged with nitrogen and heated to 250 °C at a rate of 2.3 °C min^{-1} and kept at that temperature for 2 h. After the assembly was cooled, the product mixture was centrifuged and yellow precipitates and a dark brown transparent solution were obtained. The XRD pattern of the precipitates showed characteristic peaks of ceria, and the crystallite size of the precipitates, calculated by the X-ray diffraction (XRD) line broadening technique, was > 100 nm. The precipitates are postulated to derive from the ceria surface layer of the cerium metal chips, because the properties of the precipitates were not altered by the reaction conditions.

Addition of distilled water to the transparent solution obtained as the supernatant after centrifugation of the product did not lead to any change except for dilution of the color of the solution. When the solution was kept standing for several weeks with gradual evaporation of the solvent, gelation took place liberating a small amount of a colorless supernatant, and the gel gradually shrank while remaining transparent. On the other hand, when the solution was kept in a closed bottle, it was stable for at least several months. Addition of salt solutions such as aqueous NaCl to the transparent solution immediately caused the formation of gelatinous precipitates.

Transmission electron microscopic observation of a specimen prepared by dipping a microgrid into the diluted solution followed by drying in air revealed that ultrafine particles of size 1.5–2 nm formed a thin film on the microgrid, which is believed to arise from agglomeration at the drying stage owing to the large surface energy of the particles. Electron diffraction of the film gave diffuse 111, 200, 220, 311 Debye–Scherrer rings of cubic ceria with the fluorite structure.[4] These results indicate that the dark brown transparent solution is a colloidal solution of ultrafine particles of ceria.

The colloidal particles were coagulated by addition of methanol and aqueous NH_3 to the colloidal solution. The use of NaCl solution was avoided because of possible effects of the remaining salt on the properties of the particles. The precipitates were separated from a slightly turbid supernatant by centrifugation, washed with methanol, and then air-dried. The yellow powder obtained exhibited fairly broad XRD peaks (Fig. 1);

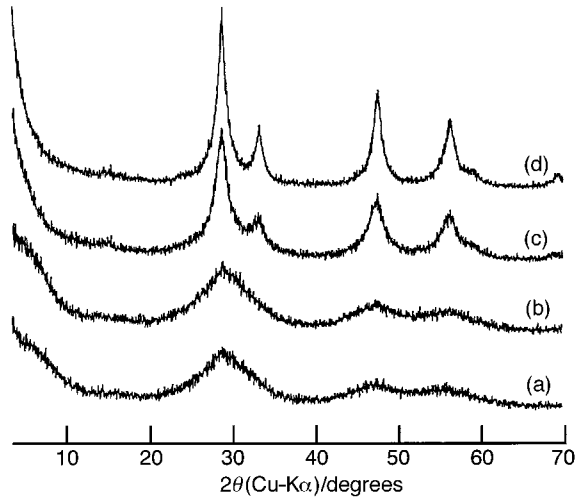

Fig. 1 XRD patterns of the powders collected from the colloidal solutions prepared by the reaction of cerium metal in 2-methoxyethanol at: (a) 200, (b) 250, (c) 280 and (d) 300 °C.

however, the peak positions were identical to the three strongest lines for cubic ceria. The crystallite size of the powder was calculated to be *ca.* 2 nm, which was essentially identical with the particle size observed by TEM, suggesting that each particle observed by TEM is a single crystal of ceria.

Various methods have been reported for the synthesis of ultrafine ceria particles.[5–13] However, as far as we are aware, the smallest particle size of ceria prepared so far is 2.6 nm, prepared by Masui *et al.*[12] using reversed micelles. Note that the reduction of particle size from 2.6 to 2 nm corresponds to the reduction of number of cerium atoms in a particle by a half and

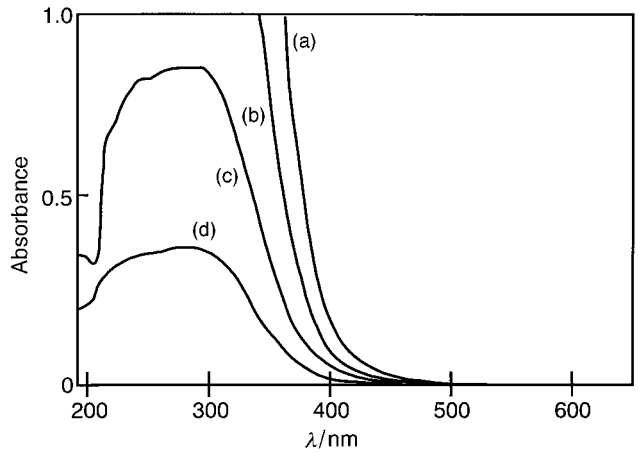

Fig. 2 Electronic spectra of the colloidal solution of ultrafine ceria particles. The original colloidal solution was obtained by the reaction of cerium metal in 2-methoxyethanol at 250 °C for 2 h, and the solution was diluted with 2-methoxyethanol to a concentration of (a) 0.172, (b) 0.086, (c) 0.043 and (d) 0.017 g L^{-1}.

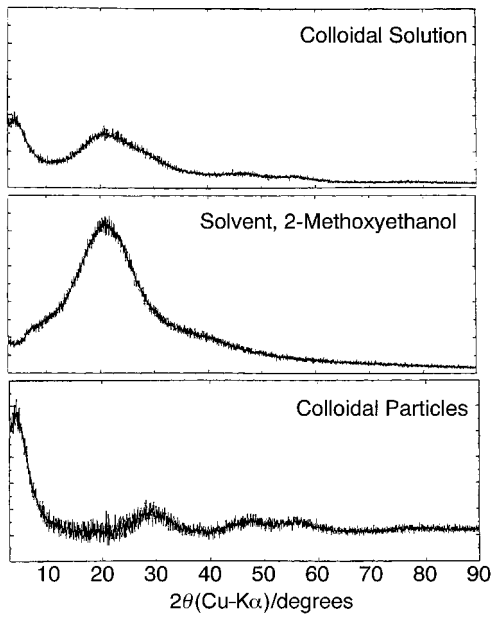

Fig. 3 XRD pattern of the ceria colloidal particles in the transparent solution (bottom) calculated by subtraction of the XRD pattern of the solvent, 2-methoxyethanol, (middle) from that of the colloidal solution (top). The XRD patterns were recorded on a Rigaku Rint-Ultima$^+$ diffractometer equipped with a θ–θ goniometer.

that a spherical ceria particle with a diameter of 2 nm contains only 100 cerium atoms.

The reaction proceeded at as low as 200 °C yielding a transparent solution, but the particle size of the ceria colloid was not decreased (Fig. 1). On the other hand, increase in the reaction temperature above 250 °C progressively increased the crystallite size of the ceria particles (8 nm by the reaction at 300 °C).

When the particles were calcined, the XRD peaks gradually sharpened, but no phases other than ceria were detected in the calcined samples. Crystal growth took place after calcination at 450 °C, *i.e.* at a much lower temperature than the lowest crystal growth temperature of 'reactive' 15.5 nm ceria powders prepared by the hydrazine method.[11]

Electronic spectra of the diluted colloidal solutions (Fig. 2) exhibited a strong absorption band at the UV region, whereas no absorption was detected above 500 nm. The observed absorbance followed Lambert–Beer's law, suggesting that the ultrafine ceria particles are well dispersed with no evidence for agglomeration under the concentrations of the UV measurement. The bandgap energies, E_i and E_d, for the ceria particles were calculated from these spectra to be 2.90 and 3.52 eV (1 eV $= 1.602 \times 10^{-19}$ J), respectively. These values were larger than those reported for the 2.6 nm ceria particles,[12] owing to the quantum size effect, although slightly larger values have been reported for ceria films.[14–16]

To ensure that the ultrafine ceria particles were not originated by any stages of the work-up process, XRD of the colloidal solutions was examined (Fig. 3). The XRD patterns of the colloidal particles, calculated by subtracting the XRD pattern of the solvent, 2-methoxyethanol, from that of the colloidal solutions, coincided with those for the particles obtained after coagulation. Therefore, it was concluded that the ultrafine ceria particles are actually present in the solution.

The present work was supported by a Grant-in-Aid for Scientific Research No. 09650922, from The Ministry of Education, Science, Sports and Culture, Japan. The authors also thank Dr T. Kubo of Osaka Application Laboratory, Rigaku Corporation for the XRD measurement of the colloidal solutions.

Pyridine-based dendritic wedges with a specific metal ion coordination site and their palladium(II) complexes

Gavino Chessa,* Alberto Scrivanti, Luciano Canovese, Fabiano Visentin and Paolo Uguagliati

Dipartimento di Chimica, Università di Venezia, Calle Larga S. Marta, 2137, Venezia, Italy. E-mail: chessa@unive.it

Received (in Cambridge, UK) 28th January 1999, Accepted 19th April 1999

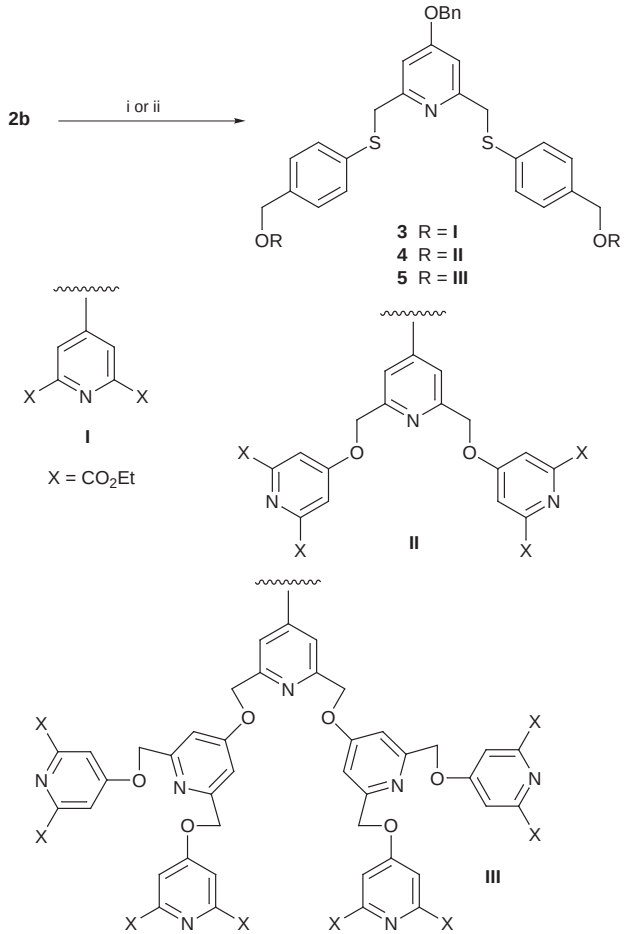
The 2,6-di(thiomethyl)pyridine sub-unit has been incorporated into pyridine-based dendritic structures providing a series of dendritic wedges, which readily form Pd^{II} complexes.

The incorporation of metal centres into a dendritic structure is a challenging idea aimed at generating materials with potentially useful features.[1–3] Numerous dendrimers, which contain coordination sites on the outer surface,[4] within the macrostructure throughout all layers,[5] and at the inner core[6] have been prepared. In contrast, except for scant coordination studies,[7] very little has been done about the construction of dendrimers with specific coordination centres within the dendritic wedges and their reaction with metal substrates. In particular, no report has yet appeared on the synthesis of dendrimers with a pyridine-based skeleton incorporating a specific coordination site for platinum-group metals.

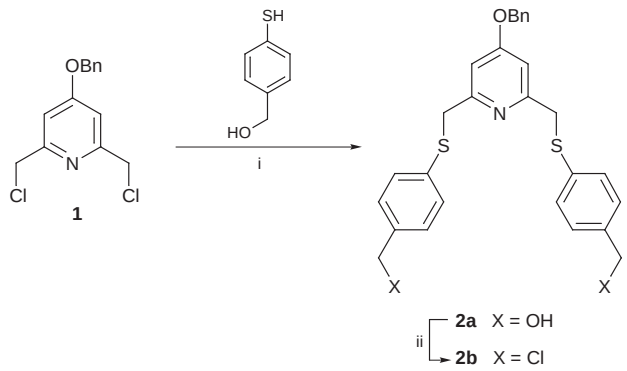
As a preliminary study of the assembly of such dendrimers we report herein the synthesis of the pyridine-based dendrons **3**–**5** containing the 2,6-di(thiomethyl)pyridine sub-unit, which has been shown to form very stable Pd^{II} complexes.[8] The complexation of Pd^{II} with **3**–**5** to give metallodendrons **6**–**8** is also reported on.

Our approach to the synthesis of the dendrons **3**-**5** is based on a convergent strategy which implies the preparation of the dendritic fragments **I**–**III** as 4-hydroxo species[9] followed by attachment to the metal binding site **2b.** The key building block **2b** (Scheme 1) was prepared by coupling 2,6-bis(chloromethyl)-4-benzyloxypyridine **1**[9] with 4-mercaptobenzyl alcohol[10] (DMF, K_2CO_3, 18-crown-6, 70 °C). This reaction occurred with preferential formation of the thioether bond, providing the hydroxymethyl derivative **2a**. Subsequent chlorination ($SOCl_2$, 50 °C) followed by attachment of the diester **I** to the resulting chloride **2b**, gave **3** in 92% yield after purification by column chromatography (SiO_2, CH_2Cl_2–2% MeOH) (Scheme 2). Similarly, the reactions of **2b** with tetraester **II** and octaester **III** yielded the dendrons **4** and **5** (Scheme 2) in 85 and 51% yield, respectively.

The dendrons obtained were fully characterised by IR and NMR techniques as well as by matrix assisted laser desorption ionization mass spectrometry (MALDI-MS; dithranol 10 mg cm^{-3} acetone matrix). The reaction of the dendritic fragment **3** with $Pd(PhCN)_2Cl_2$ in CH_2Cl_2 at 25 °C (1 : 1 Pd/**3** molar ratio) gave a stable orange microcrystalline Pd^{II} complex **6** in 76% yield (Fig. 1). Direct evidence of a successful complexation at



Scheme 2 *Reagents and conditions*: i, K_2CO_3, DMF, 70 °C, 24 h; ii, K_2CO_3, DMF, 60 °C, 48 h.



Scheme 1 *Reagents and conditions*: i, K_2CO_3, 18-crown-6, DMF, 70 °C, 24 h; ii, $SOCl_2$,50 °C, 4 h.

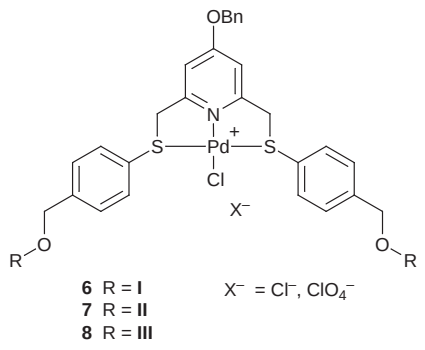


Fig. 1 Schematic representation of metallodendrons **6**–**8** (dendritic polypyridines of 0, 1, 2 generation).

the 2,6-di(thiomethyl)pyridine site is provided by the significant downfield shifts of the thiomethylene protons (1.2 ppm) and carbons (11.2 ppm) in the ^{1}H NMR and ^{13}C NMR spectra, respectively. The absence of the 3,5-pyridine protons peak at δ 6.87 further supports the complexation hypothesis. Moreover, the presence of the characteristic molecular peak at *m/z* 1074 ([**3**PdCl]$^+$) in the MALDI-TOF spectrum of **6** clearly indicates the formation of a 1:1 complex between Pd^{II} and **3**.

The complexation of Pd^{II} with the dendron **4** did not proceed smoothly under the same experimental conditions. The ^{1}H NMR spectrum of a $CDCl_3$ solution of complex **7**, isolated as its chloride salt, suggests the presence of an undesired product. A possible explanation for its formation is the competition of chloride ion as a nucleophile with other donor centres in the dendritic structure, namely the sulfur and nitrogen atoms of the 2,6-di(thiomethyl)pyridine sub-unit.[11] However, **7** was successfully purified by conversion into its yellow ClO_4^- salt, the ^{1}H NMR spectrum of which exhibits a pattern similar to those observed for **6**, furthermore the MALDI-TOF mass spectrum shows a parent ion at *m/z* 1792 coorresponding to [**4**PdCl]$^+$.

Extension of this finding to the reaction of **5** with Pd^{II} allowed us to obtain metallodendron **8**. As in the foregoing spectra, the resonances associated with the 2,6-di(thiomethyl)pyridine fragment are affected by complexation and lie at lower field than those of the uncoordinated domain. In particular, the CH_2S singlet, which is found at δ 4.21 in a uncoordinated ligand, shifts to δ 5.26 (br s) in a coordinated unit. Once again, the MALDI-TOF mass spectrum displaying the characteristic molecular peak at *m/z* 3225 ([**5**PdCl]$^+$) provides convincing evidence for the formulation of product **8**. Analytical data, ^{1}H, ^{13}C NMR and MALDI-TOF spectra of all species prepared are fully consistent with the proposed structures. In particular, for complex **8** the synthetic approach (1 : 1 Pd/**5** molar ratio and the ensuing 78% yield) and the presence of one single signal for the carboxylate ethyl protons (X = CO_2Et) strongly support the formulation of Fig. 1.

These results indicate that the presence of the 2,6-di(thiomethyl)pyridine sub-unit in dendritic wedges is particularly attractive for developing dendrimers with specifically localised metal centres. The physical properties of the metallodendrons **6**–**8** are now under extensive investigations. Of particular interest are the selectivity towards other transition metals and the influence of dendrimer framework on the metal-binding process.

We thank the MURST (Ministero per l' Università e la Ricerca Scientifica e Tecnologica) for financial support, Dr R. Seraglia (C.N.R. of Padova) for mass spectra, and Mrs L. Gemelli for technical assistance.

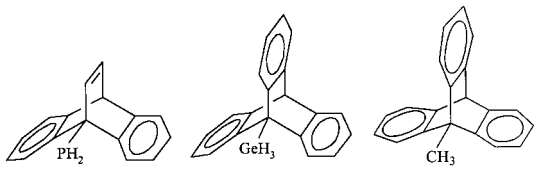
Received (in Basel, Switzerland) 9th February 1999, Accepted 13th April 1999

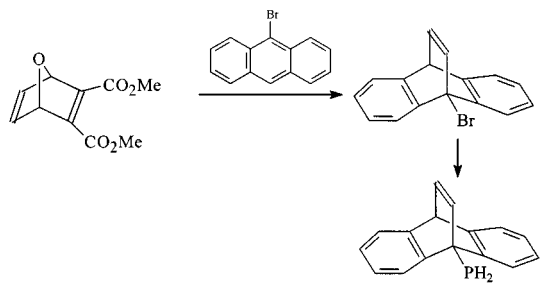
The syntheses of dibenzobarellenephosphine and tribenzobarellenegermane are described; at room temperature these primary phosphines and germanes form air-stable crystals whose structures are reported together with that of tribenzobarellenemethane.

Primary phosphines are generally air-sensitive liquid compounds. Most of the reported crystal structures with an RPH_2 moiety have therefore been determined on molecules where the phosphorus atom is coordinated to a metal atom.[1] The crystal structure of free primary phosphines could be obtained in only a very limited number of cases: (1) when the phosphorus atom is bound to a cumbersome protective aryl group ($Bu^t_3C_6H_2$),[2] to an iron dicyclopentadienyl group[3] or to a triptycyl moiety;[4] (2) after dimerisation of anthracenephosphine;[5] (3) after N-quaternisation of aminoalkylphosphines.[6] Recent results[7] indicated that benzo derivatives of barrelene were likely to lead to stable crystalline RPH_2 compounds; we have therefore taken advantage of this to attempt the synthesis of a primary phosphine which contains a double bond in the vicinity of the phosphorus atom. We report below the synthesis and the structure of the remarkably air-stable primary phosphine **1**. The synthesis of dibenzobarellenephosphine† is shown in Scheme 1.



1 **2** **3**

In the solid state the dibenzobarellenephosphine **1**‡ is located on a mirror plane perpendicular to the *b* axis with P1, C7, C8, C9, C10, H8, H9 and H10 in special positions 4c. All hydrogen atoms have been observed and refined without constraint. No significant electronic density corresponding to a hydrogen site located in the *trans* position relative to the C7–C8 bond was observed, meaning that only one rotamer is present and that no free rotation of the phosphine around the C–P bond occurs at 180 K. The dihedral angle between the mean planes of the phenyl moieties is 113.8° (angle between the central ethylene bridge and a phenyl moiety = 123.1°).



Scheme 1

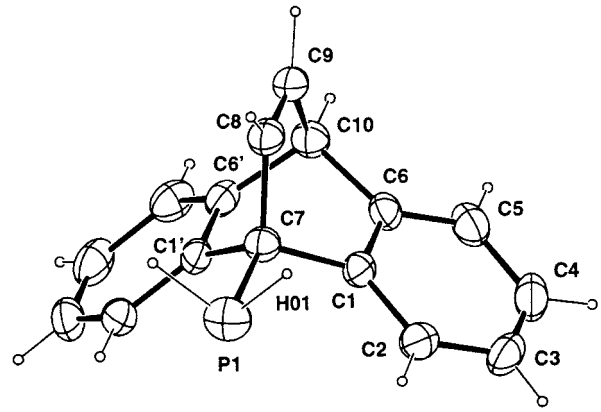


Fig. 1 Perspective view of **1**. Ellipsoids are represented with 40% probability. Selected bond distances (Å) and angles (°): P1–C7 1.859(4); C1–C6 1.402(4); C1–C7 1.536(4); C6–C10 1.522(4); C7–C8 1.539(6); C8–C9 1.314(7); C9–C10 1.520(6); P–H01 1.36(3); C1–C7–C8 105.5(2); C1–C7–C1′ 103.3(3); C1–C7–P1 113.2(2); C7–C8–C9 115.2(4); C8–C9–C10 114.1(4); C6–C10–C6′ 104.5(3); C6–C10–C9 106.1(2); H01–P–H01′ 93(2).

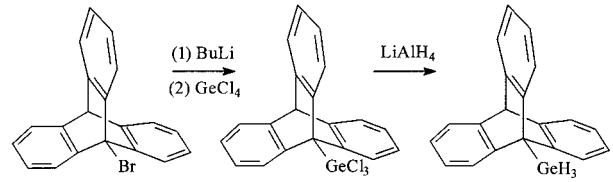
In the context of this study, we envisaged using benzobarellene derivatives to form a crystalline primary germane. Although less reactive than their silicon homologues, primary germanes are generally air-sensitive liquid (or gaseous) compounds at room temperature. As far as we know, the only crystal structure reported for $RGeH_3$ was obtained at 160 K on cyclopentadienyl germane, which melts at 200 K.[8] We report below the synthesis† (Scheme 2) and the crystal structure‡ of tribenzobarrelenegermane **2** which forms air-stable crystals with a melting point of 232 °C.

This compound is isostructural with tribenzobarellenemethane **3**,[9] whose structure,‡ to the best of our knowledge, has never been published. Both **2** and **3** show disordered structures. The molecules are located on 3-fold axes with C1, C8, Ge (resp. C9) and H8 atoms in special positions 6c of the space group $R\bar{3}$. The disorder consists of an inversion of the molecule approximately maintaining the position of the tribenzobarrelene skeleton and mainly affecting the germanium (resp. C9) atom. The refinement of such models fixing the sum of the occupations of the Ge (resp. C9) sites to 1 shows disorder ratios of 60.0(4)/40.0(4)% and 61.5(7)/38.5(7)% for **2** and **3** respectively. The relatively high values of the *R* factors and uncertainties obtained for **2** show that this compound is more affected than **3** by the disorder. Indeed, in the crystal packing,



Scheme 2

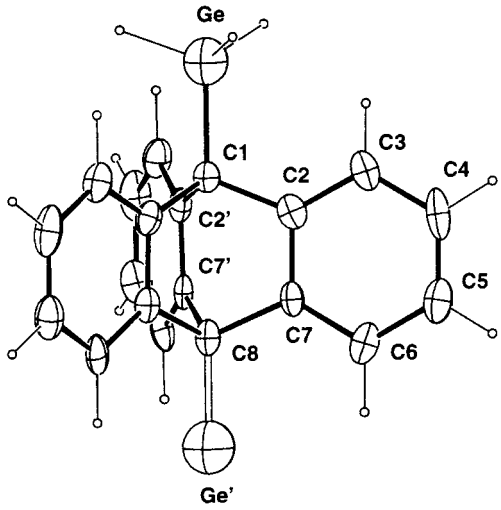


Fig. 2 Perspective view of **2**. Ellipsoids are represented with 40% probability. Selected bond distances (Å) and angles (°): C1–Ge 1.861(8); C1–Ge′ 1.77(1); Cl–C2 1.513(8); C7–C8 1.541(5); C2–C1–Ge 111.8(3); C7–C8–Ge′ 114.0(3); C2–C1–C2′ 107.1(5); C7–C8–C7′ 104.6(5) [for the isostructural **3** (Ge⇔C9): C1–C2 1.529(2); C1–C9 1.546(5); C1–C9′ 1.546(6), C7–C8 1.524(2); C2–C1–C2′ 105.0(1); C2–C1–C9 113.62(9); C7–C8–C9′ 113.07(8); C7–C8–C7′ 105.6(1)].

the shortest distances between two disordered sites of the Ge (resp. C9) atoms located along *c* axis (on both sides of a centre of inversion) are 1.557(7) and 2.065(8) Å for **2** and **3** respectively. It should be noted that a refinement of **2** in the noncentrosymmetric space group *R*3 leads to a final value of the Flack parameter[10] of $x = 0.47(28)$, large values of Δ/σ, non-positive values of $\|U_{ij}\|$ and a value of *R* of about 13%. These observations lead us to exclude the presence of a non-centrosymmetric, twinned and disordered structure as observed for the analogous tribenzobarrelenephosphine compound.[4]

EPR experiments on the dynamics of radicals produced from **1** and **2** are currently in progress.

We thank the Swiss National Science Foundation for financial support.

† *Syntheses*: All experiments were performed under dry N_2.

Bromodibenzobarellene was synthesized following a slight modification of the method reported by Mori *et al.* (ref. 11): 3.57 g (14 mmol) of 9-bromoanthracene and 3.48 g (17 mmol) of the furan–acetylene adduct in 20 ml of triglyme were sealed in a glass tube and placed in an autoclave. Very vigorous stirring was applied and the mixture was heated at 120 °C for 48 h and then at 200 °C for 24 h. The oily brown solution was washed with water (3 × 30 ml) to remove the solvent. After the usual work-up bromodibenzobarellene was separated by chromatography on silica gel using hexane–Et_2O (10 : 1) as eluant. The yellow powder was recrystallised from CH_2Cl_2–EtOH (68%): transparent crystals, mp 105 °C; δ_H($CDCl_3$, 200 MHz) 5.13 (dd, 1H), 7.05 (m, 6H), 7.26 (d, 2H), 7.71 (d, 2H); *m/z* (M^+), 282, 256, 203, 176, 150, 101, 75.

Dibenzobarellenephosphine: 4.9 ml of BuLi (1.6 M, hexane) were very slowly introduced, at −80 °C, into a solution containing 2 g (7.1 mmol) of bromodibenzobarellene dissolved in 30 ml of dry THF. After 10 min the temperature was slowly raised up to −60 °C. Then the solution was quickly cooled to −100 °C and 1.1 ml of PCl_3 (12.5 mmol) was added all at once; the solution was vigorously stirred for 30 min and gently refluxed for 1 h. The solution was then cooled in an ice bath and 0.53 g (14 mmol) of $LiAlH_4$ were carefully added. After refluxing for 2 h, the reaction was quenched with a few drops of HCl/H_2O and the residual phosphine was extracted with Et_2O (3 × 30 ml). The final product was purified by chromatography on silica gel using hexane–Et_2O (9 : 1) as eluant. Small, thin crystals were obtained directly from this solution (42%): mp 108 °C; δ_P($CDCl_3$, 80 MHz) 143.6 (t, J_{PH} 199); δ_H($CDCl_3$, 200 MHz) 3.55 (d, J_{PH} 200, 1H, PH), 5.13 (dd, 2H), 6.76 (ddd, 1H), 7.05 (m, 6H), 7.32 (m, 2H), 7.50 (m, 2H).

Tribenzobarellenegermane: 2 g (6.0 mmol) of bromotriptycene were dissolved in 30 ml of dry THF. Then 4.1 ml of BuLi (1.6 M hexane) were introduced very slowly into the solution during a few minutes at −78 °C. After 10 min the temperature was slowly raised up to 0 °C and then cooled quickly to −80 °C. 1.93 g of $GeCl_4$ (9.0 mmol) was added all at once and the solution was vigorously stirred. After 30 min a gentle reflux was applied during 1.5 h. The solution was cooled in an ice bath and 0.4 g (10.6 mmol) of $LiAlH_4$ was carefully added. After refluxing for 2 h the reaction was quenched with a few drops of HCl/H_2O and the residual germane was extracted with Et_2O (3 × 30 ml). The final product was purified *via* silica gel chromatography using hexane–Et_2O (9 : 1) as eluant. Small transparent crystals were obtained directly from this solution (35%), mp 232 °C; δ_H($CDCl_3$, 200 MHz) 2.37 (s, 3H), 4.44 (s, 1H), 6.96–7.04 (m, 6H), 7.33–7.42 (m, 6H); *m/z* 330 (M^+), 253, 226, 176, 126.

Communication 9/01083A

A Lewis acid dependent asymmetric Diels–Alder process in the cyclization of new chiral acrylamides with dienes

Doo Han Park, Sung Han Kim, Sam Min Kim, Jin Dong Kim and Yong Hae Kim*

Department of Chemistry, Korea Advanced Institute of Science & Technology, Taejon, 305-701, Korea. E-mail: kimyh@sorak.kaist.ac.kr

Received (in Cambridge, UK) 30th March 1999, Accepted 20th April 1999

Diels–Alder cycloadditions of chiral acrylamides with cyclopentadiene proceed with high diastereofacial selectivity, giving either *endo-R* to *endo-S* products depending of the Lewis acid used.

Lewis acid catalyzed addition of dienes to chiral acrylamides is a useful reaction because it provides one of the most effective methods for creating new chiral centers during the formation of six-membered rings.[1] Various types of chiral dienophiles such as chiral esters,[1] *N*-acyloxazole derivatives,[2] *N*-acylsultams,[3] acrylates[4] and acrylamides[5] have been developed. Metal coordination is important for diastereofacial selectivity in the asymmetric synthesis. Lewis acids have been used for chelate formation in Diels–Alder cyclizations to obtain high diastereofacial selectivities.[1–5] In general, the *S* form of the chiral dienophile (auxiliary) exclusively afford the *endo-R* adduct over the *endo-S* one, and the *R* form exclusively gives the *S* adduct over the *endo-R* one. Issues associated with this absolute stereochemical control depending upon Lewis acids and the structures of dienophiles provide an important challenge in the area of practical Diels–Alder reaction designs.[4a,5b]

In the hope of obtaining the opposite configuration of the *endo* adduct and understanding the mechanism, three different dienophiles **1**, **2** and **3** were prepared and reacted with dienes in the presence of various Lewis acids. Here we describe the intriguing results obtained during development of Lewis acid dependent stereocontrol toward both *endo-R* and *endo-S* configuration with high diastereofacial selectivity. In order to generalize the results, the requisite dienophiles **1**–**3** were synthesized from (*S*)-indoline-2-carboxylic acid.[6] They were purified and their optical purities (> 99.8% ee) were determined by HPLC (Daicel chiral OD column, Pr^{i}OH–n-hexane, 5 : 95). The preliminary studies involved reaction of **1**–**3** with **4** and **5**, as shown in Scheme 1.

Extremely high levels of asymmetric induction can be achieved in Diels–Alder cycloadditions of **1** or **3** with **4**; in contrast to other general dienophiles, **1** containing a carboxylate moiety reacts with **4** to give differently configured adducts depending on the Lewis acids employed; in the presence of $TiCl_4$, $Ti(OPr^i)_4$ or $SnCl_4$, **6a** was obtained as the major diastereomer (**6a** : **6b** = *endo-R* : *endo-S* = > 99 : 1; entries 4–6 in Table 1), but with $AlEt_2Cl$, $ZnCl_3$ or $BF_3{\cdot}Et_2O$ the opposite configuration of **6b** was obtained (**6a** : **6b** = 1 : > 99; entries

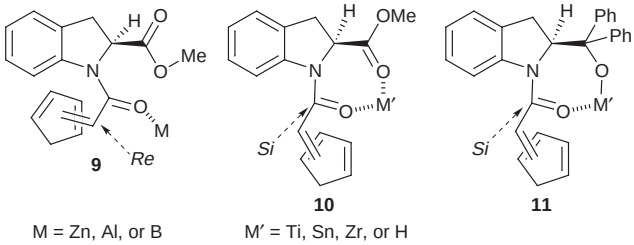

Fig 1 Possible intermediates in Diels–Alder reactions.

1–3 in Table 1). In the case of **2**, the same trend of **7b** was observed, but in a less diastereoselective manner than for **1** (entries 16 and 17). In particular, **3** containing a diphenyl-substituted tertiary alcohol moiety affords exceptionally high diastereofacial selectivities (**8a**:**8b** = >99:1, yield = >90%; entries 7–15) regardless of the natures of the Lewis acid. The *endo* configurations were readily ascertained by iodolactonization of **6a**–**8a** with I_2 in DMF.[5b] The *exo* compound cannot be lactonized under the same reaction conditions. The ratio of *endo-R* and *endo-S* was determined by HPLC with the crude **6a**–**8a** and **6b**–**8b** without purification.[7] The absolute configuration of **6a**, **7b** or **8a** was determined by reductive cleavage of **6a** to the known norbornene-2-methanol and subsequent comparison of $[\alpha]_D$ values.[8]

The differently configured adducts produced can be rationalized by the different intermediates formed between **1**–**3** and the metals of the Lewis acids. Compounds **1**–**3** react with **4** to favor formation of *endo-R* species **6a** or **8a** with $TiCl_4$, $Ti(OPr^i)_4$, $SnCl_4$ or $ZrCl_4$ probably *via* formation of seven-membered ring chelates with the acryloyl moiety of **10** or **11** having a *cisoid* conformation.[4a,5b] Helmechen and co-workers reported the first evidence of formation of a seven-membered ring chelate complex.[4a] It is noteworthy that even in the absence of any Lewis acid, **3** reacts with **4** to give an excellent chemical yield (92%) and high stereofacial selectivity (*endo*:*exo* = >99:1, *endo-R*:*endo-S* = >99:1; entry 9 in Table 1) at 25 °C after a long reaction time (24 h). The results can be attributed to the hydrogen-bond *cisoid* conformation intermediate **11** where the hydrogen acts as a Lewis acid. On the other hand, **1** or **2** prefer *endo-S* formation **6b** or **7b** with $ZnCl_2$, $AlEtCl_2$ or $BF_3{\cdot}Et_2O$, with high diastereofacial selectivity probably resulting from intermediate **9**, as shown in Fig. 1 In contrast to Ti or Sn Lewis acids, relatively weaker Lewis acids such as Zn, Al, or B may not form a seven-membered ring complex, instead forming a weak coordination with the amide carbonyl group (**9**).[4a,5b] In the case of Evans' model dienophile, an α,β-unsaturated *S*-oxazolidinone, the *endo-R* form was obtained[2a] and explained by formation of a six-membered ring intermediate with Et_2AlCl, which was clarified by a ^{13}C NMR study.[2c] However, in contrast to a significant chemical shift change[9a] in the **1**–$SnCl_4$ chelation complex **11**, ^{13}C NMR measurement of the **1**-Et_2AlCl mixture did not show significant changes in the chemical shifts for either of the amide or ester carbonyl peaks,[9b] *which can be explained by a weak coordination* (**9**) between **1** and Et_2AlCl. Species **1** and **3** also reacted with less reactive acrylic diene **5** at 25 °C to result in the same trend: for **1** with $TiCl_4$ the ratio of *endo R*:*endo S* was 97:3, while with $EtAlCl_2$ the ratio was reversed to 3:97, which is comparable to entry 1; for **3** with both $TiCl_4$ and Et_2AlCl, *endo R*:*endo S* = 97:3 and 94:6 respectively, which is comparable to entries 8 and 12.

In summary, asymmetric Diels–Alder cycloadditions of **1**, or **3** with **4** proceed with absolutely stereocontrolled diastereofacial selectivities in both *endo-S* and *endo-R* (up to >99% de) depending upon Lewis acids used and the structures of chiral dienophiles.

Metal-catalyzed transformation of D-glucal to optically active furan diol

Masahiko Hayashi,* Hirotoshi Kawabata and Kanako Yamada

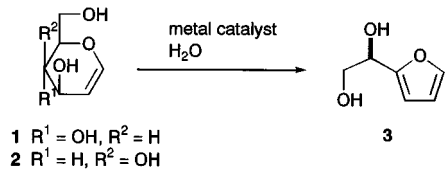
Department of Chemistry, Faculty of Science, Yamaguchi University, Yamaguchi 753-8512, Japan.
E-mail: hayashi@po.cc.yamaguchi-u.ac.jp

Received (in Cambridge, UK) 29th March 1999, Accepted 19th April 1999

The treatment of D-glucal with a catalytic amount of $Sm(OTf)_3$ or $RuCl_2(PPh_3)_3$ in the presence of 1 equiv. of H_2O afforded optically active furan diol in good yield under mild conditions.

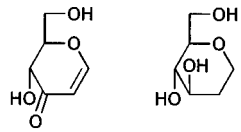
In 1975, Gonzales and co-workers reported the conversion of 3,4,6-tri-*O*-acetyl-D-glucal into 4,6-di-*O*-acetyl-2,3-dideoxy-*aldehydo*-D-erythro-*trans*-hex-2-enose in the presence of mercuric sulfate in 1,4-dioxane–sulfuric acid solution.[1,2] This mercuric ion-assisted acid glycal opening reacton has been applied to hexose and pentose derivatives to obtain acyclic α,β-unsaturated aldehydes. They also reported that the reaction of unprotected D-glucal under the same mercuric ion-assisted acidic conditions afforded optically active furan diol, 2-(D-*glycero*-1,2-dihydroxyethyl)furan. These transformations are very useful to obtain chiral building blocks, however, these reactions require acidic conditions. Therefore, the use of mild and neutral conditions to accomplish these transformations would be desirable, Here we report metal ion-catalyzed furan diol synthesis from D-glucal under mild conditions.

We recently reported the oxidation of the allylic alcohol moiety in D-glucal **1** by the aid of a catalytic amount of palladium complexes, which leads to the efficient synthesis of 1,5-anhydrohex-1-en-3-uloses.[3] During this study, we found that when the reactions were carried out in water, the formation of optically active furan diol **3** was observed (44% yield). The reaction in MeCN in the presence of water resulted in the formation of a mixture of furan diol **3**, oxidation product **4** and hydrogenated product **5**. These results promoted us to examine this transformation in detail. After examining several systems for the efficient conversion of **1** to furan diol **3**, we found that $RuCl_2(PPh_3)_3$ and $Sm(OTf)_3$ worked effectively to convert D-glucal to furan diol (Scheme 1). Some of the results obtained are summarized in Table 1. The treatment of D-glucal with 5–10 mol% of $RuCl_2(PPh_3)_3$ in the presence of 1 equiv. of H_2O afforded optically active furan diol in 64–70% yield. In the case of the reaction without H_2O, very slow dehydrogenation–hydrogenation to form **4** and **5** occured. Some rare-earth metal triflates also proved to be effective. Among the rare-earth metal triflates we examined, $Sm(OTf)_3$ exhibited the highest activity. The treatment of D-galactal **2** with 5 mol% of $Sm(OTf)_3$ afforded furan diol **3** with the same configuration. The reaction probably proceeds *via* nucleophilic attack of H_2O on glucal. Then opening of pyranose ring followed by cyclization to a five-membered ring and dehydration furnished the furan ring.



1 R^1 = OH, R^2 = H
2 R^1 = H, R^2 = OH

3



4 **5**

Scheme 1

A typical procedure is as follows: D-Glucal (204 mg, 0.356 mmol), MeCN (1.5 ml) and H_2O (0.03 ml) were placed under argon in an ampoule equipped with a magnetic stirring bar and a Young valve. After addition of $Sm(OTf)_3$ (44.8 mg, 0.07 mmol), the mixture was stirred for 40 min at 80 °C. The completion of the reaction was confirmed by TLC, then the mixture was poured into brine. Extracton with EtOAc (15 ml × 5) and concentration afforded the crude product, which was chromatographed on silica gel to give 2-(D-*glycerol*-1,2-dihydroxyethyl)furan **3** (131 mg, 70%) as a colorless oil {$[\alpha]_D$ +36.4 (*c* 1.2, $CHCl_3$) [lit.,[1] +38.0 (*c* 3.3, $CHCl_3$)]}.

The present method has the following advantages: (1) The reaction proceeds under neutral conditions, unlike the conventional mercuric ion-assisted acidic reaction; (2) highly toxic mercury can be replaced by less toxic metals; (3) operational simplicity—the direct derivatization of glycol to a protected species is possible.

A four stranded β-sheet structure in a designed, synthetic polypeptide

Chittaranjan Das,[a] S. Raghothama[b] and P. Balaram*[a]

[a] *Molecular Biophysics Unit, Indian Institute of Science, Bangalore-560012, India. E-mail: pb@mbu.iisc.ernet.in*
[b] *Sophisticated Instrumentation Facility, Indian Institute of Science, Bangalore-560012, India*

Received (in Cambridge, UK) 29th March 1999, Accepted 20th April 1999

A designed four stranded β-sheet peptide has been constructed using three internal D-proline residues to nucleate β-hairpin formation.

De novo protein design provides a firm test of our understanding of the principles that govern the folding of polypeptide chains. The key element in this approach is the construction of synthetic peptide sequences which give rise to well characterized secondary and tertiary structures.[1] The choice of sequences is based on the propensities of specific sequences to adopt well defined local folds like helices, β-turns, and β-strands.[2] There has been considerable recent success in designing helical bundles [3] and mixed α/β models,[4] but attempts to design all β-sheet structures have been far fewer. β-Sheet formation has acquired a new dimension after the recognition that such structures are involved in the pathogenesis of Alzheimer's and prion diseases.[5] Two major difficulties have retarded the development of design approaches to β-sheets. (i) The intrinsic tendency of sheet-like structures to aggregate, leading to solubility problems, was indeed recognized in early studies of the β-sheet model betabellin.[1] (ii) The absence of well determined cross-strand amino acid preferences in protein β-sheets[6] limits rational design of sequences to facilitate long-range interactions. Recent success in development of soluble β-hairpin models has resulted from the recognition that nucleating β-turns of the appropriate stereochemistry (type I′ and type II′) can facilitate hairpin formation. The sequence choices at the turns have been limited to Asn-Gly and DPro-Gly; segments which have a strong tendency to adopt type I′/II′ conformations. This is a consequence of the stereochemical imperative that the $i + 1$ residue in type I′/ II′ β-turns must adopt local left-handed helical (α_L) conformations. While in DPro, pyrrolidine ring formation restricts the N–C$^\alpha$ torsion angle to the desired value of +60 ± 20°, Asn residues have the highest propensity to adopt α_L conformations, amongst the 20 protein amino acids.[7] DPro-Gly segments have been shown to be superior to Asn-Gly segments in stabilizing β-hairpins.[8] There have been several recent reports describing construction of three-stranded β-sheet structures soluble in both organic and aqueous media.[9] We describe here the unambiguous characterization of a four-stranded β-sheet structure in a designed 26 residue synthetic peptide (Beta-4, Fig 1).† Three internal DPro-Xxx sequences were positioned to nucleate type II′/I′ β-turn conformations. In the strands, a preponderance of β-branched residues (Ile, Val, Thr) was chosen to facilitate extended strand formation. Lys/Arg residues were introduced to promote solubility and reduce the chances of aggregation. The aromatic residues Phe/Tyr were positioned so as to permit observation of long-range side chain interactions as diagnostics for structure formation.

The CD spectrum of the peptide in water showed a negative band at *ca.* 213 nm. In MeOH and MeOH–water mixtures, there is considerable intensification of this negative CD band, a feature consistent with a β-sheet structure for the peptide Beta-4. The 500 MHz ^{1}H NMR spectrum for Beta-4 in MeOH was extremely well resolved, permitting sequence specific assignments using a combination of TOCSY and NOESY experiments. All proton resonances observed for the peptide Beta-4 were sharp and there was no appreciable concentration dependence of chemical shifts in the range of 3.2 to 0.1 mM, suggesting the absence of aggregation effects. Several C$^\alpha$H resonances were observed at low field positions, ≥4.6 ppm [T3 (4.60), I4 (4.87), K5 (4.85), I8 (4.74), T9 (4.87), F10 (5.00), A11 (4.96), V15 (4.61), L16 (5.04), F17 (5.10), A18 (4.94), T23 (4.75), Y25 (5.15)]. Furthermore, large values of vicinal coupling constants $J_{\alpha HNH} \geq 8.5$ Hz were observed for several NH resonances which could be accurately measured from resolution enhanced 1D experiments [J(Hz): T3 (8.9), I4 (9.4), K5 (8.6), F10 (9.4), A11 (9.0), T14 (9.0), A18 (8.5), V19 (8.6), K22 (8.8), L24 (8.7), Y25 (8.5)]. These parameters are consistent with a large number of residues in Beta-4 adopting β-strand conformations. NOE data provide definitive confirmation of the β-sheet structure in the peptide. For all residues in the strand segments the observed $C_i^\alpha HN_{i+1}H$ ($d_{\alpha n}$) NOE was appreciably more intense than the corresponding intraresidue $N_iHC_i^\alpha H$ ($d_{n\alpha}$) NOE. This is a characteristic of residues adopting (ϕ, ψ) values in the β-strand region. Observation of several key long-range NH–NH NOEs (T3-F10, K5-I8, A11-T14, V19-K22, and V15-R26) in the NOESY spectra of Beta-4 provide evidence for the proper registry of the β-strands, as shown in Fig.1. The location of the turn segments is confirmed

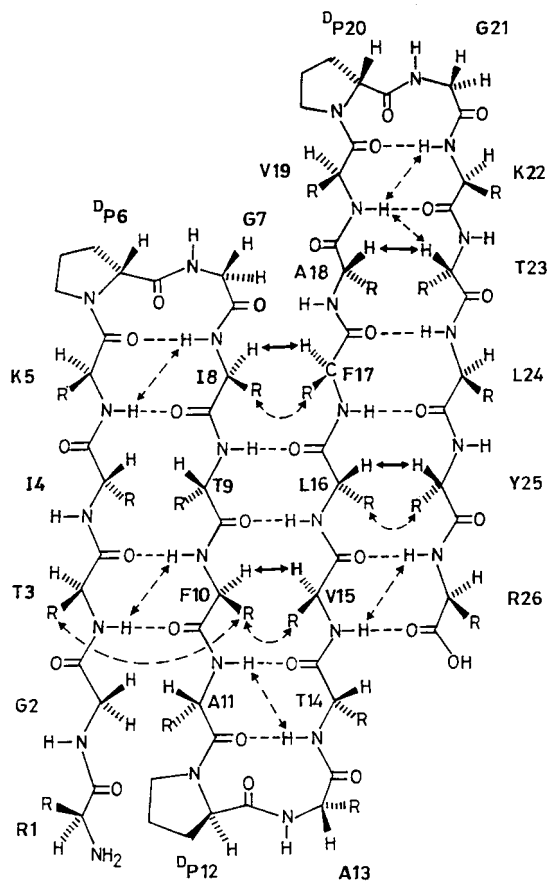

Fig. 1 Schematic representation of the target structure for the peptide Beta-4. A summary of some important long range NOEs observed for the peptide are indicated by arrows. Solid arrows indicate strong NOEs and broken arrows indicate weak NOEs.

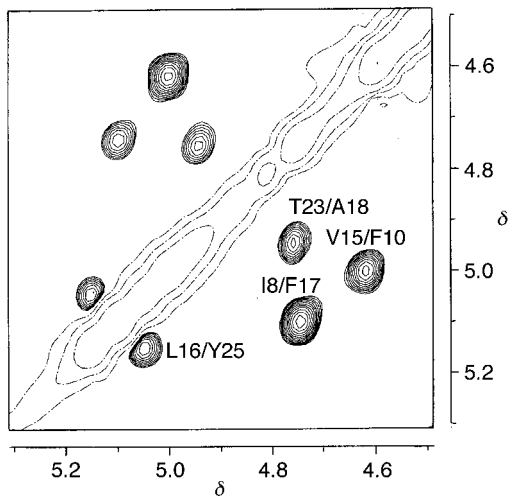

Fig. 2 Portion of the ROESY spectrum of Beta-4 in CD_3OD at 300 K, highlighting long-range $C^{\alpha}H$–$C^{\alpha}H$ NOEs.

by the observation of the sequential d_{NN} connectivities, G7-I8, A13-T14 and G21-K22. In all three turns the $i + 2$ residue must adopt local helical conformations in which these NOEs are expected. Fig. 2 shows an expanded view of the NOEs observed between $C^{\alpha}H$ protons. The observed cross-stranded interactions between I8-F17, F10-V15, A18-T23 and L16-Y25 provide clear support for the structure in Fig.1. The $d_{\alpha\alpha}$ NOE between I4 and T9 could not be detected due to overlap of these resonances with the residual OH resonance of the solvent. However, the proper registry of the two N-terminal strands is supported by the observation of both the expected cross-strand NH–NH NOEs (K5-I8 and T3-F10). Identification of several sidechain–sidechain NOEs between methyl resonances at high field and the aromatic resonances at low field provides strong evidence of compact structure of the peptide in solution. Most importantly, the NOEs observed between the aromatic protons of F10 and the methyl protons of V15 and T3 clearly support the alignment of the first three N-terminal strands. Inter-residue aromatic proton–methyl proton NOEs between I8-F17 and L16-Y25 are also clearly indicative of proper strand registry. Using a total of 100 observed NOEs, 11 dihedral angle constraints from *J* values, and 10 hydrogen bonding constraints obtained from H/D exchange data, structure calculations were performed using DYANA.[10] Fig. 3 shows a superposition of 12 calculated structures with a mean RMSD of 0.59 Å for all back bone atoms in the the well-ordered region of residues 3–25 and 1.32 Å for all heavy atoms in the same region of residues. In 50% MeOH–water most of the long range NOEs characteristic of the β-sheet structure are retained. Methyl resonances of I8 and V15 appear at extremely high field due to the shielding of aromatic rings of F10 and F17. This feature is characteristic of sidechain clustering in the β-sheet. In 50% MeOH–water both these resonances move to slightly lower field. In water these ring current effects are significantly reduced [I8 $C^{\gamma}H_3$ (0.40 ppm) in MeOH, (0.50 ppm) in 50% MeOH–water, (0.67 pm) in water]. In water, NOEs characteristic of the three β-turn segments are retained (NH–NH NOEs between G7-I8, A13-T14 and G21-K22). However, long range interstrand NOEs diagnostic of the β-sheet structure were abolished suggesting that solvent invasion disrupts the proper strand registry for β-sheet formation. Since cooperative cross-strand hydrogen bonding may be the dominant cementing force in β-sheets, competition from a strongly hydrogen bonding solvent like water may disrupt sheet formation unless the segment is sequestered in a relatively apolar environment. It is not surprising that β-sheets in proteins are often largely solvent inaccessible. The recent observation of completely solvent exposed β-sheet[11] holds promise for further refining of Beta-4 to provide additional stability for a sheet in a completely aqueous environment. Rational design of β-sheet structures will prove useful in understanding the forces of

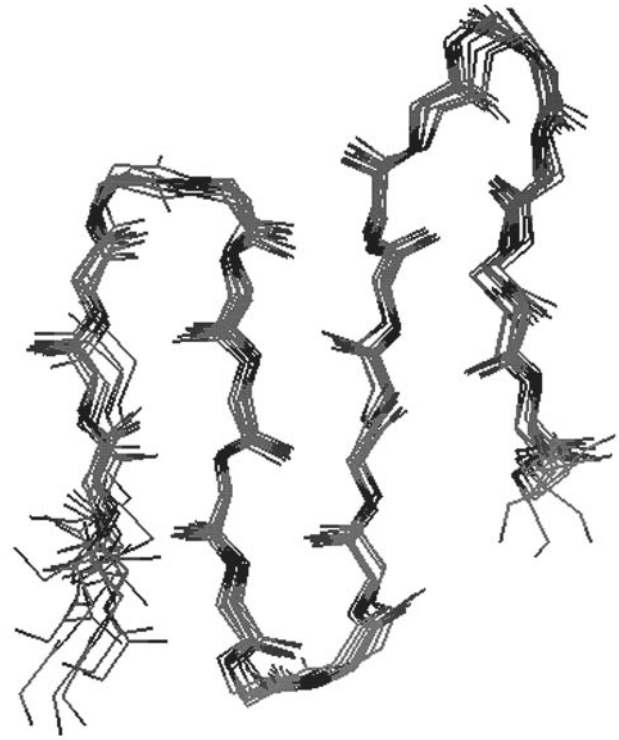

Fig. 3 Superposition of the best 12 structures of Beta-4 obtained from NMR restraints. Backbone traces illustrating the four-stranded β-sheet fold of the molecule are shown.

nucleation and structure propagation in addition to throwing light on the factors that determine the tendency of these structures to aggregate, a factor of particular importance in diseases caused by polypeptide precipitation.

Program support from the Department of Biotechnology to the Indian Institute of Science is gratefully acknowledged. The authors thank S. Kumar Singh and S. Madhusudan for help with structure calculations.

Notes and references

† The 26-residue peptide (Beta-4) was synthesized by standard solid-phase procedures based on Fmoc chemistry and purified by reverse phase HPLC (C18, 10μ) using MeCN–water (containing 0.1% TFA) gradients for elution. The peptide was characterized by its electrospray ionization mass spectrum (M observed 2775.10, M calculated 2775.30) and by complete assignment of the 500 MHz ^{1}H NMR spectrum. All NMR studies were carried out on a Bruker DRX 500 spectrometer.

Received (in Cambridge, UK) 12th January 1999, Accepted 19th April 1999

Zero field splitting parameters of planar binuclear phthalocyanines in the lowest excited triplet state have been obtained by using a time-resolved EPR method to show a delocalization of excitation over two phthalocyanine units for a homodimer and a contribution from a charge transfer configuration for a heterodimer.

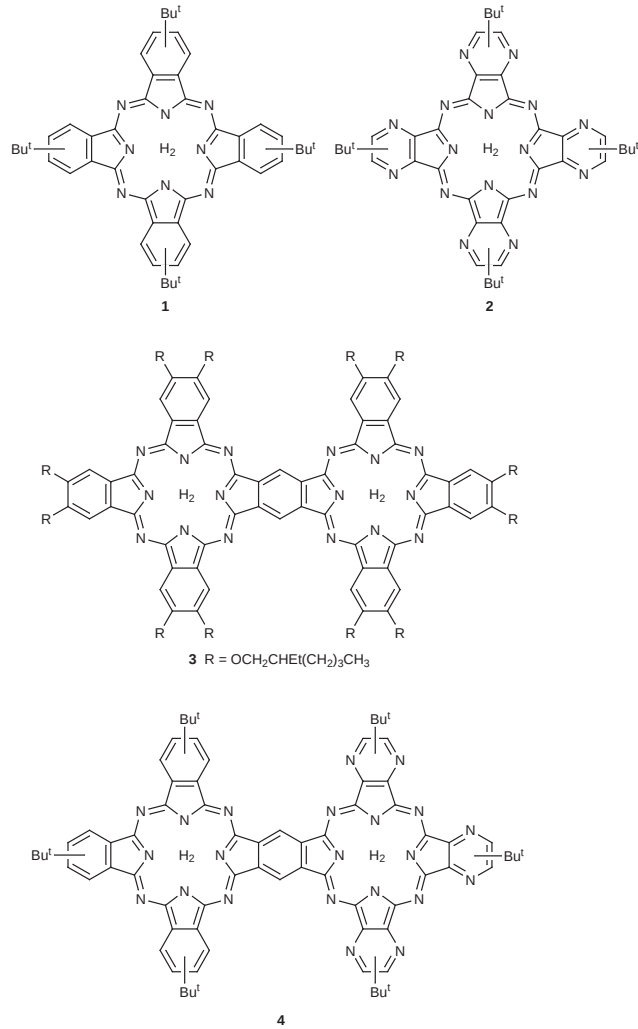
Phthalocyanine (Pc) and porphyrin (Pr) dimers have been intensively investigated as a model of photosynthetic reaction centers.[1] It has been an important objective to evaluate intramolecular interactions of these dimers in the excited state.[2]

Zero field splittings (ZFSs) of dimers in the lowest excited triplet (T_1) state, which can be obtained by EPR, are useful parameters for evaluating interactions between constituent units in dimers.[3] Although it is difficult to obtain this kind of information on Pc derivatives due to the lack of phosphorescence in the visible region and the short lifetime,[4] a time-resolved EPR (TREPR) technique has been shown to be useful for analyses of Pc derivatives,[5] and applied to several 'face-to-face' dimers having strong intramolecular interactions.[6] However, 'head-to-tail' dimers with strong interactions have not been observed in the T_1 state not only of Pc but also of Pr derivatives, while a charge transfer (CT) contribution in the T_1 state is observed for the photosynthetic reaction centers.[7] This originates from the fact that the interaction in the T_1 state is much smaller than that in the lowest excited singlet (S_1) state.

In this study, we have applied the TREPR method to two planar binuclear conjugated Pc derivatives **3** and **4**, in which two Pcs or one Pc and pyrazinoporphyrazine (Pyz) strongly interact with each other through a common benzene ring, and have succeeded in observing TREPR spectra in the T_1 state. The ZFSs of these dimers are compared with those of the corresponding monomers, and analyzed in terms of a delocalization of excitation over two units and a contribution of a CT configuration for homo- and hetero-dimers, respectively.

Pc derivatives have been reported by us previously.[8] A 1 : 1 mixture of toluene and $CHCl_3$ of spectral grade was used as solvent for the TREPR measurements. The concentrations of the samples were (0.5–1) $\times$ 10^{-3} M. All samples were deaerated by freeze-pump-thaw cycles. TREPR measurements and simulations of the T_1 spectra were carried out following the method already reported.[9,10] Molecular orbital (MO) calculations were performed for the deprotonated species under the Pariser–Parr–Pople (PPP) approximation.[11]

TREPR spectra of **1**, **3** and **4** observed at 20 K and 0.5 μs after laser excitation are shown in Fig. 1. ZFS parameters and intersystem crossing (ISC) ratios evaluated by spectral simulations are summarized in Table 1. The ISC from the S_1 state is selective to upper T_x and T_y sublevels for all Pc derivatives, where T_z is the lowest sublevel (z = an out of plane axis). This selectivity is consistent with those of metal-free porphyrins previously reported,[12] and is interpreted by contribution of



(n,π*), (σ,π*) and (π, σ*) configurations. These results indicate that the signs of the D (= $-3E_z/2$) values are positive for all Pc derivatives examined here.

It is found that the D value of **3** is much smaller than that of **1**. This decrease can be explained by a delocalization of excitation over two Pc units in the T_1 state. This is supported by a MO analysis of **3**, where the π-electrons of the HOMO and LUMO delocalize over two Pc units.[8,11] To allow a quantitative discussion, D values were calculated under a half-point charge approximation.[11,13,14] The results are summarized in Table 1, where the calculated D value (0.426 GHz) of **3** is smaller than that (0.605 GHz) of **1** in analogy with the experimental results.

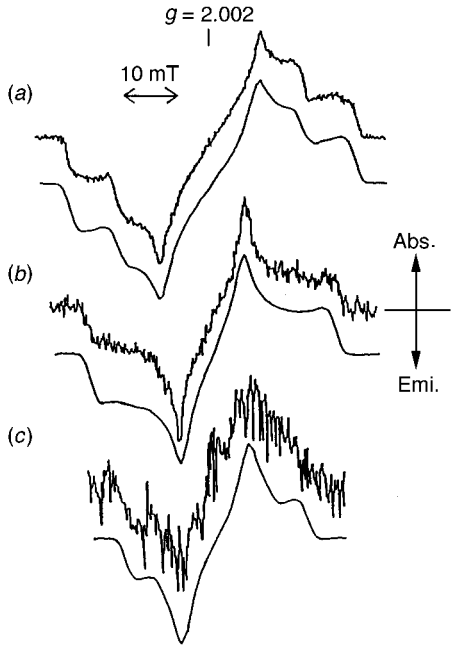


Fig. 1 TREPR spectra of (*a*) **1**, (*b*) **3** and (*c*) **4** with their simulations (lower line). These spectra were observed at 20 K and 0.5 μs after laser excitation.

Table 1 ZFS parameters and ISC ratio[a]

	D[b]/GHz	E/GHz	$P_x:P_y:P_z$	D_{calc}/GHz
1	0.758	0.070	0.46 : 0.54 : 0	0.605
2	0.900	0.080	0.47 : 0.53 : 0	0.673
3	0.645	0.105	0.35 : 0.65 : 0	0.426
4	0.480	0.040	0.4 : 0.6 : 0	0.422

[a] $D = -3E_z/2$, $E = |E_x - E_y|/2$ and P_i ($i = x, y$ and z) denotes anisotropic ISC. [b] Errors of D values are within 0.016 and 0.008 GHz for **4** and the other Pcs, respectively.

The D value (0.480 GHz) of **4** is the smallest in our Pc derivatives, and cannot be interpreted simply by the expansion of π delocalization in the T_1 state. Since the D value of **2** is larger than that of **1**, localization of excitation on the Pyz ring can be ruled out. The MO analyses of the monomers suggest that the HOMO (−7.49 eV) and LUMO (−3.74 eV) of **1** are higher than the HOMO (−7.98 eV) and LUMO (−4.02 eV) of **2**, respectively. In fact, the electron density on the Pc ring is larger than that on the Pyz ring for the HOMO of **4**, while it is smaller for the LUMO. Therefore, the small D of **4** originates from a contribution of a CT configuration between the Pc and Pyz systems. The calculated D value of **4** is smaller than that of **3** in accordance with the experimental trend.

In summary, planar and conjugated Pc dimers have been studied in terms of D values. The D value of **3** is smaller than that of **1** and can be explained by a delocalization of excitation over two Pc units in the T_1 state. The D value of **4** is further lowered and can be interpreted as the contribution of the CT configuration between the Pc and Pyz systems. The CT contribution to the D value is strikingly similar to the photosynthetic reaction center. To the best of our knowledge, 'head-to-tail' dimers with such strong T_1 interactions have not been reported in Pr and Pc derivatives to date. Therefore, these results are not only important as a model of the photosynthetic reaction center but also attractive in relation to the mechanism of electron and energy transfer in photonic devices.

Received (in Cambridge, UK) 24th March 1999, Accepted 26th April 1999

Water soluble ruthenium(II)– and rhodium(I)–phosphine complexes catalyze the hydrogenation of aqueous HCO_3^- to HCO_2^- under mild conditions with turnover frequencies up to 262 TO h^{-1}.

Reduction of carbon dioxide into useful starting materials of organic synthesis is an aim of paramount importance both for economic and environmental reasons.[1] It is intriguing that while in the dark reactions of photosynthesis carbon dioxide reacts in an aqueous medium under very mild conditions, efficient synthetic systems usually require elevated temperatures and pressures to achieve reasonable reaction rates. In homogeneous systems, both in the liquid and in the supercritical state, several ruthenium complexes, such as $[RuCl_2(PMe_3)_4]$ **1** and $[RuCl_2(dppe)_2]$ **2** showed impressive catalytic activity in the reaction of CO_2, H_2 and $HNMe_2$ yielding dimethyl formamide.[2,3] Leitner *et al*.[4] investigated the hydrogenation of CO_2 in *aqueous solutions* with $[RhCl(tppts)_3]$ **3** as catalyst [tppts = tris(3-sulfonatophenyl)phosphine] which gave formate with initial reaction rates of 7260 h^{-1} at 81 °C and 1365 h^{-1} at 23 °C in the presence of $HNMe_2$ under 40 atm total pressure (CO_2/H_2 = 1). It is of interest that under identical conditions $[RuCl_2(tppts)_3]$ **4** showed[4] a TOF of only 6 h^{-1} (23 °C), and no formic acid was detected in aqueous solutions with **3** without an amine.

Water soluble phosphine complexes of platinum metals were introduced into the homogeneous catalysis scene by Joó and Beck[5] who also noted the interaction of CO_2 with $[HRuCl(tppms)_3]$ **5** (tppms = 3-sulfonatophenyldiphenylphosphine) in aqueous solution.[6] Recently it was established that formation of the water soluble hydrides of ruthenium(II), such as **5** $[H_2Ru(tppms)_4]$ **6** and $[HRuCl(tppms)_2]_2$ **7** from $[RuCl_2(tppms)_2]_2$, **8**, tppms and H_2, and their distribution in aqueous solution is strongly pH-dependent which leads to opposite selectivities in acidic and basic solutions during the biphasic hydrogenation of unsaturated aldehydes.[7] This prompted us to reinvestigate the hydrogenation of carbon dioxide and its derivatives in aqueous solutions catalyzed by water soluble platinum group metals phosphine complexes *as a function of pH*. In addition to $[RuCl_2(tppms)_2]_2$, $[RhCl(tppms)_3]$ **9** $[HRu(ac)(tppms)_3]$ **10**, *trans*-$[IrCl(CO)(tppms)_2]$ **11**, $[PdCl_2(tppms)_2]$ **12**, and complexes of 1,3,7-triaza-7-phosphaadamantane (pta), such as $[RuCl_2(pta)_4]$ **13** and $[RhCl(pta)_3]$ **14** were also studied.[8] Here we report that **8**–**10** and **13** catalyze the hydrogenation of CO_2 in aqueous solutions under mild conditions without the need of an amine additive.

When solutions of **8**, **9** and **13** were agitated under a CO_2–H_2 atmosphere (up to 80 atm total pressure) at 24 °C, small amounts of formic acid were detected by $^1H/^{13}C$ NMR with TOFs not exceeding 1.5 h^{-1} (Table 1). However, when the solvent was changed for 0.2–1.0 M $NaHCO_3$ a substantial increase in the catalytic activity was observed and TOFs reached 262 h^{-1} with **9** at 24 °C. Further increase of the pH decreased the rate of hydrogenation (entry 7). These data represent a significant improvement over previous results in that the turnover frequencies for Ru-based catalysts are among the highest obtained so far in aqueous solutions, moreover, the reductions do not require addition of an organic co-solvent or an amine or alcohol to stabilize the product. In contrast, no formate production took place with **11**, **12** and **14** under the conditions of entry 13. Instead, **12** yielded a dark brown precipitate while the originally yellow solutions of **11** and **14** became colorless; these reactions were not investigated in further detail. We note, however, that Pruchnik *et al*.[9] observed catalysis of the reverse water gas shift reaction in aqueous solution by $[Rh_2(ac)_4(H_2O)_2]$ + pta (Rh : pta = 1 : 3); no sign of CO formation in our system with **14** was detected.

Most of the experiments were done on the hydrogenation of aqueous $NaHCO_3$ solutions; the results are summarized in Table 1. No carbon containing products other than formate were

[a] Total phosphorus to metal ratio; [M] = 2.0–2.5 mM. [b] Initial turnover frequencies in parentheses. [c] Suspensions. [d] 0.93 M HCO_2^- final solution.

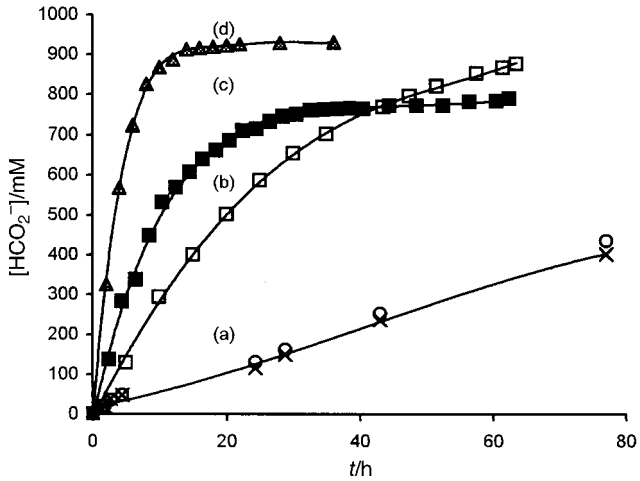

Fig. 1 Time course of formate production in reaction of HCO_3^- with H_2 catalyzed by $[RuCl_2(pta)_4]$ [(a), (b), (d)] and by $½[RuCl_2(tppms)_2]_2$ + 2 tppms (c) at 50 (c), 54 (a), 90 (b) and 103 °C (d) followed by ^1H [(a), –**x**–] or ^{13}C NMR (all other cases).

detected. With any of **8**–**10** and **13** the reactions started with no appreciable induction period (Fig. 1). Increase of the temperature from 54 to 103 °C caused an 11-fold increase of the initial rate of formate production with **13** (entries 5, 6). Despite the similarity[10] of pta to PMe_3, **13** proved considerably less active than **8**. However, the anionic ligand of the catalyst (precursor) had no significant influence: either **8** in the presence of NaI or **10** gave approximately the same rate as the unmodified **8** (entries 8, 13, 15). Both with **8** and **9** some excess of tppms proved beneficial for activity and catalyst stability—in fact **8** was almost completely inactive without added tppms; however, its catalytic activity was no further increased when the total tppms/Ru ratio exceeded 4 (entries 12–14). As expected, increase of the hydrogen pressure increased the rate of reduction with all catalysts. Conversely, while CO_2 in the gas phase was detrimental with **8** and **13**, it was essential for high reaction rates with **9** (although a much slower reaction still proceeded in its absence). The substrate bicarbonate can be produced *in situ* in the reaction of carbonates and CO_2. When a 2 ml aqueous suspension of 200 mg $CaCO_3$ was pressurized with CO_2 (20 atm) and H_2 (60 atm) and shaken in an NMR tube overnight at 24 °C with **8**, calcium formate was produced with TOF = 26.6 h^{-1}, the total TON reaching 372. Similar experiments with **9** and **13** yielded formate with TOF 18.7 and 2.5 h^{-1}, respectively (see also Table 1). The presence of $CaCO_3$ in these systems is highly beneficial, since under the same conditions CO_2 alone is reduced with TOF 1.49 (**8**), 0.11 (**9**), and 0.24 h^{-1} (**13**); the rate increase with **9** is more than 160-fold!

It is premature to speculate on detailed mechanisms of the hydrogenation of bicarbonate in these systems. It is known[7] that in aqueous KCl solutions, at the pH (8.3) corresponding to that of 1 M of $NaHCO_3$ solutions used in the present experiments, **8** + tppms + H_2 rapidly yields **6** in which the total P/Ru ratio is 4, found optimal for reductions here (entry 13). However, pH-static titrations (similar to those described in ref. 7) of **8** under H_2 in $NaHCO_3$ solutions containing an excess of tppms showed formation of only 0.4–0.6 mol H^+ for 1 mol Ru during the early phase of the reaction (instead of 2 mol required for **6**). This suggests a monohydride, possibly $[HRu(HCO_3)(tppms)_4]$ as a more likely intermediate. Both of these catalysts would account for the observed independence of the rate from the starting composition of the catalyst precursor. Assuming a constant catalyst composition in the pH range from 8.3 (1 M $NaHCO_3$) to 10.8 (0.2 M $NaHCO_3$ + 0.8 M Na_2CO_3) the lower reactivity of CO_3^{2-} (entry 7) is consistent with its known inferior tendency of oxygen exchange with H_2O compared to HCO_3^-.[11]

So far homogeneous catalytic hydrogenation of HCO_3^- in aqueous solutions has not been reported in the literature. Stalder *et al.*[12] used various heterogeneous Pd catalysts with a maximum TOF of 35 h^{-1} (Pd/C, 25 °C). Kudo *et al.*[13] studied in detail the reduction of CO_2 (40 atm) catalyzed by $PdCl_2$ in aqueous KOH at forcing conditions (106 atm H_2, 240 °C). In our opinion, based on the $CO_3^{2-}/HCO_3^-/H_2O$ equilibrium, all similar reactions using *aqueous* solutions or mixture of amines or carbonates under CO_2 pressure, in fact, may have utilized HCO_3^- as the real substrate in the catalytic cycle. This could also explain the beneficial effect of a small amount of H_2O on CO_2 reductions often observed[4b,14] in organic solvent systems.

Crystal structure of the microporous titanosilicate ETS-10 refined from single crystal X-ray diffraction data

Xiqu Wang and Allan J. Jacobson*

Received (in Bloomington, IN, USA) 16th February 1999, Accepted 20th April 1999

ETS-10 crystals up to 45 μm in size have been synthesized at 240 °C under a pressure of 80 MPa and the structure refined from single crystal X-ray diffraction data.

Microporous titanosilicates have been of interest since the discovery of important catalytic properties in titanium silicalite-1 (TS-1) in oxidation and epoxidation reactions.[1] ETS-10 is a porous titanosilicate first reported by Kuznicki *et al.*[2,3] A large number of studies have been devoted to this material owing to its interesting chemical and physical properties.[3–18] A model for the structure of the ETS-10 framework was recently proposed by Anderson *et al*. based on a detailed HREM, NMR, powder XRD and structural modeling study.[5,6] The location of the extra-framework cations and the local environments of the framework cations have also been studied by NMR, XAS and computer modeling techniques.[7,12,17] However, to date, the small crystal size of samples of ETS-10 has prevented accurate structure refinement from single crystal data, in spite of efforts to improve the syntheses.[18] The positions of the extra-framework cation sites have not yet been determined experimentally from diffraction data.

We are investigating the possibility of improving the size and crystal quality of microporous materials by using synthesis temperatures and pressures that are higher than those usually employed (≤400 °C and ≤200 MPa). By using this approach, ETS-10 crystals as large as *ca.* 45 μm have been obtained and successfully used to obtain single crystal X-ray diffraction data and to subsequently refine the structure.

In a typical synthesis Na_2TiF_6 (0.208 g, 1 mmol) and TPABr (0.26 g, 1 mmol) were mixed with H_2O (2.2 ml). This mixture (0.36 ml) together with sodium silicate solution (0.72 ml, Aldrich, 14% NaOH, 27% SiO_2) and 1 M NaOH solution (0.2 ml) were sealed in a Teflon tube in air. The tube was inserted into a high pressure vessel and heated at 240 °C under an applied pressure of 80 MPa for 3 days using a LECO HR-1B-2 high pressure–high temperature system. The reaction vessel was then removed from the oven and cooled to room temperature in air. The product was washed with water, filtered and air dried. Well developed tetragonal platy crystals of ETS-10 with sizes up to *ca.* 45 μm were formed together with silicalite-1 and quartz. The yield is *ca.* 20%. All of the reflections characteristic of ETS-10 were identified in a X-ray powder diffraction pattern of the multiphase product. Composition analysis of the crystals with a JEOL 8600 electron microprobe gave the atomic ratio Ti : Si = 1.00 : 5.07 which is consistent with the formula $Na_2TiSi_5O_{13}$ reported in the literature[5] and which was confirmed by our structure refinement. For many crystallites, Na peaks were observed but diminished in intensity during the microprobe measurement probably owing to the instability of the crystals under the measurement conditions. A few crystals which did not show loss of intensity of the Na peak gave Na : Si ratios ≈ 2 : 5. ETS-10 is usually prepared from gel compositions containing both potassium and sodium cations. Synthesis in the presence of Na^+ alone, however, has been previously reported.[18]

A tetragonal body centered unit cell with a = 7.481(1) and c = 27.407(5) Å was derived from the single crystal data measured with CCD detector. Careful checking of all of the measured frames indicated that all observed reflections were consistent with this cell. This cell corresponds to that of the ordered polymorph A (see below) predicted by Anderson *et al.*[5,6] except that the a axis length is halved. The halving is expected because the electron diffraction patterns of ETS-10 reported in the literature show streaking of all reflections with h,k = odd indicative of a high degree of disorder along a.[5,6] The unit cell observed by the single crystal X-ray diffraction is a subcell of the true unit cell. Unfortunately, our samples are very sensitive to an electron beam and consequently efforts to measure their electron diffraction patterns were unsuccessful. The powder X-ray diffraction pattern of a sample from the same synthesis is consistent with a disordered structure and differs from the calculated patterns for ordered structure models.[6] The systematic extinctions in the measured X-ray reflections based on the subcell correspond to the space group $I4_1/amd$. A disordered structure model was successfully solved and refined with this symmetry, although the converged R factors of the refinements are moderately high because of the structural disorder and small crystal size.†

The refined framework structure is consistent with the structure model proposed by Anderson *et al.*[5] The TiO_6 octahedra share *trans* vertices to form TiO_5 infinite chains. These chains are each connected to two folded chains of $Si(2)O_4$ tetrahedra to form $[TiSi(2)_4O_{13}]$ columns through vertex sharing between the octahedra and tetrahedra. The columns are packed into layers parallel to the (001) plane with the columns in neighboring layers perpendicular to each other. The layers are interconnected by $Si(1)O_4$ tetrahedra which share all their vertices with the $Si(2)O_4$ tetrahedra to form a framework structure (Fig. 1, 2). In the disordered structure model based on the subcell, neighboring column positions cannot be occupied simultaneously because the resulting interatomic distances would be too short. The unoccupied column positions correspond to wide 12-ring channels. The occupancies of the column atoms [Ti, Si(2), O(3–5)] were refined to 0.50(1) and were fixed at 50% in the final refinements. Thus, each column belongs to a (001) layer that consists of parallel columns alternating with

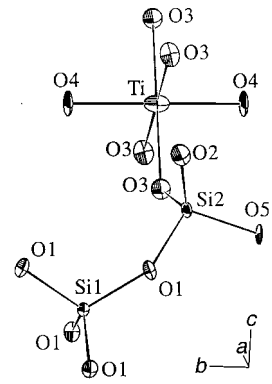

Fig. 1 Coordination environments of the Ti and Si atoms. Thermal ellipsoids are drawn with 50% probability. Bond lengths (Å): Si(1)–O(1) 1.612(7) (×4), Si(2)–O(3) 1.61(1), Si(2)–O(1) 1.615(7), Si(2)–O(5) 1.629(6), Si(2)–O(2) 1.698(4), Ti-O(4) 1.872(1) (×2), Ti–O(3) 1.99(1) (×4).

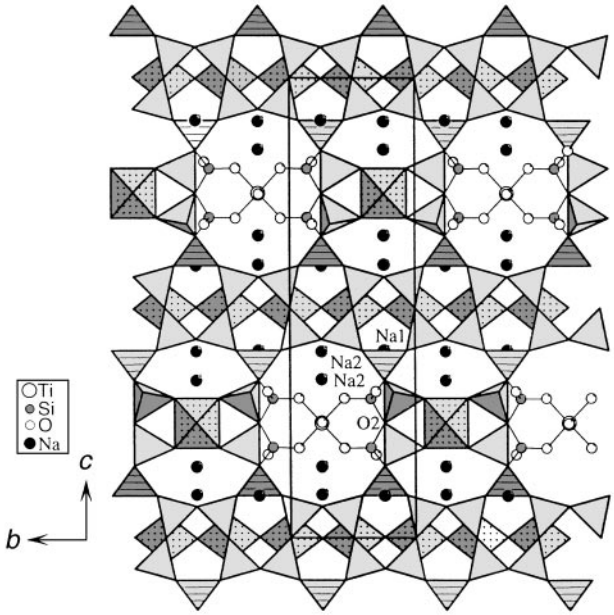

Fig. 2 Projection of the structure down (100). An ordered framework is represented with polyhedra. The $Si(1)O_4$ tetrahedra are hatched, the $Si(2)O_4$ are shaded and the TiO_6 octahedra are stippled. The non-framework Na cations are shown as filled circles.

12-ring channels. The O(2) site was found fully occupied because this site is located in the channel walls and is independent of the disorder. No disorder of the $Si(1)O_4$ tetrahedra was found in the refinements. As shown in Fig. 2, each $Si(1)O_4$ tetrahedron is connected to either a [100] $[TiSi(2)_4O_{13}]$ column plotted as ball-and-sticks or the one plotted as polyhedra. Since the neighboring (001) layers of columns are related by the 4_1 symmetry, there are four ways in which two neighboring layers are interconnected by the $Si(1)O_4$ tetrahedra to form an ordered double layer. Each of these ordered double layers may be considered as a stacking unit. Neighboring units can shift a half subcell along either [110] or [110] direction in order to form a framework. This gives rise to various stacking disorder possibilities. However, such stacking disorder does not cause blocking of the 12-ring channels. The hypothetical ordered polymorph A predicted by Anderson *et al.*[5,6] corresponds to simple ABAB… stacking. The structure model based on the subcell corresponds to fully disordered stacking.

The TiO_6 octahedron has site symmetry 2/*m* with the Ti–O bond lengths along the column axis (1.87 Å) being shorter than the others (1.99 Å). The $Si(1)O_4$ tetrahedron has site symmetry 4*m*2 with Si–O bond length 1.61 Å. The $Si(2)O_4$ tetrahedron with Si–O bond lengths 1.61–1.70 Å and O–Si–O angles 103.3–116.8° is apparently distorted but this may be a consequence of the disorder. The –O–Ti–O–Ti– backbones of the columns are nearly linear (O–Ti–O) 180°, (Ti–O–Ti) = 177.9°. The elongated thermal ellipsoids of the Ti and O(4) atoms suggest some Ti–O bond length alternation along the chain and some tilting of adjacent octahedra in the ordered structure, as predicted from previous studies.[13,17]

The sodium cations occupy two nonequivalent positions. Na(1) is located near the $Si(1)O_4$ tetrahedra and is coordinated to eight oxygen atoms at distances 2.50–2.99 Å. The occupancy of Na(1) was found, as expected, to be nearly equal to that of the column atoms. Na(2) is split into two equivalent positions 1.67 Å apart, each of which has five coordinating oxygen atoms at 2.57–2.62 Å all located on one side of the position. The nearest oxygen atom positions on the opposite side are > 3.6 Å away. The apparent one-sided coordination implies that there are disordered space-filling species such as H_2O molecules which complete the coordination sphere of Na(2), but which can not be located by the refinements because the electron density overlaps with those of the column atoms in the subcell. Substantial water loss (> 8%) below 200 °C has been reported for as-synthesized ETS-10 samples previously.[3] The splitting of the Na(2) site is related to the stacking disorder of the $[TiSi(2)_4O_{13}]$ columns.

In conclusion, we have employed a new synthesis approach to obtain ETS-10 crystals suitable for single crystal X-ray structure refinement. The structure refinement based on a disordered cell, confirms the previous structure model and provides details of the positions of both the framework atoms and extra-framework cations.

Notes and references

† *Crystal data*: space group $I4_1/amd$, a = 7.481(1), c = 27.407(5) Å, colorless plate, crystal size 0.045 × 0.045 × 0.01 mm. Mo-Kα radiation (λ = 0.71073 Å), μ = 1.1 mm^{-1}, $2\theta_{max}$ = 57°, $R(F)$ = 0.119/0.158 for 426 reflections with $[I > 2\sigma(I)]$ all 532 unique reflections and 52 variables.

Intensities were measured on a SMART platform diffractometer equipped with a 1K CCD area detector using graphite-monochromatized Mo-Kα radiation at 20 °C. A hemisphere of data (1271 frames at 5 cm detector distance) was collected using a narrow-frame method with scan widths of 0.30° in ω and an exposure time of 90 s frame^{-1}. The first 50 frames were remeasured at the end of data collection to monitor instrument and crystal stability, and the maximum correction applied on the intensities was < 1%. The data were integrated using the Brucker SAINT program, with the intensities corrected for Lorentz factor, polarization, air absorption, and absorption due to variation in the path length through the detector faceplate. The structure was solved with direct methods and refined using SHELXTL. All atom positions were refined anisotropically in the final refinements. Na(1) and Na(2) were fixed to have the same thermal parameters and a total occupancy of unity with a free occupancy ratio. CCDC 182/1236. Apparent equilibrium shifts and hot-spot formation for catalytic reactions induced by microwave dielectric heating

Xunli Zhang, David O. Hayward and D. Michael P. Mingos*

Department of Chemistry, Imperial College of Science, Technology and Medicine, South Kensington, London, UK SW7 2AY. E-mail: d.mingos@ic.ac.uk

Received (in Cambridge, UK) 16th February 1999, Accepted 21st April 1999

Microwave dielectric heating of the gas phase decomposition of H_2S catalysed by metal sulfides on a γ-Al_2O_3 support results in significant apparent shifts in the equilibrium constant, which have been attributed to the development of hot-spots in the catalytic beds; X-ray diffraction and electron microscopy measurements have indicated the formation of hot-spots with dimensions of 90–1000 μm and which involve not only the active phase, but also the support.

The acceleration of heterogeneous catalytic processes under microwave dielectric heating conditions has attracted both academic and industrial interest.[1–5] The majority of systems studied involve a catalyst which preferentially absorbs the microwaves relative to the support material and the reasons for the observed rate enhancements have been the subject of some controversy. The measurement of temperature under conditions where there are strong electric fields is problematical, but may be overcome, for example, by using optical fibre technology. Such measurements are still only capable of providing average temperatures. Both differential coupling abilities of materials and distribution of electromagnetic fields may result in localized temperature distribution in catalytic beds, but the contribution of these effects is difficult to quantify. Stuerga and Gaillard [6,7] have given a thorough theoretical analysis which has conclusively demonstrated that specific athermal effects are implausible given the small energies associated with the microwave quanta and the classical nature of the heating phenomenon and have suggested that localized enhancements of the reaction rates may be responsible for non-isothermal and heterogeneous kinetic phenomena. The majority of the experimental studies on catalytic reactions under microwave conditions have dwelled on the kinetic aspects and noted that the rates of reaction and product distributions are more consistent with a temperature 300-400 K higher than that measured for the bulk of the catalyst bed. However, for supported metal catalysts, calculations[8,9] have shown that the rate of heat transfer at 1 atm gas pressure is so high that the formation of hot-spots localised at the catalytically active sites are implausible. Here we report significant circumstantial evidence for the formation of hot-spots in the microwave experiments and have demonstrated for the first time that these hot-spots are not localised exclusively on the active catalyst, but also involve the support material. We have also estimated the dimensions of these hot-spots.

The catalytic conversion of H_2S into hydrogen and sulfur, which is commercially important for the coal and petrochemical industry,[10,11] has recently been investigated in our laboratories using parallel microwave and conventional heating conditions. The experimental set-up is illustrated schematically in Fig. 1 and the reactions were performed under continuous flow conditions using quartz reactors. The temperature in the microwave cavity was monitored using an Accufibre optical fibre thermometer (Model 10 Luxtron) which had its tip at the centre of the catalyst sample, as shown. The microwaves were generated at 2.45 GHz using an Electro-Medical Supplies Ltd generator (0–200 W) and relayed by means of a co-axial cable to a tunable cylindrical microwave cavity placed around the reactor. The catalysts used for the study were either an impregnated catalyst based on molybdenum oxide on a γ-alumina support, which was sulfided by a pre-treatment using an H_2S–H_2 flow at atmospheric pressure for 2 h, or a mechanically mixed sample of MoS_2 and γ-alumina. The reaction products were analyzed using a quadrupole mass spectrometer (QMS-200D, European Spectrometry System).

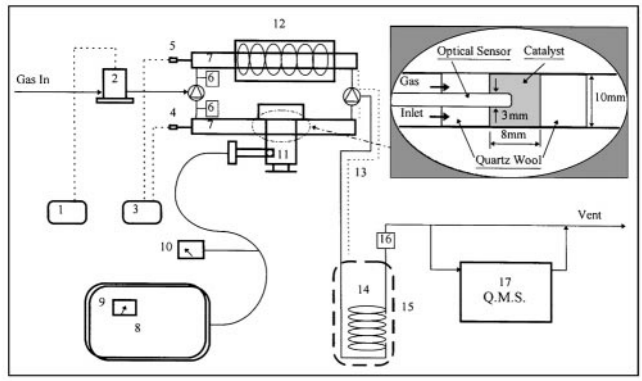

Fig. 1 Flow system for the H_2S decomposition. 1, Mass flow control unit; 2, mass flow controller; 3, temperature display; 4, optical sensor; 5, thermal couple; 6, pressure gauges; 7, quartz reactors; 8, microwave generator; 9, forward power meter; 10, reflected power meter; 11, microwave cavity; 12, conventional furnace; 13, heating tapes; 14, cold trap; 15, ice–water Dewar; 16, filter; 17, quadrupole mass spectrometer(QMS).

Fig. 2 compares the conversion efficiency for the decomposition of H_2S under microwave and conventional thermal conditions in the temperature range 500–1100 K for both the impregnated catalyst and the mechanical mixture of MoS_2 and γ-alumina (both 30% by weight MoS_2 on γ-alumina). Fig. 2 also illustrates the calculated equilibrium conversion efficiencies based on thermodynamic data of Kaliodas and Papayannakas.[12] It is noteworthy that for such an endothermic reaction the conversion efficiencies are relatively low and that for the conventional thermal reaction the experimental observed per-

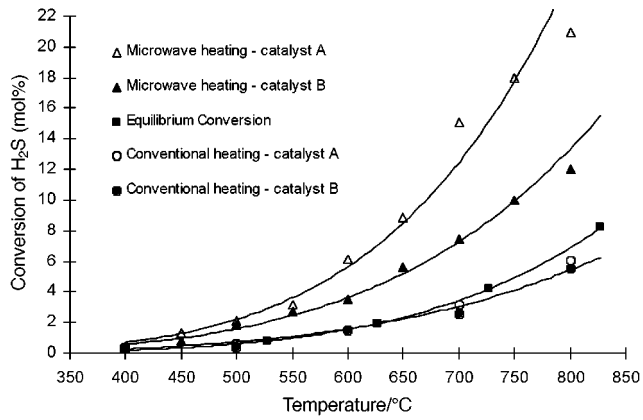

Fig. 2 H_2S conversion *vs.* temperature with mechanically mixed catalyst A and impregnated catalyst B

Table 1 Dielectric properties of the chemicals (25 °C, 2.45 GHz)

Chemical(s)	Dielectric constant, ε'	Dielectric loss, ε''	Dielectric loss tangent, tan δ
γ-Al_2O_3	2.678	0.01768	0.006604
MoS_2/γ-Al_2O_3 (impregnated)	2.971	0.2694	0.09068
$MoS_2+\gamma$-Al_2O_3 (mechanically mixed)	3.115	0.3162	0.1015
MoS_2	3.331	0.6410	0.1924

centage conversions are in good agreement with the equilibrium data. The basic reaction is given by eqn (1)

$$H_2S_{(g)} = H_{2(g)} + 1/2S_{2\,(g)} \quad (1)$$

with negligible production of other gaseous sulfur species.[12] Surprisingly, the conversion efficiency for the reaction which takes place in the microwave cavity is higher than that predicted on thermodynamic grounds. For the impregnated catalyst the percentage conversion at a temperature of 800 °C has risen from *ca*. 6.5% with conventional heating to 12% when microwaves are used. The effect is even greater for the mechanically produced catalyst, where the conversion efficiency has risen to 21% under microwave heating at 800 °C. We have concluded that these observations are not due to any athermal microwave effect, but rather that the selective features of microwave dielectric heating have induced an anisotropic temperature profile on the catalytic bed which is giving rise to 'apparent' shifts in the equilibrium constant for the reaction.

The dielectric measurements on MoS_2, the impregnated catalyst and the support materials, which are summarised in Table 1, clearly indicate that the catalysts are more 'lossy'[13] than the support materials and will initially preferentially absorb the microwave energy. The extent to which the heat is then transferred to the support has not previously been addressed. While the dielectric loss of γ-alumina is temperature dependent, particularly in the high temperature range, this temperature rise may be amplified to develop hot-spots. Such hot-spots could not only give rise to increased reaction rates, but also, if the residence times of the gases flowing over the catalyst are relatively long compared to the half-lives for the reaction, then they could create local shifts in equilibrium constant. To our knowledge attention has not been drawn previously to large equilibrium shift effects arising from this phenomenon.

We have argued that these 'apparent' equilibrium shift effects may be enhanced if the catalyst had a higher concentration of hot-spots, or had a higher temperature of hot-spots. Although, the maximum rate enhancements are achieved using a well dispersed catalyst with a high surface area, the hot-spot phenomenon is accentuated by having a poorly dispersed catalyst, such as that produced by mechanically mixing MoS_2 and γ-alumina.

Provided that the rate determining step for both forward and back reactions occurs between adsorbed species that are fully accommodated to the active catalyst temperature the equilibrium that is set-up will be characteristic of the hot-spot temperature and not the average temperature of the catalyst bed as a whole. By using this principle the hot-spot temperatures given in the second and third columns of Table 2 were calculated. The hot-spot temperatures for the impregnated and mechanically mixed catalysts are respectively *ca*. 100 and 200 °C higher than the temperature measured by the probe.

Table 2 Hot-spot temperatures calculated for impregnated catalyst and mechanical mixture of MoS_2 and γ-Al_2O_3

Probe temp./°C	Hot-spot temp./°C impregnated catalyst	Hot-spot temp./°C mechanically mixed catalyst
500	600	650
600	700	770
700	810	890
800	920	1010

X-Ray diffraction measurements on the catalyst before and after microwave heating have demonstrated some important differences compared with the parallel experiments done under thermal conditions. Firstly, some of the alumina undergoes a phase change from γ- to α-alumina—a transition which only occurs at temperatures above 1273 K.[14] It is noteworthy that the maximum average temperature recorded in the microwave experiments was 1073 K. The average crystallite size calculated from the peak widths of five intense peaks is 90 μm. Secondly, the molybdenum disulfide, which was initially evenly distributed as 150–170 μm amorphous particles (electron microscopy measurements), forms some hexagonal crystals during the microwave process. Since the melting point of MoS_2 is 1458 K, this is further evidence for the formation of hot-spots involving both the MoS_2 and the alumina support. The electron microscopy studies have also indicated that considerable migration of MoS_2 has occurred during the reaction since spheres as large as 1000 μm containing both Al_2O_3 and MoS_2 are formed. Surface area and size pore measurements have also confirmed that a considerable reorganisation has occurred and has resulted in a decrease in the surface area.

In summary, the preferential heating effects associated with microwave dielectric heating can give rise to hot-spots which result not only in rate enhancements, but also in apparent shifts in the equilibrium constant. These hot-spots probably are larger than 90 μm and may be as large as 1000 μm and have temperatures 100-200 K above that of the remainder of the bulk. The hot-spots also induce a considerable re-organisation of the catalyst under microwave conditions.

The selective nature of the dielectric heating effect cannot be reproduced easily using conventional heating methods. This phenomenon is not only interesting from an academic perspective because the results are initially counter-intuitive, but since it has the potential to increase the conversion efficiencies of reactions with low yields by an order of magnitude, whilst maintaining the same operating temperature as a conventionally heated reactor, it is not without commercial potential.

BP is thanked for endowing DMPM's Chair and EPSRC are thanked for financial support.

Bathochromic or hypsochromic effects *via* the extension of conjugation: a study of stilbenoid squaraines

Herbert Meier,* Ralf Petermann and Jürgen Gerold

Institute of Organic Chemistry, University of Mainz, Duesbergweg 10-14, D-55099 Mainz, Germany. E-mail: hmeier@mail.uni-mainz.de

Received (in Liverpool, UK) 1st February 1999, Accepted 12th April 1999

In contrast to normal conjugated oligomers, the stilbenoid squaraines 3a–d do not show a convergence of VIS/NIR absorption due to the extension of conjugation; the observed bathochromic effect in the beginning of the series is followed by a hypsochromic effect; this result seems to be characteristic for stilbenoid compounds with donor–acceptor substitution.

Due to their special chromophore, squaraines (1,3-dicondensation products of squaric acid)[1,2] not only attract theoretical interest, they are also the molecular basis for numerous applications in materials science. Electrophotography,[1] optical data storage,[3] non linear optics[4,5] and conversion of solar energy[6] should be mentioned in this context.

Recently we succeeded in the preparation of symmetrical squaraines which bear stilbenyl substituents in the 1- and 3-positions.[7] Compared to 1,3-diarylsquaraines, the extended conjugation causes a dramatic bathochromic shift of the π–π* transition at long wavelengths.[7] This finding raised the question: is it possible to increase this effect by the stepwise addition of further stilbene building blocks? For this purpose we synthesized the squaraines **3a–d**[8] (Scheme 1) which are–with the exception of **3d**—reasonably soluble in $CHCl_3$.

The condensation of the resorcinols **1a–d** with squaric acid **2** was performed at the boiling point of an azeotropic mixture of toluene and n-butanol (10 : 3). The stilbenoid components **1b–d** were generated by the Wittig–Horner reaction (Scheme 2). The substituted aniline **4** was first transformed to the aldehyde **5b** which yielded the monostilbene **7c** *via* reaction with phosphonate **6**. Formylation led to aldehyde **5c** which gave in an analogous reaction sequence *via* **7d** the higher aldehyde **5d**. The aldehydes **5b–d** were subsequently transformed *via* reaction with **8** to the stilbenoid compounds **9b–d**. Deprotection with BBr_3 yielded the dihydroxy compounds **1b–d** which served as coupling components. The starting compound **1a** was obtained by N-alkylation and subsequent ether cleavage of 3,5-dimethoxyaniline.

Many examples of conjugated oligomers show that the long wavelength absorption approaches a limiting value with

increasing number (*n*) of repeating units; we described recently this convergence behavior with the aid of exponential functions.[9] The convergence is used for the evaluation of the effective conjugation length (ECL). Surprisingly, the donor–acceptor substituted systems **3a–d** exhibit a totally different behavior. Fig. 1 demonstrates that the extension of the conjugation from **3a** to **3b** provokes a strong bathochromic effect. The shift $\Delta\lambda$ of the absorption maximum amounts to more than 250 nm and leads far into the NIR region. On going from **3b** to **3c** and finally to **3d** the λ_{max} value decreases again

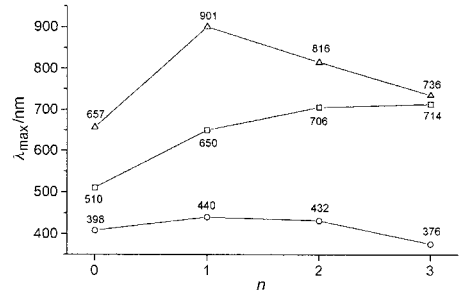

Fig. 1 Maxima of the long wavelength absorption of (△) **3a–d** (in $CHCl_3$), (□ **3a**$^+$–**d**$^+$ (in CF_3CO_2H) and (○) **10a–d** (in DMF).

Table 1 Long wavelength absorption of **3a–d** in $CHCl_3$

3	$\tilde{\nu}_{max}$/cm^{-1}	log ε	S/cm mol^{-1}
a	15221	5.602	2.42×10^8
b	11099	5.301	3.47×10^8
c	12255	5.041	3.62×10^8
d	13587	[a]	[a]

[a] The extremely low solubility of **3d** in $CHCl_3$ at ambient temperature does not permit an exact evaluation of ε and S; the limit of error for S of **3a–c** is ±5%.

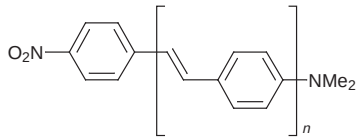
by 85 and 80 nm, respectively. Obviously the extended conjugation causes the hypsochromic effect. The intense absorption bands broaden in the series from **3a** (n = 0) to **3d** (n = 3). The absorption intensity S increases with growing extension of the chromophore (Table 1).

In order to judge whether this behavior is general or not in the series of push-pull substituted stilbenoid compounds, we made a comparison with the known compounds **10a–d**. Fig. 1 proves the principally analogous behavior of this series. However, the shifts $\Delta\lambda$[10] are considerably smaller than in the series **3a–d**. Probably the effect was not earlier detected due to the fact that the compounds **10a–d** were prepared by different groups.[11–13]



10a n = 0
b n = 1
c n = 2
d n = 3

The analysis of **3a–d** in TFA leads to the result normally observed for conjugated oligomers, namely to a monotonic increase of λ_{max} with growing number n. Protonation takes place at the terminal amino groups as ^{13}C NMR measurements prove (Scheme 3). Thus the donor–acceptor–donor character of **3a–d** is lost. The protonated series resembles the unsymmetrical cyanine and the protonated merocyanine dyes.[14,15]

Conjugation with delocalisation of charge can also be assessed *via* the ^{13}C NMR data. Table 2 shows a comparison of **3b** with its components **1b** and **2** (the correlation of the signals is based on normal and long-range ^{1}H,–^{13}C COSY measurements).

The $\Delta\delta$ values in Table 2 prove the low-field shift in the stilbene unit caused by bonding to the squaric acid. Besides the substitution position c, the alternating sequence d, f, h, j and l of carbon atoms is mainly affected. The central squaric acid unit induces positive partial charges in these positions. The protonation (deuteriation) on the nitrogen atom cancels the push-pull effect and causes strong low-field shifts, especially in the aniline building block. The $\Delta\delta'$ values indicate the differences in the chemical shifts between **3b** and **3b**$^+$.

In conclusion, the extension of the conjugation of chromophores does not always induce a bathochromic shift of the absorption. In a series of push-pull substituted systems like **3a–d** the initial strong red-shift is replaced for higher systems by a blue-shift. The distance between the donor and the acceptor groups has a decisive influence on the charge transfer transition.[16] We explain this using quinoid resonance structures, which become energetically unfavorable with growing number n, since more and more benzene rings are displaced by p-quinone rings (Scheme 3). Obviously this effect is contrary to the normal effect due to extension of conjugation; thus, a maximum of the bathochromic shift is observed in the series **3a–d**. The quantum chemical treatment[17] [MNDO and CNDO/S (S + DES CI)] of the electron transitions $S_0 \rightarrow S_1$ in squaraines localizes the charge transfer almost completely in the four-membered ring. The strong influence of the stilbene building blocks proves that this result is not valid; nevertheless, the squaraine chromophore remains a challenge for theoreticians.

$Ln_2Ti_2S_2O_5$ (Ln = Nd, Pr, Sm): a novel series of defective Ruddlesden–Popper phases

M. Goga, R. Seshadri, V. Ksenofontov, P. Gütlich and W. Tremel*

Institut für Anorganische Chemie und Analytische Chemie der Universität Mainz, Becherweg 24, D-55099 Mainz, Germany. E-mail: tremel@indigotrem1.chemie.uni-mainz.de

Received (in Cambridge, UK) 15th December 1998, Accepted 10th March 1999

The reaction of Nd_2S_2O, TiS_2 and S at 1000 °C and subsequent chemical transport with I_2 yields the new crystalline layered oxysulfide $Nd_2Ti_2S_2O_5$ that possesses a defective $Sr_3Ti_2O_7$ structure whose cuboctahedral sites within the double-perovskite layers are empty; $Nd_2Ti_2S_2O_5$ is paramagnetic and semiconducting; the synthesis of the isostructural compounds $Pr_2Ti_2S_2O_5$ and $Sm_2Ti_2S_2O_5$ is also reported.

Layered materials represent an active area of research owing to their interesting physical properties that include superconductivity[1] and charge density waves.[2] Important groups of layered compounds are bronzes $A_xM_yO_z$ (A = alkali, alkaline earth metals, lanthanides; M = Ti, V, Nb, Mo)[3] or early transition metal chalcogenides.[4] Surprisingly, chalcogenide analogues of bronzes are unknown; partial replacement of oxygen by chalcogen atoms leads to metal oxychalcogenides, a family of compounds that have received comparatively little attention so far. A number of rare-earth representatives have been reported, the simplest of them having compositions M_2O_2Q or $M_2O_2(Q_2)$ and $M_4O_4Q(Q_2)$ (Q = S, Se).[5] Most of them crystallize in layer structures where the oxide and chalcogenide ions form individual layers. We are generally interested in metallic layered materials close to the metal–semiconductor boundary that are composed of transition-metal oxide and/or transition-metal chalcogenide layers, where one of the components can act as a charge reservoir and the second electronically active component dictates the physical properties.[6] There is both experimental and theoretical evidence that a combination of the electronic properties of the individual layers may lead to materials with interesting electronic and magnetic properties;[7] therefore, a structural integration of these two types of layers represents a promising route to new electronic materials. The key problem in the design of new layered oxychalcogenides/oxypnictides is to achieve a large enough difference in the oxophilicity and chalcophilicity of the layer components that one metal is bonded to only one anion type and segregated layers (or stacks) with partial charge transfer are obtained. A combination of two metals with too similar oxo/chalcophilicity often leads to phase separation and the formation of ternary oxide and chalcogenide phases.

In the quest for new compounds with these properties we have investigated the quaternary Ln–M–O–Q phase systems (M = Ti, Nb, Mo, Mn, Fe; Q = S, Se); among others, we obtained the new layer compound $Nd_2Ti_2S_2O_5$ **1** whose synthesis, structure and properties are reported here. **1** was made by heating Nd_2S_2O, TiS_2 and S in a 1 : 1 : 1 ratio at 1000 °C. Single phase material was prepared using the following procedure: Nd_2S_2O, TiS_2 and S were mixed in a ratio 1 : 1 : 1, sealed in an evacuated quartz tube and fired at 1000 °C for one week. The corresponding Pr compound, $Pr_2Ti_2S_2O_5$ **2**, may be synthesized from the starting materials Pr_6O_{11}, TiS_2, Ti and S in a 1 : 2 : 2 : 3 ratio, $Sm_2Ti_2S_2O_5$ **3** was obtained by heating a 1 : 1 : 1 mixture of Sm_2O_3, TiO_2 and TiS_2 at 1000 °C for 1 week in a sealed quartz tube. The resulting powders are contaminated with small amounts of TiS_2 and rare earth oxysulfides. Single crystals of **1**–**3** were grown from the resulting powders by chemical transport (950 → 850 °C, 4 weeks) using iodine (3 mg cm^{-3}) as a transport agent. Red rectangular crystals of **1**, reddish brown crystals of **2** and brown–yellow platelets of **3** formed at the cold end of the tube.

A microprobe analysis by energy dispersive X-ray spectroscopy (EDX) performed in a Zeiss DSM 962/Philipps PSEM 500 scanning electron microscope (accelerating voltage 20 kV, accumulation time 1 min) equipped with a KEVEX energy dispersive spectroscopy detector indicated the presence of the elements Nd (Pr, Sm), Ti, S and O in an approximate 1 : 1 : 1 : 2 ratio in satisfactory agreement with the results of the structure determination.† The parent compouund $Nd_2Ti_2S_2O_5$ (Fig. 1) crystallizes in a defect Ruddlesden–Popper structure $Nd_2Ti_2(Q)_7$ of the $Sr_3Ti_2O_7$ type[8] and is structurally closely related to the high-T_c superconductors of the $La_2CaCu_2O_6$ type.[9] It is characterized by distorted double NdS rocksalt layers and defective double perovskite $Ti_2O_{10/2}S_2$ (=$Ti_2S_2O_5$) blocks intergrown along the *c* axis of the lattice. The perovskite $TiSO_2$ blocks contain the $TiSO_2$ octahedra linked at their corners with the twelve-coordinate site being empty. The Nd atoms in the NdS layers are eight-coordinate. The Nd–S bond length of 3.022(2) Å parallel to the *c* axis is significantly longer than the Nd–S distances of 2.855(1) Å in the *ab* plane. Furthermore, the Ti–S bond which is proximal to the NdS layer is, at 2.896(3) Å, extremely elongated and much longer than a typical Ti–S bond length, whereas the opposite Ti–O distance of 1.790(2) Å indicates significant double bond character and points to an effective 5 + 1 coordination of Ti. The Ti–O bond distances of 1.975(1) Å in the *ab* plane are in the expected distance range.

The magnetic behavior of **1** is determined by the f^3 configuration of the Nd atoms. The results of temperature dependent magnetic susceptibility measurements (Fig. 2) are

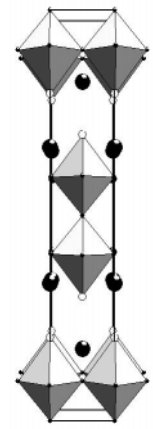

Fig. 1 Polyhedral view of the $Ln_2Ti_2S_2O_5$ structure along the *b* axis. The polyhedra represent the $TiSO_5$, large black circles the Ln atoms, open circles the S atoms, and small black circles the O atoms (selected distances [Å]: (Ln = Nd, Pr, Sm): Ln–O 2.496(3), 2.505(4), 2.474(3); Ln–S 2.855(1), 2.869(1), 2.834(1); 3.022(2), 3.025(3), 2.986(2), Ti–O(1) 1.975(2), 1.983(1), 1.961(1); Ti–O(2) 1.790(2), 1.796(2), 1.790(1); Ti–S 2.896(3), 2.881(3), 2.887(2)).

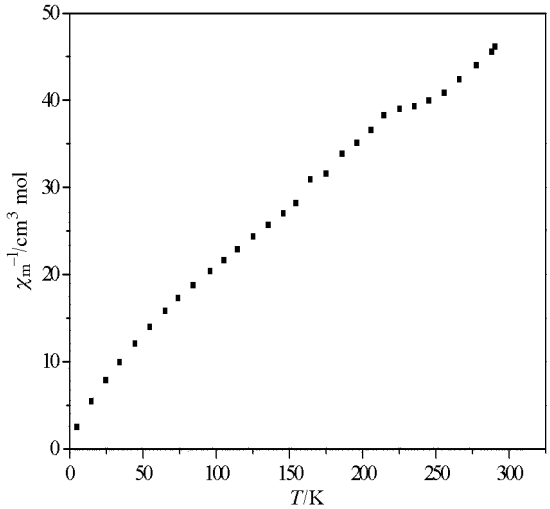

Fig. 2 Magnetic susceptibility χ_M *vs.* temperature plot for $Nd_2Ti_2S_2O_5$.

compatible with antiferromagnetically coupled Nd^{3+} centers with f^3 configuration as apparent from a room temperature magnetic moment of 10.04 μ_B (compared to a theoretical value of 14.48 μ_B for four independent Nd^{3+} centers). Above 260 K and below 175 K Curie–Weiss-type behavior is observed. The red color of $Nd_2Ti_2S_2O_5$ points to semiconducting behavior. This is in agreement with the results of LMTO-ASA calculations. The optical (diffuse reflectance) spectrum is characterized by a number of narrow bands that fall into the energy gap of 1.82 eV and can be assigned to transitions from the $^4I_{9/2}$ ground state to the excited $^4I_{11/2}$ $^4I_{13/2}$ $^4I_{15/2}$ (or $^4G_{5/2}$, $^4G_{7/2}$, $^2K_{13/2}$) states of the Nd^{3+} chromophore. The gap between filled and empty states in the LMTO-DOS is in reasonable agreement with the measured optical band gap obtained from the diffuse reflectance spectrum. In a similar fashion, it is possible to rationalize the diffuse reflectance spectra of **2** ($^3H_4$ ground state) and **3** ($^6H_{5/2}$ ground state).

The title compounds have several intriguing features, which are currently explored synthetically: (i) the R–P phases are the compounds for many high T_c superconductors and the layered manganites $Ln_{3-x}Sr_xMn_2O_7$[10] that exhibit large negative magnetoresistance effects. (ii) A series of presumably isostructural defective R–P phases $Ln_2Ti_2O_7$ (Ln = La, Nd, Sm, Gd) was reported recently by Gopalakrishnan and coworkers.[11] The materials were prepared by topotactic dehydration of $HLnTiO_4$[12] and considered metastable whereas the title compound was obtained from a high temperature reaction and should be therefore a thermodynamically stable phase. (iii) The replacement of oxide by *sulfide ions in the LnS layers* is counterintuitive as Ln is more chalcophilic than titanium. The sulfur substitution pattern can be rationalized by the amount of space accessible to the sulfide (compared to the oxide) anions through the less dense packing in the interlayer region. (iv) Electronic variation of the title compounds might be possible by cation intercalation into the unfilled voids in the LnS slab or metal substitution (*e.g.* group 5 metals for Ti).

We are indebted to the Bundesministerium für Forschung und Technologie (contract number DLR-2A523370-03N1023C1) and the Fonds der Chemischen Industrie for the financial support of this research and to Heraeus Quarzschmelze (Dr Höfer) for the donation of quartz tubes.

Total synthesis of a keramamide

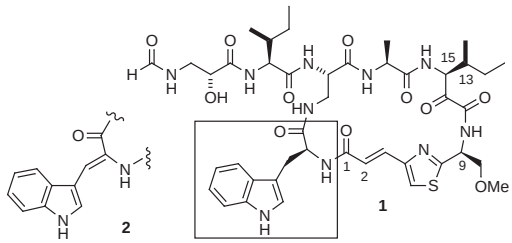
Jennifer A. Sowinski and Peter L. Toogood*

Willard H. Dow Laboratory, Department of Chemistry, University of Michigan, Ann Arbor, MI 48109-1055, USA. E-mail: peter.toogood@wl.com

Received (in Corvallis, OR, USA) 3rd March 1999, Accepted 15th April 1999

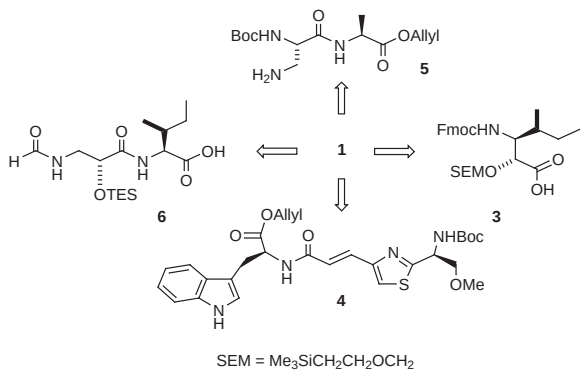
The first total synthesis of a molecule possessing the structure proposed for keramamide J is described, providing data indicating that the structure of this natural product should be re-examined.

Keramamide J (KJ; **1**)[1] is the simplest member of a class of *Theonella* natural products that collectively exhibit cytotoxic,[1–3] anti-fungal[4] and anti-oxidant activity.[5] To study the biological activities of these molecules, we required a general synthetic route that would be amenable to the synthesis of all members of this series.[4] Herein, we report our progress towards this goal, including the first total synthesis of a keramamide possessing structure **1**.



Our synthetic plan for constructing KJ is shown in Scheme 1.[6] A convergent route was devised, employing four fragments of comparable complexity (**3**–**6**). We decided to mask the electrophilic keto-amide moiety[7] as a protected α-hydroxy carbonyl group until the conclusion of the synthesis to avoid nucleophilic attack at this center. In addition, we elected to attempt ring closure between the amine of fragment **3** and the C-terminus of the alanine residue, which was anticipated to be less prone to epimerization than the tryptophan residue and easier to couple than the α-hydroxy acid. Late incorporation of side chain fragment **6** was selected to increase convergency and minimize potential side reactions during the critical macrocyclization reaction.

Thiazole **7**[8] was extended *via* reduction of the ester to an aldehyde and Wittig olefination to introduce the *E*-double bond (Scheme 2). Saponification of the ethyl ester, followed by coupling to L-tryptophan allyl ester provided fragment **4**. To obtain the hexanoic acid fragment **3**, enone **9** (Scheme 3) was



SEM = $Me_3SiCH_2CH_2OCH_2$

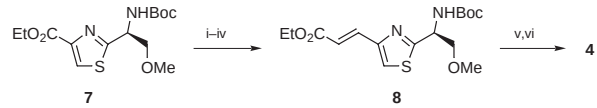
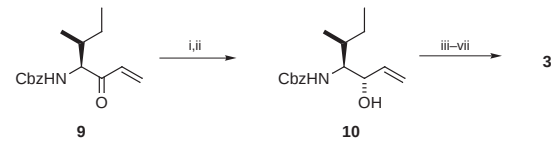


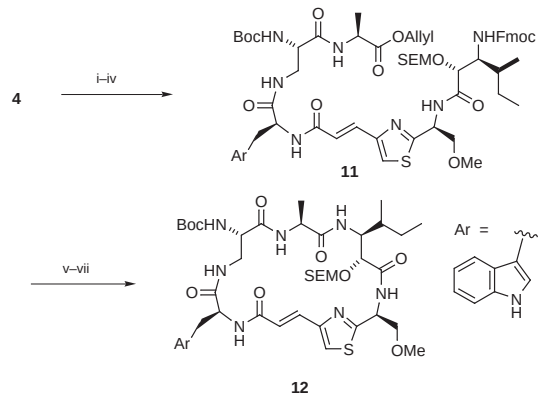
Scheme 2 *Reagents and conditions*: i, NaOH, MeOH; ii, BOP, Et_3N, HN(Me)OMe; iii, $LiAlH_4$; iv, $Ph_3P{=}CHCO_2Et$ (70% for 4 steps); v, NaOH, MeOH; vi, L-Trp-OAllyl, Ph_2POCl (68% for 2 steps).



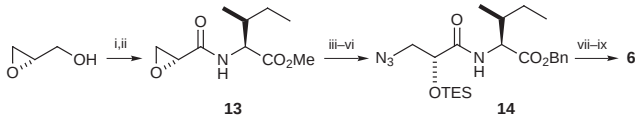
Scheme 3 *Reagents and conditions*: i, $NaBH_4$, $CeCl_3$; ii, separate (76% for 2 steps); iii, SEMCl, 2,6-lutidine; iv, O_3, DMS; v, $NaClO_2$, isobutene; vi, H_2, Pd/C; vii, FmocOSu, aq. $NaHCO_3$ (66% for 5 steps).

prepared from L-isoleucine *via* displacement of the corresponding Weinreb amide with vinyl magnesium bromide. Reduction of this enone with $NaBH_4$ under the Luche conditions[9] provided a 4 : 1 mixture of alcohols which could be separated by column chromatography. Protection of the major product (**10**)[10] as its (trimethylsilyl)ethoxymethyl (SEM) acetal, followed by a two step oxidation of the double bond, provided the carboxylic acid. Hydrogenolytic cleavage of the Cbz group and subsequent treatment with FmocOSu† gave compound **3**. Deprotection of fragment **4**, followed by condensation with acid **3**, gave the corresponding tripeptide in 77% yield (Scheme 4). Subsequent cleavage of the allyl ester and coupling to dipeptide **5** gave linear precursor to the KJ macrocycle **11**. Following deprotection of the C-terminus, and removal of the Fmoc group under standard conditions, macrocyclization proceeded smoothly to provide cyclic peptide **12** in 34–51% overall yields from intermediate **11**.

To prepare the KJ side chain, (*S*)-glycidol was oxidized to glycidic acid using $RuCl_3$ and $NaIO_4$,[11] then coupled with L-isoleucine methyl ester to give peptide **13** as a single diastereomer (Scheme 5). Attack of the oxirane by azide ion at



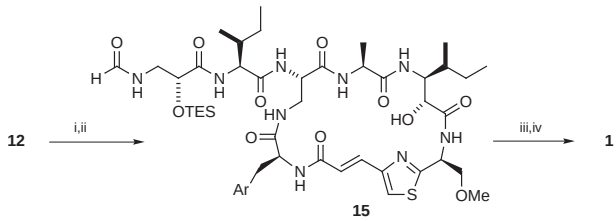
Scheme 4 *Reagents and conditions*: i, HCl, Et_2O; ii, **3**, DCC, HOBt, Pr^i_2EtN; iii, $Pd(PPh_3)_4$, dimedone; iv, **5**, DCC, HOBt, Pr^i_2EtN (56% for 4 steps); v, $Pd(PPh_3)_4$, dimedone; vi, Et_2NH; vii, $(PhO)_2PON_3$, $NaHCO_3$ (51% over 3 steps).



Scheme 5 *Reagents and conditions*: i, $RuCl_3$, $NaIO_4$; ii, L-Ile-OMe, DCC, HOBt (36% for 2 steps); iii, NaN_3, $MgSO_4$; iv, LiOH; v, $CsCO_3$, BnBr; vi, TESCl, imidazole (48% for 4 steps); vii, PPh_3, H_2O; viii, *p*-$O_2NC_6H_4$-OCHO; ix, H_2, Pd/C (79% for 3 steps).

the less substituted position, followed by transesterification and protection of the hydroxy function produced azido peptide **14**. Staudinger reduction of the azide to a primary amine,[12] followed by formylation with *p*-nitrophenyl formate and hydrogenolytic cleavage of the ester, provided fragment **6**.

Treatment of macrocycle **12** with HCl in Et_2O–MeOH–$CHCl_3$ deprotected the amine and secondary alcohol, and fragment **6** was attached using HATU† to produce alcohol **15** (Scheme 6).[13] Oxidation of the alcohol was performed under mild, non-acid conditions, using IBX† in DMSO.[14] Finally, removal of the TES group was achieved by stirring the peptide over Amberlite IR-120 suspended in EtOAc. Purification of the final product by silica gel chromatography followed by reversed-phase HPLC provided material that exhibits ^1H, ^{13}C, ^1H-^1H COSY and inverse detected ^1H–^{13}C HMQC NMR spectra consistent with the proposed structure **1**, and a high resolution mass spectrum corresponding to the expected molecular formula.



Scheme 6 *Reagents and conditions*: i, HCl, MeOH; ii, **6**, HATU, 2,4,6-collidine (48% for 2 steps); iii, IBX, DMSO; iv, Amberlite IR-120 (95% for 2 steps).

From the NMR data, it is apparent that our synthetic keramamide is not the same compound reported by Kobayashi and co-workers.[1,15] Comparison of the NMR spectra leads us to conclude that this synthetic keramamide and KJ are configurational isomers. In support of the assignment of structure **1** to the synthetic product, a very close correlation is observed between the spectral data for this compound and the data published for KF (**2**; Table 1), which differs only in the replacement of the tryptophan in structure **1** by *Z*-didehydrotryptophan. In particular, the ^1H and ^{13}C chemical shifts at C-9 and C-13 for these two compounds are in excellent agreement (^1H $\Delta\delta \leqslant 0.06$, ^{13}C $\Delta\delta \leqslant 1.3$ ppm). In contrast, the published data for KJ more closely resemble the data for keramamide G (KG) which is epimeric to KF at carbon-13.[1,16] We note that the degradation conditions used by Kobayashi to determine the absolute configuration at carbon-13 in KJ have been found previously to cause epimerization at this center in a closely related molecule and possibly could have been misleading.[3] Degradation of the synthetic keramamide under milder conditions using 30% H_2O_2 and 0.1 M NaOH (room temperature, overnight), followed by 6 M HCl (110 °C, 24 h), produced L-isoleucine containing less than 10% D-*allo*-isoleucine by chiral HPLC analysis, supporting assignment of the L-configuration to carbon-13 in the synthetic material.[17] Upon standing in aqueous solution, the synthetic material partially converted (~ 10%) to a new product possessing ^1H NMR resonances that match those observed for KJ, consistent with the notion that these two molecules differ at a single, epimerizable center.

Table 1 Selected ^1H and ^{13}C NMR resonances, and optical rotations published for keramamides F, G, J and observed for compound **1**

	δ_H		δ_C		
	H-9	H-13	C-9	C-13	$[\alpha]_D^{25}$ [a]
Keramamide G	4.81	5.49	53.7	56.7	+10.0
Keramamide J	4.75	5.49	53.7	56.1	+8.4
Compound **1**	5.31	5.19	51.4	61.0	−10.0
Keramamide F	5.33	5.25	51.7	59.7	−25

[a] Given in units of 10^{-1} degrees cm^2 g^{-1}.

Based on the preceding analysis, we conclude that our synthesis proceeded as intended to correctly provide a molecule possessing structure **1**. This work strongly indicates that the structure of KJ should be revised. However, since no natural KJ is presently available,[15] structural re-assignment will require either re-isolation or total synthesis of the correct structure.

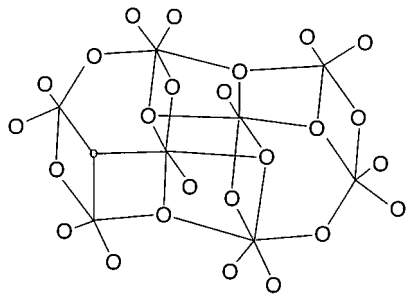
Received (in Cambridge, UK) 25th January 1999, Accepted 19th April 1999

Two new metal–oxo supported transition metal complexes, $[\{M(phen)_2\}_2(Mo_8O_{26})]$ (M = Ni or Co; phen = 1,10-phenanthroline) are synthesized by a hydrothermal method and characterized by X-ray crystallography, showing that the octamolybdate possesses a novel unprecedented structure and that $[M(phen)_2]^{2+}$ units are covalently bonded to the $[Mo_8O_{26}]^{4-}$ cluster.

Metal–oxo cluster chemistry has been actively purchased owing to interest in the chemistry itself and its various applications in fields such as catalysis, electric conductivity, magnetism, nonlinear optical properties and medicine.[1] Recently, an important advance in metal oxide cluster chemistry has been study of polyoxoanion-supported inorganic or organometallic complexes. The syntheses and structures of complexes include $[\{Cu(4,4'\text{-bipy})\}_4(Mo_8O_{26})]$,[2] and $[\{Cu(en)_2\}_2(Mo_8O_{26})]$,[3] which possess infinite extended structures, $[\{Zn(2,2'\text{-bipy})_2\}_2(V_4O_{12})]$[4] and $[La(Mo_8O_{26})_2]^{5-}$,[5] which are molecular clusters; and organometallic compounds $[(CO)_3Mn(cis\text{-}Nb_2W_4O_{19})]^{3-}$,[6] and $[\{(\eta\text{-}C_5Me_5)Rh\}(Mo_{13}O_{40})]^{2+}$,[6] which have discrete cluster structures.

We report here the syntheses and characterization of octamolybdate-supported nickel– and cobalt–phenanthroline molecular clusters $[\{Ni(phen)_2\}_2(Mo_8O_{26})]$ **1** and $[\{Co(phen)_2\}_2(Mo_8O_{26})]$ **2**. To date, α-, β- and γ- isomers of octamolybdates have been crystallographically confirmed in several salts, and recently the δ-isomer in $[(\eta\text{-}C_5Me_5Rh)_2(\mu_2\text{-}SMe)_3]_4[Mo_8O_{26}]\cdot 2MeCN$[8] and $[\{Cu(4,4'\text{-bipy})\}_4(Mo_8O_{26})]$,[2] and ε-isomer in $[\{Ni(H_2O)_2(4,4'\text{-bipy})_2\}_2(Mo_8O_{26})]$[2] have also been characterized. The results of structure determination upon $[Mo_8O_{26}]^{4-}$ in both **1** and **2** indicates a novel unprecedented ξ-isomer structural form (Scheme1).

Compounds **1** and **2** were prepared hydrothermally from a mixture of MoO_3, H_2MoO_4, $Ni(OAc)_2\cdot 6H_2O$, 1,10-phenanthroline and H_2O in a mol ratio of 1.0: 1.0: 0.8: 1.6: 450, heated at 170 °C for three days. Purple block crystals of **1** were obtained in *ca*. 35% yield. While bright red tetragonal prismatic crystals of **2** were obtained under the same reaction conditions using $Co(OAc)_2\cdot 4H_2O$. Compounds **1** and **2** were characterized by elemental analyses,† spectroscopic (IR and UV-VIS)‡ and single-crystal X-ray structure analyses.§



Scheme 1 The structure of ξ-$[Mo_8O_{26}]^{4-}$.

The crystal of **1** consists of discrete centrosymmetric heterometallic decanuclear clusters $[\{Ni(phen)_2\}_2(Mo_8O_{26})]$ (Fig. 1). The octamolybdate anion in **1** has a novel unprecedented structure mode denoted ξ- $[Mo_8O_{26}]^{4-}$ composed of a Mo_6O_6 ring capped on opposite faces by MoO_6 octahedra. The characteristic feature of this isomer is that the Mo_6O_6 ring contains two octahedral and four trigonal-bipyramidal Mo^{VI} atoms. In the ring, the linkage between any two MoO_5 trigonal bipyramids is edge-shared, while that between any MoO_6 octahedron and MoO_5 trigonal bipyramid is corner-shared. Each capping MoO_6 octahedron is linked to two MoO_6 octahedra and a trigonal bipyramid in the Mo_6O_6 ring by edge sharing and to another MoO_5 trigonal bipyramid of the ring by corner sharing. Two capping MoO_6 octahedra are attached to each other by edge sharing. The structural features of ξ-$[Mo_8O_{26}]^{4-}$ in **1** are different from those of the α-isomer consisting of six MoO_6 octahedra and two MoO_4 tetrahedra, the β-isomer consisting of eight edge-shared MoO_6 octahedra, the γ-isomer having six MoO_6 octahedra and two MoO_5 trigonal bipyramids, the δ-isomer composed of four MoO_6 octahedra and four MoO_4 tetrahedra[2,8] and the ε-isomer composed of six MoO_5 square pyramids and two MoO_6 octahedra.[2] The structure of the ξ- isomer also differs from that of (α–γ)- or (β–γ)-isomers proposed by Klemperer and Shum,[9] which, as yet has not been synthesized. Although the structure of proposed (α–γ)- or (β–γ)- isomers is also composed of four MoO_6 octahedra and four trigonal bipyramids as found in the ξ-isomer, their arrangement these isomers are different. In (α–γ)- or (β–γ)- isomers, the Mo_6O_6 ring contains four octahedral and two trigonal-bipyramidal Mo^{VI} atoms, and there are two edge-

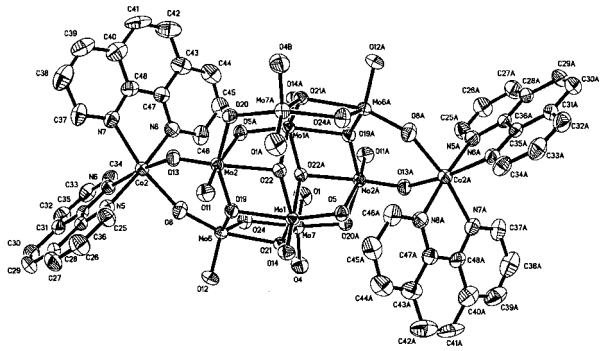

Fig. 2 Perspective drawing of one of the two crystallographically independent [{Co(phen)$_2$}$_2$(Mo$_8$O$_{26}$)] molecules in **2** (50% displacement ellipsoids). Symmetry code: i $-x + 2$, $-y + 2$, $-z$. Selected bond lengths (Å): Mo(1)–O(14) 1.688(3), Mo(1)–O(5) 1.740(3), Mo(1)–O(19) 2.190(3), Mo(1)–O(21) 1.897(3), Mo(1)–O(22) 1.911(3), Mo(1)–O(22^i) 2.504(3), Mo(2)–O(11) 1.688(3), Mo(2)–O(13) 1.736(3), Mo(2)–O(20) 1.866(3), Mo(2)–O(5^i) 2.337(3), Mo(2)–O(19) 2.024(3), Mo(2)–O(22) 2.149(3), Mo(6)–O(12) 1.696(3), Mo(6)–O(8) 1.733(3), Mo(6)–O(24) 1.831(4), Mo(6)–O(19) 1.900(3), Mo(6)–O(21) 2.236(3), Mo(7)–O(4) 1.693(4), Mo(7)–O(1) 1.685(4), Mo(7)–O(20^i) 1.947(3), Mo(7)–O(24) 2.002(4), Mo(7)–O(21) 2.159(3), Co(2)–O(8) 2.092(4), Co(2)–O(13) 2.107(4) (bond lengths in the other independent molecule are very close to the corresponding bonds above).

shared MoO_5 trigonal bipyramids in the cavity enclosed by polyhedra in the ring. More specifically, ξ-[Mo$_8$O$_{26}$]$^{4-}$ contains six O(μ_3), six O(μ_2) and fourteen O(t) atoms, while (α–γ)- or (β–γ)-[Mo$_8$O$_{26}$]$^{4-}$ contain two O(μ_4), two O(μ_3), eight O(μ_2) and fourteen O(t) atoms.

Each ξ-[Mo$_8$O$_{26}$]$^{4-}$ unit forms strong covalent interactions to two [Ni(phen)$_2$]$^{2+}$ units through terminal oxo groups of octahedral and trigonal-bipyramidal Mo sites in the Mo_6O_6 ring with Ni–O distances of 2.071(9) and 2.080(9) Å. Since the terminal oxo groups of fully oxidized polyoxomolybdate (all Mo sites in the VI oxidation state) are non-basic and unreactive, the formation of **1** reveals the oxophilicity of the [Ni(phen)$_2$]$^{2+}$ group and the structural flexibility of the octamolybdate core in adopting the ξ-structure. In the [Ni(phen)$_2$]$^{2-}$ unit, Ni is coordinated to four N donors of 1,10-phenanthroline ligands besides two terminal oxygen atoms of the octamolybdate cluster, forming a distorted octahedron with one relatively long Ni–N distance of 2.094(12) Å and three Ni–N distances in the range 2.055–2.065 Å. Compound **1** has three kinds of Mo–O bonds: 1.685(10)–1.711(11) Å for Mo–O(t), 1.731(9)–2.341(10) Å for Mo–O(μ_2) and 1.892(8)–2.244(8) Å for Mo–O(μ_3) bonds, respectively. The average Mo–O bond lengths of Mo(2), Mo(3) and Mo(4) are very similar (1.877–1.903 Å) whereas for Mo(1) Ni(phen)$_2$ this is longer (1.975 Å). It is found for Mo(2), Mo(3) and Mo(4) sites that Mo–O distances increase with increasing coordination number of oxygen (*i.e.* one < two < three), only for the Mo(1) site is this trend is not completely met, with Mo(1)–O(11)(μ_2)[2.341(10) Å] being obviously longer than Mo(1)–O(4)(μ_3) [2.042(8) Å] and Mo(1)–O(10) (μ_3)[2.146(8) Å], respectively.

There are two crystallographically independent [{Co(phen)$_2$}$_2$(Mo$_8$O$_{26}$)] molecules (Fig. 2) in the unit cell of **2** and both possess rigorous C_i symmetry in the solid state: their non-hydrogen atoms are symmetrically disposed about crystallographic inversion centers at (0,0,0) and (−1/2,1/2,−1/2), respectively. Both molecules contain a ξ-[Mo$_8$O$_{26}$]$^{4-}$ unit, with Mo–O(t) in the range 1.685(3)–1.696(3) Å [1.673(4)–1.690(4) Å second molecule]; Mo–O(μ_2) 1.733(3)–2.337(3) Å [1.734(3)–2.329(3) Å] and Mo–O(μ_3)1.897(3)–2.504(3) Å [1.903(3)–2.493(3) Å]. Average Mo–O bond lengths in molybdenum coordination polyhedra are as follows: for Mo atoms with coordination number of six, Mo(1)–O = 1.988 Å (av.) and Mo(2)–O = 1.967 Å (av.) [Mo(3)–O = 1.989 Å (av.) and Mo(4)–O = 1.964 Å (av)]; for Mo atoms with a coordination number of five, Mo(6)–O = 1.879 Å (av) and Mo(7)–O = 1.897 Å (av.) [Mo(5)–O = 1.881 Å (av.) and Mo(8)–O = 1.893 Å (av.)]. Thus average Mo–O bond lengths in five- and six-coordinated molybdenum polyhedra are very similar but the latter are significantly longer.

Palladium(II)-catalyzed oxidation of acrylate esters to acetals in supercritical carbon dioxide

Lanqi Jia, Huanfeng Jiang* and Jinheng Li

Guangzhou Institute of Chemistry, Chinese Academy of Sciences, PO Box 1122, Guangzhou 510650, China. E-mail: jhf@mail.gic.ac.cn

Received (in Cambridge, UK) 11th March 1999, Accepted 20th April 1999

The development of a new palladium(II)-catalyzed oxidation of methyl acrylate, affording methyl 3,3-dimethoxypropanoate in excellent conversion and selectivity in supercritical CO_2, is presented.

Alkyl 3,3-dialkoxypropanoates are important intermediates in organic synthesis and have been used to synthesize a variety of compounds, including coumarins,[1] porphyrins,[2] spermine metabolites[3] and loganin.[4] Previously reported methods for the preparation of alkyl 3,3-dialkoxypropanoates are not satisfactory, due to the high cost of the starting materials and the low overall yields of the process. The Pd^{II}-catalyzed oxidation of terminal olefins with water, which is well known as the Wacker reaction, produces methyl ketones.[5] A similar reaction of terminal olefins bearing electron-withdrawing groups upon treatment of alcohols catalyzed by Pd^{II} affords acetals at the terminal carbon in DME. High yields of methyl 3,3-dimethoxypropanoate (92%), however, were afforded only in the presence of HMPA. In the absence of HMPA the yield was only 46%.[6]

Using supercritical carbon dioxide ($scCO_2$) as a reaction solvent has been attracting extensive attention in recent years. First, CO_2 is inexpensive, nonflammable, nontoxic[7] and chemically inert under many conditions. $ScCO_2$, as an environmentally friendly reaction medium, may be a substitute for volatile and toxic organic solvents.[8] Secondly, $scCO_2$ possesses hybrid properties of both liquid and gas, to the advantage of some reactions involving gaseous reagents.[9] Control of the solvent density by variation of the temperature and pressure enables the solvent properties to be 'tuned' to reactants.[10] Finally, separating of CO_2 from the reaction mixture is energy-efficient and simple.

Organic reactions in $scCO_2$ have facilitated great progress in organometallic chemistry, particularly in homogeneous and heterogeneous catalysis. Several recent reports have shown that some interesting results are specifically associated with the use of $scCO_2$ as a reaction solvent.[11] Here we disclose our work on a Pd^{II}-catalyzed terminal olefin oxidation in $scCO_2$.‡ Our results show that Pd^{II}-catalyzed oxidation of methyl acrylate could be successfully processed in $scCO_2$ to give the dimethyl acetal as major product when an excess of MeOH was used (Scheme 1). Our previous experiments show that it is necessary to add an excess of MeOH to promote partial dissolution of the inorganic catalysts in $scCO_2$, since MeOH is miscible in $scCO_2$.[12]

The catalytic activity of $PdCl_2$ and $PdCl_2(MeCN)_2$ for oxidation of methyl acrylate were investigated. The reaction catalyzed by $PdCl_2$ were slightly faster than that by $PdCl_2(MeCN)_2$ (Table 1, entries 2 and 3).

It has been reported that CuCl was superior to $CuCl_2$ as the cocatalyst in the oxidation of acrylate esters.[13,6b] Interestingly, in our experiments carried out in $scCO_2$, 0.4 equiv. of $CuCl_2$ gave similar or even better results than the same amount of CuCl (Table 1, entries 8 and 9).

Hosokawa reported that the oxidation of methyl acrylate to the acetal was carried out at 50 °C in DME.[6] We found that the oxidation reaction could be completed at a lower temperature in $scCO_2$. In our experiment, the reaction afforded very good conversion and selectivity at 40 °C. The reaction was still smoothly accomplished at 27 °C, at which temperature CO_2 is a liquid, although the amount of byproducts increased slightly.

The CO_2 pressure had a great effect on the selectivity. The best results were obtained when the pressure of CO_2 was controlled between 12–13 MPa. As the pressure of CO_2 was reduced, the conversion and selectivity also declined. For example, the reaction gave **2** in a yield of only 75.8% and the

[a] Methyl acrylate (5 mmol), MeOH (1 ml ≈ 24.7 mmol), $PdCl_2$ or $PdCl_2(MeCN)_2$ (3 mol%), CuCl or $CuCl_2$ (0.4 equiv.), 12 h. [b] By GC. [c] Selectivity = [**2**/(**2** + **3** + **4**)] × 100. [d] $PdCl_2(MeCN)_2$ (1 mol%), CuCl or $CuCl_2$ (2 mol%). [e] $CuCl_2$ (2 mol%).

amount of other unidentified products increased when 9 MPa CO_2 was charged in the autoclave.

The oxygen pressure also affected the conversion and selectivity. Lower oxygen pressure (0.1 MPa) gave satisfactory conversion but the selectivity to **2** was never higher than 93.4%. The best selectivity (over 96%) was obtained as the oxygen pressure was elevated to 1.0 MPa. Using ethyl acrylate as the substrate, the reaction affords similar results, and the further experiments are now in progress.

In summary, the oxidation reaction of methyl acrylate afforded the acetal in high conversion and selectivity at lower temperature when supercritical carbon dioxide instead of DME was used as the reaction medium without the presence of HMPA. The pressure of CO_2 and O_2 had a remarkable effect on the conversion and selectivity.

The authors are grateful to the National Natural Science Foundation of China for financial support of this work (29772036) and Dr Fanglü Huang for helpful discussions.

Notes and references

† Typical procedure: Reactions were carried out in a HF-25 autoclave. Pd^{II} catalyst (0.15 mmol, 3 mol%), $CuCl_2$ (4 mmol), MeOH (1 ml, 24.7 mmol) and acrylate ester (5 mmol) were added into a 25 ml autoclave in sequence. O_2 and then liquid CO_2 were pumped into the autoclave using a cooling pump to give the desired pressure. The autoclave was then put into an oil bath under magnetic stirring for the desired reaction time. After the reaction, the autoclave was allowed to cool to −30 °C. CO_2 was vented and the surplus was extracted with n-hexane. The extract was filtrated and condensed under reduced pressure. The product was analyzed using GC (quantitative analysis) and GC-MS, ^{1}H NMR ^{13}C NMR and IR analysis (identification of products).

Received (in Cambridge, UK) 15th March 1999, Accepted 26th April 1999

The 2D honeycomb-like layered iron(III)–nickel(II) cyanide-bridged complex $[Ni(cyclam)]_3[Fe(CN)_6]_2 \cdot nH_2O$ exhibits ferromagnetic intralayer and antiferromagnetic interlayer interactions; above 3 K the magnetic properties are typical of a metamagnet with H_c = 5000 G, whereas below 3 K a canted structure is formed, leading to a long range ferromagnetic ordering.

Bimetallic assemblies with Prussian blue-like structure form a family of materials that exhibit spontaneous magnetization at T_c as high as 315 K,[1] and interesting electro-chemical, opto-electronic and magneto-optical properties.[2] The crystallization of Prussian blue analogues, however, is very difficult and it has been only quite recently that Kahn and coworkers[3] have succeeded in growing crystals of $[Mn_2(H_2O)_5Mo(CN)_7] \cdot nH_2O$ (α and β forms), which ferromagnetically order at 51 K.

One alternative route to bimetallic cyanide-bridged extended arrays is that of using hexacyanometalate building blocks with metal complexes containing polydentate ligands. This hybrid approach favours the crystallization and then their magneto-structural study. Depending on the nature of the building blocks different and fascinating extended network structures can be obtained, some of which are magnetically ordered.[4]

On reacting $[Ni(cyclam)]^{2+}$ and $[Fe(CN)_6]^{3-}$ in water using a 1 : 1 molar ratio the compound $[Ni(cyclam)]_3[Fe(CN)_6]_2 \cdot 12H_2O$ is obtained as a fine brown precipitate, however, by using a 1 : 10 molar ratio the complex $[Fe(cyclam)][Fe(CN)_6] \cdot 6H_2O$ is obtained.[5] Slow diffusion of two aqueous solutions of the reactants, into a U-tube containing silica gel, provided two kinds of well formed dark brown block-like single crystals of formula $[Ni(cyclam)]_3[Fe(CN)_6]_2 \cdot nH_2O$ (n = 12 and 22.5). X-ray analysis† reveals that both phases exhibit similar structures, which only differ in the number of water molecules (hereafter we shall discuss the results for n = 22.5, whose structure is more accurately determined). The structure consists of honeycomb-like layers (Fig. 1) and crystal water molecules that occupy the interlayer space. To form the layers, each $[Fe(CN)_6]^{3-}$ is coordinated to three $[Ni(cyclam)]^{2+}$ cations, at facial positions, through cyanide bridges, with Fe···Ni distances ranging from 5.037 to 5.202 Å, whereas each $[Ni(cyclam)]^{2+}$ cation is linked to two $[Fe(CN)_6]^{3-}$ units in *trans* positions. The *cis*-C–Fe–C angles are close to 90°, whereas the Fe–C distances are in the range 1.934(4)–1.954(4) Å. Ni^{II} ions, which are located on centres of symmetry, exhibit a *trans*-octahedral geometry; the nickel–cyanide nitrogen distances [2.123(3)–2.144(3) Å] being longer than the equatorial ones [2.059(4)–2.070(4) Å]. The Fe–C–N angles are close to linear and only vary in the small range 174.0(3)–179.1(3)°, whereas the Ni–N–C angles [165.4(3) and 154.9(3)°] deviate significantly from linearity. The layers are not planar but form an infinite staircase structure and align along the *a* axis with shortest interlayer separations of 7.688 Å, for Fe···Ni(2). This structure is similar to that reported for a hexacyanochromate(III) analogue.[4k]

The $\chi_M T$ *vs.* T plot per Fe_2Ni_3 unit (H = 50 G) is shown in Fig. 2.‡ On cooling, $\chi_M T$ increases reaching a maximum value of 15 $cm^3\ mol^{-1}\ K$ at 8 K, indicating a ferromagnetic interaction between Fe^{III} (t_{2g}^5) and Ni^{II} (e_g^2). The χ_M curve shows a maximum at *ca.* 8 K, for H < 5000 G, a clear indication of an antiferromagnetic interaction between the ferromagnetic sheets.

Below 6 K, $\chi_M T$ sharply increases again reaching a value of 60 $cm^3\ mol^{-1}\ K$ at 2 K, suggesting a canting of the local spins, which may arise from the local magnetic anisotropy of Ni^{II} and low-spin Fe^{III} ions. This phase transition is confirmed by ac susceptibility measurements which show an intense signal at 3 K. Above 3 K, the magnetic properties are typical of a metamagnet with a critical field H_c = 5000 G. For H < 5000 G,

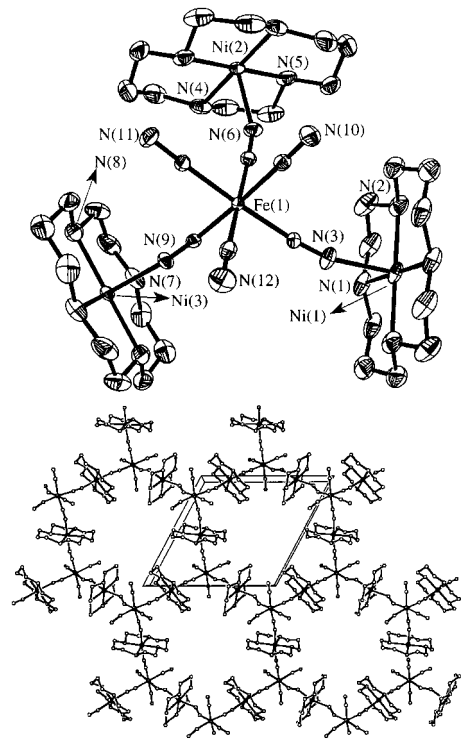

Fig. 1 Views of the asymmetric unit and 2D honeycomb-like layered. Water molecules are omitted for clarity.

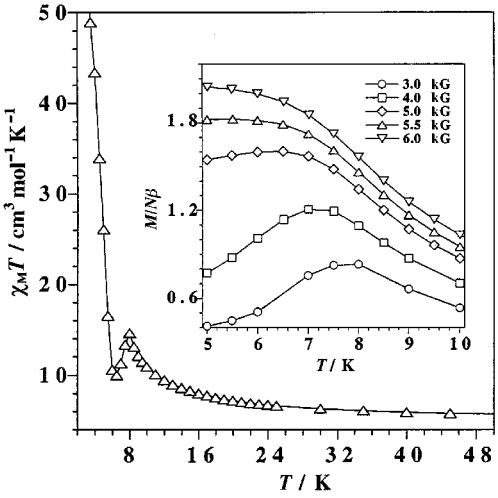

Fig. 2 $\chi_M T$ *vs.* T for H = 50 G. Inset: ($M/N\beta$) *vs.* T at various fields.

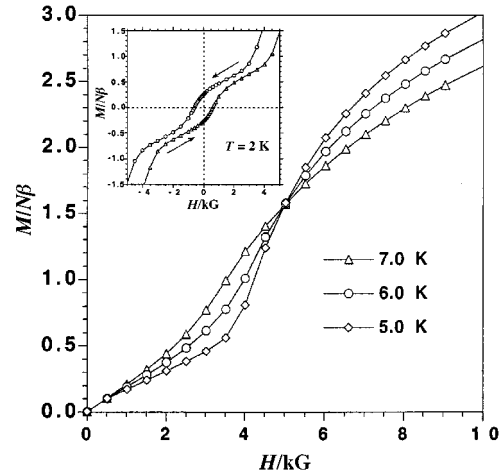

Fig. 3 ($M/N\beta$) *vs.* H at different temperatures. Inset: hysteresis loop at 2 K.

the ($M/N\beta$) *vs.* T curves (Fig. 2 inset) display a maximum which broadens as H is increased and finally disappears for $H > 5000$ G, demonstrating that a field-induced transition from an antiferro- to a ferro-magnetic ground state occurs. To confirm this metamagnetic behaviour, ($M/N\beta$) *vs.* H was measured at various temperatures (Fig. 3). As the temperature is lowered, the isotherms become increasingly sigmoidal and present a crossing point at *ca.* 5000 G, corresponding to H_c.

Below 3 K, a canted structure is formed. The magnetization curves present hysteresis loops with a remanent magnetization of 0.26 $N\beta$ and a coercive field of 600 G at 2 K (Fig. 3 inset). This canted structure is also broken when $H > 5000$ G, which is sufficient to overcome the intersheet interactions, responsible for the spin canting ground state. The chromium(III) analogue,[4k] does not exhibit any phase transition above 2 K.

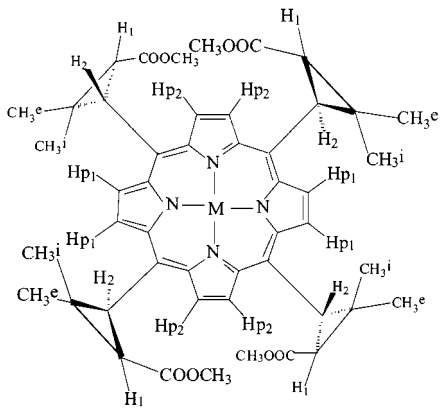
Received (in Basel, Switzerland) 25th February 1999, Accepted 11th April 1999

Catalytic asymmetric aziridination of styrene by [*N*-(*p*-toluenesulfonyl)imino]phenyliodinane was achieved by manganese and iron tetramethylchiroporphyrins; opposite enantioselectivities were obtained with the two metal centers, and possible mechanisms are proposed to explain this unexpected result.

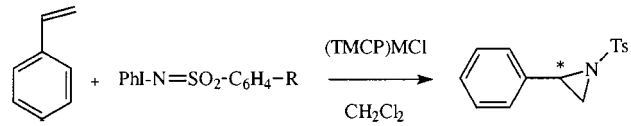
Amongst atom- and group-transfer processes, including epoxidation[1] and cyclopropanation,[2] aziridination is probably the least studied reaction. However, transition metal catalysed aziridination of olefins has been a topic of increasing interest in the past five years.[3] Several atom-transfer catalysts have been found to induce olefin aziridination by [*N*-(*p*-toluenesulfonyl)-imino]phenyliodinane (PhINTS),[4] but generally they are only moderately efficient and the mechanisms of aziridination catalysis remain unclear. A number of chiral metalloporphyrins have been shown to catalyse the asymmetric epoxidation[1] and cyclopropanation[2] of olefins, but only one example of catalytic asymmetric aziridination of alkenes has been published up to now.[5] Metallochiroporphyrins are competent catalysts in the epoxidation of aromatic olefins,[6] thus it was tempting to assess their potential in catalytic nitrogen group transfer. Herein we report the catalytic activity of several metal complexes of tetramethylchiroporphyrin (TMCP) **1** in the asymmetric aziridination of styrene, and the opposite enantioselectivities induced by the iron(III) and manganese(III) centers.



M = $Mn^{III}Cl$, $Fe^{III}Cl$, $Co^{III}Cl$, Ni^{II}, Cu^{II}, $Ru^{II}(CO)$, $Rh^{III}I$.

Initial experiments were carried out in order to probe the efficiency of various transition metals. Ni^{II}, Cu^{II}, Co^{III} and Rh^{III} were found to be inefficient and Ru^{II} nearly so [Ru(CO)(TMCP) led to 4% yield, 20% ee]. As anticipated from earlier work,[7] Mn^{III} and Fe^{III} are potent catalysts,[8] although the aziridine yields are only moderate (Table 1).[9] Unexpectedly, the iron(III) catalyst favours the synthesis of (+)-*N*-tosyl-2-phenylaziridine whereas the manganese(III) complex of the same TMCP chiral ligand preferentially leads to the (−) enantiomer. This result is reminiscent of the well documented opposite enantioface selection exhibited by (*R*)-BINAP–Rh^{I} and (*R*)-BINAP–Ru^{II} complexes in the asymmetric hydrogenation of *N*-acylaminoacrylic acids,[10] but to our knowledge this is the first demonstrated case of antagonistic metal-directed asymmetric inductions in a catalytic group-transfer process.

Table 1 Catalytic asymmetric aziridination of styrene with (TMCP) complexes[a]



Entry	Substrate	M	R	Yield[b] (%)	% ee[c]
1	Styrene	Fe	Me	27	28 (+)
2	Styrene	Mn	Me	34	57 (−)
3	Styrene	Fe	OMe	27	n.d.[d]
4	Styrene	Mn	OMe	17	33 (−)
5	Dihydronaphthalene	Mn	Me	0	—
6	*cis*-Stilbene	Mn	Me	0	—

[a] *Reaction conditions*: (catalyst : $PhINSO_2Ar$: styrene = 1 : 50 : 500). [b] Isolated yields were based on the amount of $PhINSO_2Ar$ used. [c] Values of ee were determined by HPLC analysis (Whelk-O1 column), the sign corresponds to that of $[\alpha]_D$. [d] Not determined.

The X-ray structure of the MnCl(TMCP) catalyst was solved, and an ORTEP diagram is shown in Fig. 1. The complex exhibits a strong equatorial contraction, due to a highly ruffled macrocycle: the out of plane displacements of the C_{meso} atoms with respect to the 24-atom mean plane are *ca.* 0.73(1) Å. The average [Mn–Np] bond distance is short [1.974(2) Å] when compared to other manganese(III) porphyrins,[11] and especially to the very non-planar chloro[5,10,15,20-tetrakis(pentafluorophenyl)-2,3,7,8,12,13,17,18-octaphenylporphyrinato]manga-

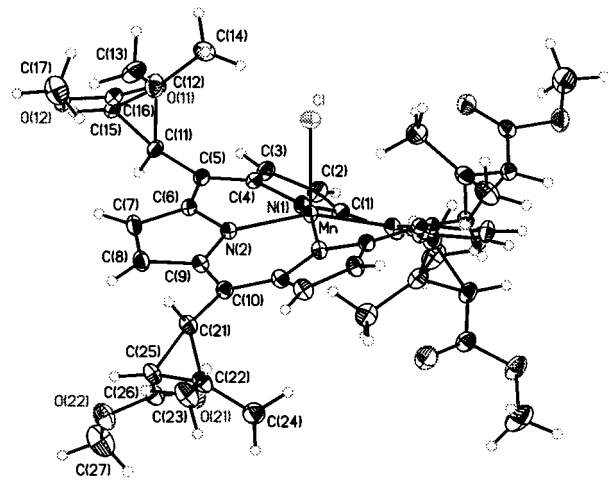


Fig. 1 ORTEP side view (30% probability) of **1** (M = MnCl). Selected bond lengths (Å): [Mn–Np] average 1.974(2), Mn–Cl 2.3475(9). Mn is displaced from the porphyrin mean plane towards Cl by 0.44(1) Å. The C_{meso} atoms are displaced alternatively up [+0.72(1) Å] and down [−0.74(1) Å] with respect to the 24-atom mean plane.

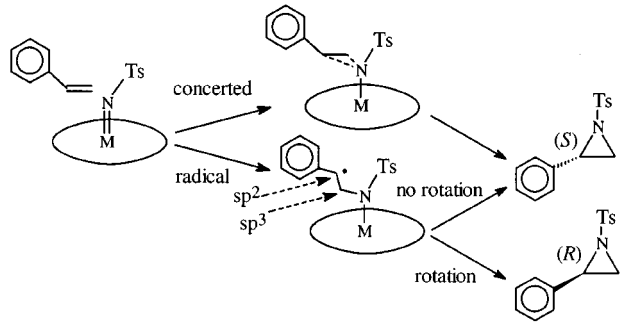

Scheme 1

nese(III) complex.[11d] The Mn–Cl bond distance [2.3475(9) Å] is similar to those observed for other chloromanganese(III) porphyrins.[11]

The MnCl(TMCP) complex is structurally very similar to FeCl(TMCP).[12] Hence, intermolecular steric interactions during the approach of the olefin towards the nitrenoid species are presumably similar for the two metal catalysts, implying that electronic effects are responsible for the observed opposite enantioselectivities. We speculate that each metal center favors one of two competing mechanisms (Scheme 1). The iron catalyst induces the preferential formation of the (+) enantiomer with the (*S*) absolute configuration[13] expected from steric exclusion during the side-on approach of the olefin in a concerted mechanism.[6b] In the case of the manganese catalyst, a radical intermediate which is sufficiently stable to allow an internal rearrangement can be invoked. Efforts towards a better understanding of these mechanisms and an extension of the scope of this catalytic system to other substrates are currently in progress.

8 The best yields were obtained with PhINTs. The nitro-substituted derivative *p*-$NO_2C_6H_4SO_2N$=IPh was unreactive, whereas the methoxy-substituted derivative *p*-$MeOC_6H_4SO_2N$=IPh increased the rate of aziridine formation. These observations suggest that electronic factors play a crucial role in the formation of the probable nitrenoid species. For similar notes and procedures for preparing the nitrene precursors, see: M. J. Södergren, D. A. Alonso, A. V. Bedekar and P. G. Andersson, *Tetrahedron Lett.*, 1997, **39**, 6897.
9 (*a*) We feel that formation of $TsNH_2$ is not entirely due to hydrolysis since experiments under highly anhydrous conditions did not lead to improved aziridine yields. We agree with P. Müller that the decomposition of the nitrene source must be competitive with the aziridination, and affords the sulfonamide after work-up;[4i] (*b*) In our case, addition of 4-phenylpyridine *N*-oxide resulted in lower yield and enantioselectivity with both catalysts.

Received (in Cambridge, UK) 26th March 1999, Accepted 28th April 1999

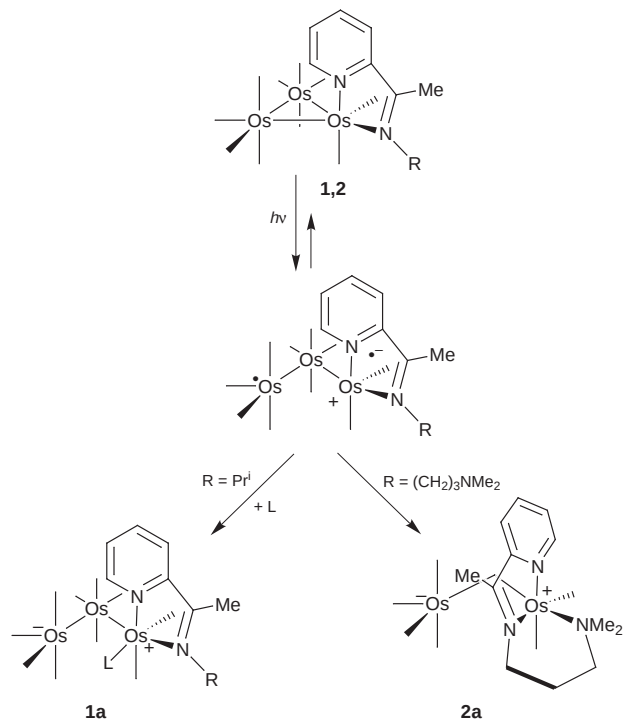
The light-induced transformation of an $Os_3(CO)_{10}$(α-diimine) cluster into an intramolecularly stabilized zwitterion has been established with time-resolved microwave conductivity, this is the first application of this technique in organometallic chemistry.

Organometallic complexes that contain a metal–metal bond and an α-diimine ligand often undergo a homolytic cleavage of the metal–metal bond on visible excitation.[1,2] For instance, in non-coordinating solvents the complexes $(CO)_5MnMn(CO)_3$(α-diimine) produce the radicals $^{\bullet}Mn(CO)_5$ and $Mn(CO)_3$(α-diimine)$^{\bullet}$ which dimerize to give $Mn_2(CO)_{10}$ and $Mn_2(CO)_6$(α-diimine)$_2$.[3] In coordinating solvents, or in the presence of an N- or P-donor ligand (L), these complexes photodisproportionate into the ions $Mn(CO)_5^-$ and $Mn(CO)_3(L)$(α-diimine)$^+$.[4]

Recently, a similar behaviour was observed for the triangular clusters $Os_3(CO)_{10}$(α-diimine), the only difference being that instead of separate radicals and ions, biradicals and zwitterions are formed.[5] The biradicals $^{\bullet}Os(CO)_4$–$Os(CO)_4$–$Os(CO)_2$(α-diimine)$^{\bullet}$ are the primary photoproducts in weakly and non-coordinating solvents, and have been observed with nanosecond time-resolved absorption spectroscopy.[5] Again, zwitterions are only produced in the presence of a Lewis base (L) or upon irradiation of the cluster in a coordinating solvent. L transforms the biradical into the zwitterion $^-Os(CO)_4$–$Os(CO)_4$–$Os^+(CO)_2(L)$(α-diimine) by coordinating to the open site of the biradical. This process, which is schematically depicted in Scheme 1, has been established with nanosecond time-resolved absorption spectroscopy for the photoreaction of $Os_3(CO)_{10}$(Pr^i-AcPy) **1** [Pr^i-AcPy = $Me_2C(H)N{=}CMeC_5H_4N$) in THF in the presence of 0.5 M MeCN.[5] The lifetime of a biradical varies from a few nanoseconds to several microseconds depending on the α-diimine and the solvent; that of a zwitterion is a few seconds in acetonitrile and several minutes in pyridine.[5] Most biradicals and zwitterions regenerate their parent cluster.

Evidence for the dipolar character of the zwitterions has been obtained from ^{1}H NMR, UV–VIS and resonance Raman data, and from their reactivity,[5] but up to now these species could not be isolated and structurally characterized. The formation of such a transient dipolar species may, however, be established by time-resolved microwave conductivity (TRMC). This technique has often been applied to characterize the charge-separated D^+–A^- states of organic donor–acceptor systems.[6–8] To our knowledge, TRMC has, however, never been used to identify dipolar excited states and short-lived intermediates in organometallic chemistry. It is shown here that TRMC measurements, applied to a particular osmium cluster, establish the dipolar character of its zwitterionic product and provide an approximate value of its dipole moment. In a TRMC experiment a dilute solution of the compound of interest is placed in a microwave cavity and the change in conductivity of the solution during and after flash-photolysis is measured in the nanosecond to microsecond time domain.[7] The conductivity of the solvent itself must be very low. We therefore used cyclohexane and benzene for the TRMC experiments and, in conjunction with this, toluene for the IR and quantum yield studies. As the triosmium zwitterions are only formed in coordinating solvents or in the presence of a Lewis base, we prepared the cluster $Os_3(CO)_{10}\{Me_2N(CH_2)_3$-AcPy$\}$ **2**, in which the α-diimine bears a pendant sidearm that may act as such a base. The general procedure for the synthesis has been described in refs. 5 and 10.

Irradiation of **2** in toluene with the 514.5 nm line of an argon ion laser afforded a species with IR ν(CO) bands (2073vw, 1985vs, 1967s, 1921w, 1893w, 1870m, br cm^{-1}), which are very close in frequency to those of the zwitterion **1a** of $Os_3(CO)_{10}$(Pr^i-AcPy) **1** in pyridine (2071w, 1988vs, 1968vs, 1925w, 1898w, 1873m, br cm^{-1}).[5] Thus, the pendant $-(CH_2)_3NMe_2$ sidearm transforms the biradical photoproduct of **2** into the zwitterion $^-Os(CO)_4$–$Os(CO)_4$–$Os^+(CO)_2\{Me_2N$-$(CH_2)_3$-AcPy$\}$ **2a** (Scheme 1) which has a lifetime of *ca*. 5 s in



Scheme 1 General scheme for the formation of the zwitterions **1a** and **2a** on irradiation of **1** (R = Pr^i) and **2** [R = $(CH_2)_3NMe_2$], respectively. The primary photoproduct of the reaction is a biradical in which the unpaired electron at the $Os(CO)_2$(α-diimine) moiety (mainly) resides at the α-diimine ligand. This biradical transforms into a zwitterion by the attack of a strong Lewis base (L) (**1a**) or by the intramolecular coordination of a pendant sidearm (**2a**).

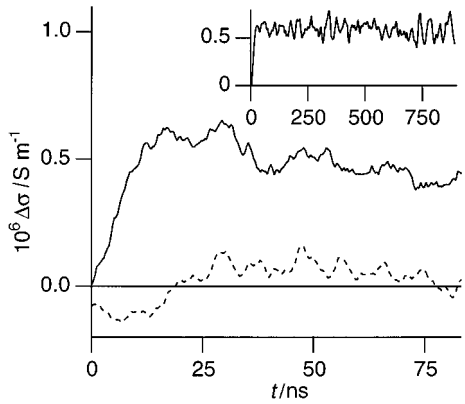


Fig. 1 Transient changes in the microwave conductivity (dielectric loss) of *ca*. 1×10^{-4} M solutions of **1** (dashed line) and **2** (full line) on 308 nm photoexcitation of cyclohexane solutions at room temperature. The inset shows the transient for **2** on a longer timescale.

toluene. As expected, the cluster **1** without such a sidearm did not produce a zwitterion in toluene.[5]

Cluster **2** therefore meets the requirement of the TRMC technique that the charge-separated species is formed in an apolar solvent. TRMC measurements were performed on **2** dissolved in both benzene and cyclohexane (absorbance per cm *ca*. 1.0 at 308 nm). For comparison a cyclohexane solution of **1**, which shows no evidence for zwitterion formation in apolar solvents,[5] was also studied. The solutions were placed in a microwave cavity (resonance frequency *ca*. 10 GHz) and were flash-photolysed using the 7 ns, 308 nm pulse from a Lumonics HyperEx 400 laser. The change in conductivity (dielectric loss) of the solutions, $\Delta\sigma$, was monitored as a change in the microwave power reflected by the cavity as described in detail previously.[7,9]

The TRMC transients found for solutions of **1** and **2** in cyclohexane are shown in Fig. 1. In agreement with the IR experiment no measureable change in the microwave conductivity, within the experimental noise, is observed for **1**. Cluster **2**, in contrast, shows a readily measureable conductivity transient which is already present within the laser pulse. The transient found for the benzene solution was similar in magnitude. The TRMC results therefore provide direct evidence for the formation of a photoproduct with a dipole moment larger than that of the ground state molecule, *i.e*. a zwitterionic state. The signal was found to decay little even on a timescale of microseconds, in agreement with the long lifetime of **2a** established in other experiments.

From the amplitude of the observed TRMC signal a value of 3.5×10^{10} D^2 s^{-1} was derived for the parameter $(\mu_*^2 - \mu_0^2)\phi_{308}/\theta_*$, in which μ_* and μ_0 are the dipole moments of **2a** and **2** respectively, ϕ_{308} the quantum yield for the formation of **2a** from **2** at 308 nm in an apolar solvent at 298 K, and θ_* the rotational relaxation time of the observed dipole. Since **2** has a close to spherical geometry, θ_*(= 190 ps) was estimated using the Stokes–Einstein relation taking 1.02×10^{-3} N s m^{-2} for the viscosity and 0.75 nm^3 for the molecular volume. The ground-state dipole moment μ_0 was determined by steady-state microwave conductivity measurements[9] at five different concentrations, and was found to be 6.0 ± 0.1 D.

The remaining parameter, ϕ_{308}, could not be determined from the transient absorption spectra since the quantum yield was too low and the differences in absorption between the cluster and the transient zwitterion were too small. It was therefore determined by a conventional steady-state experiment although the conditions (wavelength, temperature) were somewhat different from those used for the TRMC measurements. Thus, the back reaction of zwitterion **2a** to the parent cluster **2** was too fast to determine the quantum yield at room temperature. Besides, the 313 nm line of the Hg-lamp (closest in wavelength to the 308 nm line used for TRMC) was too weak. Because of this, ϕ was measured at different temperatures and wavelengths of excitation and these data were extrapolated to give a value of ϕ = 0.05 ± 0.02 at λ_{exc} = 308 nm and T = 298 K.†

Substitution of the above values of θ_*, μ_0 and ϕ_{308} in the expression $(\mu_*^2 - \mu_0^2)\phi_{308}/\theta_* = 3.5 \times 10^{10}$ D^2 s^{-1} results in a value of 13 ± 2 D for the dipole moment μ_* of **2a**. This value corresponds to a full charge separation over a distance of 2.7 ± 0.4 Å. The average covalent Os–Os distance is 2.88 Å in $Os_3(CO)_{10}(Pr^i\text{-DAB})$[11] and 2.87 Å in $Os_3(CO)_{10}$(bpy),[12] and the non-bonded distance in the η^2-imine bridged cluster $Os_3(CO)_{10}(Pr^c\text{-DAB})$ is 3.59 Å.[11] The range of the value derived from the TRMC measurements overlaps with that of the literature data but the calculated charge separation is rather small for two localised charges on the non-bonded osmium atoms.

This TRMC result confirms the zwitterionic character of the photoproduct of such an Os cluster when irradiated in the presence of a Lewis base, and even provides an approximate value of its dipole moment. To our knowledge this is the first application of this technique in organometallic chemistry. It may stimulate others to employ TRMC, not only for the characterization of transient intermediates of (photo)reactions, but in particular also for the characterization of charge transfer excited states. We emphasize again however that the method is only applicable for those compounds which are soluble in apolar solvents.

J. M. Ernsting is thanked for his assistance with the low temperature NMR experiments. This research has been financially supported by the Council for Chemical Sciences of the Netherlands Organization for Scientific Research (CW-NWO).

Supporting information: A table presenting IR, ^{1}H NMR and UV-VIS data for **1**, **2** and their zwitterions **1a** and **2a** and mass spectral data of **2** can be accessed electronically, see http://www.rsc.org/suppdata/cc/1999/991/

Notes and references

† First, ϕ was determined in toluene with 355 nm excitation between 203 and 223 K, where the zwitterion is thermally stable. Then the quantum yield was determined at 223 K for excitation wavelengths of 514.5, 488.0, 457.9 and 355 nm. The values of ϕ at this temperature were as follows: 0.026 (514.5 nm), 0.025 (488.0 nm), 0.026 (457.9 nm) and 0.024 (355 nm). Accordingly, ϕ_{308} at 223 K is estimated as 0.025 ± 0.001. Values of 0.022 and 0.019 were obtained on 355 nm excitation at 213 and 203 K, respectively. By extrapolation of these data a value of 0.05 ± 0.02 was obtained for ϕ_{308} at 298 K. The accuracy of this value is limited by the small temperature range that could be covered because of the thermal instability of the zwitterion **2a**.

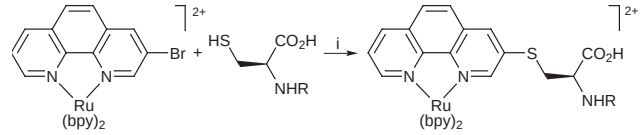
Received (in Corvallis, OR, USA) 15th February 1999, Accepted 12th April 1999

Ru^{II}-containing amino acids and short peptides are obtained in high yields *via* direct displacement reactions of $[(bpy)_2Ru(3\text{-bromo-}1,10\text{-phenanthroline})]^{2+}(PF_6^-)_2$ with amino acids and peptides that contain thiolate and phenolate nucleophiles.

Metal-containing amino acids and peptides are key components for the study of photo-induced energy– and electron–transfer processes,[1–3] as well as for the development of chemosensors and labeling reagents.[4,5] These organic–inorganic hybrid molecules have been constructed *via* three predominate approaches: (i) coordination of metal complexes to donor-containing natural amino acids (*e.g.* histidine),[6,7] (ii) conjugation of complexes to peptide termini,[2,3] and (iii) synthesis of chelator-containing amino acids followed by metal coordination.[8–12] These routes typically require the exposure of peptides to reactive metal precursors or necessitate the multistep synthesis of new amino acids. Although productive, these methods are elaborate and do not always provide full control over the final structure and absolute configuration at the metal center. Here we report a simple one-step synthesis of metal-containing amino acids and peptides *via* the direct reaction between nucleophile-containing amino acids (*e.g.* cysteine, tyrosine) and functionalized coordination compounds. Reactions of $[(bpy)_2Ru(3\text{-bromo-}1,10\text{-phenanthroline})]^{2+}(PF_6^-)_2$ **1** with free or *N*-protected amino acids, as well as short peptides, provide the Ru^{II}-containing amino acids in a single step with predetermined stereochemistry at the metal center.

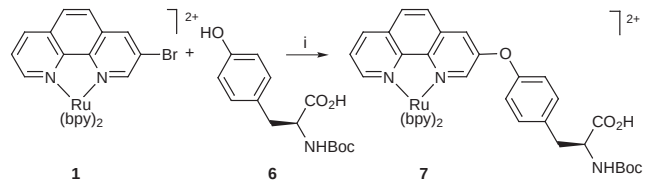
We have previously reported that functionalized tris-chelate complexes (*e.g.* **1**) are excellent substrates for palladium-mediated cross-coupling reactions[13,14] and nucleophilic aromatic substitutions.[15] This unprecedented reactivity has been attributed to the increased electrophilicity of the 3-bromo-1,10-phenanthroline ring upon metal coordination.[15] Thus, when **1** is reacted with L-cysteine **2** in the presence of a weak base (*e.g.* Na_2CO_3) a smooth reaction takes place within 1–3 h giving the desired modified amino acid **4** in good yields (Scheme 1, Table 1).† Identical reaction conditions can be utilized to incorporate the octahedral complex into *N*-protected amino acids. Thus, reacting **1** and *N*-Boc-L-cysteine **3** in DMF–H_2O (1 : 1) at slightly elevated temperatures (45–55° C) affords the protected derivative **5**. Similarly, deprotonation of the phenolic side chain in *N*-Boc-L-tyrosine **6** followed by a reaction with **1** gives the expected metal-containing amino acid **7** (Scheme 2).



Scheme 1 *Reagents and conditions*: i, Na_2CO_3, H_2O–DMF (1 : 1), 55 °C, 1 h.

The compounds synthesized represent a novel family of photo- and redox-active Ru^{II}-containing amino acids. Their absorption spectra show intense bands in the UV region due to the overlapping π–π* transitions of the bipyridine and phenanthroline ligands (Table 1). The presence of a phenanthroline moiety with a heteroatom-containing substituent results in the appearance of lower energy bands between 320–350 nm (Table 1).[15] The tris-chelated Ru^{II} centers in **4**, **5** and **7** give rise to the typical visible metal to ligand charge transfer (MLCT) bands that are centered around 450 nm. Upon excitation at this wavelength, all the Ru^{II}-containing amino acids emit intensely at 600–615 nm (Table 1). Cyclic and square-wave voltammetry show the expected $Ru^{III/II}$ couple at $E_{1/2} \cong +1.0$ V *vs.* Ag/Ag+ (Table 1).‡

Mild substitution reaction conditions can be employed for the incorporation of octahedral Ru^{II} complexes into short peptides. Thus, reacting glutathione **8** (γ-L-glutamyl-L-cysteinylglycine)



Scheme 2 *Reagents and conditions*: i, Na_2CO_3, H_2O–DMF (1 : 1), 55 °C, 1 h.

Table 1 Preparation, spectral and electrochemical data for metal-containing amino acids and peptides

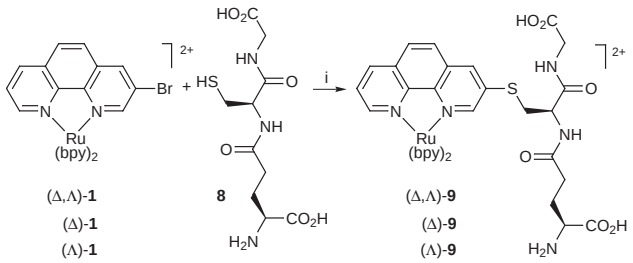
[b] Electrospray ionization mass spectra. [c] Measured in MeCN (for **5**, **7** and **10**) and MeOH (for **4**, **9**). [d] Measured in MeCN containing 0.1 M $Bu_4N^+PF_6^-$ *vs.* Ag/Ag^+. Under these conditions $E_{1/2}$ = 0.084 V for Fc/Fc^+. [e] Metal-centered emission taken in water upon excitation at 450 nm. [f] Individual yields for HPLC-purified products: **Δ,Λ-9** (60–63%), **Δ-9** (60%) and **Λ-9** (58%).



Scheme 3 *Reagents and conditions*: i, Na_2CO_3, H_2O–DMF (1 : 1), 65 °C, 1 h.

with the racemic complex **1** in a mixture of DMF–water gives the desired substituted peptide **9**, as a mixture of the two epimeric products (Scheme 3). The use of functionalized coordination compounds as building blocks permits the incorporation of coordination compounds with predetermined absolute configuration at the metal center.[16] Thus, reacting glutathione **8** with the enantiomerically-pure complexes **Λ-1** and **Δ-1** gives the diastereomerically-pure metal-containing peptides Λ-**9** and Δ-**9**, respectively (Scheme 3). The CD spectra of the various products clearly reveal the opposite absolute configuration at the two epimeric metal-containing peptides Λ-**9** and Δ-**9** (Fig. 1).[16]

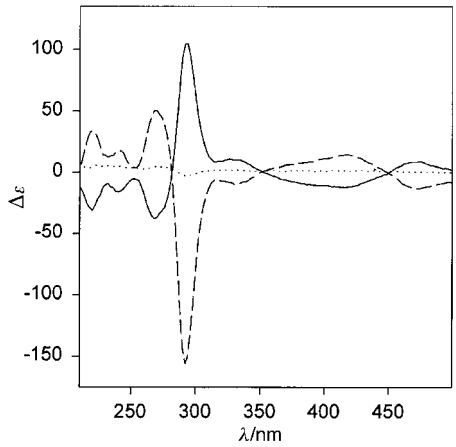


Fig. 1 CD spectra in MeOH of Λ-**9** (solid), Δ-**9** (dashed) and Λ,Δ-**9** (dotted).

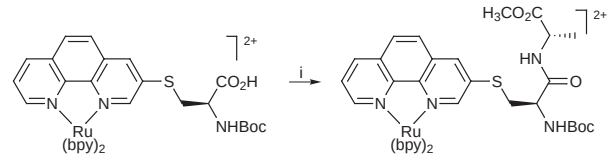
Protected metal-containing amino acids such as **5** and **7** are useful building blocks for peptide synthesis. Their condensation with other suitably protected amino acids provides short metal-containing peptides. Thus the reaction of **5** with L-alanine methyl ester in the presence of benzotriazol-1-yloxytris(dimethylamino)phosphonium hexafluorophosphate ($BOPPF_6$), *N*-hydroxysuccinimide and DMAP proceeds rapidly at room temperature to give the fully protected dipeptide **10** in high yield (Scheme 4, Table 1). As is evident from the data presented in Table 1, the short metal-containing peptides **9** and **10** exhibit photophysical and electrochemical characteristics similar to their metal-containing precursors.

The direct incorporation of metal complexes into amino acids and peptides provides a facile new route for the synthesis of novel photo- and redox-active biomolecules. Modifying the side-chains of naturally-occurring amino acids places the polypyridine Ru^{II} complexes in close proximity to the peptide backbone. These derivatives are therefore useful building blocks for the study of photophysical processes in peptides and proteins. We are currently exploring these directions *via* the construction of metallated peptides with well-defined secondary structures.



Scheme 4 *Reagents and conditions*: i, L–alanine methyl ester, $BOPPF_6$, *N*-hydroxysuccinimide, DMAP, DMF, 10 min at room temp.

We gratefully acknowledge the National Institutes of Health (GM58447) for financial support.

Notes and references

† Representative procedures: A solution of L-cysteine (20 mg, 0.13 mmol) and Na_2CO_3 (40 mg, 0.38 mmol) in degassed water (1 ml) is added to a degassed solution of **1** (40 mg, 0.042 mmol) in DMF (1 ml). The reaction mixture is kept at 55 °C for 1 h. It is then diluted with water (10 ml) and washed with CH_2Cl_2 (3 × 50 ml). The aqueous phase is evaporated to dryness and the dark red residue is HPLC-purified on a C8 semi-preparative reversed-phase column using 0.1% TFA in MeCN–0.1% TFA in H_2O (1 : 7.3) as eluent to afford **4** (34 mg, 87% yield) after lyophilization. The more lipophilic *N*-Boc protected metal-containing amino acids are chromatographed on silica gel using 0.5% saturated aq. KNO_3 in 10–15% H_2O in MeCN. In these cases the products contain a carboxylate anion as an internal counterion. The free carboxylic acid derivative can be obtained by dissolving the *N*-protected derivative in dilute aqueous HPF_6 followed by extraction into CH_2Cl_2.The organic phase is then dried (Na_2SO_4), filtered and evaporated to yield the desired product. All new compounds have been fully characterized by UV–VIS spectroscopy, ESI MS, IR and ^1H NMR as well as cyclic and squarewave voltammetry.

‡ The *N*-protected derivatives showed reversible cyclic voltammograms ($\Delta E_p \cong 60$–70 mV, $i_a \cong i_c$) while the free amines gave irreversible CV, and their $E_{1/2}$ values were determined using squarewave voltammetry.

Received (in Cambridge, UK) 26th March 1999, Accepted 28th April 1999

A remarkable co-crystallization in which two neutral clusters, $Ag_8(Se)[Se_2P(OPr^i)_2]_6$ and $Ag_6[Se_2P(OPr^i)_2]_6$, superimpose along the three-fold axis in the trigonal lattice and share a common $Ag_6[Se_2P(OPr^i)_2]_6$ unit, is reported.

Molecular cubic clusters encapsulating main-group elements are very rare[2] and they are particularly interesting from the general point of view of bonding.[3] Previously we reported the first discrete selenide-centered Cu^I cubic cluster containing diselenophosphate ligands (dsep), $\{Cu_8(\mu_8\text{-}Se)[Se_2P(OPr^i)_2]_6\}$.[4] To extend our research efforts in centered cubic cluster synthesis, herein, we report the synthesis of silver analogues and uncover an extremely rare example of co-crystallization, $Ag_8(Se)[Se_2P(OPr^i)_2]_6$ and $Ag_6[Se_2P(OPr^i)_2]_6$ share a common $Ag_6[Se_2P(OPr^i)_2]_6$ unit and have equal occupancies along the three-fold axis of the trigonal lattice. Co-crystallization of organic compounds is a common phenomenon[5] and recently it has been used to resolve the racemic 1,1′-bi-2-naphthol.[6] In organometallic chemistry many anion–cation pairs[7] as well as two neutral cluster molecules[8] in the same crystal have also been recognized. In inorganic compounds, two or three components can share the same metal core with minute differences in the composition of peripheral ligands. The most recent example is $[NEt_4]_2[(Mo_2O_2Se_6)_{0.20}(Mo_2O_2Se_7)_{0.18}(Mo_2O_2Se_8)_{0.62}]$, a dimeric molybdenum polyselenide containing a $Mo_2O_2(\mu\text{-}Se)_2$ core, reported by Mak and Guo.[9] To our knowledge, a co-crystallization as revealed in the superposition of Ag_8 and Ag_6 clusters which share a common $Ag_6[Se_2P(OPr^i)_2]_6$ unit is unprecedented.

Treatment of $NH_4Se_2P(OPr^i)_2$ (105 mg, 0.3 mmol) with $Ag(MeCN)_4PF_6$ (62.5 mg, 0.15 mmol) in CH_2Cl_2 (30 mL) at −50 °C resulted in a yellow solution after 12 h of stirring. After evaporation under vacuum, the residue was re-dissolved in 30 mL of hexanes from which a white precipitate was formed within a few minutes at ambient temperature (*ca.* 12% yield based on Ag). Upon dissolving the white precipitate in $CDCl_3$ a singlet at δ 72.7 (J_{PSe} = 654 Hz) flanked with selenium satellites was observed in the ^{31}P NMR spectrum while a doublet at δ 147 (J_{PSe} = 654 Hz) was observed in the ^{77}Se NMR spectrum.‡ These data implied that all dsep ligands are equivalent in solution. In order to understand the detailed structure of the isolated species, a single crystal X-ray diffraction analysis was undertaken and revealed a remarkable co-crystalline structure.§

The crystal structure of $\{Ag_8(\mu_8\text{-}Se)[Se_2P(OPr^i)_2]_6\}_{0.5}\{Ag_6[Se_2P(OPr^i)_2]_6\}_{0.5}$ contains $Ag_8(\mu_8\text{-}Se)[Se_2P(OPr^i)_2]_6$ and $Ag_6[Se_2P(OPr^i)_2]_6$ with equal occupancy, sharing the same $Ag_6[Se_2P(OPr^i)_2]_6$ unit. They are alternately distributed along the three-fold axis of the trigonal lattice. The thermal ellipsoid drawings (50% probability) of the octanuclear and hexanuclear silver clusters are depicted in Fig. 1 and 2, respectively. The six silver atoms of the latter form a slightly compressed octahedron with S_6 point group symmetry. This octahedron consists of two uncapped, equilateral triangles and six isosceles triangles in which each triangular face is bridged by a diselenophosphate ligand in a 'trimetallic triconnective'[10] (μ_2, μ_1) coordination mode. Silver–silver distances of 4.649(2) and 3.3578(8) Å within the isosceles triangles are observed in the hexanuclear silver cluster. Thus, the mean distance between the two uncapped Ag_3 triangles through which the three-fold axis passes is 2.0175 Å, whereas, that between two *trans* occupied Ag_3 planes is 3.3522 Å. Each silver atom of the octahedron is coordinated to three selenium atoms of three different ligands. The average Ag–Se(dsep) bond length is 2.6209(8) Å and Se–Ag–Se bond angles range from 115.80(2) to 122.62(3)°. In the octanuclear cluster, the eight silver atoms are arranged at the corners of an almost regular cube in which each square face of the cube is bridged by a dsep ligand exhibiting a 'tetrametallic tetraconnective'[10] (μ_2, μ_2) coordination mode. The coordination environment around each silver atom of the cube is very similar to that observed in the octahedron aside from the interaction to the central selenide anion. Hence two different bond lengths, 2.714(2) and 2.8675(6) Å, are observed between the central selenium atom and peripheral silver atoms so that a slightly compressed cube is observed along the three fold axis.

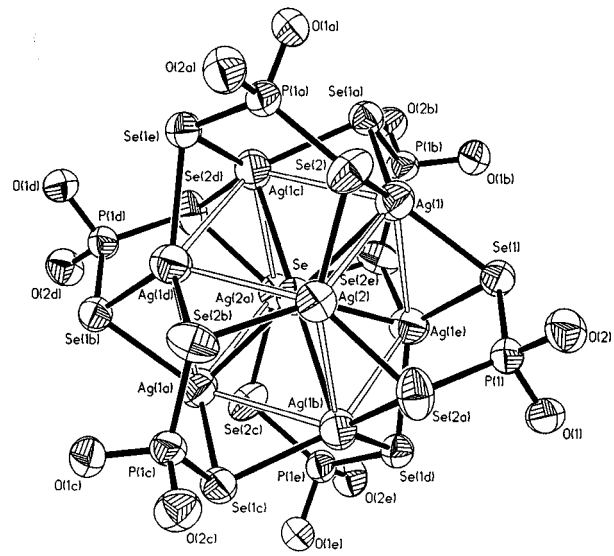

Fig. 1 Thermal ellipsoid drawing (50% probability) of $Ag_8(Se)[Se_2P(OPr^i)_2]_6$. The isopropyl groups are omitted for clarity. Selected bond lengths(Å) and angles(°): Se–Ag(2) 2.714(2), Se–Ag(1) 2.8675(5), Se(1)–Ag(1) 2.6236(8), Se(1)–Ag(1e) 2.6330(9), Se(2)–Ag(1) 2.6062(9), Se(2)–Ag(2) 2.5349(9), Ag(1)–Ag(2) 3.1800(12), Ag(1)–Ag(1e) 3.3578(8), Se(1)–P(1) 2.174(2), P(1)–O(1) 1.575(5), P(1)–O(2) 1.576(5); Ag(2a)–Se–Ag(1) 110.595(12), Ag(2)–Se–Ag(1) 69.403(12), Ag(1)–Ag(2)–Ag(1b) 93.94(4), Ag(1c)–Ag(1)–Ag(1e) 87.62(2), Ag(2)–Ag(1)–Ag(1c) 89.13(2).

† Dedicated to Professor John P. Fackler, Jr. on the occasion of his 65th birthday.

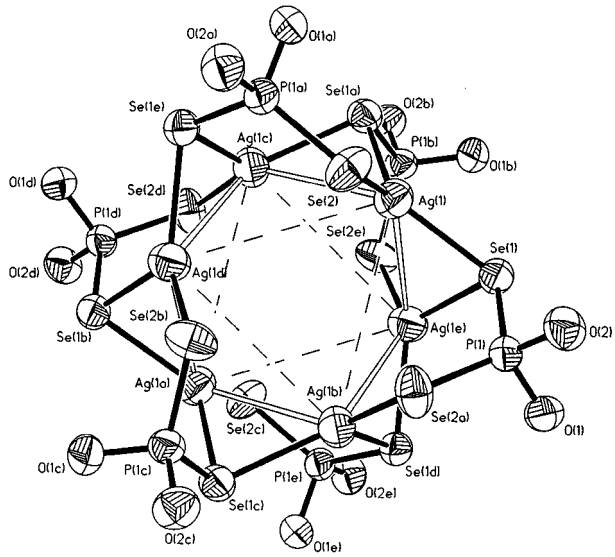

Fig. 2 Thermal ellipsoid drawing (50% probability) of $Ag_6[Se_2P(OPr^i)_2]_6$. The isopropyl groups are omitted for clarity. Selected bond lengths(Å) and angles(°): Ag(1)–Ag(1b) 4.649(2); Se(1)–Ag(1)–Se(2) 122.62(3), Se(1)–Ag(1)–Se(1a) 115.80(2), Se(2)–Ag(1)–Se(1a) 117.37(3), Se(1)–P(1)–Se(2a) 121.33(7).

Consequently a 0.1778 Å difference is seen in the Ag–Ag bond distances [3.3578(8) *vs*. 3.1800(12) Å]. The central selenide atom, in conjunction with the twelve selenium atoms of the ligands, forms a body-centered icosahedron. To our knowledge this geometry has never previously been observed in silver clusters.

An octahedral metal skeleton is commonly observed in hexanuclear silver clusters containing chalcogenide-donor ligands such as in $\{Ag_6(S_2CNPr^n_2)_6\}$,[11] $\{Ag_6[S(O)(CNPr^n)_2]_6\}$,[12] $\{Ag_6[S_2P(OPr^i)_2]_6\}$[13] and $[NMe_4]_6[Ag_6(i\text{-MNT})_6]$ [*i*-MNT = $S_2CC(CN)_2^{2-}$].[14] All six bridging sulfur atoms in these clusters are located on the two uncapped Ag_3 triangles while the terminally coordinated sulfur (or oxygen) atoms are in the belt positions of an octahedron.[13] Thus the Ag_6S_{12} (or $Ag_6S_6O_6$) core in these clusters has an idealized D_{3d} point group symmetry.[13] The S_6 point group symmetry found in the $Ag_6[Se_2P(OPr^i)_2]_6$ cluster results from the differences in bridging selenium atom positions in comparison with the bridging sulfur atom positions in $Ag_6[S_2P(OPr^i)_2]_6$.[13] On the other hand, an octanuclear silver cluster with cubic geometry is extremely rare. Examples prior to the title compound are $[Ag_8(i\text{-MNT})_6]^{4-}$,[15] and $[Ag_9(SCH_2CH_2S)_6]^{3-}$,[16] where a silver atom resides inside an extremely distorted Ag_8 cube. Furthermore, the title complex is the first discrete silver homocubane containing an encapsulated chalcogenide anion. Previously only one example[17] of a chloride-centered Ag_8 cuboidal structure was known found in the central portion of a mixed-valence, mixed-metal cluster $[Ag^I_8Ni^{II}_6\{SCMe_2CH(NH_2)CO_2\}_{12}Cl]^{5-}$.

Since the ligand bridging mode between Ag_8 and Ag_6 clusters is different, two chemical shifts should be observed in the ^{31}P NMR spectrum. Instead a single resonance flanked with selenium satellites is observed over the temperature range 300–180 K. Since the true bond connectivities are virtually identical for the phosphorus center in these two clusters and the spatial orientation magnetically is also virtually identical for all phosphorus positions, the chemical shifts are not expected to be very different. Although this possibility can not be ruled out, the fast ligand dissociation in solution or extreme lability of Ag–Se bond is the most likely reason for the single signal. This is further corroborated by the absence of one-bond coupling to $^{107/109}Ag$ nuclei of the title complex in the ^{77}Se NMR spectrum in which only a doublet arising from the coupling to ^{31}P nuclei is observed. In fact, it has been reported from multinuclear NMR studies that silver complexes of group 16 donor ligands are much more labile than their group 15 analogues in solution.[18]

We thank the National Science Council of Taiwan for support of this work.

The structure was solved by direct methods using the SHELXTL-PLUS software package,[19] and refined by full-matrix least squares on F^2. The site occupancies of Ag(2) and Se in special positions were initially set to unity. The U_{eq} of these two atoms are 0.128(1) and 0.118(2) which is nearly twice that of the averaged U_{eq} of other Ag and Se atoms. In addition, an unreasonably, high $wR2$ of 0.2996 was obtained. Therefore the site occupancy factors of Ag(2) and Se were tied and refined as a free variable. Final convergence resulted in site occupancies of 0.5. In addition, two carbon atoms of isopropyl groups were also found to be disordered and refined isotropically as an equal population model. Refinement converged to $R1 = 0.0382$ [$I > 2\sigma(I)$], $wR2 = 0.0992$ (all data) and GOF = 1.069 based on 114 variables and 2228 reflections. CCDC 182/1241. Stabilization of selenium in zeolites: an anomalous X-ray scattering study

Andreas Goldbach,† Marie-Louise Saboungi,* Lennos Iton and David L. Price

Argonne National Laboratory, Argonne, Illinois 60439, USA. E-mail: mls@anl.gov

Received (in Columbia, MO, USA) 1st January 1999, Accepted 9th April 1999

The host–guest interactions in selenium/zeolite encapsulates are investigated with anomalous X-ray scattering (AXS) to rationalize the effects of the cation on the selenium incorporation.

The intriguing prospects of quantum confinement have stimulated many strategies to synthesize and investigate the properties of mesoscopic particles.[1] The encapsulation of semiconductor clusters within open-framework structures with large surface area like zeolites is particularly advantageous[2] since the zeolite itself can play the role of a solid support for these clusters, which is a prerequisite for prospective technical applications. Large arrays of quantum dots and wires with a narrow size distribution can be generated this way owing to the regular distribution of the cavities within the zeolite. The sorption of Se into molecular sieves is a typical example. Until now, studies of these systems[3–7] have focused mostly on the structure and electronic properties of the encapsulated Se. However, little is known about the host–guest interactions in these selenium/zeolite encapsulates and the question of the driving force for the easy sorption of elemental Se into the zeolite cages has not been addressed. We note that the synthesis and characteristics of these Se/zeolite composites are distinct from those of ultramarine pigments,[8] which are aluminosilicates with chalcogen radical anions trapped inside sodalite cages.

The sorption of elemental Se into zeolites is comparable to vaporization: the intermolecular bonds of the bulk material must be overcome to produce separate Se chains and rings inside the zeolite. The counter-cations, which counterbalance the negatively charged aluminosilica framework, are the anticipated binding sites and play a crucial role on the structure of the encapsulate as shown in our recent studies.[9–12] In particular, the Raman spectra of Se in a number of cation-exchanged Y zeolites show the formation of Se_8 rings and predominant Se chains[11,12] with the fraction of rings increasing along the series La-Y, Nd-Y, Ca-Y and Sr-Y. In the present work, we demonstrate that the counter-cations do not only act as structure directing agents but also contribute significantly to the stabilization of Se inside the zeolites.

A competition experiment was carried out in which La^{3+}-ion exchanged zeolite La-Y ($Na_3La_{21}Al_{56}Si_{136}O_{384}$) was loaded with 13.5 Se atoms per supercage (La-Y/13.5Se = $Se_{108}Na_3La_{21}Al_{56}Si_{136}O_{384}$), close to the maximum uptake.[10] A detailed description of the synthesis can be found elsewhere.[10,11] This composite was then sealed in an evacuated quartz tube together with Ca^{2+}-ion exchanged zeolite Ca-Y ($Na_{13}Ca_{21}Al_{56}Si_{136}O_{384}$), the two materials being separated by a frit. Upon heating to 350 °C, Se diffuses through the frit and is redistributed between the two zeolites. After a reaction time of 11 days, as indicated by color changes, Se was almost completely transferred to the Ca^{2+}-ion exchanged zeolite Y according to the net reaction:

$$\underset{\text{orange}}{0.9\ \text{La-Y/13.5Se}} + \underset{\text{white}}{\text{Ca-Y}} \rightarrow \underset{\text{gray–white}}{0.9\ \text{La-Y/0.8Se}} + \underset{\text{orange}}{\text{Ca-Y/11.5Se}} \quad (1)$$

(La-Y/0.8Se = $Se_6Na_3La_{21}Al_{56}Si_{136}O_{384}$, Ca-Y/11.5Se = $Se_{92}Na_{13}Ca_{21}Al_{56}Si_{136}O_{384}$). The Na, Al, Si, Ca, and La content were analyzed by atomic absorption spectroscopy (AAS). The Se uptake was determined from the weight balance (> 99%). The only difference between the two forms of zeolite is the number and location of the metal ions.[10,11] Rare-earth cations form oxygen bridged clusters inside the smaller sodalite cages (6.5 Å diameter), whose windows (1.4 Å wide) are too narrow to admit molecular Se structures. In contrast, alkaline-earth cations are found also in the large supercages (13 Å diameter, 7.5 Å windows) in close proximity to the Se encapsulates.[10,11]

Since the structure of the incorporated Se is disordered with respect to the zeolite framework, crystallography does not yield information about the Se–cation interactions. Instead, we employed anomalous X-ray scattering (AXS) that has been successfully used for the study of bulk disordered materials.[13] This method exploits the strong energy variation of the complex atomic scattering factor $f(Q,E) = f_0(Q) + f'(E) + if''(E)$ in the vicinity of an X-ray absorption edge. A differential structure factor $S_z(Q)$ associated with a particular element z can be obtained from the difference of two diffraction measurements performed with incident energies some ten and some hundred eV below the absorption edge.[14] The scattering factors of the other elements in the sample do not change significantly over such an energy range. The differential pair distribution function $T_z(r)$, which is obtained from $S_z(Q)$ *via* Fourier transformation, gives information about the average spatial environment about the z atoms.[14]

In the present study we determined $S_{Se}(Q)$ for two zeolites with Se loading similar to those of eqn. (1): La-Y/11.7Se and Ca-Y/12.8Se. (The samples used for the competition experiment were too small for the X-ray measurements. Since we are presenting a difference of two measurements, the result should not be sensitive to the actual Se loadings as long as they are reasonably high and of similar magnitude in the two samples). The diffraction patterns were measured at energies 20 eV and 300 eV below the K absorption edge of Se (12658 eV). Although the Se concentration is < 15 atom% in each compound, the quality of the $S_{Se}(Q)$ data (Fig. 1) is reasonably good. The two corresponding $T_{Se}(r)$ look similar (Fig. 2). The oscillations below 2 Å are due to truncation effects caused by the limited range of Q in the $S_{Se}(Q)$ data. The first real peak is centered at 2.34 ± 0.02 Å in both distribution functions: this distance is well within the range of intramolecular bond lengths observed for bulk Se forms: 2.33 Å (trigonal Se),[15] 2.37 Å (monoclinic Se)[16] and 2.35 Å (amorphous Se).[17] The number of next-nearest neighbors was determined from the area in the radial distribution function $T_{Se}(r)$ corresponding to these peaks. The extracted coordination number CN(1) = 2.2 ± 0.3 is consistent with the existence of either infinite chains or rings [both with CN(1) = 2.0] inside the zeolite pores, corroborating the conclusion of our earlier Raman spectroscopic studies.[11,12] The second peak is located between 3.0 and 4.3 Å in both $T_{Se}(r)$ functions. At least two different types of interaction contribute to it,[18] second-neighbor Se–Se interactions at a distance of 3.7 Å and Se–O (framework) interactions at a distance of 4 Å. From the first and second nearest Se–Se distances R_1 and R_2, a bond angle of $\phi = 104 \pm 2°$ can be deduced [$R_2 = R_1\sin(\phi/2)$] which again is in the range of values found in bulk Se forms.[18] In the region above 4.5 Å, the assignment of further interactions is impossible, but significant differences between the two sets of

† Present address: Fachbereich Physikalische Chemie, Philipps-Universität Marburg Hans-Meerwein-Str., 35032 Marburg/Lahn, Germany.

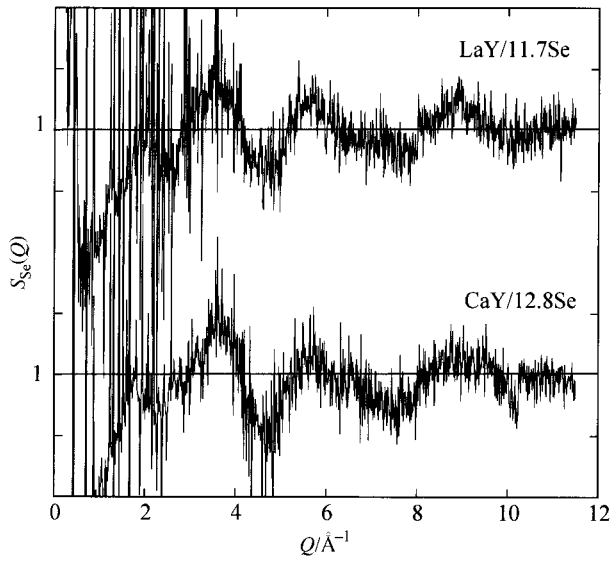

Fig. 1 Differential structure factors $S_{Se}(Q)$ of Ca-Y and La-Y loaded with 12.8 and 11.7 Se atoms per supercage, respectively, obtained from X-ray diffraction experiments at energies 20 and 300 eV below the K absorption edge of Se (12658 eV).

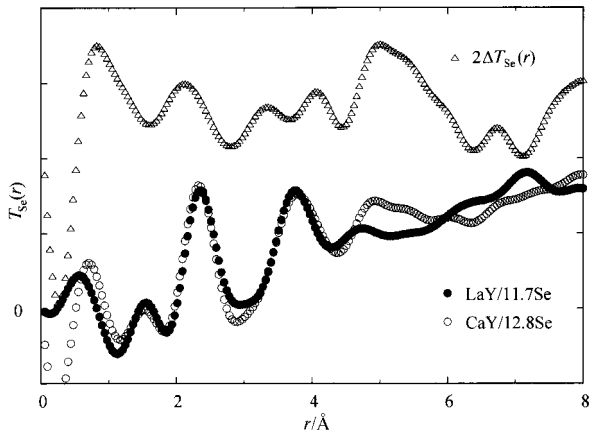

Fig. 2 Differential pair distribution functions $T_{Se}(r)$ of Ca-Y loaded with 12.8 Se atoms (open circles) and La-Y loaded with 11.7 Se atoms (filled circles) per supercage. The difference $\Delta T_{Se}(r)$ of the two $T_{Se}(r)$ functions is shown at the top: the peak around 5 Å is attributed to the Ca^{2+}–Se interaction, as discussed in the text.

$T_{Se}(r)$ functions in this region are noticeable and can be attributed to the Ca^{2+}–Se interaction, since, as discussed above, we believe that Se cation interactions exist in the Ca–Y zeolite and not in the La-Y zeolite. A corresponding peak emerges clearly around 5 Å in the difference $\Delta T_{Se}(r)$ of the two pair distribution functions (Fig. 2).

This long Ca^{2+}–Se distance is striking because it suggests a rather weak attraction. For comparison, the shortest possible Ca^{2+}–Se distance is given by the sum of the radii of Ca^{2+} (0.99 Å) and Se (1.17 Å). On the other hand, an interatomic distance of 2.965 Å is found in the ionic compound CaSe[19] where strong binding forces exist between Ca^{2+} and Se^{2-}. The attraction between Ca^{2+} and a neutral Se chain would be expected to be much weaker inside the zeolite. Probably, the geometrical requirements of both the zeolite framework and the Se chain prevent a close approach. The bond distances and angles of the zeolite encapsulated Se chains do not vary considerably from those found in bulk forms[18] and the dihedral angles are not expected to either. Thus, the short-range order appears to be rather robust and distortion of the Se chains towards the cations becomes unfavorable. Also, the Ca^{2+} ions in the supercage bind strongly to the anionic framework oxygen. In fact, the favorite Ca^{2+} site in the faujasite supercage is only slightly (0.3 Å) out of the plane of the sodalite windows.[20] Thus, they are not easily accessible for a fairly rigid Se chain. Furthermore, the electronic repulsion between the Se and the anionic framework oxygen prevents a close approach of the Se chain to the framework counteracting the weak attractive forces between Se and Ca^{2+}. On these considerations, the observed Ca^{2+}–Se distance of 5 Å appears reasonable. However, these attractive forces acting over this long range are still capable of stabilizing the Se chain significantly in the Ca-Y as opposed to the La-Y zeolite, as shown by the competition experiment described above.

In this work, we have shown that cations play an important role in the stabilization of Se in the pores of zeolites. The nature of the binding interactions has been investigated with AXS, which has allowed us to highlight the environment of the encapsulated Se with an atomic concentration of $< 15\%$: Se assumes a disordered arrangement within these porous materials. The attractive forces between the encapsulated Se and the zeolitic cations act over a surprisingly long distance of 5 Å.

We thank Drs D. E. Cox and Q. Zhu for valuable support and advice during the X-ray measurements. This work was supported by the US Department of Energy, Division of Materials Sciences, Office of Basic Energy Sciences, under Contract No. W-31-109-ENG-38. A. Goldbach gratefully acknowledges support by the Deutsche Forschungsgemeinschaft.

Novel supramolecular synthon in crystal engineering: ionic complexes of 4,4′-bipyridine and 1,2-bis(2-pyridyl)ethylene with 2,5-dichloro-3,6-dihydroxy-1,4-benzoquinone

Md. Badruz Zaman,*[ab] Masaaki Tomura[b] and Yoshiro Yamashita*[b]

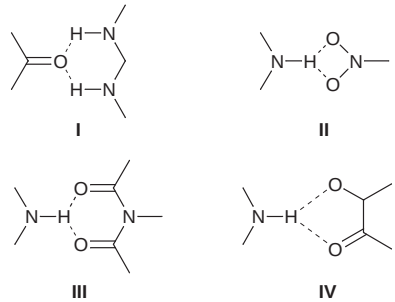
Received (in Cambridge, UK) 23rd March 1999, Accepted 26th April 1999

4,4′-Bipyridine (BPY) and 1,2-bis(2-pyridyl)ethylene (2-PDE) form bifurcated hydrogen bonds with 2,5-dichloro-3,6-dihydroxy-1,4-benzoquinone (chloranilic acid, 2H-CLA) to afford [BPY-2H]$^{2+}$[CLA]$^{2-}$ 1 and [2-PDE-2H]$^{2+}$[CLA]$^{2-}$ 2; their crystal structures exhibit a new type supramolecular synthon and links as molecular chains and zigzag tapes, respectively.

Supramoleculer synthons establish the conceptual relationship between crystal engineering and organic synthesis. Most recently, a variety of supramolecular synthons have been drawn by Desiraju[1,2] to identify the design elements for intermolecular interactions in solid. These supramolecular synthons have allowed structural chemists, organic/inorganic chemists and crystallographers to utilize the new concepts of supramolecular strategy, target identification, and synthetic methodology as parts of successful crystal engineering.

Since benzoquinone-type molecules with dihydroxy groups undergo multi-stage deprotonation and protonation processes, it is interesting to use such molecules to form characteristic intermolecular hydrogen-bonded networks.[3] On the other hand, bidentate bridging ligands are widely used with inorganic compounds to construct stable supramolecular complexes with well-designed geometries and strictly controlled self-assembly.[4] Therefore, we reasoned that by combining bipyridinium-type molecules with organic counterparts, supramolecular assemblies would be formed which exhibited intermolecular interactions. With this in mind we have used bipyridines and centrosymmetric dihalodihydroxybenzoquinones to form hydrogen-bonded networks. Thus a new type of supramolecular synthon **IV** has been exploited to understand noncovalent donor–acceptor (DA) interactions in the design of new supramolecular architectures.

Although synthons affording three-center hydrogen bonds (**I** and **II**) have been well-documented as supramolecular patterns,[5,6] synthons involving two carbonyl groups are very rare. To the best of our knowledge, the only example of synthon **III** is a recent report with an amide structure,[2] and synthon **IV** is unknown. We now report the successful realization of our aim, with the synthesis and X-ray crystal structures of the complexes from diprotonated 4,4′-bipyridine ([BPY-2H]$^{2+}$) and 1,2-bis(2-pyridyl)ethylene ([2-PDE-2H]$^{2+}$) with a dianion of 2,5-dichloro-3,6-dihydroxy-1,4-benzoquinone (chloranilate, [CLA]$^{2-}$), both of which feature novel supramolecular synthon **IV**.



The complexes† were prepared by reacting BPY and 2-PDE with an equal amount of chloranilic acid (2H-CLA) in acetone and/or a mixture of acetone–MeOH. The single crystals grew by the diffusion method over a period of two days. The crystal structures‡ reveal that molecular complexes [BPY-2H]$^{2+}$[CLA]$^{2-}$ **1** and [2-PDE-2H]$^{2+}$[CLA]$^{2-}$ **2** are formed where proton transfer takes place. The component molecules are combined *via* three-centre hydrogen bonded interactions to build a linear molecular chain or a zigzag molecular tape. The structural views of the molecular chain for **1** and the molecular tape for **2** are shown in Fig. 1 and 2, respectively.

In both **1** and **2**, bifurcated interionic [N$^+$–H···O$^-$ and N$^+$–H···O] hydrogen bonds between the nitrogen atoms of the cations and the two oxygen atoms from the anion are observed. The different N···O (2.62–3.00 Å) distances§ are associated with strong and weak hydrogen bonding interactions.[5] The N···O distances are shorter than the mean distances observed for the hydrogen bonds between anilic acids and organic donors,[3,7] indicating the strength of the charged hydrogen bond interactions. The bond lengths in the anions, such as the double

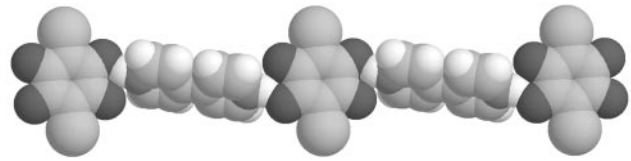


Fig. 1 View of the molecular chains of **1**.

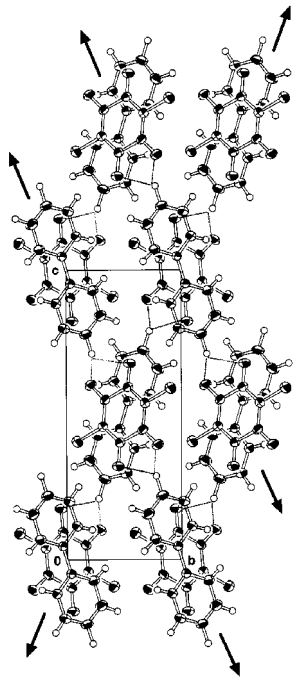

Fig. 3 Crystal packing of **1** viewed along the crystallographic *a* axis. This figure shows the cross-linked chains forming layers.

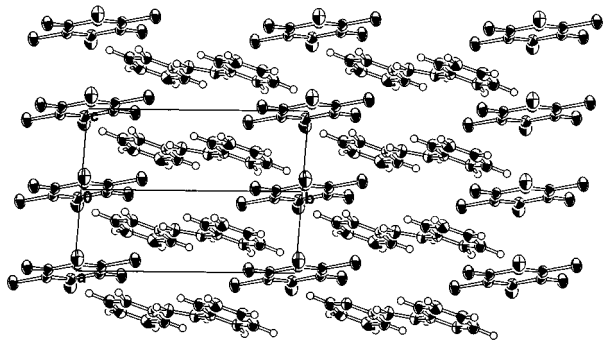

Fig. 4 Crystal packing of **2** viewed along the diagonal line of the *ac* plane. This shows the segregated stacking of the complex.

bonds (C=O, 1.235 Å for **1** and 1.238 Å for **2**) and the single bonds (C–O, 1.256 Å for **1** and 1.252 Å for **2**), are consistent with the molecular geometry of the chloranilate dianion.[7] The dihedral angles between the planes of the cations and anions are 65.8 and 23.6° for **1** and **2**, respectively.

In complex **1** one-dimensional molecular chains are observed toward the two cross diagonal lines within the *bc* plane. A view of such a two-directions cross-linked chain structure of complex **1** is shown in Fig. 3. Moreover, this structure reveals alternating DA-type pairs between the cation and anion molecules (the average distance and angle between the least-squares planes of the cation and anion are 3.42 Å and 3.8°) along the crystallographic *a* axis. Interestingly, complex **2** shows a segregated stacking assembly as DD- and AA-type pairs (Fig. 4), that is, no crossover association is observed in the tapes. The change of position of the nitrogen atoms in the ligands modifies the stacking arrangement though the supramolecular synthon pattern **IV** is unchanged. The *trans*-configuration of the linked ethylene group of the precursor 2-PDE seems to produce zigzag tape structure **2**.

This result not only describes a new supramolecular synthon motif but also highlights the molecules which will allow the design of further supramolecular architectures based on simple components. The present structures are the first examples; further studies in the field of crystal engineering will produce further enhancements, with the eventual creation of new supramolecular synthons and supramolecular architectures *via* investigation of geometrically and stoichiometrically matched donor and acceptor molecules.[8]

Received (in Cambridge, UK) 16th March 1999, Accepted 23rd April 1999

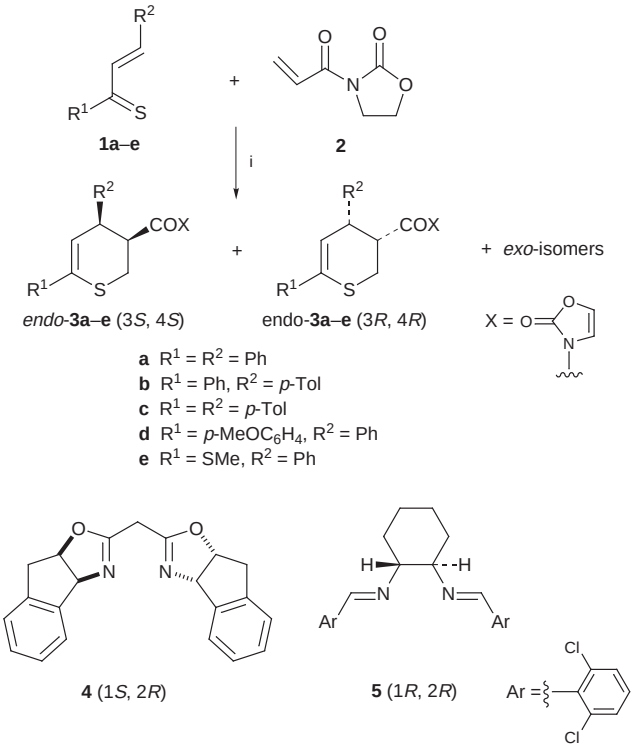
The catalytic, highly enantioselective hetero-Diels–Alder reactions of thiabutadienes using homochiral copper and nickel triflate and perchlorate bis(oxazoline) and bis(imine) complex catalysts to afford optically active dihydrothiopyrans are described for the first time.

The asymmetric hetero-Diels–Alder reaction is a powerful and versatile synthetic method and has a wide range of applications for the synthesis of not only optically active heterocycles as targets themselves but also useful compounds derived from them *via* further synthetic manipulation.[1] Despite its promising utility, however, the asymmetric hetero-Diels–Alder reaction of thiocarbonyl compounds has received much less attention and very few reports on the reaction have appeared so far.[2–4] Amongst the hitherto reported examples of asymmetric hetero-Diels–Alder reactions with thiabutadienes taking part as 4π-components, are diastereoselective methods that utilize chiral auxiliaries attached to either thiadienes or dienophiles for asymmetric induction.[3] To the best of our knowledge, the only report of an enantioselective thiadiene Diels–Alder reaction has been that recently presented by us.[4] Unfortunately, however, it required stoichiometric amounts of chiral Lewis acid to attain a high level of asymmetric induction (up to 95% ee). Therefore, our research has been focused on the development of chiral Lewis acid-induced catalytic thiadiene Diels–Alder cycloadditions giving dihydrothiopyrans with high enantiomeric excess. Here, we present for the first time the *catalytic*, highly enantioselective hetero-Diels–Alder reaction of thiabutadienes.

Prompted by the report by Ghosh and co-workers on the highly enantioselective carbo- and oxa-Diels–Alder reactions using bis(oxazoline) **4**–Lewis acid complexes as chiral catalysts,[5] we selected bis(oxazoline) **4** as the chiral catalyst ligand from among a variety of chiral bis(oxazoline) derivatives with a great deal of structural diversity employed in numerous asymmetric reactions.[6]

Initially, screening of Lewis acids used in combination with chiral ligand **4** was performed in the hetero-Diels–Alder reaction of thiabutadiene **1a** with dienophile **2** (Scheme 1) under various conditions,† and it was found that $Cu(OTf)_2$, $Cu(ClO_4)_2$, and $Ni(ClO_4)_2$ were the Lewis acids of choice in this reaction.‡ Some selected results are summarized in Table 1.

When the reaction was carried out at room temperature using 50 mol% $Ni(ClO_4)_2$–bis(oxazoline) **4** complex (run 3), cycloadduct **3a** was obtained in good yield (99%) with high enantiomeric excess (96%) of the *endo* adduct (3*S*, 4*S*),§ albeit with moderate *endo*:*exo* selectivity (76:24). It was found that at lower temperatures (−78 to 0 °C), the enantioselectivity was markedly decreased in the $Ni(ClO_4)_2$- and $Cu(OTf)_2$-catalyzed reactions (runs 1, 2, 5 and 6). The amount of the Ni^{II} catalyst could be reduced to 10 mol% while maintaining a good enantiomeric excess of 80% (run 4). The reaction using 100 mol% $Cu(OTf)_2$–**4** catalyst at room temperature (run 7) also afforded the cycloadduct **3a** in good yield (92%) with excellent enantioselectivity (98% ee). The high enantioselectivity (98% ee) was maintained in the presence of even catalytic amounts (10 mol%) of the catalyst (run 8). $Cu(ClO_4)_2$–**4** catalyst also induced good enantioselectivity (93 and 89% ee) with the use of only 5 mol% of the catalyst (runs 9 and 10).



Scheme 1 *Reagent and conditions*: i, Lewis acid–bis(oxazoline) **4** or –bis(imine) **5**.

Table 1 Asymmetric hetero-Diels–Alder reaction of thiabutadiene **1a** (using precursor dimer D) with **2** in the presence of a chiral catalyst [Lewis acid-bis(oxazoline) **4** complex] to afford cycloadduct **3a**[a]

Run	Lewis acid (mol%)	*T*/°C[b]	Yield[c] (%)	*endo*:*exo*[d]	Ee (%) (*endo*)[e]
1	$Ni(ClO_4)_2$ (50)	−65	49[f]	79:21	1
2	$Ni(ClO_4)_2$ (50)	0	90	78:22	85
3	$Ni(ClO_4)_2$ (50)	rt	99	76:24	96
4	$Ni(ClO_4)_2$ (10)	rt	80	78:22	80
5	$Cu(OTf)_2$ (100)	−78	23[f]	77:23	1
6	$Cu(OTf)_2$ (100)	0	90	79:21	78
7	$Cu(OTf)_2$ (100)	rt	92	71:29	98
8	$Cu(OTf)_2$ (10)	rt	92	70:30	98
9	$Cu(ClO_4)_2$ (5)	rt	91	77:23	93
10	$Cu(ClO_4)_2$ (5)	0	92	78:22	89

[a] Reaction was carried out in CH_2Cl_2 for 1.5–7 h with a ratio of **1a**:**2**:catalyst (Lewis acid:**4** = 1.0:1.1) = 1.2:1.0:0.05–1.0. A dithiine-type dimer (D) of **1a** was used as the precursor. Concerning the dithiine-type (D) and thiopyran-type (T) dimers used in asymmetric hetero-Diels–Alder reactions, see our earlier report [ref. 3(*b*)]. [b] rt = room temperature. [c] Isolated yield. [d] Determined by ^1H NMR spectroscopy and HPLC analysis. [e] Determined by HPLC analysis. [f] Reaction was incomplete after 3 h.

Table 2 Asymmetric hetero-Diels–Alder reaction of thiabutadienes **1a–d** (using precursor dimer T) with **2** in the presence of a chiral catalyst [Lewis acid–bis(oxazoline) **4** complex] to afford cycloadducts **3a–d**[a]

Run	**1**, **3**	Lewis acid (mol %)	Yield[b] (%)	*endo* : *exo*[c]	Ee (%) (*endo*)[d]
1	**a**	$Ni(ClO_4)_2$ (50)	84	78 : 22	91
2	**a**	$Cu(OTf)_2$ (50)	62	60 : 40	80
3	**a**	$Cu(ClO_4)_2$ (10)	89	77 : 23	90
4	**a**	$Cu(ClO_4)_2$ (5)	84	78 : 22	86
5	**b**	$Cu(OTf)_2$ (50)	65	74 : 26	85
6	**b**	$Cu(ClO_4)_2$ (10)	88	64 : 36	81
7	**c**	$Cu(OTf)_2$ (50)	60	64 : 36	83
8	**d**	$Cu(OTf)_2$ (20)	66	71 : 29	96
9	**d**	$Cu(ClO_4)_2$ (10)	86	82 : 18	86

[a] Reaction was carried out in CH_2Cl_2 at room temperature for 3 h in a ratio of **1** : **2** : catalyst (Lewis acid : **4** = 1.0 : 1.1) = 1.2 : 1.0 : 0.05–0.5. A thiopyran-type dimer (T) of **1** was used as the precursor. [b] Isolated yield. Reaction was incomplete after 3 h. [c] Determined by ^{1}H NMR spectroscopy and HPLC analysis. [d] Determined by HPLC analysis.

The Cu^{II}– and Ni^{II}–**4** catalyzed reactions between thiabutadienes **1a–d** and **2** using the corresponding thiopyran-type dimers as the precursors of **1** were examined (Table 2). It was found that the reactions also proceeded efficiently at room temperature to show satisfactory enantioselectivities (96–80% ee). In the cases of **1a–c** using either $Ni(ClO_4)_2$ or $Cu(OTf)_2$, at least 50 mol% of the catalyst was needed to preserve the high enantioselectivities (> 80% ee) (runs 1, 2, 5 and 7), while 5–10 mol% $Cu(ClO_4)_2$–**4** catalyst efficiently catalyzed the reactions to give the high ees of the *endo* adducts (runs 3, 4, 6 and 9). It is noteworthy that the reaction with the *p*-methoxyphenyl-substituted thiabutadiene **1d** showed excellent enantioselectivity (96% ee) even with the use of 20 mol% $Cu(OTf)_2$–**4** catalyst (run 8).

Finally, α,β-unsaturated dithiocarboxylic ester **1e**, which can exist as a monomer, was subjected to a chiral Lewis acid-catalyzed hetero-Diels–Alder reaction and the results are summarized in Table 3. The observed enantioselectivity was found to be largely dependent on reaction temperature, the combination of the Lewis acid and the ligand (**4**/**5**), the amount used (stoichiometric or catalytic), and the presence or absence of an additive (molecular sieves). Namely, when the reactions were performed at room temperature in the presence of 100 or 20 mol% of the catalyst [$Ni(ClO_4)_2$–**4**] (runs 1 and 2), a cycloadduct **3e** was obtained in good to fair enantiomeric excess (89–82% ee). It is noteworthy that the use of a small amount (5 mol%) of $Cu(OTf)_2$–**4** catalyst in the reaction at room temperature gave cycloadduct **3e** in 74% yield with fair enantiomeric induction (74% ee) (run 3), whereas the reactions using 100 mol% of the catalyst at either room temperature, 0 or −78 °C) afforded none of the cycloadduct; only a decomposition reaction took place. By use of ligand **5** instead of **4** complexed with 100 mol% $Cu(OTf)_2$ at low temperature (−78 °C), almost complete enantioselectivity (> 99% ee) was obtained (run 4). Disappointingly, however, the enantioselectivity was reduced to only 10% ee in the presence of 20 mol% of the catalyst (run 5). It was exciting to eventually find that in the presence of 4 Å molecular sieves as an additive,¶ the catalytic process was completely restored without any reduction of the high enantiomeric excess (> 99%) when performed at −78 °C (runs 7 and 8) rather than at room temperature (run 6).‖

Table 3 Asymmetric hetero-Diels–Alder reaction of thiabutadiene **1e** with **2** in the presence of a chiral catalyst [Lewis acid–ligand **4**/**5** complex] to afford cycloadduct **3e**[a]

Run	Lewis acid (mol%)	Ligand	*T*/°C[b]	Yield[c] (%)	*endo* : *exo*[d]	Ee (%) (*endo*)[e]
1	$Ni(ClO_4)_2$ (100)	**4**	rt	53	78 : 22	89
2	$Ni(ClO_4)_2$ (20)	**4**	rt	55	70 : 30	82
3	$Cu(OTf)_2$ (5)	**4**	rt	74	65 : 35	74
4	$Cu(OTf)_2$ (100)	**5**	−78	95	89 : 11	> 99
5	$Cu(OTf)_2$ (20)	**5**	−78	78	85 : 15	10
6	$Cu(OTf)_2$ (10)[f]	**5**	rt	78	82 : 18	86
7	$Cu(OTf)_2$ (10)[f]	**5**	−78	70	86 : 14	> 99
8	$Cu(OTf)_2$ (5)[f]	**5**	−78	74	88 : 12	> 99

[a] Reaction was carried out in CH_2Cl_2 for 3–16 h in a ratio of **1e** : **2** : catalyst (Lewis acid : **4**/**5** = 1.0 : 1.1) = 1.2 : 1.0 : 0.05–1.0. [b] rt = room temperature. [c] Isolated yield. [d] Determined by ^{1}H NMR spectroscopy and HPLC analysis. [e] Determined by HPLC analysis. [f] In the presence of powdered 4 Å molecular sieves.

Notes and references

† For example, solvent effects on enantioselectivity were observed to a greater or lesser extent, and the presence of an additive such as powdered molecular sieves (4 Å) was found to effect almost no improvement in either ee or catalytic turnover in this cycloaddition.

‡ Some other Lewis acids used were found to be inferior to $Cu(OTf)_2$, $Cu(ClO_4)_2$ and $Ni(ClO_4)_2$: *e.g.* $Co(ClO_4)_2$ (50 mol%) 50% ee, $NiCl_2$–$6H_2O$ (100 mol%) 0% ee, $Mg(OTf)_2$ (100 mol%) 1% ee, $Mg(ClO_4)_2$ (100 mol%) 64% ee, and $Zn(OTf)_2$ (100 mol%) 5% ee.

§ The absolute configuration of the major *endo* isomer of **3a** was determined by comparison of its retention time by chiral HPLC analysis and specific rotation of its derived alcohol with those of authentic samples. (ref. 3, 4).

¶ In the presence of a dehydrating agent such as $Mg(SO_4)_2$ instead of 4 Å molecular sieves, only 40% ee was observed.

‖ Recently, a new aspect of the role of molecular sieves in metal-catalyzed asymmetric 1,3-dipolar cycloaddition reactions was reported by Jørgensen *et al.* (ref. 7). See also our earlier report (ref. 4).

Stereospecific rhenium catalyzed desulfurization of thiiranes

Josemon Jacob and James H. Espenson*

Ames Laboratory and Department of Chemistry, Iowa State University of Science and Technology, Ames, IA 50011, USA. E-mail: espenson@ameslab.gov

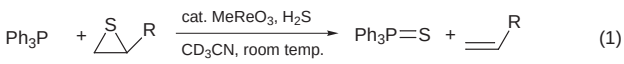
Received (in Bloomington, IN, USA) 3rd March 1999, Accepted 20th April 1999

Methyltrioxorhenium catalyzes the efficient and stereospecific desulfurization of thiiranes by triphenylphosphine at room temperature, moreso when MTO has been pretreated with hydrogen sulfide, with a Re^{V} species as the active form of the catalyst.

Desulfurization of thiiranes (episulfides) occurs thermally,[1] photochemically[2] and chemically.[3–11] One of the most widely used reactions of thiiranes is the stereospecific desulfurization by trivalent phosphorus compounds such as PPh_3.[4] These are very slow reactions, the rate constant for the reaction between PPh_3 and but-1-ene sulfide being $(0.9–1.8) \times 10^{-5}$ l mol^{-1} s^{-1} at 40 °C in different solvents. Recent studies of oxygen atom transfer[12–14] might be extended to sulfur atom transfer reactions, using organorhenium catalysts. Herein we report the results of our investigations.

Treatment of propylene sulfide with PPh_3 gave no direct reaction until catalytic amounts of $MeReO_3$ (MTO) were added.† Propylene was then formed, albeit quite slowly (Fig. 1) and only after a long induction period. The active catalyst, a Re^{V} species, from MTO and Ph_3P, is formed by a similar induction period.[15] Plausibly, an unspecified thiorhenium intermediate arises during that time.

Rhenium(v)[16] is proposed to be the active catalyst species here as well. Substitution of an oxygen atom on MTO by sulfur might perhaps eliminate the induction period, in that Re^{VII} transfers a sulfur atom to a phosphine faster than it does an oxygen atom. MTO exchanges oxygens with water[17,18] and could use H_2S to exchange one or more oxygen atoms with sulfur. As a test, H_2S was first bubbled through MTO in CD_3CN and the reaction repeated [eqn. (1)]. As predicted, the rate was significantly enhanced (Fig. 1).



(1)

Removal of H_2S by bubbling argon through the reaction prior to the addition of the phosphine and episulfide did not diminish the reactivity.‡ The general reaction with episulfides[19,20] occurs efficiently on a 2 g scale at room temperature for many thiiranes

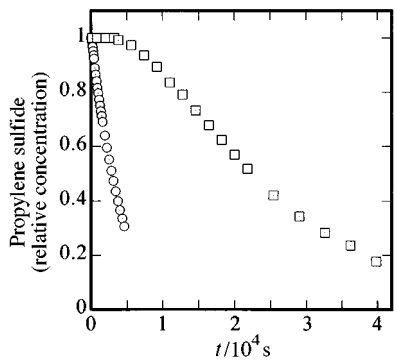


Fig. 1 Kinetics of the reaction of propylene sulfide with PPh_3 in the presence of MTO as followed by ^{1}H NMR: (□) no H_2S, [propylene sulfide] = 50 mM, [PPh_3] = 200 mM, [MTO] = 20 mM; (○) MTO solution (2 mM) rapidly pre-treated with H_2S, followed by an argon sparge, [propylene sulfide] = 100 mM, [PPh_3] = 200 mM.

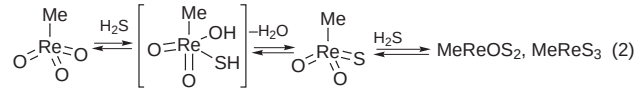
(Table 1). This desulfurization process is tolerant of various functional groups. With both epoxy and episulfido groups (entry 10), only the episulfide undergoes atom transfer. Stereochemistry is retained completely, as indicated by entries 12 and 13.

In the absence of H_2S the reaction proceeds as shown in Scheme 1. H_2S alters the reaction by forming thiorhenium complexes in exchange processes [eqn. (2)]. Direct reaction



(2)

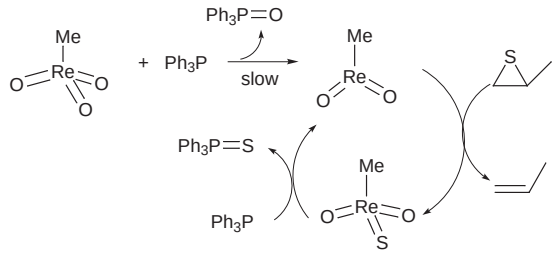
with H_2S yields Re_2S_7 from $KReO_4$ and MoS_3 from $(NH_4)_2MoO_4$.[21] The same components at elevated temperatures (> 450 °C) form reduced (Re^{V} and Mo^{IV}) sulfides.[22]

On bubbling H_2S through a solution of MTO in CD_3CN, a black solid separates out within a few minutes. It proved insoluble in all common organic solvents and in water, complicating its characterization. Excess H_2O_2 dissolved the black solid product, but the ^{1}H NMR chemical shift of the new species does not match that of the well-established diperoxo complex of MTO.

Our next approach was to prepare and study MTO complexes to establish the mechanism. Nitrogen donor ligands give well-documented complexes with MTO,[14] but complexes of MTO with phenanthroline, bipyridine and 8-hydroxyquinoline failed

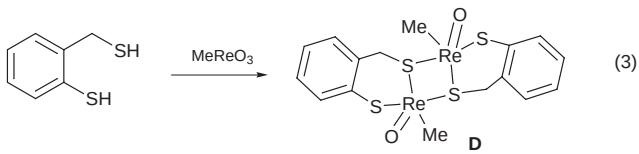
Table 1 Yields obtained in the MTO-catalyzed desulfurization of thiiranes§

Entry	Substrate	Product	Time	Yield (%)
1			3 h	100
2			5 min	100
3			5 min	96
4			5 min	100
5			1 h	100
6			4 h	89
7			6 h	100
8			9 h	50
9			1 h	90
10			2 h	100
11			1 h	100
12			30 min	100
13			30 min	100



Scheme 1

to react with H_2S. Reaction with 2-mercaptomethylthiophenol[23,24] gave a new dimeric yellow rhenium(v) complex **D** [eqn. (3)], as reported earlier.[25]



(3)

With **D** in hand it was possible to test the mechanism in Scheme 1, according to which 2 equiv. of episulfide should be desulfurized without phosphine. Fig. 2 shows the kinetics of an experiment with **D** and a four-fold excess of propylene sulfide. According to the amounts of material formed and remaining, **D** reacts with 2 equiv. of the thiirane, establishing rhenium(v) as the active catalyst. Furthermore, the reaction can be made catalytic in rhenium by the addition of PPh_3 and the use of much less **D** at the outset, although a longer time is required than with the use of the aforementioned MTO/H_2S procedure. The same rate of desulfurization as given by MTO/H_2S was achieved by bubbling H_2S through the dimer solution before the addition of the episulfide and phosphine (Fig. 2). Addition of H_2S changes the color of the solution from yellow to pink, consistent with conversion of the Re=O group of **D** to Re=S; the species responsible could not be isolated.

The question still remains, regarding the original MTO/H_2S system, of whether the reactions utilize a sulfur analogue of MTO or a rhenium(v) species that might have been formed in the system. The black solid obtained on reaction of MTO with H_2S is an oligomeric alkylrhenium sulfide. Transition metal sulfides, including high oxidation state rhenium sulfides, are known to oligomerize and some of them have been characterized. [26] When the black solid obtained on reaction with H_2S was treated with propylene sulfide, 4% desulfurization was observed in 2 h (starting with 5 mM MTO), suggesting the formation of at least some rhenium(v). The constitution of the major part was deduced by these experiments. First H_2S was bubbled through 20 mM MTO in CD_3CN until all the MTO had reacted (by ^{1}H NMR), the excess then being removed by an argon purge. Its reaction with successive 5 mM increments of PPh_3 was then monitored by ^{31}P NMR. Only Ph_3P=S was observed, and no PPh_3 detected, on addition of 15 mM PPh_3. Addition of a further 5 mM increment of PPh_3 showed very small amounts of PPh_3. Beyond that, more phosphine did not lead to more Ph_3P=S. These findings indicate the presence of a rhenium(VII) sulfide that easily transfers a sulfur atom to a phosphine to generate Re^V and phosphine sulfide. Most of product of the MTO/H_2S reaction exists as Re^{VII} on reaction with H_2S. On the basis of direct information, however, we cannot claim that another valence state, such as Re^{VI}, is not involved.

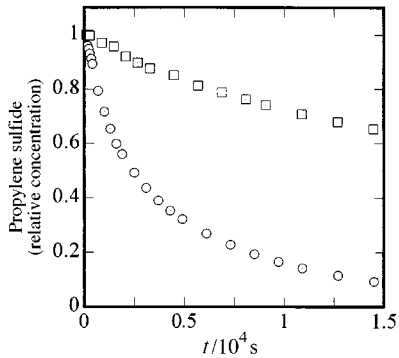


Fig. 2 Decrease in the concentration of propylene sulfide as followed ^{1}H NMR: (□) stoichiometric experiment, with [propylene sulfide] = 30 mM, [**D**] = 7.5 mM; (○) catalytic experiment, with [propylene sulfide] = 100 mM, [PPh_3] = 125 mM and [**D**] = 2 mM, at room temperature.

This is a novel catalytic system that effects the desulfurization of episulfides at ambient temperature and pressure. The reaction is stereospecific and tolerant to functional groups.

This research was supported by the U.S. Department of Energy, Office of Basic Energy Sciences, Division of Chemical Sciences, under contract W-7405-Eng-82.

Notes and references

† MTO, propylene sulfide and cyclohexene sulfide were purchased. The other episulfides were synthesized. NMR spectra were referenced to solvent peaks: δ 7.15 for C_6D_6 and δ 1.93 for CD_3CN.

‡ In a typical experiment, hydrogen sulfide was bubbled into 2 mM MTO in CD_3CN for about 5 min, as a black solid separated. The excess of H_2S was removed by sparging with argon, whereupon PPh_3 and the episulfide were added. The reaction was monitored by NMR, and yields obtained based on proton integration relative to the solvent or to an internal standard of Ph_3CH. The chemical shifts of the olefin products agreed well with reference data.

§ In a typical experiment, carried out at room temperature, H_2S was bubbled through a 2 mM MTO in CD_3CN for 5 min; excess H_2S was then removed by purging with argon. To this solution PPh_3 (125 mM) was added, followed by the thiirane (100 mM). The reaction was followed by ^{1}H NMR at 25 °C. The reaction also worked very well on a 2 g scale.

Total synthesis of (*S*)-espicufolin and absolute structure determinaton of espicufolin

Hidemitsu Uno,*[a] Katsuji Sakamoto,[a] Erina Honda[a] and Noboru Ono[b]

[a] *Advanced Instrumentation Center for Chemical Analysis, Ehime University, Bunkyo-cho 2-5, Matsuyama 790-8577, Japan. E-mail: uno@dpc.ehime-u.ac.jp*

[b] *Department of Chemistry, Faculty of Science, Ehime University, Bunkyo-cho 2-5, Matsuyama 790-8577, Japan*

Received (in Cambridge, UK) 1st March 1999, Accepted 13th April 1999

(*S*)-Espicufolin was synthesized from 1,4-dimethoxybenzene in 16 steps *via* an intramolecular acyl-transfer reaction as the key step; the absolute stereochemistry at the 14-position of natural espicufolin was determined to be *R*.

In the disease ischemia, L-glutamic acid in the brain is believed to play an important role as an excitatory neurotransmitter, increasing the level of powerful oxidants such as superoxide anion and oxygen radicals in the neuronal cells, which then cause neuronal cell death.[1] Neuronal cell-protecting compounds for such events have attracted increasing attention from scientists in many fields. In 1996, Seto *et al.* found a novel neuronal cell-protecting substance in the culture broth of *Streptomyces* sp. cu39 in the course of their screening for suppressors of glutamate toxicity using neuronal hybridoma N18-RE-105 cells and named it espicufolin (**1**, Fig. 1).[2] However, the action mechanism of espicufolin **1** was suggested not to relate to antioxidative activity, from an experiment involving buthionine sulfoximine toxicity.[2,3] From a structural viewpoint, espicufolin **1** has an anthraquinone skeleton fused with a γ-pyrone ring and one unknown stereogenic centre at the 14-position. Espicufolin **1** is considered as a new member of the pyranoanthraquinone family;[4] these compounds are also reported to show antitumor and antibiotic activity. Thus, we aimed to synthesize espicufolin **1** *via* a route which can be applied to the syntheses of other family members in addition to espicufolin analogues.

Since the regioselective Diels–Alder reaction of chloronaphthoquinone with 1-methoxycyclohexa-1,3-diene has been established as one of the most reliable methods for construction of anthraquinones bearing hydroxy groups, we required pyranonaphthoquinone **2**. First, we focussed on the preparation of the intermediate **2** from the readily available naphthol **3** (Scheme 1), which was obtained from 1,4-dimethoxybenzene in 22% yield (5 steps).[5] As attempts to introduce an acetyl group at the 2-position of **3** *via* a Friedel–Crafts reaction and a Fris rearrangement failed, probably due to steric encumbrance, we thought to utilise the neighbouring hydroxymethyl group at the 3-position. After selective acetylation of the primary hydroxy group of **3** (90%), iodination[6] of **6** was carried out in CH_2Cl_2 (0.2 mol l^{-1}) to give **5** regioselectively in 31% yield, in addition to a mixture of dimers (38%). The dimer formation was simply suppressed by using an increased volume of solvent (0.05 mol l^{-1}) to give **5** in 77% yield. Protection with a MOM group followed by saponification of the acetyl group afforded **7** in 77% yield. The alcohol **7** was condensed with (*S*)-4-methylhex-2-ynoic acid,[7] which was in turn prepared from commercially available (*S*)-2-methylbutan-1-ol according to a literature procedure,[8] by treatment with bis(2-oxo-1,3-oxazolidin-3-yl)-phosphinic chloride (BOPCl) and Et_3N to afford **8** in 97% yield.[9] By treatment of **8** with Bu^nLi at −78 °C, a smooth iodine–lithium exchange reaction followed by spontaneous intramolecular acyl transfer occurred to give 2-acylnaphthalene **9**† in almost quantitative (95%) yield as an equilibrium mixture

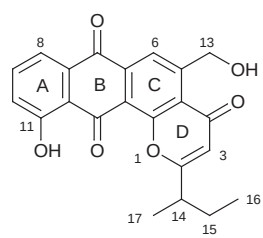

Fig. 1 Structure and numbering of espicufolin **1**.

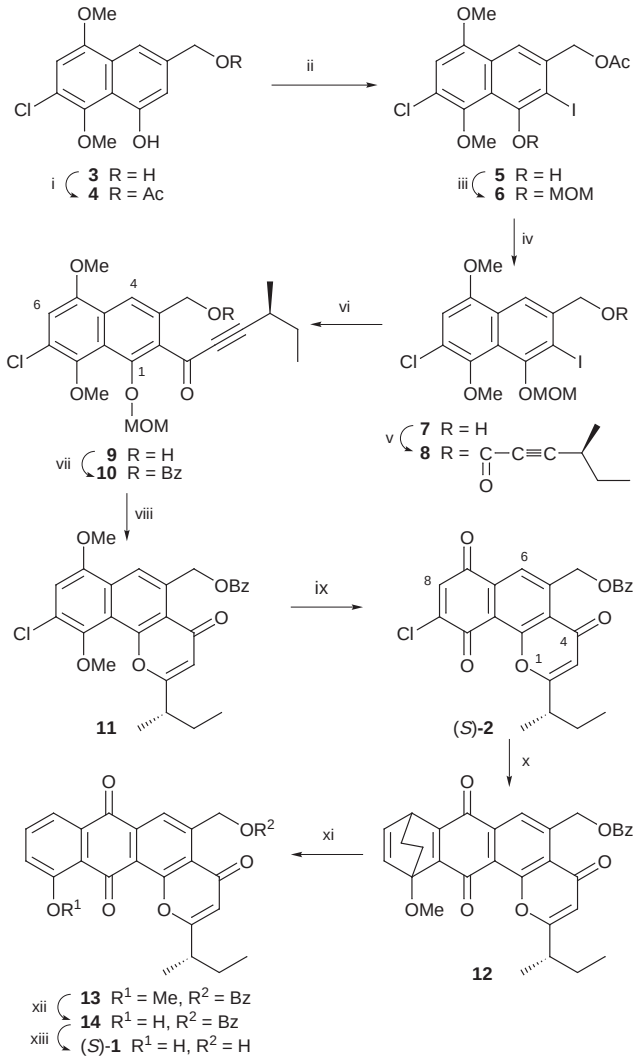

Scheme 1 *Reagents and conditions*: i, Ac_2O, $HClO_4$, CH_2Cl_2, rt; ii, I_2, *N*-methylmorpholine, CH_2Cl_2, rt; iii, NaH, MOMCl, DMF, rt; iv, NaOH, aq. THF–MeOH, rt; v, *S*-4-methylhex-2-ynoic acid, BOPCl, Et_3N, CH_2Cl_2, rt; vi, BuLi, THF, −78 °C; vii, BzCl, Py, rt; viii, HCl, aq. THF–Pr^iOH, reflux; ix, CAN, aq. MeCN, 0 °C; x, 1-methoxycyclohexa-1,3-diene, CH_2Cl_2, rt; xi, 140 °C, neat; xii, BBr_3, −78 °C; xiii, NaOH, aq. THF–MeOH, 0 °C.

with its hemiacetal form. This mixture was treated with BzCl in pyridine to give benzoate **10** in 87% yield. Removal of the MOM group from **10** under acidic conditions brought about simultaneous intramolecular cyclization forming desired γ-pyrone **11** (64%) predominantly; formation of any furanone compound could not be detected. This cyclization was formally thought to be a successful example of the *6-endo-dig* process, which usually competed the *5-exo-dig* ring closure giving furanones in the cases under basic conditions.[10] However, it is not clear at this moment if the allenic carbocation generated by protonation to the ynone carbonyl oxygen is directly attacked by the intramolecular phenolic oxygen or by water followed by dehydrative ring closure.[11] The γ-pyrone **11** was converted to the intermediate **2**† in 75% yield.

The one-pot method[5] of anthraquinone formation from naphthoquinones and 1-methoxycyclohexa-1,3-diene was applied for construction of the A ring of **1**. However, an intractable mixture was obtained due to decomposition probably by HCl. Thus, the Diels–Alder adduct from **2** and 1-methoxycyclohexa-1,3-diene was treated with pyridine to afford the diastereomeric quinone **12** in 77% yield. Heating **12** at 140 °C afforded anthraquinone **13** in good yield (74%). Demethylation of **13** with BBr_3 (75%) followed by saponification (69%) gave (*S*)-espicufolin, spectral and physical data† of which were identical to those previously reported, except for $[\alpha]_D$.[2] The value for synthetic (*S*)-**1** was $[\alpha]_D^{23}$ −11 (*c* 0.021, $CHCl_3$), whereas the authentic espicufolin kindly provided by Professor Seto was $[\alpha]_D^{23}$ +9.4 (*c* 0.020, $CHCl_3$). Therefore, the unknown stereochemistry at the 14-position can be assigned as *R*; our synthetic sample is an enantiomer of natural espicufolin. Espicufolin must therefore be synthesized starting from (*R*)-2-methylbutanol, which can be readily prepared by a literature procedure.[12]

We have achieved the synthesis of the enantiomer of neuronal cell-protecting espicufolin in 1.3% overall yield from 1,4-dimethoxybenzene in 15 steps. The absolute stereochemistry of espicufolin **1** is determined to be *R*.

Received (in Cambridge, UK) 15th April 1999, Accepted 26th April 1999

A porphyrinatoerbium–benzo-18-crown-6 conjugate offers efficient extraction and chirality sensing of amino acids under neutral conditions *via* synergistic binding of zwitterions.
