Received (in Cambridge, UK) 12th May 1998, Accepted 8th July 1998

Reports of the synthesis of new dendrimers containing organometallic fragments have increased dramatically over the past few years and examples of dendrimers containing many different metals are now known. This article highlights some of the the ways in which transition metals and their ligand systems have been incorporated into the growing number of dendrimers. Some structural details and properties of metal-containing dendrimers are described, and their applications are also discussed. The cover illustration shows Table Mountain, South Africa and a fourth generation ruthenium dendritic wedge.

Introduction

Nature has the ability to manipulate and control the structures of molecules in three dimensions. The rising demand for materials with improved and novel properties has now changed the emphasis in polymer research to new classes of materials with highly controlled molecular architectures.[1,2] New families of highly branched three-dimensional molecules, termed dendrimers, arborals or starburst polymers, have recently been prepared and have sparked great interest. Several review articles have appeared recently.[1] One of the driving forces in the study of these highly branched macromolecules has been the anticipation that these new materials will have fundamentally different properties when compared to more traditional linear polymers. While the majority of dendrimers prepared so far have been purely organic in nature, there is growing interest in the synthesis of dendrimers containing transition metals. The metal centres can be incorporated at the core, throughout the structure, or at the periphery of a dendrimer and may give compounds with novel or unusual properties. Such compounds are new materials and may have important applications, including uses as molecular devices, as antennas for harvesting light or as catalysts. Exploration of the synthesis, properties, structures and applications of these new materials is both challenging and exciting. Over the past six years, we have developed a methodology for synthesizing dendrimers containing covalent metal–carbon sigma bonds. To date, we have concentrated on compounds containing Ru–C and Fe–C bonds but we are currently investigating the synthesis of many other organometallic systems. In the following pages, we describe some of our work along with that of others in the field. Dendrimers are discussed according to the mode of bonding between the metal and dendrimer.

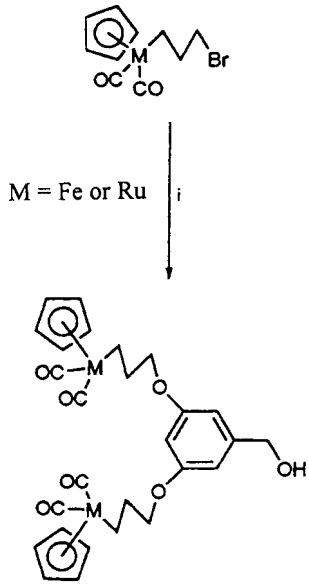
John R. Moss was born in Aberdeen, Scotland. He obtained his BSc (Hons) degree in 1965 and completed his PhD (1968) with B. L. Shaw, both at Leeds University, England. After post-doctoral fellowships with W. A. G. Graham in Canada and F. G. A. Stone at Bristol, he joined Rhodes University, South Africa in 1973 as a lecturer. In 1979, he moved to the University of Cape Town, where he is now Jamison Professor of Inorganic Chemistry and Head of the Department of Chemistry. His research interests are in the synthesis of new organotransition metal compounds and their applications as catalysts, new materials and medicines.

Meredith A. Hearshaw (née Timme) was born in Cape Town, South Africa and obtained her BSc (Hons) degree in 1993 in the First Class. She is currently completing her PhD degree on the synthesis, structure and chemistry of organometallic dendrimers under the supervision of Professors John Moss and Mino Caira at the University of Cape Town.

Dendrimers with M–C σ bonds

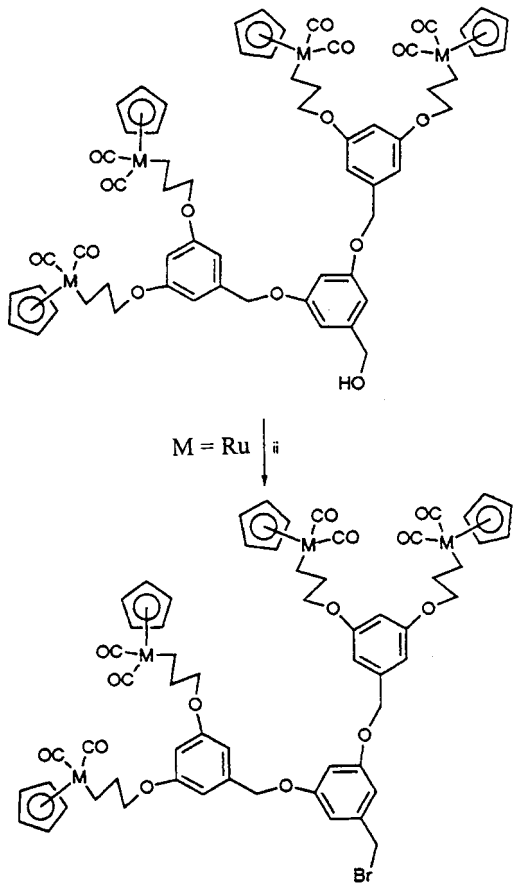
The first transition metal alkyl compound was prepared by Pope and Peachey in 1907[3] and today alkyl compounds of nearly every transition metal are known.[4] A driving force for this development has been in part due to the important applications of the alkyl species in catalytic reactions of industrial importance, for example titanium and zirconium catalysts for the polymerization of alkenes, as well as cobalt and rhodium catalysts in hydroformylation and hydrogenation reactions.[5] Our research group has worked on transition metal alkyl and functionalized alkyl compounds for many years.[4] From our studies on haloalkyl compounds,[6] we have developed methods for the preparation of organometallic dendrimers containing metal–carbon sigma bonds.[7] We applied the convergent methodology developed by Hawker and Fréchet[2] and used 3,5-dihydroxybenzyl alcohol as the monomer unit.[7] The advantage of using the convergent approach is that it allows for precise control over the number and placement of functional groups at the surface of the final dendrimer. The reactions are carried out in a stepwise fashion and the dendritic wedges were isolated, purified and characterized after each step. Since the products are all highly soluble, in spite of the large number of metals present, the reactions could be monitored by NMR spectroscopy, so that defects in branching of the wedges could be detected prior to complexation with a core molecule. Our first attempts to build dendrimers were with functionalized iron complexes of the type $Cp(CO)_2Fe(CH_2)_3Br$.[6] Although the reaction with 3,5-dihydroxybenzyl alcohol yielded the expected binulcear complex (see Scheme 1), conversion of the benzyl alcohol to the benzyl bromide gave a low yield, which we attributed to the instability of the iron-alkyl bond of the benzyl bromide. Iron dendrimers containing Cp (Cp = η^5-C_5H_5) acyl and Cp* (Cp* = η^5-C_5Me_5) monomer units have since been prepared and will be reported in further publications.[8]

We explored the reactions of $Cp(CO)_2RuR$ derivatives, *e.g.* $Cp(CO)_2Ru(CH_2)_5Ru(CO)_2Cp$ or $Cp(CO)_2RuR$ (R = alkyl) with PPh_3 and showed that no reaction occurred in refluxing THF over 25 h, forcing conditions (refluxing xylene, 140 °C) being necessary to get the reaction to go at all.[9] This suggested to us that the ligand system around the metal in these $Cp(CO)_2RuR$ derivatives was both thermodynamically stable and kinetically relatively inert. It was for this reason that we turned our attention to building up organometallic dendrimers with ruthenium–carbon sigma bonds. Thus, the reaction of 3,5-dihydroxybenzyl alcohol with $Cp(CO)_2Ru(CH_2)_3Br$ was investigated and we obtained the expected benzyl alcohol (see Scheme 1). This and higher generation dendritic wedges could



Scheme 1 *Reagents and conditions:* i, 3,5-dihydroxybenzyl alcohol, K_2CO_3, 18-crown-6, reflux, acetone, 48 h.

be converted to the corresponding benzyl bromides in good yield (see Scheme 2).[7] These ruthenium-based dendritic wedges



Scheme 2 *Reagents and conditions:* ii, CBr_4, PPh_3, room temp., 20 min.

were sufficiently stable to withstand the vigorous conditions required for their synthesis and thus it was possible to build up large dendritic wedges, and organometallic dendrimers, containing Ru–C sigma bonds. For these ruthenium complexes, the reactions of the organometallic wedges behaved similarly to the analogous organic reactions, although the yields tended to be slightly lower. The ruthenium dendrimers described above are highly soluble in common polar organic solvents and have been characterized by conventional spectroscopic (NMR, IR, MS) and analytical techniques.[7] Since the first publication in 1993, our group has made organometallic dendrimers of high purity up to the fourth generation containing 48 metal atoms and with a molecular mass of over 18 000.[7]

We have thus shown that with the correct choice of metal and ligand system, it is possible to build up very large organometallic molecules. We are currently working on dendrimers of a range of other metals, including those containing iron, cobalt, rhenium, chromium and tungsten, as well as investigating the properties and applications of some of these dendrimers.[10]

It has been shown that oxidative addition of primary alkyl or benzyl halides, RX to $[PtMe_2(NN)]$ gives $[PtXMe_2R(NN)]$ (where NN represents a diimine ligand such as 2,2′-bipyridine) and these complexes can be prepared in essentially quantitative yields.[11] The oxidative addition reactions occur in high yield but the ability to grow large oligomers is limited since the solubility decreases with chain length. This strategy was adapted to prepare star-shaped multinuclear organoplatinum complexes.[12] The oxidative addition reactions occur with a colour change from orange–red of platinum(II) to the pale yellow of platinum(IV) and hence the reactions were easily monitored by visible spectroscopy.[12] The reaction cycles were repeated until NMR spectroscopy showed that the products contained defects. The limit to growth appears to occur after formation of the Pt_{14} dendrimer, shown in Fig. 1. Growth

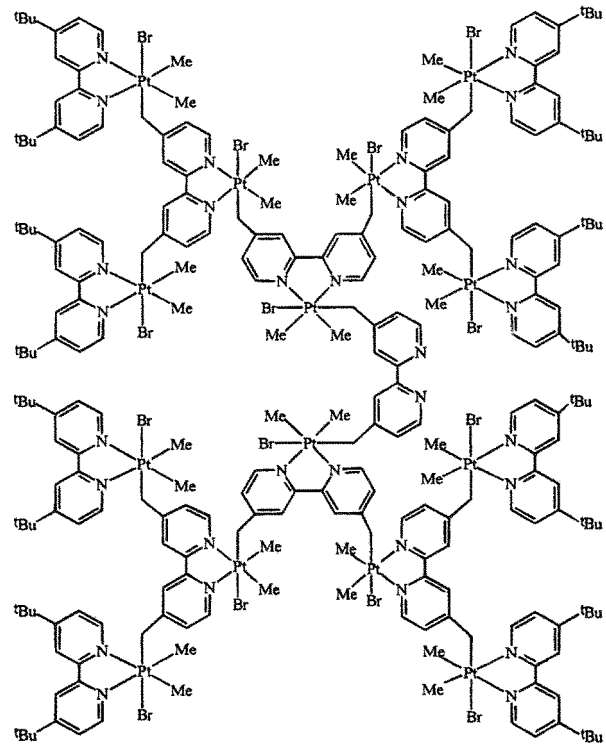


Fig. 1 The pale yellow Pt_{14} dendrimer.[11] Reprinted with permission from *Organometallics*, 1996, **15**, 43, copyright (1996) American Chemical Society.

beyond this to give the Pt_{30} dendrimer failed.[11] The limit to growth can be understood in terms of steric hindrance. The synthesis of larger platinum dendrimers was achieved by modification of the ligand. The key reagent for this work is the tetrafunctional core, 1,2,4,5-tetrakis(bromomethyl)benzene which could react with four organoplatinum(II) centres by oxidative addition of the C–Br bonds. In this approach, larger fragments are built first and then coupled to a polyfunctional core.[12] The solubility of the complexes was enhanced by the addition of the *tert*-butyl groups and the solubility of the products was found to increase with increased branching.

Recent work of the Puddephatt group has focussed on multinuclear organopalladium complexes and heterobimetallic palladium–platinum complexes. The authors wanted to see if

the oxidative addition reactions used previously could be employed. They found that incorporation of palladium in the structures is limited by the tendency of organopalladium(IV) complexes to undergo reductive elimination or alkyl halide transfer reactions. Some model complexes have been sucessfully synthesized.[13]

A sucessful route to multinuclear platinum complexes involves oxidative addition of an alkyl halide to platinum(II) providing the branching step, while ligand substitution by the bipyridine group provides a means of regenerating a reactive platinum(II) centre for the next growth cycle.[13]

Dendrimers with M–C π bonds

Ferrocene-based dendrimers

The majority of iron dendrimers reported to date have involved ferrocene derivatives. Perhaps the most obvious reason for this is that ferrocene chemistry is well established and documented and the compounds are stable. The construction of well defined dendrimers possessing redox-active organometallic units linked together in close proximity, so that there can be electronic communication between the metal sites in the dendritic structure, is a challenging target.[14] The dendrimer shown in Fig. 2 is the first example of an organometallic molecule to display

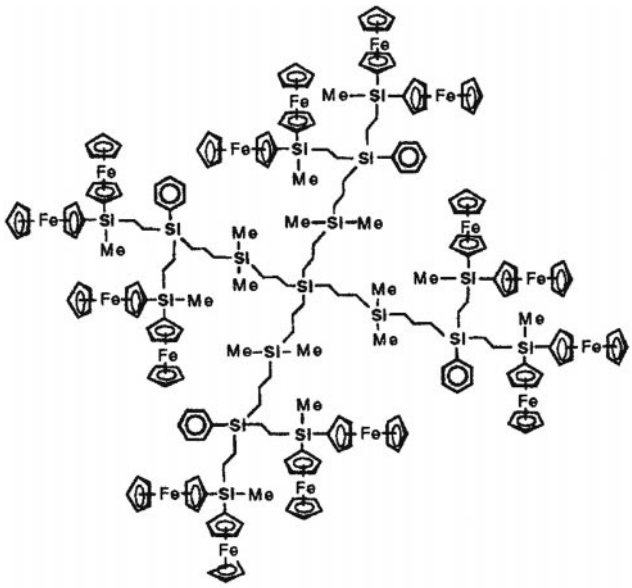

Fig. 2 A second generation silicon based dendrimer with ferrocenyl surface groups.[14] Reprinted with permission from *J. Am. Chem. Soc.*, 1997, **119**, 7613, copyright (1997) American Chemical Society.

electronic interaction between the transition metal atoms in the dendritic structure.[14]

Polymers containing ferrocene units are useful as redox catalysts for the modification of electrodes, and as biosensors.[15] $[FeCp(arene)]^+$ can serve as an excellent starting core for dendrimers since polyalkylation, polyallylation and polybenzylation of polymethyl arenes leads to various topologies.[15] The reaction of $[FeCp(C_6Me_6)]PF_6$ with excess base and an alkyl halide results in selective hexasubstitution [eqn. (1)].

$$[FeCp(C_6Me_6)]PF_6 \xrightarrow[RI\ (R\ =\ ferrocenylalkyl)]{KOR'\ (R'\ =\ H,\ Bu^t)} [FeCp\{C_6(CH_2R)_6\}]PF_6 \quad (1)$$

Cyclic voltammetry experiments showed that all six ferrocene units are electrochemically equivalent. The central cationic unit showed no influence on the oxidation process as the six outer ferrocene groups were oxidized at the same potential. The $CpFe^+$-induced hexaferrocenylalkylation of C_6Me_6 opens the route to isolable mixed-valence star-shaped molecules with independent redox centres and leads to a fully reversible six-electron redox system which may be useful for multielectron redox catalysis.[15] The multinuclear compounds have dendritic cores with organometallic surface groups.

One may also think of dendrimers as multisite guests for chemical interactions of any nature due to the regular placement of repeating residues on the dendrimer surface.[16] Ferrocenyl-functionalized amino dendrimers have been shown to include well known molecular hosts, specifically the cyclodextrins. The dendrimer serves as a three-dimensional template to organize the cyclodextrin receptors at the periphery of the dendritic structure, giving rise to large supramolecular assemblies.[16] The number of ferrocene units that can be included by the bulky cyclodextrin host is limited by the steric congestion on the surface of the dendrimer.

Fig. 3 shows the first heterometallic dendrimer containing

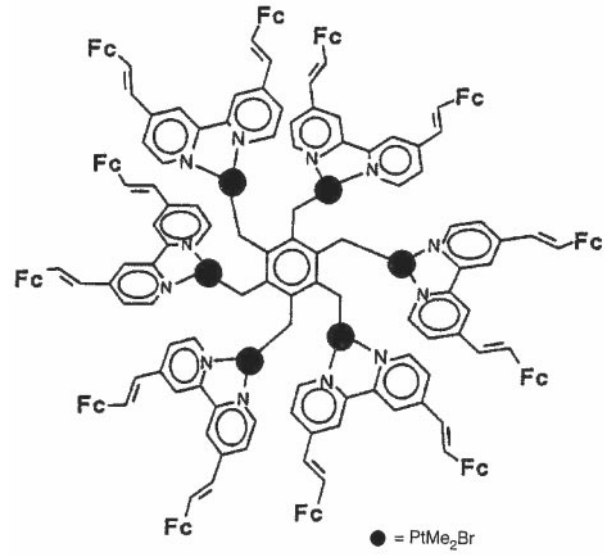

Fig. 3 A heterometallic dendrimer containing six platinum and twelve ferrocenyl centres.[17] Reprinted with permission from *Inorg. Chem.*, 1997, **36**, 2314, copyright (1997) American Chemical Society.

different transition metals in different layers.[17] This dendrimer features platinum(IV) units arranged in a concentric fashion around a central organic unit, with ferrocenyl groups as the surface functional groups. In this approach, dendritic arms containing one platinum and two ferrocenyl moieties were built first and then attached to a polyfunctional core *via* a convergent synthesis (Fig. 3).[17] The inclusion of redox-active centres into the dendrimers allows their composition to be determined by cyclic voltammetry. This alternative method of characterization may prove useful for other redox-active dendrimers.

Until recently, molecular recognition using dendrimer-based sensors was unknown. Some amido-ferrocenyl dendrimers have been synthesized and have been shown to be excellent redox sensors for the recognition of small inorganic anions such as Cl^-, NO_3^- and HSO_4^- (Fig. 4).[18] Cyclic voltamograms of these ferrocenyl dendrimers all show a single anodic reversible wave, indicating that all the iron(II)/iron(III) redox centres are independent and equivalent.[18] The dendrimers ability to sense and recognize the anions by cyclic voltammetry as the dendritic generation increases was found to be maximum for the generation (18 ferrocene groups) preceeding steric surface saturation (36 ferrocene groups). As the dendritic generation becomes higher, the ferrocenyl termini of the different dendritic branches become closer to one another, making the surface hole for the penetration of the anion smaller. Since the anions are small, the greatest effect and selectivity is found for the highest generation that is soluble because it forms the best open cavities. In comparison, endoreceptors also favour anion inclusion with open cavities where size compatibility is important.[18]

One potential role for a dendrimer is as an encapsulating shell around small molecules within it, or around the core of the

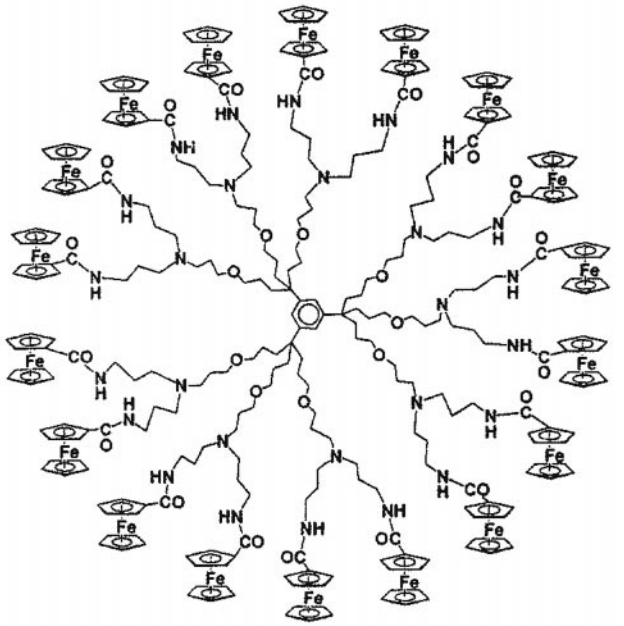

Fig. 4 An amidoferrocenyl dendrimer which acts as a redox sensor for the recognition of small inorganic anions.[18] Reprinted with permission from *J. Am. Chem. Soc*., 1997, **119**, 2588, copyright (1997) American Chemical Society.

dendrimer itself. Dendritic encapsulation offers a means of preventing facile electron transfer between closely spaced molecules which would result in loss of stored information.[19] One such application is as a molecular switch, in which an electroactive group can be held alternately in one of two binary states (corresponding to 'on' or 'off').[19] A third generation dendrimer with an electroactive core is shown in Fig. 5. The

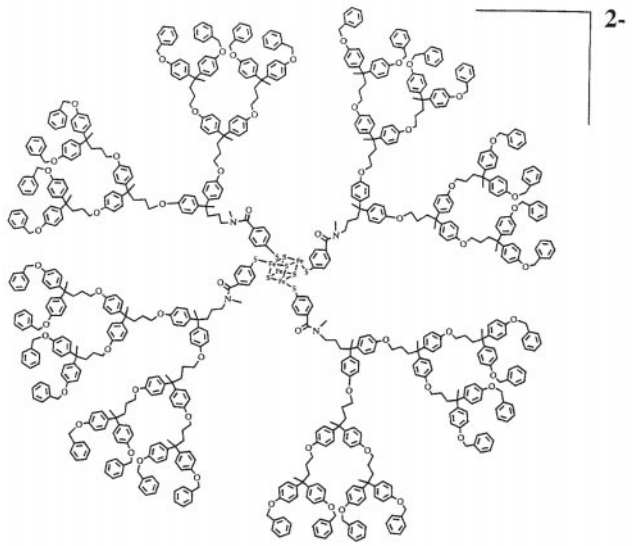

Fig. 5 An electroactive third generation encapsulated dendrimer.[19] Reprinted with permission from *Adv. Mater*., 1997, **9**, 1117, copyright (1997) Wiley-VCH.

core of one such dendrimer is an $Fe_4S_4(SR)_4^{2-}$ unit such as that found in some iron–sulfur proteins and is capable of existing in two stable redox states. Cyclic voltammetry experiments showed that as the number of branches in the dendrimer ligands around this core increased, the kinetic facility of electron transfer to and from the core decreased.[19]

From the number of ferrocene-containing dendrimers synthesized, it is evident that the ferrocene group is useful in the construction of dendrimers. The dendrimers prepared can be relatively easily characterized and their properties investigated by electrochemical methods.

Metal arene complexation

π-Complexation of transition metals to terminal arene ligands is another method of dendrimer modification. First and second generation organosilicon dendrimers have been prepared with aromatic rings on the periphery.[20] These surface-located arene rings were then π-coordinated to $Cr(CO)_3$ groups to give a new family of organometallic dendritic macromolecules containing η^6-arene coordinated $Cr(CO)_3$ groups at the periphery of the organosilicon dendritic cores; the tetranuclear compound is shown in Fig. 6. Attempts to prepare the octachromium

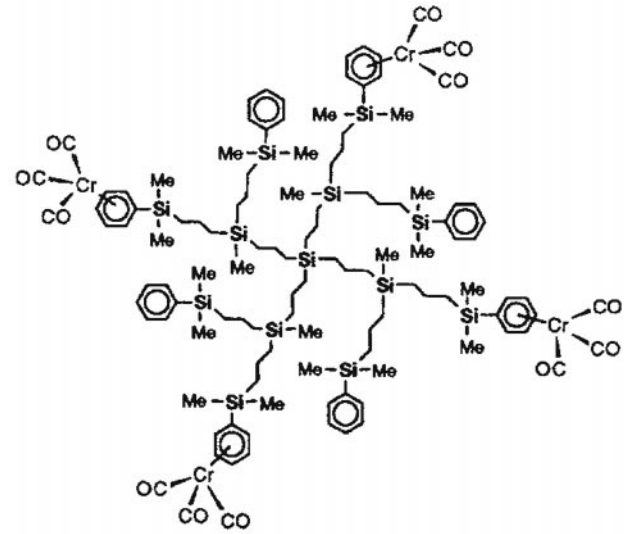

Fig. 6 The tetranuclear $Cr(CO)_3$ dendrimer.[20] Reprinted from *J. Organomet. Chem.*, 1996, **509**, 109, copyright (1996), with permission from Elsevier Science.

macromolecules failed probably due to the forcing reaction conditions which caused decomposition. The silicon dendrimers were prepared following a divergent approach which involved hydrosilylation and allylation as a means of growth.[20] These authors anticipate that the ability of the transition metals to π-complex to the peripheral aromatic rings of the novel silicon-based dendrimers should also be possible and will provide increased versatility for the design and synthesis of new families of dendritic macromolecules with different organo-transition metal groups.[20]

Dendrimers with tertiary phosphine ligands

Chemical functionality can be used as a means to control the 'placement' of the metal atom. Tertiary phosphines are known to bind to almost all transition metals of the periodic table.[21] It is thus not surprising to find a number of papers where a variety of metals, including palladium, rhodium and iridium, have been included in dendrimers *via* coordination of the metal to the surface phosphines. Thus, phosphorus-containing dendrimers up to the tenth generation and posessing either aldehyde groups or P–Cl bonds on the surfaces have been synthesized.[22] These terminal functions were reacted in order to anchor diphosphino groups on the surface of the dendrimer. The ability of the higher generation dendrimers to act as ligands towards palladium, platinum and rhodium complexes was then investigated. It was found that the end groups $\{-CH{=}NN(CH_2PPh_2)_2\}$ remained available for complexation with the metals and these new dendrimers may be of use as catalysts.[22]

Similarly, reactions of phosphorus dendrimers with ruthenium polyhydrides were investigated.[23] The new dendrimers have characteristic spectroscopic properties, in particular their ^{31}P and ^{1}H NMR spectra. Preliminary catalytic tests indicate good activity of these compounds for ketone hydrogenation.[23] The excellent coordinating ability of phosphorus to transition metals has been used to synthesize many novel organometallic

dendrimers and a number of these examples are discussed in the 'Dendrimers as catalysts' section.

Dendrimers with nitrogen donor ligands

Coordination centres in every layer

Dendrimers with coordination centres in every layer were constructed using transition metal coordination complexes as building blocks for branching or bridging to yield polynuclear compounds which behave as supramolecular systems.[24] The synthetic procedure is based on a protection/deprotection procedure in which a complex with free chelating sites is used as a ligand, and those with labile ligands play the role of metals ('complexes-as-ligands/complexes-as-metals' synthetic strategy).[25] This procedure allows the construction of large polynuclear metal complexes *via* metal–ligand coordination bonds. One of the advantages of this approach is that it is possible to introduce the desired building blocks at each stage of the synthesis. Dendrimers containing units of different chemical nature can exhibit valuable properties with specific functions, *e.g*. gradients for photoinduced directional energy and electron transfer, and sites for multi-electron transfer catalysis (see Fig. 7).[25]

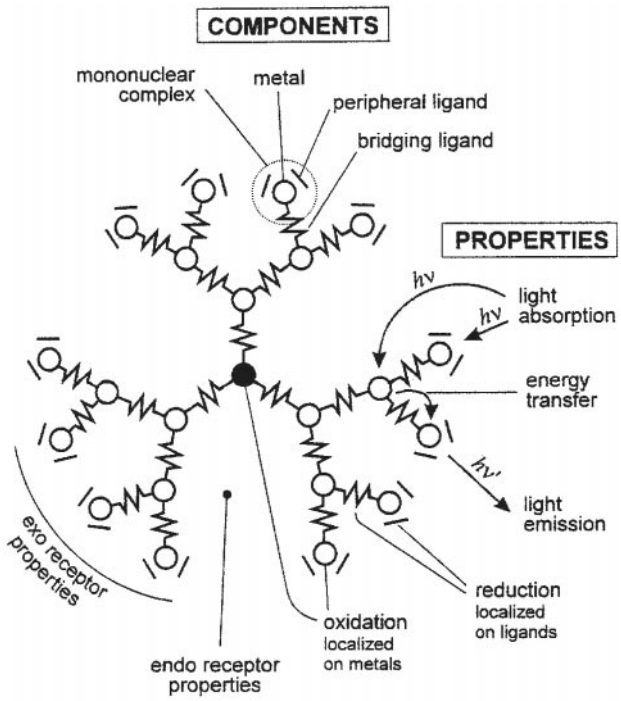

Fig. 7 Schematic representation of a luminescent and redox-active docosanuclear dendrimer with some of the properties indicated.[25] Reprinted with permission from *J. Mater. Chem*., 1997, **7**, 1227, copyright (1997) The Royal Society of Chemistry.

Because of their remarkable photophysical and electrochemical properties, ruthenium(II)– and osmium(II)–polypyridine complexes[25,26] are ideal components to synthesize luminescent and redox-active oligonuclear species where energy and electron transfer can be driven by light.[26] A great number of compounds have been synthesized using the 2,3- and 2,5-bis(2-pyridyl)pyrazine (2,3- and 2,5-dpp) bridging ligands, and the 2,2′-bipyridine (bpy) and 2,2′-biquinoline (biq) terminal ligands.[26]

The complexes studied contain several chromophoric units in addition to a large number of redox-active centres. Studies carried out on these complexes show the oxidation behaviour to exhibit a selectivity based on the nature of the metal ion and its position in the supramolecular array, thus offering a means of fingerprinting the compounds. Because of the presence of both interacting and non-interacting redox centres, these complexes are good candidates for multielectron-transfer catalysts.[26] The dendrimers reported also display luminescence in solution at room temperature.[25]

2,2′:6′,2″-Terpyridine as a ligand

The coordination of appropriate organic molecules containing multiple metal-binding sites to metal ions provides a versatile alternative to carbon–carbon or carbon–heteroatom bond formation for the construction of dendrimers.[27,28] 2,2′:6′,2″-Terpyridine (terpy), has been reported by a number of authors as a successful connecting ligand to combine preconstructed metal–ligand fragments.[29] Such connectivity permitted the analysis of the final product by electrochemical methods. It had previously been shown that benzylic halides react smoothly with the triruthenium nucleophile, [(terpy)Ru(botpy)Ru(botpy)Ru(HOtpy)][PF_6]$_6$, [botpy = bis(4′-(2,2′:6′,2″-terpyridinyl) ether, HOtpy = 2,2′:6′,2″-terpyridin-4′(1′*H*)-one].The reaction of 1 equiv. of hexakis(bromomethyl) benzene with 6 equiv. of [(terpy)Ru(botpy)Ru(botpy)Ru(HOtpy)][PF_6]$_6$ gave the octadecaruthenium complex (Fig 8).[27] MALDI TOF mass spectrometry provided a convenient and rapid method for the determination of the nuclearity.[27]

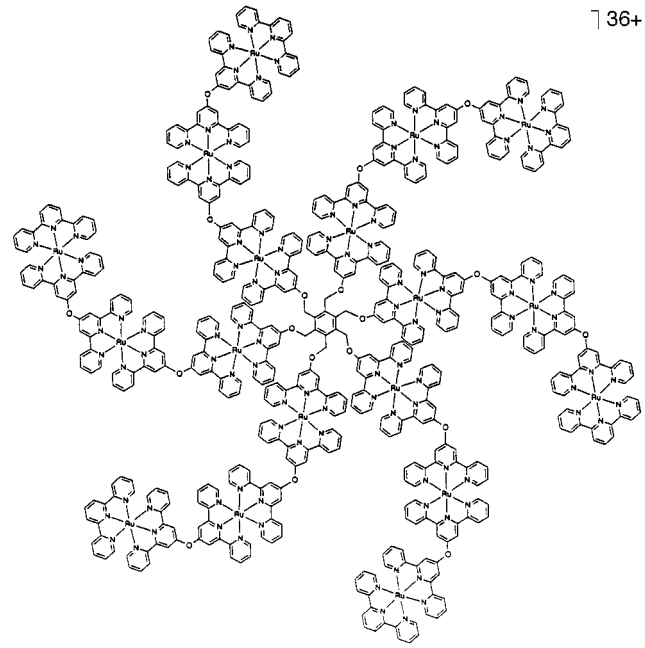

Fig. 8 An octadecaruthenium metallodendrimer.[27] Reprinted from *Inorg. Chim. Acta*, 1996, **252**, 9, copyright (1996), with permission from Elsevier Science.

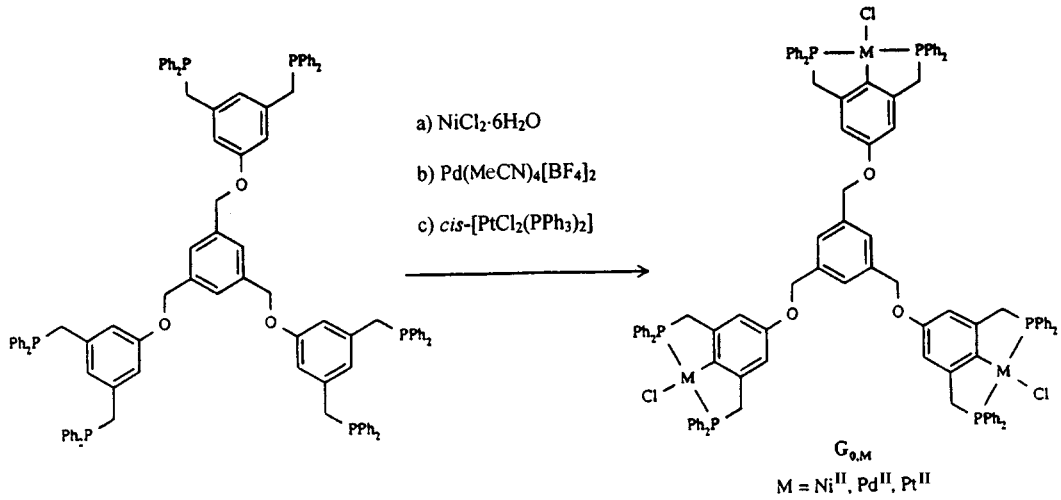
The construction of this new type of double-tiered metallodendrimer illustrates the importance of stepwise construction by means of controlled metal complexation.[29] This approach also provides versatile methodology for the synthesis of specifically assembled metallodendrimers and related polymers using a combination of the convergent and divergent approaches.[29]

Pincer-type complexes

There is considerable interest in the synthesis of well defined structures of nanometer dimensions.[30] Nanostructures can be developed in an efficient way through non-covalent interactions, *e.g*. H-bonds as opposed to covalent bonds which require multistep syntheses.[30] The early work was carried out using building blocks containing kinetically inert SCS Pd-pincer complexes, coupled *via* branched spacers. The complexes are labile when the fourth ligand is nitrile but not chloride. The coordination of the nitrile ligand to coordinatively unsaturated palladium centres was exploited to assemble the dendrimer building blocks *via* non-covalent interactions. Changing from SCS to PCP ligands made it possible to introduce a variety of transition metals.[31] Ligands derived from the coupling of 3,5-bis[(diphenylphosphino)methyl]phenoxy



Scheme 3 Reprinted with permission from *Organometallics*, 1997, **16**, 4287, copyright (1997) American Chemical Society.

groups to bi- and tri-functional spacers have been cyclometalated with $[Pd(MeCN)_4][BF_4]_2$, *cis*-$[PtCl_2(PPh_3)_2]$ or $NiCl_2 \cdot 6H_2O$ and the resulting cationic complexes converted to neutral complexes. These resulting pincer complexes were then used as building blocks for the controlled assembly of homo- and hetero-multinuclear dendrimers (see Scheme 3).[31] ^{31}P NMR spectroscopy was successfully used as a diagnostic tool for the assembly process as the chemical shift values are very sensitive towards small changes in the microenvironment around the metal centre.

Polynuclear gold(I) complexes

Very little is known about the surface coordinating properties of dendrimers.[32] A few papers on surface-complexing properties of polynuclear gold(I) complexes have been reported[32,33] Dendritic polyamines have been functionalized with terminal diphenylphosphino groups which are ideal for surface complexation of transition metals in low oxidation states and a tailor made 'spacer' bearing a group suitable for coupling.[32] A fourth generation polynuclear gold(I) complex with 32 terminal chloro(diphenylphosphino)gold(I) groups is shown in Fig. 9.[32]

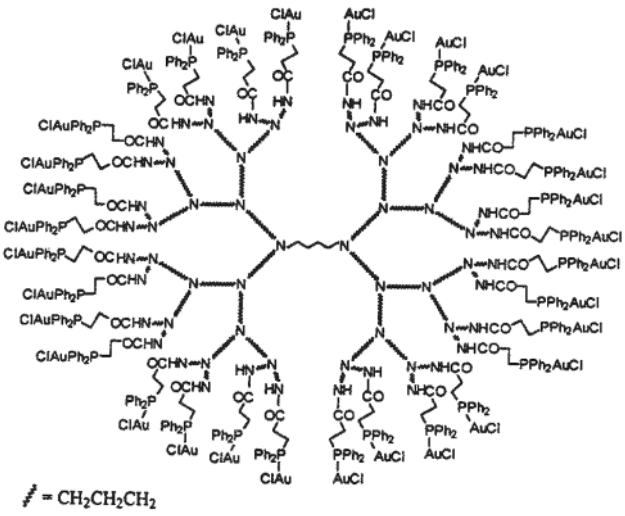


Fig. 9 A polynuclear gold(I) complex with 32 terminal chloro(diphenylphosphino)gold(I) groups.[32] Reprinted with permission from *Inorg. Chem.*, 1996, **35**, 637, copyright (1996) American Chemical Society.

X-Ray crystallography was carried out on the smaller mono- and di-nuclear gold(I) complexes. Intermolecular NH···O hydrogen bonds direct the aggregation of the molecules in the solid state to give chainlike structures. These multinuclear gold(I) complexes[32] represent a new type of metal-containing polymer with a well defined, probably spherical structure and having dendrimer molecules as supporting matrices. They have potential applications in catalysis, biochemical diagnostics and imaging.[32]

Seventh generation phosphorus-containing dendrimers containing reactive functional groups also allowed the complexation of gold derivatives.[33] These appear to be the largest polyphosphine complexes ever prepared, with 3072 $CH_2PPh_2(AuCl)$ end groups.[33]

Main group dendrimers

Much attention has been focussed on main-group-element-based dendrimers, in particular on those based on silicon because of their optical properties and importance in surface functionalization.[34] We will only mention here the recently prepared germanium/silicon dendrimers[35] in this article. The most direct method of preparation would have involved sucessive alkenylations and hydrogermylations, starting with $GeCl_4$. However allylic germanium derivatives are very sensitive to electrophilic reagents. To avoid difficulties associated with undesirable by-products and to diminish the steric strain resulting from the accumulation of branched chains, six-membered ω-ethylenic chains, which are more stable than α- or β-ethylenic chains, were used. Bis(dimethylphenylgermyl)-(methyl) silyllithium was used as the building agent. Using this method, second generation dendrimers having a molecular weight of 5590 were synthesized.[35] Very recently, some dendritic molecules with alternating silicon and germanium atoms along the dendritic backbone, including the molecular structure of a first-generation hybrid permethylated dendrimer, have also been reported.[34]

Structural details and properties of dendrimers

There has been much controversy over the exact shape of dendrimers in solution and many conflicting results have been obtained. The first attempts to calculate dendritic structures were by de Gennes and Hervet.[36] They showed the chain ends to be on the periphery and found a density minimum at the core and a density maximum at the surface. In contrast, Lescanec and Muthukumar allowed the inward folding of chain ends in their calculations which resulted in a density maximum between the dense core and the periphery.[37] Other solution studies showed dendrimers to have low intrinsic viscosities that decreased as the molecular weight increased. They concluded that dendrimers posess globular shapes and lack intermolecular entanglements.[38]

Monte Carlo calculations by Mansfield and Klushin found the chain ends to be distributed throughout the structure, and in close proximity to the core and revealed a density maximum between the centre of mass and the periphery.[39]

Our investigations of Fréchet type poly(benzylphenyl ether) dendrimers functionalized with arene tricarbonylchromium(0)

groups showed a transition from an extended to a globular structure as the generation number increased.[40] Solvent accessible surface calculations showed more backfolding to occur as the dendrimer became larger. Although the chain ends were found in all regions of the dendrimer to some extent, most were still located on the periphery of the molecule or in a solvent accessible area for those dendrimers studied. Recent rotational-echo double-resonance NMR experimnets by Wooley *et al.* used experimental constraints on molecular dynamics simulations for the prediction of dendritic structure.[41]

Generally speaking, lower generation dendrimers tend to exist in relatively open forms, but as sucessive layers are added, dendrimers adopt a spherical three-dimensional structure. Solution state properties of dendrimers are generally consistent with a globular shape with the chain ends accessible to the surface, but the precise shape and chain end locations remain uncertain.

Applications of dendrimers as catalysts

One of the most important and exciting uses of dendrimers is expected to be in the field of catalysis. There is great scope for the development of new materials that combine the advantages and minimise the disadvantages associated with heterogeneous and homogeneous catalysts.[42] One approach to such materials is to anchor homogeneous catalysts to polymer supports. Such polysiloxane polymers containing a catalytically active nickel(II) centre have been prepared.[43] However, the disadvantages encountered when anchoring catalytically active metal sites to polymers include the difficulty of accurate control of the number and location of these sites.[42] An ideal polymeric catalyst should be a soluble, multifunctional macromolecule, favouring configurations in which all active sites would be exposed towards the reaction mixture so that they are easily accessible to migrating reactants. Owing to their expected spherical nature, dendritic catalysts are expected to retain the benefits of homogeneous catalysts, such as faster kinetics and accessibility of metal sites but should be easily recoverable from a product-containing solution because of their large size. Ultrafiltration techniques could be used as a means of separation.

The most well known example of a dendrimer used as a catalyst was published in 1994.[42] Zero and first generation polysilane dendrimers were functionalized with diamino arylnickel(II) complexes on their periphery, the metal centre being fixed by a metal–carbon sigma bond to the ligand system (Fig. 10). These dendrimers have been successfully used as homogeneous catalysts for the Kharasch addition of polyhalogenoalkanes to an alkenic C═C double bond. Under mild reaction conditions (room temperature, CH_2Cl_2 as solvent) using methyl methacrylate as substrate and CCl_4 as reagent, the catalytic activity of these zero and first generation dendrimers, as shown by kinetic data, is 20 and 30 % respectively less than the monomeric compound.[42] Molecular models of these dendrimers such as that in Fig. 10, show the nickel sites to be well separated from one another at the end of long flexible branches and consequently the accessibility of the catalytically active nickel centres should be similar to the monomeric model compounds synthesized previously. All the characteristics found for the monomeric model are retained in the dendrimer catalyst system. These new dendrimers represent nanoscopic catalysts with physical characteristics such as size, solubility and dispersity of catalytic sites that are very precisely defined, so affording these molecules advantageous properties for physical separation and catalyst recycling.[42]

The excellent coordinating ability of phosphines has been used to prepare novel organometallic dendrimers. It has previously been shown that mononuclear [Pd(triphosphine)(MeCN)][BF_4]$_2$ complexes will catalyse the electrochemical reduction of CO_2 to CO.[44] The presence of a triphosphine ligand in these catalysts suggests that dendrimers containing this unit may also catalyse the reduction. Two approaches have been used to synthesize such dendrimers, the first involving sequential addition of diethyl vinylphosphonate to primary phosphines

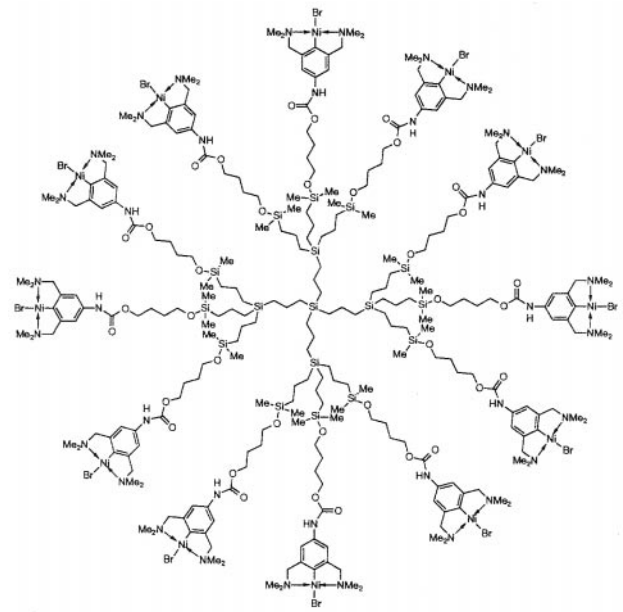

Fig. 10 Schematic structure of the first generation poylsilane dendrimer functionalized with catalytically active diamino arylnickel(II) complexes on the periphery.[42] reprinted with permission from *Nature*, 1994, **372**, 659, copyright (1994) Macmillan Magazines Ltd.

followed by reduction with lithium aluminium hydride; the second approach using the addition of bis[(diethylphosphino)ethyl]phosphine to tetravinylsilane. Small dendrimers containing 12 or 15 phosphorus atoms metallated with [Pd(MeCN)$_4$][BF_4]$_2$ have now been shown to exhibit catalytic activity for the electrochemical reduction of CO_2. These results demonstrate the feasibility of performing catalytic reactions using metallated organophosphine dendrimers.[44]

Dendritic diphosphines synthesized from polyamino dendrimers by double phosphinomethylation of each of the primary amino end-groups provides the possibility of specific complexation with a variety of transition metals including iridium, palladium and rhodium (Fig. 11).[45] The metal-containing

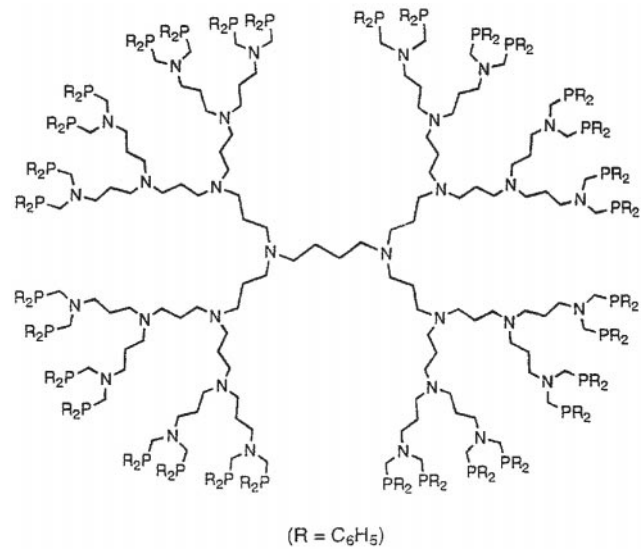

Fig. 11 The phosphinomethylated dendrimer with sixteen bidentate ligands on the outer surface provides the possibility of complexation with many transition metals.[39] Reprinted with permission from *Angew. Chem., Int. Ed. Engl.*, 1997, **36**, 1526, copyright (1997) Wiley-VCH.

dendrimers were successfully used to catalyse the Heck reaction of bromobenzene and styrene to form stilbene. The reaction mixture was analysed by gas chromatography.[45] In previous examples of catalysis with dendritic metal complexes, the catalytic activity was shown to be slightly or significantly lower than that of the corresponding monomeric parent compounds.

This system, however, showed a significantly higher activity, which is attributable to the higher thermal stability of the dendritic complexes. The strategy developed here for the synthesis of dendritic diphosphines opens up a general method for preparing transition metal-containing dendrimers for use in catalysis.[45]

Most of the optically active chelating phosphines used in enantioselective transition metal catalysis involve a chiral skeleton bearing two diphenylphosphino groups.[46] The chiral information is transferred from the ligand to the catalytically active centre *via* the arrangement of the phenyl rings of the diphenylphosphino groups.[46] Owing to the limited size of the diphenylphosphino groups, the idea of using larger phosphines represents a promising new approach.[46] The expanded phosphines should contain a chelate skeleton, *e.g.* the PCH_2CH_2P grouping, and several layers of branching units built up with optically active groups attached to the phosphorus atoms.[46] Owing to the space-filling nature of the expanded ligands, the chiral information should be forced towards the pocket of the catalyst, in which the enantioselective reaction takes place. Because the catalytic reaction takes place at the core of the dendrimer, the system resembles the prosthetic group of an enzyme. For this reason, these molecules have been termed 'dendrizymes'.

Conclusions and future developments

An exciting future is forseen for dendrimers, and transition-metal-containing dendrimers in particular. Already the rapidly growing increase in the number of publications is an indication that dendrimers represent a new and important class of compounds. It has been demonstrated in the examples above that it is possible to synthesize mono- and multi-metallic molecules with desirable characteristics and properties by careful choice of metal and ligand systems. Little work on the solid-state structures of dendrimers has thus far been carried out, presumably because of the difficulty of crystallising them. For this reason, molecular modelling is expected to play a key role in providing some of the answers concerning structures and also properties. Dendrimer research has already shifted from a purely synthetic orientation towards investigating the novel properties and exploring the potential applications of these molecules, in particular catalysis. Already we have seen their novel applications as encapsulation reagents, artificial gene-transfer materials, as building blocks for the self-assembly of larger nanostructures and in chiral recognition. Important applications will likely emerge in the next few years in a diversity of fields. New synthetic methods will continue to be important until dendrimers can be produced cheaply and easily on an industrial scale.

Only time will unveil the full range of applications of these large and beautiful molecules.

Steroidal guanidinium receptors for the enantioselective recognition of *N*-acyl α-amino acids

Anthony P. Davis* and Laurence J. Lawless

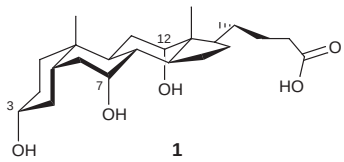
Department of Chemistry, Trinity College, Dublin 2, Ireland. E-mail: adavis@tcd.ie

Received (in Liverpool, UK) 23rd October 1998, Accepted 9th November 1998

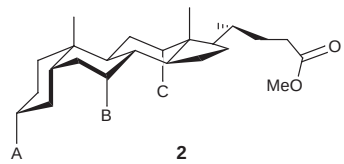
Guanidinium cations 4 and 5 extract *N*-acetyl α-amino acids into $CHCl_3$ from an aqueous medium with enantiomeric excesses of up to 80%.

Enantioselective recognition is of continuing interest in supramolecular chemistry,[1] especially where relevant to the large-scale resolution of racemates. Enantioselective phase transfer is particularly attractive, raising the possibility of 'catalytic' resolutions based on the transport of substrates through otherwise impermeable barriers.[2] Carboxylates/carboxylic acids are suitable targets for this approach, because of their ability to partition between aqueous and organic phases. Amino acids, and their *N*-acyl derivatives, are attractive substrates because of their biological significance and practical importance.[3]

Herein we describe a new strategy for the enantioselective extraction of chiral carboxylates from aqueous into organic media, and its realisation in the form of receptors which show significant enantiodiscrimination in the case of *N*-acetyl α-amino acids. In common with previous work on carbohydrate[4] and anion recognition,[5] our design exploits cholic acid **1** as a starting material. The secondary hydroxy groups in **1** can be independently modified to give differentiated, co-directed substituents as in **2**.[6] Groups A–C are spaced so as to allow, in



1

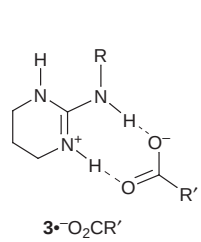


2

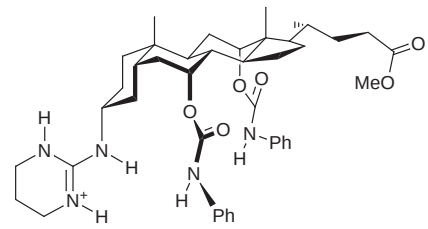
a typical case, cooperative effects on a substrate with minimum interference from intramolecular interactions. The design is suggestive of 'three-point contact', as required for the classical model of enantioselective recognition.[7]

For carboxylate extraction, it is useful that one of groups A–C should form a specific, electroneutral complex with the anionic centre. To serve this purpose we have chosen the guanidinium unit **3**, capable of binding carboxylates as shown.[8] Of the possible variations on our general theme, we report the synthesis and properties of two initial examples; the bis-phenylcarbamate **4** and its asymmetrically-substituted relative **5**. Receptor **4** was accessible from 3α-azide **6**[9] as shown in Scheme 1, while receptor **5** was prepared *via* a longer sequence with alcohol **7** as the penultimate intermediate.

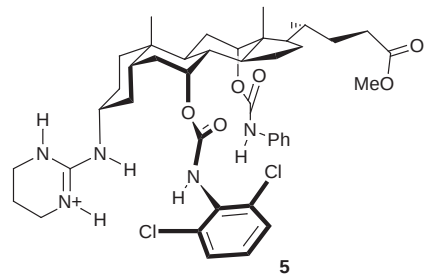
As anticipated, solutions of **4**·Cl^- and **5**·Cl^- in $CHCl_3$ were capable of extracting carboxylic acids from neutral or basic aqueous solutions, presumably through exchange of carboxylate for chloride. In the case of *N*-acetyl α-amino acids the ^1H NMR spectra of the complexed substrates were enantiomer-



3•$^-O_2CR'$



4



5

dependent, allowing the determination of enantioselectivities, as well as extraction efficiencies, by simple integration. The results are shown in Table 1. Extraction efficiencies were moderate to good for substrates with non-polar side-chains, although neither receptor was effective with the polar asparagine derivative. Receptor **4** proved remarkably consistent in its

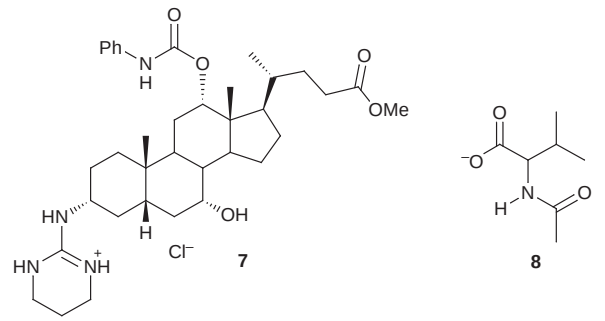
[a] Solutions of receptor in $CHCl_3$ (6 mM, 1 ml), and substrate in phosphate buffer (7–8 mM, 5 ml), were stirred vigorously for 2 h. The organic phases were isolated, dried by passage through hydrophobic filter paper, then evaporated. The residues were dissolved in $CDCl_3$ (0.6 ml) and analysed by ^{1}H NMR spectroscopy. [b] Determined by ^{1}H NMR integration of substrate α-C*H* and N*H vs*. 7/12β-*H* of receptor. [c] Determined by ^{1}H NMR integration of α-C*H* and N*H* signals for enantiomers of substrates. Assignments confirmed through control experiments with enantiopure substrates. [d] Not determined.

ability to differentiate between enantiomers, irrespective of side-chain bulk. Receptor **5** showed generally higher extraction abilities, possibly due to the greater acidity of the dichlorophenylcarbamoyl NH, and was more sensitive to side-chain structure. Perhaps surprisingly, the substrate with the most sterically hindered asymmetric centre (*N*-Ac-*tert*-leucine) gave the lowest selectivity.

^{1}H NMR spectroscopy and molecular modelling combined to suggest plausible models for the binding geometries. A Monte Carlo Molecular Mechanics (MCMM) search† on the complex between **5** and *N*-acetyl-L-valinate **8** yielded the configuration shown in Fig. 1. The carboxylate accepts H-bonds from the 7-carbamoyl and two guanidinium NH groups, while the acetyl oxygen is bound to the 12-carbamoyl NH. In support of this structure, the receptor carbamate and 2 of the 3 guanidinium N*H* signals moved downfield on complex formation, while a weak



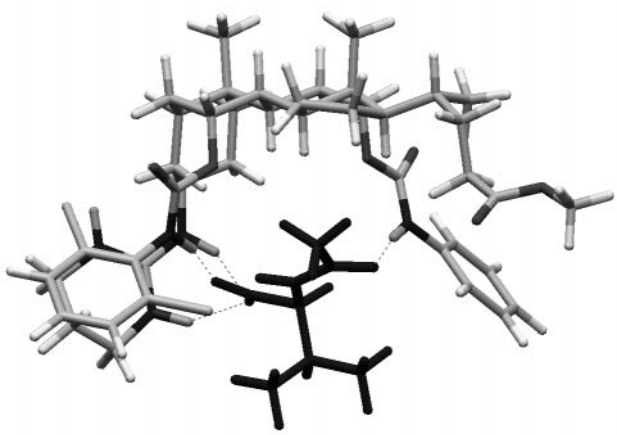


Fig. 1 Structure of **5** + L-**8** (black) derived from computer-based molecular modelling. Intermolecular hydrogen bonds are shown as broken lines.

intermolecular NOE was observed from the α-C*H* in L-**8** to the *ortho* protons of **5**-NH*Ph* (consistent with Fig. 1, allowing for some rotational freedom about the N–Ph bond‡). A similar MCMM search† on **5** + D-**8** yielded a higher-energy structure in which the acetyl O···HN interaction is missing, the 12-carbamoyl NH forming a fourth (apparently strained) hydrogen bond to the carboxylate.

Viewed as forerunners of an extended family of receptors, **4** and **5** show encouraging levels of enantioselectivity. Many variants are within easy reach, a majority with much greater differentiation between the three substituents. We hope to report examples with improved performance in the foreseeable future.

Financial support for this work was provided by Forbairt, the Irish Science and Technology Agency, Schering Plough (Avondale) Ltd., and the EU Training and Mobility for Researchers programme. We are grateful to Peter Ashton (University of Birmingham) for mass spectra, Dr John O'Brien for non-routine NMR experiments, and Freedom Chemical Diamalt GmbH for generous gifts of cholic acid.

Notes and references

† Calculations employed MacroModel V5.5 (ref. 10), the Amber* force field, $CHCl_3$ GB/SA solvation, and 5000 steps of MCMM. Six and three separate searches were conducted for the L and D substrates respectively, all from widely differing starting geometries and all yielding essentially similar final structures.

‡ Rotation about N–Ph allows an *ortho* proton to make van der Waals contact with the substrate α-CH.

Enantioselective conjugate addition of diethylzinc to enones catalyzed by a copper complex of chiral aryl diphosphite

Ming Yan, Li-Wei Yang, Kwok-Yin Wong and Albert S. C. Chan*

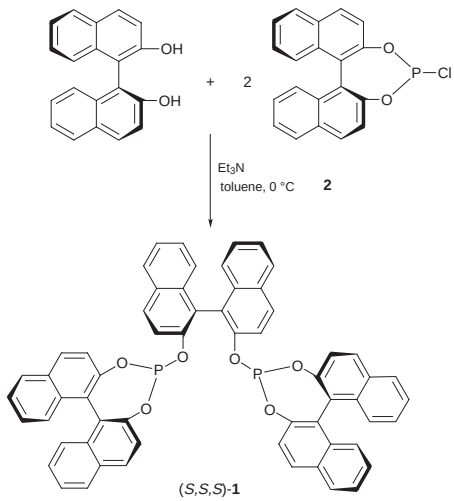
Union Laboratory of Asymmetric Synthesis and Department of Applied Biology and Chemical Technology, The Hong Kong Polytechnic University, Hong Kong, China. E-mail: bcachan@polyu.edu.hk

Received (in Cambridge, UK) 15th October 1998, Accepted 16th November 1998

The 1,4-conjugate addition of diethylzinc to cyclohex-2-enone and cyclopent-2-enone catalyzed by a copper complex of a chiral aryl diphosphite gave the desired products with 90.2 and 76.6% ee respectively.

The enantioselective conjugate addition of chiral organometallic reagents to enones is an attractive method for C–C bond formation. A number of successful methods for stereoselective 1,4-addition based on chiral auxiliaries or stoichiometric organometallic reagents have been developed, but a highly enantioselective catalytic version is still rare.[1] Ni^{II} and Co^{II} catalysts containing chiral amino alcohol ligands are of substantial interest, but they show enantioselectivity only for acyclic enones.[2] The copper complexes of chiral phosphites,[3] phosphorus amidites,[4] phosphines,[5] thiols[6] and aminophosphines[7] have been used in the catalytic conjugate addition of Et_2Zn or Grignard reagents to enones with low to moderate enantioselectivity. Recently several chiral phosphorus amidites[8] and phosphite oxazolines[9] have been used in the copper-catalyzed conjugate addition of dialkylzinc to cyclohex-2-enone with excellent enantioselectivity. These ligands shared a common feature of a bridging of binaphthol with a chiral amine through a phosphorus center. The active catalyst in the reaction has been proposed by Feringa *et al*. to be an alkyl–Cu^{I} species coordinated with two ligand molecules.[8] The C_2-symmetric bidentate ligands in these reactions are of substantial interest.[4a] Here we report the catalytic conjugate addition of Et_2Zn to enones using a C_2-symmetric chiral aryl diphosphite–$Cu(OTf)_2$ complex with good enantioselectivity and high catalytic activity.

Optically pure aryl diphosphite (*S*,*S*,*S*)-**1** was prepared by the reaction of the (*S*)-chlorophosphite **2** and (*S*)-binaphthol in the presence of Et_3N (Scheme 1). The crude product was easily purified by recrystallization in CH_2Cl_2–EtOH. The structure of the compound was supported by elemental analysis and spectral data.[10]



Scheme 1

In 1991 Pringle *et al*. reported the synthesis of (*R*,*R*,*R*)-**1** from trichlorophosphine and (*R*)-binaphthol. A Ni^0 complex of (*R*,*R*,*R*)-**1** was used in the hydrocyanation of norbornene, giving a product with 38% ee.[11] It is noticeable that the structure of **1** is entirely based on chiral binaphthol. (*S*,*S*,*S*)-**1** is fairly stable to oxygen in the solid state but is somewhat air- and moisture-sensitive in solution.

The addition of Et_2Zn to cyclohex-2-enone **3b** was used as a model (Scheme 2). The effects of reaction temperature, solvent and the ratio of (*S*,*S*,*S*)-**1** to $Cu(OTf)_2$ were investigated and the results are summarized in Table 1. In most cases complete conversion and good enantioselectivity were obtained. No 1,2-addition product was detected by GC analysis. The reaction was strongly dependent on the choice of solvents. The best solvent was found to be toluene (90.2% ee, 100% conversion). Coordinative solvents such as THF and MeCN gave substantially lower conversion rates and enantioselectivities (22.4% conversion, 72.2% ee and 6.5% conversion, 0% ee, respectively). The use of 2 equiv. (*S*,*S*,*S*)-**1** increased the enantioselectivity from 83.2 to 90.2% ee (entry 2 *vs*. entry 3). Further increase of the ratio of (*S*,*S*,*S*)-**1** to $Cu(OTf)_2$ decreased the catalytic activity (entry 1). When less than 1 equiv. (*S*,*S*,*S*)-**1** was used, the enantioselectivity decreased but the catalytic activity was still high (entry 4). The optimum reaction temperature was found to be *ca*. 0 °C. When the reaction temperature decreased to −40 °C, the reaction became sluggish and far less enantioselective (entry 8). Although the use of a low catalyst:substrate ratio was rather ineffective, it is of interest to note that increasing the concentration of the catalyst lowered the enantioselectivity (entries 9–11). The preliminary results revealed that a catalyst concentration of 0.0008–0.0012 M was optimum. The copper complexes at different concentrations may form different catalytic species. Similar results had been reported by Feringa *et al*.[4a] When EtMgCl was used in place of Et_2Zn only racemic **4b** was obtained as the major product and small amounts of 1,2-addition product were observed (entry 12).

The ^{31}P NMR spectrum of the catalyst solution (L:Cu = 2:1, toluene-d_8) showed two peaks at δ 231.6 and 149.0. The peak at δ 149.0 corresponded to free (*S*,*S*,*S*)-**1** and the low field peak at δ 231.6 is expected to be (*S*,*S*,*S*)-**1**–$Cu(OTf)_2$. When excess Et_2Zn was added at room temperature, the peak at δ 231.6 disappeared quickly and a new peak at δ 124.0 was observed. This new species may be postulated to be an Et–Cu^{I} complex containing a molecule of (*S*,*S*,*S*)-**1**. The electron-rich nature of Et–Cu^{I} caused the significant ^{31}P NMR shift. Coordinative solvents such as THF or MeCN competed with the enone substrates for the coordinating site of the Cu^{I} catalyst and

[a] 1.5 equiv. of diethylzinc was used and the reactions were carried out in toluene for 3 h. [b] The conversions and ee values were determined by GC with a Chiraldex A-TA column (30 m × 0.25 mm); no 1,2-addition product was observed. [c] The absolute cofiguration was determined by optical rotation (ref. 12). [d] Isolated yield. [e] Ethylmagnesium chloride was used. [f] A small amount of 1,2-addition product was observed.

decreased the rate of reaction as well as the enantioselectivity.

The Cu^{II} complex of (*S*,*S*,*S*)-**1** was also tested in the conjugate addition of diethylzinc to cyclopent-2-enone **3a**, cyclohept-2-enone **3c** and chalcone **5**, and the results are summarized in Table 2. Up to now the catalytic conjugate addition of organometallic reagents to **3a** has been relatively unsuccessful.[4c,8,9] With the (*S*,*S*,*S*)-**1**–$Cu(OTf)_2$ catalyst system, the conjugate addition of Et_2Zn to **3a** gave a good yield of the desired product with 76.6% ee (entry 1). To the best of our knowledge, this enantioselectivity was the best one so far obtained for this reaction. Interestingly the absolute configuration of the product was opposite to that from the conjugate addition to **3b**. The reversal of enantiofacial selectivity for **3a** was also observed previously by Rossiter *et al*.[13] The conjugate addition of Et_2Zn to **3c** gave a lower conversion rate and enantioselectivity than the reaction with **3b** and **3a** (entry 2, Scheme 2).

Table 2 The addition of diethylzinc to enones **3a**,**c** and **5** catalyzed by (*S*,*S*,*S*)-**1**–$Cu(OTf)_2$

Entry	Substrate	Solvent	*T*/°C	Conversion (%)[a]	Ee (%)[a]	Configuration
1	**3a**	Toluene	0	100 (71.3[b])	76.6	*R*[c]
2	**3c**	Toluene	0	40.0	56.0	nd[d]
3	**5**	Toluene	0	45	9.3	*R*[e]
4	**5**	THF	0	62	16.5	*R*

[a] The ee value of **4a** and the conversion were determined by GC with a Chiraldex A-TA Column (30 m × 0.25 mm). The ee value of **4c** and the conversion were determined by GC with a Chrompack CP-Chirasil-Dex CB (25 m × 0.25 mm). The ee value of **6** and the conversion were determined by HPLC with a Diacel-OD column. [b] Isolated yield. [c] The absolute configuration was determined by optical rotation (ref. 14). [d] Not determined. [e] Comparison of the retention time of **6** in HPLC with known data (ref. 9).

The conjugate addition of Et_2Zn to chalcone gave **6** with poor enantioselectivity and low conversion (entries 3 and 4, and Scheme 3). The high specificity of the matching of substrate and catalyst had been found in many other catalyst systems.[2c,8,9]

The chiral match of the three binaphthol rings is very important for efficient enantiocontrol. (*S*,*R*,*S*)-**1** was prepared and used for the addition of Et_2Zn to **3b** using the optimum reaction conditions [1 mol% $Cu(OTf)_2$, 2 mol% (*S*,*R*,*S*)-**1**, 0 °C, toluene]. Compound **4b** was obtained with only 30.6% ee (*S*).

Substituted siloxysilanes and the structure of oligomeric liquid crystals

Georg H. Mehl* and John W. Goodby

Department of Chemistry, The Faculty of Science and the Environment, The University of Hull, Hull, UK HU6 7RX. E-mail: G.H.Mehl@chem.hull.ac.uk; J.W.Goodby@chem.hull.ac.uk

Received (in Cambridge, UK) 28th September 1998, Accepted 6th November 1998

The sequential addition of 4-cyanobiphenyl moieties to a silyl core unit results in a modification of the molecular shape of the molecules from rod-like to cross-shaped. The variation of molecular size and shape determines the nature (interdigitated SmAd or monolayer SmAl) and the stability range of the liquid-crystalline phases of these materials.

The research into branched and hyper-branched systems has focused mainly on synthesis of 'number generation' and less attention has been paid to the influence of the sequential introduction of sub-molecular systems into supermolecular structures.[1,2]

In order to understand this influence it is necessary to investigate the properties of the submolecular blocks and to examine how the stepwise introduction of those units into each generation of the supramolecular scaffolding affects the properties of the system.

This allows for the examination of the relationships and interplay between discrete molecular and polymeric systems and between the submolecular units, the polymeric framework, and the topology of their interconnections.

The above relationships are of importance to low molar mass, oligomeric and polymeric liquid-crystalline systems where there is constant debate concerning the identities, dynamics and topologies of mesogenic groups, spacer chains and polymer backbones in complex macromolecular systems. These relationships are of particular importance in determining viscoelastic and rheological properties. For example, it has been shown that defined or discrete oligomeric materials can exhibit properties usually associated with polymers, whilst still retaining the fluidity and viscosity of low molar mass liquid crystals.

In order to investigate these relationshps a series of model materials was synthesised, consisting of molecules where the number of mesogenic groups attached to a central silane core was sequentially increased in number from one to four. In addition the associated solid state behaviour of each of the materials was investigated. In this systematic study we prepared and investigated a family of branched supermolecules that were designed to have a controllable number of 4-cyanobiphenyl mesogenic submolecular units attached to a central silane core. The materials were conveniently prepared *via* a synthetic route based on combining a 4'-ω-alkenyl-4-cyanobiphenyl with an (oligo)vinylsilane moiety.

Initially, 4'-(10-undecenyl)-4-cyanobiphenyl was treated with a tenfold excess of 1,3-dihydro-1,1,3,3-tetramethylsiloxane in a hydrosylation reaction that was carried out in toluene at room temperature using Karstedt's catalyst (Pt–divinyl-tetramethylsiloxane in xylene), thereby yielding [4-cyano-4′-{11-[3-hydro-1,1,3,3-tetramethyldisiloxy]undecanyloxy}biphenyl] **1**.[3–5] The target materials **2**–**5** were obtained under similar reaction conditions, but by using an excess of **1** relative to the number of reactive vinyl groups in the silane cores (alkylvinylsilanes) to which the mesogenic submolecular units were to be attached. In each case, isolation of the product (**2**–**5**, Fig. 1) was achieved by column chromatography over silica gel using a mixture of hexane–dichloromethane (6 : 1) as the eluent. The absence of peaks in the vicinity of 2.0 ppm in the ^{1}H NMR spectra was indicative (within experimental error) of complete α-addition of the vinyl groups to the hydridosilicone core unit. The ^{29}Si NMR spectra revealed the shift of the signal of the hydridosiloxane group at 10.0 ppm to values of 7.08 to 7.43 ppm after conversion (the exact value measured being somewhat dependent on the structure of the core). The signal for the silicon bonded to four alkyl groups was found to shift from 3.04 to 6.88 ppm with the concomitant increase in the number of mesogenic substituents from one to four. These results were matched by high resolution ^{1}H NMR spectra, which is not usually the case for oligomeric materials.

Calorimetric studies reveal that all of the materials exhibit liquid crystal phases. The values for the transition temperatures and the associated enthalpies and entropies for the second heating cycles of each compound are listed in Table 1. Thermal polarised light transmission microscopy reveals that as each material is cooled from the isotropic liquid into the liquid crystal state, homeotropic and focal-conic defect textures are formed. The combination of homeotropy with the hyperbolic and elliptical lines of optical discontinuity associated with focal-

conic defects is diagnostic for the presence of a smectic A phase. Mechanical shearing of the specimens in the microscope shows that the smectic A phase flows easily and has a relatively low viscosity. In addition, only a short time is required for the focal-conic defect pattern to form on cooling from the isotropic liquid, indicating that the compounds have rheological properties more in common with low molar mass materials than with oligomers or polymers.

Increasing the number of branches carrying mesogenic groups from one to four results in the isotropization temperature being increased from 50.6 °C for compound **2** to 97.9 °C for **5** indicating an increasing stability of the liquid crystal properties as a function of the number of mesogenic units. Interestingly, if the values of the reduced molar entropy ($\Delta S_{mol}/R$) are used as a measure of the degree of ordering within the liquid crystal phase at the isotropization temperature an alternating odd–even effect is manifested. The middle members, **3** and **4**, exhibit roughly similar values of 2.79 and 2.55 placing them between those of the terminal members of the series, *i.e.* 0.90 for **2** and 5.20 for **5**. Taking into account the number of mesogenic moieties per molecule [$(\Delta S_{mol}/R)/n$] reveals an odd–even effect. The odd members of the series have reduced molar entropies between 0.8 and 0.9, and the even substituted materials have values between 1.3 and 1.4 per mesogenic side-chain. This result is in line with the concept of having a higher degree of ordering in the liquid-crystalline state for the even members of the series. This can be attributed to the higher degree of molecular symmetry of the even members. The higher degree of symmetry helps in the intra- and inter-molecular packing of the mesogenic subunits or arms, which in turn aids the organization and packing of the supermolecules within the layers of the smectic phase. Moreover, the occurrence of glass transitions for materials **4** and **5**, with an increase in their vitrification temperatures from −28.6 to −22.3 °C as the series is ascended, suggests that there is a higher degree of polymeric character associated with the materials as the number of mesogenic units is increased.

The structure of the smectic A phase exhibited by the materials was investigated further using X-ray diffraction. High flux synchrotron radiation was used in order to perform temperature scans at a rate of 2 °C min^{-1} for fibre samples in Lindemann tubes. The diffraction patterns were found to be typical of the smectic A phase. The results for the *d*-spacings (*d*) for compounds **2**–**5**, as a function of the reduced temperature ($T - T_{iso}$) from the isotropization point (T_{iso}), are shown in Fig. 2. For all of the materials a reduction in the *d*-spacing was observed as the isotropization point was approached. The members with a higher degree of substitution were found to have smaller *d*-spacing than the mono- or di-substituted materials. These results agree with earlier findings for other liquid-crystalline oligosiloxanes.[5–7]

The comparison of the calculated lengths (*l*) of the simulated structures of **2**–**5** (Cerius^2, 3.0 from MSI) with the corresponding layer spacing (*d*) gives *d*/*l* values of 1.6 for **2** and between

Compound	Calc. length *l*/Å	d_{max}/l	*d*-Spacing (max)/Å	*d*-Spacing (T_{Iso-10})/Å
2	30.8	1.63	50.1	48.8
3	48.4	0.98	48.8	46.6
4	49.6	0.96	47.7	45.6
5	50.9	0.94	47.7	45.6

0.9 and 1.0 for compounds **3**–**5**, Table 2. The result for compound **2** fits with an interdigitated bilayer structure for the smectic A phase, thereby classifying the phase as smectic A_d. Interdigitation takes place *via* overlap of the aromatic regions of the dimeric molecules in adjacent lamellae. The decrease in the *d*-spacing with rising temperature for compounds **2** can then be attributed either to increased disordering of the molecules or increased overlap of the molecules. The *d*/*l* values of 0.9–1.0 for the higher homologues indicate the occurrence of a different phase structure for the smectic A phase. One possibility is that the supermolecules in their fully extended conformational structures are arranged in disordered monolayers as in a conventional smectic A_1 phase. As each molecule possesses silyl and aromatic moieties, when these molecular subunits pack together they can do so *via* internal microphase separation. Thus for a microphase separated structure an object molecule can provide mesogenic units to potential aromatic layers above and below a layer containing the silyl core units. Thus, the results are consistent with a structure where the silicone cores are located in the central regions of the layers and where some overlap of the terminal cyanobiphenyl groups occurs between layers.[5,6] This classifies the high temperture smectic phase for the materials **3**–**5** as smectic A with respect to the silane core and quasi-smectic A bilayer for the mesogenic units.

For this series the results indicate that as the number of mesogenic groups is increased the temperature range of the liquid crystal state increases. The ordering of the molecules within the structure of the mesophase tends to be higher for the members of the series that have an even number of mesogenic subunits attached to the central silicon atom. This may be due to symmetry considerations allowing for better packing of the molecules. As the mesogenic count per silyl core is increased so the mesogenic arms have less freedom of movement, and therefore certain molecular topologies become favoured, this in turn affects the physico-chemical properties.

We wish to thank the EPSRC for financial support. We are also grateful to Dr B. U. Komanschek of Daresbury Research Laboratories for technical support at DARL Station 8.2 (Non-Crystalline Diffraction). We acknowledge Dr D. Ewing and Mrs B. Worthington for providing spectroscopic analyses.

An efficient dye-sensitized photoelectrochemical solar cell made from oxides of tin and zinc

K. Tennakone,* G. R. R. A. Kumara, I. R. M. Kottegoda and V. P. S. Perera

Institute of Fundamental Studies, Hantana Road, Kandy, Sri Lanka. E-mail: ifs@ifs.ac.lk

Received (in Cambridge, UK) 1st September 1998, Accepted 19th November 1998

A photoelectrochemical solar cell made from a porous film consisting of a mixture of tin (IV) and zinc oxides sensitized with a ruthenium bipyridyl complex suppresses recombination of the photogenerated electrons and dye cations, generating a short-circuit photocurrent of *ca*. 22.8 mA cm^{-2} and an open-circuit voltage of *ca*. 670 mV in direct sunlight (900 W m^{-2}) with an efficiency *ca*. 8 %.

Dye-sensitized (DS) photoelectrochemical cells (PECs) based on nanoporous films of TiO_2 are gaining much attention as promising solar energy conversion devices.[1–6] Although dye-sensitization can be achieved with porous films of high band-gap semiconductors other than TiO_2, DS PECs as efficient as the Gratzel's cell have not been fabricated earlier using other materials. We have succeeded in constructing a DS PEC from porous films of tin(IV) oxide containing *ca*. 53% zinc oxide. The cell generates an I_{sc} of *ca*. 22.8 mA cm^{-2} and V_{oc} of *ca.* 670 mV at 900 W m^{-2} in direct sunlight. The energy conversion efficiency of *ca*. 8% at this intensity is increased to *ca*. 15 % in diffuse daylight (100 W m^{-2}) as a consequence of the increase of the fill factor from 0.5 to 0.6. Both oxides (Sn and Zn) are essential for functioning of the cell. The enhanced values of I_{sc} and V_{oc} are explained as resulting from the high probability of transfer of an electron by an excited dye molecule adsorbed at a SnO_2 crystallite to a ZnO crystallite and subsequent relaxation to the conduction band (CB) of another SnO_2 crystallite attached to the original ZnO crystallite. This process leads to efficient spatial separation of photogenerated charges (D^+ and e^-), suppressing recombinations.

Porous films consisting of SnO_2 and ZnO were prepared by the following method. A colloidal 15% aqueous solution of SnO_2 of crystallite size of *ca*. 0.015 μm. (1.5 ml), acetic acid (0.1 ml) and ZnO of crystallite size of *ca.* 2 μm (0.3 g, prepared by thermal decomposition of zinc oxalate) were ground in an agate mortar, mixed with 20 ml of methanol and agitated ultrasonically for 30 min. The solution was sprayed onto a fluorine doped conducting tin oxide (CTO) glass plate (1.25 × 1.5 cm, sheet resistance *ca*. 10 Ω □$^{-1}$) heated to 150 °C until a layer of thickness *ca*. 8–10 μm was deposited and sintered at 500 °C in air for 35 min (sintering completely removes organic compounds in the solution). The sintered film was coated with the dye {*cis*-dithiocyanato [*N*-bis(2,2′-bipyridyl-4-4′-dicarboxylic acid)]ruthenium(II)} by boiling the plate in the dye solution (2 × 10^{-4} M in ethanol) for 3 min. A lightly platinized CTO glass plate, used as the counter electrode was kept in contact with the dyed film and the edges are sealed after introducing the electrolyte (0.5 M KI + 0.03 M I_2 in acetonitrile containing 10% ethylene glycol). The construction of the cell is schematically depicted in the inset of Fig. 1.

The *I*–*V* characteristics of the cell in direct sunlight (900 W m^{-2}) and diffuse daylight presented in Fig. 1 correspond to efficiencies of 8 and 15%, respectively. In direct sunlight, the efficiency is comparable to that of the Gratzel's cell based on TiO_2. However, at lower intensities (diffuse daylight) the efficiency of the present system appears to exceed that of Gratzel's cell. When the film is 100 % SnO_2, the maximum values of I_{sc} and V_{oc} obtained are *ca*. 2.5 mA cm^{-2} and *ca.* 335 mV respectively. Introduction of even a small quantity of ZnO increases both I_{sc} and V_{oc} significantly. The optimum values of I_{sc} and V_{oc} are reached when ZnO% is *ca*. 53%, a further increase of ZnO decreases I_{sc} and V_{oc} and for a cell made from 100% ZnO, I_{sc} = *ca*. 4 mA cm^2 and V_{oc} = *ca*. 540 mV. As SnO_2 particles have much smaller dimensions compared to ZnO (r_{ZnO}/r_{SnO_2} = *ca*. 133). The surface area of SnO_2 film ($S = 3w/\rho r$, where w = weight of the oxide, ρ = density, r = radius of the particle) is *ca*. 107 times the ZnO surface when the ZnO% corresponds to the optimum. Consequently, the light absorption occurs mostly at the dye coated SnO_2. The above observation is also supported by the photocurrent action spectra of cells made with composite SnO_2/ZnO films and those of SnO_2 and ZnO. The peaks of the action spectra of SnO_2 and SnO_2/ZnO systems were observed at almost the same position (*ca*. 539 nm), whereas a pure ZnO cell showed a peak at *ca*. 528 nm, indicating that in the composite system photocurrent originates mostly *via* sensitization of SnO_2. Furthermore ZnO adsorbs the Ru-complex, very feebly compared to SnO_2.

The mechanism of photocurrent generation which can explain the observations is as follows: in the composite film the larger ZnO particles are surrounded by SnO_2 particles (Fig. 2). An excited dye molecule on a SnO_2 particle could inject an electron to the CB of SnO_2 as in normal dye-sensitization of a semiconductor. However, as the excited level of the dye is above the CB of ZnO (Fig. 2) the energetic electron (*i.e.* the 'hot carrier' which has not relaxed to the CB of the SnO_2 particle) could also be driven to the CB of a ZnO particle in its vicinity, traversing across several SnO_2 particles. This enables a significant number of dye coated SnO_2 particles to participate in

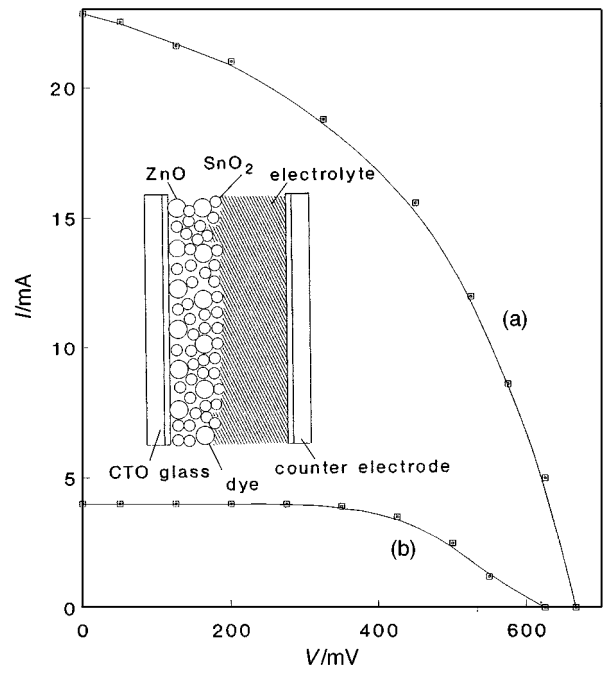

Fig. 1 *I*–*V* characteristics of the cell in (a) direct sunlight (900 W m^{-2}, measurements conducted for 1030–1130 h) and (b) diffuse daylight (100 W m^{-2}). Inset: construction of the cell.

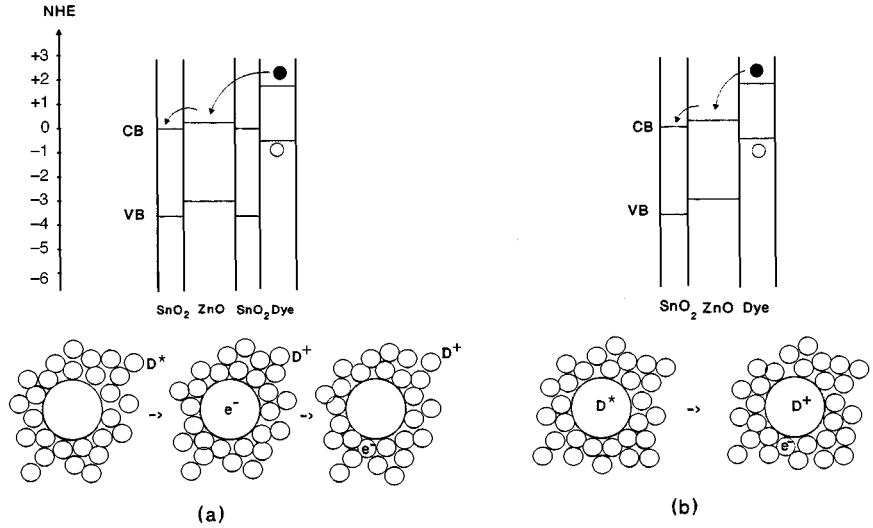

Fig. 2 An energy level diagram (NHE = normal hydrogen electrode) and a schematic diagram illustrating the transfer of an electron by an excited dye molecule (a) adsorbed at the surface of a SnO_2 particle to the CB of a ZnO particle in the vicinity and to the CB of another SnO_2 particle and (b) adsorbed at the surface of a ZnO particle to the CB of the ZnO particle and then to the CB of a SnO_2 particle.

the above electron injection process. The transfer of the electron into the CB of ZnO which is at a higher level in comparison to the CB of SnO_2 generates a V_{oc} greater than that of a cell comprising of 100% SnO_2. Subsequently the electron excited to the CB of ZnO is transferred to the CB of a SnO_2 particle in contact with the ZnO particle. As a result photogenerated negative and positive charges (D^+ and e^-) are widely separated by a ZnO barrier and the recombination is suppressed. An energy level diagram and a schematic diagram illustrating interparticle charge transfer are presented in the Fig. 2(a). The electrons separated from the dye cations are taken to CTO back contact *via* interconnection of SnO_2 particles. In DS PECs of the Gratzel type, the recombination of the photogenerated electron with the dye cation is one of the principal factors that limits the photocurrent quantum efficiency[7–10] and to some extent the V_{oc}. In the present system recombinations of this nature are largely suppressed due to rapid movement of the electron to a distance comparable to the size of the ZnO particle. This is supported by the observation that if ZnO particles of size comparable to that of SnO_2 particles are used the enhancement of I_{sc} and V_{oc} is not significant. As explained earlier, the contribution to the photocurrent from sensitization of ZnO is less effective compared to that from SnO_2. However, even this process suppresses recombinations, because the electron injected to the CB of ZnO from the excited dye molecule is immediately transferred to a SnO_2 particle in contact with ZnO [Fig. 2(b)]. Although the I_{sc} and V_{oc} of the cell are quite high, the efficiency at higher intensities are low because of the lower fill factor at higher intensities (*i.e.* 0.6 at 100 W m^{-2} and 0.5 at 900 W m^{-2}). This is the general behavior of DS PECs based on nanoporous semiconductor films. A possible cause is recombination (D^+ and e^-) across voids (where CTO surface is exposed to the electrolyte) in the film. When the surface density of voids is high, the fill factor is found to decrease. The cell remained stable during the few days of operation. Apart from fluctuations, I_{sc} and V_{oc} did not show any signs of decay.

Binuclear tin and germanium calix[4]arenes

Brian G. McBurnett and Alan H. Cowley*

Department of Chemistry and Biochemistry, The University of Texas at Austin, Austin, Texas 78712, USA. E-mail: cowley@mail.utexas.edu

Received (in Columbia, MO, USA) 6th September 1998, Accepted 17th November 1998

Ditin(II) and digermanium(II) calix[4]arenes, [Bu^{t}calix]M_2 (1, M = Sn; 2, M = Ge) have been prepared by treatment of [Bu^{t}calix]H_4 with $M(NR_2)$ (R = Me or Me_3Si); the reaction of [Bu^{t}calix]Li_4 with $SnCl_4$ affords the mixed valence ditin derivative [Bu^{t}calix]Sn_2Cl_2 3.

Calixarenes offer the prospect of serving as oxo-matrices for the construction of poly-Lewis acid or poly-Lewis base assemblies. Although there is considerable current interest in this field,[1] relatively little information is available regarding main group calixarene chemistry, particularly for systems that feature more than one main group element in the lower rim. Such poly-functionalized derivatives are limited to alkali metals,[2] aluminium,[3] gallium,[3c] silicon,[4] and phosphorus.[2,4a,5,6] We report the synthesis and X-ray crystal structures of (i) the first binuclear tin(II) calixarene, (ii) the first binuclear germanium(II) calixarene, and (iii) a calixarene that features both a tin(II) and a tin(IV) centre.[7]

The reaction of [Bu^{t}calix]H_4 with $Sn(NMe_2)_2$ took place in toluene solution at ambient temperature and afforded a 78% yield of colorless, crystalline [Bu^{t}calix]Sn_2 **1**.† The HRMS (CI) for **1** exhibited a parent peak corresponding to the composition $C_{44}H_{52}O_4Sn_2$ and an isotopic distribution consistent with the presence of two tin atoms. The ^{1}H NMR spectrum of **1** revealed the presence of two pairs of *para*-Bu^{t}ArO moieties and the ^{119}Sn NMR spectrum consisted of a single peak at δ 23.0.

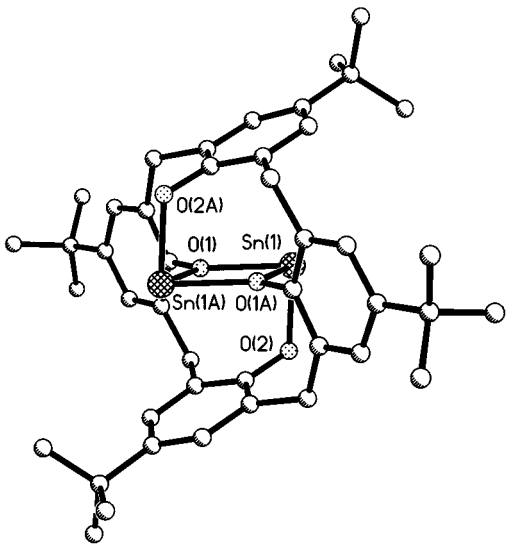

Fig. 1 Molecular structure of **1** showing the atom numbering scheme. Selected bond distances (Å) and angles (°) for **1** (the corresponding values for **2** are shown in parentheses) Sn(1)–O(1) 2.193(2) [Ge(1)–O(1) 1.997(6)], Sn(1)–O(1A) 2.169(2) [Ge(1)–O(1A) 1.991(6)], Sn(1)–O(2) 2.054(2) [Ge(1)–O(2) 1.844(6)]; O(1)–Sn(1)–O(1A) 68.22(11) [O(1)–Ge(1)–O(1A) 71.9(2)], Sn(1)–O(1)–Sn(1A) 117.78(11) [Ge(1)–O(1)–Ge(1A) 108.1(2)], O(1)–Sn(1)–O(2) 86.02(9) [O(1)–Ge(1)–O(2) 91.0(3)], O(2)–Sn(1)–O(1A) 85.78(9) [O(2)–Ge(1)–O(1A) 92.2(2)]. Because there are two half molecules in the asymmetric unit, there are two independent molecules for both **1** and **2**. The metrical parameters for these pairs of independent molecules do not differ greatly and only one such molecule is shown in either case.

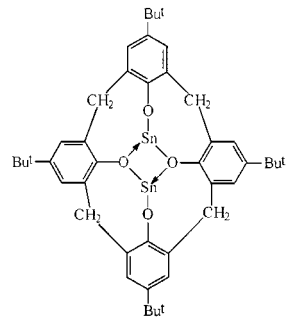
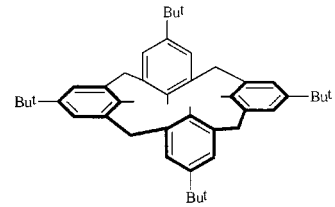
Further characterisation necessitated an X-ray crystal structure determination.‡ The solid state (Fig. 1) consists of individual molecules of **1** and CH_2Cl_2; there are no unusually short intermolecular contacts. The central structural feature of **1**, which resides on a centre of symmetry, is an Sn_2O_2 parallelogram. The bond angles at tin [68.2(1)°] and oxygen [111.8(1)°] within the Sn_2O_2 kernel deviate significantly from 90° and the two Sn–O bonds differ in length by *ca.* 0.2 Å. Each tin atom is bonded to a third oxygen and this bond distance [Sn(1)–O(2)] is *ca.* 0.1 Å shorter than those in the Sn_2O_2 parallelogram. The O–Sn–O bond angles of the SnO_3 moiety are remarkably acute as shown in the graphical abstract (sum of O–Sn–O bond angles = 240.02°). The structure of **1** can be considered to arise *via* the dimerisation of two otherwise coordinatively unsaturated $(ArO)_2Sn$ units as shown below (**A**). As a consequence of the



A



B

formation of two donor–acceptor bonds, the conformation of the calix[4]arene changes from bowl-shaped to that of a flattened partial cone (**B**).

The digermanium derivative [Bu^{t}calix]Ge_2 **2** was prepared in an analogous fashion† in 26% yield by treatment of [Bu^{t}calix]H_4 with $Ge[N(SiMe_3)_2]_2$. The virtually identical ^{1}H NMR data for **1** and **2** implied similar structures for both compounds. Confirmation was provided by X-ray analysis (Fig. 1).‡ Comparable trends are evident in the metrical parameters for **1** and **2**, namely within the central Ge_2O_2 moiety the bond angle at germanium [71.9(2)°] is smaller than that at oxygen [108.1(2)°] and the bond distance of the exterior oxygen [O(2)] is shorter than those within the ring. However, in the case of **2**, the intra-annular bond distances are the same within experimental error.

The reaction of [Bu^{t}calix]Li_4 with $SnCl_4$ in diethyl ether solution afforded a ditin derivative of composition [Bu^{t}calix]Sn_2Cl_2 **3** in 45% yield.† The observation of two peaks in the ^{119}Sn NMR spectrum† indicated that the tin atoms are present in distinctly different environments. By means of X-ray crystallography,‡ it was established that the molecular structure involves a flattened cone or boat-type conformation in which the tin atoms occupy *exo* and *endo* positions (Fig. 2). The hexacoordinate *exo* tin atom adopts a distorted octahedral geometry, being bonded to O(1), O(2), O(3), O(4), Cl(1) and Cl(2). Two of these interactions, O(1) and O(3), can be regarded as donor–acceptor bonds hence Sn(1) is in the +4 oxidation state. As expected, the Sn(1)–O(1) and Sn(1)–O(3) bond distances [av. 2.126(6) Å] are longer than the Sn(1)–O(2) or

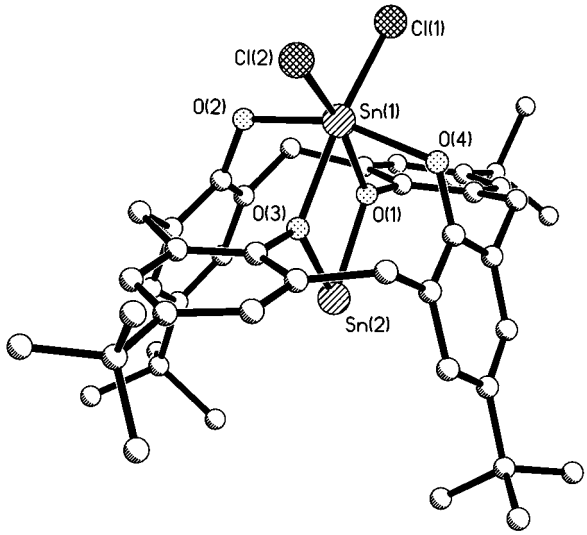


Fig. 2 Molecular structure of **3** showing the atom numbering scheme. Selected bond distances (Å) and angles (°): Sn(1)–Cl(1) 2.340(3), Sn(1)–Cl(2) 2.349(3), Sn(1)–O(1) 2.124(6), Sn(2)–O(1) 2.118(6), Sn(2)–O(3) 2.089(6), Sn(1)–O(3) 2.128(6), Sn(1)–O(2) 2.044(7), Sn(1)–O(4) 2.079(7); Cl(1)–Sn(1)–Cl(2) 100.7(1), O(1)–Sn(1)–O(3) 72.0(2), Sn(1)–O(1)–Sn(2) 107.0(3), O(1)–Sn(2)–O(3) 72.9(2), Sn(2)–O(3)–Sn(1) 107.9(3), O(2)–Sn(1)–O(4) 160.1(3).

Sn(1)–O(4) distances [av. 2.061(7) Å]. There is considerable departure from the ideal octahedral angles at Sn(1) due to the demands of the ligand system. Thus the angles O(2)–Sn(1)–O(4) [160.1(3)°] and O(1)–Sn(1)–O(3) [72.0(2)°] are unusually small whilst the Cl(1)–Sn(1)–Cl(2) bond angle is enlarged commensurately [100.7(1)°]. The *endo* tin atom, Sn(2), is two-coordinate and thus in the +2 oxidation state. The Sn(2) geometry is V-shaped with an O(1)–Sn(2)–O(3) bond angle of 72.9(2)°.

We thank the National Science Foundation and the Robert A. Welch Foundation for financial support.

† *Experimental procedures*: **1**: a solution of 4.2 mmol (0.87 g) of $Sn(NMe_2)_2$ in 30 mL of toluene was added *via* cannula to a toluene suspension of 2.1 mmol (1.37 g) of *p-tert*-butylcalix[4]arene at room temperature. Following the complete addition of $Sn(NMe_2)_2$, the solution turned clear and, after 15 min, a white precipitate formed. The reaction mixture was allowed to stir overnight and the toluene was removed *in vacuo*. The remaining white solid was washed with hexane (3 × 50 mL) and redissolved in 60 mL of CH_2Cl_2. The solution was filtered and stored for two days at −20 °C resulting in the formation of colorless X-ray quality crystals (1.45 g, 78% yield). ^{1}H NMR (300 MHz, $CDCl_3$) δ 7.22 (s, 4H, Ar), 7.19 (s, 4H, Ar), 4.46 (d, 4H, CH_2), 3.64 (d, 4H, CH_2), 1.40 (s, 18H, Bu^t), 1.25 (s, 18H, Bu^t); MS (CI) *m/z* (M^+) 877; HRMS (CI) *m/z* calc. for $C_{44}H_{53}O_4Sn_2$: 877.197873, found 877.196806 (M^+).

2: this colorless, crystalline compound was prepared in 26% yield using the procedure described for **1**. ^{1}H NMR (300 MHz, $CDCl_3$) δ 7.23 (s, 4H, Ar), 7.20 (s, 4H, Ar), 4.45 (d, 4H, CH_2), 3.63 (d, 4H, CH_2), 1.40 (s, 18H, Bu^t), 1.26 (s, 18H, Bu^t); MS (CI) *m/z* (M^+) 789; HRMS (CI) *m/z* calc. for $C_{44}H_{53}O_4Ge_2$: 785.242885, found 785.242345.

3: A diethyl ether solution of 4.0 mmol (2.50 g) of *p-tert*-butylcalix[4]arene was treated with a 1.6 M solution of *n*-BuLi (16.0 mmol, 10.0 mL) at room temperature and the resulting orange slurry and was stirred for 2 h. Neat $SnCl_4$ (0.5 mL, 4.0 mmol) was added *via* syringe to the suspension whereupon the colour changed from orange to dark red. The reaction mixture was allowed to stir overnight, following which the solvent and volatiles were removed *in vacuo*. The residual red solid was redissolved in 50 mL of toluene. The solution was filtered and stored for two weeks at −20 °C resulting in the formation of colorless X-ray quality crystals (1.68 g, 45% yield). ^{1}H NMR (300 MHz, $CDCl_3$) δ 7.36 (s, 4H, Ar), 7.26 (s, 4H, Ar), 4.47 (d, 4H, CH_2), 3.61 (d, 4H, CH_2), 1.49 (s, 18H, Bu^t), 1.19 (s, 18H, Bu^t); ^{119}SnNMR (111.85 MHz, $CDCl_3$) δ 215.5, −51.6; MS (CI) *m/z* (M^+) 877; HRMS (CI) *m/z* calc. for $C_{44}H_{52}Cl_2O_4Sn_2$: 946.127753, found 946.127928 (M^+).

Combining four different model nucleobases (uracil, adenine, guanine, cytosine) *via* metal binding and H bond formation in a single compound

Roland K. O. Sigel, Susan M. Thompson,† Eva Freisinger and Bernhard Lippert*

Fachbereich Chemie, Universität Dortmund, D-44221 Dortmund, Germany. E-mail: Lippert@pop.uni-dortmund.de

Received (in Basel, Switzerland) 21st September 1998, Accepted 9th November 1998

A cyclic arrangement of the four model nucleobases 1-methyluracilate (mura), 9-ethyladenine (eade), 9-ethylguanine (Hegua) and 1-methylcytosine (mcyt), held together by two metal entities [*trans*-$(NH_3)_2Pt^{II}$ and *trans*-$(MeNH_2)_2Pt^{II}$] and multiple H bond interactions, is presented.

Complementary and likewise non-complementary nucleobases can be cross-linked by suitable (usually linear or *trans*-square-planar) metal ions to give 'metal-modified' base pairs,[1,2] triples,[2] or quartets.[3] If combined with H bond formation, many variants are possible.[4] Here we report on an example of a nucleobase quartet which combines models of all four RNA bases uracil (U), adenine (A), guanine (G) and cytosine (C) in a single compound. In {*trans*,*trans*-[$(NH_3)_2$Pt(mura-N^3)(eade-N^7,N^1)Pt$(MeNH_2)_2$(Hegua-N^7)•mcyt]}$_2$[mcyt•Hmcyt][ClO_4]$_{4.5}$-[NO_3]$_{2.5}$•8.7H_2O **5** (Fig. 1) the four bases are joined *via* two linear metal entities and multiple H-bonding interactions. These include a Watson–Crick pair between Hegua and mcyt, which is reinforced by a fourth H-bond between the second amino proton of mcyt and a carbonyl oxygen atom of mura. In addition there is hemiprotonated 1-methylcytosine [mcyt•Hmcyt]$^+$ present in the lattice, displaying the well-known[5] threefold H bonding scheme.

The title compound was prepared in a stepwise fashion from *trans*-[$(NH_3)_2$Pt(mura-N^3)Cl] **1** as outlined in Scheme 1. Intermediates **2**–**4** have been isolated.‡ The title compound **5** was crystallized from an aqueous solution of **4** (20 mg, 0.0167 mmol dissolved in 3 mL of water), to which an excess of mcyt (6.27 mg, 0.05 mmol) had been added, with the pH adjusted to 5.3 with HNO_3. Colourless crystals of **5** suitable for X-ray crystallography§ were obtained upon slow evaporation of the solvent at 22 °C.

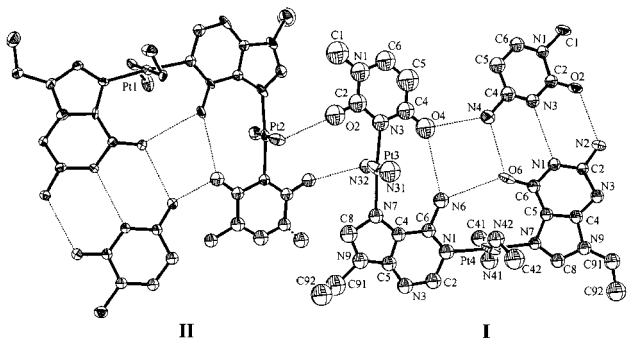

Fig. 1 View from the top of the two crystallographically independent cations **I** and **II** in **5**. The ellipsoids are drawn at 30% probability.

Compound **5** crystallizes with two crystallographically independent cations (**I**, **II**) in the asymmetric unit, which display two slightly different quartets. In the first one (**I**), the four bases give, despite moderate dihedral angles between each other, the picture of an essentially coplanar base quartet. In contrast, in cation **II** the guanine, cytosine entity on one hand, and the uracil, adenine entity on the other are markedly propeller-twisted about the Hegua-N^7–Pt^1–eade-N^1 bonds, thereby making in particular the two pyrimidine bases markedly non-coplanar (Table 1). This feature is reminiscent of the situation with an open base quartet consisting of four purine bases (A_2, G_2) and three metal ions (Pt^{II}).[3] In the present case (**II**) disorder (60 : 40) of the uracil base about the Pt^2–N^3-mura bond facilitates this feature: If, as is the case in the predominant rotamer, O^2 of mura participates in H bonding within the quartet, the CH_3 group of mura is pointing toward mcyt, thereby causing repulsion between C^5H (mcyt) and CH_3 (mura). Another effect is stacking of the guanine nucleobases of two cations **II** (3.2 Å, symmetry operation $-x + 2$, $-y + 1$, $-z + 2$).

As expected from relative orientations of the three platinated bases, exocyclic groups are involved in weak H bonding interactions (Table 1). Geometries of the Watson–Crick pairs in **I** and **II** are normal.[6] **I** and **II** are joined by two additional H bonds between NH_3 groups of Pt^2 and Pt^3 as well as O^2 and O^4/O^2 of mura ligands (Fig. 1).

We have previously observed[7] that Pt–N vectors in diplatinated adenine bases are close to perpendicular, and found that in mixed di- or tri-nuclear purine complexes this feature is likewise confirmed.[1–3] As evident from the data of **5**, addition of the pyrimidine base mura causes a marked deviation toward smaller angles. For example, in **I** this angle is 84.4(7)° and in **II** it is even smaller, 80.7(5)°. Considering the relatively large errors in nucleobase angles, it is not possible to relate this fact to a unique structural feature, *e.g.* variations in external ring angles at the sites of metal coordination.

In conclusion, a compound (**5**) has been prepared which combines four different model RNA nucleobases in a single compound. It displays simultaneously a metal-modified Hoogsteen pairing scheme (A, U), a metal-modified mispair (A, G), and a Watson–Crick pair (G, C). In principle, a corresponding quartet containing the DNA bases G, C, A and T (T = thymine) of type **II** is feasible. The (nearly) coplanar arrangement of the three metalated nucleobases in **5** contrasts that of a compound with three different bases (G, A, C) combined in a mononuclear complex, with the nucleobases arranged mutually perpendicu-

lar.[8] Considering the ever increasing number of RNA tertiary structures,[9] **5** represents a unique example of an interplay between nucleobases, metal ions and H bonds. Preliminary solution studies indicate clearly that H bonding between the metalated G base and the C model nucleobase is not only taking place in the solid state but also in solution.

‡{*trans*,*trans*-[$(NH_3)_2$Pt(mura-N^3)(eade-N^7,N^1)Pt$(MeNH_2)_2$(Hegua-N^7)•mcyt]}$_2$ [mcyt•Hmcyt][ClO_4]$_{4.5}$[NO_3]$_{2.5}$•8.7H_2O **5** was synthesized as follows: compounds **1** and **2** have been synthesized according to ref. 1, where 1-methylthymine was used instead of mura. The yields were 68% for *trans*-[$(NH_3)_2$Pt(mura-N^3)Cl] **1** and 63% for *trans*-[$(NH_3)_2$Pt(mura-N^3)(eade-N^7)]NO_3 **2**.

To a 20 mM aqueous solution of **2**, 1.2 equiv. of *trans*-[$(MeNH_2)_2PtCl_2$] were added and stirred for 36 h at 45 °C. Precipitated excess of *trans*-[$(MeNH_2)_2PtCl_2$] was filtered off and the solution concentrated at room temperature to 3 mL. After addition of 4 equiv. of $NaClO_4$ and cooling at 4 °C for 24 h, *trans*,*trans*-[$(NH_3)_2$Pt(mura-N^3)(eade-N^7,N^1)Pt$(MeNH_2)_2$Cl]-[ClO_4]$_2$•3 H_2O (**3**) could be isolated as a white powder in 61% yield. Anal. Calc. for $C_{14}H_{30}N_{11}O_{10}Cl_3Pt_2$: C, 15.8; H, 3.4; N, 14.5. Found: C, 15.8; H, 3.2; N, 14.5 %.

To a 8 mM aqueous solution of **3**, 0.95 equiv. of $AgNO_3$ were added and stirred at 40 °C in the dark overnight. After removal of AgCl, 1.2 equiv. of Hegua were added and the solution (pH 4.0, HNO_3) stirred at 40 °C for 36 h. The solution (pH 7.1, NaOH) was slowly concentrated at room temperature and precipitated excess of Hegua removed. The residue was recrystallized from water to give **4** in its hemideprotonated form {*trans*,*trans*-[$(NH_3)_2$Pt(mura-N^3)(eade-N^7,N^1)Pt$(MeNH_2)_2$($H_{0.5}$egua)]-[ClO_4]$_{2.5}$•1.25 H_2O}$_2$ in 28% yield. Anal. calc. for $C_{42}H_{77}N_{32}O_{26}Cl_5Pt_4$: C, 20.6; H, 3.4; N, 18.3. Found: C, 20.7; H, 3.4; N, 18.5%.

To a 5 mM aqueous solution of **4** (pH 5.3, HNO_3), 3 equiv. of mcyt were added and the solution evaporated to dryness at room temperature, which gave yellow crystals of **5** suitable for X-ray crystallography.

§ *Crystal data* for **5**: $C_{62}H_{122.4}O_{44.2}N_{46.5}Cl_{4.5}Pt_4$, M_r = 3166.55, triclinic, space group $P\bar{1}$, a = 15.004(3), b = 17.795(4), c = 21.662(4) Å, α = 97.81(3), β = 103.21(3), γ = 92.16(3)°, U = 5564.2(20) Å^3, Z = 2, D_c = 1.890 g cm^{-3}, μ(Mo-Kα) = 5.226 mm^{-1}, T = 126(2) K, Enraf–Nonius–KappaCCD[10] with graphite monochromator, ω-scans, 10 299 independent reflections, R_{int} = 0.043, structure solved by standard Patterson methods[11] and refined by full matrix least squares on F^2 using SHELXL-93.[12] Only a few non hydrogen atoms were refined anisotropically, because of the poor reflection to parameter ratio. Hydrogens were placed at calculated positions and no further refined. The methyl group of the uracil molecule of cation **II** is disordered over two positions (occupancy factors 0.6 and 0.4) and also the oxygens of three perchlorate anions and some of the water molecules show disorder. Another half occupied perchlorate anion shares the same position with a 25% occupied nitrate anion. 981 refined parameters gave R_1 = 0.0670 and wR_2 = 0.1697 for 6896 reflections with $I \geq 2\sigma(I)$ and R_1 = 0.1062 and wR_2 = 0.1947 for all data, minimum and maximum features in the difference Fourier map were −2.786 and 2.479 e Å^{-3} (near Pt). Institute of Chemistry, The Hebrew University of Jerusalem, Jerusalem 91904, Israel. E-mail: willnea@vms.huji.ac.il

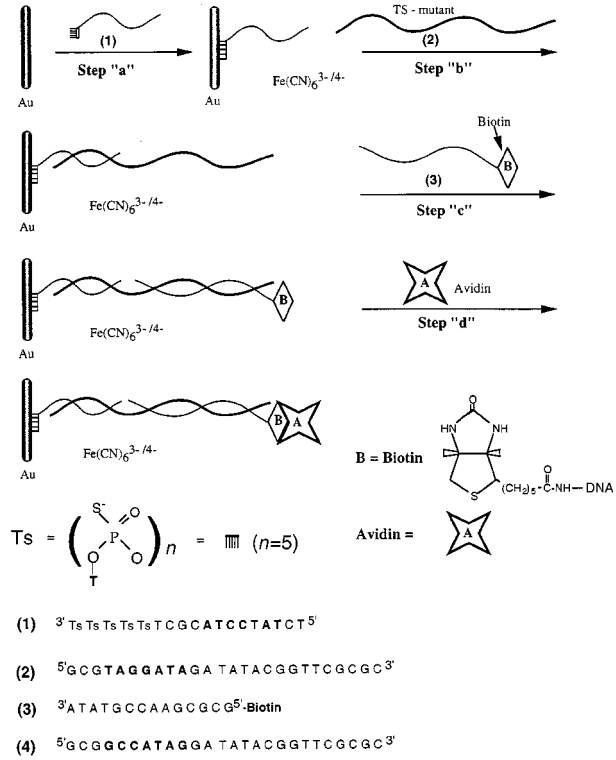
Received (in Cambridge, UK) 27th October 1998, Accepted 19th November 1998

A three-component oligonucleotide/DNA layered assembly on a Au-electrode acts as a specific biosensor for the analysis of the Tay–Sachs mutant by means of Faradaic impedance spectroscopy.

The development of DNA-sensor devices attracts substantial recent research efforts directed to gene analyses, detection of genetic disorders, tissue matching, and forensic applications.[1,2] Significant progress was accomplished recently with the assembly of biochips for the optical detection of DNA.[3] Electronic transduction of the formation of oligonucleotide–DNA complexes could reveal a significant advance in DNA analysis as it could provide quantitative information on the analyte interactions with the sensing interface.[4] The development of a DNA-sensor requires the assembly of the sensing interface on a transducer element for the appropriate electronic transduction of the analyte recognition process, and simultaneously, the tailoring of a specific and selective sensing interface. Electrochemical DNA sensors based on the electrostatic attraction or intercalation of transition metal complexes,[5,6] *e.g.*, $Co(bpy)_3^{3+}$, or dyes such as acridine or Hoechst 33258 were reported. Control of the gate interface potential of field effect transistors, FET, was employed to identify the formation of ds-DNA complexes.[7] Recently, microgravimetric quartz-crystal-microbalance, QCM, analyses were applied to sense oligonucleotide–protein[8] or oligonucleotide–DNA[9] complexes. The sensitivity of these DNA sensors is, however, low, and the specificity of the sensing interfaces needs further studies.

Impedance spectroscopy is an effective method to probe the interfacial properties (capacitance, electron transfer resistance) of modified electrodes.[10] Impedance transduction of the formation of antigen–antibody[11] or biotin–avidin[12] complexes at electrode supports was reported. The assembly of the negatively-charged oligonucleotides and specifically double-stranded (ds) oligonucleotide complexes onto electrode supports is anticipated to control the double-layer potential at the electrode surfaces. As a result, the Faradaic impedance responses of the electrode in the presence of a charged solution-solubilized redox probe, are expected to be controlled upon the formation of a double-stranded DNA oligonucleotide complex at the electrode support. Here we wish to report on the specific, sensitive and confirmative analysis of DNA using Faradaic impedance spectroscopy. As a model system we employ the Tay–Sachs (TS)[13] oligonucleotide mutant that could eventually lead to a TS-sensor device.

The 13-mer oligonucleotide **1** includes a 12-base sequence that is complementary to a part of the TS mutant **2**.[14] In addition, **1** includes a five-base thiophosphate-T tag for its assembly onto a Au-electrode.[15] A Au-electrode was interacted with **1** (50 μM, 10 h) resulting in the assembly of the sensing interface on the gold support, Scheme 1. The resulting **1**-functionalized electrode was interacted with the TS-mutant (30 ng mL^{-1}; 30 min treatment). Fig. 1 shows the impedance features presented as Nyquist plots (Z_{im} *vs.* Z_{re}) of the bare Au-electrode, curve (a), the **1**-functionalized electrode, curve (b), and the functionalized electrode after treatment with the complementary mutant, **2**, curve (c) in the presence of $[Fe(CN)_6]^{3-/4-}$ as the redox probe. Significant differences in the impedance spectra are observed upon the stepwise formation of the ds-oligonucleotide–**2**



Scheme 1 Model system for sensing and amplified impedance analysis of a Tay–Sachs oligonucleotide.

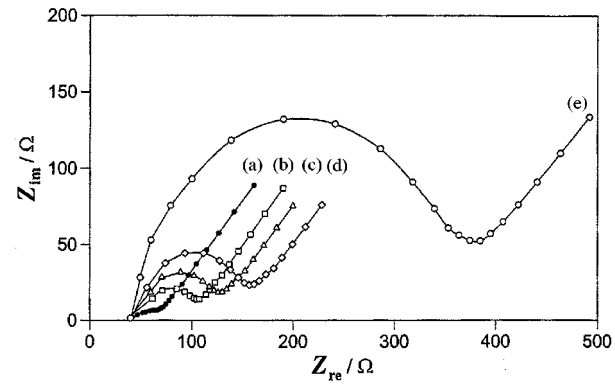


Fig. 1 Nyquist-diagram (Z_{im} *vs.* Z_{re}) for the Faradaic impedance measurements of a Au-electrode in the presence of 10 mM $[Fe(CN)_6]^{3-/4-}$ (1 : 1-mixture): (a) bare electrode, (b) **1**-functionalized electrode, (c) **1**-functionalized electrode after 30 min of incubation with **2**, (30 ng mL^{-1}) in SSC buffer (SSC = 15 mM Na citrate and 150 mM NaCl) , (d) ds-oligonucleotide complex with **2** after 30 min of incubation with **3** (40 ng mL^{-1}) in SSC buffer, (e) after 10 min of incubation with avidin (5 ng mL^{-1}) in phosphate buffer solution, pH = 7.1, 0.1 M. The impedance spectra were recorded within the frequency range 0.1 Hz–50 kHz at the formal potential of the $[Fe(CN)_6]^{3-/4-}$ redox couple. The amplitude of the alternate voltage was 5 mV.

complex. The impedance spectra follow the theoretical shapes and include a semicircle portion, observed at higher frequencies, that corresponds to the electron-transfer limited process, followed by a linear part characteristic of the lower frequency attributable to a diffusionally limited electron transfer. The respective semicircle diameters (obtained by extrapolation of the semicircles to lower frequencies on the Z_{re}-axis) correspond to the electron transfer resistances, R_{et}, at the electrode surface. The electron-transfer resistance, R_{et}, for the bare Au-electrode is *ca.* 60 Ω and it increases to *ca.* 80 Ω and *ca.* 105 Ω upon functionalization of the surface with **1** and formation of the ds-oligonucleotide complex with **2**. This is consistent with the fact that the negatively charged interface, formed upon the assembly of **1** on the electrode, repels the negatively charged redox probe. This introduces a barrier for interfacial electron transfer and an increase in the electron-transfer resistance. Formation of the ds-oligonucleotide complex with **2** enhances the double-layer potential at the electrode interface. This results in a further repulsion of the redox-probe and an increase in the electron transfer resistance at the electrode [*cf.* Fig. 1 (c)].

Although the impedance spectra change upon interaction of **2** with the oligonucleotide sensing interface reflects the hybridization process and the formation of the ds-complex with the analyte DNA, one would like to *confirm* and *amplify* the formation of the ds-complex at the sensor interface. Towards these goals the resulting ds-oligonucleotide interface was interacted with the biotinylated oligonucleotide, **3**, Scheme 1. The latter oligonucleotide is complementary to the residual sequence of the analyte DNA, and hence could be used as an oligonucleotide probe for the primary formation of the ds-DNA complex. Fig. 1(d), shows the impedance spectrum of the ds-DNA-functionalized electrode upon interaction with **3** and using $[Fe(CN)_6]^{3-/4-}$ as redox-probe. An increase in the electron transfer resistance to $R_{et} \approx 134$ Ω is observed, consistent with the formation of an additional negatively charged ds-assembly. Provided the system exhibits specificity, the latter process is observed only if the primary ds-system is formed with the sensing interface. Thus, the interaction of the modified surface with **3** provides a confirmation test for the formation of the primary ds-oligonucleotide assembly. As the secondary oligonucleotide is labeled by biotin, the subsequent reaction of the oligonucleotide-monolayer superstructure with avidin is anticipated to insulate the interfacial electron transfer due to the hydrophobic insulation of the interface. Fig. 1(e), shows the impedance spectrum of the layered ds-oligonucleotide superstructure after interaction with avidin. A substantial increase in the diameter of the semicircle is observed, implying a high electron transfer resistance, $R_{et} \approx 340$ Ω. This originates from the formation of the hydrophobic biotin–avidin complex at the electrode surface, a process that introduces a barrier for the interfacial electron transfer. Through the hydrophobic biotin–avidin complex, the latter process amplifies the initial formation of ds-oligonucleotide superstructure. The increase in the electron transfer resistance upon formation of the initial ds-oligonucleotide complex is controlled by the concentration of the analyte in the sample (and the time of interaction of the sensing interface and the sample). We were able to easily sense oligonucleotide concentrations corresponding to 3.5×10^{-12} mol mL^{-1} using this method (incubation time, 30 min). The incubation time of the sensing interface with the analyte **2** controls the loading of the electrode by the ds-assembly. The content of the ds-oligonucleotide/DNA on the electrode then controls the subsequent interfacial electron transfer resistance upon the association of **3** and avidin. The experimental incubation time, 30 min, represents an optimized parameter. Shorter incubation times perturbed the sensitivity of the system, whereas longer incubation times slightly enhanced the observed interfacial electron transfer resistance.

Several control experiments were performed to reveal the selectivity of the sensing interface. Treatment of the **1**-functionalized electrode with the biotin-labeled oligonucleotide **3** and then with avidin but without interaction of the electrode with **2**, does not lead to any noticeable changes in the impedance spectra. Thus, the sequence of changes in the impedance spectra is only stimulated if the primary analyte **2** is bound to the sensing interface. Also, the impedance responses of the sensing electrode upon interaction with oligonucleotide **4** were examined following the identical sequence of analysis. Oligonucleotide **4** includes the normal gene sequence in which the 7-base mutation shown in **2** leads to the TS-genetic disorder. No noticeable changes occur in the impedance spectrum of the **1**-functionalized electrode upon interaction with **4** or subsequent treatment of the electrode with **3** or avidin. Thus, the **1**-functionalized electrode reveals high selectivity for the detection of the TS-mutant, and the normal gene is effectively discriminated by the sensing interface. The results also indicate that the sensing interface is not affected by the non-specific binding of proteins.

In conclusion, we have demonstrated a novel sensitive method for the electronic transduction of DNA-complexes using Faradaic impedance spectroscopy. The method provides a means to sense the analyte–DNA complex, to confirm the analysis process using a biotin-labeled oligonucleotide probe, and to amplify the sensing process by the biotin–avidin complex at the sensing interface. The method reveals high specificity and selectivity. This originates from the fact that the primary sensing interface consists of an oligonucleotide that includes a limited number of bases capable of forming a single helix with the complementary analyte. Thus, any perturbation will be identified by the sensing interface. Although a detailed stability of the sensing electrode has not yet been performed, it appears that the sensing interface is stable for at least several days upon storage at 4 °C in a dry state. The examination of this biosensor assembly for the analysis of other oligonucleotides, *e.g.* c-DNA or t-RNA, is underway in our laboratory.

This research is supported by the Szold Foundation, The Hebrew University of Jerusalem.

Synthesis and characterization of a new mixed-metal oxide framework material composed of vanadium oxide clusters: X-ray crystal structure of $(N_2H_5)_2[Zn_3V^{IV}_{12}V^{V}_{6}O_{42}(SO_4)(H_2O)_{12}]\cdot 24H_2O$

Received (in Bloomington, IN, USA) 25th September, 1998, Accepted 20th November 1998

The reaction of a slurry of V_2O_5 with $LiOH\cdot H_2O$ and hydrazinium sulfate gives a dark colored solution that upon treatment with $ZnSO_4\cdot 7H_2O$ yields the novel framework material $(N_2H_5)_2[Zn_3V^{IV}_{12}V^{V}_{6}O_{42}(SO_4)(H_2O)_{12}]\cdot 24H_2O$, composed of three-dimensional arrays of the mixed-valence $\{V_{18}O_{42}(SO_4)\}$ clusters interlinked *via* $\{Zn(H_2O)_4\}$ bridging groups, containing tunnels occupied by exchangeable cations and water molecules.

Polyoxovanadates constitute an important subclass of metal oxide clusters with an exceptional capacity to form mixed-valence compounds that exhibit rich electronic and magnetic properties and have relevance to catalysis, geochemical and biochemical processes, and in materials science.[1] Well characterized clusters containing four to 34 vanadium atoms – many with mixed-valence and coupled V^{IV}-centers, ranging from closed cages and spherical shells to basket, bowl, barrel, and belt shaped open structures are known.[2] Strikingly, their structures are related to, and in principle derived from, the appropriate V_2O_5 sheet fragments.[2] Given the significance of transition metal oxide surfaces[3] and proven roles of polyoxometalate clusters in catalysis,[4] it is conceivably rewarding to attempt to design and prepare transition metal oxide based materials (*e.g.* novel surfaces and zeolitic and layered solids) with desired and controllable properties by assembling metal oxide clusters of appropriate attributes. Through this communication we describe the synthesis and characterization of a novel framework material, composed of well defined vanadium oxide clusters, prepared under mild synthetic conditions.

The reaction of a stirring slurry of V_2O_5 (2.5 mmol) in water (25 mL) at 84–86 °C with $LiOH\cdot H_2O$ (5 mmol) and hydrazinium sulfate (2.5 mmol) gave a dark colored solution that upon treatment with $ZnSO_4\cdot 7H_2O$ (1.25 mmol) yielded prism-shaped dark crystals of $(N_2H_5)_2[Zn_3V^{IV}_{12}V^{V}_{6}O_{42}(SO_4)(H_2O)_{12}]\cdot 24H_2O$, **1**, in 12 h at room temperature in 65% yield (based on V). Besides the H_2O and hydrazine absorption bands, the IR spectrum (KBr Pellet) of **1** exhibits features at 1135m $\nu(SO_4)$], 989s [$\nu(V–O_{terminal})$] and 704m and 631m cm^{-1} [$\nu(V–(\mu_3\text{-}O)$].

The extended highly symmetrical structure of **1**,[5] shown in Fig. 1, consists of three-dimensional arrays of $\{V_{18}O_{42}(SO_4)\}$ clusters each one connected to six other neighboring units *via* $\{Zn(H_2O)_4\}$ bridging groups. The building block units in the structure of **1**, shown in Fig. 2, consist of $\{V_{18}O_{42}(SO_4)\}$ clusters formed from the $\{V_{18}O_{42}\}$ shell[6] encapsulating a tetrahedral $\{SO_4\}^{2-}$ moiety with disordered oxygen atoms. The host shell, constructed from $18\{VO_5\}$ square pyramids sharing edges through 24 μ_3-oxygen atoms, behaves as a container for the $\{SO_4\}^{2-}$ group which is not an integral part of the shell. The guest $\{SO_4\}^{2-}$ group with normal S–O distances (1.472 Å) rattles inside the host shell. The square pyramidal geometry around each vanadium (V1) in twelve of the $18\{VO_5\}$ groups is defined by a terminal oxo group (O2) and four μ_3-oxygens (O1) of the shell. The geometry around vanadium (V2) in the remaining $6\{VO_5\}$ units is defined by four basal μ_3-oxo groups (O1) and an apical μ-oxygen (O3) which in turn is linearly bonded to the zinc(II) center of one of the six $\{Zn(H_2O)_4\}$ bridges, forming $\{V(2)–O(3)–Zn(H_2O)_4–O(3)–V(2)\}$ bonds, that link $\{V_{18}O_{42}(SO_4)\}$ clusters. The octahedral geometry around each zinc(II) is completed by four oxygen atoms (O4) from the aqua ligands, each one disordered over two positions, and two *trans*-μ-oxo (O3) groups.

The Zn(1)–O(4) distance (2.063 Å) and the bond valence sum (BVS)[7] value (0.36) identify O(4) oxygen as H_2O. This conclusion and the result of the manganometric titration of V^{IV} sites (12 V^{IV} per formula unit) requires two units of negative charge per $[Zn_3V^{IV}_{12}V^{V}_{6}O_{42}(SO_4)(H_2O)_{12}]$ unit which is balanced by the two $N_2H_5^+$ -hydrazinium cations. The cations and lattice waters (with disordered hydrogens) occupy the rectangular tunnels, defined by $\{V_{18}O_{42}(SO_4)\}$ and $\{Zn(H_2O)_4\}$ units, in the structure (Fig. 1). The cations are readily exchangeable by other cations (NH_4^+, Na^+, K^+, *etc.*) without noticeable change in the framework structure.

This report presents a new synthetic solid with three-dimensional structure composed of well defined vanadium oxide clusters held together without incorporating conventional ligands[8] in its structure. This underlines the potential of polyoxometalates in the design and development of well

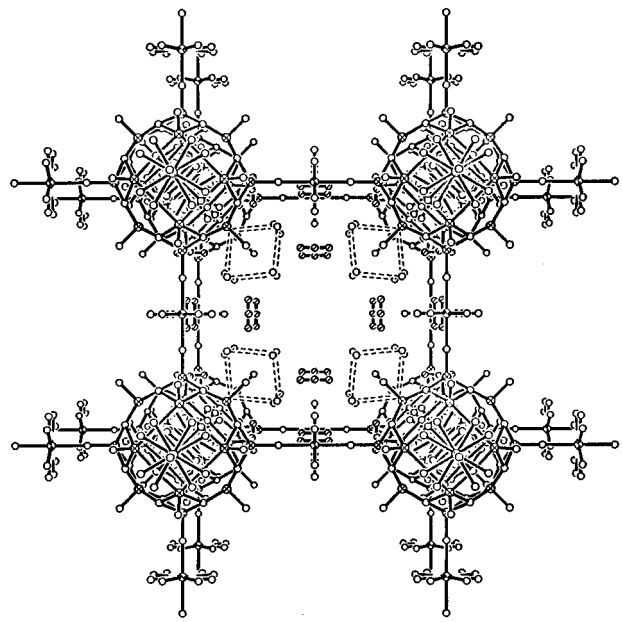

Fig. 1 View of the extended structure of $(N_2H_5)_2[Zn_3V^{IV}_{12}V^{V}_{6}O_{42}(SO_4)(H_2O)_{12}]\cdot 24H_2O$ showing interpenetrating nets of $\{V_{18}O_{42}(SO_4)\}$ clusters interconnected through $\{Zn(H_2O)_4\}$ bridging groups, and rectangular channels occupied by the hydrogen bonded water molecules (open circles) and hydrazinium ions (striped circles). Hydrogen atoms and the central cluster in the unit cell are not shown.

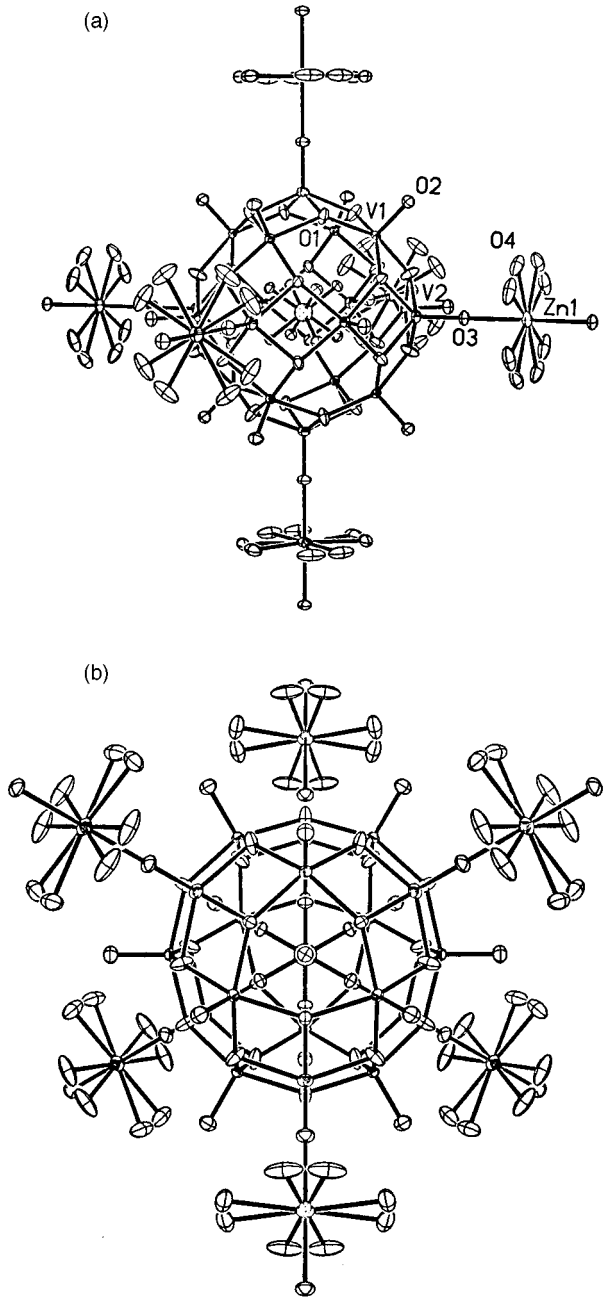

Fig. 2 (a) The building block units in the crystal structure of $(N_2H_5)_2[Zn_3V^{IV}{}_{12}V^{V}{}_6O_{42}(SO_4)(H_2O)_{12}]\cdot 24H_2O$ showing the atom labeling scheme in the asymmetric unit. (b) A view of the building unit along the threefold axis (hydrazinium ions and water molecules are omitted). Key: central circle with regular dot pattern represnts sulfur atom (S1); Atoms bonded to S1 represent O5 atoms. Displacement ellipsoids are drawn at the 50% probability level. Selected bond lengths (Å): V(1)–O(2) 1.588, V(1)–O(1) 1.9515, V(2)–O(3) 1.634, V(2)–O(1) 1.953, Zn(1)–O(4)(H_2) 2.063, Zn(1)–O(3) 2.122, S(1)–O(5) 1.472, V(1)–V(2) 2.9441 Å.

characterizable solids whose properties could possibly be correlated with their constituent units. Besides their possible catalytic, ion exchange and sorbtive properties, currently under investigation in our labs, synthetic solids, like **1,** composed essentially of metal oxide fragments may provide a model for understanding the chemical transformations catalyzed by metal oxide surfaces.[9]

Received (in Cambridge, UK) 24th September 1998, Accepted 13th November 1998

The air and moisture stable system [bmim][BF_4]–[$Ru_4(\eta^6$-$C_6H_6)_4$][BF_4] {[bmim]$^+$ = 1-butyl-3-methylimidazolium cation} presents a novel medium for conducting hydrogenations of arenes; the environmental problems associated with related aqueous–organic biphasic regimes are eliminated.

The heterogenisation of homogenous catalysts is rapidly becoming an important area of chemistry.[1] It is hoped that the advantages of both homogeneous (greater efficiency, all metal centres being involved in the process) and heterogeneous (ease of catalyst separation, greater selectivity) catalysts can be combined in one system. One increasingly attractive route to greater catalyst separation exploits the use of biphasic liquid reaction systems.[2,3] Not surprisingly, aqueous–organic biphasic systems have emerged as an important class of catalysts and have found several industrial applications.[4] However, the method is not without problems; it precludes the use of water sensitive catalysts and reagents and, from an environmental perspective, trace amounts of organic compounds in water are notoriously difficult to remove.

An alternative system that will allow the use of water sensitive reagents and catalysts and solves some of the containment problems associated with aqueous–organic systems is that based on biphasic ionic liquid–organic systems. The development of a variety of air and moisture stable ionic liquids in recent years has lead to their deployment in a number of processes.[4] Building on our previous results with the chloroaluminate(III) ionic liquids,[5] we have been investigating the [bmim][BF_4] ionic liquid {[bmim]$^+$ = 1-butyl-3-methylimidazolium cation}, which has received some attention as a solvent for the hydrogenation of olefins using Wilkinson's and related catalysts.[6] Whilst these catalysts are moderately effective they are deactivated by trace quantities of chloride ions remaining in the ionic liquid from its preparation.

The hydrogenation of arenes is an important industrial process, particularly for the generation of cleaner diesel fuels,[7] and is dominated by the use of heterogeneous catalysts. In an attempt to develop biphasic methodologies for the hydrogenation of arenes we describe herein the use of a [bmim][BF_4]–organic system. Many catalysts, especially neutral species, are not soluble in [bmim][BF_4] and therefore careful choice of catalyst is required. Ionic inorganic and organometallic compounds tend to be highly soluble in [bmim][BF_4] and for this reason we chose to investigate the cluster, [$H_4Ru_4(\eta^6$-arene)][BF_4]$_2$, which proved to be both soluble and stable. Clusters of this type were first reported by Maitlis and coworkers[8] and then later by Süss–Fink and coworkers who went on to fully characterise these intriguing electronically unsaturated cluster cations.[9] Süss-Fink and coworkers then went on to show that they could be used as catalyst precursors for the hydrogenation of fumeric acid and arenes under aqueous–organic biphasic conditions.[9–11] This provides an ideal opportunity to compare the two systems directly. Table 1 lists a number of biphasic hydrogenation reactions of arenes employing the [bmim][BF_4] ionic liquid and water with [$H_4Ru_4(\eta^6$-$C_6H_6)_4$][BF_4]$_2$ as the catalyst precursor.†

The turnover frequencies obtained in the ionic liquid and aqueous regimes are similar. This would suggest that the active catalytic species is the same in both systems. It has been clearly shown that [$H_4Ru_4(\eta^6$-$C_6H_6)_4]^{2+}$ can oxidatively add hydrogen to give [$H_6Ru_4(\eta^6$-$C_6H_6)_4]^{2+}$, which is the hydrogenating species.[10] This contrasts with many cluster-based catalyst precursors that are believed to fragment into mononuclear species during reaction.[12] Few other effective hydrogenation catalysts are known and most of these cannot be used in biphasic processes and they tend to be air and moisture sensitive.[11,13] The turnover frequencies compare well to other homogeneous arene hydrogenation systems, such as [$(\eta^6$-$C_6Me_6)_2Ru_2(\mu$-Cl)]Cl_2 which will hydrogenate benzene at 50 °C and 50 atm with a catalytic turnover of 246 mol mol^{-1} h^{-1}.[14] However, the main advantage of the ionic liquid–organic system arises from the ease of separation of the catalyst from the starting material/product stream and the subsequent purification of the solvent, allowing different compounds to be hydrogenated without contamination. The aqueous phase in a biphasic hydrogenation processes cannot be used for different arenes or returned to the environment without expensive treatment to remove trace quantities of organic compounds. Since the [bmim][BF_4] ionic liquid has no vapour pressure, organic compounds (and water) may be removed by merely placing the liquid under a high vacuum. Using this technique we have been able to repeatedly use the same batch of ionic liquid for the catalytic hydrogenation of several different arenes.

We are currently investigating the hydrogenation of functionalized arenes and heteroaromatics using a series of ionic clusters in the full range of available ionic liquids.

Table 1 Biphasic hydrogenation reactions of arenes in the [bmim][BF_4] ionic liquid and water with [$H_4Ru_4(\eta^6$-$C_6H_6)_4$][BF_4]$_2$ as the catalyst precursor

Substrate	Reaction system	Reaction conditions	Conversion (%)	Catalytic turnover[a]/ mol mol^{-1} h^{-1}
Benzene	Ionic liquid	60 atm H_2, 90 °C, 2.5 h	91	364
	Water	60 atm H_2, 90 °C, 2.5 h	88	352
Toluene	Ionic liquid	60 atm H_2, 90 °C, 3 h	72	240
	Water	60 atm H_2, 90 °C, 3 h	78	261
Cumene	Ionic liquid	60 atm H_2, 90 °C, 2.5 h	34	136
	Water	60 atm H_2, 90 °C, 2.5 h	31	124

[a] Catalytic turnover is calculated on the assumption that the tetraruthenium catalyst does not break down into monoruthenium fragments which is entirely consistent with the data.

We would like to thank to thank The Royal Society for a University Research Fellowship and ICI (Wilton) for financial support (D. J. E.).

Notes and references

† The ionic liquid [bmim][BF_4] was prepared using the literature method.[6] [$H_4Ru_4(\eta\text{-}C_6H_6)$][$BF_4$]$_2$ is very soluble and stable in this ionic liquid and is readily characterised in the ionic liquid using ^{1}H NMR spectroscopy which revealed and spectrum similar to that in conventional solvents.

Hydrogenations were carried using a Parr stainless steel autoclave (300 ml) fitted with either a glass or PTFE liner. The catalyst [$H_4Ru_4(\eta^6\text{-}C_6H_6)$][$BF_4$]$_2$ was added together with the required amount of [bmim][BF_4] ionic liquid. The autoclave was then sealed and purged with hydrogen gas (99.9995% purity) and the appropriate reaction pressure was then set at room temperature. The autoclave was then sealed and heated to the required reaction temperature and stirred for the time period required. After reaction the contents were then separated into organic and ionic liquid phases and the products analysed by ^{1}H NMR spectroscopy and GC. The only products observed were the perhydrogenated cycloalkanes, there was no evidence for the formation of partially hydrogenated products or polymeric by-products.

Neutral highly branched metallomacromolecules: incorporation of a (2,2′:6′,2″-terpyridine)ruthenium(II) complex without external counterions

George R. Newkome,* Enfei He, Luis A. Godínez and Gregory R. Baker

Center for Molecular Design and Recognition, Department of Chemistry, University of South Florida, 4202 E. Fowler Ave., Tampa, FL 33620-5250, USA.

Received (in Corvallis, OR, USA) 17th August 1998, Accepted 18th November 1998

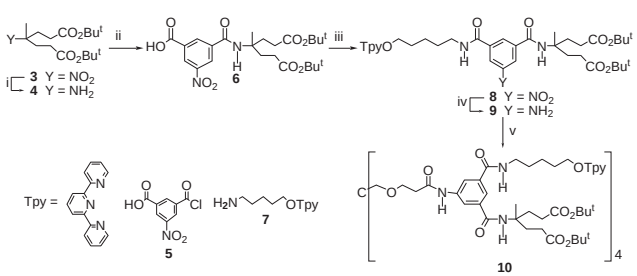
Neutral dendritic metallomacromolecules possessing four bis-terpyridine Ru^{II} linking sites with internal counter ions have been prepared and their electrochemical properties have been studied.

The assembly of highly branched metallomacromolecules has been reported, and they have been shown to possess interesting magnetic, electronic, electrochemical, photooptical and catalytic properties.[1] To the best of our knowledge, these assemblies all utilize external counter ions, *e.g.* Cl^-, BF_4^-, PF_6^-. We herein report the construction of two tiers of overall neutral, dendritic metallomacromolecules, **1** and **2**, which incorporate (2,2′:6′,2″-terpyridine)ruthenium(II) ([< Ru >]) complexes with internally counter balanced charges. The use of four [< Ru >] linkages generated a supramolecular construct of precise description, based on the structural analysis of its components, and the eight internal carboxylate ions balance the charges of these Ru^{II} centers.

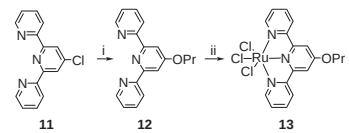
The core construct **10** was prepared from $EtNO_2$ with 2 equiv. of *tert*-butyl acrylate in liquid NH_3 affording (95%) di-*tert*-butyl 4-nitro-4-methylheptane-1,7-dioate **3**, which was converted (96%) to amine **4** by Raney Nickel reduction (Scheme 1).[2] Treatment of **4** with nitroisophthalic acid monochloride **5**[3] gave (58%) monocarboxylic acid **6**. Subsequent DCC coupling[4] of **6** with 5-aminopentyl 4′-(2,2′:6′,2″-terpyridinyl) ether[5] **7** generated **8** (92%), which was reduced[6] with 10% Pd-C and ammonium formate to afford the desired monomer **9** (90%). Treatment of **9** (4 equiv.) with a tetraacyl chloride core in the presence of Et_3N gave **10** (67%) possessing eight easily hydrolyzed *tert*-butyl ester moieties. All components were characterized by ^1H NMR, ^{13}C NMR, IR and elemental analyses, and ESI-MS.

4′-Chloro-2,2′:6′,2″-terpyridine **11**[7] was heated with PrOH and powdered KOH in DMSO[5] to give (93%) propyl 4′-(2,2′:6′,2″-terpyridinyl) ether **12**, which was refluxed with $RuCl_3·3H_2O$ in EtOH to afford (89%) the unbranched **13** (Scheme 2). The surface branching, amine **15**[8] was coupled with 4-[4′-oxa-(2,2′:6′,2″-terpyridinyl)]butanoic acid[5] **16** to afford **17** (86%), which was similarly transformed (84%) with $RuCl_3·3H_2O$ to give appendage **18** (Scheme 3). Both **13** and **18** were used without further purification due to their extremely low solubility in most organic solvents; fortunately, their purity was confirmed by elemental analyses and the analyses of the resultant assemblies.

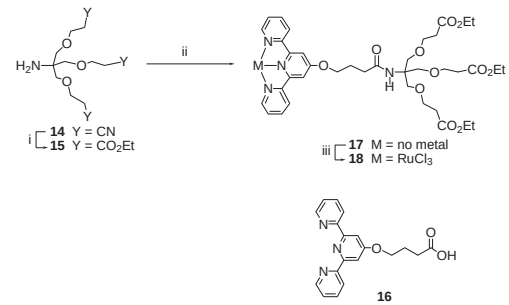
Core **10** (1 equiv.) was refluxed with 4 equiv. of either **13** or **18** in EtOH in the presence of 4-ethylmorpholine, as reducing agent, to assemble **19** (93%) or **21** (96%), respectively (Scheme 4). Although **13** and **18** possessed limited initial solubility, they dissolved upon addition of the reducing agent to give the characteristic deep-red color of the [< Ru >] complex. After



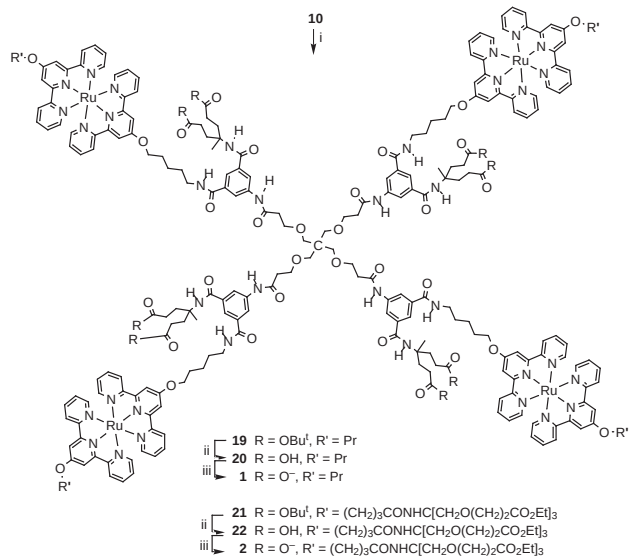
Scheme 1 *Reagents and conditions*: i, Raney nickel, H_2, 4 atm., 12 h, 25 °C; ii, **5**, Et_3N, THF, 12 h, −5 °C; iii, **7**, DCC, 1-HOBT, DMF, 24 h, 25 °C; vi, 10% Pd on C, HCO_2NH_4, MeOH, 30 min, 50 °C; v, Et_3N, $C[CH_2OCH_2CH_2COCl]_4$, THF, 12 h, 25 °C.



Scheme 2 *Reagents and conditions*: i, PrOH, KOH, DMSO, 24 h, 60 °C; ii, $RuCl_3·3H_2O$, Et_3OH, 4 h, reflux.



Scheme 3 *Reagents and conditions*: i, HCl, EtOH, 6 h, reflux; ii, **16**, DCC, 1-HOBT, DMF, 24 h, 25 °C; iii, $RuCl_3·3H_2O$, EtOH, 6 h, reflux.



Scheme 4 *Reagents and conditions*: i, **13 (→19)** or **18 (→21)** (4 equiv.), 4-ethylmorpholine, EtOH, 6 h, reflux; ii, HCO_2H, 6 h, 25 °C; iii, KOH, H_2O–MeOH, dialysis, 24 h, 25 °C.

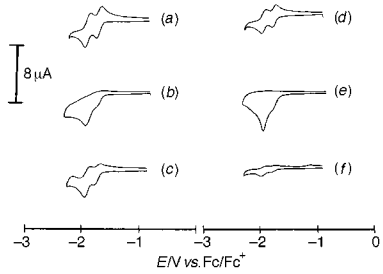


Fig. 1 CV responses for 1.0 mM solutions of (*a*) **21**, (*b*) **22**, (*c*) **2**, (*d*) **19**, (*e*) **20**, and (*f*) **1** (the smaller current observed was due to the limited solubility of **1** that presented in DMF) in Et_4NBF_4 (0.1 M) in DMF at 25 °C; scan rate 200 mV s^{-1}.

dialysis, the desired constructs were supported by the significant downfield shift (^{13}C NMR) of all terpyridine carbons. The *tert*-butyl groups were removed from **19** or **21** by treatment with formic acid,[9] affording complexes **20** (98%) or **22** (97%), respectively. The characteristic downfield shift of ^{13}C NMR ($\Delta\delta$ = 4 ppm) of the carbonyl carbon supports the transformation; the retention of the external alkyl ester moieties was evidenced by the presence of the ethyl signals. Final neutral complexes **1** (92%) or **2** (97%) were formed by addition of a slight excess of KOH into a H_2O–MeOH solution of **20** or **22**. After dialysis, the desired neutral complexes **1** and **2** were analyzed (0.00% of Cl), and only one downfield shift ($\Delta\delta$ = 3.4 ppm for **1** and 4.2 ppm for **2**) for the internal acid carbonyl carbon supports the formation of the carboxylate carbon centers. The UV–VIS spectra of the macromolecules possessing the four [< Ru >] linkages are analogous to related systems.[5,10] All the intermediate molecules and final complexes exhibit correct molecular weights. MALDI-TOF mass spectra of **19** and **21** exhibited low sensitivity and broad signals with all attempted matrices.

Electrochemical experiments with these metallodendrimers gave further insight to their electrocatalytic potential. Fig. 1(*a*) shows the two reversible waves that characterize the cathodic CV response of the two terpyridine ligands of **21**[11]. After internal deprotection of the *tert*-butyl groups, the presence of the carboxylic acid moieties in **22** results in a merging of the two redox waves and the virtual disappearance of the corresponding anodic signal [Fig. 1(*b*)]. Based on previous studies of the electrochemical reduction of pyridine and its derivatives,[12] the observed irreversibility is due to an electrochemical–chemical reaction in which a proton from the vicinal carboxylic acid group quenches the aromatic anion radical resulting in a probable 1,4-reduction of one of the pyridine rings of each terpyridine ligand. This explanation is further supported by CV experiments with neutral dendrimer **2**; as seen in Fig. 1(*c*), the lack of neighboring acidic protons, readily available in **22**, results in the recovery of the typical 'two wave' reversible response of the terpyridine ligands.

CV experiments on the first tier dendrimer series **19**, **20** and **1** showed similar voltammetric responses to those discussed above. By careful inspection of Table 1, however, the second tier assemblies **21** and **2** show slightly larger ΔE_p values than those corresponding to the first tier series **19** and **1**. This observation is in perfect agreement with previous reports[13] and has been attributed to the slower electron transfer kinetics that characterizes molecules featuring bulkier dendritic structures around their electroactive sites.

Table 1 CV data for **1**, **2**, **19**–**22**

In summary, we have constructed $[< Ru >]_4$ dendrimers possessing an overall neutral charge. The loss of external counterions in these metallomacromolecules had a marginal effect on their spectra, as well as stability and physical properties. However, the solubilities of these neutral species decreased in polar solvents, such as MeOH and H_2O. Complexes **19–22** are all slightly soluble in H_2O, whereas, **1** and **2** are insoluble in H_2O. The neutral metallodendrimers have internally balanced carboxylates, which are weaker counter ions than most others like Cl^-, NO_3^- and PF_6^-. Thus, addition of inorganic salts to these neutral species allows convenient interchange between external counter ions. Notably, **1** and **2** are not soluble in DMF, but quickly go into solution upon addition of salts like BF_4^- or PF_6^-. Another important aspect is that these neutral metallomacromolecules were more easily ionized (*i.e.* lower laser power) and gave stronger signals in MALDI-TOF mass spectrometry in comparison to the *tert*-butyl and acid metallodendrimers possessing external Cl^- or PF_6^- counter ions. The observed intramolecular proton transfer during the redox process stands to give insight into the potential chemistry within such macromolecular constructs.

We gratefully acknowledge support of this work from the National Science Foundation (DMR-96-22609; BIR-95-12208) and the Army Research Office (DAAH04-95-1-0373; DAAH04-96-1-0306).

Received (in Liverpool, UK) 21st October 1998, Accepted 17th November 1998

***N*-Benzyldiisopropylamine 1 and S_2Cl_2 give the *N*-benzylbisdithiolothiazine 2, shown by X-ray crystallography to have the typically folded tricyclic structure; 2 is debenzylated by H_2SO_4 to give the title compound 4 which atypically has a rare near-planar 1,4-thiazine ring, gives a blue anion in solution and does not extrude sulfur thermally.**

Sulfur–nitrogen heterocycles with a high proportion of heteroatoms are of theoretical and, when reasonable syntheses are available, practical interest in the chemistry of new materials. We have shown that Hünig's base and related diisopropylamines are fully sulfurated in both isopropyl groups by S_2Cl_2 in one-pot reactions to yield bis[1,2]dithiolo[3,4-*b*:4′,3′*e*]-[1,4]thiazines (*cf.* **2**, **3**)[1–4] and bis[1,2]dithiolo[4,3-*b*:3′,4′*d*]-pyrroles (*cf.* **6**, **8**),[2,4] new families of stable fully unsaturated heterocycles which are revealing a rich chemistry.

The *N*-unsubstituted parent ring systems would be particularly interesting from the structural point of view, and as intermediates in the preparation of *N*-substituted derivatives. Unfortunately these key compounds could not be prepared directly from Pr^i_2NH since this is decomposed by S_2Cl_2. Presumably the first step in the tertiary amine–S_2Cl_2 reaction is oxidation of an isopropyl group to give an iminium ion[5] which reacts further with S_2Cl_2 to form the 1,2-dithiole ring and ultimately the tricyclic system. Readily removable groups on nitrogen, such as acetyl and cyano, which would destabilise the iminium ion suppress the reaction with S_2Cl_2.[4]

We therefore treated *N*-benzyldiisopropylamine[6] **1** with S_2Cl_2 (10 equiv.) and 1,4-diazabicyclo[2.2.2]octane (DABCO) (9 equiv.) in 1,2-dichloroethane for 3 d at room temperature. Formic acid (20 equiv.) was then added and the mixture heated under reflux for 1.5 h, since this treatment gives cleaner reactions by facilitating conversion of the 3-chlorodithiolium salts into dithiole-3-ones. Products **2**† [orange crystals, mp 200–202 °C (21%)] and **3**† [orange solid, mp 209–210 °C (7%)] were obtained after chromatography (Scheme 1).

Structure **2** was confirmed by X-ray crystallography‡ which shows the molecule (Fig. 1) to have a scorpion-like conformation very similar to the *N*-ethyl analogue,[4] the benzyl ring being folded back and partially overlaying the thiazine ring (Fig. 1). The molecule has crystallographic C_s symmetry about a plane passing through S(8), N(4), C(9), C(10) and C(13). The fold angle about the N···S axis of the thiazine ring is 32°,*cf.* 34° in the *N*-ethyl analogue. The pattern of bonding in the thiazine and dithiole ring systems does not differ significantly from that observed in the *N*-ethyl analogue. The molecules pack to form corrugated sheets (Fig. 2) dominated by strong intermolecular O···S interactions [3.02 Å]. There are no intersheet interactions of note.

Treatment of a dilute solution of the *N*-benzyl compound **2** in CH_2Cl_2 with concentrated H_2SO_4 at 5–10 °C for 5 min gave the debenzylated compound **4**† (orange–red crystals, mp 222–224 °C) in quantitative yield. All its properties, including a broad *N*–H absorption at 3474 cm^{-1} and one carbonyl absorption at 1640 cm^{-1} are in agreement with the parent bis[1,2]dithiolo[3,4-*b*:4′,3′-*e*][1,4]thiazine-3,5-dione structure **4**. X-Ray analysis of the N–H species **4** shows that removal of the *N*-benzyl substituent results in a dramatic flattening of the molecule, the non-hydrogen atoms being co-planar to within

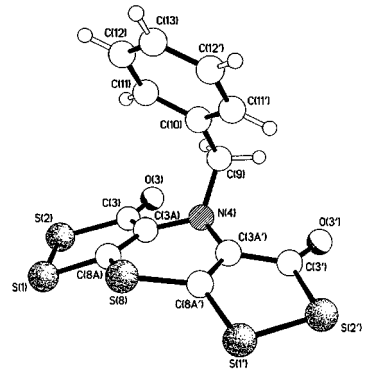

Fig. 1 The molecular structure of **2**. The geometry at N(4) is pyramidal, with the nitrogen atom lying 0.24 Å out of the plane of its substituents.

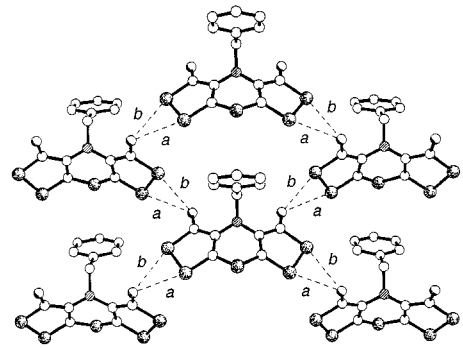

Fig. 2 Part of one of the corrugated sheets of molecules present in the crystals of **2**. The intermolecular O···S contacts (*a*) and (*b*) are both 3.02 Å.

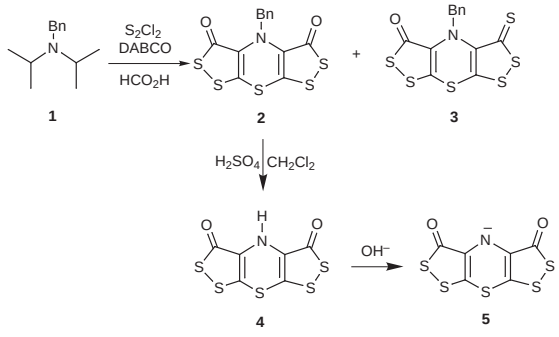

Scheme 1

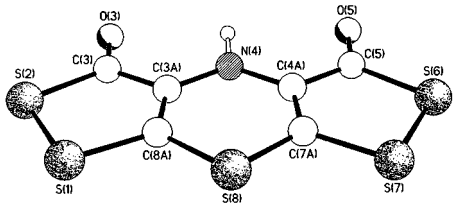

Fig. **3** The molecular structure of **4**.

0.11 Å with only a 5° fold about the thiazine N···S vector (Fig. 3)§ compared to greater than 30° for its *N*-alkyl derivatives and 27° for dibenzo-1,4-thiazine (phenothiazine).[7] The only significant change in the pattern of bonding, compared with **2**, is a small decrease in the C(3A)–N(4) distance and a slight increase in the C(8A)–S(8) bond length. The molecules pack as alternating bi-directional π–π stacked tapes, the planes of adjacent stacks being inclined by 89° (Fig. 4). The tapes are produced by head-to-tail linking of molecules *via* pairs of O···S interactions [3.08 and 3.09 Å], and orthogonal tapes by similar strength O···S, and weaker S···S, interactions [3.15 and 3.54 Å respectively]. The *N*–H hydrogen atom is not involved in any significant intermolecular interactions, possibly because of its steric congestion.

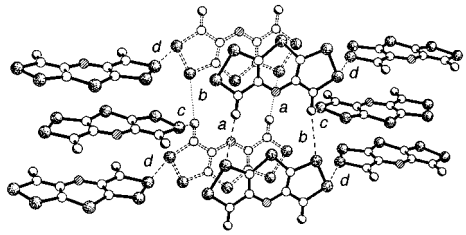

Fig. **4** Part of the array of orthogonally oriented p-stacked tapes present in the crystals of **4**, the mean interplanar separation being *ca*. 3.4 Å. The intermolecular O···S and S···S contacts are (*a*) 3.09, (*b*) 3.08, (*c*) 3.15 and (*d*) 3.54 Å.

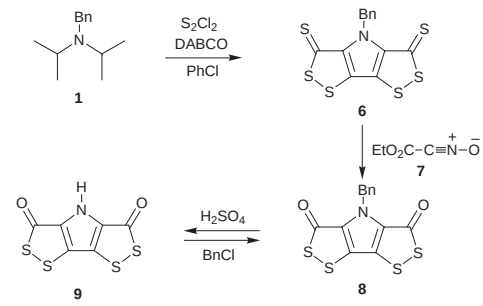
The *N*-H compound **4** readily formed purple solutions of the lithium or sodium salt **5** by reaction with LiHMDS or NaH in THF from which a hygroscopic deep purple solid could be isolated by evaporation. Compound **4**, with a UV spectrum of λ_{max} = 310 nm, ε = 8860 in THF, gave a blue solution in aq. 0.1 M NaOH with λ_{max} = 600 nm, ε = 8000. The aqueous alkaline solution was stable for a few days, and the blue spot formed by immersion of TLC plates in aq. NaOH provides a good method of detection of **4**.

Compound **4** and its sodium salt **5** either did not react with common electrophiles such as BnCl, BzCl, MeI and TMSCl under standard conditions or gave unstable products which reverted to **4** during isolation. In striking contrast with its *N*-alkyl derivatives,[2,4] **4** did not extrude sulfur on heating in chlorobenzene for 6 h or in 1,2-dichlorobenzene for 2 h. The expected product **9** (below) was made alternatively. Attempted thiation of **4** with Lawesson's reagent in refluxing THF gave an unstable product that decomposed on work-up; debenzylation of the oxothione **3** by sulfuric acid also gave an unstable product, and we have not yet succeeded in preparing thiocarbonyl derivatives of the parent structure **4**.

Treatment of **1** with S_2Cl_2 (10 equiv) and DABCO (10 equiv) in chlorobenzene for 3 d at room temperature followed by heating under reflux for 2 h gave the pyrrole **6**† [black crystals, mp 223–224 °C (13%)] (Scheme 2) formed by selective sulfur extrusion from the intermediate 1,4-thiazine.[2,4]

The pyrrole **6** was not debenzylated by the sulfuric acid treatment that is so successful with the thiazine **2**. Treatment of **6** in THF at 0 °C for 15 min with excess of ethoxycarbonyl nitrile oxide **7** generated *in situ* from ethyl chlorooximidoacetate and Et_3N[4] readily gave the corresponding dioxo derivative **8** [yellow crystals, mp 211–213 °C (decomp.) (86%)], a structure supported by all its analytical and spectroscopic properties (Scheme 2). The sulfuric acid treatment of **8** in



Scheme 2

CH_2Cl_2 at room temperature overnight did now give the debenzylated compound **9** as yellow crystals [mp 267–268 °C (decomp.) (58%)]. The structure of **9** is based upon spectroscopic data and its almost quantitative reconversion to the *N*-benzyl compound **8** with Bu^{t}OK and BnCl in DMF (Scheme 2). Unexceptionally, **9** did not give a coloured solution in 0.1 M aq. NaOH.

Thus the parent bisdithiolopyrrole **9** and bisdithiolo-1,4-thiazine **4** have been prepared in very short sequences from **1**. Whilst the properties of the former are entirely normal, the thiazine **4** is abnormal in that it is almost planar, it readily gives a highly coloured anion which is inert to substitution on nitrogen, and it does not extrude the thiazine sulfur atom on heating. It is not yet clear how these unusual properties, which appear to indicate enhanced electronic delocalisation and stabilisation, result from simply replacing an *N*-alkyl group by hydrogen, nor why the analogous compounds with one or two thiocarbonyl groups should be unstable.

We gratefully acknowledge financial support from the Dirección General de Enseñanza Superior of Spain (DGES Project ref. PB96-0101), the NATO Linkage Grant 970596, MDL Information Systems (UK) Ltd, and an RSC Journals Grant to O. A. R., and we thank the Wolfson Foundation for establishing the Wolfson Centre for Organic Chemistry in Medical Science at Imperial College.

Tributyltin radical-induced addition–carbocyclization on chiral perhydro-1,3-benzoxazines: a facile entry to enantiopure tin-containing auxiliaries

Celia Andrés, Juan Pablo Duque-Soladana and Rafael Pedrosa*

Departamento de Química Orgánica, Facultad de Ciencias, Universidad de Valladolid, Dr. Mergelina s/n. 47011 - Valladolid, Spain. E-mail: pedrosa@qo.uva.es

Received (in Liverpool, UK) 6th October 1998, Accepted 17th November 1998

***N*-Acryloylperhydro-1,3-benzoxazines 1a,b undergo stereoselective addition–carbocyclization when reacted with Bu_3SnH, leading to stannylated lactamic rings that can be transformed into enantiopure pyrrolidines.**

The design and synthesis of optically active alkylstannanes is currently considered a challenge in both organic and organometallic chemistry.[1] Activated non-racemic stannanes have been used in a variety of reactions which include allylation of aldehydes catalysed by Lewis acids,[2] tin–lithium exchange,[3] palladium cross-coupling[4] and cyclopropanation;[5] however, the number of examples reported to date is small.

Except for the ready accessibility of chiral α-heterosubstituted stannanes,[6] there is a lack of general methods for preparation of non-racemic organotin compounds and therefore chirality transfer from another reagent is generally preferred.[2,7]

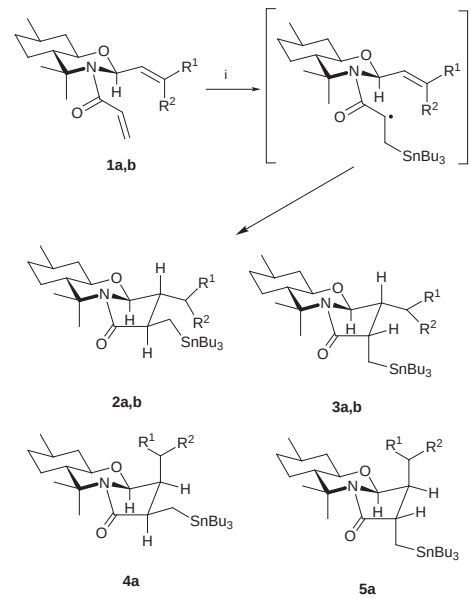
The carbon–tin bond is easily activated in the neighbourhood of a functional group.[8] In this context α-alkoxystannanes and allyltin compounds are suitable substrates for metal exchange[9] and nucleophilic addition reactions[2] respectively. On the other hand the nature of the alkyl substituents at the Sn atom is sometimes crucial since large substituents causes diminished reactivity.

As part of a project on stereoselective radical cyclizations in perhydrobenzo-1,3-benzoxazines[10] we focused our attention on the preparation of alkylstannanes attached to a perhydrobenzoxazine chiral auxiliary. This new type of structure plays a highly versatile role in synthesis since it behaves as a source of organometallic species as well as a classical organic auxiliary.[11]

Encouraged by the stereoselectivity of intramolecular radical cyclizations, the synthesis of organotin compounds was tested *via* addition–cyclization of acrylamides[10] **1a**,**b** with Bu_3SnH, a less toxic and volatile reagent than trimethyltin derivatives[12] (Scheme 1).

Treatment of **1a** with commercial Bu_3SnH in the presence of AIBN as initiator was performed under different conditions as summarized on Table 1. Attempts to use the Stork method (Bu_3SnCl + $NaCNBH_3$)[13] or palladium catalysis [$Pd(PPh_3)_3$][14] failed. The best chemical yield corresponded to a short heating of a mixture of Bu_3SnH, AIBN and the acrylamide in refluxing benzene (entry 3), or alternatively, without solvent at 80–90 °C (entry 4). This one is an extremely rapid, violent reaction and it is not recommended for preparative purposes. Slow addition of reagent (entry 1) or ultraviolet irradiation at room temperature (entry 2) causes a decrease in the chemical yield although a slight improvement in the diastereomeric ratio is observed at that temperature.

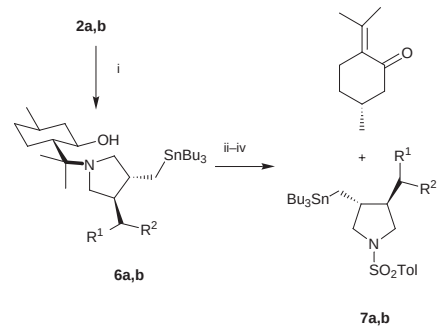
The four diastereomeric stannylated lactams **2a**–**5a**† were separated by flash chromatography and their stereochemistry was determined by NOESY experiments. Interestingly, although two stereocenters were created, addition–cyclization on acrylamide **1b** under thermal conditions (entries 5, 6) led to a mixture of only two diastereomers (**2b** and **3b**) which are epimers at the α-lactamic carbon. It is worth noting in both cases that major cyclization products **2a**,**b** showed a C-2/C-3 *trans* relationship at the newly created stereocenters. This result is contrary to that predicted by the Beckwith radical model[15] and no satisfactory reasons have been ascertained to date.[16]



Scheme 1 *Reagents and conditions*: i, Bu_3SnH (1.2 equiv.), AIBN (5–10 equiv.), 80–90 °C (see Table 1).

Table 1 Radical addition-cyclization of acrylamides **1a**,**b**

						Products (%)				
Entry	R^1	R^2	Solvent	*T*/°C	*t*/min	**2**	**3**	**4**	**5**	Yield (%)
1	Ph	H	PhH	80	720	**2a** (59)	**3a** (21)	**4a** (16)	**5a** (4)	76
2	Ph	H	PhH	25	900	**2a** (65)	**3a** (22)	**4a** (9)	**5a** (4)	48
3	Ph	H	PhH	80	30	**2a** (59)	**3a** (21)	**4a** (16)	**5a** (4)	99
4	Ph	H	–	90	5	**2a** (56)	**3a** (22)	**4a** (16)	**5a** (6)	99
5	Me	Me	PhH	80	30	**2b** (68)	**3b** (32)			98
6	Me	Me	–	90	5	**2b** (68)	**3b** (32)			99

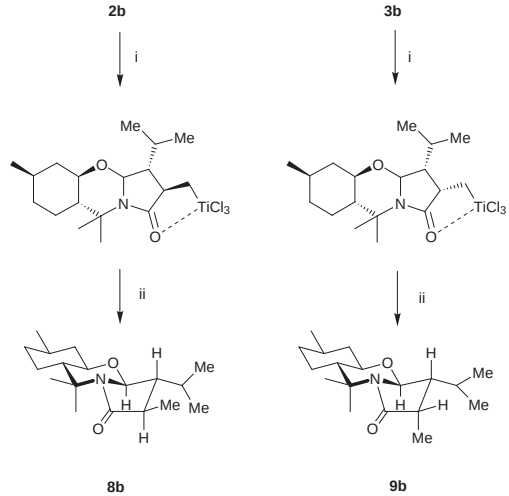


Scheme 2 *Reagents and conditions*: i, $LiAlH_4$ (5 equiv.), $AlCl_3$ (2 equiv.), THF, 0 °C, 5 min; ii, PCC (4 equiv.), CH_2Cl_2, 1 h; iii, KOH (2.5 M)–THF–MeOH (1:2:1), 2 h; iv, TsCl (2 equiv.), $Pr^1{}_2NEt$ (4 equiv.), CH_2Cl_2, 24 h.

Preliminary MO calculations (UHF/PM3) performed in our system suggested that the major lactams **2a**,**b** arise from biased conformations in which allylic 1,3-strain controls the olefinic appendage and a planar *Z* isomer is preferred for the intermediate amide radical. As a consequence, late transition states or thermodynamic equilibration can be discarded as explanations for the *trans* selectivity of such processes.

Once isolated, the major diastereomeric lactams **2a**,**b** were transformed quantitatively into the stannylated menthol derivatives **6a**,**b** by reduction with $LiAlH_4$ at 0 °C in THF. Sequential PCC oxidation of **6a**,**b** followed by treatment with methanolic KOH[17] of the intermediate amino ketone led to enantiopure stannylated pyrrolidines **7a**,**b** isolated as tosylates, although in modest overall yield (34 and 44% respectively) (Scheme 2).

On the other hand, it was interesting to explore the reactivity at the metal center and the possibility of easy destannylation. To this end, after isolation by flash chromatography, pure diastereomers **2b** and **3b** obtained in the reaction of **1b** with Bu_3SnH were subjected to Sn–Ti exchange[18] to generate the corresponding titanium homoenolates by reaction with $TiCl_4$ in CH_2Cl_2 at 0 °C (Scheme 3). This kind of metal homoenolates has been described for alkyl propionates but, to the best of our knowledge, no examples concerning lactams are known.



Scheme 3 *Reagents and conditions*: i, $TiCl_4$ (1.3 equiv.), CH_2Cl_2, 0 °C, 10 h; ii, SiO_2, CH_2Cl_2 or HCl, H_2O.

The titanium intermediates were transformed into enantiopure lactams **8b** and **9b** respectively by hydrolytic cleavage of the metal–carbon bond with silica gel or aq. HCl. It is noteworthy that the *trans* relationship of the substituent at the lactam coincides with the stereochemistry of the starting stannylated compounds, indicating that the metal interchange does not affect the configuration at the α-carbon in the lactamic ring. The reactivity of these titanium homoenolates with other electrophiles is currently being examined and the results will be published in due course.

We thank Spanish DGES for financial support (project PB95-707). One of us (J. P. D.-S.) also thanks the Spanish Ministerio de Educación y Ciencia for a fellowship (FPU program).

The stereochemistry of a retro-carbolithiation reaction

Reinhard W. Hoffmann and Ralf Koberstein

Fachbereich Chemie der Philipps-Universität Marburg, Hans-Meerwein-Strasse, 35032 Marburg, Germany. E-mail: rwho@ps1515.chemie.uni-marburg.de

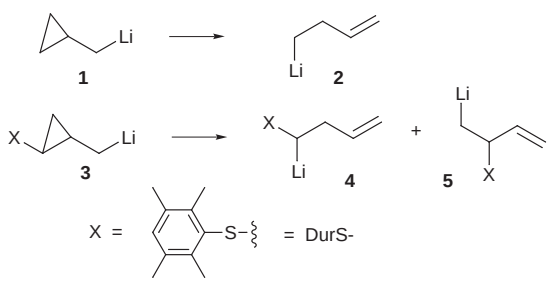
Received (in Liverpool, UK) 29th October 1998, Accepted 17th November 1998

Ring-opening of the cyclopropylmethyl lithium compound 7 to give the α-duryl thio-substituted alkyllithium compound 8 proceeds in a stereochemically defined manner at the lithium-bearing stereocentre.

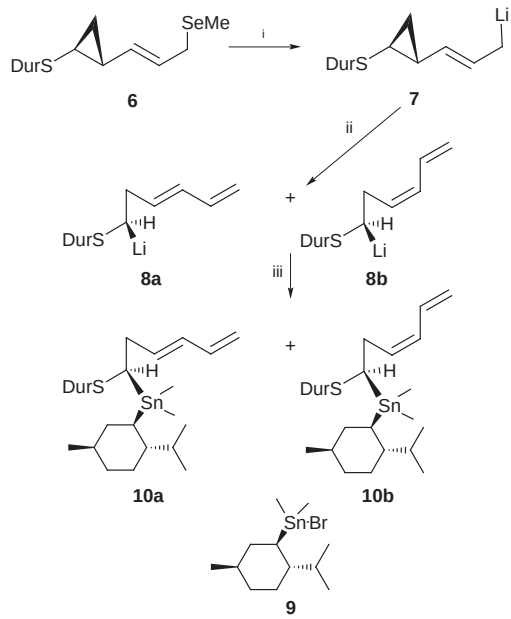
The stereochemical course of reactions in which organolithium compounds are generated may reveal fundamental details of organolithium chemistry. For instance, tin–lithium exchange to generate alkyllithium compounds has been found to proceed with retention of configuration.[1–3] The carbolithiation of vinyl sulfides has been shown to proceed in a non-stereospecific manner.[4] Here we would like to address the stereochemistry of a retro-carbolithiation reaction, the ring-opening of cyclopropylmethyl lithium compounds. The prototype of this rearrangement (**1**→**2**) was shown by Lansbury[5] to proceed at −70 °C with a half life of 53 min in Et_2O (Scheme 1).

The related ring-opening of **3** should create a chiral organolithium compound **4**. This would allow the determination of the stereochemistry in the generation of the new carbon–lithium bond, provided that the resulting organolithium compound **4** is configurationally stable and the regioselectivity of the ring opening is such as to generate compound **4** and not the isomer **5**. We surmised that both conditions would be met when X is a durylthio group. α-Durylthio alkyllithium compounds are configurationally stable at −110 °C[4] and stabilization of the negative charge by a sulfur substituent should direct the ring opening of **3** to give **4**. There remains, however, the necessity to effect the ring opening at −110 °C. We surmised that breaking of the carbon–lithium bond in **3** would be rate determining. Therefore, a delocalized allylic system at the migration origin should facilitate this process. This led us to investigate the ring-opening of the lithium compound **7**, generated by a low temperature selenium–lithium exchange reaction.[6]

The seleno ether **6** of 90% ee (determined by Mosher ester analysis of the precursor **14**) was treated with Bu^{t}Li at −107 °C in THF in a two-compartment low temperature reaction vessel (Scheme 2).[7] The organolithium compound **7** formed in this manner immediately underwent ring opening, since quenching with (−)-menthyl(dimethyl)tin bromide **9**[2,8] after 30 min led to the tin compounds **10a** and **10b** in a 9:1 *E/Z* ratio (67% yield). ^{119}Sn NMR analysis revealed that the major *E*-isomer was formed with 76% diastereomeric excess. Quenching after 10 or 60 min, or quenching with the enantiomeric reagent *ent*-**9**, generated the tin compounds with a constant de in the range of 76–82%. This shows that the organolithium compound **8** is configurationally stable under the conditions applied, and that quenching of **8** with **9** is not complicated by kinetic resolution.

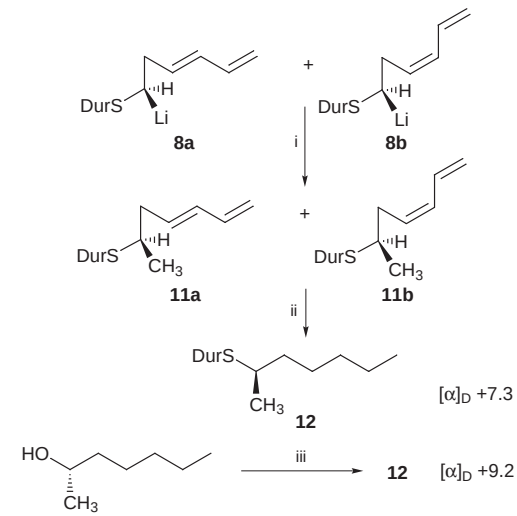


Scheme 1

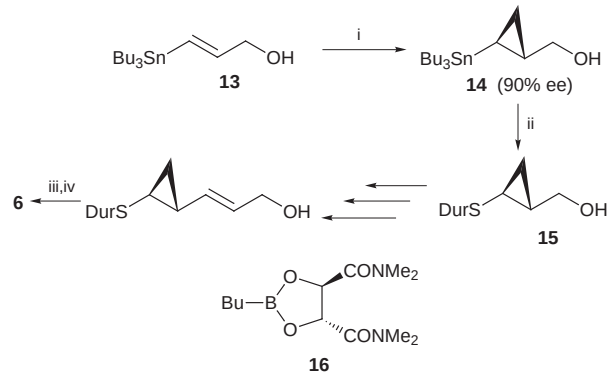


Scheme 2 *Reagents and conditions*: i, Bu^{t}Li, THF, −107 °C; ii, −107 °C, 30 min; iii, **9**.

In order to determine the stereochemistry of the ring opening process, pre-cooled MeI was added to the organolithium compound **8** after 30 min at −107 °C (Scheme 3). This resulted in 88% of a 88:12 *E/Z* mixture of the hexadienyl thioether **11**. Hydrogenation of the mixture provided uniform dextrorotatory 2-durylthiopentane **12**. The optical purity and the absolute configuration of **12** was determined with the aid of a sample prepared from (*S*)-heptan-2-ol.



Scheme 3 *Reagents and conditions*: i, MeI; ii, H_2, $(Ph_3P)_3RhCl$; iii, MsCl, pyridine; iv, DurSLi.



Scheme 4 *Reagents and conditions*: i, **16**, $Zn(CH_2I)_2$·DME; ii, Bu^nLi, $(DurS)_2$; iii, Bu^nLi, TsCl; iv, MeSeLi.

The optical purity of **12** (*ca*. 80% o.p.) corresponds to the de values of the tin compounds **10** and shows that the ring opening of **7** to give **8** proceeds with at most 10% loss of enantiomeric composition. The minor loss in enantiomeric purity of **8** during its generation at −107 °C from **7** should be associated with the ring opening process of **7**.[9]

Knowledge of the absolute configuration of the starting material **6** and that of the product **11** shows that the overall transformation proceeds with retention of configuration at the sulfur-bearing carbon atom. There is, however, some element of uncertainty regarding the stereochemistry of the individual steps. It is generally accepted[10] that the methylation of 'low reactive' sp^3-hybridized organolithium compounds by MeI proceeds with retention of configuration. If this applies also to the transformation of **8** into **11** it follows that the ring opening of **7** to give **8** proceeds with predominant retention of configuration at the lithium-bearing carbon atom.

The synthesis of the starting material **6** relied on the asymmetric cyclopropanation developed by Charette.[11] Cyclopropanation of **13** should furnish the cyclopropane **14** of the absolute configuration shown (Scheme 4). The latter was then converted to **15** and on to the selenoether **6** in a series of standard transformations (Swern oxidation, Horner olefination, DIBAL-H reduction).

We are grateful to the Deutsche Forschungsgemeinschaft (SFB 260) and the Fonds der Chemischen Industrie for support of this study.

Received (in Cambridge, UK) 28th October 1998, Accepted 12th November 1998

Repetitive Mukaiyama aldol reaction between bis(silyl ketene acetal) and dialdehyde proceeded in the presence of Lewis acid to afford poly(hydroxy ester).

The Mukaiyama aldol reaction is one of the most powerful tools for the construction of new C–C bonds in organic synthesis.[1–4] In spite of high reactivity and the subtle possibilities of side reactions in a number of aldol reactions under controlled reaction conditions, polymer synthesis utilizing this excellent reaction has not been studied extensively. Aldol-GTP (Aldol - Group Transfer Polymerization)[5,6] is the only exception, which is based on repetitive aldol reaction. Monomers for the aldol-GTP are however limited to trialkylsilyl vinyl ethers,[7,8] which give silylated poly(vinyl alcohol)s. In the Mukaiyama aldol reaction, Lewis acid activates or catalyses the reactions of silyl enolates or silyl ketene acetals with carbonyl compounds to give β-hydroxycarbonyl derivatives in excellent yield. If the same reaction occurs with the combination of bis(silyl enol ether)s and dialdehyde, this would be one of the most suitable ways for the preparation of poly(β-hydroxycarbonyl)s in a polyaddition manner. We found that bis(silyl ketene acetal)s reacted with dialdehydes in the presence of Lewis acid to afford poly-(hydroxy ester)s. Here we report a polyaddition between bis(silyl ketene acetal) and dialdehyde, which we propose to term 'aldol polymerization'. Asymmetric aldol reactions have also been studied extensively.[9] Several efficient chiral catalysts were designed for the aldol reaction. Thus, it should be possible to prepare optically active polymers if a chiral catalyst is employed in the aldol polymerization. Asymmetric aldol polymerization was also examined.

In the first place, we attempted to prepare bis(trimethylsilyl-ketene acetal) **2** as a monomer for aldol polymerization using LDA/Me_3SiOTf (Scheme 1).[10] However the monomer **2** was contaminated with a small amount of the monoketene acetal after distillation of the product, since trimethylsilylketene acetal is susceptible to hydrolysis. Monomers for polyaddition reactions always require high purity in order to obtain high molecular weight polymers. In stead of trimethylsilylketene acetal, the preparation of triethylsilyl derivatives **4** was then examined. In the literature it was reported that aldol reaction of triethylsilylketene acetals with aldehyde smoothly occurred to afford the aldol products in high yield.[11,12] We found that the hydrosilylation method shown in Scheme 2 was suitable for the preparation of **4**. Hydrosilylation of bismethacrylate **3** with triethylsilane in the presence of a rhodium catalyst afforded **4** in good yield.[13,14] More importantly, the higher stability of the triethylsilylketene acetal made it possible to use normal silica gel column chromatography for its purification. It is also possible to purify this monomer by simple distillation. As a model reaction of polyaddition, the monomer **4** was allowed to react with 2 equiv. of benzaldehyde in the presence of $TiCl_4$. Aldol reaction between **4** and benzaldehyde occurred smoothly at −78 °C to give the corresponding aldol in good isolated yield. This result encouraged us to apply the reaction to the polymer synthesis. Terephthalaldehyde **6** was chosen as the comonomer in this polymerization (Scheme 3). Results for the aldol polymerization are shown in Table 1. Since aldol reactions of silylketene acetal with aldehyde using $TiCl_4$ were reported to give excellent yields at −78 °C,[15] the polymerization was carried out at this temperature. Without Lewis acid, no reaction was detected between **4** and **6**. When neat $TiCl_4$ was added to the monomer solution in CH_2Cl_2, resulting in a heterogeneous system, the reaction afforded a polymer insoluble in common organic solvents (run 1). Addition of a 1.0 M CH_2Cl_2 solution of $TiCl_4$ to the mixture of **4** and **6** at −78 °C initiated the aldol polymerization to give the desired aldol polymer which was isolated after precipitation into MeOH–H_2O (7:3). During isolation of the polymer **7a**, a small number of the triethylsilyl ether groups in the polymer were converted to hydroxy groups (**7b**). Although this polymeric silyl ether is quite resistant towards dilute hydrochloric acid, the use of TBAF in THF led to the complete cleavage of the Si–O bonds to give poly(hydroxy ester) **7b**. The structure of the obtained polymer **7** was supported by spectroscopic analyses. The molecular weight of **7** was measured by GPC (THF as an eluent) using polystyrene calibration curves. The use of $ZnBr_2$ as Lewis acid resulted in a high yield of the polymer at room temperature (run 3). Mukaiyama aldol reaction is normally activated by stoichiometric amounts of Lewis acid, whereas catalytic activity of rare earth metal triflates has recently been reported in the same reaction.[16,17] We have found that catalytic amount of triflates such as $Yb(OTf)_3$ and $Sc(OTf)_3$ were effective for the aldol polymerization to give the polymer. In the case of $Sc(OTf)_3$, the temperature should be kept below 0 °C during its addition into the monomer solution (run 6), otherwise insoluble polymer was yielded as the main product (run 5). As another novel dialdehyde monomer for the aldol polymerization, we prepared **8**, which has somewhat better solubility than **6**. As can be seen in the polymerization of **4** with **6**, addition of a 1.0 M CH_2Cl_2

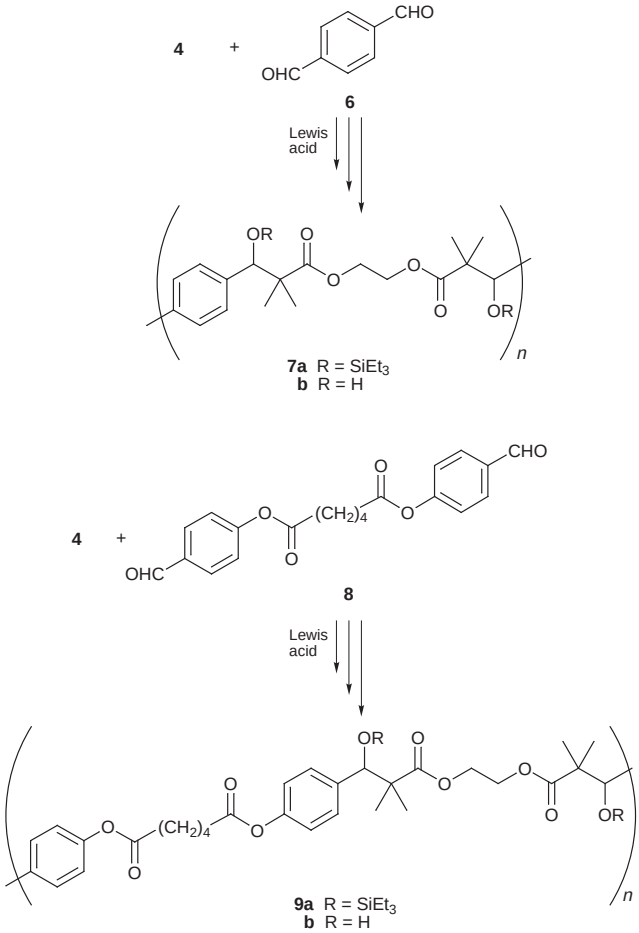

Scheme 3

solution of $TiCl_4$ to the mixture of **4** and **8** at −78 °C also yielded the desired aldol polymer **9a**. A catalytic amount of $Yb(OTf)_3$ or $Sc(OTf)_3$ as a Lewis acid catalyst also made it possible to synthesize the aldol polymer **9** having high molecular weight (runs 9 and 10). The structure of **9a** was confirmed by NMR and IR analysis.

The use of chiral Lewis acids for enantioselective aldol reactions has recently received great attention.[9] One of the efficient chiral catalyst for the asymmetric Mukaiyama aldol

10

reaction is chiral *N*-sulfonyloxazaborolidinone **10** reported by Kiyooka.[18,19] For example, benzaldehyde activated with chiral Lewis acid **10** reacted with silylketene acetal to afford the corresponding *R*-aldol product in high yield with high enantiopurity (up to 94% ee).[19] We applied this chiral catalyst for the aldol polymerization of **4** with **8**. The asymmetric polymerization was performed at −78 °C, since undesired reduction of the ester group with the hydride of **10** might take place after aldol reaction at higher temperature, which destroys the polymer main chain. Although relatively low molecular weight polymer was obtained at −78 °C, the produced polymer showed optical activity.[20] To the best of our knowledge, this is the first example of the synthesis of optically active polymer from prochiral monomer using repetitive asymmetric aldol reaction.

In summary, we have found that Mukaiyama aldol reaction could be successfully utilized for the polyaddition of bis(silylketene acetal)s with dialdehydes. Polymers having a unique main chain structure consisting of poly(hydroxy ester)s were prepared readily by this polymerization. Catalytic amounts of rare earth metal triflates such as $Yb(OTf)_3$ and $Sc(OTf)_3$ are effective for the polyaddition to give polymers with high molecular weights. It is also possible to prepare optically active polymers using chirally-modified Lewis acid catalyst.

We thank Professor T. Nakai (Tokyo Institute of Technology) for suggestions and encouragement. This work was partially supported by a Grant-in-Aid for Scientific Research in Priority Areas from the Ministry of Education, Science, Sports, and Culture, Japan (Monbusho).

Heterogeneously catalysed cleavage of carbon–carbon double bonds with hydrogen peroxide using calcined heteropolyacids on oxide supports

Christopher D. Brooks, Ling-chu Huang, Moya McCarron and Robert A. W. Johnstone*

Department of Chemistry, University of Liverpool, Liverpool, UK L69 3BX. E-mail: rj05@liverpool.ac.uk

Received (in Cambridge, UK) 27th July 1998, Accepted 13th November 1998

Reaction of an alkene with aqueous hydrogen peroxide and a catalytic quantity of a heteropolyacid adsorbed onto magnesium, aluminium or zinc oxide leads to complete, rapid cleavage of the alkene to give carbonyl compounds.

Oxidative cleavage of alkenes to ketones, aldehydes or carboxylic acids is useful synthetically. Reagents for effecting this reaction include ozone and lead tetraacetate, although the latter often gives only small yields of cleavage products.[1] Alkenes are often cleaved indirectly through intentional or incidental prior formation of 1,2-diols, followed by further oxidation. There are many reagents for effecting this last cleavage, as with sodium bismuthate, osmium tetroxide, chromium compounds, permanganates and ruthenium oxides.[1] All of these reactions are carried out in homogeneous solution and are generally stoichiometric, or they use expensive oxidants to recycle precious metal catalysts. Here, oxidative cleavage of alkenes has been attained through the use of heterogeneous calcined heteropolyacid catalysts supported on zinc, magnesium or aluminium oxide, with hydrogen peroxide as a cheap, environmentally benign oxidant.

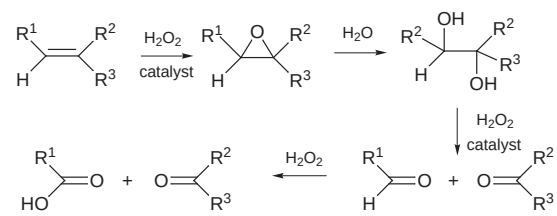
Heteropolyacids are easy to prepare from readily available tungstates, molybdates and phosphates and are soluble in organic solvents.[2] Those based on molybdenum and/or tungsten have been used as catalysts for effecting epoxidation of alkenes[3] and for ring-opening of epoxides.[4] Small yields (5–7%) of adipic acid have been reported during homogeneous conversion of cyclohexene to its *trans*-1,2-diol.[3a] Similar homogeneous oxidation of cyclopentene gave a fair to modest yield of glutaraldehyde.[3c] In homogeneous two-phase transfer systems, 12-tungstophosphoric acid and hydrogen peroxide have been reported to give epoxides and 1,2-diols from alkenes. On extended reaction, some complete cleavage of alkene was observed.[3b]

In the present work, 12-molybdophosphoric (PMA), 12-tungstophosphoric (PWA) or 6-molybdo-6-tungstophosphoric acid (PMWA) were deposited onto aluminium, zinc or magnesium oxide or hydroxide and then calcined to give heterogeneous catalysts. The alkenes shown in Table 1 were oxidatively cleaved to give acids, ketones or keto acids in high yields. In the presence of aqueous hydrogen peroxide and 2-methylpropan-2-ol as solvent, these catalysts gave very poor and often only fleeting yields of epoxides and 1,2-diols, unlike analogous oxidations reported for homogeneous heteropolyacid systems, from which high yields of epoxide can be obtained.[3] As revealed by gas chromatographic monitoring of the reactions, the initial alkene disappeared completely from the reaction medium, but final percentage yields of oxidation products such as epoxides and 1,2-diols did not remotely match the percentage disappearance of starting material. Although the formation of 1,2-diols suggested that epoxides were being formed and were then being ring-opened solvolytically, no significant amounts of 1,2-diols were found at the end of reaction when all the alkene had disappeared. However, when MeOH was used as solvent, considerable quantities of 1-hydroxy-2-methoxy derivatives were found; such solvolysis products are typical of ring-opening of epoxides by nucleophilic solvents. Unlike the 1,2-diols, the 1-hydroxy-2-alkoxy compounds appear to be stable towards cleavage under the present reaction conditions and can form significant proportions of the final reaction product. In the poorly nucleophilic solvent, 2-methylpropan-2-ol, no 1-hydroxy-2-butoxy derivatives were found and the very small quantities of 1,2-diol observed as intermediate products presumably arose from water in the hydrogen peroxide. Although in MeOH, yields of 1-hydroxy-2-methoxy derivatives reached a steady value towards the end of reaction, any 1,2-diols produced at the same time first increased in amount during the early stages of reaction and then decreased to zero towards the end. For example, during oxidation of cyclohexene with a PWA catalyst, maximum intermediate yields of some 7% epoxide and 15% cyclohexane-1,2-diol were observed during the course of oxidation, in which 100% of the alkene was converted to other products; at the end of reaction almost all of the epoxide and 1,2-diol had disappeared. Work-up of this reaction mixture for non-volatile components showed that the alkene double bond had been completely cleaved to give adipic acid in high yield and selectivity (Table 1), which had not been observed by GC monitoring. Other alkenes behaved similarly (Table 1). It is clear that these supported heteropolyacids (or their anions on the supporting oxides and hydroxides) split alkenes efficiently so as to give complete double-bond cleavage (Scheme 1). Any

Table 1 Oxidative cleavage of alkenes with supported heteropolyacids and hydrogen peroxide

Alkene	Heteropolyacid[a]	*t*/h[b]	Product (% yield)
2,3-Dimethyl-2-butene	PMWA:Mg:C:150/0.5	8	acetone[c] (91)
Cyclohexene	PMA:Al:C:150/0.5	24	adipic acid[d] (90)
1-Methylcyclohexene	PWA:Al:C:150/0.5	24	6-ketoheptanoic acid[d] (96)
Oct-1-ene	PMWA:Mg:C:150/0.5	4	heptanoic acid[d] (100)
Cyclooctene	PMWA:Al:A:150/0.5	10	epoxide[e]
Styrene	PWA:Al:C:500/4	24	benzoic acid (90)
trans-Stilbene	PWA:Al:C:500/4	24	benzoic acid (92)
trans-Stilbene	PWA:Al:C:500/4	24	*f*

[a] See text for code. [b] All reactions were carried out at 60 °C in 2-methylpropan-2-ol as solvent, except for entry *f*. [c] Isolated as its 2,4-dinitrophenylhydrazone. [d] Isolated and identified by comparison with authentic material for mp, ^{1}H NMR and mass spectrum. [e] The epoxide of cyclooctanone is well-known for its resistance to nucleophilic attack. In this instance, after about 50% conversion of alkene, its epoxide was isolated in 30% yield along with some suberic acid (7% yield). [f] This example is included to show the effect of MeOH as solvent. The bulk of the product consisted of equal amounts of the enantiomeric pair of 1-hydroxy-2-methoxy-1,2-diphenylethanes, together with surprisingly only a little of the *meso* derivative.



Scheme 1

final oxidation of aldehyde to carboxylic acid may or may not be catalysed.

Where the carbonyl formed on cleavage is an aldehyde, further oxidation to carboxylic acid ensues rapidly, since intermediate aldehydes are rarely observed, one such exception occurring in the oxidation of styrene. The oxidation of aldehydes to acids by hydrogen peroxide is known.[5] 1-Hydroxy-2-methoxy derivatives appear not to be oxidised further in these systems. For this reason, for optimum cleavage yields, either 2-methylpropan-2-ol or MeCN were used as solvent (Table 1).

For all oxidations, a blank reaction was carried out by omitting the catalyst from the reaction mixture. No oxidation was observed. To verify that leakage of catalyst from heterogeneously-supported materials to give homogeneous catalysts was not significant, parallel experiments were carried out by first refluxing the catalyst with the reaction mixture minus hydrogen peroxide and then filtering the mixture. The filtrate was used without more catalyst to determine its ability to effect oxidation of an alkene and the residue was used likewise. In all cases, the degree of oxidation observed with the filtrate as catalyst was very small but the solid residual catalysts were as efficient as the initial one. Finally, the longevity of the catalysts was examined by using the same catalyst for several successive oxidations. Generally, by the fourth cycle, the catalyst had lost most of its potency.

The catalysts were prepared in several ways to examine changes in their effectiveness with their pre-treatments. In some cases, the heteropolyacids were deposited onto preformed oxides (method A) or hydroxides (method B) but, in others, the catalyst was co-precipitated during formation of the hydroxide (method C). In all cases, the resulting solids were dried to 80 °C *in vacuo* and then calcined at either 150 or 500 °C. The catalysts are distinguished by a code. Thus, (PMA:Al:A:500/4) means 12-molybdophosphoric acid deposited onto aluminium oxide by method A and calcined at 500 °C for 4 h. Not all catalysts were equally effective for cleavage of alkenes. Generally, catalysts prepared by method B gave either inferior or no better yields than the corresponding catalysts prepared by method A or C.

In a typical catalyst preparation, 6-molybdo-6-tungstophosphoric acid (19.5 g)[6] in water (20 ml) was added to an approximately equal weight of freshly prepared and washed aluminium hydroxide, prepared from aluminium ammonium sulfate and sodium hydroxide; the mixture was stirred for 1 h. Excess of water was removed by centrifugation and the residue was washed with distilled water (3 × 20 ml). The solid product was dried at 80 °C *in vacuo* (20 mmHg) until its weight remained constant (about 2 days). The dried product was calcined by heating it either at 150° for 30 min or 500 °C for 4 h to give 45.3 g of the required catalyst, PMWA:Al:C:150/0.5.

In a typical oxidation, 1-methylcyclohexene (1.00 g; 10 mmol), dodecane (0.1 g, used as internal GC standard), hydrogen peroxide (70% w/w; 3–4 equiv. to alkene) and the catalyst (PWA:Al:C:150/0.5; 0.5 g) in 2-methylpropan-2-ol (25 ml) were stirred together at 60 °C. The progress of reaction was monitored by GC and the concentration of hydrogen peroxide was assessed with test strips (Merck). After complete conversion of the alkene or after a maximum of 24 h, the reaction was cooled, the catalyst filtered off and the filtrate was evaporated to dryness. The residue was distilled to give 6-oxoheptanoic acid, mp 33–34° (lit.,[7] 34–35 °C), identified by ^{1}H NMR spectroscopy and mass spectrometry. The other alkenes were reacted similarly and the products were isolated (see Table 1).

The authors thank the Eschenmoser Trust (L.-c. H.) and Rentokil Initial (C. D. B.) for financial assistance.

Enantioselective reduction of ketones with triethoxysilane catalyzed by chiral bis-oxazoline titanium complexes

Marco Bandini, Pier Giorgio Cozzi,* Lucia Negro and Achille Umani-Ronchi*

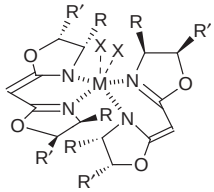
Dipartimento Chimico 'G. Ciamician', Università di Bologna, Via Selmi 2, 40126 Bologna, Italy. E-mail: umani@ciam.unibo.it; pgcozzi@ciam.unibo.it

Received (in Liverpool, UK) 7th September 1998, Accepted 17th November 1998

Chiral bis-oxazoline titanium complexes [Ti(BOX)$_2$X$_2$] prepared from C_2 chiral bis-oxazolines, BuLi and titanium salts, catalyze the enantiosective reduction of ketones in the presence of triethoxysilane.

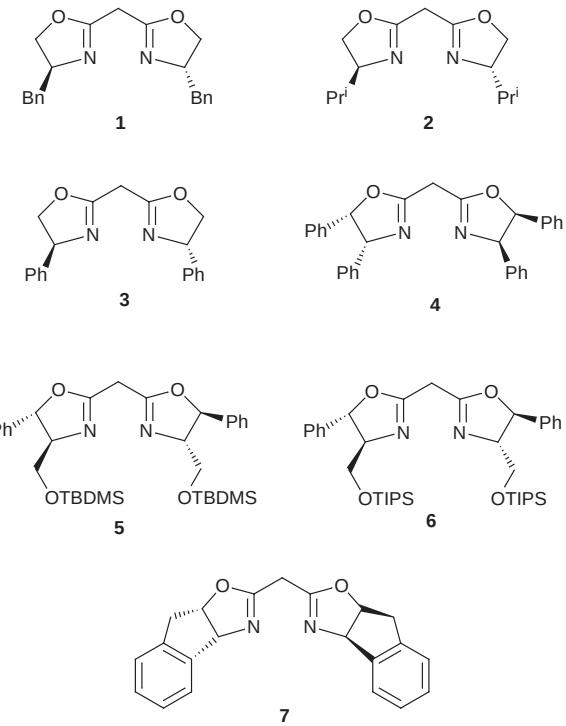
Enantioselective reduction of ketones is an important and widely utilized methodology for the preparation of key intermediates for the synthesis of drugs and biologically active compounds.[1] Corey's oxazaborolidine and related compounds play a decisive role in these chirotechnologies.[2] Recently, Buchwald has demonstrated that chiral titanium metallocenes are able to catalyze the enantioselective hydrosilylation of ketones and imines with high ees.[3] For these reactions enantiomerically pure titanocene complexes should be available. Although a new methodology to prepare the chiral C_2 metallocene complexes in high diastereomeric ratios was recently reported,[4] a resolution process is still needed to access the enantiomerically pure metal complex.[5] Based on a different strategy, *i.e*. replacing chiral metallocene with more accessible, easily prepared, chiral metal complexes, we have explored the possibility of using chiral bis-oxazolines[6] as ligands in coordinating group 4 metals and to employ the corresponding complexes in asymmetric catalysis (Fig. 1). To the best of our knowledge, until now the use of early transition metals with C_2 chiral bis-oxazolines in asymmetric catalysis has never been reported.[7]

Herein, we present a novel method for the enantioselective titanium-catalyzed hydrosilylation of ketones and α-halo ketones. The procedure involves the treatment of C_2 chiral bis-oxazolines (BOX **1–7**) with BuLi followed by the addition of a titanium salt.[8] Since the titanium complex was prepared *in situ* using a 2:1 molar ratio between the methylene bis-oxazoline and a titanium salt, we suggest that the BOX–titanium complex could have an octahedral structure (Fig. 1, M = Ti; X = Cl, F, OPr^i).[9] These new BOX–titanium complexes were treated with (EtO)$_3$SiH leading to a catalytic system for the hydrosilylation of ketones and α-halo ketones. It is noteworthy that no particular activation is necessary for the preparation of the active catalytic species. Various silyl hydrides such as Cl$_3$SiH, (EtO)$_3$SiH, Ph$_3$SiH, PhSiH$_3$ and poly(methylhydrosiloxane) were tested for asymmetric reduction catalyzed by the BOX–titanium complex. However, in general, (EtO)$_3$SiH gave better results. Initially we investigated the reaction of acetophenone with (EtO)$_3$SiH using various titanium salts and oxazolines (Scheme 1). As reported in Table 1 the best results were obtained using 3–5 mol% of the catalyst prepared from



M = Ti, Zr, Hf ; X = F, Cl, Br, OR, NR$_2$

Fig. 1 Hypothetic structure of M(BOX)$_2$X$_2$.



commercially available TiF$_4$ and oxazoline **4** as ligand. The hydrosilylation proceeded at room temperature, affording in 48 h the (*S*)-1-phenylethan-1-ol[3a] in 86% yield and 61% ee. The ee obtained in the asymmetric reaction seems to depend on the steric hindrance of the BOX ligand (entries 4,9 and 10). THF was the most suitable solvent with respect to both enantioselectivities and chemical yields. In the process of optimizing catalytic conditions with a variety of titanium salts, we found that TiF$_4$ was more effective in preparing the soluble orange–yellow BOX–titanium complexes. On the other hand, TiCl$_4$(THF)$_2$ gave insoluble complexes and we occasionally observed a definite change in the color of the reaction to blue, indicative of the presence of a Ti^{III} species.[10]

Since TiF$_4$, bis(oxazoline) **4** and (EtO)$_3$SiH afforded the best results,† the catalyst system reported in Scheme 2 was successfully applied to the asymmetric reduction of branched aromatic ketones and α-halo ketones.[11] From the data in Table 2, it is evident that the enantioselectivity is independent of the

[a] All the reactions were performed as reported in the experimental procedure. [b] Isolated yield after chromatographic purification. [c] The ee was determined by GC analysis on Megadex cyclodextrin chiral column. The configurations of **10a**,**c** were assigned by comparison of the $[\alpha]_D$ values reported in the literature. In the other cases, the absolute configuration was assigned by analogy. [d] The ee was determined on the silylated alcohol.

nature of the ketone, showing generality from aromatic substituted ketones to α-halo ketones.[12] The excellent enantioselectivity and the satisfactory yields observed in these reactions, accompanied by the simple protocol and the commercial availability of the ligands and reagents, make this procedure useful for the preparation of optically active epoxides and α-amino alcohols.[1]

Bis(oxazoline) ligands are able to replace Britzinger's C_2 metallocenes in these reductions, suggesting that other early transition metal-mediated reactions can be successfully catalyzed by early transition metals and appropriate BOX ligands. At the present time we can only speculate about the mechanism of this reaction. In particular, we are unable to definitively demonstrate that the reduction is due to the formation of an active titanium(III)[3a,b] or titanium(IV) species,[14] or if other mechanisms are involved.[15] In conclusion, we have developed a new methodology for the enantioselective reduction of ketones based on chiral titanium bis(oxazoline) complexes.

We thank the MURST (Rome) (National Project 'Stereoselezione in Sintesi Organica. Metodologie ed Applicazioni') and Bologna University (funds for selected research topics) for the financial support of this research.

Notes and references

† Typical experimental procedure: A solution of **4** (0.044 g, 0.097 mmol) in anhydrous THF (1.5 ml) was cooled to −78 °C and then BuLi (0.064 ml, 1.5 M in hexane) was added under nitrogen. The resulting pale yellow solution was stirred for 5 min at −78 °C and then warmed to 0 °C for 15 min. To this yellow solution TiF_4 was added (0.006 g, 0.048 mmol) all at once and the mixture was vigorously stirred until complete dissolution of the salt. The resulting solution was stirred for 60 min at room temperature and then $(EtO)_3SiH$ (0.240 ml, 1.2 mmol) and **8e** (0.14 ml, 0.605 mmol) were added. The mixture was stirred for 96 h at room temperature. The reaction mixture was diluted with AcOEt (5 ml) and then carefully made basic (pH 12) by the addition of aq. NaOH (1 M). The solution was stirred at room temperature until a white precipitate was formed. The solid was separated by filtration and the organic phase was collected. The aqueous phase was then extracted with AcOEt (2 × 3 ml). The organic layers were combined, dried over anhydrous Na_2SO_4, then concentrated under reduced pressure to give a yellow oil which was purified by column chromatography on silica gel (pentane–Et_2O, 9:1) (53%).

New entry for asymmetric deoxyazasugar synthesis: syntheses of deoxymannojirimycin, deoxyaltrojirimycin and deoxygalactostatin

Koji Asano, Toshikazu Hakogi, Seiji Iwama and Shigeo Katsumura*

School of Science, Kwansei Gakuin University, Uegahara, Nishinomiya 662-8501, Japan.
E-mail: katumura@kwansei.ac.jp

Received (in Cambridge, UK) 28th September 1998, Accepted 9th November 1998

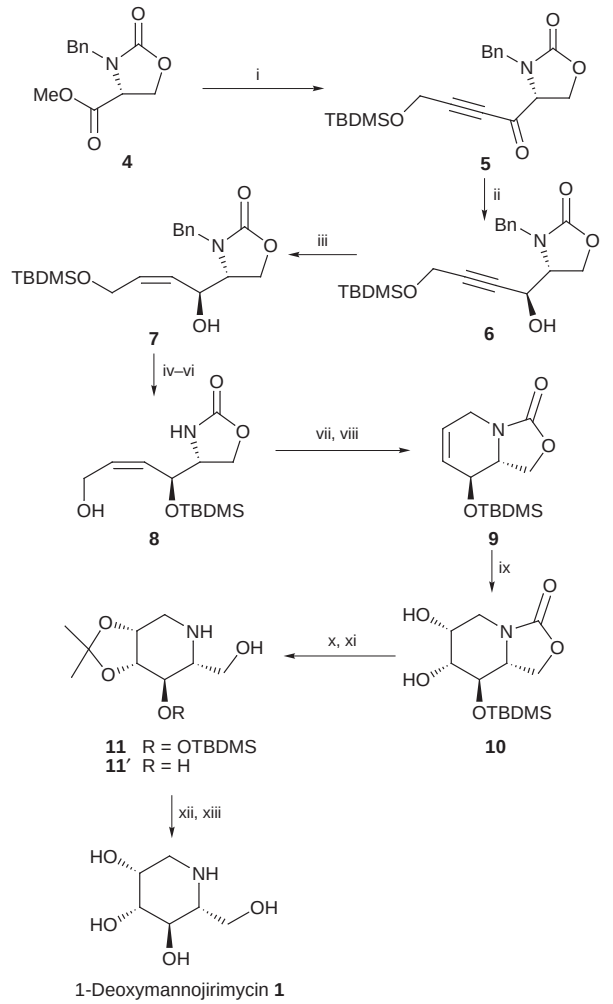
Deoxyazasugars such as deoxymannojirimycin, deoxyaltrojirimycin and deoxygalactostatin were stereoselectively synthesized starting from (*R*)-(+)-4-methoxycarbonyloxazolidinone *via* a bicyclic oxazolidinylpiperidine as a common synthetic intermediate.

Recently, polyhydroxylated piperidine alkaloids have received much attention due to their importance as glycosidase inhibitors.[1] Among them, deoxymannojirimycin **1** isolated from *Lonchocarpus* sp.,[2] deoxyaltrojirimycin **2**[3] and deoxygalactostatin **3**[4] can be regarded as deoxyazasugars based on their structural relationship to deoxysugars. Deoxy compound **1** is a moderate inhibitor of α-mannosidases and a good inhibitor of mammalian α-fucosidase, compound **2** is known as an analogue of **1** and is named in the relation with altrose, and compound **3** is a potent inhibitor of galactosidase. Because of the significant biological activities of these compounds as well as their characteristic structure, a number of synthetic efforts have been reported.[5]†

We previously developed both enantiomers of 4-methoxycarbonyloxazolidinone **4** as a chiral building block for the synthesis of natural amino alcohols, and realized the stereoselective syntheses of both γ-hydroxy-β-amino alcohols[6] and sphingolipids.[7] As part of our continuing interest in the synthetic utility of **4**, we have applied this methodology to the synthesis of deoxyazasugars. As a new flexible deoxyazasugar synthesis, we now report the stereoselective asymmetric syntheses of deoxymannojirimycin **1**, deoxyaltrojirimycin **2** and deoxygalactostatin **3** from common intermediate **9**.

Synthesis of deoxymannojirimycin **1** *via* the common intermediate **9** is shown in Scheme 1. Reaction of (*R*)-(+)-ester **4** with the lithium anion of propargyl alcohol silyl ether at −100 °C in THF gave ketone **5** [mp 31.0–32.0 °C; $[\alpha]_D^{23}$ +32.2 (*c* 0.88, $CHCl_3$)]. The successful stereoselective reduction of the ketone to produce the desired *anti* alcohol **6** was achieved with diisobutylaluminium 2,6-di-*tert*-butyl-4-methylphenoxide in 92% yield; the *anti*:*syn* selectivity was 11:1 by ^{1}H NMR analysis. Reduction with $NaBH_4$ and L-Selectride® gave a 5:3 and 1:2 mixture of *anti*- and *syn*-derivatives, respectively, and triisobutylaluminium reduction showed 9:1 selectivity. The obtained stereoselectivity can be understood by considering the reaction intermediates as shown in Fig. 1. In the case of diisobutylaluminium 2,6-di-*tert*-butyl-4-methylphenoxide reduction, two possible conformers **A** and **B** in the transition state were considered based on an intramolecular fashion of this reagent. Compared to intermediate **A**, intermediate **B** is disfavored due to steric interactions between the bulky aluminium reagent and the methylene group of the oxazolidinone ring, and hence this reaction resulted in high *anti*-selectivity. On the other hand, conformers **C** and **D** were anticipated in sodium borohydride and L-Selectride® reduction. There was considered to be no significant difference in steric interactions between these conformers due to the intermolecular fashion of the hydride attack of these reagents, and they resulted in poor selectivity, despite the fact that the L-Selectride® is sterically more demanding than $NaBH_4$.

With *anti*-alcohol **6** in hand, our attention turned to the construction of the bicyclic oxazolidinylpiperidine. Reduction of **6** along with its stereoisomer with Lindlar catalyst produced *cis*-allyl alcohol **7**,‡ which was isolated, then treated with sodium in liquid ammonia followed by acid to give the corresponding diol. Unfortunately, cyclization attempts utilizing the obtained diol *via* the tosylate of the primary alcohol were unsuccessful. The secondary hydroxy group of **7** was then protected with a TBDMS group, and the terminal silyl group was selectively removed by treatment with aq. HF in MeCN to give allyl alcohol **8**.[9] The cyclization proceeded successfully upon treatment of **8** with MsCl followed by NaH to produce



Scheme 1 *Reagents and conditions*: i, $TBDMSOCH_2C{\equiv}CLi$, THF, −100 °C (82%); ii, diisobutylaluminium 2,6-di-*tert*-butyl-4-methylphenoxide, toluene, 0 °C (92%); iii, Lindlar catalyst, H_2, MeOH (90%); iv, Na, liquid NH_3, −78 °C; v, TBDMSCl, imidazole, DMF (67% for 2 steps), vi, 55% aq. HF, MeCN, −20 °C (98%); vii, MsCl, Et_3N, DMAP, DMF; viii, NaH, DMF, 0 °C (80% for 2 steps); ix, OsO_4, NMO, Bu^tOH, H_2O (86%); x, $Me_2C(OMe)_2$, PPTS, acetone (92%); xi, 6 M aq. NaOH, dioxane, reflux, 24 h (71%); xii, conc. HCl, MeOH, reflux, 4 h (quant.); xiii, basic ion-exchange resin.

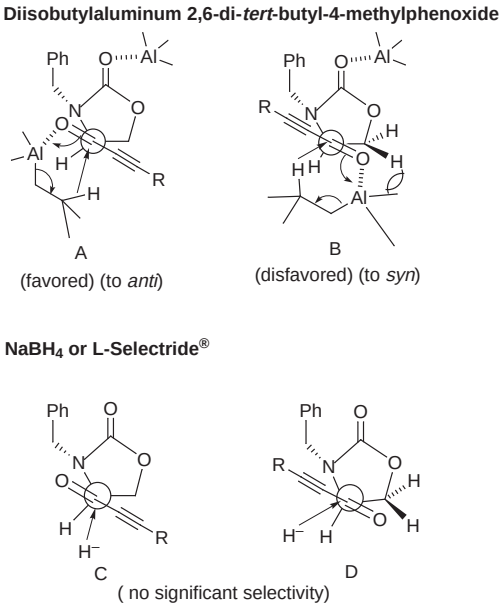


Fig. 1

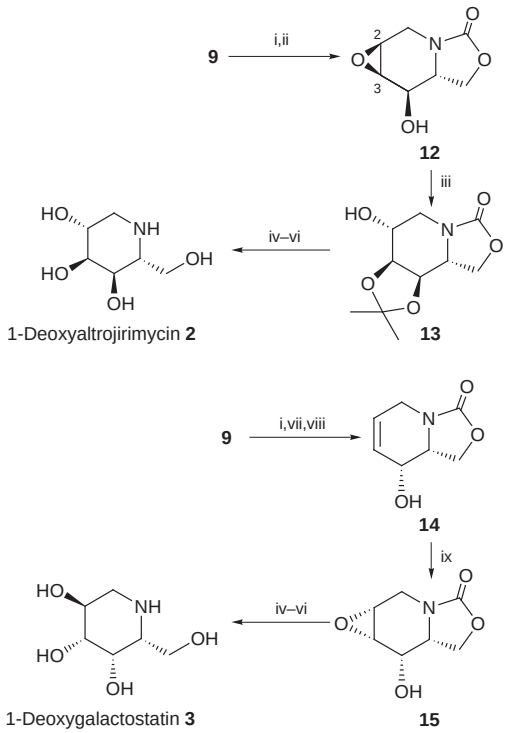
bicyclic oxazolidinylpiperidine **9**§. This compound was used as the common intermediate for the present deoxyazasugar synthesis. Oxidation of **9** with OsO_4 yielded diol **10** as the sole product, the stereochemistry of which was assumed to be *anti* to the neighbouring siloxy group at this stage. Acetonide formation followed by cleavage of the oxazolidinone ring with aq. NaOH in dioxane gave a mixture of monosilyl ether **11** and diol **11′**. Upon treatment of the mixture with acid, deoxymannojirimycin **1** was quantitatively obtained after purification with basic ion-exchange resin.¶

Next is the synthesis of deoxyaltrojirimycin **2** (Scheme 2). Epoxidation of bicyclic compound **9** after removal of the silyl group gave epoxy alcohol **12**, which was treated with BF_3–Et_2O in acetone to produce acetonide **13** [mp 123.0–124.0 °C; $[\alpha]_D^{22}$ +49.9 (*c* 0.48, $CHCl_3$)] resulting from diaxial opening of the epoxide ring. Synthesis of **2** from **13** was achieved by the same procedures as those in the deoxymannojirimycin synthesis (6 M aq. NaOH, conc. HCl; 85% for two steps).¶



Scheme 2 *Reagents and conditions*: i, TBAF, THF (98%); ii, MCPBA, CH_2Cl_2 (78%); iii, BF_3–OEt_2, acetone, 0 °C (70%); iv, 6 M aq. NaOH, dioxane, reflux, 24 h; v, conc. HCl, MeOH, reflux, 4 h (85% for 2 steps); vi, basic ion-exchange resin; vii, PDC, 4 Å molecular sieves, CH_2Cl_2 (73%); viii, L-Selectride®, $CeCl_3$, THF (77%); ix, MCPBA, $CHCl_3$, 3 d (65%).

The synthetic strategy for deoxyaltrojirimycin was applied to the synthesis of deoxygalactostatin **3** (Scheme 2), which is not a natural product but was synthesized as an analogue of deoxygalactose. Oxidation of **9** with PDC after removal of the silyl group gave the corresponding ketone. Reduction of the ketone obtained with L-Selectride® in the presence of cerium chloride produced *syn* alcohol **14** with a high degree of stereoselectivity (20:1 by ^{1}H NMR analysis; 77%). Although epoxidation of **14** with MCPBA was very slow (room temp., 3 days, $CHCl_3$), we obtained the desired α-oriented epoxide **15** in 65% conversion yield. The synthesis of deoxygalactostatin **3** was achieved from **15** by the same procedure employed in the synthesis of deoxyaltrojirimycin. Thus, formation of acetonide (52%), hydrolysis of oxazolidinone (67%), and then acid treatment (quant.) yielded deoxygalactostatin **3**.¶

In conclusion, 4-methoxycarbonyloxazolidinone **4** has been proved to be a versatile chiral building block for the syntheses of deoxyazasugars *via* bicyclic oxazolidinylpiperidine **9** as a common synthetic intermediate.

Monomer emission from pyrene adsorbed in surfactant-intercalated graphite oxide

Yoshiaki Matsuo,* Kazuya Hatase and Yosohiro Sugie

Department of Applied Chemistry, Faculty of Engineering, Himeji Institute of Technology, 2167 Shosha, Himeji, Hyogo, 671-2201, Japan. E-mail: matsuo@chem.eng.himeji-tech.ac.jp

Received (in Cambridge, UK) 28th September 1998, Accepted 13th November 1998

Monomer emission from pyrene highly concentrated in octadecyltrimethylammonium ion-intercalated graphite oxide has been observed.

Organoammonium ion-intercalated layered materials have attracted much attention because of their interesting structure, absorption of harmful molecules or photoactive ones and application as catalysts. Studies on these materials have been well summarized recently by Ogawa and Kuroda.[1] Among these studies, interesting results on fluorescence, thermal properties or photo-isomerization have been reported by immobilizing photochromic molecules such as pyrene,[2,3] azobenzene,[4,5] spiropirane,[6] *etc*., in the two dimensional space of intercalation compounds. On the other hand, we have found that graphite oxide (GO) which is classified as a covalent type of graphite intercalation compound allows formation of intercalation compounds with alkyltrimethylammonium ions and the maximum content of surfactant in the layer is very large compared with that of clays and covers a wide range.[7] Such intercalation compounds of GO are easily dispersed in chloroform, which can lead to further intercalation of aromatic molecules by casting the solution containing both the intercalation compound and guest molecules. These facts suggest that it is possible to control the adsorption state of photochromic molecules in the two dimensional space of surfactant-intercalated GO over a wide range by changing the size of the spacing between the alkyl chains of surfactant.

In this study, we chose pyrene as a probe photochromic molecule in order to characterize the surfactant-intercalated GO as a new host material for photochromic molecules. The aggregation state of pyrene was analyzed by using X-ray diffraction and fluorescence spectra as was used for the characterization of pyrene in montmollironite.[2,3]

Graphite oxide ($C_8O_{3.5}H_{2.8}$) was obtained from natural graphite powder by a modified Staudenmaier method.[8,9] Oxidation of graphite was carried out for 2 days. Intercalation of octadecyltrimethylammonium ion ($C_{18}H_{37}Me_3N^+$; $C_{18}3C_1N$) and dimethyldioctadecyl ammonium ion [$(C_{18}H_{37})_2Me_2N^+$; $2C_{18}2C_1N$] was performed by adding an aqueous solution of surfactants to a colloidal solution of GO.[7] The repeat distance along the *c*-axis (I_c) of surfactant of $C_{18}3C_1N$- and $2C_{18}2C_1N$-intercalated GO as hosts of pyrene were 3.25 and 3.11 nm, respectively. The contents of surfactant in GO were 0.33 and 0.23 mol per 100 g of GO in these intercalation compounds when calculated from weight uptake data. These values are very large when compared with those of clay minerals. The samples obtained in this study were highly soluble in chloroform. Intercalation of pyrene was performed by casting from $CHCl_3$ solution (5 ml) containing the intercalation compound (10 mg) and pyrene (2.5, 3.3 or 5.0 mg) on a quartz substrate. X-Ray diffraction was performed on a Rigaku Rint-2100 diffractometer. Absorption and luminescence spectra were recorded on a Hitachi U-3000 spectrometer and JASCO FP-777 spectrofluorometer at an excitation wavelength of 330 nm, respectively.

Casting of a $CHCl_3$ solution containing surfactant-intercalated GO and pyrene gave slightly brownish transparent films for all the samples. Fig. 1 shows the X-ray diffraction patterns of the cast films of PY-$C_{18}3C_1N$-GO, PY-$2C_{18}2C_1N$-GO, $C_{18}3C_1N$-GO and $2C_{18}2C_1N$-GO, together with that of pristine GO. In both cases, the I_c values of surfactant-intercalated GO increased to about 3.8 nm after the addition of pyrene, indicating the intercalation of pyrene into the surfactant-intercalated GO materials. These I_c values were similar to those observed for pyrene-$C_{18}3C_1N$- or pyrene-$2C_{18}2C_1N$-montmorillonites.[2] They were almost constant regardless of the amount of added pyrene. When the weight ratio of surfactant-intercalated GO to pyrene was $> 1:0.5$, a diffraction peak at $2\theta = 10.3°$ appeared in the diffractogram of both PY-$C_{18}3C_1N$-GO and PY-$2C_{18}2C_1N$-GO, probably due to saturation of pyrene in the interlayer spacing of the intercalation compounds and crystallization of excess pyrene at the surface of the samples. The molar ratios of pyrene : $C_{18}3C_1N$ and pyrene : $2C_{18}2C_1N$ are *ca.* 1 : 1 and 2 : 1, respectively, when pyrene is saturated in the layers of the intercalation compounds. In other words, saturation of pyrene occurred when the ratio of pyrene : octadecyl group was *ca.* 1 : 1.

Fig. 2 shows the UV absorption spectra of cast films of PY-$C_{18}3C_1N$-GO, PY-$2C_{18}2C_1$-GO, a pyrene film and an ethanolic solution of pyrene. In the absorption spectra of cast films of intercalation compounds containing pyrene, absorption bands due to π–π^* transitions of pyrene were observed at 340, 324, 312, 275, 264, 243 and 235 nm. For pyrene in ethanolic solution, absorption bands were observed at 334, 318, 305, 272, 261, 240 and 230 nm. The red shift (*ca.* 5 nm) of absorption bands indicated that pyrene in GO interlayers is present in a more polar environment than in ethanolic solution.

Fig. 3 shows the fluorescence spectra of PY-$C_{18}3C_1N$-GO, PY-$2C_{18}2C_1$-GO, an ethanolic solution of pyrene and crystalline pyrene. It is well known that the emission bands observed at *ca.* 390 and 450 nm arise from pyrene monomer and eximer,

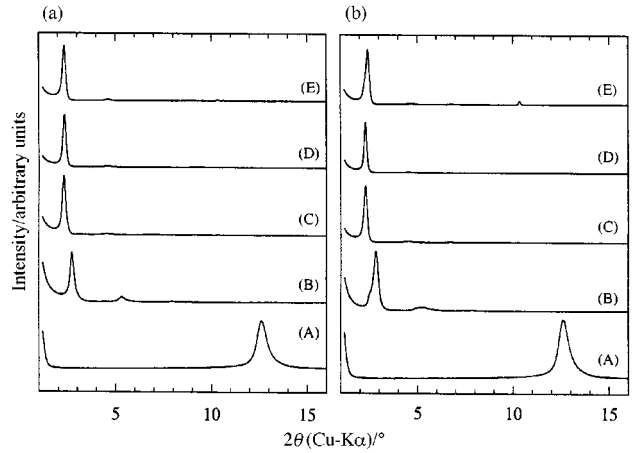

Fig. 1 (a) X-Ray diffraction patterns of (A) GO, and cast films of (B) $C_{18}3C_1N$-GO and of PY-$C_{18}3C_1N$-GO with $C_{18}3C_1N$-GO : pyrene ratios; (C) 1 : 0.25, (D) 1 : 0.33 and (E) 1 : 0.5. (b) X-Ray diffraction patterns of (A) GO, and cast films of (B) $2C_{18}2C_1N$-GO and of PY-$2C_{18}2C_1N$-GO with $2C_{18}2C_1N$-GO : pyrene ratios; (C) 1 : 0.25, (D) 1 : 0.33 and (E) 1 : 0.5.

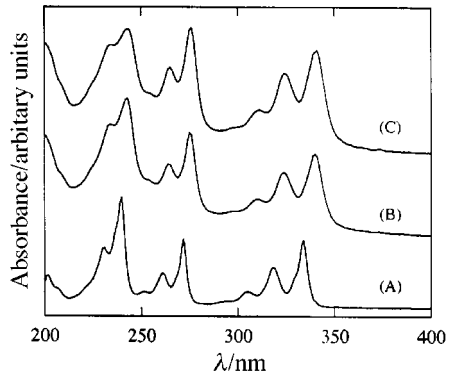

Fig. 2 The absorption spectra of (A) an ethanolic solution of pyrene, (B) PY-$C_{18}3C_1$N-GO with a $C_{18}3C_1$N-GO : pyrene ratio of 1 : 0.25 and (C) PY-$2C_{18}2C_1$N-GO with a $2C_{18}2C_1$N-GO : pyrene ratio of 1 : 0.25.

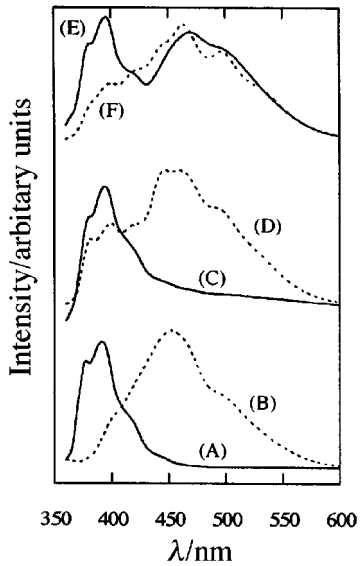

Fig. 3 The emission spectra of (A) crystalline pyrene, (B) an ethanolic solution of pyrene, and of PY-$C_{18}3C_1$N-GO with $C_{18}3C_1$N-GO : pyrene ratios of (C) 1 : 0.25 and (D) 1 : 0.33 and PY-$2C_{18}2C_1$N-GO with $2C_{18}2C_1$N-GO : pyrene ratios of (E) 1 : 0.25 and (F) 1 : 0.33.

respectively. The emission from the monomer is usually observed only in highly dilute solutions as shown in Fig. 3(A). However, in the spectra of intercalation compounds with very high pyrene content, this line was observed clearly and its relative intensity increased when the loaded amount of pyrene was decreased. Moreover, it is noteworthy that almost no emission from the eximer was observed for PY-$C_{18}3C_1$N-GO (1 : 0.25), indicating that pyrene molecules in the layer are almost completely separated from each other by alkyl chains of surfactants. This would be because the high content of surfactant in the layer of GO makes the size of single pyrene molecules suitable to occupy the space present between alkyl chains of the surfactant. On the other hand, for PY-$2C_{18}2C_1$-GO, eximer emission was preferably observed even when the pyrene content was similar to that of PY-$C_{18}3C_1$N-GO showing monomer emission. Similar results on the change of aggregation state of pyrene were reported for montmorillonite based compounds;[2] however, in the latter case, the ratio of pyrene to surfactant chain was rather lower, at most 1 : 0.36, and eximer emission was observed to a considerable extent. The difference of emission spectra of the two intercalation compounds would be due to the difference of the size of the sites for pyrene adsorption.

Finally, we would like to emphasize that these surfactant-intercalated graphite oxides are suitable host materials for including photochromic molecules in separated sites at a very high concentration. It would be possible to control their aggregation over a wide range by changing the size of the spaces between the alkyl chains of the surfactants.

The authors are grateful to Dr Kazushige Yamana of the Himeji Institute of Technology for his assistance in UV–VIS and fluorescence measurements, and for fruitful discussions.

Efficient site-specific cleavage of RNA using a terpyridine–copper(II) complex joined to a 2′-*O*-methyloligonucleotide by a non-flexible linker

Hideo Inoue,* Takako Furukawa, Masaki Shimizu, Takashi Tamura, Miwa Matsui and Eiko Ohtsuka

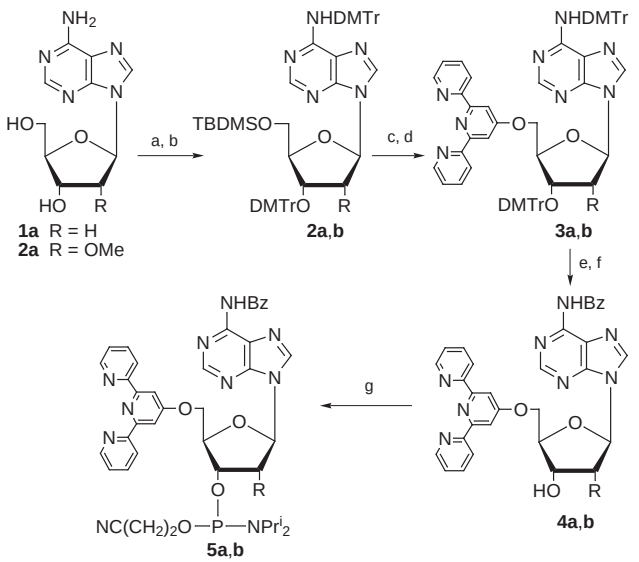
Graduate School of Pharmaceutical Sciences, Hokkaido University, Kita-12, Nishi-6, Kita-ku, Sapporo 060-0812, Japan. E-mail: inoue@pharm.hokudai.ac.jp

Received (in Cambridge, UK) 3rd November 1998, Accepted 17th November 1998

A terpyridine–Cu(II) complex conjugated to an antisense 2′-*O*-methyloligonucleotide at the 5′-end cleaved RNA predominantly at the site opposite the 5′-end in moderate yield, but the cleavage yield increased by more than two-fold when a 2′-*O*-methyloligonucleotide was allowed to bind to the single-stranded region of the RNA-antisense complex.

Recently, chemical agents that cleave RNA site-specifically without enzymatic assistance have been developed.[1] This is potentially important in antisense chemotherapy because cleavage of a specific mRNA will lead to loss of its function.[2] These agents can also be useful for studies on structure–function relationships of native RNAs.[3] One relatively active class of RNA cleavers is metal complexes covalently linked to oligonucleotides; the cleavage mechanism may involve transphosphorylation promoted by the metal. Complexes, such as terpyridine–Cu(II),[4,5] macrocyclic terpyridine derivative–Ln(III),[6,7] texaphyrin–Ln(III),[8,9] and iminodiacetate–Ln(III),[10] have been attached by a flexible linker to DNA oligomers for sequence-specific recognition. Here, we describe a new RNA cleaver with an alternative arrangement, consisting of a 2′-*O*-methyl RNA oligomer, as an efficient RNA hybridization probe,[3,11] and a terpyridine–Cu(II) complex directly attached to the 5′-end of the 2′-*O*-methyloligomer. We also demonstrate RNA cleavage by the cleaver in the presence of a cleavage facilitator.

For oligonucleotide synthesis, 5′-*O*-terpyridyl 3′-phosphoramidite derivatives of 2′-deoxyadenosine **1a** and 2′-*O*-methyladenosine **1b** were prepared, using standard methods for all steps (Scheme 1). The synthetic route involving *O*-terpyridylation[12] is easy and applicable to the other nucleosides. The two building units **5a**,**b** were used for the preparation of 5′-end-modified 2′-*O*-methyloligonucleotides.



Scheme 1 *Reagents and conditions*: for **5b** (all reactions were carried out at room temperature). a, TBDMSCl (1.2 equiv.), imidazole (2.4 equiv.), DMF, 1.5 h, 77%; b, DMTrCl (2.6 equiv.), pyridine, 23 h, 77%; c, Bu_4NF (1.2 equiv.), THF, 30 min, 99%; d, 4′-chloro-2,2′ : 6′,2″-terpyridine (1.2 equiv.), KOH, DMSO, 44 h, 90%; e, 80% $MeCO_2H$ aq, 4 h, 100%; f, successive steps: i, TMSCl (3 equiv.), pyridine, 30 min; ii, BzCl (5 equiv.), 3.5 h; iii, H_2O, 5 min; iv, 28% NH_3 aq, 30 min, 64% (overall); g, 2-cyanoethyl diisopropylchlorophosphoramidite (1.2 equiv.), diisopropylethylamine (3 equiv.), CH_2Cl_2, 50 min, 50%. DMTr = 4,4′-dimethoxytrityl.

Cleavage reactions of RNA oligomers with the terpyridine–Cu(II)-oligomer conjugates were carried out with the 5′[^{32}P]-end-labeled RNA target in a buffer at 45 °C for 20 h. Representative examples of an analysis of the cleavage products and all results are indicated in Figs. 1 and 2, respectively. Cleavage of the RNA 24-mer (R24) with the 5′-*O*-Cu(II)–terpyridyl-2′-deoxyadenosine-linked 12-mer (dA*12) occurred predominantly between U12–U13, in which U12 is positioned at the end of the 12-mer recognition region [Figs. 1 and 2(a)].† The extent of specific cleavage was 18% after 20 h [Fig. 2(c)]. Minor cleavage occurred at U13–U14 in *ca.* 1% yield. For the corresponding 5′-*O*-Cu(II)–terpyridyl-2′-*O*-methyladenosine-conjugate (Am*12), similar cleavage results were obtained. An RNA 21-mer with no sequence similarity to R24 was also specifically cleaved by a dA*-13-mer at a predetermined site, 5′U–A3′ (26% yield, data not shown).

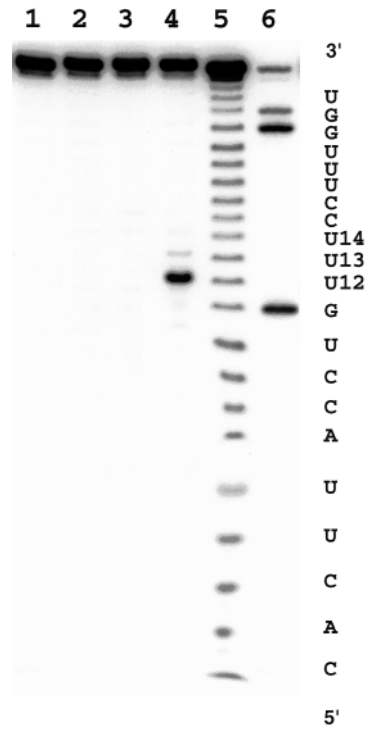


Fig. 1 Autoradiogram of products from the reaction of the labeled target R24 with the agent dA*12 after 20% denaturing polyacrylamide gel electrophoresis. The reaction was carried out for 20 h at 45 °C in a total volume of 10 μl containing: 0.1 M $NaClO_4$, 20 mM HEPES (pH 7.5), 0.1 μM RNA, 1 μM agent, and 1 μM $CuCl_2$. Lane 1: R24; lane 2: R24 + free terpyridine–Cu(II) complex + control 12-mer without terpyridine moiety; lane 3: R24 + dA*12 + EDTA (10 mM); lane 4: R24 + dA*12; lanes 5 and 6: bicarbonate and ribonuclease T1 sequencing reactions, respectively.

without t-oligo	18%	21%
with t-oligo(n)	27%	48%
with t-oligo(g)	17%	24%
(minor cleavage[a]	3%	6%)

Fig. 2 (a) Sequences of the RNA substrate and terpyridine–Cu(II)-linked oligomer agents. Nm refers to a 2′-*O*-methylnucleoside residue, and the asterisk indicates the site of the linked terpyridine moiety. (b) Sequences of the tandem 2′-*O*-methyloligomers, and schematic representation of RNA cleavage by the use of Am*12 and the t-oligo(n) (the arrow shows the cleavage site). The terpyridine–Cu(II) moiety is indicated as a black rectangle. All 2′-*O*-methyloligomers used in this study had a 2′-deoxynucleoside residue at the 3′-end. (c) Yields of site-specific cleavage of R24 by agents with or without tandem oligonucleotides.
[a] The minor cleavage site is U13–U14 site, and other reactions also gave this cleavage, but in yields of less than 1%.

For induction of RNA cleavage, the terpyridine–Cu(II) complex attached to the non-flexible linker should be close to the RNA strand. To explore the spatial orientation of the terpyridine moiety in the oligonucleotide hybrid, we prepared a terpyridine-linked duplex with a self-complementary sequence (dA*CmAmGmCmUmGmUm) and examined its melting temperature [conditions: 0.1 M $NaClO_4$, 10 mM Na phosphate (pH 7.5), 10 μM oligonucleotides, 12 μM $CuCl_2$]. It was found that the T_m value (72 °C) was very high, as compared with that (52 °C) for the control duplex without terpyridine moieties in the presence of 12 μM $CuCl_2$. These results may mean that the terpyridine moiety interacts with the end of the hybrid in an end-capping manner [Fig. 2(b)].[13]

To explore efficient RNA cleavage, which may be affected by the environment around the terpyridine–Cu(II) moiety in the RNA–agent hybrid, we carried out the RNA cleavage reaction in the presence of a 2′-*O*-methyl RNA complementary to the RNA single strand region adjacent to the terpyridyl conjugated 12-mer. The adjacent oligonucleotide was positioned in two ways: first, to provide a nick, and second a gap at the terpyridine site. In each reaction, with or without the tandem oligonucleotide [t-oligo(n) or t-oligo(g), Fig. 2(b)], Am*12 was more effective than dA*12 [Fig. 2(c)]. The cleavage efficiency for the reaction with the gapped tandem sequences was similar to that for the reaction without the additional oligonucleotide, but the cleavage site-specificity was lower. On the other hand, the reactions using the nicked tandem sequences increased the cleavage efficiency. Moreover, when Am*12 instead of dA*12 was used, the cleavage yield was 48%.‡ The spatial orientation of the terpyridine moiety probably became more suitable for RNA cleavage by the presence of the nick-forming tandem sequences and the 2-*O*-methylribose linker.

The present RNA cleaver has the metal complex at the end of the 2′-*O*-methyloligonucleotide. On the other hand, RNA cleaving metal complexes that were attached within DNA oligomers have been reported.[4,5,7,9] Some of the agents were designed to remain in a local region (such as a bulge) containing the cleavage site loose[14] while hybridized with the target RNA. This kind of agent is expected to be developed into an artificial ribonuclease that acts with catalytic turnover. Our findings, including the results on the nick-containing RNA hybrid, provide valuable information for the design of catalysts and the creation of more efficient cleavers.

We thank Prof. Donald E. Bergstrom (Purdue University) for critical reading of the manuscript. This work was supported in part by a Grant-in-Aid from the Ministry of Education, Science, Sports and Culture of Japan.

Notes and references

† For the reaction, the agent and $CuCl_2$ were directly added to the RNA solution. The addition after premixing both compounds gave similar results for the cleavage. We have used 10 molar equivalents of the terpyridine–Cu(II) agent and found that 2 molar equivalents were sufficient for the reaction. The use of such small amounts of cleavage agents has not been reported.

‡ Recently Daniher and Bashkin reported RNA cleavage using a terpyridine–Cu(II) complex attached to a flexible linker on an abasic site analog within DNA oligomers.[5] Our cleavage yield using the 2′-*O*-methyl facilitator and our data for the site-specificity of the RNA cleavage seem to be comparable with the reported data.

Received (in Liverpool, UK) 2nd October 1998, Accepted 17th November 1998

Unexpectedly, treatment of perfluoro(2,6-dimethyl-1-azacyclohexene) with 2 equiv. of PhLi in cyclohexane–Et_2O at −50 to 40 °C gives a good yield (72%) of (±)-3,3,4,4,5-pentafluoro-2,6-diphenyl-2,6-bis(trifluoromethyl)-1-azabicyclo-[3.1.0]hexane 1; the nitranion implicated in this novel conversion can be trapped with sulfuric acid, giving 2,2,4,4,5,5-hexafluoro-2(e),6(e)-diphenyl-2(a),6(a)-bis(trifluoromethyl)piperidine 5.

1-Azabicyclo[3.1.0]hexanes are not new: synthesis of the parent compound was reported in the mid-1960s,[1,2] and synthetic studies on its derivatives[3] gained impetus in the late 1980s owing to the isolation of the azinomycin antitumour antibiotics[4] which possess this ring system. Surprisingly, however, no fluorinated derivatives appear to have been described heretofore.

The polyfluorinated species **1** disclosed here was obtained serendipitously during research into the electronic and steric influences of α-substituents on the effectiveness and modes of action of 3,3,4,4,5,5-hexafluoro-*N*-fluoropiperidines, *e.g.* **3**, as selective electrophilic fluorinating agents, the ultimate objective being to develop chiral analogues of perfluoro-*N*-fluoropiperidine, the prototypical 'F^+' delivery agent of the N–F class.[5] The synthesis strategy being used centres on nucleophilic attack on perfluoro-(2,6-dimethyl-1-azacyclohexene) **2**.[6] This worked well (Scheme 1) when MeLi was used as the nucleophilic reagent: acidic work-up of the reaction mixture gave the expected N–H compound **4**† in 63% yield, and this was converted smoothly to 3,3,4,4,5,5-hexafluoro-2(a),6(a)-dimethyl-2(e),6(e)-bis(trifluoromethyl)-*N*-fluoropiperidine **3** (82% yield) on treatment with F_2 in cold $CFCl_3$ containing anhydrous KF. The stereochemistry of this new N–F compound was established beyond doubt by X-ray analysis,[7] hence the geometry of its N–H precursor **4** follows.

By contrast, similar treatment of the perfluoro imine **2** with PhLi [in c-C_6H_{12}–Et_2O (7:3) at −25 °C] gave a complex product from which, after careful addition of aqueous H_2SO_4 at −50 °C followed by flash chromatography, were isolated samples of (±)-3,3,4,4,5-pentafluoro-2,6-diphenyl-2,6-bis(trifluoromethyl)-1-azabicyclo[3.1.0]hexane **1** and 3,3,4,4,5,5-hexafluoro-2(e),6(e)-diphenyl-2(a),6(a)-bis(trifluoromethyl)-piperidine **5** in 4 and 28% yield, respectively. The structures of these products were established unambiguously by X-ray analysis (Fig. 1).‡ The *cis* disposition of the CF_3 substituents in each compound, coupled with the subsequent discovery that the yield of the azabicycloheptane **1** can be increased to 72% simply by not quenching the presumptive nitranion **6** formed from **2** and PhLi, but gradually raising the temperature of the reaction mixture to about 40 °C, prompts us to favour the reaction mechanism shown in Scheme 2. The ease of ring contraction presumably stems from the considerable relief of 1,3-diaxial $CF_3\cdots CF_3$ repulsions in the monocyclic moiety, the distance between the carbon centres of the trifluoromethyl substituents in the azabicyclohexane **1** being 33% greater than in the piperidine **5**; this belief is supported by our failure to convert the lithium salt of the diequatorial $(CF_3)_2$ analogue **4** of **5** to an

Received (in Cambridge, UK) 8th August 1998, Accepted 28th October 1998

Catalytic asymmetric Darzens reaction using cyclic α-chloro ketones promoted by chiral quaternary ammonium salts as a phase-transfer catalyst proceeded smoothly under mild reaction conditions to afford the desired products with reasonable enantioselectivities at room temperature.

The Darzens reaction, which allows the generatation of new stereocenters with complete diastereocontrol, is one of the most powerful methodologies for the synthesis of α,β-epoxy carbonyl and related compounds, and therefore has been recognized as one of the most significant C–C bond forming processes in synthetic organic chemistry. Although many trials have been performed aimed at developing an asymmetric equivalent in recent decades, many of them require a stoichiometric amount of chiral source[1] and few examples which proceed catalytically are known.[2] We have previously reported an effective catalytic asymmetric Darzens reaction promoted by a chiral quaternary ammonium salt acting as a phase-transfer catalyst (PTC).[3a] According to this procedure, the desired products were obtained with reasonable enantioselectivities in a stereoselective fashion under mild reaction conditions. Here we report recent results for a new system utilizing cyclic α-chloro ketones in the catalytic asymmetric Darzens reaction.

At the outset, we investigated the reaction of the easily prepared cyclic α-chloro ketones **1**[4] as the carbon nucleophile with various aldehydes **2** in the presence of a catalytic amount of the commercially available chiral quaternary ammonium salt PTC **A**, derived from cinchonine under mild reaction conditions. In this system, chiral quaternary carbons which are commonly considered to be difficult to create *via* direct carbon–carbon bond forming reactions, can be formed by the use of α-substituted chloro ketones. The reaction of isobutyraldehyde **2a** with α-chloro ketone **1a** *via* the use of a stoichiometric amount of LiOH in the presence of chiral PTC **A** (10 mol%) in Bu_2O proceeded smoothly to give the desired epoxide **3aa** in good yield at room temperature. The diastereoselectivity of the reaction was perfect and its enantioselectivity was found to be 69% ee *via* HPLC analysis,[5] as shown in Table 1. Next, we attempted to use as PTCs other easily prepared quaternary salts derived from cinchonine involving *O*-protected or substituted benzyl moieties. In spite of our efforts, higher enantioselectivities were not realized in the formation of **3aa** *via* use of a catalytic amount of these analogous PTCs.[6] Although the role of the 4-trifluoromethyl group on the phenyl ring is not clear in this asymmetric induction at present, we believe that the electron-deficiency of the phenyl group in the PTC skeleton plays an important role because the 4-methylated PTC, which is sterically equivalent to the 4-trifluoromethylated derivative (PTC **A**), afforded **3aa** with 0% ee. Also the unsuccessful results obtained by use of the hydroxy-protected PTC in this reaction system support the possibility that the hydrogen bonding, based upon the hydroxy group, between a catalyst and a substrate is a significant interaction in the asymmetric induction, similar to the known related reaction systems.[7] Herein, we have found that 4-trifluoromethylated quaternary salt PTC **A** derived from cinchonine appears to act as an efficient PTC in asymmetric Darzens reactions utilizing cyclic ketones.[8] Encouraged by this result, other aliphatic aldehydes such as **2be** were applied using similar reaction conditions with **1a**, revealing that the reaction with **1** proceeded smoothly to give the corresponding coupling adducts **3**. In particular, treatment of **1a** with **2d** or **2e** afforded the corresponding compounds **3ad** or **3ae** in good yield with 84 and 86% ee, respectively (entries 4 and 5). The reaction of other substrates such as **1b** with aldehydes **2b** or **2e** also gave the corresponding products with moderate ee (entries 6 and 7). The relative configurations of the coupling adducts were determined by both X-ray crystallographic analysis† using the coupling product **3ba** obtained from **1b** with **2a** and comparison of ^{1}H NMR analyses. The ORTEP figure shown in Fig. 1 reveals that it was the *trans* isomer, and other analogous products were determined

by comparison of the coupling constants observed in their ^{1}H NMR spectra. To the best of our knowledge, this is the first example of the preparation of α,β-epoxy ketones *via* catalytic asymmetric Darzens reaction with more than 80% ee.

The absolute configuration of the coupling product **3aa** was determined by transformation to the corresponding (*R*)-MTPA ester. As shown Scheme 1, **3aa** (50% ee) was treated with SmI_2[9] in THF–MeOH to afford the corresponding β-hydroxy ketone **4** [$[\alpha]_D^{28}$ −13.8 (*c* 2.7, $CHCl_3$)] as a sole product without racemization, as shown by the HPLC analysis. The stereochemistry of **4** was determined as *syn* by comparison with the literature data.[10] The following esterification afforded **5** in 85% yield. Application of the product **5** to the Mosher method[11] revealed that **5** has the β*R* configuration.

In conclusion, we have demonstrated both the catalytic asymmetric Darzens reaction under PTC conditions utilizing cyclic α-chloro ketones and enantiocontrol for the formation of the quaternary carbons *via* direct C–C bond formation. This methodology is effective for producing α,β-epoxy ketones involving a chiral quaternary carbon in optically active form.

Shioiri, *Tetrahedron Lett*., 1998, **39**, 2997; (*c*) S. Arai, H. Tsuge and T. Shioiri, *Tetrahedron Lett*., 1998, **39**, 7563.
4 D. Masilamani and M. M. Rogic, *J. Org. Chem*., 1981, **46**, 4486.
5 Use of α-bromo ketones as substrate instead of chloro ketones gave **3aa** with significantly lower enantio- and diastereo-selectivities.
6 Easily prepared PTCs substituted at the 4-position on the phenyl ring with other electron-withdrawing groups such as NO_2 or CN, and electron-donating groups such as MeO or alkyl groups, gave **3aa** with lower ee (4-NO_2, 5% ee; 4-CN, 6% ee; 4-OMe, 0% ee; 4-Bu^t, 5% ee). The PTC involving both a methyl-protected hydroxy group and a 4-trifluoromethylbenzyl unit afforded **3aa** as racemate. Other types of PTC including 2- or 3-substituted benzyl moieties also gave **3aa** with lower ee [3-CF_3, 3% ee; 2,4-$(CF_3)_2$, 17% ee].

8 A typical procedure for the catalytic asymmetric Darzens reaction is as follows: To a suspension of **1a** (53.0 mg, 0.3 mmol), PTC **A** (16.0 mg, 0.03 mmol) and aldehyde **2a** (0.06 ml, 0.6 mmol) in Bu_2O (1.5 ml) was added LiOH (28.4 mg, 1.2 mmol) at room temperature. After the mixture had been stirred for 45 h, more **2a** (0.06 ml, 0.6 mmol) was added, the mixture was stirred for an additional 16 h and the reaction mixture was quenched with 1 M HCl (3.0 ml), extracted with Et_2O (15 ml × 3), washed with brine and dried over Na_2SO_4. Removal of the solvent followed by flash column chromatography (silica gel, hexane–Et_2O, 5:1) gave the desired coupling adduct **3aa** as a colorless oil (64.2 mg, 99%, 69% ee): $[\alpha]_D^{25}$ +55 (*c* 2.1, $CHCl_3$). Ees were determined by HPLC analysis by use of DAICEL CHIRALCEL OD+OD, hexane–Pr^{i}OH, 20:1, retention time, 16.9 (major) and 18.6 min (minor).

Received (in Bath, UK) 23rd September 1998, Accepted 26th November 1998

Preparation of large crystal MCM-41 has been achieved by using calcined small crystallite MCM-41 as seeds in a multistage synthesis method. The possible formation mechanism is discussed. We believe that the newly discovered method is particularly important in making high quality thin films of mesoporous materials.

Following the discovery of the M41S family of ordered silica materials,[1,2] considerable attention has been focused on tailoring their pore structures.[3–6] For example, the diameter of hexagonally packed one-dimensional channels in MCM-41 can be tailored from 15 to over 100 Å[2–6] by a variety of methods which include using templating surfactant molecules with different alkyl chain lengths,[2] adding auxiliary organic molecules (which are solubilised in the hydrophobic region of the templating aggregates thus increasing micellar size)[2] or hydrothermal restructuring in the mother liquor over longer crystallization time or at higher reaction temperature.[3–6] The pore size uniformity or long range structural ordering can also be improved by careful choice and control of synthesis conditions.[7,8] However, there are very few reports on the control or increase in crystal size of MCM-41 despite the fact that crystal size is crucial to the fabrication and use of this material in thin film applications (such as in separation membranes) and in making molecular wires.[9] This is not surprising because, compared to the three-dimensional MCM-48, the formation of large crystals of MCM-41 would be difficult due to the one-dimensional channel structure which is subject to bending and fracture. Here we report on a new synthetic approach which involves the use of calcined MCM-41 as the seeds for further synthesis. The resulting material (herein referred to as secondary MCM-41) shows significantly improved long range structural ordering and a marked increase in crystal size.

The parent MCM-41 material (herein referred to as the primary MCM-41) was prepared following a normal procedure.† For secondary synthesis a synthetic gel of the same molar ratio was assembled except that the primary MCM-41 was used as 'silica source' instead of the fumed silica. The experimental procedures were exactly the same as described for the primary synthesis.† The MCM-41 yield, based on silica recovery, was *ca.* 60% for the primary synthesis and > 90% for the secondary synthesis.

The powder X-ray diffraction (XRD) patterns obtained from the calcined primary and secondary MCM-41 are shown in Fig 1. The pattern of the primary MCM-41 is typical of a well ordered specimen and shows an intense (100) diffraction peak and three higher order (110), (200) and (210) peaks. The pattern of the secondary MCM-41 shows an increase in the intensity of the (100) peak along with an increase in intensity and improvement in the resolution of the higher order peaks. In addition we were able to observe the (300) peak and a diffuse (220, 310) peak; these peaks are seldom observed even in the 'best' quality MCM-41 reported previously.[8] The presence of these higher order peaks indicates an improvement in long range ordering while the increase in peak intensities and associated reduction in full width at half maxima (FWHM) is a reflection of larger scattering domain (or crystal) size. The secondary synthesis does not however have any significant effect on the d_{100} spacing of the calcined samples. We note that doubling the primary synthesis time from 48 hours to 96 hours results in an increase in d_{100} spacing and a decrease in long range ordering with no apparent change in crystal size. Preliminary porosity data indicate that the surface area and pore volume of the secondary MCM-41 are slightly lower than those of the primary MCM-41. The average pore diameter (APD) is also lower for the secondary MCM-41. The lower APD taken together with the unchanging basal spacing is an indication that secondary synthesis results in a material with thicker pore walls. Thicker pore walls are expected to impart greater thermal and hydrothermal stability; indeed we have found that the secondary MCM-41 is relatively more stable to refluxing in boiling water compared to the primary material.

Transmission electron microscopic (TEM) images and selected area electron diffraction (SAED) patterns of the samples were obtained from a Jeol JEM-200CX electron microscope. The crystal size of the primary MCM-41 is in the range 400–600 Å range and no crystallites larger than 1000 Å were observed. This is similar to other normal MCM-41 specimens presented in previous reports.[10] On the other hand, the crystal size of the secondary MCM-41 is from 4000 to 8000 Å and crystallites smaller than 1000 Å were never observed. A typical TEM image together with a corresponding SAED pattern is shown in Fig. 2. It is clearly demonstrated that the secondary synthesis results in an increase in the crystal size of MCM-41 and crystallinity of the specimen has been significantly improved as indicated by

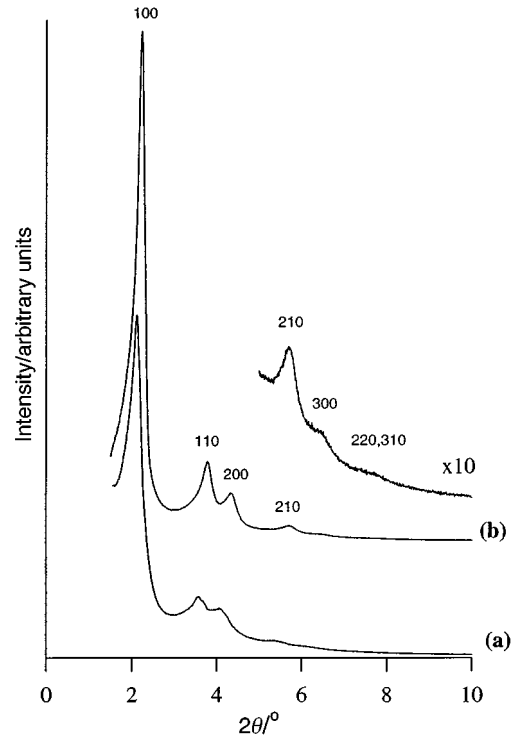

Fig. 1 Powder XRD patterns of calcined (a) primary MCM-41 and (b) secondary MCM-41.

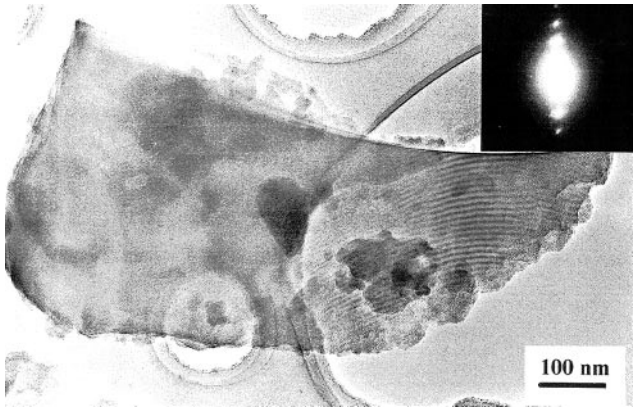

Fig. 2 TEM image and corresponding SAED pattern of a large crystal of MCM-41.

SAED patterns where four or more pairs of diffraction spots appear along the [100] direction, while only one or two pairs can been seen from the primary MCM-41 crystallites.

Thermogravimetric analysis (TGA) of the as-synthesized samples indicate that the amount of template occluded by the secondary MCM-41 is *ca.* 18% lower than in the primary MCM-41. This indicates that less amine is required during the secondary synthesis which would be the case if the primary MCM-41 (which is the silica source) remains largely intact with its crystallites acting as seeds or starting points for further MCM-41 formation. In this scenario the real source of silicate ions for crystal enlargement is amorphous silica which is usually part of any MCM-41 yield.

The extension of the MCM-41 framework is preceded by the dissolution (which is made possible by the presence of OH^- ions from TMAOH) of the 'silica source'.[11] The OH ions are used up during the dissolution and therefore the extent to which the concentration of OH ions (or pH) reduces during the crystallization period is a measure of the amount of dissolution.[11] For the primary synthesis we observed a decrease in pH from 12.4 to 11.5 after ageing for 20 hours at room temperature and a further decrease to 10.7 after heating at 150 °C for 48 hours. In contrast the gel for secondary synthesis had a pH of 11.5 which remained largely unaffected by aging at room temperature and reduced only slightly to 11.2 after heating for 48 hours at 150 °C. We attribute this smaller reduction in pH to the fact that there was much less dissolution during the secondary synthesis. In other words, if the MCM-41 particulates had dissolved extensively (to the same extent as the dissolution of fumed silica during the primary synthesis) we would have observed a larger pH decrease similar to that observed for the primary synthesis. These results along with the higher silica recovery are a strong indication that the primary MCM-41 is preserved during the secondary synthesis and that the slight decrease in pH is due to the dissolution of amorphous silica phase.

The TGA of the as-synthesized primary and secondary samples also indicated that the weight loss attributable to dehydroxylation of silanol groups (between 350 and 800 °C)[3,12] was 35% less for the secondary sample. This is a clear indication that the as-synthesized secondary MCM-41 is at a much higher level of silicate polymerization compared to its primary precursor and agrees with our suggestion that the primary MCM-41 remains largely intact during the secondary synthesis. This is further supported by our observation that on calcination the basal spacing of the primary MCM-41 reduced by 8.0% compared to a reduction of 2.5% for the secondary MCM-41. It is generally accepted that a higher extent of contraction is an indication of a less polymerized or cross-linked framework which therefore undergoes greater dehydroxylation.[11] Indeed ^{29}Si MAS NMR of the as-synthesized samples indicates that the Q4/Q3 ratio is higher for the secondary MCM-41.

According to a recent report,[13] during the preparation of MCM-41, the cylindrical surfactant and the silica aggregates are simultaneously formed. The silicate ions enter the particles from the surface perpendicular to the *c* axis of the aggregates and the molecules of the surfactant must enter along the aggregate cylinders until the density of the surfactant approaches its maximum value. In the present work, when the calcined MCM-41 crystallites were used as seeds during the secondary synthesis, it is possible that the template molecules attach themselves at the mouth of the pore channels of the primary MCM-41 and encourage crystal growth parallel to the channels and, consequently, growth of larger crystals becomes possible. This method can be applied in future preparation of large single crystals and high quality thin films of MCM-41.

R. M. acknowledges the EPSRC for an Advanced Fellowship.

Notes and references

† *Preparative procedure of the primary MCM-41*: tetramethylammonium hydroxide (TMAOH) and cetyltrimethyammonium bromide (CTAB) were dissolved in distilled water by stirring at 35 °C. The silica source, fumed silica (Sigma), was added to the solution under stirring for 1 hour. After further stirring for 1 hour the resulting synthetic gel of composition SiO_2 : 0.25 CTAB : 0.2 TMAOH : 40 H_2O was left to age for 20 hours at room temperature following which the mixture was transferred to a teflon-lined autoclave and heated at 150 °C for 48 hours. The solid product was obtained by filtration, washed with distilled water, dried in air at room temperature and calcined at 550 °C for 8 hours.

Conversion of propane into butanes catalyzed by sulfated zirconia mixed with Pt/ZrO_2

Makoto Hino[a] and Kazushi Arata*[b]

[a] *Hakodate Technical College, Tokura-cho, Hakodate 042-8501, Japan*

Received (in Cambridge, UK) 21st September 1998, Accepted 17th November 1998

An active catalyst for the conversion of propane into butanes is obtained by mechanically mixing sulfated ZrO_2 and Pt/ZrO_2.

Among conversion of light alkanes by cracking, coupling, or isomerization in heterogeneous catalytic sytems much attention has been focused on the coupling of methane, but the catalytic systems still require high temperatures to obtain satisfactory activity and selectivity.[1] Sulfated zirconia and related catalysts have received attention because of their high activities for butane isomerization.[2,3] Cheung and Gates tested Fe–Mn-promoted sulfated ZrO_2 for conversions of ethane and propane, but conversions were low, being only 0.6% for the highest propane conversion observed at 300 °C.[4–6] We have demonstrated that impregnation of sulfated ZrO_2 with noble metals such as Pt and Ir leads to pronounced activity for butane conversion, the Pt concentration being 7–8 wt%; the catalyst with Pt showed highest activity for the reaction.[7,8] These noble metal-added sulfated zirconias were applied to propane, but the conversions were still low. However, the conversion was found to be promoted by simply mechanically mixing Pt-supported zirconia (Pt/ZrO_2) with sulfated zirconia (SO_4/ZrO_2).

SO_4/ZrO_2 and 0.5 wt% Pt/ZrO_2 catalysts were prepared as described elsewhere.[3,8,9] The thus-prepared catalysts, 0.3 g SO_4/ZrO_2 and 0.3 g Pt/ZrO_2, were mixed well by kneading with a mortar and pestle. Other catalysts of sulfated Al_2O_3, TiO_2, and Fe_2O_3, together with WO_3/ZrO_2, were prepared as described elsewhere.[9]

Reactions of propane were carried out in a microcatalytic pulse reactor as described elsewhere.[8] The catalyst was heated at 300 °C for 1 h in an He flow before reaction. A slightly continual gain of conversion was observed with pulse number, and thus conversions were calculated on the basis of mol fraction as the average of the 6th–10th pulse values.

Table 1 Activities of the catalysts for the reaction of propane

Catalyst	*T*/°C	Conversion (%)	Products (%) C_1	C_2	C_4	C_5
SO_4/ZrO_2	200	0.1	Tr[a]	Tr	0.1	0
$Pt–SO_4/ZrO_2$[b]	200	0.2	0	Tr	0.2	0
$Pt–SO_4/ZrO_2$[c]	250	0.3	Tr	0.2	0.1	0
$SO_4/ZrO_2–Pt/ZrO_2$	200	3.2	Tr	0.2	3.0	Tr
$SO_4/ZrO_2–Pt/ZrO_2$[d]	200	4.2	0.1	0.7	3.4	Tr
$SO_4/ZrO_2–Pt/ZrO_2$[e]	200	4.6	0.3	1.2	3.1	0
$SO_4/ZrO_2–Pt/ZrO_2$	225	6.1	0.3	1.6	4.1	0.1
$SO_4/ZrO_2–Pt/ZrO_2$	250	10.6	1.8	4.9	3.8	0.1
$SO_4/Al_2O_3–Pt/ZrO_2$	250	8.4	2.1	6.3	Tr	0
$SO_4/TiO_2–Pt/ZrO_2$	250	8.9	2.4	6.4	0.1	0
$SO_4/Fe_2O_3–Pt/ZrO_2$	250	13.3	3.9	9.4	0	0
$WO_3/ZrO_2–Pt/ZrO_2$	250	14.0	3.3	10.7	0	0
$SO_4/ZrO_2–Pt/ZrO_2$[f]	250	5.8	5.5	0.3[g]	0	0
SO_4/ZrO_2-Pt/ZrO_2[f]	300	16.3	16.2	0.1[g]	0	0

[a] Trace. [b,c] Prepared by sulfation of zirconia gel followed by platinization and calcination ([b] 0.5, [c] 2 wt% Pt). [d,e] Reaction with [d] 0.6 or [e] 1.2 g of 0.5% Pt/ZrO_2 and 0.3 g of SO_4/ZrO_2. [f] Reaction of ethane. [g] Yield of C_3.

The reaction of propane (C_3) was carried out at 200 °C and 20 ml min^{-1} of He carrier over 0.3 g of SO_4/ZrO_2, but the conversion was only 0.1%. The addition of platinum (0.5 or 2 wt%), $Pt-SO_4/ZrO_2$ (0.3 g), was ineffective even at 250 °C as shown in Table 1. The addition of Pt was, however, effective when Pt/ZrO_2 was mechanically mixed with SO_4/ZrO_2. A mixture of 0.3 g of SO_4/ZrO_2 and 0.3 g of 0.5 wt% Pt/ZrO_2, where the Pt quantity was equivalent to that in 0.3 g of 0.5 wt% $Pt-SO_4/ZrO_2$, gave 3.2% conversion. The major product was butanes (C_4); trace amounts of pentanes (C_5) were observed in addition to ethane (C_2) and methane (C_1). Dehydrogenated materials were not observed, though ethylene and propylene were formed over Fe–Mn-sulfated ZrO_2.[5,6]

The catalysts were then examined in butane; the Pt co-impregnated catalyst, $Pt–SO_4/ZrO_2$[c] in Table 1, gave 48% conversion for the first pulse at 80 °C (catalyst amount: 0.1 g), while the mixture of SO_4/ZrO_2 and Pt/ZrO_2 only gave 8% conversion. Thus, the catalyst which is effective for butane is not efficient for propane and *vice versa*.

The effect of mixing was examined further at temperatures of 225 and 250 °C; the yields of C_4 were $\approx$4% with higher conversions of C_3, but showing lower selectivity for the formation of C_4 (Table 1). In terms of preparation temperature of the catalysts the highest activity was observed upon calcination at 600 °C for SO_4/ZrO_2 and 750°C for Pt/ZrO_2.

The effect of modifying the proportion of platinum in the catalyst was studied. Catalysts with 0.6 and 1.2 g of Pt/ZrO_2 showed 4.2 and 4.6% propane conversion at 200 °C, with 3.4 and 3.1% C_4 yields, respectively. This indicates that the effect of concentration of platinum is relatively small. In terms of isomers of C_4 the selectivity for isobutane was 60–65% in each case.

The effect of mixing of Pt/ZrO_2 for the reaction of propane was examined for other sulfated metal oxides, Al_2O_3, TiO_2, and Fe_2O_3 in addition to WO_3/ZrO_2, the acidities of which are lower relative to SO_4/ZrO_2.[3] These materials showed a noticeable effect upon mixing for the conversion reaction of butane to isobutane.[9,10] Remarkable conversions of C_3 over these substances mixed with Pt/ZrO_2 were obtained at 250 °C, but the yield of C_4 was low, at most 0.1%. Thus, high superacidity is needed to form C_4 products.

XPS experiments were carried out in order to elucidate the surface properties of Pt/ZrO_2. The binding energy of Pt 4f was 72.6 eV, which was far from that of the metallic state (71.7 eV), but close to that of cationic Pt species.[11]

The formation of higher molecular weight alkanes is brought about by catalysis of the cracking ability in addition to the protonation of propane by a superacid to form a carbonium ion.[5] This behavior was also shown by the formation of propane from ethane in the present system, although the yield was low (Table 1).

Aggregation/deaggregation processes in vanadium(II) carboxylate chemistry

Peter J. Bonitatebus, Jr. and William H. Armstrong*

Department of Chemistry, Merkert Chemistry Center, Boston College, Chestnut Hill, MA 02167-3860, USA. E-mail: william.armstrong@bc.edu

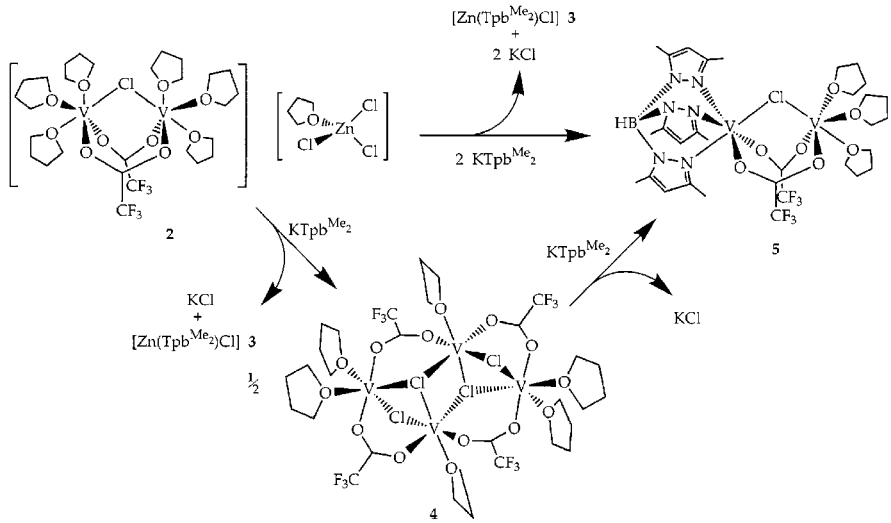
Received (in Bloomington, IN, USA) 3rd August 1998, Accepted 26th October 1998

Reactions of potassium tris(3,5-dimethylpyrazolyl)borate ($KTpb^{Me_2}$) with the low-valent mixed-metal complex $[(thf)_3V(\mu\text{-}Cl)(\mu\text{-}tfa)_2V(thf)_3][ZnCl_3(thf)]$ resulted first in $ZnCl^+$ abstraction and tetramer formation, then in asymmetric binuclear product formation through ligand substitution.

Our efforts in developing the chemistry of low-valent vanadium in an anionic oxygen ligand donor environment,[1–4] including that of vanadium(II) carboxylate coordination chemistry,[1] stems from the reported reducing and oxophilic character of these types of V^{II} complexes in both protic and aprotic media. For example, α,ω-dicarboxylic acids have been shown to promote the reaction between N_2 and vanadium(II) to yield N_2H_4 in the presence of hydroxide *via* by a proposed carboxylato-bridged V^{II} aggregate.[5] These reported conditions are mild, aqueous and heterogeneous in nature. Studies in organic, aprotic media of the interaction of V^{II} and trifluoroacetate (tfa) by Cotton *et al.* in an attempt to synthesize a multiply-bonded metal species, '$V{\equiv}V^{4+}$', resulted instead in the isolation of an oxidized oxo-centered triangular core, $[V_3(\mu_3\text{-}O)(\mu\text{-}tfa)_6(thf)_3]$ **1**.[6,7] Carboxyl group O-atom abstraction was postulated as the source of the (μ_3-O) atom in **1**, a conclusion based on the high oxophilicity of V^{II}. Although this latter report presented results of a synthetic strategy directed toward a '$V{\equiv}V^{4+}$' compound, it also served as an initial effort to homogenize and probe the original interesting N_2-fixing system.[5] Later efforts in our laboratory, under rigorously anaerobic and dry conditions using a similar preparation to that reported for **1**, demonstrated the existence and relative thermal stablility of a V^{II} carboxylate dimer, $[(thf)_3V(\mu\text{-}Cl)(\mu\text{-}tfa)_2V(thf)_3][ZnCl_3(thf)]$, **2** (Scheme 1), isolated as a highly air- and moisture-sensitive compound in good crystalline yield.[1] Herein we describe our continued effort and interest in vanadium(II) carboxylate coordination chemistry by reporting on the synthesis, structure and some properties of a novel binuclear carboxylate complex along with its tetrameric precursor—an unprecedented example of vanadium(II) isolated at this nuclearity. These new 'zinc-free' and halide-bridged multinuclear V^{II} compounds represent an important advance in probing the N_2-fixing system of Folkesson and Larsson by serving as starting materials for reactions with hydroxide or alkoxide ligands. Alkoxide donors, in conjunction with carboxylato-bridged V^{II} aggregates, are conceivably required for efficient homogeneous small molecule multielectron reduction, as were hydroxide ions in the original heterogeneous V^{II} carboxylate N_2-fixing system.[5]

Treating green-purple **2** (0.22 mmol scale) with one equivalent of potassium tris(3,5-dimethylpyrazolyl)borate ($KTpb^{Me_2}$) in 15 mL of THF (Scheme 1) and stirring overnight gave deposition of a white precipitate (KCl) which was removed by filtration. Layering the resulting blue-green filtrate with 3–5 mL of pentane and allowing it to stand for 12 h at 0 °C discharged another colorless solid, but in crystalline form, which was filtered off and identified by X-ray crystallography to be $[Zn(Tpb^{Me_2})Cl]$, **3**.† Layering and cooling the filtrate again completed the isolation of crystalline sky-blue $[V_4(\mu_3\text{-}Cl)_2(\mu\text{-}Cl)_2(\mu\text{-}tfa)_4(thf)_6]$ **4** (Fig. 1).‡ Apparently, this reaction involves scavenging the Zn^{II} of **2** as $[Zn(Tpb^{Me_2})Cl]$, **3**, using $KTpb^{Me_2}$, with concomitant KCl formation and chloride ion liberation. This freed Cl drives the cationic core of **2** to dimerize assembling a $[V_4tfa_4]^{4+}$ aggregate, compound **4**.§

The crystal structure of **4** (Fig. 1) revealed a tetramer with crystallographically imposed inversion symmetry.† Selected dimensions, listed in Fig. 1, show V–O_{thf} and V–O_{tfa} bond lengths (av. 2.139, av. 2.101 Å, respectively) to be in good agreement with those of **2** (av. 2.140, av. 2.091 Å, respectively).[1] The apical (μ_3) chloride distances in **4** (av. 2.506 Å) are only slightly shorter than similar bonds seen for the *triangulo*-trinuclear species $[V_3(\mu_3\text{-}Cl)_2(\mu\text{-}Cl)_3]^+$ (av. 2.519 Å).[8] The V···V separations in **4** (4.169, 3.637, 3.351 Å) vary within a relatively large range (0.818 Å) as a consequence of the different numbers and types of bridging groups between vanadium centers. The angle made by V(1)–Cl(1)–V(2) is also significantly widened [112.81(4)°] compared with the V–Cl–V



Scheme 1 Synthesis of carboxylato-bridged vanadium(II) aggregates.

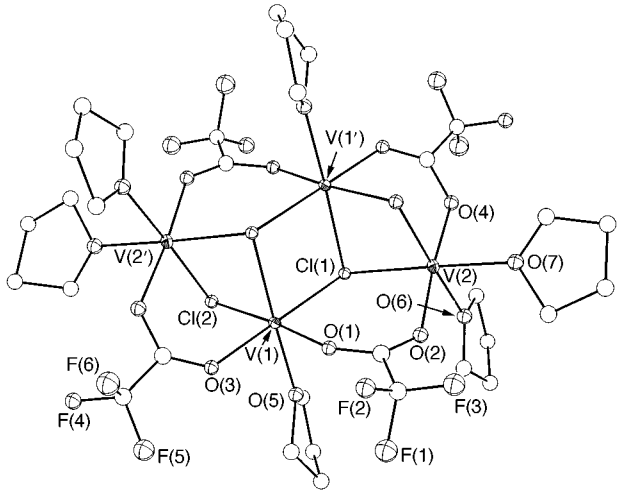


Fig. 1 Structure of **4** (hydrogen atoms are omitted for clarity). Selected bond distances (Å) and angles (°) are: V(1)–Cl(1) 2.515(1), V(1)–Cl(2) 2.481(1), V(2)–Cl(1) 2.489(1), V(1)–O(1) 2.109(3), V(2)–O(2) 2.090(3), V(1)–O(5) 2.129(3), V(2)–O(7) 2.140(4), V(1)–V(2) 4.169, V(1)–V(1′) 3.637, V(2)–V(1′) 3.351; V(1)–Cl(1)–V(2) 112.81(4), V(1)–Cl(1)–V(1′) 92.59(4), V(1)–Cl(2)–V(2′) 85.20(4), O(7)–V(2)–O(6) 86.4(2), O(1)–V(1)–Cl(2) 175.86(9), O(3)–V(1)–Cl(1) 179.90(9).

angle of **2** [100.3(1)°].[1] Compound **4** is the first example of an isolated vanadium(II) tetramer, and is resembled closest in terms of vanadium–ligand core connectivity and oxidation state by the methoxide-containing V_4^{10+} catecholato-bridged aggregate of Shilov and coworkers, the only structure reported to date from their vanadium-based N_2-fixing system.[9]

The aggregation of **2** → **4** invites a question regarding the outcome of a reaction involving **4** with one more equivalent of $KTpb^{Me_2}$. Reaction of **4** with $KTpb^{Me_2}$ in THF [or treatment of **2** with two equivalents (0.45 mmol scale) of $KTpb^{Me_2}$, Scheme 1] develops a light-brown solution from which KCl precipitates after 12 h of stirring. Filtration, pentane layering, and cooling overnight produced the neutral, asymmetric dimer $[(Tpb^{Me_2})V(\mu\text{-Cl})(\mu\text{-tfa})_2V(thf)_3]$, compound **5** (Fig. 2), in crystalline form.‡ Evidently this reaction converts the $[V_4tfa_4]^{4+}$ aggregate back to a $[V_2tfa_2]^{2+}$ core.§

The structure of **5** (Fig. 2), the first asymmetric $V_2^{II,II}$ dimer reported to date, consists of two V^{II} ions bridged by one chloride and two trifluoroacetate groups and coordinated terminally by a Tpb^{Me_2} group on one side and by THF molecules on the other.† The $V–O_{tfa}$ (av.) and V–Cl bond lengths are slightly different for each vanadium [V(1): 2.118, 2.507; V(2): 2.092, 2.456 Å respectively] reflecting the asymmetry in the molecule. These differences affect the V···V separation [3.868(1) Å] and the V–Cl–V angle [102.40(6)°] which are longer and wider as compared to **2** [3.796(2) Å, 100.3(1)°].[1]

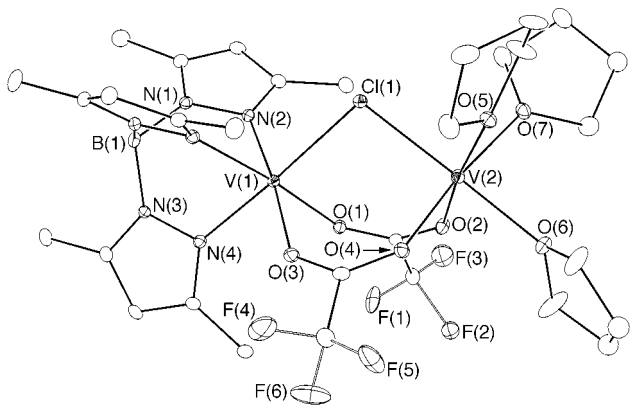

Fig. 2 Structure of **5** (hydrogen atoms are omitted for clarity). Selected bond distances (Å) and angles (°) are: V(1)–Cl(1) 2.507(2), V(2)–Cl(1) 2.456(2), V(1)–O(3) 2.122(4), V(2)–O(4) 2.091(4), V(1)–N(4) 2.150(5), V(2)–O(6) 2.152(4), V(1)–V(2) 3.868(1); V(1)–Cl(1)–V(2) 102.40(6), O(3)–V(1)–N(2) 174.7(2), O(4)–V(2)–O(7) 172.8(2).

Use of the Tpb^{Me_2-} ligand in reactions with **2**, has resulted in a doubling of the number of known bridged V^{II} carboxylates in the literature[1,10] and has encouraged aggregation/deaggregation behavior in vanadium(II) carboxylate chemistry. The first examples of a tetrameric and an asymmetrical dimeric V^{II} species were unveiled. We are currently examining the reaction chemistry of the carboxylato-bridged aggregate **4**, as a halide-rich and 'zinc-free' starting material, especially with alkoxides in the presence of reducible small molecules. Also, the use of $KTpb^{Me_2}$ for scavenging inner-sphere charge-sharing Zn^{II} ions present in other potentially reactive low-valent mixed-metal V–Zn alkoxide compounds synthesized recently in our laboratory,[11] is currently under investigation. Application of this unusual synthetic avenue, along with directed reactivity at the solvated face of **5**, will be reported elsewhere.

PFG NMR study of the transport properties of A-type zeolite membranes

Wilfried Heink,[a] Jörg Kärger,[a] Tim Naylor[b] and Ulf Winkler[a]

[a] *Universität Leipzig, Fakultät für Physik und Geowissenschaften, Linnéstr. 5, 04103 Leipzig, Germany. E-mail: kaerger@physik.uni-leipzig.de*

Received (in Cambridge, UK) 5th October 1998, Accepted 25th November 1998

The transport properties of an A-type zeolite membrane are traced by monitoring the diffusion paths of ethane and propane from *ca*. 300 nm up to 10 μm; over distances < 1 μm, the diffusivities are found to be comparable with those in a mono-crystal, while for large displacements by a factor of two to three smaller diffusivities were observed.

Offering a number of most exciting technological advantages in catalysis and gas separation, microporous membranes have become an attractive subject of applied research. Owing to their thermal and chemical stability, among them the inorganic membranes have attained special attention.

Zeolite membranes have recently been made available on a commercial basis and have been shown to be capable of achieving very high levels of separation along with very high permeate fluxes for a range of binary mixtures, for example water removal from methanol, ethanol and isopropyl alcohol.[1] The particular materials used in this study were pieces of membranes that were fragmented during handling. From scanning electron micrographs, these pieces appeared to be crystallite agglomerates with diameters of tens to hundreds of micrometers, where the crystallite diameters were of the order of micrometers.

The membranes were prepared from homogeneous solution with a composition given by the molar ratio 5 SiO_2 : Al_2O_3 : 55.12 Na_2O : 1004.66 H_2O. An aluminate solution was prepared by dissolving small pieces of aluminium wire (Aldrich, 2.4 g) in aqueous NaOH (86.56 g Analytical grade NaOH pellets in 362.46 g distilled water) over a 48 h period. A sodium silicate solution was prepared by dissolving NaOH pellets (80 g) in distilled water (340.4 g) then adding an aqueous silicate solution (BDH, 25.5% SiO_2, 7.5% Na_2O, 40.82 g) with vigorous stirring. After at least 15 min of stirring, the pre-heated aluminate solution was added, and the stirring continued for 5 min. The resultant solution was transferred to a preheated container for membrane preparation. Free-standing samples of zeolite membrane were prepared by placing the above solution in a sealed Teflon container which was placed in an oven at 50 °C for 48 h. The container was removed from the oven, drained and the zeolite film that lightly adhered to the container walls was throughly rinsed with distilled water until the rinsings were pH neutral. Samples of the membrane detached themselves during this procedure and were collected and dried at 70 °C overnight. The material was ion exchanged to the Ca-form by soaking it in 0.1 M $Ca(NO_3)_2$ overnight followed by thorough rinsing in doubly distilled, deionised water. The material was oven-dried at 120 °C for 24 h.

The pulsed field gradient (PFG) NMR method is a bulk technique, which allows the determination of the probability distribution of molecular displacements within the sample.[2,3] The displacements, which may be resolved by this technique are in the range of micrometers, with observation times of typically milliseconds.

For the preparation of the PFG NMR samples, the zeolite material was filled into glass tubes of 7.5 mm o.d. and activated by heating at a rate of 10 K h^{-1} under continuous pumping up to a final temperature of 400 °C, where it was kept for 10 h. After cooling to room temperature the probe molecules (the 'diffusants') were introduced by chilling from a calibrated gas volume with a set pressure. The amount adsorbed was afterwards checked by measuring the intensity of the NMR signal.

The diffusion measurements have been carried out by means of the home-built PFG NMR spectrometer FEGRIS 400 at a proton resonance frequency of 400 MHz with magnetic field gradient amplitudes up to 24 T m^{-1}.[3,4] The attenuation of the

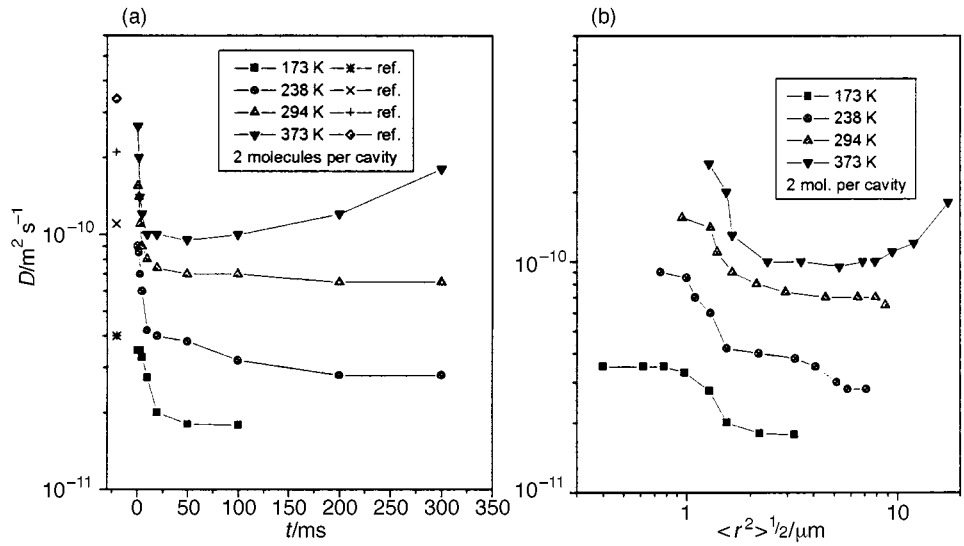

Fig. 1 (a) Ethane diffusivity in NaCaA membrane as a function of the observation time at different temperatures; ref.: results of previous PFG NMR studies with crystalline zeolite NaCaA. (b) Ethane diffusivities in NaCaA membrane as a function of the root mean square displacement at different temperatures.

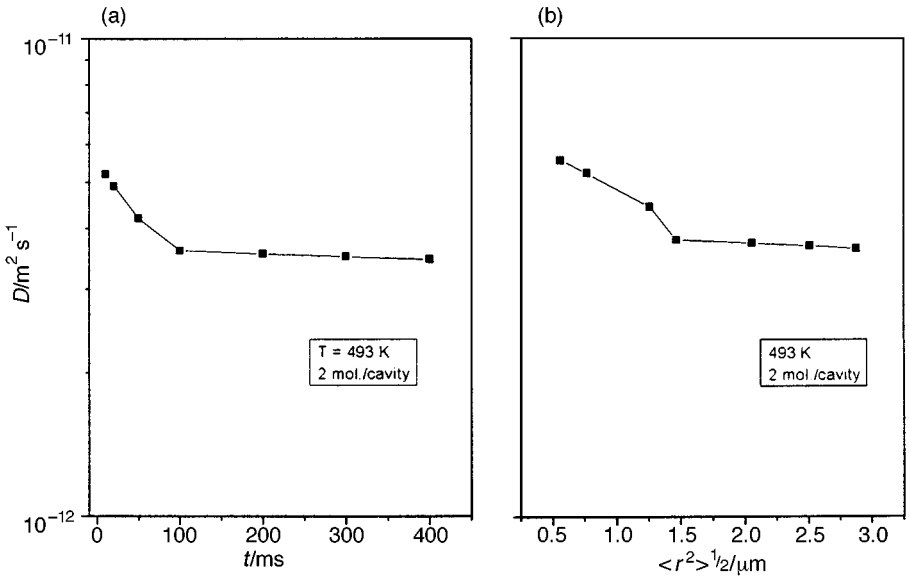

Fig. 2 (a) Propane diffusivity in NaCaA membrane: (a) as a function of the observation time and (b) as a function of the root mean square displacement.

NMR signal (the 'spin echo') *versus* the squared gradient amplitude was essentially found to follow a monoexponential decay, as to be expected for normal diffusion in a quasihomogeneous medium. The effective diffusivity was determined by comparing the signal decay with that of a standard [water, D = (2.04 ± 0.08) × 10^{-9} m^2 s^{-1} at 20 °C].[5] It is defined as the ratio

$$D = \langle r^2(t) \rangle / 6t \quad (1)$$

between the mean square displacement and the observation time.

Fig. 1(a) shows the dependence of the ethane diffusivity in the zeolite membrane at a loading of two molecules per cavity for different temperatures. For comparison, the diffusivity data of previous PFG NMR studies[6] with ethane in NaCaA zeolite crystallites are also included. It appears that these data are in reasonably good agreement with the results of the present study for sufficiently short observation times. The information provided by these studies becomes more obvious in the representation of the diffusivities *versus* the covered displacements [Fig. 1(b)]. There is a pronounced decay for displacements around 1 μm, which should be attributed to transport resistances, most likely situated at the interfaces between the individual crystallites. For shorter displacements, the majority of the diffusants do not interfer with these barriers; one is able to trace the true intracrystalline diffusion. For larger displacements, the molecules repeatedly have to overcome these transport resistances. This leads to a slight reduction of the diffusivity. The enhancement observed in the high-temperature case for displacements > *ca.* 10 μm may be associated with the occurence of long-range diffusion, when more and more molecules are able to get out of the zeolite bulk phase, either through cracks in the material or through the outer surface of the membrane particles.

As a consequence of the substantially lower mobility, propane in NaCaA offers much poorer measuring conditions. The most reliable measurements for this system have therefore been carried out at 493 K, the highest temperature accessible with our device. Fig. 2(a) and (b) represent the corresponding diffusivity data. Similarly as with ethane, for molecular displacements < *ca.* 1 μm, there is an increase in the diffusivities, which should be a consequence of unrestricted diffusion for displacements sufficiently small in comparison with the crystallite radii. It should be mentioned that previously measured diffusivities of propane in NaCaA zeolite crystallites under the same measuring conditions revealed slightly lower values (2.5 × 10^{-12} m^2 s^{-1}).[6] It is possible that the difference to the value which in the present studies is assumed to be the true intracrystallite one, is caused by slight differences in the degree of calcium exchange. Such differences should be much more significant for propane than for ethane having a smaller critical diameter.

To our knowledge, in these investigations, for the first time transition resistances between the individual crystalline compartments in nanoporous membranes have been probed microscopically. For the considered probe molecules (ethane, propane) a notable transport resistance was observed, which, however, was found to be much smaller than the surface resistance on isolated NaCaA type crystallites.[7] Further experimental evidence is required to decide whether the observed behaviour is a general feature of polycrystalline membranes.

Quinuclidine *N*-oxide: a potential replacement for HMPA

Ian A. O'Neil,*[a] Justine Y. Q. Lai[b] and Duncan Wynn[a]

[a] *Robert Robinson Laboratories, Department of Chemistry, University of Liverpool, Crown St, Liverpool, UK L69 7ZD. E-mail: ion@liv.ac.uk*

Received (in Cambridge, UK) 10th November 1998, Accepted 17th November 1998

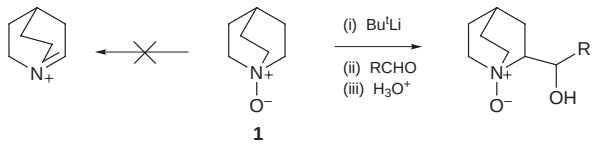
The use of quinuclidine *N*-oxide as a replacement for HMPA is described.

There are numerous significant and important reactions in organic synthesis which require the addition of hexamethylphosphoric triamide (HMPA) to render them viable.[1] HMPA is a dipolar aprotic compound with a superb ability to form cation–ligand complexes and it can enhance the rates of a wide variety of main group organometallic reactions. In addition, it can also influence the regio- and stereo-chemistry of key reactions such as enolate formation. Other reactions in which HMPA can enhance reactivity include carbanion formation, carbanion reactivity, carbanion regioselectivity (1,2 *vs*. 1,4 addition), ylide reactivity and anion reactivity. In essence, it is thought that HMPA acts as a metal binding agent, disrupting the aggregation states that enolates normally exist in.[2]

HMPA is a listed mutagen and as such does not find widespread use either in industry or academia. Several other substances, such as 1,3-dimethyl-3,4,5,6-tetrahydropyrimidin-2(1*H*)-one (DMPU) have been used as replacements but all have their limitations.[3] An amine oxide bears the same type of charge distribution as a phosphine oxide, but the dipole moment is much larger. Therefore an amine oxide would be expected to behave in a similar fashion to a reagent such as HMPA. The major problem lies with the instability of most amine oxides towards strong bases, azomethine ylide formation being the most common pathway.[4]

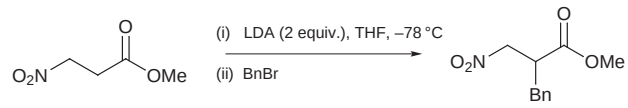
As a consequence of our previous work with amine oxides,[5] we have carried out preliminary studies using quinuclidine *N*-oxide (QNO) as a replacement for HMPA, since it is an amine oxide that is known to be stable in strongly basic conditions. Indeed, it can be deprotonated with Bu^{t}Li and the corresponding anion can be reacted with aldehydes and ketones.[6] This amine oxide is stable because elimination of lithium oxide would lead to a bridgehead iminium ion (anti-Bredt) (Scheme 1).

We chose to study four key reactions in which HMPA is known to play a vital role and we have investigated the effect of replacing the HMPA by quinuclidine *N*-oxide. The reactions examined were enolate alkylation,[7] 1,4 *vs*. 1,2 addition,[8] diastereoselective nitroaldol reactions[9] and epoxide opening.[10] Quinuclidine *N*-oxide has been prepared by the oxidation of quinuclidine with 30% H_2O_2 in MeOH.[11] However, we routinely use MCPBA as the oxidant as it is more convenient on a laboratory scale.[12] The product can be purified by chromatography on silica gel. The product is dried under vacuum over P_2O_5. It is a hygroscopic solid and needs to be stored under vacuum over P_2O_5. The quinuclidine nucleus is ideal since it is a rigid structure amenable to rapid modification. In addition, a number of functionalised derivatives can be readily made, some in chiral form.[13]



1

Scheme 1



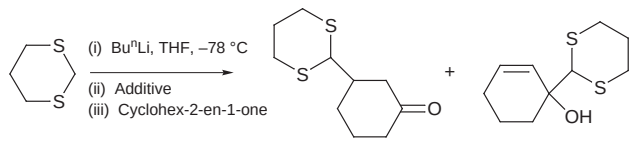
2 **3**

Additive (equiv.)	Yield (%)
0	8
HMPA (5.2)	85
DMPU (10)	85
QNO (1.4)	37
QNO (3.0)	47
QNO (5.0)	78

Scheme 2

Our investigations started with the alkylation of the dianion of methyl 3-nitropropionate, a reaction that is known to require 5 equiv. of HMPA to proceed in good yield. It was found that with just 3 equiv. of QNO the required product was isolated in a reasonable 47%, and the use of 5 equiv. gave a yield comparable to that with HMPA (Scheme 2).

We next examined the regioselectivity of addition of 2-lithiodithiane to cyclohex-2-en-1-one. In the absence of HMPA the predominant mode of addition is 1,2. When 1 equiv. of HMPA is added the 1,4 addition product becomes the major one.[8] Addition of QNO switched the reaction to give the 1,4 addition product with good selectivity (Scheme 3). Indeed, it was considerably more selective than the use of DMPU.



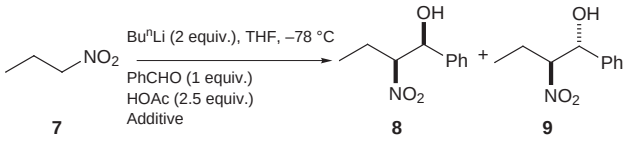
4 **5** **6**

Additive (equiv.)	Yield (%)	Yield (%)
—	8	92
HMPA (1)	88	12
HMPA (2)	95	5
DMPU (2)	82	18
QNO (1)	88	12
QNO (2)	90	10

Scheme 3

We then studied the addition of the dianion of 1-nitropropane to benzaldehyde. This gives the nitroaldol products as a mixture of diastereoisomers. In the presence of HMPA, the *syn* diastereoisomer is the major product.[9] The addition of 1.5 equiv. of QNO was also found to promote formation of the *syn* diastereoisomer giving a 4:1 mixture of diastereoisomers in 62%. The addition of more QNO did not appear to improve the selectivity (Scheme 4).

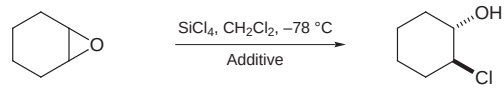
Finally, Denmark and co-workers have recently reported the use of HMPA and $SiCl_4$ to cleave epoxides to give chlorohydrins.[10] With a chiral phosphinamide, the ring opening of *meso* epoxides gave enantiomerically enriched chlorohydrins. It was gratifying to find that QNO mediated the ring opening of cyclohexene oxide to give the chlorohydrin in a yield identical



7 **8** **9**

Aditive (equiv.)	Yield (%)	Yield (%)
HMPA (5)	90	10
QNO (1.5)	81	19
QNO (3)	79	21

Scheme 4



10 **11**

Additive (equiv.)	Yield (%)
HMPA (0.1)	89
QNO (0.1)	89

Scheme 5

to that obtained using HMPA. In the absence of QNO the chlorohydrin was isolated in low yield (Scheme 5).

Significantly, QNO was found to be negative in the bacterial reverse mutation test conducted on *Salmonella typhimurium* TA98, TA100 and TA102 in the presence or absence of metabolic activation. Additionally it was also found to be negative in the test to evaluate its potential to induce micronuclei in Chinese hamster ovary cells using the cytokinesis block method in the presence or absence of metabolic activation.

In summary, we have shown that quinuclidine *N*-oxide can act as a replacement for HMPA in a range of reactions.[14] We are currently exploring other reactions known to require HMPA, and synthesising second generation quinuclidine *N*-oxides which are chiral and bear additional metal binding sites for enhanced reactivity and solubility. Their properties, applications and use in a range of asymmetric transformations will be reported shortly.

We would like to thank the EPSRC for a studentship (to D. W.). I. O. N. would like to thank the James Black Foundation for their continued financial support and Cambridge Combinatorial for a generous unrestricted research grant.

14 Alkylation of methyl 3-nitropropanoate: A solution of diisopropylamine (0.9 ml, 0.63 mmol) and quinuclidine *N*-oxide (1.78 g, 14 mmol) in dry THF (40 ml) was cooled to −78 °C. To this solution was added BuLi (4.0 ml, 1.6 M in hexane, 0.63 mmol). The solution was stirred for 30 min, then methyl 3-nitropropanoate (0.37 g, 2.8 mmol) was added. After stirring for 60 min benzyl bromide (0.4 ml, 0.35 mmol) was added. The solution was stirred for 5 h. Acetic acid (1.0 ml, 2.8 mmol) was added followed by distilled water (5.0 ml). The solution was warmed to room temperature and water (50 ml) was added. Diethyl ether (50 ml) was added, the organic layer separated and the aqueous layer extracted with diethyl ether (3 × 50 ml). The combined organic layers were washed with water (100 ml), and dried over $MgSO_4$. The solvent was removed *in vacuo*. The crude reaction mixture was purified by flash chromatography over silica gel eluting with EtOAC–light petroleum (bp 40–60 °C), 1 : 9 to give the desired product (0.48 g, 78%). The aqueous layer contains the quinuclidine *N*-oxide.

Imidodiphosphinate ligands as antenna units in luminescent lanthanide complexes

Steven W. Magennis,[a] Simon Parsons,[a] Anne Corval,[b] J. Derek Woollins[c] and Zoe Pikramenou*[a]

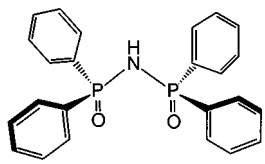
Received (in Basel, Switzerland) 16th October 1998, Accepted 24th November 1998

Imidodiphosphinate ligands form a hydrophobic shell around terbium and europium ions leading to long-lived, highly luminescent complexes.

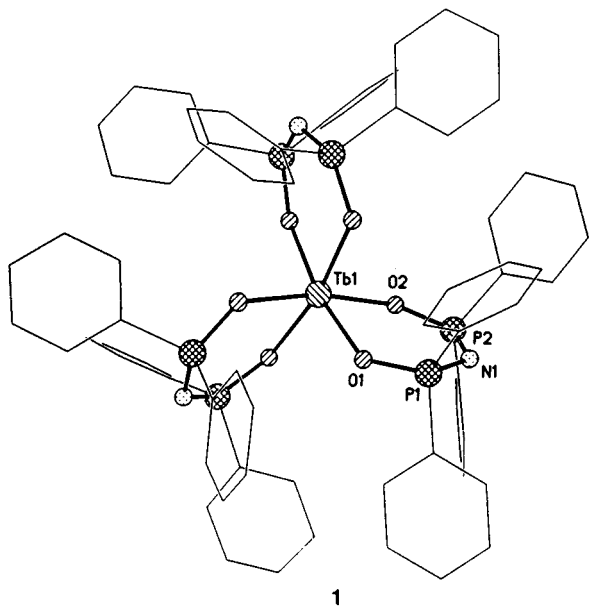
The design of miniature 'antenna' systems based on lanthanides for collecting light and converting it to a different frequency has important applications in the development of photonic devices and sensors.[1] Europium and terbium ions are attractive luminescent centers due to their visible, long-lived emission. A breakthrough in lanthanide chemistry came with the design of cryptand ligands that encapsulate the lanthanide ion, protecting it from coordinating solvent molecules that quench its emission. [2] When the arms of the cryptand are light-harvesting units they act as an antenna for collecting light and transferring the energy to the lanthanide.[1,3] Research efforts have focused on the development of ligand systems for lanthanides based on podand-type structures,[3,4] calixarenes[5] or helicates.[6] We are interested in the development of neutral lanthanide complexes with ligands that completely encapsulate the ion forming a hydrophobic shell around the metal ion. Rather than using a highly designed cryptate ligand we aim to use simple lanthanide complexation principles to govern the formation of such species. In order to achieve this, we need strong binding sites that coordinate to the lanthanide and bulky aromatic units that are 'independent/remote' from the binding site and which form the hydrophobic shell. By using remote light-harvesters (rather than harvesters that are themselves the binding units, *e.g.* polypyridines) we can optimize the ion emission by choosing the best sensitizer, aromatic unit, for the ion; this is important as it is rare to find systems that are ideal both for europium and terbium emission. While remote harvesting units have previously been successfully employed in macrocyclic supramolecular structures to enhance the lanthanide emission,[7,8] using lanthanide complexation principles should allow less synthetically challenging open chain ligands to be used.

We have chosen tetraphenyl imidodiphosphinate (tpip) as an ideal ligand with which to test our design.[9] The imidodiphosphinate binding site can chelate to the lanthanide and does not contain any O–H, C–H or N–H bonds in the binding site that can contribute to the quenching of the lanthanide emission.[10] Attached to each of these binding units are four phenyl groups that (i) play the role of remote light-harvesting units and (ii) form a hydrophobic shell around the ion. We wish now to report our studies on the europium and terbium complexes of tpip which demonstrate that the ligands act as light-collector units forming a hydrophobic shell around the ion resulting in highly luminescent europium and terbium complexes. The chemistry contrasts with the analogous lanthanide β-diketonates where the binding site is surrounded by two rather than four aryl units and short lifetimes result from lack of protection of the lanthanide from the water (which limits their applications as sensors or biolabels). [11]



Htpip

Reaction of K(tpip) with $EuCl_3$ or $TbCl_3$, in 3:1 molar ratio, leads to the formation of the neutral complexes $[Eu(tpip)_3]$ and $[Tb(tpip)_3]$, respectively. The complexes have been fully characterized and analysed by spectroscopic methods.† X-Ray quality crystals of $[Tb(tpip)_3]$ were obtained by slow evaporation from chloroform. The crystal structure (Fig. 1)‡ shows that the twelve phenyl groups surround the lanthanide ion, forming a hydrophobic cage leading to a six-coordinate terbium ion. Two molecules in the unit cell which are different in the symmetry around terbium are observed; **1** being a distorted octahedron and **2** trigonal prismatic. Edge-to-face π stacking is present in both structures with C–H to centroid distance of *ca.* 3.0 Å of two phenyl groups in different ligands. Although there is no water coordinated to terbium, in contrast with the praseodymium crystal structure, there is a short van der Waals contact, observed only in **2**, between the terbium ion and a water molecule situated at the top of the trigonal prism with a Tb–O distance of 3.85 Å (expected van der Waals 4.08 Å). The $[Eu(tpip)_3]$ crystal structure is similar to the terbium one with three molecules in the unit cell, in two of which the symmetry around europium is trigonal prismatic and the other one is a



1

Fig. 1 Crystal structure of $[Tb(tpip)_3]$.

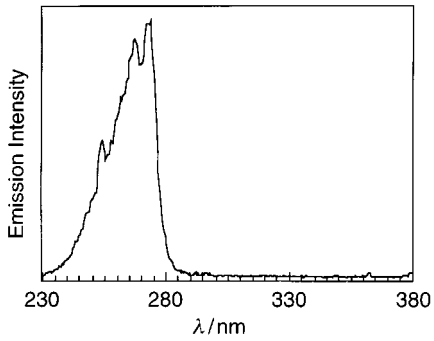


Fig. 2 Excitation spectrum of $[Eu(tpip)_3]$ in $CHCl_3$, λ_{em} = 620 nm.

distorted octahedron. The short water van der Waals distance is again observed only in the trigonal prismatic molecules. The low coordination numbers of europium and terbium are attributed to the bulkiness of the ligands, with the twelve phenyl groups forming a cage around the ion.

Upon excitation at 273 nm (ε = 5,000 $dm^3\ mol^{-1}\ cm^{-1}$) the $[Eu(tpip)_3]$ and $[Tb(tpip)_3]$ complexes exhibit strong emission, red and green respectively, characteristic of the ion. The excitation spectra of the complexes show a band centered at 270 nm, characteristic of the absorption of the ligand confirming that the emission of the complex is due to energy transfer from the ligand to the lanthanide luminescent center (Fig. 2).

Both europium and terbium complexes exhibit long lifetimes in solution compared with previously reported antenna complexes where lifetimes are optimized either for europium or for terbium. The emission lifetimes were found to be 1.8 ms for $[Eu(tpip)_3]$ and 2.8 ms for $[Tb(tpip)_3]$ in dry acetonitrile. Although there is no evidence of water coordination in the crystal structure, addition of water in the acetonitrile solution of $[Tb(tpip)_3]$ and $[Eu(tpip)_3]$ leads to shortening of the emission lifetime by 25 and 43%, respectively. The shortening in the lifetime indicates some involvement of the water molecules in the coordination sphere of the lanthanide. It may be attributed to a twist of the complex conformation in solution to fit the water molecule and agrees with the observed short water van der Waals contacts. The larger effect of water quenching in europium complexes has been well documented.[12]

The quantum yields of the complexes were measured in dry acetonitrile and determined using the method established by Haas and Stein, using $[Ru(bipy)_3]Cl_2$ (Φ = 0.028 in water) and quinine sulfate (Φ = 0.546 in 0.5 M H_2SO_4) as standards for the europium and terbium complex, respectively, taking into account the different excitation wavelength correction.[13] The values obtained are 1.3% for $[Eu(tpip)_3]$ and 20% for $[Tb(tpip)_3]$. We postulate that the quenching of the europium emission *via* an LMCT state is not as effective as in the case of calixarene complexes where the quantum yields of the europium and terbium complexes can differ by more than three orders of magnitude.[5] Further photophysical experiments are currently underway to obtain more information about the mechanism of the energy transfer. The lack of any back energy transfer processes observed when bipyridine ligands are employed in terbium complexes leads to a high quantum yield for terbium.

We have introduced the imidodiphosphinate ligands as successful 'antenna' ligands for sensitizing both europium and terbium emission. The crystal structures of the complexes show unusual six-coordinate lanthanide ions where the ligands form a hydrophobic cage around the ion. We are currently further investigating the formation of these encapsulated lanthanide complexes based on these design principles.

† *Selected spectroscopic data* $[Tb(tpip)_3]$: ^1H NMR (360 MHz, $CDCl_3$, 25 °C, TMS) δ 7.97 (24H, Ar), 7.35 (12H, *p*-Ar), 6.28 (24H, Ar); $^{31}P\{^1H\}$ NMR (146 MHz, $CDCl_3$, 25 °C, 85% H_3PO_4) δ 200.7(s); MS (FAB^+ in *m*-NBA) *m/z* 1408 (MH^+), 991 (M^+ − tpip). $[Eu(tpip)_3]$: ^1H NMR (360 MHz, $CDCl_3$, 25 °C, TMS) δ 7.48–7.54 (m, 24H, *o*-Ar), 7.21 [t, ^3J (HH) 7.4 Hz, 12H, *p*-Ar], 6.95–6.99 (m, 24H, *m*-Ar); $^{31}P\{^1H\}$ NMR (146 MHz, $CDCl_3$, 25 °C, 85% H_3PO_4) δ 37.7(s); MS (FAB^+ in *m*-NBA) *m/z* 1400 (MH^+), 983 (M^+ − tpip). The ^{31}P and ^1H NMR spectra at low temperature in deuterated dichloromethane or acetone reveal only one solution species which contains only one ligand environment. The lifetime measurements are monoexponential. The paramagnetic shifts on ^{31}P confirm the metal coordination. From these observations, we can conclude that (i) there is only one solution species (ii) all three ligands are in identical environments (iii) the ligand is bound to the metal centre. We believe that the only formulation that satisfies all these requirements is $[ML_3]$ similar to that observed in the solid state.

Isolation of the reactive intermediate in palladium-catalysed coupling of secondary phosphine–boranes with aryl halides

Annie-Claude Gaumont,[a] Michael B. Hursthouse,[b] Simon J. Coles[b] and John M. Brown[a]

[a] *Dyson Perrins Laboratory, South Parks Road, Oxford, UK OX1 3QY. E-mail: bjm@ermine.ox.ac.uk*
[b] *Department of Chemistry, University of Wales, Cardiff, UK CF1 3TB*

Received (in Cambridge, UK) 8th October 1998, Accepted 5th November 1998

$Ph_2PH{\cdot}BH_3$ is converted into its K salt with $KOSiMe_3$ in THF, and the anion reacts with (dppp)Pd(Ph)I to produce the complexed secondary phosphine–borane which decomposes to $PPh_3{\cdot}BH_3$ at −10 °C; the C_6F_5 analogue has been crystallographically characterised.

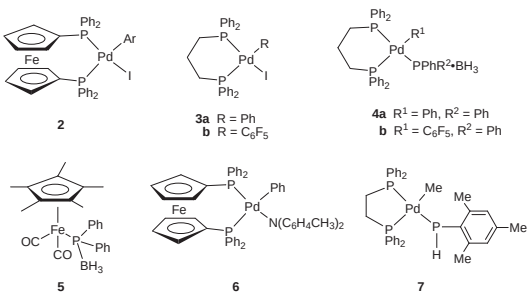
The ability of palladium complexes to effect catalysed σ-bond couplings has been extended significantly in recent years with some emphasis on the formation of C–heteroatom bonds.[1] Formation of C–P bonds has been achieved by the Pd-catalysed reaction of secondary phosphine oxides $R_2P(H)O$ with aryl triflates;[2] if the phosphine rather than the phosphine oxide is desired then either Ni or Pd catalysis with R_2PH as the nucleophile may be effective.[3] Less success has been achieved with secondary phosphine boranes, although the coupling reaction with ArI has been demonstrated.[4]

Following Imamoto's work,[4] satisfactory conditions were established for the catalytic synthesis of triarylphosphine–boranes, *e.g.* $Ar_3P{\cdot}BH_3$ **1a–d** from ArI, but less cleanly from aryl triflates (Scheme 1). An important observation was that the

	R^1	R^2
1a	H	Ph
b	*p*-MeO	Ph
c	*o*-F	Ph
d	H	*o*-An

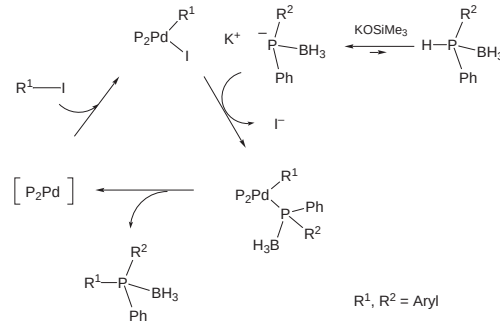
Scheme 1 *Reagents and conditions*: i, $dppfPdCl_2$ (5 mol%), K_2CO_3 (2 equiv.), MeCN, (for **1a**) room temp., 24 h, 92%; (for **1b**) room temp., 18 h, 89%; (for **1c**) 50 °C, 48 h, 74%; (for **1d**) 30 °C, 24 h, 90%.

reaction took place at ambient temperature or below (0 °C). Monitoring by ^{31}P NMR demonstrated that after completion of the reaction, only (dppf)Pd(Ar)I **2** was present when an excess of ArI was used.[5] Initial attempts at defining intermediates in the catalytic reaction were unsuccessful. When complex **2** (Ar = Ph) was generated *in situ* from either the corresponding $(dppf)PdC_8H_8$ complex[6] or $(dppf)Pd(CH_2{=}CHCO_2Me)$[7] rapid reaction with $K^+Ph_2P{\cdot}BH_3^-$ (optimally generated from the secondary phosphine–borane and $KOSiMe_3$; quantitative by NMR spectroscopy) was observed at −70 °C in THF (Scheme 2). The product $Ph_3P{\cdot}BH_3$ could be characterised in



2 **3a** R = Ph, **b** R = C_6F_5 **4a** R^1 = Ph, R^2 = Ph **b** R^1 = C_6F_5, R^2 = Ph

5 **6** **7**



Scheme 2

the solution above −30 °C, but intermediates were too ill-defined to characterise. Hence our attention shifted to the corresponding dppp complexes, known[5,8] to react more slowly than their dppf analogues in the reductive elimination step as a consequence of the smaller chelate bite angle.

Addition of $KOSiMe_3$ to an equimolar mixture of complex **3a** and $Ph_2PH{\cdot}BH_3$ in THF at −70 °C led to an immediate and quantitative change to a single new species whose distinctive ^{31}P NMR spectrum is shown in Fig. 1, revealing the *trans*-relationship of (P1–Pd–P3–B). This is consistent with the structure **4a**, whose spectrum persisted up to 0 °C. At that temperature it decomposed (half-life *ca.* 30 min.) giving rise only to $Ph_3P{\cdot}BH_3$ and an unidentified Pd product; when reaction was carried out in the presence of an excess of PhI, species **3a** was regenerated. The same type of transformation was shown to occur with other secondary phosphine–boranes and other PdArI complexes, as indicated. With more electron-withdrawing aryl groups in Ar–Pd, the elimination step was slower.

The linkage between the stoichiometric and catalytic reactions was strengthened by experiments where the breakdown of adduct **4a**, which led quantitatively to the formation of $Ph_3P{\cdot}BH_3$ **1a**, was followed by ^{31}P NMR (Fig. 2). An identical reaction was carried out with a four-fold excess of both the

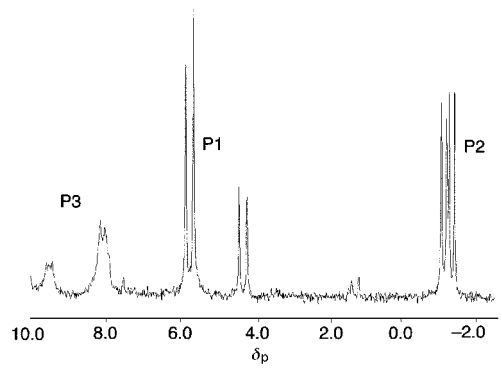


Fig. 1 The ^{31}P NMR spectrum of complex **4b** in THF solution at −50 °C, taken directly after mixing of precursors at −70 °C. Assignments: δ 9.0 (P3, J_{P2P3} 31 Hz), 5.2 (P1, J_{P1P3} 297, J_{P1P2} 43 Hz), −1.35 (P2). On standing at or above 0 °C the reductive elimination product grows in at *ca.* δ 1.

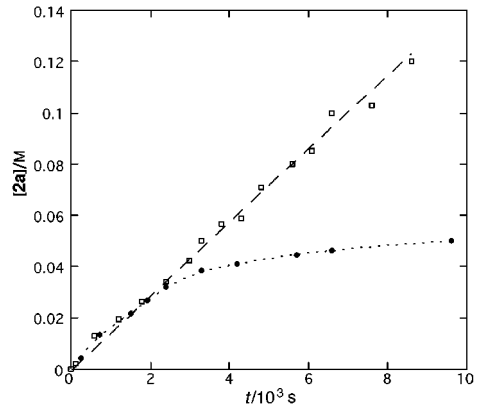

Fig. 2 (●) Stoichiometric formation of borane **1a** from breakdown of complex **4a**, 0.0532 M in THF at 0 °C, reaction followed by loss of **4a** in the ^{31}P NMR spectrum, dotted line is smoothed curve. (□) Catalytic turnover of a mixture of PhI and $KPh_2P{\cdot}BH_3$ (both 0.213 M) in THF at 0 °C in the presence of complex **3a** (0.0532 M), followed by the appearance of borane **1a**. The dashed line is the predicted rate of turnover based on the rate-constant 2.9×10^{-4} s^{-1} derived for the stoichiometric process above.

anion and PhI, and catalytic turnover was followed by the appearance of **2a**. Within experimental error, the rate of catalytic turnover is defined by the rate of the reductive elimination step. This provides firm support for the mechanism suggested in Scheme 2. A correlation between reductive elimination and catalytic turnover has been observed for the C–C bond forming step in the breakdown of (dppf)Pd(Ph)Me.[5]

In the extreme case of **3b**, the intermediate complex **4b** was formed cleanly at −70 °C but was stable in solution at ambient temperature for a significant period of time (half-life *ca*. 96 h) and could be isolated by filtration through silica and precipitation. The isolated material gives rise to phosphine–borane **2e** on redissolution and prolonged standing, accompanied by some decomposition to the phosphine oxide. In characterisation of complex **4b**, we observed an unusual [M − 1] cation peak in the electrospray mass spectrum† which will be the subject of further investigation; such behaviour has previously been observed in the mass spectra of amine–boranes.[9] Recrystallisation (CH_2Cl_2, Et_2O) gave blocks suitable for X-ray analysis.‡ The structure is shown in Fig. 3 and demonstrates a slightly distorted square planar arrangement with the Pd–P bond of the

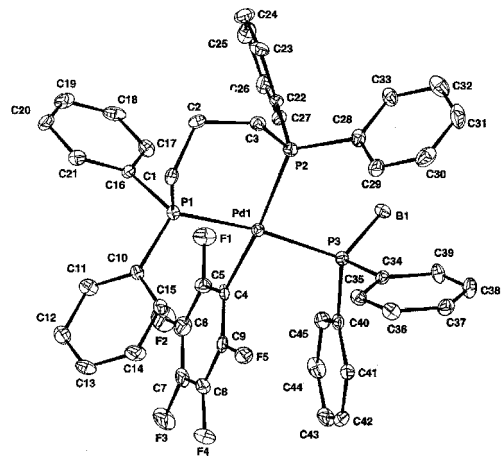

Fig. 3 The X-ray crystal structure of complex **4b**. Selected bond lengths and angles: Pd(1)–P(1) 2.337(2), Pd(1)–P(2) 2.334(2), Pd(1)–P(3) 2.375(2), Pd(1)–C(4) 2.053(6), P(3)–B(1) 1.925(6); C(4)–Pd(1)–P(2) 170.4(2), C(4)–Pd(1)–P(1) 87.6(2), P(2)–Pd(1)–P(1) 90.84(6), C(4)–Pd(1)–P(3) 88.0(2), P(2)–Pd(1)–P(3) 94.35(6), P(1)–Pd(1)–P(3) 173.09(6) B(1)–P(3)–Pd(1) 119.4(2).

phosphine borane only slightly longer than Pd–P bonds in the chelate (0.237 *vs*. 0.233 nm). The only previous example of a simple η^1-coordinated phosphine–borane structure is that of complex **5**, which is a stable isolable material.[10]

These experiments indicate that the catalytic cycle for phosphinylation of aryl iodides with secondary phosphine–boranes is very simple, and the true reactive intermediate is amenable to characterisation. Unlike the corresponding intermediate **6** observed in catalytic amination,[11] it reacts rapidly below ambient temperature and very likely does not involve prior chelate dissociation. Studies of the reductive elimination of neutral Pd phosphido complex **7** and analogous (dppe)Pd η^1-Ar η^1-(PPh_2) complexes have been carried out by Glueck and co-workers,[12] who generated these intermediates by deprotonation of cationic phosphine complexes.

Future work will be directed towards stereochemical control of the P–Pd addition step with a view to applications in the asymmetric synthesis of arylphosphines.

We thank CNRS for granting leave of absence to A-C. G., EPSRC and NATO for support and Johnson-Matthey for loans of Pd salts. We greatly appreciate an open exchange of information with Professor David Glueck (Dartmouth).

Modulating the pH-dependent redox potential of a flavin analog *via* incorporation into a self-assembled monolayer on gold

Suk-Wah Tam-Chang,* James Mason, Isaac Iverson, Ki-Oh Hwang and Christa Leonard

Department of Chemistry, University of Nevada, Reno, Nevada 89557, USA. E-mail: tchang@chem.unr.edu

Received (in Columbia, MO, USA) 10th August 1998, Accepted 19th November 1998

We report the first example of modifying the pH-dependent electrochemical properties of a flavin analog on gold by changing the pK_a value of its N^1 proton.

Flavoenzymes are important electron shuttles in a wide range of biological redox reactions.[1] The redox potential of flavin (the redox active moiety of flavoenzymes) varies by at least 600 mV, as governed by binding in different apoproteins. Non-covalent interactions (including π-stacking,[2] hydrophobic effects, hydrogen bonding, and electrostatic interactions)[3] between flavin and apoproteins play important roles; however, it is difficult to examine the effects of individual interactions in complex biological systems. A fundamental understanding of environmental effects on the flavin redox potential can be expected to provide insight into biological mechanisms for tuning the redox potential of flavoenzymes. In addition, control over its redox activity may increase selectivity of electrocatalysis in synthetic devices.[4] Monolayers prepared from alkanethiols or disulfides with electroactive derivatives[5] are commonly used for studying environmental effects on electron-transfer kinetics.[6] The present work presents novel self-assembled monolayer (SAM) formation based on an alkanethiolate derivatized flavin analog[7] and the modulation of its redox properties *via* incorporation into SAMs.

Disulfide **1** was synthesized according to the procedure outlined in Scheme 1.[8] SAMs containing isoalloxazine (the heterocyclic ring system of flavin) were prepared by immersing a gold coated (500 Å) silicon wafer in an acetonitrile solution of **1** and were characterized by cyclic voltammetry (Fig. 1). Flavin and its analogs undergo two reversible one-electron reduction steps with overlapping potentials in aqueous buffer solutions (Scheme 2).[9] The surface coverage was calculated to be *ca.* 5×10^{-10} mol cm^{-2} by integrating the area under the oxidation or reduction peak. This surface coverage coincides with a densely packed film of the flavin based on modeling the molecular area expected for a flavin unit. The pH-dependent formal potential (E^0) of the bound isoalloxazine moiety was determined from the mean value of the cathodic and anodic peak potentials. Upon changing from acidic to basic conditions, the full-widths at half maxima of the peaks increase. This change may be indicative of structural heterogeneity or differences in the rates of electron transfer for the two electron transfer steps (Fig. 1).

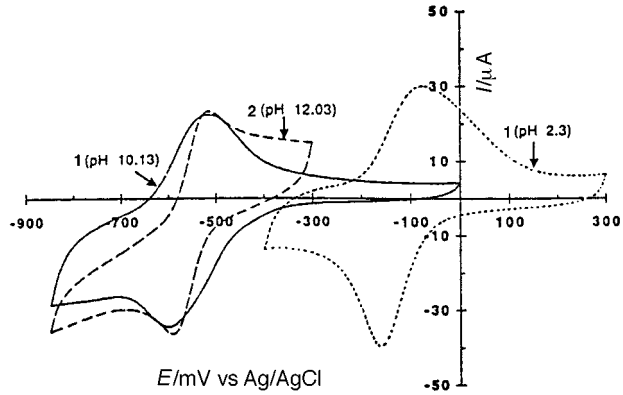

Fig. 1 Cyclic voltammogram (steady state cycle) of (a) (·····) a SAM from **1** in an aqueous buffer solution of pH 2.3, (b) (——) a SAM from **1** in an aqueous buffer solution of pH 10.13, and (c) (- - - - -) **2** (1 mM) in an aqueous buffer solution of pH 12.03. A bare gold working electrode is used in the determination of E^0 of **2**. Scan rates are 0.1 V s^{-1}.

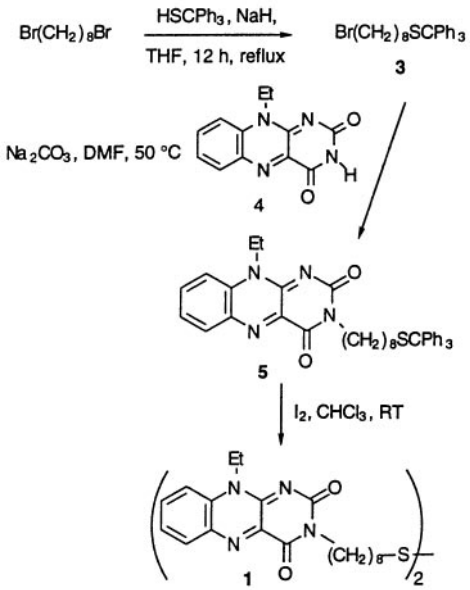
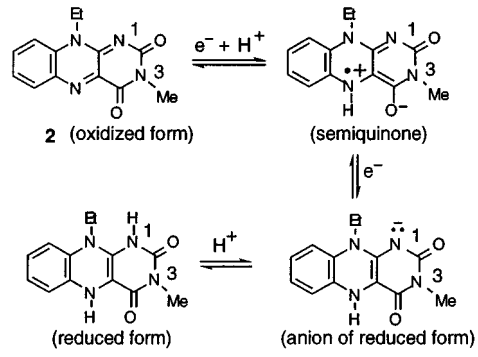
To examine the importance of microenvironment on the one-electron processes of Scheme 2, we compared the pH dependent redox potential of flavin analog **2** in solution (shown in Scheme 2) with that of immobilized isoalloxazine. As shown in Fig. 2, the formal potential of **2** dissolved in solution is linearly related to pH, with a slope of −0.057 V (pH unit)$^{-1}$ up to pH 6.7. After this inflection point the redox processes of **2** remain reversible (Fig. 1); however, the slope changes to −0.027 V (pH unit)$^{-1}$ at higher pH values;[10] The pH at the inflection point is the pK_a of the N^1-proton in the reduced form.[9–11] A pK_a value of 6.7 for the N^1-proton in the reduced form of **2** and the decrease in slope are consistent with those reported for mononucleotide (FMN) and flavin adenine dinucleotides (FAD).[9,12] In contrast, the slope of the E^0–pH plot for the monolayer of **1** is uniform until pH ≈ 10



Scheme 1



Scheme 2

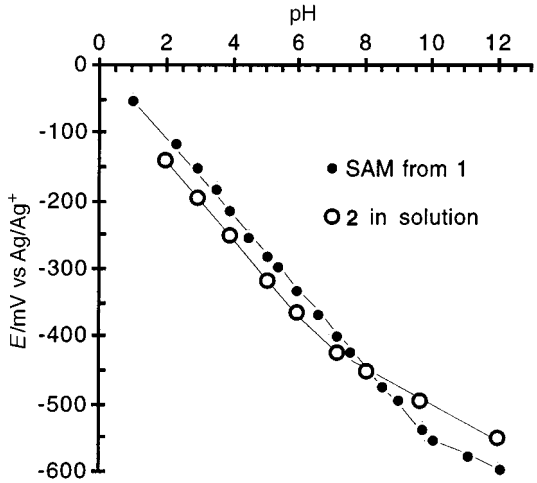


Fig. 2 The pH dependence of redox potential (E^0) of isoalloxazine of **1** in SAM compared with **2** (1 mM) dissolved in aqueous buffer solution.

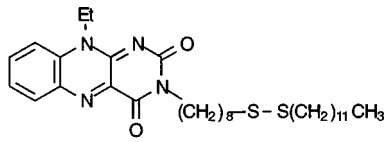
(Fig. 2). The intersection point of the linear portions yields a pK_a value of 9.7. This dramatic increase in the pK_a value indicates that the microenviroment of the N^1-proton in SAM is less polar than the aqueous solution. These results are in line with the observations of Whitesides and coworkers who demonstrated by contact angle measurements increased pK_a values of acidic groups of ω-mercaptoalkanecarboxylic and phosphonic acids upon incorporation into monolayers.[13] They proposed that a low interfacial dielectric constant and/or electrostatic interactions cause the unfavorable formation of negatively charged species in a closely packed monolayer compared with that in water.[13]

We prepared mixed monolayers from unsymmetrical disulfide **6** and dodecyl disulfide or octyl disulfide thereby reducing the surface coverage of the isoalloxazine moiety to



6

about 10% of that in the monolayer from **1**.[14] This reduction of charge/charge repulsion at the interface did not lower the pK_a value of the N^1-proton. In addition, the change in alkyl chain length of the mixed SAM in which N^1-proton is embedded did not influence its pK_a value. These results suggest that the low dielectric constant of the underlying alkyl chains may be the predominant factor influencing the dissociation constant.

In summary, our work demonstrates that the pH-dependent electrochemical properties of the isoalloxazine moiety can be modified *via* incorporation into SAMs, as well as the known mechanisms such as selective H-bonding and π-stacking.

CdS nanoparticle-modified electrodes for photoelectrochemical studies

Stephanie Drouard, Stephen G. Hickey and D. Jason Riley*

School of Chemistry, University of Bristol, Cantock's Close, Bristol, UK BS8 1TS. E-mail: Jason.Riley@bristol.ac.uk

Received (in Exeter, UK) 4th November 1998, Accepted 1st December 1998

A novel method of preparing CdS nanoparticle-modified electrodes is described and a relationship between CdS particle size and the photoelectrochemical properties of such electrodes demonstrated.

Nanocrystalline semiconductors exhibit a wide range of novel chemical and physical properties.[1] Hence research on nanocrystalline semiconductors is developing into a large interdisciplinary field. The properties of nanocrystalline particles differ from those of bulk materials for two reasons. First, the high surface area to volume ratio results in there being almost as many atoms at the surface as in the crystalline lattice. Secondly, the electronic bands are split into discrete energy levels as a result of the three-dimensional confinement of charge carriers. This quantum confinement of charge results in an increase in band gap with decreasing particle size. Indeed determination of the band edge allows the calculation of the particle size.[2] Investigations of how the interesting properties of nanoparticles may be exploited in optoelectronic devices,[3] photovoltaic[4] and clean technology applications[5] are being performed in many laboratories.

CdS is the material of choice when studying quantum confinement effects since methods of controlling the size of CdS nanoparticles are well established.[6–8] The study of charge transfer in nanoparticle systems is an active area of research. Electron exchange in colloidal CdS solutions has been extensively studied using photoelectrochemical[9] and radiolysis techniques.[10] However, if the novel properties of CdS nanoparticles are to be exploited in optoelectronic devices, methods of electrically addressing the particles directly are required. This communication is concerned with the preparation and characterisation of electrodes modified with sub-monolayers of nanoparticles; it is demonstrated that such electrodes allow the optoelectronic properties of the nanoparticles to be probed. In previous studies[11–15] of CdS coated surfaces the nanoparticles have been prepared in inverse micelles and deposited on to gold surfaces using dithiols as molecular anchors. Fourier transform IR spectroscopy,[12] UV–VIS spectroscopy,[13] X-ray photoelectron spectroscopy,[14] scanning tunnelling microscopy[15] and limited electrochemical studies have been performed on such electrodes. In this communication a novel method of preparing CdS nanoparticle modified electrodes is described and initial investigations of the optoelectronic properties of the CdS nanoparticles reported. The method of preparation is considerably simpler than that reported previously and allows deposition of CdS on to optically transparent electrodes; this facilitates studies of the optoelectronic properties of the particles. To illustrate that the CdS nanoparticles at the modified electrode surface may be addressed photoelectrochemically the photocurrent spectra are reported.

The strategy employed in the preparation of the CdS nanoparticle modified electrodes is detailed schematically in Fig. 1. The method is essentially a three-step process. First a tin oxide electrode surface is functionalised[16] using established methods. Then CdS nanoparticles are grown and grafted on to the functional groups.

The tin oxide electrodes were first cleaned in a Piranha bath at 70 °C and then placed in a solution of 3 mol dm^{-3} potassium hydroxide for *ca.* 2 h, in order to activate the surface. The electrode surface was then silanised by immersion in a 1 : 10 (3-mercaptopropyl)trimethoxysilane (MPTMS): methanol solution. The resultant surface possessed pendent thiol groups to which the CdS nanoparticles could be anchored.

The CdS colloidal nanoparticles were prepared in non-aqueous solution using a method first reported by Fischer and Henglein.[7] CdS was formed by bubbling H_2S, (2×10^{-4} mol dm^{-3}), into a 1×10^{-3} mol dm^{-3} $Cd(ClO_4)_2$ THF solution. The resultant colloids were strerically stabilised by addition of hexanethiol to the THF. It has been shown that the CdS nanoparticle size may be controlled by varying the hexanethiol concentration.

Initial attempts to attach the CdS nanoparticles to the functionalised surface involved the immersion of the electrodes in a solution containing CdS nanoparticles. This strategy proved unsuccessful; it has been reported[7] that stabiliser exchange is not possible with colloids prepared by this procedure. Hence, to obtain the CdS nanoparticle electrodes the functionalised tin oxide surfaces were immersed in the THF solution during colloid formation, in order that the surface-colloid bonds are formed as nanoparticle growth proceeds. The size of the particles was controlled by varying the hexane thiol concentration, solutions containing 0.400, 8.57×10^{-3} and 5.275×10^{-3} mol dm^{-3} of the stabiliser were studied. After rigorous washing the photoelectrochemical properties of the electrodes were investigated.

Prior to photoelectrochemical investigations of the modified electrodes the UV–VIS adsorption spectra of the parent

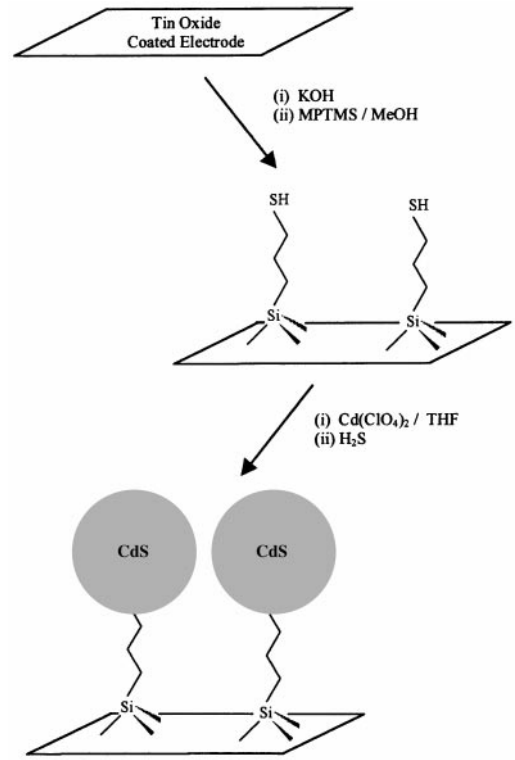

Fig. 1 A schematic of the method employed for the preparation of the CdS nanoparticle modified electrodes [MPTMS = (3-mercaptopropyl)trimethoxysilane].

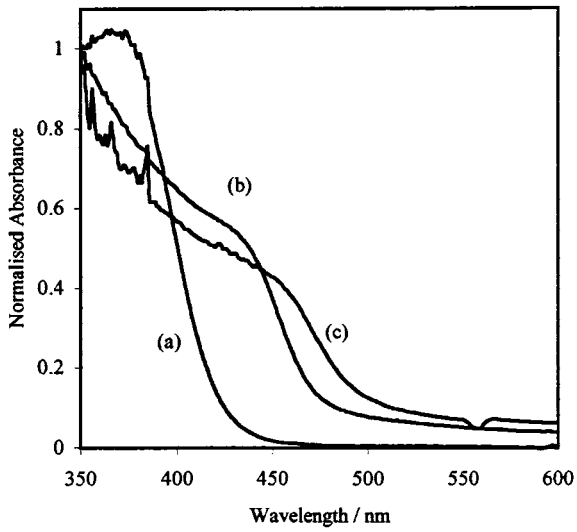

Fig. 2 Normalised UV–VIS absorbance spectra of CdS colloidal suspensions. The suspensions were prepared using varying concentrations of hexanethiol: (a) 0.400, (b) 8.57×10^{-3} and (c) 5.275×10^{-3} mol dm^{-3}.

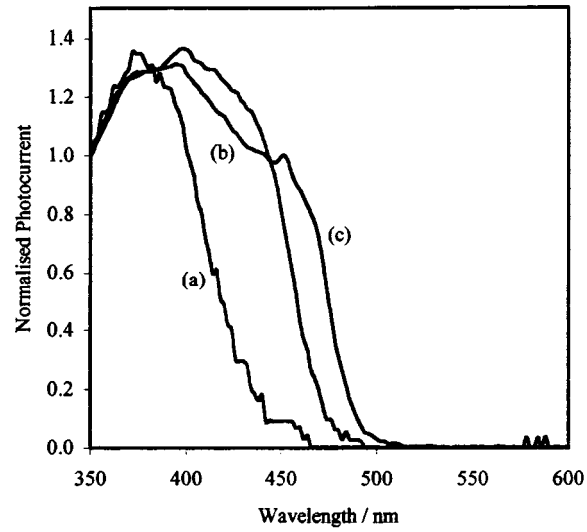

Fig. 3 Normalised photocurrent spectra of CdS nanoparticle modified electrodes. The electrodes were prepared using varying concentrations of hexanethiol: (a) 0.400, (b) 8.57×10^{-3} and (c) 5.275×10^{-3} mol dm^{-3}.

colloidal suspensions were recorded. The spectra for the suspensions prepared using the three different hexanethiol concentrations are shown in Fig. 2. It is apparent that by controlling the stabiliser concentration it is possible to change the band gap of the CdS nanoparticles formed in the solution phase. The sizes of the nanoparticles were determined from band-edge measurements. It was found that hexanethiol concentrations of 0.400, 8.57×10^{-3} and 5.275×10^{-3} mol dm^{-3} result in CdS nanoparticles in the colloidal suspension of 2, 4 and 10 nm diameter, respectively. More detailed studies of the influence of hexanethiol concentration on nanoparticle size in colloidal suspensions have been published.[7]

It was necessary to determine the band gap of the nanoparticles formed at the electrode interface in order to verify that they were of the same size as those formed in the solution phase. Unfortunately it was not possible to record the UV–VIS adsorption spectra for the modified electrodes as the CdS particles were present in sub-monolayer quantities. Hence, the optical properties of the CdS nanoparticles at the modified electrode surfaces were characterised using the more sensitive technique of photocurrent spectroscopy. All electrochemical experiments were performed at 0.2 V *vs.* Ag|AgCl| 3 mol dm^{-3} NaCl in a 1.0 mol dm^{-3} aqueous Na_2SO_3 solution buffered at pH 12. The photocurrent spectra were recorded using chopped monochromatic light and a lock-in amplifier. Photocurrent spectra for modified electrodes prepared using the three different hexanethiol concentrations are shown in Fig. 3. The excellent agreement between the UV–VIS spectra and the photocurrent spectra indicates that the particles deposited on the electrode surfaces were of the same size as those in the parent suspension.

In conclusion, a method of preparing optically transparent electrodes modified with sub-monolayers of CdS nanoparticles has been developed. Further, it has been shown that the size of the CdS nanoparticles on the surface can be controlled by varying the hexanethiol concentration. The photocurrent experiments demonstrate that the physical properties of the CdS nanoparticles at the surface can be addressed using photoelectrochemical techniques. Intensity-modulated photocurrent spectroscopy studies of the effect of quantum confinement on the kinetics of charge transfer from photoexcited CdS nanoparticles are presently in progress.

Selective adsorption of Hg^{2+} by thiol-functionalized nanoporous silica

Jennifer Brown,[a] Louis Mercier*[a] and Thomas J. Pinnavaia[b]

[a] *Department of Chemistry and Biochemistry, Laurentian University, Sudbury, Ontario, Canada P3E 2C6. E-mail: lmercien@nickel.laurentian.ca*

[b] *Department of Chemistry and Center for Fundamental Materials Research, Michigan State University, East Lansing, Michigan 48824, USA*

Received (in Cambridge, UK) 16th September 1998, Accepted 30th November 1998

Thiol-functionalized nanostructured silicas with uniform porosities exhibit selective complexation affinity for Hg^{2+}, while other metal ions (Cd^{2+}, Pb^{2+}, Zn^{2+}, Co^{3+}, Fe^{3+}, Cu^{2+} and Ni^{2+}) have little or no binding ability with the adsorbents.

Effective metal ion adsorbents have been prepared by the immobilization of thiol ligands onto the surface of various substrates, including silica gel,[1,2] clays,[3,4] polymers[5] and, most recently, mesoporous silica.[6–8] The effectiveness of such materials in binding metal ions has been attributed to the complexation chemistry between the ligand and the metal, the specificity of a particular ligand towards target metal ions being the result of a conventional acid–base interaction between the two. Although some of these thiol-functionalized adsorbents can exhibit specific interactions with soft Lewis acids (such as Hg^{2+}, Cd^{2+}, Pb^{2+} and Ag^{+}),[1–4] the selectivities of these materials are usually unremarkable because many metals have the ability to bind with thiol ligands. In this study, we have prepared a series of nanostructured thiol-functionalized silica adsorbents with uniform porosity[9–11] and investigated their affinity for heavy metal ion binding.

Nanostructured adsorbents with variable loadings of thiol groups were prepared by stirring tetraethoxysilane (TEOS) and 3-mercaptopropyltrimethoxysilane (MPTMS) in 0.116 M *n*-octylamine solutions at room temperature [the molar composition of each mixture was 0.22 surfactant : $(1 - X)$/100 TEOS : X/100 MPTMS, where $X = 0$, 2.3, 4.5, 6.9 and 9.0]. After aging for 24 h, the resulting powders were filtered, air dried and washed by Soxhlet extraction over ethanol for 24 h. The materials were labeled as HMS ($X = 0$) and MP-HMS-X, where X represents the percentage of silicon atoms in the synthesis mixture present as MPTMS.

The physical and chemical properties of the functionalized silicas, shown in Table 1, were determined using X-ray diffraction (XRD), N_2 sorptometry and ^{29}Si MAS NMR. The single-reflection XRD powder patterns denoted disordered wormhole structures, with d_{100} values ranging from 2.9–3.4 nm. The N_2 adsorption isotherms showed that the adsorbents had very high surface areas and narrow Horvath–Kawazoe pore size distributions in the micropore range (< 2.0 nm). All of these characteristics are indicative of neutral–surfactant-assembled nanostructured silica frameworks with uniform porosities.[12–14]

Table 1 Physicochemical characteristics of the thiol-functionalized nanoporous adsorbents

Adsorbent	Lattice spacing/ nm	Surface area/ $m^2\ g^{-1}$	Pore diameter/ nm	SH content/ mmol g^{-1}	Hg^{2+} adsorption capacity/ mmol g^{-1}
HMS	3.15	1408	1.95	0	0
MP-HMS-2.3	3.13	1221	1.75	0.35	0.19
MP-HMS-4.5	2.96	1331	1.65	0.68	0.28
MP-HMS-6.9	3.13	1087	1.51	1.0	0.46
MP-HMS-9.0	3.34	1063	1.48	1.3	0.59

Resonances at δ −65 in the ^{29}Si MAS NMR spectra of the adsorbents demonstrated the incorporation of MPTMS within the material frameworks. By comparing the relative integral intensities of the MPTMS signals with respect to the total signal intensity,[9,11] we deduced that the amount of thiol groups incorporated in the materials (Table 1) corresponded within experimental uncertainty to the stoichiometry of the synthesis mixture. Consequently, the surface areas and pore sizes of the materials systematically decrease as a result of the increased coverage of thiol groups on the surface of the pore channels (Table 1). No evidence of thiol group oxidation was found in the materials, as evidenced by the detection of S–H stretching bands in their FTIR spectra (2580 cm^{-1}), and the presence of symmetric signals at δ −27 in their ^{13}C NMR spectra (characteristic of R–CH_2–SH functions[7,9]).

The uptake of metal ions by the adsorbents were determined by titrating aqueous metal ion solutions into a slurry of each adsorbent, stirring for 24 h, and analyzing the supernatant solution for metal ion content using flame AAS (cold-vapour AAS for Hg). This process was repeated until no significant metal ion uptake by the materials was observed. Thus, each adsorbent was tested for their ability to adsorb Hg^{2+}, Cd^{2+}, Pb^{2+} and Zn^{2+} from independent homoionic solutions at neutral pH. The adsorbents exhibited little or no affinity for these metals, with the exception of Hg^{2+}. The very efficient binding of Hg^{2+} ions reduced the metal concentrations to negligible levels (< 10 ppb) until saturation was reached [Fig. 1(a)]. The Hg^{2+} adsorption capacities of the materials systematically increased in proportion to the thiol group content in the materials [up to

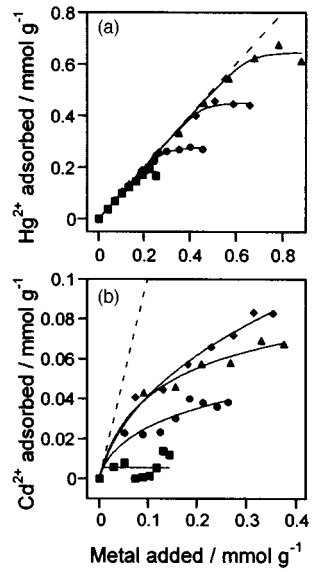

Fig. 1 Homoionic (a) Hg^{2+} and (b) Cd^{2+} uptake curves for MP-HMS-X adsorbents [$X = 2.3$(■), 4.5(●), 6.9(◆) and 9.0(▲)]. The x-axis denotes the total amount of metal added to the system per unit mass of adsorbent. The dashed lines are the unity slopes representing the theoretical total uptake of metal ions.

0.65 mmol g^{-1}, Fig. 1(a)]. Approximately one half of the incorporated thiol groups in each adsorbent is accessible for Hg^{2+} binding (Table 1). The constricted nature of the microporous channels most likely controls access of Hg^{2+} ions to the adsorbents' binding sites.[8,9] Multidentate SH binding with the Hg^{2+} ions may also contribute to the high S:Hg stoichiometry. Of the other metals studied, only Cd^{2+} demonstrated some interaction with the adsorbents [Fig. 1(b)]. As in the case of Hg^{2+}, a correlation between the thiol group content in the adsorbents and the Cd^{2+} loading is denoted, but saturation of the binding sites is reached at very low levels [$<<0.1$ mmol g^{-1}, Fig. 1(b)]. Significant residual concentrations of Cd^{2+} remained in the treated solutions, even at low metal concentrations [Fig. 1(b)]. The adsorbents thus demonstrate considerably weaker affinity for Cd^{2+} than for Hg^{2+}.

By the uptake process described above, the adsorbents were also used to treat a mixed metal solution containing nearly equimolar amounts of Cd^{2+}, Pb^{2+}, Zn^{2+}, Hg^{2+}, Co^{3+}, Fe^{3+}, Cu^{2+} and Ni^{2+}. The uptake of Hg^{2+} from this mixed metal ion solution was virtually identical to the uptake observed for the homoionic solutions [Fig. 1(a)]. Negligible adsorption of the other metals was observed. This demonstrates the remarkable selectivity of the nanoporous adsorbents for Hg^{2+} binding.

That Hg^{2+} ions exhibit high binding affinity towards the immobilized thiol groups is not unexpected. What is unique for the nanostructured adsorbents, however, is their extreme lack of affinity towards other d^{10} metal ions (Cd^{2+}, Zn^{2+} and Pb^{2+}) which usually bind strongly with these ligands (especially in the absence of other competing ions), as observed previously for thiol-functionalized silica gel[1] and montmorillonite.[3] We propose that, while Hg^{2+} has the ability to bind with the thiol groups lining the framework pore channels of the nanoporous adsorbents (representing the bulk of the adsorbent binding sites), the other metal ions are unable to bind to intraframework, complexing only with the comparatively low number of thiol groups present at the external surface of the adsorbent particles.

By comparing these results with those of other sorption studies on similar materials,[1–3] we infer that the uniform porosity of the nanostructured adsorbents is ultimately responsible for their selective adsorption behaviour. The inability of Cd^{2+}, Zn^{2+} and Pb^{2+} to bind to the thiol groups in the adsorbent pore channels may tentatively be explained by the thermodynamic inability of these ions to coordinate within the confined spaces of the pore channels. Using thermodynamic data tables[15] and the model reaction $H_2S + M^{2+} \longrightarrow MS + 2H^+$ to represent the metal ion binding process, we estimate the ΔG^0 value for the reaction in which M = Hg was calculated as -181.6 kJ mol^{-1}, while the free energies of the reactions in which M = Cu, Cd, Pb, Ni and Fe were -85.7, -45.3, -40.9, -0.5 and 11.9 kJ mol^{-1}, respectively. We postulate that the restricted volumes of the channels reduce the ΔS^0 values of the above reactions, resulting in positive (non-spontaneous) ΔG^0 values for most of the intraframework metal–ligand reactions. Only in the reaction with Hg^{2+} is the change in enthalpy (ΔH^0) sufficiently negative to overcome this unfavourable entropy effect and maintain reaction spontaneity. Further investigations are currently underway to verify this hypothesis and to better elucidate the factors involved in metal-ion binding to nanoporous adsorbents.

Received (in Bath, UK) 21st September 1998, Accepted 9th November 1998

In the selective catalytic reduction (SCR) of NO by ammonia, over-exchanged Fe-ZSM-5 prepared by sublimation of $FeCl_3$ into H-ZSM-5, shows superior catalytic activity and stability in a wide temperature range; its activity is promoted by the presence of water in the feed while SO_2 is a weak poison at low but a promoter at high temperatures; its remarkable durability towards H_2O and SO_2 makes this zeolite catalyst a potential choice in Denox applications for stationary sources and heavy Diesel engines with ammonia or urea reductants.

In the selective catalytic reduction (SCR) of nitrogen oxides, metal-exchanged MFI-type zeolites, in particular Cu-ZSM-5, have received much attention due to their ability to catalyze the SCR not only by hydrocarbons,[1–3] but also by ammonia.[4] The insufficient stability of these catalysts has so far prevented their practical application in flue-gas abatement devices. Faced with the tail-gases of combustion engines containing high amounts of water, and often also SO_2, they suffer structural changes leading to deactivation. For the use of hydrocarbon reductants, water is also known as a reversible poison while it has been reported to promote the SCR activity with the reductant ammonia.[4]

In view of these problems, the recent discovery of the remarkable stability of over-exchanged Fe-ZSM-5 in the SCR of NO with isobutane[5] has been considered a breakthrough in flue-gas catalysis research. Further progress has to cope with a reproducibility problem in the preparation of these materials[6] and with the fact that the reductant isobutane that provides the highest reaction rates with these catalysts is impractical for any commercial purpose. We report here a superior catalytic performance of over-exchanged Fe-ZSM-5 in the SCR of nitrogen oxides with ammonia. The catalyst provides excellent activity and selectivity over a wide temperature range. It is promoted by water and, in certain temperature ranges, also by SO_2 (with or without water) and does not suffer any deactivation from these feed components on a time scale of 10–15 h.

The Fe-ZSM-5 was prepared on the basis of a Na-ZSM-5 (Si/Al ≈ 14, Chemiewerk Bad Köstritz, Germany). Iron was introduced by a modified sublimation technique derived from a route described in ref. 7 (sublimation of $FeCl_3$ vapour into the H-form of the zeolite under vacuum). Subsequently, the catalyst was calcined in air at 823 K without any washing step. Elemental analysis showed that this preparation provides an Fe/Al ratio of 1 : 1, which is a formal exchange degree of 300%. The sample will be, therefore, denoted as Fe-ZSM-5-14-300 indicating the Si/Al ratio and the formal exchange degree by the last two figures. A Cu-ZSM-5-14-220 prepared by the conventional ion-exchange method described by Iwamoto *et al.*[8] was also obtained from the same Na-ZSM-5 for use as a reference material.

The SCR of NO by ammonia was carried out in a microcatalytic flow reactor. A calibrated mass spectrometer and a combined non-dispersive IR/UV detector were employed to analyse the reaction product. The feed gas contained 1000 ppm NO, 1000 ppm NH_3, and 2% O_2 (balance He) and was loaded by 2.5% H_2O and/or 200 ppm SO_2 in the poisoning experiments. Under standard reaction conditions, 260 ml min^{-1} of this mixture were fed over 35 mg of catalyst, which results in a space velocity of 304 000 h^{-1}.

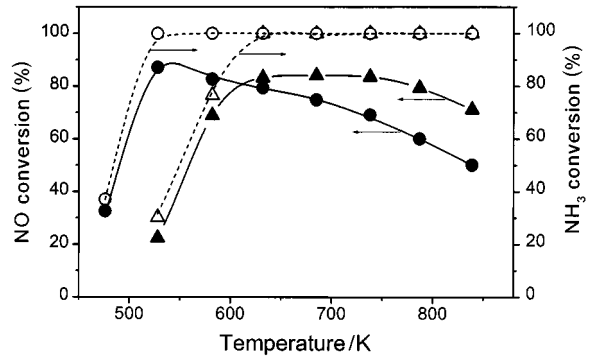

Fig. 1 Selective catalytic reduction of NO by NH_3 with over-exchanged Fe-ZSM-5 and comparison with over-exchanged Cu-ZSM-5. Dry condition: 1000 ppm NO, 1000 ppm NH_3, 2% O_2, balance He; 304 000 h^{-1}, (▲, △) Fe-ZSM-5-14-300, (○, ●) Cu-ZSM-5-14-220, filled symbols, NO conversion, open symbols, NH_3 conversion.

Fig. 1 shows the conversions of NO and NH_3 at different reaction temperatures over Fe-ZSM-5-14-300 and Cu-ZSM-5-14-220. Cu-ZSM-5 is very active for the SCR with ammonia, and the conversions obtained with our preparation are at all temperatures well above those reported in the literature for a somewhat lower space velocity.[4] Fe-ZSM-5-14-300 provides the same conversions as Cu-ZSM-5-14-220 proving inferior only in the low-temperature region (≤573 K). Over this catalyst, the temperature window for high NO conversion is significantly wider than over the Cu catalyst: NO conversions >75% can be held between 573 and 823 K. The ammonia conversion is close to the NO conversion below 423 K, but is 100% at all temperatures above, which makes ammonia slip rather unlikely with such catalysts. Remarkably, the only oxidation product is nitrogen, neither NO_2 nor N_2O formation were detected in the whole temperature range. With Cu-ZSM-5-14-220, ammonia oxidation becomes significant already at 523 K, and since the NO conversion decreases steadily with increasing temperature, the copper catalyst is inferior in the ammonia utilization at almost all temperatures.

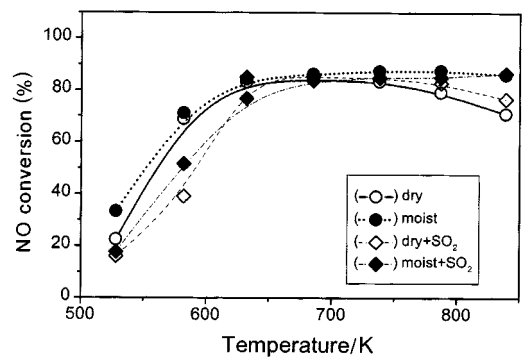

Fig. 2 Influence of water and sulfur dioxide on the NO conversion over Fe-ZSM-5-14-300. Space velocity, 304 000 h^{-1}, dry condition: 1000 ppm NO, 1000 ppm NH_3, 2% O_2, balance He. Moist condition: as dry, with 2.5% H_2O added, '+SO_2', with 200 ppm SO_2 added.

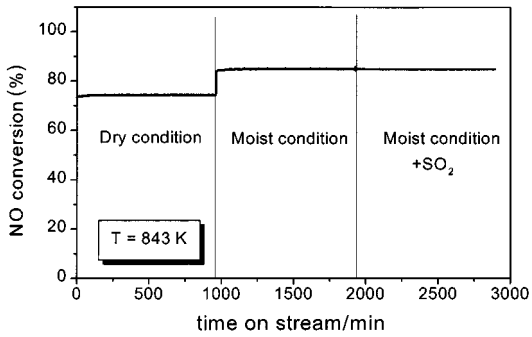

Fig. 3 Durability of Fe-ZSM-5-14-300 under the influence of water and SO_2: dry condition; moist condition; moist condition + SO_2 as in Fig. 2.

The impact of H_2O and/or SO_2 on the NO conversion over Fe-ZSM-5-14-300 is shown in Fig. 2. It is evident that SO_2 exerts a poisoning influence at low temperature both in dry and in moist feed. Remarkably, this effect is reversed at higher temperature: Above 700 K, the NO conversion is always higher with SO_2 present. On the other hand, water promotes the activity at all temperatures over our Fe-ZSM-5, which is similar to the behaviour found with Cu-ZSM-5.[4,9] This is most favourable at the upper end of the temperature range where an NO conversion of 85% (at *ca*. 300 000 h^{-1}) may be held up to a reaction temperature of 850 K in a moist feed stream.

The durability of Fe-ZSM-5-14-300 in various feed mixtures was tested at 840 K (Fig. 3). Under dry conditions, a slight increase of the NO conversion (by *ca*. 3% in 15 h) can be noted. Upon addition of 2.5% H_2O to the feed, a sudden increment in the NO conversion of *ca*. 10% is achieved. Addition of SO_2 into the wet feed does not lead to further changes. No deactivation of the catalyst is observed either in 15 h time-on-stream in moist feed or under the simultaneous action of H_2O and SO_2. It should be noted that such conditions would cause severe deactivation with the Cu-ZSM-5 system.[3]

The preparation of the Fe-ZSM-5 catalyst is critical also for its application to the SCR with ammonia. An Fe-ZSM-5 catalysts obtained by conventional aqueous exchange, which resulted in a formal exchange degree of < 100%, was inferior to Fe-ZSM-5-14-300.[9] In a recent paper,[10] Fe-ZSM-5 prepared by aqueous exchange with subsequent precipitation provided NO conversions below 50%, with considerable N_2O formation at lower temperatures, at a space velocity of only 180 000 h^{-1}. Notably, in the SCR of NO by isobutane, our Fe-ZSM-5-14-300 sample could not compete with Cu-ZSM-5-14-220, and the NO conversions achieved[9] were much lower than those reported by Feng and Hall.[5] In addition, the air calcination step in the catalyst preparation (*vide supra*), which proved deleterious for the SCR with isobutane[9] in accordance with the literature,[6] had a slightly deactivating effect only in the low-temperature range but did not did not affect the peak conversion with ammonia.[9] This implies that the active sites required by the two reactions may be different.

In conclusion, over-exchanged Fe-ZSM-5 prepared by a sublimation technique shows highly promising catalytic performance in the SCR of NO by ammonia. Studies concerning the structure of the active sites in this catalyst and about its behaviour with respect to the oxidation of SO_2 are under way.

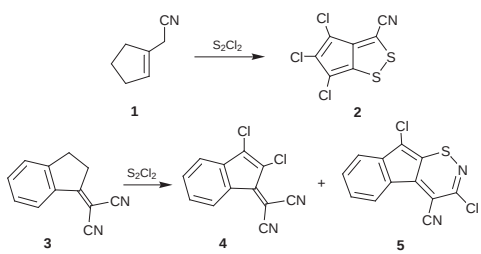
Received (in Liverpool, UK) 8th October 1998, Accepted 18th November 1998

Disulfur dichloride converts 1-(dicyanomethylene)indane 3 into the methyleneindene 4 and the red indeno-1,2-thiazine 5; it also converts inden-3-ylacetic acid 7 into methyleneindenes 8 and 9, dithiolone 10 and the deep purple thiophenone 11; upon melting crystals of 4 and 11 are strongly birefringent and 5 exhibits thermochromicity; mechanisms are outlined for the novel transformations and X-ray crystal structures for 5 and 10 are analysed.

During a search for materials with both novel and useful electronic and optical properties we discovered a simple route to some heterocyclic pseudoazulenes[1] which constitute a new class of discotic liquid crystals where the mesophases are not supported by long aliphatic chains or by H-bonding.[2] The new discotic mesomorphism appears to arise from interactions of central aromatic structures with polarised chlorine, sulfur and cyano groups. In a continuation of this work disulfur dichloride, S_2Cl_2, is shown to react with simple organic substrates to provide new members of this family of molecules which exhibit liquid crystalline behaviour.

We have shown, for example, that S_2Cl_2, NCS and Hünig's base in THF converted 1-(cyanomethyl)cyclopentene **1** into the dark blue trichlorocyclopenta[*c*][1,2]dithiole **2**, crystals of which showed strong birefringence upon melting on a hot stage polarising microscope.[1] We have now selected related indeneacetonitrile and indeneacetic acid derivatives for reaction with the same reagents.

When 1-(dicyanomethylene)indane **3**[3] was treated with 5 equiv. each of S_2Cl_2, Hünig's base and NCS in THF at 0 °C for 3 d and then heated at reflux for 5 h, chromatography gave 2,3-dichloro-1-(dicyanomethylene)indene **4** (90%) as orange crystals, mp 133–135° and then 163–165 °C, and 3,9-dichloroindeno[1,2-*e*][1,2]thiazine **5** (9%) as red crystals, mp 206–208 °C (Scheme 1). The structures of both products followed from their analytical and spectroscopic data and structure **5** was confirmed by X-ray crystallography (Fig. 1).† The ring systems are co-planar to within 0.02 Å with Cl(3) and Cl(9) lying 0.07 and 0.02 Å out of this plane, respectively. The molecules pack to produce slightly distorted close-packed hexagonal sheet arrays, the shortest intermolecular contacts being between the cyano nitrogen atom in one molecule and Cl(3) in a centrosymmetrically related counterpart and *vice versa* (3.18 Å) and between Cl(9) in one molecule and S(1) in the next (3.51 Å) about an independent inversion centre. Adjacent sheets are π-stacked (3.45 Å separation) with the thiazine rings in one sheet overlaying the C_5 rings of another and *vice versa*.



Scheme 1

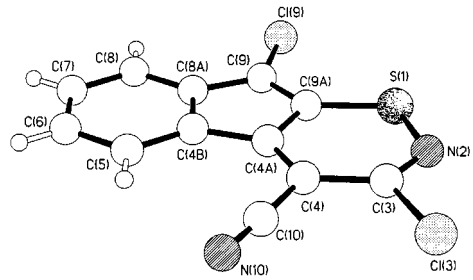


Fig. 1 The molecular structure of **5**.

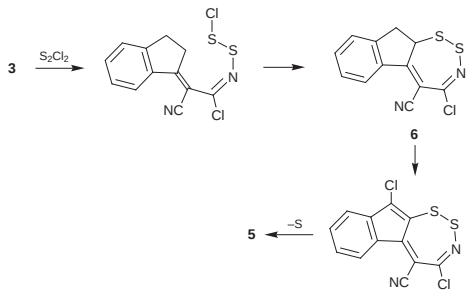
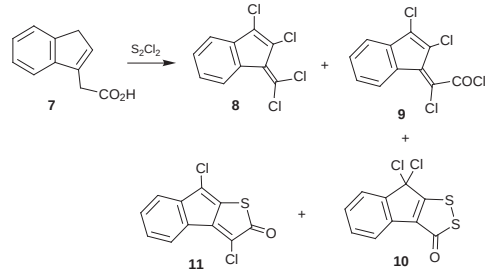
The dichloroindene **4** presumably arises by extensive chlorination and dehydrochlorination, which we have observed in other S_2Cl_2 reactions.[1,4,5] Upon melting on a hot stage polarising microscope, compound **4** exhibited strong birefringence indicative of liquid crystallinity, whilst the indenothiazine **5** showed reversible thermal transitions from red to blue crystals and gave a blue molten phase. Compound **5** also gave blue solutions in common organic solvents, with λ_{max} = 653 nm, ε = 946 in CH_2Cl_2.

A possible pathway, initiated by addition of S_2Cl_2 to a nitrile bond,[6] for the conversion of dicyanide **3** into thiazine **5** is outlined in Scheme 2.



Scheme 2

Inden-3-ylacetic acid **7**[7] was similarly treated with S_2Cl_2, Hünig's base and NCS in THF, $CHCl_3$, or $(CH_2Cl)_2$ to give four products (Scheme 3) in varying yields: the yellow tetra-



Scheme 3

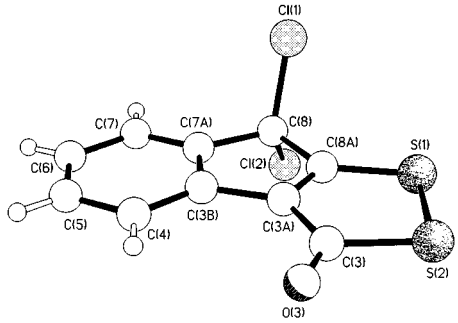


Fig. **2** The molecular structure of **10**.

chloroindene **8**, mp 80–83 °C, in up to 32% yield, the deep yellow acid chloride **9**, mp 96–98 °C (33%) and two unexpected sulfur heterocyclic compounds **10**, mp 97–98 °C (yellow, 51%) and **11**, mp 88–90 °C and then 124–125 °C (deep purple, 37%); combined yields were up to 85%. Structures **8–11** are based on analytical and spectroscopic data, and structure **10** was confirmed as 8,8-dichloro-3,8-dihydroindeno[2,3-*c*][1,2]dithiol-3-one by X-ray crystallography (Fig. 2).† The crystals contain two independent molecules each with very similar geometries, the fused ring systems being co-planar to within 0.09 Å in one and to within 0.04 Å in the other. The out of plane distortions are a consequence of a slight folding (6° in one molecule and 3° in the other) about an axis passing through C(8) and bisecting the C(3A)–C(3B) bond. Pairs of independent molecules are arranged to form essentially co-planar tetrads, interlinked *via* strong O···S interactions[8] [Fig. 3(*a*)–(*d*)] ranging between 2.88 and 3.14 Å. Both the benzo and dithiolo rings are involved in π–π stacking with their symmetry equivalent neighbours.

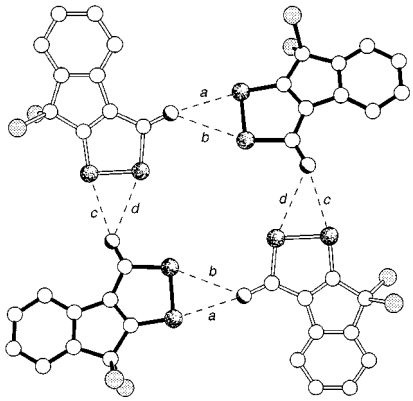

Fig. **3** One of the near co-planar tetrads present in the crystals of **10**. The intermolecular O···S contacts are (*a*) 2.91, (*b*) 3.14, (*c*) 2.88 and (*d*) 3.10 Å. The closed and open bonds serve to distinguish between the two crystallographically independent molecules present in the asymmetric unit.

The highly delocalised 3,8-dichloro-2*H*-indeno[2,1-*b*]thiophen-2-one structure **11** is tentatively assigned to the purple product; this retains the carbon connectivity of the starting material **7**, now fully unsaturated and substituted. Encouragingly, compound **11** also showed birefringence on melting on a hot stage polarising microscope.

Routes to the dithiolone **10** and thiophenone **11** from **7** can be envisaged (Schemes 4 and 5). The former is based upon the propensity of the reagents to form 1,2-dithioles with activated allylic substrates, accompanied by extensive chlorination–dehydrochlorination.[4,5,9] The latter, in a new type of S_2Cl_2 reaction, is based on the rare conversion of acids into acid chlorides by S_2Cl_2.[10] An intermediate in this transformation *e.g.* **12**, could be diverted by cyclisation, ultimately to form **11**.

Thus we have shown that some very simple indenes are readily converted by S_2Cl_2 directly into new liquid crystalline and thermochromic materials.

Effect of a cobalt(II) complex on the radical reaction of vinyl type sulfides. A 'radico-catalysis'

Masaru Tada,* Tomohiro Uetake and Yoshinobu Hanaoka

Department of Chemistry, the Advanced Research Center for Science and Engineering, and Materials Research Laboratory for Bioscience and Photonics, Waseda University, Shinjuku, Tokyo 169-8555, Japan.
E-mail: mtada@mn.waseda.ac.jp

Received (in Cambridge, UK) 4th November 1998, Accepted 27th November 1998

Vinyl type sulfides show increased radicophilicity at the β-position *via* the coordination to a cobalt(II) complex, and hence the balance between Smiles rearrangement and an *ortho*-substitution, in vinyl type sulfides having an intramolecular alkyl radical, is lost to favor the latter reaction.

Acid and base catalysis generates a 'paired electron hole' [eqn. (1)] and a 'paired electron pool' [eqn. (2)], respectively. Likewise radical catalysis can be defined as the generation of 'unpaired electron density' at the reaction center [eqn. (3)].

Acid catalysis: RX + Acid ⟶ $R^{\delta+}$---X---$Acid^{\delta-}$ (1)
Base catalysis: RX + Base ⟶ $R^{\delta-}$---X---$Base^{\delta+}$ (2)
Radico-catalysis: RX + •(Rad) ⟶ $R^{\delta\bullet}$---X---$Rad^{\delta\bullet}$ (3)

We have demonstrated that a cobalt(II) complex, cobaloxime(II),[1]† accelerates the radical substitutions on the sulfur of a thioester group [eqn. (4)][2] and the radical 1,2-rearrangement of a thioester group [eqn. (5)].[2,3] Caddick *et al*.,[4] Aldabbagh and

$$Me\bullet + RCOSAr \xrightarrow{[Co^{II}]L} MeSAr + RCO\bullet \quad (4)$$

(5)

Bowman,[5] and Tada *et al*.[6] showed the usefulness of the sulfur function in the radical annelation on indole and benzimidazole systems, in which the intramolecular alkyl radicals attack the *ipso*-position to yield indoleno or benzimidazoleno carbocycles by the extrusion of the sulfur function. We have suggested the effect of cobaloxime(II) in the radical annelation of 2-phenylthioindole *via* an intramolecular *N*-alkyl radical.[6]

Here we report another type of radico-catalysis by cobaloxime(II) in the radical annelation of benzothiophene and uracil derivatives. Coordination of a vinyl type sulfide to cobalt(II) generates an unpaired electron (spin) density on the sulfur, which can delocalize to the β-position of the vinyl group as shown in Fig 1. The coordination has been proven *via* an EPR

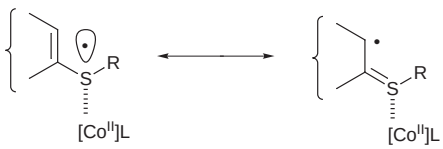

Fig. 1 Resonance expression of spin delocalization in a sulfur–cobalt(II) complex.

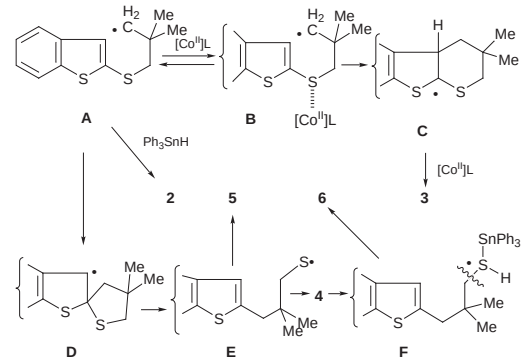
study by us[7] and characterized by back donation from cobalt(II) to sulfur. The bonding force of this back donation makes the unstable two-centered three electron bond feasible.

Homolysis of triphenyltin cobaloxime produces a triphenyltin radical and cobaloxime(II) [eqn. (6)] but the former dissipates *via* reaction with a halide to leave an organo radical [eqn. (7)]. Thus the organo radical and cobaloxime(II) coexist in the reaction system and associate by the coordinative interaction discussed above [eqn. (8)]. The interaction of the vinyl type

$Ph_3Sn[Co]L \longrightarrow Ph_3Sn\bullet + [Co^{II}]L$ (6)
$RBr + \bullet SnPh_3 \longrightarrow R\bullet + Ph_3SnBr$ (7)
$R\bullet + [CO^{II}]L \longrightarrow (R\bullet)\text{---}[CO^{II}]L$ (8)

sulfide and the cobalt(II) species may increase the radicophilicity of the vinyl moiety.

Thus 3-(benzothiophen-2-ylthio)-2,2-dimethylpropyl bromide **1** was treated with triphenyltin cobaloxime under heating and the products **3** and **5** were obtained as shown in Scheme 1. The thermolysis gives the cobaloxime(II) radical and the intermediate radical **A** which interact with each other by the coordination discussed above to give radical **B** and thus product **3** (Scheme 2).



Scheme 2

Treatment of bromide **1** with Ph_3SnH–AIBN gave the products **4** and **6** after Smiles rearrangement by an addition–elimination mechanism (**A**→**D**→**E** in Scheme 2)[8] and the reduction product **2**. Thus the cobaloxime(II) in the reaction system evidently accelerates the radical attack on the 3-position of benzothiophene and *ortho*-substitution becomes competitive with the radical Smiles rearrangement.[8–10] On the other hand, in

	2	3	4	5	6
$Ph_3Sn[Co]L$ / 130 °C‡	—	17%	—	70%	—
Ph_3SnH–AIBN / 80 °C§	11%	—	71%	—	14%

Scheme 1

	7	8	9	10	11	12
n = 1 Ph_3Sn[Co]L‡	—	—	73%	—	—	—

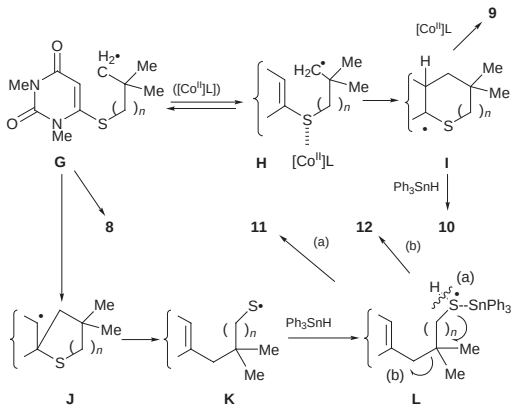
Scheme 3

addition to product **2**, only the products of Smiles rearrangement were obtained without cobaloxime(II). The formation of the product **6** is accounted for by radical substitution on sulfur through the radical intermediate **F**. A reasonable mechanism for formation of these products is shown in Scheme 2.

Next we tested the effect of cobaloxime(II) on the radical from *n*-(1,3-dimethyluracil-5-ylthio)-2,2-dimethylalkyl bromide **7** and a similar acceleration effect was observed for the *ortho*-substitution, as shown in Scheme 3. Bromide **7** (*n* = 1) gave the substitution product **9** in the presence of cobaloxime(II) whereas the reaction with Ph_3SnH gave the addition product **10** and the products **11** and **12** formed *via* Smiles rearrangement (Scheme 4).

Both Smiles rearrangement *via* a six-membered intermediate (**J**) (*n* = 2) and *ortho*-addition *via* a seven-membered intermediate (**I**) (*n* = 2) are slow and the only product from the reaction of Ph_3SnH and bromide **7** (*n* = 2) is the direct reduction product. The reaction with triphenyltin cobaloxime, however, gave the *ortho*-substitution product **9** (*n* = 2) as a major product, however the intramolecular radical addition is still slow and hydrogen abstraction form the solvent to give product **8** (*n* = 2) is the dominant process. A reasonable mechanism for formation of **8**–**12** is illustrated in Scheme 4. The intermediate radical **I** (*n* = 1) which gives **10** (*n* = 1) is formed even without cobaloxime(II), although with lower efficiency, while radical **I** (*n* = 2) which gives **9** (*n* = 2) is formed only with the assistance by cobaloxime(II). The intermediates **I** (*n* = 1,2) give products **9** (*n* = 1,2) with hydrogen elimination by cobaloxime(II) and the product **10** (*n* = 1) *via* hydrogen abstraction from the tin hydride. Products **11** and **12** derive from the intermadiate **L** (*n* = 1) *via* hydrogen elimination [route (a)] and the fragmentation process [route (b)], respectively, after Smiles rearrangement (Scheme 4).



Scheme 4

All the experimental results shown here suggest an acceleration effect of cobalt(II) species on the radical attack of an alkyl radical on a vinyl type sulfide. Thus the coordination of a vinyl sulfide to a paramagnetic cobalt(II) complex generates a spin density at the β-position and makes the β-position more radicophilic. We propose a term 'radico-catalysis' for this effect even though the reaction is stoichiometric and not 'catalytic' in the correct sense.

Experimental details and structural assignments of the products will be reported in a full paper.

The present work was supported by Waseda University and the Ministry of Education, Culture, and Sports of Japan through an Annual Project Program and a Grant-in-Aid for Scientific Research, respectively

Facile synthesis of amino-functionalised ferrocenes and vanadocenes

Sam Bradley, Patrick C. McGowan,* Karrie A. Oughton, Mark Thornton-Pett and Mark E. Walsh

School of Chemistry, University of Leeds, UK LS2 9JT. E-mail: p.c.mcgowan@chem.leeds.ac.uk

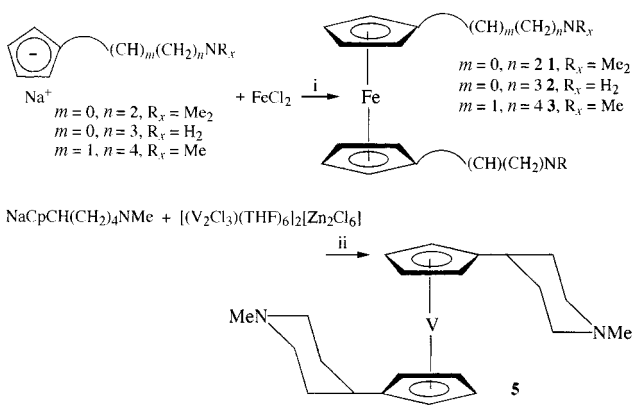
Received (in Cambridge, UK) 6th November 1998, Accepted 27th November 1998

We report a general and high yielding route to the synthesis of late and early metallocenes; reported is an amino-functionalised vanadocene which is an unusual example of a 1,1-substituted vanadocene outside of a group 14 substituted derivative.

The importance of metallocenes has been documented recently with potential applications in several areas of chemistry.[1,2] There has been a considerable amount of research done with functionalised ferrocenes, and besides potential therapeutic activity,[3] other useful functions with these types of molecules have been their ability to recognise neutral molecules,[4] as well as cations and anions.[5] Multidentate functionalised ferrocenes have also been prepared where there are more than two donor heteroatoms.[6] These, like many bis-functionalised ferrocenes, start with ferrocene as the starting material and quite often there are many steps to arrive at the end product. For example, there has been a report of one primary alkylaminoferrocene synthesised in small amounts, but this takes four steps starting from ferrocene.[7] Whilst it is relatively facile to make the mono-functionalised aminoferrocene, it is somewhat more difficult to make the bis-functionalised analogues. The main problem about preparing bis-1,1-aminoferrocenes is the poor yield of the substitution of the second ring.

Conversely, research into vanadocene chemistry has been remarkably low. This is unfortunate given the potential anti-tumour properties of such complexes,[8] but one of the main problems is the highly sensitive nature of these compounds.[2] With both of these criteria in mind, this paper presents a general, convenient and efficient method of synthesising bis-functionalised ferrocenes and vanadocenes from the parent substituted cyclopentadienyl analogue and the appropriate metal halide. We have deliberately chosen a late and an early metal derivative to show the general nature of the methodology.

A high yielding route to synthesise and isolate the pure amino-functionalised sodium cyclopentadienide salt routinely on a scale of 15–20 g has been developed.[9] Using this method, we can methodically and easily vary the length of the spacer group between the cyclopentadienyl group and the amino group; the substituents attached to the nitrogen atom can also be modified. This paper describes the high yielding route to different bis-1,1-amino-ferrocenes and -vanadocenes which have different spacer groups and end groups. Yields have been typically 65–80%.



Scheme 1 Reagents and conditions: i, THF, 65–76%; ii, THF, 72%.

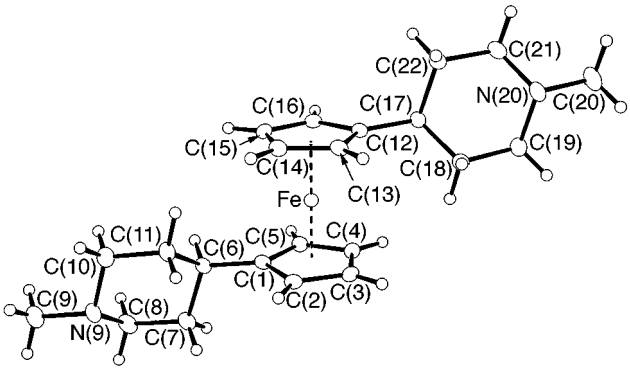


Fig. 1 X-Ray structure of ferrocene **3**.

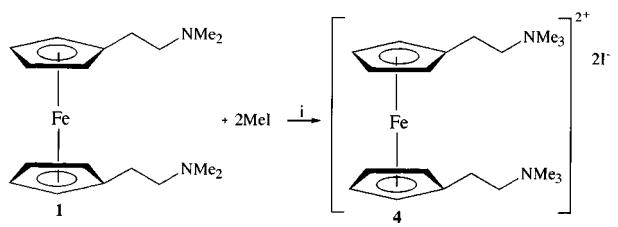
Reaction of 2 equivalents of $NaCp(CH_2)_2NMe_2$ with $FeCl_2$ yields $Fe[Cp(CH_2)_2NMe_2]_2$ **1** in 76% yield as an analytically pure yellow–orange oil (Scheme 1).† Using this versatile and facile method, we can produce primary alkylaminoferrocenes as well. As already mentioned, these compounds are notoriously difficult to synthesise by other means[7] and to our knowledge $Fe[Cp(CH_2)_3NH_2]_2$ **2** is only the second example of this type. It is synthesised by readily available starting materials such as $FeCl_2$ and 2 equivalents of $NaCp(CH_2)_3NH_2$ and has the advantage that it is high yielding and is one step. Decreasing the flexible nature of the substituted arm has a profound effect on the ferrocene in that we can isolate an orange solid $Fe[CpCH(CH_2)_4NMe]_2$ **3** as opposed to the oils obtained for **1** and **2**.‡ The molecular structure§ of **3** can be seen in Fig. 1 and the steric encumbrance of the piperidyl groups is evident as they lie *trans* to each other.

Complex **1** reacts with equivalents of MeI to afford the ferrocene salt $Fe[Cp(CH_2)_2NMe_3]_2^{2+}2[I]^-$ **4** (Scheme 2) which was recrystallised from methanol. **4** crystallises as a yellow microcrystalline analytically pure material which was characterised by ^1H and ^{13}C spectroscopy and again occurs in high yield, 75%. It is methanol and water soluble and air stable. Alternative entry into this class of compound has been achieved by a three step synthesis from ferrocene to yield ferrocene-1,1′-diylbis(methyltrimethylammonium iodide).[10]

The functionalised sodium cyclopentadienide salts can also be used to prepare early metal metallocenes. The only heteroatom ring substituted vanadocenes that we are aware of are $(C_5H_4EMe_3)_2V$ (E = Si, Ge, Sn).[11] Thus, outside of the group 14 ring substituted vanadocenes, we report here an unusual fully characterised example of a 1,1-substituted



Scheme 2 Reagents and conditions: i, Et_2O, 75%.

vanadocene. This has been synthesised using the starting material $[(THF)_3V(\mu\text{-}Cl)_3V(THF)_3]_2[Zn_2Cl_6]$[12] and $NaCpCH(CH_2)_4NMe$ to yield compound **5** in 72% yield. This highly air and water sensitive paramagnetic material is deep purple in colour and difficult to characterise. The X-ray crystal structure§ has been determined and is isomorphous with **3**. We are currently carrying out oxidation reactions of this and other analogues of amino-substituted vanadocenes.[13] It is important to note that, for both the vanadocene and ferrocene analogues highlighted in this paper, we have had no need to use chromatographic techniques and they have been synthesised as analytically pure compounds.

We have also embarked on a strategy of synthesising ligands where there would be more chance of the nitrogen moiety interacting with a metal centre. Therefore we synthesised the ligand **6**. During the course of this work the preparation of the ligand **6** and the thallium salt and the reactivity with group IV transition metals have been reported.[14] We have used our methodology to isolate the sodium salt **7** from the reaction of **6** with NaH giving the new compound **7** which is air and water sensitive. This has been characterised by ^1H and ^{13}C NMR. Like previously reported compounds[9] this compound undergoes exchange with the deuterated solvent (CD_3CN) where the protons from the ring exchange with the deuterons of the solvent.

$$\underset{\mathbf{6}}{C_5H_5CH_2C_6H_4N} + NaH \xrightarrow{THF} \underset{\mathbf{7}}{NaCpCH_2C_6H_4N}$$

In summary, we feel that the generality of our procedures will allow the isolation and tailoring of many types of amino-substituted metallocenes in high yields starting from the sodium salts of the substituted cyclopentadiene and a transition metal halide salt. We have proved this by the isolation of amino-functionalised ferrocenes; especially significant is the isolation of the primary alkylaminoferrocenes. We have also found an effective route into amino-functionalised vanadocenes, which have been synthesised and fully characterised for the first time.

Notes and references

† All compounds were characterised by CHN analyses, ^1H, ^{13}C NMR and FAB mass spectrometry.

‡ A typical procedure is as follows: to a solution of $FeCl_2$ (1 g, 0.0078 mol) in THF (30 ml) was added two equivalents of $NaCpCH(CH_2)_4NMe$ (2.9 g, 0.0176 mol). An orange colour was observed. After several hours the THF was removed under vacuum, and the residues extracted twice with toluene (20 ml) and then dried under vacuum. The product was recrystallised from toluene. Yield = 1.9 g, 67%.

What is the mechanism of phosphoryl transfer in protein kinases? A hybrid quantum mechanical/molecular mechanical study

Jason C. Hart, David W. Sheppard, Ian H. Hillier* and Neil A. Burton

Department of Chemistry, University of Manchester, Manchester, UK M13 9PL. E-mail: ian.hillier@man.ac.uk

Received (in Cambridge, UK) 17th November 1998, Accepted 20th November 1998

Hybrid QM/MM studies suggest that the conserved aspartate in protein kinases is not protonated during the phosphoryl transfer reaction, and thus does not act as a general base.

Protein kinase enzymes are critical to the regulation of cellular signalling pathways and changes in their activity has been linked to several diseases including cancer and diabetes. These enzymes phosphorylate serine (Ser), threonine (Thr) and tyrosine (Tyr) residues at target proteins *via* transfer of the γ-phosphate of adenosine triphosphate (ATP). Around 2000 different protein kinase enzymes are predicted from the human genome[1] and structural data suggest that a conserved catalytic core is present in all such enzymes.[2] A conserved phosphoryl transfer mechanism is predicted with the regions of the protein outside the catalytic core influencing substrate specificity.

A conserved aspartate (Asp) residue is present in the active site which has been widely proposed to act as a general base during the phosphorylation reaction,[3] which involves nucleophilic attack of Ser at the γ-phosphate centre. It has been suggested that the role of Asp is to deprotonate Ser, providing a more powerful nucleophile to achieve phosphate hydrolysis leading to the products shown in Fig. 1(*b*). On the other hand, recent experimental data on serine[4] and tyrosine[5] kinases have questioned whether Asp is basic enough to remove the proton from Ser (compare solution pK_a of 4 and 14 for Asp and Ser, respectively) or Tyr residues. An alternative role is proposed of aligning the OH group before reaction[4] with proton transfer to Asp occurring after the O–P bond is formed.

In an attempt to elucidate the mechanism of phosphoryl transfer in this important class of enzymes we here describe hybrid quantum mechanical (QM)/molecular mechanical (MM) calculations of the potential energy surface associated with this reaction. Such studies have been helpful in the study of the reactions in a variety of enzymes.[6–11] We employ our hybrid QM/MM code[11] which couples the QM code GAUSSIAN 94[12] with the MM code AMBER 4.0[13] to perform the calculations.

We utilised the crystal structure of cAMP dependent kinase (cAPK) complexed with ATP and a peptide inhibitor,[14] building a model of the native system by replacing the alanine residue of the inhibitor with Ser. Energy minimisation of this new residue, keeping the remainder of the active site fixed, was carried out using AMBER. This structure was used as a starting point for subsequent QM/MM calculations with the QM part of the structure consisting of the 46 atoms shown in Fig. 2. The QM region contains the Ser substrate, the conserved Asp and a lysine (Lys) residue (although our conclusions are not altered if Lys is modelled by MM), the triphosphate group and the two Mg ions which coordinate the triphosphate. The bulk of the enzyme and the non-reacting parts of the peptide and ATP substrates were kept fixed during the modelling of the reaction and were represented by around 6200 MM atoms including crystallographic waters. We chose to use the PM3[15] Hamiltonian in the QM calculations due to its success in modelling phosphoryl transfer reactions.[16]

The reaction products resulting from proton transfer from Ser to Asp along with nucleophilic attack at phosphorus leading to ADP and a phosphorylated serine (pSer) dianion [Fig. 1(*b*)] were found to be higher in energy than the reactant structure [Fig. 1(*a*)] by 36 kcal mol^{-1}. However, an alternative product [Fig. 1(*c*)] involving an ionised Asp and a pSer monoanion were found to be lower in energy than the reactants by 24 kcal mol^{-1}. Our computational scheme allows the various contributions to the large energy difference (60 kcal mol^{-1}) between structures in Fig. 1(*b*) and (*c*) to be identified. In the absence of Lys-154 and the rest of the enzyme, the two structures have essentially the same energy in spite of the bulk pK_as favouring the structure in Fig. 1(*c*). This is due to the stabilisation of the phosphate dianion by the magnesium ions. However, interaction with the bulk of the enzyme leads to the preferential stabilisation of the structure in Fig. 1(*c*), with Lys-154 contributing ~20 kcal mol^{-1}. Thus, as a number of authors[17] have emphasised, it is the

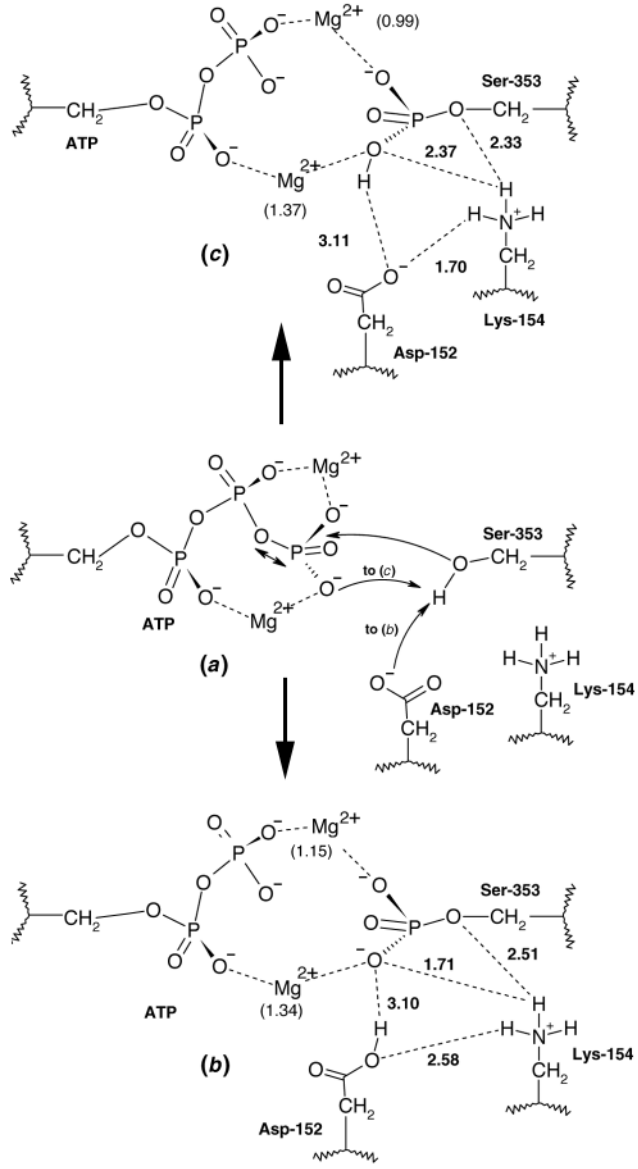

Fig. 1 Alternative mechanisms of phosphoryl transfer in protein kinase, with optimised structures (Å) and, in parenthesis, atomic charges.

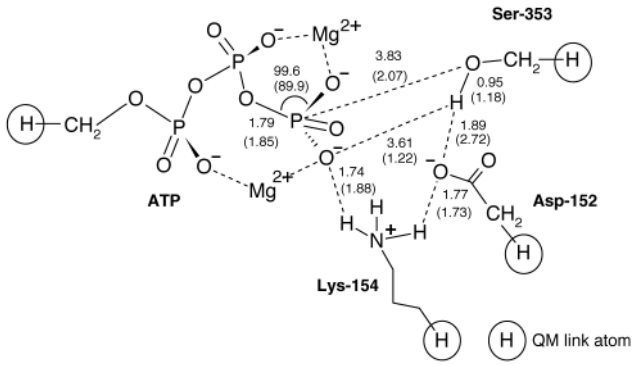

Fig. 2 Optimised reactant, and in parenthesis, transition state geometry (Å) in cAMP dependent kinase.

local electrostatic microenvironment that is important in determining the effective pK_as of the residues, rather than the bulk values (6.3[18] and 4.0[19] for pSer and Asp respectively).

In view of this result we have modelled the potential energy surface for the reaction which involves proton transfer from Ser to a terminal oxygen of ATP and nucleophilic attack at the phosphorus atom of ATP leading to the structure shown in Fig. 1(*c*) without the formation of a high energy serine anion intermediate. The properly characterised transition state (Fig. 2, imaginary frequency 2064*i* cm^{-1}) involves a concerted cleavage of the Ser O–H and P–O(bridge) bonds and formation of H–O(P) and P–O(Ser) bonds, and has a barrier of 39 kcal mol^{-1}. The alternative mechanism involving transfer of the proton from Ser to Asp either before or after O–P bond formation leads to a neutral Asp residue [Fig. 1(*b*)] and has higher barriers in the region of 45–50 kcal mol^{-1}, as well as leading to the higher energy product.

Thus although our calculations at the PM3 level are only semi-quantitative they do suggest that the role of the Asp residue may not be as a general base, but rather to stabilise protonated pSer in the active site [Fig. 1(*c*)]. Such stabilisation by protonation is often observed when two charged groups are in close proximity[20] and the position of a proton between Asp and Glu residues in a protein has been established by high resolution crystallography.[21] The relative pK_a values of pSer and Asp in model systems would suggest that protonation of pSer will be favoured in line with our computational results. A similar mechanism may also be involved in other enzyme catalysed phosphoryl transfer reactions, such as those involving protein tyrosine phosphatases, where a conserved Asp residue is found and is considered to be a general acid.[22] Here protonation of the phosphate terminal oxygen rather than Asp may occur in the reactants. Thus possible enzyme mechanisms other than those in which the Asp is a general acid or base should be considered in these important and widely occurring classes of enzymes.

We thank the EPSRC for support of this work.

A non-hydrolytic route to organically-modified silica

John Hay,*[a] David Porter[b] and Hema Raval[a]

[a] *Department of Chemistry, School of Physical Sciences, University of Surrey, Guildford, UK GU2 5XH. E-mail: j.hay@surrey.ac.uk*

[b] *SMC, DERA, Farnborough, Hampshire, UK GU14 0LX*

Received (in Bath, UK) 21st September 1998, Accepted 26th November 1998

A versatile route to organic–inorganic hybrid nanocomposite materials is described, where organically modified silicon halides and alkoxides are reacted together in a solvent-free non-hydrolytic sol–gel process.

The combination of organic species and inorganic minerals and networks has attracted much interest in recent years for a number of reasons,[1–4] including the development of next generation passive (*e.g.* semi-structural[5]) and active (*e.g.* electronic[6]) materials. Much work has focused on the preparation of sol–gel hybrids, such as the combination of inorganic oxides (particularly silica) with polymers[4,5,7] and the organic modification of silica ('Ormosils') starting from alkylalkoxysilanes.[8–10] All of these methods use the well established hydrolytic route to the oxide. In recent years, the group of Corriu[11–13] and others including ourselves[14,15] have reported the synthesis of inorganic oxides *via* a non-hydrolytic sol–gel route which involves the reaction of a 'metal' halide with an oxygen donor such as an alkoxide, an ether, an alcohol, *etc.* One advantage of this approach is that it can avoid the use of solvents and their associated drawbacks. In addition, residual silanol groups in the product should be substantially reduced because of the different mechanism involved. The method has been extended to the formation of copolysiloxanes[16] and erbium doped methyl-modified silicates.[17] To the best of our knowledge, there have been no reports to date of the extension of this method to the preparation of hybrid Ormosils with a variety of organic groups.

Here, we describe the synthesis of organic–inorganic hybrids using the non-hydrolytic sol–gel method starting from organically modified precursors. Silica hybrids are particularly accessible by this route since the necessary precursors such as alkylalkoxysilanes and alkylchlorosilanes are in many cases commercially available. Related hybrids such as those based on alumina suffer from the serious drawback of the high, sometimes pyrophoric, reactivity of the metal–alkyl bonds. The silica hybrids are represented by the general equations shown below:

$$RSiCl_3 + 0.75Si(OR')_4 \rightarrow [RSi_{1.75}O_3]_n + 3R'Cl \quad (1)$$

$$RSiCl_3 + RSi(OR')_3 \rightarrow [R_2Si_2O_3]_n + 3R'Cl \quad (2)$$

The use of a single organically-modified precursor [eqn. (1)] leads to an Ormosil with only one type of organic modifying group. If both precursors are organically modified [eqn. (2)], the resulting hybrid can contain two different types of organic modification. The organic groups can be alkyl (groups of varying length from methyl to decyl have been used), vinyl or aryl. In a typical experiment, the hexyl-modified silica was formed by reacting hexyltrichlorosilane (5.62 g, 26 mmol) with tetraethylorthosilicate (TEOS) (4.00 g, 19 mmol) in the presence of iron(III) chloride catalyst (0.071 g, 0.73%) under nitrogen. The material gelled within 1–2 days at 35 °C. The resulting solid (containing a colourless liquid) was subjected to Soxhlet extraction using diethyl ether for three days, yielding a white, semi-transparent waxy product (3.92 g, 84%). Elemental analysis gave: C, 39.9; H, 8.1 (Calc. C, 39.5; H 7.2%). The organic content calculated from the elemental analysis is 48.0%, in good agreement with the theoretical value of 46.7%. Thermogravimetric (TG) analysis in nitrogen at a heating rate of 10 K min^{-1} from 40 to 900 °C showed a weight loss of 47%, in excellent agreement with the theoretical organic content. The diffuse reflectance IR spectrum showed C–H stretching vibrations at 2860–2970 cm^{-1}, an $SiCH_2$ deformation band at 1400–1420 cm^{-1} and various Si–O–Si vibrations between 480 and 1210 cm^{-1}. Preliminary BET surface area analysis gave values well below 1 m^2 g^{-1} for the total surface area, but isotherms are complex and are the subject of further work.

Gelation could normally be accomplished at temperatures of 90 °C or below using iron(III) chloride as catalyst.[14] Gel times at 90 °C typically range from a few minutes to several hours depending on the nature of the organic modification. For long alkyl chains and phenyl groups, gel times were longer for the organically-modified systems than for pure silica because of the combined effects of reduction of the concentration of reacting groups and steric hindrance by the bulky organic groups. The presence of short alkyl chains such as methyl and ethyl in the halide precursor had little effect on gel times, the effect of reduced functionality presumably being counterbalanced by the electron-donating capacity of the alkyl groups increasing the reactivity of the silicon halide. This effect is particularly marked in the case of vinyl-modified systems, where use of vinyltrichlorosilane in place of silicon(IV) chloride could reduce the gel times by an order of magnitude. The non-hydrolytic approach therefore provides a rapid route to the Ormosils.

The non-hydrolytic route produces a volatile by-product, in this case an alkyl, aryl or vinyl chloride, hence the liquid produced in the above experiment. The by-product and any unreacted starting materials are easily separated from the product by Soxhlet extraction. In the case of vinyl-substituted silica, and perhaps also the aryl-substituted materials, a possible side reaction is electrophilic attack of 'R^+' (a possible intermediate in the non-hydrolytic reaction[11]) on the double bond leading in the vinyl case to addition of RCl across the double bond. IR and solid state ^{13}C CPMAS NMR spectroscopy show the presence of unreacted vinyl group and suggest that any side reaction is insignificant. The double bond vibrations are clearly visible in the IR spectrum at 1610, 1000 and 960 cm^{-1}, while the ^{13}C NMR spectrum (Fig. 1) shows intense vinyl carbon resonances at δ 130.4 and 137.0. The existence of an Si–C bond is indicated by an IR absorption at *ca.* 1400 cm^{-1} and a large peak in the ^{29}Si CPMAS NMR spectrum at δ −79.8

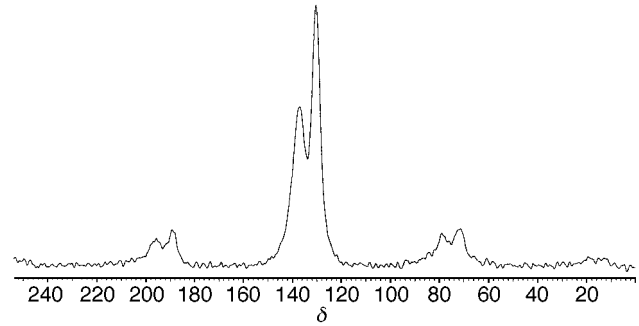

Fig. 1 ^{13}C NMR spectrum of vinyl-substituted silica.

consistent with the presence of the T^3 species.[18] Peaks due to T^2 [R–Si$(OSi)_2$(OR)] (δ −71.2), Q^3 and Q^4 species are also present as expected.

In general, TG analysis to 900 °C showed weight losses in good agreement with the theoretical organic content of the hybrids since all organic material is expected to volatilise by this temperature. The physical nature of the hybrids varies according to the type of organic modification with short alkyl chains leading to solid Ormosils, while those containing longer alkyl chains (C_8–C_{10}) are rubbery in appearance. DSC, however, shows no obvious glass transitions from −70 to 200 °C.

Molecular modelling using the Cerius² software package (Molecular Simulations Inc.) suggests that hybrids such as hexyl-modified silica could form a layered structure, but we have no experimental evidence to support this prediction. Future work is planned using extended X-ray absorption fine structure (EXAFS) to attempt to clarify this. None of the hybrids shows any evidence for crystallinity or other structural ordering by X-ray diffraction (XRD). Potential packing problems in the system may inhibit formation of an ordered structure. The synthesis of the hexyl-modified silica was carried out at a lower temperature and a longer reaction time than usual to try to facilitate ordering of the organic and inorganic components of the hybrid; however, XRD provides no evidence for such ordering.

Surface area analysis of these hybrids is complex. BET nitrogen adsorption isotherms and mercury porosimetry suggest the hybrids have low surface area, but further work is in progress to characterise these materials more fully.

Current work is aimed at characterising the properties of these hybrids more fully and assessing their use as precursors to new microporous silicas. Preliminary results show that removal of the organic component at elevated temperatures can lead to microporous silicas with surface areas above 150 $m^2\ g^{-1}$.

The authors thank EPSRC and the Defence, Evaluation and Research Agency (DERA) for the award of a CASE studentship (to H. R.). We also thank DERA for undertaking XRD analysis, the University of Durham for provision of solid state ^{13}C and ^{29}Si NMR services and Quantachrome for mercury porosimetry work. This work was carried out as part of Technology Group 4 (Materials and Structures) of the MOD Corporate Research Programme.

‘Molecular Chinese blinds’: self-organization of tetranitrato lanthanide complexes into open, chiral hydrogen bonded networks

C. V. Krishnamohan Sharma and Robin D. Rogers*

Department of Chemistry, The University of Alabama, Tuscaloosa, AL 35487, USA. E-mail: RDRogers@Bama.ua.edu

Received (in Columbia, MO, USA) 20th July 1998, Accepted 3rd July 1998

Lanthanide ions, with their unique electronic properties, rich stereochemistry, and consistent structural patterns offer a novel approach to the design of polar/chiral networks.

In recent years a wide variety of networks have been designed using the two major branches of crystal engineering (*i.e.* organic solids and inorganic coordination polymers), yet the rational design of polar/chiral networks continues to be an elusive and challenging goal for crystal engineers.[1–5] The difficulty results from synthetic strategies which rely upon the propagation of molecular symmetry into crystalline symmetry through rigid directional forces (hydrogen bonds and/or metal-coordination bonds), because such symmetry driven open networks tend to crystallize in *centrosymmetric* space groups.[3,6] However, using lanthanides, one can easily induce dissymmetry at metal centers simply by coordination with suitable ligand(s) which may thus result in controllable 1D, 2D, or 3D chiral networks with the aid of complementary hydrogen bonding functional groups.

In order to explore the role of lanthanide metal complexes in the context of crystal engineering, we have synthesized lanthanum nitrate metal complexes of 1,2-bis(4-pyridyl)ethane (bpe). $La(NO_3)_3{\cdot}6H_2O$ (0.433 g, 1 mmol) was reacted with bpe (0.368 g, 2 mmol) in EtOH (25 mL) and heated until both the reactants were completely dissolved. Crystals of **1**, $[bpeH]^+[La(NO_3)_4(OH_2)(bpe)]^-$, were obtained within 2–3 days. Complex **1** is also formed when $La(NO_3)_3$ and bpe are reacted in 1:2 or 1:3 molar ratios in 3:1 solvent mixtures of MeCN–MeOH.[7]†

Compound **1** crystallizes in the chiral space group $C222_1$.‡ The lanthanum cations are 11-coordinate, complexed with four bidentate nitrate anions, two bridging bpe ligands, and one water molecule resulting in an anionic 1D coordination polymer. The two protons of the water molecule along with oxygen atoms of adjacent nitrate anions constitute complementary divergent hydrogen bonding recognition sites on the backbone of the 1D coordination polymer (Fig. 1).

The hydrogen bonded nature of the 1D polymers [H···O, O···O, O-H···O; 2.155(3), 2.818(3) Å, 135.7(2)°] leads to the formation of a pleated-sheet structure with unusual cavities (Fig. 2). Each of these cavities is threaded by two linear 1D hydrogen bonded chains of the monoprotonated $bpeH^+$ molecules (N···N, 2.664(3) Å) resulting in an unprecedented polypseudo-rotaxane-type architecture.[8] To the best of our knowledge, this is the first structure to be reported with these unique 2D threading/interweaving structural features, *i.e.* threaded pleated-sheets, or a ‘chinese blinds’ structure. Also, formation of **1** under different experimental conditions, sug-

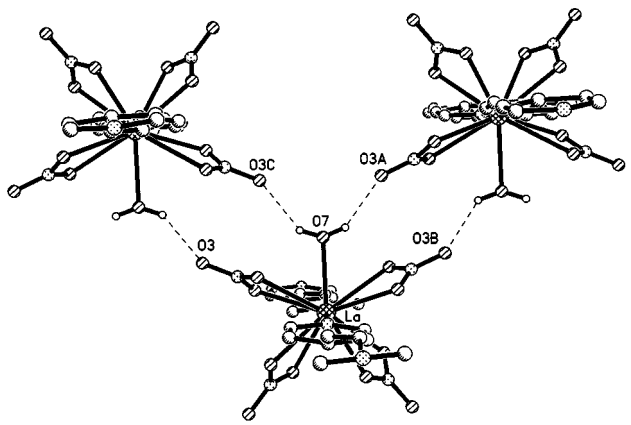

Fig. 1 Hydrogen bonded self-assembly of $[La(NO_3)_4(OH_2O)(bpe)]^-$ anions in **1**. The 1D coordination polymers run perpendicular to plane of the paper.

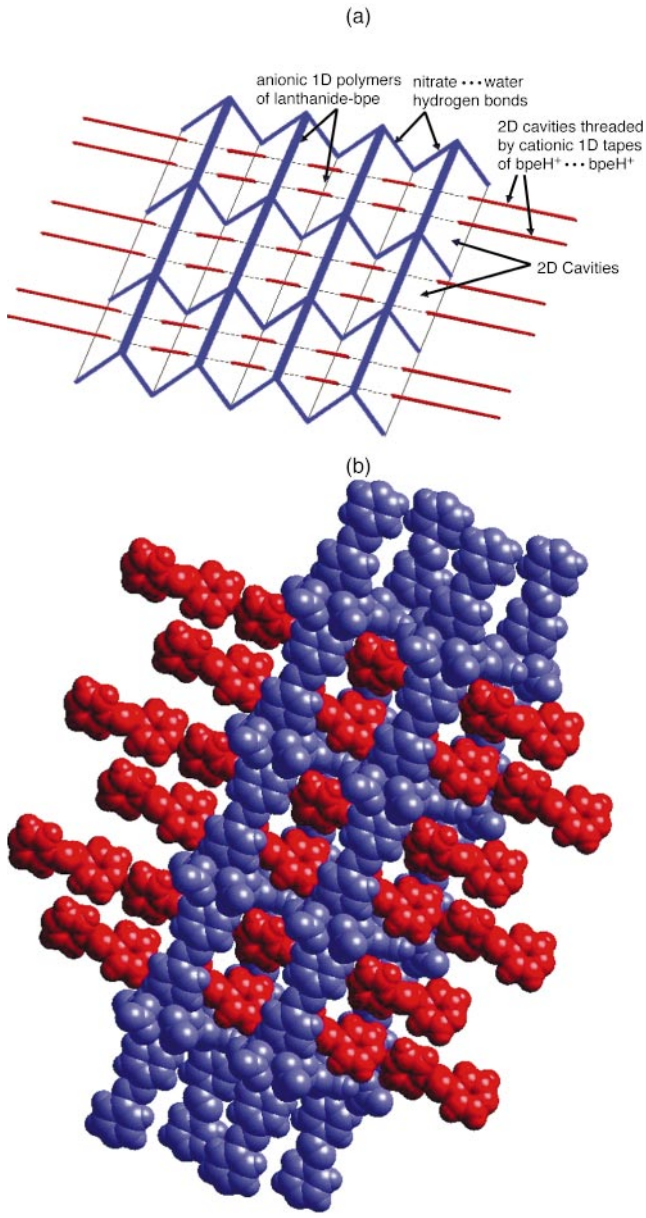

Fig. 2 Schematic (a) and space-filling (b) representations of a single sheet of **1** with the chiral 2D pleated-sheet of $[La(NO_3)_4(OH_2)(bpe)]^-$ (blue) threaded by 1D linear chains of $bpeH^+{\cdots}bpeH^+$ (red).

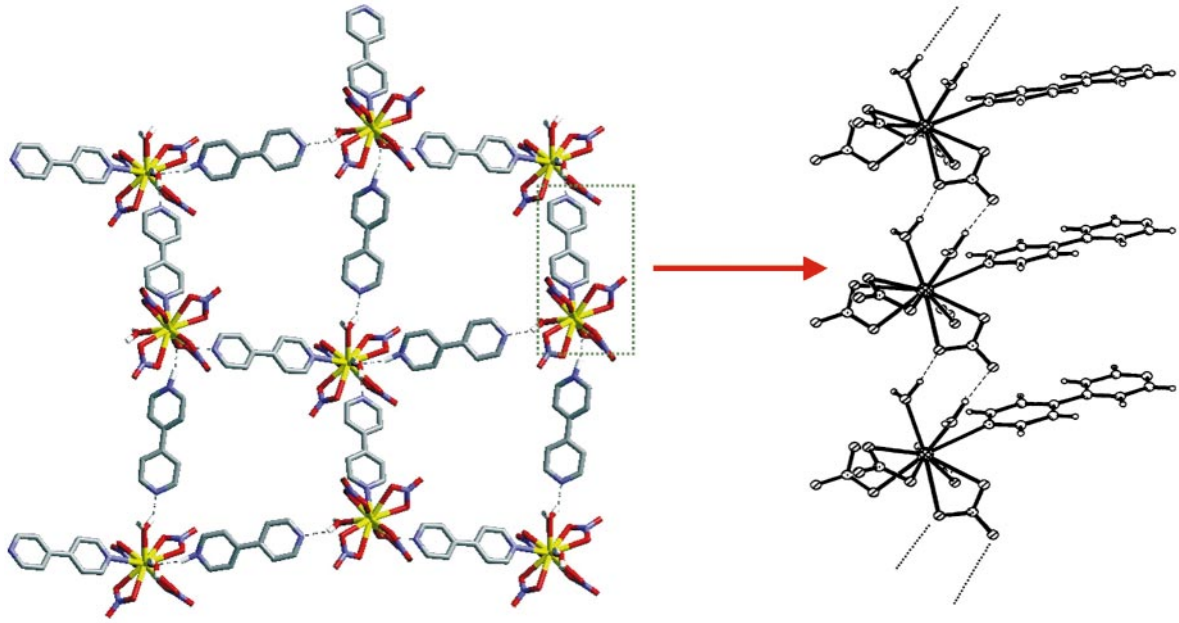

Fig. 3 A portion of the chiral, open 3D grids formed by **2a** resulting from hydrogen bonding between the complex anion, $[La(NO_3)_4(OH_2)_2(bipy)]^-$, and cation, $bipyH^+$. Two such independent networks interpenetrate.[9] The square grids are locked into place by hydrogen bonding between NO_3^- and H_2O groups in the third dimension.

gests strong complementary interactions among the various building blocks associated in the self-organization. Further, the nitro groups that are not part of the hydrogen bonding network interdigitate with neighboring 2D pleated-sheets through off-set stacking for efficient close packing.

The interesting open, chiral networks in **1** prompted us to carefully examine the 20 (many of them isostructural) $Ln(NO_3)_3$ complexes in the Cambridge Structural Database (April 1997 release) with the more rigid 4,4′-bipyridine (bipy). These complexes may be classified into three structurally distinct series: neutral hydrogen bonded cocrystals, metal–ligand coordination complexes, and organic cation–inorganic anion pairs. Two different isostructural series are particularly important to the crystal engineer in the design of open, chiral networks, each crystallizing in the chiral space group $P2_12_12_1$: the charged coordination complexes $[bipyH]^+[Ln(NO_3)_4(OH_2)_2(bipy)]^-$ (Ln = La, Ce, Pr, Nd: **2a-d**) and the neutral, hydrogen bonded cocrystals $[Ln(NO_3)_3(OH_2)_3]\cdot 2bipy\cdot H_2O$ (Ln = Nd, Pr: **3a**,**b**). In the former series complementary hydrogen bonding of the complex anions and $bipyH^+$ results in a well defined infinite chiral 3D open architecture (Fig. 3) that undergoes self-interpenetration.[9] The latter complexes form hydrogen bonded layered structures where bipy molecules function as pillars between the layers.[10]

We have synthesized further examples of **2** and **3** to determine the commonality of this approach. $La(NO_3)_3\cdot 6H_2O$ (0.433 g, 1 mmol) was reacted with 4,4′-bipyridyl (0.312 g, 2 mmol) in MeOH (15 mL) and single crystals of $[bipyH]^+[La(NO_3)_4(OH_2)_2(bipy)]^-$ **2a**, were obtained over a period of two weeks. The neutral hydrogen bonded crystals of $[La(NO_3)_3(OH_2)_3]\cdot 2bipy\cdot H_2O$ **3c**, were obtained when $La(NO_3)_3$ and bipy were reacted in 1:2 molar ratio in a solution mixture of xylene and MeOH.§

The crystal structures of **1**-**3** suggest a simple and efficient way to design chiral crystals with predictable networks and further suggest that lanthanides form exotic supramolecular networks which are of importance not only for their aesthetic appeal, but also for their potential use in the design of functional solids. Lanthanides, with their interesting electronic, spectral, and magnetic properties coupled with their availability, propensity to form isostructural complexes, and range in ionic radii are thus, attractive targets for exploring such structure–function correlations.

Notes and references

† The complexation properties of $Ln(NO_3)_3$ with softer N-donor ligands (*e.g.* 4,4′-bipyridyl) are sensitive to the solvent of crystallization. Any slight variations in nature of the solvent, acidity, basicity, or solvent:water ratio leads to drastic changes in the complex formed.

‡ *Crystal data* for **1**, M = 774.4, orthorhombic, space group $C222_1$, a = 14.9977(2), b = 16.3302(1), c = 11.8663(2) Å, V = 2906.24(6) Å^3, D_c = 1.770 Mg m^{-3} for Z = 4. 3369 unique absorption corrected reflections measured at 173 K with a Siemens CCD area detector diffractometer ($4 < \theta < 56°$), on convergence gave final values of R = 0.019, R_w = 0.046. The synthesis, isolation and preliminary characterization of all-carbon [60]fullerene dimers C_{121} and C_{122} are reported.

We here report data concerning the synthesis and preliminary characterization of all-carbon fullerene derivatives C_{121} **1**, a new dumbbell-like dimer, and C_{122} **2**. The existence of these molecules was first suggested by Osterodt and Vogtle,[1] and Strongin *et al*.[2] recently succeeded in the synthesis of C_{122}. C_{121} and C_{122} were previously detected in the mass spectra of $C_{60}CBr_2$,[3] $C_{60}CH_2$[1] and $C_{60}(CO_2Et)_2$.[4]

Recently we succeeded in the synthesis, separation and characterization of **1** and **2**. The synthesis was based on the reaction described in Scheme 1. Typically, 50 mg of $C_{60}CBr_2$ and 250 mg of C_{60} were mixed and gently ground. The powder was then heated in an argon atmosphere (flow 50 ml min^{-1}) up to 450 °C at a rate of 5 K min^{-1} and subsequently cooled to room temperature. The resulting black powder was soluble in CS_2 and *o*-dichlorobenzene, giving a red–brown solution (the same product could be obtained by using $C_{60}CHCO_2Et$ instead of $C_{60}CBr_2$, and a higher temperature, *i.e*. 550 °C). The product was a mixture of unreacted C_{60} and other phases, as detected by gel permeation chromatography, GPC (toluene, 340 nm detection, 12 ml min^{-1}). The GPC peak at 1320 ml was collected‡ and found to contain **1** and **2** as major and minor phases, respectively. The yield in **1** was about 10% and it increased slightly with an increase in the $C_{60}/C_{60}CBr_2$ ratio. The amount of **2** decreased when increasing the $C_{60}/C_{60}CBr_2$ ratio; the formation of **2** could be suppressed when using a large excess of C_{60} (more than ten-fold) but in this case the separation of the dimer product from the mixture was more difficult. The separation between C_{60}, **1** and **2** was made by GPC in recycling mode. In Fig. 1 a GPC experiment for the mixture of **1** and **2** is shown. After 24 h the separation between the two peaks was large enough to allow the collection of pure samples of C_{121} and C_{122}. The GPC elution volume for **1** was smaller than for C_{60} or $C_{60}CBr_2$ and similar to that of **2**, indicating that their molecular volumes are roughly the same but higher than those of C_{60} or $C_{60}CBr_2$. The laser desorption and ionization time of flight (LDI TOF) mass spectrum§ of **1** is presented in Fig. 2. The peak at *m/z* 1452.9, with a characteristic isotopic pattern, was assigned to C_{121} (negative ionization, calculated *m/z* 1453.3). A small C_{122} peak was also observed in the mass spectrum of C_{121}. This is probably due to the association of C_{61} clusters under the mass spectroscopy conditions, since the C_{122} peak increased with the laser power. The LDI TOF mass spectrum of **2** presented an intense peak for C_{122} (*m/z* 1465.4, calc. *m/z* 1465.3) but no C_{121} peak, irrespective of the laser power (Fig. 3).

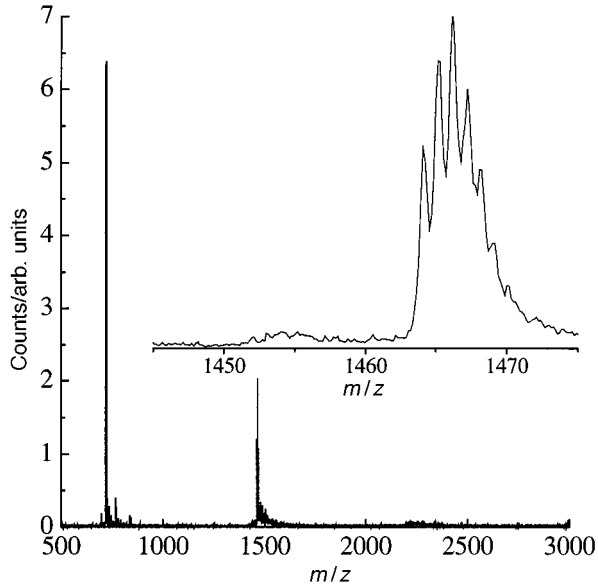

Fig. 3 LDI-TOF MS of C_{122}; inset is a detail of the dimer peak, linear mode, negative ionization.

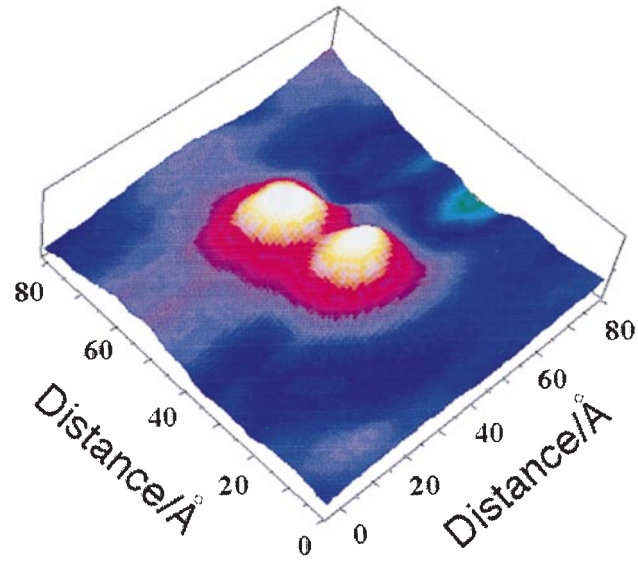

Fig. 4 An STM image of C_{122} deposited on graphite (sample voltage −0.5 V, current 0.5 nA, 80 K, ultra-high vacuum).

The UV–VIS spectra¶ of **1** and **2** showed peaks at 430 and 700 nm, usually observed for 1,2-dihydrofullerenes. IR spectroscopy‖ measurements revealed the presence of the C_{60} cage and some additional peaks due to the lower symmetry of **1** and **2** relative to C_{60}. In the spectra of **1**, a peak appearing at 1022.4 cm^{-1} was assigned to a cyclopropane skeletal stretch,[5] expected at 1017–1025 cm^{-1}.

So far, we have been unable to obtain a ^{13}C NMR spectrum of **2**, either because of its low solubility or the presence of impurities or other isomers in the sample. The ^{13}C NMR spectrum** of **1** was also rather difficult to obtain, due to the low C_{121} solubility and a low relaxation rate for the carbon nuclei. Sixteen low signal-to-noise lines were observed between δ 140–148 (16 lines expected in this region for a C_{2v} symmetry C_{121} molecule), in agreement with the high symmetry of this dimer. Three additional lines were sometimes observed in the cluster at δ 142, possibly related to either the presence of C_{122} or other impurities in the sample. A small upfield resonance at δ 67.7 could be assigned to the four sp^3 fullerene cyclopropane carbons. This value suggests a 6:6 closed connection to the fullerene core,†† in agreement with the proposed carbene attack mechanism (for an extensive discussion of ^{13}C NMR in fullerene derivatives, see ref. 6 and the references cited therein). The bridge between the two fullerenes could not be identified beyond doubt; its intensity should be eight times smaller than most of the fullerene cage carbons. We tentatively assign a δ 48.8 resonance to the carbon bridge.

We also performed scanning tunnelling microscopy (STM) measurements on samples of **1** and **2** deposited on graphite. Fig. 4 shows an image of **2**; the size of the dimer is in agreement with that expected. STM images of **1** were similar to that of **2**, also showing dumbbell-like structures.

The LDI TOF mass spectrum of C_{121} showed extensive fragmentation around *m/z* 1452 and 720 as well as the presence of both odd- and even-numbered carbon clusters. These peaks are likely to be the result of the addition/loss of C_2 units to/from C_{121} in the mass spectrometer. The even-numbered carbon clusters were produced by aggregation of C_{61} and subsequent loss/addition of C_2 units. Whether the detected odd-numbered carbon clusters are stable or only transient species in the mass spectrometer still remains an open question. However, these results suggest that either weakly bound or spirane-like clusters are formed under the mass spectrometry conditions without the coalescence of the fullerene spheres. The elimination of C_2 units in the mass spectra of fullerene derivatives does not seem to require the formation of closed clusters, since it takes place for both even- and odd-numbered carbon clusters. Further studies on the laser-induced decomposition of odd-numbered carbon clusters should give an insight into the formation mechanism of fullerene molecules.

In conclusion, we succeeded in the synthesis and isolation of all-carbon fullerene dimers C_{121} and C_{122}. The dumbbell-like structure of these dimers is supported by ^{13}C NMR, IR, UV–VIS, mass and STM measurements.

We thank Professor K. Saigo, Dr M. Hayashi and Dr K. Kinbara, University of Tokyo, for help provided during this work. The authors acknowledge support from the Japan Science and Technology Corporation (JST-CREST).

Received (in Bath, UK) 20th August 1998, Accepted 26th November 1998

A one-pot synthesis procedure is described for the production of catalytically active titanium-incorporated mesoporous silica; the nature and accessibility of Ti(IV) sites derived from two different Ti sources was elucidated by means of catalytic tests, UV–VIS and photoluminescence spectroscopy.

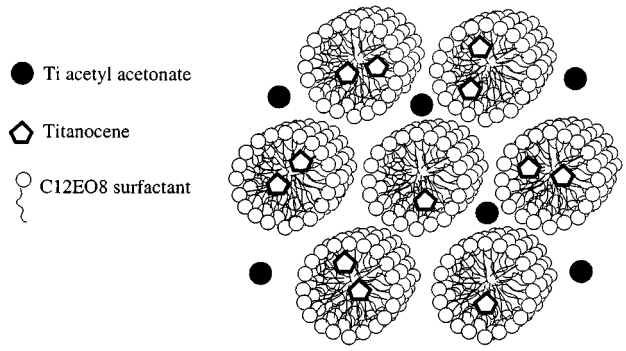
Titanosilicates are of great interest for various catalytic applications.[1] TS-1, a microporous titanium silicate containing catalytically active tetrahedral Ti(IV) sites, was first synthesised by Taramasso *et al.*[2] and was found to catalyse a wide range of low-temperature oxidations with hydrogen peroxide. In 1994, Corma *et al.*[3] and Pannavaia and coworkers[4] published their work on introducing titanium into the silica framework of MCM-41, and since then a considerable number of papers have been written dealing with various aspects of Ti-incorporated MCM-41, reviewed by Maschmeyer.[5] These materials can be prepared in principally two ways: (i) Grafting titanium species to the mesopore surfaces *via* a post-synthetic procedure[6] and (ii) substituting Ti into the silica framework by adding a titanium alkoxide precursor to the MCM-41 synthesis gel.[3,4]

Here, we describe a novel 'one-pot' method for the synthesis of titanium-incorporated mesoporous silica *via* a true liquid crystal templating (TLCT) process.[7] The advantage of this method over those previously described for Ti-MCM–41 is that no post-synthetic, and potentially damaging, treatment of the mesoporous silicates is required, and the disordered side products often associated with classical MCM-41 formation are avoided. Two types of titanium precursor were used for comparison: titanium cyclopentadienyl dichloride (Aldrich) and Tilcom TAA (Tioxide Specialities Ltd). Tilcom TAA consists of a 75 wt% solution of diisopropoxy bis(pentane-2,4-dionato)titanium(IV), or titanium acetylacetonate, in isopropanol. The titanium content of Tilcom TAA is 9.9 wt%. The precursors were dissolved directly in the synthesis gel consisting of a 1 : 1 : 2.1 weight ratio of octaethylene glycol monododecyl ether ($C_{12}EO_8$, Fluka), 10^{-2} M HCl and tetramethoxysilane (TMOS, Aldrich), respectively. For 1.5 g of surfactant template, 0.06 g of titanocene dichloride or 150 μl of Tilcom TAA were added.

The hexagonal mesoporous product formed overnight, under constant vacuum (to remove the methanol TMOS hydrolysis by-product), at room temperature. The deep orange colour of the titanocene-doped as-synthesised material suggested that the titanocene complex remained unhydrolysed throughout the synthesis (hydrolysis products would have been light orange/yellow). It is also supposed that owing to the hydrophobic nature of the cyclopentadienyl ligands, the transition metal was located primarily in the central hydrocarbon regions of the polyoxyethylene (POE) cylindrical micelles (Scheme 1), *i.e.* on the internal surfaces of the mesopores once the materials were calcined. The POE micelles therefore protected the complex from the aqueous regions of the synthesis mixture, pointing to a potentially general method for mesopore functionalisation.

We propose that due to the high solubility of Tilcom TAA in the aqueous regions of the liquid crystalline synthesis gel, a large proportion of the titanium sites in the final calcined products were buried in the silica framework (Scheme 1). Calcination of the materials at 500 °C produced silicate structures consisting of hexagonal arrays of long channels of *ca.* 25 Å diameter (as determined by TEM and N_2 adsorption measurements with BJH calculation). The hexagonal symmetry of the materials was confirmed by polarising microscopy (characteristic optical texture under crossed polarisers) and small-angle X-ray diffraction. After calcination at 500 °C, the hexagonal structure remained intact (seen by X-ray diffraction), but the location of the titanium species remained to be determined. The Ti contents in the calcined materials were calculated from the initial gel compositions, assuming complete hydrolysis and condensation to SiO_2, and complete removal of the organic template by calcination. Assuming all of the titanium species remained implanted in the mesoporous structures after calcination, the titanium metal loading for the products were 0.92 wt% for the titanocene-doped material (Ti[CP]) and 1.18 wt% for the Tilcom TAA-doped product (Ti[ACAC]). The amount of titanocene dichloride lost during the calcination process by evaporation/sublimation is not actually known; this would of course affect the Ti content in the calcined material.

Catalytic tests (data not shown) on Ti[CP] showed that it was both active in the epoxidation of octene using *tert*-butylhydroperoxide (TBHP) as the source of oxygen,[8] and in the peroxidative bromination of phenol red (phenolsulfonephthalein) to tetrabromophenol blue (3′,3″,5′,5″-tetrabromophenolsufonephthalein).[9] No catalytic tests were done on Ti[ACAC], only on the calcined Ti[CP], as this appeared to be the most promising material from the spectroscopic studies. The epoxidation reaction was carried out at 80 °C under an inert argon atmosphere, and the reaction mixture consisted of 0.15 mol oct-1-ene, 0.0075 mol mesitylene, 0.0075 mol TBHP and 0.265 g Ti[CP] catalyst. Samples were taken from the reaction mixture at regular intervals and the reaction products were quantified by GC analysis. Octene was in large excess and acted as the solvent as well as reactant, mesitylene was the standard



Scheme 1 Representation of the assumed locations of the titanium precursors, Ti acetyl acetonate and titanocene dichloride within the hexagonal liquid crystal phase.

for GC analysis. The reaction rate calculated after the first hour of reaction was 84 mol epoxide per mole Ti per hour; this value was comparable (within 30%) with the reaction rates obtained for grafted Ti–MCM-41 materials[6] in a previous study. Our catalytic test results show that the material is active in the epoxidation of octene, with high selectivity for the epoxide (no other octene oxidation products were observed). The activity of the catalyst suggests that isolated tetrahedral Ti(IV) species were present.[1,5]

The peroxidative bromination test gave a qualitative indication of the catalytic activity of the catalyst, and the formation of bromophenol blue from phenol red was monitored by UV–VIS spectroscopy.† Our Ti[CP] catalyst again had slightly lower but comparable catalytic activity to the TiMCM materials described in the literature.[9]

The diffuse reflectance UV–VIS spectrum for calcined Ti[CP] had an intense maximum absorbance centred at 220 nm (Fig. 1). The electronic transition responsible for this absorption band in the UV diffuse reflectance spectrum is a ligand to metal charge transfer (LMCT) transition from oxygen to tetrahedral Ti(IV).[10–16] There were additionally two further much less intense absorption peaks at 330 and 460 nm, which may have been due to degradation products of the cyclopentadienyl ligands of the titanocene precursor.[17] Calcined Ti[ACAC] produced a somewhat different UV–VIS absorption spectrum from Ti[CP]. The maximum absorption peak had a similar intensity to that for Ti[CP], but was displaced to 240 nm and was somewhat broadened with respect to the Ti[CP] absorption band. The displacement of the main adsorption peak to longer wavelength for the framework-substituted Ti[ACAC] product was likely to be due to a somewhat different chemical environment for the tetrahedrally coordinated Ti atoms in the structure. The fact that the band was broadened with respect to the Ti[CP] material suggested that there was a greater number of chemically differing Ti sites within the Ti[ACAC] structure, absorbing at different wavelengths.

In the case of isolated tetrahedral Ti(IV) sites, photoluminescence is due to the reverse LMCT process to that

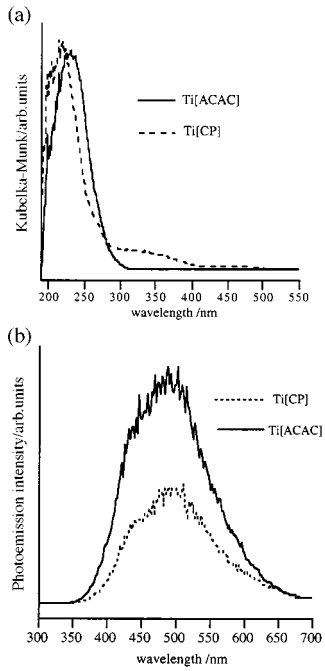


Fig. 1 (a) UV–VIS diffuse reflectance spectra recorded using a Perkin Elmer spectrometer equipped with an integrating sphere attachment. The absorbance output from the instrument was converted using the Kubelka-Munk algorithm. (b) Photoluminescence spectra recorded at 77 K (λ_{ex} = 250 nm) using a SPEX FLUOROLOG-2 1680 spectrometer. For all UV–VIS spectroscopy measurements samples were ground to fine powders and inserted into quartz cells purpose-made for *in situ* thermal treatments. Samples were pre-oxidised and spectroscopy measurements were conducted under strict exclusion of air.

responsible for the UV diffuse reflectance absorption.[10,11,18] The photoemission spectra for materials containing tetrahedral coordination Ti(IV) sites contain features in the range 400–600 nm. Photoluminescence spectra obtained for the Ti[CP] and Ti[ACAC] samples at 77 K were characterised by two main emission maxima at 440 and 490 nm. Both these emission bands had a maximum excitation at 250 nm. In agreement with the diffuse reflectance spectra, the excitation band for the Ti-[ACAC] material was broader than for Ti[CP].

The major difference between the photoemission spectra for Ti[CP] and Ti[ACAC], both reoxidised and degased in the same way, was that the Ti[ACAC] emission bands were 2–3 times more intense than the Ti[CP] bands. Adsorption of oxygen onto the Ti-doped samples only partially quenched the photoemission signals, though somewhat more for the Ti[CP] sample than for the Ti[ACAC] sample. This suggested that more of the Ti(IV) sites in the Ti[ACAC] sample were inaccessible (*e.g.* situated within the silica framework) to the oxygen than in Ti[CP].[17] These results agree substantially with what could be predicted from the partitioning behaviour of the titanium precursor in the original synthesis gels.

Our results have shown that a one-pot TLCT synthesis procedure can be used to introduce catalytically active sites into mesoporous silica. The accessibility of the Ti(IV) sites to external gaseous probe molecules (oxygen in the case of our photoluminescence studies) has been found to depend on the hydrophobic or hydrophilic nature of the titanium precursor used in the synthesis gel. We propose that this method for producing metal-incorporated mesoporous materials may be generalised to many other species of catalytic interest.

M. E. R. thanks the EPSRC for a PhD Studentship; guidance from Dr M. Attfield for the epoxidation test and helpful discussions with Dr G. Martra are gratefully acknowledged.

Notes and references

† The reaction solution consisted of 0.1 mM phenol red, 0.05 M KBr, 5 mM H_2O_2 and 0.05 M Hepes buffer (pH ≈ 6.5); 0.16 g of finely ground Ti[CP] catalyst was added to this. The samples were continuously shaken throughout the tests using an electrical flask shaker (moderate speed), and at regular intervals decanted samples were taken for spectroscopic analysis.

A novel parachute-shaped C_{60}–porphyrin dyad

Peng Cheng, Stephen R. Wilson and David I. Schuster*

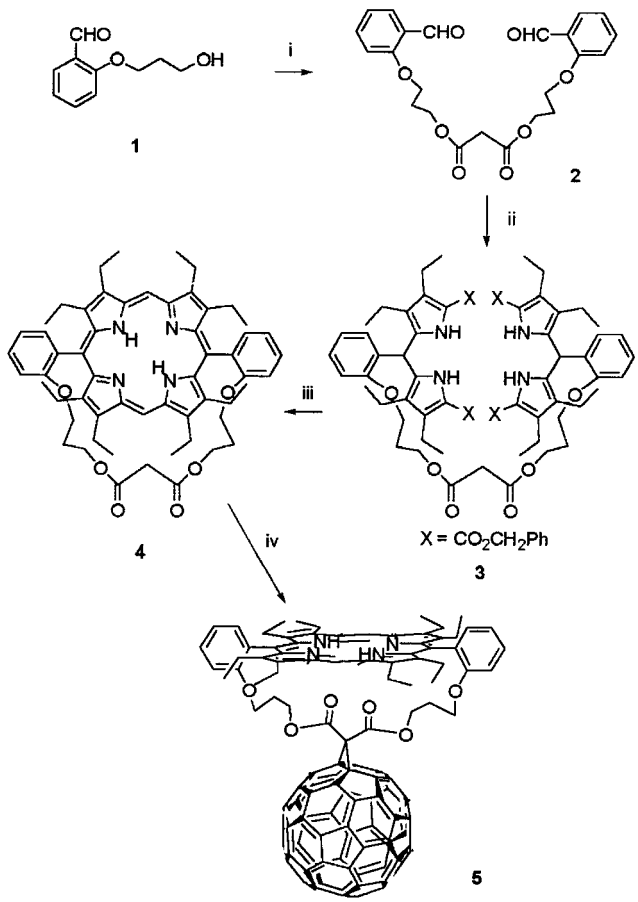
Department of Chemistry, New York University, 100 Washington Square East, New York, NY 10003, USA. E-mail: david.schuster@nyu.edu

Received (in Corvallis. OR, USA) 14th September 1998, Accepted 23rd November 1998

A novel covalently linked C_{60}–porphyrin dyad has been prepared by cyclopropanation of C_{60} with a strapped porphyrin malonate; its fluorescence spectrum shows strong quenching of the porphyrin singlet excited state by the attached C_{60}.

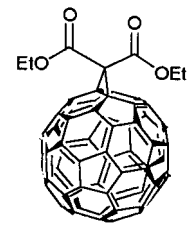
Photosynthetic model systems rely on spatially organized units with suitable photochemical and electronic properties. Recently much attention has been focused on using C_{60} as the electron acceptor in donor–acceptor systems due to its unique shape and redox properties.[1–3] To continue a project aimed at studying interactions between two chromophores in covalently linked C_{60}–porphyrin dyads with flexible and rigid tethers,[3] we became interested in the synthesis of a novel parachute-shaped dyad in which the two π-systems are forced into a face-to-face arrangement.

We synthesized a key intermediate porphyrin **4** using a strapped porphyrin strategy[4] in order to avoid tedious chromatographic separation of two *ortho*-linked atropisomers (Scheme 1). Esterification of 2-(3-hydroxypropyl)benzaldehyde with malonyl dichloride gave compound **2**. Condensation of the dialdehyde with 4 equiv. of benzyl 3,4-diethylpyrrole-2-carboxylate[5] gave compound **3**. Hydrogenation of **3** followed by reaction with methyl orthoformate catalyzed by trichloroacetic acid led to strapped porphyrin **4**, which was separated in 12% yield by flash column chromatography (silica gel, CH_2Cl_2–MeOH 20:1). The porphyrin malonate was then attached to C_{60} *via* Bingel cyclopropanation[6] accomplished by the action of CBr_4 and DBU.[7] The dyad **5**† was isolated in 25% yield by preparative TLC (silica gel, CH_2Cl_2–MeOH 25:1).



Scheme 1 *Reagents and conditions*: i, malonyl dichloride, Et_3N, CH_2Cl_2, 0 °C; ii, benzyl 3,4-diethylpyrrole-2-carboxylate, HCl, EtOH, reflux, 5 h; iii, H_2, 10% Pd/C, Et_3N, THF, room temp., 5 h, then $CH(OCH_3)_3$, Cl_3CCO_2H, CH_2Cl_2, room temp., 48 h; iv, C_{60}, CBr_4, DBU, toluene, room temp.

The structure of dyad **5** was confirmed by spectral data including ^{1}H MMR, ^{13}C NMR, ^{3}He NMR, UV–VIS and MALDI-TOF mass spectra.‡ The ^{1}H NMR spectrum in $CDCl_3$ exhibits the expected features with correct integration ratios, which is similar to the spectrum of porphyrin **4** except for the disappearance of the two protons on the methylene carbon between the two carbonyl groups. The ^{13}C NMR spectrum of **5** shows eight of the nine resonances for the sp^3 carbon atoms, 24 of the 28 resonances in the region δ 97.0–160.0 arising from the sp^2 carbon atoms of the C_{60} moiety and the porphyrin, as well as a resonance (δ 161.53) for the malonate carbonyl groups, clearly demonstrating that dyad **5** has C_{2v} symmetry. Interestingly, the dyad made from ^{3}He@C_{60} shows a peak at δ −8.5 relative to ^{3}He gas *via* ^{3}He NMR spectroscopy, whereas typical methano-1,2-dihydrofullerenes-C_{60} like **6** have a ^{3}He NMR



6

resonance at δ −8.1.[8] The upfield shift is attributable to the shielding effect of the porphyrin ring current. Calculations indicate that the average distance between the center of the four pyrrole N atoms and the center of the two sp^3 carbons on the C_{60} is 6.4 Å in the CVFF minimized structure (InsightII 97.2, Discover 3). The two tethers make the system relatively rigid.

The UV–VIS spectrum of **5** displays strong absorption bands due to both the porphyrin and fullerene moieties. Fig. 1 shows the UV–VIS spectrum of **5** together with that of porphyrin **4** and **6** for comparison. Since the porphyrin dominates the visible region whereas C_{60} dominates the UV region, the electronic spectrum of **5** is a virtual superimposition of the two independent chromophores present in the molecule, indicating no appreciable ground state interaction between the two π-systems.

In CH_2Cl_2, porphyrin **4** displays fluorescence maxima at 635 and 698 nm (Fig. 2). The dyad **5**, excited at 580 nm, shows an emission spectrum with characteristic features of the porphyrin. However, the porphyrin emission is efficiently quenched by the attached C_{60} by a factor of 40. It remains to be clarified from time-dependent measurements whether the quenching of the

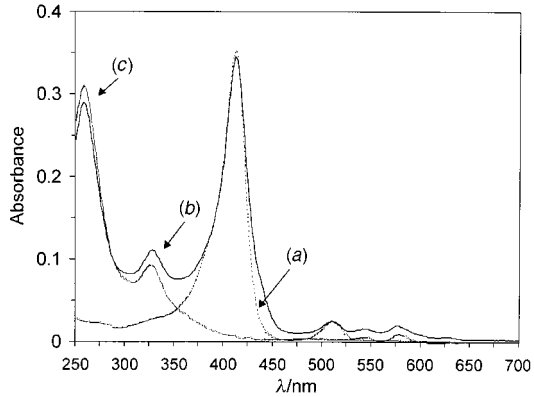


Fig. 1 UV–VIS spectra of (*a*) **4**, (*b*) **5** and (*c*) **6** in CH_2Cl_2 (2.5×10^{-6} mol dm^{-3}).

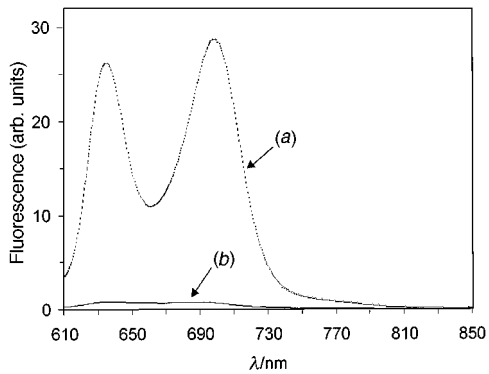

Fig. 2 Fluorescence spectra of (*a*) **4** and (b) **5** in CH_2Cl_2 (2.5×10^{-6} mol dm^{-3})

porphyrin fluorescence results from photoinduced energy transfer and/or electron transfer.

We thank Dr Anthony Khong (Yale University) for the ^{3}He NMR measurement. Financial support of this research by the US National Science Foundation is gratefully acknowledged. We also thank Andreas Hirsch (Erlangen) and François Diederich (ETH, Zürich) for communication prior to publication of independent synthesis of rigid C_{60}–porphyrin cyclophanes.[2]

Notes and references

† Detailed procedures for the synthesis and spectroscopic data of **4** and **5** will be reported elsewhere.

Received (in Liverpool, UK) 7th October 1998, Accepted 26th November 1998

Selectivity of enclathration and desolvation of xylene isomers by a dicarboxylic host depends on temperature.

Selective inclusion of guest species during crystallization is becoming of increasing importance in both the chemical and pharmaceutical industries, thus giving rise to the study of this phenomenon.[1,2] Recently, 1,1′-binaphthyl-2,2′-dicarboxylic acid (BNDA) was reported as a new clathrate host, and was found to exhibit clathrate formation selectivity for guests containing hydroxy groups.[3] However, a dependence of this selectivity upon the thermodynamic conditions of crystallization, such as that described here for the inclusion of xylene isomers, has not been discussed before.

Crystallization of BNDA from xylene isomers at room temperature gives three different channel-type clathrates.† In these crystals the BNDA molecules are incorporated into infinite zigzag chains created by H-bonded carboxylic group dimers. In the BNDA/*m*-xylene clathrate [Fig. 1(*a*)] these chains run along the *c*-axis and stack parallel to the *ac* plane in a 'face-to-face' mode, while in the BNDA/*p*-xylene clathrate [Fig. 1(*b*)] the chains are displaced by 1.5 Å along the *c*-axis. There are two BNDA molecules in the asymmetric part of the unit cell of the BNDA/*o*-xylene clathrate [Fig. 1(*c*)] which form zigzag chains in the [011] direction. Owing to the packing of these chains, two different channels are formed in the crystal.

In addition, simultaneous differential scanning calorimetric (DSC) and thermogravimetric (TG)‡ investigations of the thermal decomposition of these clathrates have been performed (Fig. 2). The release of the guest molecules during a linear temperature scan occurs in the temperature intervals 50–100 °C and 100–120 °C for the BNDA clathrates of *o*- and *p*-xylene, respectively. The observed mass losses correspond to the results of the X-ray structure analysis. Heats of clathrate decomposition have been calculated from the DSC curves to be 58 ± 1 and 49 ± 2 kJ mol^{-1} for the *p*- and *o*-xylene clathrates, respectively. These values are considerably higher than the heat of evaporation of xylenes (36 kJ mol^{-1}), suggesting specific stabilizing interactions in the clathrate crystals. The *m*-xylene clathrate of BNDA, however, causes problems in the TG-DSC because of its high instability; during sample preparation for an experiment the crystals lost *ca*. 30% of the included *m*-xylene molecules. Therefore, the determined host–guest ratio does not exactly correspond to the X-ray data. Nevertheless, based on the mass loss during the TG-DSC experiment a heat of decomposition of *ca*. 30 ± 5 kJ mol^{-1} has been estimated. The lower precision is caused by the uncertainty of the DSC baseline due to the sample instability. Taking into account this limited accuracy the heat of decomposition of the BNDA/*m*-xylene clathrate is much lower than the values determined for the stable BNDA clathrates and compares to the heat of evaporation of xylene.

The decomposed products obtained by vacuum desolvation (0.5 mbar, 8 h) of the BNDA clathrates at different temperatures were also characterized by X-ray powder diffraction.§ The BNDA clathrates with *m*- and *o*-xylene can be decomposed to

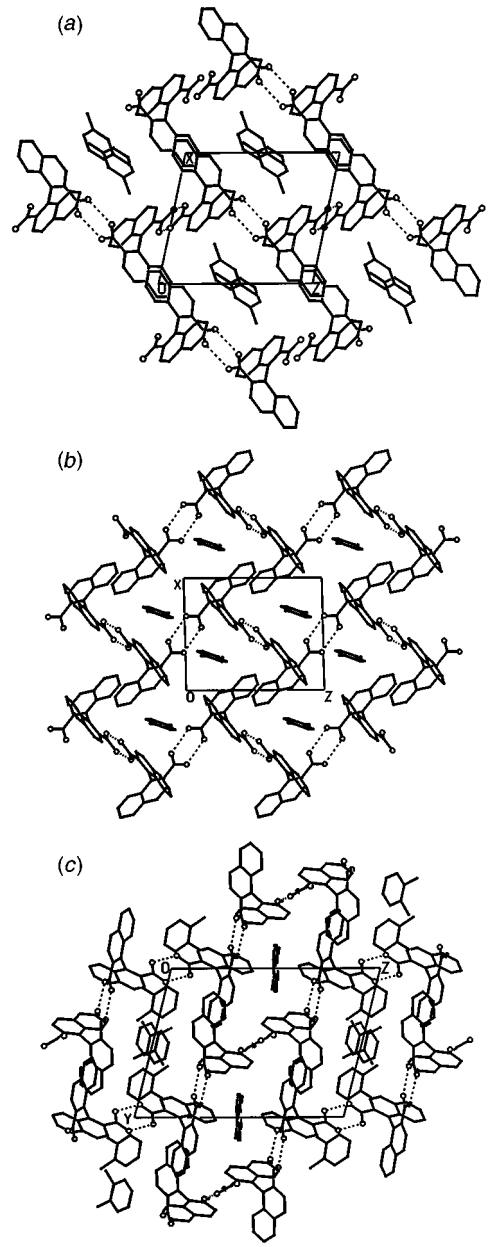

Fig. 1 Packing structures of the clathrates between BNDA and (*a*) *m*-xylene, (*b*) *p*-xylene and (*c*) *o*-xylene.

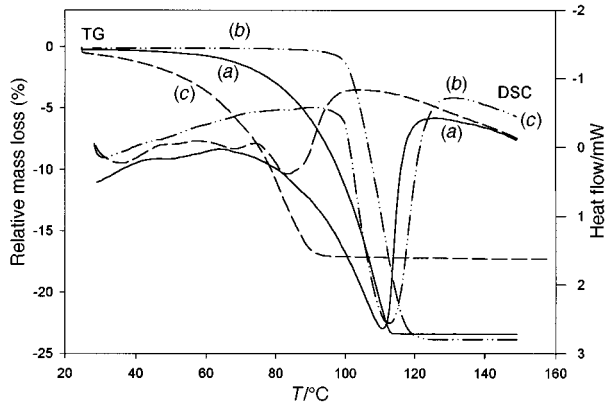

Fig. 2 Thermal degradations of (*a*) BNDA/*o*-xylene, (*b*) BNDA/*p*-xylene and (*c*) BNDA/m-xylene clathrates.

yield a desolvated phase **P1** of BNDA at 50 °C while the desolvation of the BNDA/*p*-xylene clathrate at higher temperature (100 °C) gives only a guest free phase **P2**. Recently, a crystal structure of the orthorhombic phase **P2** has been reported,[4] whereas single crystals of the triclinic phase **P1** have only now been obtained at 80 °C from an equimolar mixture of xylene isomers and its crystal structure has been determined.† The measured diffraction patterns of the desolvated samples correspond to theoretical diffractograms calculated from the appropriate structure data.

The different stabilities of the BNDA/xylene clathrates outlined above suggest a probable enclathration selectivity for the different xylene isomers, which prompted us to study the formation of BNDA clathrates from an equimolar mixture of the three xylene isomers. X-Ray diffraction and TG-DSC techniques were used to identify the obtained crystals. The crystallization temperature was varied within over −10 to +80 °C. If the crystallization temperature is between −10 and +10 °C a stable BNDA/*p*-xylene clathrate was found. Around room temperature a mixture of crystals of BNDA/*p*- and *o*-xylene clathrates was formed. TG-DSC curves of this crystal mixture are presented in Fig. 3 showing the two phases as distinctive steps. At +40 and +60 °C crystals of the BNDA/*o*-xylene clathrate were obtained, and crystals of the triclinic phase **P1** were formed at +80 °C. However, crystallization of the *m*-xylene clathrate from the mixed solution did not occur.

Thus, formation of clathrates or guest free host compounds and enclathration selectivity for a given host may be controlled by varying the crystallization temperature. These findings can be applied to purification and separation problems of isomeric mixtures or for the preparation of compounds of interest in

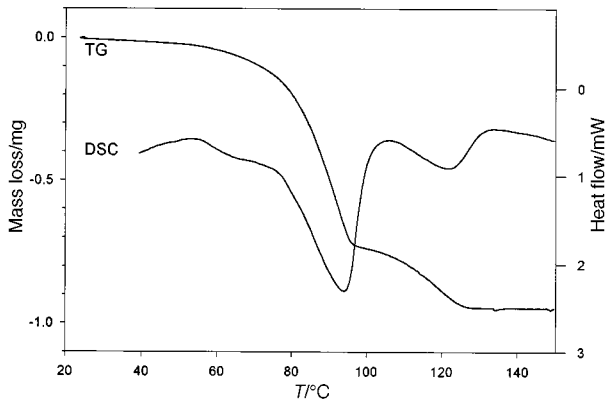

Fig. 3 Thermal degradation of the mixture of BNDA/*o*- and *p*-xylene crystals obtained at room temperature from a solution of an equimolar mixture of the three xylene isomers.

different crystal forms having different stability, composition, solubility *etc*.

† *Crystal data*: intensity data were collected at room temperature on a Syntex $P2_1$ diffractometer using Cu-Kα radiation (λ = 1.54178 Å) for the BNDA/*m*-xylene crystal and on an Enraf-Nonius CAD-4 diffractometer using Mo-Kα radiation (λ = 0.71073 Å) for the other three crystals.

BNDA/*o*-xylene: $C_{60}H_{48}O_8$, M = 896.98, triclinic, $P\bar{1}$, a = 10.843(2), b = 12.954(3), c = 17.599(4) Å, α = 103.64(3), β = 94.69(3), γ = 92.39(2)°, V = 2389.4(9) Å^3, Z = 2, D_c = 1.180 g cm^{-3}, μ(Mo-Kα) = 0.080 mm^{-1}, F(000) = 892, crystal size 0.2 × 0.35 × 0.45 mm, 10244 independent reflections. Final R = 0.0876 for 4648 reflections with $I > 2\sigma(I)$ and $wR2$ = 0.3288 for all data.

BNDA/*m*-xylene: $C_{30}H_{24}O_4$, M = 448.49, triclinic, $P\bar{1}$, a = 10.117(2), b = 10.556(2), c = 11.864(3) Å, α = 77.19(3), β = 77.81(3), γ = 86.63(2)°, V = 1207.5(5) Å^3, Z = 2, D_c = 1.233 g cm^{-3}, μ(Cu-Kα) = 0.651 mm^{-1}, F(000) = 472, crystal size 0.2 × 0.4 × 0.5 mm, 3400 independent reflections. Final R = 0.0544 for 2470 reflections with $I > 2\sigma(I)$ and $wR2$ = 0.1477 for all data.

BNDA/*p*-xylene: $C_{30}H_{24}O_4$, M = 448.49, triclinic, $P\bar{1}$, a = 10.117(2), b = 10.520(1), c = 11.913(1) Å, α = 83.48(1), β = 89.27(1), γ = 72.64(2)°, V = 1202.0(3) Å^3, Z = 2, D_c = 1.239 g cm^{-3}, μ(Mo-Kα) = 0.082 mm^{-1}, F(000) = 472, crystal size 0.35 × 0.5 × 0.5 mm, 5228 independent reflections. Final R = 0.0486 for 3938 reflections with $I > 2\sigma(I)$ and $wR2$ = 0.1493 for all data.

Polymorph **P1** of BNDA: $C_{44}H_{28}O_8$, M = 684.66, triclinic, $P\bar{1}$, a = 9.932(2), b = 11.320(2), c = 15.733(3) Å, α = 81.75(3), β = 80.57(3), γ = 89.34(3)°, V = 1726.8(6) Å^3, Z = 2, D_c = 1.317 g cm^{-3}, μ(Mo-Kα) = 0.091 mm^{-1}, F(000) = 712, crystal size 0.1 × 0.3 × 0.5 mm, 7529 independent reflections. Final R = 0.0624 for 3528 reflections with $I > 2\sigma(I)$ and $wR2$ = 0.2227 for all data.

The structures were solved by direct methods using the program SHELXS-86. The refinement of the structures against all $|F^2|$ data was carried out by the program SHELXL-93 with anisotropic displacement parameters for non-hydrogen atoms, and isotropic parameters for the guest molecules in the BNDA/*o*-xylene complex and the disordered O atoms in the polymorph **P1**. The H-atoms of all structures were placed at the calculated positions. CCDC 182/1100.

‡ *Thermal analysis*: The thermal decomposition of the different clathrate phases was studied by means of a simultaneous TG-DSC 111 system (Seteram, France) using open aluminium crucibles, sample weights of *ca*. 4 mg, a linear heating rate of 5 K min^{-1} and argon at 1 l h^{-1} as purge gas for all measurements. Crystals of an average size of 0.5–1 mm were taken from the mother liquor, quickly dried on filter paper and transferred into the crucible for immediate weighing and performance of the TG-DSC experiments

§ *X-Ray powder diffaction analysis*: Experiments were performed using a horizontal goniometer HZG 4 (Präzisionsmechanik Freiberg, Germany) and Cu-Kα radiation.

Novel discotic mesogen: synthesis and liquid crystalline behavior of TAAB (tetrabenzo[*b,f,j,n*][1,5,9,13]tetraazacyclohexadecine) derivatives with long alkoxy chains†

Seok Ho Kang,[a] Miok Kim,[a] Hyung-Kun Lee,[a] Yoon-Sok Kang,[b] Wang-Cheol Zin[b] and Kimoon Kim*[a]

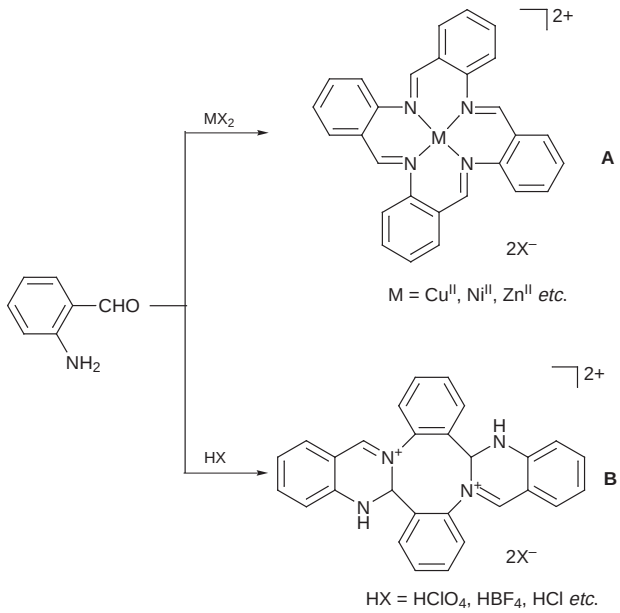
[a] National Research Initiative Center for Smart Supramolecules, Department of Chemistry, and [b] Department of Materials Science and Engineering, Pohang University of Science and Technology, San 31, Hyojadong, Pohang 790-784, South Korea. E-mail: kkim@postech.ac.kr

Received (in Cambridge, UK) 9th November 1998, Accepted 27th November 1998

The self-condensation of 3,4-dialkoxy-2-aminobenzaldehyde (alkoxy = *n*-$C_8H_{17}O$, *n*-$C_{10}H_{21}O$ and *n*-$C_{12}H_{25}O$) in the presence of HBF_4 gives the tetrafluoroborate salt of diprotonated octaalkoxy-TAAB which exhibits a hexagonal columnar mesophase over a wide range of temperatures including room temperature.

Discotic liquid crystals are well-known examples of supramolecular assemblies based on self-organization.[1] The columnar arrangement of disk-like mesogens such as triphenylenes, porphyrins and phthalocyanines is a promising architecture for anisotropic materials with potential applications such as one-dimensional conductors,[2] photoconductors,[3] molecular wires and fibers,[4] light emitting diodes[5] and photovoltaic cells.[6]

We are interested in studying new discotic mesogens.[7] Among the potential discotic mesogens we chose to examine was the macrocyclic compound tetrabenzo[*b,f,j,n*][1,5,9,13]-tetraazacyclohexadecine (TAAB). Metal complexes of TAAB (**A**), which have been known for over three decades, are synthesized by the self-condensation reaction of *o*-aminobenzaldehyde in the presence of metal ions (Scheme 1).[8] Without metal ion templates, however, the self-condensation reaction produces various polycyclic compounds including the eight-membered ring macrocyclic compound 4b,5,15,16-tetrahydrodibenzo[3,4:7,8][1,5]diazocino[2,1-*b*:6,5-*b*]diquinazoline-11,22-diium ion (**B**)‡ (Scheme 1).[9] In fact, no metal-free TAAB derivatives have been reported until now. Furthermore, no liquid crystalline compound having a TAAB core is known. Herein we describe the first successful synthesis of metal-free TAAB derivatives having long alkoxy substituents on the phenyl rings and their liquid crystalline behavior.



Scheme 1

The synthesis of metal free, octaalkoxy-TAAB compounds **5a–c** is shown in Scheme 2. 3,4-Dihydroxybenzaldehyde **1** was alkylated with alkyl bromide (alkyl = *n*-octyl, *n*-decyl and *n*-dodecyl) and subsequently converted into the corresponding 2-nitrobenzaldehyde by nitration. The key step for the synthesis of TAAB derivatives is the reduction of the 3,4-dialkoxy-2-nitrobenzaldehyde **3**. The proper choice of reducing agent is crucial because these reduction reactions are undoubtedly complicated by competing inter- and intra-molecular condensation reactions. Attempts to reduce **3** with previously-used reducing agents such as titanium(III) chloride and ferrous sulfate gave none of the desired product, while sodium sulfide gave only a 10% yield. However, the 3,4-dialkoxy-2-aminobenzaldehyde **4** could be prepared by hydrogenation of **3** with H_2 and Pd/C in 60–83% yield. In contrast to 2-aminobenzaldehyde, the dialkoxyaminobenzaldehydes are stable at room temperature; their stability increases with increasing alkyl chain length.

The self-condensation of **4** using HBF_4 in refluxing EtOH gives the tetrafluoroborate salt of diprotonated octaalkoxy-TAAB (**5a–c**) in 14–21% yield. The products have been characterized by NMR, UV–VIS, IR and mass spectroscopy and gave satisfactory elemental analyses.§ Their simple ^1H and ^{13}C NMR spectral patterns are consistent with the 16-membered

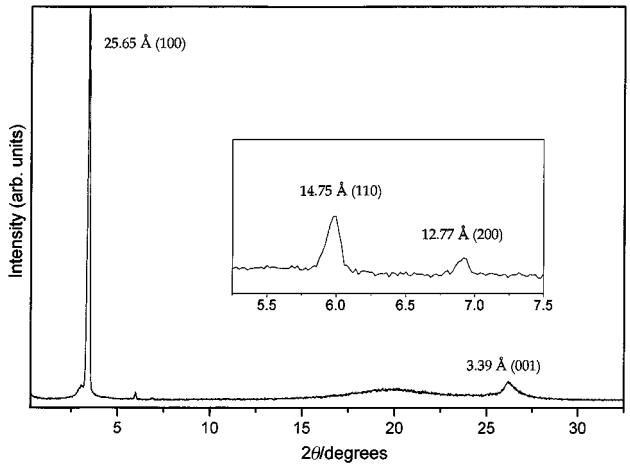

Fig. 1 X-Ray diffraction pattern of **5c** taken at room temperature.

TAAB core being in a diprotonated form. This is in sharp contrast to the fact that the self-condensation of simple 2-aminobenzaldehyde under the same conditions yields **B** having an eight-membered ring core (Scheme 1). This is the first example of the self-condensation reaction of an *o*-amino-benzaldehyde without metal ion templates leading to the formation of the 16-membered macrocyclic TAAB core. The electron-donating alkoxy substituents appear to stabilize the diprotonated TAAB core in **5**.

The diprotonated TAAB derivatives **5a–c** show mesomorphic behavior over a wide range of temperatures as revealed by differential scanning calorimetry (DSC), polarizing microscopy and X-ray diffraction measurements (Table 1). For example, **5c** shows a columnar mesophase at room temperature and transforms into an isotropic liquid at 249 °C. These transitions are not observed by DSC due to the low isotropic transition enthalpy, but are observed by polarizing microscopy. In optical microscopy a pseudo-focal conic texture is observed, which is typical for columnar mesophases. The compound starts decomposing just above the clearing point.

In order to clarify the mesomorphism of these compounds, we performed X-ray diffraction experiments at room temperature. The X-ray diffraction pattern (Fig 1) of the mesophase of **5c** shows a set of sharp reflections in the small-angle region which correspond to reciprocal spacings in a ratio of $1:\sqrt{3}:\sqrt{4}$. These peaks were assigned to the (100), (110) and (200) reflections from a hexagonal arrangement with a lattice constant a = 29.62 Å. In the wide-angle region, X-ray diffraction measurement also shows two broad and diffuse rings. The first one corresponds to a spacing of 4–5 Å, which is related to the liquid-like correlation between the molten aliphatic chains. The second ring at 3.39 Å is presumably related to the periodic stacking of the macrocyclic subunits within the columns. A molecular mechanical calculation suggests that the diprotonated TAAB core has a saddle-shaped conformation similar to those for metal complexes of unsubstituted TAAB reported earlier.[8b] The saddle-shaped macrocycles are stacked along the column with a mean interplanar distance of 3.39 Å. The columns are in turn arranged in a two-dimensional hexagonal array.

In summary, we synthesized novel discotic liquid crystals containing the macrocyclic TAAB core. The key to the successful synthesis of the stable diprotonated TAAB core is the introduction of electron–donating alkoxy substituents. The long alkoxy chains stabilize not only the precursor 3,4-dialkoxy-2-aminobenzaldehyde but also the diprotonated TAAB core formed by self-condensation of the precursor. These macrocyclic compounds exhibit hexagonal columnar mesophases over a wide range of temperatures including room temperature, demonstrating that the saddle-shaped macrocyclic core may be successfully used as a new discotic mesogen. These novel liquid crystalline materials may have interesting physical properties which are currently under investigation. The successful syntheses of the metal-free TAABs open up new possibilities for synthesizing a variety of metal complexes using these compounds as ligands. We are also working along this line.

This work was supported by the Creative Research Initiative Program (the Korean Ministry of Science and Technology). The X-ray diffraction measurements were performed at the Pohang Accelerator Laboratory (Beamline 3C2). We thank Mr Woo Sung Jeon for molecular mechanical calculations and Professor G. V. Smith for helpful suggestions in preparation of the manuscript.

Notes and references

‡ Old literature (ref. 8,9) refers to compound **B** as (TAAB)$(HBF_4)_2$ or $[(TAAB)H_2][BF_4]$, but these abbreviations are misleading because the macrocycle core **B** is different from that of **A**.

§ All the compounds have been fully characterized by ^{1}H NMR, UV–VIS, IR and mass spectroscopy and gave satisfactory elemental analyses. *Selected data* for **5c**: $\delta_H(CDCl_3$, 300 MHz) 0.87 (t, 24H, CH_3), 1.44 [m, 144H, $(CH_2)_9$], 1.73 (m, 16H, CH_2), 3.83 (q, 16H, OCH_2), 6.42 (s, 4H, Ar), 6.58 (s, 4H, Ar), 7.96 (s, 4H, N=CH); $\delta_C(CDCl_3$, 75 MHz) 14.51, 23.13, 24.91, 26.56, 29.75, 29.89, 30.24, 30.33, 32.40, 69.39, 69.66, 99.92, 117.70, 119.87, 124.68, 138.44, 149.29, 154.71, 157.56; ν_{max}(KBr)/cm^{-1} 1635 (C=C), 1555 (C=N); *m/z* (FAB) 1887.7 ($M + H^+ - 2HBF_4$); Calc. for $C_{124}H_{214}N_4O_8B_2F_8$: C, 72.21; H, 10.46; N, 2.72. A most user-friendly protocol for ring closing metathesis reactions

Alois Fürstner* and Lutz Ackermann

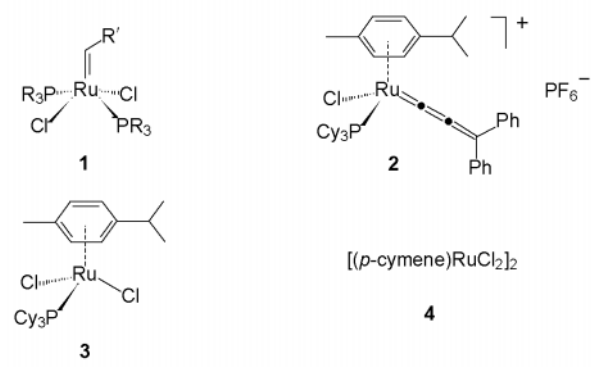
Max-Planck-Institut für Kohlenforschung, D-45470 Mülheim/Ruhr, Germany.
E-mail: fuerstner@mpi-muelheim.mpg.de

Received (in Cambridge, UK) 10th November 1998, Accepted 25th November 1998

Ring closing metathesis reactions (RCM) can be conveniently achieved in a photo-assisted manner simply by heating a solution of the diene substrate, catalytic amounts of commercially available [(*p*-cymene)$RuCl_2$]$_2$ 4 and PCy_3 in CH_2Cl_2 under neon light.

The advent of well-defined ruthenium-based metathesis pre-catalysts has triggered an explosive growth of interest in this transformation in both the organic and polymer chemists' communities.[1] Among them, the ruthenium carbene complexes **1** (R′ = Ph, $CH{=}CPh_2$) developed by Grubbs *et al*. set the standards in the field.[2] These reagents turned out to be very efficient and highly tolerant pre-catalysts for all kinds of metathesis reactions and have therefore found numerous applications in the synthesis of complex target molecules and the preparation of speciality polymers.[1,3]

Although the rapidly increasing demand has led to the development of considerably improved methods for the preparation of **1**,[4,5] the recent literature also documents a search for alternative metathesis initiators of comparable performance and improved accessibility. In this context, we have introduced the cationic, 18-electron ruthenium allenylidene species **2** as a



versatile pre-catalyst for various ring closing metathesis (RCM) reactions.[6] This compound is easily prepared by cleaving the chloride bridges of commercially available [(*p*-cymene)$RuCl_2$]$_2$ **4** with PCy_3, followed by treatment of the resulting monomer **3** with 1,1-diphenylprop-2-ynyl alcohol in the presence of $NaPF_6$. Other groups have reported alternative methods for activating compound **3**: thus, Noels *et al*. found that this complex converts into an efficient catalyst for ring opening metathesis polymeri-

14			72	15

[a] Using (*p*-cymene)$Ru(PCy_3)Cl_2$ **3** (2.5 mol%) as the pre-catalyst instead of the *in situ* mixture. [b] GC yield. [c] Using [(*p*-cymene)$RuCl_2$]$_2$ (5 mol%) + PCy_3 (11 mol%). [d] Using [(*p*-cymene)$RuCl_2$]$_2$ (15 mol%) + PCy_3 (30 mol%).

zations (ROMP) upon treatment with diazo alkanes,[7] whereas Hafner *et al*. initiated ROMP reactions with **3** after exposure to UV light (200 W Hg lamp).[8] These latter procedures, however, either require hazardous additives or special photochemical equipment and have not yet been applied to RCM.

We now report an even more convenient method for the activation of this key compound. Thus, heating a solution of a diene in the presence of catalytic amounts of **3** or, preferably, a mixture of commercially available $[(p\text{-cymene})RuCl_2]_2$ **4** and PCy_3 effects a clean and very efficient cyclization of the substrate, provided that the reactions are exposed to neon light or strong daylight.† Several aspects of this method are noteworthy:

(i) Light emitted by neon tubes commonly used for the lighting of laboratories is sufficient.

(ii) The reactions are performed in standard laboratory glassware (DURAN®) which absorbs 50% of UV light with λ = 300 nm and more than 95% of UV light with $\lambda \leqslant 285$ nm.[9]

(iii) Control experiments carried out in the dark clearly prove the photochemical effect on the rate of reaction.[10]

(iv) Refluxing CH_2Cl_2 turned out to be the best solvent.[11]

(v) Under these photo-assisted conditions, the reactions proceed very cleanly and reproducibly and neither activation by hazardous diazo alkanes nor any special photochemical devices or equipment is necessary.

(vi) Although the rate of reaction is slower than that obverved with Grubbs carbenes, the isolated yields are good to excellent and comparable to those obtained with **1** in all RCM experiments carried out so far. Note that a slow initiation is a disadvantage in polymerization reactions, whereas it is of minor importance for RCM.

(vii) As can be seen from the examples compiled in Table 1, this new procedure tolerates a wide range of functional groups in the substrates, including esters, amides, ketones, ethers, silyl ethers, acetals, glycosides, sulfones, sulfonamides, and even unprotected secondary hydroxy groups.

(viii) This new procedure applies to all ring sizes including medium-sized and macrocyclic ones. Furthermore it allows the preparation of even trisubstituted olefins in the five- and six-membered ring series as shown in entries 3–5 of Table 1.[12]

Finally—and most importantly—we would like to stress that this new protocol is distinguished by a hitherto unrivaled 'low tech' nature. It requires only commercially available reagents, avoids the (multi-step) preparation of peculiar complexes as well as the use of hazardous additives and needs no special equipment whatsoever; importantly, however, its efficiency and scope favorably compare with all current alternatives described in the literature. Therefore we believe that this extremely simple, yet highly productive methodology may help to increase the popularity of RCM even further and should find many applications in advanced organic synthesis.

Studies to elucidate the mechanism of the photochemical activation step on a molecular level are underway and will be reported in due course.

Notes and references

† *Representative procedure*: A solution of *N*,*N*-bis(allyl)toluene-*p*-sulfonamide (1.00 g, 3.99 mmol), $[(p\text{-cymene})RuCl_2]_2$ **4** (61 mg, 0.1 mmol) and PCy_3 (62 mg, 0.22 mmol) in CH_2Cl_2 (40 ml) was refluxed under Ar for 16 h in a well-illuminated hood. The solvent was removed *in vacuo* and the residue was purified by flash chromatography on silica using hexane–EtOAc (10:1) as eluent. This affords *N*-tosyl-2,5-dihydro-1*H*-pyrrole as colorless crystals (799 mg, 90%), mp 123-124 °C; δ_H(300 MHz, $CDCl_3$) 7.70 (d, *J* 8, 2H), 7.29 (d, *J* 8, 2H), 5.63 (s, 2H), 4.10 (s, 4H), 2.41 (s, 3H); δ_C(75 MHz, $CDCl_3$) 143.8, 134.7, 130.1, 127.8, 125.8, 55.2, 21.9; *m/z* 223 (35, $[M^+]$), 155 (32), 91 (77), 68 (100), 41 (24).

Vapor-phase transport synthesis of ZnAPO-34 molecular sieve

Lixiong Zhang and George R. Gavalas*

Chemical Engineering 210-41, California Institute of Technology, Pasadena, CA 91125, USA.
E-mail: gavalas@cheme.caltech.edu

Received (in Bloomington, IN, USA) 3rd September, 1998, Revised manuscript received 19th November 1998, Accepted 20th November 1998

ZnAPO-34 molecular sieve can be synthesized by the vapor-phase transport technique using triethylamine as a structure-directing agent.

Aluminium phosphate molecular sieves (AlPO-n) are crystalline framework structures formed from alternating AlO_4 and PO_4 tetrahedra.[1,2] Their pore sizes and adsorption properties are similar to those of zeolites but their framework is electrically neutral. By substitution of divalent ions of metals like Co or Zn for part of the aluminium ions, the framework acquires negative charges balanced by acidic protons possessing acidic catalytic activity.[3]

Since the first report on AlPO preparation,[1] interest in these materials has increased because of their potential as adsorbents, catalysts or catalyst supports[4,5] and, more recently, as membranes for gas separations.[6] The attractive properties of AlPOs that distinguish them from zeolites are their generally higher thermal stability and easier incorporation of metals in the framework.[1,4]

Zeolites and AlPOs are conventionally prepared by hydrothermal synthesis,[7] but zeolites can be prepared by other techniques as well, such as solvothermal synthesis[8] and vapor-phase transport (VPT).[9–11] The VPT technique involves crystallization of dry gel in a vapor phase containing organic template and water, and has certain advantages over other methods including minimum use of expensive organic template, elimination of the need to separate products from mother liquid, and production of molecular sieve coatings on various substrates.

Since 1990 when Xu *et al.*[9] first synthesized ZSM-5 by exposure of dry amorphous aluminosilicate gels in a vapor of ethylenediamine, triethylamine (Et_3N) and water, zeolites, such as ANA, FER, MOR and CHA, have been synthesized by several groups by VPT.[10,11] However, the VPT technique has not been applied so far to aluminophosphate molecular sieves. The purpose of this communication is to report synthesis of ZnAPO-34 molecular sieve by the vapor-phase transport technique.

Hydrothermal synthesis of ZnAPO-34 is normally carried out using tetraethylammonium hydroxide (TEAOH) as a structure-directing agent (SDA).[12] However, because TEAOH is non-volatile, we carried out the VPT synthesis using Et_3N as the SDA. Before attempting VPT synthesis we verified that normal hydrothermal synthesis of ZnAPO-34 using Et_3N is feasible. The hydrogel for the hydrothermal synthesis was the same as reported in literature[12] except that Et_3N was used instead of TEAOH. The product was characterized by XRD and SEM and, as shown in Fig. 1(a), it has the same cubic morphology as that prepared using TEAOH.[12] Analysis of the powder XRD pattern shown in Fig. 2(a) verified the that the product was ZnAPO-34 and the unit cell constants calculated were a = 13.746, b = 13.746, c = 14.730 Å (trigonal system, hexagonal axes) in agreement with those reported previously.[13]

VPT synthesis of ZnAPO-34 using Et_3N as organic template was carried out next. Dry gels for this synthesis were prepared by adding the specified quantities of zinc acetate, aluminium isopropoxide, and phosphoric acid into water successively. The system was stirred vigorously at room temperature to a homogeneous mixture each time prior to the addition of the next component. The resulting mixture was dried either at room temperature or at 90 °C overnight. VPT syntheses of ZnAPO-34 were conducted in a 23ml Teflon-lined stainless steel autoclave.

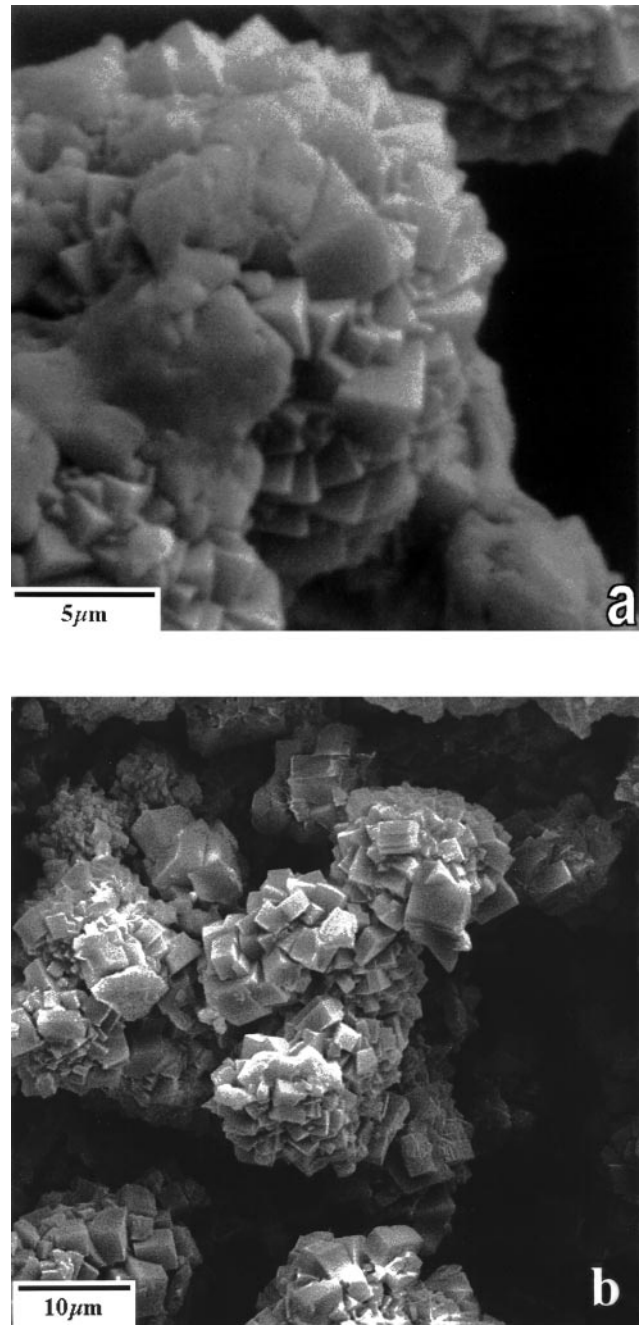

Fig. 1 Scanning electron micrograms of (a) product prepared by hydrothermal synthesis using Et_3N as a structure-directing agent; (b) product prepared by the VPT technique.

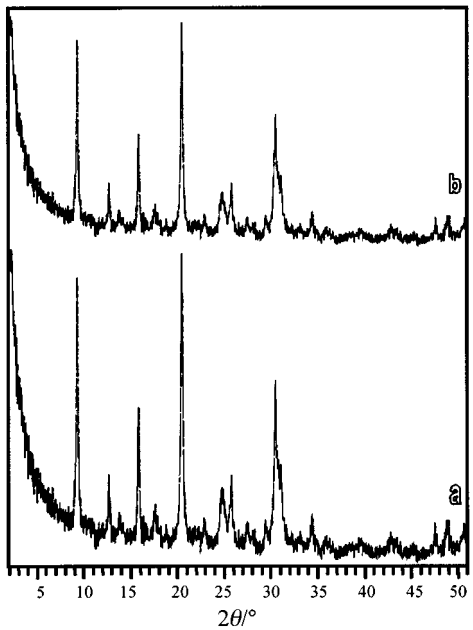

Fig. 2 XRD patterns of (a) product prepared by hydrothermal synthesis using Et_3N as a structure-directing agent; (b) product prepared by the VPT technique.

About 6 ml of a mixture of Et_3N and water was poured into the bottom of the autoclave. The dry gel was placed on a Teflon plate, which was installed in the autoclave above the liquid level. The autoclave was placed into a convection oven preheated to 170 °C and maintained at that temperature for 24 h. The autoclave was subsequently quenched in tap water and the products were washed, dried and characterized by SEM and XRD.

Table 1 lists the synthesis composition and resulting products. In the first set of experiments, the dry gel was prepared using the composition $0.4ZnO:0.8Al_2O_3:1P_2O_5:75H_2O$. Fig. 1(b) shows that the morphology of the resulting product is the same as that of Fig. 1(a). The XRD pattern of the product shown in Fig. 2(b) is also identical to that of Fig. 2(a).

Table 1 Experimental conditions and results.

Entry	Composition for synthesis of amorphous gel	Liquid phase	Result by XRD
1	$0.4ZnO:0.8Al_2O_3:1P_2O_5:75H_2O$[a]	$2Et_3N:150H_2O$	ZnAPO-34
2	$0.4ZnO:0.8Al_2O_3:1P_2O_5:150H_2O$[a]	$2Et_3N:150H_2O$	ZnAPO-34
3	$0.4ZnO:0.8Al_2O_3:1P_2O_5:150H_2O$[b]	$2Et_3N:150H_2O$	ZnAPO-34
4	$0.4ZnO:0.8Al_2O_3:1P_2O_5:150H_2O$[b]	$99Et_3N:1H_2O$	ZnAPO-34
5	$0.4ZnO:0.8Al_2O_3:1P_2O_5:150H_2O$[b]	$2Et_3N$:150EtOH	Amorphous
6	$0.4ZnO:0.8Al_2O_3:1P_2O_5:300H_2O$[b]	$2Et_3N:150H_2O$	ZnAPO-34
7	$0.4ZnO:0.8Al_2O_3:1P_2O_5$:150EtOH[b]	$2Et_3N:150H_2O$	Amorphous
8	$0.4SiO_2:0.8Al_2O_3:1P_2O_5:150H_2O$[b]	$2Et_3N:150H_2O$	SAPO-34

[a] Gel was dried at ambient temperature. [b] Gel was dried at 90 °C.

The other preparations listed in Table 1 involved the following variations. Some gels were prepared with different amounts of water or were dried at 90 °C. In one preparation the liquid phase contained 99% Et_3N. In another it contained Et_3N and ethanol instead of water. Finally in one experiment the gel was prepared with ethanol instead of water. As shown in Table 1, the VPT synthesis product was always ZnAPO-34 as long as the gel was initially prepared using water and the liquid placed at the bottom of the autoclave contained water. Even 1% water contained in sample 4 was evidently sufficient. However, if the gel was prepared using ethanol or if the liquid introduced into the autoclave was an ethanol–Et_3N mixture, the product was amorphous. Entry 8 in Table 1 shows that SAPO-34 can also be prepared using VPT method with Et_3N as the structure-directing agent.

Funding of this work by Elf Atochem, North America, Inc. is greatly appreciated. We thank Ms Lin Luo for analyzing the XRD patterns.

Atom transfer polymerisation of methyl methacrylate mediated by solid supported copper catalysts

David M. Haddleton,* Dax Kukulj and Arnaud P. Radigue

Department of Chemistry, University of Warwick, Coventry, UK CV4 7AL. Fax: +44 (0)1203 524112. E-mail: d.m.haddleton@warwick.ac.uk

Received (in Cambridge, UK) 27th October 1998, Accepted 27th November 1998

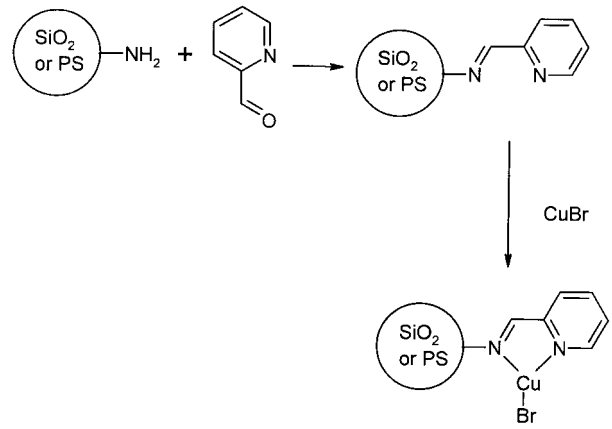
Atom transfer polymerisation of methyl methacrylate can be effected using solid supported copper(I) pyridylmethanimine catalysts which facilitate easy removal and reuse of the catalyst.

Controlled polymerisation of vinyl monomers, such as methacrylates, acrylates and styrene, is of continuing interest for the synthesis of polymers of specific composition and structure.[1] Controlled, or living, free-radical systems are attracting increasing attention as processes which are tolerant to protic species in the medium, *e.g.* from solvents, monomers, impurities, *etc.* Transition metal mediated living radical polymerisation, or atom transfer polymerisation, has been developed by Matyjaszewski[2–4] and Sawamoto,[5,6] utilising Cu(I)X/bipyiridines (X = Cl, Br) and $Ru_2Cl_2(PPh_3)_3$, respectively.[7] In our laboratories we have been developing catalysts based on Cu(I)X and alkylpyridylmethanimine Schiff base ligands.[8–12] The attraction of these catalysts is that the Schiff base ligands are simple to synthesise and allow scope to vary the catalyst properties (*e.g.* redox potential, solubility) by varying the appropriate substituent groups.

Typical [monomer] : [catalyst] ratios are 100 : 1 with stoichiometric amounts of initiator and catalyst, in order for acceptable rates of polymerisation. A potential solution to this problem is the use of supported catalysts. Inorganic supported catalysts, *e.g.* silica, have found widespread use in the polymerisation of olefins.[13] The extension of this approach to the use of functionalised inert poly(styrene) as supports for vanadium ethylene polymerisation catalysts has also been recently described.[14] This recent work prompts us to report our own work where we have been utilising supported catalysts for living radical polymerisation reactions; to the best of our knowledge this is the first example of the use of inert poly(styrene) supports for a non-co-ordination type polymerisation.

We describe herein polymerisation of MMA mediated by Cu(I)Br supported Schiff base complexes (prepared from both primary amine functionalised silica gel and cross-linked poly(styrene) resins) *via* an atom transfer polymerisation process. In order to evaluate the potential of supported catalysts for atom transfer polymerisation, four different solid supports were tried in combination with CuBr. In the first two examples, the ligand was covalently attached to the solid support, either primary amino-functionalised silica gel (SiO_2) or amino-functional cross-linked poly(styrene) beads (PS), Scheme 1. In the second and third examples, free ligand was used in conjunction with primary amine-functionalised and non-functionalised silica gel. The reactions were performed with 33 vol. % MMA in toluene solution with ethyl-2-bromoisobutyrate as the initiator.

Addition of CuBr to ligated silica produces a dark brown–orange free flowing powder, Scheme 1.† Atom transfer polymerisation of methyl methacrylate proceeds effectively at 90 °C, reaching 70.4% conversion with a number average molecular mass, M_n, of 15 500 after 300 min, reaction 1 in Table 1.† The polydispersity index, PDI, remains approximately 1.5 throughout the reaction which is slightly broader than observed in conventional homogeneous atom transfer polymerisation



Scheme 1

(typically ≈1.2[9,12]) but is lower than that obtained for conventional free-radical polymerisation and suggests that the reaction is proceeding by reversible activation of the C–Br ω-terminus of the growing polymer chain, as in conventional atom transfer polymerisation. As conversion increases, M_n also increases but is significantly higher than that predicted and suggests an inefficient initiation process. The reaction mixture remained a deep red–brown colour throughout the polymerisation. Once agitation was ceased the supported catalyst settled to the bottom of the flask leaving a colourless solution which was easily separated from the catalyst.

To demonstrate the living character of the polymerisation, a regrowth experiment was performed. Firstly, MMA was

Table 1 Molecular weight and conversion data for poly(methyl methacrylate) produced using atom transfer polymerisation with various supported CuBr catalysts

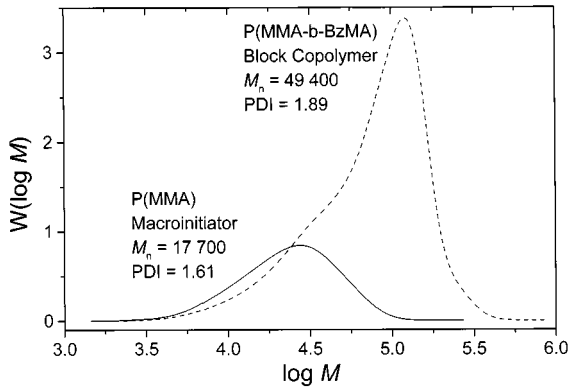

Fig. 1 Molecular weight distributions for the reinitiation of P(MMA) with benzyl methacrylate (BzMA) showing that the majority of chains are still active. Peak areas scaled for conversion.

polymerised under similar conditions to reaction 1, yielding a polymer of M_n = 17 700 and PDI = 1.61. This polymer was then isolated by precipitation into hexanes and used as a macroinitiator in homogenous atom transfer polymerisation to polymerise benzyl methacrylate (BzMA), yielding a block copolymer of M_n = 49 400 and PDI = 1.89. Fig. 1 shows the molecular weight distributions of both the macroinitiator and the final block copolymer. The increase in molecular weight suggests formation of block copolymer. Broadening on the low molecular weight side indicates that some termination has occurred removing active end-groups thus reducing re-initiation efficiency.

The solid supported catalyst was used in several subsequent reactions, Fig. 2. The initial polymerisation was performed under similar conditions to reaction 1, except three times as much silica supported ligand was used in order to achieve a higher rate of reaction. Reuse of the catalyst was achieved by the addition of MMA, toluene and initiator (no additional CuBr or ligand) to the washed supported catalyst. The second use of catalyst leads to polymer in high conversion on leaving overnight. This was repeated three additional times giving a total of five uses of the same solid supported catalyst over a five day period, Fig. 2. Care was taken to keep the catalyst under nitrogen at all stages to avoid degradation from exposure to oxygen. It is apparent that the catalyst is effective for each reuse; however, activity is reduced as observed by the decrease in the rate of polymerisation. The reduction in catalytic activity may be due to several reasons: (i) some loss of the supported catalyst when removing the polymer solution and subsequent washing, (ii) oxidation of the Cu(I) to Cu(II) during the reaction, and (iii) degradation due to side reactions compounded over several uses. The polydispersity indices for this series of polymers are higher than observed in reaction 1 ($\approx$2 *vs.* $\approx$1.5) and seem to be due to the higher concentration of solid supported ligand leading to an increased reaction rate which in turn leads to a higher concentration of free radicals in solution and thus a higher amount of termination due to radical–radical reactions.

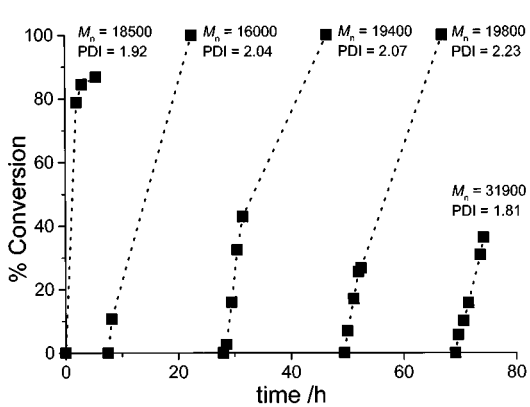

Fig. 2 Conversion *vs.* time for the four monomer additions in reaction 1.

Catalyst derived from pyridylmethanimine ligand covalently bound to cross-linked poly(styrene) beads, reaction 2, Table 1,† performs similarly to that on silica. Atom transfer polymerisation of MMA with this catalysts gives 75.2% conversion with a number average molecular mass, M_n, of 11 700 after 300 min. Again, M_n increases only slightly with conversion (but is higher than predicted), the polydispersity indices are similar, $\approx$1.5, and the catalyst settles to the bottom of the flask when stirring is ceased leaving a colourless solution. The rates of polymerisation for reactions 1 and 2 are very similar.

In addition to using catalysts covalently bound to the support, silica gel and amino functionalised silica gel (reactions 3 and 4, respectively‡) were added to a conventional atom transfer polymerisation to physically adsorb the catalyst, Table 1. Both of these reactions give lower polydispersity indices, $\approx$1.4 for silica and $\approx$1.3 for amino-functional silica, than the covalently bound catalysts of reactions 1 and 2. Indeed, the polydispersities are comparable to those of homogenous atom transfer polymerisation. After allowing the support to settle, a slight yellow colour remained in the solution due to some free catalyst/ligand.

In summary, solid supported atom transfer polymerisation catalysts promote effective polymerisation of methyl methacrylate. This allows the facile removal of the catalyst and also reuse of the catalyst in subsequent reactions. It is also possible to use the polymers produced to reinitiate polymerisation and produce block copolymers.

We would like to thank the EPSRC (D. K. GR/L10314) and Elf-Atochem (A. P. R.) for funding of this work.

Notes and references

† The supported catalyst was prepared by adding pyridine-2-carbaldehyde (0.714 g) to amine functionalised silica gel (3.00 g, 1.05×10^{-3} mol NH_2 g^{-1}) (or amino functional cross-linked poly(styrene) beads, 2.8×10^{-3} mol NH_2 g^{-1}) in 50 mL of dry toluene and refluxed for 5 h. The suspension was allowed to settle and the solvent was decanted off. Take up of the aldehyde on the support was monitored by NMR and UV of the residual pyridine-2-carbaldehyde in the solution against internal standards. To the support (0.967 g) was added MMA (10.0 mL), toluene (20.0 mL) and ethyl-2-bromoisobutyrate (0.137 mL) and the mixture degassed by three freeze–pump–thaw cycles followed by the addition of CuBr (0.134 g). Supported copper concentration was monitored by ICP analysis. The mixture was then placed in an oil bath at 90 °C. At the end of the reaction the reaction flask was removed from the oil bath and the insolubles allowed to settle (approximately 30 min due to the viscosity of the solution). The clear solution was removed *via* cannula.

‡ A solution of toluene (20 mL), MMA (10 mL), ethyl-2-bromoisobutyrate (0.137 mL) and *N*-(*n*-pentyl)-2-pyridylmethanimine (0.342 g) and silica gel (1.02 g) (or amine functionalised silica gel) and CuBr (0.134 g) was added and the flask placed in an oil bath at 90 °C.

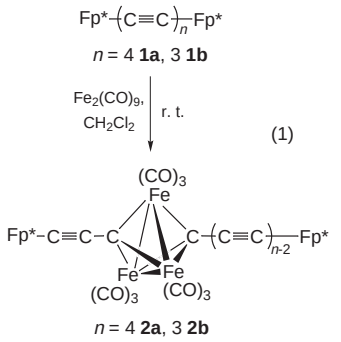
Received (in Cambridge, UK) 9th November, Accepted 3rd December 1998

Reaction of the polyynediyldiiron complexes, Fp*–(C≡C)$_n$–Fp* [Fp* = Fe(η^5-C$_5$Me$_5$)(CO)$_2$; n = 3, 4], with Fe$_2$(CO)$_9$ at room temperature results in C≡C bond cleavage to give the bis(μ$_3$-alkylidyne) complexes, Fp*–C≡C-μ$_3$-C–Fe$_3$(CO)$_9$–μ$_3$-C–(C≡C)$_{n-2}$–Fp*, a trinuclear cluster complex sandwiched by the two conjugated (C≡C)$_x$–Fe systems.

Carbon–carbon bond cleavage reaction on transition metal species has for a long time been an intriguing subject in the field of organotransition metal chemistry[1] since such studies should provide new strategies for activation and functionalization of hydrocarbons. C(sp)–C(sp) (C≡C) bond cleavage and coupling reactions on polynuclear systems have had several precedents over the last three decades and the group 9 metal systems [M(η$_5$-C$_5$R$_5$): M = Co, Rh, Ir] have been studied most extensively.[2] Previously reported C≡C cleavage reactions, however, require vigorous reaction conditions such as pyrolytic reactions. During the course of the synthetic study of polynuclear C$_{2n}$ complexes (2n = 2, 4, 6, 8) derived from the corresponding polyynediyldiiron complexes, Fp*–(C≡C)$_n$–Fp* **1** [Fp* = Fe(η^5-C$_5$Me$_5$)(CO)$_2$],[3] we observed C≡C bond cleavage reaction of **1** under very mild reaction conditions.

Reaction of the octatetraynediyldiiron complex **1a** with Fe$_2$(CO)$_9$ in CH$_2$Cl$_2$ (or THF, benzene) for 7 h at ambient temperature afforded orange complex **2a** (18% yield)† as a single product after removal of insoluble materials by filtration [eqn. (1)]. Complex **2a** was also obtained by reaction with



Fe$_3$(CO)$_{12}$. The ^{1}H NMR spectrum of **2a** contains two Cp* signals indicating an unsymmetrical structure and only η^1-CO ligands are detected by IR. The most characteristic spectroscopic feature of **2a** is the highly deshielded quaternary carbon signals [δ_C (CDCl$_3$) 270.1, 289.6], which suggest formation of a complex bearing two μ$_3$-alkylidyne functional groups, *i.e.* a C≡C bond in the C$_8$ linkage is cleaved by the action of the iron carbonyls. The C≡C bond cleavage position is definitely confirmed to be the inner C3≡C4 bond as revealed by X-ray crystallography [Fig. 1(a)].‡ The (μ$_3$-C)$_2$Fe$_3$(CO)$_9$ unit adopts a typical bicapped μ3-alkylidyne structure as indicated by its structural parameters: (i) the Fe$_3$ moiety is virtually an equilateral triangle with Fe–Fe separations of Fe31–Fe41 2.498(2), Fe31–Fe51 2.514(2), Fe41–Fe51 2.518(2) Å; (ii) the μ$_3$-alkylidyne carbon atoms are located almost equidistant from the three iron centers [Fe–μ$_3$-C: C3–Fe31: 1.955(5), C3–Fe41 1.981(8), C3–Fe51 1.972(8), C4–Fe31 1.962(9), C4–Fe41 1.962(7), C4–Fe51 1.942(5) Å]. These parameters are comparable to those of previously reported μ$_3$-alkylidyne triiron cluster compounds.[4] The acetylenic moiety is essentially linear and clear bond alternation is observed: [Fe11-C1 1.900(6), C1≡C2 1.228(9), C2–C3 1.389(9), C4–C5 1.39(1), C5≡C6 1.21(1), C6–C7 1.38(1), C7≡C8 1.19(1), C8–Fe21 1.904(7) Å; C–C–C(or Fe11,21) 173.9–179.1(8)°]. The absence of **2b** (see below) in the reaction mixture indicates that the present C≡C cleavage reaction involves an intramolecular process.

C≡C cleavage was also observed for an analogue, the hexatriynediyl complex **1b** (10% yield)[5] [eqn. (1)]. Spectroscopic and crystallographic analyses of the product **2b**† reveal cleavage between the central C3≡C4 bond, and the structural parameters for the Fe–C≡C–(μ$_3$–C)Fe$_3$(μ$_3$–C)–C≡C–Fe moiety [Fe–Fe 2.503–2.538(4), C–Fe$_3$ 1.92–2.00(1) Å, Fe1–C1 1.87(1), C1≡C2 1.26(1), C2–C3 1.38(1), C4–C5 1.37(1), C5≡C6 1.23(1), C6–Fe2 1.88(1) Å; C–C–C(or Fe1,2) 172–176(1)°] are similar to those of **2a**.

The present C≡C cleavage reaction of **1a**,**b** is in sharp contrast to the results of the reactions of the lower congeners, the butadiynediyl (**1c**: n = 2) and ethynediyl complexes (**1d**: n = 1), which afford other types of products (**4**–**6**)[3b] The C≡C units

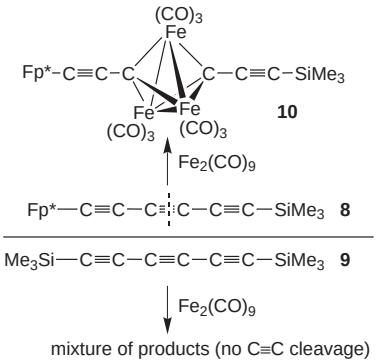
5 (from **1c**)



Scheme 1

in **1c**,**d** are directly bonded to the iron atoms, and their formation mechanism should involve reaction of the C≡C moiety with a diironcarbonyl species, $Fe_2(CO)_x$, followed by interaction with either of the adjacent atoms, Fe or C, associated with decarbonylation (M–M bond formation) and/or CO-migration.[6] In contrast, **1a**,**b** contain two kinds of C≡C functional groups; one directly bonded to the Fp* group and the other sandwiched by the two C≡C groups. Because the latter can avoid steric repulsion with the bulky Fp* group, the ironcarbonyl species would first interact with the central C≡C moiety to induce the cleavage reaction. In accord with this consideration, reaction of **1a** with $Co_2(CO)_8$ gave adduct **7** with tetrahedral C_2Co_2 cores (55% yield),§ where the central C≡C bonds interact with the dicobalt species [Fig. 1(b)].

In order to examine the effect of the substituents at the C_x termini, C_6-silyl derivatives (the precursors for **1b**),[5] Fp*–C≡C–$SiMe_3$ **8** and Me_3Si–(C≡C)–$SiMe_3$ **9**, were subjected to reaction with $Fe_2(CO)_9$ (Scheme 1). The reaction of **8** resulted in C≡C cleavage at the C3≡C4 bond to give the bis-μ_3-alkylidyne complex **10** (22% yield)§ analogous to **2**, whereas **9** gave a mixture of products, which did not show any ^{13}C NMR resonances > δ250 indicating absence of C≡C cleavage. Thus at least one Fp* substitution at the C_x termini is crucial for C≡C bond cleavage. The details of the mechanism of C≡C cleavage, however, is not clear at present. Interaction with diironcarbonyl species would give an adduct with a tetrahedral C_2Fe_2 core[7] analogous to the structure of **7** and subsequent addition of a third iron atom would induce C≡C bond cleavage and formation of an Fe_3 triangle. Electron-donating groups such as Fp* may stabilize the electron-deficient intermediate, which should be formed prior to C≡C cleavage.[2e]

Thus the present study reveals the possibility of C≡C bond cleavage of a polyyne linkage under very mild conditions. The obtained bis(μ_3-alkylidyne) complexes **2** belong to a new class of compounds, where the trinuclear cluster core containing d electrons is sandwiched by two π-conjugated $(C{\equiv}C)_x$–M systems. Interaction of M–$(C{\equiv}C)_n$–M′ with various metal species is now under further study and results will be reported in due course.

We are grateful to the Ministry of Education, Science, Sports, and Culture of the Japanese Government and the Ishikawa Foundation for Carbon Science and Technology for financial support of this research.

Excellent performance of lithium doped sulfated zirconia in oxidative dehydrogenation of ethane

Shaobin Wang, K. Murata, T. Hayakawa, S. Hamakawa and K. Suzuki

National Institute of Materials and Chemical Research, Tsukuba, Ibaraki 305-8565, Japan.
E-mail: swang@nimc.go.jp

Received (in Cambridge, UK) 6th November 1998, Accepted 23rd November 1998

Sulfated zirconia doped with lithium catalysts are found to be effective for the oxidative dehydrogenation of ethane to ethylene, giving 98% ethane conversion and 70% selectivity towards ethylene as well as 68% ethylene yield at 650 °C.

The selective oxidation of alkanes into their corresponding olefins has been of great interest in recent years. Ethane is an abundant component in natural gas, however, it receives the least attention due to the existing thermal cracking process. Conversion of ethane into ethylene by oxidative dehydrogenation (ODH) has several advantages and been studied over several oxide-based catalysts. Catalysts containing vanadium, molybdate and lithium are found to be effective for this reaction. However, most of these systems are based on alumina, silica, titania and magnesia.[1–4] Little work has concentrated on zirconia, in particular, sulfated zirconia based catalysts. Sulfated zirconia as a super acid solid is known as a very active catalyst for the conversion of small hydrocarbons.[5,6] One of the authors has discovered the excellent performance of Li-doped sulfated zirconia in the oxidative coupling of methane (OCM).[7] The oxidative coupling of methane to C_2-hydrocarbons is inevitably accompanied by the concurrent conversion of ethane to ethylene. Here we report the results of sulfated zirconia based catalysts for the oxidative dehydrogenation of ethane into ethylene.

The zirconia sample was prepared by two steps.[7] The resultant ZrO_2 was then used to prepare sulfated zirconia (SZ) by wetness impregnation using ammonium sulfate, and then calcined at 700 °C for 3 h with a corresponding anion content of 6 wt%. After this, zirconia samples were impregnated with lithium chloride, and calcined at 700 °C for 3 h. The loading of lithium was varied between 2 and 8 wt%. A series of Li-doped sulfacted zirconia (SZ) catalysts were also prepared using different Li precursor compounds at 5 wt% Li content by wetness impregnation as described above. The catalytic tests were carried out in a fixed-bed vertical-flow reactor constructed from a high-purity alumina tube (id = 6 mm) packed with 1.0 g catalyst samples and 2 g quartz sand and mounted inside a tube furnace. The feed, consisting of 10% ethane, 10% oxygen and 80% nitrogen, was introduced into the reactor at a flow rate of 60 ml min^{-1}. The reactants and products were analysed using a gas chromatography (GC-8A) equipped with a Porapak Q column using flame ionisation detector (FID) for hydrocarbons and a 5Å molecular sieve column for CO, CO_2, CH_4, O_2, N_2, and H_2 using thermal conductivity detector (TCD). Before catalyst testing, an empty tube loaded with only quartz sand was evaluated for the oxidative dehydrogenation of ethane under various conditions. It is found that the homogeneous contribution was negligible since ethane conversion was < 2% at 650 °C.

Table 1 presents the performance of ethane ODH over supports (ZrO_2 and SZ) and LiCl-based catalysts with 3.5 wt% Li as well as Li_2ZrO_3 catalyst. It is found that the main products of ethane oxidative dehydrogenation are C_2H_4, CO and CO_2 with lower amounts of other products such as CH_4, EtOH, and C_3H_6. Ethane conversion increases with the increasing temperature over all catalysts, however, ethylene selectivity exhibits varying patterns with temperature depending on catalyst. For zirconia, sulfated zirconia and Li/ZrO_2, ethylene selectivity increases with temperature.

However, a decreasing trend of ethylene selectivity is observed on Li/SZ at 600–650 °C. Li_2ZrO_3 shows similar ethylene selectivity at the same temperature range. For zirconia and sulfated zirconia, ethane conversions are > 60% with ethylene selectivity of *ca.* 30% at 650 °C. However, sulfated zirconia exhibits slightly higher catalytic activity and selectivity towards ethylene. Doped lithium chloride on supports remarkably improves ethane conversion and selectivity to

Table 1 Catalytic behavior of ethane ODH over zirconia-based catalysts at 650 °C

			Conversion (%)		Selectivity (%)				Yield (%)
Catalyst	S_{BET}/m^2 g^{-1}	*T*/°C	C_2H_6	O_2	C_2H_4	CO	CO_2	CH_4	C_2H_4

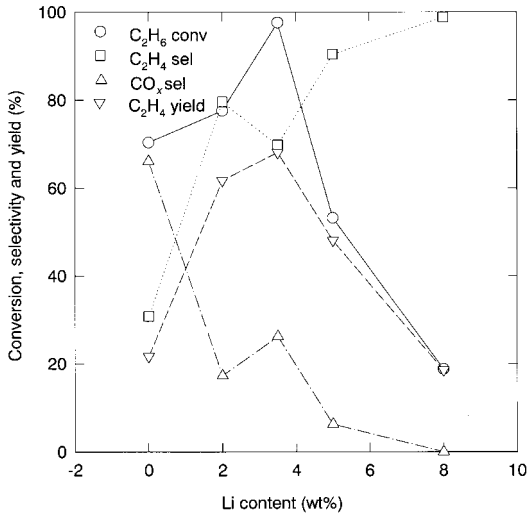

Fig. 1 Effect of Li content in the LiCl/SZ system on catalytic activity.

ethylene. For $LiCl/ZrO_2$, ethane conversion is enhanced to 87% and ethylene selectivity is increased to > 60%. Similarly, ethane conversion and ethylene selectivity over LiCl/SZ are also significantly improved with 70% selectivity at 98% conversion, giving 68% ethylene yield. LiCl/SZ also exhibits higher ethylene selectivity than Li/ZrO_2, suggesting that sulfation of zirconia modifies the surface properties and could promote ethylene selectivity. It has been found that Li/SZ shows better catalytic performance than Li/ZrO_2 in OCM reaction.[7] Another catalyst, Li_2ZrO_3, shows the lowest catalytic activity, but the highest ethylene selectivity and the ethylene yield is lower than that over the two supports (ZrO_2 and SZ). Several researchers have reported that Li-doped catalysts are much more selective to ethylene in ethane ODH because of the increase of in number of active sites for dehydrogenation.[9,10]

Conway and Lunsford[8] found that 5 g Li^+–MgO–Cl^- could produce a C_2H_6 conversion of 75–79% at a C_2H_4 selectivity of 70% with 58% ethylene yield at 650 °C under a flow rate of 60 ml min^{-1}. Ji *et al.*[9] also obtained 60% ethane conversion with 75% ethylene selectivity, giving 45% ethylene yield over Li/La/CaO catalysts at 650 °C. Therefore, the values obtained in this work are much better than the above results.

From Table 1, it can be seen that the catalytic activity is not dependent on the surface area. XRD measurements indicate that two phases (monoclinic and tetragonal ZrO_2) coexist in sulfated zirconia while monoclinic ZrO_2 with a trace of tetragonal ZrO_2 is present in ZrO_2. Li/ZrO_2 and Li/SZ catalysts consist of monoclinic ZrO_2 and a fraction of Li_2ZrO_3 crystallites. The peak intensities for Li_2ZrO_3 are higher for Li/SZ, suggesting that a larger amount of Li_2ZrO_3 is present in Li/SZ. Therefore, it is deduced that the synergistic effect of multiphases in the catalyst are responsible for the catalytic activity and selectivity. For Li doped catalyst, chlorine present in catalyst can also play an important role for the higher selectivity over these catalysts. Some researches have revealed that chlorine can promote the decomposition of ethyl radicals to ethylene.[10,11] Further work on catalyst surface characterisation is in progress to elucidate the active sites for the reaction.

The effect of lithium precursor ($LiNO_3$, LiCl, LiF and Li_2CO_3) in sulfated zirconia systems on the catalytic conversion, ethylene selectivity and yield was also studied. It is found that $LiNO_3$ and LiCl doped SZ catalysts exhibit higher ethane conversions, but that $LiNO_3$/SZ shows the lowest ethylene selectivity. The other three lithium doped SZ catalysts show similar ethylene selectivity. In terms of ethylene yields, LiCl doped sulfated zirconia catalyst generally gives the highest values; the overall order is: LiCl/SZ > $LiNO_3$/SZ > LiF/SZ > Li_2CO_3/SZ.

It is also found that lithium content affects the catalyst performance. The dependence of activity, selectivity and yield of LiCl/SZ catalysts with different lithium content at 650 °C is shown in Fig. 1. It can be seen that ethylene selectivity is enhanced over all Li-doped SZ catalysts. However, the ethane conversion and ethylene yield depend on lithium content. A maximum value can be attained over 3.5 wt% Li/SZ.

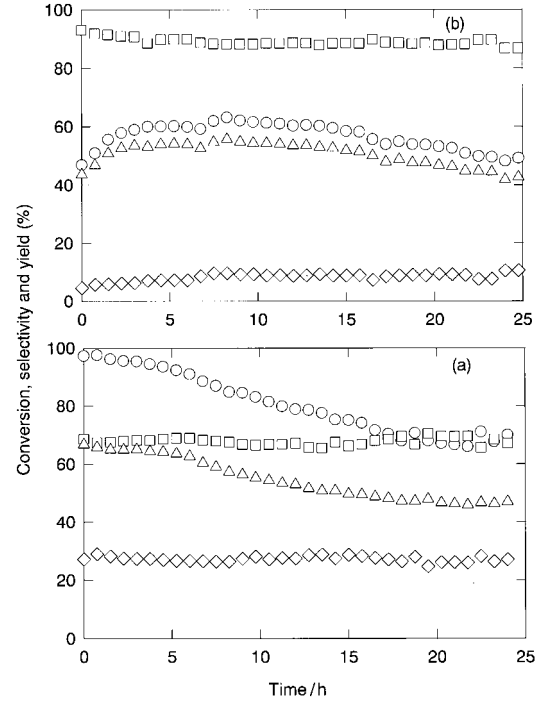

Fig. 2 Catalytic activity of ethane ODH as a function of time over LiCl/SZ at 650 °C.

Fig. 2 shows the catalytic performance of 3.5 wt% LiCl/SZ and 5 wt% LiCl/SZ catalysts at 650 °C in terms of reaction time. One can see that the two catalysts show different stability behaviour. For 3.5 wt% LiCl/SZ ethane conversion and ethene yield decrease gradually over 15 h and then remains nearly unchanged thereafter. Ethane conversion and ethene yields are reduced from 98 and 68% to 70 and 46%, respectively. Ethene and CO_x selectivities stay at the same level during 24 h of testing. The ethane conversion and ethene yield over 5 wt% LiCl/SZ increases in the first 10 h and then decreases, however, the deactivation rates are much slower than those of 3.5 wt% LiCl/SZ. After 25 h testing, ethane conversion and ethene yield are 50 and 42%, respectively. Like the behavior of 3.5 wt% LiCl/SZ, ethene and CO_x selectivities show no alteration. Investigations on 2 wt% LiCl/SZ and 8 wt% LiCl/SZ reveal that 2 wt% LiCl/SZ shows similar catalytic behaviour as 3.5 wt% LiCl/SZ while 8 wt% LiCl/SZ presents the same characteristics as that of 5 wt% LiCl/SZ. All these results seem to suggest that LiCl loading on catalysts is a crucial factor influencing the catalyst performance. Too high a LiCl content with result in a decrease in activity.

In summary, sulfation of zirconia promotes selectivity towards ethylene in the oxidative dehydrogenation of ethane. LiCl-doped SZ exhibits not only a high ethane conversion but also high selectivity towards ethylene and also high stability.

Received (in Cambridge, UK) 16th July 1998, Accepted 3rd August 1998

Synthetic flavylium compounds can exist in several forms (*multistate*) that can be interconverted by more than one type of external stimulus (*multifunctional*). The intricate network of their reactions, when examined from the view point of 'molecular-level devices', reveals very interesting properties.

Introduction

Great effort is currently being devoted to the design of molecular-level switching devices and, more generally, to the chemistry of signal generation, transfer, conversion, storage, and detection (semiochemistry).[1] By reducing the switching elements to molecular size, the memory density of computers could be increased by several orders of magnitude and the power input decreased very significantly.[2] Apart from future applications for information processing at the molecular level,[3] the study of compounds capable of existing in different forms that can be interconverted by external stimuli is a topic of great fundamental interest.[1–9] Molecules that can exist in two forms which are interconvertible by an external input are rather common. Typical examples of such bistable systems are the so-called photochromic compounds, where the input causing the switching between the two species is light.[10] Systems capable of existing in more than two forms (*multistate*) that can be interconverted by more than one type of external stimulus (*multifunctional*) are less common.[11,12] Such multistate/multifunctional systems can behave as complex logic devices and can therefore play the role of models for an initial understanding of the chemical basis of important biological processes.

Fernando Pina has been Professor of Chemistry at the Faculdade de Ciências e Tecnologia, Universidade Nova de Lisboa, since 1985, and coordinator of its photochemistry research unit. He is editor of Rev. Port. Quim. *His research interests are focused on the areas of supramolecular chemistry, proton-transfer, chemosensors and molecular-level devices.*

Mauro Maestri has been Professor of Chemistry at the University of Bologna since 1983. His research interests are mainly devoted to photochemistry, photophysics, electron-transfer processes, supramolecular chemistry and molecular-level devices.

Vincenzo Balzani has been Professor of Chemistry at the University of Bologna since 1972. He was Director of the FRAE-CNR Institute of Bologna (1977–1988) and Chairman of the European Photochemistry Association (1988–1992). He has obtained several awards, including the Ziegler–Natta Lectureship of the German Chemical Society (1993) and the Centenary Lectureship of the Royal Chemical Society UK (1995–1996). His research interests include photochemistry, photophysics, electron-transfer processes, supramolecular chemistry, and molecular-level devices.

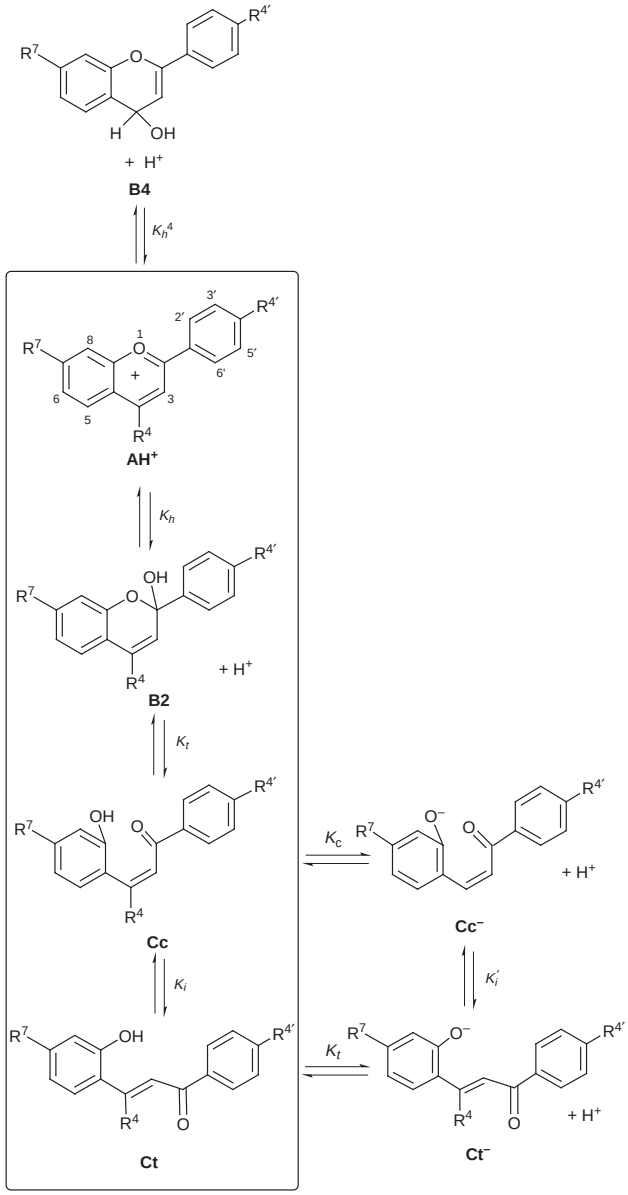
Like anthocyanins,[13] which are one of the most important sources of colour in flowers and fruits, synthetic flavylium salts in aqueous solutions undergo various structural transformations[14–17] that can be driven by pH changes and, particularly in the flavylium salts, also by light excitation. Such transformations are often accompanied by quite dramatic colour changes or colour disappearance. In the last few years we have investigated in a systematic way the thermal and photochemical reactions of several synthetic flavylium salts.[18–23] The main purpose of our studies has been to emphasize the multistate/multifunctional character of the chemistry of these compounds and, more generally, to show that examination of complex chemical systems from the view points of 'molecular-level devices' and 'molecular level logic functions' may reveal very interesting aspects and may be useful to introduce new concepts in the field of chemical research.

Nature of the species involved

The basic scheme for the discussion of the structural transformations of flavylium-type compounds is that shown in Scheme 1.[14–17] As we will see below, other forms may also be involved, depending on the nature of the substituents in the 4-, 7-, and 4′-positions. The flavylium cation $\mathbf{AH^+}$, which is the stable form in strongly acid solution, can be easily prepared by acid condensation of salicylaldehyde and acetophenone derivatives, as well as by other routes.[24] In moderately acidic or neutral solution, the thermodynamically stable form is the neutral *trans*-2-hydroxychalcone species **Ct**, which is formed from $\mathbf{AH^+}$ through the two intermediate compounds **B2** and **Cc**. **B2** is a hemiacetal species, obtained by hydration of the flavilyium cation, and **Cc** is a *cis*-2-hydroxychalcone, formed from the hemiacetal **B2** through a tautomeric process. The interesting feature of these systems is that the $\mathbf{AH^+}$ and **B2** forms can be reversibly interconverted by pH changes,[14–17] whereas **Cc** and **Ct** can be interconverted by photoexcitation.[18–23,25–28] Since the **B2** and **Cc** forms are in tautomeric equilibrium, it follows that pH and light stimulations can be used to cause interconversion of the four fundamental forms (Scheme 1). Furthermore, the $\mathbf{AH^+}$ form exhibits acid properties not only in the 2-, but also in the 4-position, to give the **B4** basic species. In their turn, **Cc** and **Ct** can undergo deprotonation to give the respective $\mathbf{Cc^-}$ and $\mathbf{Ct^-}$ monoanions which, being *cis*/*trans* isomers, can in principle be interconverted by light excitation. As we will see later, depending on the nature of the substituents, other acid/base equilibria and *cis*/*trans* couples may be present. It is therefore clear that in these systems pH changes coupled with light excitation may cause very intricate series of chemical reactions, with dramatic changes in the absorption spectra (*i.e.* in the colour of the system). A further interesting aspect is that some of the species exhibit fluorescence; this is not only another analytical 'handle' to control the

behaviour of the system, but also a very interesting signal for the purpose of information processing.

Several works concerning the thermodynamic as well as the kinetic aspects of the thermal reactions of flavylium-type compounds have long since been reported in literature,[13–17] whereas the photochemical and photophysical aspects have been examined more recently.[14–23,28] As we shall see below, pH jump, temperature jump, and flash photolysis experiments allow the measurement of the rate constants of some of the reactions involved, and steady state titration experiments (by using UV–VIS and NMR techniques) allow the measurement of equilibrium constants. In order to illustrate the complex reaction network of these systems, we will now focus on the behaviour of the 4′-methoxyflavylium ion[19] (Scheme 1; $R^4 = R^7 = H$, $R^{4'} = OCH_3$).



Scheme 1 Structural transformations of the flavylium-type compounds. Only the most important forms are shown.

Thermal reactions of the 4′-methoxyflavylium ion

A very careful spectral and kinetic investigation of the transformations undergone by the 4′-methoxyflavylium ion was originally performed by McClelland and Gedge.[16] By using the pH jump technique, they found that seven different species are involved, as transient or equilibrium compounds, depending on the experimental conditions (Scheme 1). The absorption spectra of the strongly colored 4′-methoxyflavylium ion **AH**$^+$ (λ_{max} = 435 nm, ε = 42000 M^{-1} cm^{-1}), the colorless *trans*-4′-methoxychalcone **Ct** (λ_{max} = 350 nm, ε = 18000 M^{-1} cm^{-1}), and the **B2** and **Cc** mixture are shown in Fig. 1.

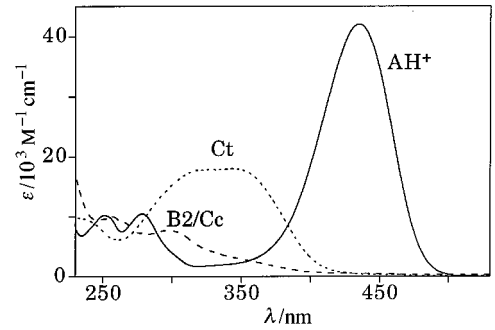


Fig. 1 Absorption spectra in aqueous solution at 25 °C of the 4′-methoxyflavylium compound: **AH**$^+$ at pH 1.0, **Ct** at pH 4.0 and **B2**/**Cc** mixture at pH 7.0. Reprinted with permission from ref. 19.

The molar fraction distribution[16,27a] of the various species in aqueous solution at 25 °C as a function of pH, obtained from the equilibrium constants (*vide infra*), is shown in Fig. 2. The

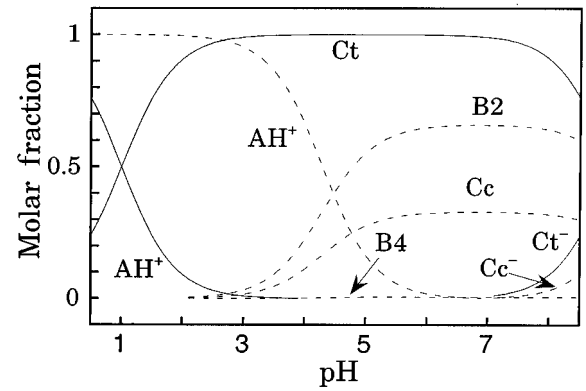

Fig. 2 Molar fraction distribution in aqueous solution at 25 °C as a function of pH for the 4′-methoxyflavylium compound. Solid lines refer to the species obtained at the thermodynamic equilibrium. Dashed lines refer to species obtained bringing **AH**$^+$ solutions from pH 1 to higher pH values by the pH jump technique or by exciting **Ct** solutions by flashed light. Such species reach a pseudo-equilibrium on the second time scale and then undergo a very slow thermal reaction to **Ct**. Reprinted with permission from ref. 19.

thermodynamically stable form in the pH range 2–8 is the *trans*-4′-methoxychalcone, **Ct**, which, at higher pH, is transformed into its anion, **Ct**$^-$ (Fig. 2, solid lines). In strongly acidic solutions, **AH**$^+$ becomes thermodynamically stable; however, **Ct** cannot be converted to **AH**$^+$ because of the very large activation barrier which involves isomerization of **Ct** to the intermediate compound **Cc** (Scheme 1). Furthermore, a solution of **AH**$^+$ is almost indefinitely stable at room temperature below pH 3, since under such conditions a very large kinetic barrier prevents conversion of **AH**$^+$ to the thermodynamically stable **Ct** form *via* the hydrated (pseudobase) species **B2** and the **Cc** isomer (Scheme 1). At higher pH, however, **AH**$^+$ is very reactive.[16] For example, starting from an aqueous solution of **AH**$^+$ at 25 °C and pH 1, a pH jump to pH 4.29 leads within a few seconds to a pseudo-equilibrium consisting of 50% **AH**$^+$, 33.2% **B2**, 0.3% **B4**, and 16.5% **Cc** (Fig. 2, dashed lines). A much slower reaction follows (half-life 19.7 h), resulting in complete conversion to the thermodynamically stable form **Ct**.

At pH 8, **AH**$^+$ reacts mainly with solvent water[16] (half-life 0.44 s) to produce 64% **B4**, 24% **B2**, and 12% **Cc**, the last two being in equilibrium with each other (half-life of the equilibration, 7×10^{-5} s). This is followed by another fast reaction (half-life 66 s) in which **B4**, a product of kinetic control of the initial neutralization of **AH**$^+$, is converted *via* **AH**$^+$ to **B2** and **Cc**,

yielding a pseudo-equilibrated mixture of 66.3% **B2**, 33.1% **Cc**, and 0.6% **B4** (Fig. 2, dashed lines). A much slower reaction (half-life 9.9 h) then occurs, resulting in complete conversion to **Ct**.

Photochemical behaviour of the 4′-methoxyflavylium ion

As described above, in the pH range 2–8 the colorless *trans*-4′-methoxychalcone **Ct** is the thermodynamically stable species and therefore it is the final product of the transformations of the strongly colored 4′-methoxyflavylium ion $\mathbf{AH^+}$. Even at pH 1, when $\mathbf{AH^+}$ is the thermally stable species, **Ct** can be kinetically stable because of the high energy barrier of its transformation to **Cc**. **Ct**, however, can be converted into $\mathbf{AH^+}$ by a photochemical reaction.[19] As expected from the thermal behavior of the system, the photoreaction causes a transient or an almost permanent effect depending on temperature and pH of the irradiated solution.

Continuous irradiation[19]

Continuous irradiation of 2.3×10^{-5} M aqueous solutions of **Ct** at pH 1.0 with 365 nm light causes strong spectral changes, with five isosbestic points and formation of a very intense band in the visible region with maximum at 435 nm [Fig. 3(*a*)]. Analysis of

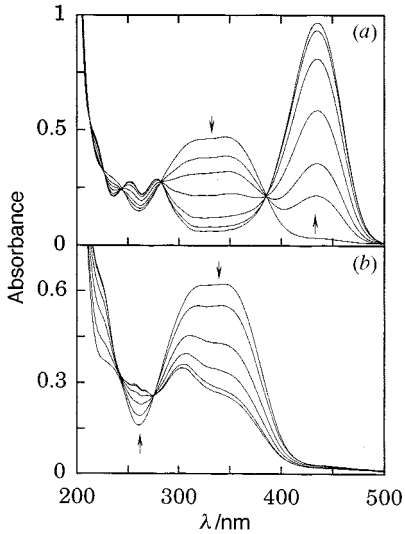

Fig. 3 Spectral changes caused by continuous irradiation of an aqueous solution of the **Ct** form of 4′-methoxyflavylium ion with 365 nm light: (*a*) pH 1.0, [**Ct**] = 2.5×10^{-5} M; the curves correspond to the following irradiation times: 0, 0.5, 1, 2, 4, 7 and 12 min. (*b*) pH 7.0, [**Ct**] = 3.2×10^{-5} M; the curves correspond to the following irradiation times: 0, 0.25, 1.5, 3, 6 and 10 min. Reprinted with permission from ref. 19.

the spectral changes shows that the photoreaction converts **Ct** into $\mathbf{AH^+}$, without formation of sizeable amounts of other products. The quantum yield of the photoreaction is 0.04, independent of the presence of dioxygen in solution. At pH 1.0, no back reaction takes place and irradiation with 434 nm light, corresponding to the maximum of the absorption band of $\mathbf{AH^+}$ (Fig. 1), does not cause any effect.

When irradiation of **Ct** is carried out at pH 4.0, the quantum yield of the photoreaction leading from **Ct** to $\mathbf{AH^+}$ does not change, but the expected thermal back reaction of $\mathbf{AH^+}$ to **Ct** is observed. The rate of the back reaction increases with temperature (activation energy 93 kJ mol^{-1} at pH 4.0). Irradiation at pH 7.0 causes the spectral changes shown in Fig. 3(*b*). At this pH the disappearance of **Ct** does not cause any increase of absorbance in the visible spectral region, showing that $\mathbf{AH^+}$ is not formed. Furthermore, the back reaction is very fast so that complete disappearance of **Ct** cannot be observed. This is in full agreement with the expectations based on the data shown in Fig. 2, which indicate that at pH 7.0 the pseudo-equilibrated mixture of products is constituted essentially by the open **Cc** and closed **B2** *cis* forms. Their absorption spectrum, as is always the case for aromatic derivatives of ethylene,[29] is less intense and slightly blue-shifted compared to the spectrum of the *trans* form (Fig. 1). Under such conditions, irradiation of the mixture with 313 nm light causes the reverse *cis* → *trans* photoisomerization reaction with an apparent quantum yield of *ca*. 0.5 (based on the total light absorbed by **Cc** and **B2**).

Interestingly, **Ct** and $\mathbf{AH^+}$ exhibit intense fluorescence bands with λ_{max} at 430 and 530 nm, respectively.[19] The fluorescence lifetime is shorter than 1 ns in both cases. It is worth noting that the occurrence of the above-described thermal and photochemical reactions can also be followed by fluorescence measurements.

Pulsed irradiation[19]

Flash photolysis is a powerful technique for investigating the kinetics of conversion of the various forms of flavylium ions.[27c] Even using a simple flash-photolysis apparatus with a time resolution of *ca.* 0.2 s it is possible to obtain kinetic data that can complement and/or replace those obtainable by the pH jump technique.

Flash excitation[19] of a 6.0×10^{-5} M aqueous solutions of **Ct** at 25 °C and pH 3.0 or 7.0 causes a bleaching in the 300–400 nm region that can be assigned to the disappearance of **Ct**. At pH 3, a strong increase in absorbance in the 400–500 nm region is observed, as expected for the formation of $\mathbf{AH^+}$. The absorbance *vs.* time traces show that **Ct** disappears within the time scale of the flash, but its disappearance does not lead directly to $\mathbf{AH^+}$. One or more intermediate products are formed (**Cc** and **B2** according to Scheme 1), which then convert completely to $\mathbf{AH^+}$ in a few seconds. At pH 7.0, the decrease of absorbance in the 300–400 nm region, corresponding to the disappearance of **Ct**, is not accompanied by an increase in absorbance in the visible region because in neutral solution $\mathbf{AH^+}$ is not stable and the main products of the photoreaction are **B2** and **Cc** (Fig. 2). None of the thermal and photochemical processes observed are affected by the presence of oxygen in the solution and the degree of reversibility of the system is satisfactory.[19]

In conclusion, the photochemical behaviour is in very good agreement with the behaviour observed by pH jump experiments. Although **Cc** is obviously the primary product of flash excitation, the observed species and their survival time (from seconds to years) before going back to the thermodynamically stable form **Ct** depend on temperature and pH.

Flavylium ions with OH substituents

In flavylium compounds that carry an OH substituent in the 4′- and/or 7-positions other forms, not present in the above discussed 4′-methoxyflavylium compound, can be obtained because of the deprotonation of the OH group, as illustrated in Scheme 2 for the 4′-hydroxyflavylium ion.[21] The new species are the quinoidal base **A**, obtained by simple deprotonation of the $\mathbf{AH^+}$ flavylium cation, and the dianionic $\mathbf{Cc^{2-}}$ and $\mathbf{Ct^{2-}}$ forms, obtained by second deprotonation of **Cc** and **Ct**. The roles played by these forms depend on the specific compound and pH conditions. For example, in the case of 4′-hydroxyflavilium ion the $\mathbf{Ct^{2-}}$ species exhibits fluorescence and the $\mathbf{Cc^{2-}}$ one undergoes photoisomerization to $\mathbf{Ct^{2-}}$ (*vide infra*).[21] Interestingly, for the 4-methyl-7-hydroxy- and 4′,7-dihydroxyflavylium compounds both the $\mathbf{AH^+}$ cation and the **A** quinoidal base exhibit fluorescence. Moreover, in the former compound, for which only two forms ($\mathbf{AH^+}$ and **A**) are observed, the pK_a of the ground state (4.4) is higher than the apparent pK_a of the excited state (0.7) and a very efficient adiabatic excited state proton transfer reaction (yield = 0.95) transforms $\mathbf{AH^{+*}}$ into **A***. These results show that 4-methyl-7-hydroxyflavylium

behaves as a four-level system and suggests that it could be used, in principle, to obtain a laser effect.[20]

Energy level diagrams

As discussed above for the 4′-methoxyflavylium compound, pH jump, temperature jump, and flash photolysis experiments allow the measurement of the rate constants of some of the reactions involved, and steady state titration experiments (by using UV–VIS and NMR techniques) allow the measurement of equilibrium constants. The values obtained for the most important processes of four flavylium compounds are gathered in Table 1.

From an operative viewpoint, the complex equilibria involving the species present at moderately acid pH (Scheme 2) can be described in terms of a single acid–base equilibrium between the acid species **AH**$^+$ and a conjugated base '**CB**' having a concentration equal to the sum of the concentrations of the species **A**, **B4**, **B2**, **Cc** and **Ct** [eqn. (1)],

$$\mathbf{AH}^+ \overset{K_a'}{\rightleftharpoons} \text{'}\mathbf{CB}\text{'} + H^+ \qquad (1)$$

where $K_a' = K_a + K_h + K_h 4 + K_h K_t + K_h K_t K_i$. The equilibrium constant of such an overall process is also given in Table 1. By using the data shown in Table 1, an energy level diagram can be constructed for each compound. Simplified versions of such diagrams (*e.g.* Fig. 4) can then be used to illustrate the behaviour of the various compounds[18–23] and to discuss the effect of the substituents.[22]

An intuitive way to describe the interconversion processes in flavylium-type compounds is their description using an hydraulic analogy.[22] Using such an analogy, the behaviour of an aqueous solution of flavylium ions upon a pH jump from 1.0 to 4.2 can be schematically represented as in Fig. 5. In the case of 4′-hydroxyflavylium, **Cc** converts very slowly to **Ct** and thus **B2** and **Cc** accumulate, whereas for 4′,7-dihydroxyflavylium and 7-hydroxyflavylium **Cc** converts very rapidly to **Ct** so that **Cc** and **B** disappear as soon as they are formed.

The hydraulic analogy can also be used to illustrate the photochemical behaviour of these compounds, the light playing the role of a pump. The scheme shown in Fig. 6 is appropriate for 4′-hydroxyflavylium.[22]

Properties of the network of chemical processes

As mentioned in the introduction, molecular or supramolecular systems capable of existing in different forms (*multistate*) that can be interconverted by different external stimuli (*multifunctional*) are interesting for both basic and application reasons. As we have seen above, the flavylium compounds can be interconverted into a number of different transient and stable forms using two different inputs, namely light or changes in pH. Several interesting aspects emerge when the resulting networks of chemical processes are analyzed in terms of 'molecular-level devices' and 'molecular level logic functions'. To illustrate these aspects, we will discuss the case of the 4′-hydroxyflavilylium compound (Scheme 1, $R^4 = R^7 = H$ and $R^{4'} = OH$; Fig. 4). For the sake of simplicity, in the following discussion the **A**, **B4** and **B2** transient species have been neglected since in the compound under examination they are always in rapid equilibrium with either **AH**$^+$ or **Cc**.

A write-lock-read-unlock-erase cycle

It is well known that photochromic systems represent potential molecular-level memory devices.[10–12] A number of problems, however, must be solved for practical applications. A most challenging one is to find systems with multiple storage and non-destructive readout capacity, *i.e.* the record can be erased when necessary, but is not destroyed by the readout. The 4′-hydroxyflavylium ion[21] (as well as the 4′-methoxyflavilium ion)[19] can be taken as the basis for an optical memory system with multiple storage and non-destructive readout capacity through a *write-lock-read-unlock-erase* cycle. This behavior can be described making reference to Figs. 4 and 7:

(i) At pH 4–7, the stable or kinetically inert (depending on pH) colorless **Ct** species can be photochemically converted (365 nm light) into the thermodynamically unstable, but relatively inert, **Cc** form (*write*).
(ii) Using a second stimulus (addition of acid), **Cc** can be converted into the kinetically inert or thermodynamically stable (depending on pH) **AH**$^+$ form (*lock*); if the initial pH is 1, the **Cc** species autolocks as **AH**$^+$.
(iii) The **AH**$^+$ species is photochemically inactive and shows an absorption spectrum clearly distinct from that of **Ct**, so that it can be optically detected (*read*).
(iv) Upon addition of base, **AH**$^+$ can be reconverted into **Cc** (*unlock*).
(v) **Cc** can be reconverted to the initial **Ct** form by a thermal or a photochemical reaction (*erase*).

Reading without writing in a write-lock-read-unlock-erase cycle

A generally overlooked difficulty with photochromic systems is that the starting form (**Ct** in the above discussion) is the photoreactive one, so that it cannot be read by absorption spectroscopy without writing. With the 4′-hydroxyflavylium ion, this difficulty can be overcome starting from **AH**$^+$, which is the thermodynamically stable form at pH 1 (Figs. 4 and 8).[21] Since this form is not photosensitive, it can be read by light excitation (*i.e.* by recording its absorption spectrum) without writing. Then it can be unlocked by a pH jump to 12 which yields the metastable $\mathbf{Cc}^{2-}$ form. At this stage, one can write the optical information obtaining the stable (locked) $\mathbf{Ct}^{2-}$ form that can then be read. When necessary, the information stored into

Table 1 Thermodynamic and kinetic constants for the structural transformations of some synthetic flavilium compounds[a]

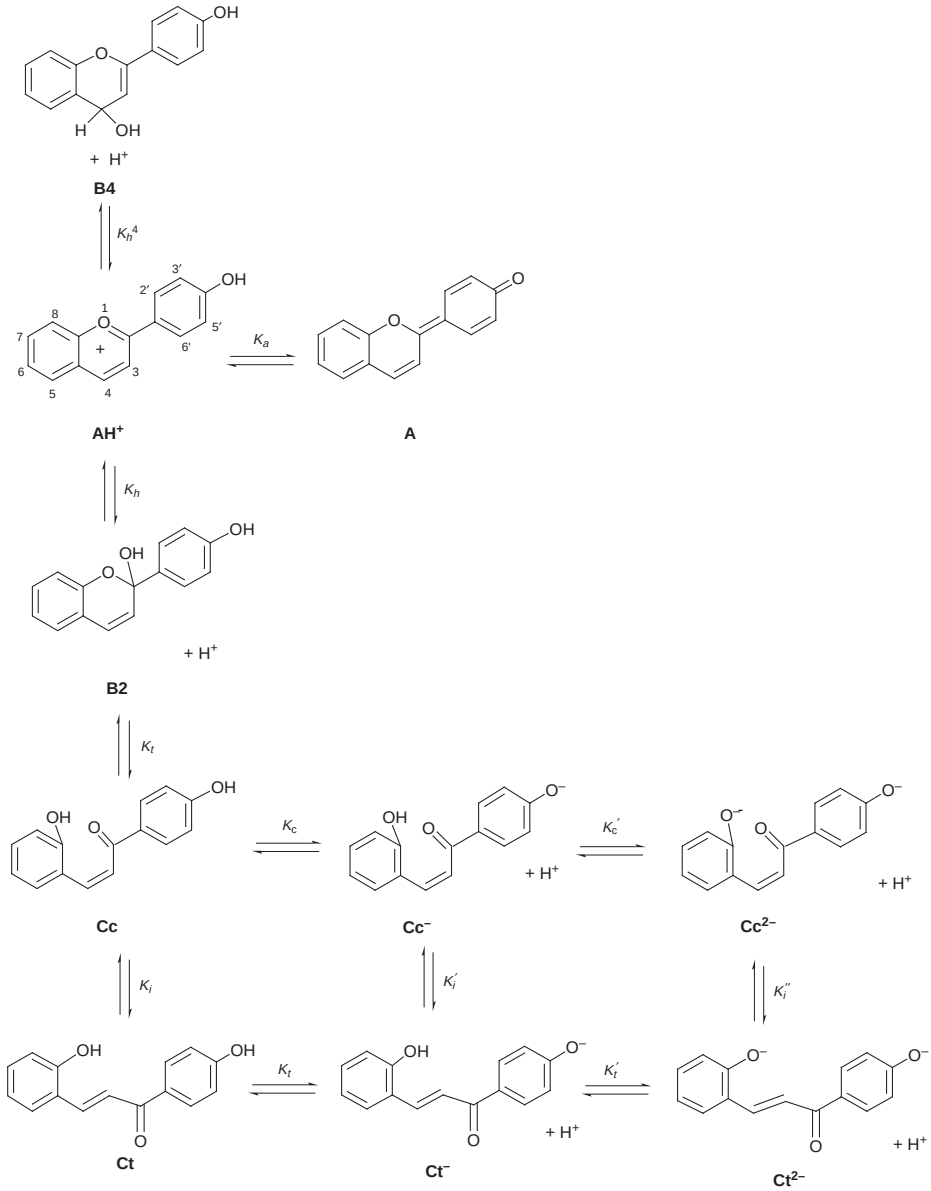

Scheme 2 Structural transformations of the 4′-hydroxyflavylium compound.

Ct²⁻ can be unlocked by a pH jump yielding **Ct** and can then be erased by light excitation. The same performance can be obtained starting from **Ct²⁻**.

Permanent and temporary memories

In our brain there are shallow and deep memory forms.[30] The network of processes interconverting the various species of the 4′-hydroxyflavylium ion allows the presence of different levels of memory.[21] Once the permanent (deep) **AH⁺** form of memory has been obtained (*write* and *lock*, Fig. 9), a jump to pH 12 leads to the formation of a temporary (shallow) memory state, **Cc²⁻**, whose spontaneous slow erasure to give the deep **Ct²⁻** memory can be accelerated by light. Reset can then be accomplished by a back pH jump to pH 4.

Oscillating absorbance patterns

Another feature of the 4′-hydroxyflavylium ion should be emphasized.[21] Starting from **AH⁺**, alternation of pH jump and light excitation causes oscillation patterns of absorbance at different wavelengths, as shown in Fig. 10. Such patterns may be interesting for signal generation purposes.

Logic operations

From a logic viewpoint,[6,7,9,31] simple (bistable) photochromic systems perform YES/NO functions. Multistate/multifunctional molecular-level systems can be taken as bases for more complex logic operations. Chemical systems capable to perform AND,[31] OR,[31] XOR,[32] and XNOR[33]logic operations at the molecular level have been recently reported. With the 4′-hydroxyflavylium compound, light excitation and pH jumps can be taken as inputs, and absorbance or fluorescence as outputs. Starting from the non-emitting **Ct** species, and taking the emission of **AH⁺** at 515 nm as output signal, a jump to pH 1 alone or light excitation alone are not able to generate the output, whereas when these two imputs are applied in series, the output is obtained (AND logic function).[21]

Multiple reaction patterns

It can be interesting to observe that in the network of processes of the 4′-hydroxyflavylium compound some species are interconnected by multiple reaction patterns.[21] For example, in order to go from **AH⁺** to **Ct** three different routes can be chosen (Fig. 11). (i) A jump to pH 12 with formation of **Cc²⁻**, followed by excitation with 313 nm light to obtain **Ct²⁻**, and a jump to pH 6. (ii) A jump to pH 6 to form **Cc**; at this stage, one can choose between two sub-routes, *i.e.* (iia) light excitation with 313 nm

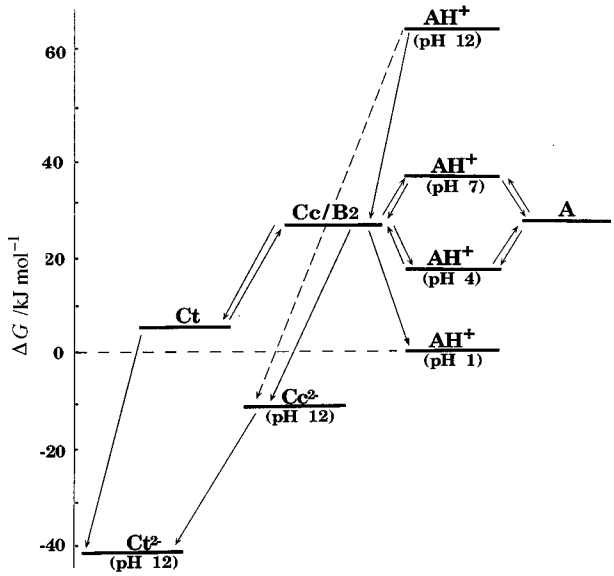

Fig. 4 Energy level diagram for the species involved in the pH jump and flash-photolysis experiments carried out on the 4′-hydroxyflavylium compound. pH values are indicated in brackets. For the sake of simplicity the species **Cc** and **B2** are represented by the same energy level. The ratio between the concentrations of **Cc** and **B2** is *ca.* 1. Reprinted with permission from ref. 21.

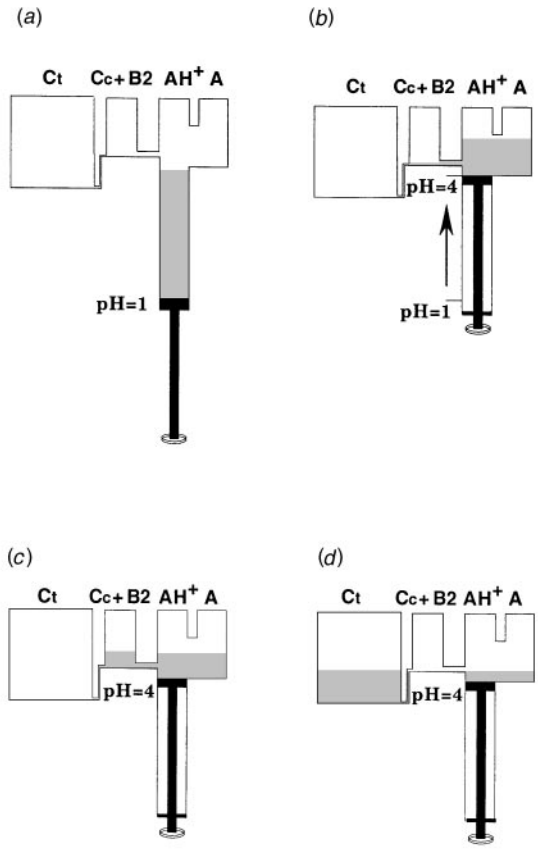

Fig. 5 Hydraulic analogy for a pH jump from pH 1.0 to 4.0: (*a*) the system is equilibrated at pH 1.0; (*b*) the system has been taken to pH 4.0; the pH jump has an effect comparable to raising the piston and the figure represents the situation immediately after the proton transfer process; (*c*) when the *cis*→*trans* isomerization is very slow it is possible to obtain an intermediate (pseudo-equilibrium) state involving the species **AH**$^+$, **A**, **B2** and **Cc**; (*d*) thermodynamic equilibrium at pH 4.0. Reprinted with permission from ref. 22.

light, or (iib) a jump to pH 12 to merge into the preceeding path which goes *via* **Cc**$^{2-}$ and **Ct**$^{2-}$. Once **Ct** has been obtained, one can go back to **AH**$^+$ by two different routes: (iii) light excitation at 365 nm to obtain **Cc** and subsequent jump to pH 1, or, *vice versa*, (iv) a jump to pH 1 and subsequent light excitation at 365 nm. Interestingly, in some cases, *i.e.* starting from **Ct** at pH 6, one obtains the same result (**AH**$^+$) regardless of the order in which light excitation (365 nm) and the pH jump (pH 1) are applied. In other cases, however, this is not true. For example (not shown in Fig. 11), starting from **AH**$^+$ at pH 1, light excitation followed by a pH jump to pH 12 leads to **Cc**$^{2-}$,

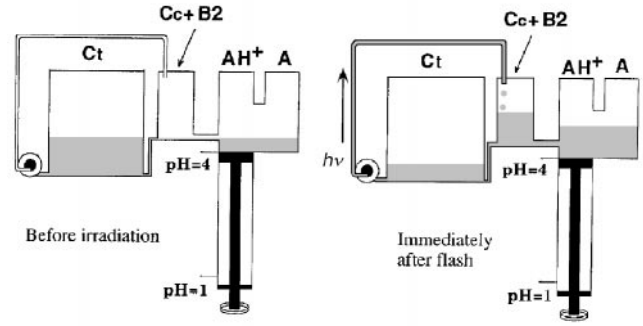

Fig. 6 Hydraulic analogy for the photochemical reaction of **Ct**. Light behaves like a pump that increases (in a transient mode as represented, or in steady state) the quantity of liquid in the reservoir **Cc**. Reprinted with permission from ref. 22.

whereas when the two inputs are applied in the reverse order one gets $\mathbf{Ct^{2-}}$. Since $\mathbf{Cc^{2-}}$ and $\mathbf{Ct^{2-}}$ exhibit very different spectroscopic properties (*e.g.* $\mathbf{Ct^{2-}}$ exhibits fluorescence whereas $\mathbf{Cc^{2-}}$ does not), from the state of the systems after the two inputs one can establish in which sequence the two inputs have been applied.

Color-tap effect

Because of the competition between the pH dependent rate of the reaction leading from the uncoloured **Cc** form to the colored $\mathbf{AH^+}$ and **A** species and the pH independent back *cis* → *trans* isomerization, the amount of colored species formed upon light excitation depends on the pH of the solution. In other words, the pH of the solution plays the role of a tap for the color intensity generated by light excitation.[22] This also means that this system can be viewed as a light-switchable pH indicator. In the case of 4′,7-dihydroxyflavylium the color-tap effect is larger than for 7-hydroxyflavylium.

Conclusions

Synthetic flavylium compounds can exist in several forms (*multistate*) that can be interconverted by more than one type of external stimulus (*multifunctional*). The intricate network of their reactions, when examined from the view points of 'molecular-level devices' and 'molecular level logic functions', reveal that these systems exhibit very interesting properties.

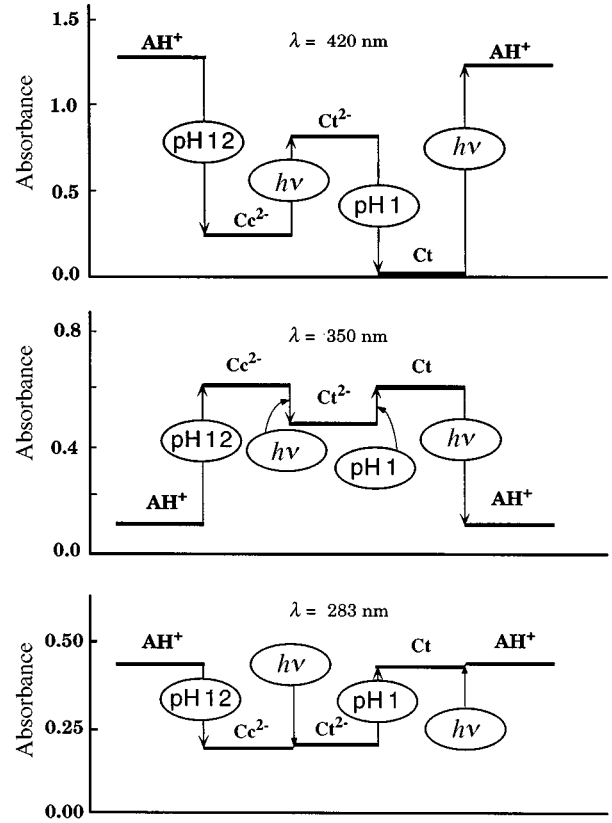

Fig. 10 Absorbance oscillations caused by alternate pH jump and light excitation on a 3.3×10^{-5} M aqueous solution starting from the $\mathbf{AH^+}$ form of the 4′-hydroxyflavylium compound at pH 1. Reprinted with permission from ref. 21.

In our brain, neurons store, exchange, and retrieve information *via* extremely complicated chemical processes. Synthetic multistate/multifunctional systems may play the role of models to begin understanding the chemical basis of complex biological processes. It is not at all clear whether 'wet' artificial systems can find real applications, for example in molecular-scale computers.[34] However, the study of molecular or supramolecular species capable of existing in different forms that can be interconverted by external stimuli is a topic of great interest since it introduces new concepts into the field of chemistry and

stimulates the ingenuity of research workers engaged in the 'bottom up' approach to nanotechnology.

Evidence for zirconocene dications in Kaminsky type catalysts

Malcolm L. H. Green and Jörg Saßmannshausen

Inorganic Chemistry Laboratory, South Parks Road, Oxford, UK OX1 3QR. E-mail: malcolm.green@icl.ox.ac.uk

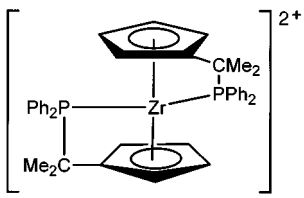
Received (in Cambridge, UK) 22nd October 1998, Accepted 25th November 1998

Low temperature NMR studies indicate that the dicationic salts $[Zr(\eta\text{-}C_5H_4CMe_2C_6H_4Me\text{-}p)_2]^{2+}[MeB(C_6F_5)_3]^-{}_2$ and $[Zr(\eta\text{-}C_5H_4CMe_2Ph)_2]^{2+}$ $[MeB(C_6F_5)_3]_2^-$ are formed when the neutral compounds $[Zr(\eta\text{-}C_5H_4CMe_2Ph)_2Me_2]$ and $[Zr(\eta\text{-}C_5H_4CMe_2C_6H_4Me\text{-}p)_2Me_2]$ and $[Zr(\eta\text{-}C_5H_4CMe_2Ph)_2Me_2]$ are treated with 2 equivalents of $B(C_6F_5)_3$.

Cationic zirconocene complexes are of great interest as catalysts for hydrogenation,[1] isomerisation[2] and especially olefin polymerisation reactions.[3–8] The donor free 14-electron $[Zr(\eta\text{-}C_5H_5)_2R]^+$ cation is believed to be an active species in Ziegler–Natta type olefin polymerisation. However, they are extremely reactive and not isolable. The corresponding 16-electron donor stabilised cations of the type $[Zr(\eta\text{-}C_5H_5)_2R(L)]^+$ or the 18-electron cations $[Zr(\eta\text{-}C_5H_5)_2R(L)_2]^+$ are known where the donor ligands are nitriles, cyclic ethers[9–16] or tertiaryphosphines.[17]

Recently, we described the reactions of the compounds $[Zr(\eta\text{-}C_5H_5)(\eta\text{-}C_5H_4CMe_2Ph)Me_2]$ **1**, $[Zr(\eta\text{-}C_5H_5)(\eta\text{-}C_5H_4CMe_2C_6H_4Me\text{-}p)Me_2]$ **2**, $[Zr(\eta\text{-}C_5H_4CMe_2Ph)_2Me_2]$ **3**, and $[Zr(\eta\text{-}C_5H_4CMe_2C_6H_4Me\text{-}p)_2Me_2]$ **4** with the Lewis acid $B(C_6F_5)_3$ which gave monocations, *e.g.* $[Zr(\eta\text{-}C_5H_5)(\eta\text{-}C_5H_4CMe_2Ph)Me_2]^+[MeB(C_6F_5)_3]^-$. The NMR evidence indicated there was intramolecular phenyl coordination to the cationic zirconium centre.[18] These complexes may be regarded as models of solvated cationic zirconocene species presumed to be present in toluene solutions of Kaminsky type olefin polymerisation catalysts.

Metallocene dications $[M(\eta\text{-}C_5H_5)_2L_2]^{2+}X^-{}_2$ have been reported,[19–22] (M = Ti, Zr; L = H_2O or MeCN; X = $CF_3SO_4^-$ ClO_4^-, BPh_4^-) and notably recent work by Erker and coworkers (**A**).[17]



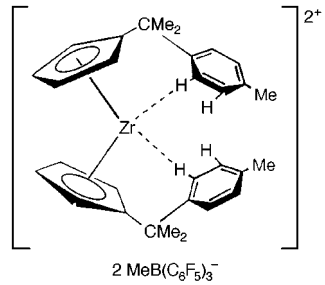
A

Here we report evidence for the formation of dicationic zirconocenes stabilised by metal-arene interactions.

The previously described[18] compounds $[Zr(\eta\text{-}C_5H_4CMe_2Ph)_2Me_2]$ **3** and $[Zr(\eta\text{-}C_5H_4CMe_2C_6H_4Me\text{-}p)_2Me_2]$ **4** were treated with 2 equivalents of $B(C_6F_5)_3$ in CD_2Cl_2. The reactions were monitored by NMR spectroscopy. At −60 °C the reaction of **4** proceeds cleanly to give a single product, which the NMR data below clearly indicate is the salt $[Zr(\eta\text{-}C_5H_4CMe_2C_6H_4Me\text{-}p)_2]^{2+}[MeB(C_6F_5)_3]_2^-$ **5**.

The NMR spectroscopic evidence supporting the structure proposed for **5** is:

(i) A broad signal at δ 0.40 in the ^{1}H NMR spectrum and a corresponding broad signal at δ 9.58 in the ^{13}C NMR spectrum which can be assigned to the separate $[MeB(C_6F_5)_3]^-$ anion.[23] This observation is further strengthened by the chemical shift difference $\Delta\delta(m,p\text{-F})$ between the *m*- and *p*-^{19}F of the anion.[24] Values of $\Delta\delta(m,p\text{-F})$ between 3 and 6 ppm indicate coordination of the anion to the zirconium centre whilst values < 3 ppm indicate non coordination of the anion. The observed value of $\Delta\delta$ 2.8 ppm corresponds to a solvent-separated ion pair.



5

(ii) The absence of a Zr*Me* signal in ^{1}H and ^{13}C NMR together with the integration of the $[MeB(C_6F_5)_3]^-$ anion (6H) indicates the abstraction of *two* rather than *one* methide group from the metal.

(iii) Unlike the reaction product of **4** with *one* equivalent of $B(C_6F_5)_3$ [18] the dication **5** possesses a C_2 axis, which renders the two phenyl groups and the two cyclopentadienyl ligands equivalent. Therefore only four signals for the phenyl group and four signals for the cyclopentadienyl ligand are observed in the ^{1}H NMR spectrum. Furthermore, unlike the reaction product of **4** with 1 equivalent of $B(C_6F_5)_3$, the signals for the cyclopentadienyl hydrogens are *sharp*, as seen in Fig. 1 showing the ^{1}H NMR spectrum of the reaction product of **4** with 1 equivalent of $B(C_6F_5)_3$ and Fig. 2, the spectrum of the dication **5** formed with 2 equivalents of $B(C_6F_5)_3$.

(iv) One of the proton signals of each of the cyclopentadienyl ligands of **5** is significantly shifted *upfield* (δ 3.70) which can be explained by the magnetic anisotropy of the phenyl group. In contrast to the ^{1}H NMR spectrum of the reaction product of $[Zr(\eta\text{-}C_5H_5)(C_5H_4CMe_2C_6H_4Me\text{-}p)Me_2]$ **2** and 1 equivalent of $B(C_6F_5)_3$, where one of the cyclopentadienyl hydrogen signals is shifted *downfield* (δ 6.94), due to a *deshielding* effect of the phenyl ring,

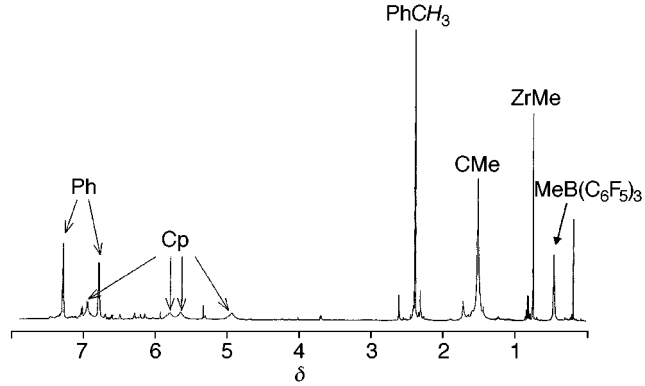


Fig. 1 ^{1}H NMR spectrum of **4** with 1 equivalent of $B(C_6F_5)_3$ at −60 °C.

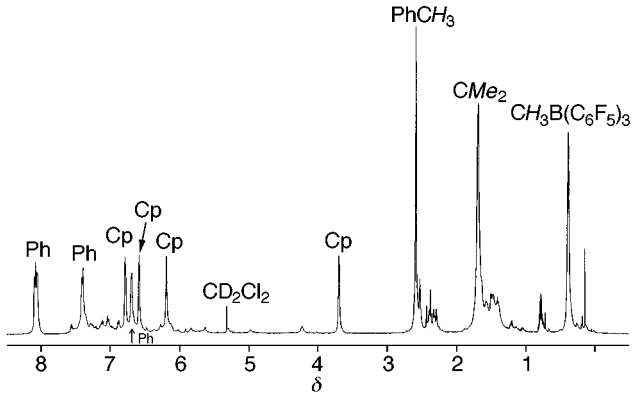

Fig. 2 ^{1}H NMR spectrum of **4** with 2 equivalents of $B(C_6F_5)_3$ at −60 °C.

here the phenyl ring is located slightly differently probably due to the more sterically crowded environment around the zirconium metal and the cyclopentadienyl hydrogen encounters a *shielding* effect. Interesting is the corresponding ^{13}C signal, which is observed at δ 128.43 (assignment *via* CH correlation spectroscopy).

(v) Similar to the ^{1}H NMR of the reaction product of **2** with 1 equivalent $B(C_6F_5)_3$, one of the phenyl hydrogen signals is shifted *upfield* to δ 6.69 (*cf.* Fig. 2). This can be assigned to a hydrogen coordinated, or close to, to the zirconium centre. Similar observations of upfield shifts of coordinated phenyl-hydrogen have been made before,[25] notably by Horton *et al.*[26]

(vi) Warming the sample of **5** to −40 °C changes the NMR spectra giving new peaks which are identical to the previously described monocation $[Zr(\eta\text{-}(C_5H_4CMe_2C_6H_4Me\text{-}p)_2Me]^+[MeB(C_6F_5)_3]^-$ [18] and the presence of excess $B(C_6F_5)_3$ also appears in the ^{19}F NMR spectrum. This reaction is reversible and on re-cooling the sample to −60 °C the original spectrum is restored. Further warming above −40 °C increases the amount of the monocation, however some decomposition products are also observed.

The reaction between $[Zr(\eta\text{-}C_5H_4CMe_2Ph)_2Me_2]$ **3** and 2 equivalents of $B(C_6F_5)_3$ also gives a product with similar properties to **5**. However it is less soluble than **5** and this restricts investigations at −60 °C. Nonetheless the data are fully consistent with the proposed formulation of the product $[Zr(\eta\text{-}C_5H_4CMe_2Ph)_2]^{2+}$ $[MeB(C_6F_5)_3]^-{}_2$ **6**. Crystals of **6** were not suitable for X-ray crystallography due to twinning. The NMR data for the compounds **5** and **6** are available as supplementary data (see http://www.rsc.org/suppdata/cc/1999/115).

In conclusion the reaction of **3** and **4** with 2 equivalents of $B(C_6F_5)_3$ leads to the formation of dicationic complexes **5** and **6**. These complexes have been characterised by NMR spectroscopy and elemental analysis. The dications of **5** and **6** can be viewed as a model for the cationic species $[Zr(\eta\text{-}C_5H_5)_2(solvent)_2]^{2+}$ and these may well be present in aromatic solutions of Kaminsky-type zirconocene olefin polymerisation catalysts systems.

We would like to thank Dr L. H. Doerrer and Dr D. Häußinger for helpful discussions.

The first total synthesis of (±)-pallescensin B

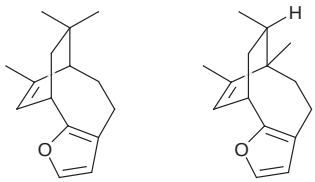
Wen-Cheng Liu and Chun-Chen Liao*

Department of Chemistry, National Tsing Hua University, Hsinchu, Taiwan 300. E-mail: ccliao@faculty.nthu.edu.tw

Received (in Cambridge, UK) 9th November 1998, Accepted 20th November 1998

The first total synthesis of the title compound has been accomplished using an intramolecular Diels–Alder reaction of a masked *o*-benzoquinone, anionic [1,3]-rearrangement of a vinylbicyclo[2.2.2]octenol and intramolecular hetero-Michael addition of a hydroxy enone as the key steps.

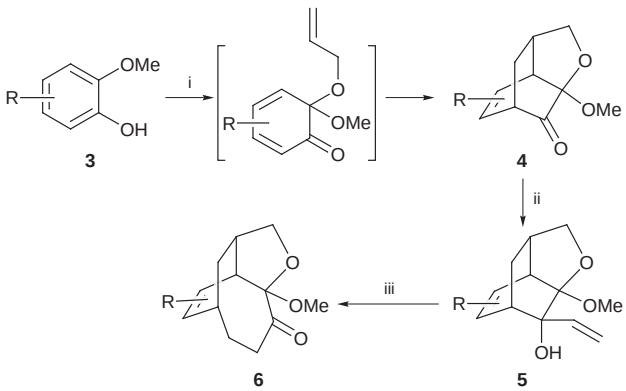
Pallescensins are a group of furanosesquiterpenoids isolated from the marine sponge *Disidea pallescens* by Cimino *et al*.[1] The common feature of these terpenoids is that they all contain a furan moiety; however they have carbon skeletons of varying complexity. Among the pallescensins, pallescensin B **1** presents the most complex architecture, with a unique bicyclo[4.2.2]decane system fused to a furan moiety. Interestingly, bicyclo[4.2.2]decane skeletons are relatively rare among natural products, the only other known example being nakafuran-8 **2**.[2]



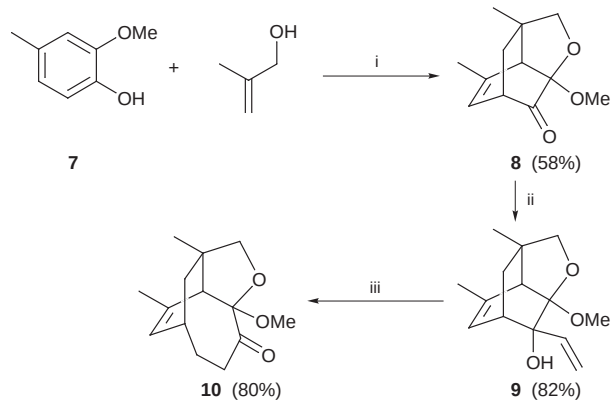
1 **2**

The synthesis of the bicyclo[4.2.2]decane skeleton poses a considerable challenge. Although a few methods exist for their synthesis,[2,3] they lack versatility and provide the desired skeleton only after several steps. Despite the long sequence of reactions it requires, Uyehara's approach to this skelecton is noteworthy.[2] Quite recently, we have developed a novel and efficient four-step methodology starting from 2-methoxyphenols, *via* anionic [1,3]-rearrangement of vinylbicyclo[2.2.2]-octenol derivatives as the key step, for the stereocontrolled synthesis of functionalized bicyclo[4.2.2]decenones (Scheme 1).[4] We herein report the first total synthesis of (±)-**1** clearly expressing the utility of the aforementioned methodology.

It was planned to use compound **10** as the key intermediate to achieve the synthesis of **1**, as we expected compound **9** to undergo anionic [1,3]-rearrangement. Synthesis of compound **10** was accomplished as shown in Scheme 2. Accordingly, the



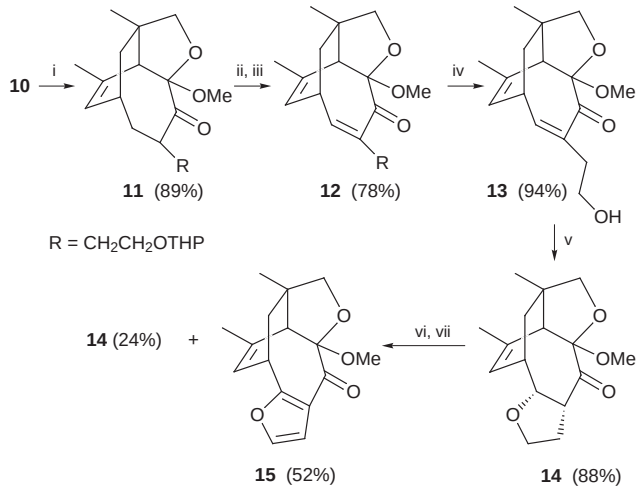
Scheme 1 *Reagents and conditions*: i, allyl alcohol, $PhI(OAc)_2$, CH_2Cl_2; ii, CH_2=CHMgBr; iii, KH, 18-crown-6.



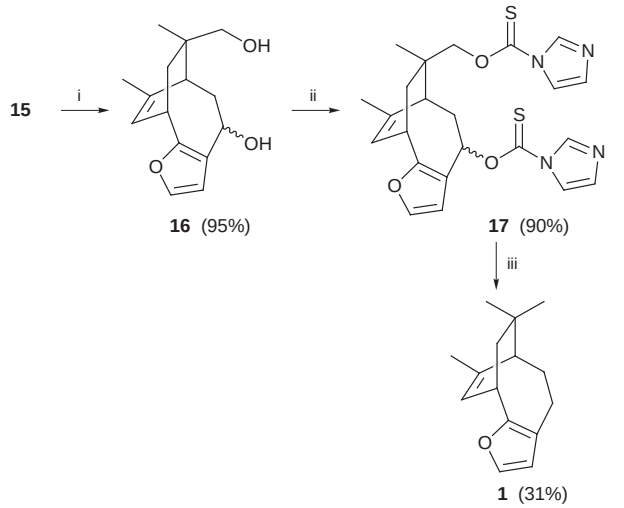
Scheme 2 *Reagents and conditions*: i, $PhI(OAc)_2$, $NaHCO_3$, 55–60 °C; ii, CH_2=CHMgBr, $ZnBr_2$, −78 °C to room temp.; iii, KH, 18-crown-6, 1,4-dioxane, reflux.

requisite bicyclo[2.2.2]octenone derivative **8** was prepared from 2-methoxy-4-methylphenol **7** in 58% yield, following a procedure developed in our laboratory for the synthesis of similar compounds.[5] Stereoselective addition of vinylmagnesium bromide to compound **8** in the presence of zinc bromide at −78 °C afforded **9** in 82% yield as the only discernible product. Subsequent anionic [1,3]-rearrangement of **9** proceeded smoothly to provide **10** in 80% yield (Scheme 2).

With compound **10** in hand, the stage is set for the construction of the furan ring, which was accomplished *via* seven synthetic steps, as shown in Scheme 3. The required two-carbon unit was introduced *via* alkylation of **10** using 1-bromo-2-(2-tetrahydropyranyloxy)ethane in the presence of KH at 0 °C in THF to obtain compound **11** in 89% yield as a 1:1 mixture of diastereomers. Then compound **11** was converted into the corresponding enone **12** using Saegusa's procedure[6] in two steps and in about 78% yield. The removal of the THP group was achieved *via* transacetalization with Pr^{i}OH catalyzed by PPTS to obtain the alcohol **13** as a single product. Intra-



Scheme 3 *Reagents and conditions*: i, RBr, KH, THF, 0 °C; ii, KH, TMSCl; iii, $Pd(OAc)_2$, MeCN; iv, Pr^{i}OH, PPTS, 55 °C; v, NaOH, MeOH, 80 °C; vi, KH, TMSCl; vii, DDQ, benzene, reflux.



Scheme 4 *Reagents and conditions*: i, SmI_2, MeOH, THF; ii, 1,1′-thiocarbonyldiimidazole, $ClCH_2CH_2Cl$, reflux; iii, Bu_3SnH, AIBN, toluene, reflux.

molecular Michael addition of **13** by treatment with 6 M aq. NaOH in MeOH at 80 °C furnished the tetrahydrofuran **14** as a single stereoisomer in 88% yield. The assigned stereochemistry of compound **14** was based on NOE experiments. Aromatization of **14** was accomplished *via* treatment of its silyl enol ether (KH, TMSCl) with DDQ in refluxing benzene to obtain the desired compound **15** in 52% yield, along with 24% of **14** (Scheme 3).

With construction of the complete carbon framework of **1** accomplished, the remaining task was to deoxygenate **15**. Towards this end, reduction of **15** with SmI_2 in the presence of MeOH was carried out first to obtain the diols **16** as a mixture of epimers,[7] which were converted then into a mixture of the corresponding bis-thiocarbamates **17** in 90% yield. The last hurdle to target compound **1** was passed by means of reduction of **17** with tin hydride initiated by AIBN in refluxing toluene (Scheme 4).[8] The structure of **1** was unambiguously established by its IR, ^1H and ^{13}C NMR, low and high resolution mass spectral data.[9] The UV, ^1H NMR and mass spectral data of synthetic (±)-**1** were found to be essentially identical with those reported by Cimino *et al*. for the natural product.[1]

Thus the synthesis of (±)-**1** was accomplished in 13 steps from readily available starting materials. In conclusion, the synthesis of (±)-**1** described here clearly exhibits the versatility of our methodology for the construction of the bicyclo[4.2.2]-decane skeleton and also confirms the structural assignments of the natural product.

The authors thank the National Science Council of the Republic of China for the financial support of this research work. We also thank Dr P. Dharma Rao for helpful discussions.

Synthesis of an unsymmetrical bis-lexitropsin-1,2,9,9a–tetrahydrocyclopropa[*c*]benzo[*e*]indol-4-one (CBI) conjugate

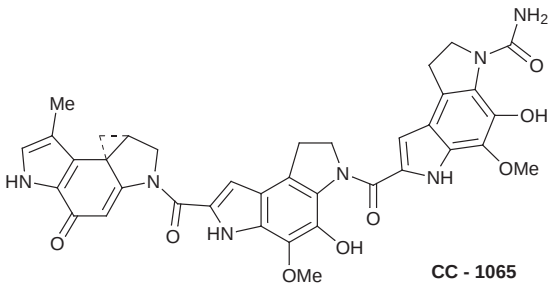
Guofeng Jia, Hirokazu Iida and J. William Lown*

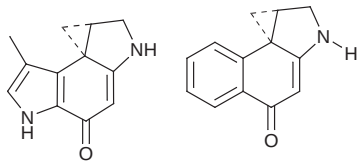
Department of Chemistry, University of Alberta, Edmonton, AB, Canada T6G 2G2.
E-mail: annabella.wiseman@ualberta.ca

Received (in Corvallis, OR, USA) 8th October 1998, Accepted 23rd November 1998

A practical synthesis of a novel bis-functionalized precursor of 1,2,9,9a-tetrahydrocyclopropa[*c*]benzo[*e*]indol-4-one (CBI) is described; the first unsymmetrical bis-lexitropsin–CBI precursor conjugate was thereby synthesized.

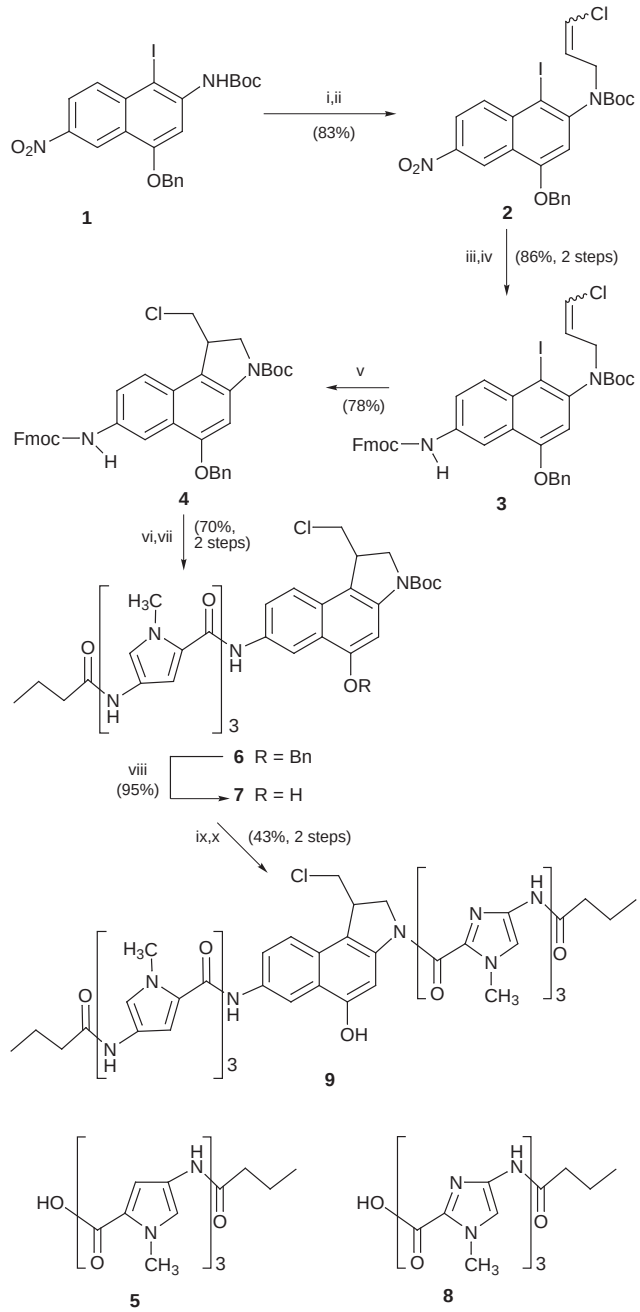
CC-1065, an antitumor antibiotic isolated from the culture of *Streptomyces zelensis*,[1] is one of the most potent cytotoxic agents ever discovered and has a wide spectrum of activity against tumor cells *in vitro* and *in vivo* as well as against microbial organisms.[2] However, CC-1065 cannot be used in humans because it was found that it caused delayed death in experimental animals.[3] In the search for compounds with better antitumor selectivity and DNA sequence specific binding





properties, many CC-1065 analogs have been synthesized in attempts to avoid the undesired side effects while retaining its potency against tumor cells.[4] As a successful example of modification of 1,2,8,8a-tetrahydro-7-methylcyclopropa[*c*]-pyrrolo[3,2-*e*]indol-4-one (CPI), the DNA alkylating moiety of CC-1065, Boger first reported that the simplified moiety, 1,2,9,9a-tetrahydrocyclopropa[*c*]benzo[*e*]indol-4-one (CBI), and its analogs were more stable and more potent than the CPI counterparts.[5]

In our group, attempts have been made to link CPI with lexitropsins, the well-established DNA minor groove binders. It was found that some optimized CPI–lexitropsin conjugates exhibit up to 10000 times higher potency than CC-1065 against KB human cancer cells.[3] Molecular modeling studies predicted that a CBI moiety bearing a lexitropsin carrier on both sides should be more firmly bound to its DNA target sequence and might therefore show enhanced potency. This strategy is designed to exploit binding-driven bonding of the alkylating moiety. We have already reported the synthesis of conjugates of CBI bearing two identical lexitropsins which containing pyrrole units.[6] Studies on lexitropsins or information reading molecules show that replacement of pyrrole units by imidazoles in lexitropsins may cause a change in the base site recognition from AT to GC in minor groove of B-DNA.[7] In order to permit targeting of mixed DNA sequences and to thereby investigate the effects of DNA sequence selective ability, we herein



Scheme 1 *Reagents and conditions*: i, NaH; ii, ClCH=CHCH$_2$Cl, Bu$_4$NI; iii, hydrazine hydrate, FeCl$_3$, C; iv, FmocCl, Et$_3$N; v, Bu$_3$SnH, AIBN; vi, TBAF; vii, **5**; viii, HCO$_2$NH$_4$, Pd/C; ix, HCl; x; **8**.

describe the synthesis of an unsymmetrical bis-lexitropsin–CBI conjugate, which contains two different lexitropsins. In our previous work,[6] the CBI moiety was obtained by an *in situ* primary radical trap with TEMPO. Here, the CBI moiety was synthesized by using a more concise and shorter route which was recently developed by Patel and co-workers.[8]

Deprotonation of carbamate **1**[6] using NaH, followed by alkylation of the resulting anion with 1,3-dichloropropene in the presence of the phase transfer catalyst Bu_4NI gave an mixture of *Z* and *E* isomers of vinyl chloride **2**. Selective reduction of the nitro group of **2** using hydrazine,[9] followed by protection of the amino group, provided **3**, the desired precursor for the intramolecular aryl radical cyclization on to a tethered vinyl chloride.[8] A deoxygenated solution of **3** in dry benzene was heated at reflux for 15 h in the presence of 2 equiv. of Bu_3SnH and a catalytic amount of AIBN to give the fully protected bifunctionalized CBI prodrug form, racemic **4**.† Although not investigated in detail, no reaction occurred when nitro compound **2** was treated under the same conditions as amine **3**.

Detachment[10] of the Fmoc group from **4**, followed by coupling with polypyrrole carboxamide **5**[11] using HOBt and EDCI as the coupling agents[11b,c] afforded the hybrid **6**. Hydrogenolysis[8a] of **6** served to remove the benzyl ether almost quantitatively and provided **7**. Acid-mediated deprotection of **7**, followed by coupling with polyimidazole carboxamide **8**[11] using EDCI provided the final bis-lexitropsin–CBI precursor conjugate **9**‡ in fair yield.

In summary, we have described a synthesis of the bis-functionalized CBI precursor containing two different protective groups and obtained the corresponding unsymmetrical bis-lexitropsin conjugate. Results on the DNA sequence preferences and biological evaluation will be reported in due course.

We are grateful for a research grant (to J. W. L.) from the Natural Sciences and Engineering Research Council of Canada.

Received (in Bloomington, IN, USA) 3rd August 1998, Revised manuscript received 19th November 1998, Accepted 20th November 1998

A novel method for trimethylsylilation of micro- and mesoporous titanosilcates using BSTFA [N,O-bis(trimethylsilyl-)trifluoroacetamide] renders Ti-MCM-41 and SiO_2/TiO_2 aerogels active for olefin epoxidation with aqueous H_2O_2, and even improves the activity of TS-1.

The importance of hydrophobicity for titanosilicate catalyzed oxidation reactions with aqueous H_2O_2 has been the subject of much recent research. The hydrophobicity of the interior pores of titanosilicalite (TS-1) and Al-free Ti-beta renders them active for aqueous H_2O_2 oxidation of alkanes and alkenes.[1,2] By comparison, Al containing Ti-beta is less efficient, mainly because of framework Al induced hydrophilicity.[3] Because of their mesoporous nature (25–100 Å pores) Ti-MCM types[4,5] would be useful as oxidation catalysts for larger, higher value molecules. However, Corma and coworkers[5] observed that because of its hydrophilic nature, Ti-MCM-41 was much less effective for oxidation with aqueous H_2O_2 than even Al-Ti-beta. Therefore it is not surprising that efforts to render Ti-MCM's hydrophobic and hence, more active, were undertaken: Tatsumi *et al*.[6] trimethylsilylated Ti-MCM-41 and Ti-MCM-48 using trimethylsilyl chloride and hexamethyldisiloxane and observed increased oxidation activity.[4] Amorphous silica/titanias with even wider pores present opportunity for further increasing the range of oxidation substrates. Recently non-catalytic and hydrophilic amorphous silica/titanias have been made hydrophobic and catalytic by substituting alkoxy groups in the silica precursors with alkyl or phenyl groups during the sol–gel synthesis.[7,8]

Herein we report a simple and effective technique for trimethylsilylation of microporous crystalline TS-1, mesoporous Ti-MCM-41(Ti-MCM), and SiO_2/TiO_2 aerogels (Ti-Agel). The resultant materials are hydrophobic and have enhanced activity for olefin epoxidation with aqueous H_2O_2.

TS-1 was synthesized by the method of Thangaraj and Sivasanker.[9] Corma's method[5] for the preparation of Ti-MCM-41 was modified by using a single precursor for titanium and silicon: Gelest diethoxysiloxane–ethyltitanate copolymer (no. in Gelest catalogue = PSITI-019), $[(EtO)_2SiO][(EtO)_2TiO]$, Si : Ti ≈ 15. The general method for the preparation of aerogel catalysts was that of Dutoit *et al*.,[10] with acetylacetone-modified titanium isopropoxide. The sol–gel was continuously extracted with supercritical CO_2 at 40 °C at 24.2 MPa for 5 h. The resulting fluffy yellow powder was calcined at 400 °C for 1 h in N_2 followed by 600 °C for 5 h in air.

A typical procedure for the trimethylsilylation of catalysts is as follows: a mixture of *N,O*-bis(trimethylsilyl)trifluoroacetamide [$CF_3COSiMe_3)_3$]=$NSiMe_3$ or BSTFA] (1.0 g) and toluene (8 g) was added to the catalyst (0.5 g). The mixture was stirred for 2 h at room temperature, filtered, and the solids washed with toluene and air dried. The dried materials' hydrophobicity was evidenced by their floating on water. In addition, using a TGA method derived from Anderson and Klinowski[17] we obtained the following hydrophobicities (mg water adsorbed silylated/mg water adsorbed non-silylated at 50 °C) for TS-1, Ti-MCM, and TiAgel respectively: 1.04, 0.41, 0.68. As expected, the ratio for trimethylsilylated TS-1 was near unity because trimethylsilylation is not expected to affect the interior pore system. However, for the mesoporous materials the ratio is less than unity consistent with trimethylsilylation of the accessible surface. Other trimethylsilylating agents such as trimethylsilyl chloride and hexamethydisilazane were also used successfully. However, these required more severe conditions and, in the case of the chloride, resulted in loss of Ti from the aerogels. While BSTFA has been used to derivatize organics and end group cap chromatographic columns,[11] there is no reference to using it to modify catalysts. Characterization data for the catalysts are given in Table 1.

BSTFA treatment of TS-1 introduces IR bands consistent with trimethylsilylation. Because of the strong asymmetric stretch of the silicate lattice at *ca*. 1225–1230 cm^{-1}, we are unable to detect the diagnostic symmetric methyl deformation in the 1250–1260 cm^{-1} region.[12] We do see the antisymmetric methyl deformation at *ca*. 1400 cm^{-1}, as well as bands at *ca*. 725 and 700 cm^{-1} that may be assigned to the antisymmetric Si–C and the symmetric Si–C stretching modes, respectively.

Table 1 Characterization data for TS-1, Ti-MCM and Ti-Agel[a]

[a] Elemental analysis by inductively coupled plasma spectroscopy (ICP): MCM: Ti-MCM-41, Ti-Agel: SiO_2/TiO_2 Aerogel, syl: trimethylsilylated I_{960}: assumed to be ν(Si–O–Ti):[10] I_{1090}: ν(Si–O–Si).[10] A_1: absorbance of band due to isolated Ti. A_2: absorbance of band due to $(Ti–O)_n$ oligomers. SA: BET N_2 surface area/$m^2\ g^{-1}$. PV: BJH N_2 pore volume ml g^{-1}. APD: BJH N_2 av. pore diameter/Å. [b] No TiO_2 phases observed by XRD in any of the samples. [c] Position of 960 band, KBr pellet technique. [d] Si/Ti charged = 15. [e] Shoulder at ≈320 nm indicates anatase.

Bands near 1680 and 1750 cm^{-1} are assigned to the amide group of trifluoroacetamide (the silylation byproduct) and residual BSTFA, respectively. The IR spectrum of Ti-Agel is very similar to that of Ti-MCM, which is to be expected since the latter is composed of amorphous walls. For both Ti-MCM and Ti-Agel, silylation added bands to the IR spectra that can be attributed to $SiMe_3$ groups, especially the very distinctive band at 1250–1260 cm^{-1}, and the CH_3 rocking modes at *ca*. 840 and 755 cm^{-1}.[12]

The IR band at *ca*. 960 cm^{-1} (the 960 band) has been attributed to Si–O–Ti bonds as a fingerprint for tetrahedral Ti substitution in silicate lattices,[10] or to Si–OH groups.[13, 14] We hypothesize that for our TS-1 loss of silanol groups after trimethylsilylation results in a decrease in the 960 band intensity. The intensity of the 960 band of Ti-MCM decreased on silylation, in agreement with Tatsumi *et al*.[6] However, the 960 band of Ti-Agel decreases only slightly upon trimethylsilylation, consistent with a smaller fraction of silanols available to the silylating agent compared to MCM. Based upon the pronounced hydrophobic nature of the silylated material these must be the ones which confer hydrophilicity to the base aerogel.

Analysis of the UV–VIS data[15] for all of the base materials indicates the presence of isolated Ti and oligomeric $(Ti–O)_n$ species; in addition, TS-1 and Ti-MCM are contaminated by anatase. The non-isolated Ti-species may have a detrimental effect on the epoxidation reaction, since they have been reported to decompose H_2O_2 homolytically.[16] Ti-isolation, as measured roughly by the ratio of the absorbance of band due to isolated Ti to the band due to $(Ti–O)_n$ oligomers, (A_1/A_2), is better for Ti-Agel compared with Ti-MCM. This may be ascribed to the acac modification performed on the Ti-precursor for Ti-Agel, which slows down the condensation rate of the hydrolyzed Ti species.[10] The effect of trimethylsilylation on the UV–VIS spectra of the samples is not great, indicating that the silylation procedure probably did not result in reaction with the isolated Ti sites or H_2O_2 destroying sites.

N_2 adsorption measurements on Ti-MCM confirmed that surface area and pore size decrease on trimethylsilylation.[6] Our Ti-MCM contains microporosity, probably related to the titania or silica/titania impurities resulting from the high Ti-concentration in the synthesis gel. For Ti-Agel, trimethylsilylation decreases surface area and mesopore volume as expected. Because of limitations in the N_2 adsorption techniques, the effect of trimethylsilylation on the microporosity of TS-1 could not be determined.

Trimethylsilylation of the available surfaces of TS-1, Ti-MCM, and Ti-Agel increased the efficiency of olefin epoxidation reactions with dilute aqueous hydrogen peroxide (Table 2). Especially striking were the results with Ti-MCM and the aerogels where epoxidation yields were dramatically increased after the treatment. Rendering the catalyst surfaces hydrophobic has either improved access of the olefin to the active sites or has diminished the inhibitory effect of water.[1] Either scenario should result in increased catalytic activity.

In the case of the TS-1 the improved activity after trimethylsilylation may be attributed to better wetting of the microcrystallite surface with the olefin. While it is possible that the increase in activity is related to loss of oligomeric $(Ti-O)_n$ H_2O_2 decomposition sites after trimethylsilylation, lack of changes in the UV–VIS and the probably very low concentration of reaction sites for silylation argue against this.

It is important to note that the trimethylsilylation technique described in this communication results in nearly equivalent epoxidation activity for any of the titanosilicates studied, the only requirement being the presence of isolated, tetrahedral Ti sites. Especially striking is the treatment of normally inert aerogel; we believe this to be the first report of *post synthesis* activation of this material. In addition the expectation of epoxidizing molecules too large to fit in the pores of TS-1 has been realized for the Ti-aerogel after the silylation treatment. *cis*-Cyclooctene is epoxidized readily by Ti-Agel-syl compared to almost no reaction with either TS-1 or TS-1-syl.

In summary we have demonstrated a general method for significantly increasing the activity of titanosilicate oxidation catalysts using aqueous hydrogen peroxide by rendering their surfaces hydrophobic by treatment with the trimethylsilylating agent BSTFA.

Table 2 Effect of trimethylsilylation on the epoxidation activity of Ti-Agel, Ti-MCM, and TS-1 titanosilicates[a]

Catalyst	$\%H_2O_2$	Olefin[b]	Epoxide yield[c]
Ti-Agel	10	1-Oct	0.2
Ti-Agel	10	COT	0.5
Ti-Agel-syl	10	1-Oct	6
Ti-Agel-syl	10	COT	32
Ti-MCM	3	1-Oct	0.5
Ti-MCM-syl	3	1-Oct	23.6
TS-1	10	1-Oct	2.4
TS-1	10	COT	0
TS-1-syl	10	1-Oct	12.9
TS-1-syl	10	COT	0.5

[a] *Reaction conditions*: olefin (3 ml), aq. H_2O_2 (1 ml), catalyst (50–100 mg)[d] stirred at room temperature for 24 h. [b] 1-Oct: oct-1-ene, COT: *cis*-cyclooctene. [c] Yield of the corresponding epoxide was based on initial H_2O_2 concentration. The only significant byproduct with oct-1-ene was octan-1-al (5–10%); with cyclooctene no byproducts were observed. [d] 100 mg with Ti-Agel and TS-1, 50 mg with Ti-MCM.

Syntheses and structures of quinuclidine-stabilized four- and five-coordinate mono- and di-chlorogallane

Bing Luo, Victor G. Young, Jr. and Wayne L. Gladfelter*

Department of Chemistry, University of Minnesota, Minneapolis MN 55455, USA. E-mail: gladfelt@chem.umn.edu

Received (in Columbia, MO, USA) 10th September 1998, Accepted 18th November 1998

Hydride/chloride redistribution reactions provided high yields of $GaCl_2H$(quin) I, $GaCl_2H(quin)_2$ II, $GaClH_2$(quin) III and $GaClH_2(quin)_2$ IV(quin = quinuclidine) and structural characterization of compounds II and IV authenticate the unusual five-coordinate geometry for gallium hydride complexes.

Organogallium compounds are used extensively to prepare solid state materials such as GaN.[1] In metal organic chemical vapor deposition (MOCVD) processes, for instance, the high volatility, long shelf-life and chemical reactivity of compounds such as $GaMe_3$ have made them especially attractive molecular precursors. One of the drawbacks of organogallium compounds is the presence of direct Ga–C bonds that can lead to unwanted incorporation of carbon into the solid state product. In sensitive opto-electronic devices such as lasers, even trace quantities of carbon can seriously degrade performance.[2] Replacement of the carbon-based ligands with hydrides appears as an attractive alternative but suffers from the lower stability and more difficult syntheses of the compounds. We report in this paper the preparation and structure of mono- and di-chlorogallanes stabilized by quinuclidine. Strong donors, including trimethylamine,[3,4] quinuclidine[5] and tricyclohexylphosphine,[6] stabilize GaH_3, which in the absence of the donor exists as Ga_2H_6 and decomposes above −30 °C.[7] The presence of chloro ligands offers attractive synthetic routes to molecules that can be used as single source precursors in CVD processes.

Unstabilized mono- and di-chlorogallane have been synthesized by the reaction of $GaCl_3$ with trimethylsilane[8,9] and have been stabilized by direct reaction with donors. Chloride/hydride exchange has proven to be successful for the syntheses of other substituted gallanes,[10,11] and the following alternative routes bypass the need to prepare and purify $[GaClH_2]_2$ and $[GaCl_2H]_2$. All reactions were conducted under an atmosphere of prepurified nitrogen. A diethyl ether (20 mL) solution of $GaCl_3$ (0.957 g, 5.44 mmol) was added to a stirred, 30 mL ether solution of GaH_3(quin) (quin = quinuclidine) (0.500 g, 2.72 mmol) at room temperature over a period of 1 h. The resulting mixture was stirred at room temperature for an additional 6 h, at which point an additional equivalent of quinuclidine (5.44 mmol) dissolved in ether was added. This delayed addition of quinuclidine facilitated the ligand redistribution reaction [eqn. (1)], which presumably required an available coordination site

$$2\ GaCl_3 + GaH_3(quin) + 2\ quin \rightarrow 3\ GaCl_2H(quin) \quad (1)$$

on the gallium. The reaction mixture was stirred for another 14 h, then filtered. Upon concentration and storage at −15 °C, the colorless filtrate yielded 1.65 g (80% yield) of crystalline $GaCl_2H$(quin) **I**.[12] Compound **I** decomposed without melting at 92 °C. Chemical ionization mass spectrometry revealed the presence of an intense parent ion (plus one) at *m/z* 252. A strong ν_{GaH} (KBr pellet) was observed in **I** at 1946 cm^{-1}; however, no hydride resonance was observed in ^1H NMR spectrum. Compound **I** was also prepared in 25% yield by addition of quinuclidine to an ether suspension comprised of 4 equiv. of LiH and 1 equiv. of $[NH_4][GaCl_4]$.

Reaction of **I** with one equivalent of quinuclidine at room temperature in ether produced the bis(quinuclidine) adduct in high yield. Needle-like crystals of $GaCl_2H(quin)_2$ **II**,[13] were stable up to 174 °C and appeared to decompose gradually above this temperature. Coordination of the second ligand shifted the ν_{GaH} to 1882 cm^{-1}. While AlH_3 and related aluminium hydrides form many five-coordinate structures, this is uncommon in gallium hydride chemistry where the only reported examples of five-coordinate hydrido complexes of gallium contain chelating ligands.[14–17]

Crystalline monochlorogallane derivative, $GaClH_2$(quin) **III**, was synthesized in 81% yield by the related ligand redistribution reaction shown in eqn. (2).

$$GaCl_2H(quin) + GaH_3(quin) \rightarrow 2\ GaClH_2(quin) \quad (2)$$

Following addition of an ether solution of GaH_3(quin) to an ether solution of **I**, the reaction mixture was refluxed for 40 h. After filtration and concentration, crystals of **III**[18] were isolated upon cooling the solution to −15 °C. The ν_{GaH} (KBr) was lowered to 1892 cm^{-1}, characteristic of replacing one of the electronegative chloro ligands in **I** with a hydride. In addition to resonances from the quinuclidine ligand, the ^1H NMR spectrum (in C_6D_6) displayed a broad resonance at δ 5.14 assignable to the GaH_2 unit.

Reaction of **III** with excess quinuclidine in refluxing ether followed by crystallization at −15 °C formed the five-coordinate complex, $GaH_2Cl(quin)_2$ **IV**.[19] Batches of crystalline **IV** typically exhibited three absorptions (1891s, 1852m and 1817w cm^{-1}) in the Ga–H stretching region of the IR spectrum (KBr). Given the symmetry of the compound (*vide infra*), we expect only two absorptions and suggest that the crystals were mixtures of **III** and **IV**. Thus, only the peaks at 1852 and 1817 cm^{-1} are assigned to **IV**. These are similar to the values of 1854 and 1837 cm^{-1} reported for $GaH_2[2,6\text{-}(Me_2NCH_2)_2C_6H_3]$.[16] This interpretation was consistent with the elemental analytical data that were always closer to the values calculated for **III**.

Compounds **I**, **II** and **IV** were characterized using single crystal X-ray crystallography. Each molecule of **I** sits on a crystallographic mirror plane that passes through Ga(1), N(1) and H(1) in addition to three of the quinuclidine carbons (Fig. 1).[20] The hydride ligand was located, and its position and isotropic thermal parameters were refined. The basic arrangement of the four ligands is that of a slightly distorted tetrahedron where the angles listed in the figure caption show that the larger, heavy atom ligands are splayed back away from the hydride.

Despite the observation that bulk samples of **IV** were contaminated with **III**, a suitable single crystal was selected for study. The five-coordinate complex **IV**, sits on a crystallographic twofold axis collinear with the Ga(1)–Cl(1) bond (Fig. 2).[20] The structure is close to a perfect trigonal bipyramid bearing the quinuclidine ligands in the axial positions. The only significant deviation is an enlarged H(1)–Ga(1)–H(1C) angle of 127(2)°. The corresponding Cl(1) Ga(1)–H(1) angles are diminished to 116.9(9)°; a pattern consistent with Bent's rule.[21] Comparing the bond distances of **I** and **IV**, we find an increase for all of the heavy atoms for **IV** appropriate for the increase in coordination number. The Ga–H distances, however, decrease from 1.66(5) Å in **I** to 1.51(2) Å in **IV**.

The structure of the five-coordinate dichlorogallane **II**, was also trigonal bipyramidal; however, the hydride was not located (Fig. 3).[20] As in the structure of **IV**, small angular deviations from the ideal geometry were observed and were consistent

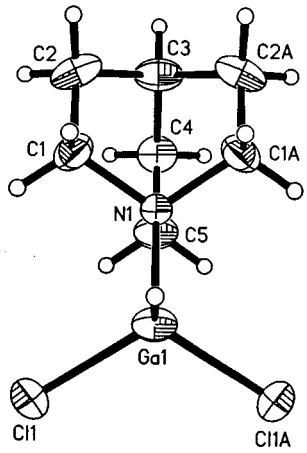

Fig. 1 Structure of **I** showing 50% thermal ellipsoids. Selected bond distances (Å) and angles (°): Ga(1)–N(1) 2.017(3), Ga(1)–H(1) 1.66(5), Ga(1)–Cl(1) 2.185(1); N(1)–Ga(1)–Cl(1) 103.40(6), Cl(1)–Ca(1)–Cl(1A) 108.24(6), N(1)–Ga(1)–H(1) 110(2), Cl(1)–Ga(1)–H(1), 115.2(8).

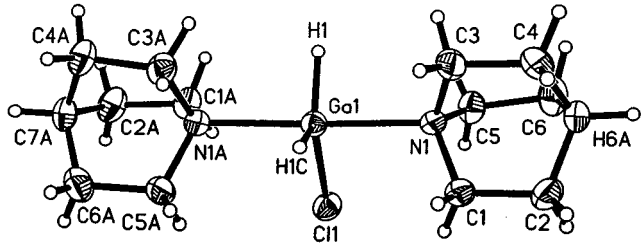

Fig. 2 Structure of **IV** showing 50% thermal ellipsoids. Selected bond distances (Å) and angles (°): Ga(1)–N(1) 2.259(2), Ga(1)–H(1) 1.51(2), Ga(1)–Cl(1) 2.2653(8); N(1)–Ga(1)–N(1A) 178.25(9), N(1)–Ga(1)–Cl(1) 90.88(4), N(1A)–Ga(1)–H(1), 89.1(9), N(1)–Ga(1)–H(1) 90.1(9), Cl(1)–Ga(1)–H(1) 116.6(9), H(1)–Ga(1)–H(1C) 127(2).

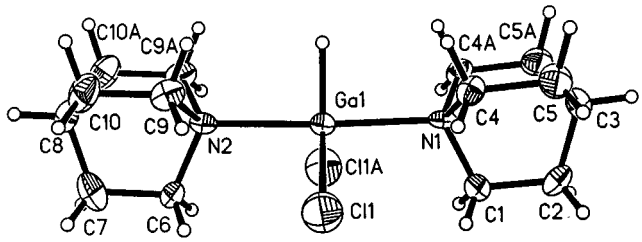

Fig. 3 Structure of **II** showing 50% thermal ellipsoids and the idealized position of the hydride ligand. Selected bond distances (Å) and angles (°): Ga(1)–N(1) 2.254(8), Ga(1)–N(2) 2.232(8), Ga(1)–Cl(1) 2.246(2); N(1)–Ga(1)–N(2) 177.2(3), Cl(1)–Ga(1)–Cl(1A) 113.0(2), Cl(1)–Ga(1)–N(1) 91.0(1), Cl(1)–Ga(1)–N(2) 90.5(1).

with Bent's rule. The crystallographically independent Ga–N distances [2.254(8) and 2.232(8) Å] were similar the value found in **IV** [2.259(2) Å].

All attempts to prepare the five-coordinate trichlorogallium complex, $GaCl_3(quin)_2$, were unsuccessful and always resulted in nearly quantitative isolation of $GaCl_3(quin)$ **V**.[22] It is intriguing that the five-coordinate geometry is only stable enough relative to the four-coordinate structure to allow isolation with the mixed H/Cl ligand complexes. While replacing hydrides with chlorides will increase the Lewis acidity, it will also increase the steric repulsion. Our results suggest that the maximum stability is achieved in **IV** where two chlorides and one hydride are present. Quinuclidine does not differ qualitatively from other donors, rather the combination of improved donor strength and smaller cone angle causes a quantitative shift in the appropriate equilibria that stabilize the five-coordinate products.

This research was supported by a grant from the National Science Foundation (CHE-9616501).

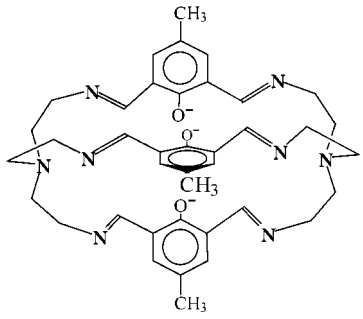
Received (in Basel, Switzerland) 23rd September 1998, Accepted 18th November 1998

Lanthanide ions act as templates in the formation of dinuclear Ln(III) complexes with a cryptand ligand bearing three phenolate groups; the presence of both lanthanide ions into the cavity of the cryptand was confirmed by X-ray structure analysis and spectroscopic data.

Encapsulating ligands can enhance some interesting properties that make complexes of the lanthanide(III) ions valuable for the development of different technological applications such as the selective extraction of metals, NMR shift and relaxation reagents, contrast-enhancing agents in magnetic resonance imaging and fluoroimmunoassay agents.[1] In particular, current interest in binuclear lanthanide complexes arises from their potential value in studying the nature and application of lanthanide metal–metal compounds in lasers[2] and phosphors,[3] the molecular recognition processes which govern lanthanide(III) cation pairing events[4] and their application in novel tunable photonic devices.[5]

Although a dinuclear europium(III) cryptate, synthesised by reaction of a europium salt with a preformed macrotricyclic tetralactam containing 1,10-phenanthroline units, has been reported without structural details[6] no examples, to date, of dinuclear lanthanide cryptates derived from iminophenolato-cryptands have appeared. This is surprising as several examples of homo- and hetero-polynuclear complexes of lanthanides with macrocycles have been described in the literature.[7–9] Here we report the first examples of dinuclear lanthanide complexes of an iminophenolate cryptand together with the crystal structure of a dilutetium(III) complex.

Metal-templated reactions between triethylammonium 2,6-diformyl-4-methylphenolate and tris(2-aminoethyl)amine in the presence of hydrated lanthanide nitrates (Ln = Gd–Lu) in a 3:2:2 mole ratio in absolute ethanol for *ca.* 12 h yield orange solids of formula $[Ln_2L(NO_3)_2][NO_3]\cdot xH_2O\cdot y$EtOH† where L is the anionic cyptand shown in Scheme 1. Their FAB mass spectra display intense peaks corresponding to fragments $[Ln_2L(NO_3)_2]^+$ and $[Ln(L+H)]^+$, confirming the presence of the macrobicycle in the complex. It is found that in all cases the former peak is clearly more intense than the latter, particularly in case of Tb, Ho, Tm and Lu for which the peak due to $[Ln_2L(NO_3)_2]^+$ appears with 100% base peak intensity.



Scheme 1 Anionic cryptand L.

Slow evaporation of ethanolic solutions of the lutetium cryptate gave orange crystals of X-ray quality. The structural analysis of this complex‡ confirmed the presence of two metal ions in the cavity of the anionic Schiff-base macrobicycle receptor. The crystals contain the cation $[Lu_2L(NO_3)_2]^+$, an independent nitrate anion and highly disordered molecules of ethanol and water. Fig. 1 illustrates the structure of the cation. Both lutetium(III) ions have crystallographically identical coordination environments; each is bound to one bridgehead nitrogen atom, three imino-nitrogen atoms, and to the three μ-phenolate oxygen atoms. Eight coordination is completed by one oxygen of a monodentate nitrate ion and the coordination polyhedron can be best described as distorted dodecahedron. The Lu–azomethine nitrogen distances are in the range 2.359–2.445 Å, similar and even shorter than those found in literature.[11] A strong interaction between Lu and the phenolate oxygens is shown by the short distance between them that falls in the range 2.286–2.363 Å. Only two X-ray crystal structures

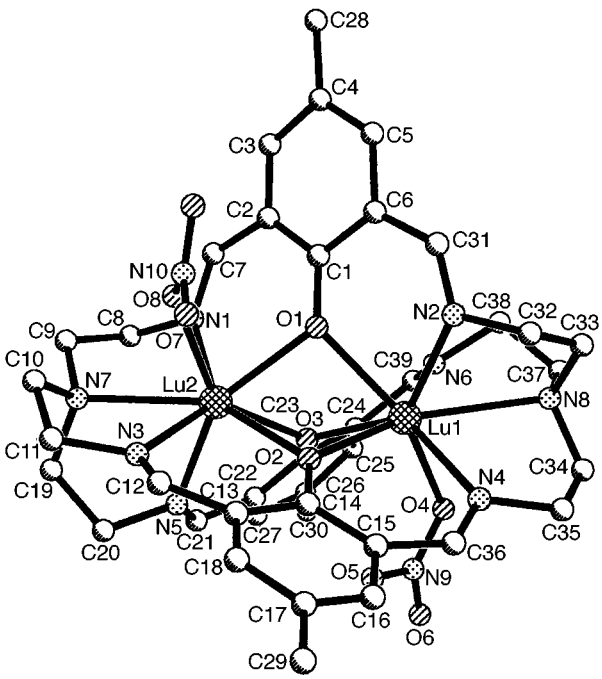


Fig. 1 Crystal structure of $[Lu_2L(NO_3)_2]^+$; hydrogen atoms are omitted for simplicity. Selected bond lengths (Å): Lu(1)–O(3) 2.288(8), Lu(1)–O(2) 2.347(8), Lu(1)–O(1) 2.316(9), Lu(1)–N(6) 2.359(11), Lu(1)–O(4) 2.372(9), Lu(1)–N(4) 2.421(12), Lu(1)–N(2) 2.445(10), Lu(1)–N(8) 2.675(9), Lu(2)–O(1) 2.286(8), Lu(2)–O(7) 2.329(10), Lu(2)–O(3) 2.329(8), Lu(2)–O(2) 2.363(8), Lu(2)–N(1) 2.363(11), Lu(2)–N(5) 2.420(12), Lu(2)–N(3) 2.414(13), Lu(2)–N(7) 2.609(10).

of binuclear lutetium complexes with macrocycles have been reported.[9] In both cases the macrocycle receptors are calixarenes. The distance between the lutetium ions encapsulated into the cryptate we present here is 3.447(1) Å. This is considerably shorter than those reported in the literature (3.56 and 3.68 Å).[9]

The cryptand adopts a conformation resembling a triple helix twisting around a pseudo C_3-axis which runs through the two bridgehead nitrogen atoms. Both metal ions are deviated from this axis; nevertheless, the deviation is so slight that the symmetry of the cryptate can also be described as threefold. The angles between the phenolate ring planes are 69.9, 76.2 and 79.9°, while the distances between each two phenolate oxygens are O(1)···O(2) 2.73 Å, O(1)···O(3) 2.53 Å and O(2)···O(3) 2.80 Å. The distance between the bridgehead nitrogens is 8.65 Å, longer than that found for mononuclear lanthanide cryptates (8.36 Å)[12] with the protonated macrobicycle L, but shorter than that of $[Cd_2L]^{3+}$ (9.01 Å).[13] This shows that the cryptand can expand or contract to fit the metal size or to accommodate two metal ions inside the cavity.

That the dinuclear structure is retained in solution is evidenced by the proton NMR spectrum run in $(CD_3)_2SO$. The spectrum of the related mononuclear lutetium complex[12] shows two signals for the azomethine hydrogens [δ 8.87 (d), 8.43 (s)], the latter is ascribed to the coordinated azomethines and the former arises as a consequence of proton transfer from the phenolic groups to the non-coordinated azomethines.[12,14–16] There is also a very broad signal centered on δ 12.50 which may be assigned to the O···HN$^+$ protons and signals due to the aromatic hydrogens [δ 7.73 (d, J = 1), 7.59 (d, J = 1 Hz)], ethylene bridges [δ 3.82 (3H), 3.68 (3H), 3.59 (3H), 3.27 (3H), 3.08 (3H), 2.94 (3H), 2.81 (6H)] and the methyl groups [δ 2.27 (s)]. The proton NMR spectrum of the dilutetium cryptate is simpler in the low field region and agrees with an effective C_3 symmetry in solution. As expected, the very broad signal due to the phenolic protons presented in the mononuclear complex spectrum does not appear in that of the binuclear complex. Likewise, the two signals due to the azomethine hydrogens and the signals due to the aromatic protons became now in one signal for each type [δ 8.45 (s), 7.57 (s), respectively]. A complicated group of very broad signals [δ 2–4 (m)] due to the ethylene bridges are present indicating that the protons bonded to the same carbon atom are non-equivalent. The signal of the methyl groups [δ 2.29 (s)] is also observed.

Mononuclear lanthanide(III) cryptates derived from ligands closely related to L (the *para*-substituent on the phenol being *t*-Bu, CH_3O or Cl) have been prepared by transmetallation of the appropriate sodium cryptates.[14–17] Attempts to introduce a second lanthanide ion cation have been unsuccessful, and it has been stated that this is probably due to the high coordination numbers and large radii of the lanthanides.[15]

In order to design cryptand receptors for more than one lanthanide(III) ion certain key features must be kept in mind: the high coordination numbers preferred by these cations, their large ionic radii and their high charge. In this respect the influence of the lanthanide contraction would suggest that accommodation of two cations from the second half of the series would be preferred. To be useful for dinuclear reception the ligands must have a large receptor cavity comprised of an adequate number of suitably disposed donor atoms. The anionic cryptand L possesses these features together with three phenolic groups which can serve as endogenous anionic groups capable of providing bridges between the lanthanide(III) ions so helping to overcome the electrical repulsions that would otherwise occur between two tripositive ions placed in close proximity. Previously we have described the lanthanide-assisted synthesis of Schiff-base macrobicycles as mononuclear lanthanide cryptates.[12] In the present work we have extended the application of this metal template method to assemble homodinuclear lanthanide(III) cryptates so providing the first opportunity to study the properties of two lanthanide ions held in close proximity and isolated from interaction with the solvent.

We thank the Xunta de Galicia (XUGA20903B96) for financial support and Dr Miguel Maestro for his help in X-ray crystal structure details. C. P. also acknowledges Xunta de Galicia for a postgraduate fellowship.

Designing enzymatic resolution of amines

Shuichi Takayama, Shelly T. Lee, Shang-Cheng Hung and Chi-Huey Wong*

Department of Chemistry and the Skaggs Institute for Chemical Biology, The Scripps Research Institute, 10550 North Torrey Pines Road, La Jolla, CA 92037, USA. E-mail: wong@scripps.edu

Received (in Corvallis, OR, USA) 15th October 1998, Accepted 23rd November 1998

A new strategy, utilizing IR and mass spectrometry, has been developed to design appropriate reagents and reaction conditions for enantioselective enzymatic protection of amines with readily removable protecting groups.

Stereoselective enzymatic acylation of alcohols *via* transesterification in organic solvents has become a useful strategy in enzymatic synthesis.[1] This method has been further improved to eliminate the problems of reversible reactions and product inhibition by using irreversible acyl donors,[2,3] and among these reagents enol esters have proven to be the most useful.[3] Much less developed, however, is the enzymatic protection of amines,[4] as two major problems are often encountered: (i) amines are much more nucleophilic than alcohols and react non-enzymatically with the esters commonly used in the enzymatic acylation of alcohols, and (ii) unlike esters, which can be readily cleaved under basic conditions, once amines are acylated, harsh conditions are often required to liberate the free amine.

We have systematically investigated a number of potentially useful amine protecting reagents and their reactivities and conditions in order to develop a general strategy for the selection of appropriate protecting reagents. To tackle the first problem, the reactivities of a number of amine protecting reagents were studied by comparing, with TLC, the amount of spontaneous background reaction with an amine in a non-reaction-suppressing (toluene) or reaction-suppressing solvent (3-methylpentan-3-ol),[4d,i,j] and by measuring the IR absorption maxima of the carbonyl groups [ν(C=O)]. The ν(C=O) values reflect the C=O bond length and correlate with the reactivity of carbonyl compounds; the larger the wavenumber, the shorter the C=O bond, and the more reactive the carbonyl group (Fig. 1).[5] The correlation between the IR absorption maxima and the reactivity is most accurate for comparing compounds with similar structures, but can also be useful for estimating the reactivity of dissimilar esters and carbonates.

As seen in Fig. 1, amine protecting reagents can be categorized into three categories depending on their reactivity with amines of interest: (*a*) reagents that react spontaneously with amines; (*b*) reagents that spontaneously react with amines but can be suppressed under special conditions; (*c*) reagents that do not react spontaneously with amines. Based on our experience, reagents in category (*a*) are not useful for selective enzymatic protection of amines. Reagents in category (*b*) may be useful under conditions that suppress spontaneous reactions (high dilution and/or use of a reaction-suppressing solvent such as 3-methylpentan-3-ol[4i,j]). Reagents in category (*c*) are perhaps the most useful and can be used under any condition compatible with the enzyme, so the use of high concentrations of reactants is not a problem and in many cases is actually beneficial for the reaction. Since reagents in category (*b*) do not have good leaving groups, they are poor reagents for protecting alcohols, and in fact can be used to selectively protect amines in the presence of hydroxy groups (Table 1, entry 6). In contrast, some of the reagents in categories (*a*) and (*b*) possess good leaving groups and are thus useful for the protection of alcohols and amino alcohols (*e.g.* **7**–**9**).

To solve the second problem of liberating free amines, we then selected reagents that will give readily removable amine protecting groups.[6] These exercises allowed us to quickly identify several novel (*e.g.* **6**, **8**, **11**), and some known (*e.g.* **9**,[4i] **10**[4e]) enzymatic amine protecting reagents, along with suitable reaction conditions for their use.

Benzylisopropenyl carbonate **8** is also a mildly activated reagent that gives benzyl carbamates under spontaneous reaction suppressing conditions. Dibenzyl carbonate **11** is a less reactive version of reagent **8** and useful for amine resolution when used under highly concentrated reaction conditions.

Previous attempts to use **11** in amine resolutions have been unsuccessful,[4e,7] perhaps due to poor design of reaction conditions.

Allyl pent-4-enoate **6** is a less reactive version of **9** and can be used under highly concentrated conditions whereas reagent **9** requires use of spontaneous reaction-suppressing conditions.

Representative new examples of using these protecting reagents/reaction conditions for enzymatic resolution of amines, including the pharmaceutically important 1-amino-indane,[4j] are shown in Table 1. Reagents **6**, **10** and **11** are especially useful, given that they are readily available, that the

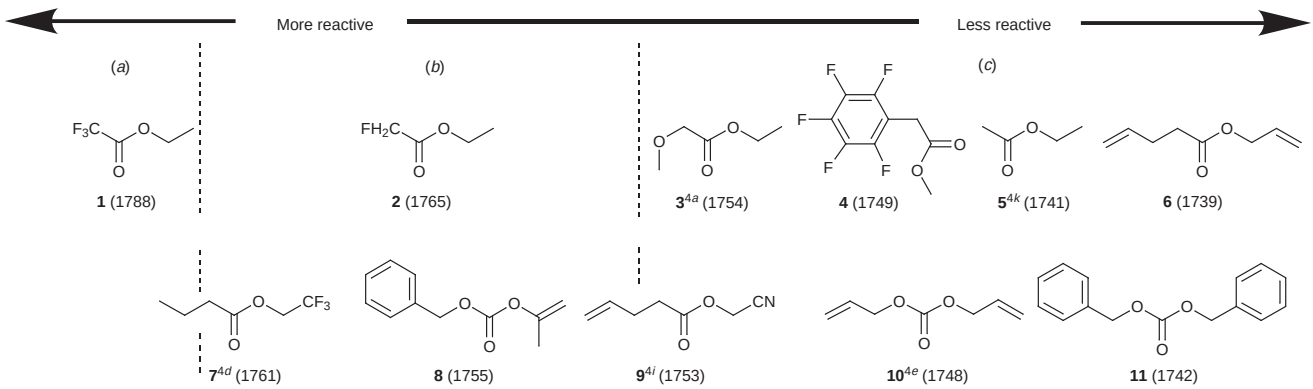

Fig. 1 Reactivity of protecting reagents and their usefulness in enzymatic protection: (*a*) too reactive, (*b*) useful under spontaneous reaction suppressing conditions and (*c*) useful under reaction promoting conditions. The number in parenthesis is IR absorption maxima for the carbonyl group.

Table 1 Examples of amine resolution using the newly designed amine protecting reagents and reaction conditions†

[a] A: toluene (high concentration), *Candida antarctica* lipase (CAL); B: hexane (dilute), CAL. [a] Isolated yield. [b] In 10^{-1} deg cm^2 g^{-1}.[c] Concentration (*c*) in $CHCl_3$ shown in parenthesis.

reaction conditions are simple and user friendly (does not even require a pH meter), and that they give amides and carbamates that are widely utilized as amine protecting groups.[6]

Finally, since the efficiency of enzymatic reactions may not correlate with chemical reactivity, quantitative mass spectrometry[8] has been used to compare reagents **6** and **11** for their efficiency in *Candida antarctica* lipase catalyzed protection of amines. The amount of protected amine, formed in an enzymatic reaction containing equimolar amounts of protecting reagents **6** and **11** but with a limiting amount of amine, was measured by directly injecting a quenched reaction mixture into a mass spectrometer and comparing the peak intensities of the products to those of internal standards.‡ Compound **6** was found to be approximately five times as efficient as **11** in enzymatic amine protection. Thus, the chemical reactivity of a reagent determined by its IR absorption combined with a rapid assessment of its enzymatic reactivity using mass spectrometry illustrated in this study provides a new effective strategy for the development of new protecting reagents and conditions for efficient enzymatic amine resolutions. We have used **6** and **11** for enantioselective enzymatic transformation of more than 50 amines so far and work is in progress to further expand the scope of their application.

We thank Dr J. Wu and Professor G. Siuzdak for mass spectral analysis, and the NIH (GM 44154) for financial support.

Notes and references

† Condition A: Amine (0.94 mmol), toluene (230 μl), protecting reagent (1.69 mmol), molecular sieves 4 Å powder (114 mg) and *Candida antarctica* lipase (20 mg) was stirred for 48–70 h at 24 °C. The mixture was directly chromatographed (SiO_2; hexanes–Et_2O, 3:1) to give the products. The ees were determined by HPLC (Chiralpak AD or Chiralcel OD-H).

Condition B: (±)-Methylbenzylamine (168 mg, 1.39 mmol), hexane (10 ml), **8** (197 mg, 1.03 mmol), molecular sieves 4 Å powder (920 mg), and *Candida antarctica* lipase (240 mg, Sigma) was stirred for 60 h at 24 °C. The reaction was filtered through Celite, the filtrate was diluted with Et_2O, washed (dilute HCl; brine), dried ($MgSO_4$) and concentrated *in vacuo*. The residue was chromatographed (SiO_2; hexanes–Et_2O, 4:1) to give the product (120 mg, 34%).

‡ Measurement of reaction efficiency using mass spectrometry: (*R*)-α,4-Dimethylbenzylamine (35 mg, 0.29 mmol), **6** (80 mg, 0.57 mmol), **11** (138 mg, 0.57 mmol), toluene (3 ml) molecular sieves 4A (300 mg), and *Candida antarctica* lipase (20 mg) was stirred for 24 h at room temperature. After filtering through Celite, a portion of the filtrate (5 μl) was mixed with an internal standard (10 μl of a 1:1 solution of **14**:**12**), and injected directly into a PE SCIEX API100 electrospray mass spectrometer in the positive ionization mode. The relative amount of products formed was determined by the peak intensity ratio of the $[M + H^+]$ peaks (218/204 = 14.5) of the pent-4-enamides and the $[M + Na^+]$ peaks (292/278 = 3.14) of the benzyl carbamates (14.5:3.14 = 4.6:1).

Synthesis of a key intermediate for corossolin using hydrolytic kinetic resolution of epoxides

Qian Yu, Yikang Wu, Li-Jun Xia, Min-Hua Tang and Yu-Lin Wu*

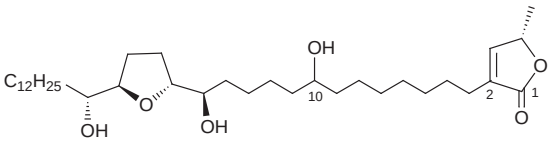
State Key Laboratory of Bio-organic and Natural Products Chemistry, Shanghai Institute of Organic Chemistry, Chinese Academy of Sciences, Shanghai 200032, China. E-mail: ylwu@pub.sioc.ac.cn

Received (in Cambridge, UK) 16th November 1998, Accepted 4th December 1998

A convergent synthesis of the key intermediate for corossolin has been achieved using hydrolytic resolution of epoxides as the key step, which extends the scope of the applicable substrates for hydrolytic kinetic resolution to cover multifunctionalized large molecules.

Annonaceous acetogenins (AAs) are a relatively new class of natural products, which have been isolated from the tropical and subtropical plants of the *Annonaceae* family. They are characterized by one or more tetrahydrofuran rings, together with a terminal α,β-unsaturated γ-lactone on a 35- or 37-carbon chain. A majority of these compounds exhibit[1] high cytotoxicity and immunomodulating activities, which make these compounds potential parasiticidal, insecticidal, and above all, powerful tumoricidal agents.

As part of our research on the synthesis[2] of annonaceous acetogenins, we performed first a total synthesis[2c] of the



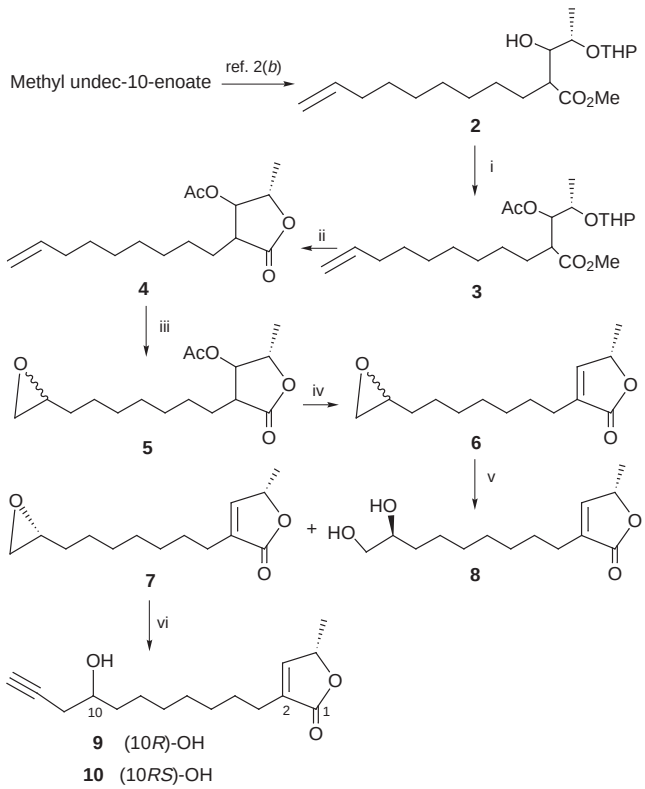
(10*RS*)-epimer mixture of corossolin **1**,[3] and later of both[4] 10-epimers, in an effort to establish the configuration at C-10 of natural corossolin, which was not given in the original structural determination. In our latter work, both epimers of the epoxide fragment were constructed through the chiron approach. Herein we report a more convenient synthesis of the (10*R*)-epoxide **7**, the key intermediate of natural (10*R*)-corossolin, using Jacobsen's hydrolytic kinetic resolution (HKR)[5] to resolve the terminal epoxides as the key step.

The HKR method uses readily accessible cobalt-based chiral salen complexes as catalyst and water as the only reagent to afford chiral epoxides and diols of high ee in excellent yields. These advantages have made it a very attractive asymmetric synthetic tool. However, up to now HRK has *only* been applied to the resolution of simple[6] epoxides of small molecular weight such as styrene oxide, or monofunctional unbranched alkyl-substituted[7] epoxides. In the present work, we pushed the limits further, extending the scope of the applicable substrates to cover multifunctionalized large molecules when developing a facile access to the key intermediate[4] in our previous synthesis of AA.

The substrate for the HKR, the 'racemic' epoxide, was prepared as shown in Scheme 1. Starting from the commercially available methyl undec-10-enoate, the alcohol **2** was prepared in 80% yield by aldol condensation with the aldehyde derived from ethyl L-lactate employing our previous[2b,c] procedure. Conversion of **2** to the acetate ester **3** was achieved in 91% yield. Treatment of **3** with 10% aq. H_2SO_4 in THF removed the THP protecting group and the newly unmasked hydroxy group underwent an intramolecular ester exchange reaction to give lactone **4** in 83% yield. Subsequent epoxidation of **4** with MCPBA gave **5**, which on β-elimination using DBU gave the unsaturated lactone **6** in high yield. The two diastereomers of **6** could not be differentiated on silica gel, presumably due to the large distance between the two stereogenic centers.

The HKR was performed with (*R*,*R*)-salen–Co(OAc) complex (0.5 mol%) and H_2O (0.55 equiv.) to yield epoxide **7** (46%) and diol **8** (38%). The diol **8** could be recycled[4] to **7** in 52% yield, or to the diastereoisomer of **7** in 82% yield. Due to the difficulty in separating chiral epoxide **7** from the salen catalyst, the measurement of its diastereoisomeric excess was performed on **9** and **10**, which were derived in 78% and 85% yields from **7** and **6**, respectively, by reaction with lithium trimethylsilylacetylide. The diastereoisomeric purity of **9** was 99.0% as shown by HPLC (OJ column, 95:5 of hexane–Pr^{i}OH) with the C-10 epimer mixture compound **10** as reference. This is in excellent agreement with the result of optical rotation measurements (+15.1 and +15.3 for **9** and the authentic[4] sample from the chiron approach, respectively). The diastereoisomer of **7** can also be prepared from the (*S*, *S*)-salen–Co(OAc) complex using HKR of **6**.

In conclusion, with HKR of terminal epoxides as the key step, we have developed a short and efficient synthesis (six steps from methyl undec-10-enoate with the overall yield > 24.3%



Scheme 1 *Regents and conditions*: i, Ac_2O, Py, (91%); ii, 10% H_2SO_4, THF, (83%); iii, MCPBA, CH_2Cl_2, (91%); iv, DBU, THF, 2 h, (96%); v, (*R*,*R*)-salen–Co(OAc) (0.5 mol%), dist. H_2O, 40 h, (46% for **7**, 38% for **8**); vi, Bu^{n}Li, trimethylsilylacetylene, $BF_3{\cdot}OEt_2$, −78 °C, (78% and 85%, respectively, 99.0% de).

without taking into consideration the recycled **7** from **8**) of a key intermediate of (10*R*)-corossolin. The present approach is simpler than and therefore superior to the chiral pool method, in which the starting materials are (2*R*)-2,3-*O*-isopropylideneglyceral and azelic acid monoethyl ester (requiring a total of nine steps with 13.4% overall yield[4]), or (2*S*)-1,2-*O*-isopropylidenebutane-1,2,4-triol [derived[5] from (*S*)-malic acid] and a substituted γ-lactone prepared by White's method[9] (in eight steps[8] with 15.1% overall yield for a similar compound). It should be noted that the present approach also provides a facile access to other[10] annonaceous acetogenins with a C-10 hydroxy group.

Chiral bis(oxazolinyl)phenylrhodium(III) complexes as Lewis acid catalysts for enantioselective allylation of aldehydes

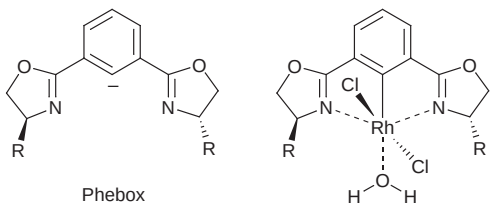
Yukihiro Motoyama, Hiroki Narusawa and Hisao Nishiyama*

School of Materials Science, Toyohashi University of Technology, Tempaku-cho, Toyohashi, Aichi 441-8580, Japan. E-mail: hnishi@tutms.tut.ac.jp

Received (in Cambridge, UK) 5th October 1998, Accepted 4th November 1998

The reaction of (Phebox)$SnMe_3$ 1 [PheboxH = 2,6-bis(oxazolinyl)benzene] and [(*c*-octene)RhCl]$_2$ in the presence of CCl_4 provided air-stable and water-tolerant (Phebox)$RhCl_2(H_2O)$ complexes 2 which acted as asymmetric catalysts for the enantioselective allylation of aldehydes in up to 80% ee.

The development of chiral Lewis acid catalysts, particularly for carbon–carbon bond forming reactions, is one of the most challenging and formidable endeavors in organic synthesis.[1] Among various carbon–carbon bond forming reactions, asymmetric allylation of carbonyl compounds is a valuable means of constructing chiral functionalized structures, and therefore many chiral allylmetal reagents have been designed and synthesised.[2] Although numerous reactions using a stoichiometric amount of chiral allylmetal reagents have been reported,[3] there are only a few reports of catalytic processes using chiral Lewis acid complexes, including chiral (acyloxy)borane (CAB) complex and allylsilanes[4] or allylstannanes,[5] binaphthol-derived chiral titanium complexes and allylstannanes[6] or allylsilanes,[7] and BINAP-derived chiral silver complexes and allylstannanes.[8] The key to success in developing a new chiral Lewis acid catalyst is the choice of the central metal and the design of the chiral ligands. Traditional Lewis acids, such as boron, aluminium, titanium and tin, are extremely moisture-sensitive, and are known to form oligomers in solution. Furthermore, chiral complexes are almost always generated *in situ*, so there are a variety of species having different Lewis acid activity and enantioselectivity. On the other hand, transition metal complexes are generally insensitive to water and form a single well-defined species.[9,10] Here we report a catalytic enantioselective allylation reaction of aldehydes with allyltributylstannane catalyzed by new air-stable and water-tolerant rhodium(III) complexes **2** bearing a 2,6-bis(oxazolinyl)phenyl group (Phebox) as chiral ligands.[11] The Phebox ligand bonds *via* a central carbon–metal covalent bond and both of the oxazoline rings.



The (Phebox)$RhCl_2(H_2O)$ complexes **2**† were easily synthesized by the transmetalation reaction of [(*c*-octene)$_2$RhCl]$_2$ and (Phebox)$SnMe_3$ **1** in CH_2Cl_2 followed by treatment with CCl_4.‡ These complexes are air-stable enough to be purified by silica gel chromatography (Scheme 1).

The optimized allylation reaction conditions employed benzaldehyde and allyltributylstannane§ in the presence of 5 mol% of the (*S*,*S*)-(Phebox)$RhCl_2(H_2O)$ complex **2** as a chiral catalyst (Scheme 2). The absolute configuration of the allylated product was determined to be *S* by comparison of its optical rotation value with literature data.[3e] The rate of this allylation reaction was strongly dependent on the solvent: the allylation reaction proceeded smoothly in CH_2Cl_2, but when using THF or an aromatic solvent such as benzene or toluene, the reaction rates were remarkably slow although the enantioselectivities was almost the same (entries 1–4). In the presence of 4 Å molecular sieves this catalytic reaction was accelerated while the enantiomeric excess of the product **3** was not changed (Table 1, entries 4 *vs*. 5). The selectivity did not improve when the reaction temperature was lowered to 0 °C (entries 5 *vs*. 6). The substituent on the oxazoline rings had a significant effect on the chemical yields and ees (entries 5, 7–9). Notably, the enantioselectivity reaching 61% ee using Bn-Phebox-derived complex **2c**. It is worth noting that the complex **2** can be recovered almost quantitatively from the reaction medium by silica gel chromatography, and the recovered complex **2** catalyses the reaction with almost the same catalytic activity and enantioselectivity (entries 5 *vs*. 10).

[g] Determined by chiral HPLC analysis using Daicel CHIRALPAK AD.

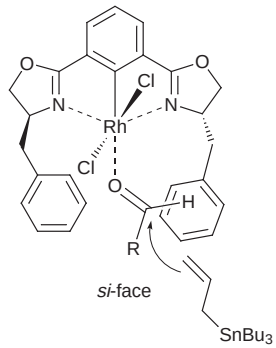

Fig. 1

Table 2 summarizes the results obtained for the allylation reaction of a variety of aldehydes catalysed with the complex **2c**. The characteristic features of the results are as follows: (i) an electron-donating substituents at the *para*-position of benzaldehyde increases the enantioselectivity; (ii) a methyl group at the *ortho*-position of benzaldehyde decreases the selectivity; (iii) all reactions result in high yields and comparable enantioselectivities with both aromatic and aliphatic aldehydes; (iv) in the reaction with enals, 1,2-addition reaction occurs exclusively; (v) in all of the cases, allyltributylstannane attacks to the *si*-face of the aldehyde's C=O plane.

A transition state that accounts for the observed stereoselectivities is shown in Fig. 1. The allylstannane approaches the carbonyl *si*-face because the *re*-face is shielded by the substituent on the oxazoline ring of the Phebox ligand.

In summary, we have demonstrated the effectiveness of Phebox–Rh^{III} complexes as chiral transition metal Lewis acid catalysts for the enantioselective addition of allyltributylstannane to aldehydes. Application of these complexes to other asymmetric reactions is now under investigation.

This work was partly supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture, Japan.

Notes and references

† We previously reported the synthesis of **2a** by the transmetalation of $RhCl_3(H_2O)_3$ and **1a** in 47% yield (see ref 12). However, the chemical yield of Ph-Phebox-derived **2b** is very low (16%) by this method.

‡ We have already reported that the (dMe-Pybox)RhCl complex prepared from the dMe-Pybox and $[(c\text{-octene})_2RhCl]_2$ readily reacted with alkyl chlorides to form Rh^{III} species *via* an oxidative addition reaction, see ref. 13(*a*). And recently, Vrieze reported the same oxidative addition of carbon–chloride bonds to rhodium(I) complexes containing terdentate nitrogen ligands $[2,6\text{-}(CR^1{=}NR^2)_2C_2H_3N]$, see ref. 13(*b*).

§ Other substituted allylstannane reagents gave lower yields and enantioselectivities when catalyzed by **2a**: allyltrimethylstannane (48%, 35% ee), allyltriphenylstannane (7%, 27% ee).

Total synthesis of (+)-pramanicin and stereochemical elucidation of the natural product

Anthony G. M. Barrett,*[a] John Head,[b] Marie L. Smith[a] and Nicholas S. Stock[a]

[a] *Department of Chemistry, Imperial College of Science, Technology and Medicine, South Kensington, London, UK SW7 2AY. E-mail: m.stow@ic.ac.uk*

[b] *Celltech Therapeutics, 216 Bath Rd, Slough, Berkshire, UK SL1 4EN*

Received (in Liverpool, UK) 14th October 1998, Accepted 27th November 1998

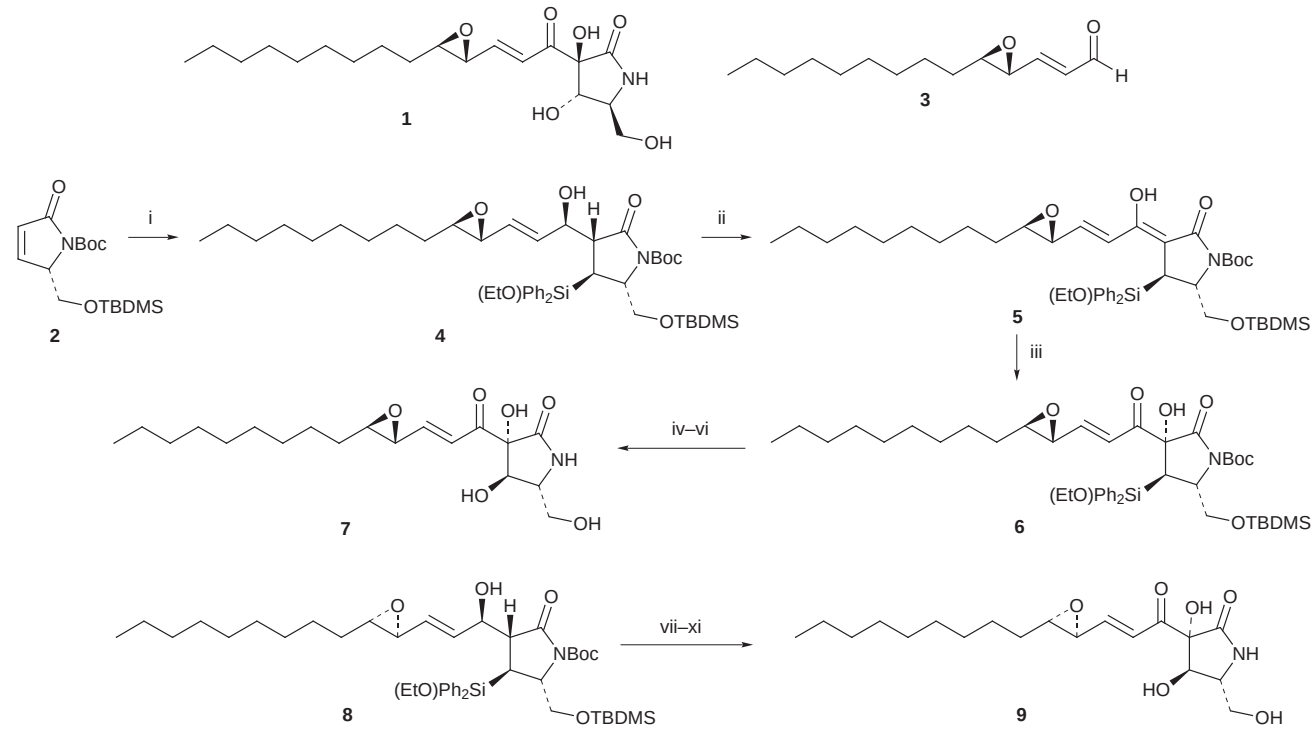
Total synthesis of (+)-pramanicin is achieved through a 'one pot' Michael addition of an aminosilyl zincate species to an α,β-unsaturated lactam and quenching of the resultant enolate with an α,β-unsaturated γ,δ-epoxy aldehyde.

(−)-Pramanicin **1**, recently isolated from a fungus belonging to the *Stagonospora* species, contains a highly functionalised γ-lactam-based head group with a functionalised lipophilic side chain.[1] The isolated compound shows antifungal activity towards various fungal pathogens including *Candida albicans*, *Candida parapsilosis* and *Cryptococcus neoformans*. The latter micro-organism is responsible for meningitis infection in AIDS patients and therefore pramanicin **1** poses an interesting target for synthesis. Recently, Harrison and co-workers have elucidated the biosynthesis of pramanicin and showed that the carbon skeleton derives from eight acetate units and a serine residue.[2]† Herein we report the total synthesis of (+)-pramanicin **9** which unequivocally establishes the full relative and absolute stereochemistry of the natural product.

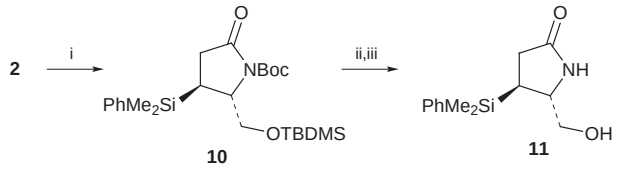
Retrosynthetically, pramanicin can be divided into two fragments, the suitably protected lactam **2** derived from L-glutamic acid and the side chain epoxy aldehyde **3**.‡ We envisaged that these two components could be joined *via* the addition of a silyl entity (masked hydroxy group) in a conjugate fashion to **2** and trapping of the resultant enolate with the aldehyde **3**. The addition of this silyl group should occur in an *anti* fashion to the TBDMS protected hydroxymethyl pendant, thus establishing the correct stereochemistry of the secondary alcohol following Tamao oxidation[4] (Scheme 1).

Thus, reaction of lactam **2**§ with a 1:1 mixture of (diethylamino)diphenylsilyllithium and diethylzinc at −78 °C and trapping of the resulting enolate with the aldehyde **3** followed by ethanolysis of the sensitive silylamine furnished compound **4** (60%). This reaction clearly establishes the complete carbon backbone of pramanicin with a readily oxidisable alkoxysilyl appendage. Confirmation of the stereochemical outcome of the silyl zincate addition has been made *via* addition of the phenyldimethylsilyl[5] group to lactam **2** under identical conditions and removal of the protecting groups to afford **11** for single crystal X-ray analysis¶ (Scheme 2).

Oxidation of the β-hydroxy lactam **4** to the corresponding diketone **5** could only be accomplished using Dess–Martin periodinane as oxidant. Chromium based reagents led to extensive decomposition and no reaction was observed using manganese dioxide. The diketone **5** proved to be unstable to prolonged exposure to air and to chromatography thus preclud-



Scheme 1 *Reagents and conditions*: i, $(Et_2N)Ph_2SiLi$, Et_2Zn, −78 °C, then **3**, THF, −78 °C, then EtOH, NH_4Cl, 24 h, 60%; ii, Dess–Martin periodinane, CH_2Cl_2, 0 to 25 °C; iii, dimethyldioxirane, $Ni(acac)_2$ (cat.), acetone, H_2O, 0 °C, 60% from **4**; iv, MCPBA (3 equiv.), KHF_2 (2.5 equiv.), DMF, 0 °C, 53%; v, SiO_2,45 °C, 0.1 mmHg, 84%; vi, H_2SiF_6 (20–25% aq.), THF, 0 to 25 °C, 53%; vii, Dess–Martin periodinane, CH_2Cl_2, 0 to 25 °C; viii, dimethyldioxirane, $Ni(acac)_2$ (cat.), acetone, H_2O, 0 °C, 59% from **8**; ix, MCPBA (3 equiv.), KHF_2 (2.5 equiv.), DMF, 0 °C, 70%; x, TFA, CH_2Cl_2, 0 to 25 °C, 78%; xi, H_2SiF_6 (20–25% aq.), THF, 0 to 25 °C, 55%.



Scheme 2 *Reagents and conditions*: i, $PhMe_2SiLi$, Et_2Zn, THF, −78 °C, 99%; ii, TBAF, THF, 80%; iii, TFA, CH_2Cl_2, 85%.

ing its purification. Therefore immediate oxidation of the diketone unit with dimethyldioxirane and a nickel(II) acetylacetonate[6] catalyst gave hydroxy dione **6** as a single diastereoisomer in excellent overall yield (60%). The ethoxy(diphenyl)silyl group blocked the top face of the diketone directing reaction to the opposite face and thus setting the configuration of the tertiary alcohol as required. Tamao oxidation of silane **6** proceeded smoothly at low temperature with MCPBA as oxidant to produce the secondary alcohol with retention of configuration as desired. The use of peracetic acid or hydrogen peroxide as alternative oxidants gave only intractable mixtures of products. Removal of the Boc group *via* thermolysis on silica under vacuum[7] followed by deprotection of the TBDMS moiety using fluorosilicic acid[8] furnished compound **7** (Scheme 1). Comparison of **7** with authentic pramanicin by NMR analysis revealed very slight differences in the chemical shift of the protons associated with the alkene and the epoxide ring system. Alternatively, synthesis of diastereoisomer **8** using *ent*-**3** as the enolate quench (62%) and elaboration as before yielded isomer **9**. This diastereoisomer **9** was identical by ^1H and ^{13}C NMR spectroscopy with authentic pramanicin (see Fig. 1). Whilst the Merck group[1] established the relative stereochemistry of the γ-lactam ring of the natural

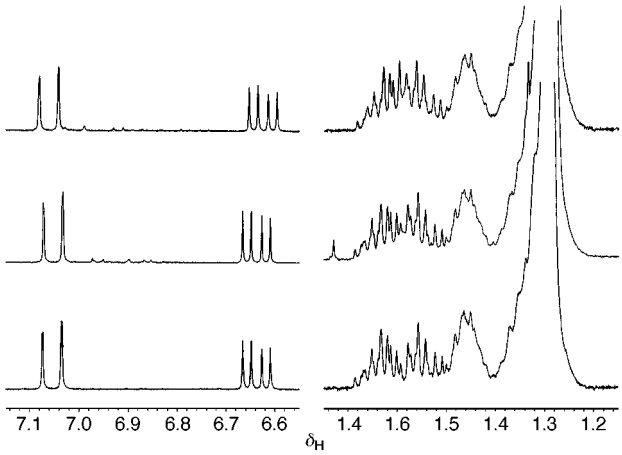


Fig. 1 ^1H NMR (400 MHz, $CDCl_3$) spectra showing olefinic resonance's (left) and protons α to epoxide ($\delta \sim 1.6$, right); top: diastereoisomer **7**; middle: diastereoisomer **9**; bottom: authentic pramanicin.

product and that the side chain epoxide was *trans*, they did not establish the stereochemistry of the side chain relative to the lactam entity. In their paper, pramanicin was depicted (arbitrarily) as *ent*-**7**. This work clearly establishes the relative stereochemistry to be as in isomer **9**. However, the optical rotation of isomer **9** ($[\alpha]_D^{25}$ +28.8, *c* 0.21 in MeOH) is of opposite sign to that reported for authentic pramanicin ($[\alpha]_D^{25}$ −31.5, *c* 0.21 in MeOH) and thus indicates the absolute stereochemistry of pramanicin to be that of **1**.‖

We thank Dr R. E. Schwartz at the Merck Research Laboratories for the generous donation of authentic pramanicin, GlaxoWellcome Research Ltd. for the endowment (to A. G. M. B.), the Wolfson Foundation for establishing the Wolfson Centre for Organic Chemistry in Medical Science at Imperial College, the Royal Society for a Dorothy Hodgkin Fellowship (to M. L. S.), Celltech Therapeutics for their financial support (to N. S. S.) and the EPSRC.

Notes and references

† Harrison and co-workers have also published a biomimetic synthesis of the fatty acid side chain of pramanicin in racemic form; see ref. 3.

‡ Aldehyde **3** was prepared from (*E*)-dodec-2-enol *via* Sharpless asymmetric epoxidation, oxidation to the aldehyde using Dess–Martin periodinane, Horner–Emmons homologation under standard conditions and reduction of the α,β-unsaturated ester using DIBAL-H followed by oxidation to give aldehyde **3**, again employing Dess–Martin periodinane as oxidant (55% overall)

§ Lactam **2** was prepared from pyroglutamic acid methyl ester *via* $NaBH_4$ reduction to the alcohol, protection of the alcohol as the TBDMS ether and Boc protection of the amide under standard conditions. α-Selenation employing LDA and phenylselenyl bromide followed by *syn* elimination using hydrogen peroxide and pyridine afforded lactam **2** (46% overall).

¶ Full details of the X-ray crystallographic studies on lactam **11** will be reported elsewhere.

‖ Note added at proof: Harrison and co-workers have recently determined the absolute stereochemisty of the lactam entity of pramanicin from biosynthetic considerations; see ref. 9.

O-Neophyl-type 1,2-phenyl rearrangement initiated by electron transfer: development of kinetic probes of dissociative electron transfer

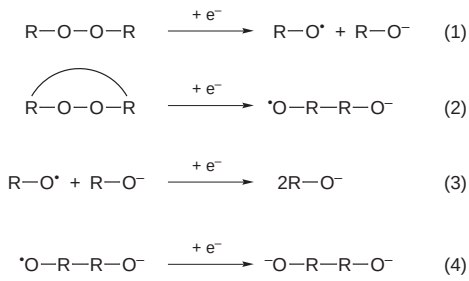
Robert L. Donkers, Joseph Tse and Mark S. Workentin*

Department of Chemistry, The University of Western Ontario, London, ON, Canada N6A 5B7. E-mail: mworkent@julian.uwo.ca

Received (in Corvallis, OR, USA) 7th October 1998, Accepted 18th November 1998

The first example of an O-neophyl-type rearrangement in a distonic radical anion was found in the electron transfer induced dissociative reduction of 9,10-diphenyl-9,10-epidioxyanthracene.

Electron transfer (ET) to endoperoxides and peroxides results in the cleavage of the weak oxygen–oxygen (O–O) bond.[1–5] This process proceeds in peroxides and endoperoxides generally by a dissociative ET mechanism,[1–6] in which ET and O–O bond fragmentation are concerted [eqn. (1) or (2)]. Only in the case of



tert-butyl-*p*-cyanoperbenzoate is there evidence for a transition to a stepwise mechanism with formation of the intermediate radical anion.[5] Such mechanistic studies are important because electron transfer processes of peroxides and endoperoxides play a key role in their activity in chemical and biological systems.[7,8] For example, Fe^{II}-promoted ET reduction of the O–O bond in the antimalarial endoperoxide artemisinin and its semi-synthetic derivatives has recently been shown to be the key step in its antimalarial activity.[9,10] In the cases studied to date using direct electrochemical methods, the alkoxy radical fragment produced in the dissociative reduction (R–O· for acyclic peroxides or ·O–R–R–O⁻ for endoperoxides) is reduced in a second ET [eqn. (3) or (4)]; *i.e*. no reactivity resulting from the alkoxyl radical fragment is observed.[1–5] Since the initial O–O bond reduction is dissociative, the alkoxyl radical fragment is generated at the electrode that is at a potential more negative than the reduction potential of the R–O· fragment. Therefore, the alkoxyl radical is reduced spontaneously because of the large driving force. Here we report the first observed[11] reactivity from the alkoxyl radical in the ·O–R–R–O⁻ distonic radical anion formed in a heterogenous dissociative ET, namely a 1,2-phenyl migration (O-neophyl rearrangement). This O-neophyl-type rearrangement of a phenyl group to the alkoxyl radical fragment occurs in the distonic radical anion formed by electrochemical single ET to the O–O bond in the endoperoxide 9,10-diphenyl-9,10-epidioxyanthracene (**DPA-O_2**). In addition to being the first example of this type of reaction, this rearrangement occurs at the expense of the reduction of the alkoxyl radical portion of the distonic radical anion [eqn. (4)]. This suggests that systems such as these can be developed as kinetic probes of the rate of the second heterogeneous ET [eqn. (3) and (4)].

Electrochemical reduction of **DPA-O_2** was investigated in MeCN and DMF solutions containing 0.1 M tetraethylammonium perchlorate (TEAP) using cyclic voltammetry (CV).[12] In MeCN, **DPA-O_2** is reduced with a peak potential (E_p) of −1.12 V *vs*. SCE at a scan rate (v) of 0.1 V s^{-1} and the E_p shifts to more negative potentials with increasing scan rate. The irreversible reduction wave is very broad, with a peak width ($E_p - E_{p/2}$) of 148 mV (at 0.1 V s^{-1}) and α values[13] of 0.32, 0.27, 0.23 and 0.21 at 0.1, 1, 5 and 10 V s^{-1}. These voltammetric characteristics are consistent with the reduction of **DPA-O_2** being dissociative.[6] A representative cyclic voltammogram is shown in Fig. 1(*a*). Following the dissociative reduction wave there is a second reversible redox couple at a more negative potential. The reduction wave of this couple[14*a*] is not well-defined until the potential is scanned to more negative values. This feature and the reversibility of this 1 F mol^{-1} process[14*b*] are illustrated in Fig. 1(*b*). This reversible reduction at −1.804 V *vs*. SCE was identified as 9-phenoxy-10-phenylanthracene (**PPA**) by product isolation and characterization, and by its standard reduction potential ($E°$). The amount of **PPA** formed in the CV experiment depends on the scan rate and the time the potential is held at values more negative than *ca*. −1.9 V. Based on peak current measurements (i_p) the formation of **PPA** is quantitative on the cyclic voltammetry timescale at very slow scan rates and when the potential is held at the negative potentials.[15] Also observed in the CV on the return cycle are two weak oxidation waves; these disappear on addition of a weak acid (see Fig. 1) and are assigned to electrogenerated basic intermediates. In no case was there evidence for direct reduction of the distonic radical anion leading to the corresponding 9,10-diol, **DPA-$(OH)_2$** (Path **A** in Scheme 1), contrary to that observed in all other peroxide/endoperoxide systems studied to date.[1–5]

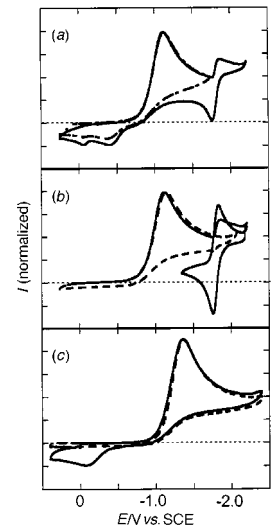


Fig. 1 (*a*) Cyclic voltammogram showing the reduction of a 2 mM solution of **DPA-O_2** in 0.1 M TEAP/MeCN at 0.2 V s^{-1}. (*b*) CV as in (*a*) where the potential was held at the negative potential limit for 30 s prior to the positive scan. The CV shown in the dashed line is that measured after the addition of 5 equiv. of 2,2,2-trifluorethanol. (*c*) Cyclic voltammogram showing the reduction of a 2.8 mM solution of **DMA-O_2** in 0.1 M TEAP/MeCN at 0.1 V s^{-1} both in the presence (solid line) and the absence (dashed line) of 2,2,2-trifluoroethanol.

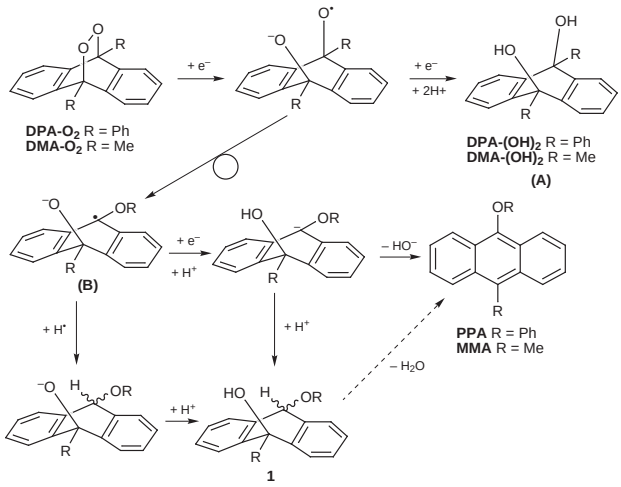

Scheme 1

In contrast, reduction of 9,10-dimethyl-9,10-epidioxyanthracene (**DMA-O_2**) generates the corresponding 9,10-diol [**DMA-$(OH)_2$**] quantitatively *via* a two-electron (2 F mol^{-1}) reduction (Path **A** in Scheme 1). No evidence for 9-methoxy-10-methylanthracene (**MMA**) was found. Other voltammetric characteristics are similar to **DPA-O_2**: E_p = −1.35 V *vs*. SCE at 0.1 V s^{-1}, a peak width ($E_p - E_{p/2}$) of 153 mV (at 0.1 V s^{-1}) yielding α values of 0.31, 0.27 and 0.25 at 0.1, 1 and 10 V s^{-1}. Since this is a two electron process the shift of E_p to more negative potentials by 113 mV/(log ν) gives an average α value of 0.25.

We rationalize formation of **PPA** in the reduction of **DPA-O_2** by an O-neophyl-type rearrangement from the initially formed distonic radical anion (path **B** in Scheme 1); specifically the distonic radical anion undergoes a 1,2-phenyl migration to the alkoxyl radical center to generate the carbon-centered radical intermediate. At the potential where **DPA-O_2** is reduced (E_p = −1.12 V *vs*. SCE) the resulting diarylphenoxymethyl radical is not expected to be reduced.[16] This intermediate can be reduced at more negative potentials and eventually lead to **PPA** *via* aromatization with loss of OH^-. This result is consistent with the CV results and was verified by the constant potential electrolysis studies. Electrolysis at −1.2 V does not result in formation of **PPA**; instead it generates *via* a 1 F mol^{-1} process a product that forms **PPA** quantitatively after work-up of the electrolysis mixture. However, if the electrolysis is performed at more negative potentials (−1.6 V) **PPA** is formed quantitatively consuming 2 F mol^{-1}. Likewise if the electrolyses are performed in the presence of a weak acid like 2,2,2-trifluorethanol or acetanilide, **PPA** is not the initial product, but it is the only product isolated after work-up. We suggest that in these latter experiments **1** is formed by trapping the intermediate formed after the O-neophyl rearrangement. No **DPA-$(OH)_2$**, which is stable to the work-up conditions, is isolated.

The O-neophyl rearrangement occurs exclusively; no diol, which would be generated on reduction corresponding to eqn. (4), is observed. Thus, the rearrangement must occur with a rate faster than the rate of the heterogeneous ET reduction of the alkoxyl radical formed on the dissociative reduction. The reduction potential of $Ph_3C–O^{\cdot}$ ($E°_{Ph_3CO^{\cdot}/Ph_3CO^-}$) is −0.03 V *vs*. SCE;[4] thus the driving force for reduction of the alkoxyl radical at −1.2 V is favorable by at least 23 kcal mol^{-1}. By analogy to the rate constant reported by Falvey *et al*. for the rearrangement of the triphenylmethoxyl radical to α-phenoxydiphenylmethyl radical we expect the O-neophyl rearrangement to be occurring with a rate constant in the order of 5×10^{10} s^{-1} or greater.[17] Thus, the rate of the second ET cannot compete with the O-neophyl rearrangement. This puts an upper timescale by which to compare the rate of the second heterogenous ET. Similar O-neophyl rearrangements were not reported during the electrochemical reduction of $Ph_3CO–OCPh_3$ or $Ph_3CO–OBu^t$,[4] suggesting that there may be a stereoelectronic effect on the rearrangement in the **DPA-O_2** system.

In the reduction of **DMA-O_2** the corresponding 1,2-methyl shift or β-scission does not compete with reduction of the distonic radical anion. Although the β-scission reaction is not known for $Ph_2MeCO^{\cdot}$ the rate constant of the 1,2-methyl shift rate is estimated to be 4.4×10^6 s^{-1}.[17] This provides a lower rate limit to compare the second heterogenous ET.

Observation of this O-neophyl rearrangement in the reduction of **DPA-O_2** may provide a method to quantify the partitioning ratio (if any) between the charge and spin in the distonic radical anions formed on reduction of unsymmetrically substituted endoperoxides (for example, 9-methyl-10-phenyl-9,10-epidioxyanthracene). Studies of this type are currently in progress. Also in progress are studies addressing the generality of this type of rearrangement on the reduction of other polycyclic aromatic endoperoxides and other aryl substituted endoperoxides, in an attempt to provide 'clock' reactions for secondary reduction of distonic radical anions (and its implications on the theory of dissociative ET).

11 The reduction of 9,10-dihydro-9,10-epidioxyanthracene was reported in the paired electrosynthesis of anthracene and oxygen on the femtolitre scale: C. Amatore and A. R. Brown, *J. Am. Chem. Soc*., 1996, **118**, 1482.
12 Electrochemical experiments were performed using standard equipment and electrodes as described in ref. 1. All potentials were calibrated internally to ferrocene ($E°_{Fc^+/Fc}$ is 0.449 and 0.475 *vs*. SCE in MeCN and DMF, respectively). Data in DMF is similar and will be reported in the full account of this work.
13 The transfer coefficient (or symmetry factor) α is defined as $\partial\Delta G^{\ddagger}/\partial\Delta G°$, where $\Delta G^{\ddagger}$ is the free energy of activation and $\Delta G°$ is the free energy of the ET.
14 (*a*) The reduction of **DPA-O_2** is a 1 F mol^{-1} process except under the conditions indicated later. Full details including simulations will be reported separately. (*b*) Determined by comparison of the peak current (i_p) of PPA formed in an electrolysis with that measured with a known concentration of an authentic sample of **PPA**.
15 At higher scan rates the amount of **PPA** formed in the CV is less than quantitative; its presence by CV is absent at scan rates higher than 75 V s^{-1}. In product studies the amount of product derived from the O-neophyl rearrangement is always quantitative. This may be due to a rate limiting aromatization.
16 The reduction potential of the triphenylmethyl radical is at least −1.2V *vs*. SCE and that of tritolylmethyl radical is −1.36 V *vs*. SCE (S. Bank, C. Ehrlich and J. A. Zubieta, *J. Org. Chem*., 1979, **44**, 1454).

New 1,4,7-triazacyclononane-based functional analogues of the Fe/Cu active site of cytochrome *c* oxidase: structure, spectroscopy and electrocatalytic reduction of oxygen

James P. Collman,* Reinhold Schwenninger, Miroslav Rapta, Martin Bröring and Lei Fu

Department of Chemistry, Stanford University, Stanford, CA 94305, USA. E-mail: jpc@chem.stanford.edu

Two new covalently linked functional model compounds for the Fe_{a3}/Cu_B active sites of heme-copper oxidases have been prepared and characterized by novel synthetic methodologies; the X-ray structure of the Zn form and the electrocatalytic reduction of O_2 by the Fe/Cu forms are reported.

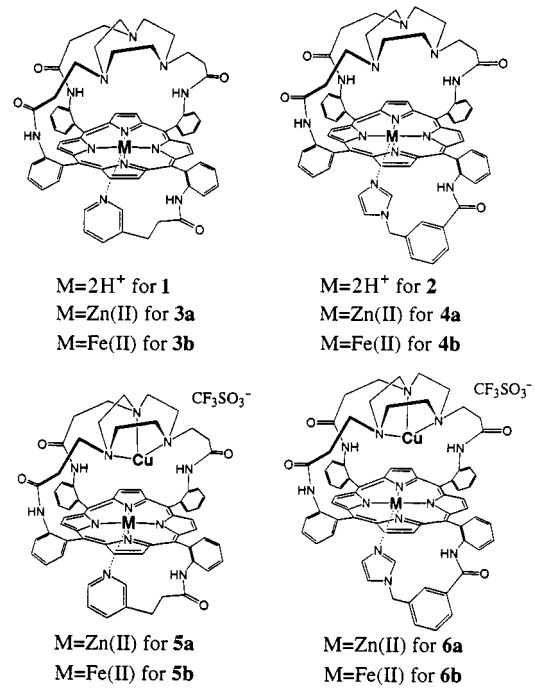
Cytochrome *c* oxidase (C*c*O) is a membrane-bound metalloenzyme which catalyzes the $4e^-$, $4H^+$ reduction of O_2 to H_2O.[1] Toxic intermediates such as H_2O_2 and HO_2^- are not released during this exergonic reaction. The energy produced by the O_2 reduction is coupled to proton translocation, contributing to the protomotive force which drives conversion of ADP to ATP.[2] Recent X-ray structures of bacterial[3] and mammalian[4] forms of this enzyme have initiated increased activity among biomimetic chemists.[5] There are several unresolved issues concerning the mechanism of O_2 reduction at the heme a_3/Cu_B bimetallic center: (a) the role of the Cu_B and Tyr residue in O_2 binding and activation, (b) the nature of the peroxy-intermediate, and (c) the possible involvement of an imidazole ligand in the proton pumping mechanism.[1,6]

The construction of covalently-linked functional model compounds which closely resemble the Fe_{a3}/Cu_B active site is an important part of the effort to resolve these issues. We have previously reported the synthesis and catalytic activity of two such model compounds prepared by a congruent multiple Michael addition methodology.[7] Of these, the 1,4,7-triazacyclononane- (TACN) 'capped' Co/Cu and *N*,*N*′,*N*″-tribenzyltris(aminoethyl)amine- (TBTren) 'capped' Fe/Cu complexes have shown $4e^-$, $4H^+$ electrocatalytic reduction of O_2 to H_2O at physiological pH. Prompted by these encouraging results we have developed a more flexible synthetic strategy[8] and prepared two new TACN-capped porphyrins, **1** and **2** (Scheme 1), with different covalently attached axial ligands.

Herein, we describe a new methodology for the selective incorporation of Zn(II) or Fe(II) into these new ligands. We present ^{1}H NMR analysis of the free base, Zn(II), Fe(II), Zn(II)/Cu(I), and Fe(II)/Cu(I) forms as a useful tool for partial elucidation of the conformations of these complexes in solution. Furthermore, we report the crystal structure of the pyridine-tailed Zn(II) complex—the first structural characterization within this family of compounds. Finally we present preliminary results on the electrocatalytic reduction of O_2 to H_2O by these new Fe/Cu model compounds.

Porphyrinato–Zn(II) complexes **3a** and **4a** are diamagnetic, redox-inactive analogues of the porphyrinato–Fe(II) complexes. These are easily prepared by reaction of the free base with an excess of zinc acetate, followed by basic-alumina filtration using a solvent saturated with NH_3(g). Selective introduction of Fe(II) into the porphyrin is achieved by the reaction of the free base porphyrin with excess $FeBr_2$ without using external base, followed by basic-alumina filtration.[9] Final Zn(II)/Cu(I) and Fe(II)/Cu(I) complexes **5** and **6** are prepared by the reaction of the appropriate porphyrinato complex with copper(I) triflate.[10]

The ^{1}H NMR spectra of **2** and its Zn(II) complex **4a** are compared in Fig. 1. The desired $\alpha_3\beta$ symmetry of the porphyrin



Scheme 1

core can be deduced from the pattern of β-pyrrolic and phenyl resonances.[11] The broad, upfield-shifted CH_2 resonances of the TACN ligand confirm the flexible structure of the cap as well as its location above the porphyrin ring. Introduction of Zn(II) into the porphyrin results in significant upfield shifts for the axial ligand resonances: signals *ortho* to the coordinated nitrogen are shifted by > 3.5 ppm, reflecting the close proximity to the porphyrin ring. The two *ortho* proton resonances of the axial base in the Fe(II)CO forms[9] are at higher field than in the Zn(II)

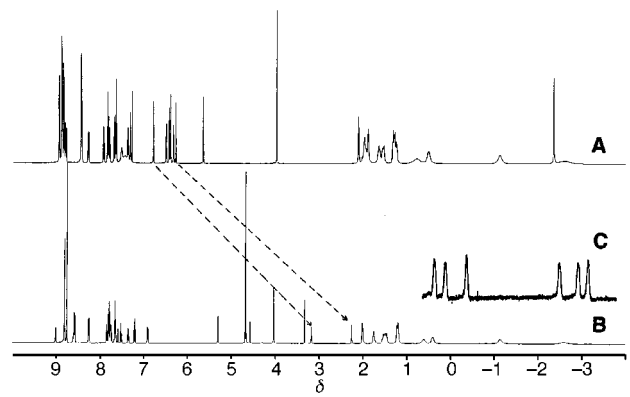


Fig. 1 ^{1}H NMR spectra ($CDCl_3$) of the free base porphyrin **2** (spectrum A) and its Zn(II) complex **4a** (spectrum B). Dashed lines illustrate upfield shifts for the axial ligand resonances in complex **4a**. Trace C shows sharpening of the TACN cap resonances in Zn(II)/Cu(I) complex **6a**.

Selected bond lengths (Å) and bond angles (°): Zn–N(1) 2.064(9), Zn–N(2) 2.075(8), Zn–N(3) 2.095(8), Zn–N(4) 2.095(8), Zn–N(12) 2.109(9); N(1)–Zn–N(2) 88.1(3), N(1)–Zn–N(3) 159.0(4), N(1)–Zn–N(12) 100.4(4), N(2)–Zn–N(3) 89.2(3), N(2)–Zn–N(4) 160.2(4), N(2)–Zn–N(12) 101.9(3), N(3)–Zn–N(4) 87.5(3), N(3)–Zn–N(12) 100.5(4), N(4)–Zn–N(12).

complexes, which is consistent with stronger coordination of the axial ligand to Fe(II). The high-field portion of the spectrum for the Zn(II)/Cu(I) complex **6a** (Fig. 1, trace C) shows a significant sharpening of the TACN cap resonances, consistent with a single conformation in solution.

The geometry of the empty-cap porphyrinato–Zn(II) complex **3a** was further eluciated by single crystal X-ray diffraction.[12] The thermal-ellipsoid plot is shown in Fig. 2 with key bond distances and bond angles. The zinc atom shows an expected distorted square-pyramidal geometry with the four porphyrin nitrogens in equatorial positions [average Zn–N distance of 2.074(9) Å] and a pyridine ligand occupying an apical position [Zn–N_{pyr} distance of 2.109(9) Å]. The Zn atom is displaced 0.37 Å from the porphyrin plane, which shows a moderate degree of ruffling similar to those of related Zn and Fe porphyrin complexes.[13] The TACN cap is in a chair conformation which is probably preferred for efficient crystal packing. This conformation must change upon coordination of Cu(I) in order to achieve effective binding to all three nitrogen ligands. Other bond distances and bond angles are similar to those of the related compounds and will be analyzed in detail elsewhere.

In their reduced forms, Fe(II)/Cu(I) complexes **5b** and **6b** show UV–VIS spectra identical to those of the Fe(II)–porphyrinato precursors.[9] On the other hand, incorporation of Cu(I) (as the triflate salt) has a significant effect on the complexes' reactivities toward O_2, as well as their solubilities in organic solvents. Reversible binding of O_2 to the emtpy-cap Fe(II) complexes becomes irreversible with the FeCu complexes, resulting in the formation of an apparent peroxo–Fe(III) (O_2^{2-}) Cu(II) intermediate [λ_{max} 422 nm (Soret)]. In dry toluene or acetononitrile a 'peroxo-signature' around 800 cm^{-1} can be detected by IR spectroscopy. Addition of protic solvent (*e.g.* methanol) or exposure to the atmosphere results in complete disappearance of this vibrational mode, indicating a fast decomposition of the peroxo-species in the presence of protons.

The electrocatalytic reduction of O_2 by these Fe/Cu complexes have been studied by rotating graphite disc–platinum ring voltammetry.[14] Both new complexes show predominantly $4e^-$ reduction of O_2 to H_2O, with a negligible production of peroxide, as determined by the comparison of the ring and disc currents. The half-wave potential for the electroreduction of O_2 is 45 mV more positive for the imidazole-tailed complex **6b** in comparison with the pyridine-tailed complex **5b**. These results show that our new Fe/Cu complexes are functional models of the C*c*CO Fe_{a3}/Cu_B active site, and together with our related studies,[7] represent a prime example of fine-tuning their catalytic properties by small structural changes in the porphyrin ligand. We consider these new robust, capsule-like Fe/Cu complexes to be ideal model compounds for solution catalytic studies and for the isolation and structural characterization of various forms of the cytochrome *c* oxidase Fe_{a3}/Cu_B active site.

Functional transformation of aldehydes and ketones *via* homolytic induced decomposition of unsaturated peroxy acetals and peroxy ketals

L. Moutet, D. Bonafoux, M. Degueil-Castaing and B. Maillard*

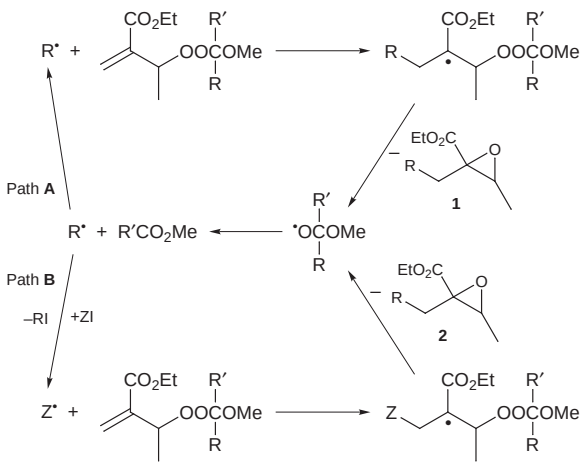
Laboratoire de Chimie Organique et Organométallique, associé au CNRS UMR 5802, Université Bordeaux 1, F-33405 Talence-Cedex, France. E-mail: b.maillard@lcoo.u-bordeaux.fr

Received (in Cambridge, UK) 30th October 1998, Accepted 23rd November 1998

Induced decomposition of unsaturated peroxy acetals prepared from trimethyl orthoformate, dodecanal or 2-methylundecanal and 2,3-dimethyl-2-hydroperoxybut-3-ene, in the presence of ethyl iodoacetate, CCl_4 or dodecanethiol, allowed respectively their iodo-, chloro- and hydrodecarbonylation with yields of over 70%; the same reaction applied to the monoperoxy ketal or diperoxy ketal of cyclohexanone in the presence of ethyl iodoacetate resulted in its functional transformation in methyl 6-iodohexanoate or 1,5-diiodopentane with respective yields of 65 and 40%.

In the last decades, reactions involving free radicals have been increasingly used[1] in synthesis for the creation of carbon–carbon and carbon–heteroatom bonds. Another important field of interest for free radical reactions is the functional transformations one, pioneered by Barton and his group[2] with the development of the chemistry related to *O*-acyl thiohydroxamates. This allows the reductive decarboxylation of an acid or its decarboxylative transformation into a halide, sulfone, nitrile, alcohol *etc*. This methodology is based on a free radical chain reaction, in which the decarboxylation step is the classical generation of an alkyl radical from an acyloxy one.

In the last few years, our attention turned to the reactivity of unsaturated peroxy acetals and peroxy ketals, *via* polymer chemistry,[3] since it was shown that their corresponding alkoxy radicals undergo a very rapid β-scission reaction[4] to generate an alkyl radical. Thus, the homolytic induced decomposition of unsaturated peroxy acetals and peroxy ketals, derived from the ethyl 2-(1-hydroperoxyethyl)propenoate, was applied for the preparation of glycidic esters[5] (Scheme 1, path **A**). As this method of producing glycidic esters requires the preparation of a specific unsaturated peroxy derivative for each application, we developed a more general method[6] using ethyl 2-[1-(1-methoxy-1-methylethylperoxy)ethyl]propenoate (Scheme 1, path **B**, R = R′ = Me). In the light of these results and taking into account the fact that no general method for the decarbonylative functionalization of aldehydes has been described,[7] we decided to approach these transformations using the induced decomposition of unsaturated peroxy acetals. Indeed, applying the type of methodology that we have just described (Scheme 1, path **B**, R′ = H), it appeared possible to generate an alkyl iodide from the aldehyde, as it could be obtained from the hemiacetal *via* Suarez's method.[8]

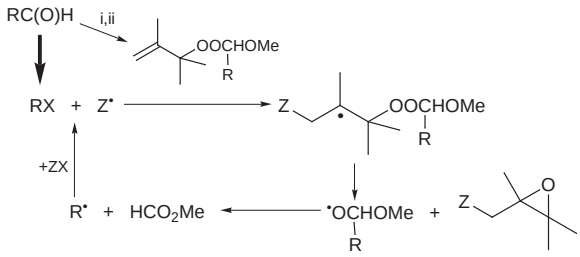


Scheme 1

The decomposition of benzoyl peroxide in a cyclohexane solution of peroxy acetal, obtained from dodecanal, in the presence of a stoichiometric amount of ethyl iodoacetate (relative ratios 0.1:5:1:1.1) afforded the desired 1-iodoundecane (Scheme 1, path **B**, R = $C_{11}H_{23}$, R′ = H) in a 60% yield. In order to check the general character of this reaction, ethyl iodoacetate was replaced by CCl_4: 1-chloroundecane was obtained but with a much lower yield than the corresponding iodide, even when operating in neat perhalogeno solvent (25%). Moreover, in addition to the expected epoxide **2** (Z = CCl_3), the formation of epoxide **1** (R = $C_{11}H_{23}$) with a 46% yield was observed, showing that competition occurred for the alkyl radical between chlorine atom abstraction and addition to the activated double bond of the peroxy acetal. Thus, in order to achieve an effective decarbonylative functionalization of the aldehyde, it appears that the double bond of the peroxy acetal should not be too reactive towards the produced alkyl radical, but very reactive towards the radical $Z^{\cdot}$, formed in the atom transfer with ZX.

Allylic hydroperoxides, possessing a terminal double bond with no electron-withdrawing substituent on it, appeared to be attractive candidates as starting materials for the synthesis of the desired unsaturated peroxy acetals. The easy preparation of allylic hydroperoxides by reaction of singlet oxygen with alkenes[9] prompted us to test the ones produced from the photooxygenation of 2,3-dimethylbut-2-ene (2,3-dimethyl-2-hydro-peroxybut-3-ene), 2-methylbut-2-ene (a mixture of 2-methyl-2-hydroperoxybut-3-ene and 3-methyl-2-hydroperoxybut-3-ene) and 6,7,7-trimethylbicyclo[3.1.1]hept-5-ene (7,7-dimethyl-5-hydroperoxy-6-methylenebicyclo[3.1.1]heptane). The thermolysis of benzoyl peroxide in mixtures of the corresponding peroxy acetals of dodecanal and CCl_4 (relative molar ratios: 0.1:1:5) afforded the 1-chloroundecane in 72, 62 and 42% yield, respectively. These results led us to replace ethyl 2-(1-hydroperoxyethyl)propenoate with 2,3-dimethyl-2-hydroperoxybut-3-ene. The general method for achieving decarbonylative functionalization of the aldehyde is summarized in Scheme 2.

Having determined the appropriate nature of the unsaturated peroxide, it was necessary to optimize the temperature of the reaction. Indeed, in addition to the expected 1-chloroundecane, methyl dodecanoate was obtained (with a yield of about 5% relative to the peroxy ketal). The formation of this compound could be attributed to the disproportionation, in the solvent cage, of the oxyl radicals formed by the spontaneous decomposition of the unsaturated peroxy acetal.[10] Performing the same reaction at room temperature with initiation by BEt_3–O_2 (a BEt_3 solution in hexane was added slowly to the mixture of the other reactants prepared under air, the needle of the syringe being in the liquid) confirmed this origin since no methyl dodecanoate was detected under these conditions and 1-chloro-



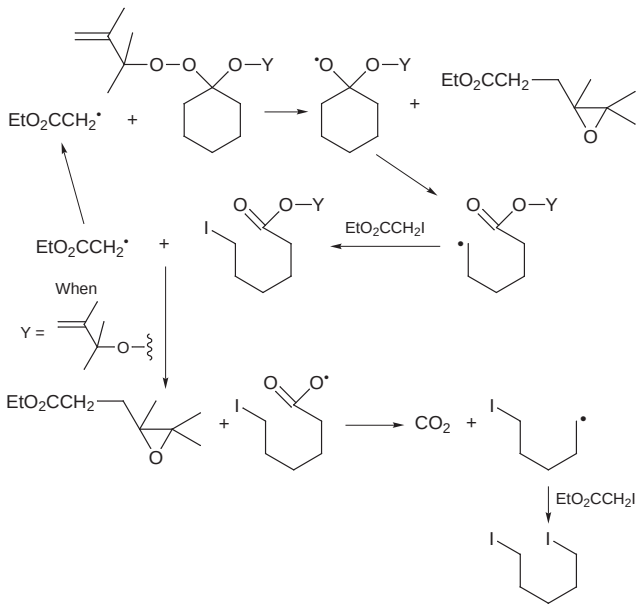
Scheme 2 *Reagents and conditions*: i, $HC(OMe)_3$, TsOH; ii, 2,3-dimethyl-2-hydroperoxybut-3-ene, TsOH.

undecane was obtained with a yield of 86% relative to the starting aldehyde. The iododecarbonylation of dodecanal realized using the same conditions (ethyl iodoacetate–peroxyacetal–cyclohexane: 1.1:1:5; BEt_3–O_2; room temperature) led to 1-iodoundecane with a yield of 75% relative to aldehyde.

The halodecarbonylation of 2-methylundecanal confirmed the general character of this approach since 2-chloroundecane and 2-iodoundecane were also isolated with yields of about 75%.[11] Peroxy acetals formed from aldehydes bearing a tertiary alkyl group have not been studied as a consequence of their lower stability.[12] Moreover, since the decarbonylation of the corresponding acyl radical is a much faster process[13] than that for the one bearing primary and secondary alkyl groups, there is less synthetic need for the setting of such a reaction.

In order to identify possible extensions of this induced decomposition of unsaturated peroxy acetals we decided, on the first hand, to perform the same reaction with both aldehyde derivatives, replacing ethyl iodoacetate by dodecanethiol to achieve the reductive decarbonylations. In each case, undecane was obtained with a yield of about 75%. Thus, this reaction appears to be an attractive alternative, under less drastic conditions, to the direct one designed from the aldehyde by Berman *et al.*[14]

On the other hand, the efficiency of this reaction prompted us to check a possible extension of this methodology to ketones. We therefore tried to achieve the iododeacylation of cyclohexanone. The peroxy ketal was prepared by addition of the hydroperoxide to 1-methoxycyclohexene, with acid catalysis by TsOH, since the reaction of the hydroperoxide with the corresponding acetal leads to a mixture of monoperoxy ketal and diperoxy ketal. The addition of BEt_3 to a non-degassed solution of ethyl iodoacetate and 1-(1,1,2-trimethylprop-2-enylperoxy)-1-methoxycyclohexane in cyclohexane, under the conditions previously described, afforded the desired methyl 6-iodohexanoate (65%) (Scheme 3, Y = Me). The homolytic induced decomposition of cyclohexanone diperoxy ketal, obtained from the corresponding acetal, under the same conditions, but using 2.2 equiv. of ethyl iodoacetate, produced 1,5-diiodopentane in a 40% yield (Scheme 3, Y = CH_2=$CMeCMe_2O$).



Scheme 3

In conclusion, homolytic induced decomposition of unsaturated peroxy acetals and mono- and di-peroxyketals appears to be a promising way of achieving decarbonylative functionalization of aldehydes and deacylative functionalization of ketones. The search for new X–Z molecules able to generate other useful transformations is in progress in our laboratory.

11 Reaction of the aldehyde with trimethyl orthoformate in presence of TsOH yielded, after elimination of methyl formate and excess orthoformate, the raw acetal. Addition of 2,3-dimethyl-2-hydroperoxybut-3-ene (ref. 6) to the acetal, with continuous distillation of MeOH under vacuum (ref. 5), produced the peroxy acetal. After elimination of TsOH by washing the ethereal solution with sodium carbonate and water, followed by drying over magnesium sulfate, the solvent was removed under vacuum. BEt_3 in hexane was added to a solution of the peroxy acetal and the required atom transfer agent in the reaction solvent (cyclohexane, $CHCl_3$ or CCl_4) until total disappearance of the peroxy acetal as determined by ^1H NMR spectroscopy. After elimination of the solvent and the low boiling reaction products, the expected product was separated by column chromatography (SiO_2).

Stereoselectivity in the double reductive alkylation of pyrroles: synthesis of *cis*-3,4-disubstituted pyrrolidines

Timothy J. Donohoe,*[a] Rakesh R. Harji[a] and Rick P. C. Cousins[b]

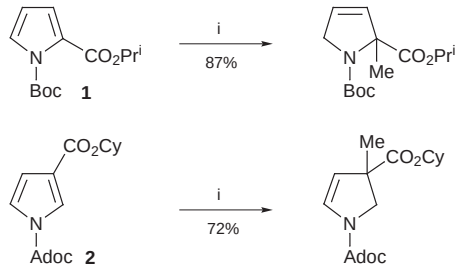
Received (in Liverpool, UK) 23 November 1998, Accepted 26th November 1998

The preparation and Birch reduction of a 1,3,4-tri-substituted pyrrole is described: the heterocycle is loaded with electron-withdrawing groups and undergoes a double reductive alkylation reaction to yield *cis*-3,4-disubstituted pyrrolidines.

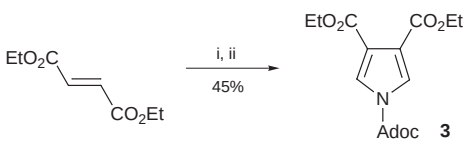
The Birch reduction is a particularly useful synthetic reaction capable of transforming aromatic substrates into partially unsaturated products.[1] We have recently investigated and developed the partial reduction of heterocycles and found that Birch reductive alkylation of electron-deficient pyrroles takes place readily (Scheme 1).[2] For example, the transformation of pyrroles **1** and **2** into either 2- or 3-pyrroline isomers is a high yielding process that enables introduction of an alkyl group adjacent to the activating ester.[3–5] In each case, we believe that addition of electrons to the pyrrole forms a dianion which deprotonates ammonia to furnish an enolate; this reacts with an external electrophile to produce the observed products.



Scheme 1 *Reagents and conditions*: i, Na (3 equiv.), NH_3/THF, then MeI (excess), −78 °C.

Recently we have attempted to expand this work by using more highly-substituted pyrroles as substrates for the Birch reduction. In these cases diastereoisomeric products can be formed and we now present data that shows a high level of stereochemical control is possible. In addition, we also describe a *double* reductive alkylation reaction whereby two alkyl groups can be introduced onto the heterocycle in one step.

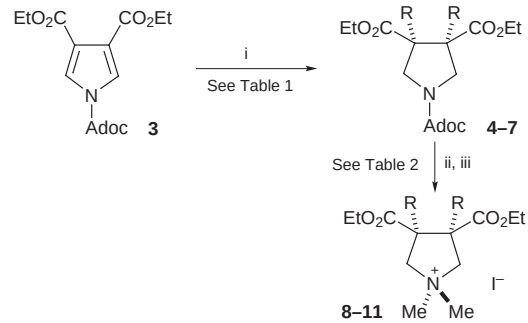
Studies began with the preparation of electron-deficient pyrrole **3** using standard methodology (Scheme 2). Reaction of $TsCH_2NC$,[6] $KOBu^t$ and diethyl fumarate gave a 3,4-disubstituted pyrrole which was protected, on nitrogen, as a adamantyloxycarbonyl (Adoc) derivative using adamantyl fluoroformate (45% overall yield from diethyl fumarate).



Scheme 2 *Reagents and conditions*: i, $TsCH_2NC$, Bu^tOK, THF; ii, Adoc-F, MeCN, Et_3N.

Subjection of pyrrole **3** to reductive alkylation conditions (6 equiv. Li in NH_3) is described in Scheme 3. We routinely add $(MeOCH_2CH_2)_2NH$ (10 equiv.) to Birch reductions as this amine appears to 'mop-up' lithium amide formed during the reaction and reduces the presence of undesirable by-products.[5]† Isoprene 'quenches' excess electrons in the reaction after reduction is complete (addition of isoprene caused the reaction to turn from deep blue to yellow—this colour was dissipated upon addition of an alkyl halide). The first reaction was quenched with MeI and produced a single product in good yield. We identified the pyrrolidine **4** (R = Me) from ^{1}H NMR spectroscopic data (Table 1).‡ We were then able to repeat the reaction and quench with a variety of electrophiles to generate compounds **5**–**7** in good yields (Table 1). In every case ^{1}H NMR spectroscopy showed that an alkyl group had been introduced α to each of the two esters, and also revealed the presence of the four protons adjacent to the pyrrolidine nitrogen.

Unfortunately, the NMR spectra of **4**–**7** did not allow us to assign relative stereochemistry and this was subsequently proved by conversion to the corresponding quarternary ammonium salts *via* a two step sequence (Scheme 3). Assignment of *cis* relative stereochemistry to compounds **4**–**7** would mean that the two *N*-methyl groups on (*meso*) salts **8**–**11** are diastereotopic, and could therefore resonate at different chemical shifts. On the other hand, *trans* stereochemistry would make the *N*-methyl groups of **8**–**11** (now C_2 symmetrical) homotopic and they would therefore have identical chemical shifts. Gratifyingly, salts **8**–**11** each displayed two (3H) singlets in the ^{1}H NMR spectrum,‡ thus allowing us to assign with confidence the stereochemistry of **4**–**7** as shown (Table 2).



Scheme 3 *Reagents and conditions*: i, Li (6 equiv.), NH_3, THF, $(MeOCH_2CH_2)_2NH$, −78 °C, then isoprene (3 drops), then RI (excess); ii, TFA, CH_2Cl_2; iii, MeI, $KHCO_3$, MeOH.

Table 1 Birch reduction of **5**

Entry	RX	*cis*/*trans*	Yield (%)	Compound
1	MeI	⩾20:1	77	**4**
2	EtI	⩾10:1	82	**5**
3	Bu^iI	⩾10:1	79	**6**
4	Allyl-I	⩾10:1	70	**7**

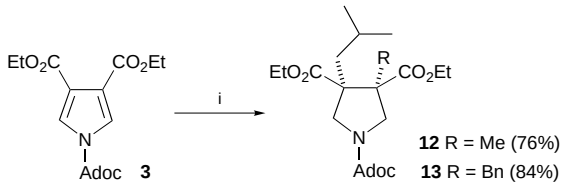
Table 2 Quaternary ammonium salts

Entry	R	δ_H(NMe) ($CDCl_3$)	Yield (%)	Compound
1	Me	3.52, 3.77	52	**8**
2	Et	3.67, 3.81	61	**9**
3	Bu^i	3.69, 3.77[a]	55	**10**
4	Allyl	3.65, 3.83	58	**11**

[a] NMR run in acetone-d_6.

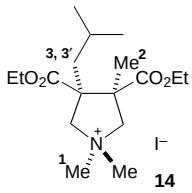
Compounds **4**–**7** were formed with high levels of stereoselectivity; such ratios were formulated by examination of the NMR spectra of the crude reaction mixtures. As far as the formation of **4** is concerned we were able to prepare an authentic sample of the *trans* isomer by another route and (in comparison with this standard) could not observe the *trans* isomer in the crude reduction reaction. Although each of the other cases was assigned ⩾10:1 selectivity without comparison to a standard, we believe this is a conservative estimate. Not only were the Birch reduced products **5**–**7** free from detectable impurities but also the amines formed by Adoc deprotection and the salts **8**–**11** appeared as single isomers by NMR spectroscopy.

We noticed that the alkylation step of the Birch reduction proceeded at different rates with the electrophiles that were used. Not surprisingly, reaction with Bu^{i}I was much slower than reaction with MeI. Using this information we developed a protocol for the sequential dialkylation of the pyrrole with two different electrophiles (Scheme 4). So, reaction of **3** with



Scheme 4 *Reagents and conditions*: i, Li (6 equiv.), NH_3, THF, $(MeOCH_2CH_2)_2NH$, −78 °C, then isoprene (3 drops), then Bu^{i}I (excess) , then RX (excess).

lithium metal as before but quenching with excess Bu^{i}I and then (after 2 min) excess MeI (or BnBr) enabled the synthesis of **12** and **13** in good yields. In both cases the reaction gave a single product as judged by ^{1}H NMR spectroscopy. Further proof of the identity of **12** was obtained by conversion to **14** under standard conditions (**14** appeared as one isomer) and subsequent NOE studies (Fig. 1). The NOE experiment described shows that **14** is the *cis* isomer. With all of this evidence for *cis* stereoselectivity in the dialkylation reaction, compound **13** was assigned as *cis* by analogy.



14

Irradiate	Percent NOE observed 1	2	3	3'
1	X	1	0	3
2	1	X	4	5
3	1	4	X	9
3'	3	6	8	X

Fig. 1 NOE studies on **14**

In terms of mechanism, we suggest that **3** accepts two electrons and forms dianion **A** (Fig. 2). Dianion **A** is then basic enough to deprotonate ammonia and form enolate **B**. Presumably, the presence of an ester group at C-4 means that the C-4,5 alkene in **B** is susceptible to further reduction by addition of two electrons and protonation at C-5 (by ammonia) to give **C**,[7] which is then alkylated twice. Presumably, the relative stereochemistry is determined by the facial selectivity of the second alkylation step (reaction of **D**) and it is surprising that such high levels of control are observed. Additional experiments show that both potassium and sodium metals give identical selectivity to lithium, thus dampening arguments based on chelation. However, we have preliminary results which show that, remarkably, the ammonia solvent is essential in order to achieve high stereoselectivity. We cannot comment on the exact role of the ammonia at this point, but note that Schultz has previously observed a similar relationship between solvent and the stereoselectivity displayed by enolates generated in the Birch reduction.[8]

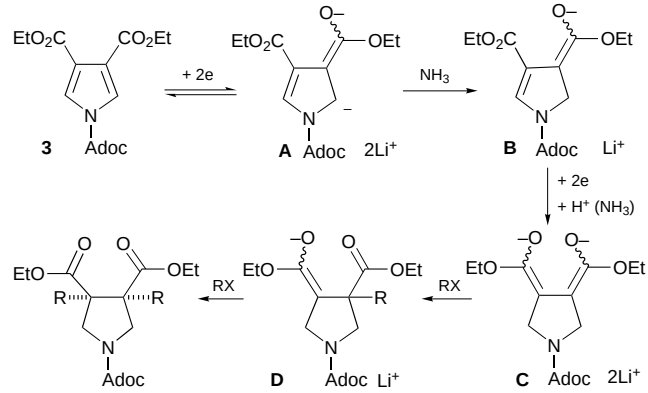


Fig. 2

We believe this type of reaction will be of use in both natural product synthesis and medicinal chemistry and that, as this reaction results in the formation of two adjacent quarternary chiral centres with control of relative stereochemistry, it is worthy of further study.

We wish to thank GlaxoWellcome (CASE award to R. R. H.) and Zeneca Pharmaceuticals (Strategic Research Fund) for financial support.

Notes and references

† We assume that $(MeOCH_2CH_2)_2NH$ is acidic enough to become deprotonated by lithium amide. Presumably, the anion derived from the amine additive is chelated and is a relatively unreactive species compared to lithium amide itself. We also note that $(MeOCH_2CH_2)_2NH$ is not acidic enough to protonate any enolate formed in the reaction, hence allowing us to add 10 equiv. without complication.

Total synthesis of sulfur-containing pyrroloiminoquinone marine product, (±)-makaluvamine F using hypervalent iodine(III)-induced reactions

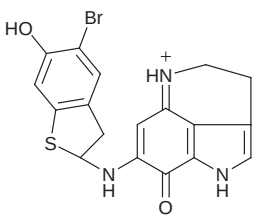
Yasuyuki Kita,* Masahiro Egi and Hirofumi Tohma

Graduate School of Pharmaceutical Sciences, Osaka University, 1-6 Yamada-oka, Suita, Osaka 565-0871, Japan. E-mail: kita@phs.osaka-u.ac.jp

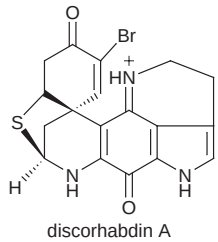
Received (in Cambridge, UK) 9th November 1998, Accepted 20th November 1998

The first total synthesis of potent cytotoxic makaluvamine F 1, a sulfur-containing pyrroloiminoquinone marine product, has been accomplished using hypervalent iodine(III)-induced reactions.

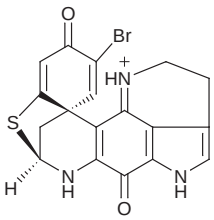
The makaluvamines,[1] a new family of marine alkaloids, were isolated from the Fijian sponge *Zyzzya cf. marsailis* (A–F) and the Indonesian sponge *Histodermella* sp. (G). Among them,



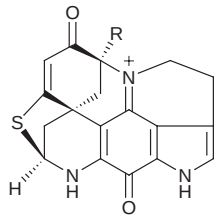
makaluvamine F **1**



discorhabdin A (prianosin A)

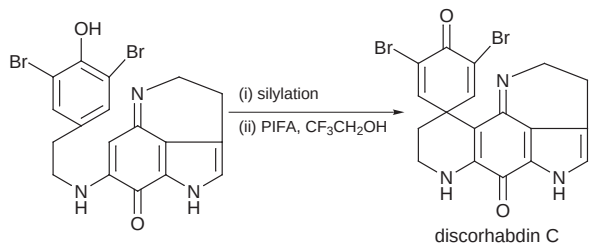


discorhabdin B

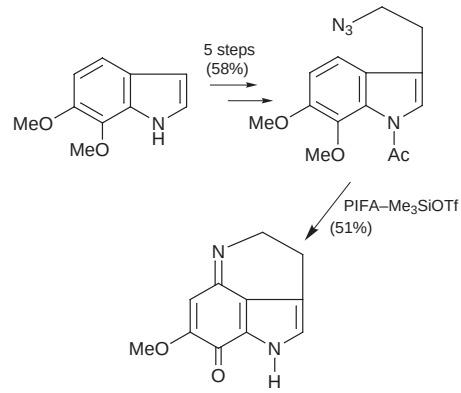


discorhabdin D (prianosin D) (R = H)
prianosin C (R = OH)

makaluvamine F **1** exhibits the most potent biological activity [*e.g.* cytotoxicity towards the human colon tumor cell-line HCT-116 (IC_{50} = 0.17 μM) and inhibition of topoisomerase II][1,2] and has an α-aminodihydrobenzothiophene skeleton which is a labile *N*,*S*-acetal structure present in all sulfur-containing discorhabdins.[3] Synthetic studies towards makaluvamines and discorhabdins have been carried out by several groups.[4] We have also reported the total synthesis of discorhabdin C (Scheme 1)[5] and a facile and efficient synthesis of pyrroloiminoquinone derivatives **2** using the hypervalent iodine(III) reagent, phenyliodine(III) bis(trifluoroacetate) (PIFA) (Scheme 2).[6] However, in most cases these efforts have been



Scheme 1



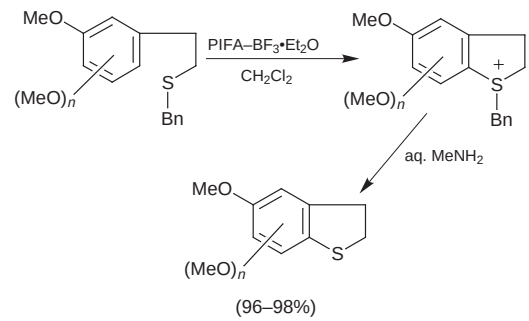
Scheme 2

devoted only towards the preparation of the pyrroloiminoquinone and spirodienone units.

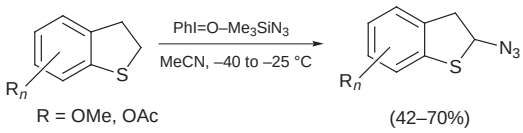
To the best of our knowledge, the total syntheses of sulfur-containing discorhabdins and **1** have not yet been reported, in spite of their potent cytotoxicity and their unique structure. This is probably due to the difficulty of construction of the labile and highly strained *N*,*S*-acetal skeletons. We report herein the first total synthesis of potent cytotoxic makaluvamine F **1** using hypervalent iodine(III)-induced reactions. Our synthetic strategy for the total synthesis of **1** involves a final coupling reaction between **2** and 2-aminodihydrobenzothiophene derivative **3**.

In order to construct **3** bearing the *N*,*S*-acetal skeleton, it was first essential to develop an efficient route for the synthesis of the starting dihydrobenzothiophene bearing a hydroxy group. In our previous report, various dihydrobenzothiophenes were prepared from phenol ethers bearing an alkyl sulfide sidechain *via* intramolecular cyclization using PIFA–BF_3·Et_2O followed by treatment with aq. $MeNH_2$ without yielding any sulfoxides (Scheme 3).[7] Using this method, 6-benzyloxy-5-bromodihydrobenzothiophene **4** was synthesized effectively.

Next, we attempted to introduce the azido group at the 2-position of **4**. Subsequent to the first report by Böhme and Morf,[8] acyclic α-azido sulfides have generally been synthesized stepwise, *via* halogenation followed by azidation of sulfides,[9] or *via* thioketals.[10] On the other hand, α-azidation of dihy-



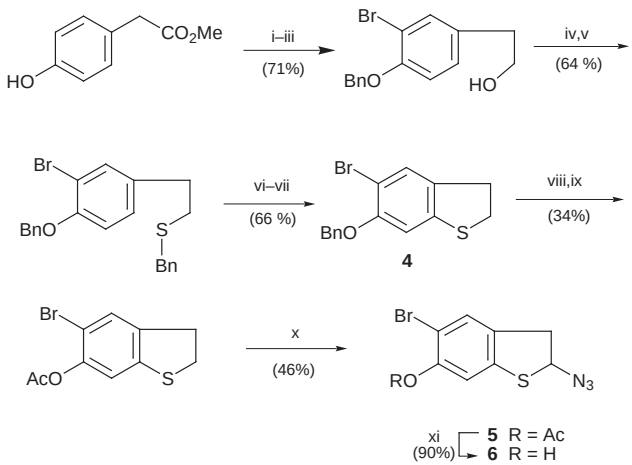
Scheme 3



Scheme 4

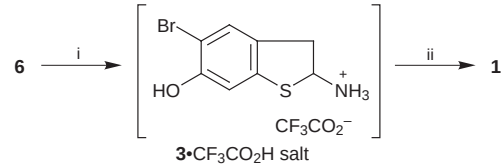
drobenzothiophenes has never been reported, probably due to readily occurring side reactions such as aromatization, sulfoxide formation, benzylic oxidation and α-oxidation of the sulfur atom under oxidative conditions. We examined the known stepwise methods to obtain α-azidodihydrobenzothiophene. However, the aromatization occurred exclusively to give benzothiophene derivatives in the initial halogenation step.

Very recently, we developed a novel and direct α-azidation of dihydrobenzothiophenes using a combination of PhI=O and Me_3SiN_3 (Scheme 4).[11] However, the azidation of **4** gave only a trace amount of the expected α-azido compound. This is because there appears to be a large number of reactive sites on phenol ether **4** toward the hypervalent iodine-induced azidation. Hence, we then performed the azidation after debenzylation followed by acetylation of **4** to give the corresponding α-azido compound **5** in 46% yield. After hydrolytic deprotection of the 6-acetoxy group, 2-azido-5-bromo-6-hydroxy-dihydrobenzothiophene **6** was finally obtained. The route to **6** from commercially available methyl (4-hydroxyphenyl)acetate is outlined in Scheme 5.



Scheme 5 *Reagents and conditions*: i, Br_2, AcOH; ii, BnBr, K_2CO_3, EtOH; iii, $LiAlH_4$, THF; iv, I_2, PPh_3, imidazole, PhMe; v, AcSBn, NaOH, MeOH; vi, PIFA–BF_3·OEt_2; vii, aq. $MeNH_2$; viii, BF_3·OEt_2, EtSH; ix, Ac_2O, NaOAc, aq. NaOH; x, PhI=O–Me_3SiN_3, MeCN, −40 to −25 °C; xi, 5% NaOH, MeOH.

Sequential attempts to transform the azido group to the amino group by catalytic hydrogenation or other reductive methods under non-acidic conditions proved unsatisfactory (*i.e.* 2-amino-5-bromo-6-hydroxydihydrobenzothiophene **3** was found to be quite labile under basic conditions). Furthermore, Wittig-type reactions between the phosphine imine prepared from **6** and several quinones were also unsuccessful. Finally, we found that the catalytic hydrogenation of **6** using 10% Pd-C in the presence of 4 equiv. of TFA resulted in complete reduction to give **3** as a TFA salt in quantitative yield without any side reactions. The final coupling reaction in MeOH between both synthetic precursors, **3** (TFA salt) and **2**, proceeded in 86% yield



Scheme 6 *Reagents and conditions*: i, H_2, 10% Pd-C, EtOH–TFA; ii, **2**, MeOH, room temp.

to give the TFA salt of **1**, whose spectral data were identical to those previously reported[1] (Scheme 6).

In conclusion, the first total synthesis of (±)–makaluvamine F has been achieved *via* a facile construction of the labile *N*,*S*-acetal skeleton by a combination of hypervalent iodine oxidation reactions. Synthetic studies towards more complicated sulfur-containing discorhabdins and their analogs are now underway.

Photochemical C–H bond activation of the diruthenium bridging methylene complex, $Cp_2Ru_2(\mu\text{-}CH_2)_2(CO)_2$: insertion of norbornadienes into the methylene C–H bond and unprecedented intramolecular H–D exchange between the two methylene units

Munetaka Akita,* Sadahiro Nakanishi, Hideki Musashi and Yoshihiko Moro-oka*

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, 4259 Nagatsuta, Midori-ku, Yokohama 226-8503, Japan. E-mail: makita@res.titech.ac.jp

Received (in Cambridge, UK) 30th October 1998, Accepted 16th November 1998

Two photochemical reactions of the diruthenium bis-μ-methylene complex $(\eta^5\text{-}C_5H_5)_2Ru_2(\mu\text{-}CH_2)_2(CO)_2$ are described: (i) insertion reaction of norbornadiene into the methylene C–H bonds leading to $(\eta^5\text{-}C_5H_5)_2Ru_2(\mu\text{-}CHR')_2(CO)_2$ (R′ = 5-*exo*-norbornenyl) and (ii) H exchange between the two methylene units, involve μ-methylidyne intermediates generated *via* C–H bond activation of the μ-methylene ligand.

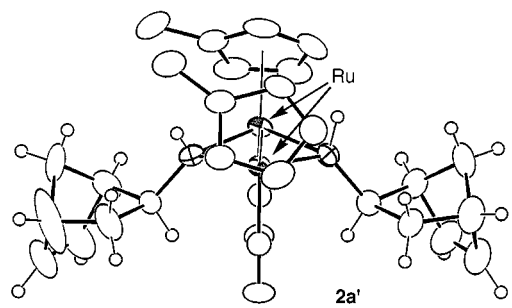
C1 species (CH_x) are pivotal intermediates in surface catalyzed reactions, such as catalytic conversion of CO and hydrocarbons,[1] and organometallic compounds containing the CH_x ligands have been studied extensively as model compounds for surface-bound species.[2] Although C–C coupling of C1 species is a key step of the carbon chain propagation during the catalytic processes, only a limited number of successful C–C coupling reactions of bridging hydrocarbyl complexes, in particular, μ-CH_2 complexes, have been reported so far, and most of the C–C coupling processes involve coordination of an unsaturated C–C bond (or alkylidene species) to the metal vacant site followed by insertion into the M–μ-CR_x bond.[3,4d] During the course of our studies of the photochemical reactions of the diruthenium di-μ-methylene complex $Cp_2Ru_2(\mu\text{-}CH_2)_2(CO)_2$ **1a**,[4] we found an unusual C–C coupling reaction at the bridging methylene carbon atom and unprecedented H exchange between the two methylene carbon atoms, which should involve μ-methylidyne species as a key intermediate.

Irradiation of a THF solution of the di-μ-methylene complex **1a**[4a] in the presence of an excess of norbornadiene (nbd) for 5 h gave a yellow isomeric mixture of products (**2a**; 89% yield) after TLC separation (Scheme 1). The significant change in the ^{1}H NMR signals of the μ-CH_x part compared to **1a** [(i) intensity: 2H (from 4H); (ii) ^3J = 11.7 Hz for μ-CH (from ^2J = 0.6 Hz for μ-CH_2)]† suggested the occurrence of a C–C coupling reaction at the μ-methylene carbon atom. The molecular structure of the η^5-C_5H_4Me derivative (**2a′**) was determined by X-ray crystallography,‡ which revealed (i) insertion of the C=C bond in nbd into the C–H bonds of both of the μ-methylene ligands, and (ii) C–C coupling from the less sterically congested *exo*-side of nbd. Reaction of the μ-methylene-μ-ethylidene complex **1b** resulted in exclusive insertion into the μ-methylene part to give the 1:1 adduct **3b**, as indicated by a similar change in the μ-CH_2 signals and the unchanged μ-$CHCH_3$ pattern.† Furthermore, the photochemical C–C coupling reaction was also observed for the cyclohexyl isocyanide complex **1c**, while the dppe derivative **1d** remained unreacted.§ We also attempted the C–C coupling of **1a** with a variety of unsaturated hydrocarbons such as 2- or 7-substituted nbd, norbornene, cyclohexa-1,4-diene, butadiene, quadricyclene, ethyl acrylate and 1,1-diphenylethylene. However, only a few 2-substituted nbds (Me and Me_3Si derivatives) afforded 1:1 adducts **3** (R = H); the others did not give any C–C coupling product.[5]

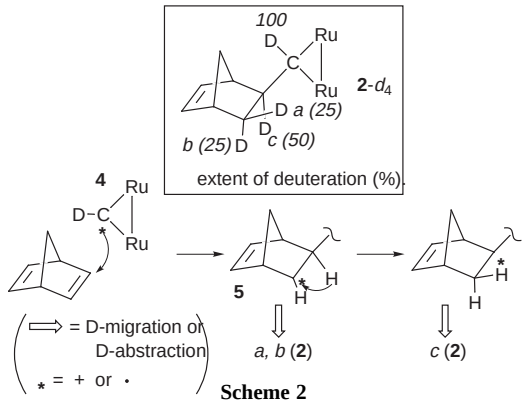
For elucidation of the reaction mechanism, a labeling experiment using **1a**-d_4 [(μ-$CD_2)_2$] was carried out and the distribution of the deuterium atoms was determined by ^{1}H and ^{13}C NMR, as illustrated in Scheme 2. The D distribution over the moiety originating from the C=C bond in nbd clearly indicated that the C–C coupling process was not a simple insertion reaction into the C–D bonds, but consisted of a multistep reaction sequence. The result may be interpreted in terms of a μ-methylidyne intermediate **4** as summarized in Scheme 2. Possible candidates for **4** are the decarbonylated μ-methylidyne species $Cp_2Ru_2(\mu\text{-}CH)(H)(\mu\text{-}CH_2)(CO)$ **4′**, suggested by the H–D exchange reaction (see below)[6] and the radical species **4″**, generated by H abstraction. Addition of **4′** or **4″** to the π-

	R	L	products
1a	H	CO	**2a** (89 %)
1a'	H	CO	**2a'** (80 %)
1b	CH_3	CO	**3b** (38 %)
1c	H	CNCy	**2c** (23 %)
1d	H	dppe	–

(**1a'**, **2a'**: η^5-$C_5H_4CH_3$ derivatives)



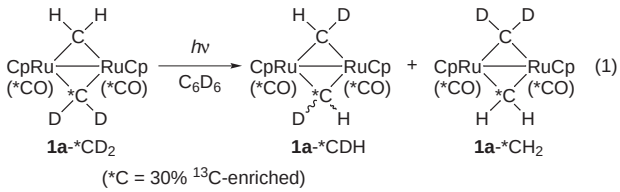
Scheme 1



Scheme 2

electrons of nbd should form intermediate **5**. Direct H recombination gives **2**-d_4 deuterated at either of sites *a* or *b*, whereas a 1,2-H shift finally leads to deuteration at the site *c*, and the driving force for the 1,2-H migration should be formation of the tertiary cation (or radical), which is more stable than the secondary one (**5**). Subsequently, the C–C coupling reaction will be completed by either intramolecular H(D) migration (**4′**) or intermolecular H(D) abstraction [**4″**: from **2**-d_2 (radical chain reaction)]. Although the mechanism involving H migration can account for the D distribution, the reaction is not retarded by addition of cation and radical quenchers (*e.g.* MeOH and hydroquinones, respectively) and intermediate **4** cannot be trapped by diphenylethylene and ethyl acrylate (cation and radical trapping agents).

In order to obtain further information on the properties of the μ-methylene complexes, a benzene-d_6 solution of the labeled compound $Cp_2Ru_2(\mu\text{-}CH_2)(\mu\text{-}{}^*CD_2)({}^*CO)_2$ (**1a**-*CD_2; *C = *ca*. 30% ^{13}C-enriched) was subjected to irradiation *in the absence of nbd* (Scheme 3). As a result, the intensity of the quintet μ-*CD_2 signals of **1a**-*CD_2 [δ_C 107.4 (*cis* isomer), 108.8 (*trans* isomer)] diminished and instead there appeared the triplet (*cis*-**1a**-*CDH: δ_C 107.7) and then the singlet signals (*cis*-**1a**-*CH_2: δ_C 108.8) as shown in Fig. 1.¶ An equilibrated mixture of the isotopomers was obtained after 40 h irradiation. The spectral changes unequivocally indicates that the hydrogen atoms attached to the two methylene carbon atoms exchange with each other. Similar isomerization was also observed for $Cp_2Ru_2(\mu\text{-}CD_2)(\mu\text{-}CHCH_3)(CO)_2$ **1b**-d_2, which was converted



Scheme 3

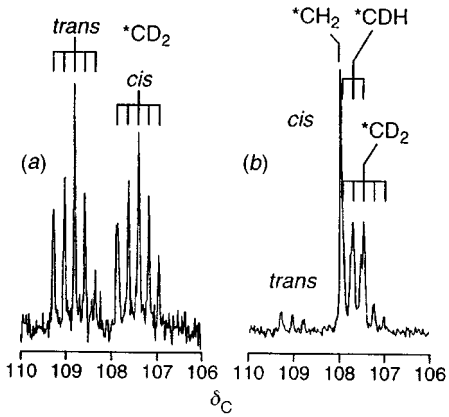


Fig. 1 ^{1}H decoupled ^{13}C NMR spectra of **1a**-*CD_2:expanded views of the μ-CH_2 region (*a*) before and (*b*) after irradiation for 40 h.

to $Cp_2Ru_2(\mu\text{-}CDH)(\mu\text{-}CDCH_3)(CO)_2$. A plausible intermediate for the exchange reaction of **1a** is the μ-methylidyne species $Cp_2Ru_2(\mu\text{-}CH)(\mu\text{-}CH_2)(H)(CO)$ **4′** formed by decarbonylation followed by H migration from the bridging carbon atom to the ruthenium center; the H–D exchange reaction would be completed by a 1,3-H(D) shift, reversed H(D) migration and CO recombination.

In summary, we have reported the two photochemical C–H bond cleavage reactions of the bridging alkylidene complexes **1**; the present work reveals a new type of functionalization of bridging alkylidene complexes by way of μ-alkylidyne intermediates. In addition, combined with our previous results of the $CH_3\leftrightarrow CH_2$–H[4b] and $CH_2\leftrightarrow$CH–H interconversions[4c] on diruthenium systems, our results suggest the occurrence of analogous interconversions of CH_x species (x = 1–3) on a catalyst surface.

We are grateful to the Ministry of Education, Science, Sports, and Culture of the Japanese Government for financial support of this research.

Phosphorus octaethyltetraphenylporphyrins [(oetpp)P(Me)(X)]PF_6 (X = Me, OH, F) having saddle (X = Me) or ruffled (X = OH, F) conformations

Akihiro Yamamoto, Wataru Satoh, Yohsuke Yamamoto* and Kin-ya Akiba*

Department of Chemistry, Faculty of Science, Hiroshima University, 1-3-1 Kagamiyama, Higashi-Hiroshima 739-8526, Japan. E-mail: akiba@sci.hiroshima-u.ac.jp

Received (in Cambridge, UK) 5th October 1998, Accepted 8th December 1998

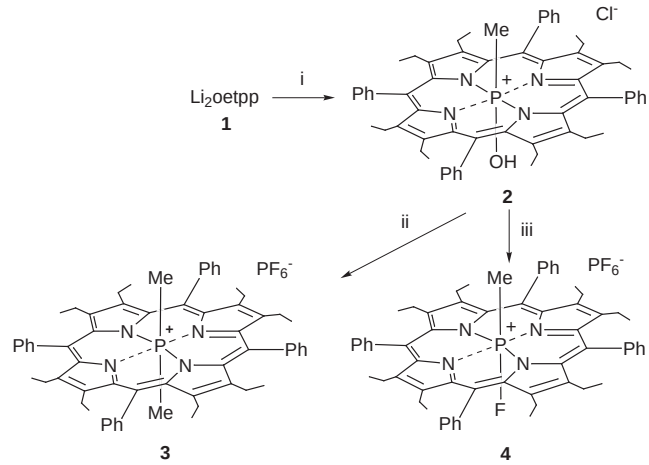
X-Ray crystallographic structures of [(oetpp)P(Me)(X)]PF_6 revealed that the axial ligand (X) plays a major role in changing the conformation of the porphyrin core from saddle (X = Me) to ruffled (X = OH and F).

There has been considerable interest in the conformations of metalloporphyrins since they have a profound influence on the physicochemical properties of the macrocycle such as redox potential and electron transfer rates, and therefore its reactivity in a protein.[1] The interest has prompted the synthesis of many substituted porphyrins in which deformations (mainly saddle type deformation) from planarity are induced by crowding of substituents at the periphery of the macrocycle.[2] There is now a considerable body of information describing the structural and spectroscopic properties of highly non-planar octaalkyltetraphenylporphyrins bearing transition metals[3] which show saddle conformations. Although those bearing main group elements have not been reported, phosphorus octaalkyltetraphenylporphyrins are interesting because phosphorus has been the smallest atom which can occupy the center of a porphyrin ring. Recent report on X-ray crystallographic structures of $[(oep)P(X)(Y)]^+Z^-$ revealed essentially ruffled conformations in order to accommodate the small phosphorus atom. The electronegativities of the axial ligands (X and Y) played a major role in determining the deformation, for example, $[(oep)P(Me)_2]PF_6$ showed a planar conformation.[4] Here we report the synthesis and X-ray structures of phosphorus octaethyltetraphenylporphyrins, [(oetpp)P(Me)(X)]PF_6 (X = OH **2**, Me **3**, F **4**), which showed strong effects of the axial ligands on the conformations, *i.e.*, a saddle conformation was observed in $[(oetpp)P(Me)_2]PF_6$ (**3**-PF_6) but ruffled ones were observed in [(oetpp)P(Me)(OH)]ClO_4 (**2**-ClO_4) and [(oetpp)P-(Me)(F)]PF_6 (**4**-PF_6).

The reaction of oetppLi_2 **1** with $MePCl_2$ was carried out under dichloromethane reflux for 12 h. After removal of the solvent and excess of $MePCl_2$, the residue was subjected to neutral alumina column chromatography (CH_2Cl_2) to give [(oetpp)P(Me)(OH)]Cl (**2**-Cl) (Scheme 1). After counter anion exchange **2**-ClO_4 was obtained pure for elemental analysis.

The hydroxy group of **2**-Cl was substituted by a methyl group by the reaction of **2**-Cl with phosphorus trichloride followed by treatment with an excess of trimethylaluminium in dichloromethane to yield $[(oetpp)P(Me)_2]PF_6$ (**3**-PF_6) in 79% yield after counter anion exchange according to the method recently reported by us for group 15 element porphyrins.[5] [(oetpp)P-(Me)(F)]PF_6 (**4**-PF_6) was obtained in 61 % yield by the reaction of **2**-PF_6 with phosphorus trichloride (Scheme 1).[6]

Crystals of **2**-ClO_4, **3**-PF_6 and **4**-PF_6 suitable for X-ray analysis were grown from dichloromethane–*n*-hexane. The crystallographic analyses of **3**-PF_6 and **4**-PF_6 are not of good quality owing to extensive disorder of the counter anion (PF_6^-) and dichloromethane as a solvent in **4**-PF_6, but the structures of the porphyrin core could be definitely determined. Figs. 1–3 show ORTEP drawings of **2**-ClO_4, **3**-PF_6 and **4**-PF_6 (counter anions and dichloromethane in **4**-PF_6 are omitted for clarity). The crystal structure of **3**-PF_6 exhibits a distorted saddle conformation which is characterized by large displacements of $C_{pyrrole\text{-}\beta}$ atoms from the mean plane of the core. By contrast, the



Scheme 1 *Reagents and conditions*: i, $MePCl_2$, CH_2Cl_2, reflux, 12 h; ii, PCl_3, CH_2Cl_2, reflux, 3 h, then $AlMe_3$ in hexane, CH_2Cl_2, room temp., 12 h; iii, KPF_6; then PCl_3, CH_2Cl_2, room temp., 12 h.

crystal structures of **2**-ClO_4 and **4**-PF_6 exhibit ruffled conformations which are characterized by significant C_{meso} displacements from the core and twist of the pyrrole rings so that the β carbons lie above and below the core plane. **4**-PF_6 is more distorted than **2**-ClO_4 as is evident from the average displacement of the C_{meso} atoms from the mean plane of the molecule (**4**-PF_6, 1.20 Å; **2**-ClO_4, 1.07 Å).

The results can be explained based on the conclusions found for [(oep)P(X)(Y)]Z.[4] The introduction of the electronegative axial substituents [X = OH **2** and X = F **4** in (oetpp)P(Me)(X)] reduces the size of the central phosphorus atom and the average P–N bond distances become shorter [1.94(1) Å in **3**-PF_6 (X = Me), 1.849(4) Å in **2**-ClO_4 (X = OH) and 1.810(8) Å in **4**-PF_6 (X = F)], and leads to the ruffled conformation becoming preferable in **2**-ClO_4 and **4**-PF_6 in order to accommodate the

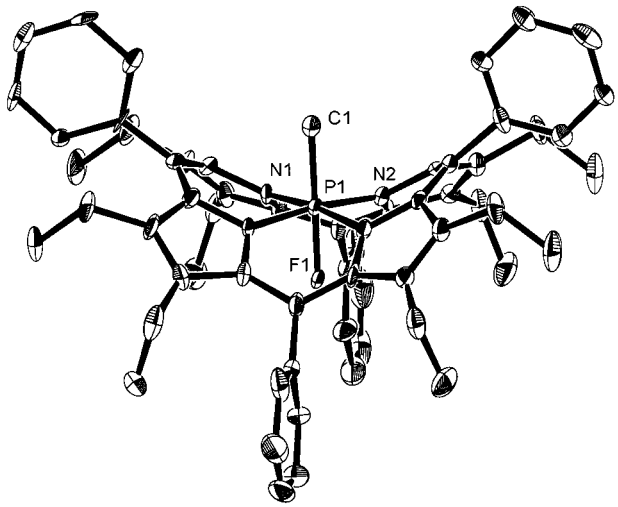

Fig. 3 Molecular structure of **4**-PF_6. Selected bond lengths (Å): P–C1 1.83(2), P–F 1.648(9), P–N1 1.827(8), P–N2 1.793(8).

smaller phosphorus atom. Although metal size dependence of the degree of deformation of saddle conformations has already been investigated for transition metals,[3] such large electronic effects of the axial ligands to change the fundamental conformations have never been observed. The structures of **2**-ClO_4 and **4**-PF_6 are the first examples for metallooctaalkyltetraphenylporphyrins showng ruffled conformations.

It is interesting that the Q(0,0) band of ruffled **2** (627 nm) and **4** (622 nm) are siginificantly blue shifted in the UV–VIS in comparison with that of **3** (667 nm) and free base octaethyltetraphenylporphyrin (686 nm) with saddle conformation.[2] Since such a large shift has not been observed in the [(oep)P(Me)(Y)]Z series, the shift can be ascribed to the difference of core conformations. In order to rationalize the results further structural and spectroscopic studies are now in progress.

Received (in Cambridge, UK) 22nd October 1998, Accepted 8th December 1998

The redox behaviour of a $Ce_{0.68}Zr_{0.32}O_2$ mixed oxide is reversibly modified by alternating high temperature (1223 K) reduction with either mild (823 K) or high temperature (1223 K) re-oxidation treatments.

Ceria/zirconia mixed oxides constitute a real alternative to pure ceria in advanced three way catalyst (TWC) formulations.[1,2] It has been shown that the incorporation of zirconium into the ceria lattice improves its textural stability[3,4] and redox behaviour.[5–7] The Ce/Zr mixed oxides also show enhanced OSC (oxygen storage capacity)[8] which has been interpreted as due to the occurrence of bulk reduction at moderate temperatures.[9] This would also explain the remarkably high OSC values they exhibit even when heavily sintered.[10] Moreover, in spite of the inherent loss of surface area, the high temperature ageing treatments under reducing conditions may actually improve their reducibility and OSC properties.[7] This behaviour contrasts with the severe deterioration of redox properties always observed for pure ceria on ageing.[11,12] Recent studies which directly compare the reduction behaviour of Ce/Zr mixed oxides with that of pure CeO_2 clearly demonstrate this point.[7,10]

We report on the strong influence of the re-oxidation conditions on the redox behaviour of $Ce_{0.68}Zr_{0.32}O_2$ previously reduced at high temperature. Alternate mild (823 K) and high temperature (1223 K) re-oxidation treatments, after reduction at 1223 K in each case, result in very different, but reversible, redox behaviours. The mild re-oxidation leads to enhanced oxide reducibility whereas subsequent high temperature re-oxidation induces the opposite effect: severe loss of reducibility. This behaviour can be reproduced in a cyclic manner, demonstrating the reversibility of this effect.

The starting Ce/Zr oxide, hereafter denoted LS, had a BET surface area of 23 $m^2\ g^{-1}$ and was prepared by coprecipitation, calcination and then prolonged ageing (140 h) in wet synthetic air at 1173 K.

Fig. 1 shows the TPR-MS (temperature programmed reduction-mass spectrometry) traces for H_2O (*m/z*: 18) evolution recorded when a series of the above-mentioned redox treatments were applied successively. The TPR experimental conditions were: amount of sample: 200 mg; H_2(5%)–Ar flow rate: 60 $cm^3\ min^{-1}$; heating rate: 10 $K\ min^{-1}$; top limit temperature: 1223 K; heating time at 1223 K: 2 h. Before running any of the TPR–MS experiments, the oxide sample was routinely oxidised either under mild (MO) or high temperature (HTO) conditions. The MO treatment consisted of: heating from 298 to 823 K in flowing O_2(5%)/He at 10 $K\ min^{-1}$ followed by a 1 h isothermal step at 823 K, cooling to 473 K, also under flowing O_2(5%)–He, and finally cooling to 298 K in a flow of He. The HTO treatment is similar to the MO, the only difference being that the top limit re-oxidation temperature was 1223 K. As confirmed by the magnetic balance data, both MO and HTO protocols ensure the full oxidation of the sample. Likewise, our magnetic balance and TPD studies confirm that the final cooling step from 473 to 298 K, in flowing He, does not induce any significant reduction of the oxide. However, it allows us to avoid any possible contribution to the TPR–MS traces from chemisorbed oxygen species. TPD–MS results also show that both MO and HTO re-oxidation treatments lead to heavily dehydroxylated oxide samples. In summary, the reported TPR–MS traces should be interpreted as due only to the sample reduction with inherent creation of oxygen vacancies.

The high temperature reduction treatment consisted of heating the MO pre-treated LS oxide under flowing H_2 (60 $cm^3\ min^{-1}$) from 298 up to 1223 K (heating rate: 10 $K\ min^{-1}$), followed by a dwell at 1223 K for 5 h, evacuation at 1223 K (1 h) in a flow of He, cooling to 298 K also in flowing He, and a further MO re-oxidation treatment. The resulting oxide sample will be hereafter referred to as SR.

Traces (a) and (b) in Fig. 1 present the TPR–MS diagrams recorded for the LS and SR samples respectively. Compared

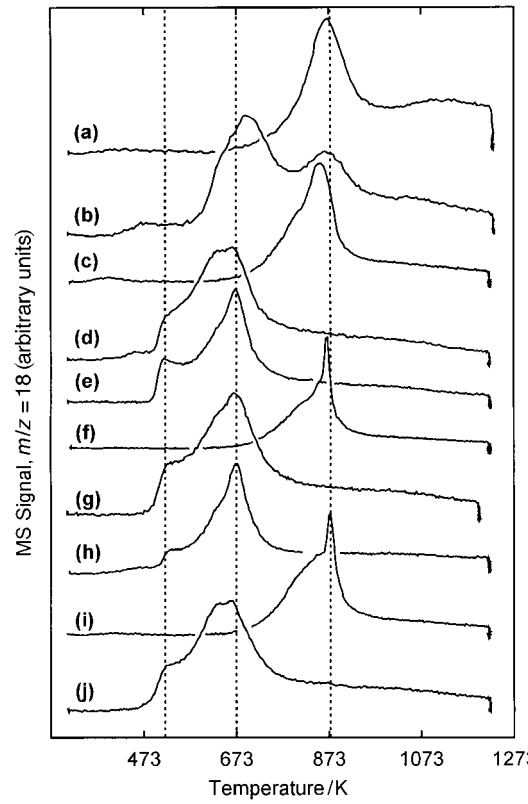

Fig. 1 Influence of the pre-treatment conditions on the reducibility of a Ce/Zr mixed oxide (CZ-68/32-LS). TPR–MS traces corresponding to the sample pre-treated as follows: (a) fresh oxide sample, (b) SR pre-treatment, (c) HTO, (d) MO, (e) MO, (f) HTO, (g) MO, (h) MO, (i) HTO, (j) MO. Experiments (b)–(f) were recorded successively on the same oxide sample. For details of the SR, HTO and MO treatments, see text.

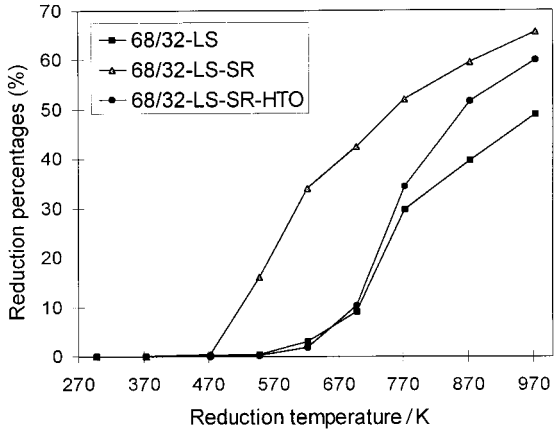

Fig. 2 Reduction percentage of $Ce_{0.68}Zr_{0.32}O_2$ obtained from the magnetic susceptibility measurements and expressed as $Ce^{3+}/(Ce^{3+} + Ce^{4+})$ as a function of the reduction temperature [1 h at each temperature under H_2(5%)–He flow].

with the LS oxide, the reducibility of the SR sample is significantly enhanced. The Faraday microbalance has proved to be particularly useful in characterising the redox behaviour of ceria based catalytic materials.[11–14] As in pure ceria, the reduction of Ce/Zr mixed oxides transforms diamagnetic Ce^{4+} cations into paramagnetic Ce^{3+} species. Thus, the evolution of the magnetic susceptibility as a function of the step by step reduction treatment provides direct information about the changing redox state of the oxide. In Fig. 2, the evolution of the reduction percentage expressed as $Ce^{3+}/(Ce^{3+} + Ce^{4+})$ clearly confirms the improved reducibility of the SR sample.

The oxide resulting from the TPR experiment in Fig. 1(b) was further re-oxidised at high temperature by following the HTO protocol. The resulting sample is referred to as SR-HTO. The corresponding TPR–MS diagram is shown in Fig. 1(c). Compared with Fig. 1(b), the main reduction peak in Fig. 1(c) is strongly shifted upwards in temperature, implying a considerable deterioration of sample reducibility. This is also seen in the magnetic balance results reported in Fig. 2.

Fig. 1(d)–(j) show the evolution of the redox properties of the oxide during the series of successive TPR–MS/Re-oxidation (MO or HTO) treatments. When the sample resulting from the TPR–MS experiment shown in Fig. 1(c), is re-oxidised by following the MO protocol, the subsequent TPR–MS diagram [Fig. 1(d)] shows a 200 K shift in the reduction peak towards lower temperatures. By repeating the MO and TPR–MS routine, a trace [Fig. 1(e)] very close to the previous one was obtained. By contrast, the TPR–MS reduction peaks are then shifted upwards again [Fig. 1(f)] by applying the HTO re-oxidation procedure to this sample. The last four TPR–MS diagrams [Fig. 1(g)–(j)] allow us to confirm that this behaviour is fully reversible. No change of the BET surface area was observed throughout the whole series of experiments.

The above results prompted us to investigate the effect of an intermediate re-oxidation temperature (923 K). Fig. 3(b) shows the corresponding TPR–MS trace. The diagrams recorded after re-oxidation at 823 K (a) and 1223 K (c) are also included for comparison. We can conclude that the choice of the re-oxidation conditions may critically modify the redox properties of the oxide. Fig. 3 shows that a moderate increase of the re-oxidation temperature, from 823 to 923 K, has a strong influence on the reducibility of the oxide.

In conclusion, these results may help towards a better understanding of the behaviour of this family of TWC redox materials. Our results suggest the convenience of performing specific studies aimed at establishing the effect of the ageing treatments under real TWC operation conditions on the redox behaviour of these mixed oxides. Finally, our observations are also relevant for comparative purposes: the pre-treatment conditions appear to play an important role in determining the redox behaviour of the resulting oxides. Consequently, the pre-treatment routine should be carefully controlled when comparative evaluations of Ce/Zr mixed oxides are to be made.

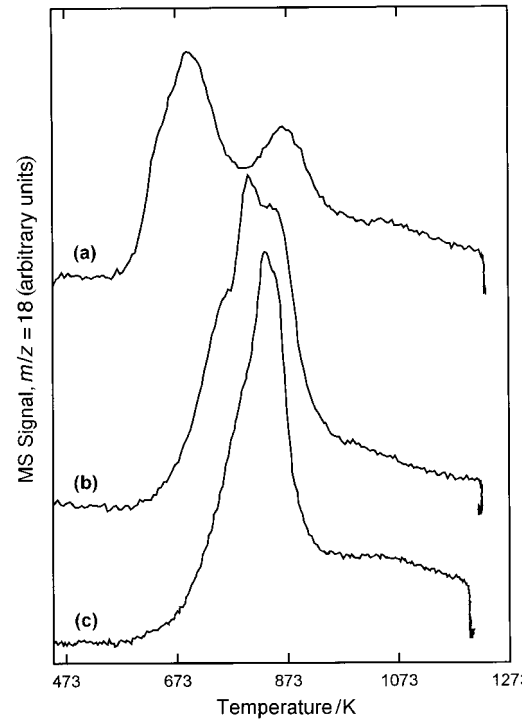

Fig. 3 Influence of the oxidising pre-treatment on the reducibility of a Ce/Zr mixed oxide (CZ-68/32-LS). TPR–MS traces corresponding to: (a) SR sample (MO pre-oxidation protocol); (b) SR sample further heated under O_2(5%)–He at 923 K (experimental pre-oxidation protocol similar to the MO and HTO procedures); (c) SR sample further submitted to the HTO treatment.

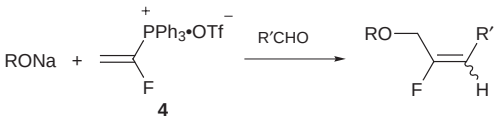
Received (in Cambridge, UK) 13th October 1998, Accepted 7th December 1998

α-Fluorovinylphosphonium salts 3 and 4 were synthesized and underwent Michael addition followed by Wittig olefination to give the corresponding monofluoroethylene compounds in good yields.

The replacement of a hydrogen atom by a fluorine atom often causes large changes in the biological activity of organic compounds, and the preparation of such fluorinated compounds has recently received much attention in the fields of medical and agricultural chemicals.[1] Although some methods for the direct exchange of the hydrogen by the fluorine are well-accepted, special techniques and equipment are required.[2] Thus, the development of versatile fluorinated building blocks has become a significant task in this field.[3] We have considered the title compounds as promising candidates for a monofluorinated building block which would be stable and easy to handle. As vinyltriphenylphosphonium bromide (Schweizer reagent) exhibits excellent performance,[4] we would expect similar reactivity for the title compound. This report describes the first preparation and reaction of the α-fluorovinylphosphonium salts as useful reagents for introducing a monofluoroethylene moiety into carbonyl compounds.[5]



Our synthetic route for the preparation of the α-fluorovinylphosphonium salts **3** or **4** is depicted in Scheme 1. Initially, we examined the convenient preparation of α-fluorovinyldiphenylphosphine **2** as a precursor for the salts. Since it is well-documented that nucleophilic addition followed by elimination of the fluoride for producing 1,1-difluoroethylene derivatives is facile,[6] it was therefore anticipated that the reaction of lithium diphenylphosphide[7] and 1,1-difluoroethylene **1** should afford the facile preparation of the phosphine **2**. The modest yield we encountered when conducting the reaction in THF–toluene at −78 °C led us to controlling the reaction temperature. When the reaction was conducted over the temperature range of −60 to −40 °C, the yield improved to 86%. However, if the reaction temperature exceeded −40 °C, undesirable 1,1-bis(diphenylphosphinyl)ethylene was produced as a by-product.

[a] Isolated yield. [b] Determined by capillary GC–MS analysis. [c] Salt **3** was used in place of **4**.

Quaternization of the phosphine **2** with MeI proceeded smoothly to give the α-fluorovinyldiphenylmethylphosphonium iodide **3** in 91% yield; however, reaction of **2** with aryl halides or aryl triflates did not take place under various conditions. Kitamura and co-workers have described the direct S-arylation of benzo[*b*]thiophenes to produce the 1-arylbenzo[*b*]thiophenium salt.[8] This prompted us to use the diaryliodonium salts for P-arylation of the phosphine **2** instead of S-arylation of the sulfides. After many unsuccessful experiments, the α-fluorovinyltriphenylphosphonium triflate **4** was finally obtained by the reaction of diphenyliodonium triflate in the presence of CuCl in 1,1,2,2-tetrachloroethane at 140 °C in 82% yield.† We believe that this P-arylation method provides a new route for the synthesis of the aryl phosphonium salts.

The β-ethoxy-α-fluoroethyltriphenylphosphonium ylide, generated *via* the addition of an ethoxide anion to **4** in ethanol at room temperature, reacted with benzaldehyde to provide 1-benzylidene-1-fluoro-2-ethoxyethane as a 43:57 mixture of the *E* and *Z* isomers in 75% yield (Table 1, entry 4).‡ The *E*:*Z* ratio was determined by capillary GC–MS analysis. The geometrical isomers were characterized from their NMR spectra. The coupling constants with fluorine showed a value of 20 Hz for the *E* isomer and 39 Hz for the *Z* isomer. The effects of the reaction conditions on these relative *E*:*Z* ratios have not been studied. Some selected data are shown in Table 1. The reactivity of salt **4** was much higher than that of salt **3** (compare the yields in entries 1 *vs*. 2 and 3 *vs*. 4). Although aromatic aldehydes and an α,β-unsaturated aldehyde gave good results, the aliphatic aldehyde gave poor results. Studies on the synthesis of a variety of monofluorinated heterocyclic ring systems are now in progress in our laboratory.

This work was supported by the Mitsubishiyuka Foundation, the Yamanouchi Foundation, and a Grant-in-Aid for Scientific Research (10650836) from the Ministry of Education, Science, and Culture, Japan.

Notes and references

† Preparation of **2**: To a solution of lithium wire (0.54 g, 83.8 mmol) in 40 ml of THF was added diphenylchlorophosphine (6.0 ml, 33.4 mmol) at

room temperature under argon. The solution was stirred for 3 h and followed by the addition of 40 ml of toluene. After stirring for an additional 1 h, the solution was cooled to −60 °C. At this temperature, argon was replaced with 1,1-difluoroethylene. The mixture was gradually warmed to −40 °C and quenched with sat. NH_4Cl solution. After the usual workup, the residue was chromatographed on silica gel (hexane–EtOAc 100:1) to give the desired product (6.3 g, 86%): ν(neat)/cm^{-1} 3056, 1622, 1482, 1435, 1153, 1095, 1027, 997, 916, 885, 742 and 694; δ_H($CDCl_3$) 4.97 (1H, ddd, *J* 2.9, 6.3, 50.8), 5.39 (1H, ddd, *J* 2.9, 21.0, 23.4), 7.25–7.80 (m, 10 H); HRMS: 230.0661(M^+); Calc. for $C_{14}H_{12}FP$: C, 73.04; H, 5.25. Found: C, 72.96; H, 5.28%.

Preparation of **4**: A mixture of α-fluorovinyldiphenylphosphine **2** (1.47 g, 6.4 mmol), diphenyliodonium triflate (3.30 g, 7.7 mmol), copper(I) chloride (63.3 mg, 0.64 mmol), a catalytic amount of Cu wire (30 mg) and 4 Å molecular sieves (0.5 g) in 1,1,2,2-tetrachloroethane (1.5 ml) was heated at 140 °C for 30 min under argon. After cooling the reaction mixture to room temperature, it was chromatographed on silica gel (CH_2Cl_2 then CH_2Cl_2–acetone 2:1) to give the desired product (2.41g, 82%). Further purification for the combustion analysis was conducted by recrystallization from Bu^tOH–Et_2O: mp 101.2–101.7 °C; ν(KBr)/cm^{-1} 3137, 3062, 3007, 1632, 1588, 1581, 1486, 1482, 1441, 1370, 1257, 1227, 1172, 1152, 1114, 1029, 995, 935, 913, 760, 736, 709, 689 and 641; δ_H($CDCl_3$) 5.79 (1H, ddd, *J* 6.4, 7.3, 49.3), 6.49 (1H, ddd, *J* 6.4, 21.5, 29.8), 7.7–8.0 (m, 15 H); *m/z* (FAB) 307 (M^+ − OTf); Calc. for $C_{21}H_{17}F_4O_3PS$: C, 55.27; H, 3.75. Found: C, 55.08; H, 3.67%.

‡ *General procedure*: To a solution of NaH (1.2 equiv.) in EtOH (5 ml) under Ar was added α-fluorovinyltriphenylphosphonium triflate (0.5 mmol) at room temperature. The resulting solution was stirred for 10 min, benzaldehyde (1.2 equiv.) was added to the solution, and the reaction mixture was stirred for 16 h. After the usual workup, column chromatography (silica gel, hexane–EtOAc 30:1) of the residue afforded 27.7 mg of (*E*)-1-benzylidene-2-ethoxy-1-fluoroethane and 39.1 mg of (*Z*)-1-benzylidene-2-ethoxy-1-fluoroethane (total 75% yield). (*E*)-isomer: ν(neat)/cm^{-1} 2978, 2924, 2873, 1685, 1598, 1489, 1447, 1380, 1261, 1143, 1098, 997, 883, 750, 699 and 630; δ_H($CDCl_3$) 1.25 (3H, t, *J* 6.84), 3.58 (2H, q, *J* 6.83), 4.18 (2H, d, *J* 22.95), 6.45 (1H, d, *J* 20.02), 7.24–7.38 (5H, m); *m/z* 180 (30, M^+), 151 (46), 135 (60), 133 (56), 115 (80), 109 (100), 104 (30); Calc. for $C_{11}H_{13}FO$: C, 73.31; H, 7.27. Found: C, 73.54; H, 7.44%. (*Z*)-isomer: ν(neat)/cm^{-1} 3025, 2978, 2865, 1695, 1598, 1496, 1450, 1351, 1099, 880, 755 and 694; δ_H($CDCl_3$) 1.27 (3H, t, *J* 6.83), 3.60 (2H, q, *J* 6.83), 4.12 (2H, d, *J* 15.14), 5.76 (1H, d, *J* 38.57), 7.21–7.53 (5H, m); *m/z* 180 (52, M^+), 151 (52), 135 (76), 133 (62), 115 (90), 109 (100); Calc. for $C_{11}H_{13}FO$: C, 73.31; H, 7.27. Found: C, 73.44; H, 7.35%.

Hydrogen bonded assemblies of a cyclic trimeric hydroxy gallium(III) derivative: $[\{Me_2Ga(\mu\text{-}OH)\}_3{\cdot}3H_2O]_2{\cdot}$18-crown-6

Paul D. Croucher, Alexander Drljaca, Stavroula Papadopoulos and Colin L. Raston*

Department of Chemistry, Monash University, Clayton, Melbourne, Victoria 3168 Australia.
E-mail: c.raston@sci.monash.edu.au

Received (in Columbia, MO, USA) 5th October 1998, Accepted 8th December 1998

Addition of hydrolysed trimethylgallium to an excess of 18-crown-6 in water affords an alkyl μ-hydroxo bridged Ga(III) trimer in solution (pH *ca.* 6) and the solid, isolated as the hydrogen bonded assembled supermolecule $[\{Me_2Ga(\mu\text{-}OH)\}_3{\cdot}3H_2O]_2{\cdot}$18-crown-6.

The oxidation and reaction of group 13 alkyl compounds with water is often extremely exothermic and under controlled conditions it is possible to isolate some metal oxide/hydroxide intermediate compounds *en route* to complete hydrolysis to the alkane and metal hydroxides.[1] These compounds have provided information about the hydrolysis reactions and certain derivatives have also been found to function as co-catalysts in the Ziegler–Natta polymerisation of olefins.[2] The oxide, hydroxide and mixed oxide–hydroxide chemistry of aluminium, and also indium, has been extensively studied.[3] In contrast, there have been relatively few studies concerning analogous gallium chemistry.[3–11] The first organogallium–oxo compound reported $[Bu^tGa(\mu_3\text{-}O)]_9$ was characterised by mass spectrometry and NMR spectroscopy,[12] soon followed by the synthesis and structural authentication of the only known cyclic trimeric hydroxy derivative of gallium, $[Bu^t_2Ga(\mu\text{-}OH)]_3$.[5] This compound was originally identified as an impurity formed during the synthesis of $[Bu^t_2Ga(\mu\text{-}PH_2)]_3$.[13] More recently, the structural characterisation of the largest galloxane hydroxide isolated thus far, $[Ga_{12}Bu^t_{12}(\mu_3\text{-}O)_8(\mu\text{-}O)_2(\mu\text{-}OH)_4]$, has been described.[4] Further studies on the stabilization and structural characterisation of controlled hydrolysis products of $[Ga(2,4,6\text{-}Me_3C_6H_3)_3]$ by deprotonation reactions involving alkyllithium reagents have also been reported.[14]

In addressing the difficulties associated with isolating the intermediates formed during the hydrolysis of substitutionally labile alkyl metal compounds from aqueous solution we use a crown ether to promote supramolecular complexation and crystallisation. A similar technique has been used to crystalise a known dinuclear aqua cation formed during the hydrolytic polymerisation of Cr(III).[15] In the present study we show that using this supramolecular self assembly approach results in the formation of a new alkyl μ-hydroxo bridged Ga(III) trimer, $[\{Me_2Ga(\mu\text{-}OH\}_3{\cdot}3H_2O]_2{\cdot}$18-crown-6, which has been characterised in solution and in the solid state.

Addition of an aqueous solution of hydrolysed trimethylgallium to 2 equiv. of 18-crown-6 in water at room temperature (pH of the mixture *ca.* 6) results in the formation of colorless crystals of $[\{Me_2Ga(\mu\text{-}OH)\}_3{\cdot}3H_2O]_2{\cdot}$18-crown-6 (Fig. 1)† suitable for X-ray crystallography. It is noteworthy that the product yield is enhanced by increasing the concentration of 18-crown-6 relative to hydrolysed Me_3Ga in the reaction mixture; molar ratios for 18-crown-6: hydrolysed Me_3Ga of 2 : 1, 1 : 1 and 0.5 : 1 afford the trimer in 70, 40 and 20% yield respectively. The ^{1}H NMR spectrum of the complex in acetone exhibits a singlet at $\delta -0.45$, assigned to the Me_2Ga units, a less intense singlet at δ 4.46, assigned to the GaOH protons, and a singlet at δ 3.59 assigned to the ethylene groups of the 18-crown-6. The integration, 6 : 1 : 4 respectively, is consistent with the proposed formulation. In acetone hydrogen bonding interactions (Fig. 2) between GaOH groups and solvent are likely and in this context we note that in chloroform the singlet for GaOH shifts to δ 1.43. The trimeric complex was found to be insoluble in hexane and water which contrasts with previous findings for the *tert*-butyl analogue $[Bu^t_2Ga(\mu\text{-}OH)]_3$.[6]

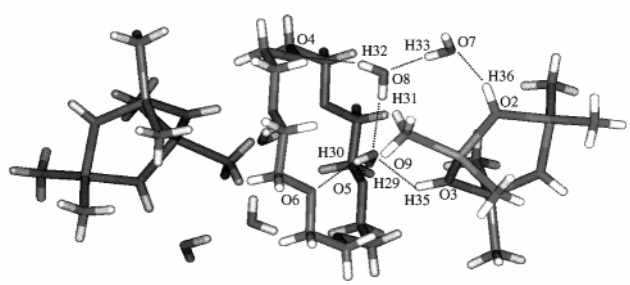

Fig. 1 The molecular structure of $[\{Me_2Ga(\mu\text{-}OH)\}_3{\cdot}3H_2O]_2{\cdot}$18-crown-6.

The variable-temperature ^{1}H NMR spectra of the complex show shifts in the singlet due to GaOH from δ 4.4 (+30 °C) to a doublet (2 : 1) at 5.2 (−60 °C) which may be due to the hydrogen bonding interactions of two of the three possible bridging OH groups with water molecules hydrogen bonded to the crown ether (Fig. 1). This change was not observed in the variable-temperature ^{1}H NMR spectra of $[Bu^t_2Ga(\mu\text{-}OH)]_3$[6] and is consistent with the presence of the crown ether complex in solution. Addition of D_2O to the complex in acetone results in the spontaneous disappearance of the O–H signal, indicating very fast proton exchange on the bridging OH groups. By comparison the OH signal for $[Bu^t_2Ga(\mu\text{-}OH)]_3$ in D_2O disappeared slowly over 120 h (slow proton exchange).[6] This is to be expected since terminal methyl groups sterically crowd the bridging OH groups less thus providing greater access to the bulk solvent (for exchange) than *tert*-butyl groups on the same gallium trimer.

The ^{13}C{^{1}H} NMR spectrum at 20 °C contains two singlets at δ 11.04 and 71.40 due to 18-crown-6 and Me_2Ga groups, respectively. The positive ion electrospray mass spectrum (ESMS) confirmed the trimeric nature of the complex in the gas phase {$[Me_2Ga(OH)]_3$ = 350.1 u}. IR spectroscopic data confirm the presence of the O–H and C–O (18-crown-6) groups (ν_{O-H} 3420 cm^{-1}, ν_{C-O} 1110 cm^{-1}).

The compound crystallises in the space group $P\bar{1}$ with the asymmetric unit comprised of one $[GaMe_2(OH)]_3$ cluster and half a crown ether molecule, bound together by a chain of three hydrogen bonded water molecules (Fig. 1).‡ Crystallographic symmetry places one cluster on each side of the crown ether

molecule which is arranged with adjacent oxygen atoms alternating between pointing towards one of the gallium clusters and to its symmetry relative, *i.e.* three up and three down. Two water molecules hydrogen-bond with each face of the crown, the first bridging two crown ether oxygens, O···O 2.88(1) and 2.82(1) Å, while the second bridges the first water molecule O···O 2.68(1) Å and the remaining crown ether oxygen O···O 2.83(1) Å. The hydrogen bonding sphere of the first water molecule is completed by a hydrogen bond to one of the hydroxy groups from the gallium cluster O···O 2.82(1) Å while a third water molecule connects the second water molecule and the gallium cluster *via* hydrogen bonding to a second hydroxy of the cluster O···O 2.69(1) Å. Hydrogen bonding distances and angles in the supermolecule are shown in Table 1.

In conclusion we have shown the supramolecular hydrogen bonded self assembly of a novel cyclic trimeric hydroxy gallium(III) derivative with 18-crown-6 [{$Me_2Ga(\mu$-$OH)\}_3\cdot 3H_2O$]·18-crown-6. Evidence for the presence of the supermolecule was obtained from both solid state and solution studies. Furthermore, X-ray crystallographic data showed that in the solid state each supermolecule exists as a discrete unit comprising of two gallium trimer clusters hydrogen bonded through six lattice water molecules to a central crown ether. We are currently investigating using this approach to crystallise other group 13 alkyl hydroxy compounds from aqueous solution.

A new method of intercalation by anion exchange in layered double hydroxides

Eduardo L. Crepaldi, Paulo C. Pavan and João B. Valim*

Department of Chemistry, Faculdade de Filosofia, Ciências e Letras de Ribeirão Preto, Universidade de São Paulo, Av. dos Bandeirantes 3900, CEP.: 14.040-901, Ribeirão Preto, SP Brazil. E-mail: jobvalim@usp.br

Received (in Cambridge, UK) 4th November 1998, Accepted 1st December 1998

A new anion exchange method of intercalation in layered double hydroxides (LDHs), based on the formation and organic phase extraction of a salt between dodecylsulfate anions and a cationic surfactant (CTA), is described which is shown to be a very fast and efficient way to obtain a wide variety of LDH-intercalated organic and inorganic anions, using the precursor Zn(II)–Cr(III)–dodecylsulfate LDH.

Layered double hydroxides (LDHs), or the so-called hydrotalcite-like compounds, can be represented by the general formula $[M^{II}_{1-x}M^{III}_x(OH)_2](A^{m-})_{x/m}\cdot nH_2O$. The structure of this kind of compound, based on the stacking of positively charged layers with hydrated anions in the interlamellar domain, confers relatively high mobility on these anions.[1–3]

Direct synthesis of LDHs can be conducted by various methods, *e.g.* coprecipitation,[1,2] the salt–oxide method,[2,3] hydrothermal synthesis,[1] as well as less studied methods.[4,5] However, there are some indirect methods based on the use of LDH precursors prepared by direct synthesis in order to obtain a new different compound. Indirect synthesis can traditionally be conducted using three main techniques: (i) direct anion exchange, using an LDH intercalated with chloride (sometimes nitrate or perchlorate) as the precursor;[2,3,6] (ii) anion exchange by elimination of the precursor interlamellar species (usually carbonate or terephthalate) susceptible to acid attack;[7–9] and (iii) regeneration of the material obtained by the calcination of an LDH intercalated with carbonate (eventually others), in a solution containing the anion of interest.[1,10–12]

In this work a new method of anion exchange in a surfactant-intercalated LDH is described. The mechanism involved is based on the formation of a salt between an anionic surfactant (sulfated or sulfonated) and a cationic one (*e.g. N*-cetyl-*N*,*N*,*N*-trimethylammonium bromide, CTAB, or benzyldimethylalkylammonium chloride, BAC).[13] The salt is then removed from the aqueous medium into an organic phase such as dichloromethane, chloroform, di- and tri-chloroethanes or hexane.

The LDH precursor used in this method should contain an anionic surfactant (in this work dodecylsulfate, DS, was used) in the interlayer domain. The precursor was synthesised by the coprecipitation method at constant pH (7.0 ± 0.2), with a Zn : Cr ratio of 3 : 1.[2] This one-step synthesis is very easy to perform. The product obtained is well-crystallised without further treatments, as can be seen from the powder X-ray diffraction (PXRD) pattern of this precursor in Fig. 1a (Siemens X-ray diffractometer D5005, Cu-K_α = 1.5406 Å). This fact can be attributed to the self organisation of DS anions in the interlamellar domain, promoted by interactions between the hydrophobic chains. The obtained basal spacing is very close to those reported in the literature.[8] The high crystallinity of the precursor is very important for the synthesis of LDHs by indirect methods since the crystallinity of the product is directly related to that of the precursor.[1,9,12]

The anion exchange was carried out by adding 20 mL of a 0.15 M CTAB solution to an aqueous mixture containing 20 g of a suspension of the precursor (approximately 1.3 g of Zn–Cr–DS–LDH), 50 mL of the solution of the anion of interest containing an excess of the amount necessary for a quantitative exchange and the organic phase (30 mL of chloroform was used). The surfactant anion was removed from the interlayer domain by the formation of the salt with the cationic surfactant, which migrates to the organic phase favouring the concomitant intercalation of the anion of interest. The formation of this salt and its migration to the organic phase are fast and so is the anion exchange process. The surfactant salt is insoluble (or only sparingly soluble) in the aqueous phase, so its migration to the organic medium enhances the efficiency of the process by displacing the equilibrium to the surfactant salt formation. A schematic illustration of the process is shown in Fig. 2. The contact time was 30 minutes, after which the material obtained was washed three times with chloroform, once with acetone and twice with water, and separated by centrifugation. The materials obtained were dried under vacuum. No pH control was carried out, except in the case of polyoxometalate, where the pH was adjusted to 5.0 in order to obtain the decavanadate species.[14]

To test this method a great variety of anions, including chloride, carbonate, some carboxylates, decavanadate and a tetrasulfonated phthalocyanine, were used to displace the DS anion. The occurrence of anion exchange without the addition of the cationic surfactant was tested using the carbonate anion to substitute the DS anion. The choice of carbonate anion to test the exchange without the addition of CTAB was made due to its high stability when intercalated, compared with the other anions used. The occurrence of the exchange starting from the dried precursor was also checked.

The presence of bromide anions (CTAB counter ion) in the obtained materials was also tested using a model 9635 ionplus series bromide electrode from Orion Res. Inc.

The PXRD patterns of the samples obtained by anion exchange are shown in Fig. 1. A well-organised hydrotalcite-

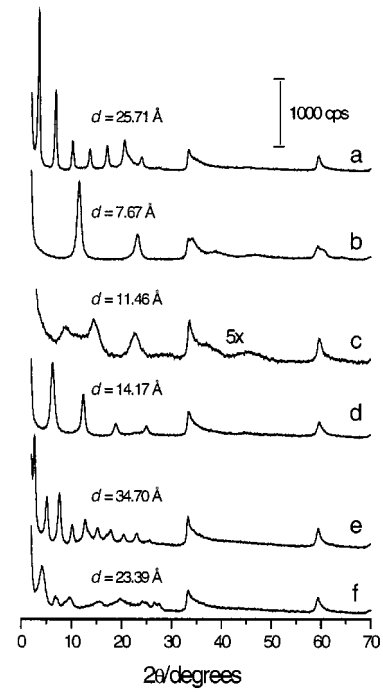

Fig. 1 PXRD patterns for the prepared samples: (a) DS-intercalated LDH precursor; and LDH anion-exchanged by (b) carbonate; (c) decavanadate; (d) terephthalate; (e) cholate; and (f) copper(II) phthalocyaninetetrasulfonate.

like compound with a basal spacing close to reported data[3] was obtained (see Fig. 1b) by the exchange of dodecylsulfate by carbonate anions (using the precursor suspension). Similar results were obtained when the precursor was dried and re-suspended (particles were dispersed by brief sonication, for less than 1 min). The exchange of DS with chloride anion (data not shown, d = 7.78 Å) presented similar results to those obtained for carbonate anion. Without the addition of CTAB, the anion exchange of DS with carbonate did not occur. Even when the contact time was increased to 24 h, the resulting PXRD pattern was very close to that obtained from the precursor.

Based on these results, it is possible to conclude that the presence of CTAB in the medium is necessary to promote anion exchange. The extraction of the salt formed between the cationic and anionic surfactants into the organic phase should enhance the exchange process, making it faster and more efficient. The exchange process by this method is not affected if the precursor is dried before use. This is a very important observation, since the literature reports that drying the precursor can hinder the anion exchange when using both methods, the one based on chloride (or nitrate or perchlorate) containing precursors[2,6] and the one based on the acidification of carbonate (or terephthalate) containing precursors.[7–9]

The PXRD pattern for decavanadate anion exchange is shown in Fig. 1c. The low crystallinity obtained is characteristic of LDHs intercalated with decavanadate, and the basal spacing obtained is close to reported data.[8,9] The intercalation of carboxylate anions also presented good results, as can be seen in Fig. 1d and e for terephthalate and cholate respectively. High structural organisation is again observed, as well as phase purity. Similar results were obtained for the naphthoate anion (data not shown, d = 20.54 Å). Note that, even though cholate is considered to be a surfactant, the exchange occurs successfully, emphasising the fact that the formation of the water-insoluble salt is characteristic of sulfated and sulfonated surfactants. Furthermore, the cholate anion was successfully intercalated with a basal spacing (34.70 Å) greater than that obtained for the DS anion, showing that it is possible to expand the interlayer spacing by this anion exchange method. The basal spacing obtained for the naphthoate intercalate is close to reported data,[10] and indicates that this anion was intercalated as a bilayer in the interlayer domain.

The intercalation of the phthalocyanine anion showed a material with crystallinity and basal spacing (see Fig. 1f) comparable with those reported for a similar compound.[12] In this case it is also important to note that the negative charge of this anion is derived from sulfonate groups, although no salt formation was observed between this macrocycle anion and CTA. This was demonstrated by the observation that the chloroform phase collected at the end of the preparation process did not show the characteristic blue colour of this anion.

A quantity of the anionic–cationic surfactant salt was prepared separately in order to take its PXRD pattern, which showed very intense and sharp peaks (data not shown). These peaks were not observed in the solid PXRD patterns, but were observed in the PXRD pattern of the residue from the evaporation of the organic phase used in the anion exchange. Chemical analysis showed the presence of a small amount of sulfur in some samples, which is probably due to high affinity adsorption of DS anions with LDHs.[15]

The analysis of bromide in the materials obtained showed a concentration in the range 0.15 to 0.22% (in mass). This amount of bromide anions can be assigned to both adsorbed and intercalated bromide. However, if we consider that all this bromide is intercalated, neutralising the layer charges, we will obtain a relation of only 1.0 to 1.5% of substitution by bromide anions.

Based on these results, we conclude that through this method it is possible to obtain a wide variety of organic or inorganic anions intercalated in LDHs in a simple manner. The synthesis of a precursor containing DS anions is required, but this can be carried out very easily. Moreover, this method presents great versatility: (i) it can be applied within a large range of pH values, depending only on the pH range supported by the substituting anion and by the LDH; (ii) the anion exchange is very fast and efficient; (iii) the maintenance of the precursor in a suspension is not necessary; and (iv) the formation of the water-insoluble salt with an ammonium quaternary surfactant is specific for sulfated and sulfonated surfactants.

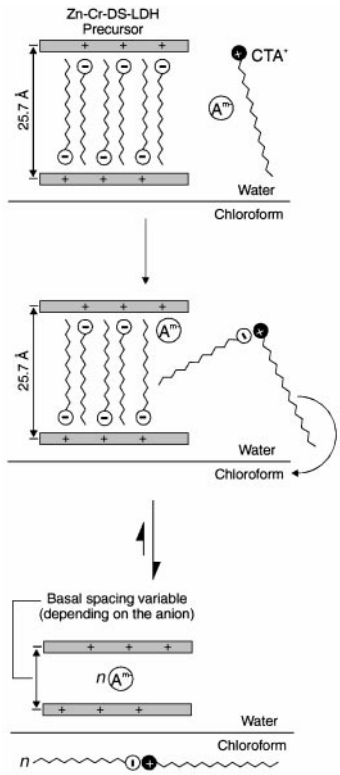

Fig. 2 Schematic representation of the proposed mechanism.

Self-assembly of free-base tetrapyridylporphyrin units by metal ion coordination

Long Pan,[a] Bruce C. Noll[b] and Xiaotai Wang*[a]

[a] *Department of Chemistry, University of Colorado at Denver, Campus Box 194, PO Box 173364, Denver, CO 80217, USA. E-mail: xwang@carbon.cudenver.edu*

[b] *Department of Chemistry and Biochemistry, University of Colorado at Boulder, Boulder, CO 80309, USA*

Received (in Columbia, MO, USA) 16th September 1998, Accepted 8th December 1998

The first free-base *meso*-tetraarylporphyrin coordination polymer is assembled from *meso*-tetrapyridylporphyrin and $HgBr_2$ *via* 4-connected peripheral ligation, and it possesses a novel one-dimensional structural motif with large inter-porphyrin cavities.

There has been recent research interest in crystal engineering supramolecular architectures assembled from metal ions and polydentate ligands by coordinate covalent bonding.[1] Functionalized *meso*-tetraarylporphyrin ligands have been employed to ligate metal ions using the donor atoms (*e.g.* N) on the four *meso*-aryl substituents.[2] Incorporation of such tetraarylporphyrin units into supramolecular oligomers or polymers *via* peripheral ligation is attractive for several reasons. Tetraarylporphyrin molecules are robust, rigid and highly symmetrical and thus serve as desirable, slab-like building blocks for synthesizing microporous materials with large cavities and channels that have potential catalytic activity.[3] Supramolecular systems containing multiporphyrin units have applications as biomimetic models for the study of energy/electron transfer processes in photosynthesis.[4–7] Understanding such processes is fundamental for developing molecule-based opto-electronic materials.[8]

However, investigations of the aforementioned *meso*-tetraarylporphyrin coordination polymers are still lacking in scope. To our knowledge, only three infinite network structures have been reported by Robson and coworkers,[2] which contain metalloporphyrin units connected by additional metal ions *via* all four *meso*-peripheral functions on each metalloporphyrin molecule. Also noteworthy are the structures of several coordination polymers obtained by recrystallization of Zn- or Cu-*meso*-tetraarylporphyrins from certain organic solvents without additional metal ions.[9] In these materials, it is the ligation of two of the functionalized aryls on each metalloporphyrin molecule to the metal centers of two adjacent metalloporphyrins that forms the infinite structures. Although several groups have described the use of free-base *meso*-tetrapyridylporphyrin in assembling porphyrin oligomers,[6,10] no *coordination polymers* built upon free-base *meso*-tetraarylporphyrin units have been reported in the literature. We are interested in exploring self-assembly of free-base *meso*-tetraarylporphyrin building blocks and metal ions of various coordination environments. Our strategy involves using functionalized *meso*-aryl groups to ligate metal ions. These porphyrins are readily available commercially or synthetically.[9b] The use of unmetallated porphyrins avoids the possible ligation of the metal center in the cavity of one metalloporphyrin molecule to the periphery of another metalloporphyrin molecule. Such additional linkages could complicate the design and engineering of solid state structures. In this communication, we report the synthesis and X-ray crystal structure of a novel one-dimensional infinite polymer in which free-base *meso*-tetrapyridylporphyrin (hereafter H_2TPyP) units are interconnected by mercury(II) centers *via* peripheral pyridyl ligation.

Under ambient conditions, a methanol solution (50 mL) of $HgBr_2$ (0.111 mg, 0.31 mmol) was added to a chloroform solution (50 mL) of H_2TPyP (0.047 mg, 0.076 mmol), leading to the precipitation of a purple, microcrystalline solid. This solid was isolated by filtration, washed thoroughly with methanol and then chloroform, and dried under vacuum for 12 h to give 0.071 g of product (70% yield based on H_2TPyP). As shown in the IR spectra (KBr), the pyridine ring vibrational band of H_2TPyP (1629 cm^{-1}) is significantly shifted to 1600 cm^{-1} upon pyridyl N-coordination to mercury. A combustion analysis (for C, H and N) of the product supports an empirical formula of $Hg(H_2TPyP)_{0.5}Br_2$ ($C_{20}H_{13}N_4Br_2Hg$)† that is further confirmed by single crystal X-ray analysis (see below). This material is insoluble in common solvents. Moreover, it is air- and moisture-stable, exhibiting no sign of decomposition or degradation in the EA and IR analyses after being exposed in air for weeks. The air and moisture stability of $Hg(H_2TPyP)_{0.5}Br_2$ is as expected for Hg(II) complexes with pyridine-type ligands.[11]

Crystals suitable for single crystal X-ray analysis were obtained by layering a dilute methanol solution of $HgBr_2$ (0.01 M, 4 mL) over a dilute chloroform solution of H_2TPyP (0.0025 M, 4 mL). Platelike red–purple crystals were formed as the solvate of empirical formula $Hg(H_2TPyP)_{0.5}Br_2{\cdot}CHCl_3$ as revealed by X-ray crystallography.‡ The infinite solid state structure may be viewed as composed of the building-block unit $Hg_2(H_2TPyP)Br_4{\cdot}2CHCl_3$ shown in Fig. 1. In the extended one-dimensional motif shown in Fig. 2, the Hg(II) center is ligated to two bromides and two pyridyl nitrogens, thereby adopting a distorted tetrahedral geometry. This is a rare example of a crystallographically characterized tetrahedral mercury(II)–

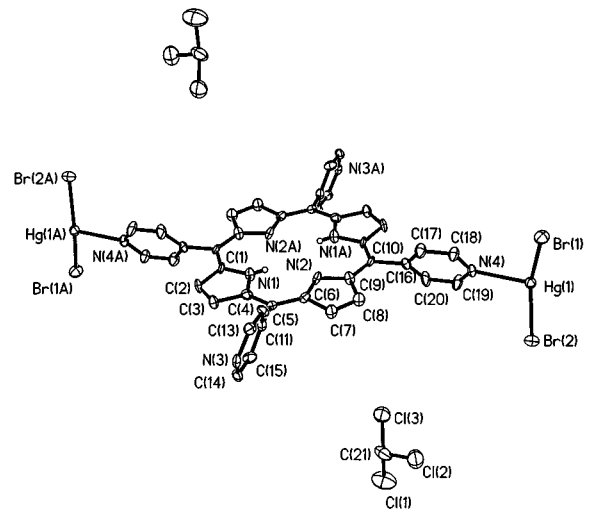

Fig. 1 Molecular structure of the building-block unit $Hg_2(H_2TPyP)Br_4{\cdot}2CHCl_3$, with all hydrogen atoms omitted except the two in the porphyrin cavity. Atoms labeled with A are related to atoms without this letter by an inversion symmetry operation.

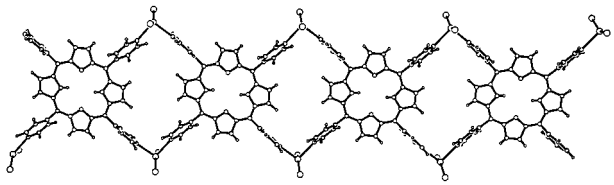

Fig. 2 View of the extended one-dimensional motif in $Hg(H_2TPyP)_{0.5}Br_2{\cdot}CHCl_3$. H_2TPyP molecules are bridged by $HgBr_2$ moieties through pyridyl ligation, forming interporphyrin cavities. Solvent molecules ($CHCl_3$) are not shown.

nitrogen complex of general formula HgL_2X_2, where L = pyridine or its derivatives and X = halide.[11] In addition, the four pyridyl rings are twisted with respect to the plane of the parent porphyrin ring. The N(3)- and N(3A)-containing pyridyl rings each form a dihedral angle with the porphyrin ring at 73.2°. The corresponding dihedral angles for N(4)- and N(4A)-containing pyridyl rings are 67.8° each. The Hg(1)–Br(1) and Hg(1)–Br(2) bond distances are 2.4671(10) and 2.4770(10) Å respectively; the average of 2.472 Å is close to the average shortest Hg–Br distance (2.48 Å) in $HgBr_2$.[12] The Hg–N distances range from 2.482(6) to 2.410(6) Å.

The one-dimensional structural motif shown in Fig. 2 is unprecedented in porphyrin- or metalloporphyrin-based *coordination polymers*. In this framework $HgBr_2$ moieties act as linkers to bridge the H_2TPyP molecules with each Hg(II) center connecting two pyridyls from adjacent porphyrins. This results in relatively large interporphyrin cavities in the extended chain. The size of the cavity is measured by the Hg···Hg distance (14.2 Å) and the shortest distance between the two *meso*-carbons of two adjacent porphyrins (9.72 Å). Inside the cavity, the distances between the van der Waals surfaces are estimated at 8.4 Å between the diagonal pyridyls and 3.7 Å between the β-hydrogens of the two adjacent porphyrin molecules. The two neighboring porphyrin ring planes within a chain are parallel but are canted by *ca.* 1.60 Å. Solvent ($CHCl_3$) molecules (not shown) partially fill the interchain space, and they are not included in the interporphyrin cavities. When removed from the mother liquor, crystals of $Hg(H_2TPyP)_{0.5}Br_2{\cdot}CHCl_3$ lose $CHCl_3$ and collapse rapidly, showing no sharp peaks in X-ray powder diffraction patterns. The resultant solid does not absorb CH_2Cl_2, $CHCl_3$, CH_3OH or benzene to form inclusion compounds. It seems that crystallinity of the one-dimensional $Hg(H_2TPyP)_{0.5}Br_2{\cdot}CHCl_3$ cannot be sustained after loss of interchain space-filling solvent of crystallization. Networks of higher dimensionalities may be required for porphyrin coordination polymers to function like porous materials.

Currently, we are studying the physical properties of $Hg(H_2TPyP)_{0.5}Br_2$ using a combination of photoacoustic, reflection UV–VIS and fluorescent spectrometries. Additionally, we are examining different metal ions as potential linkers to assemble porphyrin coordination polymers of higher dimensionalities, including 2-D sheets and 3-D networks.

The authors gratefully acknowledge support for this work from the University of Colorado at Denver in the forms of startup funding and Junior Faculty Development Awards (X. W.).

Pyrazolyl[(methylthio)methyl]borates: hybrid ligands providing nitrogen and sulfur donors

Show-Jen Chiou, Pinghua Ge, Charles G. Riordan,* Louise M. Liable-Sands and Arnold L. Rheingold

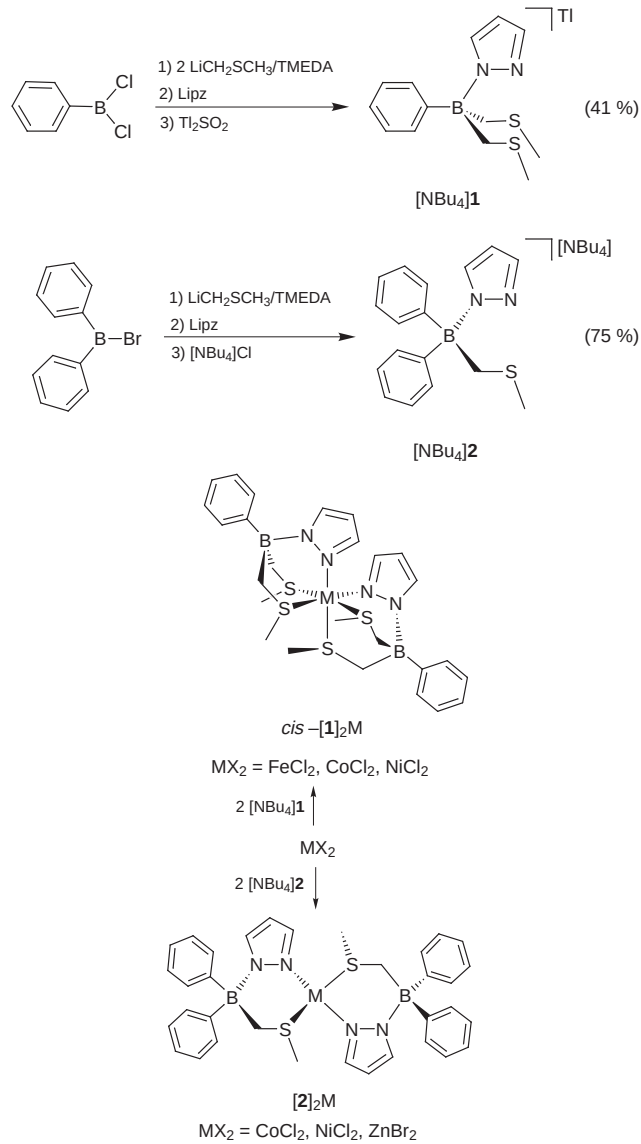
Department of Chemistry and Biochemistry, University of Delaware, Newark, DE 19716, USA. E-mail: Riordan@udel.edu

Received (in Bloomington, IN, USA) 19th October 1998, Accepted 4th December 1998

Two new borate ligands, $PhB(CH_2SCH_3)_2(pz)^-$ ($\mathbf{1}^-$) and $Ph_2B(CH_2SCH_3)(pz)^-$ ($\mathbf{2}^-$) (pz = 1-pyrazolyl), have been prepared to provide mixed donor sets, 'NS_2' and 'NS', respectively, to transition metal ions.

Metalloenzyme catalytic sites often contain coordination spheres that consist of a mixture of nitrogen and sulfur ligands in the forms of histidine, cysteine and methionine residues. Representative examples include the zinc sites in liver alcohol dehydrogenase[1] and methionine synthase,[2] the nickel sites in carbon monoxide dehydrogenase/acetyl coenzyme A synthase[3] and cobalt- and iron-containing nitrile hydratases.[4] A fundamental understanding of the chemical transformations performed by these enzymes would be advanced by the preparation of synthetic representations of these sites. To this end, we have designed and prepared a new series of borate ligands that contain nitrogen and sulfur donors. This first report highlights the preparation, and spectroscopic and structural characterization of representative metal ion derivatives of a tridentate 'NS_2' ligand ($\mathbf{1}^-$) and a bidentate 'NS' ligand ($\mathbf{2}^-$). Face-capping 'N_xS_y' chelate complexes derived from borates have been reported recently by Parkin and co-workers.[5] However, our contribution combines the synthetic flexibility of pyrazolyls and thioethers into a versatile ligand class wherein steric and electronic properties may be intimately tuned by judicious choice of substituents at the 3-pyrazolyl position *and* on sulfur.[6,7] While the ligands may be viewed as hybrids of Trofimenko's hydridotris(pyrazolyl)borates, Tp^-,[8] and our phenyltris((alkylthio)methyl)borates, $PhTt^-$,[9] we find that the metal complexes possess properties not predicted from such a simplified extrapolation.

The synthesis of ligands $\mathbf{1}^-$ and $\mathbf{2}^-$ proceeded smoothly using the one-pot, stepwise protocol outlined in Scheme 1. Using the appropriate borane, the thioether substituent(s) was/were added first followed by the pyrazolyl group. The ligands were isolated cleanly by precipitation from water as either the Tl^+ or N^+Bu_4 salts in moderate to good yield. The metal complexes were prepared *via* metathesis from the appropriate metal halide (Scheme 1). For example, synthesis of *cis*–$[\mathbf{1}]_2Ni$ proceeds in 60% yield from the reaction of 2 equiv. of $[NBu_4]\mathbf{1}$ and $NiCl_2{\cdot}6H_2O$ in methanol. Recrystallization from CH_2Cl_2–Et_2O yielded purple blocks. Analytical and combustion data† were consistent with the indicated formula that was corroborated by X-ray diffraction analysis.‡ The molecular structure of *cis*–$[\mathbf{1}]_2Ni$ is depicted in Fig. 1 with selected metric parameters given in the caption. The coordination geometry is octahedral with four sulfur and two nitrogen donors. The most noteworthy and unexpected feature of the structure is the *cis* configuration. The Ni–N bond lengths of 2.063(2) and 2.053(2) Å are similar to those in the all-nitrogen analogue containing two different Tp^- ligands, $[Tp^{3\text{-}i\text{Pr},4\text{-}Br}][Tp^{3,5\text{-}Me2}]Ni$, 2.05–2.16 Å.[10] The four Ni–S distances are all similar averaging to 2.47 Å. This value matches that in the S_6 derivative, $[PhTt]_2Ni$, 2.433 Å.[9] The *trans* influence of pyrazolyl and thioether donors is similar in this case as evidenced by experimentally indistinguishable Ni–S distances for sulfur *trans* to nitrogen *vs*. sulfur *trans* to sulfur. Consistent with little-to-no preference for *cis vs. trans* structures in NiS_4N_2 complexes are the *trans* structures of $[([9]aneS_2N)_2Ni]^{2+}$ and $[([10]aneS_2N)_2Ni]^{2+}$ in which nine- and ten-membered macrocycles, respectively, are the chelating ligands.[11] The macrocycles differ from $\mathbf{1}^-$ in that secondary amines are the nitrogen donors rather than pyrazoles. Analogous derivatives of Fe(II) and Co(II) have been prepared. Spectroscopic data are consistent with exclusive production of *cis*–$[\mathbf{1}]_2Fe$ and *cis*–$[\mathbf{1}]_2Co$.† *cis*–$[\mathbf{1}]_2Fe$ appears to be a spin-crossover complex with a room temperature magnetic moment of 4.1 μ_B. *cis*–$[\mathbf{1}]_2Co$ is high spin with a magnetic moment of 4.1μ_B, close to the spin-only value. For comparison, in the all sulfur analogs, $[PhTt]_2Fe$ exhibits spin-crossover behavior and $[PhTt]_2Co$ is low-spin.[10] Complete details will be reported elsewhere.[12]



Scheme 1

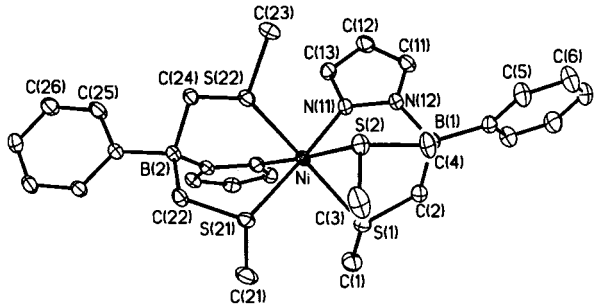


Fig. 1 (a) Thermal ellipsoid plot of *cis*-[**1**]$_2$Ni at 30% probability level showing the atom labeling scheme. The hydrogen atoms are omitted for clarity. Selected bond distances (Å) and bond angles (°): Ni–N(11) 2.053(2), Ni–N(31) 2.067(2), Ni–S(1) 2.4678(8), Ni–S(2) 2.4545(7), Ni–S(21) 2.4859(6), Ni–S(22) 2.4620(7), S(1)–Ni–S(2) 82.92(3), S(1)–Ni–N(11) 92.27(6), S(2)–Ni–N(11) 86.46(6), N(11)–Ni–N(31) 92.99(8), N(11)–Ni–S(21) 176.87(6), S(1)–Ni–S(22) 161.22(3).

Four coordinate complexes [**2**]$_2$M, (M = Ni, Co and Zn), have been prepared in 70–80% yield from the bidentate ligand, **2**$^-$, (Scheme 1).† The molecular structure of pink [**2**]$_2$Co has been determined (Fig. 2).‡ The geometry is tetrahedral with two sulfur and two nitrogen donors. The solution magnetic moment, 4.0 μ_B, is consistent with three unpaired electrons. While this represents the first crystallographically determined structure of Co(II) with two nitrogen and two *thioether* sulfur ligands, there are molecular precedents that contain two nitrogen and two thiolate donors.[13] The ligand bond angle of 100.11(1)° (N–Co–S) is larger than that of the bis[(methylthio)methyl] chelate, Ph_2Bt^- [86.31(1)°], reflecting the sp^2 hybridization of the pyrazolyl nitrogens.[14] Each six-membered chelate ring is in the twist-boat conformation. [**2**]$_2$Co and the isostructural Zn complex, [**2**]$_2$Zn, are chiral possessing C_2 point symmetry. Consistent with C_2 symmetry, the ^{1}H NMR spectrum of [**2**]$_2$Zn contains well resolved methylene resonances for the diastereotopic protons.† Although the phenyl substituents on boron are also expected to be magnetically inequivalent, their resonances are not well separated and appear as broad features. [**2**]$_2$Ni is square planar based on its NMR (diamagnetic) and electronic spectra. Interpretation of the proton NMR spectrum of [**2**]$_2$Ni, displaying signals qualitatively analogous to those observed for [**2**]$_2$Zn, specifically diastereotopic methylene and broad aryl resonances, is consistent with a single isomer in solution. To date, crystallographic data collected on [**2**]$_2$Ni has not yielded a chemically reasonable solution. Consequently, the identity of the single isomer, *cis* or *trans*, remains unknown. Given the disposition of ligand substituents in [**1**]$_2$Ni, it is attractive to propose that the single isomer is *cis*-[**2**]$_2$Ni. This geometry provides the favorable electronic configuration of placing the strong σ-donor nitrogen ligands *trans* to the thioethers. Efforts to improve the quality of the crystals for X-ray analysis continue. Additionally, we aim to distinguish the isomeric form of [**2**]$_2$Ni in solution using molecular dipole moment measurements.

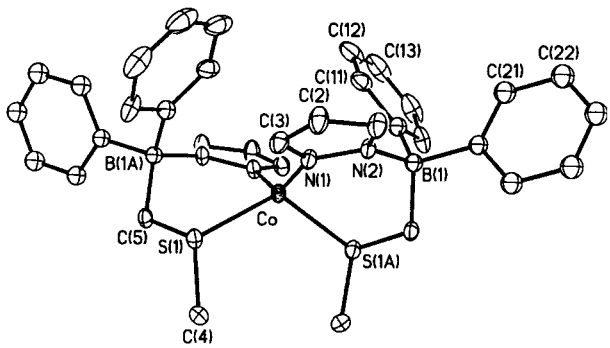

Fig. 2 (a) Thermal ellipsoid plot of [**2**]2Co•2C_6H_{14} at 30% probability level showing the atom labeling scheme. The hydrogen atoms and solvent molecules are omitted for clarity. Selected bond distances (Å) and bond angles (°): Co–S(1) 2.362(1), Co–N(1) 1.957(3), S(1)–Co–N(1) 101.1(1), S(1)–Co–S(1A) 117.67(7), S(1)–Co–N(1A) 100.1(1), S(1A)–Co–N(1) 100.1(1).

Research in progress is directed toward utilizing the new donor sets as supporting ligands for the preparation of synthetic analogues for the zinc sites in methionine synthase, cobalt-containing nitrile hydratase and the nickel sites in CO dehydrogenase.

Synthesis and study of an acridine substituted Tröger's base: preferential binding of the (–)-isomer to B-DNA

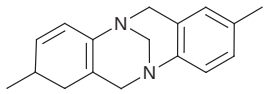
Arnaud Tatibouët, Martine Demeunynck,* Chantal Andraud, André Collet and Jean Lhomme

[a] *LEDSS, UMR CNRS 5616, Université Joseph Fourier, BP53, Grenoble cedex, 38041 France*
[b] *UMR CNRS 117, École Normale Supérieure de Lyon, Stéréochimie et Interactions Moléculaires, Lyon cedex 07, 69364 France*

Received (in Cambridge, UK) 11th November, 1998, Accepted 10th December 1998

The acridine substituted Tröger's base 4 was prepared, resolved and the (−)-(7*R*,17*R*) enantiomer was shown to bind preferentially to calf-thymus B-DNA.

The development of molecular probes to study local conformations in DNA is of major interest; until now, only chiral metal complexes have been studied for enantioselective recognition of DNA conformations.[1] We report herein that combining the geometry and chirality of Tröger's base[2] (methanodibenzo-



Tröger's Base **1**

[1,5]diazocine) **1** with the DNA binding properties of acridines[3] leads to a new family of C_2-chiral DNA binding molecules, such as **4**. The geometry of the Tröger's base unit gives the molecules a helix shape which can be similar or opposite to the helicity of DNA (Fig. 1). A preliminary molecular modelling study[4] suggested that the binding of such probes to DNA should be enantioselective.

Compound **4** was prepared in two steps from monoacetylated proflavine **2** (Scheme 1).[5] Condensation of **2** with formaldehyde in TFA[6,7] gave the diacetamido derivative (±)-**3** (76%). Treatment of **3** under basic conditions (EtOH, NaOH) cleaved the two acetamido groups without affecting the methanodiazocine bridge, to give (±)-**4** (90%). The structure of **4** was supported by detailed 2D ^{1}H NMR studies.[8]

Resolution of (±)-**4** was achieved by crystallisation of its dibenzoyltartrate salts; (+)-**4** showed = $[\alpha]_D^{20}$ +4650 (*c* 9 × 10^{-3}, 95% EtOH). The enantiomeric excess (ee) was close to 80% (NMR).† Similarly, (+)-dibenzoyltartaric acid gave (−)-**4**. The circular dichroism (CD) spectra of both enantiomers are shown in Fig. 2.

The presence of the primary amino functions on the acridine rings of **4** turned out to be of major importance in the design of a molecule binding selectively to DNA. Solubility in water is considerably increased as compared to the parent unsubstituted molecule.[6] More important, the basicity is much higher (pK_a 5.5 and 6.8 *cf.* 3.2 for **1**)[9] and protonation occurs on the acridine ring nitrogens and not on the nitrogens of **1** (UV–VIS data). This protects **4** from racemization as is usually observed in acidic media for Tröger's base (such as **1**).[10] Indeed compound **4** did not racemize in 0.1 M HCl in DMF (20 °C, 40 days).

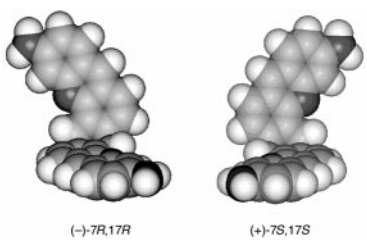


Fig. 1 Molecular modelling representation of the two enantiomers of **4**.

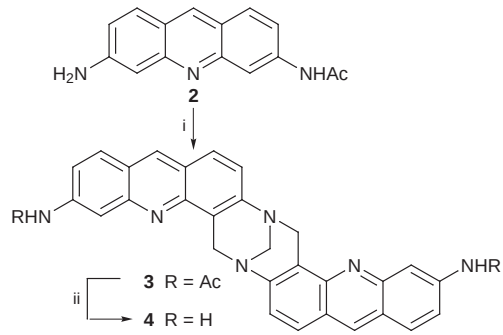

Scheme 1 *Reagents and conditions*: i, HCHO (1.5 equiv.), TFA, room temp., 4 h; EtOH–NaOH (10 M) (3 : 1), 85 °C, 6 h.

The absolute configuration of the enantiomers was assigned as follows. Enantiomer (+)-**4** displays a broad positive band of weak intensity at low energy (380–470 nm, $\Delta\varepsilon$ +26 M^{-1} cm^{-1}), and a strong bisignate system at high energy with maxima at 290 ($\Delta\varepsilon$ +218 M^{-1} cm^{-1}) and 250 nm ($\Delta\varepsilon$ −163 M^{-1} cm^{-1}). The low energy CD band corresponds to a broad UV absorption at 350–450 nm, whereas the bisignate pattern is centred on a strong UV band at 272 nm (ε 101400 M^{-1} cm^{-1}). There is evidence that each component of the bisignate system comprises at least two mutually overlapping bands. Given the two-fold symmetry of **4** and the nature of its chromophore, we assume that the bisignate pattern is due to the exciton coupling[11] of some long-axis polarised transitions of the aminoacridine units. Based on simple geometric arguments, we expect that in **4** the symmetric (*A*) coupling and the antisymmetric (*B*) coupling of these transitions in the two acridine units are polarised along the C_2 axis and perpendicularly to that axis, respectively. This picture together with the further assumption that the *A* coupling is at higher energy than the *B* coupling[12] leads us to assign the (*S*,*S*) configuration to (+)-**4**.

In the past, application of the exciton chirality method to **1** itself has lead to a wrong assignment of its absolute configuration,[13] because the direction of polarisation of the considered transitions have not been correctly established. For this reason we found it desirable to verify the consistency of our

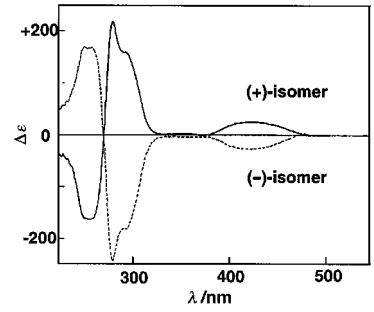

Fig. 2 Circular dichroism spectra of (+)-**4** (solid line) and (−)-**4** (dotted line) in ethanol (10^{-4} M). For (+)-**4**: $[\alpha]_D^{20}$ +4200 (*c* 1.6 × 10^{-3}, ethanol) and for (−)-**4**: $[\alpha]_D^{20}$ −4800 (*c* 1.5 × 10^{-3}, ethanol).

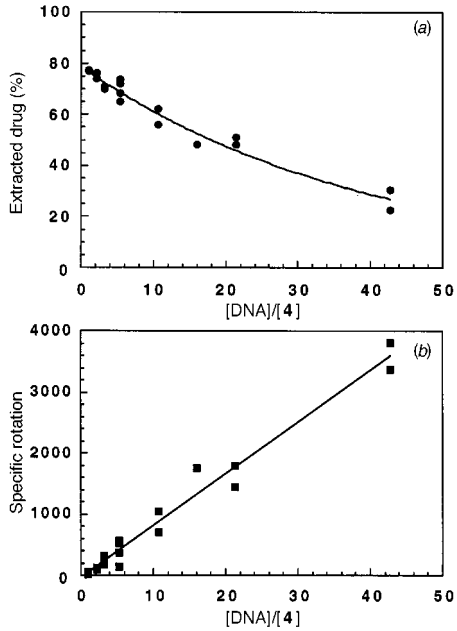

Fig. 3 (*a*) Percent of **4** extracted in butanol as a function of DNA(bp) : **4** ratio. The concentration was calculated from the absorbance measured at 390 nm (ε = 18 800 M^{-1} cm^{-1} in butanol); (*b*) Optical activity of the butanol layer as a function of the DNA(bp) : **4** ratio. The specific rotation ($[\alpha]_D^{20}$) was recorded in 95% ethanol, the concentration being calculated from the absorbance at 390 nm (ε = 20 000 M^{-1} cm^{-1} in 95% ethanol).

assumptions regarding the exciton mechanism in **4**. This was done by semi-empirical calculations[14] of the electronic transitions in **4** and in the corresponding monomeric fragment. The calculated absorption spectrum of the monomer shows two strong transitions at 325 and 310 nm, which are polarised along the long axis. The corresponding transition levels in the dimer are each split into two levels which are almost degenerate and orthogonally polarised (314/314 nm and 283/282 nm); in each pair, one of the components is parallel and the other perpendicular to the C_2 axis. These features are in line with the exciton mechanism and account for the splitting of each component of the bisignate couplet in the experimental CD spectrum.

The UV–VIS spectrum of (±)-**4** was recorded in the presence of increasing concentrations of calf thymus DNA in phosphate buffered solutions (pH 7). Large changes of the spectrum were observed, characterised by the appearance of a new broad band centred at 467 nm, whose intensity increased when the DNA to drug ratio *r* was increased in the range 0–10. These experiments demonstrate that **4** interacts with DNA. The variations observed in the presence of increasing amounts of DNA are similar to those occurring when the spectrum of **4** was recorded at acidic pHs. The simplest interpretation is that the interaction with DNA is accompanied by protonation of the two acridines. The existence of acidic domains surrounding the DNA molecule has already been proposed by Lamm *et al.*[15] Comparison of the CD spectra of **4** in the presence of calf thymus DNA and in 3 M HCl solution leads to the same conclusion.

Liquid–liquid partition[16] of (±)-**4** between an aqueous solution of DNA and butanol revealed that the binding of **4** to calf thymus DNA is enantioselective. Solutions containing various ratios of (±)-**4** and calf thymus DNA in phosphate buffered aqueous solution (pH 7) were mixed with butanol, in which **4** is soluble and DNA is not. After vigorous stirring, the two phases were separated and analysed by CD spectroscopy. The butanol layers gave spectra showing a broad positive band centred at 420 nm, similar to that of the (+)-enantiomer recorded independently under the same conditions. The intensity of this band increased with the DNA : **4** ratio *r*. The spectra of the aqueous phases were similar to those of solutions of (−)-**4** added to various concentrations of calf thymus DNA in phosphate buffer (pH 7). These results indicate that (+)-**4** and (−)-**4** distribute differently between the DNA-containing aqueous phase and butanol, and that (−)-**4** preferentially associates to calf thymus DNA. The enantioselectivity was evaluated by determining the quantities and ees of **4** extracted in the butanol layer (from the UV absorbance and rotation, respectively). The results are reported in Fig. 3(*a*) and 3(*b*) for DNA : drug ratios *r* varying in the range 1–40. As expected, when the DNA : **4** ratio increased, the quantity of **4** extracted in the butanol phase decreased, while the corresponding ee increased (*e.g.* 30% ee when 50% of **4** was extracted and 70% ee when only 20% of **4** was extracted).

The 7*R*,17*R* configuration of (−)-**4** is consistent with the best fit of this enantiomer to right-handed B-DNA,[17] either through intercalation or by interaction in the groove. Work is in progress to determine the mode of interaction.

Communication 8/08822E

A small supramolecular system which emulates the unidirectional, path-selective photoinduced electron transfer (PET) of the bacterial photosynthetic reaction centre (PRC)

A. Prasanna de Silva and Terence E. Rice

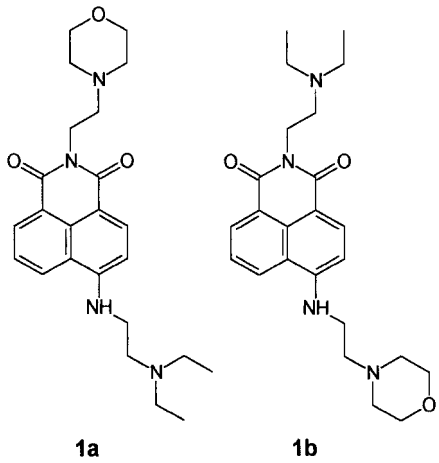
School of Chemistry, Queen's University, Belfast, Northern Ireland, UK BT9 5AG. E-mail: a.desilva@qub.ac.uk

Received (in Cambridge, UK) 23rd November 1998, Accepted 4th December 1998

The singlet excited state of the 4-aminonaphthalimide fluorophore in 1a and 1b directs electron transfer from intramolecular but external amine groups along only one of two available paths.

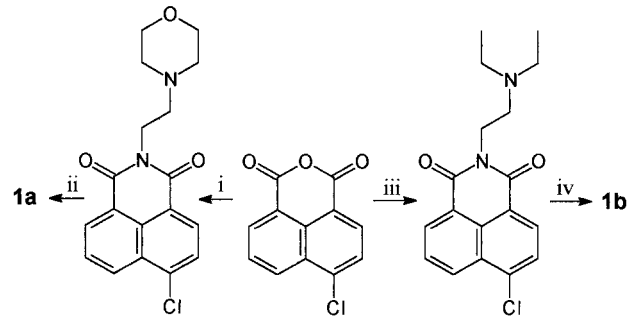
The availability of high-resolution X-ray structural information concerning the engines of photosynthesis, such as the bacterial reaction centres[1] and the antenna complexes,[2] challenges chemists to emulate their functions.[3] One of the most enigmatic aspects of PRC function is the unidirectional, path-selective electron transfer from the photoexcited porphyrin special pair to a quinone moiety along the L-branch rather than the symmetry-related M-branch. The path-selectivity in the PRC was established by picosecond transient absorption signatures which distinguished between the nearly identical bacterichlorophyll stations along the two possible electron paths.[4] In the present instance, we use pH-dependent steady-state fluorescence spectroscopy to distinguish between the two possible PET paths in a small supramolecular system[5] by means of the acid–base characteristics of two rather similar amine PET donors. As an additional point of interest, unidirectionality is much sought after in several research areas of photoscience and molecular electronics.[6] We now provide a simple basis for unidirectionality in PET processes.

Many aminoalkyl substituted fluorophores show weak fluorescence in basic solution owing to rapid PET from the amine unit to the fluorophore. Protonation of the amine arrests this PET process and causes a sharp fluorescence recovery.[7] We use the fluorescent 4-aminonaphthalimide chromophore[8] as the core of our system **1** since its photogenerated molecular-scale



1a **1b**

electric field can be used to control electron transfer rates.[9] Two nearly identical PET paths are provided for the fluorophore to choose from, in the form of two dialkylaminoethyl sidechains only differing in their dialkyl substituents. Such a choice of PET paths is also available to the porphyrin special pair in the PRC. The thermodynamic driving force for PET is equal in **1a** and **1b** for any given amine receptor. **1a** and **1b** are isomers which differ only in the placement of one oxygen and two hydrogen atoms at the termini. So the major difference between **1a** and **1b** regarding PET is the relative orientation of the photogenerated electric field of the 4-aminonaphthalimide excited state towards a given amine receptor. Supramolecular systems composed of a fluorophore flanked by two dissimilar receptors are also useful as selective sensors[10] and as AND logic gates.[11] Synthesis of **1a** and **1b**† is easily achieved in two steps (Scheme 1) starting from commercially available materials.



Scheme 1 *Reagents* i, 2-(morpholino)ethylamine, PhMe; ii, 2-(diethylamino)ethylamine; iii, 2-(diethylamino)ethylamine, PhMe; iv, 2-(morpholino)ethylamine.

The electronic absorption and fluorescence emission spectra of **1a** and **1b** are measured as a function of pH. The absorption spectra show variations across some pH ranges. These absorbance (A) changes are analyzed according to eqn. (1)[12] and the pK_a values obtained are given in Table 1. The variations in fluorescence emission spectra are largely confined to changes in the quantum yield (ϕ_{Flu}). These are plotted in Fig. 1 and analyzed according to eqn. (2).[13]

Table 1 Optical and acid–base parameters of **1a** and **1b**[a]

	1a	**1b**
$\lambda_{Abs\ pH\ =\ 3.0}$/nm (log ε)[b]	432 (4.19)	433 (4.21)
$\lambda_{Abs\ pH\ =\ 7.0}$/nm (log ε)[b]	432 (4.19)	452 (4.23)
$\lambda_{Abs\ pH\ =\ 10.8}$/nm (log ε)[b]	450 (4.20)	452 (4.23)
$\lambda_{Isosbestic}$	439	437
pK_a (morpholinoethyl)[c]	—[d]	5.8
pK_a (diethylaminoethyl)[c]	8.6	—[d]
λ_{Flu}/nm[e]	526	524
$\phi_{Flu\ pH\ =\ 3.0}$	0.53	0.52
$\phi_{Flu\ pH\ =\ 7.0}$	0.66	0.062
$\phi_{Flu\ pH\ =\ 10.8}$	0.030	0.070
$FE_{pH\ =\ 3.0/pH\ =\ 7.0}$[f]	0.81	8.4
$FE_{pH\ =\ 7.0/pH\ =\ 10.8}$[f]	21	0.83
pK_a' (morpholinoethyl)[g]	5.8	5.7
pK_a' (diethylaminoethyl)[g]	8.7	9.1

[a] 10^{-5} M **1a** or **1b** in aerated H_2O–MeOH (1 : 1, v/v). Fluorescence emission spectra are obtained by excitation at the isosbestic wavelength. [b] Extinction coefficient ε in units of dm^3 mol^{-1} cm^{-1}. [c] *via* Absorbance measurements. [d] Absorbance change is not large enough to permit analysis according to eqn. (1). [e] Value changes little with pH. [f] Fluorescence enhancement factor due to protonation in the specified pH range. [g] *via* Fluorescence measurements.

$$\log[(A_{max} - A)/(A - A_{min})] = pH - pK_a \quad (1)$$

$$\log[(\phi_{Flu\,max} - \phi_{Flu})/(\phi_{Flu} - \phi_{Flu\,min})] = pH - pK_a' \quad (2)$$

Considering **1a**, we find there is only one clear sigmoidal step corresponding to proton-triggered fluorescence recovery as expected of a PET system. The fluorescence is enhanced by an order of magnitude. The corresponding pK_a' value (8.7) clearly belongs to the strongly basic diethylaminoethyl unit attached to the 4-amino position. There is a smaller sigmoidal step corresponding to weak fluorescence quenching due to protonation. This is due to the formation of an intramolecular hydrogen bond between the protonated amine and the imide carbonyl oxygen.[14] The corresponding pK_a' value (5.8) can be easily assigned to the morpholinoethyl unit attached to the imide position. We note that the two dialkylamino groups are held far enough apart by the rigid chromophore in **1a** (and **1b**) to prevent mutual perturbation of pK_a values.

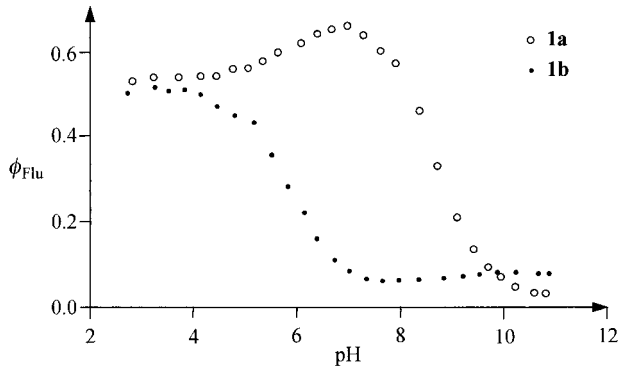


Fig. 1 Fluorescence quantum yields of **1a** and **1b** as a function of pH.

System **1b** shows the fluorescent PET switch behaviour with emission enhancement due to protonation of the morpholinoethyl unit connected to the 4-amino position. The dominant sigmoidal step has pK_a' = 5.7. The minor sigmoidal step has pK_a' = 9.1 which can be associated with the diethylaminoethyl group on the imide position. The slight fluorescence quenching seen upon protonation is again due to the intramolecular hydrogen bonding discussed above for **1a**.

The above analysis shows that in each case the electron transfer originates from the dialkylamino unit attached to the 4-amino position irrespective of the difference in PET driving force for the two alkylamino moieties. In the case of **1b** it is particularly remarkable that the PET path of apparently smaller PET driving force is selected by the supramolecular system. The morpholino unit is clearly a poorer PET donor than the diethylamino group when used in conjunction with porphyrin fluorophores for instance.[15] The PET path selection by the supramolecular system shows the remarkable marshalling efficiency of the excited state dipole of the 4-aminonaphthalimide fluorophore.[9] Unidirectional PET (but not path selectivity) has also been arranged with the ground state dipole of α-helical oligopeptides.[16] Taken together, these results demonstrate the capability of local electric fields to direct electron traffic. It is interesting that local electric fields due to the protein matrix of the PRC are among the possible causes advanced for the path-selectivity of PET.[17]

In conclusion, the simple technique of pH-dependent fluorescence is combined with the carefully designed, but structurally simple supramolecular systems **1a** and **1b** in order to emulate the one-way electron transfer seen within the PRC.

We thank EPSRC, DENI and Dr H. Q. Nimal Gunaratne for support and help.

Communication 8/09119F

A novel open-framework zinc phosphate with intersecting helical channels

S. Neeraj, Srinivasan Natarajan and C. N. R. Rao*

Chemistry and Physics of Materials Unit, Jawaharlal Nehru Centre for Advanced Scientific Research, Jakkur P.O., PO Box 6436, Bangalore 560 064, India. E-mail: cnrrao@jncasr.ac.in

Received (in Cambridge, UK) 16th November 1998, Accepted 9th December 1998

A new open-framework zinc phosphate, possessing two interpenetrating 8-membered helical channels, has been synthesized under mild hydrothermal conditions.

Materials required for enantioselective separation and synthesis are becoming increasingly important in recent years.[1] For example, it is known that chiral rhodium complexes supported on a zeolite matrix give rise to asymmetric hydrogenation of *N*-acyldehydrophenylalanine derivatives with an enantioselectivity of > 95%.[2] In this context, it is desirable to have materials which are chiral or possess helical channels. There have been some efforts to make chiral solids which could also be shape-selective. Zeolite-β (polymorph A) is chiral with a 4-fold screw axis but it has not been possible to synthesize this material in a pure form.[3] Chiral open-framework phosphates have been prepared in the presence of chiral metal complexes and structure-directing agents.[4,5] Recently, a chiral tin(II) phosphate has been prepared using an achiral template, and both the enantiometers of this material have been isolated and characterized.[6] A helical metal borophosphate with the helix running along the 6_1 screw axis has also been reported.[7] Very recently, Gier *et al*.[8] have reported chiral zinc and beryllium arsenates with three-dimensional helical structure containing two independent crosslinked helical channels. We have been able to isolate a new chiral zinc phosphate formed under hydrothermal conditions in the presence of an achiral structure-directing amine, diethylenetriamine. Here we report the synthesis and structure of a chiral zinc phosphate, $[NH_3(CH_2)_2NH_2(CH_2)_2NH_3]^{3+}[Zn_4(PO_4)_3(HPO_4)]^{3-}\cdot H_2O$, **1**.

Compound **1** was synthesized hydrothermally using diethylenetriamine (DETA) as the structure-directing agent[9] and characterized by single crystal X-ray diffraction using the Siemens SMART system.[10] The asymmetric unit contains 32 non-hydrogen atoms and the atomic coordinates are given as supplementary data (see http://www.rsc.org/suppdata/cc/1999/165). The structure is built from the networking of ZnO_4, PO_4 and HPO_4 tetrahedral units. The vertex linkage between these units creates an anionic framework of formula $[Zn_4(PO_4)_3(HPO_4)]^{3-}$ and charge compensation is achieved by the protonated amine $[NH_3(CH_2)_2NH_2(CH_2)_2NH_3]^{3+}$. The structure has one water molecule in the channels formed by the networking of the various units.

The most interesting aspect of this Zn phosphate is that it crystallizes in a polar space group $P2_1$. The entire framework of **1**, can be considered to be built from the networking of three-, four-, six- and eight-membered rings. The three- and four-membered rings are connected together, edge wise, forming one-dimensional helical columns along the *b* axis as shown in Fig. 1 which shows how these columns are interconnected *via* the HPO_4 group forming an eight-membered channel system along the *a* axis. This eight-membered channel along the *a* axis is connected to another eight-membered channel along the *b* axis, forming a helical interconnected one-diemsional channel system within which the amine and water molecules are situated. Fig. 2 shows the connectivity between the ZnO_4 and PO_4 moieties that creates the other eight-membered channel system along the *b* axis. Thus, **1** possesses an interpenetrating eight-membered channel system. There is a strong hydrogen bonded interaction between the framework and the structure-directing amine providing structural stability. The framework density[11] (number of tetrahedral framework atoms in 1000 Å^3) for this material is 16.7, indicating a degree of openness comparable to aluminophosphate moecular sieves such as AlPO-12[11] and AlPO-16.[11]

A few comments on the structural parameters of **I** would be in order. Of the sixteen oxygens in the asymmetric unit, one

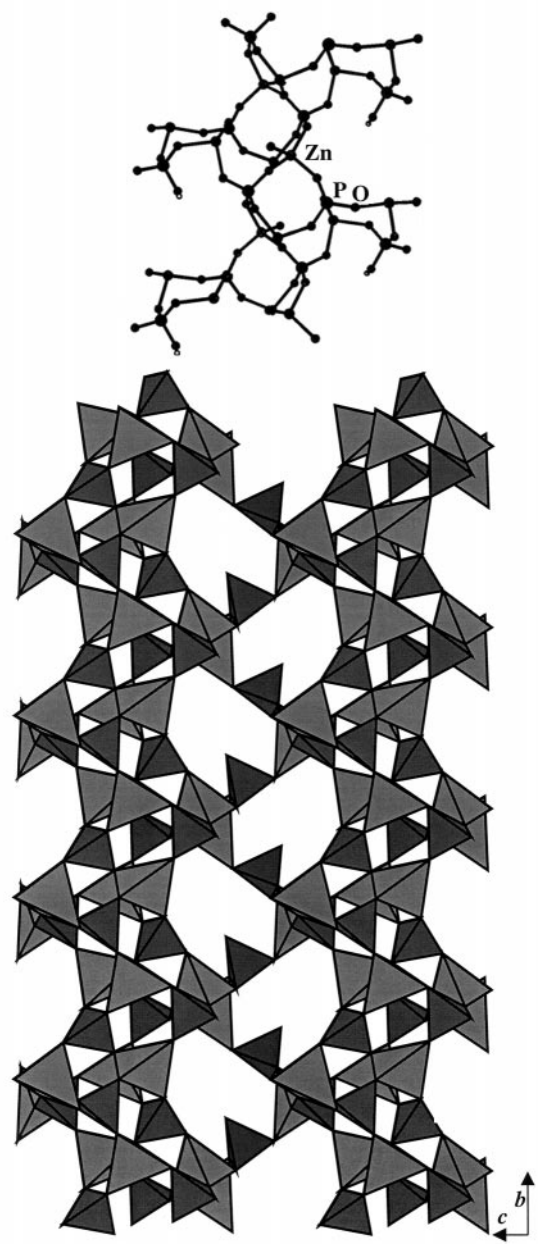

Fig. 1 Structure of $[NH_3(CH_2)_2NH_2(CH_2)_2NH_3]^{3+}[Zn_4(PO_4)_3(HPO_4)]^{3-}\cdot H_2O$ showing the eight-membered cavities (channels) along the *100* direction and the helical channels. Amine and water molecules are omitted for clarity. The connectivity in the one-dimensional columns is also shown.

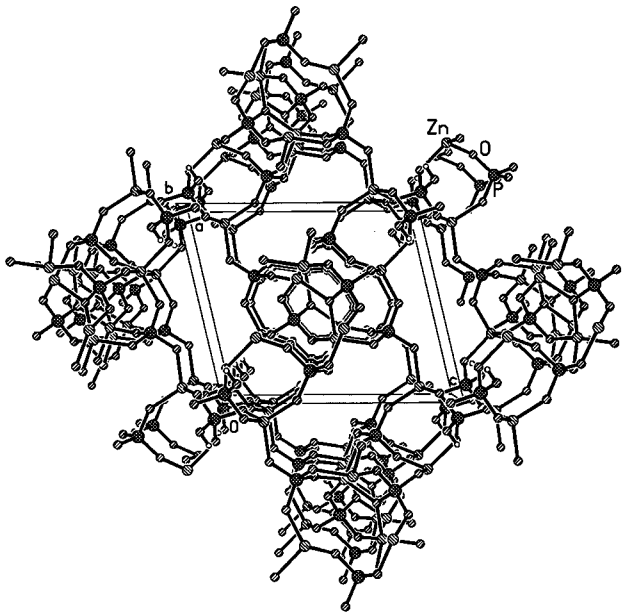

Fig. 2 Structure of $[NH_3(CH_2)_2NH_2(CH_2)_2NH_3]^{3+}[Zn_4(PO_4)_3(HPO_4)]^{3-}\cdot H_2O$ showing the eight-membered channels along the *010* direction. Amine and water molecules are not shown.

makes a trigonal connection with two Zn atoms and one P atom forming a three-membered ring and one is a terminal oxygen while the remainder of the oxygens form Zn–O–P linkages. The P–O bond distances are in the range 1.502–1.581 Å (av. 1.537 Å) and the bond angles are in the range 104.8–114.5° (av. 109.5°), in agreement with those observed previously in such materials. The P–O distance of 1.581 Å [P(3)–O(16)] indicates protonation leading to the formation of the HPO_4 unit. The Zn atoms are all connected with P through oxygens, with the Zn–O distances in the range 1.890–2.004 Å (av. 1.954 Å). The O–Zn–O bond angles are in the range 94.5–120.6° (av. 109.4°). The longest Zn–O distance and the largest O–Zn–O angle are found for oxygens involved in three-coordination.

Synthesis of optically pure threonine-containing dipeptides by regio- and stereo-controlled ring expansion of aziridine-2-imide derivatives

Giuliana Cardillo,* Luca Gentilucci and Alessandra Tolomelli

Dipartimento di Chimica 'G. Ciamician', Università di Bologna and C.S.F.M, via Selmi 2, 40126 Bologna, Italy. E-mail: Cardillo@ciam.unibo.it

Received (in Liverpool, UK) 8th September 1998, Accepted 3rd December 1998

The regio- and stereo-selective ring expansion of chiral *N*-(α-amino acyl)aziridine-2-imides to oxazolines and subsequent ring opening to optically pure threonine-containing dipeptides with the desired stereochemistry is described.

β-Hydroxy α-amino acids are structural units present in a large number of naturally occurring biologically active compounds.[1] For instance, hexadepsipeptide antibiotic azinothricin,[2] depsipeptides variapeptin and citropeptin,[3] and the macrocyclic lactone antiobiotic lysobactin[4] contain in their sequence several β-hydroxy-α-amino acids linked together.

The importance of these amino acids has stimulated the development of numerous methods for their stereoselective synthesis.[5] Nevertheless a conceptually new strategy for the preparation of non-proteogenic α-amino acid derivatives starting from suitable heterocyclic compounds has been recently investigated for direct use in peptide coupling reactions. Ring-opening coupling reactions of enantiomerically pure 3-hydroxy β-lactams with various (*S*)-amino acid esters to give the corresponding dipeptides have been described by Ojima *et al*.,[6] while access to non-proteogenic peptide fragments of lysobactin from chiral azetidin-2-ones has been recently reported by Palomo *et al*.[7]

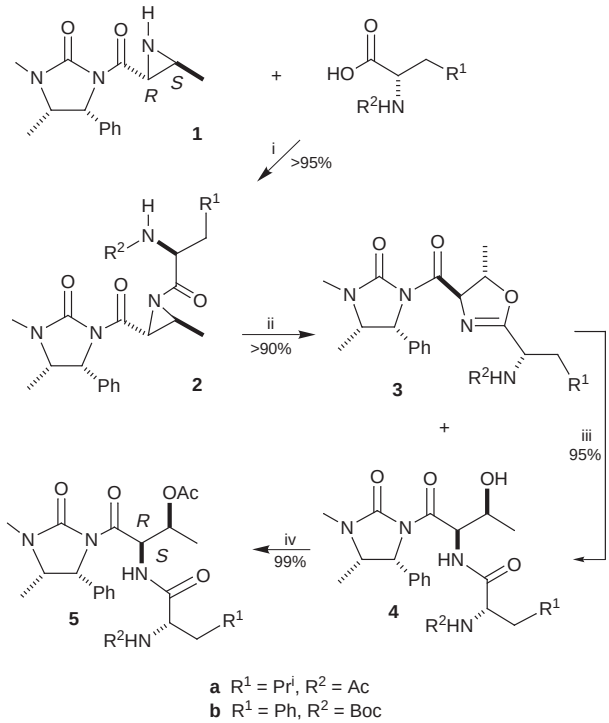
We describe here a new and efficient strategy for the synthesis of threonine-containing dipeptides starting from enantiomerically pure aziridine-2-imides *via* a ring expansion to oxazolines[8] that occurs in a regio- and stereo-controlled manner.[9]

Thus the enantiopure aziridine (2′*R*, 3′*S*)-**1**[10] was treated with *N*-acetylleucine and DCC in CH_2Cl_2–MeCN giving compound **2a** in 95% yield, which spontaneously converted into oxazoline-4-imide **3a** (Scheme 1), obtained in quantitative yield and purified by flash chromatography. Hydrolysis of **3a** performed with TsOH in MeOH–H_2O gave dipeptide **4a** in almost quantitative yield. The *trans* configuration of aziridine **2a** was retained in **3a** as shown by the oxazoline coupling constant value of H4 and H5 ($J_{H4–H5}$ = 4.7 Hz; lit.,[11] J_{trans} = 4–7 Hz). The regiochemistry of the aziridine ring expansion was easily established by ^{1}H NMR analysis of **3a** and confirmed by ^{1}H NMR decoupling experiments on **4a**.

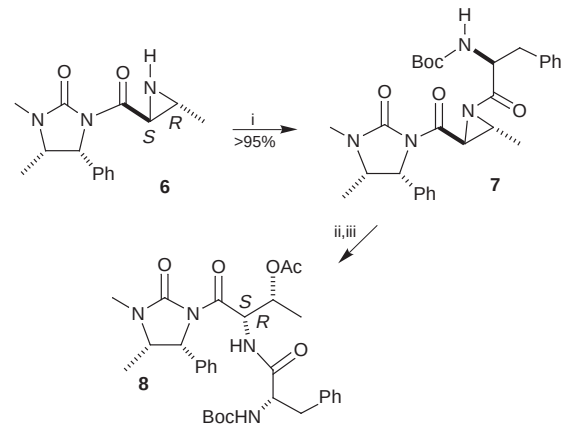
In a similar way, **2b** was obtained by treatment of **1** with *N*-Boc-phenylalanine and DCC. The ring expansion of **2b** was promoted by $BF_3{\cdot}Et_2O$ in the presence of trace water and afforded at once the (*S*)-Phe-(2′*R*, 3′*S*)-Thr derivative **4b**, which is immediately treated with Ac_2O to give **5**.[12] Under these acidic conditions, fast ring opening of oxazoline **3b** to **4b** was observed, **3b** being detected in only trace amounts in the ^{1}H NMR spectrum of the crude reaction mixture.

These results show that (2*R*, 3*S*)-threonine can be easily introduced in a polypeptide sequence. The design and synthesis of modified peptides offers opportunities for drug preparation. Among the modifications designed to obtain higher biological activity and greater resistance to enzymatic hydrolysis, the substitution of non-proteinogenic amino acids in a polypeptide sequence is of current interest.

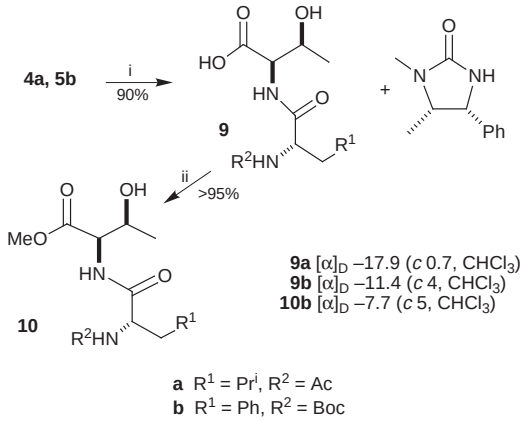
In order to prepare the (2*S*, 3*R*)-threonine-containing dipeptide, the *trans* aziridine **6**[10] was treated with *N*-Boc-phenylalanine and DCC to give **7**. The ring expansion was performed under the conditions reported for **2b** and compound **8** was finally isolated in good yield after acetylation. The ^{1}H NMR and ^{13}C NMR spectra confirmed the structure (Scheme 2).



Scheme 1 *Reagents and conditions*: i, DCC (1.1 equiv.), CH_2Cl_2–MeCN, 12 h, room temp.; ii, $BF_3{\cdot}Et_2O$ (1 equiv.), CH_2Cl_2, room temp.; iii, TsOH (1.1 equiv.), MeOH–H_2O, room temp.; iv, Ac_2O (1.2 equiv.), pyridine (1.2 equiv.), CH_2Cl_2, 2 h, room temp.



Scheme 2 *Reagents and conditions*: i, DCC (1.1 equiv.), CH_2Cl_2–MeCN, 12 h, room temp.; ii, $BF_3{\cdot}Et_2O$ (1 equiv.), CH_2Cl_2, room temp.; iii, Ac_2O (1.2 equiv.), pyridine (1.2 equiv.), CH_2Cl_2, 2 h, room temp.

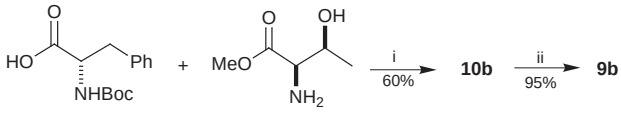


Scheme 3 *Reagents and conditions*: i, LiOH (3 equiv.), H_2O_2 (4 equiv.), THF–H_2O, 2 h, 0 °C; ii, CH_2N_2.

Finally, to obtain the free dipeptide, **4a** was submitted to non-destructive removal of the chiral auxiliary under Evans' conditions,[13] by means of LiOOH in THF–H_2O (Scheme 3). After 2 h the *N*-acetyl-(*S*)-Leu-(2*R*, 3*S*)-Thr dipeptide **9a** was recovered in good yield. Longer reaction times should be avoided; indeed, after 6 h the reaction mixture contained 10% of epimerized product.

On the basis of these results, **5b** was hydrolysed over 2 h giving without any epimerization the *N*-Boc-(*S*)-Phe-(2*R*, 3*S*)-Thr dipeptide **9b**,[14] which was essentially pure after work-up according to analysis of the crude reaction mixture. Compound **9b** was converted by means of CH_2N_2 into the corresponding methyl ester **10b**.[15]

In order to confirm the stereochemistry of the aziridine ring expansion *via* an S_Ni mechanism for **2** and **7**, an authentic sample of dipeptide **8b** was prepared from commercially available (2*R*, 3*S*)-threonine and (*S*)-phenylalanine (Scheme 4).



Scheme 4 *Reagents and conditions*: i, DCC (1.1 equiv.), CH_2Cl_2–MeCN, 12 h, room temp.; ii, LiOH (2 equiv.), H_2O_2 (3 equiv.), THF–H_2O, 1 h, 0 °C.

The (2*R*, 3*S*)-threonine methyl ester and *N*-Boc-(*S*)-phenylalanine were coupled with DCC in CH_2Cl_2–MeCN and the desired dipeptide derivative was obtained in satisfactory yield. This compound was treated with LiOOH in THF–H_2O[13] and afforded the corresponding carboxylic acid. Both **9b** and **10b** showed ^{1}H NMR and ^{13}C NMR spectra which were identical, and optical rotation values which were comparable, with the authentic samples.

In conclusion, we have reported a new method that permits the synthesis of β-hydroxy α-amino acids coupled with other α-amino acids, starting from aziridine derivatives. Furthermore, due to the observed retention of configuration in the ring expansion of the starting aziridine, the stereochemistry of the final dipeptide can be fixed by using the appropriate starting material.

We thank the University of Bologna for funds for selected research topics.

Model systems for flavoenzyme activity: aromatic stacking in sol-gel matrices

Michael D. Greaves, Trent H. Galow and Vincent M. Rotello*

Department of Chemistry, Lederle Graduate Research Center, University of Massachusetts at Amherst, Amherst, MA 01003, USA. E-mail: rotello@chem.umass.edu

Received (in Columbia, MO, USA) 18th September 1998, Accepted 7th December 1998

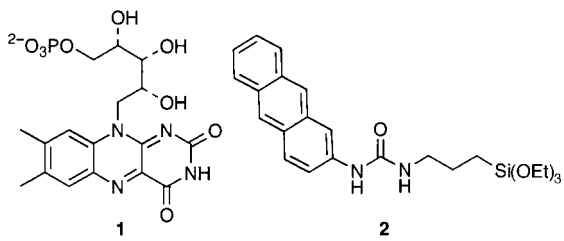
Silicate matrices effectively replicate both the isolation and preorganization found in the active sites of flavoenzymes.

The peptide scaffolding found in proteins performs two crucial roles in defining the active site environment. First, it provides isolation of this active site from unwanted interactions with water and other entities. Second, it presents reactive functionality in the geometry required for efficient recognition and catalysis. While researchers have been able to use solution-based model systems to explore key aspects of both isolation[1] and recognition,[2] the creation of models that simultaneously replicate both functions remains an intimidating prospect.[3]

One means of obtaining isolation is through the use of nanoporous[4] and mesoporous[5] media. In recent research we have demonstrated efficient hydrogen bond recognition of flavin mononucleotide (FMN)[6] in sol-gel silicates.[7] In these systems, incorporation of the flavin into the cybotactic region of the silicate effectively modeled the isolation provided by the active site. Hydrogen bond recognition of the flavin was then provided by doping with a diaminopyridine-based receptor, replicating the enzyme-cofactor hydrogen bonding found in the flavoenzymes.[8]

Aromatic–aromatic interactions are an important motif in flavoenzyme architecture (Fig. 1). As with hydrogen bonding, aromatic stacking plays a dual role in flavoenzyme function, providing efficient recognition of the flavin cofactor, and serving to modulate its reactivity.[9] In recent investigations, we created effective solution-phase models for enzyme–cofactor aromatic stacking.[10] We report here the use of silicate sol-gels to provide both isolation and preorganization for flavin–aromatic complexes, effectively replicating the role of the protein scaffolding.

Flavin-containing sols were prepared *via* the addition of dilute acid and tetraethyl orthosilicate (TEOS) to an aqueous solution of flavin mononucleotide (FMN) **1**, followed by



1 **2**

sonication to homogeneity. Aromatic stacking interactions were probed by addition of varying quantities of anthracene derivative *2* to the sol.[12] Sols were then poured into cuvettes and sealed: wet gels formed within 100 h.

The optical transparency of the silicate matrix allowed direct spectroscopic observation of aromatic stacking. As shown in Fig. 2, increasing quantities of receptor **2** resulted in decreased flavin fluorescence emission. This is consistent with solution-based studies, where we have established that aromatic stacking between the electron-rich anthracene and the electron-poor flavin effectively quenches flavin fluorescence.[13]

During the course of hydrolysis and gelation, there is negligible change (< 2%) in the volume of our sol-gels. We can therefore calculate an approximate pore volume by calculating

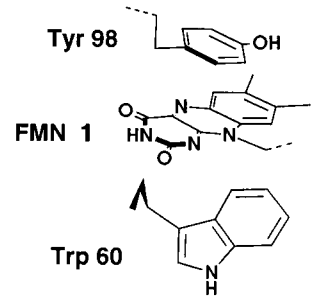


Fig. 1 Flavin binding site of the flavodoxin isolated from *Desulfovibrio vulgaris* (ref. 11).

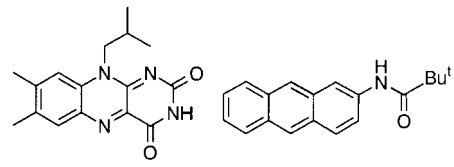
the quantity of EtOH released during the hydrolysis of the orthosilicate. Assuming complete hydrolysis of TEOS, the final gel will be 17% silicate and 83% EtOH. Given this volume, the association constant for the FMN **1**–receptor **2** complex can be fitted to a 1 : 1 binding isotherm,[14] providing an estimated binding constant of 200 ± 50 M^{-1} (Fig. 3).[15] This is considerably higher than that observed for N^{10}-isobutylflavin **3**[16] with acylated aminoanthracene **4** (< 3 M^{-1}), demonstrating



3 **4**

an active role of the silicate matrix in preorganizing the flavin **1**–receptor **3** complex in the sol-gel. This result is consistent with our previous studies,[17] further demonstrating this unusual matrix-assisted recognition enhancement.

In summary, we have demonstrated that aromatic stacking to a sol-gel-bound flavin can be established through addition of an

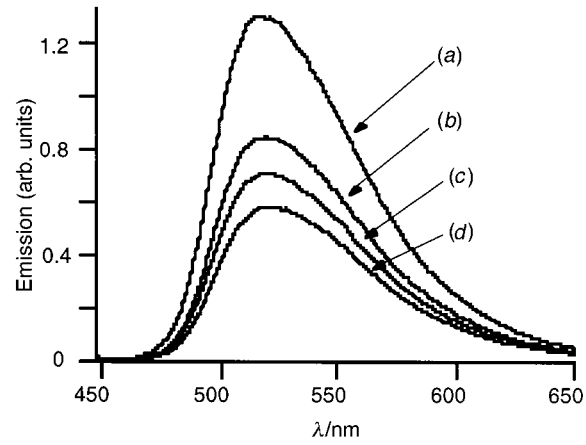


Fig. 2 Flavin fluorescence emission profiles of sol-gels containing FMN **1** and receptor **2**: (*a*) 0, (*b*) 10, (*c*) 20 and (*d*) 30 equiv. **2**. [FMN] = 0.0196 mmol dm^{-3}. Excitation wavelength = 445 nm; uncertainty of fluorescence values = ±5%.

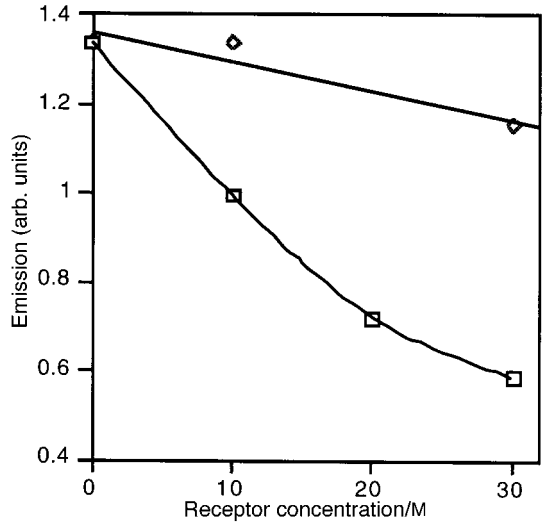

Fig. 3 Plot of flavin (**1**/**3**) fluorescence emission *vs.* receptor (**2**/**4**) concentration (□) **1** + **2** in sol-gel and (◇) **3** + **4** in EtOH. [FMN] = 0.0196 mmol dm^{-3}, [**3**] = 0.236 mmol dm^{-3} (calculated concentration of FMN inside the porous sol-gel matrix).

anthracene-based receptor. This interaction is greatly enhanced in the sol-gel relative to solution-phase studies. This indicates that the silicate matrix replicates the two-fold role of the protein scaffolding of flavoenzymes: isolation of the active site,[18] and preorganization of the active site functionality. Application of silicate sol-gels to the creation of functional flavoenzyme models is currently underway, and will be reported in due course.

12 Synthesized in 75% yield from 2-aminoanthracene and 3-(triethoxysilyl)propyl isocyanate.

13 *N*-Alkylurea analogs of **2** shows essentially identical quenching behavior as for **2**, demonstrating that hydrogen bonding to the urea is not involved in flavin recognition.

14 Solution studies have shown that additional anthracene–flavin interactions have little effect on flavin fluorescence, allowing selective monitoring of the 1 : 1 complex. The large excesses of receptor **2** used should minimize the effect of 2 : 1 receptor flavin binding on the receptor available for the first binding event.

15 The uncertainty presented is the asymptotic standard error. As this system is not in the standard state, the calculated K_a value is for comparison purpose only.

16 N^{10}-Isobutylflavin **3** was used for these studies due to the low solubility of **1** in EtOH.

17 M. Greaves and V. Rotello, *J. Am. Chem. Soc.*, 1997, **119**, 10 569.

18 At the concentrations of flavin **1** used in these sol-gel experiments, there is no deviation from ideal fluorescence dependence on concentration. This indicates that there are no flavin–flavin interactions occurring, demonstrating site isolation of the flavin species.

1,8-Diazabicyclo[6.6.6]eicosa-4,11,17-triyne: a flexible cage for protons, copper(I) and silver(I)

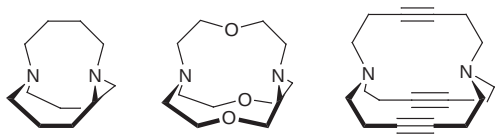
Andreas Kunze, Rolf Gleiter* and Frank Rominger

Organisch-Chemisches Institut der Universität Heidelberg, Im Neuenheimer Feld 270, D-69120 Heidelberg, Germany. E-mail: rolf.gleiter@urz.uni-heidelberg.de

Received (in Liverpool, UK) 16th October 1998, Accepted 30th November 1998

X-Ray structure analysis of the diprotonated cage of 3 and its silver(I) and copper(I) complexes reveals in all three cases the *in,in* conformation and a significant shortening of the intrabridgehead distance from 5.05 Å in 3 to 4.85 Å for 3·2H$^+$, 4.23 Å for 3·Cu$^+$ and 4.61 Å for 3·Ag$^+$.

Investigations of bicyclic compounds with nitrogen atoms at the bridgehead positions prove that mono- and di-protonation depends on the intrabridgehead distance and on the conformation(s) at the nitrogen atoms.[1] In the case of 1,6-diazabicyclo-[4.4.4]tetradecane **1**, where the nitrogen atoms adopt the *in,in*



1 **2** **3**

conformation,[2] monoprotonation yields a very stable species due to a very strong intramolecular hydrogen bond between the two bridgehead positions,[2] rendering diprotonation rather difficult.[3] For the [1.1.1]cryptand **2**,[4–6] which also shows the *in,in* conformation, inside protonation of both nitrogens has been reported. This finding can be traced back to the larger N···N distance in **2** [3.88(2) Å][5] as against in **1** [2.806(3) Å].[2] In **2**·2H$^+$ the N···N distance was found to be enlarged to 3.91(1) Å.[5] Reports on the accommodation of ions other than H$^+$ in bicyclic bridgehead diamines are sparse. For the encapsulation of Li$^+$ in **2**[6] the other functions were held at least partly responsible.

Our recently prepared 1,8-diazabicyclo[6.6.6]eicosa-4,11,17-triyne **3**[7] resembles a stretched **1** and shows an even larger N···N distance [5.049(2) Å] than **2**. However, the steric effects of the bridges, as encountered in **1** and related species, should be reduced due to the linear and rigid triple bonds. Therefore we studied the reactions of **3** with protons and metal ions.

The protonation of **3** with TFA was investigated in $CDCl_3$, CD_3OD and D_2O as solvents.† In $CDCl_3$ 1.5 equiv. of TFA are necessary to generate **3**·H$^+$, while in CD_3OD only 0.5 equiv. are required. Monoprotonation reduces the symmetry of **3** (D_3) to C_3, which yields six signals in the ^{13}C NMR spectrum of **3**·H$^+$. In the ^{1}H NMR spectrum (CD_3OD, 200 MHz) only four lines are found at δ 2.43, 2.79, 3.43 (in a ratio of 2 : 1 : 1) and 7.89 (the proton at the nitrogen atom). Five equivalents of TFA in $CDCl_3$ have to be added to obtain a two-fold protonation of **3**.† The shape of the ^{1}H NMR spectra of **3**·H$^+$ and **3**·2H$^+$ prove that the rapid equilibration between the two enantiomorphic helical conformations found in **3** is still present.

In all cases the protonation equilibrium is achieved instantly after addition of the acid. Even deprotonation succeeds easily with molar amounts of KOH. In **3**·H$^+$ and **3**·2H$^+$ we find a fast intermolecular proton exchange with solvents such as CD_3OD and D_2O. This behaviour is in contrast to the experiences gained from **1** and **2** and can be classified as the reaction of a normal tertiary amine. X-Ray investigations of **3**·2H$^+$ show‡ that both bridgehead hydrogens are inside the cage [Fig. 1(*a*)].

Interestingly, the encapsulation of two protons in the cavity of **3** causes a contraction of the N···N distance by 0.2 Å to 4.845(3) Å (see Table 1) and an increase of the inward pyramidization of the nitrogens by about 3° to *ca.* 112°, which is close to the ideal tetrahedral angle. The torsional angle between the triple bonds is reduced to 42.7(5)°. The distance between the two bridgehead protons in **3**·2H$^+$ amounts to 3.066(3) Å. An intramolecular proton exchange of **3**·H$^+$ in 1,1,2,2-tetrachloro[$^2H_2$]ethane could not be detected up to 130 °C.

Stirring a solution of **3** under argon in CH_2Cl_2 with a small excess of MOTf (M = Cu, Ag) at room temperature for three days leads to 1 : 1 complexes for both metals in almost quantitative yields. The spectroscopic properties of **3**·Cu$^+$ and **3**·Ag$^+$ suggest that the metal is situated in the center of the cage.† NMR and IR studies give no hints of a binding interaction between the metal ion and the surrounding triple bonds, so it can be said that the ligand coordinates mainly with the bridgehead nitrogens, effecting a linear N–M$^+$–N geometry. The structural assignment is supported by X-ray investigations of single crystals of both complexes.‡ It is seen [Fig. 1(*b*), (*c*)] that the metal ion is located in the center of the cage, forcing the bridgehead positions even closer together. **3**·Ag$^+$ displays, like **3**, D_3 symmetry, while **3**·Cu$^+$ reveals C_{3h} symmetry. The N–

M–X[c]/Å	—	—	2.460(4)–2.576(4)	2.493(4)–2.527(4) *2.498(4)–2.539(4)*
Θ[d] (°)	55.5(3)	42.5(3)–42.9(3)	6.3(3)–7.9(3)	8.2(3) *16.2(3)*
d(C≡C)/Å	1.188(2)	1.192(4)	1.189(6)–1.195(6)	1.194(6)–1.199(6) *1.195(6)–1.204(6)*

[a] Ref. 7. [b] Data in italics refer to the second independent complex cation in the asymmetric unit. [c] M–X is the distance between the metal and the center of the triple bonds. [d] Torsional angle between the triple bonds.

M$^+$–N bond angles for **3**·Cu$^+$ and **3**·Ag$^+$ amount to 176.6(3) and 178.9(3)°, respectively. Relevant data for **3**·Cu$^+$ and **3**·Ag$^+$ are collected in Table 1 and compared with **3** and **3**·2H$^+$.

As a consequence of the shortening of the N···N distance in **3**, the torsion angle between the triple bonds is reduced considerably in **3**·Cu$^+$ and **3**·Ag$^+$. The distances between the centers of the alkyne groups and the metal ions [**3**·Cu$^+$: 2.460(4)–2.576(4), **3**·Ag$^+$: 2.493(4)–2.539(4) Å] are larger than for other alkyne silver or copper complexes [Cu$^+$–center of alkyne : 2.02(1) Å, Ag$^+$–center of alkyne : 2.33(1) Å].[8] In both metal complexes the bridgehead atoms show an ideal tetrahedral conformation. The mean N–Ag$^+$ and N–Cu$^+$ distances [2.311(3) and 2.114(2) Å, respectively] are rather expanded with regard to the values reported for homoleptic two-coordinated silver(I) amine complexes, *e.g.* $Ag(NH_3)_2NO_3$ [2.121(1) Å][9] and comparable complexes of copper(I) (average value: 1.88 Å).[10] Many of the known mononuclear two-coordinated copper(I) complex cations deviate considerably from the ideal linear structure to coordinate further ligands and come up to the preferred four-coordinate tetrahedral geometry. Although in **3**·Cu$^+$ potential ligands (the triple bonds) are within reach, this tendency seems to be effectively blocked due to the extended N–Cu$^+$–N arrangement.

The triflate salts of **3**·Cu$^+$ and **3**·Ag$^+$ are stable to air and not light sensitive. None of the silver(I) halides is obtained by treatment of solutions of **3**·Ag$^+$ TfO$^-$ in CH_2Cl_2 or MeOH with Me_2NH_2Cl, Et_3NHBr and Bu_4NI at room temperature, indicating remarkable stability. The aptitude of **3** as a flexible ligand for further metal ions is currently under investigation.

We thank the Deutsche Forschungsgemeinschaft (SFB 247), the Fonds der Chemischen Industrie, DEGUSSA AG and the BASF Aktiengesellschaft, Ludwigshafen, for financial support.

Weak hydrogen bonding between acetylenic groups: the formation of diamondoid nets in the crystal structure of tetrakis(4-ethynylphenyl)methane†

Elena Galoppini*[a] and Richard Gilardi[b]

[a] *Department of Chemistry, Rutgers University, Newark NJ 07102, USA. E-mail: galoppin@andromeda.rutgers.edu*
[b] *Laboratory for the Structure of Matter, The Naval Research Laboratory, Washington, D.C. 20375, USA*

Received (in Columbia, MO, USA) 5th October 1998, Accepted 7th December 1998

The crystal structure of tetrakis(4-ethynylphenyl)methane 1 shows interwoven diamondoid lattices formed by weak hydrogen bonds between the acetylenic groups, while 1,3,5,7-tetrakis(4-ethynylphenyl)adamantane 2 crystallizes in a non-symmetrical network.

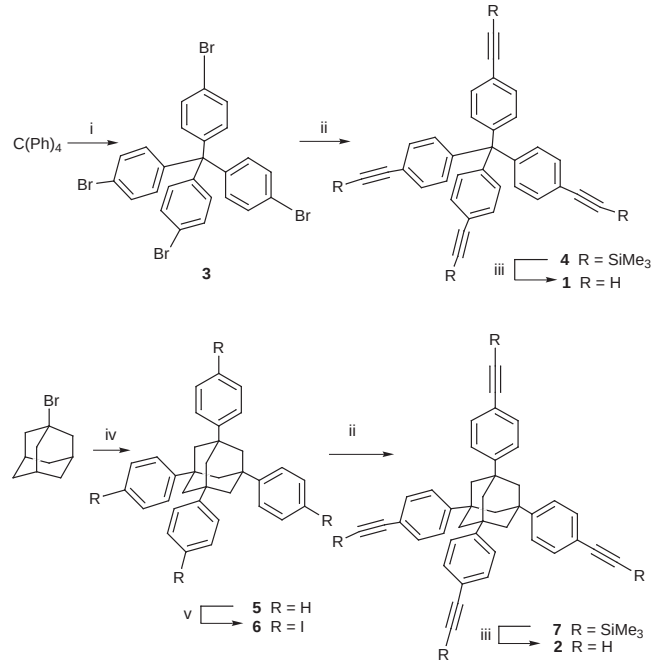
Organic crystals or polymers having large and dimensionally-fixed cavities are expected to exhibit unprecedented structural and physical properties.[1] A particularly attractive kind of network with a regular array of cavities can be obtained, in theory, by connecting the four vertices of tetrahedral organic molecules.[1e,2] This mode of assembly has been termed diamondoid due to its resemblance to the lattice structure of diamond.

Tetraphenylmethane and adamantane are useful building blocks for diamondoid networks. We are studying a series of derivatives bearing acetylenic groups on all four vertices. Ethynes are versatile functional groups for connecting building blocks because they possess rigid-rod geometry, complex with metals and undergo coupling and polymerization reactions.[3]

Fortuitously, the crystal structure‡ of the first model compound, tetrakis(4-ethynylphenyl)methane **1**, contained highly symmetric diamondoid networks formed by van der Waals association, or weak hydrogen bonding, between acetylenic groups. Crystal structures reported by others for a series of terminal alkynes show that the acidic C≡CH groups act as hydrogen donors and form close contacts with hydrogen bonding groups and also with π-systems, including ethynyl and phenyl groups.[4] These kinds of interactions possess the properties of weak (1–2.2 Kcal mol^{-1}) hydrogen bonds and are called C(alkyne)H···π hydrogen bonds.[4a]

While numerous examples exist of diamondoid networks formed by strong hydrogen bonding groups, such as carboxylic acids[1e] and pyridones,[1c] or by metal complexes,[1d] only a few involve van der Waals interactions, such as Br···N and Br···Ph.[4a] To the best of our knowledge, the crystal structure of **1** is the first diamondoid network sustained by C≡CH···C≡C close contacts. Interestingly, C≡CH···Ph interactions, often observed in the crystal structures of phenylsubstituted alkynes,[4a] were not observed in **1**.

Compound **1**§ was prepared in two steps and 67% yield from the known tetrabromide **3**[5] (Scheme 1). Compound **1** crystallizes in a body-centered space group, $I\bar{4}$, and molecules sit on unit cell center and corner sites that require S_4 symmetry (Fig. 1). A three-dimensional network is formed by weak hydrogen bonds between the alkynyl groups from four separate molecules that meet (*i.e.* come close) at nodes in the network that are also S_4 in their local symmetry. The molecule at the center of the cell forms linkages only to molecules that are 1.5 unit cells up and down in the *c* axis direction; they, in turn, link to other molecules that are 3.0 *c* axis translations above and below the origin molecule, and in so doing form cages that resemble super-adamantane models, which are outlined in Fig. 2. The super-adamantane cages are distorted, with a cross-cage distance of 21.7 Å (3 unit cell lengths) in the *c* direction, and two equal cross-cage distances of only 18.3 Å perpendicular to the *c* axis. The structural topology mimics closely that of tetrakis(4-bromophenyl)methane,[1a] which crystallizes in the same space group, and has nodes where four bromine atoms approach one another.



Scheme 1 *Reagents and conditions*: i, Br_2, Fe (ref. 5); ii, Et_3N, CuI, $[Ph_3P]_2PdCl_2$, $Me_3SiC{\equiv}CH$, reflux, 81%; iii, TBAF, MeCN, 85%; iv, $AlCl_3$, C_6H_6, reflux, 50% (ref. 7); v, $(CF_3CO_2)_2IPh$, I_2, $CHCl_3$, 70% (ref. 7).

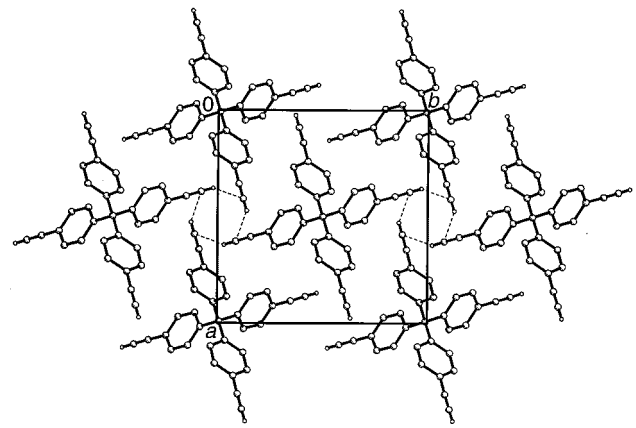


Fig. 1 Crystal structure of **1**. Molecules sit on four-fold S_4 sites at (0, 0, 0) and (0.5, 0.5, 0.5). The quartet-clusters of H-bonds shown about the S_4 sites (0.5, 0, −0.25) and (0.5, 1.0, −0.25) are 5.43 Å (*viz*. 3/4*c*) below the plane passing through the central atom. The C≡CH···C≡C distance is 2.76 Å, and the H-bond makes an angle of 152° with CH and 86° with C≡C.

† Experimental details and extra crystallographic views are available from the RSC web site, see: http://www.rsc.org/suppdata/cc/1999/173/

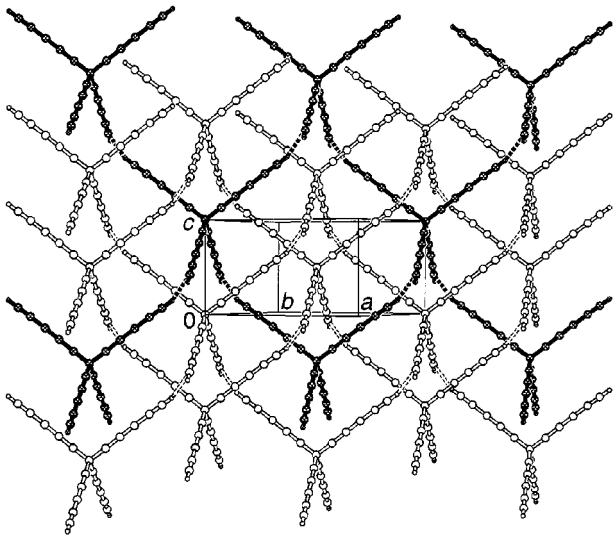

Fig. 2 A schematic view of the three interwoven diamondoid nets, one of which is accented in bold. For clarity, the phenyl groups have been replaced by three 'atoms' in a straight line.

The repetition of a single linked cage by crystal lattice translations produces a three-dimensional network, but origin molecules located at +*c* and +2*c* serve as generators of two more networks which penetrate the holes of the first network, and coexist without (close) interaction. The assembly is thus comprised of three identical interwoven diamondoid networks (Fig. 2). The hydrogen bonded alkyne moieties are neither perpendicular (inter-line angle of 90°) nor antiparallel (180°), but approach at an intermediate inclination, with an inter-linear angle of 110.6° between lines passing through the ethynes of H-bonded neighbors in the cluster. The inter-alkyne hydrogen bond H4B···C4B (2.76 Å), is the only intermolecular distance less than the expected van der Waals' contact (2.90 Å).[6] Hydrogen atom positions were normalized to give linear 1.08 Å C–H bonds before calculating all H-bond parameters. The closest C–H approach is to the terminal C atom; distances to the other alkyne C atom and to the midpoint of the alkyne bond are greater.

To assess whether a diamondoid motif would occur upon changing the tetrahedral core, we prepared 1,3,5,7-tetrakis(4-ethynylphenyl)adamantane **2**§ (Scheme 1.)[7] In the crystal structure‡ of **2**, both C≡CH···C≡C and C≡CH···Ph interactions are present, but the lattice is not diamondoid. Compound **2** crystallizes from benzene–hexane in a monoclinic packing arrangement (*C*2/*c*), with two molecules of **2** and a half-molecule of benzene in the asymmetric unit of the crystal (Fig. 3). Crystals of **2** grown from a few solvents other than benzene also showed asymmetric lattices.

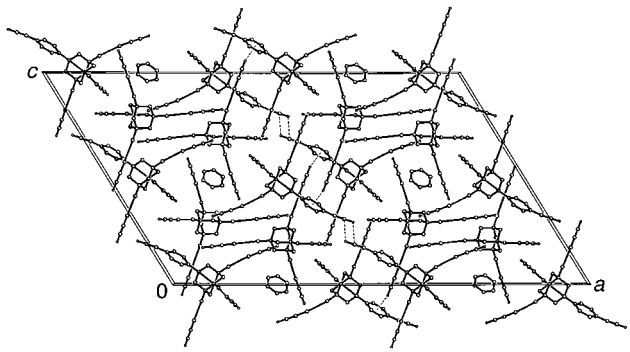

Fig. 3 Crystal structure of **2**. Sixteen molecules of **2** and four benzene molecules occupy each cell; those on the bottom and top faces are shown twice. For clarity, the phenyl groups have been replaced by three 'atoms' in a straight line.

In contrast to **1**, where all alkynes are involved in extended CH··π networks, only two of eight independent alkyne termini of **2** participate in close contacts. One alkyne hydrogen atom points directly at the face of a neighboring near-perpendicular phenyl ring, with CH···C(Ph) approaches of 2.55, 2.60 and 2.75 Å, a typical CH··π interaction mode. The other close contact is an almost antiparallel (side-by-side) approach between two C≡CH termini related by a 2-fold rotation, with a C···H distance of 2.60Å and a C···C distance of 3.17Å (expected[6] van der Waals contacts are 2.9 and 3.4 Å). Similar alkynyl contacts of both types have been reported before.[2a,8]

In summary, the crystal structure of **1** is the first example of a diamondoid packing motif formed by weak hydrogen bonding between acetylenic groups. We are currently investigating hydrogen bonding of **1** and **2** with other compounds and expanding the family of ethynyl-substituted tetrahedral building blocks.

A novel entry to 5a-carba-hexopyranoses from carbohydrates based on a 6-*exo-dig* radical cyclization: synthesis of 5a-carba-β-D-mannopyranose pentaacetate

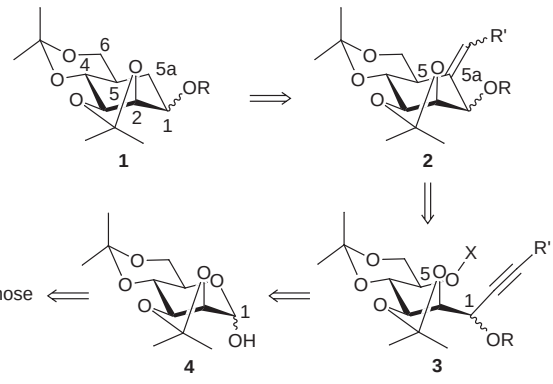
Received (in Cambridge, UK) 12th November 1998, Accepted 24th November 1998

Carbohydrate-derived 2,3:4,6-diacetonides which are homologated at C-1 by reaction with phenyl acetylide undergo a 6-*exo-dig* radical cyclization, from a radical located at C-5, to yield highly functionalized cyclohexanes that are correlated with carba-sugars.

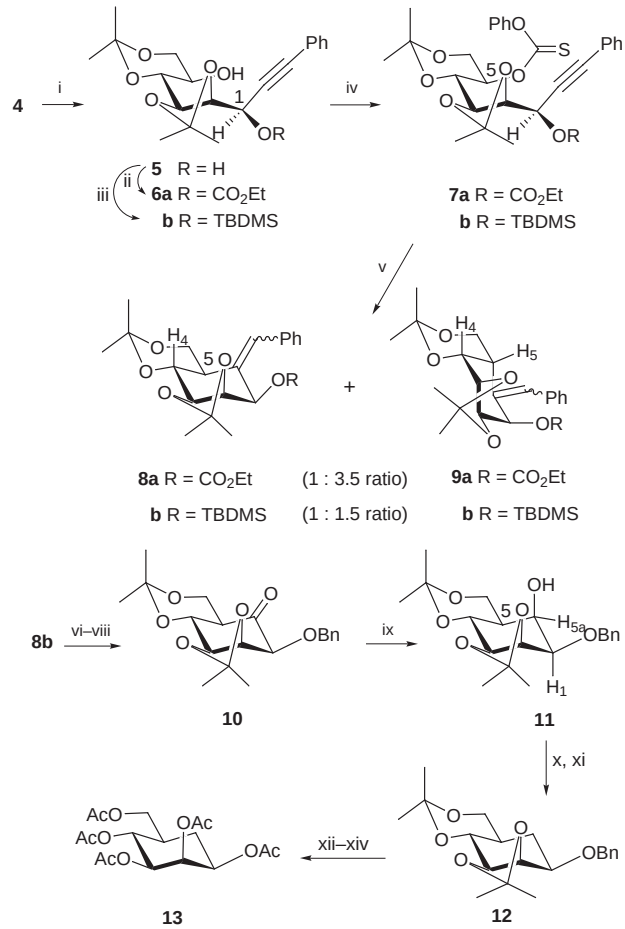
The term 'carba-sugar' is currently used to describe monosaccharide analogs having a methylene group instead of the ring oxygen atom.[1] Carba-sugars derived from hexopyranoses, 'carba-pyranoses' (*e.g.* **1**), were first prepared more than three decades ago by McCasland and co-workers[2] prior to their isolation from natural sources as components of important antibiotics.[3] Many of these substances, owing to their close structural resemblance to carbohydrates, are endowed with an interesting range of biological activities[4] which has triggered the development of different synthetic approaches for their preparation.[1,5,6] However, to the best of our knowledge only one synthetic approach involving radical ring closure[7] leading to 6-deoxy-5a-carba-pyranosides has been reported.[8] A very recent report by Maudru, Singh and Wightman[9] on the synthesis of carba-pyranoses by 6-*exo-dig* radical cyclization of carbohydrate derived alkynes prompts us to disclose our own results in this area.

As a continuation of our interest in the synthesis of highly functionalized carbocycles[10] from carbohydrates,[11] we turned our attention to the preparation of 5a-carba-hexopyranosides by radical ring closure of carbohydrate derived alkynes. Here we report some preliminary results which have resulted on the synthesis of 5a-carba-β-D-mannose pentaacetate **13**. Our general approach, outlined in Scheme 1 for D-mannose, correlates retrosynthetically the methylene group of the carba-pyranoside (*e.g.* **1**) with an exocyclic double bond in a highly functionalized cyclohexane (*e.g.* **2**). The latter could thus be obtained by a 6-*exo-dig* radical cyclization of a carbohydrate derived alkyne (*e.g.* **3**) easily derived from a pyranose 2,3:4,6-diacetonide derivative (*e.g.* **4**).

Accordingly mannose diacetonide **4** (Scheme 2), prepared in one single step from D-mannose by kinetic acetonation,[12] was treated with lithium phenylacetylide to yield, as a very major isomer, diol **5** in 65% isolated yield.† Chemoselective protection of the prop-2-ynylic hydroxy group could be accomplished by the use of either ethyl chloroformate (**6a**, 60%)[13] or TBDMSCl (**6b**, 65%).‡ The hydroxy group at C-5 in **6a**, or **6b**, was next treated with phenyl chlorothioformate[14] to furnish derivatives **7a** (85%) and **7b** (80%), respectively, which upon reaction with Bu_3SnH and AIBN[15] (toluene, 90 °C, 0.02 M) afforded tricyclic derivatives **8**§ and **9**§ in 95% combined yield. The synthetic scheme was next continued with compound **8b**§ [two isomers: δ 2.89 (ddt, $J_{4,5}$ = $J_{5,6ax}$ = 10.8 Hz, $J_{5,6eq}$ = 4.5 Hz, $J_{5,Holef}$ = 2.8 Hz, H-5 one isomer), 2.48 (ddt, $J_{4,5}$ = $J_{5,6ax}$ = 11.1 Hz, $J_{5,6eq}$ = 5.1 Hz, $J_{5,Holef}$ = 2.3 Hz, H-5 other isomer)]. Accordingly, after a change in the protecting group at



Scheme 1



Scheme 2 *Reagents and conditions*: i, PhC≡CLi, THF, −78 °C; ii, $ClCO_2Et$, Py, CH_2Cl_2, 0 °C; iii, TBDMSCl, Et_3N, DMAP, CH_2Cl_2; iv, ClC(S)OPh, Py, MeCN, 85 °C, 1 h; v, Bu_3SnH, AIBN, toluene (0.02 M), 90 °C; vi, TBAF, THF; vii, HNa, Bu_4NI, BnBr; viii, O_3, MeOH–CH_2Cl_2 (1:1), −78 °C, then Me_2S; ix, BH_3·SMe_2, THF; x, HNa, CS_2, MeI; xi, Bu_3SnH, AIBN, toluene, 90 °C; xii, H_2, Pd/C, MeOH; xiii, AcOH–THF–H_2O (4:2:1), 60 °C; xiv, Ac_2O, Py.

C-1 in **8b** (OTBDMS→OBn), ozonolysis was carried out to yield ketone **10**, which upon reduction ($BH_3 \cdot SMe_2$) gave, in a stereoselective manner, the highly functionalized cyclohexane **11** ($J_{5a,1}$ = 3.8 Hz) (75%, three steps). The hydroxy function at C-5a was deoxygenated under radical conditions, *via* its xanthate,[14,15] to afford 5a-carba-D-mannopyranoside derivative **12** (85%, two steps). Hydrolysis of the acetals followed by hydrogenation and acetylation gave 5a-carba-β-D-mannose pentaacetate **13**[16]¶ (87%, three steps).

In our opinion, several aspects of the synthetic scheme deserve further comment: (i) the choice of a 2,3:4,6-diacetonide derivative has reduced the protecting group manipulations in the synthetic scheme to a minimum; (ii) the selection of a phenylacetylide as the radical acceptor was made on the basis of the beneficial effects of the phenyl group in alkyne cyclizations;[17,18] (iii) unlike other approaches to carba-sugars from carbohydrates,[8,9] in this synthetic scheme an hexose is correlated with its corresponding carba-pyranoside; (iv) the present method permits access to fully functionalized cyclohexanes (*e.g.* **11**) of potential interest in the synthesis of biologically active compounds;[4] (v) by changing the protecting group of the hydroxy function α to the radical acceptor some stereocontrol has been attained in the cyclization reaction in favor of the isomer with *trans* 6,6-ring fusion[19] (**8**, Scheme 2); (vi) similar chemistry carried out on **9a** or **9b** would allow access to 5a-carba-α-L-gulopyranose.

In conclusion we have disclosed a novel entry into functionalized cyclohexane derivatives and carba-sugars from monosaccharides by 6-*exo-dig* cyclization of alk-6-ynyl radicals. Our approach complements the one recently described by Maudru *et al*.[9] in the sense that it allows for functionalization at all positions of the cyclohexane ring. The application of this synthetic scheme to other pyranose derived diacetonides is currently under study.

Notes and references

† Compound **5** was the major isomer observed in the crude reaction mixture and could be easily separated by chromatography. The stereochemistry at C-1 was probed at a later stage on the synthesis. The corresponding epimer at C-1 was also observed (> 4:1 ratio) together with some isomeric 2,3:5,6-diacetonides (^{13}C NMR).

‡ Compounds resulting from the reaction of both hydroxy groups were always present, in yields ranging from 10–15%, and could be easily separated by chromatography.

§ Compounds **8a** and **8b** existed as two isomers (*ca.* 1:1 ratio), corresponding to the orientation of the phenyl group in the exocyclic double bond. Conversely, only one isomer at the phenyl group was observed for the *cis*-fused products **9a** and **9b**.

¶ The spectral properties (^1H NMR, C_6D_6, 400 MHz) were in accord with those reported in the literature (ref. 16): $[\alpha]_D$ +2.0 (*c* 0.6, $CHCl_3$), lit.,[16a] +2.9 (*c* 1.1, $CHCl_3$); lit.,[16b] +2.53 (*c* 1.67, $CHCl_3$); lit.,[16c] +2.9 (*c* 1.28, $CHCl_3$).

Structural isomers of $M(dca)_2$ molecule-based magnets. Crystal structure of tetrahedrally coordinated sheet-like β-$Zn(dca)_2$ and β-$Co/Zn(dca)_2$, and the octahedrally coordinated rutile-like α-$Co(dca)_2$, where dca^- = dicyanamide, $N(CN)_2^-$, and magnetism of β-$Co(dca)_2$

Received (in Cambridge, UK) 10th November 1998, Accepted 15th December 1998

β-$Zn(dca)_2$ and 0.12% Co(II) doped β-$Zn(dca)_2$ contain tetrahedrally coordinated metal ions within a corrugated sheet network structure [dca = dicyanamide, $N(CN)_2^-$], β-$Co(dca)_2$ is a spin-canted antiferromagnet (T_N = 9 K), while the rutile-like octahedral α-form is a ferromagnet.

We have recently described an important new class of molecule-based magnets of type $M(dca)_2$ which possess a rutile-like single net structure.[1] In this α-structural type, the metal ions are octahedrally coordinated to six dicyanamide (dca) ligands *via* the nitrile and amide N-donor atoms, each dca therefore being a 3-connector. The Co(II) and Ni(II) compounds are ferromagnets, with T_c = 9 and 20 K respectively, while the Cu(II) compound is a near-paramagnet, with Jahn–Teller distorted Cu–N(amide) bond lengths. α-$Mn(dca)_2$ and α-$Fe(dca)_2$ are spin-canted antiferromagnets with T_N values of 16 and 19 K, respectively.[2] Kepert and Kurmoo[3] and Miller and Epstein and coworkers[4] have subsequently reported some of the same α-type compounds. Here, we describe a structural isomer of the β-type in which the metal ions are each tetrahedrally coordinated to four dca ligands *via* nitrile N-donor atoms to form an infinite sheet structure. This structure has been refined for colourless crystals of β-$Zn(dca)_2$ and for deep blue crystals of Co(II) doped β-$Zn(dca)_2$. As indicated earlier by Köhler,[5] the blue β-$Co(dca)_2$ phase can be prepared by removal of pyridine from $Co(dca)_2(pyridine)_2$. We report here antiferromagnetic coupling and magnetic order in β-$Co(dca)_2$ prepared in this way and compare these to the magnetic behaviour observed in the ferromagnetic α-isomer.

β-$Zn(dca)_2$ was prepared by reaction of $Zn(NO_3)_2{\cdot}6H_2O$ with sodium dicyanamide in water in a 1:2 mole ratio. Colourless crystals were obtained by slowly diffusing the reagents together. The 0.12% Co(II) doped crystals were prepared by mixing hot aqueous solutions of $Zn(NO_3)_2{\cdot}6H_2O$ and $Co(NO_3)_2{\cdot}6H_2O$ with one of Na(dca). Deep blue crystals formed from the pink solution. Doubling of some of the C–N bands from coordinated dca occurs in the IR spectrum probably because of the presence of two structurally distinct dca ligands in $Zn(dca)_2$ and in $Co/Zn(dca)_2$.†

The structures of α-$Co(dca)_2$, β-$Zn(dca)_2$ and 0.12% β-$Co/Zn(dca)_2$ were solved by single-crystal X-ray crystallography. The structure of α-$Co(dca)_2$ is isomorphous with the other members of the α-$M(dca)_2$ compounds discussed above.[1–4] It possesses a rutile-like structure with octahedral cobalt ions and three-connecting dca ligands [Co-N(nitrile) 2.092(2) Å, Co–N(amide) 2.150(3) Å].‡ These values are obviously much closer together than in the Jahn–Teller distorted Cu [1.975(1) and 2.478(2) Å, respectively],[1] and are shorter than those found in Mn [2.189(1) and 2.290(2) Å].[2] In all three structures the metal–amide bonds are longer than the metal–nitrile bonds.

As both β-isomer structures are isomorphous, we will discuss only the $Zn(dca)_2$ structure in detail.‡ The structure consists of tetrahedral Zn atoms [N–Zn–N 108.05(9)–111.9(2)°]bridged by two-connecting dicyanamide ligands [Zn–N 1.958(4), 1.936(4) and 1.960(3) Å]. The kinked nature of the dca bridge, aided by some bending at the coordinating nitrogen donors [C–N–Zn 155.3(3), 165.4(4) and 171.9(4)°], allows the tetrahedral ions to be bridged into a corrugated square-grid sheet structure (Fig. 1). The sheets stack in the direction of the *c* axis and are interdigitated. As a result, the shortest Zn···Zn distances (4.447 Å) are between sheets, with the intrasheet Zn···Zn distances (*via* the dca bridges) being 7.584 and 7.606 Å. The structure of the 3D rutile-like α isomer is obviously markedly different to the 2D sheet structure for the β isomer described here. The former contains octahedral metal ions and three-connecting dca ligands, while the latter contains tetrahedral metal ions and two-connecting dca ligands (*i.e.* the amide nitrogens do not coordinate).

The structures described above of β-$Zn(dca)_2$ were determined at 123 K. The room temperature structure was also determined,‡ and found to possess a different space group (*Cmcm*, *vs Pnma* at 123 K). Further investigation showed a reversible phase change occurring between 210 and 220 K. A second phase change occurred at 120 K which resulted in fragmentation of the crystal. The topology and connectivity of the structure in the room temperature phase is the same as in the 123 K phase. The phase change arises due to ordering of one of the two crystallographically unique dca ligands (dca1). At room temperature dca1 is disordered over two positions, which are related by a mirror plane. The ligand 'leans over', with its mean plane making an angle of 16.6° to this mirror plane (on which lie the metal atoms and nitrile nitrogen atoms of dca1). The mirror plane arises because the lean of dca1 is disordered equally between the two alternative directions. In the 123 K structure, however, this ligand becomes ordered, with all the dca1 ligands in a sheet tilting in the one direction only, and the mirror plane symmetry is lost.

The deep blue β-$Co(dca)_2$ was produced by depyridination under vacuum of $Co(dca)_2(pyridine)_2$.[5] Although the powder was largely amorphous and diffracted extremely weakly, the pattern was suggestive of being isomorphous with β-$Zn(dca)_2$. The visible spectra (diffuse reflectance) of neat β-$Co(dca)_2$ and of Co doped $Zn(dca)_2$ are identical thus indicating that the tetrahedral coordination geometry around Co(II) is the same; λ_{max}/nm 602, 565(sh), 483w (sh). Upon exposure to the

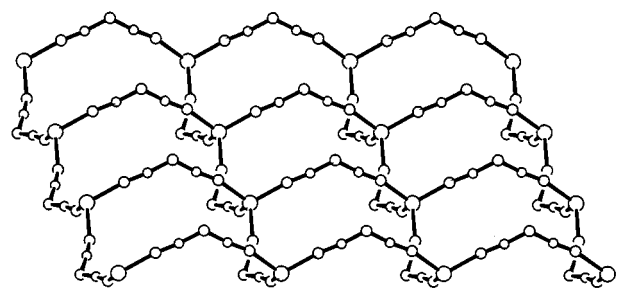

Fig. 1 The puckered, square-grid sheets of β-$Zn(dca)_2$.

atmosphere, the powder turns from blue to pink. Again, although the diffraction was very weak, the X-ray powder diffraction pattern was suggestive of the presence of the rutile-like α-Co(dca)$_2$. The diffuse reflectance visible spectra was also now reminiscent of the α phase; λ_{max}/nm = 1131(br), 510, 481.

The magnetic moment, per mol of Co, of the 0.12% Co(II) doped Zn(dca)$_2$ sample remains constant at 4.6 μ_B over the range 300–15 K. This was anticipated for a magnetically dilute tetrahedral d^7 ion having a $^4A_2$ ground state influenced by spin–orbit coupling. Together with the lack of any observed long-range order under small applied-fields, the data are consistent with random doping of the diamagnetic Zn(II) sites by Co(II), much like traditional doping into zinc oxide hosts. In contrast, the magnetic properties of neat β-Co(dca)$_2$ are indicative of antiferromagnetic coupling and a magnetic phase change occurring at *ca*. 9 K, due to spin canted antiferromagnetism (weak ferromagnetism). This contrasts markedly with α-Co(dca)$_2$ which displays a ferromagnetic transition, also at 9 K.[1] In a magnetic field of 1 T, the effective magnetic moment, per Co, of the β-isomer decreases a little from 4.55 μ_B at 300 K to 4.3 μ_B at 22 K before increasing sharply to reach a maximum of 4.45 μ_B, then decreasing rapidly towards 2.39 μ_B at 2 K (Fig. 2). The corresponding χ values show small deviation from Curie-Weiss behaviour above 25 K with $\theta = -4.5$ K [*cf.* α-Co(dca)$_2$, $\theta = +6.1$ K]. Long range magnetic order is clearly evident in the magnetisation data measured in small applied fields. It can be seen in Fig. 2 that the field-cooled (FCM) and zero-field cooled (ZFCM) magnetisation values increase rapidly below 9.5 K under fields of 10, 50 and 100 Oe. The temperature at which the FCM and ZFCM data diverge changes a little with field *viz.* 9.0 K (10 Oe), 8.83 K (50 Oe), 8.65 K (100 Oe). The ZFCM data likewise pass through a field-dependant maximum.

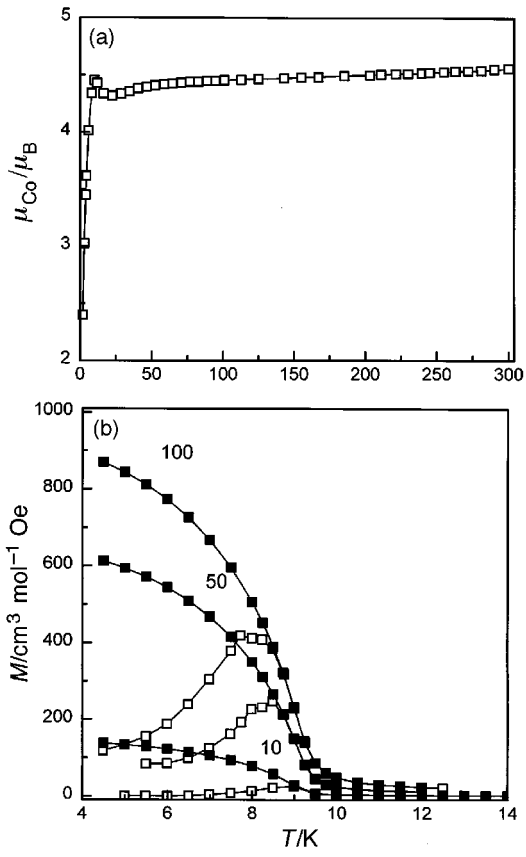

Fig. 2 (a) Plot of μ(per Co) *vs* temperature for β-Co(dca)$_2$ in a field of 1 T. (b) Plots of field-cooled (FCM) (■) and zero-field cooled (ZFCM) (□) magnetisation *vs* temperature for β-Co(dca)$_2$ in fields of 10, 50 and 100 Oe.

A powder sample of β-Co(dca)$_2$ displays hysteresis in magnetisation with a coercive field of 538 Oe and remanent magnetisation of 0.22 $N\mu_B$ at 2 K. High field magnetisation data in fields of up to 5 T show small diversions from linearity without reaching saturation and with a small value of only 2.37 $N\mu_B$ at 5 T. This contrasts markedly with the rapid saturation behaviour noted in the ferromagnetic α-isomer and is indicative of antiferromagnetic coupling. The nature of the ordered state is therefore one of a spin-canted antiferromagnet as was also found in α-Mn(dca)$_2$ and α-Fe(dca)$_2$. Such ordering is becoming increasingly common in homometallic molecular magnets.[2–4,6]

This work was supported by a grant (to K. S. M.) and a fellowship (to S. R. B.) from the Australian Research Council. The help of Mr R. Mackie, Physics Department, Monash University with the powder XRD measurements is gratefully acknowledged.

The carbonylation of methyl iodide and methanol to methyl acetate catalysed by palladium and platinum iodides

Jun Yang, Anthony Haynes and Peter M. Maitlis

The Department of Chemistry, The University of Sheffield, Sheffield, UK S3 7HF. E-mail: P.Maitlis@Sheffield.ac.uk

Received (in Cambridge, UK) 25th November 1998, Accepted 8th December 1998

Palladium(II) salts catalyse the carbonylation of methyl iodide in methanol to methyl acetate (5 atm CO, 140 °C) in the presence of a large excess of iodide, even without amine or phosphine co-ligands; platinum(II) salts show similar reactions but are a little less effective.

The substantial current interest in reactions catalysed by palladium–phosphine or palladium–amine[1,2] complexes prompts us to disclose new data on methanol carbonylation catalysts. We find that palladium(II), in the presence of an excess of iodide, catalyses the carbonylation of methyl iodide in methanol to methyl acetate at 5 atm CO, 140 °C. Under these conditions phosphine or amine co-ligands are not required.

The BP–Monsanto process for making acetic acid, methyl acetate, and/or acetic anhydride from methanol relies in its key (organometallic) steps on the carbonylation of methyl iodide catalysed by a rhodium and iodide system.[3] The *Cativa* process recently developed by BP Chemicals uses a closely related but more effective system based on a promoted iridium/iodide catalyst.[4,5] A number of other catalyst systems have been examined,[6] but because of the economic importance of the process, the search for new catalysts continues.

Although various carbonylation reactions involving palladium complexes have been described, they generally require co-ligands such as amines or phosphines.[7] If they are not present, the process is quickly deactivated with the formation of (inactive) palladium metal.

A palladium catalysed carbonylation of methyl iodide would be expected to comprise a cycle with individual steps similar to those found for rhodium and iridium, and since palladium complexes generally undergo carbonylation, migratory insertion and reductive elimination very easily, the slow rate determining step in the methyl iodide carbonylation cycle is probably the oxidative addition. In rhodium and iridium chemistry this step is enhanced by a more nucleophilic metal centre,[8] which can be achieved for example, by increasing the electron density at the metal with basic ligands. This could account for the reported use of ligands such as bipy in the palladium catalysed carbonylations.

We first investigated methyl iodide carbonylation using chelate N-ligands ('N–N'), including bipyridyl and the very convenient Ar-BIAN ligands [bis(arylimino)acenaphthenes, derived from acenaphthenequinone and an aromatic primary amine, $ArNH_2$, Ar = phenyl, 4-tolyl, *etc.*] which can easily be 'tuned' by changes in the aryl substituents.[2] Reactions related to methanol carbonylation have also been modelled on palladium complexes, for example,[2]

$$[Pd(tmeda)(Me)(OR)] + CO\ (1\ atm,\ 25°C) \xrightarrow{Me_2CO} MeCO_2R + Pd^0\ [tmeda = Me_2NCH_2CH_2NMe_2;\ R = Ph,\ CH(CF_3)_2]$$

but we found no catalytic turnover (< 1 in 16 h) on carbonylating the chelate-iodomethyl complexes, [Pd('N–N')-(Me)(I)] in neat methanol.

However, catalytic reactions occurred in the presence of methyl iodide (Table 1). The complexes [Pd(4-Tol-BIAN)-(Me)(I)], and [Pd(bipy)(Me)(I)], $[Pd(PPh_3)_2Cl_2]$ all gave turnovers in the range 10–20/16 h; the Ar-BIAN ligands were slightly better than bipy, and both were comparable to triphenylphosphine.

Substantial further improvements were achieved on addition of 40–100 equiv. per palladium of either a base or an ionic iodide.† Under our operating conditions the highest turnovers (*ca.* 110/16 h) were found using $[Pd(PPh_3)_2Cl_2]$ and Bu_4NI as additive. Slightly lower turnovers were obtained for other additives such as triethylamine, LiI, and other quaternary ammonium iodides. Higher amounts of a given iodide led to higher turnovers. Addition of small amounts of water (100–500 equiv./Pd) led to decreased turnovers but did not quench the reaction. Separate investigations showed that the role of amines was to generate the quaternary ammonium iodides by reaction with MeI.

When the solution containing $[Pd(PPh_3)_2Cl_2]$ and Bu_4NI was examined by ^{31}P NMR spectroscopy at the end of a catalytic reaction, there was no sign of PPh_3 coordinated to palladium. The only signal (δ 22.2) that could be detected was due to $[PPh_3Me]I$.

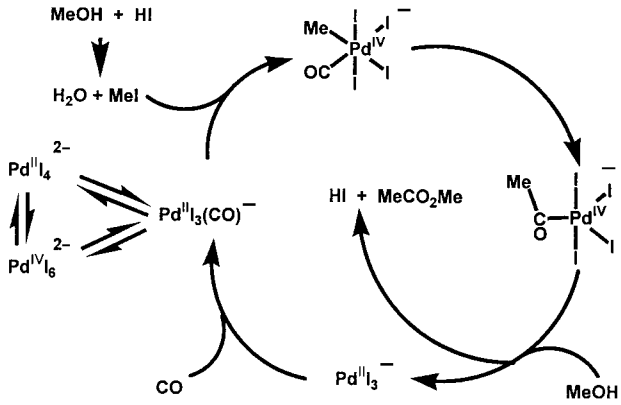
Thus the PPh_3 has become detached during the catalysis. To examine whether the ligand plays an important role, we investigated the catalytic behaviour of simple salts of palladium without any amine or phosphine co-ligands. Palladium iodide proved to be an effective catalyst by itself in the presence of excess iodide (but with no other stabilising ligand), giving a typical turnover of *ca.* 75/16 h.

A rather parallel reactivity sequence was provided by platinum. Again here $[PtI_4]^{2-}$ (formed *in situ*) was effective (turnover *ca.* 70/16 h), as were phosphine and amine complexes $[PtL_2Cl_2]$ [L_2 = $(PPh_3)_2$ > 4-Tol-BIAN ≈ bipy, ≈ $\{P(C_6H_{11})_3\}_2$].‡ Again, ^{31}P NMR examination of the catalyst solution using $[Pt(PPh_3)_2Cl_2]$ at the end of the reaction showed

Table 1 Carbonylation of methyl iodide and methanol to methyl acetate promoted by palladium or platinum complexes and anionic iodide[a]

Catalyst	Iodide additive/mmol	Turnover
[Pd(4-Tol-BIAN)(Me)(I)][b]	—	< 1
[Pd(4-Tol-BIAN)(Me)(I)][c]	—	10 ± 2
[Pd(4-Tol-BIAN)(Me)(I)]	—	20 ± 5
$[PdCl_2(PPh_3)_2]$	—	9 ± 2
$[PdCl_2(PPh_3)_2]$	Bu_4NI (0.4) or $(C_5H_{11})_4NI$ (0.4)	110 ± 5
$[PdCl_2(PPh_3)_2]$	LiI (1) or Et_3N (1)	95 ± 10
$[PdCl_2(PPh_3)_2]$	Bu_4NI (0.4) + water (100–500)	60 ± 5
$[PdCl_4]^{2-}$	Bu_4NI (0.5) or LiI (1)	80 ± 5
$[PdI_2]$	LiI (1)	70 ± 5
$[PtCl_2(PPh_3)_2]$	—	9 ± 2
$[PtCl_2(PPh_3)_2]$	Bu_4NI (0.4)	30 ± 5
$[PtI_4]^{2-}$	Bu_4NI (0.5) or LiI (1)	65 ± 5
$[Ni(NO_3)_2]$	Bu_4NI (0.5) or LiI (1)	15 ± 5
$[NiCl_2(PPh_3)_2]$	Bu_4NI (0.4)	15 ± 5

[a] *Conditions*: catalyst (0.01 mmol), methyl iodide (6 mmol, except where indicated) and iodide (as specified), and methanol (50 mmol) in Fisher–Porter tubes operating at a pressure of 5 atm CO, 140 °C, for 16 h. Analysis of the product (methyl acetate) was by GC (PE 8700; 10 m supel-Q-plot column, FID). Total turnover = number of equivalents of methyl acetate produced per equivalent of catalyst. [b] As *a* above but without any methyl iodide. [c] As for *a* above but with 0.6 mmol methyl iodide.



Scheme 1 A possible catalytic cycle for methanol carbonylation based on Pd^{II}/Pd^{IV}.

the presence of only $[PPh_3Me]I$ (δ 22.2). When K_2PtCl_4 + MeOH + MeI + Bu_4NI + CO (5 atm/16 h/140 °C) was used as the catalyst system, a ν(CO) 2063 cm^{-1} was observed in the IR spectrum of the residue once the volatiles had been removed. This is precisely the wavenumber quoted by Calderazzo and coworkers for $[Pt(CO)I_3]^-$,[9] and suggests that this species is involved in our catalytic cycle. No metal carbonyl was detected at the end of our palladium catalysed reactions, but Calderazzo and coworkers noted that $[Pd(CO)I_3]^-$ readily lost all its CO when the pressure was removed, and thus it is not surprising that we did not observe it.

Palladium catalysed methanol carbonylation, in the presence of very large amounts of specific promoters, such as sulfolane, and preferably an amine (*e.g.* 2,2′-bipyridyl) has been described in patents by van Leeuwen (Shell).[10] Those methanol carbonylation reactions required both quite severe conditions (for example, 182 °C/110 bar CO) and the addition of promoters such as bipyridyl; methanol carbonylation in the absence of such promoters was not claimed and platinum salts were specifically excluded from the Shell patents.

There do not appear to have been any reports of platinum catalysed carbonylations to methyl acetate, though the carbonylation of methanol to methyl formate has been noted,[6] and Kozitsyna and Moiseev reported that an unusual diphenylphosphido–platinum species in the presence of BF_3 did catalyse the carbonylation of methyl acetate to acetic anhydride.[11]

Nickel in the presence of iodide has long been known to catalyse methanol carbonylation, but only under drastic conditions (200–300 atm/230–350 °C).[12] We have tried nickel catalysts under our conditions and find activity but at quite a low level in the presence of 50–100 equiv. of iodide.

In summary, we have shown that, in the presence of excess iodide, palladium and platinum salts catalyse the carbonylation of methyl iodide in methanol to methyl acetate at 5 atm CO, 14 °C. The reactions taking place are best described by,

$$MeI + MeOH + CO \rightarrow MeCO_2Me + HI$$

followed by,

$$HI + MeOH \rightarrow MeI + H_2O$$

Catalytic cycles involving either M^{II}/M^{IV} or M^0/M^{II} (M = Pd, Pt) seem possible and an example of the former is illustrated in Scheme 1. It may be noted that iodide can stabilise Pd^{IV} as in Cs_2PdI_6.[13]

We thank BP Chemicals for support and Dr G. Sunley for carrying out some extra experiments.

Notes and references

† Bromide and chloride were also effective as promoters but less so than iodide.

‡ The ligands do seem to have a (second order) effect on the reaction; for example the tricyclohexylphosphine complexes $[M\{P(C_6H_{11})_3\}_2Cl_2]$ (M = Pd, Pt) are significantly less effective than the corresponding triphenylphosphine complexes. An effect of the counter-cation is also evident. Both these points are currently under investigation.

Unique guest inclusion within multi-component, extended-cavity resorcin[4]arenes

Leonard R. MacGillivray*[a] and Jerry L. Atwood*[b]

[a] *Steacie Institute for Molecular Sciences, National Research Council of Canada, Ottawa, Ontario, Canada K1A 0R6. E-mail: lmacgil@ned1.sims.nrc.ca*

[b] *Department of Chemistry, University of Columbia-Missouri, Columbia, Missouri, 65211 USA. E-mail: chemja@showme.missouri.edu*

Received (in Cambridge, UK) 12th November 1998 Accepted 9th December 1998

Co-crystals involving *C*-methylcalix[4]resorcinarene 1 and substituted pyridines obtained from $MeNO_2$–benzene and MeCN–benzene yields multi-component complexes 1·4(4-picoline)·$MeNO_2$ 2 and 1·4(1,10-phenanthroline)·MeCN·benzene 3 in which the cavity of 1 is extended by four pyridines supramolecularly and the included solvent serves as a guest.

There is currently a great deal of interest in utilizing noncovalent forces for the construction of multi-component host frameworks (*e.g.* molecular capsules) that display recognition properties analogous to their monomolecular predecessors (*e.g.* carcerands).[1–3] These frameworks typically involve replacing covalent bonds with supramolecular synthons that retain the structural integrity of the parent host molecule. Notably, in addition to providing access to systems which are difficult to obtain using conventional molecular synthesis,[3] such frameworks can display properties not found in the molecular analog (*e.g.* reversible formation)[4] which, in some instances, can bear relevance in understanding related biological phenomena (*e.g.* virus formation).[5]

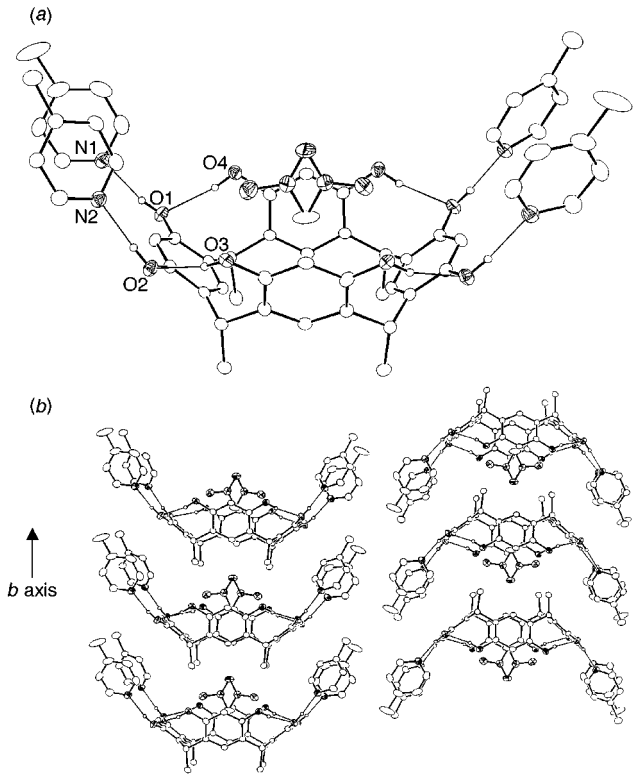

Fig. 1 ORTEP perspective of (*a*) the six-component assembly **2**, and (*b*) self-inclusion displayed by **2**. Selected interatomic distances (Å): O(1)···O(4) 2.840(3), O(1)···N(1) 2.740(3), O(2)···O(3) 2.806(3), O(2)···N(2) 2.704(3).

Along these lines, we have recently shown that it is possible to extend the cavities of resorcin[4]arenes (*e.g. C*-methylcalix[4]resorcinarene **1**) supramolecularly using aromatic-based hydrogen bond acceptors.[2] Our initial attempt at a discrete system, **1**·4(py)·py (py = pyridine), consisted of six molecules comprised of two different components in which four molecules of py participate in four O–H···N hydrogen bonds, as two stacked dimers, along the upper rim of **1**, to form a cavity large enough to host a fifth py. Here, we now demonstrate that it is possible to isolate a guest within a discrete supramolecular cavity based upon **1**, in **1**·4(4-pic)·$MeNO_2$ **2** (4-pic = 4-picoline), which is different than that of the 'substituents' hydrogen bonded to the upper rim of the macrocycle. By employing similar conditions used to form **2**, we also demonstrate that is possible to expand the chemistry of these systems to a chelating agent, 1,10-phenanthroline (1,10-phen), in **1**·4(1,10-phen)·MeCN·benzene **3**, which assembles to form both conventional and bifurcated O–H···N hydrogen bonds along the upper rim of **1**. Such observations are important since, in addition to showing that it is possible to fully mimic host–guest properties of monomolecular calix[4]arenes supramolecularly, they confirm generality in this approach with respect to both upper rim substitution and guest inclusion.

Addition of **1** (0.020 g) to a boiling aliquot of 4-pic (2 ml) yielded a yellow precipitate. Attempts to grow crystals of this material suitable for single crystal X-ray analysis failed. The precipitate was then heated and $MeNO_2$ (3 ml) followed by benzene (2 ml) were added dropwise, with continuous heating, according to eqn. (1), until the solid dissolved. Yellow crystals of **2** suitable for X-ray analysis formed, upon cooling, within a day. The formulation of **2** was confirmed by single crystal X-ray analysis† and ^{1}H NMR spectroscopy.

1 + 4-pic (excess) + $MeNO_2$ (excess) + benzene (excess) → **1**·4(4-pic)·$MeNO_2$ **2** (1)

A view of the six-component complex **2** is shown in Fig. 1(*a*). In a similar way to **1**·4(py)·py,[2] four molecules of 4-pic have assembled along the upper rim of **1** such that they form stacked dimers and participate in four O–H···N hydrogen bonds with two opposite resorcinol units of **1** [O···N separations (Å): O(1)···N(1) 2.740(4), O(2)···N(2) 2.704(4)]. Unlike **1**·4(py)·py, however, the cavity created by the five molecules is occupied by a guest which is different than the walls of the host. Specifically, a molecule of $MeNO_2$, which lies disordered across a crystallographic two-fold rotation axis, has assembled within **1** and interacts with **1** *via* C–H···π-arene interactions. Thus, by selecting a guest with an appropriate size, shape, and chemical exterior to assemble within **1**·4(4-pic), full structural mimicry, in a single step and virtually quantitative yield, of those host–guest properties displayed by upper rim substituted monomolecular calix[4]arenes has been achieved.[9] In other words, this approach to discrete, extended cavity frameworks based upon **1** is not limited to two component **1**·4(pyr)·pyr (where pyr = pyridine, substituted monopyridines) systems.[2]

A view of the crystal structure of **2** is shown in Fig. 1(*b*). Unlike **1**·4(py)·py, **2** self-assembles in the solid state such that

the complexes self-include and lie in an antiparallel fashion along the crystallographic *b* axis. Indeed, the ability of **2** to exhibit self-inclusion may be attributed to the small size the $MeNO_2$ guest which, unlike **1**·4(py)·py, allows neighbouring molecules of **1** to assemble within the cavities created by the 4-pic moieties.‡

That this approach to discrete extended cavity frameworks based upon **1** may be expanded to a system involving a bifurcated hydrogen bond and a different guest is demonstrated by **3**. When **1** (0.020 g) was added to a boiling aliquot of MeCN (4 ml) in the presence of 1,10-phen (0.027 g) a white microcrystalline solid formed. Attempts to grow single crystals of this material suitable for single crystal X-ray analysis failed. Colorless crystals of **3** suitable for X-ray analysis were obtained by redissolving the solid, by heating, in the presence of benzene (2 ml), according to eqn. (2), and allowing the solution to slowly cool. The formulation of **3** was confirmed by single crystal X-ray analysis§ and ^{1}H NMR spectroscopy.

1 + 4(1,10-phen) + MeCN (excess) + benzene (excess) → **1**·4(1,10-phen)·MeCN·benzene**3** (2)

A view of the seven-component complex **3** is shown in Fig. 2. In a similar way to **2**, four molecules of 1,10-phen have assembled along the upper rim of **1** and lie approximately orthogonal to two opposite resorcinol units of the macrocycle. Unlike **2**, however, in addition to conventional O–H···N forces, the phenanthroline moiety interacts with **1** *via* a bifurcated hydrogen bond. In particular, three phenanthroline units participate in conventional O–H···N hydrogen bonds [O···N separations (Å): O(1)···N(1,2) 2.77(1), 3.20(1); O(2)···N(3,4) 2.67(1), 3.38(1); O(5)···N(5,6) 2.73(1), 3.40(1)] while a fourth participates in a bifurcated interaction [O···N separations (Å): O(6)···N(7,8) 2.77(1), 3.00(1)]. Interestingly, in the case of the former, the longest O···N separations are associated with the 'outer' region of the upper rim of **1** while, in the case of the latter, the longest distance is associated with the 'inner' region. As a consequence of these forces, a cavity has formed, inside which a molecule of MeCN is located, interacting with **1**, in a similar way to the $MeNO_2$ guest of **2**, *via* C–H···π-arene interactions.¶ The molecule of benzene, which completes **3**, is then observed to lie sandwiched between two opposite phenanthroline moieties, in a region above a resorcinol unit of **1**, such that the aromatic participates in two edge-to-face π–π interactions with the bipyridines.[10] To the best of our knowledge, in addition to **3**, an assembly involving 'resorcinol' and a chelating agent such as 1,10-phen has not been observed.

In a similar way to **1**·4(py)·py,[2] **3** self-assembles in the solid state such that the cavities of **1** lie at approximately right angles to each other. Thus, in a similar way to the guest of **1**·4(py)·py, the 1,10-phen moieties, owing to their size and location above **1**, preclude self-inclusion of **1** as observed in **2**.

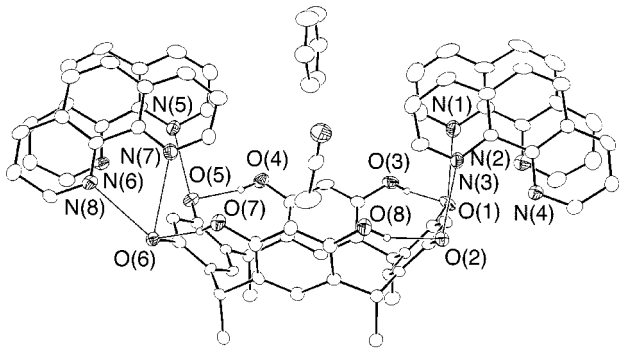

Fig. 2 ORTEP perspective of the seven-component assembly **3**. Selected interatomic distances (Å): O(1)···O(3) 2.73(1), O(1)···N(1) 2.77(1), O(1)···N(2) 3.20(1), O(2)···O(8) 2.76(1), O(2)···N(3) 2.67(1), O(2)···N(4) 3.38(1), O(4)···O(5) 2.75(1), O(5)···N(5) 2.73(1), O(5)···N(6) 3.40(1), O(6)···O(7) 2.78(1), O(6)···N(8) 2.77(1), O(6)···N(7) 3.00(1).

The results reported herein demonstrate that by using appropriately functionalized molecular components, it is possible to mimic host–guest properties of calix[4]arenes supramolecularly with respect to both upper rim substitution and guest inclusion. With these observations realized, focus can be placed upon determining if mimicry of those methods that involve sterochemical control to extending the cavity of **1** (*e.g.* C_4 *vs.* C_{2v}) can be achieved.[11] If one also considers that this approach stemmed from a crystal engineering design strategy,[12] such observations attest to the utility in using a supramolecular synthon, such as the resorcinol-based system[13] employed here, for rational solid state design.

We are grateful for funding from the National Science Foundation and the Natural Sciences and Engineering Research Council of Canada (doctoral scholarship, L. R. M.).

Observations on the versatility of methylenecyclopropanes as olefinic components in the intramolecular Pauson–Khand reaction

Hervé Corlay,[a] Eric Fouquet,[b]† Emmanuel Magnier[b] and William B. Motherwell*[b]

Received (in Cambridge, UK) 21st September 1998, Accepted 9th December 1998

Cyclopropyl tethered methylenecyclopropanes can function in the intramolecular Pauson–Khand reaction either as simple alkene components, or give rearranged hydroindenones in which neither of the two carbon atoms of the alkyne component form part of the cyclopentenone unit in the product.

Extensive and elegant studies by Binger[1] have established that transition metal mediated reactions of alkylidenecyclopropanes with olefinic and acetylenic acceptors provide a valuable method for cyclopentanoid construction. The essentially contemporaneous introduction of the intramolecular variant by ourselves[2a] and by the Nakamura group[2b] has led, *via* a series of systematic studies using both nickel(0) and palladium(0) catalysts,[2] to greatly improved levels of regiocontrol, and recent detailed stereochemical studies by Lautens[2h] have further enhanced the synthetic potential of this methodology.

Within this framework, it was therefore of interest to extend our studies to encompass the intramolecular variant of the highly useful Pauson–Khand reaction[3] using such substrates. Our primary objective, as encapsulated in Fig. 1(*a*), was to attach the tethering chain to the cyclopropyl unit, and hence to examine the possibility of generating highly strained tricyclic systems. During the course of our own work, a systematic study describing the contrasting tethering connectivity implied in Fig. 1(*b*) has been published.[4] In this latter case, however, as in the similarly precedented concept of using the enhanced reactivity of an allylidene cyclopropane as the diene component in Diels–Alder reactions,[5] a spiro fused cyclopropyl adduct is necessarily formed.

In the first instance, we elected to study the behaviour of the readily prepared[2f,g] methylenecyclopropanes **1a** and **1b** using octacarbonyldicobalt and the mild amine *N*-oxide protocol developed by Schreiber[6] (Scheme 1). The obtention of the

tricyclic adducts **2a** and **2b** confirmed the validity of this approach and the isolation of **2b** as a single diastereoisomer also established, as expected, that the *trans* stereochemistry of the substituents around the methylenecyclopropane was preserved in the cycloaddition product.

We were therefore encouraged to extend the scope of this approach to the methylenecyclopropane **1c**, in which the additional methyl group was expected to lead to the formation of the adducts **2**, containing two contiguous quaternary carbon centres (Table 1). In the event, under the previously described reaction conditions, the anticipated tricyclic product **2c** was not formed, and initial spectral data clearly indicated that cyclopropyl ring opening had occurred to give a bicyclic hydroindenone derivative containing an exocyclic carbon–carbon double bond. The full complexity of this bizarre rearrangement and the precise structures **3** of the rearranged cycloadducts were only revealed however through a careful systematic study of further substrates **1d–f** in which the progressive incorporation of additional substituents on the cyclopropyl ring and on the alkyne provided regio- and stereo-chemical markers to trace the outcome of the reaction in terms of carbon atom connectivity (Table 1, entries 1–4). The relative location and stereochemistry of the substituents in cycloadducts **3c–f** was rigorously established using a combination of 2D NMR, NOESY and

HMBC experiments. Thus, careful scrutiny of structures **3** uncovers the remarkable fact that *neither* of the two carbon atoms of the tethered alkyne have been incorporated into the cyclopentenone unit of the final product in this intramolecular variant of the Pauson–Khand reaction. It was also of interest to note that cyclisation proceeded smoothly using the all-carbon tethering chain in the terminal alkyne **1f**, thereby providing a concise route to the usefully functionalised bicyclo[4.3.0]non-1-en-3-one **3f** (entry 4). From both a mechanistic and preparative standpoint the preservation of the original cisoid geometry of the substituents (R and CH_3) around the cyclopropyl ring in the rearranged adducts is also significant, as is the fact that **3e** was isolated as a single geometrical isomer, most probably of *E* configuration.

Finally, from a preparative standpoint, we have also been able, through a judicious choice of experimental conditions, to suppress the rearrangement pathway, and hence to redirect the course of the reaction towards the formation of our originally desired tricyclic systems, as shown for the prototypical substrates **1c**, **1d** and **1e** (Table 1, entries 5, 6 and 7).

From the foregoing examples, it is clear that the presence of the additional methyl group is necessary in order to isolate the skeletally rearranged products **3**. While detailed mechanistic speculation is premature at this stage, it seems reasonable to postulate that the formation of the standard metallacycle **4** (Scheme 2) occurs in all cases as an early common intermediate. At lower temperatures and preferably in the presence of a more coordinating cosolvent such as THF, the major reaction pathway then follows the normal sequence of events to give products of type **2**. At higher temperatures in refluxing benzene, however, the relief of strain in those substrates possessing the additional methyl group engenders rearrangement. A formal mechanistic rationale involves 'edge' attack[7] on the proximal bond of the cyclopropyl ring by the suitably aligned neighbouring cobalt atom (Co_B) to give a π-allyl complex whose protonolysis on the sp^2 carbon would lead to the cation **5**. Such an opening would proceed with retention of configuration at the migrating terminus. Formation of the metallacycle **6** followed by proton loss to liberate the diene system then leads to **7** which can either rearrange or formally be considered as an equivalent of the necessary metallacyclic framework **8** for insertion of carbon monoxide and reductive elimination to afford products of type **3**.

The inherent reactivity of the methylenecyclopropane unit in the present intramolecular variant of the Pauson–Khand reaction can therefore be harnessed, by virtue of controlling a bifurcated reaction pathway, either for the construction of tricyclic systems with preservation of the cyclopropyl ring, or for the preparation of heavily functionalised and stereochemically complex bicyclo[4.3.0]non-1-en-3-one derivatives.

We acknowledge the Centre National de la Recherche Scientifique (CNRS) and the Royal Society for the award of a Fellowship (to E. F.), Atochem for the provision of a studentship (to H. C.) and the Ministère des Affaires Etrangères for a Bourse Lavoisier (E. M.). We also thank Drs W. J. Kerr, D. A. Widdowson and especially Dr P. Kočovský for very helpful mechanistic discussions. We are also grateful to the University of London Intercollegiate Research School (ULIRS) for mass spectral measurements.

A remarkably stable indium trihydride complex: synthesis and characterisation of $[InH_3\{P(C_6H_{11})_3\}]$

David E. Hibbs, Cameron Jones* and Neil A. Smithies

Department of Chemistry, University of Wales, Cardiff, PO Box 912, Park Place, Cardiff, UK CF1 3TB. E-mail: jonesca6@cardiff.ac.uk

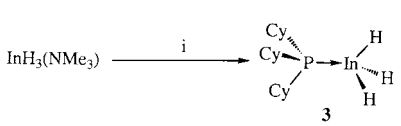
Received (in Cambridge, UK) 27th November 1998, Accepted 15th December 1998

The reaction of $[InH_3(NMe_3)]$ with $P(C_6H_{11})_3$ affords the first example of a phosphine–indium trihydride complex, $[InH_3\{P(C_6H_{11})_3\}]$, which exhibits remarkable thermal stability; the X-ray crystal structure of the complex is described.

The utility of Lewis base adducts of AlH_3 and GaH_3 as chemical vapour deposition precursors to thin films of the group 13 metal[1] or semiconducting materials[2] has led to their chemistry being extensively studied over the last decade.[3] Until very recently no corresponding InH_3 complexes were known, presumably because of thermal instability that arises from the weakness of the In–H bond. We have reversed this situation with the syntheses of $[InH_3\{CNPR^iC_2Me_2NPr^i\}]$ **1** and $[InH_3(NMe_3)]$ **2**,[4,5] the former being stabilised by coordination to a highly nucleophilic 'Arduengo' carbene. Despite this, **1** is not stable in the solid state above −5 °C (decomp. > −20 °C in solution) and **2** is only stable in dilute solutions below −30 °C. It seems likely that if InH_3 complexes are to find similar applications to their aluminium and gallium counterparts, then examples will need to be found that are stable at room temperature. Herein we report the synthesis and structural characterisation of such a compound, $[InH_3(PCy_3)]$ **3** (Cy = cyclohexyl), which represents the first example of a phosphine adduct of InH_3, and the first InH_3 complex to have had its hydride ligands located by X-ray crystallography.

Treatment of an ethereal solution of $[InH_3(NMe_3)]$[5] with 1 equiv. of PCy_3 at −40 °C led to the high yield formation (71%) of **3** after recrystallisation from toluene (Scheme 1). Interestingly, **3** could not be formed from the direct reaction of PCy_3 with $LiInH_4$ (LiH elimination) which is in contrast to the high yield preparation of $[GaH_3(PCy_3)]$ **4** from the reaction of $LiGaH_4$ and PCy_3 in diethyl ether.[6] In addition, there was no evidence for the formation of **3** from the reaction of a 1 : 1 mixture of PCy_3 and anhydrous HCl with $LiInH_4$ in diethyl ether at −40 °C {*cf.* the formation of $[AlH_3(PCy_3)]$ **5** by a similar route[7]}.

Compound **3** is remarkably thermally stable and decomposes in the solid state only at temperatures in excess of 50 °C to indium metal, hydrogen gas and PCy_3 (*cf.* **4**, decomp. > 130 °C;[6] **5**, decomp. > 160 °C[7]). At room temperature (25 °C) crystalline samples of **3** showed only minimal decomposition over a period of 7 days under an argon atmosphere, as determined from the ^{1}H NMR of the sample after that period. Surprisingly, **3** also displays considerable stability to oxygen and moisture in the solid state as it shows no decomposition in air over 24 h at room temperature. In benzene solutions samples of **3** are less stable but still take *ca.* 1 h to decompose at 25 °C. As has been suggested for **4** and **5**, the unusual stability of **3** can probably be attributed to the steric properties of the phosphine ligand.



3

Scheme 1 *Reagents and conditions*: i, PCy_3, $-NMe_3$, Et_2O, −40 °C, 2 h.

The solution NMR data† for **3** support its proposed structure. Its ^{1}H NMR spectrum exhibits the expected resonances for the phosphine ligand in addition to a broad hydride resonance that integrates for three hydrogens at δ 5.61 (*cf.* δ 5.58 in **1**[4,5]) which is significantly downfield with respect to the related resonances in **4** (δ 4.32[6]) and **5** (δ 4.25[7]). The ^{31}P NMR spectrum of **3** displays a singlet at δ 7.43 which can be compared to δ 11.1 for the free ligand.[7] A strong, broad In–H stretching absorbance was observed at 1661 cm^{-1} (*cf.* 1640 cm^{-1} for **1**[5]) in its IR spectrum (Nujol mull). This is at a lower frequency than the corresponding M–H stretches in **4** (1800 cm^{-1})[6] and **5** (1750 cm^{-1})[7] and reflects the relative weakness of the M–H bonds in **3**. No molecular ion was seen in the mass spectrum of **3** but a fragment corresponding to the free phosphine ligand was observed.

An X-ray crystal structure analysis‡ of **3** (Fig. 1) was carried out and it was found to be isomorphous to its aluminium and gallium counterparts, **5** and **4**, respectively. The quality of the X-ray data allowed the three hydride ligands to be located from difference maps and their positional and isotropic thermal parameters to be refined. The complex is monomeric and shows no evidence of intermolecular interactions through bridging hydrides. As in **4**, the metal centre has a slightly flattened tetrahedral geometry [P–In–H 101.4° (av.), H–In–H 116.2° (av.)] with an average In–H distance of 1.68 Å. This distance compares well with the only other structurally characterised terminal In–H bond in a neutral complex, *viz.* 1.69(3) Å in $[InH\{2\text{-}Me_2NCH_2(C_6H_4)\}]_2$.[8] Not surprisingly both these distances are shorter than bridging In–H distances, *e.g.* 1.87 Å (av.)

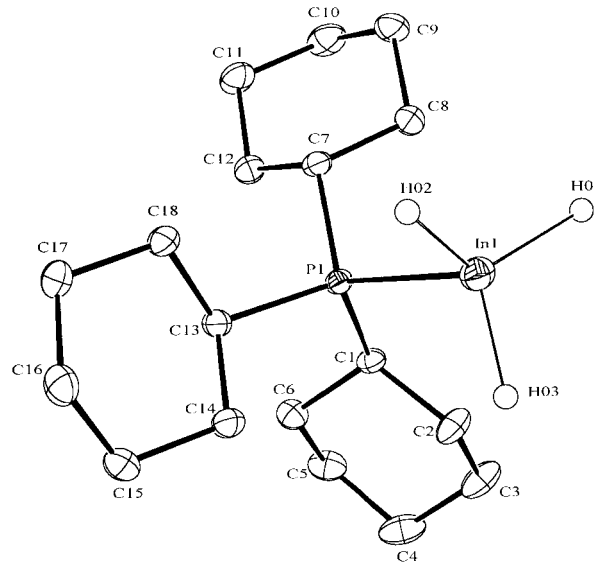


Fig. 1 Molecular structure of $[InH_3\{P(C_6H_{11})_3\}]$ **3**. Selected bond lengths (Å) and angles (°): In(1)–P(1) 2.6474(6), In(1)–H(01) 1.81(2), In(1)–H(02) 1.62(3), In(1)–H(03) 1.62(3), P(1)–C(13) 1.8433(17), P(1)–C(7) 1.8448(17), P(1)–C(1) 1.8632(17); P(1)–In(1)–H(01) 103.4(7), P(1)–In(1)–H(02) 97.3(11), P(1)–In(1)–H(03) 103.6(11), H(01)–In(1)–H(02) 121.3(13), H(01)–In(1)–H(03) 111.0(13), H(02)–In(1)–H(03) 116.4(16).

in $[Li(tmeda)_2][Me_3In–H–InMe_3]$.[9] The In–P distance in **3** [2.6474(6) Å] is in the normal region for such interactions though is slightly longer than In–P distances in four co-ordinate tertiary phosphine adducts of indium halides, *e.g.* 2.569 Å in $[InI_3(PPr^i_3)]$[10] and 2.603 Å in $[InI_3(PPh_3)]$.[11]

The remarkable thermal stablity of **3** has prompted us to begin an investigation of its chemistry and the preparation of a range of related phosphine– and arsine–indium hydride complexes. The results of these investigations will form the basis of a later publication.

We gratefully acknowledge financial support from the EPSRC (studentship for N. A. S.).

Unexpected formation of 3,3a,4,7a-tetrahydrobenzofuran-2,5-diones as well as arene carboxylic acids upon formal double *exo* nucleophilic addition of $R^1R^2C^-COO^-$ to anisolechromium tricarbonyl complexes

Received (in Liverpool, UK) 16th November 1998, Accepted 30th November 1998

Bis(trimethylsily)ketene acetals of the general structure 2 (R^1 = H, Me, R^2 = Me, Et, Pr^i, CMe = CH_2) react at −78 °C in the presence of Bu^{t}OK with a series of arenechromium tricarbonyl complexes 3 to give as expected, after oxidation with I_2 followed by silica gel chromatography, arylcarboxylic acids 7. In the case of anisolechromium tricarbonyl 8, besides the *m*-methoxyarylcarboxylic acids, tetrahydrobenzofuran-2,5-diones 11, are formed as the result of a double nucleophilic addition.

Complexation of an arene group to $Cr(CO)_3$ allows, *via* an addition–oxidation sequence, the introduction of various substituents on the arene nucleus and, as a result, the construction of complex molecules.[1] Although a large array of substituted aryls bearing various functional groups (CN, CO_2R, *etc*.) have been prepared since the pioneering work of Semmelhack and Card,[2,3] a method to directly introduce a carboxylic acid has still been lacking.

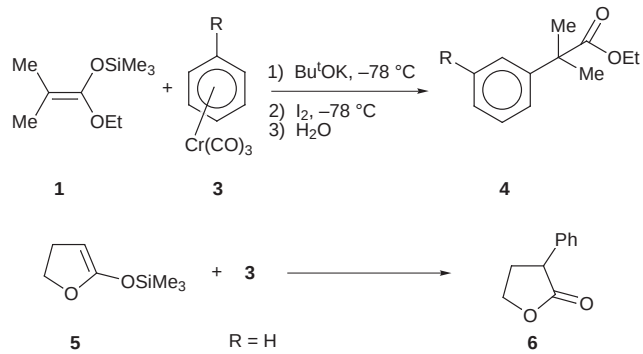
During our investigations directed towards the synthesis of pyrrole-containing aryl acids from arenechromium tricarbonyl complexes,[4] we were faced with this problem. Here we describe a successful approach based on the interaction of arenechromium tricarbonyl complexes with potassium enolates originating from bis(trimethylsilyl)ketene acetals[5,6] which leads to not only arylcarboxylic acids, but also to the unexpected formation of γ-functionalized cyclohexenones from anisole.

The following set of transformations allowed the reactivity of such potassium enolates towards arenechromium tricarbonyl to be assessed.

Thus, a solution of complex **3** (R = OPh, 1.53 g, 5 mmol) and of the ketene acetal **1** (1.36 g, 7.5 mmol) in THF (10 ml) was treated at −78 °C with a slight excess of Bu^{t}OK (1 M) in THF (8 ml) in the presence of HMPA (6 ml). After 1.5 h at this temperature, a solution of I_2 (6.20 g, 5 equiv.) in THF (15 ml) cooled to −78 °C was slowly added. The solution was then progressively warmed to room temperature overnight. Treatment with Et_2O and aqueous sodium bisulfite, followed by extraction with Et_2O and evaporation of the solvents *in vacuo*, left an oil which was chromatographed on silica gel. Elution with mixtures of light petroleum–Et_2O gave the aryl ester **4** (0.72 g, 52%) (Scheme 1).[7] Under the same conditions, the silyl enol ether of butyrolactone **5** led to α-phenylbutyrolactone **6** (30%).[7]

The bis(trimethylsilyl) acetals **2** behaved similarly. For example, a solution of complex **3** (R = OPh, 0.6 g, 2 mmol) and acetal **2** (R^1 = H, R^2 = Me, 0.9 g, 4 mmol) in THF (10 ml) was treated at −78 °C with a THF solution of Bu^{t}OK (5 ml) in the presence of HMPA (3 ml), then with I_2 (2.1 g) in THF (10 ml) to give, after workup and silica gel chromatography as above, fenoprofen **7** (0.38 g, 79%).[7] This transformation is of a general scope giving the known acids in fairly good yields (Table 1).

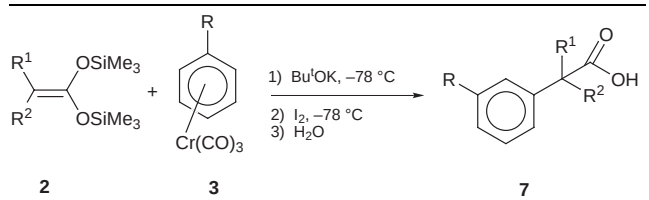
Surprisingly, in the case of complex **8**, derived from anisole, the course of the reaction was different. Under exactly the same



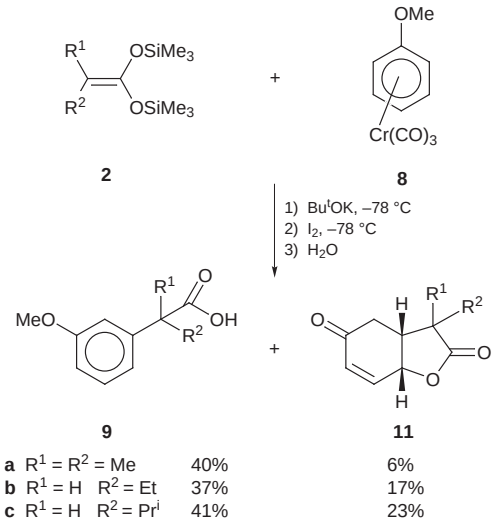
Scheme 1

reaction conditions, this complex gave with **2** (R^1 = H, R^2 = Pr^i) a mixture of two compounds which could be separated by silica gel chromatography. The physical data of the less polar product corresponded to those of the expected arylcarboxylic acid **9c** (41%).[7] The ^{13}C NMR spectrum of the more polar compound (23%), obtained as white crystals, mp 72 °C, showed signals at δ 195.50, 142.73 and 131.49, typical for a cyclohexenone, and also signals at δ 175.92 and 72.27, which agree with the presence of a γ-lactone. The ^1H NMR spectrum is also in accord with the presence of these two functional groups, with signals at δ 6.76 (dd) and 6.19 (d) for the protons of the double bond, and at δ 5.15 (dm) for a proton geminated to oxygen. Taken together, these data are fully consistent with **11c**, 3-isopropyl-3,3a,4,7a-tetrahydrobenzofuran-2,5-dione (Scheme 2).[7] **11a** and **11b** (together with the known acids) were

Table 1



Entry	**2**/equiv.	R^1	R^2	R	Yield of **7** (%)
1	2	H	Me	H	68
2	2	H	Me	OPh	79
3	2	H	Et	H	66
4	1.5	H	Et	OPh	61
5	2	H	Pr^i	H	94
6	1.5	H	Pr^i	OPh	85
7	2	Me	Me	H	63
8	2	Me	Me	OPh	77
9	1	H	CMe=CH_2	H	23



Scheme 2

obtained under the same conditions. A final confirmation of the structure came from a radiocrystallographic study on **11a**, shown in the CAMERON projection in Fig. 1.[8]

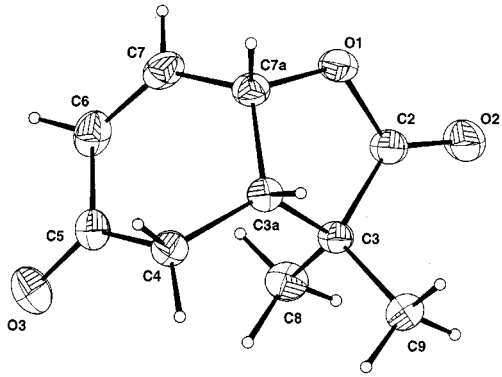


Fig. 1 X-Ray structure of **11a**. Important bond distances (Å): C(5)–O(3), 1.209(2); C(6)–C(7), 1.313(3); C(7a)–O(1), 1.457(2); O(1)–C(2), 1.351(2): C(2)–O(2), 1.193(2).

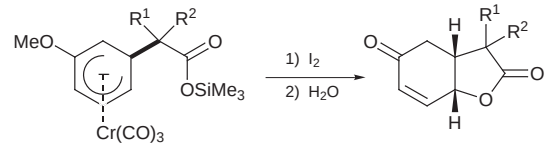
As expected for anisole,[9,10] addition of the enolate to the arenechromium system took place at the *meta* position to give **10**, but it was followed by the concomitant formation of a cyclohexenone (originating from the dienol ether) and of a lactone (originating from the trimethylsilyl carboxylate group). Although the formation of 3-substituted cyclohexenones *via* nucleophilic addition to anisolechromium tricarbonyl complexes is a known and important process,[11–13] the formation of fused systems containing a 4-substituted cyclohexenone such as **11** has to the best of our knowledge not been observed up to now.

The mechanism of this transformation, which corresponds to a formal (3 + 2) cycloaddition, is still a matter of speculation. Nevertheless, the presence of the methoxy group is fundamental since no lactones were detected in its absence (*vide supra*): its role is probably to activate the γ-position or to stabilize a crucial intermediate for the ring-closing step. Moreover, two observations could militate in favour of two successive *exo* addition reactions, the second one taking place after the oxidation step, probably on an iodinated ring. First, **11** could not be detected before the iodine treatment of the intermediate **10**,[14,15] second, the *cis* junction of the two rings could indicate that the carboxylato group enters also in an *exo* way although isomerization of a *trans*-fused system to a *cis*-fused one could occur during the purification step (Scheme 3).



Scheme 3

To summarise, arylcarboxylic acids can be obtained in one step from readily available bis(trimethylsilyl)ketene acetals and arenechromium tricarbonyl complexes together with products resulting from an intramolecular trapping reaction. Work is in progress to establish the mechanism of the latter transformation, to find the conditions that would make the bicyclic lactones the exclusive products of the reaction, and to attempt their enantioselective synthesis since in the case of **11b**,**c** three contiguous chiral centers are formed with high diastereoselectivity.

Preparation, characterisation and slow quantitative dissociation of a novel asymmetric *N*-unsubstituted dialkylsulfimide

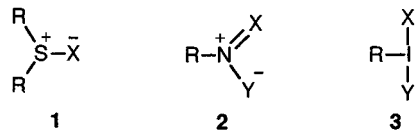
Anthony D. M. Curtis,[a] Ray McCague,[b] Christopher A. Ramsden*[a] and Muhammad R. Raza[a]

[a] *Department of Chemistry, Keele University, Keele, Staffordshire, UK ST5 5BG. E-mail: cha33@cc.keele.ac.uk*
[b] *Chirotech Technology Ltd.,Cambridge Science Park, Milton Road, Cambridge, UK CB4 4WE*

Received (in Liverpool, UK) 26th October, 1998, Accepted 8th December 1998

(±)-*S*-Imino-4,5-dihydro-3*H*-dinaphtho[2,1-*c*:1′,2′-*e*]thiepine, a novel asymmetric *N*-unsubstituted sulfimide, undergoes slow, quantitative N–S bond cleavage in $CDCl_3$ solution at 20 °C with a half-life of 20 h.

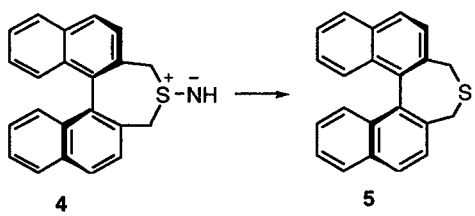
Sulfimides, sulfoxides and sulfur ylides **1** (X = NR, O or CR_2) belong to a general family of 'non-classical' molecules that are associated with three-centre, four-electron [3*c*-4*e*] bonds.[1]† This large family includes 1,3-dipoles, *e.g.* **2**,[2] and hypervalent compounds, *e.g.* **3**.[3,4] Whether represented by 1,3-dipolar,



1 **2** **3**

hypervalent or hetero-ylide structures, the fundamentally similar bonding in these non-classical molecules leads to common modes of reaction.[1] These include '*syn*-addition' and 'ligand coupling': in the latter mode of reaction the [3*c*-4*e*] bond is transformed into a lone pair and either a σ-bond between ligands X and Y (*e.g.* 1,3-dipoles **2** and hypervalent molecules **3**) or a second lone pair on a single ligand X (*e.g.* ylides and hetero-ylides **1**).[1] Transfer of nitrene or an alkylnitrene from a chiral sulfimide **1** (X = NH or N–alkyl) to prochiral substrates is a potentially useful application of ligand coupling and this has prompted us to seek a suitably reactive chiral *N*-unsubstituted sulfimide for evaluation.

N-Unsubstituted diarylsulfimides **1** (R = Ar, X = NH) are stable compounds and relatively unreactive, decomposing to the diarylsulfide only at 100 °C or above.[5–7] In contrast, the dialkyl derivatives **1** (R = alkyl, X = NH) are reported to be very unstable with respect to decomposition to the dialkylsulfide.[7–9] To be synthetically useful a suitable sulfimide should be sufficiently stable for convenient preparation but ideally should be reactive at ambient temperature. The sulfide precursor must also be accessible and robust enough to facilitate recovery and regeneration of the sulfimide. We have now identified a novel chiral *N*-unsubstituted sulfimide that fulfils these requirements. In particular, we report the preparation of the asymmetric (C_1) unsubstituted sulfimide **4** from the dissymmetric (C_2) sulfide **5** and its slow and quantitative first-order thermal dissociation back to the sulfide precursor **5** (Scheme 1). The process **4** → **5** can be formally classified as a ligand coupling in which the ligand is nitrene (:NH), and in principle this reaction provides a source of singlet nitrene in a chiral environment. This behaviour

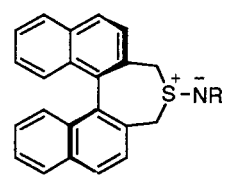


4 **5**

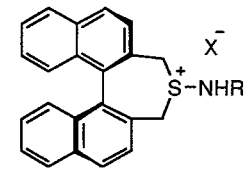
Scheme 1

is consistent with the general classification described above but the ease of dissociation is surprising since thioethers are not particularly good leaving groups in related reactions.[10] Since the enantiomers of sulfide **5** can be separated using column chromatography (triacetylcellulose),[11] sulfimide enantiomers **4** can be separately prepared by amination of homochiral sulfide **5** and, furthermore, homochiral sulfide regenerated during reactions of sulfimide enantiomers **4** can be recycled without the need for resolution.

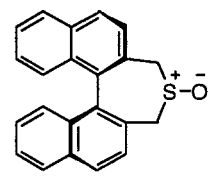
Initially we attempted to prepare the novel sulfimide **4** *via* the *N*-tosyl derivative **6**. Treatment of the racemic sulfide **5**[11] in CH_2Cl_2 with chloramine-T (1.12 equiv.) and hexadecyltributylphosphonium bromide (0.06 equiv.) gave the (±)-*N*-tosylsulfimide **6**, mp 225 °C (decomp.) (86%).‡ All attempts to



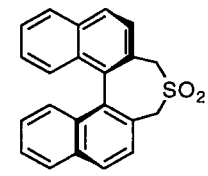
6 R = Ts
7 R = CONHPh



8 R = H, X = OMes
9 R = Ts, X = Cl



10



11

obtain the free sulfimide **4** by acid catalysed removal of the tosyl group[5,6] were unsuccessful. In an alternative approach, reaction of the sulfide **5** with *O*-mesitylenesulfonylhydroxylamine[12] (1.5 equiv.) gave the (±)-*S*-aminosulfonium salt **8**, mp 199 °C (decomp.) (87%). All spectroscopic properties of compounds **6** and **8** supported the assigned structures. In particular, the ^{1}H NMR spectrum ($CDCl_3$) of the salt **8** showed two pairs of doublets (*J* 12 and 14.5 Hz) at δ 3.71, 3.94, 4.42 and 4.78 due to the four non-equivalent methylene protons.

For direct comparison of spectroscopic properties we have also made the asymmetric (C_1) sulfoxide **10** and the dissymmetric (C_2) sulfone **11**. Oxidation of the sulfide **5** with sodium perborate tetrahydrate (1.0 equiv.) in glacial AcOH gave the novel sulfoxide **10**, mp 239–241 °C (92%) and use of 2 equiv. gave the novel sulfone **11**, mp > 260 °C (75%). As expected the ^{1}H NMR spectrum ($CDCl_3$) of the sulfoxide showed four discrete doublets (δ 3.26, 3.51, 3.92 and 4.36), (*J* 12 or 14 Hz) for the non-equivalent methylene protons. In $CDCl_3$ the spectrum of the sulfone showed only a singlet (δ 4.11) for the four methylene protons but in C_6D_6 solution two doublets (δ 3.49, *J* 14 Hz and δ 3.62, *J* 14 Hz) consistent with the dissymmetric structure **11** were observed.

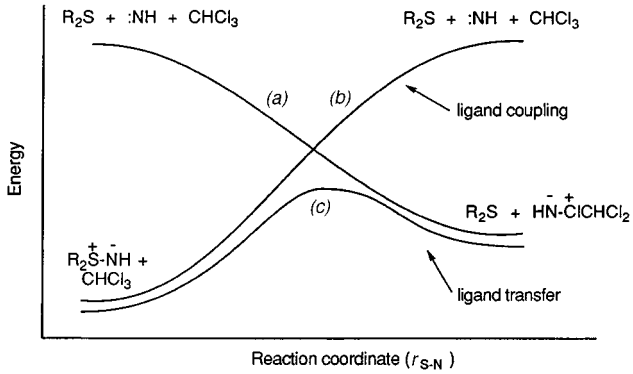


Fig. 1 A bond forming–bond breaking analysis and the possible role of solvent in the S–N bond dissociation of *N*-unsubstituted sulfimides.

The salt **8** can be converted into the free sulfimide **4** in solution by treatment with a number of bases including LDA, DBU and DABCO. The *N*-unsubstituted sulfimide **4** is too unstable to be isolated but is sufficiently stable in solution at room temperature to allow investigation of its properties, and it appears to be indefinitely stable in solution at 0 °C and below. Treatment of a toluene solution of compound **8** at −80 °C with LDA (1.0 equiv.) followed by addition of phenyl isocyanate (3.0 equiv.) gave the adduct **7**, mp 142 °C (decomp.) (67%). In a similar manner the *N*-tosylsulfimide **6** (88%), identical to an authentic sample, was obtained *via* the salt **9** by *in situ* treatment of the sulfimine **4** with TsCl. The ^{1}H NMR spectrum of the free sulfimide **4** in $CDCl_3$ solution was obtained by treatment of the salt **8** with 1 equiv. of base. Using DBU, a spectrum with two pairs of doublets (δ 3.03, 3.56, 3.72 and 4.16), (*J* 12 or 14 Hz) assignable to the four non-equivalent methylene protons was obtained. As expected, this spectrum closely resembles that of the stable and closely related sulfoxide **10** and the signals are up-field relative to those for the corresponding protons in the cation **8**. In agreement with their C_1 symmetry, non-equivalence of the CH_2 groups was also observed in the ^{13}C NMR spectra of sulfimide **4** (δ 54.25 and 56.59) and sulfoxide **10** (δ 54.62 and 57.08). In contrast, the C_2 symmetric sulfide **5** and sulfone **11** each show a single CH_2 signal, which appear at δ 32.35 and δ 58.24, respectively.

When an NMR sample of the sulfimide **4** was re-examined after 24 h the spectrum showed that a significant amount of the sulfide **5** was present. The rate of transformation of the sulfimide, generated in $CDCl_3$ solution using LDA (1.0 equiv.), was followed by monitoring the decay of the proton doublet at δ 4.16 using $CHCl_2CHCl_2$ in a sealed capillary (δ 5.96) as internal reference. Slow but quantitative transformation to the sulfide **5** took place over a period of 4 days, during which the sulfide proton signals appeared and simultaneously the sulfimide signals decayed. The dissociation **4** → **5** has a half-life (*ca.* 20 h) which is independent of concentration, suggesting reaction kinetics that are first-order or pseudo-first-order. We have not yet been able to determine the fate of the NH fragment, the products of which may include N_2 and NH_3.[5–9]

Thermal dissociation of a simple *N*-unsubstituted sulfimide to a sulfide and singlet nitrene at room temperature is an unexpected process in which an electron-rich nitrogen atom is transformed in one step into an electron-deficient nitrogen. In the gas phase this process is also extremely endothermic. Using the AM1 semi-empirical MO method,[13] we have calculated the energy of dissociation for the process Me_2S^+–N^-–H → Me_2S + NH to be 106.8 kcal mol^{-1} and to have an energy profile of the type described by the curve (*b*) in Fig. 1. Solvation of the sulfimide and sulfide are unlikely to change this profile but solvation of the nitrene may be significant. Singlet nitrene has a low energy, unoccupied p-orbital that can interact with a lone pair on solvent molecules such as $CHCl_3$ to form a hetero-ylide (*i.e.* HN^-–Cl^+–R). Participation of the solvent may therefore facilitate the reaction by providing an alternative mechanism ('ligand transfer') as shown by curve (*c*) in the Bell–Evans–Polanyi analysis[14] in Fig. 1. This mechanism is consistent with pseudo-first-order kinetics and the proposed iminochlorinane intermediate is analogous to the isolable iminoiodinanes, *e.g.* TsN^--I^+Ph.[15] This mode of stabilisation of singlet nitrenes is consistent with experimental observations that CH_2Cl_2 stabilises the singlet-state character of nitrenes.[16] A similar model for lone pair stabilisation of nitrenes has been proposed by Gleiter and Hoffmann.[17] NMR studies in inert solvents to eliminate solvent participation, *e.g.* saturated hydrocarbons, were precluded by solubility and availability. When the sulfimide **4** was generated in C_6D_6 solution sulfide formation still occurred but the reaction was not as clean as in $CHCl_3$: a very complex mixture of additional products was observed and none were formed in any significant amount.

In conclusion, we have obtained a chiral *N*-unsubstituted sulfimide having sufficient levels of stability and reactivity to enable studies of its nitrene transfer onto prochiral substrates. Cleavage of the S–N bond probably occurs by interaction with solvent (ligand transfer) to give a reactive intermediate rather than by formation of the free nitrene (ligand coupling). These preliminary results may be relevant to the role of solvent in nitrene mediated reactions. We plan further investigations of the chemistry and modes of reaction of this interesting system and related species.

Notes and references

† These bonds are sometimes described as two-centre, four-electron [2*c*-4*e*] bonds but in this context 'centre' strictly refers to the centres of the three atomic orbitals that interact to form molecular orbitals. In these bonds two of the atomic orbitals happen to be on the same atom but it is important to retain the description [3*c*-4*e*] to emphasise the similarity of bonding and properties to closely related systems, *e.g.* **2** and **3**.

Crystallographic evaluation of the mobility of 2-naphthoic acid included in heptakis(2,6-di-*O*-methyl)-β-cyclodextrin

Kazuaki Harata

Biomolecules Department, National Institute of Bioscience and Human-Technology, 1-1 Higashi, Tsukuba, Ibaraki 305-8566, Japan. E-mail: harata@nibh.go.jp

Received (in Columbia, MO, USA) 15th September 1998, Accepted 4th December 1998

Analysis of anisotropic temperature factors of the title compound revealed the rigid-body thermal motion of 2-naphthoic acid, which has root mean squared amplitudes of 0.3 Å for translational motion and 6° for libration.

Cyclodextrins are cyclic oligosaccharides consisting of glucose units and form inclusion complexes with a variety of guest molecules. X-Ray structures of numerous crystalline complexes of cyclodextrins and their derivatives have revealed guest molecules included in the macrocyclic cavity.[1] The guest molecules have relatively high mobility in the host cavity because they are weakly bound by van der Waals forces, electrostatic forces, hydrogen bonds, *etc*. instead of chemical bonds. However, no attention has been paid to the mobility of included guest molecules. Analysis of not only the mean structure of inclusion but also the mobility of the guest molecule is essential to elucidate the characteristics of included guests. The crystallographic temperature factor is a measure of the mobility of the atoms, groups or molecules.[2] Analysis of temperature factors is expected to provide information on the dynamic state of guest molecules in crystalline complexes. Here we deal with the thermal motion of 2-naphthoic acid included in heptakis(2,6-di-*O*-methyl)-β-cyclodextrin. The crystal structure of the 1 : 1 complex has been reported.[3]† The naphthalene ring of the guest molecule is inserted into the host macrocycle from the O6 side while the carboxy group protrudes outside the host cavity.

The molecular fluctuation of 2-naphthoic acid was evaluated by the TLS method[4] which has been applied for the analysis of thermal motion of molecular crystals.[4,5] The anisotropic temperature factor is expressed by a linear combination of translation (T), libration (L) and screw motion (S), as described in eqn. (1), where G_{ijkl} and H_{ijkl} are functions of the atomic coordinates.

$$u_{ij} = \Sigma G_{ijkl}\boldsymbol{L}_{kl} + \Sigma H_{ijkl}\boldsymbol{S}_{kl} + \boldsymbol{T}_{ij} \quad (1)$$

Tensor elements for these motions were determined by the least-squares fit to observed anisotropic temperature factors. The quantity minimized was $\Sigma w_{ij}(\Sigma G_{ijkl}\boldsymbol{L}_{kl} + \Sigma H_{ijkl}\boldsymbol{S}_{kl} + \boldsymbol{T}_{ij} - u_{ij})$.[2] The inverse value of the estimated standard deviation of u_{ij} was used as weight w_{ij}. The center of libration was so determined that the $\boldsymbol{S}$ tensor was symmetrical. The tensors of $\boldsymbol{T}$, $\boldsymbol{L}$, and $\boldsymbol{S}$ are given in Table 1. From the eigenvalues of $\boldsymbol{T}$ and $\boldsymbol{L}$ tensors, the root mean squared amplitudes of translational and rotational vibration were estimated as 0.35, 0.27 and 0.27 Å and 4.6, 5.1 and 7.7°, respectively, for the three principal axes. Therefore, 2-naphthoic acid has a rotational vibration of about 6° and a translational vibration of about 0.3 Å. The discrepancy factor for observed and calculated values of u_{eqv} (Table 2), $\Sigma|u_{eqv}^{obs} - u_{eqv}^{cal}|\Sigma u_{eqv}^{obs} = 0.048$, indicates that the magnitude of atomic thermal motion is mostly derived from the rigid-body motion. In contrast, the discrepancy factor of 0.24 for u_{ij} is large. The reason is obvious from the comparison between observed and reproduced temperature factors as shown in Fig. 1. Differences in the orientation of thermal ellipsoids are observed for C5, C6, C7, C8, O1 and O2 and significant disagreements are found in off-diagonal u_{ij} elements for these atoms. A possible explanation for the disagreement is the effect of torsional vibration of the carboxy group around the C2–C11 bond. The local motion of the carboxy group affects the libration parameters and as a result disagreement also occurs for C5, C6, C7 and C8, which are located on the other end of the guest molecule. Such internal motion is coupled with the rigid-body motion and not distinguishable. The TLS model was also applied for the host molecule, but the discrepancy factors of 0.31 and 0.50 for u_{eqv} and u_{ij}, respectively, indicate that the thermal motion of the host molecule is not a simple rigid-body motion because of the high conformational flexibility of the macrocyclic ring.

As shown in Fig. 1, the largest translational motion is in the direction of the short axis of the naphthalene ring. Intermolecular contacts with host molecules impose restrictions on the movement of the guest molecule. Motion in the direction perpendicular to the molecular plane is prohibited by a methyl group and CH_2 groups,[2] which are marked with asterisks in Fig. 1. The carboxy group, which is coplanar with the naphthalene ring within an atomic deviation of 0.05 Å, forms a water-mediated hydrogen-bond bridge with an adjacent host molecule. The C1, C4, C5 and C8 atoms of the naphthalene ring have contacts with the O6 oxygen atoms of the host of 3.5–3.8 Å. Two methyl groups of an adjacent host molecule related *via* a two-fold screw axis are inserted from the secondary hydroxy side and have contacts with the C6 and C7 atoms of the naphthalene ring with a shortest distance of 3.5 Å. The center of libration (O1) is shifted by 0.83 Å towards the C2 atom from the

C5	0.133	0.136	C10	0.103	0.105			

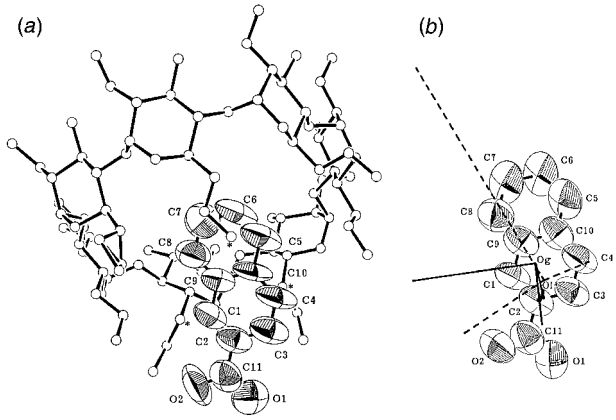

Fig. 1 ORTEP drawings of (*a*) observed and (*b*) reproduced thermal motion of 2-naphthoic acid. Principal axes of translation (solid lines) are drawn from the center of gravity (Og). The length of the axes corresponds to eigenvalues of the ***T*** tensor. Dashed lines denote principal axes of libration drawn from the center of libration (Ol).

center of gravity (Og). The largest libration is around the principal axis located on the guest plane,which makes an angle of about 30° with the long axis of the naphthalene ring. In cyclodextrin complexes, guest molecules generally have greater thermal motion than the host molecules. The present result demonstrates that rigid-body motion is predominant in the thermal motion of the guest molecule and is interpreted in terms of the TLS model.

Confinement of C_{70} in an extended saddle shaped nickel(II) macrocycle

Peter D. Croucher, Jodie M. E. Marshall, Peter J. Nichols and Colin L. Raston*

Department of Chemistry, Monash University, Clayton, Melbourne, Victoria 3168 Australia.
E-mail: c.raston@sci.monash.edu.au

Received (in Columbia, MO, USA) 5th October 1998, Accepted 8th December 1998

Saddle shaped {2,3,6,8,11,12,15,17-octamethyldibenzo-[*b*,*i*]1,4,8,11-tetraaza(1,4)annulene}nickel(II), Ni(OMTAA), acts as a heterotropic divergent receptor molecule with C_{70} forming a 1 : 1 complex in the solid state, where the extended supramolecular array consists of zigzag alternating C_{70}–Ni(OMTAA) chains and corrugated sheets of close contact C_{70} molecules.

Host–guest chemistry of globular molecules including fullerenes,[1–18] carboranes,[19] and P_4E_3 (E = S, Se),[1,20] has recently gained prominence in forming inclusion nanostructures, crystal engineering, and in their purification. A major challenge in forming supermolecules involving such molecules is gaining control over the inherently weak host–guest interactions. Complementarity of curvature and maximising the number of points/area of van der Waals contact are important factors in the formation of stable host–guest complexes, at least in the absence of hydrogen bonding, and electrostatic and coordination interactions. Competition between the host–host, host–guest and guest–guest interactions is important in determining the structure of the resulting supramolecular array. This is particularly evident in fullerene chemistry where interfullerene interactions play a major role in the structures of inclusion complexes.[5–15] The interactions of solvent with all species and crystal packing forces provide additional variables.

Recently we reported that Ni(TMTAA), Fig. 1 (R = H), acts as a divergent heterotopic receptor with C_{60}, 1,2-dicarbododecaborane and the chalcogenides P_4S_3 and P_4Se_3;[1,20] the saddle shape of the host arises from otherwise unfavourable interactions between the –{NC(Me)}$_2$CH– methyl groups and the hydrogen atoms on the aromatic rings. Here we report the structure of a 1 : 1 inclusion complex of C_{70} in an extended nickel(II) macrocycle, Ni(OMTAA) (Fig. 1, R = Me). It is noteworthy that there is only one structurally authenticated inclusion complex of C_{70}, a 2 : 1 complex with calix[6]arene.[5]

[Ni(OMTAA)C_{70}] crystallised from a 2 : 1 toluene solution of the two constituents with the host in excess.† The X-ray structure determination‡ revealed that a 1 : 1 complex formed, a molecule of each component comprising the asymmetric unit. Surprisingly it is isostructural to that complex formed between Ni(TMTAA) and C_{60}. It appears that the larger macrocycle and fullerene allows for a similar packing to that of the smaller macrocycle and fullerene. However, the interplay between the fullerene and the host is, in the present structure, complicated somewhat by the long axis present in C_{70}. There are close contacts between the two supramolecular synthons involving the nickel centre, Ni···C 3.20(1) and 3.22(1) Å for the phenylene and {NC(Me)}$_2$CH– lined faces respectively. The extended structure has each fullerene in each saddle in a zigzag motif, Fig. 2. A third macrocycle–fullerene interaction is observed between a pseudo-cavity, defined by the backside face of a phenyl ring and one methyl group from each of the {NC(Me)}$_2$CH– moieties, and a third fullerene residing with its long axis running within the long pseudo-mirror-plane of the Ni(OMTTA) molecule, Fig. 2(a). The interaction is comprised of a π···π stacking of a five membered ring of the fullerene and the phenyl of the host, ring centroid–ring centroid distance 3.30(1) Å; methyl groups in close contact with the fullerene have C···C distances at 3.44(1) and 3.20(1) Å respectively for

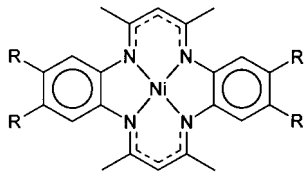

Fig. 1 Ni(TMTAA), R = H, and Ni(OMTAA), R = CH_3.

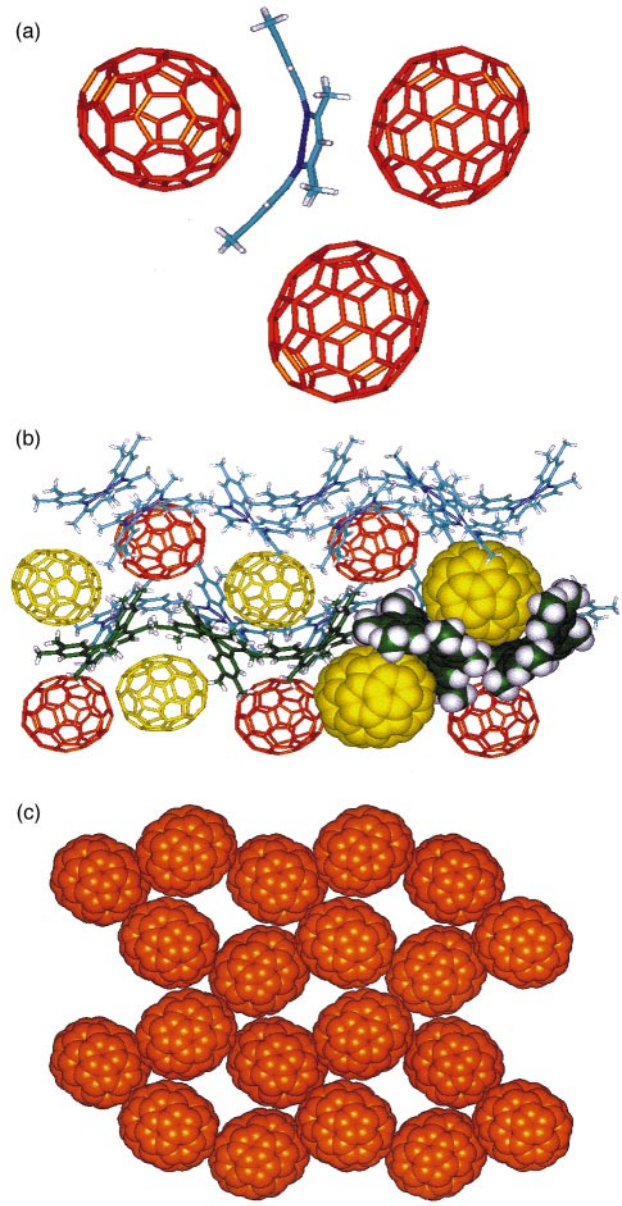

Fig. 2 Structure of [Ni(OMTAA)C_{70}] showing (a) three guest interactions for each macrocycle. (b) The alternating sheets of close-contact fullerenes and Ni(OMTAA) molecules respectively. (c) The corrugated sheet of close contact fullerenes in [Ni(OMTAA)C_{70}].

{NC(Me)}$_2$CH– and 3.17(1) and 2.93(1) Å for the phenyl methyls.

Rather than lie flat across the phenylene face of Ni(OMTAA), the C_5 axis of C_{70} intersects with NiN_4 plane at 33.(1)° along the valley formed by the phenyl rings, and at 15.1(1)° across the valley, and lies almost flat against the {NC(Me)}$_2$CH– face, corresponding angle 15.4(1)°. The elliptical fullerene makes close contact with five other fullerenes forming a two-dimensional corrugated sheet consisting of slightly offset fullerene chains, Fig. 2(b). Within each ridge or trough, the C_5 axes of each C_{70} are arranged in a zigzag fashion with a five-membered ring of one fullerene and a six-membered ring of another fullerene in the chain π-stacking, albeit with a slight deviation from coplanarity, making a point of closest contact at 3.14(1) Å. One of the poles of the fullerene, *i.e.* the five-membered ring through which the C_5 axis passes, forms a classical π···π stacking interaction with that of an adjacent fullerene such that one of the participating fullerenes is on a ridge, the other in a trough. The fourth and fifth close contact points to each fullerene run at right angles to the grain of the sheet, as defined by the ridges and troughs, and continue on to form a chain which has the C_5 axes aligned in a zigzag fashion and contiguous fullerenes alternating between ridge and trough positions. These points are those of closest contact to each fullerene, C···C 3.05(1) Å. Interestingly, the C_5 axes of the C_{70} in this structure and one of the C_5 axes of C_{60} in the [Ni(OMTAA)C_{60}] structural analogue are aligned similarly within their respective supramolecular arrays despite the spherical nature of the C_{60}.

The pole of the fullerene not involved in the π···π interfullerene interaction, aligns itself with one of the {NC(Me)}$_2$CH– methyl groups making a C···C point of close contact at 3.05(1) Å. Four other fullerene molecules make van der Waals contact with the phenylmethyl and {NC(Me)}$_2$CH– methyl groups of Ni(OMTAA). The phenylmethyl groups at one end of the Ni(OMTAA) molecule make two van der Waals contact points with those of an adjacent molecule of opposite curvature to form an S-shaped fragment –CH_3···CH_3 2.88(1) Å. A second host–host interaction involves offset side-by-side molecules, again with opposing curvature, such that the central {NC(Me)}$_2$CH– proton aligns itself with the aromatic proton of its neighbour H···H 2.91(1) Å {NC(Me)}$_2$CH– methyl groups make close contact at 2.89(1) Å and crystallographic symmetry makes the third contact point identical to the first. Ni(OMTAA) makes van der Waals contact with two further host molecules through the methyl groups on both the phenyl and {NC(Me)}$_2$CH– moieties. Consequently, the supramolecular array consists of sheets of fullerene layered between intercalating sheets of Ni(OMTAA) [Fig. 2(c)].

The 1 : 1 complex [Ni(OMTAA)C_{70}] is isostructural with [Ni(OMAA)C_{60}] despite the difference in host shape and increased host–host interaction. This finding gives insight into now studying the supramolecular chemistry of higher fullerenes *via* extending the arms of the nickel macrocycle to accommodate the large fullerenes in an isostructural system.

We thank the Australian Research Council for support of this work.

Notes and references

† [Ni(OMTAA)C_{70}] was obtained by mixing hot toluene solutions of the nickel(II) macrocycle (20 mg, 0.04 mmol) and C_{70} (16 mg, 0.02 mmol) and cooling the resultant solution slowly whereupon black plate-like crystals of the complex were deposited. Cold toluene was added quickly to the cooled mixture and the crystals were removed by filtration and washed with dichloromethane until the filtrate became colorless giving [Ni(OMTAA)C_{70}] (20 mg, 80% yield).

‡ *X-Ray crystallography*: [Ni(OMTAA)C_{70}]: data were collected on an Enraf Nonius CCD and were corrected for Lorenzian and polarisation but not absorption. The structure was solved using TEXSAN. All non-hydrogen atoms were refined anisotropically using a full-matrix least-squares refinement against *F*. Hydrogen atoms were included at calculated positions with a riding model. *Crystal data*. $C_{96}H_{30}N_4Ni$, M = 1298.02, monoclinic, space group $P2_1/n$, a = 14.9165(5), b = 18.8797(7), c = 19.5635(4) Å, β = 105.490(1)°, U = 5309.3(3) Å^3, Z = 4, D_c = 1.624 g cm^{-3}, Mo-Kα radiation, λ = 0.71073 Å, T = 123 K, μ = 4.35, 4235 reflections observed, 910 parameters, R = 0.0649, wR_2 = 0.0474. Received (in Cambridge, UK) 25th November, 1998 Accepted 10th December 1998

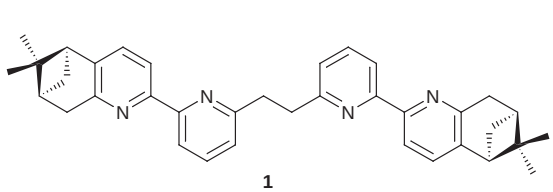
A new enantiomeric pair of ligands in which a 2,2′:6′,2″:6″,2‴-quaterpyridine has been split into two 2,2′-bipyridine binding domains by a CH_2CH_2 spacer has been prepared: reaction with Ag(I) gives dinuclear double helicates whereas Cu(I) gives a library of $\{CuL\}_n^{n+}$ complexes (n = 2,3,4,5) of which the compounds with n = 2,3 have been structurally characterised as double helicates and cyclohelicates respectively.

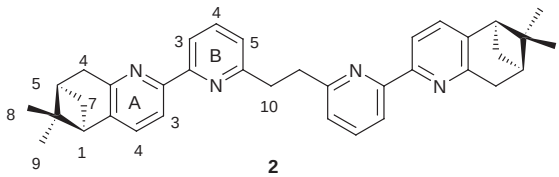
It is established that oligopyridines can give helicates upon coordination to metal centres[1,2] and that structural development of the ligand allows subtle control to be exerted over the consequences of helication; for example, chiral ligands may be used to give a diastereomeric excess of left- or right-handed helicates[3,4] or spacers may be introduced which might lead to the formation of closed circular structures.[4–8] To date, only two examples of cyclohelicates with chiral ligands have been reported, and in each case the reactions were diastereoselective, giving trinuclear[8] or hexanuclear[4] solid state complexes. Here we report the formation of a library of $\{CuL\}_n^{n+}$ species from reactions of a new chiral helicand based upon a spaced 2,2′:6′,2″:6″,2‴-quaterpyridine (qtpy).

The new chiral ligands all-(*S*)-**1** and all-(*R*)-**2** were obtained in 80–85% yield using standard methods and were fully characterised. The ligands exhibited equal and opposite optical rotations in chloroform (**1**: $[\alpha]_D^{23°}$ +82.2°; **2**: $[\alpha]_D^{23°}$ −82.3°) and circular dichroism (CD) spectra. The spectra exhibited two principal absorptions (**1**: $\Delta\varepsilon_{255}$ +5.8, $\Delta\varepsilon_{307}$ −1.7; **2**: $\Delta\varepsilon_{255}$ −6.2, $\Delta\varepsilon_{301}$ +2.4) which correspond to π–π* transitions in the electronic spectra at 256 and 299 nm. The ligands are chiral analogues of **3** which has been shown to form dicopper(I) double helicates[9–12] and we were interested in comparing the diastereoselectivities obtained upon the formation of double helicates with **1** and **2** with the corresponding qtpy ligands **4** and **5**.[13]

Ultrasonication of a 1:1 stoichiometric mixture of AgO_2CCH_3 or $[Cu(MeCN)_4][PF_6]$ and **1** or **2** in MeOH (Ag or Cu) or MeCN (Cu) gave solutions from which colourless or orange hexafluorophosphate salts of stoichiometry $[\{AgL\}_n][PF_6]_n$ or $[\{CuL\}_n][PF_6]_n$ were isolated in near quantitative (≥97%) yield after recrystallisation of the initial precipitates by the diffusion of diethyl ether vapour into MeOH or MeCN solutions. In each case, the compounds only exhibited a single spot on tlc analysis (SiO_2, MeCN, H_2O, aqueous KNO_3).



1



2

To simplify the discussion, only complexes with **1** will be explicitly discussed. Those with **2** parallel the behaviour exactly. In the case of the silver complex, both ES (MeCN or MeOH) and MALDI TOF (2,6-dihydroxybenzoic acid matrix) mass spectrometry showed an intense peak at *m/z* 1414 corresponding to $\{[Ag_2(\mathbf{1})_2][PF_6]\}^+$ but no peaks corresponding to higher nuclearity species and suggesting a double-helical formulation. This is further supported by the observation of a single solution species in the ^{1}H NMR spectrum (CD_3CN). The signals corresponding to H^{5B}, $H^{4A,4B}$ and the ethylene bridge protons are broadened at ambient temperature but show no change over a temperature range −40 to +75 °C suggesting that a low energy intramolecular process is responsible for the broadening rather than a chemical exchange process. The complex is optically active and solutions in MeCN exhibit $[a]_D^{23}$: +73.1° and CD spectra with $\Delta\varepsilon_{220}$ +26, $\Delta\varepsilon_{298}$ −31 and De_{322} +64. The band at 322 nm with a large $\Delta\varepsilon$ is characteristic of a double helicate and the sign of $\Delta\varepsilon$ allows the unambiguous assignment of *P* helical chirality to the double helix obtained with **1** and *M* helical chirality to the complex with **2**.[3,13,14] To conclude, the reaction of **1** or **2** with AgO_2Ac leads only to dinuclear double helicates.

The case of the copper(I) complexes was far more complicated. Solutions in CD_3OD exhibited two subspectra in a ratio of 10:7 and comparison of chemical shifts with the double-helical copper(I) complexes of **3** strongly suggested the formation of a mixture of *P* and *M* dinuclear double helicates. Recrystallisation from MeOH yielded orange needles together with smaller amounts of fluffy solid consisting of small orange crystals. The ^{1}H NMR spectrum of the fluffy crystalline solid (in CD_3OD) corresponded to the dominant species, but within 10 min the solution had equilibrated to give the 10:7 ratio of complexes, the most characteristic signals of which are doublets assigned to H^{5B} at δ 7.16 and 7.03 for the major and minor species respectively. The ES MS of either type of crystal in MeOH revealed only peaks assigned to $\{[Cu_2(\mathbf{1})_2][PF_6]\}^+$ and $[Cu_2(\mathbf{1})_2)]^{2+}$. The needles consisted of a 1:1 mixture of the two species and a solid state structural determination confirmed the formulation as a dinuclear double helicate.†

The structural determination of the complex $\{[Cu_2(\mathbf{2})_2][PF_6]_2\}_2 \cdot 3Et_2O$ showed that the needles were a *quasi*-racemate containing equal amounts of the diastereomeric *P* and *M* double helicates in the crystal (Fig. 1). Each copper is in a distorted four coordinate environment and the bond angles and distances are typical with Cu–N distances of 1.995(4)–2.072(4) Å and bite angles of 81.2–82.2°. The Cu···Cu distances in the individual cations are 5.885 and 5.958 Å comparable to the complexes of **3**[10] but much longer than those with **4** and **5**.[13]

Dissolution of any of the crude solids, or the crystalline materials obtained from MeOH in CD_3CN resulted in orange solutions whose ^{1}H NMR spectra contained between three and

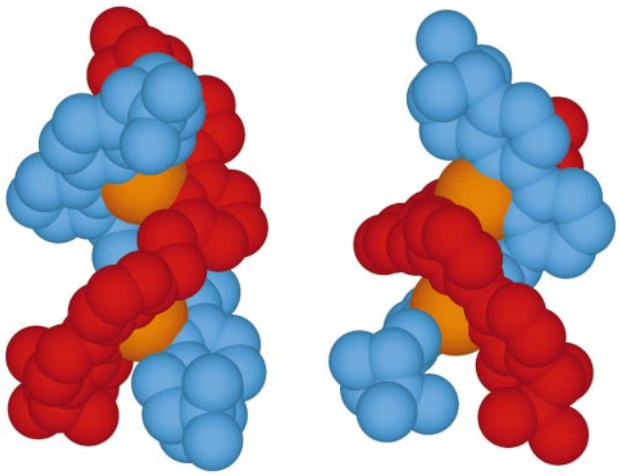


Fig. 1 The solid state structures of the *M* and *P* cations in $[Cu_2(\mathbf{2})_2][PF_6]_2 \cdot 3Et_2O$; hydrogen atoms have been omitted for clarity.

five species (as monitored by the upfield H^{5B} resonances) depending upon the concentration of the sample. Systematic and reversible changes in the spectra and speciation occurred upon varying the concentration, or upon titrating CD_3OD into CD_3CN solutions (or *vice versa*). ES MS studies of the MeCN or MeOH solutions revealed the presence of ions assigned to $[Cu_2(\mathbf{1})_2)]^{2+}$, $\{[Cu_2(\mathbf{1})_2][PF_6]\}^{+}$, $[Cu_3(\mathbf{1})_3]^{3+}$, $\{[Cu_4(\mathbf{1})_4][PF_6]\}^{3+}$ $\{[Cu_5(\mathbf{1})_5][PF_6]_2\}^{2+}$ and $\{[Cu_5(\mathbf{1})_5][PF_6]_3\}^{3+}$ (all charges confirmed by partial mass isotopomer distribution) and allowed the assignment of the subspectrum containing a δ 5.94 resonance for H^{5B} to the trinuclear species. Higher concentrations favoured the formation of higher nuclearity species and at concentrations below 10^{-4} M only the dinuclear species were present in MeCN according to both ^{1}H NMR and ESMS measurements.

Diffusion of Et_2O vapour into MeCN solutions of the complexes at an initial concentration that the NMR studies indicated significant amounts of the trinuclear species should be present resulted in the formation of triangular orange crystals, fresh solutions of which only exhibited (in CD_3OD) the subspectrum containing the δ 5.94 ^{1}H NMR resonance; upon standing the mixture of complexes was regenerated. A solid state structure determination† revealed a pair of diastereomeric *P* and *M* cyclic $[Cu_3(\mathbf{1})_3]^{3+}$ cations (Fig. 2). The bond angles and distances are similar to those in $[Cu_2(\mathbf{2})_2][PF_6]_2$ and the three Cu centres are in a distorted tetrahedral geometry (bite angles 80.0–82.4°, Cu–N 1.981–2.048 Å) and describe a triangle with Cu···Cu distances of 6.905–6.983 Å. The pinene groups point outwards giving the cation an outer diameter of *ca*. 20.5 Å and a height of 8 Å. The shortest distance between the ligands is around 3.7 Å (C···C) or 2.2 Å (shortest H···H), making the cavity at the centre of the triangle too small to include any guests. By

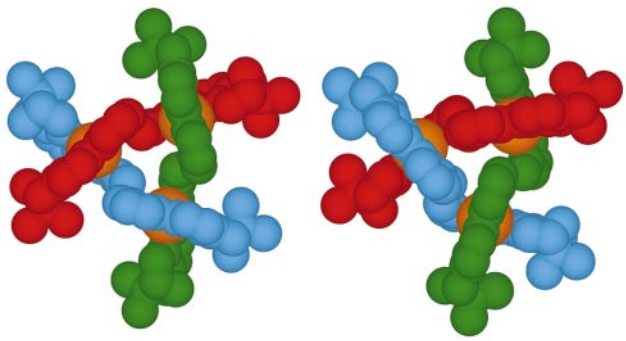

Fig. 2 The solid state structures of the *M* and *P* cyclohelicate cations in $[Cu_3(\mathbf{1})_3][PF_6]_2 \cdot 0.75MeCN$, hydrogen atoms have been omitted for clarity.

analogy, we assume that the higher nuclearity species are also cyclohelicates.

In both of the complexes structurally characterised, the spacer reduces interactions between the chiral substituents and the other ligand strand such that the diastereoselectivity is reduced[13] and in the solid state, *quasi*-racemates are obtained. In contrast to previously reported cyclohelicates, which in the solid state exhibited diastereoselective formation of *P* or *M* helicates, our system shows no solid state diastereoselectivity. In contrast, modest diastereoselectivity is shown in solution; equilibrated MeOH solutions containing only the 10:7 mixture of diastereomers of the dinuclear double helicate have CD responses indicating an excess of the *P* helicate with **1** and the *M* helicate with **2**.

Detailed studies of the speciation and chiroptical properties of these systems are underway; however, we have established that in MeCN solution a library[5] of copper(I) helicates is formed. We should like to thank the Schweizerischer Nationalfonds zur Förderung der wissenschaftlichen Forschung and the University of Basel for support.

Novel amine-modified TiO_2–SiO_2 aerogel for the demanding epoxidation of substituted cyclohexenols

Marco Dusi, Christian A. Müller, Tamas Mallat and Alfons Baiker*

Laboratory of Technical Chemistry, Swiss Federal Institute of Technology, ETH-Zentrum, CH-8092 Zürich, Switzerland. E-mail: baiker@tech.chem.ethz.ch

Received (in Cambridge, UK) 29th October 1998, Accepted 3rd December 1998

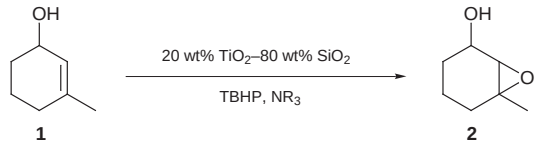
Amine additives provided high selectivity (up to 98%) in the epoxidation of sensitive alkyl-substituted cyclohexenols with a TiO_2–SiO_2 aerogel and Bu^{t}OOH; heterogenization of the catalyst system resulted in a new bifunctional catalyst.

Recently, active and selective titania–silica epoxidation catalysts have been prepared by the solution sol-gel technique.[1–4] The advantages of this preparation method are the intimate molecular-scale mixing of Ti in the silica matrix and high surface area of the materials. The drying conditions have also been recognized to play an important role: removal of the solvent entrapped in the tenuous gel network by semicontinuous extraction with supercritical CO_2 at near ambient temperature results in mesoporous textural properties, providing access of bulky reactants to the active sites.[2] An aerogel with a TiO_2 content of 20 wt% (20LT), prepared by this method, showed outstanding performance in the epoxidation of cyclic olefins with alkyl hydroperoxides.[5,6]

In the epoxidation of primary and secondary allylic alcohols, high selectivities were achieved in the presence of (basic) zeolite 4 Å or $NaHCO_3$ used as additives.[7] There are also some other examples in the literature on the enhancement of epoxide selectivity when the acidity of a Ti- and Si-containing catalyst is tuned by alkali metal exchange or addition of an inorganic base to the reaction mixture.[8–11] In the epoxidation of alkyl-substituted cyclohexenols, such as 3-methylcyclohex-2-en-1-ol **1** and 3,5,5-trimethylcyclohex-2-en-1-ol (isophorol), 20LT provided the epoxides only as minor products (< 10% selectivity). Unfortunately, the acid-catalyzed side reactions could not be suppressed by any of the known methods. For comparison, good to high yields of the epoxides of alkyl-substituted cyclohexenols were obtained by stoichiometric oxidations,[12–15] but no efficient catalytic method is available yet for this type of epoxidation reaction.[16]

Here we report a new strategy for the selective epoxidation of alkyl-substituted cyclohexenols by adjusting the surface properties of titania–silica with small amounts of amines. The epoxidation of 3-methylcyclohex-2-en-1-ol **1** with TBHP (*tert*-butyl hydroperoxide) was chosen as a model reaction (Scheme 1).

A 20LT aerogel was prepared by the solution sol-gel method as described previously.[2] The solvent was extracted semi-continuously with supercritical CO_2 at 40 °C and 240 bar. The raw aerogel was calcined in air at 400 °C for 5 h. X-Ray analysis showed that the amorphous material possessed a good Ti dispersion, high surface area (S_{BET} = 680 m^2 g^{-1}) and mesoporous structure (mean pore diameter: 9 nm, pore size maximum: 40 nm, pore volume: 1.5 cm^3 g^{-1}).



1 **2**

Scheme 1

Prior to epoxidation, 0.1 g 20LT was dried *in situ* in Ar at 200 °C for 16 h. Under standard conditions, epoxidation was carried out at 60 °C in Ar using 10 mmol substrate, 2.5 mmol TBHP, 0.1 g activated molecular sieves 4 Å, the amine modifier, 0.5 ml dodecane (internal standard) and toluene (total volume: 10 ml). Conversion and selectivities were determined by GC analysis and iodometric titration. The conversion of **1** is related to the stoichiometric initial amount of TBHP (4:1) and given in mol% of the maximal attainable value, and the epoxide selectivity is quoted with reference to the substrate consumed.

In the absence of amine the allylic alcohol **1** was readily converted non-oxidatively, and the epoxide **2** was only a minor product (Table 1). Major reactions were the acid-catalyzed isomerization and dehydration of **1**, and oligomerization of **1** and **2**. Note that the epoxidation activity of titania–silica is attributed to the Lewis acidity of the $(Si–O)_4Ti$ sites, whereas the surface silanol groups represent Brønsted acidic sites active in the aforementioned side reactions.[17,18] Addition of 1 or 10 mol% amine (related to **1**) suppressed the acid-catalyzed side reactions and good to high epoxide selectivity was achieved. Interestingly, no correlation between the basicity of the amine additive and the epoxide selectivity could be established.

The amount of amine additive played an important role in the selectivity enhancement, as illustrated in Fig. 1. Only 1 mol% of triazine was sufficient to suppress the acid-catalyzed reactions and reduce the conversion of **1** to 100% or below. Note that the substrate:TBHP molar ratio was 4:1, and that the conversion is related to the initial amount of TBHP. Addition of 5 mol% of triazine afforded the highest epoxide yield of 56%, correspond-

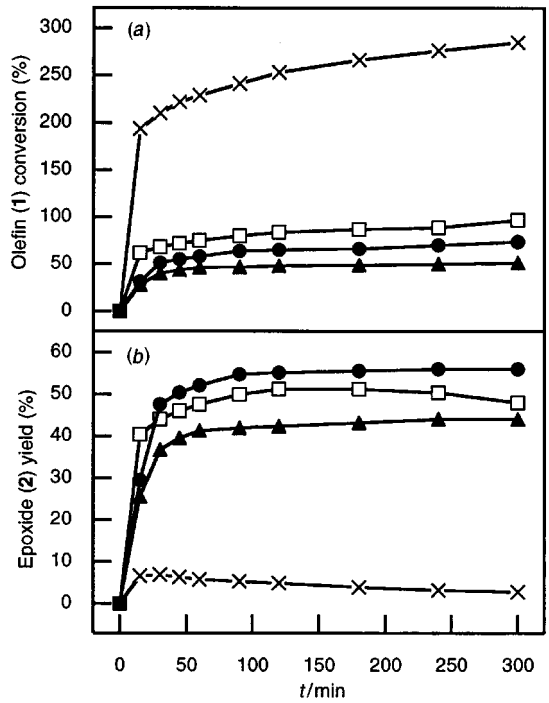

Fig. 1 Influence of the amount of triazine on (*a*) the conversion of **1** (related to the initial amount of TBHP) and (*b*) the yield of **2**: (×) 0, (□) 1, (●) 5 and (▲) 10 mol% based on **1**.

ing to over 90% epoxide selectivity at medium conversion. The results show that the amounts of amine additives quoted in Table 1 may be far from the optimum values.

On the basis of preliminary kinetic studies we propose that the amines have a rather complex effect. At low concentrations they interact mainly with the surface silanol groups, and deactivate (block) these Brønsted sites. This positive effect on selectivity depends only marginally on the pK_a value of the amine, as all amines tested are more basic than the oxygen atom of **1**. At higher concentrations, interaction of the amines with the Ti site seems to be dominant, leading to lower epoxidation activity. This effect is similar to the detrimental influence of alcoholic solvents, which was suggested to be due to their competition with TBHP for the active sites.[17] Also, at high amine concentrations (usually ⩾5mol%) the base-catalyzed ring opening of **2** became important.

Intrigued by the good results of the epoxidation of **1** with Me_2NBu as additive, we prepared a new catalyst with immobilized aminoalkyl groups. An aerogel containing 10 wt% TiO_2 was designed with surface $Me_2N(CH_2)_3$ groups (designated $10LT_A$). To a solution of $(MeO)_4Si$ (135 mmol) and $Ti(acac)_2(OPr^i)_2$ (12.5 mmol) (75% in Pr^iOH) in Pr^iOH (10 ml), the hydrolysant consisting of water (750 mmol) and HNO_3 (15 mmol) in Pr^iOH (40 ml) was added at room temperature. After 6 h stirring, a solution of $Me_2N(CH_2)_3Si(OMe)_3$ (15 mmol) in Pr^iOH (82 ml) was added. The solution gelated within 12 h. After ageing for 7 days at room temperature, the solvent was removed by extraction with supercritical CO_2 at 40 °C and 230 bar. On the basis of a thermoanalytical investigation, the amine-modified aerogel was calcined only at 100 °C for 1 h, in order to avoid decomposition of the $Me_2N(CH_2)_3$ groups. The BET surface area of the mesoporous calcined sample amounted to 312 $m^2\ g^{-1}$. The pore volume was 1.0 $cm^3\ g^{-1}$ and the average cylindrical pore diameter was calculated to be 11.6 nm. The good titania dispersion (relative contribution of Si–O–Ti entities) was confirmed by FT-IR from the ratio of Si–O–Ti (950 cm^{-1}) and Si–O–Si (1210 cm^{-1}) peak areas.

This catalyst also converted the allylic alcohol **1** selectively to the epoxide **2**. At 30% conversion of **1**, which was attained in 18 min, the epoxide selectivity was 78%. As compared to the reaction with 20LT and Me_2NBu (Table 1), the lower epoxide selectivity of $10LT_A$ is likely due to the too high amine content. The catalyst was also tested in the epoxidation of *trans*-hex-2-en-1-ol. Under conditions similar to the oxidation of **1** but at 90 °C, the epoxide yield was 48% after 1 h reaction time. Recycling $10LT_A$ twice (after washing and drying) afforded 33 and 31% yields. The lower yields were partly due to catalyst loss during recycling (17%), and the difference between the performance of fresh and used catalysts decreased at higher reaction times. Epoxide selectivity was barely influenced by recycling (70 and 72% for the first and third runs, respectively). Besides, $10LT_A$ did not catalyze the epoxide ring opening reaction, indicating the suppressed acidity of this amine-modified catalyst.

We have attempted to apply amine modifiers in the epoxidation of other cyclic allylic alcohols. The epoxidation of isophorol over 20LT without amine additive at 363 K resulted in byproducts mainly by non-oxidative reactions, and only 10% epoxide selectivity at 221% conversion (related to initial TBHP concentration) was obtained in 1h. Using $PhMeCHNH_2$ (1 mol%) the side reactions were diminished and 58% epoxide selectivity at 72% substrate conversion was achieved. The influence of alkyl substituents on the epoxidation of cyclohexenols is presently under investigation.

In conclusion, in the epoxidation of alkyl-substituted cyclic allylic alcohols with a titania–silica aerogel and TBHP, small amounts of amines suppress the acid-catalyzed, non-oxidative side reactions. In the best case, 1 mol% of Me_2NBu (related to 3-methylcyclohex-2-en-1-ol reactant) afforded 98% epoxide selectivity at 30% conversion, and over 70% epoxide yield at high conversion. On the basis of this observation, a novel bifunctional, recyclable catalyst has been developed. This modified aerogel contains both Lewis acidic $[(SiO)_4Ti]$ and Lewis basic $[C_3H_6N(CH_3)_2]$ sites. It is hoped that tuning the acid–base and redox properties will further improve the performance of this catalyst.

Financial support by Hoffmann-La Roche AG, Switzerland and the 'Kommission für Technologie und Innovation' is gratefully acknowledged.

Received (in Cambridge, UK) 28th October 1998, Accepted 15th December 1998

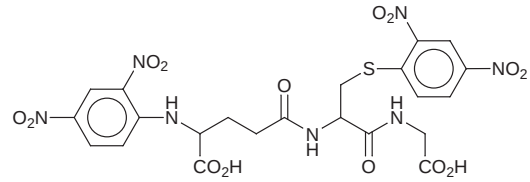
Molecular imprinting of albumin with *N*,*S*-bis(2,4-dinitrophenyl)glutathione (GSH-2DNP), a glutathione (GSH) derivative, leads to an imprinted protein with GSH binding sites; chemical mutation of the protein results in formation of an artificial enzyme with high glutathione peroxidase (GPX) activity.

The catalytic efficiency of an enzyme is dependent on its ability to recognise substrates, and the generation of recognition sites for substrates plays an important role in enzyme imitation.[1] In general, two strategies have been used to generate this recognition, the monoclonal antibody technique and molecular imprinting.[2,3] Glutathione peroxidase (GPX, EC 1.11.1.9) is an important antioxidative enzyme that catalyzes the reduction of a wide variety of hydroperoxides by glutathione (GSH).[4] The enzyme is composed of four identical subunits; the active site in each subunit contains a selenocysteine residue (catalytic group) and a GSH binding site.[5] Based on the structure of this enzyme, we have previously developed a strategy for generating catalytic antibodies with GSH binding sites and GPX activity using monoclonal antibody preparation technology and chemical mutation.[6] This study shows that the binding site for substrate GSH and the catalytic moiety selenocysteine are critical factors for catalysis.

Here we describe a new strategy for generating a GPX mimic with a GSH binding site using bioimprinting and chemical mutation. The method consists of five basic steps: (i) unfolding the conformation of the starting protein under acid conditions; (ii) addition of the imprinting molecule (or template), to allow it to interact with the denatured protein to form a new conformation with substrate binding sites; (iii) crosslinking the protein with a bifunctional reagent to fix the new conformation of the protein; (iv) dialysis of the protein to remove the imprinting molecules; and (v) conversion of the active serine residues in the binding site of the crosslinked protein into selenocysteines to incorporate catalytic groups. Thus, there are both substrate binding sites and catalytic groups in the printed protein and thus it should display an enzyme activity.

We chose a GSH derivative, *N*,*S*-bis(2,4-dinitrophenyl)glutathione (GSH-2DNP), as the imprinting molecule. The unstable thiol group and amino group of GSH were protected by reaction with 2,4-dinitrofluorobenzene to give GSH-2DNP. The derivative is structurally similar to the substrate molecule GSH. After the conformation of the starting protein (egg albumin) had been unfolded by denaturation, the imprinting molecule (GSH-2DNP) was allowed to interact with the unfolded protein to form a new conformation *via* hydrogen bonds, ion pairing and hydrophobic interactions. The new conformation was then fixed using glutaraldehyde. The cavities, which were left in the printed protein after removing GSH-2DNP by dialysis, were able to recognize the substrate GSH. The serine residues located in the binding sites of the imprinted protein were active and could be converted into the catalytic groups of GPX (selenocysteines) by chemical mutation.[6,7]

The preparation of the imprinted enzyme is as follows: egg albumin (1 ml of a 1 mg ml^{-1} solution) was adjusted to pH 3.0 with 0.1 M HCl and stirred at room temperature for 1 h. The imprinting molecule, GSH-2DNP (5 mg), was added to the protein solution and stirred for 1 h. The pH was then adjusted to 8.0 with 0.1 M NaOH and glutaraldehyde solution (1%; 100 μl) was added. The reaction mixture was stirred at 5 °C for 12 h and dialyzed for 48 h against 50 mM phosphate buffer, pH 7.0. The dialyzed solution was activated by adding 10 μL of phenylmethanesulfonyl flouride (20 mg ml^{-1} solution in MeCN) and incubated at 25 °C for 3 h. A portion of 1 M NaHSe (100 μl; 100 μmol) prepared according to the method of Klayman and Griffin[8] was added to the activated solution, and incubated at 40 °C for 30 h under nitrogen atmosphere. The solution was oxidized by air at 4 °C for 5 h and was centrifuged to remove the solid selenium. The crude imprinted protein was purified by gel filtration on a superose B-12 column, and the first peak was collected; the crosslinked protein in this peak proved to be the dimer by HPLC. The non-printed protein was also prepared from egg albumin using the same conditions in the absence of GSH-2DNP, and used as a control.



GSH-2DNP

The selenium content was determined by 5,5′-dithiobis(2-nitrobenzoic acid) titration,[7] and 1.89 ± 0.15 equiv. of selenium

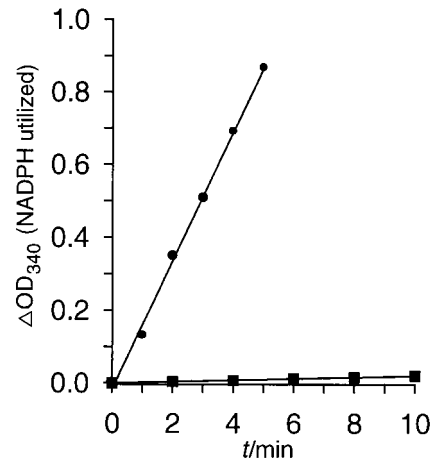


Fig. 1 Printed and non-printed protein-catalyzed reduction of H_2O_2 by GSH: (●) printed protein and (■) non-printed protein. The catalytic reaction containing GSH (1 mM), H_2O_2 (0.5 mM), glutathione reductase (1 unit), NADPH (0.25 mM) and 0.2 μM enzyme mimic (pH 7.0 at 25 °C) was monitored *via* NADPH decrease in absorbance at 340 nm. The absorbance change was corrected for the background reaction between H_2O_2 and GSH.

per printed protein molecule was detected. The GPX activity of the printed protein was measured by a coupled enzyme system containing glutathione reductase, GSH, NADPH and H_2O_2.[6] The printed protein-catalyzed reduction of H_2O_2 by GSH was initiated by adding the substrate H_2O_2. The initial rate of the printed protein (0.2 μM)-catalyzed removal of H_2O_2 (with NADPH) by GSH was found to be 8.2×10^{-3} M min^{-1} during the initial 5 min of reaction (Fig. 1). However, the initial rate of the non-printed protein (0.2 μM)-catalyzed reaction was only 9.5×10^{-5} M min^{-1}. The GPX activities of the printed and non-printed proteins were calculated to be 817 ± 28 and 10 ± 3 U μmol^{-1}, respectively. The printed protein displays a high GPX-like activity and is only seven times less than that of the native GPX from rabbit liver (5780 U μmol^{-1}).[6] Compared with ebselen (PZ51, 0.99 U μmol^{-1}), the best GPX mimic known,[6] the GPX activity of the printed protein is 820 times that for PZ51. The apparent catalytic rate constant for H_2O_2 (k_{cat}) was measured to be 785 min^{-1} ([GSH] = 1 mM).

It was found that GSH-2DNP inhibited the GPX activity of the printed protein, while the GPX activity of the non-printed protein was unaffected by GSH-2DNP, indicating that specific binding sites for the imprinting molecule have been obtained.

Thus, bioimprinting of albumin with a GSH derivative led to the generation of cavities for binding GSH. The high catalytic activity of the printed protein and the inhibition by the imprinting molecule provide strong evidence that the catalysis achieved is a function of specific binding sites generated by protein imprinting. Although the formation of active sites requires further investigation, the initial results suggest that this approach is a new method for generating imprinted enzymes with high GPX activity.

Received (in Cambridge, UK) 18th November 1998, Accepted 4th December 1998

Template-directed co-condensation was used to synthesize organo-functionalized MCM-41 silica hexagonal mesophases containing binary combinations of covalently linked phenyl and amino, thiol or allyl moieties; similar methods were used to prepare a phenyl-functionalized organo-MCM-48 silica with cubic structure.

The direct synthesis of ordered MCM-41 silica mesophases containing covalently coupled organic moieties has been recently reported.[1–5] These materials could have important uses in optical applications,[5] catalysis,[6,7] metal-ion extraction[8] and adsorption processes.[9] Here we extend the method of template-directed co-condensation to the synthesis of MCM-41 structures containing two distinct types of covalently linked organic functionalities. We show that allyl, thiol or amine moieties can be incorporated along with phenyl residues into the hexagonally ordered mesophase. In addition, we report the direct synthesis of an organo-MCM-48 cubic mesophase with covalently linked phenyl functionalities by adaptation of a previously reported method involving hydrothermal phase transformation.[10]

Bifunctionalized organosilica–surfactant mesophases with hexagonal MCM-41-type structure were synthesized at room temperature and pressure from alkaline solutions of hexadecyltrimethylammonium bromide (CTAB) containing varying molar ratios of tetraethoxysilane (TEOS), phenyltriethoxysilane (PTES), and another organotrialkoxysilane [$(RO)_3Si–R'$, R′ = CH_2CHCH_2 (allyltrimethoxysilane, ATMS), $(CH_2)_3NH_2$ (3-aminopropyltriethoxysilane, APTES) or $(CH_2)_3SH$ (3-mercaptopropyltriethoxysilane, MPTES). The molar composition of a typical synthesis was: 0.12 CTAB : 0.50 NaOH : 1.0 total siloxane : 130 H_2O.‡ Acidic extraction of the surfactant from the as-synthesized products was used to prepare the corresponding organo-functionalized mesoporous silica materials.

Transmission electron microscopy (TEM) [Fig. 1(a)] and small-angle X-ray powder diffraction (SAXRD) indicated that well ordered hybrid mesophases were formed when the total amount of organotrialkoxysilanes in the synthesis mixture was *ca.* 20 mol% or less. Under these conditions, it was possible to covalently link two organic functionalities into the ordered silica framework without disruption of the long range mesoscopic order established by self-assembly of the surfactant template. For example, materials perpared from 10 mol% of PTES and 10 mol% of ATMS, MPTES or APTES, showed four reflections that were assigned to the (100), (110), (200) and (210) reflections of hexagonally ordered MCM-type structures with unit cell parameters between 4.4 and 4.6 nm.§ The *d* spacings were similar to those reported for non-functionalized MCM-41, as well as ordered organosilica mesophases prepared from co-condensation of TEOS and a single organotrialkoxysilane.[1,3] Bifunctionalized mesoporous derivatives, prepared by surfactant extraction, were generally less ordered than the as-synthesized products, except for materials prepared from PTES and APTES which showed four diffraction peaks.§ In each case, significant contractions in the unit cell length to values below 4 nm were observed.BET data gave a surface area of 1220 $m^2\ g^{-1}$ and pore diameter of *ca.* 3.5 nm for a surfactant-extracted material prepared from 5 mol% of phenyl- and 5 mol% amino-trialkoxysilanes.

MCM-41 type materials prepared from 20 mol% PTES and 20 mol% ATMS showed evidence for extensive structural disorder (broad reflections at d = 3.61 and 1.87 nm) and lattice contraction (a = 4.17 nm) in the as-synthesized materials, presumably due to the decreasing number of fully condensed Si (Q^4) centres associated with the higher levels of organosiloxane linkages. Surfactant extraction gave only a single, broad ill defined peak, indicative of collapse of the partially ordered channel structure in these hybrid materials.

Incorporation of the covalently linked organic groups was confirmed by ^{29}Si solid-state CP NMR spectroscopy which showed distinct resonances for siloxane [Q^n = $Si(OSi)_n(OH)_{4-n}$, n = 2–4] and organosiloxane [T^m = $RSi(OSi)_m(OH)_{3-m}$, m = 1–3] environments (graphical abstract). The integrated signal due to the latter approximately doubled when

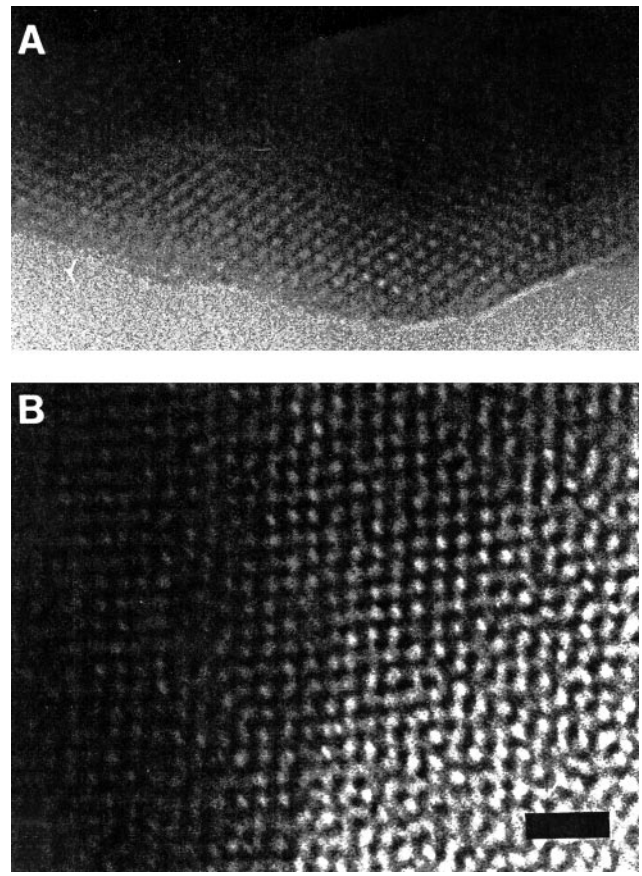

Fig. 1 TEM micrographs of (A) as-synthesized bi-functionalized phenyl-amino-MCM-41 mesophase (10 mol% PTES/10 mol% APTES) showing hexagonally ordered channel structure, (B) phenyl-functionalized MCM-48 mesophase (10 mol% PTES) showing cubic structure viewed down the < 110 > zone. Scale bar (both micrographs) = 10 nm.

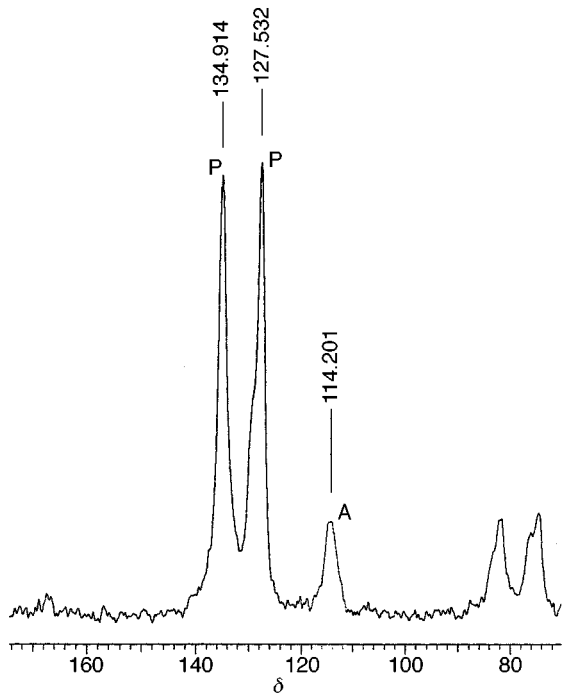

Fig. 2 ^{13}C CP MAS NMR spectrum for a bifunctionalized organo-MCM-41 mesophase showing resonances for intact phenyl (P) and allyl (A) moieties.

the total amount of organoalkoxysilanes in the synthesis mixture was increased from 20 to 40%. In most cases, the Q^3 and T^2 linkages were predominant, indicating that the organosilica mesophases contained significant amounts of uncondensed Si–OH centres. The bifunctional nature of the materials was confirmed by ^{13}C CP MAS NMR studies which showed intact phenyl moieties along with unmodified allyl, amine or thiol groups (Fig. 2).¶ This was consistent with FTIR spectra of the surfactant-extracted materials which showed characteristic absorption bands for the covalently-linked organic residues.‖

Organosilica–surfactant mesophases were also synthesized at 100 °C from alkaline solutions of hexadecyltrimethylammonium chloride (CTACl) containing varying molar ratios of TEOS and PTES, APTES, MPTES or ATMS; typically the molar composition was: 0.64 CTACl : 0.25 NaOH : 1.0 total siloxane : 62 H_2O.** Under these conditions, which utilise lower surfactant concentrations than are normally required for MCM-48 synthesis, the cubic mesophase is formed by an ethanol-induced phase transformation of a MCM-41 precursor.[10] SAXRD data for a functionalized silica mesophase prepared from 10 mol% PTES gave four reflection peaks at d = 3.93, 3.52, 2.15 (broad) and 1.79 nm that were indexed to the (211), (220), (400)/(420) and (431) reflections, respectively, of a cubic *Ia*3*d* mesophase with unit cell length of 9.62 nm. TEM images confirmed the formation of an ordered MCM-48-type material [Fig. 1(b)] and ^{13}C CP NMR showed resonances (δ 127.5, 135.0) corresponding to the covalently linked phenyl moieties. FTIR peaks at 702 and 3000–3100 cm^{-1} also confirmed the presence of the phenyl functionality. SAXRD profiles of the surfactant extracted, phenyl-functionalized MCM-48 silica showed three main reflections (d = 3.93, 2.10, 1.49 nm) which were indexed to the (100), (110) and (210) peaks of a hexagonally ordered organo-mesoporous material. The apparent structural collapse of the cubic material in the absence of the surfactant was consistent with TEM images which showed a marked decrease in the amount of cubic pore order in the sample. BET analysis gave a surface area of 1040 $m^2\ g^{-1}$ for the surfactant extracted product.

Analogous samples functionalized with amino, thiol or allyl groups gave only broad XRD peaks, with no evidence of an ordered organo-MCM-48 (or MCM-41) mesophase. ^{13}C CP NMR and FTIR data on these samples indicated that the organic groups were not incorporated to any significant extent into the silica materials. This suggests that APTES, MPTES and ATMS did not undergo significant condensation, or that the functional groups are labile under the reaction conditions, or both. In particular, the elevated temperature of the synthesis method is likely to increase the rate of formation of the Q^n centres at the expense of the T^m linkages.

Our results suggest that bifunctionalization of the MCM-41 mesostructure could provide a general route to multi-component inorganic–organic hybrids and their (partially) ordered mesoporous derivatives. Such materials extend the complexity of self-organized inorganic matter and should be useful in processes requiring controlled confinement, for example where the channel reactivity needs to be coupled with the hydrophobic/hydrophilic balance of the localized environment. Because the 3-D channel network of MCM-48 is less susceptible to pore blockage compared with the linear channel structure of MCM-41, organoMCM-48 materials could have specific technological advantages. However, significant advances are required to improve the structural stability of these organized materials.

We thank Dr David C. Apperley (University of Durham) for solid-state NMR data, Dr S. J. Roser (University of Bath) for help with SAXRD data, and the EPSRC for financial support to S. R. H.

Reaction of (dimethylvinylidene)carbene with indole-3-carbaldehyde and its application in the synthesis of β-(dehydroprenyl)indole-based natural products

Jyh-Horng Sheu,* Chun-An Chen and Buo-Horng Chen

Department of Marine Resources, National Sun Yat-Sen University, Kaohsing, 804, Taiwan.

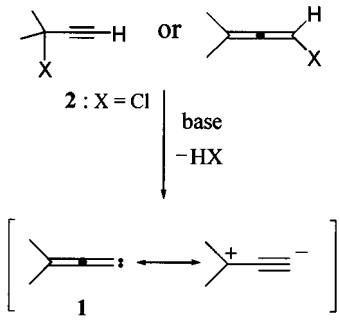
Received (in Cambridge, UK) 9th November 1998, Accepted 7th December 1998

Reaction of (dimethylvinylidene)carbene with indole-3-carbaldehyde gives various dehydroprenyl-based indoles. Efficient synthesis of the indole natural products yuehchukene and murrapanine, using this reaction as a key step, is also described.

The cyclopropanation of nucleophilic olefins with (dimethylvinylidene)carbene **1**, generated by the elimination of hydrogen halide from propargyl halides or halloallenes (Scheme 1),

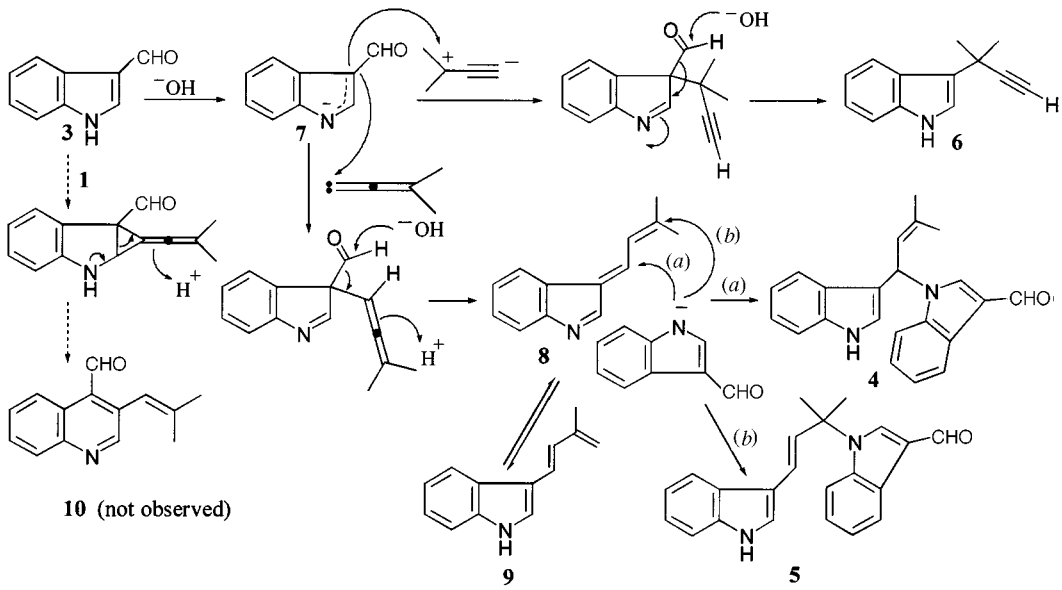


Scheme 1

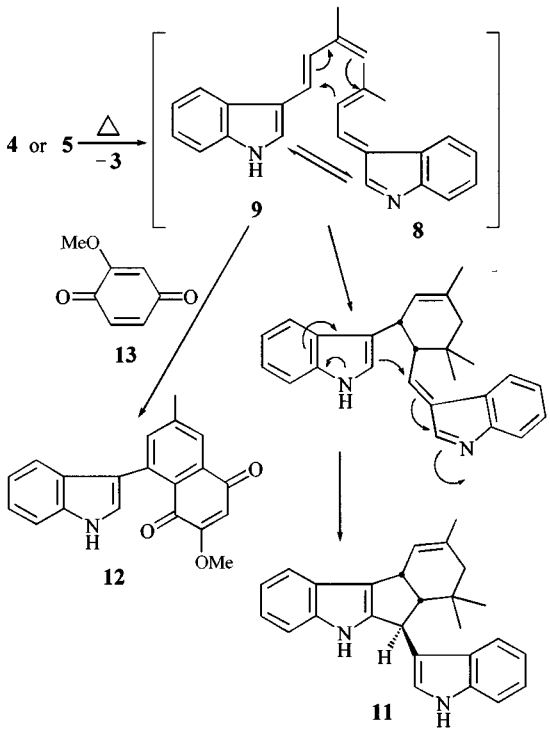
represents an important carbon–carbon bond-forming process, involving introduction of a dehydroprenyl group into organic substrates,[1–6] and has found use in natural product synthesis.[7,8] Interaction of **1** with indole itself[9] and α- and/or β-methyl indoles has been studied,[10] however, reaction between **1** and indoles containing an electron-withdrawing group at C-2 or C-3 has not been investigated. In connection with our previous studies on the regioselectivity of **1** towards different olefins[11] and synthesis of β-(dehydroprenyl)indoles,[12] we have investigated the reaction of **1** with indole-3-carbaldehyde. We report herein the preliminary results of this work directed to the introduction of a dehydroprenyl unit onto the β-carbon of indole. Application of this reaction in the synthesis of indole natural products containing a β-dehydroprenyl group is also described.

Treatment of 3-chloro-3-methylbut-1-yne **2** with aq. KOH, a catalytic amount of dibenzo-18-crown-6 and THF in the presence of indole-3-carbaldehyde **3** under reflux gave a mixture which was separated to afford two bis-indoles, 3-[3-methyl-1-(3-formylindol-1-yl)but-2-enyl]indole **4**† (44%) and 3-[(*E*)-3-methyl-3-(3-formylindol-1-yl)but-1-enyl]indole **5**‡ (6%), and 3-(1,1-dimethylprop-2-ynyl)indole **6**[9] (8%). Alkyne **6** was considered to be derived from the electrophilic addition of the carbene **1** at C-3 to the β-carbon of anion **7** and subsequent decarbonylation. Electrophilic addition of the carbene at C-1 to the β-carbon of the indolide anion **7** and subsequent decarbonylation, on the other hand, would lead to the formation of indole **8**, a tautomer of β-(dehydroprenyl)-indole **9**, as the reactive intermediate. Further condensation of anion **7** at the C-2 and C-4 positions of the side-chain of **8** could give β-prenylindoles **4** and **5**, respectively. The mechanism of this reaction was proposed as portrayed in Scheme 2. The formation of **4** and **5** revealed that β-dehydroprenylation of indole had taken place, but that the product was unstable in the form of **8** or its tautomer **9** under the above reaction conditions, and had undergone *in situ* Michael condensation with anion **7**.

Interaction of carbene **1** with α- and/or β-methylindoles, and indole itself, has been shown to give mostly ring expansion of the cyclopropane intermediates, which were assumed to be formed by addition of carbene to the nucleophilic 2,3-double bond of indoles, to give 3-vinylquinolines.[9,10] However, the



Scheme 2



Scheme 3

reaction of **1** with **3** did not give the expected quinoline **10**, probably due to the stronger acidity of indole-3-carbaldehyde **3** in comparison with α- and/or β-methylindoles and indole itself. Thus, interaction of indole **3** with base gave indolide anion **7**, which reacted predominantly *via* nucleophilic attack by C-3 upon carbene **1**, and led to the formation of dehydroprenylindoles and/or the following prenylindoles. This study shows that the presence of an electron-withdrawing group, in this case the formyl group at the β-position of indole, could prevent the formation of quinoline and steer the reaction towards β-alkylation products.

The above reaction provides a new method for the β-prenylation of indole in a simple and efficient manner. Furthermore, elimination of **3** from both **4** and **5** to give β-(dehydroprenyl)indole **9** should be achieved easily as the anion **7** is stable due to delocalisation of the negative charge, and is considered to be a good leaving group. Thus, the above reaction may be useful for the synthesis of β-(dehydroprenyl)indole-base compounds. In order to demonstrate the potential of this carbon–carbon bond-forming reaction we applied the above reaction as a key step in the synthesis of two bioactive indole natural products, yuehchukene **11**[13,14] and murrapanine **12**,[15] which were isolated from *Murraya* species. The structures of these two compounds reveal that they are derived from β-(dehydroprenyl)indole **9**. We found that heating both **4** and **5** in a neutral solution of ethylene glycol at 165–170 °C yielded yuehchukene in 42% yield. Thermal reaction of **4** and **5** with methoxyquinone **13** (3 equiv.) under the above reaction conditions afforded murrapanine in 65% yield. The above one-step reactions are considered to give β-(dehydroprenyl)indole **9** first *via* elimination of **3** (recovered quantitatively), followed by subsequent Diels–Alder reaction (Scheme 3) as described previously.[12] The dehydroprenyl unit of the carbon skeleton of natural products **11** and **12** were constructed completely from carbene **1** in this synthesis. It is worth mentioning here that this is the first synthesis of a dehydroprenylated indole natural products using (dimethylvinylidene)carbene **1** as the isoprenoid unit of the carbon skeleton.

In conclusion this is the first reaction of vinylidenecarbene with indoles having an electron-withdrawing substituent on the 2,3-double bond. The above reaction provides an efficient method for introducing an appropriate 'isoprene' group into the β-position of indole, making use of inexpensive and readily available propargyl chloride **2** and indole-3-carbaldehyde **3** as starting materials. The above result suggests that reaction of vinylidenecarbene with indoles containing different functional groups at C-2 and C-3 should be further investigated. The scope of this chemistry is now being explored in our laboratory.

Intramolecular non-bonded interaction between selenium and oxygen as revealed by ^{17}O and ^{77}Se NMR spectroscopy and natural bond orbital analysis

Hiroto Komatsu, Michio Iwaoka and Shuji Tomoda*

Departement of Life Sciences, Graduate School of Arts and Sciences, The University of Tokyo, Komaba, Meguro-ku, Tokyo 153-8902, Japan. E-mail: tomoda@selen.c.u-tokyo.ac.jp

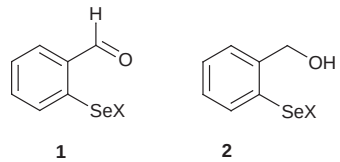
Received (in Cambridge, UK) 20th October 1998, Accepted 30th November 1998

^{17}O and ^{77}Se NMR spectroscopic measurement and natural bond orbital (NBO) analysis of 2-formyl- and 2-hydroxymethyl-benzeneselenenyl derivatives (ArSeX; X = Cl, Br, CN, SPh, SeAr, Me: Ar = C_6H_4CHO, $C_6H_4CH_2OH$) provided strong evidence for the intramolecular non-bonded interaction between selenium and oxygen due to orbital interaction between the oxygen lone pair and the low-lying σ^*_{SeX} antibonding orbital ($n_O \rightarrow \sigma^*_{SeX}$).

Non-bonded interactions involving selenium are an important factor that often dictates the structure and reactivity of organoselenium compounds, some of which are known to be useful for asymmetric synthesis[1] as well as for enzyme-mimetic catalytic reactions.[2] We have recently studied the non-bonded interaction between selenium and nitrogen (Se···N)[3] and selenium and fluorine (Se···F)[4] to characterize the mechanism of the interactions. While the former interaction is stabilized chiefly *via* orbital interaction (donor–acceptor interaction),[3] the stabilization mechanism of the latter may be slightly more electrostatic in nature.[4] From the viewpoint of electronegativity scale,[5] it is expected that the interaction between selenium and oxygen (Se···O) may be intermediate. However the results of the recent publications on the mechanism of Se···O interactions are variable to leave the interaction mechanism of Se···O uncertain.[6]

Herein we report the first systematic NMR study of Se···O interactions. The conclusions drawn from the present NMR study have been corroborated by *ab initio* molecular orbital calculations combined with natural bond orbital (NBO) analysis proposed by Weinhold.[7]

Model compounds, ^{17}O-enriched 2-formylbenzeneselenenyl derivatives (**1a–f**) and 2-(hydroxymethyl)benzeneselenenyl derivatives (**2a–f**), were synthesized from the corresponding



1 **2**

b: X = Br
c: X = CN
d: X = SPh (**d'**: X = SMe)
e: X = SeAr (**e'**: X = SeMe)
f : X = Me

^{17}O-enriched diselenide (**1e**) according to literature methods.[8] These compounds were obtained in spectrally pure form except for **1d** and **2d**, which slowly disproportionated into the corresponding diselenides (**1e** and **2e**) at room temperature.

Since ^{17}O nuclear spin is a quadrupole, attempts at observing the one-bond spin–spin coupling constant between the non-bonded ^{17}O and ^{77}Se ($^1J_{Se\cdots O}$), which was thought to provide direct information as to the intramolecular non-bonded interaction between these nuclei, was unsuccessful. The ^{17}O NMR chemical shift data (δ_O) for compounds **1** and **2**, obtained at 67.70 MHz, are collected in Table 1 along with those of ^{77}Se NMR chemical shift (δ_{Se}), measured at 95.35 MHz. Three notable features are seen from Table 1.

First, within the series of compounds **1**, a monotonous downfield shift of δ_O is observed on going from **1a** to **1f** (δ_O = 493.0 → 561.6), while exactly the opposite trend is apparent for δ_O for **2** (δ_O = 24.9 → 10.6). Secondly, δ_O values for **1** (δ_O = 493.0–561.6), each of which possesses an sp^2-hybridized oxygen, are shifted toward upfield ($\Delta\delta_O$ = −76 to −7) compared with that of a reference benzaldehyde, which lacks the selenium moiety (δ_O = 569),[9] whereas δ_O values for **2** (δ_O = 24.9–10.6), each of which bears an sp^3-hybridized oxygen, are shifted downfield ($\Delta\delta_O$ = 24.2–9.9) compared to that of reference compound benzyl alcohol (δ_O = 0.7).[10] The mutually inverse effect on the relative chemical shift ($\Delta\delta_O$) precludes the possibility of major inductive through-bond electronic effects of the selenium moiety (SeX). These experimental data strongly suggest that a Se···O interaction (attractive or repulsive) may exist at least in one of these compound series. It should be noted that the absolute magnitude of these shifts ($\Delta\delta_O$) steadily decrease on going from **a** through **f** for both series. Thirdly, comparison of ^{77}Se chemical shifts (δ_{Se}) between compounds **1** and **2** possessing the same substituent X reveals that the former (1114.1–259.5) is considerably lower than the latter (987.1–157.2), clearly suggesting that there should be a stronger Se···O interaction in series**1** than in **2** ($\Delta\delta_{Se}$ = 25.3–190.0): the significant downfield shift may be caused on the selenium nucleus by the anisotropic deshielding effect of the formyl C=O bond of **1** if the selenium lies coplanar with the C=O bond.

It is well known[11] that a linear dependence of ^{17}O NMR chemical shift on the amount of electronic charge on the oxygen atom generally exists within a series of structurally similar compounds: for an sp^2-hybridized oxygen atom, the higher the charge, the larger the magnitude of upfield shift of ^{17}O NMR chemical shift, while exactly the opposite trend is observed for sp^3-hybridized oxygen. According to this rule, the dependence of the chemical shift (δ_O) on substituent X seen from Table 1 suggests that for both series of compounds (**1** and **2**) the electronic charge on the oxygen atom in the conformation with

Table 1 ^{17}O and ^{77}Se NMR chemical shifts (δ_O and δ_{Se}) of **1** and **2**[a]

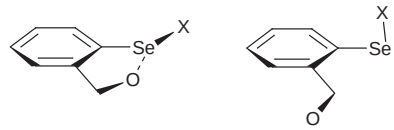
[a] Measured in $CDCl_3$ at 298 K. [b] Measured at 67.70 MHz with D_2O as an external standard. [c] Relative ^{17}O NMR chemical shift with respect to PhCHO (δ_O = 569).[9] [d] Measured at 95.35 MHz with Me_2Se as an external standard. [e] Relative ^{17}O NMR chemical shift with respect to $PhCH_2OH$ in acetone (δ_O = 0.7).[10] [f] $\Delta\delta_{Se} = \delta_{Se}(\mathbf{1}) - \delta_{Se}(\mathbf{2})$.

Se···O interaction should decrease monotonously on going from **a** to **f**.

Strong theoretical evidence for the existence of attractive Se···O interaction as well as for the definitive trend of the electronic charge at oxygen atom for both series of compounds has been obtained with *ab initio* molecular orbital calculations[12] and natural bond orbital (NBO) analysis.[7] See http://www.rsc.org/suppdata/cc/1999/205 for summary of results as electronic supplementary information. Initial conformational search of **1** and **2** at the RHF/3-21G* level indicated two stable conformational isomers for both series of model compounds (Scheme 1). Conformer **A**, in which the O–Se–X angle is nearly 180°, has a close Se···O contact, whereas conformer **B**, in which the Se–X bond is almost perpendicular to the plane of the phenyl ring, does not. For all model compounds calculated with 6-31G(d,p) basis for C, H, N, O, S, and Cl and Huzinaga's 43321/4321/311(d) basis set for Se and for Br,[13] conformer **A** was found to be more stable by ΔE_{tot} = 0.44–9.99 kcal mol^{-1}, strongly suggesting that the Se···O interaction may be attractive in all cases in consonant with the trends manifested by the ^{17}O and ^{77}Se NMR chemical shift data.



A **B**

Scheme 1

Natural population analysis (NPA) of these conformers indicates the following three intriguing points with regard to the electron population at oxygen atom in conformers **A** and **B** (q_A and q_B). First, the populations at the oxygen atom of **2** (*ca.* −0.8 e) are uniformly greater than those of **1** (*ca.* −0.6 e) irrespective of substituent X. Secondly, relative oxygen populations with respect to the reference compounds (PhCHO for **1** and $PhCH_2OH$ for **2**) for conformer **A** (Δq_A) are negative, indicating that Se···O interaction might induce a small increment of electron density at the oxygen and that this is larger in **1** (Δq_A = 0.000 to −0.025) than in **2** (Δq_A = −0.001 to −0.008). Thirdly, such a tendency is attenuated on going from **a** to **f** for both series, which may imply that the magnitude of the Se···O interaction is diminished in this order. In full agreement with the previous observation[11] on the linear relationship between the charge at oxygen and ^{17}O NMR chemical shift, Δq_A indeed exhibits a linear correlation with $\Delta\delta_O$ (r^2 = 0.89 and 0.90 for series **1** and **2**, respectively), indicating that conformer **A** is more stable for both series **1** and **2**.

NBO deletion analysis, which is known to be an effective method of quantitative evaluation of attractive orbital interaction alone,[7] has been applied to conformer **A** for both compound series to estimate the strength of the Se···O interaction due to orbital interaction mechanism (E_{del}). Series **1** has E_{del} = 16.6–6.1 kcal mol^{-1} and **2** has E_{del} = 6.8–1.9 kcal mol^{-1}. A remarkable linear correlation was observed between the Se···O distance ($d_{Se\cdots O}$) and the NBO deletion energy (E_{del}) for each series (r^2 = 0.98 for **1** and 0.96 for **2**), which may suggest that the attractive Se···O interaction should arise chiefly from orbital interaction. NBO second-order perturbation analysis indicated that the major orbital interaction is that between the oxygen lone pair (n_O) and the low-lying σ^*_{SeX} antibonding orbital ($n_O \rightarrow \sigma^*_{SeX}$). It is apparent that this interaction energy explains most of E_{del} in all cases. Interestingly an excellent linear correlation was observed between the relative chemical shift ($\Delta\delta_O$) and E_{del} for each series of model compounds. For series **1**, the slope of the correlation is negative (r^2 = 0.96), whereas for **2** it is positive (r^2 = 0.90), indicating that both upfield shift for series **1** and downfield shift for series **2** should be roughly proportional to the magnitude of the Se···O interaction due to orbital interaction mechanism (E_{del}). It is particularly noteworthy that highly electronegative substituent (X), such as CN, shows almost no deviation from linearity, which may preclude the possibility of electrostatic mechanism of Se···O interaction in these compounds.

In summary, the linear correlations among the three parameters for conformer **A** of both series **1** and **2** namely, $\Delta\delta_O$, E_{del} and Δq_A, are in full accord with the existence of attractive nonbonded Se···O interactions, the major mechanism of which is most likely to be the orbital interaction between the oxygen lone pair (n_O) and the low-lying σ^*_{SeX} antibonding orbital. Possible enhanced strength of the attractive Se···O interaction in **1** *cf.* **2** may be most simply explained in terms of π-conjugation between the formyl group and the phenyl ring in **1**, which may encumber free rotation around the C(Ph)–CH bond to generate a stable conformation of **1** with a Se···O distance that is shorter ($d_{Se\cdots O}$ = 2.58–2.86 Å) than those of **2** ($d_{Se\cdots O}$ = 2.82–3.17 Å).

Synthesis of a chiral dendrimer based on polyfunctional amino acids

Andreas Ritzén and Torbjörn Frejd*

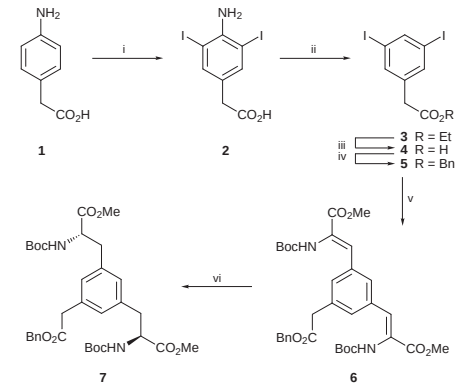
Organic Chemistry 1, Department of Chemistry, Lund University, PO Box 124, SE-221 00, Lund, Sweden. E-mail: torbjorn.frejd@orgk1.lu.se

Received (in Liverpool UK) 24th November 1998, Accepted 10th December 1998

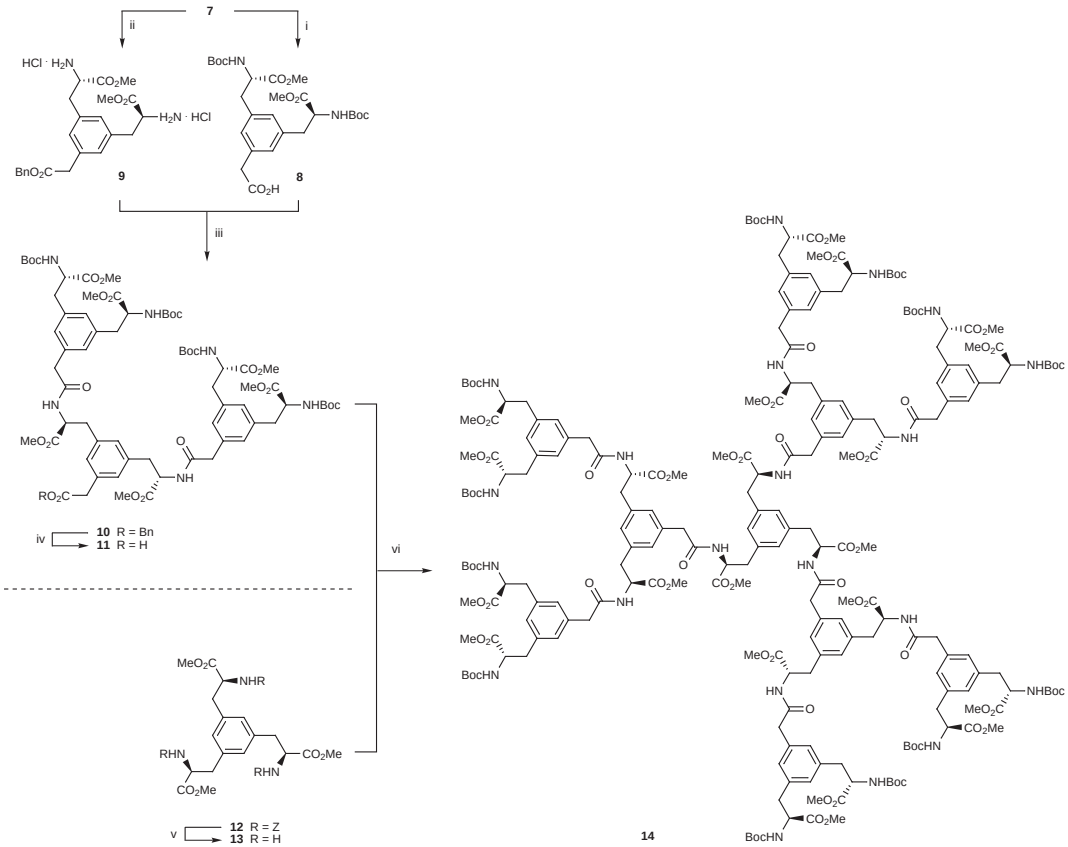
A chiral, nonracemic dendrimer of generation two based on aromatic bis- and tris-amino acids has been synthesised.

The design and synthesis of functional dendrimers has been the focus of much research during the last ten years.[1,2] Chiral, nonracemic dendrimers with well-defined stereochemistry are a particularly interesting subclass, with potential applications in asymmetric catalysis and chiral molecular recognition.[3] For biological applications, polyionic, water-soluble dendrimers will be of interest.[4] Here we report the synthesis of a chiral, nonracemic dendrimer **14** (see Scheme 2) based on synthetic, di- and tri-functional amino acids.

The dendrimer **14** is assembled from nine units of the bis-amino acid **7** and one unit of protected phenyltrisalanine **12**.[5] The synthesis of **7** is described in Scheme 1, and is based on a Heck coupling–hydrogenation protocol which has been used in our laboratory before.[5–7] Starting from 4-aminophenylacetic acid **1**, iodination with ICl gave **2**.[8] Removal of the amino group *via* stepwise diazotization and reduction proved difficult, and *in situ* generation of the diazonium salt in refluxing EtOH was the only satisfactory method found. Under these conditions, the diazonium salt was immediately reduced by EtOH giving **3** as



Scheme 1 *Reagents and conditions*: i, ICl (2.0 equiv.), HCl (1 M), room temp. 18 h, 65%; ii, H_2SO_4, $NaNO_2$ (3.0 equiv.), EtOH (99.5%), reflux, 1 h, 55%; iii, NaOH (2 M), reflux, 3 h, then HCl, 92%; iv, $KHCO_3$ (1.1 equiv.), BnBr (1.1 equiv.), DMF, 60 °C, 2 h, 58%; v, H_2C=C(NHBoc)CO_2Me (2.0 equiv.), $Pd(OAc)_2$ (0.10 equiv.), $NaHCO_3$ (5.0 equiv.), $Bu_4N^+Cl^-$ (2.0 equiv.), DMF, 60 °C, 8 h, 43%; vi, {Rh(COD)[(S,S)-Et-DuPHOS]}$^+OTf^-$ (0.009 equiv.), H_2 (40 psi), MeOH, room temp., 6 h, > 99%, > 98%, ee dr > 99 : 1.



Scheme 2 *Reagents and conditions*: i, Pd/C (5%), EtOH (99.5%), H_2 (1 atm), room temp., 3 h; ii, 3 M HCl in EtOAc, 30 min, room temp.; iii, **8** (2.0 equiv.), TFFH (2.4 equiv.), DIEA (4.8 equiv.), DMF, room temp., 5 min, then **9** (1.0 equiv.), room temp., 1 h, then repeat acylation with **8** (1.0 equiv.), TFFH (1.2 equiv.), Pr^i_2NEt (2.4 equiv.), 57% overall from **7**; iv, Pd/C (5%), EtOH (99.5%), H_2 (1 atm), room temp., 3 h; v, Pd/C (5%), EtOH (99.5%), H_2 (1 atm), room temp., 6 h; vi, **11** (4.0 equiv.), TFFH (4.4 equiv.), Pr^i_2NEt (8.8 equiv.), DMF, room temp., 5 min, then **13** (1.0 equiv.), room temp., 1 h, 87% overall from **12**.

the ethyl ester, which had to be replaced by a benzyl ester to give **5**. Unfortunately, reduction of the diazonium salt of **2** with benzyl alcohol failed. Heck coupling with methyl 2-[(*tert*-butoxycarbonyl)amino]acrylate[7] gave the unsaturated derivative **6**, which was hydrogenated with a chiral Rh^{I}-Et-DuPHOS† catalyst[9] to give **7**.

The convergent synthesis of dendrimer **14** from **7** and **12** is shown in Scheme 2. Since **14** is a polyamide related to a peptide, but possibly more sterically congested, an efficient peptide coupling reagent with minimum steric bulk and high reactivity was desired for the formation of the amide bonds. Based on these considerations, we chose to use TFFH[10]† for the amide bond formations. To this end, hydrogenolysis of **7** yielded **8**, while acidolysis of **7** with HCl in EtOAc (generated from AcCl and EtOH) gave **9**. Acylation of **9** with 2 equiv. of **8** using TFFH proved difficult, and a substantial amount of monoacylated material was recovered. To achieve satisfactory results, **9** had to be acylated twice, first with 2 equiv. of **8** and then with 1 equiv., in two consecutive operations. With this procedure, the dendritic wedge **10** was formed in 57% yield from **7**.

Hydrogenolysis of **10** yielded the free acid **11**, and similar treatment of **12** yielded triamine **13**. Acylation of **13** with 4 equiv. of **11** using TFFH finally yielded dendrimer **14** in 87% yield after a single acylation. This coupling thus proceeded with higher efficiency than that leading to the dendritic wedge **10** above. The reason for this counterintuitive outcome is unclear at present. The identity of **14** was confirmed by NMR and MALDI MS analyses (calc. 4488.9 [M + Na], found 4488.7).

While **14** was synthesised in fully protected form, deprotection of the methyl esters, the Boc groups, or both, will yield a polyionic compound with potentially interesting properties. Studies in this direction are in progress in our laboratory.

We thank the Swedish Natural Science Research Council, the Crafoord Foundation, the Knut and Alice Wallenberg Foundation, and the Royal Physiographic Society in Lund for financial support, and Mr Hasse Karlsson, Department of Medical Biochemistry, Göteborg University, for recording the MALDI mass spectrum.

Strong intramolecular π–π interactions favor the formation of 2 : 1 (L : M) lanthanide complexes of tris(2-benzimidazolylmethyl)amine

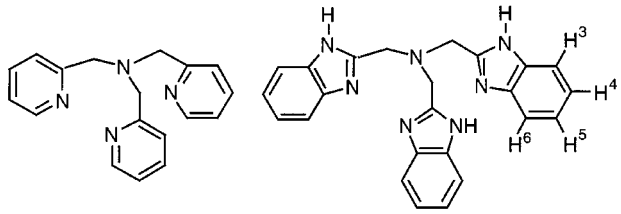
Received (in Basel, Switzerland) 8th October 1998, Accepted 13th December 1998

Reaction of the tripodal ligand tris(2-benzimidazolylmethyl)amine with lanthanides(III) in the presence of counterions ClO_4^-, OTf^- or Cl^- results, even for ligand to metal ratios lower than 2, in the formation of bisligand complexes showing strong p–p interactions between the benzimidazole rings both in solution and in the solid state.

The search for strongly luminescent lanthanide complexes has motivated the synthesis of lanthanide(III) complexes containing only neutral aromatic N-donor ligands.[1] So far, such complexes have been reported only for the tridentate ligand terpyridine (terpy) and for terpy analogues containing benzimidazole side arms.[2,3] These tris(ligand) complexes are formed in a non-aqueous solvent, in absence of coordinating anions and at ligand to metal ratios L/M ⩾ 3. The high stability against ligand dissociation shown by the benzimidazole derivative has been attributed to the presence of intramolecular π stacking interactions.[4] We have recently synthesized, and characterized by crystallographic and NMR studies, some 1 : 1 lanthanide(III) complexes of the tripodal neutral N-donor ligands tris[(2-pyridyl)methyl]amine (tpa) and tris[(2-pyrazinyl)methyl]-amine.[5] Attempts to add a second ligand to these complexes in the presence of coordinating counterions failed. On the other hand, in the presence of non-coordinating anions, addition of an excess of tripodal ligand to the mono(ligand) complexes resulted in the formation of hydroxo-derivatives.[6] In order to investigate whether π–π interactions could stabilize the 2 : 1 complexes, we studied lanthanide(III) complexation by the tripodal N-donor ligand tris(2-benzimidazolylmethyl)amine (ntb), and analogue of tpa in which the pyridine arms are replaced by a benzimidazole. Indeed, ntb demonstrates a strong stabilization of the 2 : 1 complexes in solution as well as in the solid state.



Reaction of $Ln(ClO_4)_3 \cdot 6H_2O$ (Ln = La, Nd, Eu) with 2 equiv. of ntb in acetonitrile yields complexes $[Ln(ntb)_2][ClO_4]_3 \cdot 2MeCN \cdot 3Et_2O$ (**1**, Ln = La; **2**, Ln = Nd; **3**, Ln = Eu) in which the two tripodal ligands encapsulate the lanthanide ion and shield it entirely from solvent molecules (see below).† Reaction of $LuCl_3 \cdot 6H_2O$ with ntb in a 2 : 1 (ntb/Lu) ratio in methanol yields also the bis(ligand) complex $[Lu(ntb)_2]Cl_3 \cdot 7H_2O \cdot 0.5MeOH$ **4**. This is the first example, to our knowledge, in which a neutral N-donor ligand displaces all the strongly coordinating chloride ions. An X-ray diffraction study‡ allowed the determination of the crystal structures of the complexes **1**–**4**, which all present the same structural arrangement for the cation $[Ln(ntb)_2]^{3+}$. The crystal structure of the cation $[Eu(ntb)_2]^{3+}$ is shown in Fig. 1. The coordination geometry is best described as a distorted bicapped trigonal antiprism, in which the lanthanide ion is eight-coordinated by two tetradentate ligands with a pseudo-C_3 symmetric arrangement. The most important feature of these structures is the presence of strong π–π interactions[7] between the benzimidazole rings as shown by the interplanar distances and angles reported in Table 1. Very recently preliminary results on the crystal structures of supramolecular networks using $[Ln(ntb)_2][ClO_4]_3$ as building blocks have been reported.[8] In these structures the stacking interactions between the benzimidazole units are completely lost probably due to the hydrogen-bonding interaction with the 4,4′-bipyridyl space present in the assembly.

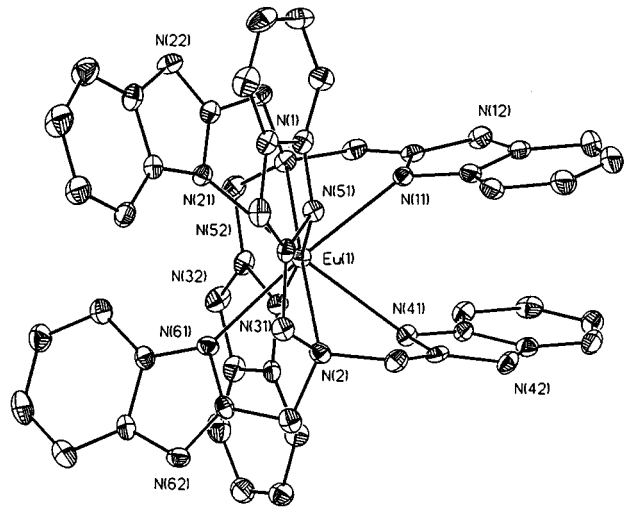


Fig. 1 Crystal structure of the cation of $[Eu(ntb)_2]^{3+}$ **3** with thermal ellipsoids at 30% probability. Selected bond lengths (Å): Eu–N(1) 2.713(4), Eu–N(2) 2.725(4), Eu–N(31) 2.507(4), Eu–N(11) 2.504(4), Eu–N(51) 2.503(4), Eu–N(641) 2.500(4), Eu/N(21) 2.496(4), Eu–N(61) 2.479(4).

The titration of $Ln(OTf)_3$ (Ln = La, Eu, Lu) with ntb in anhydrous acetonitrile was followed by ^1H NMR spectroscopy under a dry argon atmosphere. For a metal to ligand ratio of 1 : 1 two sets of signals were observed (Fig. 2) which were assigned to the 1 : 1 and 2 : 1 ntb complexes. The presence of the two complexes in solution was confirmed by electrospray mass spectrometry. Comparison of the chemical shift of the benzimidazole ring protons in the 1 : 1 and 2 : 1 complexes of lanthanum

Table 1 Interplane distances and angles between the planes of the benzimidazole rings

	α_1/°	d_1/Å	α_2/°	d_2/Å	α_3/°	d_3/Å
$[La(ntb)_2][ClO_4]_3$	13.3	3.55	12.2	3.50	34.0	3.48

$[Lu(ntb)_2]Cl_3$	16.7	3.15	19.9	3.18	2.31	3.20

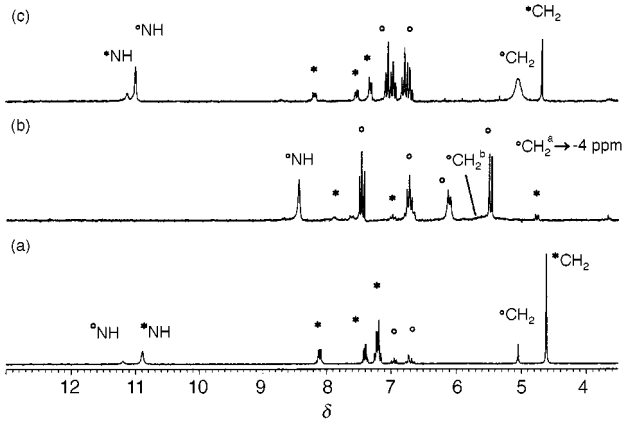

Fig. 2 ^{1}H NMR spectra at 298 K of: (a) a 1 : 1 mixture of $La(OTf)_3$ and ntb in anhydrous acetonitrile; (b) a 1 : 1 mixture of $Eu(OTf)_3$ and ntb in acetonitrile; (c) a 1 : 1 mixture of $Lu(OTf)_3$ and ntb in acetonitrile [(*) indicates the 1 : 1 complex and (○) indicates the 2 : 1 complex].

reveals an upfield shift of 0.4–1.00 ppm for the bis(ntb) complex in agreement with the presence of intramolecular π-stacking interactions in solution.[9] Integration of the NMR signals of the two species gave an approximate value of the ratio (K_2/K_1) of the stepwise formation constants of the 2 : 1 and 1 : 1 complexes. This ratio varies along the series: 0.03 for La, 14 for Eu, 3 for Lu. While for La, $K_1 > K_2$, the value of the ratio K_2/K_1 indicates, in the case of Eu and Lu, a strong preference of the ntb ligand for the formation of the 2 : 1 complexes. This is a rare behavior in coordination chemistry which has only previously been observed twice for lanthanides in presence of tripodal amines with phenolato or phosphinato donors.[10,11] As expected, this ratio is dependent on the counter anion, with the coordinating anions opposing the formation of the 2 : 1 complex. In this respect, it is striking that the bis(ntb) complex already exists in methanol solution of $LuCl_3·6H_2O$ and ntb in a 1 : 1 ratio, as shown by ^{1}H NMR and ESMS.

The high formation constant in water solution of the 2 : 1 complex of the tripodal aminophenol ligand reported by Orvig and coworkers[10,11] was attributed to an entropic effect associated with the release of water molecules. On the other hand, the entropy changes associated with the complexation of strongly basic polydentate amines with lanthanide perchlorate in anhydrous acetonitrile are large and negative and the complexes are enthalpy stabilized.[10] In the Ln–ntb system it is unlikely that an entropy effect related to a change in coordination number is responsible for the observed anomaly ($K_2 > K_1$). The preference for the bis(ntb) complexes might be rather of enthalpic origin and related to the strong π–π interactions found in solution as well as in the solid state.

As a consequence of this π–π stacking of the ligands the metal is completely shielded from the solvent since no water molecule is coordinated to the lanthanide ions in the solid state. This is also true in solution, since comparison of the luminescence lifetimes of $[Tb(ntb)_2](OTf)_3$ in MeOH and MeOD gave a value for the number of coordinated methanol molecules close to zero ($q = 0.35 \pm 0.5$).[12]

A new pillared structure with double-layers of alumina

Fathi Kooli,* Takayoshi Sasaki and Mamoru Watanabe

National Institute for Research in Inorganic Materials, 1-1 Namiki. Tsukuba, Ibaraki 305-0044 Japan.
E-mail: kooli@nirim.go.jp

Received (in Cambridge, UK) 2nd November 1998, Accepted 4th December 1998

Addition of a suspension of exfoliated titanate nanosheets into an Al_{13} pillaring solution produced a novel pillared structure associated with double layers of Al_{13} cations, which can be converted to a mesoporous alumina-pillared titanate with a 2.4 nm spacing by subsequent heat-treatment.

Pronounced interest has been focused on preparation of layered metal oxides pillared with inorganic compounds. The pillaring process is effective for the formation of porous materials such as molecular sieves, catalyst supports, *etc*.[1] In general, most layered oxides are not easily pillared with bulky inorganic cations owing to their inaccessibility to their interlayer space. It is required to develop new intercalation techniques to form large pillars in layered oxides. One of these technique is the pre-pillaring method, in which the interlayer spacing of the oxides is expanded with long-alkylamine chains[2] followed by intercalation of large inorganic polyoxocations such as $[AlO_4Al_{12}(OH)_{24}(H_2O)_{12}]^{7+}$ ('Al_{13}').

For swollen smectite clays, many routes have been examined to prepare new materials which are thermally more stable and more porous than those pillared by conventional techniques. For example, a pillared montmorillonite with a basal spacing of 2.6 nm was prepared by refluxing or hydrothermally treating a mixed solution of Al_{13} polyoxocations and a salt of a rare earth element (*e.g*. Ce or La nitrate) at 130–200 °C.[3,4] This spacing is much larger than those normally reported for pillared clays,[1] and is believed to result from the formation of large polymeric Ce/La-bearing Al_{13} polyoxocations upon hydrothermal treatment of the solution.[3]

Recently, delamination of various layered host materials has been studied extensively,[5] and restacking of the exfoliated single layers in the presence of the bulky cations gives an alternative route to pillared materials.[6] Sasaki *et al.*[7,8] reported that a layered protonic titanate with lepidocrocite-type structure was exfoliated into its single layers in a tetrabutylammonium hydroxide solution. Here, applying this exfoliation route, we found a novel pillared structure with a double-layer arrangement of Al_{13} polyoxocations. By heat-treatment, this phase was converted into a mesoporous alumina-pillared titanate characterized by a larger interlayer spacing and higher specific surface area in comparison with comparable materials produced *via* a pre-pillaring method.

The layered protonic titanate ($H_{0.7}Ti_{1.83}\square_{0.17}O_4\cdot H_2O$, 1 g) was exfoliated into single sheets upon treatment with 200 cm^3 of a tetrabutylammonium hydroxide (TBAOH) solution (0.016 mol dm^{-3}) for 7 days at room temperature. The ratio of TBA cations to protons in the titanate was adjusted to unity, which is a favorable condition for delamination.[8] The Al_{13} solution was prepared by moderately hydrolyzing an aluminium nitrate solution (0.2 mol dm^{-3}) with tetramethylammonium hydroxide (TMAOH) at room temperature. The OH/Al molar ratio was adjusted to 2.5, where Al_{13} polyoxocations are predominant. The colloidal suspension of the titanate was poured into the Al_{13} solution and aged overnight under stirring at 80 °C. The ratio of Al (mmol)/titanate (g) was 16. The product was collected by centrifugation, washed with distilled water, and dried in air.

Fig. 1(a) shows a powder X-ray diffraction pattern of the protonated titanate with a basal distance of 0.94 nm.[9] The colloidal suspension did not display basal reflections, indicating that the titanate single-sheets were dispersed in the aqueous medium.[8] Addition of the titanate suspension to the Al_{13} solution gave a product with a basal diffraction series of 2.6 nm [Fig. 1(b)]. This new phase with larger spacing has not been reported previously for Al_{13}-pillared materials prepared under such mild conditions. Two possibilities may explain this high expansion: (i) the co-presence of TBA and Al_{13} cations in the interlayer space or (ii) the incorporation of a large amount of aluminium polyoxocations. Thermogravimetry showed only a small broad exothermic peak around 370 °C following a weight loss of 4%, suggesting only a small amount of residual organic cations in the pillared material. After this weight loss, the material had a gallery height of 2.5 nm, and thus indicates that possibility (i) is not valid. Therefore, it can be concluded that the large expansion is mainly due to the presence of a large amount of aluminium polyoxocations in the interlayer space.

The new phase shows two noticeable features in terms of structural and compositional data as compared with the Al_{13}-monolayer pillared titanate: (i) a large interlayer distance of 2.6 *vs*. 1.6 nm (corresponding to intercalation of a monolayer of

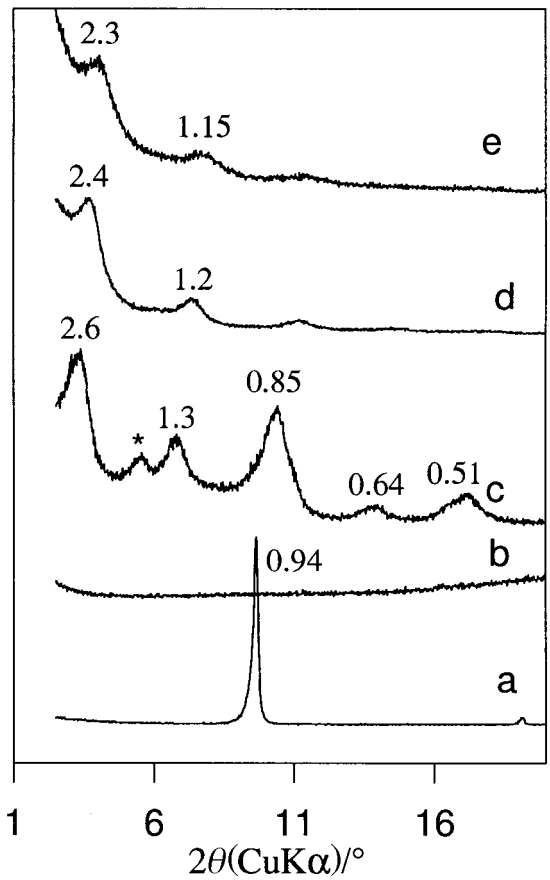

Fig. 1 PXRD patterns of (a) protonated titanate, (b) colloidal suspension of exfoliated titanate and (c) the resulting product prepared after exfoliation and reaction with Al_{13} solution. (d) and (e) correspond to the product (c) heat-treated at 500 and 600 °C, respectively. (*) phase at 1.6 nm (see text).

Al_{13} cations).[10,11] By taking into account the basal spacing of the protonated titanate which accommodates a monolayer of H_2O and H_3O^+, the net interlayer expansion may be estimated as 1.94 nm [= 2.6 − (0.94 − 0.28)]. This is approximately double that of 0.94 nm [= 1.6 − (0.94 − 0.28)] for the monolayered phase.[11] (ii) A double amount of Al_{13} cations. On the basis of chemical analysis, the new product has a composition of $(Al_{13})_{0.22}Ti_{1.83}\square_{0.17}O_4 \cdot 2.88\ H_2O$ whereas the amount of Al_{13} cations in the 1.6 nm phase has been reported to be close to 0.11 mol per chemical formula.[11]

These two features strongly suggest that the titanate obtained in this study accommodates Al_{13} cations in a double-layer arrangement. Nazar *et al*.[12] identified a new aluminium polyoxycation cluster formed by the dimerization of two Al_{12} polyoxocations (tentatively formulated as $Al_{24}O_{72}$) which was facilitated by refluxing an Al_{13} solution at high temperatures. This new polyoxycation is about 1.4 nm in size and considerably larger than Al_{13} cations (*ca*. 1 nm).[13] The expected spacing for the intercalation of such a dimeric polyoxocation, however, does not approximate to the large interlayer expansion observed in this study. Furthermore, the formation of the 2.6 nm phase under mild conditions at room temperature should be noted, which excludes formation of the $Al_{24}O_{72}$ polyoxocation.

The Al_{13} polyoxocations are generally believed to hold a theoretical charge of 7+ while the above empirical formula suggests a 3.2+ charge for Al_{13}. A similar situation has also been reported for Al_{13}-intercalated montmorillonite clay.[14] Thus the actual aluminium polyoxocation will probably be modified from $(Al_{13})^{7+}$. Neighboring Al_{13} polyoxocations in a bilayer are expected to mutually condense *via* apical water molecules. Such condensation should be effective in relaxing the electrostatic repulsion between the polyoxocations and lead to charge balance with the host layers interleaving the bilayer. A simple model for the condensation would give the following composition for the modified Al_{13} as $[AlO_4Al_{12}(OH)_{24}O_2(H_2O)_8]^{3+}$.

The intercalation of Al_{13} would probably be irreversible, since the interlayer gallery was little changed before and after treatment of the Al_{13}-product in a solution of sodium chloride (1 mol cm^{-3}) overnight at 80 °C. The pillared structure of the present material was preserved up to 600 °C, while the basal spacing shrunk from 2.6 to 2.4 nm [Fig. 1(c) and 1(d)]. The shrinkage could be attributed to dehydroxylation of the aluminium species upon heating. The pillared material collapsed at 600 °C and TiO_2 and α-Al_2O_3 started to crystallize. The trace '1.6 nm', phase also collapsed.

The sample calcined at 500 °C had a type IV nitrogen adsorption isotherm (in the IUPAC classification) with a large hysteresis loop of type H4.[15] The specific surface area was *ca*. 300 $m^2\ g^{-1}$ with a pore volume of 0.25 mL liquid nitrogen per gram of material. The surface area of the pillared titanate was greatly enhanced in comparison with protonic titanate (1–2 $m^2\ g^{-1}$), and also much higher than those of pillared titanates, (100–200 $m^2\ g^{-1}$).[10,11] The average pore diameter is 3.5 nm and the pore size distribution shows a maximum at *ca*. 4.0 nm. Further study is now being conducted to clarify the effect of different experimental parameters on the physico-chemical properties of these materials.

Photoinduced electron transfer from pyrene to methylviologen in polystyrene latex dispersions as studied by diffuse reflectance laser flash photolysis

K. Nakashima,*[a] T. Miyamoto[a] and S. Hashimoto[b]

[a] *Department of Chemistry, Faculty of Science and Engineering, Saga University, 1 Honjo-machi, Saga 840-8502, Japan. E-mail: nakashik@cc.saga-u.ac.jp*

Received (in Cambridge, UK) 22nd September 1998, Accepted 15th Decemer 1998

Fluorescence and diffuse reflectance flash photolysis studies revealed that photoinduced electron transfer from pyrene to methylviologen was enhanced in polystyrene latex dispersions, and also that the back electron transfer was markedly suppressed in the dispersions, resulting in effective charge separation.

Latex particles represent a new type of organic solid material which can be employed as a micro-substrate for photoreactions. The surface consists of organic polymers embedded sparsely with functional groups such as sulfate, carboxyl or amino groups. This structure leads latex particles to have two types of adsorption sites on the surface: (1) the polymer matrix which affords continuous adsorption domains to non-polar and low polarity adsorbates, and (2) the functional group which gives discrete adsorption sites to ionic and highly polar species. Such a feature is not found in any other solid materials which are employed as adsorbents. Furthermore, latex particles have many other advantageous features as described in previous papers.[1,2]

We have investigated several photoreactions, such as electronic energy transfer[3,4] and electron transfer,[2,5] on the surface of polystyrene (PS) and poly(butyl methacrylate) latexes in aqueous dispersions, and demonstrated the usefulness of the latexes as micro-substrates for the photoreactions. Here, we report photoinduced electron transfer (PET) from pyrene (Py) to methylviologen (MV^{2+}) in PS latex dispersions.

The PS latex was synthesized by standard emulsion polymerization in the presence of sodium dodecyl sulfate. The latex was purified by repeated dialysis. The diameter of the latex particles was determined to be 85 nm with an Otsuka ELS-800 dynamic light scattering spectrophotometer. Fluorescence spectra were recorded on a Hitachi F-4000 spectrofluorometer. Transient absorption spectra were observed with a nanosecond diffuse reflectance laser photolysis system, the set-up of which was similar to that described previously.[6]

We measured fluorescence spectra of Py in the absence and presence of MV^{2+} [Fig. 1(a)]. It is well known that the fluorescence of Py is quenched by MV^{2+} through PET as follows:[7,8]

$$\mathrm{Py} + h\nu_a \rightarrow \mathrm{Py}^* \quad (1)$$

$$\mathrm{Py}^* + \mathrm{MV}^{2+} \xrightarrow{\mathrm{PET}} \mathrm{Py}^{\cdot+} + \mathrm{MV}^{\cdot+} \quad (2)$$

$$\downarrow \text{Fluorescence}$$

$$\mathrm{Py} + h\nu_f$$

Thus, we can observe the PET reaction by monitoring the fluorescence quenching of Py. As seen from Fig. 1(a), the fluorescence of Py is effectively quenched by MV^{2+} in the latex dispersion even when the MV^{2+} concentration is at a level of μM, which is several tens of times smaller than that needed for quenching in aqueous solutions. This means that PET in the latex dispersions takes place several tens of times more efficiently than in aqueous solutions. The marked enhancement of PET can be ascribed to the increase in local concentrations of the donor and acceptor on the latex surface, as confirmed by the adsorption isotherms (data not shown). The effective adsorption of the donor (Py) onto the latex surface is also evidenced by the vibronic fine structure of the fluorescence. The intensity ratio between the band I and III [the so-called I_1/I_3 value; Fig. 1(a)] is well known to be a measure of polarity around the probe.[9,10] The I_1/I_3 value obtained is 1.13 for the latex dispersion, which is much closer to the values for benzene (1.05)[10] and propan-1-ol (1.09)[10] than that for water (1.81). This means that most of the Py molecules are located on the latex particles.

There are generally two purposes for employing solid surfaces as substrates for PET: (A) to enhance PET by condensing and orienting the reactants, and (B) to suppress the back electron transfer to achieve effective charge separation.[11] We have shown in Fig. 1 the usefulness of the PS latex particles for realizing purpose (A). To examine (B), we intended to observe transient absorption spectra. As the latex dispersion is very turbid, a conventional (*i.e.* transmittance mode) flash photolysis technique is of no use for the system. Therefore, we employed the diffuse reflectance mode. The transient absorption spectra for the PS latex dispersion containing Py and MV^{2+} are shown in Fig. 2. The band at 408 nm is assigned to the $MV^{\cdot+}$ cation radical, and the band at 461 nm to the $Py^{\cdot+}$ cation radical [Fig. 2(a)]. We note from Fig. 2 that these radical bands remain for > 1 ms. If we consider that charge recombination between the products usually takes place on the time scale of picoseconds or nanoseconds in homogeneous solutions, we can see

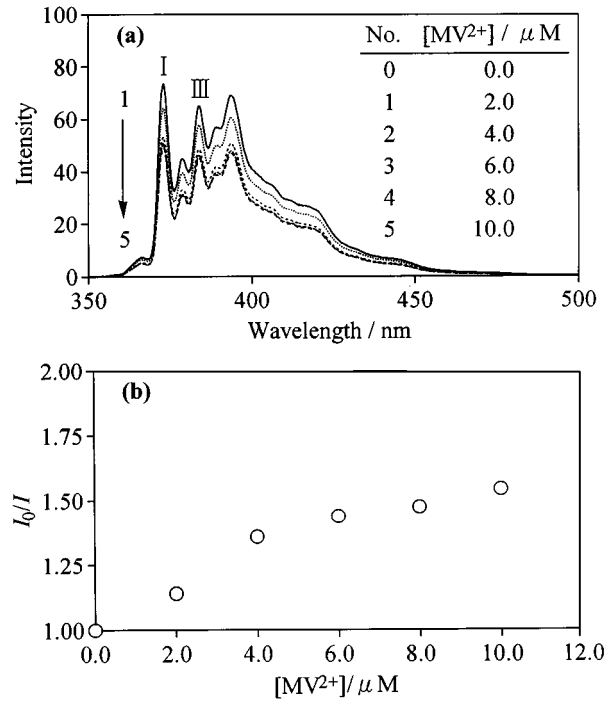

Fig. 1 Fluorescence spectra (a) and Stern–Volmer plot (b) for a Py/MV^{2+} pair in a PS latex dispersion. Concentrations: [Py] = 0.514 μM, [PS] = 1.00 g L^{-1}. The samples are excited at 334 nm. The spectra are corrected by subtracting background scattering of excitation light.

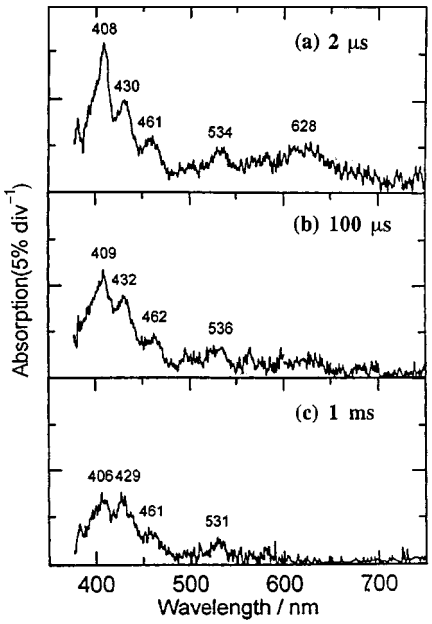

Fig. 2 Transient absorption spectra of a Py/MV^{2+} pair in a PS latex dispersion. Concentrations: [Py] = 250 μM, [MV^{2+}] = 300 μM, [PS] = 54.2 g L^{-1}.

that the back electron transfer is markedly suppressed in the latex dispersion. Thus, the present result demonstrates the usefulness of the latex system for performing effective charge separation.

In order to understand the remarkable effect of the latex system on suppression of charge recombination, we show in Fig. 3 a schematic diagram for behavior of the reactants and products of the PET reaction on the latex surface. Before the PET reaction, Py molecules are mostly adsorbed onto the continuous PS area by hydrophobic interaction, while MV^{2+} molecules are adsobed onto the sulfate groups by electrostatic attraction. After the PET reaction, both of the products will be

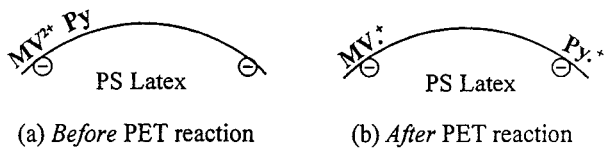

Fig. 3 Schematic representation for the behavior of Py, MV^{2+} and their PET reaction products on a PS latex surface.

fixed at the sulfate groups owing to electrostatic interaction. The fixation of the products seems to result in suppression of the back electron transfer.

Recently, Hsiao and Webber investigated PET reactions from pyrene and anthracene derivatives to a viologen analogue using a PS latex dispersion.[12] They also observed a remarkable increase in the efficiency of charge separation for some donor–acceptor pairs, although the forward PET reactions were not improved by the use of the latex dispersion. They ascribed the remarkable increase in the yield of the charge separation to a 'compartmentalization effect' of the latex particles. It is likely that there are compartments (holes) on the latex surface which accommodate limited types of the products and/or reactants. The existence of such compartments is also suggested in our experiments for the present system and also for another system.[2] The Stern–Volmer plot [Fig. 1(b)] shows a downward curve, indicating that the fluorescence of Py is partly protected from quenching by MV^{2+} on the PS latex particles. We can attribute this protected quenching to the likelihood that some portion of Py molecules on the latex surface is incorporated into the holes in the latex particles (see ref. 2 for detailed discussion). In conclusion, it seems that both a 'fixation effect' and 'compartmentalization effect' play an important role in PET processes in latex systems.

Bis(2-methoxyethyl)aminosulfur trifluoride: a new broad-spectrum deoxofluorinating agent with enhanced thermal stability

Gauri S. Lal,* Guido P. Pez, Reno J. Pesaresi and Frank M. Prozonic

Air Products and Chemicals Inc, 7201, Hamilton Boulevard, Allentown, PA 18195-1501, USA.

Received (in Corvallis, OR, USA) 2nd November 1998, Accepted 7th December 1998

Bis(2-methoxyethyl)aminosulfur trifluoride (Deoxo-Fluor™) is effective for the conversion of alcohols to alkyl fluorides, aldehydes/ketones to the corresponding *gem*-difluorides and also for the transformation of carboxylic acids to their trifluoromethyl derivatives; it is a less thermally sensitive, broader-spectrum alternative to the traditional dialkylaminosulfur trifluoride (DAST) deoxofluorination reagents.

In view of the importance of organofluorine compounds in the pharmaceutical and agrochemical industries, efforts aimed at the development of simple, safe and efficient methods for their synthesis have escalated in recent years.[1–5] The conversion of carbon–oxygen to carbon–fluorine bonds by nucleophilic fluorinating sources (deoxofluorination) represents one such technique which has been widely used for the selective introduction of fluorine into organic molecules.[6] This transformation has been accomplished routinely with the dialkylaminosulfur trifluorides, such as DAST (NEt_2SF_3), for laboratory scale reactions.[7] However, utilization of DAST for larger scale applications has been limited by its well known thermal instability.[8,9] DAST and related dialkylaminosulfur trifluorides are said to undergo catastrophic decomposition (explosion or detonation) with gas evolution on heating to > 90 °C.[10]

We now report on bis(2-methoxyethyl)aminosulfur trifluoride (Deoxo-Fluor) **1**, a new deoxofluorinating agent which is a less thermally sensitive and very effective alternative to DAST. It permits the facile conversion of alcohols to alkyl fluorides, aldehydes/ketones to the corresponding *gem*-difluorides, and also the transformation of carboxylic acids to the corresponding trifluoromethyl derivatives with, in some cases, superior performance to DAST.

Deoxo-Fluor reagent is obtained in a manner analogous to that of DAST[9] by reacting the *N*-trimethylsilyl derivative of bis(2-methoxyethyl)amine with SF_4 in Et_2O at −30 °C. The crude product is distilled (60 °C, 0.1 mmHg) to afford a light yellow oil in 70% yield [$\delta_H(CDCl_3)$ 3.5 (t, 4H), 3.15 (t, 4H), 3.05 (s, 6H); $\delta_F(CDCl_3)$ 55 (s, br, 2F), 28 (s, br, 1F]. A comparison of the thermal stability of Deoxo-Fluor and DAST, as determined by differential scanning calorimetry (DSC), is illustrated in Fig. 1. While the onset of decomposition is almost the same for both compounds (~140 °C), DAST degrades much more rapidly and with somewhat larger heat evolution (1700 *vs.* 1100 J g^{-1} for **1**). Deoxo-Fluor showed a much more gradual exotherm over a wider temperature range. These preliminary results indicate that the latter should be safer to use than DAST on a larger, practical scale.

The broad applicability of **1** for the deoxofluorination of organic substrates is illustrated by its reaction chemistry, as shown in Table 1. Primary, secondary and tertiary alcohols react at relatively low temperatures (−78 °C to ambient), giving moderate to excellent yields of the corresponding alkyl fluorides. Fluorination of the anomeric hydroxy group of the sugar was particularly effective, giving the desired compound in 95% yield. The fluorination of aldehydes and ketones con-

[a] Ratio α:β = 9:91.

ducted in CH_2Cl_2 at room temperature in the presence of 0.1 equiv. of HF, generated *in situ* with added EtOH, afforded excellent yields of the corresponding *gem*-difluoro products from both aliphatic and aromatic carbonyl compounds. The relatively greater thermal stability of **1** was exploited for the fluorination of electron-deficient ketones and carboxylic acids, which are traditionally less reactive substrates. As illustrated in Table 1, **1** reacted readily with carboxylic acids, giving acyl fluorides. These were subsequently converted to the trifluoromethyl derivatives on heating for an extended period in the neat reagent at 90 °C. DAST has not been generally employed for the fluorination of carboxylic acids and we are only aware of one report of such an application.[11]

The broad-spectrum reactivity of the Deoxo-Fluor reagent coupled with its potentially greater margin of safety in use and commercial availability[12]should lead to its widespread application for the synthesis of specialty organofluorine compounds. Detailed studies of its thermal behavior and reactivity with a wider range of functional groups are in progress.

Recent developments in Ramberg–Bäcklund and episulfone chemistry

Richard J. K. Taylor†

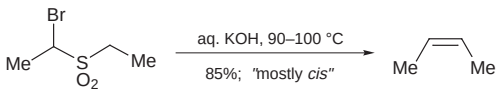
Department of Chemistry, University of York, York, UK Y010 5DD. E-mail: rjkt1@york.ac.uk

Received (in Cambridge, UK) 24th August 1998, Accepted 11th September 1998

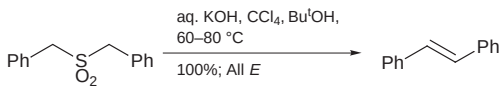
A brief historical review of the Ramberg–Bäcklund rearrangement is presented along with a summary of its applications to the synthesis of bioactive target molecules. Recent developments in this area originating from the author's laboratories, mostly from the past five years, are reviewed. These include: (i) the isolation of episulfones from the Ramberg–Bäcklund rearrangement, (ii) the preparation of episulfones by the oxidation of episulfides, (iii) the generation and synthetic applications of episulfone α-anions, (iv) the epoxy-Ramberg–Bäcklund rearrangement, (v) the tandem conjugate addition-Ramberg–Bäcklund rearrangement, and (vi) utilisation of the Ramberg–Bäcklund rearrangement in natural product synthesis and related areas, including recent applications for the synthesis of *C*-glycosides.

(*a*) Introduction

Since its discovery in 1940,[1] the Ramberg–Bäcklund rearrangement, the base-mediated conversion of α-halogenated sulfones into regio-defined alkenes (Scheme 1), has attracted a considerable amount of interest from both synthetic and mechanistic viewpoints.[2] The development of the Meyers' modification (Scheme 2),[3] in which the sulfone undergoes *in situ* halogenation-Ramberg–Bäcklund rearrangement, has further extended the synthetic utility of this process.



Scheme 1



Scheme 2

The strengths of the procedure from a synthetic perspective are: (i) the ease with which the requisite sulfones can be constructed and the conjunctive nature of the sequences, (ii) the unambiguous location of the resulting alkene moiety and the applicability of the procedure to all alkene substitution patterns including tetrasubstituted variants, (iii) the efficiency with which strained alkenes (*e.g.* cyclobutenes, unsaturated cyclophanes)[2,3] can be prepared, (iv) the applicability of the procedure to conjugated polyene synthesis, either by using allylic sulfones[2] or *via* the vinylogous[4] and Michael-induced[5] variants of the Ramberg–Bäcklund rearrangement. Predictably high stereocontrol is not a feature of the Ramberg–Bäcklund rearrangement, but in general *Z*-alkenes predominate when mild bases are employed, whereas stronger bases favour *E*-alkenes.[2]

The utility of the Ramberg–Bäcklund rearrangement can be seen from applications to the synthesis of natural products and related analogues. Recent examples from other groups, shown in Fig. 1, include a formal total synthesis of brassinolide,[6] the total syntheses of (+)-solamin,[7] (+)-eremantholide A[8] and (−)-conduritol E derivatives,[9] the preparation of enediyne[10] and ciguatoxin[11] analogues, and the synthesis of an advanced intermediate to the *C*-aryl glycoside chrysomycin A.[12]

In terms of the mechanism of the Ramberg–Bäcklund reaction, considerable progress was made in the 1950s and 1960s.[2] Elegant studies by Bordwell, Neureiter, Paquette and others have resulted in the general acceptance of the mechanistic sequence illustrated in Scheme 3. Indirect support was obtained for the intermediacy of episulfones (thiirane 1,1-dioxides): they were prepared by other procedures (*e.g. via* addition of diazoalkanes to sulfenes[13]) and then it was established that they gave alkenes under the conditions normally employed for the Ramberg–Bäcklund rearrangement.[14]

My interest in synthetic and mechanistic aspects of the Ramberg–Bäcklund rearrangement was stimulated by Dr D. Neville Jones, my Ph.D. supervisor. Although a considerable amount of research had already been carried out by that time, I became convinced that the full potential of the process had yet to be realised. However, it was a number of years before the opportunity arose to make any personal contributions to this area of chemistry. This article summarises these recent contributions and includes some, as yet, unpublished results.

(*b*) The isolation of episulfones from α-halo sulfones

As part of a programme to synthesise novel sulfur-containing analogues of thromboxane A_2,[15] Richard Batten, Guy Casy, Vinod Kansal, Simon Lane, Stephen Quick, Alan Sutherland and Stamatis Vassiliou developed a number of procedures to prepare substituted thianes.[15,16] This presented an opportunity to explore some novel Ramberg–Bäcklund chemistry, investigating the utility of the rearrangement for the conversion of

Richard Taylor graduated from the University of Sheffield and then carried out his PhD under the supervision of Dr D. Neville Jones working in the area of thiasteroid synthesis. After postdoctoral periods with Dr Ian T. Harrison (Syntex Research, Palo Alto; prostaglandin synthesis) and Professor Franz Sondheimer, University College London; annulene synthesis), he was appointed to a lectureship at the Open University in Milton Keynes (1975–1979). A move to the University of East Anglia, Norwich, followed and in 1993 he was appointed to a Chair of Organic Chemistry at the University of York. His research interests centre on the synthesis of bioactive natural products and related compounds, and the development of new synthetic methodology utilising organometallic and organosulfur chemistry. His awards include the Royal Society of Chemistry's Hickinbottom Fellowship for independent creativity in experimental organic chemistry (1985–1987) and the Royal Society of Chemistry's Tilden Medal and Lectureship (1999/2000). He is currently UK Regional Editor of the international journal Tetrahedron and a member of the Executive Board of Tetrahedron Publications.

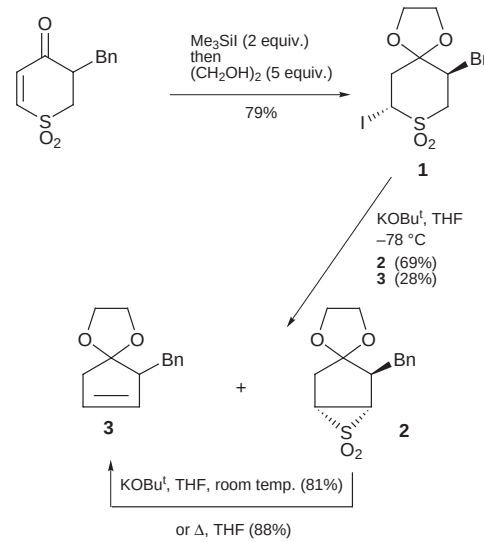
thiane dioxides into cyclopentenoid natural products [see section (*f*)].[17] As part of this study, Alan Sutherland carried out the Ramberg–Bäcklund rearrangement of α-iodo sulfone **1** at low temperature. Surprisingly, because these reactions were generally very clean, two products were obtained (Scheme 4). The expected cyclopentene **3** was accompanied by a major crystalline by-product (69% yield) which no longer contained an iodide group, but neither did it possess alkenyl protons or carbons in its NMR spectra. We eventually concluded that the mystery by-product had to be the episulfone **2** (this finally being confirmed by X-ray crystallography). Episulfone **2** was stable



Scheme 4

for months on storage at −18 °C but, as expected, gave cyclopentene **3** on thermolysis or treatment with base. This was the first time that an episulfone had been isolated from an α-halo sulfone under the conditions of the Ramberg–Bäcklund reaction and it provided unambiguous proof of its intermediacy in the rearrangement process.[18]

After the initial discovery, the reaction conditions conditions were optimised and Alan Sutherland, Stephen Jeffery, Simon Pyke, Wendy Loughlin, Richard Ewin and Carlos Morales prepared the 'parent' episulfone **4** and a range of stable, functionalized analogues from α-halo sulfones in high yields (Fig. 2).[19,20] All of the compounds have been fully characterised and X-ray crystal structures were obtained on compounds **2** and **5**. It is not essential to use α-iodo sulfones in this process: episulfone **5** was also prepared from the corresponding α-bromo (74%) and α-chloro (85%) sulfones.

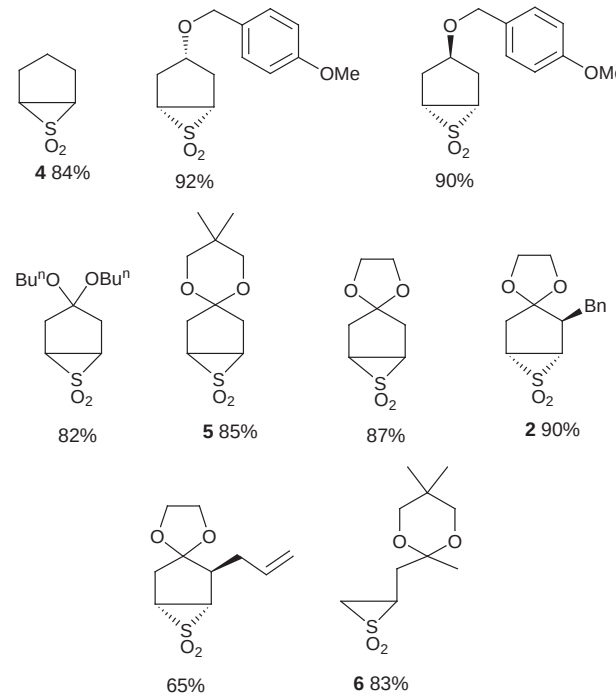


Fig. 2 Episulfones prepared from α-iodo sulfones (isolated yields shown).

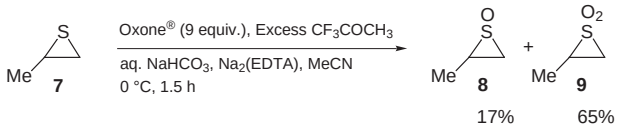
Although most of the episulfone isolation programme was carried out using thiane dioxides, we believe that this procedure

for episulfone preparation is likely to be widely applicable: this is illustrated by the efficient conversion of an acyclic α-iodo sulfone into episulfone **6**.[20] In addition, Simpkins recently reported the preparation of 1-ethyl-2-methylepisulfone from the corresponding acyclic α-iodo sulfone using a similar procedure.[21]

(*c*) Preparation of episulfones by the oxidation of episulfides

Having disproved one widely accepted belief concerning episulfones—that they cannot be prepared from α-halo sulfones—we turned our attention to another. A wide range of organic sulfides, both acyclic and cyclic, are readily oxidised to give the corresponding sulfoxides and sulfones. Episulfides (thiiranes), however, have proved anomalous: under controlled conditions they can be oxidised to episulfoxides but, despite many attempts,[22] there were no authenticated[23] reports of episulfones being prepared from either episulfides or episulfoxides by an oxidative pathway. Given the accessibility of episulfides, we decided to reinvestigate their oxidation. The choice of oxidant was prompted by the recent report[24] that methyl(trifluoromethyl)dioxirane (TFDO) converts sulfides directly into sulfones *via* sulfurane intermediates, and does not proceed by way of sulfoxides. Such a procedure seemed to be ideally suited to the preparation of episulfones from episulfides, particularly as a convenient *in situ* method for preparing TFDO from Oxone® ($KHSO_5$ triple salt) and 1,1,1-trifluoroacetone has been described by Yang *et al.*[25] Paul Johnson therefore investigated the oxidation of propene episulfide **7** under these conditions (Scheme 5). This particular episulfide was chosen because it is commercially available and gives a reasonably stable and well characterised episulfoxide **8**.[26]



Scheme 5

To our delight, and somewhat surprisingly in view of previous studies, treatment of propene episulfide **7** with Oxone®/trifluoroacetone under Yang's conditions gave the corresponding episulfone **9** in 65% isolated yield, together with 17% of episulfoxide **8**, after chromatography. Having made this discovery, we went on to demonstrate that a range of episulfones can be prepared by the Oxone®/trifluoroacetone oxidative procedure (Fig. 3).[27]

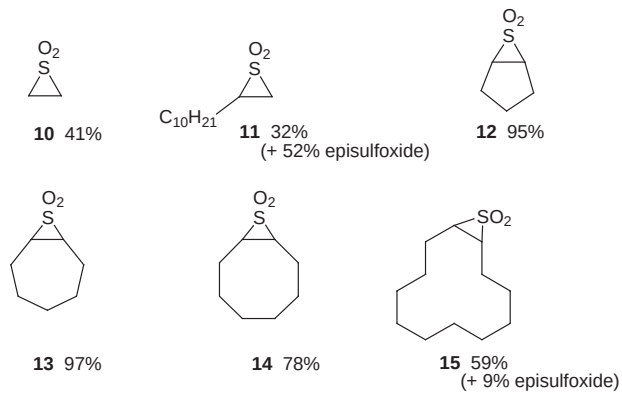


Fig. 3 Oxone®/trifluoroacetone preparation of episulfones **10–15**.

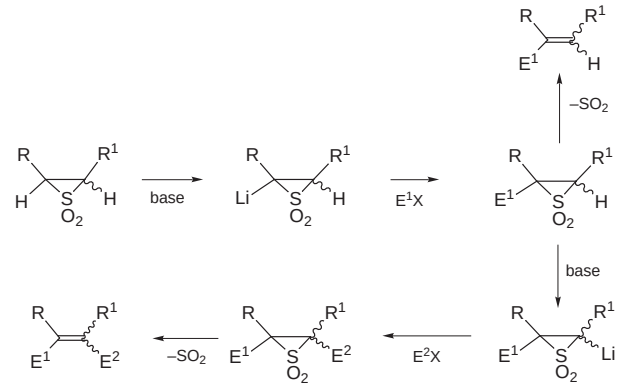
The ease with which bicyclic episulfones can be obtained is particularly noteworthy as the standard diazoalkane/sulfene methodology is not readily applicable to such systems. It should be noted that a preliminary study using 'isolated' TFDO, which readily oxidises a range of sulfides to sulfones,[24] has revealed that it converts episulfides into episulfoxides in good yield but that, surprisingly, episulfones are not formed in any significant amount. More research is needed, but it seems likely that the active oxidant in the Oxone®/trifluoroacetone mixture which promotes episulfone production is not TFDO but some other peroxidic species.

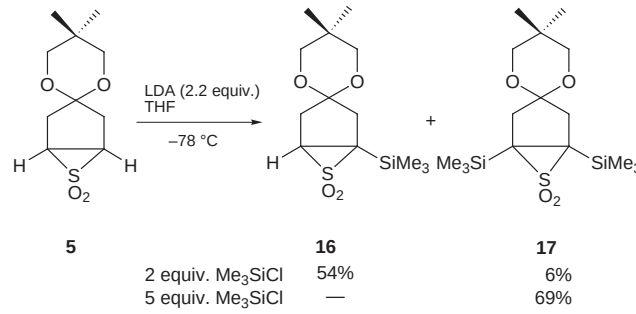
(*d*) The generation and synthetic applications of episulfone α-anions

With straightforward routes now available for episulfone preparation we decided to investigate their synthetic applications. Simon Pyke therefore set out to generate α-sulfonyl anions from episulfones and examine their trapping reactions with electrophiles. We thought that this methodology could provide a useful new procedure for the stereocontrolled synthesis of alkenes with a range of substitution patterns: this is illustrated in Scheme 6 for the production of tri- and tetrasubstituted alkenes.



Scheme 6

In order to establish the viability of this proposal we chose to study the deprotonation-trapping of episulfone **5** due to its accessibility, stability, and the fact that stereoisomeric alkylated episulfones and alkenes are not possible, therefore simplifying product analysis. Extensive experimentation with a range of bases and electrophiles gave only trace amounts of the required adducts (as the alkenes).[28] Wendy Loughlin then achieved success using an *in situ* trapping approach in which the electrophilic trapping agent is premixed with the substrate before the addition of the base (Scheme 7). Using this



Scheme 7

procedure, with trimethylsilyl chloride as the electrophile, we could produce good yields of mono- or di-silyl adducts, **16** or **17** respectively, depending on the excess of electrophilic trapping agent. Andy Graham prepared a good quality crystal of disilylated episulfone **17** and its structure was confirmed by

Madeleine Moore and Giles Wilson using X-ray crystallography: this is the first reported X-ray structure of a tetrasubstituted episulfone and the long carbon–carbon episulfone bond length (1.686 Å) is particularly noteworthy.[29]

Using similar procedures, Wendy Loughlin and Andy Graham prepared a range of silyl and stannyl episulfone adducts (Fig. 4), most as relatively stable, fully characterised crystalline solids.[29] Carbon-based electrophiles were also employed successfully, although the yields of the adducts were rather low. Complementary research on episulfone α-anions has recently been described by Simpkins *et. al.*,[21,30] and they have shown that *C*-alkylation and hydroxyalkylation can be performed much more efficiently by use of the Bu^t-P$_4$-phosphazene base.

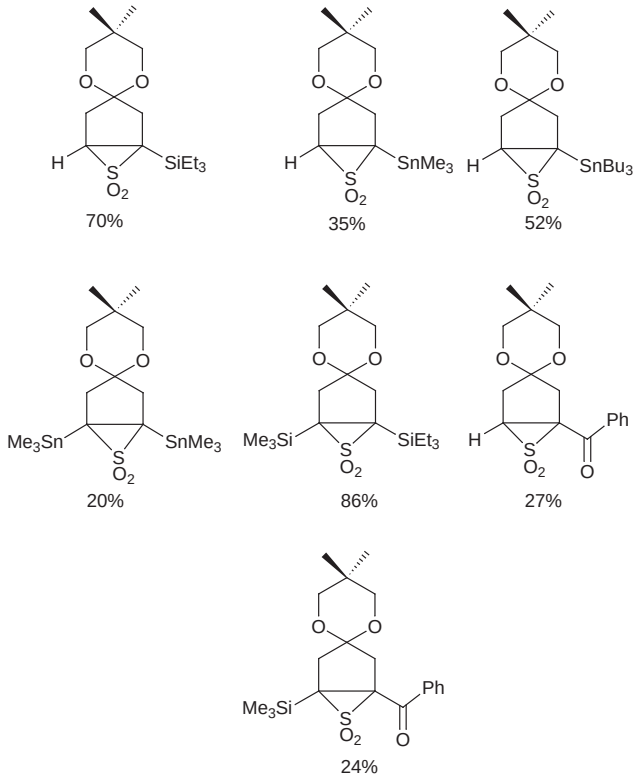


Fig. 4 Episulfones prepared from episulfone α-anions (isolated yields shown).

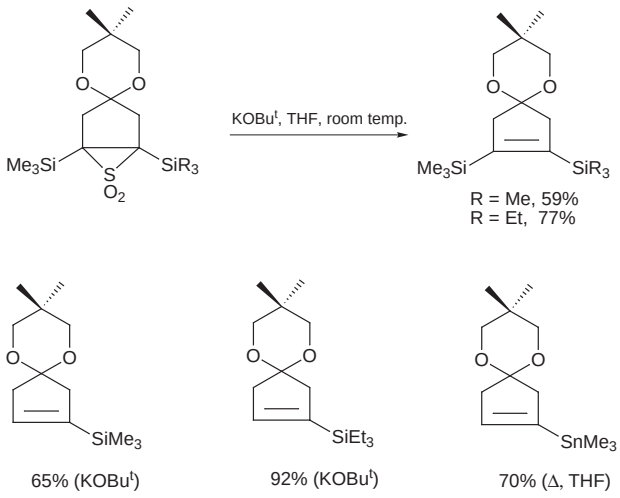
The functionalized episulfones were efficiently converted into novel 1,2-bis(silyl)alkenes, vinylsilanes and vinylstannanes by treatment with potassium *tert*-butoxide or thermolysis (Scheme 8).



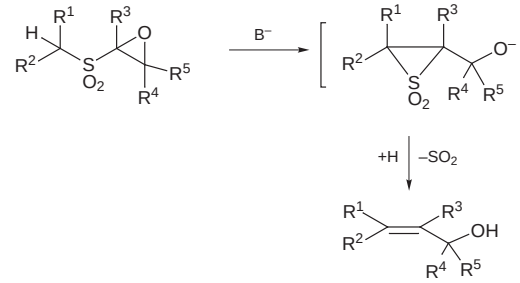
Scheme 8

(*e*) New variants of the Ramberg–Bäcklund rearrangement

More recently, we have developed two novel variants of the Ramberg–Bäcklund rearrangement.

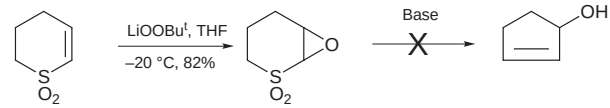
(*i*) The epoxy-Ramberg–Bäcklund reaction

The first of these variants was suggested in discussion with Mark Gamble. We envisaged a new variant of the Ramberg–Bäcklund rearrangement in which the leaving group is incorporated into a three membered ring (Scheme 9). A major advantage of this new variant compared to the traditional Ramberg–Bäcklund rearrangement is that alkene formation is accompanied by the introduction of allylic functionality. Thus, the epoxy-Ramberg–Bäcklund reaction would provide a new method for the synthesis of allylic alcohols from readily available sulfonyl oxiranes.



Scheme 9

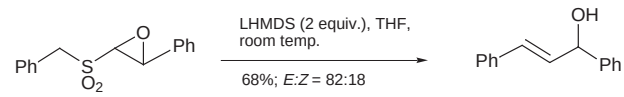
Initial studies to establish the viability of this idea were carried out by Arne Grumann, who had what we believed to be the ideal starting material, **18**, to hand (Scheme 10). Thus, the required epoxide **19** was easily prepared but, despite a considerable amount of effort, we were unable to devise conditions to effect the ring contraction to give cyclopentenol.



18 **19**

Scheme 10

We reasoned that the spirocyclic intermediate required for this transformation would be just too strained when starting with a bicyclic epoxide. When Paul Evans started his research in this area we therefore investigated an acyclic system (Scheme 11).



Scheme 11

We were delighted to observe the success of this new process and Paul Evans and Paul Johnson have since applied it to a range of substrates (Fig. 5).[31,32] As can be seen, the epoxy-Ramberg–Bäcklund reaction can be employed to prepare mono-, di- and tri-substituted alkenes, is often high yielding and can exhibit a high degree of stereoselectivity.

We are currently optimising this epoxy-Ramberg–Bäcklund reaction, exploring the thiirane and aziridine variants, and optimising a tandem epoxidation-epoxy-Ramberg–Bäcklund procedure (Scheme 12). We are also utilising the methodology for the synthesis of natural products such as sphingosine.

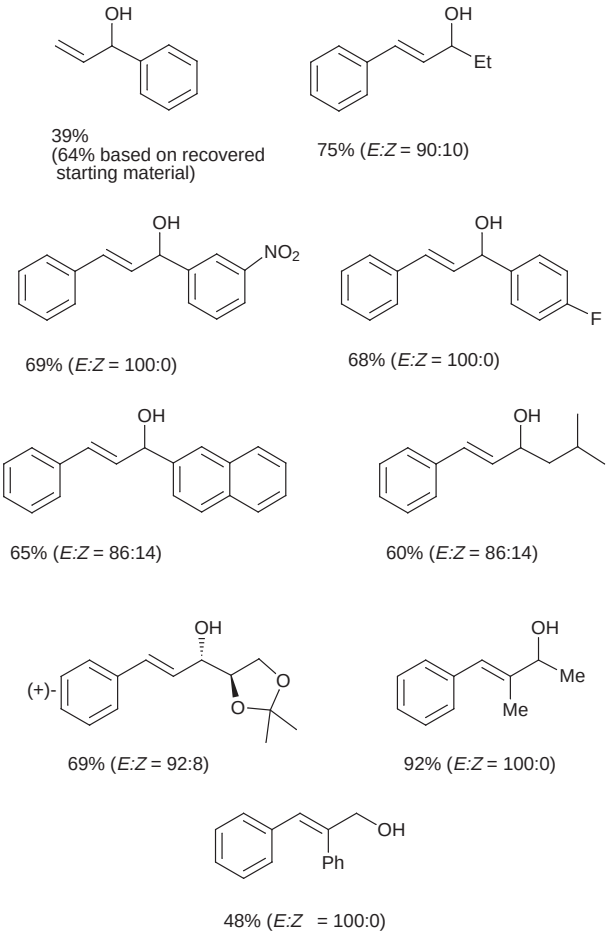


Fig. 5 Products of the epoxy-Ramberg–Bäcklund rearrangement (using LiOBu^t in THF; isolated yields shown).

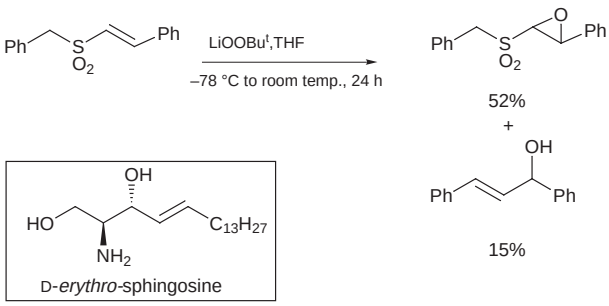
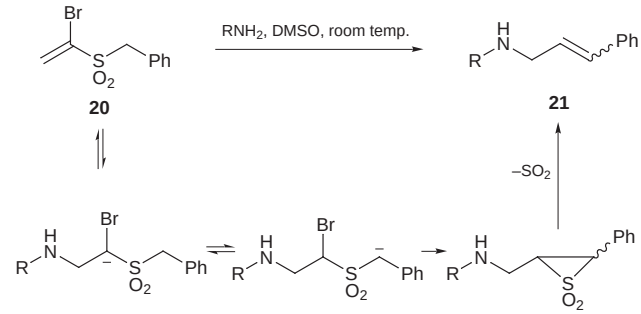


Scheme 12

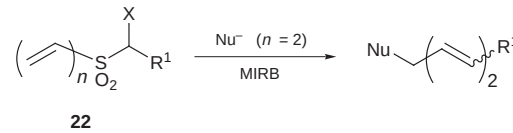
(*ii*) Tandem conjugate addition-Ramberg–Bäcklund rearrangements

Serendipity played a major part in the discovery of the second variant of the Ramberg–Bäcklund rearrangement. Paul Evans was attempting to prepare sulfonyl aziridines to study the feasibility of the aziridine-Ramberg–Bäcklund rearrangement. However, treatment of bromovinyl sulfone **20** with amines did not produce the corresponding aziridines, as expected,[33] but generated allylamines **21** instead (Scheme 13).

We presume that this process proceeds by the sequence shown in Scheme 13, *i.e.* conjugate addition to bromovinyl sulfone **20** followed by α-sulfonyl anion equilibration and Ramberg–Bäcklund rearrangement. This process is related to the Michael-induced Ramberg–Bäcklund (MIRB) reaction shown in Scheme 14.[5] The MIRB process is of limited utility, however, due to the apparent requirement for a dienyl sulfone (**22**, n = 2); similar reactions involving vinyl sulfones (n = 1) are unknown.

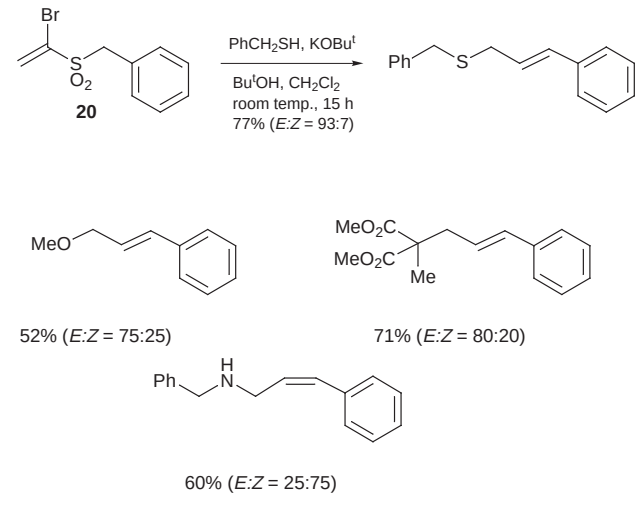


Scheme 13



Scheme 14

The novel tandem conjugate addition Ramberg–Bäcklund sequence was investigated with several other nucleophiles (Scheme 15).[34] We believe that this is a generally useful procedure as bromovinyl sulfones are readily prepared from the corresponding vinyl sulfones by a bromination–dehydrobromination sequence and they are excellent Michael acceptors. Thus, thiolates, alkoxides, amines and malonates all gave successful addition-rearrangements. The stereochemical outcome of the these reactions reflects the basicity of the reaction medium: with amines as nucleophiles/bases, *cis*-isomers predominate, whereas the more basic conditions employed in the other processes favoured formation of the *trans*-alkenes.



Scheme 15

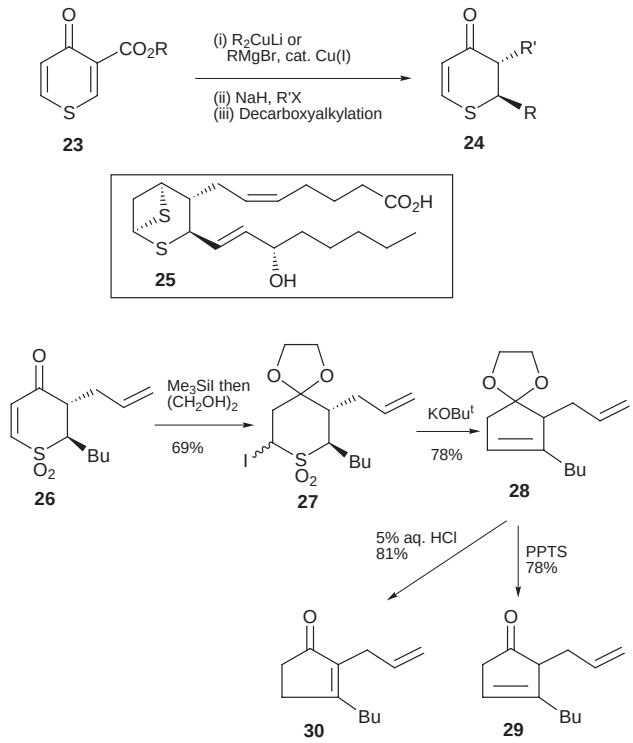
(*f*) Applications of the Ramberg–Bäcklund rearrangement in natural product and bioactive target molecule synthesis

We have utilised the Ramberg–Bäcklund rearrangement for the synthesis of a number of natural products and related compounds of biological interest.

(*i*) Cyclopentene-based natural products and related compounds

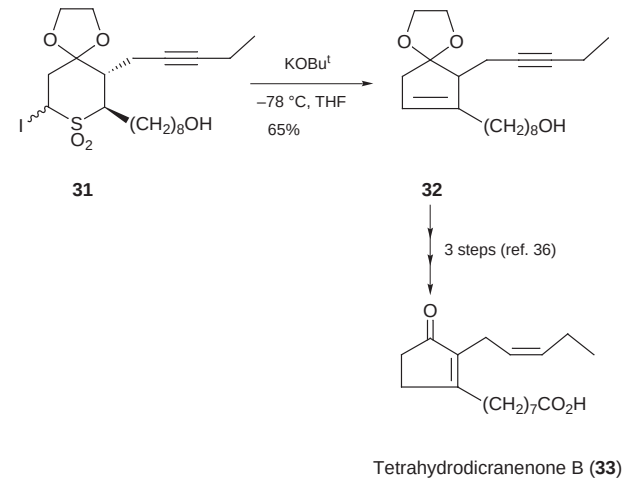
As referred to earlier, Guy Casy, Simon Lane and Stephen Quick developed a general organocopper-based route to convert

3-alkoxycarbonylthiin-4-ones **23** into 2,3-disubstituted 2,3-dihydrothiin-4-ones **24** as part of a programme to prepare thiathromboxane A_2 (**25**) and novel thiathromboxane analogues (Scheme 16).[15,16] We envisaged utilising the Ramberg–Bäcklund rearrangement to convert the sulfones derived from these 2,3-disubstituted 2,3-dihydrothiin-4-ones into 2,3-disubstituted cyclopentenones as shown in Scheme 16. We wrote to Professor Leo Paquette outlining our ideas. Receiving an encouraging response, Guy Casy prepared dioxide **26** by oxidation of the corresponding sulfide and introduced the iodide substituent with concomitant ketone protection giving adduct **27**. Ramberg–Bäcklund rearrangement proceeded smoothly to produce cyclopentene **28** which was converted into either the non-conjugated cyclopentenone **29**, or its conjugated isomer **30**, by acidic hydrolysis.[17] Matsuyama's group reported the use of the Ramberg–Bäcklund rearrangement to prepare cyclopentenes at about the same time.[35]



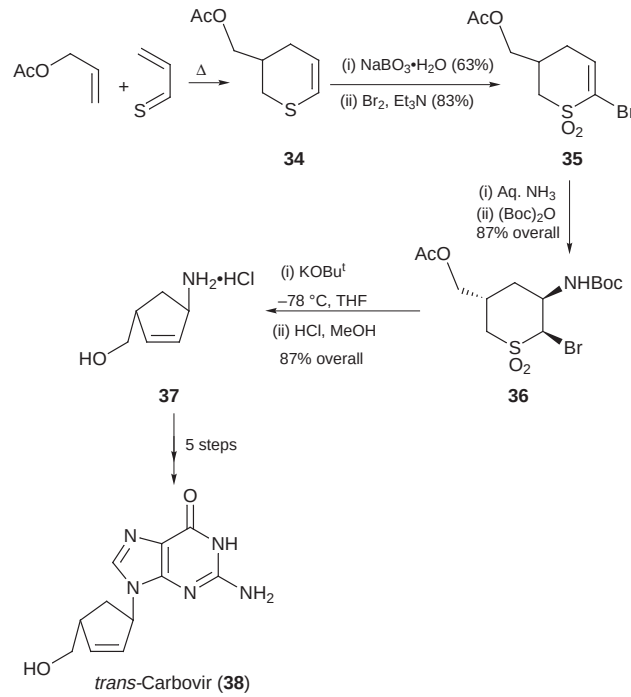
Scheme 16

Guy Casy went on to utilise this mild Ramberg–Bäcklund route to cyclopentenes as part of a formal total synthesis of the naturally occurring antibacterial agent tetrahydrodicranenone B (**33**), as shown in Scheme 17.[17] α-Iodo sulfone **31**, prepared using similar organocopper methodology to that shown in Scheme 16, underwent Ramberg–Bäcklund rearrangement to give cyclopentene **32** which can be converted into tetrahydrodicranenone B in three efficient steps using the chemistry developed by Moody, Roberts and Toczek.[36]



Scheme 17

Arne Grumann later employed a similar Ramberg–Bäcklund ring contraction, this time on α-bromo sulfone **36**, as the key step in the first synthesis of *trans*-carbovir **38** (Scheme 18).[37] *cis*-Carbovir is a fraudulent nucleoside which acts as a potent inhibitor of HIV reverse transcriptase. The 5-substituted unsaturated thiane **34** was prepared from thioacrolein *via* a hetero-Diels–Alder process. An important subsequent step involved conjugate addition of ammonia to unsaturated sulfone **35** to produce α-bromo sulfone **36** in an efficient and stereoselective manner. The use of α-bromo-α,β-unsaturated sulfones as precursors to Ramberg–Bäcklund substrates should be generally useful methodology (see also Scheme 15). Ramberg–Bäcklund reaction of **36** followed by deprotection gave amine hydrochloride **37** which was elaborated using the Traube method to complete the synthesis of *trans*-carbovir.[37]

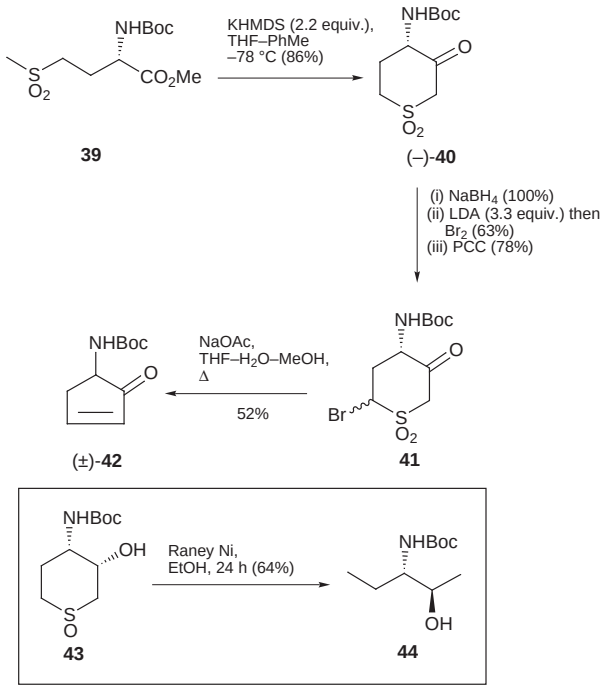


Scheme 18

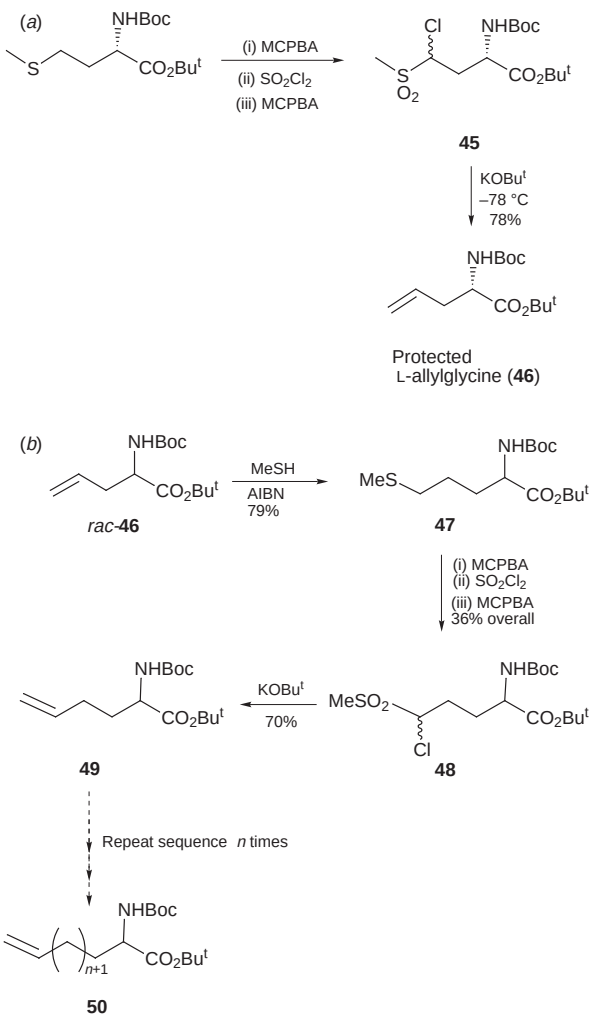
About this time we became interested in synthetic applications of amino acids. Mark Gamble first prepared amino cyclopentanes using glutamic acid-derived sulfones.[38] He then studied the cyclisation reactions of methionine-derived sulfones such as **39** (Scheme 19). The cyclisation to produce the enantiomerically pure thiane dioxide **40** proceeded in high yield and the product was subsequently elaborated to give α-bromo sulfone **41**. This compound underwent Ramberg–Bäcklund rearrangement to give the protected amino cyclopentenone **42**, unfortunately in racemic form.[39] Attempts to desulfurise the cyclic sulfones in this sequence were unsuccessful but Tim Ockendon and Peter O'Brien found that the sulfoxides corresponding to **39** also underwent cyclisation, and Raney nickel desulfurisation of intermediates such as **43** provided a method for preparing protected *anti*-1,2-amino alcohols like **44**.[39]

(*ii*) Unsaturated amino acid synthesis

The interest in methionine chemistry referred to in the previous section provided the stimulus for Marcel Schaeffer to investigate the Ramberg–Bäcklund reactions of L-methionine-derived α-chloro sulfones [Scheme 20(*a*)]. He showed that



Scheme 19

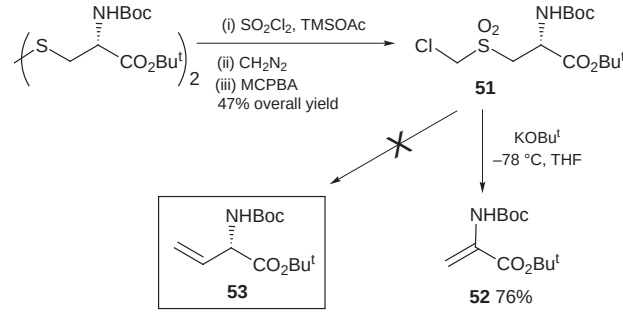


Scheme 20

chloro sulfone **45** underwent efficient conversion into allyl glycine derivative **46** and demonstrated, with Zhao-Xia Guo, that racemisation could be avoided by carrying out the reaction at −30 °C or lower.[40]

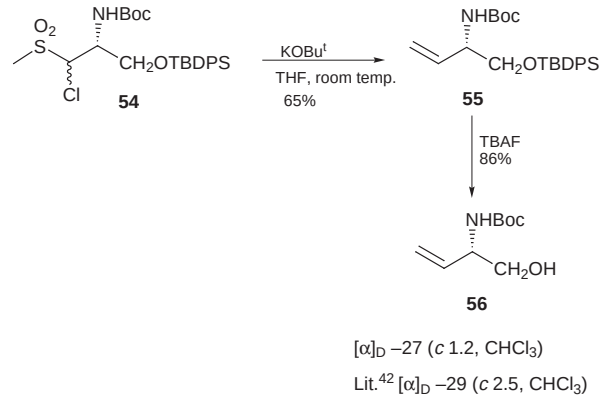
In unpublished and unoptimised work, Zhao-Xia Guo went on to demonstrate that this sequence could be employed in an iterative manner [Scheme 20(*b*)]. Thus, the radical addition of methanethiol to the protected allylglycine **46** gave sulfide **47** which was easily elaborated *via* α-chloro sulfone **48** to give butenyl glycine derivative **49**. In principle, this sequence could be employed to prepare the series of unsaturated amino acid derivatives **50** (n = 0,1,2 *etc*.).

In order to complete the sequence, Tim Ockendon attempted to prepare the corresponding vinyl glycine derivative **53** (Scheme 21). He utilised a modified version of the sulfinyl



Scheme 21

chloride procedure developed by Ottenheijm *et al*.[41] to prepare α-chloro sulfone **51** in a regioselective manner. Unfortunately, treatment of **51** under standard Ramberg–Bäcklund conditions gave 1,2-elimination, producing alkene **52**, and none of the required product **53** was observed. We were, however, able to prepare the corresponding vinyl glycinol **56** using Ramberg–Bäcklund methodology (Scheme 22). α-Chloro sulfone **54** was thus converted into alkene **55** which was desilylated to give the known[42] alcohol **56** in enantiomerically pure form.



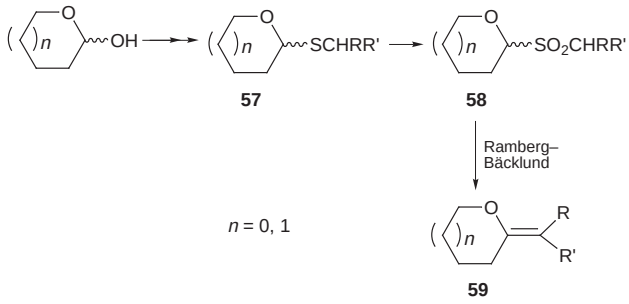
Scheme 22

(*iii*) *exo*-Glycal synthesis

As part of a project to design and synthesise novel analogues of sialyl Lewis^x,[43] Paul Murphy prepared a number of thioglycosides **57**. These compounds provided us with the opportunity to obtain the corresponding *S*-glycoside dioxides **58** and investigate their Ramberg–Bäcklund rearrangements (Scheme 23).

The sequence illustrated in Scheme 23 leads to *exo*-glycals **59**. The parent 1-*exo*-methylene compounds (**59**, R = R′ = H) have been used as glycosidase inhibitors[44] and are valuable synthetic intermediates.[45–51] Scheme 24 summarises synthetic applications of the glucose-derived *exo*-methylene compound **60**. The corresponding substituted *exo*-glycals **59** (R, R′ ≠ H) are also of considerable interest.[52]

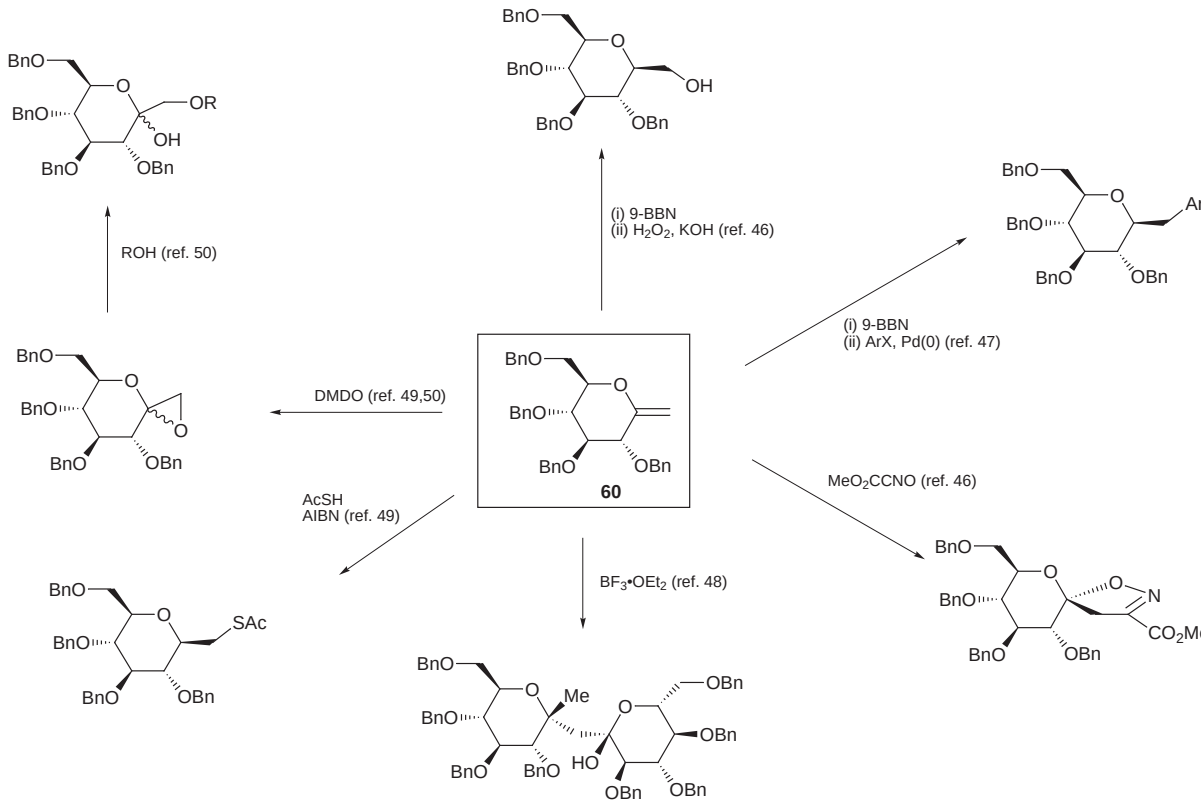
A number of procedures have been published for the preparation of *exo*-methylene glycals[44–51] but the method of



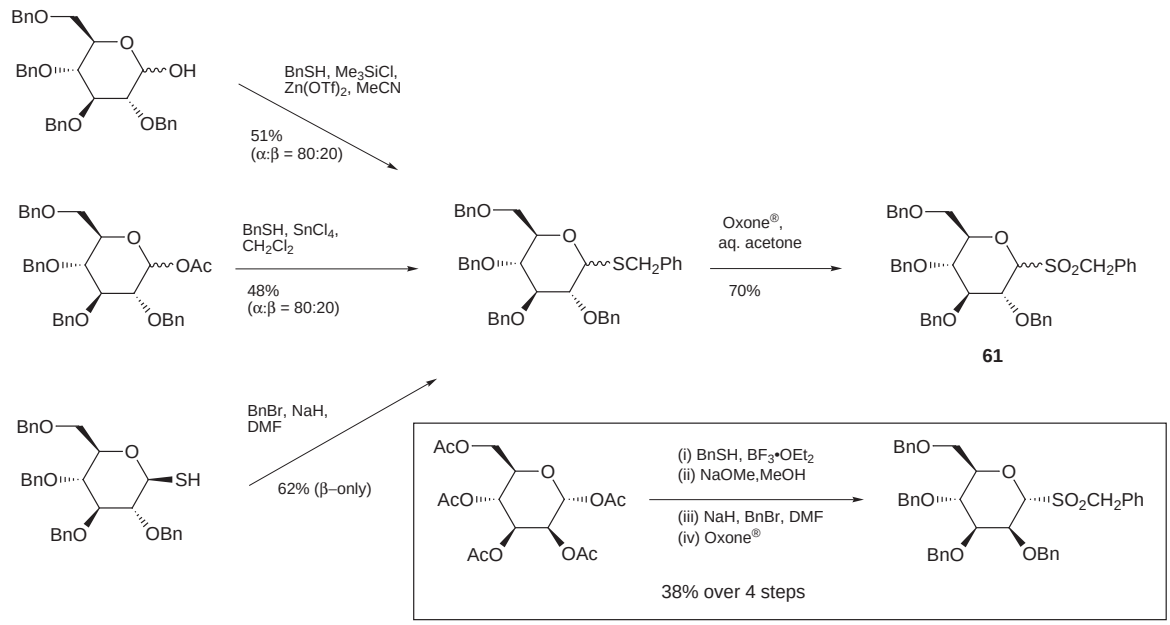
Scheme 23

choice would appear to be methylenation of the corresponding lactones using dicyclopentadienyl(dimethyl)titanium (or the Tebbe reagent).[47,51] There is no general method to prepare substituted *exo*-glycals **59** (R, R′ ≠ H), however.[53] Paul Murphy, Frank Griffin and Duncan Paterson therefore set out to explore the Ramberg–Bäcklund route to *exo*-glycals.[54,55] Scheme 25 summarises some of the procedures used to prepare the *S*-glycosides[56] and thus the sulfones needed for the Meyers' variant of the Ramberg–Bäcklund rearrangement.[3] Similar procedures were used to prepare related glucose-derived sulfones and *S*-glycoside dioxides derived from other sugars.

We were delighted to observe that the required transformations to produce *exo*-glycals proceeded efficiently using

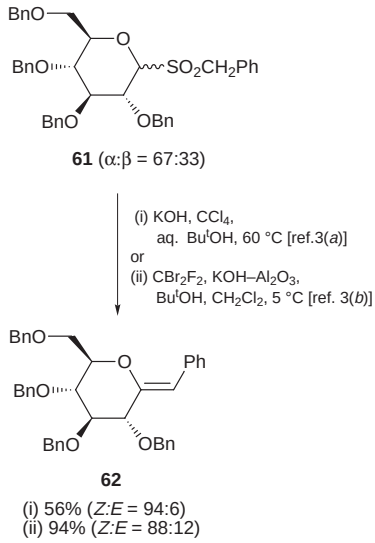


Scheme 24



Scheme 25

Meyers' original conditions[3a] (CCl_4, KOH) and the modified conditions (CBr_2F_2, KOH, Al_2O_3) recently reported by Chan *et al*.[3b] This is shown in Scheme 26 for the glucose derived benzyl sulfone **61**: phenyl glycal **62** was produced in reasonable yield using the Meyers' conditions and excellent yield by the Chan procedure, the *Z*-product predominating in both cases.



Scheme 26

We then proceeded to prepare a range of *exo*-glycals using this Ramberg–Bäcklund methodology (Fig. 6). As can be seen, the glucose-derived methylene compound **63a** was prepared, as were the phenyl, methyl and ethyl substituted alkenes **63b–d** (all with the *Z*-alkene predominating). Although unoptimised, galactose, mannose, xylose, fucose and ribose derived alkenes **63e–i** were equally accessible. Tetrasubstituted alkenes **63j–l** were also prepared by this methodology, although in these cases the required transformation was only observed using the Meyers' conditions. Further work is needed to optimise these yields, but the availability of highly hindered glycals, particularly adamantene derivative **63l**, is noteworthy.

The ease with which anomeric carbanions eliminate C-2 alkoxides to give *endo*-glycals has been a longstanding problem in *C*-glycoside synthesis until recently.[57] It should be noted that the Ramberg–Bäcklund methodology is compatible with 2-alkoxy substituents. Investigations are therefore underway to probe the mechanisms of these reactions.[54]

As mentioned, *exo*-glycals have proved to be valuable glycosidase inhibitors[44,52] but for our methodology to be of use in this area it is important to be able to remove the hydroxy group protection without reducing or hydrolysing the enol ether moiety. Benzyl protection is not suitable for this purpose and Duncan Paterson has explored the compatibility of other protecting groups with the Ramberg–Bäcklund conditions (Scheme 27). Sulfone **64**, protected by *tert*-butyldimethylsilyl (TBDMS) groups, was therefore prepared. Ramberg–Bäcklund rearrangement of **64** proceeded smoothly and desilylation was accomplished using tetrabutylammonium fluoride (TBAF). This two step sequence produced the unprotected enol ether **65** (which was acetylated for characterisation purposes).

We have also investigated synthetic applications of these novel *exo*-glycals. As shown in Scheme 28, Marie-Lyne Alcaraz utilised the *Z*-phenyl derivative **62** in a formal synthesis of the *C*-glycoside **68**, recently reported as a new β-glycosidase inhibitor by Schmidt and Dietrich.[58] Thus, hydroboration using borane–THF followed by oxidation gave a separable 25 : 75 mixture of α- and β-alcohols **66** and **67** in 65% overall yield. Schmidt and Dietrich converted alcohol **67** into enzyme inhibitor **68** in five high yielding steps.[58] The advantage of our new procedure is the brevity of the synthetic route: Schmidt and

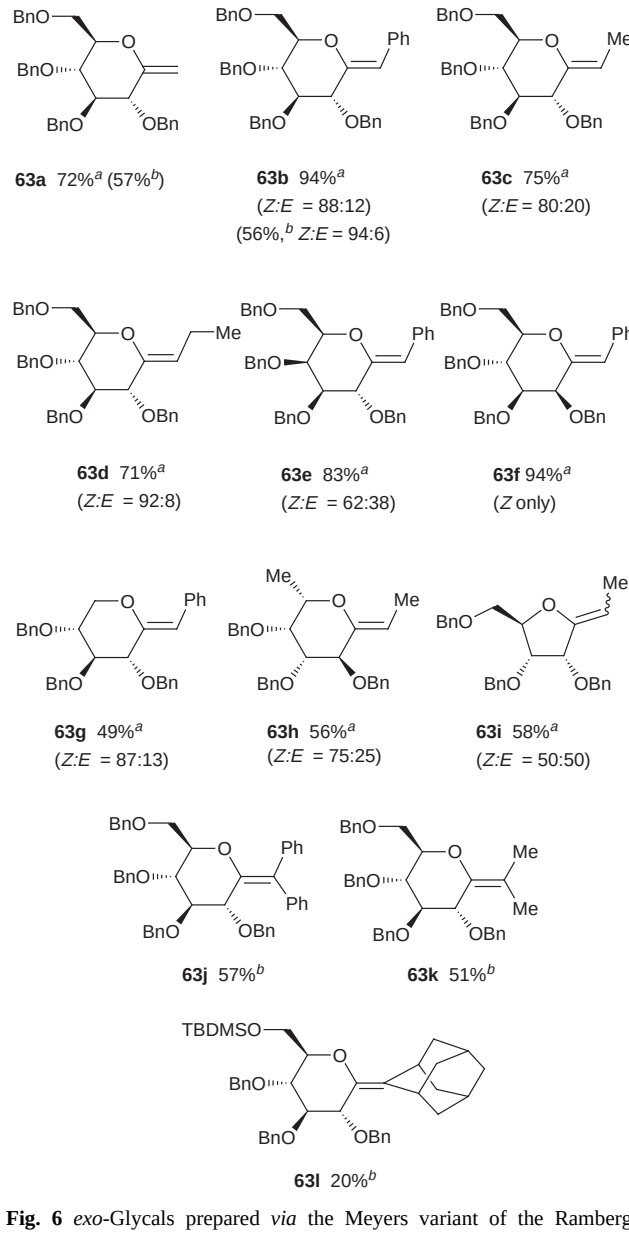


Fig. 6 *exo*-Glycals prepared *via* the Meyers variant of the Ramberg–Bäcklund rearangement. [a] Using CF_2Br_2 [ref. 3(*b*)]. [b] Using CCl_4 [ref. 3(*a*)].

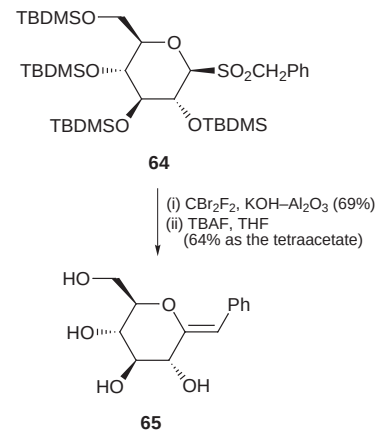
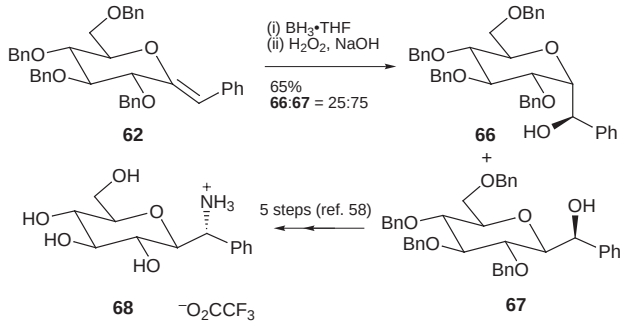


Scheme 27

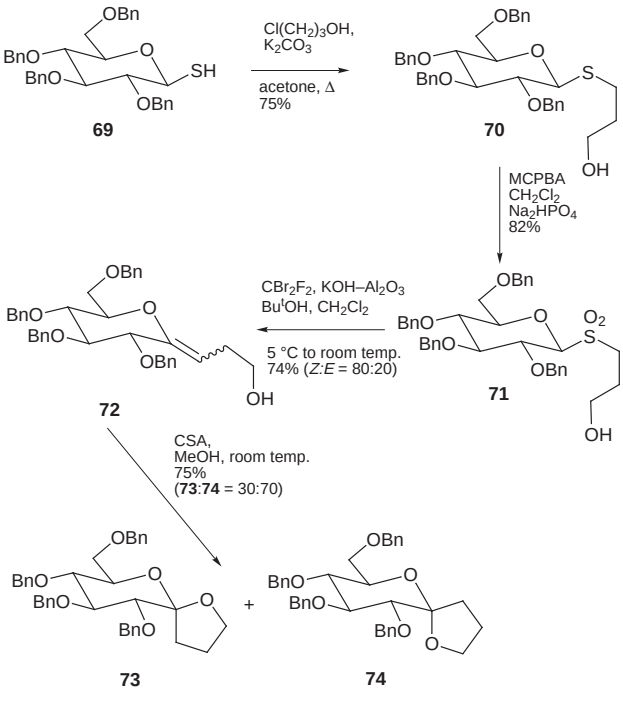
Dietrich required eight steps to prepare alcohol **67** from D-glucal.[58]

Frank Griffin employed this new methodology to prepare the spirocyclic sugars **73** and **74** (Scheme 29). These compounds,



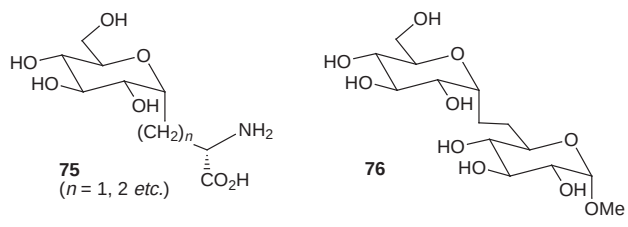
Scheme 28

which are simplified analogues of natural products such as papulacandin D,[59] have recently been prepared by a photolytic route.[60] In our new synthesis (Scheme 29), the benzylated thioglucose derivative **69**[56b] was alkylated giving sulfide **70** which was oxidised to sulfone **71**, both steps proceeding in good yield. The Ramberg–Bäcklund rearrangement proceeded smoothly on the unprotected alcohol **71** using Chan's CBr_2F_2 conditions[3b] giving *exo*-glycal **72** in 73% yield. Cyclisation was effected by treatment of enol ether **72** with camphorsulfonic acid (CSA) in methanol to produce a separable mixture of spiroacetals **73** and **74** (30 : 70) in 75% yield.



Scheme 29

We are currently optimising this Ramberg–Bäcklund methodology for *exo*-glycal synthesis, and exploring its applications for the synthesis of more complex *C*-glycosides and *C*-disaccharides. For example, routes to carba-glycopeptides[61] **75** and carba-disaccharides[62] such as methyl carba-isomaltoside **76** using the Ramberg–Bäcklund chemistry are currently being investigated.[63]



Summary

Major advances have been made in Ramberg–Bäcklund and episulfone chemistry over the past few years. Procedures have been developed which enable episulfones to be produced from α-halo sulfones or from episulfides by oxidation. Episulfone deprotonation-trapping reactions have been developed to provide a new method of preparing novel vinylsilanes and vinylstannanes, and new variants of the Ramberg–Bäcklund rearrangement have been discovered which produce functionalised products such as allylic alcohols and amines. Mild conditions have been developed for the classical Ramberg–Bäcklund rearrangement and applied to the synthesis of cyclopentene-based natural products and unsaturated amino acids. In addition, the Meyers' variant of the Ramberg–Bäcklund rearrangement has been utilised in a new route to *exo*-glycals commencing from *S*-glycoside dioxides. Ongoing work to further apply this new methodology, for example to the synthesis of sphingosines and novel *C*-disaccharides, promises further interesting and useful discoveries ahead.

Acknowledgements

This article is dedicated to Dr D. Neville Jones, who taught me all about the Ramberg–Bäcklund rearrangement (and many other things) and stimulated a life-long interest in organosulfur chemistry, and to Dr Ian Harrison, who extended this interest in organosulfur compounds and also introduced me to prostaglandins, thromboxanes and other arachidonic acid metabolites. Without the influence of these two outstanding teachers and scientists none of the research described in this article would have been possible.

I would like to pay tribute to the co-workers mentioned in the text for their practical skills, intellectual contributions and, in particular, for their enthusiasm when ploughing what has usually been a lone furrow alongside the organometallic and natural product teams. I would also like to thank the industrial collaborators and other group members for their contributions over the years and the EPSRC for financial support.

This article was written during a period as short term visitor at the University of Auckland in May–June, 1998: I would like to thank Professor Paul Woodgate and all of his colleagues for their stimulating company and for making the visit so memorable.

Paper 8/06615I

Aufbau synthesis of a mixed-metal anion receptor cage

Ramón Vilar, D. Michael P. Mingos,* Andrew J. P. White and David J. Williams

Department of Chemistry, Imperial College of Science Technology and Medicine, London, UK SW7 2AY. E-mail: d.mingos@ic.ac.uk

Received (in Basel, Switzerland) 26th October 1998, Accepted 8th December 1998

The isolation and structural characterisation of square planar [Ni(atu)$_2$] (Hatu = amidinothiourea) has provided a rational basis to synthesise the novel mixed-metal cage compounds [Ni$_4$Pd$_2$(atu)$_8$X]X$_3$ (X = Cl, Br); one of these cages (when X = Cl) has been crystallographically characterised showing that the chloride anion is encapsulated in the centre of the cage forming eight hydrogen-bonds with N–H groups from the ligands and two Lewis acid–base interactions with two palladium(II) ions.

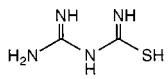
The inclusion of guest molecules into host structures has attracted great interest over the past two decades.[1] This interest has been stimulated by the potential properties of these supermolecules as chemical sensors,[2] nanoscale devices[3] and systems with biological markers.[4] Whilst the supramolecular chemistry of cationic or neutral guests has been widely studied,[5] that of anions has received much less attention.[6] Examples of molecular containers (such as squares and cages) have been reported to selectively encapsulate anionic guests.[7] The incorporation of transition metal centres into such molecular containers may either enhance their Lewis acidity or introduce magnetic, electrochemical and luminescent properties into the host molecules.[8]

Recently we have reported the selective encapsulation of anions (Cl **1**, Br **2**) inside the hexanuclear nickel cages [Ni$_6$(atu)$_8$]$^{4+}$ (Hatu = amidinothiourea and atu is its deprotonated form).[9] These cages self-assemble according to eqn. (1) only in the presence of the templating anions F$^-$, Cl$^-$ and Br$^-$.

$$4\,Ni(ClO_4)_2 + 8\,Hatu \longrightarrow 4\,[Ni(atu)_2] \xrightarrow{2\,NiX_2} [Ni_6(atu)_8X]X_3 \quad (1)$$

X = Cl **1**, Br **2**

Hatu =



Here, we report the synthesis and structural characterisation of the square planar precursor [Ni(atu)$_2$] **3**. The isolation of this complex has made it possible to rationally synthesise the new mixed-metal cage compounds [Ni$_4$Pd$_2$(atu)$_8$X]X$_3$ (X = Cl **4**, X = Br **5**) which retain the basic octahedral metal framework observed in **1** and **2** but selectively include the palladium ions in *trans*-positions. Although there are a number of examples of anion encapsulation by homonuclear cages, few examples of mixed metal cages have previously been reported.

When a solution of Ni(ClO$_4$)$_2$ in methanol was mixed with 2 equivalents of amidinothiourea [Hatu = H$_2$NC(=NH)-NHC(=NH)SH] a dark orange solution was obtained from which a crystalline material was separated after addition of diethyl ether. A single crystal analysis of the compound confirmed its formulation as *trans*-[Ni(atu)$_2$] (Fig. 1).

Amidinothiourea can coordinate to metal centres using either two nitrogens (N,N) or one nitrogen and one sulfur (N,S). The molecular structure of **3** reveals the coordination mode to be N,N′. This is in striking contrast to what is observed in the only other structurally characterised complex of this ligand, with palladium, where N,S coordination occurs.[10] This suggested that the non-coordinated sulfur atoms in **3** are available for coordination to additional metal centres. This was partially

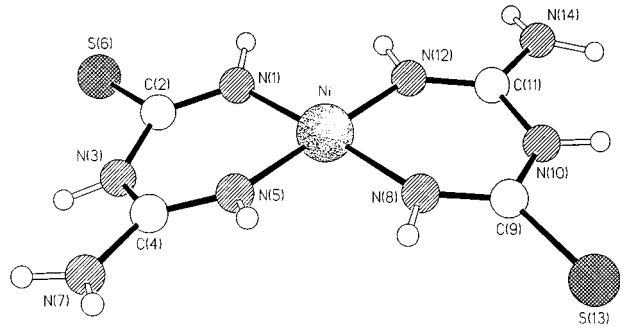


Fig. 1 The molecular structure of one of the independent molecules present in the crystals of **3**. Ni–N distances are in the range 1.843(5)–1.872(4) Å.

corroborated when addition of NiX$_2$ salts (X = Cl, Br) to this solution yielded the recently reported hexanickel cages **1** and **2**, albeit with an isomerisation of the square-planar complex from *trans*- to *cis*-.

When a solution of [Pd(PhCN)$_2$Cl$_2$] in CH$_2$Cl$_2$ was added to a solution of **3** in methanol (in a 1 : 2 ratio) a change in colour to a brighter orange was immediately observed. After 2 h the volume of methanol was reduced and diethyl ether added. A crystalline material precipitated and was formulated as [Ni$_4$-Pd$_2$(atu)$_8$Cl]Cl$_3$ **4** on the basis of spectroscopic and elemental analyses.† Crystals suitable for crystallographic analysis were obtained by slow evaporation of diethyl ether into a methanol solution of **4**. The molecular structure of **4** is shown in Fig. 2.

The X-ray analysis‡ revealed the presence of an octahedral Ni$_4$Pd$_2$ mixed-metal cage complex with one of the chloride anions encapsulated at its centre. The overall geometry is very similar to that of the all-nickel counterpart **1**,[9] but with the nickel atoms in the *trans*-positions replaced by palladium atoms (*vide infra*). The geometry at each nickel centre is square-planar with Ni–N distances ranging between 1.847(5) and 1.887(9) Å,

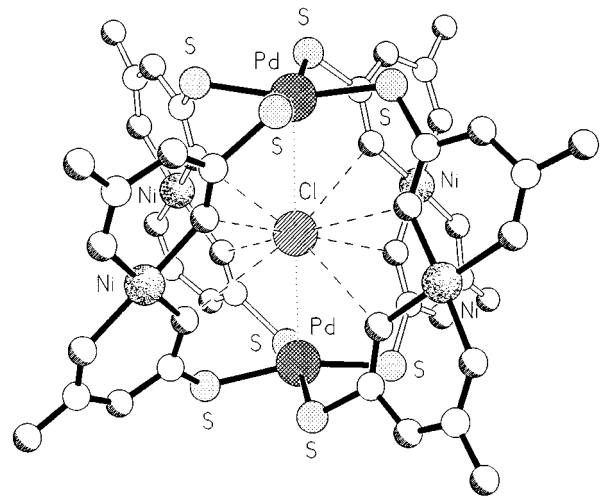

Fig. 2 The molecular structure of the mixed-metal cage cation **4** showing the encapsulation of a chloride anion. The Ni–N distances are in the range 1.847(5)–1.887(9) Å, Pd–S between 2.315(2) and 2.323(2) Å and N···Cl 3.29–3.39 Å; the Pd···Cl distances are 3.169(2) and 3.190(2) Å.

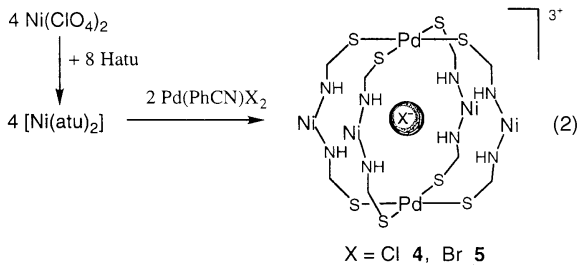
whereas that at the palladium centres is distinctly pyramidal, the palladium atoms lying *ca.* 0.31 Å out of the planes of their substituents towards the encapsulated chloride anion [the Pd–S distances range between 2.315(2) and 2.323(2) Å]. As in **1** the anion is displaced slightly towards one of the MS_4 metal atoms, the Pd···Cl distances being 3.169(2) and 3.190(2) Å. The 'retaining' N–H···Cl hydrogen-bonds have N···Cl distances ranging between 3.29 and 3.39 Å. The cage as a whole exhibits a small helical twist with the north and south PdS_4 units being rotated by *ca.* 17° with respect to each other about the Pd···Pd vector. Although the cage has helicity, the crystals are racemic, there being equal numbers of Δ and Λ forms present. The 'non-encapsulated' chloride anions link adjacent cages *via* additional N–H···Cl hydrogen-bonds, with the voids formed between the cages being filled by the methanol and diethyl ether solvent molecules.

An intriguing difference between the hexanickel cages **1** and **2**,[9] and the mixed-metal Ni–Pd cages reported in this paper (**4** and **5**) is their colour: the former are dark green while the later are dark orange. Ni(II) square planar complexes are generally red or orange. However, the coordination of ligands above or below the square-plane commonly results in a change in their colour to dark green or blue.[11] This has been attributed to interactions between these ligands and the metal d_{z^2} orbital in the axial positions of the square planar unit. The change in colour for **1** and **2** underlines the importance of the acceptor–donor interaction between the NiS_4 units and the encapsulated halide.

The generality of the *aufbau* process for the synthesis of **4** is supported by the ability to synthesise the analogous bromide species. When a mixture of $Ni(ClO_4)_2$/2 Hatu was reacted with $[Pd(PhCN)_2Br_2]$ an orange product was obtained. This product was recrystallised from methanol–diethyl ether and was formulated on the basis of IR, ^{1}H NMR and elemental analyses as the cage compound $[Ni_4Pd_2(atu)_8Br]Br_3$ **5**.

The formation of the above complexes can be rationalised on the basis of the sequence of reactions shown in eqn. (2).



(2)

These results have demonstrated that the formation of octahedral cage complexes of amidinothiourea, which are capable of encapsulating halide anions, are not limited to the self-assembly processes but can be built up using well defined coordination chemistry principles. The isolation of mixed-metal cages such as those described above, open up the possibility of fine tuning the chemical and spectroscopic properties of this interesting class of anion receptor molecules.

Dearomatising cyclisations of lithiated *N*-benzylbenzamides

Anjum Ahmed, Jonathan Clayden* and Samreen A. Yasin

Department of Chemistry, University of Manchester, Oxford Road, Manchester, UK M13 9PL. E-mail: j.p.clayden@man.ac.uk

Received (in Liverpool, UK) 22nd October 1998, Accepted 3rd December 1998

On treatment with Bu^{t}Li in the presence of HMPA, *N*-benzylbenzamides undergo anionic cyclisation with dearomatisation to give an extended amide enolate which reacts with electrophiles to yield bicyclic cyclohexadiene derivatives.

Dearomatisation is an attractive strategy for the synthesis of functionalised six-membered ring compounds,[1] and the Birch reduction has long been the most important dearomatising reaction of substituted benzene rings.[2] More recent methods include addition to chromium–arene complexes, oxidations wtih *Pseudomonas putida*,[3] MAD-promoted nucleophilic attack on aromatic aldehydes and ketones,[4] or radical cyclisation.[5] We have recently described a dearomatising anionic cyclisation of naphthalenes, in which a lithiated tertiary 1-naphthamide undergoes intramolecular attack on the naphthalene ring to generate a benzo[*e*]isoindolinone.[6] We now report that similar conditions promote the dearomatising cyclisation of simple benzamides to give tetrahydroisoindolones.

N-Benzylbenzamides **1** and **2** undergo benzylic deprotonation (α to nitrogen) on treatment with Bu^{t}Li, and the α-lithiated species can be alkylated with MeI or BnBr to yield **4**–**6** (Scheme 1).[7] When we carried out this deprotonation in the presence of HMPA, the organolithium **3** was no longer stable over a period of hours at −78 °C, and slowly underwent a new kind of dearomatising anionic cyclisation.[8] Adding MeI after 16 h gave no **4** or **6**, but instead a regio- and stereo-isomeric mixture of cyclised isoindolinones **8** or **9** in 71–73% yield (Scheme 2). In a similar manner, an aqueous quench provided tetrahydroisoindolones **10** and **11**, which are surprisingly resistant to air oxidation, in yields of 80–89%.

At least 6 equiv. of HMPA are essential for high-yielding cyclisations at −78 °C: in pure THF the organolithium **3** (R = Bn) survived for 16 h and returned **2** in quantitative yield upon aqueous quench. DMPU (*N*,*N*'-dimethylpropyleneurea) can be used in place of HMPA, but acceptable yields are then obtained only if the temperature is raised to −40 °C for the 16 h period. TMEDA fails to promote the cyclisation. Organolithium cyclisations are often faster in the presence of lithium-coordinating additives such as HMPA, DMPU or TMEDA:[9] these are assumed to work by promoting dissociation of the organolithium to an ion pair.[10] It would then be the ion pair which cyclises, by a mechanism which is as yet unclear, but may be electrocyclic. Besides our naphthamide cyclisation,[6] there

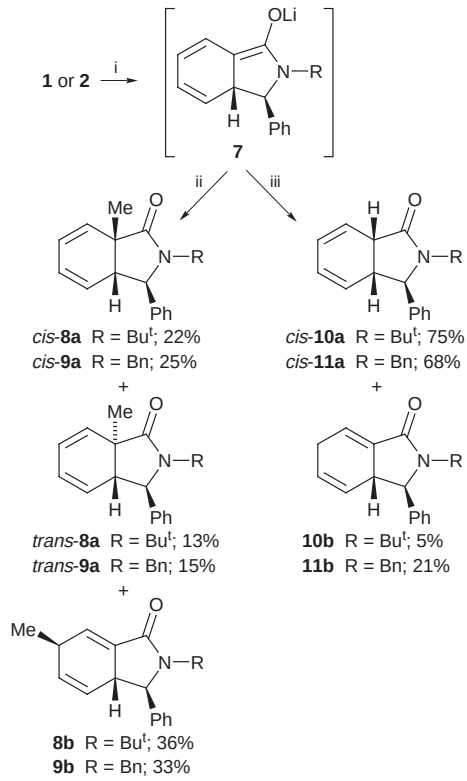
6 R = Bn, E = Me; 45%[b]

Scheme 1 *Reagents and conditions*: i, Bu^{t}Li (3 equiv.), THF −78 °C, 6 h; ii, MeI or BnBr. [a] HMPA added 5 min before BnBr. In the absence of HMPA, only starting material was recovered. [b] Deprotonated in presence of HMPA (−78 °C, 20 min). Remainder consists largely of cyclised material as described below.



Scheme 2 *Reagents and conditions*: i, Bu^{t}Li (1.3 equiv.), HMPA (6 equiv.), THF, −78 °C, 16 h; ii, MeI; iii, H_2O.

are few precedents for cyclisation of an organolithium onto an aromatic ring,[11] and only one which results in loss of aromaticity.[12] Curran has described a closely related radical cyclisation of an *N*-benzyl-*N*-*tert*-butylbenzamide[13] which yields a rearomatised isoindolone.

Whatever the detailed mechanism of the cyclisation, it must produce the extended enolate **7**, with the phenyl group lying *exo* to the 6,5-fused ring system. Enolate **7** evidently reacts both α and γ to the amide carbonyl group,[14] leading to the observed mixture of regioisomers.† We observed only one stereoisomer of the γ-alkylated compounds **8b**–**11b**; we assigned their stereochemistry by means of an X-ray crystal structure of **8b**

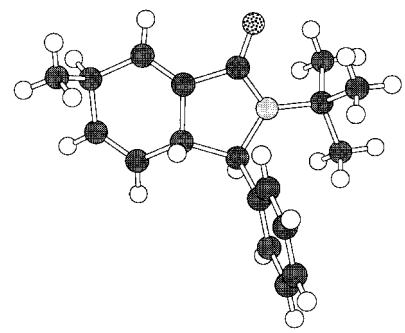


Fig. 1 X-Ray crystal structure of **8b** (R = Bu^t).

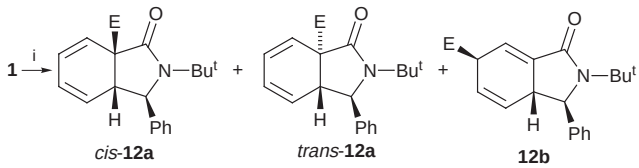
(Fig. 1), which shows the cyclohexadiene ring as a boat bearing the methyl group pseudoaxially.‡ The α-alkylated compounds **8a** and **9a** were formed as stereoisomeric mixtures, with the *cis* ring junction favoured (as in the related naphthamide series[6]). Their relative stereochemistry was elucidated by NOE studies. The major stereoisomers are formed by attack of the electrophile on the *exo* face of the bicyclic enolate **7**.

The same three classes of products, in varying ratios, were obtained when other electrophiles were used to quench the cyclisation, as shown in Scheme 3 and Table 1. Harder alkylating agents apear to favour α-attack on **6** (MeOTf > MeOTs > MeI); more sterically demanding alkylating agents appear to be more stereoselective.



Scheme 3 *Reagents and conditions*: i, Bu^{t}Li (1.3 equiv.), HMPA (6 equiv.), THF, −78 °C, 16 h; ii, E^+.

It was also possible to improve the regioselectivity of the alkylation step by varying the enolate counterion or solvent. Table 2 shows the result of reforming the enolate **7** with Bu^{s}Li, LiHMDS, NaHMDS or KHMDS, and alkylating it with BnBr (Scheme 4). The lithium enolate generated by deprotonation with Bu^{s}Li reacts more regioselectively than the same enolate formed by the reaction in the presence of HMPA, and the presence of hexamethyldisilazane leads almost solely to the α-alkylated product. The sodium and potassium enolates reacted less regioselectively, but the potassium enolate gave an almost quantitative yield of isolated regioisomers.

Table 2 Alkylations using various bases

Received (in Basel, Switzerland) 2nd November 1998, Accepted 8th December 1998

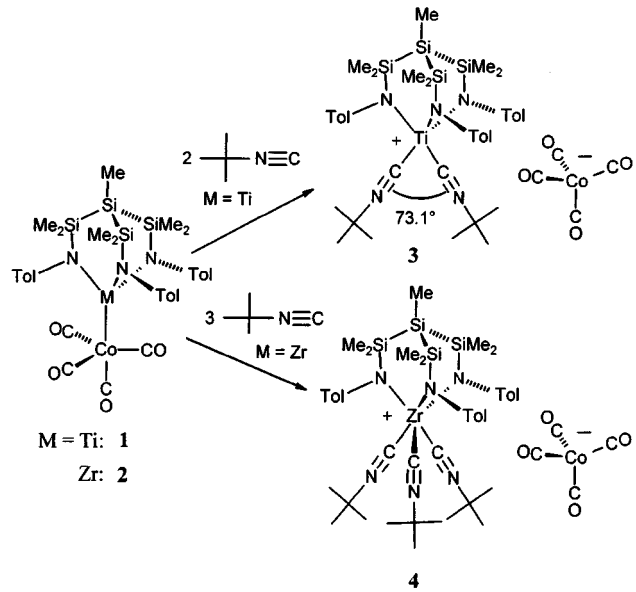
The ionic cleavage of Ti–Co and Zr–Co bonds occurs upon reaction with Bu^{t}NC and the products [MeSi{SiMe$_2$N(*p*-Tol)}$_3$Ti(CNBu^t)$_2$][Co(CO)$_4$] 3 and[MeSi{SiMe$_2$N(*p*-Tol)}$_3$Zr(CNBu^t)$_3$][Co(CO)$_4$] 4 were characterized by single crystal X-ray diffraction; the importance of the nucleophilicity of the late transition metal fragment in reactions of the unsupported early–late heterobimetallics is demonstrated.

In many cases, early–late heterobimetallic complexes display the reactive behaviour of pairs of metal nucleophiles and electrophiles which are 'masked' by the existence of a metal–metal bond and which is cleaved during the course of the reaction.[1–5]

In order to assess the validity of the concept of combining metal nucleophilicity and electrophilicity we decided to reduce the basicity of the late transition metal fragment to the degree at which polar additions to suitable unsaturated substrates no longer take place.[6] Instead, the heterolytic cleavage of the metal–metal bond and 'solvation' of the Ti-group fragment by the substrate was thought to be a possible reaction pathway yielding the *extremely rare* case of an ionic dissociation of the metal–metal bond between transition elements *without* concomitant redox reaction.[7] Redox disproportionation is observed in the well known reaction of $Co_2(CO)_8$ with donor ligands.[8] Here, we wish to give a first account of these investigations which led to the conversion of metal–metal bonded dinuclear complexes to fairly stable organometallic salts. More importantly, we could demonstrate that subsequent addition of a stronger metal nucleophile led to the re-formation of the polar metal–metal bond.

The objects of study were the heterobimetallic complexes [MeSi{SiMe$_2$N(*p*-Tol)}$_3$M-Co(CO)$_4$] (M = Ti **1**, Zr **2**)[9] in which the late transition metal fragment is characterized by low nucleophilicity.[6] Reaction of **1** and **2** with Bu^{t}NC in toluene led to the clean conversion to products which contain two and three molecules of isocyanide associated with every Ti and Zr centre, respectively, as established by elemental analysis. The formation of both compounds **3** and **4** occurred cooperatively, *i.e.* without detection of intermediates, and the products crystallized directly from the reaction mixture in yields of 75 and 77%, respectively. A single ν(CO) band at 1875 cm^{-1} in the IR spectra of both compounds indicated the presence of the tetracarbonyl cobaltate anion[10] and their low solubility in the aromatic reaction medium indicated an ionic species. In both cases it proved to be possible to obtain single crystals of the apparently salt-like compounds directly from the reaction mixture. It was therefore possible to establish their structure by X-ray crystallography and to confirm their formulation as [MeSi{SiMe$_2$N(*p*-Tol)}$_3$Ti(CNBu^t)$_2$][Co(CO)$_4$] **3** and [MeSi{SiMe$_2$N(*p*-Tol)}$_3$Zr(CNBu^t)$_3$][Co(CO)$_4$] **4** (Scheme 1).†

The [Co(CO)$_4$]$^-$ anion in the crystal structure of **3** was found to be highly disordered which precluded the complete refinement of the structural data. However, the presence of the pentacoordinate titanium complex cation [MeSi{SiMe$_2$N(*p*-Tol)}$_3$Ti(CNBu^t)$_2$]$^+$ could be established unambiguously. In contrast, the X-ray diffraction experiment performed on a single crystal of compound **4** yielded a data set of good quality and permitted full refinement of the structure which is depicted in Fig. 1.‡



Scheme 1 Ionic cleavage of the Ti–Co and Zr–Co bonds.

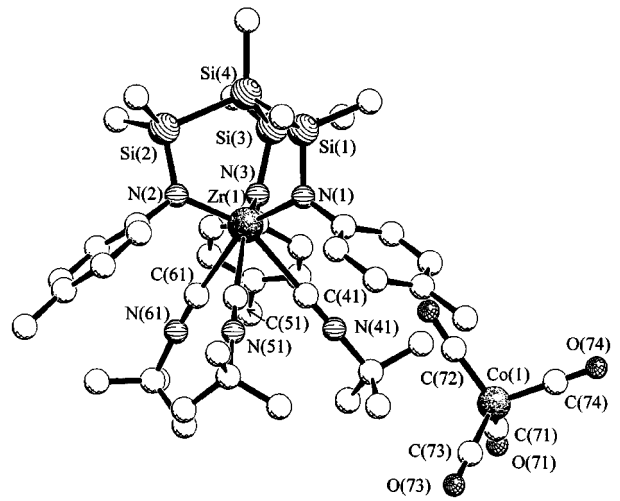


Fig. 1 Molecular structure of **4** in the crystal. Principal bond lengths (Å) and interbond angles (°): Zr(1)–N(1) 2.074(4), Zr(1)–N(2) 2.076(5), Zr(1)–N(3) 2.082(5), Zr(1)–C(41) 2.431(7), Zr(1)–C(51) 2.448(7), Zr(1)–C(61) 2.440(7), Co(1)–C(71) 1.7332(9), Co(1)–C(72) 1.722(8), Co(1)–C(73) 1.769(8), Co(1)–C(74) 1.741(8); N(1)–Zr(1)–N(2) 105.8(2), N(1)–Zr(1)–N(3) 108.0(2), N(2)–Zr(1)–N(3) 108.9(2), C(41)–Zr(1)–C(51) 70.6(2), C(41)–Zr(1)–C(61) 72.1(2), C(51)–Zr(1)–C(61) 71.4(2).

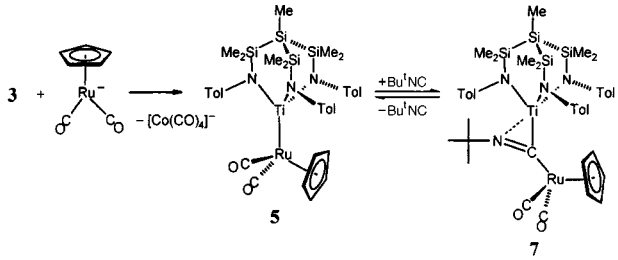
The crystal structure of **4** clearly establishes the ionic cleavage of the metal–metal bond by which the slightly distorted tetrahedral $[Co(CO)_4]^-$ anion [OC–Co–CO′ 107.2–110.5°] and the trigonally distorted octahedral cation $[MeSi\{SiMe_2N(p\text{-}Tol)\}_3Zr(CNBu^t)_3]^+$ were generated. Owing to the sixfold coordination at the Zr-centre the Zr–N distances [2.073(4), 2.077(5), 2.082(5) Å] are somewhat greater than those found in previously reported four-coordinate tripodal amidozirconium complexes, in particular, the Zr–Co dinuclear complex **2** [2.037(5), 2.044(5), 2.032(5) Å].[9] Remarkably, the Zr–C bond lengths of the coordinated isocyanide ligands [2.439(7), 2.448(7), 2.430(7) Å] are significantly greater than those found in all known structurally characterized isocyanide–zirconium species [Zr–C 2.31–2.37 Å].[11]

In view of the previously observed insertions of isocyanides into the highly polar metal–metal bonds of unsupported early–late heterobimetallics[3] it was of particular interest to explore how the complex salts **3** and **4** would react with the strong metal nucleophile $[RuCp(CO)_2]^-$. In principle, two reaction pathways were conceivable, the direct nucleophilic attack at the C-atom of a coordinated, and thus activated, isocyanide ligand generating the metallaiminoacyl complexes. Alternatively, rapid nucleophilic substitution of the isocyanide ligands could intially lead to the M–Ru heterodinuclear complexes **5** and **6** which would over a period of several hours insert the displaced isocyanide. The latter was established by NMR and IR spectroscopy in the reaction of **3** with $K[RuCp(CO)_2]$ in C_6D_6. Almost instantaneous formation of the M–Ru complex **5** was observed[3] which, subsequently, was partially converted to the insertion product **7** (Scheme 2).‡ This result is pertinent to the previously proposed mechanism of the insertion of unsaturted polar substrates into the metal–metal bonds, which we derived from a kinetic study, and supports the notion that predissociation of the heterodinuclear complex and addition of the ionic fragments to the substrate does not appear to be the decisive step.[4] Rather, as proposed by us, the substrate coordinates to the early transition metal centre in the dinuclear complex, thus lablizing and polarizing the metal–metal bond which is cleaved in the subsequent rearrangement of the nucleophilic metal fragment to give the insertion product.



Scheme 2 Reaction of **3** with $K[RuCp(CO)_2]$, initially yielding the Ti–Ru complex **5** which subsequently reversibly inserts Bu^tNC.

In view of the incomplete insertion of Bu^tNC into the metal–metal bonds we studied the reaction leading to **7** in more detail by reacting **5** with varying amounts of isocyanide and determining the conversion of **5** to **7** by ^1H NMR spectrocopy as well as the reverse reaction taking place upon dissolution of isolated solid **7**. The insertion/de-insertion equilibrium depicted in Scheme 2 could thus be established for **5** and **7** with an equilibrium constant $K = [\mathbf{7}]/[\mathbf{5}][Bu^tNC] = 0.91\ dm^3\ mol^{-1}$ in toluene at 298 K.

We thank the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, the European Commission (TMR network and Erasmus Program), the EPSRC and the DAAD and British Council for funding. We dedicate this paper to Professor Bernt Krebs, Universität Münster, on the occasion of his 60th birthday.

The synthesis and ring-opening metathesis polymerization of peptide functionalized norbornenes

Stefano C. G. Biagini,[a] R. Gareth Davies,[a] Vernon C. Gibson,*[b] Matthew R. Giles,[b] Edward L. Marshall,[b] Michael North*[a] and David A. Robson[b]

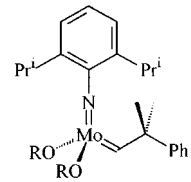
[a] *Department of Chemistry, University of Wales, Bangor, Gwynedd, UK LL57 2UW. E-mail: m.north@bangor.ac.uk*
[b] *Department of Chemistry, Imperial College of Science, Technology and Medicine, Exhibition Road, South Kensington, London, UK SW7 2AY. E-mail: v.gibson@ic.ac.uk*

Received (in Liverpool, UK) 20th October 1998, Accepted 15th December 1998

Norbornene monomers bearing two and three amino acid residues have been synthesized and the ring-opening metathesis polymerization of the monomers investigated using Mo(=CHCMe$_2$Ph)(=N-2,6-Pr$^i_2$C$_6$H$_3$)(OR)$_2$, [R = CMe$_3$ 1a, CMe$_2$CF$_3$ 1b, CMe(CF$_3$)$_2$ 1c].

The preparation of macromolecular biomimetic compounds requires careful control of the primary, secondary, and tertiary structures of the polymeric material. Typically, polymerization processes have failed to address these requirements due to lack of control over the polydispersity of the polymer which needs to be as near to monodisperse as possible, or due to the limited diversity of functional groups present in the final polymer.[1] Ring-opening metathesis polymerization (ROMP) using well-defined transition metal initiators, gives products with a narrow molecular weight distribution, and offers a high degree of control over the final molecular weight of the products. The latest generation initiators have also allowed the introduction of a wide range of functionalities within ROMP products. Furthermore, the living nature of the polymerization allows the preparation of block copolymers.[2]

We have previously described the use of ROMP methodology in the synthesis of biomimetic polymers based upon amino acids,[3] antibiotics[4] and nucleic acids.[5] Other workers have also reported the preparation of carbohydrate derived polymers.[6] Here we describe our initial results towards the preparation of polymers incorporating peptide units. Our strategy was based upon the preparation of the monomers by coupling norbornene derivatives **2a**,**b**[7] to different amino acid and peptide moieties. This would allow the introduction of peptides chosen for their specific folding pattern (*e.g.* α-helical) and thus provide further control of the macrostructure of the polymer product. The well-defined initiators Mo(=CHCMe$_2$Ph)(=N-2,6-Pr$^i_2$C$_6$H$_3$)(OR)$_2$ [R = CMe$_3$ **1a**, CMe$_2$CF$_3$ **1b**, CMe(CF$_3$)$_2$ **1c**] developed by Schrock and co-workers[8] were employed for the ROMP reactions.



1a; R = Me$_3$C
1b; R = (CF$_3$)Me$_2$C
1c; R = (CF$_3$)$_2$MeC

Acids **2a**,**b** could be converted into the corresponding acid chlorides† **3a**,**b** by reaction with oxalyl chloride and DMF (Scheme 1). Compounds **3a**,**b** are crystalline solids and are convenient starting materials for the synthesis of the desired peptides **4**–**8a**,**b**. Thus, reaction of compounds **3a**,**b** with the methyl esters of alanine,‡ phenylalanine, phenylglycine, or proline gave monomers **4**–**7a**,**b** respectively, whilst reaction of **3a**,**b** with the dipeptide derivative phenylalanyl–phenylalanine methyl ester gave tripeptide derivatives **8a**,**b**.

Preliminary studies indicated that both the *exo*- and *endo*-isomers of monomers **4**–**8** could be polymerized by initiators **1a**–**c**. However, the polymerization of the *exo*-monomers was more facile (in line with previous reports of the ROMP of *endo*- and *exo*-norbornene derivatives[8]) and the isolated polymers were easily characterized, so monomers **4**–**8a** were selected for a more detailed study. The polymerization of each of monomers **4**–**8a** was then investigated as shown in Scheme 2, utilizing each of initiators **1a**–**c**, the results being given in Table 1. In each case, the polymerization was first carried out using 10 equiv. of monomer **4**–**8a** to allow the propagating alkylidene resonance to be detected by ^{1}H NMR spectroscopy, and the polymerization was then repeated using approximately 100 equiv. of the monomer to prepare a larger sample of the polymer. The initiators **1a**–**c** were tolerant of the amide bond(s)

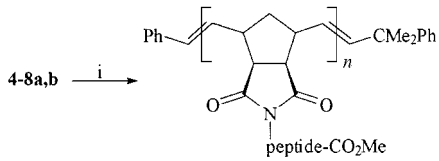
[a] Determined by ^{1}H NMR spectroscopy. [b] Determined by TMA analysis. [c] Calculated from the monomer to initiator ratio. [d] M_n and M_w values were obtained by GPC using $CHCl_3$ as eluent, a differential refractometry detector, and two PLgel 10 μl mixed columns calibrated using polystyrene standards ranging in molecular weight from 1560 to 10^6 except where indicated by *. In these cases, the polymers were not soluble in $CHCl_3$, so molecular weight data were obtained by MALDI-TOF mass spectrometry. The experimentally determined M_ns are lower than M_n(calc) reflecting the tendency of MALDI-TOF to detect components of lower mass preferentially.[9] [e] Calculated as M_w/M_n. [f] Measured in $CHCl_3$ except where indicated by ** when DMSO was used as solvent. [g] Determination of the %cis alkenes in the polymer was not possible due to signal overlap.



Scheme 2 *Reagents*: (i) a, **1a**–**c**, CH_2Cl_2, b, PhCHO.

in monomers **4**–**8a**, even when the polymerizations were left for three days. However, the polymers derived from monomer **4a** using initiators **1a**,**b** were found to be insoluble in organic solvents and so could not be fully characterized. These polymers are therefore not included in Table 1. Monomer **4a** contains the two amino acids (glycine and alanine) with the least hydrophobic sidechains and this probably accounts for the poor solubility of polymers derived from this monomer, as all of the other monomers gave polymers which were soluble in at least some organic solvents.

The ^{1}H NMR results show the expected trend of increasing *cis*–*trans* ratio associated with using initiators possessing increased fluorination of the ancillary ligands.[2] This trend is also apparent in the glass transition temperatures (T_g), which decrease with increasing *cis* content. All of the polymers were optically active which suggests that the chirality of the amino acids has been preserved during the polymerizations as has previously been observed for amino acid derived monomers.[3] The fact that all of the polymers derived from the same monomer have similar specific rotations suggests that the chemical environment around the peptide chains is not significantly affected by changes in the stereochemistry of the polymer backbone. All of the polymers exhibited low PDIs, and in each case, a propagating alkylidene signal could be observed in the ^{1}H NMR spectrum, indicating that the polymers were formed by a living polymerization process.

In conclusion, we have shown that peptide derived norbornenes **4**–**8** are suitable substrates for ROMP using well-defined molybdenum-based initiators. It is possible to control the stereochemistry of the polymers by varying the structure of the initiator. Our work in this area is continuing and further results using peptides that are known to adopt preferred conformations will be reported in due course.

The authors thank the EPSRC for financial support and studentships to R. G. D. and D. A. R., and Ciba-Geigy and the EPSRC for a studentship to M. R. G. Mass spectra were acquired by the EPSRC national service centre, and T_g data were obtained by the ULIRS service for thermomechanical analysis (TMA) at Birkbeck College, University of London. The staff of these services are thanked for their efforts.

A novel ruthenium-catalysed tandem diyne cycloisomerisation—cross metathesis process

Roland Stragies, Matthias Schuster and Siegfried Blechert*

Institut für Organische Chemie, Sekr. C3, Technische Universität Berlin, Straße des 17. Juni 135, 10623 Berlin, Germany. E-mail: sibl@wap0105.chem.tu-berlin.de

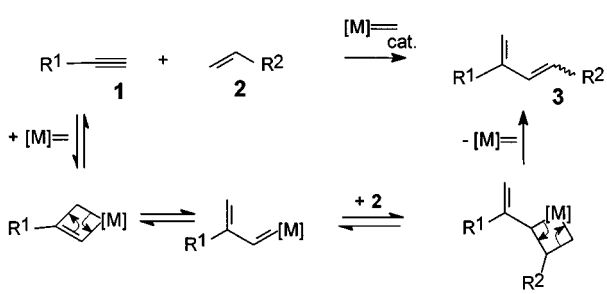
Received (in Cambridge, UK) 7th October 1998, Accepted 21st December 1998

Ruthenium-catalysed cycloisomerisation of hepta-1,6-diynes in the presence of functionalised terminal olefins yields five-membered cyclic products with variable unsaturated side chains and is applicable to the synthesis of highly functionalised hetero- and carbocycles.

The development of well-defined catalysts tolerating a variety of functional groups has significantly widened the scope of olefin metathesis as a synthetic method.[1] Whereas there are numerous examples for the ring closing metathesis (RCM) of dienes and its application in the field of natural product synthesis,[2] little is known about comparable reactions involving alkynes.[3] Only the RCM of enynes has found synthetic application.[4] Very recently, Fürstner and Seidel[5] reported the RCM of diynes to macrocyclic cycloalkynes and acyclic alkynes as stoichiometric by-products. Herein, we describe a tandem process that consists of a diyne cyclisation to a small ring and a cross metathesis with a terminal alkene and its application to the synthesis of functionalised unsaturated carbo- and heterocycles.

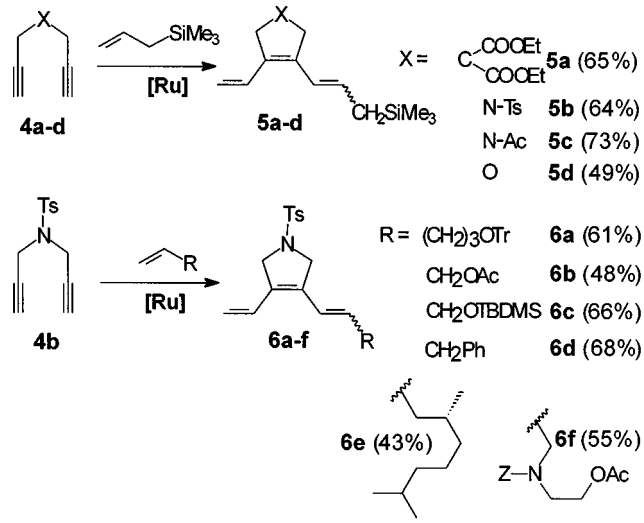
Recently, we presented a selective yne–ene cross metathesis.[6] This reaction was found to be initiated by attack of the catalytic ruthenium–alkylidene complex at the triple bond (Scheme 1), thus, resulting in the formation of a conjugated alkylidene complex. Reaction of this reactive intermediate with the alkene component gives the cross coupling product in a selective manner. In the course of systematic investigations into the metathesis of alkynes[7] it has now been found that the introduction of a second triple bond into the alkyne component at a certain distance leads to an initial diyne cycloisomerisation event without affecting the subsequent cross coupling step.

In the initial experiments hepta-1,6-diyne **4a** was employed. We decided to use allyltrimethylsilane as the alkene component, since it has previously been proven to be a highly efficient cross metathesis coupling agent.[8] When **4a** and 3 equiv. of allyltrimethylsilane were reacted with 10 mol% of the ruthenium catalyst $Cl_2(PCy_3)_2Ru{=}CHPh$ (Cy = cyclohexyl) [Ru] introduced by Grubbs and coworkers,[9] a carbocyclic product (**5a**) was isolated in 65% yield (Scheme 2).† In contrast, all attempts to perform the same reaction under catalysis of Schrock's molybdenum catalyst[10] $PhMe_2CCH{=}Mo{=}N[2,6\text{-}(^iPr_2C_6H_3)][OCMe(CF_3)_2]_2$ ([Mo]) failed. This result is not surprising considering reports describing a [Mo]-catalysed cyclopolymerisation[11] of **4a**.

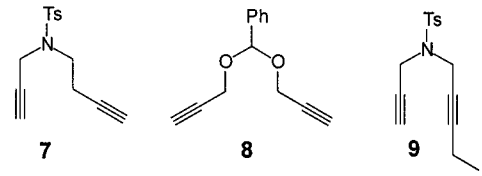


Scheme 1 Reaction path of yne–ene cross metathesis.

Accordingly, all further experiments were conducted under catalysis of [Ru] using the standard conditions mentioned above.‡ Like **4a**, simple N- and O-containing symmetrical diynes are also transformed into heterocyclic products as demonstrated by the synthesis of dihydropyrroles **5b** and **5c** and dihydrofuran **5d**. We also attempted to prepare S-containing heterocycles from diynic sulfides, sulfoxides, and sulfones. Although these heptadiynes have been described as suitable substrates for the [Mo]-catalysed cyclopolymerisation process,[12] rapid isomerisation into the corresponding allenes and no metathesis was observed under our reaction conditions. To further investigate the scope of the reaction we employed various functionalised terminal olefins as alkene components. The use of protected alcohols resulted in formation of the heterocyclic products **6a–c** in acceptable yields. In addition, a terpene derivative and an N- and O-protected amino alcohol were successfully transformed into **6e** and **6f**, respectively. These examples demonstrate that structurally diverse olefins undergo the tandem reaction. With the exception of compounds containing sterically demanding substituents (**6c**, *E*/*Z* = 5 : 1; **6f**, *E*/*Z* = 2.5 : 1) all products were isolated as *E*/*Z* isomer mixtures (1 : 1–1 : 1.5). This lack of selectivity is a common problem of cross metathesis.[1,8] With respect to a second problem often encountered in methathetical cross couplings, the tendency of the coupling partners to self-react, the tandem process proved to be remarkably selective. In all reactions only traces of alkene homodimer were identified. To study the accessibility of six- and seven-membered heterocycles we prepared the appropriate diynic precursors **7** and **8**, respectively. However, no cyclisation took place in the presence of allyltrimethylsilane under standard reaction conditions. Instead, products resulting from yne–ene cross metathesis of the silane with one or both triple bond(s) were identified. This finding indicates the importance of the distance between the two triple

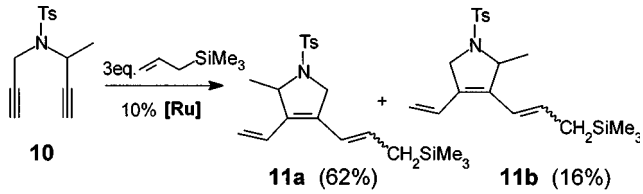


Scheme 2 Products of diyne cycloisomerisation–cross metathesis tandem reactions.



bonds for the cycloisomerisation step. The failure of **9** containing a disubstituted triple bond to undergo the cyclisation might be attributed to a kinetic barrier caused by the additional ethyl substituent.

The [Ru]-catalysed reaction of unsymmetrical diyne **10** with allyltrimethylsilane (Scheme 3) demonstrates that the cyclisation–cross metathesis tandem process shows regioselectivity. Considering that **11a** and **11b** were formed in a 4 : 1 ratio under standard conditions, higher selectivities could be observed using different substituents or reaction partners under optimised conditions.



Scheme 3 [Ru]-catalysed reaction of asymmetric diyne **10** with allyltrimethylsilane giving regioisomeric **11a** and **11b**.

For the novel tandem process described above the reaction path depicted in Scheme 4 is proposed. The reaction is assumed to start with the reversible addition of the catalytic carbene complex at one of the triple bonds. Intramolecular addition of the resulting conjugated ruthenium–alkylidene complex to the second triple bond gives rise to a cyclic carbene complex, which directly cross-reacts with the alkene component.

In summary, a new tandem metathesis reaction suitable for the synthesis of functionalised carbo- and heterocycles has been developed. The reaction shows atom economy[13] and combines the cyclisation of a hepta-1,6-diyne with a cross metathesis. A variety of differently substituted five-membered carbo- and heterocycles has been prepared. We are currently exploring the possibility of enhancing the regio- and stereoselectivity of the reaction.

X-Ray structure and solvolytic activity towards phosphate diesters of a zirconium(IV) complex

Eugen Stulz and Christian Leumann*

Department of Chemistry and Biochemistry, University of Bern, Freiestrasse 3, CH-3012 Bern, Switzerland. E-mail: leumann@ioc.unibe.ch

Received (in Basel, Switzerland) 20th November 1998, Accepted 8th December 1998

The X-ray structure of the complex $Zr^{IV}(acac)_2$(salicylideneaminoethanol) [$Zr(acac)_2$(sae)] could be solved, and the reactivity of the complex towards phosphate diester solvolysis was investigated showing substantial rate acceleration over background in benzene–methanol solution (*ca.* 10^8) and in aqueous medium (*ca.* 10^5).

The development of artificial nucleases is an attractive feature in the design of new compounds for application in antisense therapy, or as new tools in gene technology.[1] Predominantly metal complexes as activators for phosphate ester hydrolysis are under intense investigation, since metal ions are known to promote phosphoester transesterification reactions with high rate accelerations.[2] Especially with dinuclear Co(II) complexes[3] and with lanthanide ions,[4] including high-valent Ce(IV)[5] and Th(IV),[6] remarkable activities were observed.

We have investigated complexes of Zr(IV)[7] as activators for phosphate ester solvolysis, because of (i): its high stable oxidation state +IV (ideally suited for electrostatic activation); (ii): its hard Lewis acid character (promising strong interactions with phosphates);† and (iii): its maximum coordination number of eight. In general, tetravalent metal ions are known to hydrolyse phosphate esters more efficiently than tervalent ions.[8] The hydrolytic activity of Zr^{4+} towards phosphate diesters has first been described 60 years ago.[9] Only recently, while our investigations were underway, two reports addressing the hydrolytic activity of $ZrCl_4$ with bis(*p*-nitrophenyl) phosphate (BNPP) **1**[10] appeared. However, neither catalytic behaviour nor a detailed structure of the complexes used were disclosed. Here we report, for the first time, the catalytic activity of the Zr(IV) complex $Zr(acac)_2$(sae) **2** (sae = salicylideneaminoethanol) in phosphate diester solvolysis.

The Zr(IV) complex **2** was prepared from $Zr(acac)_4$ and the ligand H_2sae according to a known procedure.[11] Recrystallisation of **2** from hot toluene produced crystals suitable for X-ray analysis. Complex **2** crystallises in a centrosymmetric dimeric form, **2**–**2**, with the inversion centre in between the two zirconium atoms held together *via* two oxygens of the aminoethanolato-sidechains.‡ The geometry of the zirconium ligand sphere is dodecahedral. Extension to the maximum coordination number eight around zirconium can be considered to be the driving force for dimerisation. Fig. 1 shows the refined structure of **2**–**2**.§ Considerable changes in the UV–VIS spectrum of **2** were observed upon changing from aprotic to protic solvents. This indicates a weak acid–base interaction between zirconium and the protic solvents, and is in accordance with **2** existing predominantly in the monomeric, solvated form under these conditions.

The reactivity of **2** towards phosphate diester cleavage was investigated in C_6D_6–methanol (1 : 1) as solvent owing to the low solubility of **2** in pure protic solvents. The progress of the solvolysis reaction was monitored by ^{31}P NMR spectroscopy.

Upon mixing of **2** (4 mM) with dimethylphosphate (DMP) **3** (16 mM) in C_6D_6–MeOH (1 : 1) the ^{31}P NMR spectra showed a small, broad signal (δ −6; 4.2%) and a large, sharp signal (δ 2.8; 95.8%). The former signal was assigned to zirconium-complexed DMP, the latter refers to free DMP **3**. From this a dissociation constant of 76.2 mM was calculated. This value is significantly higher than the previously reported dissociation constant of $ZrCl_4$ with **1** in water (K_M = 1.3 mmol dm^{-3}).[10b]

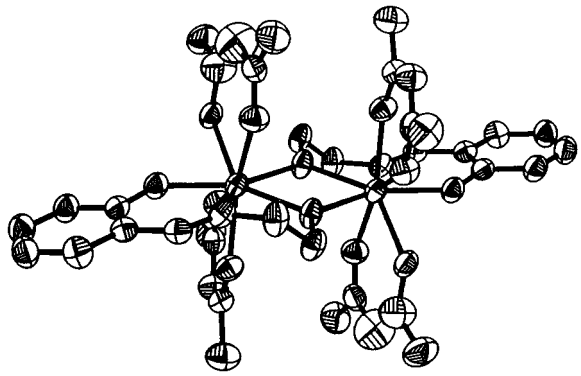

Fig. 1: ORTEP plot of **2**–**2**. Thermal ellipsoids are drawn at the 50% probability level; hydrogens are omitted for clarity.

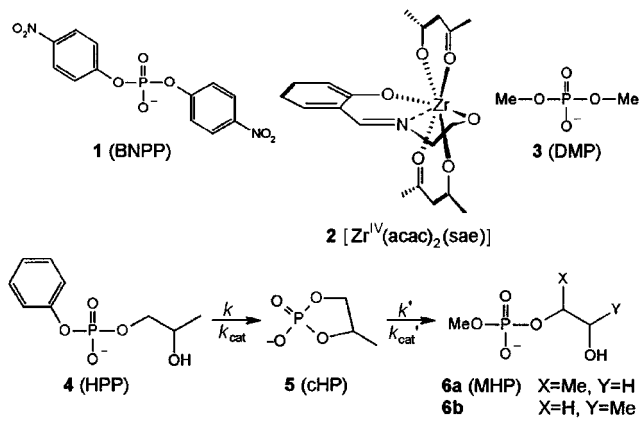
Analysis by ^{31}P NMR spectroscopy [C_6D_6–MeOH (1 : 1)] revealed that the 'RNA-model' 2-hydroxypropyl phenyl phosphate (HPP) **4** (δ −5.2) reacts in the presence of catalytic amounts of **2** to initially give the cyclic phosphate (cHP) **5** (δ 15.5), which further reacts with methanol to give a mixture of the two isomeric methyl hydroxypropyl phosphates (MHP) **6a** (δ 2.3) and **6b** (δ 1.1) in comparable ratios (Scheme 1). The reactions were performed in unbuffered¶ solutions at 28 °C with either variable concentrations in complex **2** ([**2**] = 1, 2, 3, 4 mM) at constant phosphate concentration ([**4**] = 24 mM) or *vice versa* ([**4**] = 8, 12, 24, 28 mM; [**2**] = 2 mM). The variations of phosphate concentrations *vs.* reaction time were fitted to the model for a consecutive irreversible first-order reaction[12] and gave the pseudo first-order rate constants k_1 and k_1' (Fig. 2).

At constant zirconium concentration (2 mM) the rate constants k_1 (2.77×10^{-4} s^{-1}) and k_1' (1.18×10^{-4} s^{-1}) were independent of phosphate concentration thus proving the catalytic reactivity of **2**. At constant phosphate concentrations (24 mM) a linear dependence on the concentration of complex



Scheme 1

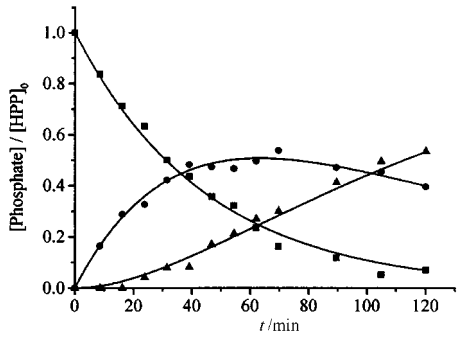


Fig. 2 Time dependent variation of the concentrations of HPP **4** (■), cHP **5** (●), MHP **6** (▲) with curve fitting according to the equations for a consecutive irreversible first-order reaction.[12] [**2**] = 2 mM, [**4**] = 8 mM.

2 is observed. From this linear correlation, the second-order rate constants were determined to be k_2 = 0.14 dm^3 mol^{-1} s^{-1} and k_2' = 0.058 dm^3 mol^{-1} s^{-1}. These values are slightly lower than the reported values for the hydrolysis of 2-hydroxypropyl *p*-nitrophenyl phosphate with Zr^{4+} (2.2 dm^3 mol^{-1} s^{-1}),[10a] but indicate a reactivity that is comparable to that of lanthanide complexes.[13]

From the kinetic measurements the initial rates v_0 for the cyclisation reaction **4**→**5** were also evaluated. The plots of log (v_0) *vs.* log ([**2**]) (with [**4**] = const. = 24 mM) or *vs.* log ([**4**]) (with [**2**] = const. = 2 mM) revealed that the reaction is first order in both reactants giving a clean overall second-order reaction. This indicates that the active species is a distinct 1 : 1 complex between **2** and phosphate diester. The initial rates (for [**2**] = const.) allowed an analysis according to Michaelis–Menten kinetics. From the Eadie–Hofstee plot, the values K_M = 68.6 mmol dm^{-3} and k_{cat} = 0.013 s^{-1} could be obtained. The K_M value is almost identical to the dissociation constant of **3** with **2** (76.2 mmol dm^{-3}), obtained by direct ^{31}P NMR measurement, and therefore represents a true dissociation constant for a 1 : 1 Zr(IV)–phosphate complex. The discrepancy between this K_M value and that for the system $ZrCl_4$ and **1** (1.3 mmol dm^{-3})[10b] indicates activity of higher order Zr(IV) complexes in the latter case formed upon mixing of $ZrCl_4$ with water.

Compared to the uncatalysed reaction ($k_{1,0}$ = 1.9 × 10^{-11} s^{-1}; $k_{1,0}'$ = 1.24 × 10^{-11} s^{-1})¶ the reaction rates k_{cat} and k_{cat}' (determined from the pseudo first-order reaction rates $k_1' K_M$/[**2**]; k_{cat}' = 0.0043 s^{-1}) represent a rate acceleration of 6.8 × 10^8 for the cyclisation of **4**→**5** and 3.5 × 10^8 for the re-esterification **5**→**6**. These rate accelerations agree well with the reported reactivity of Zr^{4+}.[10] In contrast to earlier reports, however, the transesterification reactions described here were catalytic in zirconium and proceed *via* a well defined 1 : 1 Zr(IV) : phosphate stoichiometry.

We investigated also the reactivity of **2** towards **4** in the presence of water (C_6D_6–MeOH–H_2O 5 : 5 : 1; T = 40 °C). The best conditions for solubility of **2** were found to be in buffered solution (100 mM Tris-HCl) at pH 9.0 (**2** dissociates under acidic conditions and is barely soluble at higher pH values; no pH rate profile could therefore be measured). In this system the activity of **2** ([**2**] = 1.5 mM, [**4**] = 12 mM) dropped significantly to a rate acceleration of only 75 over background (k_1 = 9.7 × 10^{-7} s^{-1}; $k_{1,0}$ = 1.3 × 10^{-8} s^{-1}), but catalytic turnover was still observed. This loss of reactivity may be due to the deactivation of the zirconium in the presence of water or hydroxide.

In aqueous medium without organic cosolvents (H_2O; pH 7.0; 10 mM Tris-HCl; 10 mM KCl and $MgCl_2$; 5 mM $CaCl_2$. T = 37 °C), catalyst **2** ([**2**] = 4.5 × 10^{-5} M, nearly sat. soln.) hydrolysed **1** ([**1**] = 1.6 × 10^{-5} M) with an observed pseudo first-order rate constant $k_{1,obs}$ = 1.5 × 10^{-5} s^{-1}. This leads to a rate acceleration of 2.9 × 10^5, compared to the uncatalysed reaction (5.1 × 10^{-11} s^{-1}).[14] No significant background reaction was observed under these conditions, therefore hydrolysis of **1** is not due to the salts added to mimic physiological conditions. Although this reaction was performed with excess **2** over **1**, it shows that **2** is still highly active towards **1** even in water.

In conclusion, we have shown that the Zr(IV) complex **2** exhibits substantial activity towards phosphate diesters in transesterification or hydrolysis, despite the fact that **2** is charge-neutral and cannot compensate for the negative charge of the substrates.

We thank Professor Helen Stoeckli-Evans (Université de Neuchâtel, Switzerland) for collecting the X-ray diffraction data of **2** and the 'Stipendienfonds der Basler Chemischen Industrie' for financial support.

Notes and references

† A preliminary ^{1}H NMR experiment in D_2O using $Zr(OAc)_4$ (68 mM), which should give polymeric structures to a lesser extent than $ZrCl_4$ (S. Hannane, F. Bertin and J. Bouix, *Bull. Soc. Chim. Fr.*, 1994, **131**, 262) and dimethyl phosphate (DMP **3**, 270 mM) showed rapid formation (< 2 min) of a Zr(IV)–DMP complex (δ 3.55, broad signal; free DMP: δ 3.43). The signals were not enough resolved to allow determination of an association constant, but approximately 2 equiv. DMP were complexed. This agrees with other observations.[10b]

‡ *Crystallographic data*: $C_{38}H_{46}N_2O_{12}Zr_2$; M = 905.21; triclinic, $P\bar{1}$, a = 11.6425(2), b = 12.0019(2), c = 15.7179(3) Å, α = 89.321(3), β = 70.008(3), γ = 86.675(3)°, V = 2060.4(7) Å^3, T = 223 K, Z = 2 (dimers), μ = 0.566 mm^{-1}; 16331 total reflections; 7494 independent reflections; R_{int} = 0.0711, R_1 = 0.0889; $R(\sigma)$ = 0.1133, wR_2 = 0.1252. CCDC 182/1123. See http://www.rsc.org/suppdata/cc/1999/239/ for crystallographic files in .cif format.

§ In the unit cell, **2**–**2** appears as two symmetrically independent molecules. The structural differences however are rather small and mainly occur in the conformation of the acac-ligands along the O···O-edges. This is a known structural feature of Zr(IV)–acac complexes (R. B. VonDreele, J. J. Stezowski and R. C. Fay, *J. Am. Chem. Soc.*, 1971, **93**, 2887; J. V. Silverton and J. L. Hoard, *Inorg. Chem.*, 1963, **2**, 243). For simplicity reasons, Fig. 1 only shows one of the two conformers.

¶ The background rate constants were measured at [NaOMe] = 1 mM to be $k_{2,0}$ = 2.93 × 10^{-3} dm^3 mol^{-1} s^{-1} and $k_{2,0}'$ = 1.97 × 10^{-3} dm^3 mol^{-1} s^{-1}. The pH of C_6D_6–MeOH (1 : 1) was 8.2 corresponding to [MeO$^-$] = 6.3 × 10^{-9} M and did not change during the catalytic and background reactions. With $k_{1,0}$ = $k_{2,0}$ [MeO$^-$] the first order background rate constants were extrapolated to the conditions used in the catalysed reactions.

Complexation of stable carbenes with alkali metals

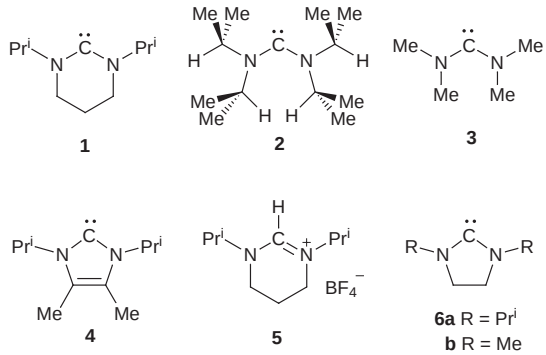
Roger W. Alder,* Michael E. Blake, Christel Bortolotti, Simone Bufali, Craig P. Butts, Emma Linehan, Josep M. Oliva, A. Guy Orpen and Michael J. Quayle

School of Chemistry, University of Bristol, Cantock's Close, Bristol, UK BS8 1TS. E-mail: rog.alder@bristol.ac.uk

Received (in Liverpool, UK) 13th November 1998, Accepted 10th December 1998

Stable diaminocarbenes, including imidazol-2-ylidenes, undergo complexation with lithium, sodium and potassium species; the crystal structure of a complex of 1,3-diisopropyl-3,4,5,6-tetrahydropyrimid-2-ylidene 1 with $KN(SiMe_3)_2$ is reported.

There is a vast literature concerning carbene complexes of metals. N-Heterocyclic carbenes are reported to complex with 48 elements, but Group 1 metals are notable by their absence.[1] We report ^{13}C NMR shift evidence concerning interaction between stable ylidic diaminocarbenes **1**–**3** and imidazol-2-ylidene **4** with lithium, sodium and potassium species in toluene and THF solutions, and the X-ray structure of $[\mathbf{1}\cdot KN(SiMe_3)_2]_2$. Since carbenes like **1**–**4** are often generated by C-deprotonation of formamidinium and related cations by bases with alkali metal counterions (*e.g.* $KOBu^t$, NaH, and LDA),[2–6] the observation of complexation with these ions is important in understanding of the properties of these carbenes in solution.



Carbene **1** can be prepared in 40% yield by deprotonation of **5** with $NaN(SiMe_3)_2$ in THF at −78 °C, exchange of solvent to toluene to permit azeotropic removal of $HN(SiMe_3)_2$, followed by distillation of **1**, which melts close to ambient temperature (all operations involving diaminocarbenes were performed under dry N_2). Precursor **5** is conveniently made by refluxing an equimolar mixture of $Pr^iNH(CH_2)_3NHPr^i$ and NH_4BF_4 in $HC(OEt)_3$ as solvent, with azeotropic removal of EtOH. Diaminocarbene **1** is the first example where the N–C–N group is part of a six-membered ring, and appears to be thermodynamically stable to dimerisation, unlike the five-membered ring analogue **6a**.[7] Thus **1** is stable when generated from **5** using a deficiency of base, but generation of **6a** under these conditions leads to rapid dimerisation, due to catalysis by the dihydroimidazolium precursor.[8]

A solution of free **1** in toluene-d_8 shows resonances at δ_C 236, 58, 36, 22 and 21. The ^{13}C shift of the carbene centre in stable carbenes typically occurs between δ_C 200 and 300,[2–6] but is substantially shielded in known metal complexes, and so provides a sensitive probe for complexation. The chemical shift of the carbene centre in **1** depends on the amount and nature of the alkali metal species present in toluene-d_8 solution (limiting shifts are given in Table 1), but is only affected by the presence of massive amounts (*ca.* 6 equiv.) of $LiN(SiMe_3)_2$ in THF-d_8, presumably because of competition from the solvent for Li. The chemical shifts of **1** and **3**, and of their complexes with Li^+, Na^+ and K^+ ions, have been calculated (Table 1), using the B3LYP/6-31G*/GIAO method.[9] The changes observed on complexation in solution are, not surprisingly, smaller than those calculated for complexation to the bare cations.

Addition of 12-crown-4 in portions to solutions of **1** in toluene-d_8 generated from **5** using lithium 2,2,6,6-tetramethylpiperidide (LiTMP) leads to quantitative precipitation of $LiBF_4\cdot$12-crown-4 (no NMR signals for free 12-crown-4 are observed until > 1 equiv. has been added), with the ^{13}C NMR shift of the carbene centre moving smoothly from δ_C 218 to 236, indicating that the equilibrium between free **1** and the lithium complex is fast on the NMR timescale. It appears that the $LiBF_4$ formed in the reaction is soluble until the 12-crown-4 is added. On the other hand, portionwise addition of 2 equiv. of $LiN(SiMe_3)_2$ in toluene-d_8 to a solution of free **1** in toluene-d_8, generated using $NaN(SiMe_3)_2$ as described above, leads to the ^{13}C signal moving to δ_C 218, but subsequent addition of 12-crown-4 leads to a limiting shift of δ_C 224, suggesting the formation of a soluble tertiary complex containing 12-crown-4, $LiN(SiMe_3)_2$ and carbene **1**.

Portionwise addition of 2 equiv. of $NaN(SiMe_3)_2$ to free **1** in toluene-d_8 leads to the chemical shift moving smoothly to δ_C 224. When 15-crown-5 is then added in portions, the chemical

DFT structure for **1**	1.353	116.2
5	1.310(2)	125.1(2)
2	1.372(6) (av.)	121.0(5)

shift moves back to δ_C 236 as the free carbene is released. In a similar way, the addition of 2 equiv. of $KN(SiMe_3)_2$ in toluene leads to a chemical shift of δ_C 228. On standing, crystals were obtained from this solution and subjected to X-ray structure determination.† The structure [Fig. 1(a)] shows that dimeric molecules are present with the $N(SiMe_3)_2$ groups acting as bridging ligands. The K···C distance of 3.00 Å is much greater than the M···C distances for non−alkali metal complexes of imidazol-2-ylidenes,[1] which are typically < 2.3 Å. The Cambridge Structural Database[10] yielded no data on potassium complexes with σ-bound sp^2 carbon ligands. However, in the infinite chain structure of $(Me_3Si)_3CK$, the K···C distance is 3.10 Å,[11] while $Me_3Sn(Cl)N{\equiv}CK$ possesses a significantly shorter K···C distance of 2.75 Å,[12] and in KCN itself, the K···C distance is 2.8 Å.[13] Thus the K···C distance in $[\mathbf{1}\cdot KN(SiMe_3)_2]_2$ appears to be normal, but suggests that the interaction is largely of an electrostatic ion–dipole nature. Mixed complexes of $KN(SiMe_3)_2$ with $LiN(SiMe_3)_2$ and with $NaN(SiMe_3)_2$, displaying a similar dimeric core structure but with two THF ligands co-ordinated to the potassium, show K···O(THF) distances of 2.69 and 2.71 Å respectively.[14] In the light of this structural evidence, it is not surprising that complexation of **1** is more difficult to observe in THF solution.

The structural parameters of the carbene ligand itself are similar to those obtained from B3LYP/6-31G* DFT calculations for free **1**, and to those observed for **2** (Table 2). In the complex, the isopropyl groups are oriented away from the bulky $N(SiMe_3)_2$ groups, as might be expected. However, the same conformation is observed‡ for **5** [Fig. 1(b)], and is also calculated to be preferred by free **1**. The decrease in the N–$C_{carbene}$–N angle on deprotonation of **5** is striking, but some decrease has been observed in every other comparable case.[2,3,5] The increase in the $C_{carbene}$–N distance on deprotonation of **5** is also in line with previous examples, and suggests some decrease in π-bonding in **1** compared with **5**.

Complexation with alkali metal species also occurs with imidazol-2-ylidene **4**, although the upfield shifts are somewhat less than for **1** (Table 1). Bis(diisopropylamino)carbene **2** is much more hindered that **1** due to the buttressing effect of the isopropyl groups,[4] and we see little evidence for complexation in this case. Conversely, the least hindered carbenes[15] like **3** should be better ligands and their behaviour may be affected by the presence of metal species even in THF. This carbene has been generated using LDA or LiTMP bases and all attempts so far to remove the lithium species have resulted in precipitates which could not be separated without destroying the carbene. The question of alkali metal co-ordination to **3** and bis(*N*-piperidyl) carbene is particularly important with regard to the rates and mechanism of dimerisation of these carbenes. Metal ions might act as Lewis acid catalysts for dimerisation, as is observed for protons,[8,15] but strong complexation should eventually suppress dimerisation. Preliminary results suggest the latter effect is dominant, thus reaction of $HC(NMe_2)_2\cdot Cl$ with LiTMP in toluene-d_8 leads to a solution of **3** in which its half-life is extended to many days as compared to a few hours in THF. Addition of 2.4 equiv. of LiOTf to THF solutions of **3** generated using 2.6 equiv. of LiTMP leads to an upfield shift (Table 1) and halves the rate of dimerisation. The half-life of **3** in the absence of lithium may therefore be quite short, although Denk *et al*.[7] have reported that **6b**, which is surely less hindered than **3**, can be observed at ambient temperatures when prepared by reaction of the corresponding thione with potassium metal. The dimerisation of **3**, and the influence of metal species on this process, are the subject of continuing studies.

We thank EPSRC for support (grant GR/K76160) and for studentships to M. E. B. and M. J. Q; J. M. O. thanks the EEC for support (TMR contract ERBFMBICT97).

Biosynthesis of dictyopterene A: stereoselectivity of a lipoxygenase/hydroperoxide lyase from *Gomphonema parvulum* (Bacillariophyceae)

Marc Hombeck, Georg Pohnert and Wilhelm Boland*

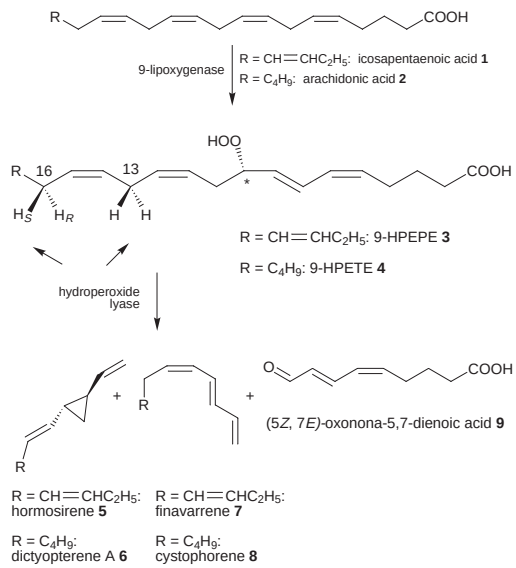
Max-Planck-Institute for Chemical Ecology, Tatzendpromenade 1a, D-07745 Jena, Germany. E-mail: Boland@ice.mpg.de

Received (in Liverpool, UK) 29th October 1998, Accepted 21st December 1998

(9*S*)-Hydroperoxyicosatetraenoic (9*S*-HPETE) acid is shown to be an intermediate in the biosynthesis of dictyopterene A in the freshwater diatom *Gomphonema parvulum*; the stereochemistry of (9*S*)-HPETE and the position of the hydrogen atom at C(16) lost during fatty acid cyclisation and oxidative cleavage of the hydroperoxide were investigated using trapping experiments and chirally deuterium labelled fatty acids.

Fatty acid derived C_8 and C_{11} hydrocarbons like finavarrene **7**, hormosirene **5** or dictyopterene A **6** act as pheromones in marine brown algae (Scheme 1).[1] The same compounds occur in heterocontophytic diatoms[2,3] and in higher plants,[4] however here, their biological function is unknown. Brown algal derived cyclopropanes and cycloheptadienes are secreted as mixtures of enantiomers with often well defined compositions that depend on species and habitat. Hormosirene **5** is a particularly interesting example. Both enantiomers are known and, in general, the ee of the secreted mixtures (52–92% ee) is characteristic for the species, sometimes even for the habitat.[1] This raises questions about how the stereochemistry of the cyclopropane is established and how the ratio of enantiomers is controlled in the biosynthetic pathway.

In earlier work we demonstrated that both brown algae[5] and diatoms[2] exploit the pool of unsaturated C_{20} fatty acids for the biosynthesis of C_8 and C_{11} hydrocarbons. Cell free extracts of the diatom *G. parvulum* were shown to oxidatively cleave deuterium labelled arachidonic acid into two isotopically labelled fragments, namely **6** and 9-oxononadienoic acid **9**. Performing the transformation in the presence of $^{18}O_2$ resulted in incorporation of one ^{18}O in the C(9)-aldehyde group. This suggests an initial functionalisation of the fatty acid to



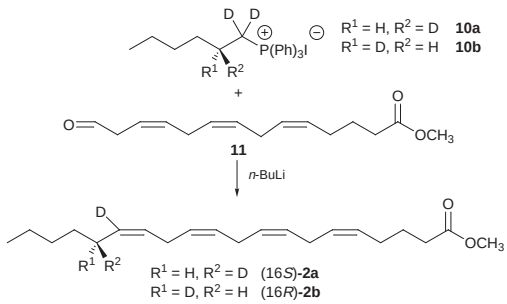
Scheme 1 Biosynthesis of C_9 and C_{11} hydrocarbons in the diatom *G. parvulum*.

9-hydroperoxyicosatetraenoic acid (9-HPETE) **4** followed by oxidative cleavage of the reactive intermediate into the bifunctional **9** and the olefin **6**. By analogy, the more highly unsaturated icosapentaenoic acid **1** could serve as the precursor for **5** (Scheme 1)

In principle, the configuration and ee of cyclopropanes **5** and **6** could be controlled either by the ee of the 9-OOH group directing all subsequent steps, by selective abstraction of one enantiotopic hydrogen atom at the methylene group of C(16), or by the folding of the fatty acids within the enzyme active site. To evaluate the influence of the two different stereogenic centres on the reaction course, we approached the absolute configuration and ee of the postulated **4** intermediate by a trapping experiment yielding 9-hydroxyicosatetraenoic acid (9-HETE). The hydrogen atom eliminated from C(16) was identified by using chiral, deuterium labelled arachidonic acid precursors and MS analysis of the metabolites after GLC separation on chiral stationary phases.

G. parvulum produces icosapentaenoic acid **1** derived **5** as the major volatile product (56% ee)[2] and small amounts of the arachidonic acid metabolites, **6** (24% ee) and cystophorene **8**. Addition of (labelled) arachidonic acid to a cell free extract of *G. parvulum* resulted in an 800-fold increase in the amount of **6** and **8** and the extracted metabolites could be analysed by MS without significant interference from a background of unlabelled, natural products. When the experiment was carried out in the presence of excess glutathione and glutathione peroxidase,† a system known to reduce hydroperoxy fatty acids rapidly and universally,[6] 9-HETE could be isolated together with small amounts of various autooxidation products. In the absence of glutathione and glutathione peroxidase no free **4** or 9-HETE could be detected. Independent experiments with synthetic 9-HETE excuded this compound as biosynthetic intermediate of **6** and confirmed the involvement of **4** *en route* to **6, 8** and **9** (Scheme 1). Following RP-HPLC purification and esterification of 9-HETE with *N*-(dimethylaminopropyl)-*N*′-ethylcarbodiimide–hydrochloride in aqueous MeOH,[7] the ee of the resulting ester was determined by HPLC on cyclodextrin as the chiral stationary phase.‡ On comparison with authentic compounds (SIGMA, Deisenhofen, Germany), the configuration of the hydroxy acid was established as (9*S*)-HETE (71% ee), reflecting the configuration and the ee of the unstable precursor **4**. The ee of (9*S*)-HPETE formed by the intact system should be even higher, since significant autooxidation of **2** occurred during the experiment with the crude enzyme preparation. Comparison of this value with the very low ee of the product (1*S*,2*R*)-**6** (24% ee, GLC on γ-cyclodextrin), clearly demonstrated that the HOO group of **4** at C(9) is not controlling the product stereochemistry.

To identify which hydrogen atom at C(16) is lost during olefin formation, the enzyme preparation was incubated with deuterium labelled (16*S*)-[15,16-$^2H_2$]-**2a** or (16*R*)-[15,16-$^2H_2$]-**2b**. The chiral precursors were synthesised from chiral epoxyheptanol-derived Wittig reagents of type **10** and 14-oxotetradecatrienoic acid methyl ester[8,9] **11** in 96 and 95% ee respectively[10] (Scheme 2).



Scheme 2 Synthesis of deuterated (16*S*)-[15,16-$^2H_2$]-**2a** and (16*R*)-[15,16-$^2H_2$]-**2b**.

The olefinic metabolites of **2a**,**b** were extracted by solid-phase microextraction (SPME)[2] and analysed by GC-MS, using a chiral stationary phase for separation of the enantiomers (*vide supra*). Administration of (16*S*)-[15,16-$^2H_2$]-arachidonic acid **2a** yielded [1′,2′-$^2H_2$]dictyopterene A **6** with a molecular ion at 152 Da, confirming the presence of two deuterium atoms in each of the two enantiomers (Fig. 1A). Incubation of (16*R*)-[15,16-$^2H_2$]-arachidonic acid **2b** afforded labelled **6** showing, for both enantiomers, the same pattern of molecular ions at *m/z* 152 (45%) and 151 (55%). Thus, due to a kinetic isotope effect (KIE), the expected C(16)-H_R was not exclusively attacked, but also the C(16)-H_S generating a mixture of [1′,2′-$^2H_2$]-**6** and [1′-^{2}H]-**6** from (16*R*)-**2b**. In addition, larger amounts of [7,7-$^2H_2$]-**8**, the product of a hydrogen atom loss from C(13), were produced (Fig. 1B). Both dideuterated compounds apparently resulted from reaction paths which avoided the abstraction of the kinetically unfavoured C(16)-^2H_R of **2b**.

The isotope effect was quantified by incubating the crude enzyme preparation with excess of an equimolar mixture of **2** and [16,16-$^2H_2$]-**2**. Product analysis by GC-MS revealed that the unlabeled precursor was the preferred substrate for the formation of **6** (**6**:[2′^{2}H]-**6** = 4.5:1) and confirmed loss of the hydrogen atom as rate limiting. Moreover, in the same experiment labelled **8** was produced in excess ([7,7-$^2H_2$]-**8**:**8** = 6.5:1) indicating that a single enzyme is responsible for the production of **8** and **6**. If a second lyase, removing hydrogen atoms from C(13) of the precursor had been present in the crude enzyme preparation, a ratio of [$^2H_2$]-**8**:**8** = 1:1 should have resulted due to the absence of a KIE for this position. Thus, the dynamic product channelling, following the administration of

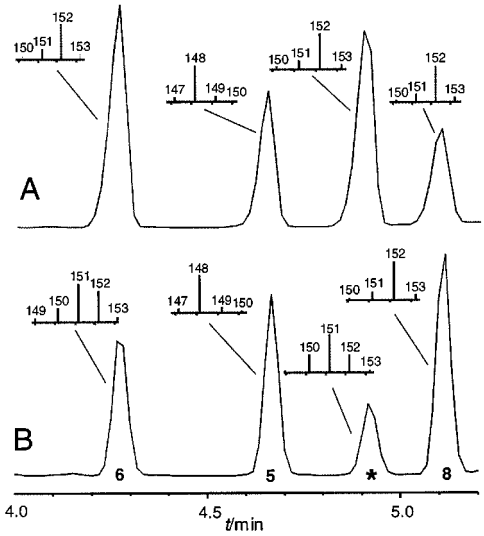


Fig. 1 GC-profile of labelled and unlabelled C_{11} hydrocarbons in *G. parvulum* with inserts of their mass spectra showing the region of the molecular ion. (A) after treatment with (16*S*)-[15,16-$^2H_2$]-**2a**. (B) after treatment with (16*R*)-[15,16-$^2H_2$]-**2b**. The large amount of 6-butylcyclohepta-1,4-diene (*) (dictyotene) results from a thermal [3.3]-sigmatropic rearrangement of **6** in the injection port of the GC and does not reflect the actual concentration of dictyotene in the hydrocarbon mixture.

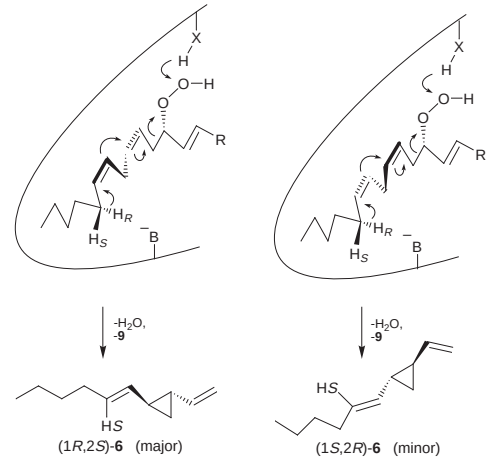

Scheme 3 Proposed folding alternatives of intermediate **4** at the active centre of the *G. parvulum* hydroperoxide lyase leading to enantiomers of **6**. Whether or not the transformation proceeds *via* ionic or radical intermedates remains to be established.

labelled and unlabelled precursors, is highly indicative of a single hydroperoxide lyase exerting only a limited control on the orientation of the substrate at the active site, generating either predominately **6** or **8**, depending on the ease of hydrogen abstraction. Accordingly, the rather low ee of **6** could be also attributed to the limited control over the folding of **4** in the enzyme active site, as illustrated in Scheme 3.

Although the model of limited control over the substrate orientation at the active centre and during the catalytic process, is in accord with the experimental findings, the involvement of two enzymes, each responsible for the (predominant) production of a distinct enantiomer, cannot be ignored. Further work with isolated enzymes is required to provide a conclusive answer to the question on the origin of enantiomeric mixtures of C_{11} hydrocarbons in diatoms and marine brown algae.

Financial support by the Deutsche Forschungsgemeinschaft, Bonn, and the Fonds der Chemischen Industrie, Frankfurt, is gratefully acknowledged. We thank the BASF AG, Ludwigshafen, and the Bayer AG, Leverkusen, for generous supply of chemicals and solvents. We also thank Professor D. Czarnecki, Loras College, Dubuque, Iowa, USA, for stock cultures of the diatoms, and Professor H. G. Floss, Seattle, USA, for laboratory facilities.

Notes and References

† *Ca.* 10^7 cells of *G. parvulum* in phosphate buffer (5 ml, 0.01 M, pH 7) were sonicated and the cell debris was removed by centrifugation. The supernatant was treated with glutathione (0.1 g, reduced form) and glutathione peroxidase (10 units) prior to addition of **2** (30 μl, 10% in EtOH). After 3 h 9-HETE was detected by RP-HPLC (Econosphere, C18, MeOH–H_2O–HAc 75:25:0.25, UV 235 nm for monitoring).

‡ The enantiomers were separated on a Chiralcel OB column[11] (Daicel Chem. Ind., hexane–propan-2-ol 99:1, 1 ml min^{-1}, baseline separation, UV 235 for monitoring).

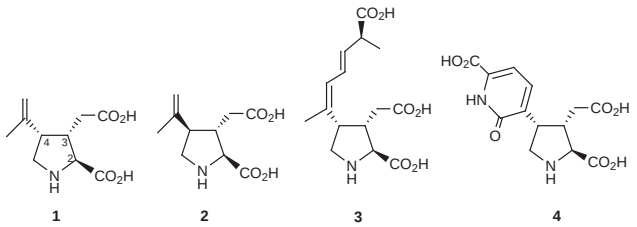
Received (in Cambridge, UK) 2nd November 1998, Accepted 11th December 1998

Titanium-mediated diene metallabicyclisation–elimination–functionalisation has been utilised for the preparation of *syn*-3,4-disubstituted and *syn,syn*-2,3,4-trisubstituted pyrrolidines in high yield and excellent stereoselectivity; this methodology has been employed in a total synthesis of (−)-α-kainic acid starting from L-serine.

(−)-α-Kainic acid **1**, isolated from the marine algae *Digenea simplex*[1] and *Centrocerus clavulatum*[2] and from the Corsican

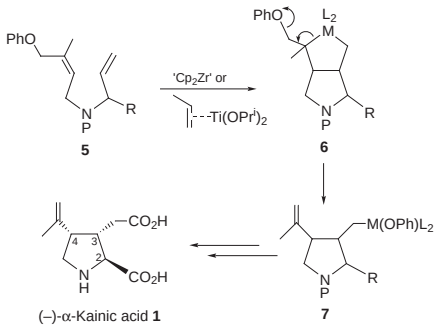


1 **2** **3** **4**

moss *Alsidum helminthocorton*,[3] has generated a great deal of interest because of its potent neuroexcitatory activity. With the discoveries of α-allokainic acid **2**, the domoic acid family (*e.g.* domoic acid **3**) and the acromelic acid family (*e.g.* acromelic acid A **4**), the synthetic community has been stimulated to design efficient, stereocontrolled routes to 2,3,4-trisubstituted pyrrolidines.[4]

Given our interest in the kainoid area,[5] and our ongoing research into synthetic applications of diene metallabicyclisation reactions,[6] we envisaged a new approach to kainic acid as shown in Scheme 1. Thus, zirconium- or titanium-mediated metallabicyclisation of diene **5** should produce the metallabicycle **6** which would be expected to undergo rapid β-elimination to generate the archetypal kainoid 4-isopropenyl substituent. This sequence would produce organometallic reagent **7** which could then be functionalised to introduce the requisite 3-carboxymethyl substituent of the kainoids.

Other cyclisation–elimination approaches to the kainoids have been investigated but stereochemical control has been poor.[7] Similar problems were encountered when we explored the zirconium-mediated sequence outlined in Scheme 1, although a successful synthesis of (−)-α-kainic acid was accomplished.[8] Here we describe the use of Sato's (η_2-propene)Ti(OPr^i)$_2$ reagent[9] in the metallabicyclisation–elimination sequence, and demonstrate that the procedure produces 3,4-disubstituted and 2,3,4-trisubstituted pyrrolidines with extremely high stereoselectivity. We then describe the application of this methodology to the synthesis of (−)-α-kainic acid **1**: to the best of our knowledge, this is the first application of diene metallabicyclisation–elimination methodology in natural product synthesis.



Scheme 1

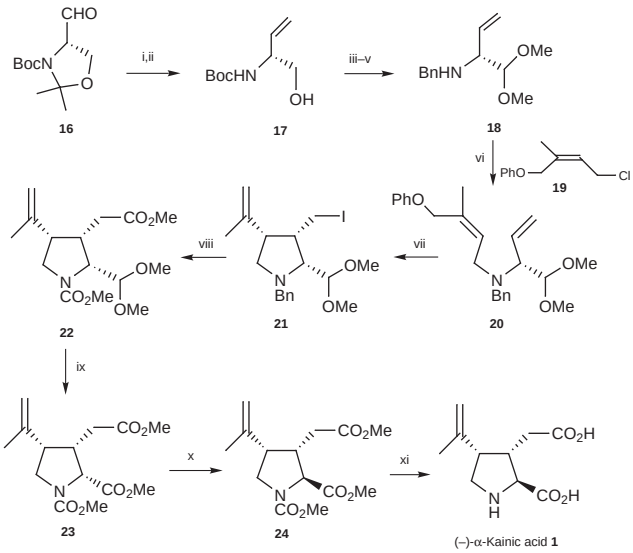
Model studies were first carried out to assess the viability of the (η_2-propene)Ti(OPr^i)$_2$ procedure for the stereoselective preparation of pyrrolidines (Table 1).† As can be seen (entry 1), treatment of diene **8** with Ti(OPr^i)$_4$/2 Pr^{i}MgCl produced, after protonation, the 3,4–disubstituted pyrrolidine **9a** in an excellent yield with a 6:1 ratio of *syn:anti* diastereomers. The alkyl–titanium intermediate could also be halogenated giving alkyl halides **9b** and **9c** in good yield.

Cyclisation of the trisubstituted alkenes **10** and **12** also proceeds efficiently and with excellent *syn*-selectivity giving **11** as the only product (entries 2 and 3). Further studies are in progress to rationalise this much improved stereoselectivity. We next looked at the titanium-mediated cyclisation–elimination reaction of the 2-methyl substituted system **13**. We were delighted to observe that in this case the high C-3/C-4 *syn*-selectivity was retained, as only the two separable diastereoisomers **14** and **15** were isolated.‡ Remarkably,[9c] the major product was the *syn, syn*-diastereomer **14** in which all three substituents were on the same face of the pyrrolidine. This stereochemical assignment was confirmed by comparison of the ^{1}H NMR spectra of **14** and **15** with **9a** and related systems,[8] and

Table 1 Titanium-mediated diene metallabicyclisation–elimination–trapping reactions (*cis*:*trans* ratios determined by ^{1}H NMR spectroscopy)

	Starting diene	Electrophile	Major product	Yield (%) (*syn:anti*)
1	 **8**	H^+ (**9a**) I_2 (**9b**) Br_2 (**9c**)	 **9a–b**	**9a** E = H, 85% (6:1) **9b** E = I, 72% (6:1) **9c** E = Br, 67% (6:1)
2	 **10**	H^+	 **11**	84% (*syn* only)
3	 **12**	H^+	 **11**	86% (*syn* only)
4	 **13**	H^+	 **14** **15** 4:1	74%

by NOE studies (*e.g.* H-2 and H-4 enhanced by irradiation at H-3). It has been demonstrated that all *syn*-analogues of kainic acid can be epimerised at C-2 to give the kainoid structure.[10] Thus, a titanium-mediated metallabicyclisation approach for the synthesis of kainic acid could commence with L-serine and include an epimerisation step after cyclisation. The strategy has now been implemented successfully (Scheme 2).



Scheme 2 *Reagents and conditions*: i, $Ph_3P^+CH_3Br^-$ KHMDS, THF, −78 °C (80%); ii, Dowex (H^+) resin, aq. MeOH (93%); iii, Dess–Martin oxidation; iv, HCl/MeOH; v, PhCHO, $NaBH(OAc)_3$, $ClCH_2CH_2Cl$ (31% for 3 steps); vi, K_2CO_3, cat. NaI, MeCN, reflux (88%); vii, $Ti(OPr^i)_4$, Pr^iMgCl (2 equiv.), Et_2O, −50 °C to room temp., then I_2, 0 °C [56% (78% based on recovered **20**)]; viii, Bu^tLi (2.2 equiv.), Et_2O, −80 °C, then excess $ClCO_2Me$, −80 °C, then excess $ClCO_2Me$, $ClCH_2CH_2CI$, reflux, 2 h (61%); ix, Jones' oxidation then CH_2N_2 (65%); x, LiHMDS (2.5 equiv.), THF, 0 °C, then MeOH (80%); xi, NaOH/MeOH, reflux (70%).

Thus, L-serine was converted into the (*S*)-Garner aldehyde **16** using our improved procedure.[11] Wittig methylenation and acid hydrolysis gave the Boc protected vinylglycinol **17**[11,12] which underwent Dess–Martin oxidation to a very unstable aldehyde which was immediately subjected to *N*-Boc deprotection–acetal formation to give an amino acetal which was then reductively aminated with benzaldehyde to give **18** in 31% yield over three steps. The ee of this amine was shown to be 93% by comparison with racemic material using HPLC on a chiral column [Chiralpak AS, 1:99 Pr^iOH–hexane, R_t 324 s (*vs*. 287 s)]. This is the first preparation of an acetal-protected vinylglycinal, a compound that could be useful in other synthetic applications. Alkylation with allyl chloride **19** then gave the cyclisation precursor **20** in 88% yield.§ Allyl chloride **19** was prepared by Horner–Wadsworth–Emmons elaboration of 2-phenoxyacetone with methyl diethyl phosphonoacetate (94%, *E*:*Z* = 2:1) followed by chromatographic separation, reduction of the resulting α,β-unsaturated ester (DIBAL-H) and chlorination (TsCl, DMAP).

Ti^{II}-mediated cyclisation–iodination of **20** gave the *syn*,*syn*-pyrrolidine **21** as the only cyclised product in 56% yield (78% based on recovered diene **20**). Lithium–halogen exchange and quenching with excess methyl chloroformate gave **22** in 61% overall yield. Jones' oxidation cleaved the acetal and oxidised the aldehyde produced to the corresponding acid which was treated with CH_2N_2 to give ester **23**. Compound **23** is a protected derivative of the so-called β-kainic acid: the titanium methodology provides a very convenient stereoselective route to these compounds which are reported to have interesting anti-convulsant properties.[13]

Epimerisation at C-2 was successfully achieved using LiHMDS (2.5 equiv.) and quenching with MeOH.[10*b*] Using this procedure, complete conversion into the epimeric ester **24** was observed [TLC (SiO_2: EtOAc–light petroleum, 1:2) **23**, R_f 0.30; **24**,[14] R_f 0.31]. Saponification of **24** was accompanied by *N*-deprotection giving (−)-α-kainic acid **1**, which was spectroscopically consistent with authentic material and corresponded well in terms of polarimetry {$[\alpha]_D$ −15.2 (*c* 0.95, H_2O); lit.,[15] −15.0 (*c* 0.5, H_2O)} and mp [mp 244–247 °C (decomp.); lit.,[15] mp 237–243 °C (decomp.)].

In conclusion, we have developed a new enantioselective synthesis of (−)-α-kainic acid **1** which has as its cornerstone a totally stereoselective titanium-mediated diene metallabicyclisation process. The total synthesis is high yielding (3.5% in twelve steps from commercially available material). This new route contrasts to other cyclisation–elimination approaches to the kainoids where stereochemical control has been poor,[7] and although our procedure does require epimerisation at C-2 to obtain the kainoid structure, it also provides a route to β-kainoids. In addition, kainoid analogues with a range of different substituents at C-3 and C-4 are available *via* this route. From a general methodological viewpoint, the new procedure for the stereoselective preparation of *syn*,*syn*-2,3,4-trisubstituted pyrrolidines is noteworthy.

We are grateful to the BBSRC and Roche Discovery Welwyn for a CASE award (A. D. C.).

Notes and references

† All new compounds were fully characterised spectroscopically and by HRMS/elemental analysis.

‡ During the course of our studies Sato *et al.* also reported the stereoselective synthesis of a 2,3,4-trisubstituted pyrrolidine *via* titanium-mediated diene metallabicyclisation [ref. 9(*c*)], although their system was not suitable for elaboration to produce kainoids.

§ Initial studies were carried out with a protected alcohol as the C-2 substituent. Metallabicyclization was successful and completely stereoselective, but problems were encountered when trying to adjust the oxidation state of the C-2 substituent.

Sulfur oxidation in supercritical carbon dioxide: dramatic pressure dependant enhancement of diastereoselectivity for sulfoxidation of cysteine derivatives

R. Scott Oakes, Anthony A. Clifford, Keith D. Bartle, Mark Thornton Pett† and Christopher M. Rayner*

School of Chemistry, University of Leeds, Leeds, UK LS2 9JT. E-mail: chrisr@chem.leeds.ac.uk

Received (in Liverpool, UK) 3rd December 1998, Accepted 8th December 1998

The diastereoselective sulfoxidation of chiral sulfides derived from methionine and cysteine has been investigated in conventional solvents and in supercritical carbon dioxide ($scCO_2$); use of *tert*-butyl hydroperoxide and Amberlyst™ 15 ion exchange resin is particularly effective for sulfoxide formation, and with cysteine derivatives shows a dramatic pressure-dependant increase in diastereoselectivity (up to > 95% de) in $scCO_2$ compared with conventional solvents, where no diastereoselectivity is observed; the stereochemical configuration of the major product of the oxidation of Cbz-CysSMe-OMe has been confirmed as *anti* using X-ray crystallography.

The development of new methods for addressing environmental problems associated with organic synthetic procedures continues to be one of the major challenges facing synthetic organic chemists, and will remain so for the foreseeable future. Supercritical carbon dioxide ($scCO_2$) is currently being investigated as an environmentally friendly solvent by a number of research groups, and has been demonstrated as being an effective medium for a limited number of organic transformations (*vide infra*). Supercritical fluids are substances above their critical temperatures and pressures, whose properties are intermediate between those of gases and liquids, and which can be controlled by both temperature and pressure.[1] Pure carbon dioxide has a critical temperature of 31 °C and critical pressure of 74 atmospheres, both of which are readily achievable using commercially available equipment. Advantages include: low toxicity, ready availability, ease of removal and disposal and/or recycling. Other advantages which are particularly relevant for carrying out reactions in $scCO_2$ are: fine control of solvent properties by changes in temperature and pressure; the ability to homogenise reaction substrates, electrically neutral metal complexes and gases like oxygen and hydrogen; enhanced diffusion rates; and potential for product processing.[2]

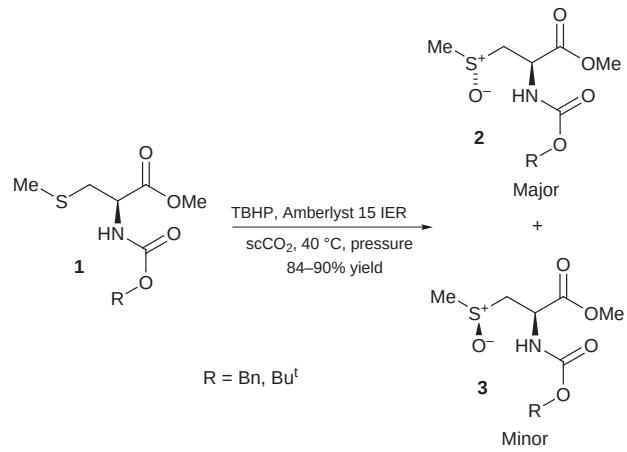
Supercritical fluids have also been shown to be excellent media for a number of reactions.[3] In our laboratories, we have recently shown that it is possible to fine tune the *endo*/*exo* selectivity of the Diels–Alder reaction between cyclopentadiene and methyl acrylate by controlling the density of the reaction medium by varying the temperature and pressure of the $scCO_2$.[4] However, in this case, the changes observed were modest, and gave no real preparative advantage. We now report some results which clearly show definite advantages of carrying out reactions in $scCO_2$ in addition to the environmental and processing reasons stated above.

We have recently developed a new method for the oxidation of simple sulfides to sulfoxides in conventional solvents and $scCO_2$[5] using *tert*-butyl hydroperoxide (TBHP) as oxidant with Amberlyst 15 ion exchange resin catalyst (Scheme 1).[6] High yields and excellent selectivity for sulfoxide formation are obtained, even with an excess of oxidant, and this method provides an attractive alternative to procedures currently available for use under conventional conditions as well as in $scCO_2$.[7]

We now report the results of studies on the oxidation of more complex substrates, which have potential for diastereoselective oxidation, to see whether using $scCO_2$ as solvent has any particular advantages in addition to the environmental and product processing benefits mentioned above.

Recent studies on the sulfoxidation of cysteine derivatives have shown that, although in general they may be expected to give diastereoselective oxidation, this can in practice be difficult to achieve without significant substituent modification, requiring preparation of the MEM esters of *S*-benzyl (or larger) derivatives for good results, with no significant selectivity being observed with the methyl esters[8] or reported for *S*-methyl derivatives.[8,9] With this in mind, we chose to investigate the oxidation of a range of conventionally protected cysteine and methionine derivatives, firstly as more complex examples of substrates for oxidation, but also to determine if carrying out the reaction in $scCO_2$ had any significant effect on the diastereoselectivity of the reaction.

Initial studies using our TBHP/Amberlyst reagent system showed that oxidation of Cbz-methionine methyl ester proceeded efficiently in either toluene or $scCO_2$, but with no diastereoselectivity as determined by ^1H NMR analysis, presumably due to the remote nature of the existing chiral centre and the sulfur atom in the substrate.‡ A potentially more promising substrate, CBz methyl cysteine methyl ester, was oxidised in high yield, but also gave no appreciable diastereoselectivity in toluene or CH_2Cl_2 in accord with previous literature results.[8] On attempting the reaction in $scCO_2$ (200 bar, 40 °C), high yields were obtained (Scheme 1), but also significant diastereoselectivity (Fig. 1). As from our previous work on the Diels–Alder reaction,[4] we were aware that the density of the medium, controlled by varying either temperature or pressure, can have an effect on reaction selectivity, and it may be possible to fine tune the reaction conditions to optimise such selectivity. In this case, by varying the pressure at a constant temperature of 40 °C, we were able to optimise the diastereoselectivity of the reaction to > 95% de (Fig. 1). This is a particularly dramatic enhancement considering that no selectivity was observed under conventional reaction conditions.



Scheme 1

† Author to whom communications regarding X-ray crystal structure determination should be addressed.

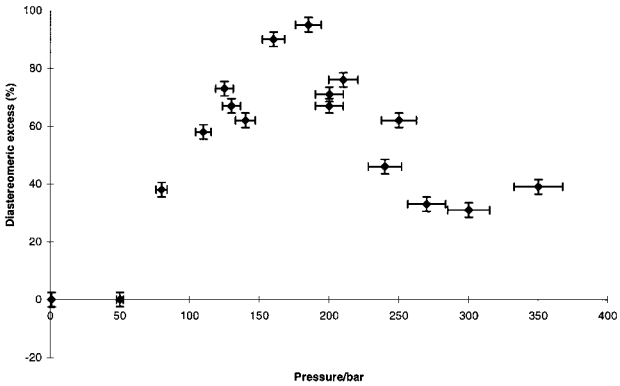


Fig. 1 Variation of diastereoselectivity for oxidation of Cbz-CysSMe-OMe.

Similar effects were also observed in the case of Boc methyl cysteine methyl ester, although with less impressive selectivities (up to 31% de). Note that in both cases, at a constant temperature, the selectivity rises to a maximum at around 180 bar then falls off as pressure is increased further. The relative stereochemistry of the major isomer for the oxidation of Cbz-CysSMe-OMe has been confirmed as the *anti* isomer **2** (R = Bn) by X-ray crystallography§ (Fig. 2).

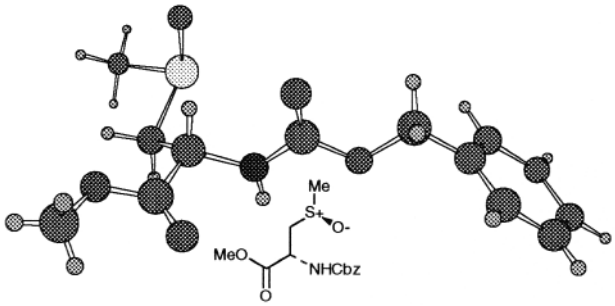

Fig. 2 X-Ray crystal structure of major diastereomer from oxidation of Cbz-CysSMe-OMe in $scCO_2$.

We had previously rationalised this kind of fine-tuning of reaction conditions by the adjustment of the nearest neighbour solvent molecules with respect to the transition states.[4] This would be particularly important for processes with highly ordered transition states such as Diels–Alder reactions. In the case of this work, the situation is less clear and factors such as hydrogen bonding and/or conformation[10] may also play an important role. The fact that essentially no diastereoselectivity is observed in conventional solvents, however, strongly suggests that the nature of the reaction medium is playing a crucial role in inducing the stereoselective reaction.

Whilst the actual reasons for this effect may be the subject of some debate, there is no doubt that it is potentially very important in the area of stereoselective synthesis, particularly if it can be shown to be applicable to other types of reaction, with similar levels of amplification of stereoselectivity. We are currently investigating both the causes and generality of this effect, and the results of these studies will be reported in due course.

Notes and references

‡ Experimental procedure: As with all reactions under high pressure, adequate safety precautions must be taken. For carrying out reactions in $scCO_2$, a stainless steel cyclindrical vessel was used with a volume of 20 ml. The seal between vessel and lid is maintained by a Viton high pressure 'O'-ring. Stirring is accomplished using a remote magnetic stirrer. A Swagelok pressure relief valve with a release pressure of 6000 psi is employed as a safety precaution. The pressure is measured utilising a Farnells Electronics™ pressure transducer (0–5000 psi). Reagents can be injected into the system *via* a Rheodyne injector valve. The system is pressurised using a Varian™ 8500 syringe pump, which draws from a BOC 100.00 CP grade CO_2 cylinder (*ca*. 50 bar head pressure), and has a cooled pump head. Temperature control is achieved by locating the vessel in a modified GC oven. Diastereomeric ratios were determined by ^{1}H NMR analysis to ±2.5% de. Errors along the pressure axis were set at 5% to allow for inaccuracies in other variables such as temperature, reagent quantities and volumes, and pressure.

Amberlyst™ 15 resin (0.5 g), the sulfide (up to 4.0 mmol) and a magnetic stirrer were placed in the reaction vessel described above, at room temperature. The vessel was sealed and pressurised to *ca*. 50 bar with CO_2 and the oven temperature maintained at 40 °C. Agitation was started at a rate of 600 rpm. The pressure was increased to *ca*. 100–120 bar, at which point the TBHP (1.1 equiv. of *ca*. 4.0 M solution in toluene) was injected and the pressure further increased to the desired reading. Agitation was maintained at this temperature and pressure for 24 h. On completion, the pressure was released slowly *via* a vent into a CH_2Cl_2 trap (20 ml). When atmospheric pressure was reached, the reaction vessel was washed through with CH_2Cl_2 (2 × 1 ml, at 50 bar). The vessel was opened and the Amberlyst™ 15 washed with MeOH (2 × 5 ml) and removed by filtration. The solutions were combined and the solvent was removed *in vacuo*. Column chromatography of the residue gave the desired sulfoxides in 82–97% yield.

§ *Crystal data* for **2** (R = Bn) (ref. 11): $C_{13}H_{17}NO_5S$, M = 299.34, orthorhombic, space group $P2_12_12_1$, a = 7.87930(10), b = 8.19550(10), c = 22.0906(4) Å, V = 1426.50(4) Å^3, T = 100(2) K, Z = 4, D_c = 1.394 Mg m^{-3}, μ(MoKα) = 0.245 mm^{-1}, 27208 reflections collected, 2747 independent reflections, R(int) = 0.0282, all non-H atoms anisotropic, all H-atoms constrained to idealised positions. Final R indices [based on 2724 reflections with $I > 2\sigma(I)$], R_1 = 0.0256, wR_2 = 0.0706. The absolute structure of the molecule was confirmed by the refinement of an enantiopole parameter to −0.02(6). CCDC 182/1113. Aldehydes and ketones as dipolarophiles: application to the synthesis of oxapenams

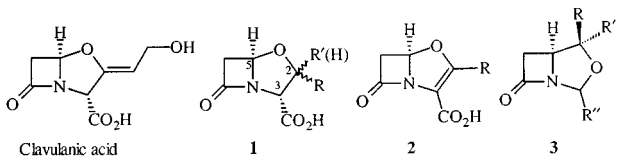
Mark D. Andrews,[a] Giles A. Brown,[a] Jonathan P. H. Charmant,[a] Torren M. Peakman,[a] Arlene Rebello,[a] Kenneth E. Walsh,[a] Timothy Gallagher*[a] and Neil J. Hales*[b]

[a] *School of Chemistry, University of Bristol, Bristol, UK BS8 1TS. E-mail: t.gallagher@bristol.ac.uk*
[b] *Zeneca Pharmaceuticals, Mereside, Alderley Park, Macclesfield, UK SK10 4TG*

Received (in Liverpool, UK) 6th November 1998, Accepted 4th December 1998

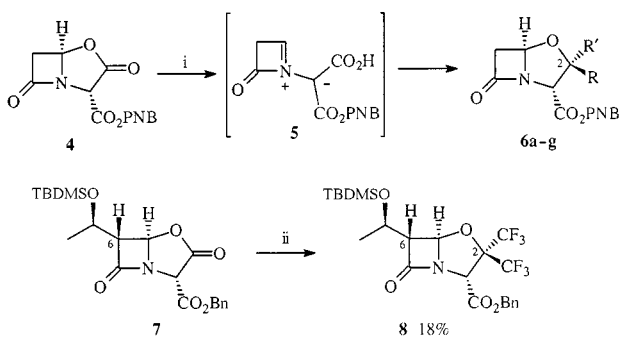
2-Substituted (6a–e) and 2, 2-disubstituted oxapenams (6f–g) are obtained in one step by thermolysis of the β-lactam-based oxazolidinone 4 in the presence of aldehydes and reactive ketones respectively; the *C(6)*-substituted oxazolidinone variant 7 reacts with hexafluoroacetone to give the enantiomerically pure oxapenam 8.

β-Lactams continue to represent a versatile and commercially significant class of antibiotics and the promise of an enhanced or novel biological profile has done much to stimulate the design and synthesis of new structural variants.[1] The oxygen-based clavams, of which the potent β-lactamase inhibitor clavulanic acid[2] is the best known example, also includes oxapenams **1**[3] and oxapenems **2**,[4] together with the isomeric isoclavams **3**.[5] These oxygen-containing bicyclic β-lactams,



which constitute an interesting and comparatively new class of β-lactams, incorporate significant strain as compared to their more stable sulfur-based analogues (penams). As a consequence, oxapenams are thermally and hydrolytically sensitive molecules, which places a significant demand on the range and efficiency of approaches that may be employed for the synthesis of these compounds.[6]

Here we describe a flexible but also very direct route for the synthesis of both 2-substituted and 2,2-disubstituted oxapenams represented by general structure **1**. The process that has been developed is summarised in Scheme 1 and involves a formal 1,3-dipolar cycloaddition reaction (to establish the bicyclic skeleton of the oxapenams) by exploiting aldehydes and reactive ketones as 1,3-dipolarophiles.[7] The successful application of this chemistry to oxapenams not only represents a novel entry to this class of molecule but also represents a significant



Scheme 1 *Reagents and conditions:* i, aldehyde/ketone (1.1–1.5 equiv.), MeCN, 81 °C, 24–48 h, then chromatography (for R and R′, see Table 1); ii, CF_3COCF_3, MeCN, 81 °C, 24 h.

extension to the recently reported azomethine ylide approach to bicyclic β-lactams.[8]

Thermolysis of the readily available β-lactam-based oxazolidinone **4** (PNB = $CH_2C_6H_4$-4-NO_2)[8] (which was carried out using deoxygenated MeCN, either at reflux or in a sealed tube at 81 °C) in the presence of either an aldehyde or a ketone (1.1–1.5 equiv.) provides racemic oxapenams **6a–g** in a single step albeit in moderate (19–56%) yield. The scope of this chemistry is illustrated by the examples shown in Table 1 and a

Table 1 Synthesis of oxapenams **6a–g**

Aldehyde/ketone	Oxapenam	Yield (%) (*exo* : *endo*)
PhCHO	 **6a**	19 (1 : 1)
4-$O_2NC_6H_4CHO$	 **6b**	21 (1 : 1)
4-ClC_6H_4CHO	 **6c**	26 (1 : 1)
4-$F_3CC_6H_4CHO$	 **6d**	21 (1 : 1)

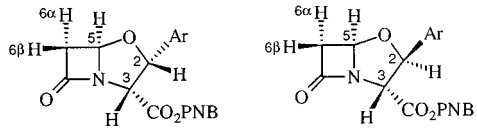
	 **6f**	56
	 **6g**	25

range of 2-substituted oxapenams (derived from aldehydes) and 2,2-disubstituted oxapenams (derived from ketones) have been obtained. The same cycloaddition sequence has also been applied to the C(6)-substituted oxazolidinone variant **7**, which underwent reaction with hexafluoroacetone to provide the enantiomerically pure 2,2-bis(trifluoromethyl)oxapenam **8** {$[\alpha]_D^{24}$ +34.1 (*c* 0.09, CH_2Cl_2)} in 18% isolated yield.

The most important feature of the process shown in Scheme 1 is the very direct nature of this entry to oxapenams, which compensates for the modest yields observed. While aldehydes and reactive ketones appear to be reactive towards the azomethine ylide **5** (produced by fragmentation of **4**),[8c] a number of ketones (cyclohexanone, cyclopentanone, diethyl 2-oxomalonate, pyridine-4-carbaldehyde), either failed to trap or to give characterisable products. This may indicate the relative instability of the product oxapenams to either the thermal reaction conditions and/or chromatographic isolation, and such factors are likely contributors to the modest yields of oxapenams **6** that have been obtained.†

The cycloaddition pathway shown in Scheme 1 is, however, efficient in terms of the level of both regio- and stereo-control observed, but we were also concerned to establish this stereochemical outcome rigorously. Assignments in this area have often been based on the presumption that the thermodynamically more stable *trans* relationship between *C(3)* and *C(5)* predominates and by application of an empirical observation, the Bentley–Hunt rule.[6c] The reliability of this rule, and consequently its value as a diagnostic tool, has recently been questioned.[9] We, like others,[3c] have relied on NOE difference spectroscopy to assign the stereochemistry of oxapenams. With aldehydes, approximately equal amounts of the *exo* and *endo* adduct C(2) diastereomers were isolated and in the case of both **6d** and **6e**, the *exo* and *endo* isomers were separated and relative stereochemistry—C(2) *vs.* C(3) *vs.* C(5)—was assigned on the basis of NOE difference spectroscopy.‡ Only the oxapenam (clavam) regioisomer has been detected in the cases that we have examined and the thermodynamically more stable *trans* relationship between C(3) and C(5) (as defined by NOE and X-ray crystallography) is favoured; this latter stereochemical outcome is consistent with that observed previously in the synthesis of carbapenams, Δ^1-carbapenems and penams.[8]



exo-**6d**, Ar = $C_6H_5CF_3$ *endo*-**6d**, Ar = $C_6H_5CF_3$
exo-**6e**, Ar = C_6F_5 *endo*-**6e**, Ar = C_6F_5

The structure of the hexafluoroacetone adduct **6f** has been established by X-ray crystallographic analysis§ which confirmed both the regiochemistry of the cycloaddition reaction (clavam *vs*. isoclavam) and the relative stereochemistry between C(3) and C(5).

In summary, utilisation of aldehydes and reactive ketones as dipolarphiles for the azomethine ylide strategy provides a very direct entry to both 2-substituted and 2,2-disubstituted oxapenams. This not only represents a novel route to an unusual class of bicyclic β-lactams but also enhances the scope and value of the underlying cycloaddition based methodology.

We thank Zeneca Pharmaceuticals for a Studentship (to G. A. B.), the EPSRC (Grant GR/K88569) and the University of Bristol for a University Research Fellowship (to T. G.), and we acknowledge use of the EPSRC's Chemical Database Service at Daresbury.[10]

Notes and references

† Thermolysis of **4** in the presence of dibenzosuberone gave the corresponding cycloadduct in only 6% yield after 24 h, but on continued heating (to 48 h), complete decomposition of this product was observed. In a qualitative sense, we have observed a correlation between enhanced thermal and chromatographic stability of oxapenams and an increase in the electron withdrawing nature of the C(2) substituent(s).

‡ NOE difference analysis involved irradiation of all ring protons (H2, H3, H4, H6α and H6β). The proton irradiated is indicated in bold and the proton(s) enhanced are shown in brackets. *Exo*-**6d**: **H2** δ 5.61 (H3, H6β, *ortho* protons of $C_6H_4CF_3$); **H3** δ 5.08 (H2); **H5** δ 5.85 [H6α, H6β (weak)]; **H6α** (H5, H6β); **H6β** [H6α, H2, H5 (weak)]; *endo*-**6d**: **H2** δ 5.53 (H5, *ortho* protons of $C_6H_4CF_3$); **H3** δ 4.43 (*ortho* protons of $C_6H_4CF_3$); **H5** δ 5.53 [H2, H6α, H6β (weak)]; **H6α** (H5, H6β); **H6β** [H6α, H5 (weak)]. Similar observations (with the exception of the aromatic proton enhancements) were recorded for *exo*- and *endo*-**6e**. *Exo* and *endo* adducts for the other entries shown in Table 1 were readily correlated using ^{1}H NMR data. As illustrated for *exo*- and *endo*-**6d**, chemical shifts (300 MHz, CD_3CN) followed a clear pattern with signals for H2, H3 and H5 corresponding to the *exo* isomer consistently appearing at lower field than those associated with the isomeric *endo* adduct. The structure of cycloadduct **8** was also established by NOE spectroscopy. All new compounds have been characterised by spectroscopic methods and either microanalysis or high resolution mass measurement.

Diastereoselective iodoamidation of 3-acetyloxybut-1-enylamines: simple synthesis of a precursor of aza sugars involving a pyrrolidine ring

Woo Song Lee, Ki Chang Jang, Jin Hyo Kim and Ki Hun Park*

Department of Agricultural Chemistry, Gyeongsang National University, Chinju 660-701, Korea.
E-mail: khpark@gshp.gsnu.ac.kr

Received (in Cambridge, UK) 20th November 1998, Accepted 23rd December 1998

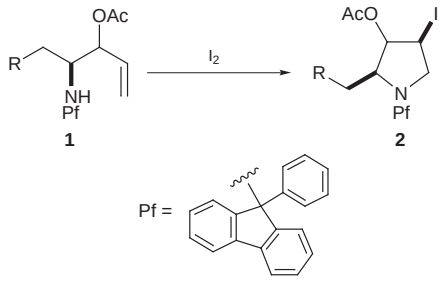
3-Acetyloxybut-1-enylamines 3–9 were easily transformed using iodine to pyrrolidine derivatives 3a–9a, precursors for aza sugars, *via* a diastereoselective iodoamidation.

Since the discovery that polyhydroxylated pyrrolidines are potent glycosidase inhibitors with potential therapeutic utility in the treatment of various diseases such as diabetes,[1] cancer[2] and viral infections,[3] much attention has been concentrated on the development of convenient and efficient routes to these compounds. In general, synthetic routes to aza sugars require azide displacement/reduction and intramolecular N-alkylative cyclisation with protecting group manipulation,[4] starting from carbohydrates or non-carbohydrates. Here we report the highly diastereoselective iodoamidation of 3-acetlyoxybut-1-enylamines **1** for the preparation of pyrrolidine derivatives **2** (*e.g.* anisomycine,[5] 3,4-dihydroxyprolinol,[6] swainsonine[7] and lentiginosine[8]) (Scheme 1).

The requisite substrates **3**–**9** were prepared easily by the usual method from commercially available L-tyrosin, L-phenylalanine and L-serine.[9]† Fortunately, each diastereomeric allylic alcohol given by the Grignard reaction could be isolated in pure form by column chromatography. We chose the 9-phenylfluoren-9-yl (Pf) group for protection of the amine since this protecting group has been shown to inhibit deprotonation at the α-position of α-amino aldehydes.[10] α-Amino aldehydes having the Pf group are very stable to Grignard reaction conditions.[11]

Compound **3** was treated with I_2 under biphasic conditions (aq. $NaHCO_3$–THF–Et_2O = 2 : 1 : 1) at room temperature for 3 h to give the all *trans* pyrrolidine **3a** (*vide infra*) as the sole product in high yield *via* a diastereoselective iodoamidation. Although THF, MeOH, CH_2Cl_2 and MeCN have been found to be acceptable solvents for iodoamidation, these solvents required much longer reaction times and resuted in 35–50% recovery of the starting material. As shown in Table 1, the optimum reaction conditions involved biphasic conditions to improve reactivity and affording pyrrolidine **3a**.

Treatment of **4** under the same conditions afforded a 25 : 1 ratio of the *cis* and *trans* isomers of pyrrolidine **4a**. Compounds **5** and **6** were cyclized according to these standard conditions to give the expected the corresponding pyrrolidines *trans*-**5a** and *cis*-**6a** in high yield, respectively. Compound **7** was also exposed to the same reaction conditions to give *cis*-**7a** in a ratio of 20 : 1 in 66% yield. In the case of starting materials *trans*-**8** and *cis*-**9**,‡ this solvent mixture was not suitable. Thus, compounds **8** and **9** were treated with I_2 in THF to give the corresponding *trans*-**8a** and *cis*-**9a** in 92% (based on 65% conversion) and 88% (based on 80% conversion) yields, respectively (Table 2). The structures of all pyrrolidines **3a**–**9a** were confirmed by their characteristic spectroscopic data.§



Scheme 1

The relative stereochemistries of the products **3a** and **4a** were determined from their ^{1}H NMR spectra based on the coupling constant values and 2D NOE experiments. For *trans*-**3a**, proton H_3 (t like, $J_{2,3}$, $J_{3,4}$ = 5.1 Hz) adjacent to the acetyloxy group gave weak correlation with protons (H_2 and H_4) adjacent to the *p*-tolylmethyl and iodine groups, but strong NOE cross peaks were observed between H_2–H_4 and H_2–H_{5b}, thereby allowing one to assign its relative stereochemistry. In pyrrolidine *cis*-**4a**, proton H_3 (t like, $J_{2,3}$, $J_{3,4}$ = 6.9 Hz) adjacent to the acetyloxy group displayed strong mutual correlation with the protons (H_2 and H_4) adjacent to the *p*-tolylmethyl and iodine groups, thereby verifying the structure of *cis*-**4a** as shown in Fig. 1.

Based on the coupling constant values in the high-field ^{1}H NMR spectra of *trans*-**3a** and *cis*-**4a**, the stereochemistries of *trans*-**5a** (H_3, t like, $J_{2,3}$, $J_{3,4}$ = 5.1 Hz) and *cis* **6a** (H3, t like, $J_{2,3}$, $J_{3,4}$ = 6.9 Hz) could be determined from each coupling constant value. The stereochemistries of *trans*-**8a** (H3, dd, $J_{2,3}$ = 4.8, $J_{3,4}$ = 3.4 Hz) and *cis* **9a** (H3, dd, $J_{2,3}$ = 2.4, $J_{3,4}$ = 4.2 Hz) were also confirmed using coupling constant values.

Although numerous construction methods for the electrophilic cyclisation have been developed,[12] the closest literature precedent to this haloamidation has been independently studied by the groups of Takahata[13] and Yoshida.[14] Takahata has shown that iodine-induced lactamization of γ,δ-unsaturated thioimidates proceeds regioselectively to provide γ-lactams. Yoshida has reported that *N*-(*p*-tolylsulfonyl)pent-4-enylamines were subjected to stereoselective haloamidation to afford mainly *cis* substituted pyrrolidines. Although these methodologies have been proven to be useful protocols, they are of limited use for the direct synthesis of polyhydroxylated aza sugars because these reactions proceed *via* 5-*exo*-*trig* cyclisation. Thus, we are the first to observe chiral induction on the pyrrolidine ring through an diastereoselective iodoamidation and to succeed in

using a strong electron-donating group, 9-phenylfluoren-9-yl (Pf), on an amine moiety.

In conclusion, we found that optically active starting materials **1** as chiral building blocks are converted easily to pyrrolidine derivatives **2** *via* a diastereoselective iodoamidation. These species should be valuable for the total synthesis of polyhydroxylated aza sugars having a pyrrolidine ring and may be suitable for substitution with various nucleophiles (NaN_3, amines, alcohols, thiols and Grignard compounds), giving novel aza sugar derivatives. Thus, we are currently investigating the preparation of all six diasteromers of anisomycin and other 3,4-dihydroxyprolinols.

Notes and references

† Starting materials **3**–**9** were prepared by a sequential reaction, namely, free animo acids were treated with TMSCl in MeOH to give methyl esters, the amino groups of which were protected with PfBr in CH_2Cl_2. The methyl esters were then subjected to reduction and Swern oxidation to afford aldehydes, which were reacted with vinylmagnesium bromide to give separable allylic alcohols.

‡ The relative stereochemistries of the corresponding acetonides *trans*-**8** (J = 8.1 Hz for the proton on oxygen) and *cis*-**9** (J = 1.0 Hz for the a proton on oxygen) were confirmed by coupling constant analysis.

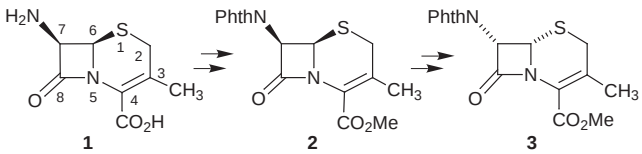
Received (in Cambridge, UK) 16th November 1998, Accepted 16th December 1998

Two complementary strategies have been developed in order to convert a cephalosporin derivative, characterized by the 'natural' absolute configuration of the two stereogenic centers, into its enantiomer, as an optically pure compound.

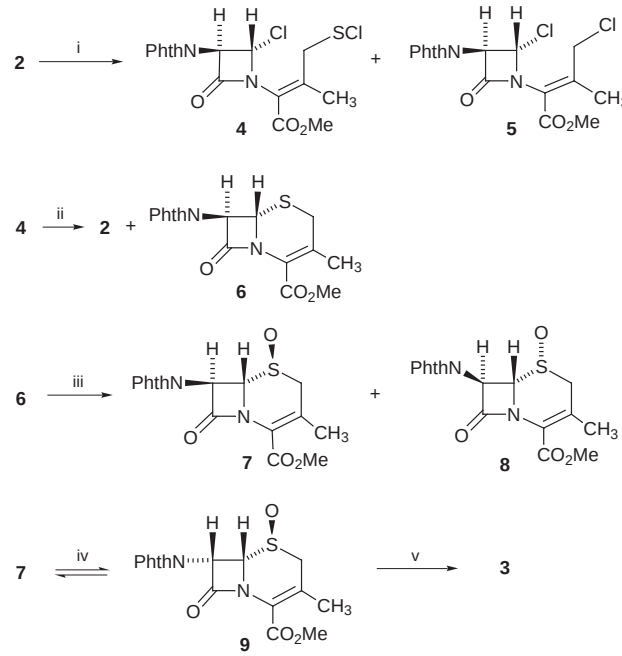
In the field of bioactive molecules asymmetry plays a fundamental role;[1] chiral drugs, in particular, are developed as single enantiomers,[2] since the optical antipode of the active compound must be regarded as a different substance with possible different biological targets. In the course of our studies aimed at developing cephem derivatives with altered biological activity, we sought a means of synthesizing, in homochiral form, bis-epimeric (relative to the stereochemistry of the natural compound) cephalosporins, starting from a commonly available β-lactam precursor (Scheme 1). Totally stereoselective syntheses of β-lactams with altered chirality have already been described by other research groups, but they have principally focused their attention on penam derivatives, usually in mono-epimeric forms, or on monobactam compounds.[3] A route to a cephalosporin enantiomer has been recently disclosed, where 6-aminopenicillanic acid (6-APA) has been used as the starting material.[4] Here we report on two alternative strategies which lead to the cephalosporin enantiomers of natural occurring (6*R*,7*R*)-cephalosporins, starting from 7-aminodesacetoxy-cephalosporanic acid (7-ADCA) **1**. In view of this target we have explored pathways to both epimeric forms, at C-6 and C-7, of the protected cephem derivative **2** obtained from **1**, followed by epimerization of the other stereogenic center to finally produce the cephalosporin antipodal form **3**.

The first strategy we describe here (Scheme 2) for the epimerization at the C-6 position exploits the well-known chlorinolysis of the thiazolidine ring of penicillins first developed by Kukolja,[5] followed by reconstruction of the isomerically modified skeleton.[6] Although this procedure is also cited by other authors,[4,7] and also worked well in our hands on penam derivatives, it failed when, in our case, it was applied on the cephem derivative, leaving the substrate **2** unreacted in the presence of added chloride ion, or it led to decomposition products under forced conditions. After many exploratory reactions, **2** was converted in high yields into a 2 : 3 mixture of the azetidinone sulfenyl chloride **4** and the chloro derivative **5** by reaction with an equimolar amount of chlorine and a slight excess amount of $TiCl_4$, at −15 °C. The two compounds were then isolated by chromatography over deactivated silica gel. In marked contrast to the penam congeners,[5] in our case only the *trans* isomers were produced. It is also worth noting that the allylic sulfenyl chloride **4**, in the presence of chlorine or of a Lewis acid, is highly susceptible to nucleophilic displacement of SCl_2 with formation of the unwanted derivative **5**. This compound in fact can also be readily prepared from **4** by treatment with 1 equiv. of chlorine. On the other hand, **4** formed as the only isolable product when **2**, as a solid powder, was rapidly treated with an excess of freshly distilled sulfuryl chloride, at 0 °C, and practically at the same time the reaction quenched with a large amount of toluene. The ring closure step was performed by treatment of **4** with 1 equiv. of $SnCl_2$ dihydrate, in dioxane, at the reflux temperature for 15 min to give a 1 : 2 mixture of the *cis*/*trans* isomers **2** and **6**, which were separated by chromatography on silica gel.

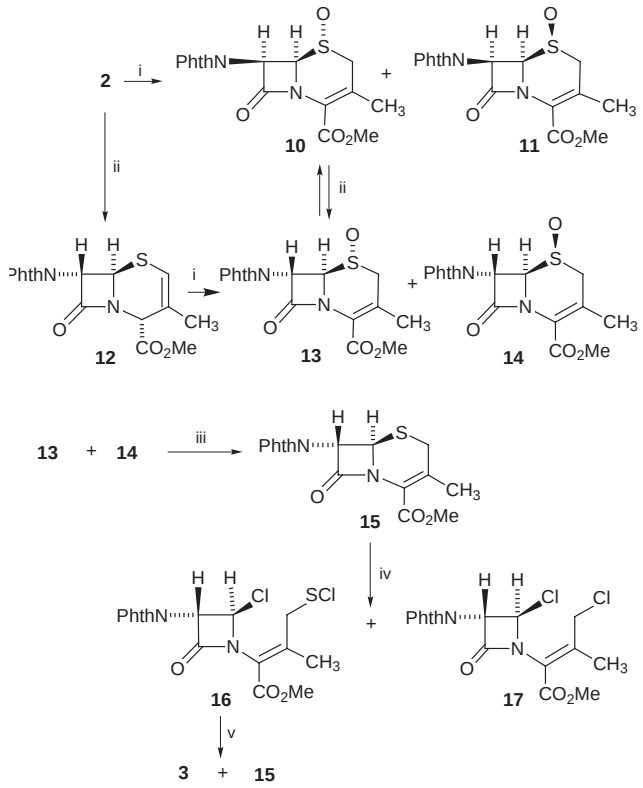


Scheme 1

Oxidation of **6** with MCPBA gave a 1 : 1 mixture of the two sulfoxide epimers **7** and **8**,[8] which were separated by taking advantage of their marked difference in solubility. The (1*R*)-sulfoxide **8**, in contrast to its epimer **7**, is practically insoluble at room temperature in many solvents such as methanol, acetone and THF; **7** in fact was completely recovered as a pure compound by treating the reaction mixture with EtOAc. Compound **7** was then equilibrated by base to partially give the stereoisomer **9** (a 2 : 1 mixture in favour of **7**), with a *cis* arrangement of the β-lactam hydrogens. The equilibrium position between the two epimers, verified also by starting from the *cis* isomer, was slowly reached with Et_3N in CH_2Cl_2, but very rapidly with a stronger base like DBU; in both cases there



Scheme 2 *Reagents and conditions*: i, $Cl_2/TiCl_4$, CH_2Cl_2, −15 °C, 87% (**4** : **5** *ca.* 2 : 3) [or SO_2Cl_2 (instant treatment), 0 °C, to give only **4**, 66%]; ii, $SnCl_2 \cdot 2H_2O$, 1,4-dioxane, reflux, 15 min, 45% (**6** : **2** *ca.* 2 : 1); iii, MCPBA, $CHCl_3$, 25 °C, 3 h, 95% (**7** : **8** *ca.* 1 : 1); iv, DBU, CH_2Cl_2, 25 °C, immediate reaction (**9** : **7** *ca.* 1 : 2); v, PBr_3, CH_2Cl_2, 0 °C, immediate reaction, 52%.



Scheme 3 *Reagents and conditions*: i, MCPBA, $CHCl_3$, 25 °C, 3 h (**10** : **11** *ca*. 9 : 1, 78%; **13** : **14** *ca*. 1 : 1, 84%); ii, DBU, CH_2Cl_2, 25 °C (**2** to **12**, 2 h; **13** : **10**, *ca*. 2:1, immediate reaction); iii, PBr_3, CH_2Cl_2, 0 °C, 10 min, 90%; iv, Cl_2, CH_2Cl_2, −15 °C, 10 min, 70% (**16** : **17** *ca*. 5 : 2)[or SO_2Cl_2 (instant treatment), 0 °C, 60% (**16** : **17** *ca*. 5 : 1)]; v, $SnCl_2{\cdot}2H_2O$, 1,4-dioxane, reflux, 15 min, 47% (**3** : **15** *ca*. 1 : 2).

is no loss of material and the remaining *trans* isomer was quantitatively recovered by chromatography. (1*R*)-Sulfoxide **8**, probably because of its very low solubility even in DMSO, does not seem to undergo equilibration at any observable rate. Finally, reduction of **9** with PBr_3[9] gave the enantiomer **3** of derivative **2** of 7-ADCA as an optically pure compound. As expected, the enantiomers gave equal and opposite CD spectra, thus showing also the stereochemical correctness of the individual reaction steps.[10] It is worth pointing out that the 7-phthalimido group, besides being relatively chemically stable, could play an important role in determining the isomer ratio in the epimerization steps. It is also easily removable,[11] thus giving potential access to pharmacologically useful 7-amidic substitution.

In order to complete the general strategy to the stereochemical manipulation of the cephem nucleus, we have also developed a complementary, which, *mutatis mutandis*, ideally represents the 'mirror image' of the one we have just described (see Scheme 3). Partial epimerization at C-7 was realized by base treatment of the cephalosporin (1*R*)-sulfoxide derivative **10**:[9] **13**, which is the enantiomer of **7**, formed in 65% yield, the remaining 35% being the starting *cis* isomer **10**. More conveniently, complete epimerization at C-7 in **2** occurred by treatment with DBU to give the Δ^2-derivative **12**. Oxidation of **12** to the sulfoxides **13** and **14** was the necessary step in order to obtain retro-isomerization of the double bond to Δ^3. Compound **15**, which is the optical antipode of **6**, was obtained by PBr_3 reduction at the sulfoxide moieties of the two S-1 epimers. According to this procedure, the overall yield from **2** to **15** was practically quantitative.

The enantiomer **16** of the sulfenyl chloride **4** was then obtained (together with **17**) by chlorinolysis (Cl_2 or SO_2Cl_2) of the C-6–S-1 bond. In this case, the presence of $TiCl_4$ was not only unnecessary, but even lowered the reaction rate and yields. Pure **16** then followed the same destiny as its enantiomer **4**: ring closure gave a 2 : 1 mixture of **15** together with, once more, the required enantiomer **3** of the natural cephem derivative **2**. Chromatographic separation afforded **3** as a chemically and optically pure material (overall yield 6.0%, starting from **2**; recovered isomers, to be re-used in the reaction sequel, were not taken into account), which showed identical chemical–physical properties to the sample obtained by the other reaction pathway.[10]

In conclusion, the present work describes a versatile 'circular' strategy, exemplified by two complementary reaction sequences, to convert a natural cephalosporin derivative into its optical antipode. The chemical transformations involved, even if the overall efficiency of the routes is low due to the yields of some stages being poor, appear significative in the cephalosporin chemistry context. Along the reaction paths, in fact, all the possible stereoisomers of cephalosporin sulfides and sulfoxides, susceptible of further chemical elaborations, have been encountered.[12]

Funds are from Italian CNR (Consiglio Nazionale delle Ricerche) and the Ministry of University and Scientific and Technological Research. Thanks are due to Dr M. C. Gaudiano for CD spectra.

Novel spiro-polymers with enhanced solubility

Saad Makhseed and Neil B. McKeown*

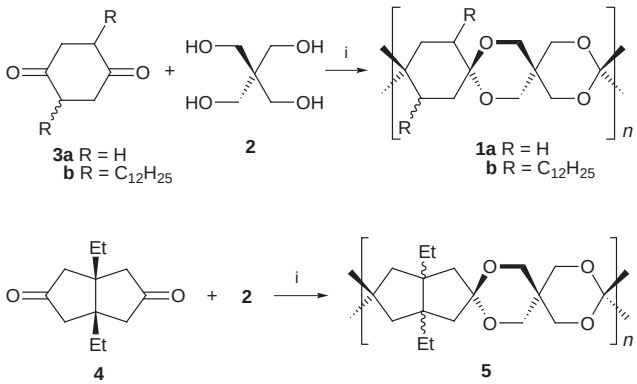
Department of Chemistry, University of Manchester, UK M13 9PL. E-mail: neil.mckeown@man.ac.uk

Received (in Cambridge, UK) 2nd November 1998, Accepted 11th December 1998

Well-defined spiro-polymers which are freely soluble in organic solvents can be prepared from the ketal-forming reaction between pentaerythritol and either a diketone bearing alkyl solubilising groups or a diketone which generates a contorted polymeric structure.

Ladder polymers are of interest as high performance materials due to their great rigidity, lack of rotational freedom and high thermal stability which arises because mass deterioration requires the scission of two covalent bonds within the same cyclic subunit.[1] However, they are difficult materials to make due to the need for an efficient polymerisation reaction that forms cyclic inter-monomer linkages. Spiro-polymers are a subclass of ladder polymers in which adjacent rings share a common atom.[1,2] Spiro-polyketals such as **1a**, readily prepared from pentaerythritol **2** and cyclohexane-1,4-dione **3a** (Scheme 1), are particularly attractive synthetic targets because the two bonds of the cyclic ketal-linking group form almost simultaneously during polymerisation. In addition, ketal formation is an efficient equilibrium process which can be driven to completion by the removal of water. Unfortunately, the regular structure of **1a** results in a highly crystalline material which has poor solubility in all solvents, including refluxing toluene. This leads to the formation of low molar mass products due to precipitation at an early stage of the polymerisation and prohibits molecular mass determination of the resulting material.[3,4] In addition, the possibility that **1a** is cross-linked by non-cyclic acetal linkages cannot be disproved by solution-based structural characterisation.

Our interests lie in the utilisation of spiro-polyketals as molecular-scale scaffolding for the assembly of rigid polymeric networks. However, soluble materials are required in order to assess the efficiency of ketal formation for macromolecule construction and to facilitate solution-based molecular mass determination. There are two common strategies for the improvement of the solubility of rigid polymers; decorating the polymer with solubilising groups (*e.g.* alkyl groups)[5] or introduction of structural irregularities which reduce the linearity of the polymer.[6] Here we describe the use of both of these approaches for obtaining soluble spiro-polyketals.



Scheme 1 *Reagents and conditions*: i, TsOH, toluene, reflux, 48 h.

The replacement of **3a** with 2,5-didodecylcyclohexane-1,4-dione **3b**, prepared by the base catalysed dialkylation of dimethyl 2,5-dioxocyclohexane-1,4-dicarboxylate followed by ester hydrolysis and decarboxylation,[7] in the spiro-polymerisation with **2** gives **1b** in good yield. This material is soluble in aprotic solvents (*e.g.* THF, CH_2Cl_2) and has ^{1}H and ^{13}C NMR spectra which are consistent with the proposed structure. Analysis using gel permeation chromatography (GPC) of a THF solution of **1b** (Table 1), using a calibration based on polystyrene standards, and NMR end-group analysis indicates only a modest degree of polymerisation ($<DP> \approx 8$–10), however, even this figure represents at least 24 spirocycles per molecule, on average.

It is known that alkyl chains adjacent to the ketone group have an adverse steric effect on ketal formation.[8] Therefore, we sought a diketone which could accommodate alkyl solubilising groups at sites where they would not interfere with ketal formation. The readily prepared 1,5-dialkylbicyclo[3.3.0]-octane-3,7-diones satisfy this criteria. It was found that 1,5-diethylbicyclo[3.3.0]octane-3,7-dione **4**, prepared from dimethyl 3-oxopentane-1,5-dioate and hexane-3,4-dione using the Weiss–Cook reaction,[9,10] undergoes ketalisation with **2** to give polymer **5** in good yield (Scheme 1). Despite the absence of long alkyl solubilising groups, polymer **5** is freely soluble in aprotic organic solvents (*e.g.* toluene, THF, CH_2Cl_2, DMSO). This solubility must arise from the non-linearity of the dione precursor **4** which results in a randomly contorted structure similar to the dynamic random coil configuration adopted by flexible polymers in solution (Fig. 1).

Both GPC and ^{13}C NMR end-group analysis (Table 1) indicates that **5** has a reasonable average molecular mass for a polymer derived from small-scale step-growth polymerisation ($<DP> \approx 28$–30). End groups give rise to clear signals corresponding to the carbonyl group (δ 215), the methylene groups adjacent to the carbonyl (δ 47.2; Fig. 2) and the methylene groups on the terminal pentaerythritol (δ 70.1). Calculation of average molecular mass was based on comparing the sum of the intensities of the two types of end-group methylene carbon signals with the combined intensity of the two types of methylene units within the main body of the polymer at δ 43.0–45.5 (Fig. 2) and 63.5–65.0. The apparent

Table 1 Yield, molecular mass data and glass transition temperatures for polymers **1b** and **5**. Molecular mass data is a range obtained for several samples

Polymer	Yield (%)	$<M_n>$ (gpc)	$<M_w>/<M_n>$	$<M_n>$ (NMR)	T_g/°C
1b	85	(5–6) × 10^3	1.6–1.8	(4–5) × 10^3	45[a]
5	88	(12–14) × 10^3	1.8–2.5	(8–9) × 10^3	180

[a] Sample appears to be partially crystalline (m.p. = 120 °C).

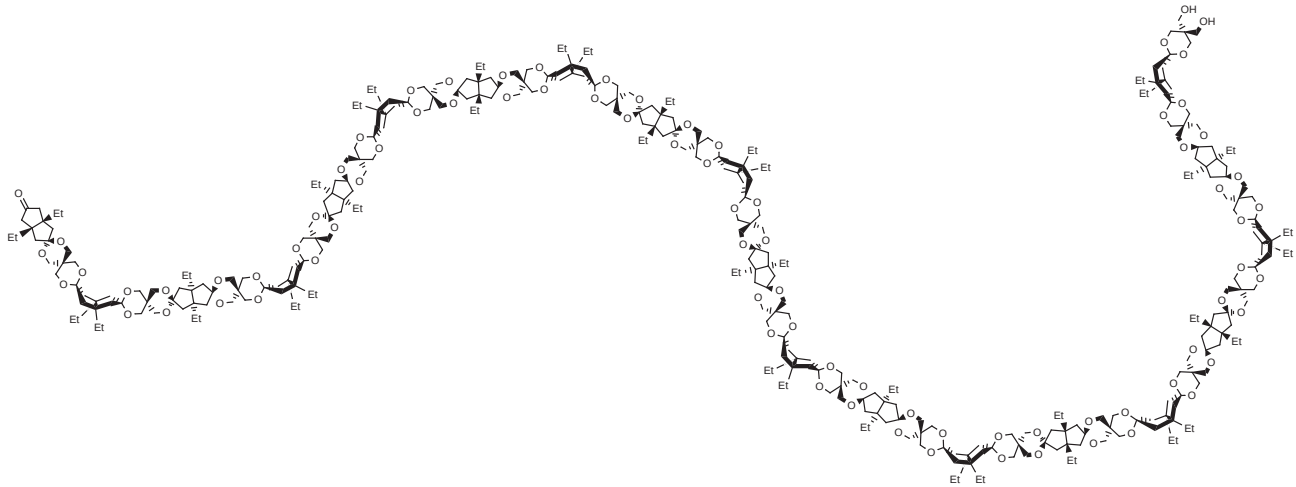


Fig. 1 A two-dimensional representation of the contorted configuration of polyketal **5** resulting from the bent shape of diketone **4**.

overestimation of the molecular mass by GPC, with respect to the absolute value estimated from end-group analysis, is attributable to the greater hydrodynamic volume per unit mass of rigid polymer **5** as compared to the polystyrene standards used for calibration. The observation of both ketone and alcohol end-groups in the ^{13}C NMR spectrum suggests that reaction conditions (*e.g.* higher concentration, longer reaction time) could be found for obtaining polymer **5** with greater molecular mass.

The irregular structure and low flexibility of polymer **5** results in it being a glassy solid with a high glass transition temperature (Table 1). Thermogravimetric analysis indicates that this material is stable up to 280 °C and it appears indefinitely stable in the solid phase but, unless suitable precautions are taken, it possesses only limited stability in solution towards hydrolysis. This study confirms that spiropolymers of reasonable molecular mass can be achieved by ketal formation. In particular, the use of unhindered but non-linear diketones such as **4** gives well-defined (*i.e.* not cross-linked) soluble polyketals which possess an unusual combination of rigidity and structural irregularity.

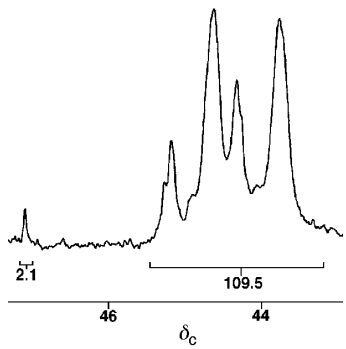

Fig. 2 Detail from the ^{13}C NMR spectrum of polyketal **5** showing the signal due to the methylene group adjacent to the terminal carbonyl (δ 47.2) and the methylene units derived from diketone **4** in the main body of the polymer (δ 43.0–45.5). Average molecular mass calculations used the stated intensities of these peaks together with those derived from the terminal pentaerythritol methylene signal (δ 70.1) and another well-defined group of signals at δ 63.5–65.0 from the pentaerythritol methylene signals in the main body of the polymer.

We thank Kuwait University for the provision of a studentship (S. M.).

Addition of nucleophiles to electron-deficient alkenes: structural studies on the incipient reaction and the zwitterionic intermediate

Paul C. Bell and John D. Wallis*

Chemical Laboratory, School of Physical Sciences, University of Kent, Canterbury, UK CT2 7NH. E-mail: jdw@ukc.ac.uk

Received (in Liverpool, UK) 2nd November 1998, Accepted 1st December 1998

Three distinct interactions between a Me_2N group and an electron-deficient alkene located in the *peri* positions of a naphthalene ring comprise an almost complete cyclisation, an incipient reaction, and a less favourable orientation of the nitrogen lone pair with respect to the alkene, which can be related to the electronic characteristics of the alkene substituents; the cyclised material is zwitterionic and is composed of the enolate of a β-dicarboxylic diester and a trialkylarylammonium cation.

Insight into bond forming and bond breaking processes in chemical reactions have been gained by analysing the geometries of interaction between pairs of functional groups which have been measured by X-ray diffraction.[1] Most notably, a reaction coordinate for the addition of a nucleophile to a carbonyl group was constructed from the structures of a range of molecules in which a tertiary amino group and a carbonyl group were held in close proximity.[2–4] Kirby and Jones studied the spontaneous cleavage of tetrahydropyranyl acetals and glucosides, and were able to show correlations between the length of the exocyclic C–O bond and reactivity.[5–7] Similar studies have been made on the addition of nucleophiles to triple bonds, notably nitriles[8–10] and alkynes.[11–13] The addition of a nucleophile to an electron-deficient carbon–carbon double bond is a very important reaction in organic synthesis. To begin a study of the correlation between the bond formation and bond breaking processes in this type of reaction, we have measured the interactions between a Me_2N group and different electron-deficient alkenes located in the *peri* positions of naphthalenes **1**–**3** by X-ray crystallography.† The quite distinct molecular

structures of these three compounds are presented in Fig. 1, and selected details of their molecular geometries are given in Table 1.

Results for compound **1** show that the nucleophilic addition of the Me_2N group to the alkene is almost complete, and that the structure lies much nearer to the zwitterionic formulation **5** in which a trialkylarylammonium cation and the enolate of a β-dicarboxylic diester coexist. The hexamethylguanidinium salt of the enolate of dimethyl ethylmalonate, **6**, has been reported previously.[14] In the zwitterion **5** the carbon–nitrogen bond [1.651(3) Å] is nearly fully formed, and the π bond of the alkene is almost completely broken [1.471(3) Å, *cf.* 1.510(6) Å in **6**]. The newly formed five-membered ring adopts a half chair conformation with the largest torsion angle [17.1(2)°] about the new N(1)–C(11) bond so that the *N*-methyl groups are displaced by different amounts from the naphthalene plane [C(18), −1.512(3); C(19), 0.860(3) Å].

In contrast, structures **2** and **3** are closer to their uncyclised formulations. However, there is a stronger interaction between the functional groups in **2** than in **3** as indicated by the shorter N(1)···C(11) distance, the lengthening of the alkene bond, and the orientation and in-plane displacement of the Me_2N group into a more favourable position for bond formation with the alkene. Thus, the N(1)···C(11) separations in **2** and **3** [2.413(2) and 2.679(2) Å respectively] are *ca*. 0.8 and 0.5 Å within the sum of the van der Waals radii for these atoms, and the alkene bond is lengthened to 1.354(2) Å in **2** whereas it is only 1.341(2) Å in **3**. Both substituents in **3** are displaced in the plane of the aromatic system in the same sense by *ca*. 2° away from their idealised positions; the Me_2N group is moved towards the other *peri* substituent, which has moved away. In comparison to this, the structure of **2** shows an increase of a further 2° in the displacement of the Me_2N group towards the alkene, but the alkene is displaced by 2° towards the Me_2N group, indicative of a larger attraction between these groups. The larger N(1)···C(11) separation in **3** is partly attained by an increase in the exocyclic

Table 1 Selected molecular geometry for **2**, **3** and **5** presented in order of decreasing attractive interaction between the *peri* groups

	x/Å	*y*/Å	α (°)	β (°)	γ (°)	δ (°)
5	1.651(3)	1.471(3)	128.6(2)	108.8(2)	113.3(2)	109.9(2)
2	2.413(2)	1.354(2)	124.3(2)	115.9(1)	120.4(1)	120.2(1)
3	2.679(2)	1.341(2)	122.3(2)	118.3(2)	123.5(2)	122.5(2)

	ε (°)	θ (°)	C(18)–N(1)–C(1)–C(2)	C(19)–N(1)–C(1)–C(2)	Naphthalene–alkene angle[a]
5	131.4(2)	114.9(2)	−71.9(2)	49.5(3)	65.5(1)
3	120.3(1)	112.5(1)	−81.5(2)	49.2(2)	64.0(2)
2	117.6(2)	118.0(1)	−105.0(2)	25.9(3)	54.4(1)

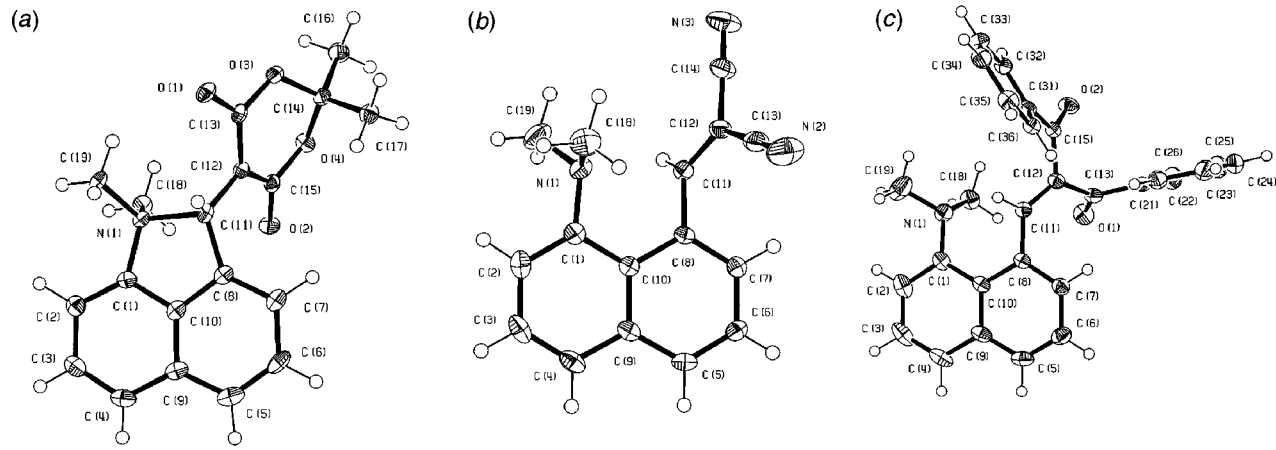

Fig. 1 The structures of molecules (*a*) **5**, (*b*) **2** and (*c*) **3** with atomic displacement parameters drawn at the 50% level.

bond angle at C(10) by *ca*. 3° in the naphthalene system. Furthermore, while the Me_2N group in **3** is oriented such that the axis of its lone pair would lie at 30° to the N(1)···C(11) vector, and thus poorly aligned with the α-C atom of the alkene, in **2** the alignment is considerably better, with the axis of the lone pair lying only 13° away from the N(1)···C(11) vector. Indeed, the orientation of the Me_2N group in **2** is very similar to that in the cyclised material **5**. There is evidence in **2** for a slight pyramidalisation at the alkene's α-C atom, C(11), where this atom deviates from the plane of its three neighbours by 0.087(7) Å towards the amino nitrogen atom. The failure of the nitrogen lone pair to be attracted to the alkene in **3** is due to the reduced conjugation of the carbonyl groups with the double bond. The torsion angles between the carbonyl groups and the alkene bond are 52.2(3) and –146.6(2)°. In **2** the cylindrical π-system of the nitrile groups ensure conjugation with the alkene, and compound **5** has cyclised since the carbonyl groups are held in conjugation with the developing carbanionic centre by the dioxane ring. The degrees of interaction between the *peri* groups in the three compounds studied mirror the pK_as of the methylene derivatives used to prepare them from **4**.[15] In contrast, the intrinsic rate constant for the reaction of secondary amines with benzylidene derivatives containing the same electron-attracting β-substituents as structures **1**–**3** is highest for the dinitrile $PhHC{=}C(CN)_2$.[16]

The structure of zwitterion **5** is particularly interesting. The enolate grouping shows an asymmetric geometry with the $^{-}$C(12)–C(13)=O(1) fragment showing a greater degree of enolate character than the $^{-}$C(12)–C(15)=O(2) moiety as indicated by a longer C=O bond [1.236(2) *cf*. 1.224(2) Å] and shorter C–C bond [1.409(3) *cf*. 1.428(2) Å]. This higher enolate character may be induced by the formation of a particularly short intermolecular hydrogen bond by O(1) with the naphthalene ring hydrogen atom *ortho* to the positively charged ammonium substituent [O(1)···H(2), 2.20(2) Å, O(1)···H(2)–C(2), 164(2)°]. In addition, each carbonyl oxygen atom makes an intramolecular contact with a methyl hydrogen atom and is involved in further intermolecular contacts with hydrogen atoms (O···C range: 2.38–2.53 Å). Similar contacts were observed between enolate **6** and hexamethylguadinium ions (2.31–2.59 Å) although in this case the enolate geometry was symmetrical [$^{-}$C–C: 1.412 and 1.413, C=O, 1.229 and 1.233 Å).

NMR studies on **2, 3** and **5** dissolved in $CDCl_3$ are consistent with **5** retaining its cyclic zwitterionic structure. The chemical shift for the *N*-methyl groups in **5** (δ 3.37) is *ca*. 0.7 ppm downfield of the corresponding resonances in **2** and **3**, and the shift of the methine hydrogen (δ 7.06) is *ca*. 1.6 ppm upfield of those for the alkenyl hydrogens in **2** and **3**. In the ^{13}C NMR spectrum of **5** the ring sp^3 carbon atom resonates at δ 99.1 and the signal from the carbanionic carbon occurs at δ 69.8. Further work to build up a more detailed picture of the reaction coordinate for nucleophilic addition to an alkene is in progress.

We thank the EPSRC for a studentship, SmithKline Beecham for financial support, the EPSRC mass spectrometry service for data, the EPSRC X-ray crystallography service for three data sets, and the Cambridge Structural Database.[17] We thank Professor R. F. Hudson and Professor A. Williams for helpful discussions.

New insights into the origin of NO_2 in the mechanism of the selective catalytic reduction of NO by propene over alumina

Frederic C. Meunier,* John P. Breen and Julian R. H. Ross

Centre for Environmental Research, University of Limerick, Limerick, Ireland. E-mail: frederic.meunier@ul.ie

Received (in Cambridge, UK) 2nd November 1998, Accepted 24th December 1998

The formation of NO_2 as a reaction intermediate in the selective catalytic reduction of NO by C_3H_6 in the presence of a large excess of O_2 over alumina is shown not to occur through the direct oxidation of NO by O_2.

Selective catalytic reduction (SCR) of NO_x by hydrocarbons has received much attention as a possible means to control the emissions from diesel and lean-burn engines. The work by Burch *et al.* has unveiled many of the features of the NO reduction over Pt-based materials.[1,2] Yet, the mechanisms of SCR reactions over alumina, one of the most active metal oxides for the SCR of NO by hydrocarbons,[3] and alumina promoted by metal oxides such as CoO_x remain unclear.[4] It has been suggested that when using propene as a reductant, the initial step of the SCR reaction is the oxidation of NO by O_2 to form NO_2 which in turn reacts with the reducing agent to form N_2.[5–7] The results of the experiments reported in this paper bring a new insight into the formation of NO_2 over alumina during the propene-SCR of NO, resulting in a necessary re-evaluation of the current theories on the reaction mechanism.

The γ-alumina used in these experiments was supplied by Alcan (AA400, 150 $m^2\ g^{-1}$) and was calcined in air at 923 K for 6 h prior to use. The reactants (NO and C_3H_6) and products of reaction (CO_2, CO, NO_2, N_2O, NH_3) were analysed by FT-IR spectroscopy (7 m path length Foxboro® gas-cell fitted in a Nicolet® 550 FT-IR). No hydrogen cyanide nor any other products were detected in the experiments reported here. The N_2 concentration was calculated during steady state conditions on the basis of a 100% nitrogen balance on the other N-containing products detected. A quartz microreactor (4 mm internal diameter) was used for the catalytic tests, the catalytic bed being held in place by quartz wool plugs. No reaction was observed when the reactants were passed through the reactor in the absence of a catalyst bed. The results reported here were obtained at steady state conditions and were found to be reproducible.

Fig. 1(*a*) shows the NO_2 yield obtained during the oxidation of NO (500 ppm) by O_2 (2.5%) over alumina and Fig. 1(*b*) shows the calculated NO_2 yield obtained at the thermodynamic equilibrium of the reactions described by eqn. (1) as a function of temperature:

$$NO + \tfrac{1}{2}\,O_2 \leftrightarrow NO_2 \qquad (1)$$

As it has often been reported in the literature, the alumina catalyst exhibited very poor activity for the NO oxidation reaction with yields of NO_2 attaining equilibrium conversions only at temperatures above 900 K. Fig 1(*c*) shows the NO yield obtained during the decomposition of NO_2 to $NO + \frac{1}{2}\,O_2$ (the reverse reaction of that discussed above) and Fig. 1(*d*) shows the calculated NO yield obtained at the thermodynamic equilibrium of the same reaction as a function of temperature. The activity of the alumina for the backward reaction of eqn. (1) was somewhat greater than that of the forward reaction but yet again the equilibrium limit was only reached at a temperature of about 900 K.

Fig. 2 shows the propene conversion [Fig. 2(*a*)] and yields of the different N-containing products of the reaction between NO (500 ppm), propene (500 ppm), and O_2 (2.5%) over alumina at 813 K and at varying *W*/*F*s (ratio of catalyst weight to feed flow rate). Fig. 3(*a*) shows the varying molar ratios of NO_2/NO obtained from the results of the experiments shown in Fig. 2. The NO_2/NO ratio at the thermodynamic equilibrium of reaction (1) at 813 K calculated using the initial concentration values of NO and O_2 is shown in Fig. 3(*b*). The conversion of propene [Fig. 2(*a*)] increased with increasing *W*/*F* values, reaching 100% conversion at $W/F = 180$ mg s cm^{-3}. The yield of N_2 [Fig. 2(*b*)] followed a similar trend to that of propene conversion, increasing steadily with increasing *W*/*F* values and then levelling off when all the propene was converted, *i.e.* at

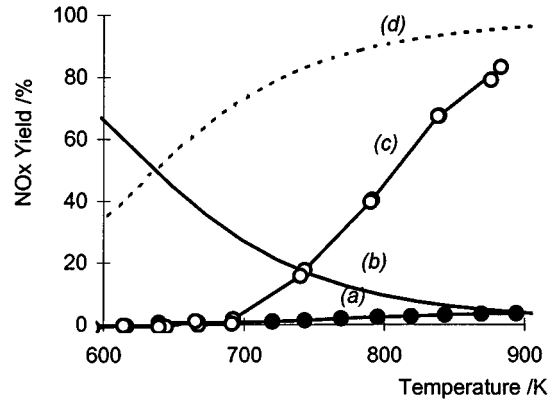

Fig. 1 *(a)* Experimental NO_2 yield (●) obtained during the oxidation of NO over γ-Al_2O_3 and (*b*) NO_2 yield limit (—) associated with the thermodynamic equilibrium of the reaction $NO + \frac{1}{2}\,O_2 \leftrightarrow NO_2$ as function of temperature. *(c)* Experimental NO yield (○) obtained during the decomposition of NO_2 to $NO + \frac{1}{2}\,O_2$ over γ-Al_2O_3 and (*d*) NO yield limit (---) associated with the thermodynamic equilibrium of the reaction $NO + \frac{1}{2}\,O_2 \leftrightarrow NO_2$ as function of temperature. Feed: 500 ppm NO or NO_2 + 2.5% O_2 in Ar, $W/F = 60$ mg s cm^{-3}.

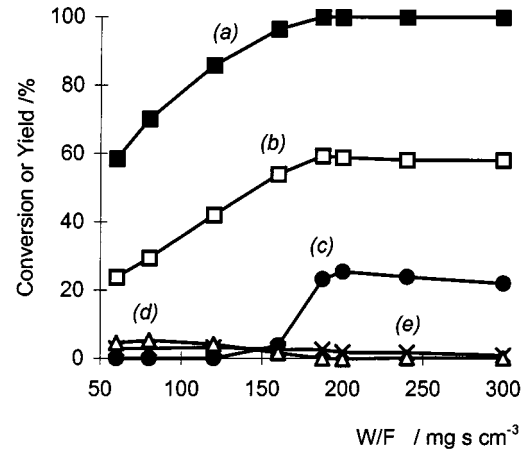

Fig. 2 Selective catalytic reduction of NO using propene over γ-Al_2O_3 at 813 K: (*a*) propene conversion (■), (*b*) N_2 yield (□), (*c*) NO_2 yield (●), (*d*) NH_3 yield (Δ) and (*e*) N_2O yield (×) as a function of the *W*/*F*. Feed: 500 ppm NO + 500 ppm C_3H_6 + 2.5% O_2 in Ar, 200 mg of alumina.

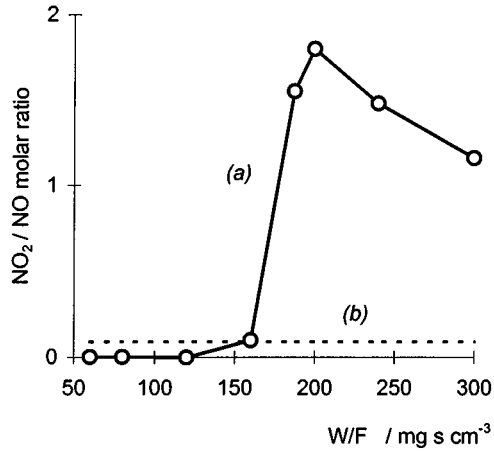

Fig. 3 Selective catalytic reduction of NO using propene over γ-Al_2O_3 at 813 K as a function of the *W*/*F*: NO_2 to NO ratio (*a*) experimental (○) and (*b*) at the thermodynamic equilibrium of the reaction NO + $\frac{1}{2}$ O_2 ↔ NO_2 (---). Feed: 500 ppm NO + 500 ppm C_3H_6 + 2.5% O_2 in Ar, 200 mg of alumina.

W/*F*s greater than 180 mg s cm^{-3}. The striking feature of Fig. 2 is the sharp rise in the production of NO_2 [Fig. 2(*c*)] as soon as the conversion of propene reaches 100%. At propene conversions lower than 95%, the presence of NO_2 was not detected (*i.e.* < 2.5 ppm). Upon completion of the conversion of propene, the NO_2 yield reached a value of approximately 25% (corresponding to 127 ppm of NO_2). With further increase in the values of *W*/*F*, the NO_2 yield gradually decreased. The gradual decrease in the concentration of NO_2 was accompanied by a similar increase in the concentration of NO (not shown in Fig. 2) while the concentrations of all the other products of reaction were either steady (N_2) or decreased (N_2O and NH_3). Interestingly, Fig. 3 shows that in the region of 100% propene conversion (*W*/*F* ≥ 180 mg s cm^{-3}), the experimental values of the molar ratios of NO_2/NO were greater than 1. Hence, these values were more than 10 times greater than the value of the thermodynamic equilibrium ratio of NO_2/NO (*i.e.* 0.09) calculated at the same temperature. The same results were obtained whether the *W*/*F* was varied with increasing or decreasing values.

Further experiments carried out using the same reactant concentrations, at constant *W*/*F* (60 mg s cm^{-3}) and varying temperature also showed that, at the temperature of 100% conversion of propene, there was a sharp increase in the yield of NO_2. At 843 K, propene conversion was not complete and NO_2 was not detected; however, at 873 K propene was fully converted and NO_2 yields of 30% were obtained (this value again being well in excess of levels obtained from equilibrium calculations). The sharp increase in the NO_2/NO ratio at the temperature of 100% conversion of propene was the same regardless of whether the reaction temperatures were increased or decreased.

It is evident from the results of experiments described in this paper that NO_2 could not be observed when propene was present in the product streams. This can be explained by the work of a number of different authors,[4,6,7] who have shown that alumina is very active for the reduction of NO_2 by propene to form N_2. However, upon complete combustion of the propene, the NO_2 could not be reduced and was therefore detected in the reactor effluent. Fig. 2 and 3 show that the maximum NO_2/NO ratio occurred at a *W*/*F* value of 200 mg s cm^{-3}, and at higher *W*/*F*s the ratio decreased towards the equilibrium ratio. This was probably due to the slow decomposition of the NO_2 to NO and O_2 (in the absence of propene) which Fig. 1(*c*) shows can occur over the alumina catalyst. Surprisingly, the catalytic data reported on alumina in this paper and the corresponding thermodynamic calculations show that most of the NO_2 observed upon completion of propene conversion during the SCR of NO did not arise from the direct oxidation of NO by O_2 [eqn. (1)]. A mechanism involving the direct reaction of NO, O_2 and NO_2 could not exceed thermodynamic limits. Therefore, the current model of the alkene-SCR reaction over alumina-based catalysts needs to be re-evaluated.[5–7]

At least two alternative solutions could be proposed to explain the formation of the high concentrations of NO_2 observed. First, a mechanism involving consecutive steps could occur in which a nitro or a nitrite compound, *e.g.* nitromethane CH_3NO_2, is formed along with CO (or CO_2) from the reaction of propene, O_2 and NO [eqn. (2-1)]. Organic nitro or nitrite species have often been quoted as possible intermediates of SCR reactions.[8] The subsequent oxidation of this organo-NO_x species would yield NO_2 [eqn. (2-2)]

$$C_3H_6 + \tfrac{3}{2}\,O_2 + 2\,NO \rightarrow 2\,CH_3NO_2 + CO \qquad (2\text{-}1)$$

$$CH_3NO_2 + \tfrac{7}{4}\,O_2 \rightarrow NO_2 + CO_2 + \tfrac{3}{2}\,H_2O \qquad (2\text{-}2)$$

Overall, eqn. (2-1) and (2-2) combine to give:

$$C_3H_6 + 5\,O_2 + 2\,NO \rightarrow 2\,NO_2 + 2\,CO_2 + CO + 3\,H_2O \qquad (2\text{-}3)$$

This mechanism is supported by the fact that thermodynamic calculations show that the reactions given by eqn. (2-1) and (2-2) are strongly exergonic over the temperature range investigated here (*e.g.* $\Delta G°_{813K}$ = −298 kJ mol^{-1} and −734 kJ mol^{-1}, respectively). Regarding a second possible mechanism, the oxygen needed to form the NO_2 could be supplied by another molecule of NO, *i.e.* in a disproportionation reaction, and not by the O_2. An example of mechanism of SCR of NO involving a disproportionation of NO to N_2 and NO_2 was proposed by Smits and Iwasawa .[9] These authors suggested that one of the roles of the hydrocarbon, NO and O_2 was to form a radical molecule R* (*e.g.* 1-nitro-*sec*-propyl) which in turn could propagate the disproportionation reaction:

$$4\,NO\ (+R^*) \leftrightarrow N_2 + 2\,NO_2\ (+R^*) \qquad (3)$$

The thermodynamics of the disproportionation reaction described by eqn. (3) essentially favour the right hand-side of the equation at temperatures below 600 °C (and are independent of the concentration of O_2) and therefore this mechanism could be responsible for the high yields of NO_2 observed. Hence, one of the possible role of the alumina (a known mild oxidiser) during alkene-SCR reactions would be to allow the formation of organic-nitro or nitrite species [eqn. (2)] and/or the formation of a hydrocarbon-based propagator [eqn. (3)]. Experiments using $N^{18}O$ and $^{16}O_2$ are planned and should give some evidence of the origin of the oxygen in NO_2 (*i.e.* by observing either $N^{18}O^{18}O$ or $N^{18}O^{16}O$) to determine which of the two models proposed is the most likely.

The conclusion of this work is that the formation of NO_2 during the propene-SCR of NO over alumina is not obtained by direct oxidation of NO by O_2 but that a more complex mechanism has to be considered.

Part of this work was funded by the European Community, through the Environment and Climate Programme, Contracts E5V5-CT94 and ENV4-CT97-0658.

Hybrid P-chiral diphosphines for asymmetric hydrogenation

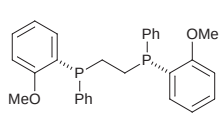
Duncan Carmichael, Henri Doucet and John M. Brown*

Dyson Perrins Laboratory, South Parks Road, Oxford, UK OX1 3QY. E-mail: bjm@ermine.ox.ac.uk

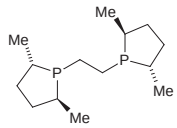
Received (in Liverpool, UK) 6th November 1998, Accepted 8th December 1998

A family of diphosphine ligands has been prepared by Michael addition of *o*-anisylphenyl phosphide to diethyl vinylphosphonate and elaboration to phospholanes based on hexane-2,5-diol or mannitol; some preliminary results of Rh-complex catalysed hydrogenations are reported.

The scope of asymmetric hydrogenation of alkenes has been gradually extended both in reactant structure and catalyst efficiency over many years.[1] For rhodium catalysis, the early work of the Monsanto group using the P-chiral diphosphine DIPAMP has provided an enduring standard.[2] Only phospholane ligands in the DUPHOS and BPE series have exhibited superior enantioselectivity over a broad front.[3]



1 (*R*,*R*)-DIPAMP

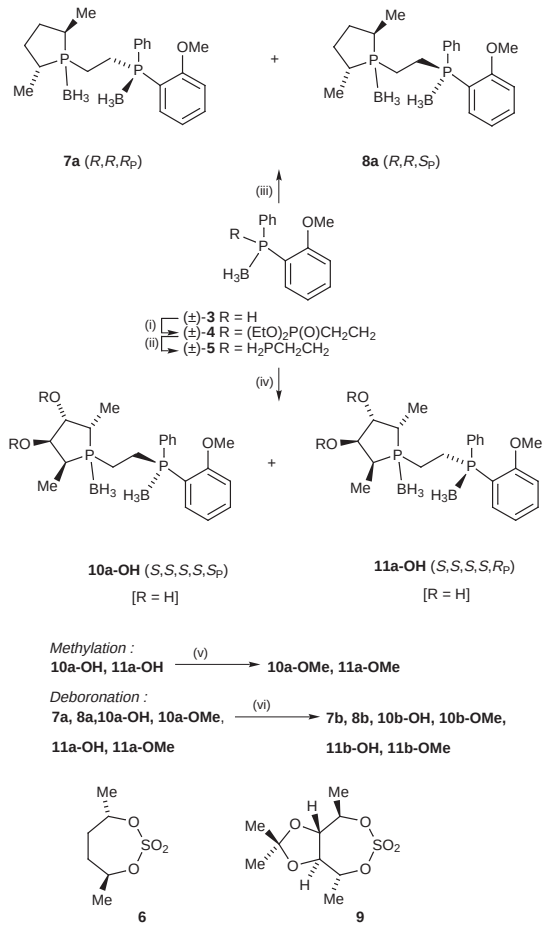


2 (*S*,*S*)-MeBPE

It is a commonly held belief that C_2 symmetric diphosphine (or diol or diamine) ligands are endowed with superior properties in catalysis, their attractiveness augmented by ease of synthesis.[4] An alternative view, stated most clearly by Achiwa and co-workers,[5] is that intermediates in a catalytic cycle lack the intrinsic symmetry of the ligand and consequently the two chelating atoms must fulfil different roles. The implication is that lack of symmetry may be a positive advantage in an appropriate case. In previous work we have endeavoured to separate the functions of the two chelating phosphorus atoms in asymmetric hydrogenation.[6] The synthesis of a new class of unsymmetrical ligands permits that approach to be extended further.

Our basic idea was to combine the phosphorus moieties of DIPAMP **1** and BPE **2** in a single ligand. The synthesis is based on conjugate addition of racemic phosphineborane **3**[7] to diethyl vinylphosphonate (Scheme 1).[8] Alane reduction of the product **4** gave the primary phosphineborane **5**. Following deboronation, stepwise double nucleophilic displacement on the cyclic sulfate **6**[9] *via* BuLi deprotonation permitted synthesis of the target compounds **7a** and **8a** as a diastereomeric mixture in good yield. These were separated by MPLC, with some difficulty (EtOAc–pentane). The analogous compounds **10a-OH** and **11a-OH**, prepared from the mannitol derivative **9**,[10] proved much more amenable to chromatographic separation, and subsequently afforded the pure methyl ethers **10a-OMe** and **11a-OMe**.[11] The absolute configuration of product boranes was established by CD in comparison with that of the diborane from *(S,S)*-DIPAMP, the phospholane part being essentially CD transparent in the 240-400 nm region. This set of procedures gives access to a family of unsymmetrical 1,2-phosphinoethane ligands as their stable diborane complexes.[12]

In most cases hydrogenation experiments were carried out by *in situ* deboronation[13] and reaction with $(COD)_2RhBF_4$ to generate the catalyst. In initial studies of the hydrogenation of simple dehydroamino acids and esters, two questions were posed: Is the enantioselectivity governed predominantly by one of the two phosphorus nuclei in the ligand? Does the alternative



Scheme 1 *Reagents*: (i) CH_2=CHP(O)$(OEt)_2$, KOBu^t, THF, 95%; (ii) DABCO, C_7H_8; AlH_3, Et_2O; H_2O then CaH_2; (iii) BuLi, THF, −78 °C then **6** then further BuLi; Me_2S•BH_3, 45% overall; (iv) BuLi, −78 °C then **9**; then repeat; Me_2S•BH_3, 30% isolated overall for (ii), (iv); (v) NaH, MeI, THF, ⩾80%; (vi) HBF_4•OMe_2 then $NaHCO_3$.

match or mismatch of arylphosphine and phospholane chirality have a significant effect on enantioselectivity? The results recorded in Table 1 provide answers to these points but also some surprises. A broad conclusion from these and parallel results is that the 'matched' ligand[14] gives significantly higher ees than the 'mismatched' ligand, and also that the phospholane configuration is dominant in defining the stereochemical course of hydrogenation, but to an extent that depends on the substrate. In the case of the bulkier pivalamide **13** and benzamide **14**, the configuration of the arylphosphine part plays a very minor role. In comparison to the mannitol derived ligands **11**, the simple phospholanes **7b** and **8b** gave significantly inferior results in these and related cases and were thus investigated in less detail.

Further results of interest came from a study of the itaconate esters and half-esters recorded in Table 2. Here the mismatched diastereomers of ligand **10b** gave poor ees and are not included. For the 1-substituted monoester **15**, the hydroxy ligand **11b-OH** gives a superior ee to its methyl ether. The reverse is true for the 3-substituted monoester **16**, where the methyl ether **11b-OMe**

Table 1

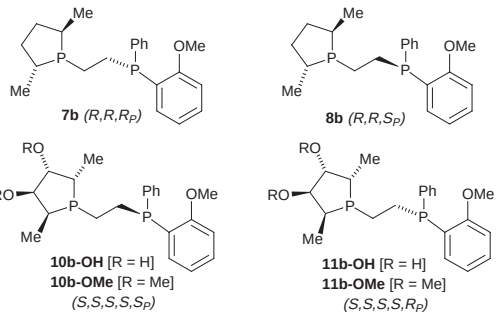
	10b-OH	72 *S*
	11b-OH	**90** *S*[a]

Conditions: substrate : catalyst 100 : 1, $(COD)_2RhBF_4$ as precursor ($HBF_4{\cdot}OMe_2$ deboronation *in situ*), 1.3 bar, MeOH, 1–3 h. [a] TfO^- instead of BF_4^-.



provides the product of higher enantioselectivity. Changing the solvent from MeOH to CH_2Cl_2 led to inferior rates and selectivities in both these cases.

These preliminary results indicate that, contrary to expectation, the enantioselectivity is sensitive to remote oxygen substituents in the phospholane ring. Inspection of molecular models indicates that the MeO- or HO- groups are axial in the 5-membered ring of the phospholane, and in the vicinity of substituents on the coordinated alkene. Hence the opportunity exists for cooperative association through H-bonding between ligand and coordinated reactant.[15] The combination of good enantioselectivities in simple unoptimised reactions make this an attractive series of ligands for further investigation with the potential for rational structural alteration, and the impetus of additional synthetic power and mechanistic information arising from the distinct role of the two ligating atoms. The results nicely complement those of Börner and co-workers on asymmetric hydrogenation with mannitol-derived diphospholanes.[16]

Table 2

Perfluoroheptadecan-9-one: a selective and reusable catalyst for epoxidations with hydrogen peroxide

Michiel C. A. van Vliet, Isabel W. C. E. Arends and Roger A. Sheldon*

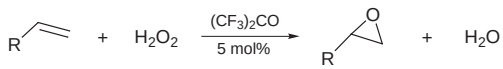
Laboratory of Organic Chemistry and Catalysis, Delft University of Technology, Julianalaan 136, 2628 BL Delft, The Netherlands.E-Mail: secretariat-ock@stm.tudelft.nl

Received (in Cambridge, UK) 25th November 1998, Accepted 16th December 1998

Perfluoroheptadecan-9-one is a selective and mild catalyst for the epoxidation of a wide variety of alkenes with hydrogen peroxide; after the reaction the catalyst can be easily recovered and reused without noticable decomposition.

Following the seminal publication of Horváth and Rábai[1] in 1994 there has been increasing interest in the concept of fluorous biphasic catalysis.[2] The use of catalysts soluble in the fluorous phase facilitates catalyst separation from substrate and products which are soluble in a second (*e.g.* hydrocarbon) phase. Attachment of long perfluoroalkyl groups ('fluorous ponytails') to *e.g.* phosphine ligands, renders metal complexes soluble in fluorocarbons and insoluble in most organic solvents. In most cases catalytic activity is preserved only when the perfluoroalkyl group is not directly attached to the ligand but is separated by a spacer, mostly a $–CH_2CH_2–$ group.[2] In this way the electronic properties of the ligand are not significantly affected by the strongly electron-withdrawing perfluoroalkyl moiety.

A few examples of the application of fluorous biphasic chemistry to catalytic oxidations have been reported.[3] In all the reported cases the unique electron-withdrawing properties of the perfluoroalkyl group were not exploited. On the other hand, the use of hexafluoroacetone as a mild and selective catalyst for the epoxidation of alkenes with highly concentrated hydrogen peroxide (Scheme 1) has been known for more than 25 years.[4]



Scheme 1

Although rates are rather low, the reaction proceeds under very mild conditions and affords very acid-sensitive epoxides in high yields. A major disadvantage, however, is the high volatility of hexafluoroacetone and its application at reflux temperature (80 °C) requires a cryogenic condensor to avoid loss of the catalyst. Our approach to improve this catalyst was to replace the trifluoromethyl groups by larger perfluoroalkyl groups. The advantages are clear: the catalyst is less volatile† and the use of long perfluoroalkyl groups render it highly soluble in a fluorous phase and sparingly soluble in common organic solvents.

As is shown in Table 1 perfluoroheptadecan-9-one[5] was *ca.* four times as active as hexafluoroacetone in the epoxidation of cyclooctene with anhydrous H_2O_2[6] in refluxing EtOAc. Screening of several solvents revealed that polar, non-basic solvents, such as halogenated hydrocarbons and trifluoroethanol, were superior. Perfluoroheptadecan-9-one was only sparingly soluble in halogenated hydrocarbons. When 5 mol% was used it did not dissolve completely even in boiling 1,2-dichloroethane. Addition of 10 vol% of a cosolvent, *e.g.* EtOH or EtOAc, increased the solubility of the catalyst, resulting in a higher reaction rate. In this case the two requirements, anhydrous hydrogen peroxide and the need for a cosolvent, could be met by using hydrogen peroxide in EtOAc, easily prepared by azeotropic drying.[6]

Table 2 shows the results for epoxidation of several alkenes catalyzed by perfluoroheptadecan-9-one in refluxing 1,2-dichloroethane. Most epoxides are obtained in excellent yields, except for extremely acid-sensitive epoxides like camphene

Table 1 Epoxidation of cyclooctene with anhydrous H_2O_2 in EtOAc catalysed by perfluoroketones[a]

Catalyst	Initial rate mol mol^{-1} h^{-1}	Yield (%)[b]

Methylenecyclohexane[d]	47	0.5	62
2-Methylundec-1-ene[d]	13	2	63
Dec-1-ene[d]	1.9	18	57

[a] Conditions: 5 mmol alkene, 1 mmol diglyme (internal standard), 0.25 mmol perfluoroheptadecan-9-one (5 mol%), 10 mmol H_2O_2 in 5 ml trifluoroethanol. Reflux under N_2. Analysis by GC. [b] 5 mol% of recovered catalyst was used. [c] No catalyst was added. [d] 5 mol% of Na_2HPO_4 was added.

oxide and α-pinene oxide. These epoxides can be obtained in moderate yields by buffering the reaction mixture with a small amount of base (Na_2HPO_4).

Simple cooling of the reaction mixture in an ice-bath (0 °C) gave crystallisation of the catalyst. Filtration and washing with a small amount of cold solvent gave the pure catalyst in about 80% yield. Quantitative GC measurements showed that the catalyst was not decomposed under the reaction conditions and was completely removed from the reaction mixture after filtration.‡ An interrupted catalytic experiment§ showed that no catalytically active material was present in the filtrate. A catalytic experiment on a larger scale (1 g of catalyst) gave a recovery of the catalyst of 92% after cooling to 0 °C and filtration. The recovered catalyst was still active in epoxidation with the same rates and yield.

The reaction could also be performed with 60% aqueous hydrogen peroxide in boiling trifluoroethanol. This solvent is known to be an excellent solvent in combination with aqueous hydrogen peroxide.[7] Table 3 shows the results for the epoxidation of several alkenes catalysed by perfluoroheptadecan-9-one in boiling trifluoroethanol. The yields are moderate to high, but the formation of acid-sensitive epoxides is only possible when the reaction medium is buffered by a phosphate buffer (*e.g.* 5 mol% of Na_2HPO_4). In this solvent simple cooling of the reaction mixture also resulted in crystallisation of the catalyst, but the recovery was generally lower than in dichloroethane. GC measurements indicated that a part of the catalyst remained dissolved in the reaction mixture after filtration.

We are currently investigating the scope of perfluoro ketones as catalysts for oxidations with hydrogen peroxide.

Notes and references

† Hexafluoroacetone is a gas. Perfluoroheptadecan-9-one is a solid with a melting point of 110 °C and an atmospheric boiling point of about 170 °C.

‡ The *ca.* 20% loss of the catalyst is attributed to losses incurred during sampling and mechanical losses associated with the small scale of the reactions (200 mg of catalyst).

§ A standard catalytic experiment was interrupted by cooling to 0 °C at 70% conversion. The catalyst was removed by filtration. The filtrate was again heated under reflux. The reaction proceeded but with a rate about 30 times lower; comparable to the blank reaction.

Highly efficient oxidation of alcohols and aromatic compounds catalysed by the Ru-Co-Al hydrotalcite in the presence of molecular oxygen

Tsuyoshi Matsushita, Kohki Ebitani and Kiyotomi Kaneda*

Department of Chemical Science and Engineering, Graduate School of Engineering Science, Osaka University, 1-3 Machikaneyama, Toyonaka, Osaka 560-8531, Japan. E-mail: kaneda@cheng.es.osaka-u.ac.jp

Received (in Cambridge, UK) 20th November 1998, Accepted 15th December 1998

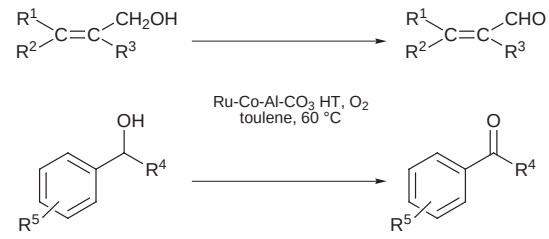
The ruthenium hydrotalcite having cobalt cations, Ru-Co-Al-CO_3 HT, is an effective heterogeneous catalyst for the oxidation of various kinds of alcohols in the presence of molecular oxygen.

From the standpoints of atom economy and environmental friendliness,[1,2] much attention has been paid to the development of selective oxidations catalysed by metal compounds using molecular oxygen as oxidant.[3–6] Hydrotalcites of layered mineral materials consist of cationic Brucite layers separated by layers of anionic species.[7] Changing the element ratios in the Brucite layer and selection of different anionic species enables tuning of the surface basicity.[8] Additionally, various metal elements can be introduced into the Brucite layer *via* the isomorphic substitution of Mg^{II} or Al^{III} cations at the octahedral sites, which are expected to be the active sites of the catalysts.[3] Thus, the interaction of introduced metal cations (M^1) with other cations (M^2) through M^1–O–M^2 bonds would lead to unique catalytic reactions using the functionalised hydrotalcites. Here, we have designed a highly active catalyst of the hydrotalcite containing Ru and Co cations for the oxidation of various alcohols and hydrocarbons in the presence of molecular oxygen. This heterogeneous catalyst has the advantages of using molecular oxygen and a simple work-up procedure over other homogeneous oxidizing reagents.[1] Furthermore, this hydrotalcite is reusable without appreciable loss of activity and selectivity for the above oxidation.

Various Ru hydrotalcites having divalent metal cations M^{II} in place of Mg^{II} ($Ru:M^{II}:Al = 0.3:3.0:1.0$) were prepared according to a modified version of a procedure in the literature.[7] A representative example is for the hydrotalcite having cobalt, aluminum, and ruthenium in the Brucite layer and CO_3 anions in the interlayer (Ru-Co-Al-CO_3 HT). A mixture of $RuCl_3{\cdot}3H_2O$ (1.53 mmol), $CoCl_2{\cdot}6H_2O$ (15.3 mmol) and $AlCl_3{\cdot}6H_2O$ (5.10 mmol) were dissolved in distilled water (10 ml). To an aqueous solution of Na_2CO_3 (13.3 mmol) and NaOH (46.4 mmol) was slowly added the above solution, and then the resulting mixture was heated at 65 °C for 18 h with stirring. The obtained slurry was cooled to room temperature and filtered, washed with distilled water and dried at 110 °C for 12 h, yielding 2.05 g of powder. The structure of the powder was confirmed by its X-ray diffraction pattern, and the basal spacing was estimated to be 7.9 Å, which is similar to that of the Ru–Mg–Al–CO_3 HT (7.92 Å); calc. for Ru-Co-Al-CO_3 HT ($Ru:Co:Al = 0.3:3.0:1.0$): Co, 20.1; Al, 7.4; Ru, 7.0%. Found: Co, 19.5; Al, 7.4; Ru, 7.3%. X-Ray photon spectroscopy (XPS) for the Ru-Co-Al-CO_3 HT: Co $2p_{3/2}$ = 780.6 eV, FWHM = 3.1 eV; Ru $3d_{5/2}$ = 282.7 eV, FWHM = 2.0 eV. XPS for the Ru-Mg-Al-CO_3 HT: Ru $3d_{5/2}$ = 281.7 eV, FWHM = 2.5 eV. The XPS peak positions are refered to Al_{1s} at 73.7 eV].

A typical example for the oxidation of alcohols is as follows (Scheme 1). Into a reaction vessel with a reflux condensor were placed cinnamyl alcohol (0.80 g, 6.0 mmol), the Ru-Co-Al-CO_3 HT (0.90 g) and toluene (15 ml). The resulting mixture was stirred at 60 °C under an O_2 atmosphere. After 40 min, the hydrotalcite was separated by filtration. GC analysis of the filtrate showed a quantitative yield of cinnamaldehyde. Removal of the solvent under reduced pressure was followed by column chromatography on silica to yield cinnamaldehyde (0.707 g, 89%). Isolated hydrotalcites were washed with aqueous 10% Na_2CO_3 (30 ml) and water, and could be reused without appreciable loss of activity for the above oxidation; the first, second and third runs of the experiment using the spent hydrotalcites gave cinnamaldehyde with > 92% GC yield.

Ru hydrotalcites having divalent metal cations in place of Mg^{II} were examined as catalysts for the oxidation of cinnamyl alcohol in the presence of molecular oxygen, as shown in Table 1. Generally, cinnamaldehyde is the main product under the



Scheme 1

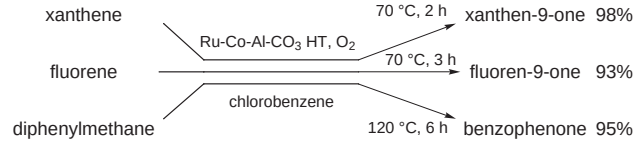
13			7 h	99	91
14			2 h	100	97 (82)

[a] Reaction conditions: substrate (2 mmol), Ru-Co-Al-CO_3HT (0.3 g), toluene (5 ml), 60 °C, O_2 atmosphere. [b] Yields of aldehydes and ketones were determined by GC analysis using internal standards, based on alcohols. [c] Values in parentheses are isolated yields. In the case of the product isolation experiments, the reaction scale was three times as much as that given in footnote (*a*).

above conditions. The hydrotalcite with Ru cations in the Brucite layer, Ru-Mg-Al-CO_3 HT, has been previously found to be a good catalyst (entry 5).[3] Substitution of Mg ions with Co ions in the Brucite layer of the above Ru-Mg-Al-CO_3 HT drastically enhanced the catalytic activity (entries 1 and 5). The Ru-Mn-Al-CO_3 HT was also an effective catalyst, while the introduction of Fe and Zn cations resulted in low yields of cinnamaldehyde.

Oxidation of various kinds of alcohols using the Ru-Co-Al-CO_3 HT in toluene was carried out at 60 °C. Typical results for the oxidation of aromatic and aliphatic alcohols were summarized in Table 2. Cinnamyl alcohol and its derivative gave α,β-unsaturated aldehydes in almost quantitative yield (entries 1 and 2). In the cases of benzylic alcohols, the corresponding aldehydes were obtained in high yield (entries 6–11). It is notable that benzoic acids (over-oxidation products) were barely detected under the above conditions. Further, the hydrotalcite catalyst is applicable for the oxidation of aliphatic allylic alcohols (entries 3–5) and heterocyclic alcohols including sulfur and nitrogen species in spite of slow reaction rates (entries 12 and 13).† A secondary saturated alcohol, octan-2-ol, was smoothly converted into the corresponding ketone (entry 14), while primary saturated alcohols such as octan-1-ol showed extremely low reactivity for this oxidation. Interestingly, the hydrotalcite could also efficiently oxygenate the benzylic



Scheme 2

positions of aromatic compounds, *i.e.* xanthene, fluorene and diphenylmethane, to give the corresponding ketones (Scheme 2).

The hydrotalcite catalyst was easily separated from the reaction mixture and was reusable without an appreciable loss of activity and selectivity for the above oxidations.

In the oxidation of cinnamyl alcohol, the Co-Al-CO_3 HT (Co : Al = 3 : 1) barely catalysed the oxidation, and the activity of Ru-Co-Al-CO_3 HT was much higher than that of a physical mixture of Co-Al-CO_3 HT and Ru-Mg-Al-CO_3 HT (Table 1, entry 6). These results indicate that it is the synergism derived from interaction of Co and Ru cations in the Ru-Co-Al-CO_3 HT that enhances the catalytic activity. The XPS results show that the oxidation state of the Ru cations of Ru-Co-Al-CO_3 HT was higher than that of Ru-Mg-Al-CO_3 HT; the Ru $3d_{5/2}$ electron binding energy of Ru-Co-Al-CO_3 HT was similar to that of RuO_3.[9] Presumably, the Ru cation species with higher oxidation states, *i.e.* Ru^{IV} to Ru^{VI}, induced by the introduction of Co cations are responsible for high catalytic activity in the above oxidation.[5] From Table 1, the basicity of hydrotalcites is not correlated with the catalytic activity for the oxidation.[3] At present, we think that substitution of Mg cations with divalent Co cations in the Brucite layer might lead to generation of an active species having a high oxidation state for the Ru ions, *e.g.* Ru=O species.[10]

In conclusion, the ruthenium hydrotalcite having Co cations was found to be an effective heterogeneous catalyst for the oxidation of various kinds of alcohols in the presence of molecular oxygen. This heterogeneous oxidation can be regarded as an environmentally benign chemical process because of the use of molecular oxygen, the simple work-up procedure and the reusability of the hydrotalcite catalyst.

Notes and references

† The oxidations of aliphatic allylic alcohols and 2-pyridylmethanol hardly proceeded in the presence of the Ru-Mg-Al-CO_3 HT under these reaction conditions.

Buta-2,3-dienylstannanes, effective reagents for regioselective buta-1,3-dienylation of aldehydes and acetals

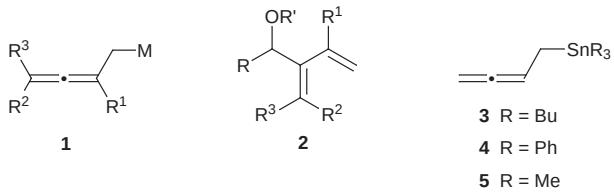
Meiming Luo, Yoshiharu Iwabuchi and Susumi Hatakeyama*

Faculty of Pharmaceutical Sciences, Nagasaki University, Nagasaki 852-8521, Japan.
E-mail: susumi@net.nagasaki-u.ac.jp

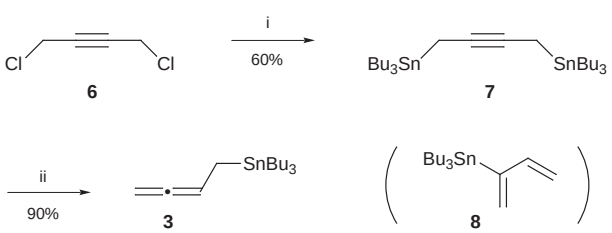
Received (in Cambridge, UK) 20th November 1998, Accepted 11th December 1998

Two buta-2,3-dienylstannanes, 1-tri-*n*-butylstannylbuta-2,3-diene and 1-triphenylstannylbuta-2,3-diene, have been prepared and shown to react with aldehydes and acetals under Lewis acid catalyzed conditions producing (buta-1,3-dien-2-yl)methanol derivatives in high yields.

Recently, buta-2,3-dienylsilanes **1** (M = SiR_3)[1,2] and buta-2,3-dienylboronates **1** [M = $B(OR)_2$],[3] have appeared as useful reagents for the synthesis of (buta-1,3-dien-2-yl)methanol derivatives **2** from aldehydes and acetals. In addition, we have demonstrated that these dienols **2** are valuable precursors for the syntheses of a variety of natural products.[1,4] As part of our interest in developing a catalytic asymmetric reaction of a buta-2,3-dienylmetal **1** with an aldehyde using a chiral Lewis acid,† we directed our attention to buta-2,3-dienylstannanes **1** (M = SnR_3) which are unprecedented as synthetic reagents. Here, we report the first practical syntheses of 1-tri-*n*-butylstannylbuta-2,3-diene **3** and 1-triphenylstannylbuta-2,3-diene **4** and their Lewis acid catalyzed reactions with aldehydes and acetals.

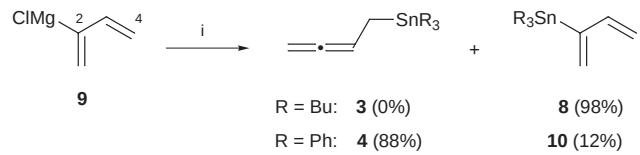


Reich and co-workers reported[5] that treatment of 1,4-bis(trimethylstannyl)but-2-yne with HCl in $CDCl_3$ caused protomonodestannylation to give 1-trimethylstannylbuta-2,3-diene **5**. However, to the best of our knowledge, the results of this NMR experiment have not been further examined in detail. This situation allowed us to examine in detail protomonodestannylations of 1,4-bis(trialkylstannyl)but-2-ynes as one possible route to buta-2,3-dienylstannanes (Scheme 1). After many discouraging results, we eventually found good reaction conditions wherein large quantities of 1-tri-*n*-butylstannylbuta-2,3-diene **3** are obtained with > 95% purity from 1,4-bis(tri-*n*-butylstannyl)but-2-yne **7**. Thus, treatment of **7**, prepared by the reaction of 1,4-dichlorobut-2-yne **6** with tri-*n*-butylstannyllithium,‡ with concentrated HCl in a 16:1 mixture of Et_2O and THF at 0 °C gave **3** cleanly in 90% yield.§ This HCl-promoted protomonodestannylation also turned out to proceed in a reasonable yield (77%) in Et_2O although the reaction was rather sluggish even at room temperature. When THF was used as solvent for this reaction, the yield of **3** decreased to 42%, possibly because of its further protodestannylation giving buta-1,3-diene. It is important to note that purification of **3** by silica gel column chromatography caused isomerization to 2-tri-*n*-butylstannylbuta-1,3-diene **8**. The ratio of **3** and **8** was at best 1 : 1 under these unsatisfactory conditions and varied depending upon the amount of silica gel used. This isomerization, however, could be completely suppressed by use of silica gel pretreated with Et_3N. Compound **3** thus purified was thermally stable and no isomerization occurred during distillation.



Scheme 1 *Reagents and conditions*: i, Bu_3SnLi, THF, −78 °C; ii, conc. HCl, Et_2O–THF, 0 °C.

We also investigated the reaction of Ph_3SnCl or Bu_3SnCl with the Grignard reagent **9**[6] prepared from chloroprene (2-chlorobuta-1,3-diene) (Scheme 2). We found that, in the case of Ph_3SnCl, the reaction occurred preferentially at the C4 position to give a 88 : 12 mixture of 1-triphenylstannylbuta-2,3-diene **4** and 2-triphenylstannylbuta-1,3-diene **10** in quantitative yield. Recrystallization of this mixture from *n*-hexane afforded pure **4** in 73% yield.¶ Interestingly, as previously reported,[7] Bu_3SnCl reacted with the Grignard reagent **9** with complete C2 selectivity to give 2-tri-*n*-butylstannylbuta-1,3-diene **8** quantitatively.



Scheme 2 *Reagents and conditions*: i, Bu_3SnCl or Ph_3SnCl, THF, −78 °C.

Having developed practical methods for the preparation of buta-2,3-dienylstannanes **3** and **4**, we then investigated their Lewis acid catalyzed reactions with various aldehydes and acetals (Scheme 3). Table 1 summarizes Lewis acid catalyzed additions of **3** and **4** to aldehydes. It is evident that this reaction has broad applicability for the preparation of **12** (R^2 = H) and $BF_3{\cdot}Et_2O$ is the catalyst of choice, except for the two examples listed in entries 8 and 10. It is also apparent that **3** is much more reactive than **4** in this reaction. Compound **3** was found to gradually isomerize to **8** under these conditions, whereas compound **4** did not undergo such Lewis acid catalyzed isomerization.

As can be seen from Table 2, both **3** and **4** again reacted with acetals in good yields. The mixed titanium reagent [$3TiCl_4{\cdot}Ti(OPr^i)_4$] was found to give better results than $BF_3{\cdot}Et_2O$, especially in the cases of aliphatic acetals (entries 1, 2, 10 and 11). Conversely, the reaction of cinnamaldehyde dimethyl acetal with **3** took place almost quantitatively under $BF_3{\cdot}Et_2O$

[a] Reactions were carried out at −78 °C in the indicated solvent (0.13 mol dm^{-3}) using buta-2,3-dienylstannane (**3**: 2 equiv. **4**: 1.2 equiv.), acetal (1 equiv.) and Lewis acid (1 equiv.). [b] Isolated yield. [c] Most of the aldehyde was recovered.

catalyzed conditions and $3TiCl_4{\cdot}Ti(OPr^i)_4$ produced poor result in this particular case (entries 4 and 5).

In conclusion, we have successfully synthesized two buta-2,3-dientylstannanes, 1-tri-*n*-butylstannylbuta-2,3-diene **3** and 1-triphenylstannylbuta-2,3-diene **4**, in >95% isomeric purity for the first time. These buta-2,3-dienylstannanes react with various aldehydes and acetals regioselectively in a 1,3-rearrangement fashion to give (buta-1,3-dien-2-yl)methanol derivatives in excellent yields. In comparison with the related silicon[1] and boron reagents,[3] buta-2,3-dienylstannanes have the advantage of broad applicability in buta-1,3-dienylations of both aldehydes and acetals. The development of a catalytic asymmetric reaction of buta-2,3-dienylstannanes with aldehydes is the focus of current investigations.

This work was supported by the Japan Society for the Promotion of Science (postdoctoral fellowship for M. L.). We gratefully acknowledge the Tosoh Corporation (Nanyo Research Laboratory, Japan) for providing chloroprene.

Notes and references

† A catalytic asymmetric version of this process using either buta-2,3-dienylsilanes or buta-2,3-dienylboronates has not been successfully achieved yet.

‡ Prepared according to Reich's method for 1,4-bis(trimethylstannyl)but-2-yne (ref. 5).

§ Experimental procedure for **3**: To a stirred solution of **7** (7.93 g, 12.5 mmol) in Et_2O (80 ml) with cooling in an ice bath was added a mixture of concentrated HCl (1.3 ml) and THF (5 ml). After stirring at 0 °C for 8 h, the reaction mixture was basified with 5% NaOH (10 ml) and extracted with Et_2O. The extract was washed with water, dried over $MgSO_4$, and concentrated *in vacuo*. Purification by column chromatography [SiO_2 (30 g) pretreated with Et_3N (30 g); *n*-hexane] afforded **3** (3.86 g, 90%), bp 150 °C (0.2 mmHg) (Kugelröhr).

¶ Experimental procedure for **4**: A flame-dried flask was charged with THF (30 ml) and Grignard reagent **9** (1.6 mol dm^{-3} in THF, 12.5 ml, 20 mmol) under argon and then a solution of Ph_3SnCl (7.71 g, 20 mmol) in THF (15 ml) was added dropwise at −78 °C. After being stirred at −78 °C for 30 min, the reaction mixture was quenched with 5% NaOH (10 ml) and extracted with Et_2O. The extract was dried over $MgSO_4$, concentrated *in vacuo*, and chromatographed [SiO_2 (30 g) pretreated with Et_3N (30 g); *n*-hexane] to give an 88 : 12 mixture of **4** and **10** as a colorless viscous oil (8.05 g) which solidified during overnight storage in a refrigerator. Recrystallization of this crystalline solid from *n*-hexane afforded **4** (5.86 g, 73%) as colorless crystals (mp 54–55 °C).

Epitaxial growth of WO_{3-x} needles on (10 $\bar{1}$0) and (01 $\bar{1}$0) WC surfaces produced by controlled oxidation with CO_2

Andrew P. E. York,[a] Jeremy Sloan[a,b] and Malcolm L. H. Green*[a]

[a] *Inorganic Chemistry Laboratory, University of Oxford, South Parks Road, Oxford, UK OX1 3QR. E-mail: malcolm.green@chem.ox.ac.uk*

[b] *Department of Materials, University of Oxford, Parks Road, Oxford, UK OX1 3PH*

Received (in Bath, UK) 23rd September 1998, Accepted 4th January 1999

The controlled oxidation with CO_2 of both high surface area (high S_g) and low surface area WC to form WO_{3-x} needles, has been observed *in situ*, inside a controlled environment transmission electron microscope (CETEM), and also *ex situ*, in a standard flow reactor; the tungsten oxide needles, which consist mainly of distorted γ-$WO_{2.72}$, propagate in an epitaxial fashion from the (10 $\bar{1}$0) and (01 $\bar{1}$0) surfaces of the parent WC crystals; possible mechanisms for the formation of the needles are proposed.

Recently, WC was shown to be an active catalyst for the conversion of methane and carbon dioxide to synthesis gas (CO + H_2).[1,2] During the course of these studies, it was found that catalyst deactivation due to oxidation of WC by CO_2 leads to the formation of tungsten oxides, which are inactive for methane reforming. Such materials are, however, useful in a wide variety of applications including some catalytic processes (*e.g.* metathesis),[3] in optoelectronic devices,[4] as gas sensor materials,[5] and have recently been developed as precursor materials for the synthesis of inorganic fullerene-like (IF) materials based on 2H-WS_2 layered chalcogenide structures.[6–8] While using CETEM to probe the deactivation mechanism of the carbide, we observed the propagation of oxygen deficient tungsten oxide needles from specific crystal faces of the parent carbide. We describe here their *in situ* and *ex situ* formation from both high and low surface area WC particles by controlled oxidation with CO_2.

High surface area (high S_g) WC (40 m^2 g^{-1}) was synthesised by reacting WO_3 with a mixture of 20% CH_4–H_2 (100 ml min^{-1}), ramping the temperature from room temperature to 750 °C at a rate of 1 °C min^{-1}.[2] This material was then characterised by XRD and found to be hexagonal WC with an average particle size radius of 7.62 nm (Scherrer method). The low surface area (low S_g) WC (Alfa Chemicals, 99.5%) exhibited average particle sizes of *ca.* 2.5 μm, estimated by high resolution transmission electron microscopy (HRTEM).

The oxidation of WC in the presence of CO_2 was initially investigated *in situ* in a 400 kV CETEM, described previously.[9,10] Cooling effects due to the thermal conductivity of CO_2 have been taken into account in the reaction temperatures quoted. Both WC samples were heated, under differential pumping conditions, in the temperature range 550–650 °C with an introduced partial pressure of 5 mbar CO_2. The onset of oxidation for high S_g WC was observed at 550–560 °C by formation of WO_{3-x} needles from the surfaces of the WC crystals. For low S_g WC, needle growth started at 580–590 °C, suggesting a slightly higher activation energy for this oxidation. In both cases, needle growth could be observed *in situ* in real time and Fig. 1(a) shows a typical example of growth observed from a cluster of high S_g WC crystallites after *ca.* 20 min at 580 °C. In the case of low S_g (*i.e.* large particle size) WC, parallel multiple needle growth was also observed from the facets of individual WC crystallites. Fig. 1(b) shows six WO_{3-x} needles growing from the (01 $\bar{1}$0) facet of a WC with its [10 $\bar{1}$0] zone axis orientated parallel to the electron beam (SAED not shown). This reaction was subsequently repeated *ex situ* for

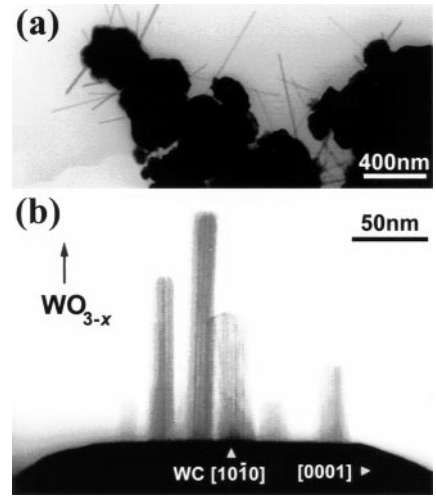

Fig. 1 (a) Micrograph showing WO_{3-x} needle formation from clusters of high S_g WC observed by CETEM. (b) Micrograph showing multiple parallel WO_{3-x} needle growth occurring from the (10 $\bar{1}$0) (alternatively (01 $\bar{1}$0)) face of a single WC crystal in the same [01 $\bar{1}$0] orientation as the example in Fig. 2 (SAED pattern not shown).

both the low and high S_g carbides in a standard flow reactor at ambient pressure and in the temperature range 600–800 °C using a CO_2 flow rate of 100 ml min^{-1} for 24 h. At 750–800 °C, the yield of WO_{3-x} needles from WC from both specimens was quantitative. Partially oxidised WC showing epitaxial needle growth was observed in samples oxidised at 600–750 °C.

For the low S_g WC, it was possible to correlate the WO_{3-x} needle growth with respect to either the (10 $\bar{1}$0) or the (01 $\bar{1}$0) face of the parent carbide; growth from the hexagonal (0001) face was not observed. The middle section of Fig. 2 shows a HRTEM micrograph of the interface between a WO_{3-x} needle grown on the surface of a WC crystallite. The inset indexed SAED pattern **I** (obtained from **I′**) corresponds to a [01 $\bar{1}$0] projection of the parent carbide. The dense microstructure of this crystal is visible below the carbide/oxide interface in the micrograph. Inset **II** is a fast Fourier transform (FFT) computed from region **II′** in the micrograph and shows the calculated diffraction behaviour of the oxide needle. The indicated strong reflections in the centre of **II** correspond to the 0.375 nm layers in the oxide needle. Diffuse streaking in the horizontal rows of diffraction maxima (small arrowheads) correspond to planar disorder occurring parallel to the needle axis (indicated by arrow **A**, micrograph). Substructure reflections, two of which are denoted **A** and **B**, are also visible along these rows. Inset **III**, obtained from the oxide/carbide interface (region **III′**), is an FFT showing the composite diffraction behaviour at the interface. In this pattern, the strong reflections corresponding to the oxide layers are now aligned along [10 $\bar{1}$0] of the WC pattern (large arrow). It is significant that reflection **A** (and its equivalents) from the oxide is now coincident with the WC 0001 reflection (and its equivalents) in **III**, suggesting that the

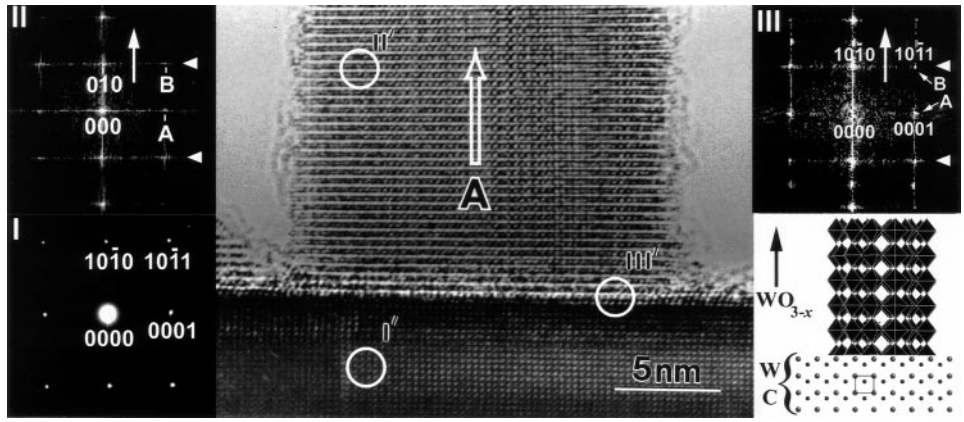

Fig. 2 Micrograph showing the interface between WO_{3-x} needle and WC parent crystal. The inset patterns correspond to: **I**, [01 $\bar{1}$0] SAED pattern obtained from region **I′** corresponding to the parent WC crystal; **II** FFT obtained from region **II′** corresponding to the WO_{3-x} needle; and **III**, FFT obtained from region **III′** corresponding to the WO_{3-x}/WC interface. At the lower right is a schematic representation of the composite microstructure at the interface. The unit cell of the parent carbide (a = 0.2907 nm; c = 0.2837 nm) is indicated.

substructure of the oxide is constrained by that of the carbide, as in a template relationship. This could also be a source of the strain and disorder indicated by the streaking in **II** and **III**. A schematic representation of the overall microstructure is given at the lower right of Fig. 2.

The projection of the oxide in **II** and **III** closely resembles a [001] projection of the phase γ-$WO_{2.72}$ and reflections **A** and **B** (corresponding to 0.284 and 0.220 nm, respectively), are close to (006) and (016) (corresponding to 0.276 and 0.223 nm, respectively) of this oxide.[11,12] Also, the microstructures of the epitaxially grown oxide and γ-$WO_{2.72}$ are very similar as revealed by a comparison of an enlarged region of Fig. 2 [Fig. 3(a)] and an image simulation[13] calculated for a [001] projection of the latter [Fig. 3(b)].

The possible mechanisms for needle formation from the carbides should be addressed. It is proposed that the first step in the formation of the oxide needles is the dissociation of carbon dioxide on the WC surface, according to reaction (1), in agreement with the proposed mechanism for the reforming of methane published by Green and coworkers.[1,2,14] According to this mechanism, oxidation of WC by CO_2 is solely a surface phenomenon and gas-phase dioxygen is not involved.

$$WC + CO_2 = WO_x + CO \quad (1)$$

After the formation of surface oxide, two possible needle propagation mechanisms may be envisaged: (i) an insertion/diffusion mechanism whereby the oxide forms layer-by-layer resulting in platelets that are pushed from below as oxidation diffuses into the carbide crystal; and (ii) a gas-phase reaction involving the transport of oxide from the carbide surface to the oxide needle tips. If mechanism (i) were responsible, progressive consumption of the carbide crystals from the inside should have been observed, but this was not the case.

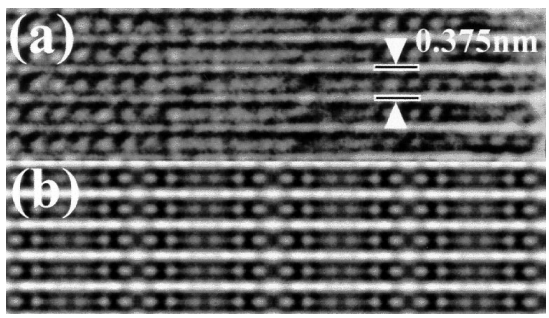

Fig. 3 (a) Enlargement of a segment of the WO_{3-x} needle in Fig. 2. (b) Image simulation calculated for a [001] projection of γ-$WO_{2.72}$ computed using a 1.4 nm thick foil at −70 nm defocus. There is a close (though not perfect) correspondence between the two microstructures.

Mechanism (ii) allows for the epitaxial growth of the needles from the WC crystal surfaces which is apparently observed. Possible support for this is given by the observation of amorphous material on the surface of the needle and the carbide (see Fig. 2) which may correspond to the sublimate feedstock. In addition, the vapour pressure of WO_3 at 550 and 650 °C, and 1 atm (*i.e.* similar conditions to those employed for *ex situ* needle growth) is 5×10^{-4} and 0.0193 mmHg respectively,[15] indicating that tungsten oxide will have a significant presence in the gas-phase. Therefore, we propose that needle growth proceeds *via* mechanism (ii).

The epitaxial growth of orientated WO_{3-x} needles on (10 $\bar{1}$0) and (01 $\bar{1}$0) WC facets by controlled oxidation has been demonstrated. Such a process may, with further development, allow greater control over the stoichiometry and morphology of the produced tungsten oxide needles. We will discuss the issues raised by this work more fully in a future publication.

A. P. E. Y. is grateful to CANMET for financial support; we would also like to thank Ron Doole of the Department of Materials for his assistance with the CETEM.

Modification of [M]-MSU-X mesoporous silicate pore morphology by post-synthesis treatment

Stephen A. Bagshaw*

Advanced Materials Group, Industrial Research Limited, PO Box 31-310, Lower Hutt, New Zealand.

Received (in Cambridge, UK) 26th November 1998, Accepted 24th December 1998

[M]-MSU-X mesoporous silicates prepared from selected low concentration non-ionic polyethylene oxide surfactants have been subjected to post synthesis hydrothermal treatment which significantly modifies the pore morphologies forming stable hexagonal or lamellar structures through an internal dissolution-redirection mechanism.

The development of synthetic methods to improved templated mesostructured materials[1–3] for catalytic and molecular sieving applications is attracting considerable attention. The search for inexpensive and environmentally benign routes to specialised materials and fine chemicals is also an area of considerable scientific and technological interest. Recent work has shown that mesostructured silica,[4] metallo-silicates[5] and alumina[6] may be templated by inexpensive and non-toxic non-ionic polyethylene oxide (PEO) and tri-block co-polymer surfactants under near ambient reaction conditions.[4]

The pore architectures of these so-called MSU-X molecular sieve materials were described as three-dimensional interconnecting networks of 'worm-like' channels.[7,8] Hexagonal mesoporous silicas have previously been reported[9,10] from very high alkyl-PEO surfactant concentrations (50 wt%) and strongly acidic reaction media. Here we describe an improved yet very simple, inexpensive and environmentally benign synthesis route to [M]-MSU-X mesoporous silicates that exhibit worm-like, hexagonal and lamellar pore architectures. A possible mechanism for the pore rearrangement is briefly discussed.

[M]-MSU-X mesostructures have been prepared from selected members of the Brij® series of commercially available alkyl-PEO surfactants. These materials have been found to consistently exhibit greater lattice regularity than any of the Tergitol 15-S®, Triton® or Pluronic® series of surfactants that have been previously employed at low surfactant concentration (Fig. 1).[4–6,7] If any [M]-MSU-1 material with worm-like pore morphology was dried and treated in water at 373 K under autogenous pressure for approximately 72 h its pore symmetry became significantly reordered and thermally induced lattice contraction upon calcination became almost negligible. Only when high regularity [M]-MSU-1 materials prepared from the Brij® series of surfactants were treated however, were lamellar and hexagonally symmetric structures observed.

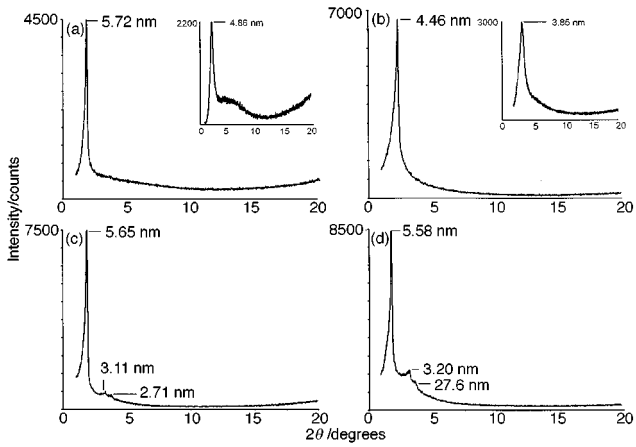

Fig. 1 XRD patterns of 7SAB Brij 76 templated [Ti]-MSU-1 (a) as-prepared, (b) calcined, (c) hydrotreated 72 h and (d) hydrotreated 72 h and calcined. Inset (a): as-prepared 5SAB Tergitol 15-S-12 templated [Ti]-MSU-1, (b) calcined 5SAB-C. (λ = 0.179026 nm.)

[Si]-, [Al]-, [Zr]- and [Ti]-MSU-1 silicates were prepared according to a method previously reported utilising the $N^0(N^+)X^-I^+$ assembly route.[5] Reordered [M]-MSU-1 materials were then prepared by treating the dried samples in distilled water (1 g sample per 30 mL water) at 100 °C in a sealed container for predetermined times.[11] The samples were recovered, dried in air and, in this instance, calcined at 600 °C for 4 h to remove the template. A Tergitol 15-S-12 templated [Ti]-MSU-1 sample is labeled 5SAB and a Brij 76 templated [Ti]-MSU-1 sample is labeled 7SAB, with suffixes HT-3 for 72 h hydrothermal treatment and C for calcination.

Low-angle powder X-ray diffraction (XRD) analyses (Fig. 1) show the single and multiple reflection patterns of [Ti]-MSU-1 samples in the as-prepared, hydrothermally treated and calcined forms. The as-prepared samples [Fig. 1(a)] exhibit intense first-order d_{100} reflections indicative of mesostructures possessing non-ordered worm-like pore structures with no long-range symmetry. It is however, immediately apparent from comparison of the peak widths and intensities, that the relations between structural repeat units are considerably more regular in the Brij 76 templated sample (Fig. 1) than in the Tergitol 15-S-12 templated sample (Fig. 1 inset). Calcination produced lattice contractions in the order of 20% and intensity increases of the d_{100} reflections that have been previously well documented.[1–10] Hydrothermal treatment of the as-prepared 7SAB sample for 72 h however, results in the appearance of two additional reflections [Fig. 1(c)]. The *d* spacings are not simple multiples, which would be expected for a lamellar system so are therefore probably best described by a hexagonal symmetry or at the very least, to pore symmetry similar to that observed for hexagonal MCM-41 type materials.[1,2] The appearance of additional XRD reflections were not observed for materials prepared from other non-ionic surfactant templates, such as Tergitol 15-S-12, although there is evidence for improvement in the pore ordering of all [M]-MSU-X materials.[12]

An important consequence of the hydro-treatment is that calcination of the treated samples results in negligible lattice contractions. This result indicates that the hydro-treatment causes hydrolysis and condensation of the silicate structure beyond that caused during the initial formation reaction.

Nitrogen adsorption isotherms of the various samples reflect important differences between [M]-MSU-X mesostructures prepared with Brij® surfactants, over other surfactants, and hydrothermally treated samples. The isotherm of 7SAB-C is characteristic of a material with pore diameter in the small mesoporous region exhibiting a shallow step with a definite point of inflexion at P/P_0 = 0.25 and no hysteresis of the desorption branch. Samples prepared with other PEO surfactants (*e.g.* 5SAB-C) generally exhibit no point of inflexion in the same region, indicating slightly smaller pore diameters

Table 1 Textural properties of worm-like and hexagonally symmetric[Ti]-MSU-1 mesoporous metallo-silicates

[Ti]-MSU-1 sample	d_{100} lattice spacing[a]/ nm	Lattice contraction[b] (%)	BET surface area[c]/ $m^2\ g^{-1}$	Pore diameter[d]/nm	Pore volume[e]/ $cm^3\ g^{-1}$	Wall thickness[f,g]/nm
5SAB	4.85					
5SAB-C	3.85	21	800	1.8[h]	0.35	2.0
5SAB-HT-3	4.55					
5SAB-HT-3C	4.50	0.7	970	2.4[i]	0.70	2.1
7SAB	5.70					
7SAB-C	4.45	22	920	2.2[a]	0.50	2.3
7SAB-HT-3	5.65					
7SAB-HT-3C	5.60	1.2	970	3.6[b]	1.10	2.0

[a] ±0.05 nm. [b] ±0.1%. [c] 10 $m^2\ g^{-1}$. [d] ±0.5 nm. [e] ±0.05 $cm^3\ g^{-1}$. [f] ±0.5 nm. [g] Wall thicknesses calculated by subtracting pore diameter from d_{100} lattice spacing value assuming that the d_{100} value is equivalent to the distance between adjacent pore centres. [h] Average pore diameter calculated from adsorption isotherm using HK model for cylindrical pores. This model tends to over-estimate pore diameters if pores are above 2.0 nm diameter. [i] Average pore diameter calculated from adsorption isotherm using BJH model for cylindrical pores. This model tends to under-estimate pore diameters.

(Table 1).[7] After hydrothermal treatment the shallow step is replaced by a well defined, high volume step in the upper capillary condensation region of the isotherm (P/P_0 = 0.55) indicative of well defined mesopores. Some hysteresis of the desorption branch becomes evident which may be a result of necking of the pores but is also possibly a consequence of the high adsorption partial pressure given that hysteresis is generally observed in mesostructured materials where the adsorption step is above P/P_0 = 0.45.

Selected area transmission electron micrograph (TEM) of the as-prepared materials (not presented) display the worm-like pore architecture previously reported for MSU-X materials.[4] Fig. 2 suggests that as a result of the hydrothermal treatment, the worm-like pore morphology has largely been replaced by a structure exhibiting ordering in two dimensions. In the present image the most obvious new feature appears as a lamellar phase coincident with the preexisting worm-like structure. When this evidence is combined with XRD data and the fact that the samples are calcined it seems reasonable to conclude that regular pores exist both parallel and perpendicular to the electron beam and that areas of hexagonal symmetry are being observed.

We suggest that hydrothermal treatment of templated silicate mesostructures causes structural modification through a dissolution/reprecipitation mechanism. Initially a diffuse inner layer of silica at the pore/template interphase, as invoked by Edler and White,[13] dissolves at the elevated temperature of the treatment. This dissolved silica reaches supersaturation within the interphase and then reprecipitates into a more dense phase on the pore wall. Only when the template is retained within the pore void can this dissolved silica be redirected to form on the pore walls. Such behaviour is observed for S^+I^- MCM-41 materials[11,13] but not for $S^+X^-I^+$ nor $S^\circ I^\circ$ templating.[12] It is by no means obvious that it would be observed in $N^+X^-I^0$ or $N^0\ I^0$ templated systems.

The data presented here however show definite beneficial effects of hydrothermal treatment on the non-ionically templated silicate systems. The exact mechanism whereby the worm-like pore morphology transforms into the more regular arrangement is currently under investigation. We are also currently investigating possible improvements in the molecular sieving and catalytic properties of the modified samples over regular MSU-X materials in the isomerisation of terpene substrates.

The author gratefully acknowledges the assistance of the New Zealand Lotteries grant board and Karen Reader for TEM analyses. This work was funded as part of a contract with the New Zealand Foundation for Research Science and Technology.

$[\{Cu(bipy)(H_2O)Pt(CN)_4\}_2]\cdot 2H_2O$: the first synthesis and crystal structure of a discrete heterometallic square cyano-bridged compound with terminal cyano ligands

Larry R. Falvello* and Milagros Tomás*

Department of Inorganic Chemistry and Aragón Materials Science Institute, University of Zaragoza-C.S.I.C., Plaza San Francisco s/n E-50009 Zaragoza, Spain. E-mail: falvello@LRF1.unizar.es

Received (in Basel, Switzerland) 21st September 1998, Accepted 13th December 1998

The synthesis and crystal structure of a square cyano-bridged compound with terminal cyano ligands are presented together with a discussion of the influence of H_2O molecules on the stability of the terminal cyanides and therefore on the discrete nature of the compound.

The particular characteristics of the cyanide group have accorded it wide-ranging interest in various research areas.[1,2] One of the more interesting characteristics of $C\equiv N^-$ is its ability to act either as a terminal or as a bridging ligand. When it acts as a bridging ligand between metal atoms it usually gives rise to polymeric compounds[2] with 1-D, 2-D or 3-D networks. Except for some clusters such as those with the 'Mo_6Cl_8' core,[3] few discrete cyanide-containing molecules with more than three metal atoms have been synthesized and structurally characterized; and particularly rare are those with cyano–metal rings.[1]

Although square or distorted square cyano-bridged fragments, both homo- and hetero-nuclear, have been found embedded in polymeric compounds,[4–6] only very few discrete molecules with square cyano-bridged structures have been reported,[1] characterized mostly on the basis of molecular weight determinations.[7] Only two, the homonuclear compounds $[Cp_2Ti(CN)]_4$ and $[(\eta^2\text{-tmtch})Cu(CN)]_4$ (tmtch = 3,3,6,6,-tetramethyl-1-thia-4-cycloheptyne) have been fully characterized by single-crystal X-ray diffraction studies.[8] No structures of heteronuclear, square, cyano-bridged compounds have been reported.

It may be that the scant information available to date on discrete cyano-bridged ring compounds is the result of a scarcity of appropriate cyano-containing starting materials and the difficulty of obtaining crystalline compounds suitable for X-ray diffraction studies. We report here the synthesis of a discrete cyano-bridged ring using a 'stoichiometrically inappropriate' starting material and the preparation of single crystals by an unconventional method.

Polymerization can easily occur when the starting cyano compound contains more cyano groups than those required for the formation of the discrete ring. So it would seem that appropriate starting materials for obtaining discrete square homometallic $\{M(CN)\}_4$ or heterometallic $\{M(CN)M'(CN)\}_2$ rings should contain an average of one cyano group per metal. In fact, $[(\eta^2\text{-tmtch})Cu(CN)]_4$ was obtained beginning with CuCN, with only one CN group per metal center; and $[Cp_2Ti(CN)]_4$ was prepared using a starting material, $\{Cp_2TiCl\}_2$, which only incorporates one CN group per Ti upon reacting with NaCN.

Structures of discrete square cyano-bridged compounds with terminal CN groups are not known, but there are some examples of other kinds of compounds with terminal CN groups that do not form polymers.[6,9] For instance, in the compound $[\{Cu(dien)M(CN)_6\}_n][Cu(dien)(H_2O)(\mu\text{-}CN)M(CN)_5]_n$,[6] in addition to an unbounded chain of fused heterometallic rings, the discrete dianionic unit with five terminal cyanides, is also present.

$[Pt(CN)_4]^{2-}$ compounds can react using the basic character of the Pt atom and have been extensively studied for their formation of conducting metal stacks.[10] $[Pt(CN)_4]^{2-}$ can also form complexes using its terminal CN ligands, giving rise to polynuclear compounds with 3-D networks such as in $[NMe_4][CuPt(CN)_4]$[11] or 2-D networks as in the Hofmann-type clathrates $[M(NH_3)_2Pt(CN)_4]$.[5] 1-D networks have been proposed for Zr or Hf in $[M(\eta^5\text{-}C_5H_5)_2Pt(CN)_4]_n$, although no X-ray diffraction data are available owing to the amorphous character of the solids.[12] $[Pt(CN)_4]^{2-}$ also reacts with rare earth metals, forming interesting 1-D networks that contain both terminal and bridging cyano groups.[13] However, to our knowledge no discrete heteronuclear compounds derived from $[Pt(CN)_4]^{2-}$ and containing bridging CN ligands, have been structurally characterized.

The reaction of $[NBu_4]_2[Pt(CN)_4]$ with $Cu(NO_3)_2\cdot 2.5H_2O$ and 2,2′-bipyridyl produces the immediate precipitation of the deep blue solid $[\{Cu(bipy)(H_2O)Pt(CN)_4\}_2]\cdot 2H_2O$ **1**.† The IR spectrum of compound **1** shows four absorptions in the CN region: 2208, 2195, 2156 and 2149 cm^{-1}. Those at 2208 and 2195 cm^{-1} correspond in all likelihood to the two *cis*-bridging CN groups, since bridging CN usually appears at higher energy than does terminal CN.[2] Thus, the bands at 2156 and 2149 cm^{-1} correspond to the two *cis*-terminal CN ligands. Crystals suitable for X-ray diffraction can be obtained—together with a variety of other compounds—by an unusual procedure, dissolution of compound **1** in a concentrated solution of NH_4OH and then slow evaporation of the NH_3. Compound **1** is very insoluble, and its solubility in NH_4OH is probably due to the coordination of NH_3 to the copper, which breaks the bridging cyanide system. The evaporation of the NH_3 regenerates the tetranuclear compound. This method, breaking the bridging cyanide system and slow regeneration of the insoluble compound, can probably be applied to the crystallization and even formation of other compounds, especially cyanide complexes. The magnetic properties and the nature of the other compounds are presently under study. Fig. 1 shows a view of one molecule of $[\{Cu(bipy)(H_2O)Pt(CN)_4\}_2]$.‡ The molecule consists of two $Pt(CN)_4$ fragments and two $Cu(bipy)(H_2O)$ moieties held together by CN bridges. The bridging cyanide ligands bind to platinum through their carbon atoms and to the copper centers through nitrogen, and the *cis*-disposition of the bridging CN moieties at each of the metal centers yields the square shape of the core of the complex. The molecule sits on a crystallographic inversion center. The square planar coordination about each platinum center is completed by two terminal CN groups. Each Cu center has a terminal chelating bipy ligand, which is nearly coplanar with the square core of the complex. The coordination about copper is completed by an apical aqua ligand [Cu–O 2.227(6) Å], giving a distorted square pyramidal coordination environment. As the molecule is centric, the two square pyramids at opposite corners of the Pt_2Cu_2 square have opposite polarities. There is also one unligated molecule of water in the crystallographic asymmetric unit, or two per molecule of complex **1**. Both the ligated [O(1)] and unligated [O(2)] water

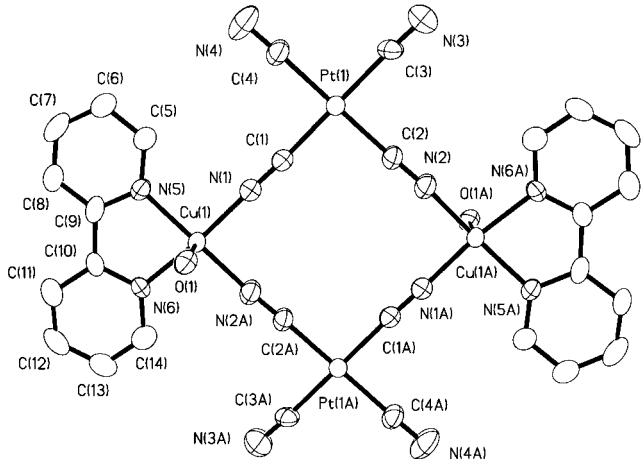

Fig. 1 Crystal structure of **1** with atom labelling scheme (50% probability ellipsoids). Hydrogen atoms and solvent molecules are omitted for clarity. Selected bond lengths (Å) and angles (°): Pt(1)–C(1) 1.973(8), Pt(1)–C(2) 1.973(7), Pt(1)–C(3) 1.985(8), Pt(1)–C(4) 1.987(8); Cu(1)–N(1) 1.958(7), Cu(1)–N(2A) 1.961(6), Cu(1)–N(5) 2.010(6), Cu(1)–N(6) 1.994(6), Cu(1)–O(1) 2.228(6), C(1)–N(1) 1.145(10), C(2)–N(2) 1.144(10), C(3)–N(3) 1.114(11), C(4)–N(4) 1.136(10); N(5)–Cu(1)–N(6) 81.5(3).

molecules are involved in significant hydrogen bonds. The bound water molecule acts as an H-bond donor to the terminal nitrogen atom N(4) of another molecule, with O(1)···N(4′) 2.82(1) Å. The free water molecule acts as a hydrogen bond donor to terminal nitrogen atom N(3) of two different molecules, with O(2)···N(3′) 2.85(1) Å and O(2)···N(3″) 2.94(1) Å. So the terminal nitrogen atoms of both pendant cyanide ligands serve as hydrogen bond acceptors in the extended structure. There is also a hydrogen bond between the bound and free water moieties, with O(1)···O(2) 2.76(1) Å.

The fact that the apical water molecule in the coordination environment of copper is not substituted by cyanide nitrogen to give rise to an extended structure can be explained as the result of several factors. First of all, the fifth and sixth coordination constants of copper are relatively small, especially when the first four ligands are nitrogen donors.[14] So a factor internal to the molecule, the propensity of copper not to accept a fifth nitrogen donor, may be responsible for the incorporation of water and the concomitant impediment to polymer formation. It remains true, however, that cases exist in which cyanide participates in a copper coordination environment consisting of five nitrogen atoms; the $[(Cu(dien)M(CN)_6\}_n]^{n-}$ chain is just such an example.

The hydrogen bonding that is found in the solid is also a key factor, and may be crucial, in determining the structure that we observe, since the formation of significant hydrogen bonds satisfies the nucleophilicity of the terminal nitrogen atoms and serves as a blocking factor, both spatially and electronically, against coordination of these nitrogen atoms to other metal centers.

In conclusion, the use of a starting material with excess cyanide in an environment favorable to the formation of hydrogen bonds with the cyanide nitrogen as acceptor, can give rise to discrete molecules with terminal cyanide ligands such as the tetranuclear square heterometallic complex **1**.

Oxidized caesium/nanoporous carbon materials: solid-base catalysts with highly-dispersed active sites

Mark G. Stevens, Denise Chen and Henry C. Foley*

Center for Catalytic Science and Technology, Department of Chemical Engineering, University of Delaware, Colburn Laboratory, Academy Street, Newark, Delaware, 19716, USA. E-mail: foley@che.udel.edu

Received (in Bloomington, IN, USA) 23rd October 1998, Accepted 6th January 1999

By vapor depositing Cs metal on nanoporous carbon materials and then oxidizing, a solid-base catalyst is produced that is quite active for the aldol condensation of acetone to isophorone.

In previous work we have shown that Cs/NPC materials are very powerful base catalysts.[1] The materials prepared from vapor deposition of elemental Cs provide a greater than 9 : 1 ratio of the less stable *cis*-but-2-ene over the *trans* isomer in the isomerization of but-1-ene at 273 K. They have a strong affinity for hydrogen,[2] since they can cleave the energetic C–H bond in benzene to promote condensation to biphenyl. Therefore, we sought to explore the activity of the oxidized state of Cs/NPC as a catalyst.

By preparing nanoporous carbon (NPC) with methods discussed previously,[1–4] we obtain high carbon solids that contain nanopores[3,4] with dimensions narrowly distributed around a mode of 0.5 nm and transport pores[5] with dimensions near 10 nm. These transport pores are *critical* for access to the catalytic sites contained in the nanopores.[6] Into these nanopores, the vapor of elemental caesium is rapidly and strongly adsorbed in a highly dispersed state.[1] The resultant materials are paramagnetic,[1] and EPR measurements[2] indicate that electrons of Cs are donated to the carbon. Since the Cs is atomically dispersed within the nanopores, oxidation should yield basic sites that are highly dispersed throughout the carbon. In contrast, aqueous impregnation of Cs salts will lead to large crystallites formed within the macro- and meso-pores.

Utilizing X-ray diffraction as a structural probe, upon exposure of the Cs/NPC to air we find a set of sharp lines superimposed upon the broad background of NPC (Fig. 1). These lines are consistently produced by air exposure of samples prepared in the range of 10–15 wt.% Cs. The lines do not correspond to those exhibited by the various Cs oxides, hydroxides or carbonates whose powder X-ray patterns are well known. It is interesting that when the Cs level is raised to 65 wt.% and the sample is air exposed, the X-ray pattern consists of just four sharp lines at 2θ = 13.05, 26.19, 39.72, and 53.88° (Cu-Kα radiation, λ = 0.15406 nm), corresponding to *d*-spacings of 6.781, 3.400, 2.267, and 1.700 Å, respectively, indicating that a crystalline form of Cs hydrous oxide has formed.[7] It is plausible that the X-ray pattern for air exposed Cs/NPC prepared at the lower loading of Cs corresponds to an intermediate hydrous oxide structure.

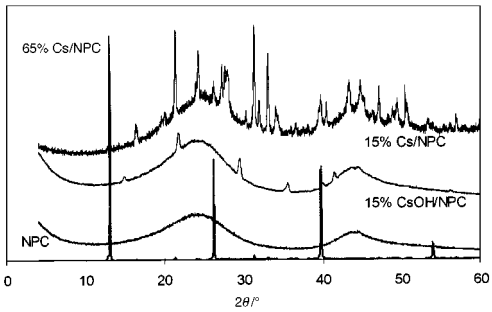

Fig. 1 Scaled XRD plots of NPC, 15% Cs on NPC, 65% Cs on NPC and 15% CsOH on NPC. Radiation used was Cu-Kα (λ = 0.15406 nm).

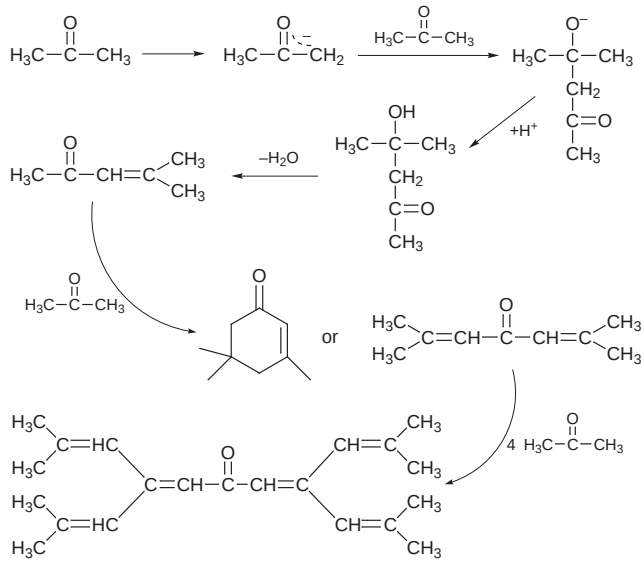
To determine if this oxide of vapor-deposited Cs on NPC led to a different level of activity than that obtained by impregnation with an aqueous salt, we chose to study the base-catalyzed aldol-condensation of acetone. Starting with Cs/NPC, this reaction would be expected to rapidly oxidize the Cs/NPC *in situ*, since water is a by-product of the coupling steps. Secondly, since the condensation products may react further to produce higher molecular weight species, inclusion of transport porosity within the carbon support should be critical to avoid rapid catalyst deactivation.

The liquid phase isophorone process[8] operates at 6–10% acetone conversion with a sodium hydroxide catalyst, an isophorone yield around 70% and losses due to heavies production. A more energy-intensive, vapor-phase process is also employed in which the acetone is passed over solid oxide type bases. Both processes incur a great deal of separations costs, requiring as many as four distillation columns operating under vacuum to reduce further by-product formation. In 1995, isophorone sold for \$4+/lb and the sole United States supplier was Union Carbide. The total world capacity was ≈156 MM lb./yr. Isophorone's uses range from a high-boiling, low-evaporative solvent for synthetic polymers to an insecticide (when converted to 3,5-xylenol). The fastest growing market for isophorone is as a building block for light-stable polyurethane.[9]

The base-catalyzed condensation of acetone (Scheme 1) begins with the extraction of the acidic α-proton to form the enolate anion, which attacks a second acetone to form the tetrahedral alkoxide ion intermediate, which is protonated to form the aldol. At elevated temperatures the aldol releases water to form mesityl oxide, which can undergo subsequent condensation steps. Upon the condensation of the aldol to form the



Scheme 1 The base-catalyzed, aldol-condensation reaction of acetone.

disubstituted enone, the material may simply form the conjugated diene-one product or the industrially significant, cyclic isophorone. The conjugated nature of the enone product allows for continued additions, forming higher molecular weight species that can accumulate rapidly in an all-nanoporous catalyst, thus restricting access to the active sites within the nanopores and shutting down reaction.

Experiments were carried out in a gas-phase flow reactor.† A steady argon flow (150 cm^3 min^{-1}) carried acetone vapor from a room-temperature gas sparger through the heated catalyst bed. Unreacted acetone and the heavier products were condensed and analyzed quantitatively by gas chromatography and mass spectrometry. The major product was isophorone along with mesityl oxides and higher-molecular-weight species that were lumped into a fraction called 'heavies'. Acetone conversion and selectivity to isophorone obtained over the vapor-deposited Cs/NPC catalyst for various temperatures are displayed in Table 1. Acetone conversion and selectivity to isophorone both maximize at 225–250 °C. At 20 °C isophorone selectivity drops due to increased mesityl oxide formation. At temperatures above 250 °C the activity of the catalyst dropped even though the selectivity to isophorone remained high. This was most likely due to the accumulation of heavy products in the pores. Each catalyst dropped to $< 20\%$ of its initial activity within 5 h and gained approximately 10% of its initial weight. At 225 and 250 °C the turnovers (mol of acetone converted/mol Cs) before catalyst deactivation were at a maximum of ≈ 10 (Table 1).

Significantly, the effect of air exposure on the catalyst before reaction was to *increase* its initial activity. Catalyst samples that were not air-exposed before reaction did not produce isophorone in the first hour on stream. After this induction period, however, they behaved as the air exposed samples did.

When compared to catalysts prepared by vapor deposition of elemental Cs, those samples that were prepared with CsOH solution‡ were less active and less selective. The selectivity to isophorone over the catalyst prepared by vapor deposition was *ca.* 60% throughout the experiment, whereas the selectivity for the solution-impregnated sample began at 45% and declined to 30%. Both materials gained approximately 10% of their initial weight in non-volatile compounds.

The vapor deposition of Cs led to catalysts that maintained their high selectivity to isophorone even as their activities dropped. The selectivity to isophorone remained 60% over a conversion range from 0–20%. As the acetone conversion approached 20% the loss in selectivity due to heavies formation became more significant. Attempts made to achieve higher conversions were not successful since the catalyst deactivated more rapidly due to non-volatile product accumulation.

Finally, as control experiments, we tested the NPC support alone without Cs and a sample of Cs-loaded NPC containing only nanopores.§ Neither material led to any significant acetone conversion. The Cs on all-nanoporous carbon catalyst, however, did increase in mass by an amount equal to 10% of its initial mass.

The GCMS data obtained indicate that the higher-energy, non-cyclic trimer was the species that led to heavies formation; none of the heavy materials identified contained cyclic fragments. This makes sense since the protons that are active for base extraction are α to the carbonyl or conjugated. The non-cyclic trimer has 12 of these active protons and the isophorone has only 3 that are not sterically hindered. Hence the key to reducing heavies formation and deactivation is to promote ring formation over oligomerization. Since the heat of formation and the activation energy to form the non-cyclic products are higher, a reduction in temperature should favor the isophorone product. Also, ring formation should have a lower (more negative) $\Delta S^{\ddagger}$, therefore, a decrease in temperature should again favor its formation. Secondly, any variable that reduces the overall conversion or catalyst basicity should reduce heavies formation. Thus, less basic metals such as potassium or sodium, lower acetone concentrations in the feed, and shorter contact times in the reactor should favor isophorone production.

Caesium, vapor-deposited into the carbon and then oxidized, is more active than Cs deposited from a salt in aqueous solution. The Cs hydrous oxide that results from oxidation of the vapor-deposited element is certainly a different phase; by examining the X-ray diffraction patterns of the two materials we were able to confirm this. The samples prepared with the CsOH solution showed patterns indicative of large hydroxide crystals. In contrast, the used vapor-deposited Cs/NPC material displayed an X-ray diffraction pattern with sharp lines, but the lines did not match any of the known caesium hydroxides or oxides. This set of results points to a new approach in the synthesis and use of solid Brønsted bases for continuous-flow organic synthesis. By preparing a carbon with both nanopores and mesopores, we can vacuum deposit cesium in a highly dispersed state, convert it to an active form *via* oxidation, and provide the necessary avenues for rapid molecular ingress and egress.

Table 1 Conversion, carbon selectivity towards isophorone and Cs^0 turnovers at various temperatures. Argon flow rate: 150 cm^3 mol^{-1} saturated with acetone at 25 °C

T/°C	Conversion (%) (per g Cs)	Isophorone selectivity (%)	Cs Turnovers
200	6.1	54	5.34
225	11.9	61	10.43
250	11.4	60	10.04
275	5.2	57	4.56
300	3.8	57	3.38

† A Tylan mass flow controller regulated an argon (Matheson Grade) carrier-gas flow. The argon flow served two purposes: to purge the reactor system of air and to carry acetone at its room-temperature vapor pressure from a bubbler to the reactor. The reactor consisted of a ½″ o.d. quartz tube heated by heat tape, the temperature of which was regulated by an Omega PID temperature controller. The catalyst was placed in the heated zone of the reactor between two plugs of glass wool. After leaving the reactor, the acetone–argon stream was cooled and condensed into a catch pot by a shell and tube condenser, through which flowed −10 °C chilled glycol. Samples were taken by removing all the liquid from the catch pot with a syringe inserted through a serum cap, weighed, spiked with a biphenyl standard, and analyzed on a Varian GC with an FID detector.

‡ A sample of CsOH/NPC was prepared by stirring the NPC with 50% CsOH solution for 1 h, filtering, and vacuum drying at 350 °C for 24 h.

§ NPC prepared by the pyrolysis of poly(furfuryl alcohol) alone at 850 °C for 8 h under helium produces a purely nanoporous material with no pores larger than 2 nm.

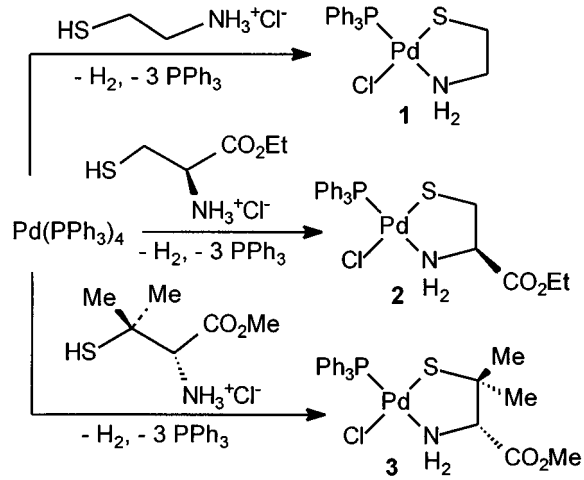
Received (in Basel, Switzerland) 23rd November 1998, Accepted 28th December 1998

The hydrochlorides of cysteamine, cysteine ethyl ester and penicillamine methyl ester, react with $Pd(PPh_3)_4$ to yield low symmetry complexes of palladium(II) that incorporate the *N,S*-aminothiolato ligand and triphenylphosphine; the complex with cysteine ethyl ester, structurally characterized by X-ray diffraction, proved to be an effective catalyst for the hydrocarboxylation of styrene with high selectivity (98%) towards 2-phenylpropanoic acid.

Low symmetry complexes of the transition metals in general, and the platinum group metals in particular, are of interest because of their potential as selective catalysts in homogeneous reactions. Geometric and electronic asymmetry is associated with increased stability of one of the possible key intermediates, which should give rise to improved selectivity. The preferred ligands in many selective catalytic reactions are sophisticated diphosphines. However, these are often even more expensive than the precious metal itself. This report is part of our efforts to evaluate the use of inexpensive, low symmetry ligands from the chiral pool, in structurally well characterised complexes, to promote selective homogeneous catalytic reactions.[1]

Cysteine ligand type containing complexes are not very common,[2] but we have shown that chelate assisted oxidative addition to Pt(0) is a reaction that can introduce acidic hydrogen containing cysteamine and cysteine ethyl ester ligands in the coordination sphere of the metal.[3] However, in the case of palladium the expected metal complexes would contain the often-unstable Pd–H bond. In a new approach, we have added an acid to quench the possible palladium hydride in order to obtain stable palladium(II) complexes in one step. The stoichiometric addition of acid has been achieved by the use of the hydrochlorides of the ligands.

The hydrochlorides of cysteamine ($HSCH_2CH_2NH_2{\cdot}HCl$), cysteine ethyl ester [$HSCH_2C^*H(CO_2Et)NH_2{\cdot}HCl$] and also penicillamine methyl ester [$HSCMe_2C^*H(CO_2Me)NH_2{\cdot}HCl$] reacted with $Pd(PPh_3)_4$ to yield the corresponding *N,S*-aminothiolato chloro triphenylphosphine complexes in good yield, with displacement of three PPh_3 ligands, oxidation of the metal and evolution of hydrogen (Scheme 1). In this way, complexes **1**–**3** were obtained as stable crystalline solids.† The *cis*-P,S coordination was established by single crystal X-ray analysis. Complex **2** exhibits a very short Pd–S distance of 2.253(2) Å that is effectively equal to the Pd–P distance of 2.254(2) Å, owing to the non-bridging coordination of the sulfur and the low *trans* influence of the chloro ligand.‡[4] Complexes **1**–**3** are stable in solution and do not form sulfur-bridged dimers or polymers, even when exposed to air. In these complexes four very different atoms coordinate the metal, but only when the asymmetric carbon containing cysteine and penicillamine are used, is the symmetry plane of the square planar complex broken and the compounds become optically active. Fig. 1 shows that in the solid state,[5] the ethyl carboxylate substituent in the chelate ring of **2** adopts an axial orientation and the oxygen of the carbonyl group approaches the coordinated nitrogen.§



Scheme 1

Catalytic hydrocarboxylation of olefins is an interesting reaction for the synthesis of the pharmacologically useful 2-arylpropionic acids, provided that a selective catalyst towards the branched acid is used.[6] Complex **2** has been subjected to a preliminary evaluation in the hydrocarboxylation of styrene as a model aryl olefin, with oxalic acid under CO pressure and no added co-catalysts. Complex **2** has been found to be active, and its selectivity in 2-phenylpropanoic acid (2-PP) was very high (Table 1). Hydrogenation was the main side reaction, and it was always under 0.2%. In low conversion conditions (*i.e.*, when the reaction was stopped after 2 h), yields increased steadily with temperature. After 24 h, 75% conversions were reached and selectivities as high as 98% in branched acid (2-PP) were maintained. However, at 100 and 120 °C, lower than expected conversions were observed. This result, together with the fact that after depressurisation of the reactor, palladium black is observed,¶ lead us to believe that the catalytic species suffers degradation under such reaction conditions. The catalytic reaction is faster at higher temperatures, but so is the decomposition of the catalyst.

The 2-phenylpropanoic acid product is racemic in all cases. Considering the fact that the reaction medium is strongly acidic, and that as proposed[7] it is reasonable to think that two free coordination sites are needed for this reaction, we are suggesting at this stage structure **A** for the active species. The relatively low bulk of **A** is consistent with branched selectivity. Also, the lack

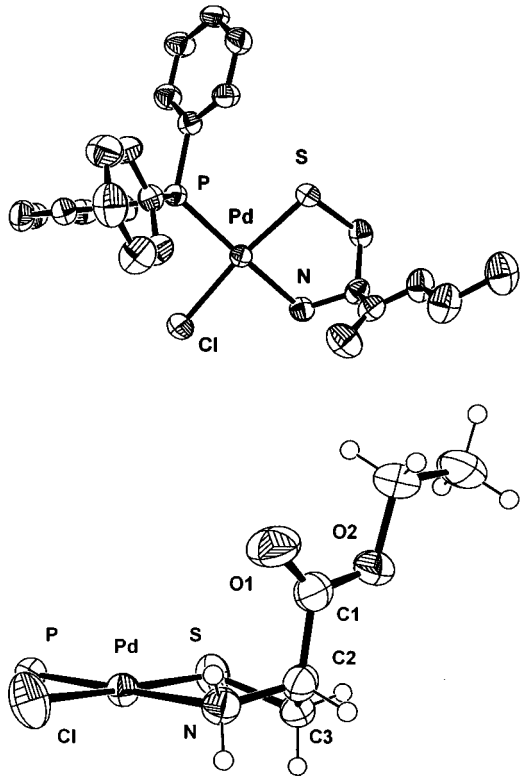


Fig. 1 The above projection of complex **2** includes all non-hydrogen atoms (ORTEP-III, 50% probability). In the nearly eclipsed projection below, the aryl rings have been omitted and the hydrogen atoms have been included, to fully appreciate the axial position of the ethoxycarbonyl group. The C1–C2 bond forms an angle of 84.5(3)° with the coordination plane of the metal and the O1–C1–C2–N torsion angle is 12.1(8)°. Selected distances (Å) and angles (°): Pd–S 2.253(2), Pd–P 2.254(2), Pd–N 2.097(5), Pd–Cl 2.349(2), S–C3 1.826(6), N–C2 1.483(7), C1–C2 1.509(8), C2–C3 1.482(8), C1–O1 1.192(7), C1–O2 1.323(8); S–Pd–P 92.92(6), S–Pd–N 85.7(1), Cl–Pd–P 93.63(6), Cl–Pd–N 87.7(1).

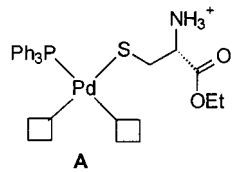
Table 1 Complex **2** as a catalyst in the hydrocarboxylation of styrene. Conversion and selectivity towards 2-phenylpropanoic acid (2-PP) in the reaction of styrene with oxalic acid under CO, at different temperatures over 2 and 24 h[a]

	2 h		24 h	
T/°C	Conversion (%)	Selectivity (%)	Conversion (%)	Selectivity (%)
60	0.6	—	30	98
80	7	98	75	98
100	12	97	68	97
120	16	97	67	96

[a] Conditions: 2 mmol styrene + 2.5 mmol $H_2ox{\cdot}2H_2O$ in 10 mL of DME solvent; [styrene]/[**2**] = 50; CO pressure: 30 bar. No oxygen or co-catalysts present.

of chiral induction would be consistent with structure **A**, in which the asymmetric centre is displaced away from the metal. At this point, we rule out complete detachment of the sulfur ligand in the active species, because the activities and selectivities observed with **2** were not those of a simple Pd(II) + PPh_3 system with a phosphine/palladium ratio of unity, which is the ratio in complex **2**.‖ Furthermore, relevant results by Claver, van Koten and coworkers[8] with aryl aminothiolato complexes



A

of palladium, seem to indicate that sulfur ligands promote high branched selectivity.

From a purely practical, synthetic point of view complex **2**, which is readily prepared from affordable, easily accessible reagents, catalyses the conversion of styrene to 2-phenylpropanoic acid (98%) by reaction with oxalic acid under CO (30 bar), with a 75% yield at 80 °C in 24 h. Further work on the synthesis, structure and evaluation of this novel class of compounds in catalysis is under way and will be reported in due course.

This work was financially supported by the DGICYT, project PB91-0663-CO3; and the CICYT and DGR, project QFN95-4725-CO3. We thank C. Claver for supplying a pre-print of ref. 8. M. P. thanks the UAB for a temporary teaching appointment as her only support towards her doctorate.

Notes and references

† Synthesis of **1**: A solution of $HSCH_2CH_2NH_2{\cdot}HCl$ (0.52 mmol) in methanol (5 ml) was slowly added to $Pd(PPh_3)_4$ (0.52 mmol) in toluene (20 ml) and stirred under nitrogen at 60 °C for 3 h to afford an orange solution. Concentration of the solution caused precipitation of the product as an orange solid, which was purified by recrystallization in acetone–diethyl ether to yield $[PdCl(SCH_2CH_2NH_2)(PPh_3)]$ **1** as dark orange crystals (65% yield). The same procedure can be used for compounds **2** and **3**. Compounds **1**–**3** gave satisfactory spectral (^1H, ^{31}P and ^{13}C NMR and IR) and analytical data.

‡ *Crystal data* for **2**: $C_{23}H_{25}ClNO_2PPdS$; M = 552.32; orthorhombic, a = 7.929(5), b = 10.330(2), c = 28.769(6) Å, V = 2356(2) Å^3; T = 293 K; space group $P2_12_12_1$, Z = 4; μ = 10.8 cm^{-1}; 2069 independent reflections for 277 parameters; $R(F)$ = 0.023 for 1910 reflections with $I > 2\sigma(I)$ and $R_w(F^2)$ = 0.063 for all 2069 reflections; S = 1.129; Flack parameter 0.01(4). CCDC 182/1134. See http://www.rsc.org/suppdata/cc/1999/277/ for crystallographic files in .cif format.

§ The IR stretching frequencies for the CO and NH_2 groups, and the distance between the oxygen and hydrogen atoms O1···H–N of 2.18(4) Å, do not support the existence of hydrogen bonding. The eclipsed conformation could be favoured by an electrostatic interaction between the negatively charged oxygen and a positively charged *quaternary* nitrogen.

¶ Powder X-ray diffraction showed it to be finely divided metal, and not palladium sulfide of any crystallinity. This palladium black does not catalyse the reaction, even when triphenylphosphine is added.

‖ Working in the same conditions as used for **2**, we have found the selectivity of $PdCl_2$ or $PdCl_2(MeCN)_2$ plus 1 equiv. of PPh_3 to be 85–88% in 2-PP, although the second precursor is faster.

Reduction of sulfur monoxide on a hexanuclear ruthenium complex

Teiji Chihara,*[a] Takahiro Tase,[b] Haruo Ogawa[b] and Yasuo Wakatsuki*[a]

[a] *The Institute of Physical and Chemical Research (RIKEN), Wako, Saitama 351-0198, Japan. E-mail: waky@postman.riken.go.jp*

[b] *Department of Chemistry, Tokyo Gakugei University, Koganei, Tokyo 184-8501, Japan*

Received (in Cambridge, UK) 23rd December 1998, Accepted 12th January 1999

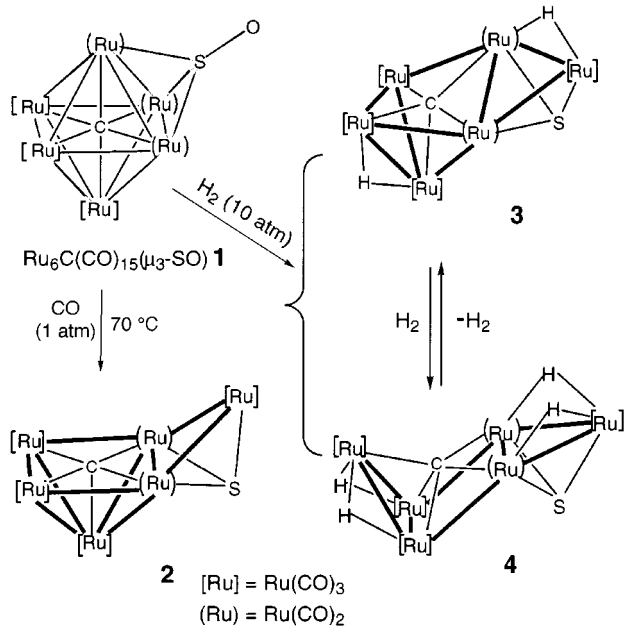
The sulfur monoxide unit, which originates from a gaseous SO_2 molecule trapped on a Ru_6-cluster, is easily reduced either by CO or H_2 to the sulfide ligand with concomitant skeletal cluster rearrangement, where the resulting cluster shape depends largely on the amount of the reducing agent taken up by the cluster.

Removal of SO_2 from combustion gases by reduction to sulfur is of great research interest because harmless S_8 is often a more desirable product than oxidized forms such as SO_4^{2-}.[1,2] The heterogeneous system, 0.5% Ru/γ-Al_2O_3, is one of the most active agents for the catalytic reduction of SO_2 with H_2 in the gas phase.† The presence of Al_2O_3 is crucial, since Ru metal alone has no catalytic activity.[3] It is likely that, aside from the role of Al_2O_3 as the carrier of fine metal particles, the Lewis acid character of Al_2O_3 assists in the reduction.[4,5] On the basis of the often-referred cluster–surface analogies,[6] reduction of SO_2 on high nuclearity metal clusters would be a good model for SO_2 reactions on metal particles.[1,7] Shriver and coworkers found that the cluster-bound SO_2 in the trinuclear cluster $[Fe_3H(CO)_9(SO_2)]^-$ is transformed to a μ_3-SO ligand on reduction with Na·Ph_2CO, but prior acetylation of the ligating SO_2 to give an AcOSO ligand was necessary for its complete reduction to the sulfide complex $[Fe_3(CO)_9S]^{2-}$.

Although $[Fe_3(CO)_9(SO)]^{2-}$ represents the first example of a cluster-bound SO made by reductive cleavage of SO_2, addition of excess reducing agent to the isolated SO complex resulted in degradation of the cluster, and hence reactivity of this highly important intermediate could not be studied.[8] In the high nuclearity cluster complex, $[Ru_6C(CO)_{15}(\mu\text{-}SO_2)]^{2-}$, which we recently prepared, the bound SO_2 can easily be converted to an SO ligand, $Ru_6C(CO)_{15}(\mu_3\text{-}SO)$ **1**, by addition of a Lewis acid such as BF_3.[9] Herein we describe the first reduction-reactivity of the SO ligand on polynuclear cluster complexes, which may have relevance to a stepwise reduction of SO_2 on heterogeneous metal surfaces.

A dichloroethane solution of **1** was heated at 70 °C for 6 h under one atmosphere of CO. A dark-purple crystalline complex was isolated in 74% yield after chromatography on silica gel, and was structurally characterized as $Ru_6C(CO)_{16}S$ **2**.‡ As shown in Scheme 1, the reaction is accompanied by incorporation of an additional CO into the cluster, cleavage of two of the metal–metal bonds and swinging of the S-capped metal triangle to open the upper part of the original octahedral metal skeleton of **1** (Scheme 1). An 88-electron Os cluster having a related structure, $Os_6(CO)_{16}(\mu_4\text{-}S)(\mu_3\text{-}S)$, has been isolated by Adams and Yang as one of the products of the thermolysis of $HOs_3(CO)_{10}(\mu\text{-}SPh)$.[10]

The reduction of SO to S on the cluster was also achieved by reaction with H_2. A dichloroethane solution of complex **1** was allowed to react with H_2 (10 atm) and 1.5 equiv. CO in an autoclave. After 6 h at 70 °C, four complexes were isolated after silica-gel column chromatography: the known trinuclear complex, $Ru_3(CO)_9(\mu_2\text{-}H)_2(\mu_3\text{-}S)$ (12%),[11] red–purple crystalline $Ru_6C(CO)_{16}(H)_2S$ (**3**, 30%), dark-orange crystals of $Ru_6C(CO)_{16}(H)_4S$ (**4**, 9%), and a brown powder (*ca.* 15%) which appears to be a heptanuclear ruthenium complex containing sulfur and CO as determined by elemental analysis, IR, and



Scheme 1

ESMS. The new compounds **3** (Fig. 1) and **4** (Fig. 2) were characterized by single-crystal X-ray diffraction analyses.‡ Complex **3** has a shape analogous to that of **2** but, as a result of cleavage of an additional metal–metal bond [Ru3···Ru6 3.920(1) Å], the pentagonal unit is now very much distorted. Two new hydride ligands, which are bridging the Ru1–Ru3 and Ru5–Ru6 bonds, supply the electrons needed to break the

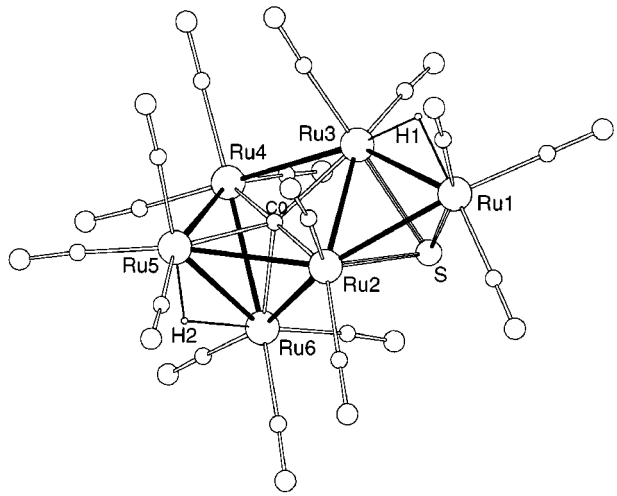


Fig. 1 X-Ray crystal structure of $Ru_6C(CO)_{16}(H)_2S$ **3**. Selected bond distances (Å): Ru1–Ru2 2.8071(5), Ru1–Ru3 2.8603(5), Ru2–Ru3 2.7308(5), Ru2–Ru5 2.8656(5), Ru2–Ru6 2.8765(5), Ru3–Ru4 2.9794(5), Ru3···Ru6 3.920(1), Ru4–Ru5 2.9261(5), Ru4–Ru6 2.8358(5), Ru5–Ru6 2.8249(5), Ru1–S 2.318(1), Ru2–S 2.383(1), Ru3–S 2.389(1).

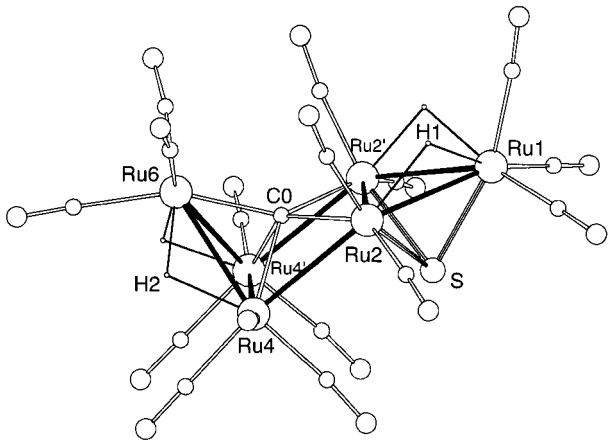

Fig. 2 X-Ray crystal structure of $Ru_6C(CO)_{16}(H)_4S$ **4**. Selected bond distances (Å): Ru1–Ru2 2.854(1), Ru2–Ru3 2.721(1), Ru2–Ru4 2.869(1), Ru4–Ru5 2.808(1), Ru4–Ru6 2.860(1), Ru2···Ru6 3.8939(1), Ru1–S 2.359(4), Ru2–S 2.375(3).

metal–metal bond. In complex **4**, two more hydrogen atoms are present and one more metal–metal bond (either Ru2–Ru5 or Ru2–Ru6 in **3**) has been broken. The solid-state molecular structure of **4** has a mirror plane that passes through Ru1, Ru6, and the carbide carbon atom (C0) of the chair-like cluster skeleton. The carbide ligand is well exposed, its distances from the metal square Ru2–Ru2′–Ru4–Ru4′ and the metal triangle Ru4–Ru4′–Ru6 are 0.39 and 0.80 Å, respectively. A carbon atom of this type has attracted much interest as being relevant to metal-surface bound carbon atoms in heterogeneous catalysis.[12]

Despite the large change in skeletal shape, complexes **3** and **4** are interconvertible cleanly, although slowly, at room temperature. The transformation was monitored by observing the characteristic IR bands of these complexes in the ν(CO) region. Keeping a dichloromethane solution of **3** under 15 atm H_2 at room temperature gave **4** in 80% conversion after 2 weeks, while formation of any other by-products was not detected. The reverse reaction was more facile. When a dichloromethane solution of **4** was allowed to stand under argon for 4 days, dihydrogen was released to generate **3** almost quantitatively. In contrast, **2** did not react with H_2 under similar conditions. The reactions are summarized in Scheme 1. Further, it may be mentioned that the trinuclear complex $Ru_3(CO)_9(\mu\text{-}H)_2(\mu_3\text{-}S)$ obtained as a minor product in the present reaction of **1** with H_2 (*vide supra*) has a structure[11] similar to that of the S-capped metal triangle moiety in **4**. It is interesting that recent reports have described facile metal–metal bond cleavage on solid metal surfaces induced by adsorption of small molecules such as H_2.[13]

In conclusion, reduction of sulfur oxide to S on high nuclearity clusters should take place smoothly either by CO or H_2 once the cluster bound SO_2 is transformed to SO. The first step, reduction of SO_2 to SO, appears more difficult since $[Ru_6C(CO)_{15}(\mu\text{-}SO_2)]^{2-}$ or $Ru_6C(CO)_{16}(\mu\text{-}SO_2)$ do not react under similar conditions. Either much more severe conditions or assistance by a Lewis acid will be required for the initial reduction process.

Fast carbonyl exchange in the solid state for β-cyclodextrin/(arene)Cr(CO)$_3$ inclusion complexes

Silvio Aime,* Holly C. Canuto, Roberto Gobetto and Fabio Napolitano

Dipartimento di Chimica I.F.M., Università di Torino, Via P. Giuria 7, 10125 Torino, Italy. E-mail: aime@ch.unito.it

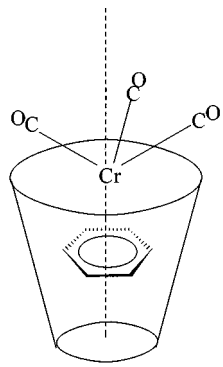
Received (in Basel, Switzerland) 20th November 1998, Accepted 28th December 1998

The exchange of carbonyls is a common feature for metal carbonyl compounds in solution whereas in the solid state high interatomic potential energy barriers cause this occurrence to be highly unlikely; it is shown that the compartmentalization of (arene)Cr(CO)$_3$ in the β-cyclodextrin cavity removes any constraint and thereby facilitates the rotation of the Cr(CO)$_3$ group in the solid state.

Cyclodextrins (CDs) that are naturally occurring oligomers of amylose which consist of six to eight glucose units are known to form inclusion compounds with various moieties including neutral molecules and organometallic complexes.[1] The ability of the cyclodextrin molecule to include guest compounds into its internal hydrophobic cavity has been extensively studied and found to be dependent on the size of the internal cavity which can vary from 5 to 7 to 8 Å for α-, β- and γ-cyclodextrins respectively.

Although properties of cyclodextrin inclusion compounds have been studied extensively there have been relatively few reports on their molecular dynamics in the solid state. With regards to organometallic complexes, reports on the inclusion compound formed between ferrocene and β-cyclodextrin (β-CD) indicated that inclusion into the cavity altered the dynamics in the solid state of the guest molecule compared to that observed for the pure compound.[2–5]

We were interested in investigating motion in the solid state of other previously reported inclusion compounds formed between β-cyclodextrin and organometallic complexes whose solid state dynamics of the pure compound had been well documented. This was found to be the case for (arene)Cr(CO)$_3$



(arene = C_6H_6, C_6H_5Me, $C_6H_4Me_2$) complexes where the motion in the solid state had been previously investigated by several authors.[6–8]

It was found that in a polycrystalline sample of $(C_6H_6)Cr(CO)_3$, the arene rotates freely along its principal coordination axis whereas the carbonyl moiety is rigid on the NMR timescale at ambient temperature. Calculations based upon the X-ray crystal structure showed that there is a large potential energy barrier for the rotation of the $Cr(CO)_3$ unit as a consequence of the strong interatomic interactions with the neighbouring molecules.[9,10] This situation is clearly depicted in the ^{13}C CP MAS NMR spectrum [Fig. 1(*a*)] which shows single resonances for the C_6H_6 ligand at δ 95 and the carbonyl group (isotropic peak at δ 234) each showing the typical spinning side band (SSB) manifold which for the carbonyl resonance is indicative of a chemical shift anisotropy of *ca*. 390 ppm. Such a value has been commonly observed for solid state specimens of metal carbonyls containing terminal bound CO.[11]

In the β-CD/$(C_6H_6)Cr(CO)_3$ adduct the arene is reorienting freely as observed in the polycrystalline specimen.[6] This is proven firstly by the observation of a single ^{13}C resonance for the benzene ring in the ^{13}C CP MAS NMR spectrum [Fig. 1(b)] at the same chemical shift as the pure compound. Further support for the occurrence of free arene rotation is gained by looking at the ^{2}H NMR solid state spectrum of the inclusion compound containing as a guest molecule the perdeuterated $(C_6D_6)Cr(CO)_3$ isotopomer.† A typical powder pattern[12] with an inner separation between the main components of 71.0 kHz is observed at 300 K. This behaviour is consistent with the occurrence of a fast-exchange regime (> 10^8 s^{-1}) for the arene ring executing six-site nearest-neighbour jumps within the β-cyclodextrin cavity.

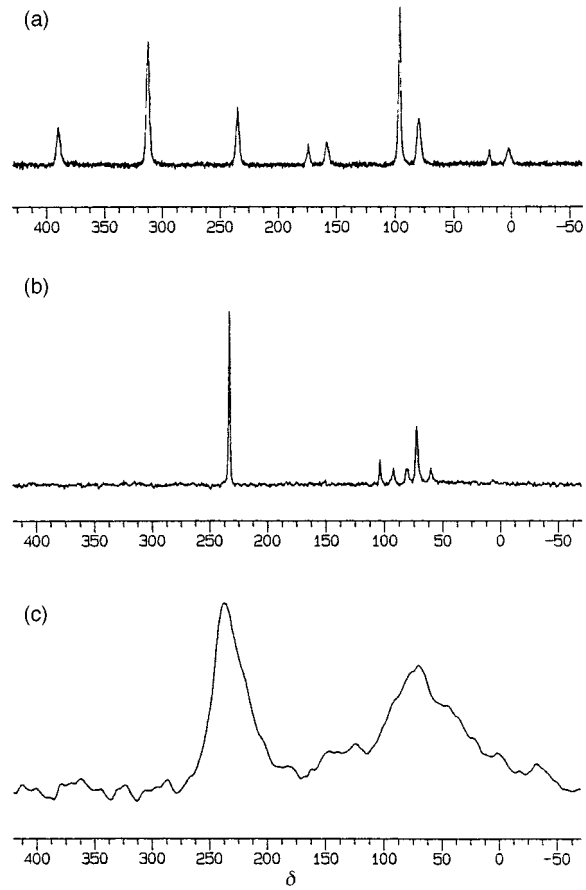


Fig. 1 Solid state ^{13}C NMR spectra recorded at 67.8 MHz for (a) CP MAS of $(C_6H_6)Cr(CO)_3$, (b) CP MAS of β-CD/$(C_6H_6)Cr(CO)_3$ adduct and (c) CP-static β-CD/$(C_6H_6)Cr(CO)_3$ adduct. All spectra was recorded for ^{13}CO enriched‡ samples, with cross polarization (contact time 5 ms) and a recycle delay of 20 s. For (a) and (b) the sample spinning speed was 5000 Hz.

Contrary to what is observed for the polycrystalline sample, in the inclusion compound, the carbonyl moiety acquires a substantial mobility which averages out the CSA responsible for the appearance of the SSB manifold in the high field ^{13}C NMR spectra of metal carbonyls under magic angle spinning [Fig. 1(b)]. Thus the ^{13}C CP MAS NMR spectrum of $(C_6H_6)Cr(CO)_3$ compartmentalized in the β-CD cavity is strictly analogous to the solution spectrum.

At ambient temperature the T_1 of the ^{13}CO resonance in the crystalline $(C_6H_6)Cr(CO)_3$ specimen is *ca.* 30 s, a value significantly shorter than those reported[13] for binary metal carbonyl resonances. This behaviour is likely to be the result of the dipolar interaction to the arene protons modulated by the intramolecular motion of the π-bonded C_6H_6 ring. At the same temperature and magnetic field strength, the T_1 of the CO resonance in the inclusion compound is only 1 s. This observation clearly indicates a high mobility of the carbonyl moiety. It is also worth noting that, in chloroform solution at 6.7 T and 298 K, the T_1 of the carbonyl resonance of $(C_6H_6)Cr(CO)_3$ is 23 s. Indeed the concurrence of a short T_1 and of the lack of the SSB manifold allows the attainment of higher sensitivity of the ^{13}C NMR spectrum of the included species than that of the crystalline sample and even of the solution spectrum.

Further evidence of the dynamic state of the carbonyl moiety has been obtained by recording the static spectrum of the inclusion compound [Fig. 1(c)]. The ^{13}CO resonance displays a bandwidth at half height of *ca.* 20 ppm, *i.e.* remarkably smaller than that commonly found in the static spectra of metal carbonyls.[11]

The motion of the carbonyl ligands is still in fast exchange also at temperatures as low as −100 °C where the ^{13}C CP MAS NMR spectrum is identical to that recorded at ambient temperature. This observation unambiguously shows that the high rotational barrier of the carbonyls[14] is overcome when the metal complex is included in the CD.

The observation of a narrow ^{13}C NMR carbonyl resonance in the static spectrum and the almost negligible asymmetry of its shape appear to be in agreement with the fast rotation of the $M(CO)_3$ unit around its principal coordination axis. A consequence of this type of motion is that the anisotropy of the axially symmetric ^{13}CO tensor is reduced by a factor of $(3\cos^2\beta - 1)/2$ where β is the angle between the principal chemical shift tensor axis and the rotational axis.[15] In the case of the β-CD/$(C_6H_6)Cr(CO)_3$ adduct the structure of the guest molecule[16] is such that the angle β is close to the value of the magic angle. Thereby rotation about the principal rotation axis would be expected to decrease the chemical shift anisotropy to a value close to zero also in the static spectrum.[14] An isotropic (or almost isotropic) reorientation of the whole molecule, which in principle would justify the absence of chemical shift anisotropy, has to be ruled out on the basis of the features of the deuterium NMR spectrum which is typical of a C_6 rotation.

The scrambling of carbonyls is a very common feature in metal carbonyl compounds in solution but it is highly unlikely in the solid state. Our findings show that the stereochemical non-rigidity of the carbonyl moieties may be re-established in a solid sample provided that the intermolecular interactions responsible for the high potential energy barriers in the crystalline framework of the pure compound are removed.

The observed behaviour would seem to suggest that the β-CD cavity provides a lower energy pathway for the rotation of the $M(CO)_3$ group.

Analogous results have been obtained by recording the ^{13}C CP MAS spectra of the inclusion complexes of β-CD with (toluene)$Cr(CO)_3$ and (*o*-xylene)$Cr(CO)_3$.

This work has been carried out with the support of the EU-TMR Program (Contract No. FMRX CT 96 0091). H. C. C. gratefully acknowledges the EU-SOCRATES Program for supporting her leave from QMW College (University of London).

Notes and references

† ^{13}C enriched $(C_6H_6)Cr(CO)_3$ was prepared by irradiating the compound in a benzene solution under 1 atm of ^{13}CO (99% enriched) using a 125 W high pressure mercury lamp for 2 h.[17]

‡ $(C_6D_6)Cr(CO)_3$ was obtained by reacting $(C_6H_6)Cr(CO)_3$ in a 1 : 1 mixture of C_6D_6 and $(CD_3)_2CO$ in a sealed vessel at 142 °C for 18 h, in a manner similar to that previously reported for other arene substitutions in ref. 18.

A catalytic symmetrical etherification

Laurence Bagnell, Teresa Cablewski and Christopher R. Strauss*

CSIRO Molecular Science, Bag 10, Clayton South,Victoria 3169, Australia. E-mail: chris.strauss@molsci.csiro.au

Received (in Cambridge, UK) 17th November 1998, Accepted 5th January 1999

A novel, catalytic, thermal etherification produces minimal waste and can be carried out under almost neutral conditions.

Most methods for etherification use either strongly acidic or basic conditions.[1–3] Their disadvantages have been summarised by Lemaire and co-workers, who explored hydrogenolysis of hemiacetals as an alternative.[4] The long-established Williamson synthesis[5] is still the most common procedure. It involves substitution of an alkyl halide (RX) by a strongly basic alkoxide or phenoxide (*e.g.* KOR or NaOR) and so is unsuitable if base catalysed elimination of HX from RX can compete.[6,7] A stoichiometric amount of waste salt (KX or NaX) is also produced. Importantly, inorganic salts account for the bulk of industrial chemical wastes.[7] Besides polluting soil and ground water, salts can lower the pH of atmospheric moisture and have been implicated in the formation of acid-dew.[8] Hence, their minimisation is essential.

Our research is directed toward technologies and methodologies for environmentally benign organic chemistry.[6,9] We now report a catalytic etherification that produces minimal organic waste and that can be carried out without the addition of acid or base.[10]

For a symmetrical ether, an excess of alcohol (ROH) and a catalytic amount of RX are heated. A solvolytic displacement reaction[11*a*] between RX and ROH affords R_2O along with HX or its elements [hereafter referred to as HX; eqn. (1)]. The liberated HX reacts with another molecule of ROH to form water and to regenerate RX [eqn. (2)]. If the rates of these forward reactions are comparable, the concentration of HX will be low throughout and that of RX will remain relatively constant. Although HX and RX are stoichiometric reactants or products in eqn. (1) and (2), they do not appear in the sum [eqn. (3)]. The net process involves condensation of two molecules of ROH to give R_2O plus water.

$$RX + ROH \rightleftharpoons R_2O + HX \quad (1)$$

$$HX + ROH \rightleftharpoons RX + H_2O \quad (2)$$

$$2\,ROH \rightleftharpoons R_2O + H_2O \quad (3)$$

A widely accepted mechanism of etherification catalysed by strong acids (commonly, sulfuric acid is used) involves protonation of the hydroxy function of an alcohol to give the corresponding oxonium ion as a better leaving group.[1,2] The reaction then can proceed through substitution by another molecule of the alcohol or by elimination of water, followed by acid-catalysed addition of the alcohol to the resulting olefin. Although the overall reaction is also satisfied by eqn. (3), the solution would remain acidic throughout.

By contrast, the present process requires participation by the counterion X^- and utilises ostensibly neutral conditions. For it to operate efficiently, X^- should be a good leaving group [to satisfy eqn. (1)], an effective nucleophile [to accommodate eqn. (2)] and a weak base to minimise competing elimination reactions.[12] Bromide and iodide possess these properties.[13] To the best of our knowledge, a critical participatory role for the counterion of the acid has not previously been envisaged or recognised.

The examples presented in Table 1 were obtained by heating the reactants in glass-lined pressure vessels without water removal. Conversions rather than yields have been quoted, owing to the catalytic nature of the systems, and by-product formation was negligible in all cases. Neat Bu^nOH was unreactive at 200 °C (entry 1), but in the presence of a catalytic amount of Bu^nBr it afforded $Bu^n{}_2O$ without significant consumption of the haloalkane (entry 2). A comparable result was obtained with $PhCH_2CH_2OH$ at 220 °C (entries 4 and 5). Styrene or 1-phenylethyl derivatives, that might have been anticipated through mechanisms involving elimination, were not detected. Cyclopropylmethanol, although highly acid-labile,[14] was stable at reflux (entry 6), but in the presence of a catalytic amount of cyclopropylmethyl bromide, it condensed to form bis(cyclopropylmethyl) ether, without significant depletion of the bromide or rearrangement (entry 7), until the conversion was approximately 50%. This result indicated that the concentration of acid was not sufficiently high to affect the cyclopropylmethyl group.

As the reaction further progressed though, phase separation occurred and HBr accumulated in the aqueous medium. Consequently, the rate of etherification slowed and the unreacted alcohol and the product ether were decomposed by the acid to give cyclobutyl and homoallyl alcohols along with mixtures of ethers containing cyclopropyl, cyclobutyl and homoallyl functionalities.[14]

Nonetheless, the examples in Table 1 demonstrated the process, its applicability for base- or acid-labile compounds (entries 5 and 7, respectively) and the catalytic role of RX.

Table 1 Example reactions and conditions

Entry	Starting material(s)	*T* /°C	*t*/h	Major product(s)	Conversion(%)
1	Bu^nOH	200	2	no reaction	—
2	Bu^nOH (10 ml) + Bu^nBr (1 mol)	200	1	$Bu^n{}_2O$	26
3[*a*]	Bu^nOH (10 mol) + Bu^nBr (1 mol) + LiBr (1 mol	200	1	$Bu^n{}_2O$	54
4	$PhCH_2CH_2OH$	220	22	$(PhCH_2CH_2)_2O$	< 1
5[*a*]	$PhCH_2CH_2OH$ (10 mol) + $PhCH_2CH_2Br$ (1 mol)	220	21	$(PhCH_2CH_2)_2O$	76
6	Cyclopropylmethanol	120	24	no reaction	
7[*a,b*]	Cyclopropylmethanol (10 mol) + cyclopropylmethyl bromide (0.9 mol)	115	24	bis(cyclopropylmethyl) ether	51
8[*a,c,d,e*]	Bu^sOH (10 mol) +Bu^sBr (1 mol)	150	5	$Bu^s{}_2O$(1 : 1 mixture of diastereoisomers)	8
9[*a,c,d,e*]	Bu^sOH (10 mol) +Bu^sBr (1 mol) +LiBr (1 mol)	150	5	$Bu^s{}_2O$(1 : 1 mixture of diastereoisomers)	18

[*a*] Concentration of bromo derivative essentially unchanged after the reaction. [*b*] Extended heating led to acid catalysed decomposition. See text. [*c*] Optically pure Bu^sOH also afforded a 1 : 1 mixture of diastereoisomers, suggestive of an S_N1 mechanism. [*d*] Prolonged heating led to some evolution of gas. [*e*] Neat Bu^sOH did not react at 150 °C for 5 h.

The pathway was investigated by heating $PhCH_2CH_2OH$ with Bu_4NBr (not entered in Table 1). After 20 h at 200 °C, $(PhCH_2CH_2)_2O$ was not detected (but $PhCH_2CH_2OBu^n$ was produced by Hoffmann degradation, in low conversion). $PhCH_2CH_2Br$ and $(PhCH_2CH_2)_2O$ formed only after a few drops of acid (HOAc) were added to the reaction mixture, followed by further heating. This experiment indicated that the presence of X^- was insufficient to drive the reaction and that HX was required. We have also found that the process can be started from eqn. (2). In an example, HBr (9 mol%) was heated with $PhCH_2CH_2OH$ at 200 °C. After 3 h, the product mixture was no longer acidic and contained $PhCH_2CH_2Br$ (9%) and $(PhCH_2CH_2)_2O$ (6%) along with unreacted $PhCH_2CH_2OH$. These results were all consistent with the pathway in eqn. (1)–(3) and indicated that mechanisms proposed for acid-catalysed etherification[1,2] may in some cases need to accommodate possible participatory roles of the counterion.

As mentioned above, although hydroxy and alkoxy functions are not readily displaced from carbon atoms, protonation in strong acid greatly facilitates their leaving.[1,2] Indeed, HBr and HI have been employed as cleavage agents for ethers for well over a century.[15] Conversely, the rate of solvolytic displacement of alkyl halides by alcohols [the forward reaction in eqn. (1)] can be accelerated by a small amount of water.[11b] However, excess water would shift unfavourably the position of equilibrium in eqn. (2) and promote the reverse reaction in eqn. (3). These opposing factors indicate that, for etherification, depletion of water should be beneficial but complete removal may be detrimental. Also, when the concentration of alcohol is 10–50 times larger than that of RX, the first order rate constant of eqn. (1) can rise considerably.[16] Thus the rate and extent of reaction in eqn. (1) will depend on the relative concentrations of RX and ROH as well as on the concentration of water present. Entries 3 and 9 were consistent with reports that the addition of alkaline metal salts also can accelerate solvolytic processes,[17] including the rate of ionisation of RX.[18] Our results and published data[11,16–18] indicate that the catalytic process would operate most effectively at low to moderate conversions and should be amenable to continuous processing. This aspect and the preparation of unsymmetrical and polyethers will be discussed elsewhere.

Received (in Basel, Switzerland) 26th October 1998, Accepted 13th December 1998

Two new octanuclear Cr(III) carboxylate complexes are reported illustrating a temperature dependent route to high nuclearity species.

A vast amount of research is currently focused on the investigation of magnetic exchange interactions in polynuclear assemblies and more specifically upon molecules which possess high spin ground states. Although the use of carboxylate ligands has proved a rich source of high nuclearity complexes for both manganese[1] and iron[2] similar studies with chromium(III) carboxylates have thus far been much more restricted. This is probably due to the relative kinetic inertness of Cr(III) and the inherent stability of the low nuclearity complexes—in particular oxo-centred Cr(III) triangles—once formed. Further reaction of $\{Cr_3O\}$ units has so far only produced $\{Cr_4O_2\}$ cores[3] despite the fact that these units can be thought of as building blocks in the formation of larger structures for Mn[1] and Fe.[2] The most significant exception is a report of a dodecanuclear Cr cage with pivalate ligands, formed by heating an ill-defined material of stoichiometry '$[Cr(OH)(O_2CCMe_3)_2]$' under an inert atmosphere.[4] We now report that this reaction is applicable to other carboxylates and other metals, and that the topology of the resulting cages can be controlled by temperature. We also show that electrospray mass spectrometry (ESMS) is an excellent tool for demonstrating nuclearity of such cages in solution.

Reaction of $Cr(NO_3)_3{\cdot}9H_2O$ (0.050 mol) with KO_2CPh (0.178 mol) in H_2O (500 cm^3) at *ca.* 80 °C gives a blue precipitate in >90% yield which has solubility in several organic solvents. ESMS† of this material dissolved in CH_2Cl_2–MeOH indicates a structure based on a typical oxo-centred $\{Cr_3O\}$ unit $[Cr_3O(O_2CPh)_6(H_2O)_2(OH)]$ **1**: *m/z* (% intensity) found (calc.) = 950.7 (67%) (951.7, M^+). Higher *m/z* peaks assigned as MeOH adducts with consistent isotopic splitting patterns are also seen. Unfortunately whether **1** is trimeric or contains oligomers of trimers is not certain.

Complex **1** undergoes complicated thermal rearrangements upon heating. Heating **1** at 210 °C *in vacuo* for 2 h caused elimination of H_2O yielding a pale green–blue powder. Extraction with CH_2Cl_2 followed by slow evaporation of the solution over a period of seven months at ambient temperature gave crystals of $[Cr_8(OH)_8(O_2CPh)_{16}]$ **2** (yield *ca.* 15%).‡ The structure of **2** (Fig 1)§ reveals eight octahedrally coordinated Cr atoms linked by eight bridging hydroxides and sixteen 1,3-bridging O_2CPh ligands forming a sixteen membered ring. The hydroxide ligands line the cavity in the centre of the 'wheel' pointing alternately slightly above and below the Cr_8 ring. Eight of the O_2CPh ligands bridge Cr atoms around the outside of the 'wheel' almost in-plane with the wheel, while the remaining eight ligands bridge alternately above and below the ring at an angle of *ca.* 90° forming two hydrophobic pockets.

The wheel may be formed in small amounts from the thermolysis and crystallise slowly, however the ESMS of the crude green–blue powder formed after thermolysis shows the predominant species present to be of similar mass to oxo-centred triangles, but with the MeOH adducts having greater relative intensity compared with **1** than in the spectra prior to heating. The balance of evidence is that heating to 210 °C disrupts the triangular units of **1**, probably by driving off terminally coordinated water, with **2** forming during crystallisation. ESMS of redissolved crystals of **2** did not show any significant peaks due to polynuclear species.

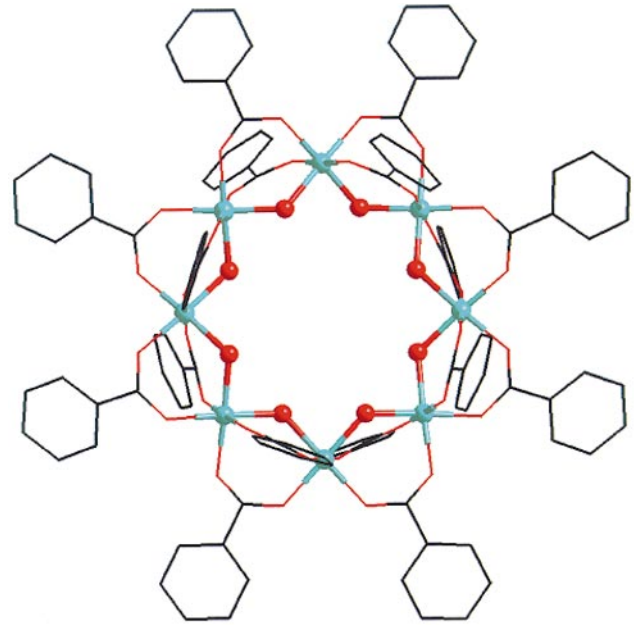

Fig. 1 The structure of **2**. Bond length ranges: Cr–O(benzoate) 1.925–2.002, Cr–O(hydroxide) 1.930–1.969 Å (av. esd 0.013 Å). Bond angle ranges: *cis* at Cr 84.5–95.6, *trans* at Cr 175.2–179.5° (av. esd 0.6°) (Cr, blue; O, red, μ-OH ball, other O atoms line; C, black lines).

Heating **1** at 400 °C under a stream of N_2 for 1 h eliminates more H_2O, yielding a dark green solid. Extraction with CH_2Cl_2 followed by addition of Pr^nOH (1:3, v/v) gave crystals of $[Cr_8O_4(O_2CPh)_{16}]$ **3** after 7 d in 70% yield.‡ The structure of **3** (Fig. 2)§ shows a distorted $\{Cr_4O_4\}^{4+}$ cubane core where each μ_4-oxide bridges to a further Cr atom creating a larger Cr_4 tetrahedron. The structure can also be considered to be formed from two orthogonal distorted $\{Cr_4O_2\}$ butterfly units and has non-crystallographic T_d symmetry. Twelve of the sixteen O_2CPh ligands link the cubane Cr atoms to the outer Cr atoms while four of the O_2CPh ligands are found in the unusual bidentate bridging mode capping the final two coordination sites on the outer Cr atoms. This coordination leads to the outer Cr sites being considerably more distorted from octahedral geometry than the Cr atoms of the central cubane. The Cr–O bond lengths to these chelating benzoates are also longer, which suggests these groups may be substituted which might allow new chemistry to be performed at these sites. Peaks in the ESMS are seen, both prior to crystallisation and for pure **3**, at *m/z* (% intensity) found (calc.) = 1232.3 (27%) [1231.9, (**3** + $2Na)^{2+}$]; 1220.1 (31%) [1220.4, (**3** + $Na)^{2+}$]; 1088.1 (100%) [1087.8, (**3** − 2 $O_2CPh)^{2+}$]. In contrast to **2** therefore, we can conclude that **3** is present in solution, and is the major product of the thermolysis.

The Cr(III) starting materials are perfectly set up to promote oligomerisation *via* conversion of coordinated H_2O to hydrox-

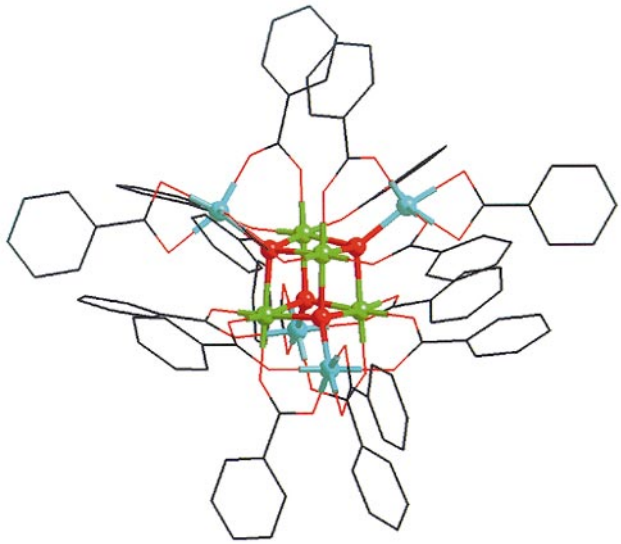

Fig. 2 The structure of **3**. Bond length ranges: Cr–O(1,3-bridging benzoate) 1.927–1.985, Cr–O(chelating benzoate) 2.009–2.056, Cr–O(oxide) 1.966–2.039 Å (av. esd 0.008 Å). Bond angle ranges: *cis* at Cr (metal atoms of central cubane) 81.7–99.1, *trans* at Cr(cubane) 172.8–179.7, *cis* at Cr (outer metal atoms) 64.7–109.4, *trans* at Cr (outer metal atoms) 154.9–74.2° (av. esd, 0.3°) (Cr atoms of central heterocubane, green; outer Cr, blue; O, red, μ_4-O ball, other O atoms line; C, black lines).

ide or oxide bridges rather than relying upon the serendipitous formation of such bridges in solution reactions. Furthermore, controlling the temperature of these rearrangement reactions permits isolation of different nuclearity products and we believe this route is applicable to other metals. IR and elemental analysis strongly suggests that the iron analogue of **3** can be made by the same route. The structure of **3** is also very similar to a mixed-valent Co cage, made by an entirely different route, with benzoate ligands which has been reported by Christou *et al*.[9] No other cages containing this metal-array have been described.

Preliminary magnetic measurements on both **2** and **3** indicate antiferromagnetic exchange between the Cr centres. The susceptibility data¶ for **2** could be modelled with one exchange parameter, $J = 12.0\ cm^{-1}$; while for **3** two exchange terms were required: $J_1 = 2.1\ cm^{-1}$, and represents the exchange between Cr atoms within the central heterocubane (green in Fig. 2), while $J_2 = 3.4\ cm^{-1}$, models the exchange between the central Cr atoms and the outer tetrahedron. The latter model is not ideal at present, but the fit is sufficiently good to be satisfied that these exchange parameters are broadly correct.

We thank the EPSRC(UK) for funding for a diffractometer, an electrospray mass spectrometer and for a Fellowship (to M. M.), and NATO and COST Action 518 for supporting the collaboration between Edinburgh and Florence.

Notes and references

† Electrospray mass spectra were obtained on a Finnegan LCQ spectrometer with the sample dissolved in CH_2Cl_2 which was added to MeOH prior to injection into the spectrometer.

‡ Satisfactory elemental analyses were obtained for **2** and **3**.

§ *Crystal data*: for $C_{106}H_{84}Cr_8O_{40}\cdot 1.5CH_2Cl_2$ **2**: monoclinic, space group *C*2/*c*, $a = 24.219(7)$, $b = 23.534(7)$, $c = 23.318(10)$ Å, $\beta = 95.37(5)°$, $V = 13232(8)$ Å^3, $M = 2541.1$, $Z = 4$ (the molecule lies on a twofold axis), $\mu = 0.764\ mm^{-1}$, $T = 150.0(2)$ K, $R1 = 0.1344$.

For $C_{112}H_{80}Cr_8O_{36}\cdot 5\ CH_2Cl_2$ **3**: monoclinic, space group $P2_1/c$, $a = 16.165(8)$, $b = 45.24(3)$, $c = 17.638(10)$ Å, $\beta = 110.52(5)°$, $V = 12079(12)$ Å^3, $M = 2842.4$, $Z = 4$, $\mu = 0.993\ mm^{-1}$, $T = 150.0(2)$ K, $R1 = 0.1025$.

Data collection, structure solution and refinement were performed using programs SIR92,[5] DIRDIF[6] and SHELXL-97.[7] All crystals of **2** were badly twinned leading to the poor refinement which is sufficient to unambiguously derive connectivity. Diffuse lattice solvent (1.5 CH_2Cl_2 per formula unit) was treated by the van der Sluis-Spek method.[8] Only Cr and O atoms were refined anisotropically. Full details have been deposited and will be published later. CCDC 182/1128. See http://www.rsc.org/suppdata/cc/1999/285/ for crystallographic files in .cif format.

¶ Variable-temperature magnetic measurements on **2** and **3** in the region 1.8–325 K were made using a SQUID magnetometer (Quantum Design) with samples sealed in gelatine capsules. Diamagnetic corrections for sample holders and samples were applied to the data. The data were fitted with Hamiltonians: for **2,** $H = JS_xS_{x+1} + JS_8S_1$ ($1 \leqslant x \leqslant 7$); and for **3**, $H = J_1(S_1S_2 + S_1S_3 + S_1S_4 + S_2S_3 + S_2S_4 + S_3S_4) + J_2\{S_5(S_1 + S_2 + S_4) + S_6(S_2 + S_3 + S_4) + S_7(S_1 + S_2 + S_3) + S_8(S_1 + S_3 + S_4)\}$.

Communication 8/08304E

Uncatalysed hydrogen-transfer reductions of aldehydes and ketones

Laurence Bagnell and Christopher R. Strauss*

CSIRO Molecular Science, Bag 10, Clayton South, Victoria 3169, Australia. E-mail: chris.strauss@molsci.csiro.au

Received (in Cambridge, UK) 17th September 1998, Accepted 5th January 1999

Aldehydes and ketones are reduced to the corresponding alcohols by transfer hydrogenation at high temperature with EtOH, Pr^{n}OH or Pr^{i}OH as hydrogen donors in the absence of catalysts and base.

Hydrogen-transfer occurs when covalently bonded hydrogen changes its site of attachment, either inter- or intra-molecularly.[1] The reduction of aldehydes and ketones usually involves unlike donors and acceptors.[2–4] It has been long considered that catalysts are required,[3] that alcohols are preferred hydrogen donors[5] and that base promotion is beneficial.[4,6] For example, Meerwein–Ponndorf–Verley (MPV) reductions are typically conducted using a stoichiometric amount of $Al(OPr^i)_3$ and excess Pr^{i}OH.[4,7] However, such conditions can give substantial amounts of side-products[4] and generate environmentally undesirable salts during work-up.[8]

Our work toward the development of cleaner processes for preparative organic chemistry has produced new thermolytic methods.[9] Now we report hydrogen-transfer reactions that employ elevated temperatures without added metallic catalysts, acids or bases.

The starting aldehydes and ketones were heated with low-boiling alcohols in stainless steel autoclaves, with or without glass liners, at 220–230 °C. After cooling, the products were isolated by rotary evaporation and/or distillation. Solvent extraction was avoided and recycling of the unreacted volatile alcohols was facilitated.

Initially, EtOH, Pr^{n}OH or Pr^{i}OH were evaluated as the sources of hydrogen, with PhCHO as the reductant. BzOH was formed at comparable rates in these alcohols, including in all-glass systems. After treating PhCHO for 24 h in Pr^{i}OH at 225 °C (entry 1 in Table 1), the product mixture comprised BzOH (92% isolated yield), starting material (4%) and (*E*)-4-phenylbut-3-en-2-one (the aldol by-product from the reaction of the starting PhCHO with Me_2CO formed by oxidation of the Pr^{i}OH; 2%). $PhCO_2H$ and $PhCO_2Bz$ (possible by-products from Cannizzarro and Tishchenko reactions, respectively) were either present in trace amounts or not detected. Thus, the reaction proceeded slowly but selectively and competing processes were retarded in the absence of added base.

A similar result was obtained for the reduction of cinnamaldehyde (entry 2).[10] The major product was (*E*)-cinnamyl alcohol. 3-Phenylpropanol (up to 7%) was formed by reduction of the double bond followed by that of the aldehydic function. The stability of cinnamyl alcohol under similar conditions (entry 7) confirmed this reduction sequence.

High-boiling hydrocarbons have been used by others as hydrogen donors for the reduction of carbonyl compounds, at temperatures around 400 °C.[11,12] However, in contrast with the present work (which employed considerably lower temperatures), α,β-unsaturated carbonyl compounds were selectively hydrogenated at the carbon–carbon double bond, while the carbonyl group remained intact.[11]

Herein, cyclohexanone and acetophenone afforded cyclohexanol and 1-phenylethanol, respectively (entries 5 and 6). The rate of reduction of ketones was slower than that for aldehydes. Dehydration of the products was not observed.

To the best of our knowledge, this is the first report of synthetic hydrogen-transfer reductions by low-boiling alcohols such as Pr^{i}OH, Pr^{n}OH or EtOH, alone. Significantly, in all cases so far examined, the products were the same as those reported for corresponding MPV reactions.[13] A co-ordinating metal was not added to our experiments, so despite the similarities of the products, an alternative mechanism is obligatory to that proposed for MPV reactions by Jackman and Mills[14] and widely accepted.[4,6,15]

In summary, this environmentally benign method of selective transfer-hydrogenation employs inexpensive, renewable reagents and affords minimal waste, with no inorganic salts introduced or formed. It offers considerable promise for cleaner processing and for biomimetic applications. Investigation of the converse approach, *i.e.* the use of low-boiling aldeydes and ketones for Oppenauer-type oxidations[16] of alcohols, is underway.

An unusual ring expansion from the Zav'yalov pyrrole synthesis: formation of oxacino[2,3-*c*]pyrroles

Christopher D. Gabbutt,[a] John D. Hepworth,[a] B. Mark Heron,*[a] Mark R. J. Elsegood[b] and William Clegg[b]

Received (in Liverpool, UK) 18th November 1998, Accepted 22nd December 1998

Enamino acids 2 and 5 undergo a facile cyclisation to afford the pyrrole 3 and isoindole 6 ring systems; a novel two atom ring expansion ensues when derivatives 5b,d are subjected to the cyclisation conditions, resulting in the formation of the new oxacino[2,3-*c*]pyrrole system, the structure of which is confirmed by X-ray crystallography.

The pyrrole unit[1] occurs in a diversity of natural products, pharmaceutical agents and polymers.[2] The synthesis of this ring system has been the subject of intense activity and has featured in a number of review articles.[3,4] Despite such activity, routes to 2,5-unsubstituted pyrroles and routes which involve the formation of the C-2–C-3 bond are particularly rare.[4] There are several routes to pyrroles that utilise 1,3-dicarbonyl compounds and α-amino acids as the starting components, but in all of these examples the resulting pyrrole retains a carboxylate function at C-2.[5] In 1973, Zav'yalov reported an efficient route to the pyrrole system (Scheme 1),[6] which has been scarcely utilised in the last 25 years.[7] We now report the application of this methodology to the synthesis of some novel substituted pyrroles and fused analogues and describe a unique ring expansion reaction to afford the new oxacino[2,3-*c*]pyrrole system.

Dimethylaminomethylene ketones **1** and **4** were obtained by standard protocols.[8] Their addition–elimination reaction with a range of α-amino acids in aq. EtOH containing NaOAc gave the crystalline enamino acids **2** and **5** in high yields (Scheme 2).†

Heating a solution of enamino acids **2a**,**b** and **5a**,**c** in Ac_2O containing Et_3N proceeded with the instantaneous formation of a deep red colour which was accompanied by the vigorous evolution of CO_2 (lime water bubbler) as the internal reaction temperature reached reflux. In the case of **5b**,**d**, however, evolution of CO_2 was only slight. After *ca*. 30 min the reaction mixture was allowed to cool and was subjected to an aqueous work-up. TLC examination of the crude reaction mixtures typically revealed the presence of a fast running major component contaminated with dark base line material rendering initial purification by flash chromatography easy.

The cyclisation of enamino acid **2a** proceeded with the expected regioselectivity of cyclisation on to the more electrophilic ketonic carbonyl group rather than the ester function to afford a single pyrrole, **3a**, confirmed by the presence of signals in its ^{1}H NMR spectrum associated with the ethyl ester moiety. Of particular note is the efficient preparation of **3b**. Existing routes to compounds of this type are often laborious and low yielding.[3c,f,h,4] Formation of the pyrroles **3** and isoindoles **6** and **9** is chemoselective, and in no instances did we observe the presence of any α-amino ketones resulting from a Dakin–West reaction.[9]

The ^{13}C NMR spectra of **7** (from **5b**) and **8** (from **5d**) contained an additional low field signal at δ 168.9 (OAc) and 192.8 (C=O), respectively, when compared to the isoindoles **6a** and **b**. Elemental analysis and HRMS for **7** and **8** confirmed that both contained an additional CO_2 unit. The structure of **8**‡ was established as the oxacino[2,3-*c*]pyrrole by X-ray crystallography (Fig. 1). The ^{1}H NMR spectrum of **8**§ displayed marked broadening of the signals associated with the aliphatic functions indicating that the molecule is undergoing conformational interconversion. The resolution of the spectrum was improved when it was recorded at low temperature (253 K).

It is evident from the ^{1}H NMR data that the eight-membered ring of **8** is in equilibrium between a number of conformers.[10] However, **7** does not display this behaviour, probably as a

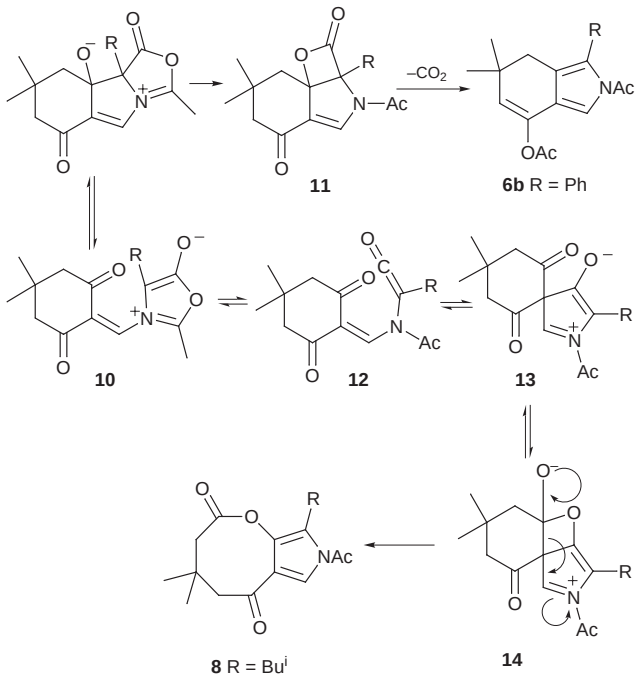
consequence of the rigidity imparted to the ring by the enol acetate function.

Scheme 3 depicts a possible mechanism for the formation of the isoindoles **6** and oxacinopyrrole **8**. It is well established that the acylation of *N*-substituted amino acids proceeds with the formation of mesoionic 1,3-oxazolium-5-olates (munchnones) and evidence has accrued that these are tautomeric with *N*-acyl ketenes.[11] The mesoionic heterocycle **10** may react by two distinct pathways. We propose that, when R = phenyl, the extended conjugation imparts stability to the munchnone tautomer which then attacks the proximal C=O group. The alkoxide species thus generated forms the lactone **11** with concomitant oxazole ring cleavage. Cycloreversion of CO_2 and subsequent *O*-acylation completes the route to the dihydroisoindoles **6a**,**b**. Conversely, **10** is destabilised when R = alkyl and the munchnone undergoes ring–chain tautomerism to the *N*-acyl ketene **12**. Intramolecular acylation of the enamine function affords the spirocycle **13**. Oxetane ring formation and subsequent ring cleavage of **14** effects the ring expansion to the oxacinopyrrole system. It is noteworthy that the formation of the oxacinopyrroles only occurs with the combination of an α-alkyl amino acid and a cyclohexane-1,3-dione; replacement of either one of these components results in the formation of the pyrrole or isoindole as, for example, **9** which is derived from 2-hydroxymethylene-1-tetralone and glutamic acid 5-methyl ester.



Scheme 3

In conclusion, this pyrrole synthesis is highly versatile and permits access to 2,5-unsubstituted pyrroles, 3-hydroxypyrrole derivatives, isoindoles and the novel oxacino[2,3-*c*]pyrroles.

We thank the EPSRC for the provision of a mass spectrometry service at the University of Wales, Swansea.

Scandium triflate catalyzed *in situ* Prins-type cyclization: formations of 4-tetrahydropyranols and ethers

Wen-Chun Zhang, Ganapathy S. Viswanathan and Chao-Jun Li*

Department of Chemistry, Tulane University, New Orleans, Louisiana 70118, USA.
E-mail: cjli@mailhost.tcs.tulane.edu

Received (in Corvallis, OR, USA) 11th November, 1998, Accepted 16th December 1998

The reaction of aldehydes with homoallyl alcohols catalyzed by scandium triflate generates tetrahydropyran-4-ol and ethers in good yields.

The acid-catalyzed olefin–aldehyde condensation, known as the Prins reaction, is one of the fundamental reactions for carbon–carbon bond formation.[1] However, the synthetic application of this important reaction has been under-explored due to the classical conditions of strong acids (*e.g.* sulfuric acid) and high reaction temperatures, which often generate a mixture of a range of products. The importance of the tetrahydropyran ring is exemplified by the ring's function as the backbone of various carbohydrates and natural products.[2] Its importance calls for the continuing search for methods of synthesizing tetrahydropyran derivatives.[3] Recently, during our investigation of indium-mediated reactions under solventless conditions,[4] we observed the formation of tetrahydropyran-4-ols and 4-bromotetrahydropyran derivatives. In order to explain the formation of the tetrahydropyran derivatives, we postulated that the product was generated through a tandem carbonyl allylation–hemiacetal formation–Prins reaction. We speculated that the reaction of a homoallyl alcohol with an aldehyde should generate the

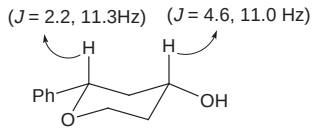

Fig. 1 Coupling constants in **4a**.

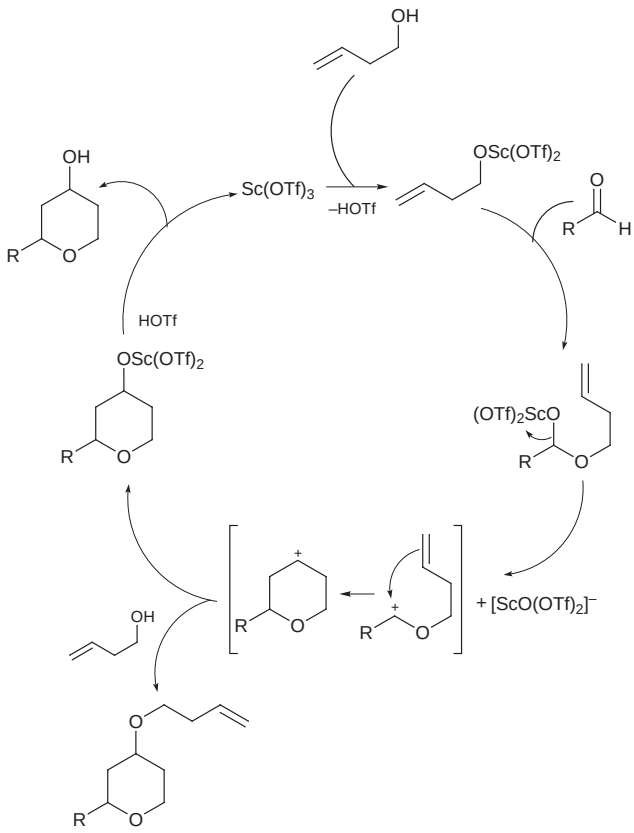
corresponding tetrahydropyran derivatives. Subsequently, by controlling the reaction conditions, we have developed an efficient synthesis of 4-chlorotetrahydropyrans **3** mediated by indium trichloride [Scheme 1, route (*a*)].[5] We also conceived that if we replaced the chloride ion with a non-nucleophilic anion, then the tetrahydropyranol **4** or its ether **5** would become the major products [route (*b*)]. However, to do so we would need a Lewis acid to facilitate the Prins reaction. It appears that the scandium triflate chemistry developed by Kobayashi and others would be the best choice for this reaction.[6] Here, we report that the reaction of aldehydes with homoallyl alcohols catalyzed by scandium triflate generates the corresponding desired products readily (Scheme 1).[7]

When a mixture of benzaldehyde and but-3-en-1-ol was stirred with $Sc(OTf)_3$ in $CHCl_3$ under a refluxing temperature overnight, 63% of a tetrahydropyran ether **5a** was isolated together with 14% of the corresponding tetrahydropyranol **4a**.† Measurement of the coupling constants of the benzylic hydrogen (J = 2.2 and 11.3 Hz) as well as the hydrogen on the carbon bearing the hydroxy group (J = 4.6 and 11.0 Hz) of the tetrahydropyranol **4a** indicated a structure where the hydroxy and the phenyl groups are in a *cis* relationship and are equatorial (Fig. 1). The formation of other stereoisomers is negligible as shown by the ^{1}H NMR measurement of the crude reaction mixture. A variety of other aromatic aldehydes reacted similarly generating the corresponding products (Table 1) in good isolated (overall) yields. Aliphatic aldehydes were less effective for the reactions. Other solvents that we have tested (such as CH_2Cl_2, hexane, toluene,THF and Et_2O) were not as effective as $CHCl_3$ for the reaction. The catalytic cycle of this Prins-type reaction is postulated in Scheme 2. A similar mechanism has been used to explain a cross-allylation of aldehydes by Nokami and co-workers very recently.[8] In conclusion, we have developed an effective $Sc(OTf)_3$-catalyzed Prins-type reaction to form tetrahydropyranols and related ether derivatives. The conditions for the catalyzed reaction are much milder than the classical Prins reaction using strong acids. Presently, we are evaluating a range of synthetic potentials of this catalyzed reaction.



Scheme 2 Proposed mechanism for the $Sc(OTf)_3$ catalyzed tetrahydropyran formations.

We are grateful to US NSF-EPA, LEQSF and the NSF Early CAREER Award program for partial support of this research.

Notes and references

† Typical experimental procedure: A mixture of **1** (2 mmol), but-3-en-1-ol **2** (4 mmol) and scandium triflate (5 mol%) was mixed in $CHCl_3$ (5 ml). The reaction mixture was refluxed under nitrogen overnight. After concentrated *in vacuo*, the crude reaction mixture was subjected to column chromatography on silica gel eluting with hexane–EtOAc (gradient eluent: 27 : 1 to 3 : 1) to yield products **4** and **5**.

A robust structural motif in inclusion crystals of norbile acids

Michihiro Sugahara, Kazuki Sada and Mikiji Miyata*

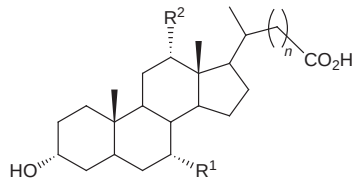
Material and Life Science, Graduate School of Engineering, Osaka University, 2-1 Yamadaoka, Suita, Osaka 565-0871, Japan. E-mail: miyata@ap.chem.eng.osaka-u.ac.jp

Received (in Cambridge, UK) 16th November 1998, Accepted 8th January 1999

Four norbile acids (norcholic, nordeoxycholic, norchenodeoxycholic and norlithocholic acids) include various organic compounds and have a common robust motif in their crystal structures based on a cyclic hydrogen bond network and steric complementarity in the lipophilic parts.

The development of robust structural motifs in the crystalline state has attracted much attention as 'supramolecular synthons'[1] for the design of molecular cavities in nanoporous organic materials. However, most focus on directional strong intermolecular interactions such as multiple hydrogen bonding groups.[2] The design of robust motifs using steric complementarity or other weak interactions is still in its infancy: layer structures of long alkyl compounds,[3] herring-bone motifs or π–π stacking of polyaromatic compounds[4] or tetraarylporphyrins[5] are known. We describe here a novel robust motif based on the steric complementarity of the liophilic parts in inclusion crystals of norbile acids.

Norbile acids (**1a**–**4a)** were prepared from commercially available bile acids (**1b**–**4b**) by degradation of the side chain.[6]



n = 1	**1a** R^1 = OH, R^2 = OH	**2a** R^1 = H, R^2 = OH
	3a R^1 = OH, R^2 = H	**4a** R^1 = H, R^2 = H
n = 2	**1b** R^1 = OH, R^2 = OH	**2b** R^1 = H, R^2 = OH
	3b R^1 = OH, R^2 = H	**4b** R^1 = H, R^2 = H

Trace formation of inclusion crystals was investigated by recrystallization from more than eighty organic compounds. The guest incorporation and stoichiometries were determined by thermogravimetric analysis, IR spectroscopy and using a Karl Fischer moisture content meter. Table 1 shows the guest compounds, the host–guest ratios and the structural type of the host assemblies. Inclusion compounds of **2a** have already been reported by us,[7] and the other three norbile acids also form inclusion crystals with many organic compounds as **2a** does. In some cases, **1a** includes guest compounds as well as one molecule of water. Compared to the lack of inclusion ability of **4b**,[8] various organic compounds are included in **4a**.

The X-ray diffraction patterns of the inclusion crystals indicate that they exhibit several types of host framework, depending on the guest molecules. It is noteworthy that the B type structure in Table 1 is observed in the crystal structures of all four norbile acids. The crystal structures of the inclusion crystals of acetone were further characterized by X-ray crystallography (Fig. 1).† They are all isostructural, despite the different number and locations of the hydroxy groups in the steroidal skeleton. This remarkable structural feature is a bilayer structure that is formed by hydrogen bonding between the hydrophilic faces (α-faces) of the steroidal plane and van der Waals association between the lipophilic faces (β-faces). In the hydrophilic layer, a cyclic hydrogen-bond network involves two hydroxy groups in the 3-positions and two carboxylic acids in the side chains from four different host molecules (Fig. 2). This cyclic hydrogen bond network forms a wavy sheet structure, which stacks in an antiparallel manner without any void space in the liopophilic layers. A caged inclusion cavity forms between the side chains due to the unbalanced molecular structure with the wide steroidal plane and the rod-like side chain. The guest compounds are included in 2:1 host–guest stoichiometry in the cavity.

In contrast, bile acids have diverse crystal structures. That is, **1b** and **2b** form bilayer structures,[9] while **3b** and **4b** form helical[10] and non-layer[8] structures, respectively. In these cases all hydrogen bond groups contribute to the formation of such

The distances of the cyclic host–host hydrogen bond sequence, O(3)H•••O(23a)=C–O(23b)H•••O(3)•••O(23a)=C–O(23b)H•••O(3) are 2.63, 2.73, 2.61 and 2.79 Å for **1a**, 2.64, 2.75, 2.61 and 2.79 Å for **2a**, 2.71, 2.64, 2.76 and 2.65 Å for **3a**, 2.72, 2.60, 2.79 and 2.62 Å for **4a**.

host-inherent assemblies involving different hydrogen bond networks. In the case of norbile acids, however, the groups at the 7 and 12 positions do not join the networks, yielding the common assembly mentioned above. This is attributed to the side chains being shortened by one methylene group. The restrained chains have carboxy groups orientated in different directions, explaining the different hydrogen bond networks. Moreover, the wavy structure of the host molecules causes steric complementarity of the lipophilic β-faces. Accordingly, the molecules form the wavy layers which stack with good complementarity, leading to the robust structural motif.

This paper describes the new robust motif in the crystal structures of the norbile acids. The robustness is mainly caused by steric complementarity between the lipophilic layers. Molecular recognition and guest-dependent polymorphism of the host assemblies is currently under investigation.

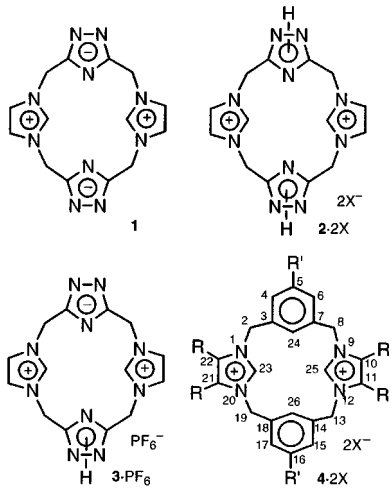
Received (in Liverpool, UK) 2nd November 1998, Accepted 21st December 1998

Imidazolium units represent the main structural motifs for the formation of unconventional C–H···Cl$^-$ hydrogen bonds which become the noncovalent forces driving the anion interactions exibited by dicationic [1$_4$]imidazoliophanes in the solid state, while C–H···O hydrogen bonds with water play a crucial role in governing the conformation of the solid–state aggregates, as well as in solution, wherein NMR studies also reveal the importance of hydrogen bonds in controlling the tendency to anion binding.

The molecular diversity within molecular *hosts* permits the design of new architectures with capacity for specific biological or physical properties.[1] The increasing interest in anion recognition phenomena is mainly directed towards synthetic receptors based on positively charged moieties.[2] Consequently, the primary noncovalent driving forces are controlled by electrostatic interactions,[2] whereas hydrogen bonding forces[3] are known to play a significant role in a few host systems.[4] Developing the chemistry of heterocyclic betaines, we have reported the first examples of quadrupolar architectures within [1$_4$]heterophanes built up from imidazolium methylene triazo-

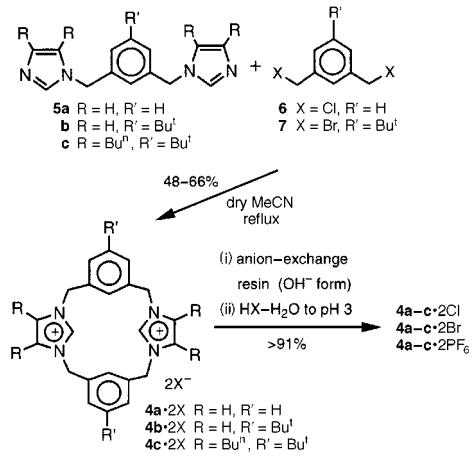


late subunits, *e.g.* the bis-betaine **1**, as well as its precursors the dicationic macrocycle **2** and betaine **3**.[5] We now report the synthesis and structural properties of simple dicationic [1$_4$]heterophanes **4·2X** containing two imidazolium nuclei in a 1,3-alternating manner as models for anion recognition.

The dicationic phanes **4·2X** were prepared following a '3+1' convergent approach (Scheme 1), efficiently applied for synthesizing the dicationic azolophane **2**. Thus, macrocyclization of the trinuclear compounds **5a**–**c**† with 1,3-bis(halomethyl)benzenes **6** or **7** produced the title phanes **4a**–**c·2X**.‡

The targeted macrocycles were characterized on the basis of their spectroscopic data.§ Furthermore, the structure of macrocycles **4a·2Cl·2H$_2$O** and **4b·2Cl·3.5H$_2$O** were confirmed by X-ray crystallography.¶‖

Concerning **4a·2Cl·2H$_2$O**, the dication **4a** adopts a chair-like conformation (Fig.1 and 2). Regarding hydrogen bonds,** in



Scheme 1 '3+1' Convergent synthesis of dicationic imidazoliophanes **4·2X**.

the highly directional C–H···Cl$^-$ interactions (θ *ca.* 160°), each chlorine counterion is three-centered between a *m*-xylyl hydrogen atom, *e.g.* H6, and the acidic hydrogen atom on the imidazolium ring, *e.g.* H10, the latter being the shortest hydrogen bond interaction (2.54 Å, θ = 157°).†† Moreover, there are *weak* interactions with water.**

The molecular shape of dication **4b** assumes a cone-like conformation in contrast with the partial cone-like arrangement observed for **4a**. However, both dications **4a** and **4b** have similar molecular cavity dimensions: a square of 5 Å side.[5] The assemblages depicted in Fig. 3 show that the asymmetric unit of **4b·2Cl·3.5H$_2$O** contains two different dication—**A** and **B**. Dication **A** has the propensity to form hydrogen bonds with one of the chlorine counterions (Cl2), meanwhile dication **B** interacts with one water molecule (O7).‖**

For the title dications **4a–c·2X** (X = Cl$^-$, Br$^-$, PF_6^-) reported, the ^{1}H NMR spectra showed a sharp singlet for the methylene

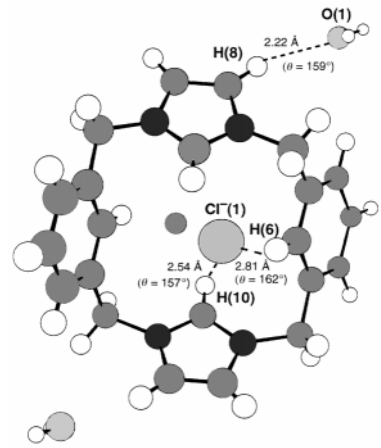


Fig. 1 Molecular structure of **4a·2Cl·2H$_2$O**, showing the non-covalent interactions.

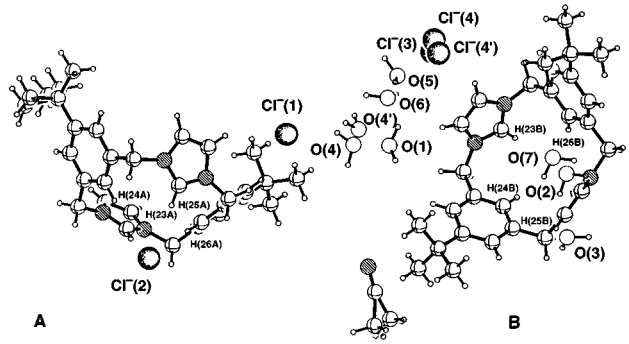

Fig. 3 Unit cell diagram for **4b·2Cl·3.5H$_2$O·0.5CH$_3$N**.

proton atoms, indicating the rapid interconversion of the different possible conformations, comparable to those of [1$_4$]azolophane **2·2X**.[5]‡‡ Moreover, the δ_H values of H-23 and H-25 (Im$^+$) together with H-24 and H-26 (aromatic fragments) are sensitive to the nature of the anion and to the solvent polarity, moving to lower fields.

As a consequence of the hydrogen bonding with the counteranion present in the macrocycle, the acidic H-23 and H-25 hydrogen atoms are shifted downfield in comparison with standard values for these protons within azolophanes (*e.g.* **2·2X**) and a variety of *N*-azolylimidazolium salts with different spacers.[5,8] Furthermore, significant changes in δ_H were induced by addition of various tetrabutylammonium salts [*ca*. 6 mM] to a DMSO-d_6 solution of the model dication **4c·2PF$_6$** [*ca*. 3 mM]. The major deshielding effect observed was up to 302 Hz for the imidazolium ring protons H-23 and H-25, and followed the order $H_2PO_4^- > F^- > CH_3CO_2^- > CN^- > Cl^-$.

In summary, a convergent '3 + 1' synthesis led to model dicationic heterophanes based on imidazolium units as molecular recognition motifs for anions. Structural studies both in solution and in the solid-state reveal that dications **4·2X** are unusual hydrogen bond donor-rich organic macrocycles, and their anion interactions are controlled by hydrogen bonding networks. These simple dicationic systems may be exploited for template phenomena and transport processes.

Notes and references

† Protophanes **5a–c** (ref. 6) were obtained by reaction of conveniently substituted imidazoles with a 1,3-bis(halomethyl)benzene **6** or **7** (ref. 7).

‡ Counterion exchange was performed by treatment of the [1$_4$]heterophanes **4a–c·2X** with a strongly basic anion exchange resin (ref. 8) followed by immediate collection of the eluates in acid solutions (either aq. HCl, aq. HBr or aq. HPF_6) to pH 3–4, following a standard protocol (ref. 5, 8).

§ As for ES mass spectra, the heterophanes **4a·2X** revealed characteristic peaks for the successive loss one and two counterions.

¶ *Crystal data* for **4a·2Cl·2H$_2$O:** $C_{22}H_{26}Cl_2N_4O_2$, M = 449.37, colorless crystal, 0.53 × 0.53 × 0.43 mm^3 size, monoclinic, a = 8.627(2), b = 15.788(1), c = 8.735(2) Å, β = 113.38(1)°, V = 1092.0(3) Å^3, space group $P2_{1/c}$, Z = 2, ρ = 367 g cm^{-3}, Mo-Kα radiation (graphite crystal monochromator, λ = 0.71073 Å), μ = 0.324 mm^{-1}, T = 200(2) K. Of 2828 reflections measured, 1910 were unique with R_{int} = 0.019, of which only 1674 reflections were observed with $I > 2\sigma(I)$, final GoF = 1.076, refined to R_1 = 0.027, wR_2 = 0.067. For **4b·2Cl·3.5H$_2$O·0.5CH$_3$CN**: $(C_{30}H_{38}N_4Cl_2)\cdot 3.5H_2O\cdot 0.5CH_3CN$, M = 609.13, colorless crystal, 0.26 × 0.23 × 0.26 mm^3 size, triclinic, a = 12.240(4), b = 12.837(5), c = 21.579(8) Å, α = 90.50(3), β = 96.55(4), γ = 98.03(3)°, V = 3334(2) Å^3, space group $P\bar{1}$, Z = 4, ρ = 1.213 g cm^{-3}, Mo-Kα radiation (graphite crystal monochromator, λ = 0.71073 Å), μ = 0.233 mm^{-1}, T = 200(2) K. Of 12321 reflections measured, 11718 were unique with R_{int} = 0.0509 and 5375 observed with $I > 2\sigma(I)$, final GoF = 1.029, refined to R_1 = 0.1032, wR_2 = 0.2512. Data collected on a Nonius CAD-4 single-crystal diffractometer, ω–2Θ scans. Lorent and polarization corrections were applied and the data were reduced to F_o^2 values. The structures were solved by direct methods using the program SHELXS (ref. 9), were further refined using SHELXL (ref. 10), and the major occupancy non-hydrogen atoms refined anisotropically. The hydrogen atoms, located by Fourier difference synthesis, were isotropically refined with a common thermal parameter. Crystals of compound **4b·2Cl** were very unstable, and were mounted on a X-TEMP2 device (ref. 11). CCDC 182/1132.

‖ The atom numbering system is not the same as that obtained from the X-ray analysis.

** For **4a·2Cl**, the most relevant geometrical data for hydrogen bonds, distances (Å) and angles (°) (with esds) are: C(10)–H(10), 0.976 (19), C(10)···Cl$^-$(1), 3.456 (2), H(10)···Cl$^-$(1), 2.538 (19), C(10)–H(10)···Cl$^-$(1),156.7 (1.5); C(6)–H(6), 1.005 (18), C(6)···Cl$^-$(1), 3.781 (2), H(6)···Cl$^-$(1), 2.811 (19), C(6)–H(6)···Cl$^-$(1), 162.3 (1.3). Concerning interactions with water, the C–H···O hydrogen bond connects the trifurcated acceptor (O1) with the cationic ring, *e.g*. H8, the *m*-xylene ring, *e.g*. H2, and the spacer, *e.g.* H27.

†† Steiner (ref. 12) pointed out that hydrogen bonds from C–H groups to halide ions are only rarely discussed in the literature, even though stronger C–H donors exhibit CH···Hal$^-$ distributions of similar shape as for O/N–H donors and can be analyzed in the same way. As for the (NN)C(sp^2)–H fragment, the mean C–H···Cl$^-$ distance of 2.54 Å was found (ref. 12). Within NH···Hal$^-$ bonds, we should mention the calix[4]pyrroles described by Sessler (ref. 13) as anion binding agents in CH_2Cl_2 solution and in the solid state. Both in the chloride and fluoride complexes, the anions occupy a perching position above the main plain of the nitrogen atoms.

‡‡ ^{1}H NMR spectra were recorded at room temperature (22 °C) on a Varian Gemini 300 spectrometer operating at 300 MHz, in polar aprotic solvents (DMSO-d_6, CD_3CN).

Heterolytic dihydrogen activation in an iridium complex with a pendant basic group

Dong-Heon Lee,[a] Ben P. Patel,[a] Eric Clot,[b] Odile Eisenstein*[b] and Robert H. Crabtree*[a]

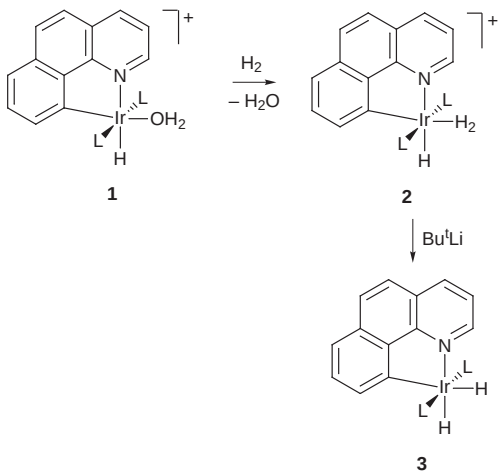
Received (in Bloomington, IN, USA) 4th November 1998, Accepted 22nd December 1998

Experimental and theoretical studies show that H_2 reacts with an Ir phosphine complex having a basic pendant amino group to give either an H_2 or an Ir–H···H–N hydrogen-bonded hydride complex, depending on the basicity of the phosphine ligands.

Heterolytic hydrogen activation by a transition metal complex can occur by deprotonation of an intermediate dihydrogen complex by an external base, as shown in several studies.[1–6] We have shown that appending an NH_2 group at the 2-position of a cyclometalated 7,8-benzoquinolinate ligand (bq-NH_2) can lead to ligand binding *via* both M–L bonds and –N–H···L hydrogen bonds.[7] Since the pendant NH_2 group is basic, we have now examined the possibility that the pendant group can act as an internal base to deprotonate an adjacent H_2 ligand.

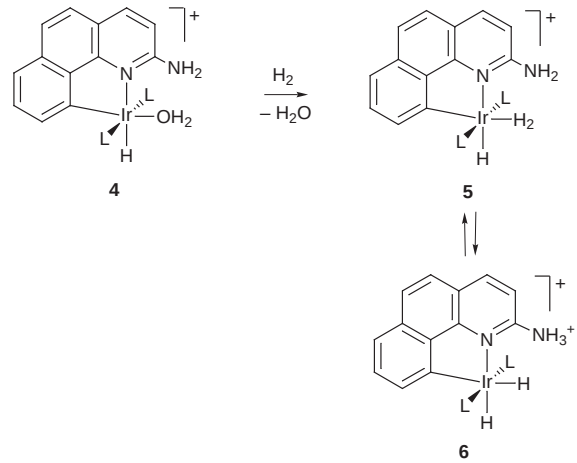
We have compared the reactivity of a series of bq-NH_2 complexes with that of the corresponding unsubstituted benzoquinolinate analogue (bq-H) that lacks the pendant group. In the comparison bq-H system, the known cationic aqua complex, $[IrH(bq\text{-}H)(OH_2)(PPh_3)_2]BF_4$ **1**, reacts with H_2 to give a cationic H_2 complex, **2**, previously characterized in detail.[8] Addition of Bu^{t}Li as base leads to deprotonation of the H_2 ligand to form the known neutral dihydride, $[IrH_2(bq\text{-}H)(PPh_3)_2]$ **3** (Scheme 1).



1 **2** **3**

Scheme 1

The aqua complex, $[IrH(bq\text{-}NH_2)(OH_2)(PPh_3)_2]BF_4$ **4a**, in the new pendant amine system also reacts with H_2 to give, not the corresponding H_2 complex, **5a**, but *via* heterolytic activation to give the dihydride, **6a**, instead (Scheme 2). Complex **6a** was fully characterized as $[IrH_2(bq\text{-}NH_3)(PPh_3)_2]BF_4$ and its identity is shown, for example, by the spectral data. The reaction is accompanied by the loss of both the ^{1}H NMR triplet hydride resonance at δ −16.4 and the amino resonance at δ 6.1 characteristic of **4a**, and the appearance of two sharp, mutually coupled (dt, $^2J_{HH'}$ 8.5; $^2J_{PH}$ 14.6 Hz) hydride resonances at δ −23.2 and −25.7, and a broad resonance at δ 3.8, which are respectively assigned to the *cis*-hydrides and the NH_3^+ protons.



4 **5** **6**

Scheme 2 L = PPh_3, **a**; $PMePh_2$, **b**; PEt_2Ph, **c** or PBu^n_3, **d**.

This conversion is completely reversible: removing the dihydrogen gas from the solution with a stream of dinitrogen causes the resonances at δ −23.2 and −25.7 to disappear, and the signal at δ −16.1 to reappear in the ^{1}H NMR spectrum. Complex **6a** readily loses H_2 in the solid state, and as a result we were unable to isolate it for elemental analysis or IR studies.

Theoretical work (DFT-B3PW91)† on the model systems $[IrH(bq\text{-}NH_2)(H_2)(PH_3)_2]^+$ **7a** and $[IrH_2(bq\text{-}NH_3)(PH_3)_2]^+$ **8a** gave the unexpected result that the H_2 complex is the more stable form by 12 kcal mol^{-1}, contrary to the result in the experimental system. In considering why there might be a difference between the experimental pair **5**/**6** and the theoretical model pair **7**/**8** (Scheme 3), we considered the possibility that the change from PPh_3 to PH_3 was responsible. If so, we felt that the more basic alkyl phosphines would be a better experimental comparison.

Accordingly, we studied the species, $[IrH(bq\text{-}NH_2)(OH_2)(P\text{-}Bu^n_3)_2]BF_4$ **4d**, made *via* the standard route,[7,8] where the aryl groups have been replaced by alkyls. Hydrogen was passed for 1 min at −80 °C in the presence of anhydrous $MgSO_4$ to facilitate removal of water. Even with such a small change, we find that the H_2 complex, **5d**, is now formed on reaction with H_2, not the dihydride **6d**. The identity of the H_2 complex followed from the ^{1}H NMR data, which show two separate resonances below 230 K, a broad one at δ −4.7 for the coordinated H_2 molecule and a sharp one at δ −17.2 for the

Table 1 IR data for [IrH(bq-NH_2)(CO)$(L)_2$](BF_4) which shows the order of donor power of the phosphines studied

Ligand (L)	ν_{CO}/cm^{-1}
PPh_3 (**9a**)	2026.5
$PMePh_2$ (**9b**)	2021.8
PEt_2Ph (**9c**)	2015.3
PBu^n_3 (**9d**)	2004.6

classical hydride. These chemical shifts are close to those for the unsubstituted analogue [IrH(bq-H)$(H_2)(PPh_3)_2$]BF_4 **2**.[8] The HD complex (d^1-**5b**)shows a $^1J_{HD}$ coupling of 29.3 Hz.

Similar results were obtained with other basic phosphines, PEt_2Ph and $PMePh_2$, so the result is general. In no case was an equilibrium seen between dihydrogen complex **5** and hydride **6**. This implies that moving to a more basic phosphine decreases the acidity of the coordinated H_2 ligand in **5** and correspondingly increases the basicity of the terminal hydride in **6**. This results in the proton moving completely from the NH_3^+ group of **6** to the terminal hydride to give **5** on changing from PPh_3 to any of the more basic phosphines.

This large change of structure is rather surprising for such a relatively small change in ligand, and we wanted to verify that the basicity of the phosphines was indeed varying in the expected manner. Reaction of the aqua complex, **4** with CO (1 atm) in CH_2Cl_2 gave the carbonyl species [IrH(bq-NH_2)(CO)$(L)_2$]BF_4 (**9**, L = PPh_3, **a**; $PMePh_2$, **b**; PEt_2Ph, **c**; PBu^n_3, **d**). The IR data obtained for these complexes (Table 1) verifies that the basicity is indeed higher for the more highly alkylated phosphines. Having only one CO but two L groups makes this system much more sensitive to change of phosphine than Tolman's LNi$(CO)_3$ system,[9] but the trends are essentially the same.

Returning to the theoretical work, we have a rare case where the quantum model PH_3 is inadequate to reproduce the experimental observations on a PPh_3 complex. In order to model the more electron-accepting PR_3 groups, we have now moved to PFH_2 (**7b**/**8b**), PF_2H (**7c**/**8c**), and PF_3 (**7d**/**8d**); of course these are far more electron-withdrawing than the experimental PPh_3 group, but we were only interested in seeing if the correct trends could be reproduced. Indeed, as shown in Table 2, the calculated energies for **7** and **8** do alter in the expected fashion, confirming that the acid/base character of the Ir–H/Ir–(H_2) system shows an unexpectedly strong dependence on the nature of the phosphine.

Table 2 The theoretical structural (Å) and energetic parameters (kcal mol^{-1}) of dihydrogen complex **7** and dihydride **8** with change of phosphine

	7		**8**		
Ligand	d_{HH}	$d_{H\cdots H}$	d_{NH}	$d_{H\cdots H}$	ΔE^a
PH_3	0.861	1.854	1.135	1.412	−12
PFH_2	0.851	1.829	1.090	1.548	−2.5
PF_2H	0.856	1.873	1.093	1.502	+0.5
PF_3	0.847	1.849	1.073	1.618	+3.0

[a] E(**8**) − E(**7**) is reported, so negative values imply the dihydrogen complex is more stable.

The structural parameters of **7** and **8** from the theoretical work (Table 2) are in good agreement with the solid state structure of [IrH(bq-NH_2)(CO)$(L)_2$]PF_6 for which experimental structural data is available.[10] For all phosphine ligands, **7** and **8** both correspond to energy minima. In **7**, the dihydrogen ligand is always coplanar with the *cis*-Ir–H bond and the pendant NH_2 group is coplanar and conjugated with the bq ligand. As expected, the H–H distance in **7** decreases (from 0.861 to 0.847 Å) with increasing F substitution on the phosphine (Table 2) showing the effects of the diminished back-donation along the series. In **8**, the N–H bond interacting with the hydride *via* a dihydrogen bond[11] is elongated, especially for PH_3 (d_{NH} = 1.135 Å) where the hydride is the most basic and the dihydrogen bond distance is the shortest ($d_{H\cdots H}$ = 1.412 Å). The compounds cannot be isolated because they lose hydrogen too readily, consistent with the presence of a strong N–H···H–Ir interaction. This 1.4 Å H···H distance is significant because it is considerably shorter than any so far suggested for a dihydrogen bond, consistent with a particularly strong interaction, and is even in the range proposed for stretched dihydrogen complexes, so the species could even be considered as representing an arrested intermediate stage of heterolytic H_2 activation. Going from PH_3 to PF_3 leads to an elongation of $d_{H\cdots H}$ to 1.618 Å, however, beyond the upper limit of 1.6 Å proposed for stretched H_2 complexes, showing the strong sensitivity of the structure to the nature of the phosphine.

This work shows that the very strong dependence[1,2,20] of the pK_a of the H_2 ligand has interesting effects on the reactivity of these complexes toward H_2 and on the structure of the resulting hydrides even with relatively small changes in the ligand sphere. The pK_a of the H_2 ligand seems to be unusually sensitive to back bonding effects, even though the changes in d_{HH} are relatively modest (Table 2). From a theoretical standpoint, great care should be taken in modelling such systems.

We thank the NSF (R. H. C.), the University of Montpellier and CNRS (O. E.) for funding and Bruno Chaudret (Toulouse) for discussions.

Notes and references

† *Computational details*: All the calculations were performed with the Gaussian 94 set of programs[12] at the B3PW91 level[13,14] level. Iridium was represented with the Hay–Wadt relativistic core potential (ECP) for the 60 innermost electrons and its associated double-ζ basis set.[15] Phosphorus atoms were also represented with Los Alamos ECPs and their associated double-ζ basis set[16] augmented by a polarisation d function.[17] A 6-31G(d,p) basis set[18,19] was used for the atoms bound directly to Ir (H, C, and N) and for the atoms of the amido group (N and H), all the other atoms have been described with a 6-31G basis set.[18] Full geometry optimisations within C_s symmetry (the bq-NH_2 ligand is planar) have been carried out within the framework of DFT (B3PW91).

FEATURE ARTICLE

New approaches to rate enhancement in heterogeneous catalysis

Graham J. Hutchings

Department of Chemistry, Cardiff University, PO Box 912, Cardiff, UK CF1 3TB

Received (in Cambridge, UK) 12th August 1998, Accepted 29th October 1998

Rate enhancement, or promotion, of heterogeneous catalysts has long been viewed as an empirical subject, and many catalysts have been designed on the basis of large catalyst screening programmes. This paper addresses recent advances in this topic and indicates that much progress is being made on the basis of a molecular approach, in contrast to the previous empirical methodology, and in particular highly effective enantioselective heterogeneous catalysts can be designed. Two catalyst systems are selected for detailed discussion, namely enantioselective hydrogenation using cinchona-modified platinum catalysts and the modification of zeolites with chiral molecules.

Introduction

The design of high activity heterogeneous catalysis is considered crucial for the successful operation of the chemical industry. Most bulk chemical and petrochemical processes could not be operated commercially without a heterogeneous catalyst. Recently, there has been an increased awareness that heterogeneous catalysts could significantly improve a large number of fine chemical processes. Historically, most people would consider that current commercial heterogeneous catalysts are designed mainly by empirical large scale testing programmes. While this is not strictly true, there remains one area that has received very limited attention and this concerns the effect of rate enhancement, or promotion, of heterogeneous catalysts caused by additional catalyst components that are often inactive for the reaction if used alone. This is a subject that has been almost exclusively studied in industrial laboratories and the results are typically only disclosed in the patent literature. Most commercially operated catalysts involve promoters; for example, the effect of the addition of K^+ to the Fe Fischer Tropsch synthesis or ammonia synthesis catalysts is well known.[1] The dichotomy between academic and industrial research is well exemplified in the research concerning oxides and phosphates as catalysts for heterogeneous hydrocarbon oxidation. Most academic studies are concerned with the reaction mechanism on non-promoted systems whereas most industrial studies are concerned with promoted catalysts.[2,3] The origin of the rate enhancement effects observed in these complex systems remains obscure[2] mainly because the precise structure of the active site is unknown. This problem is best exemplified by vanadium phosphate catalysts for the oxidation of butane to maleic anhydride, since even though they have been the subject of over a thousand research papers and patents[2,4] the structure of the active site remains a matter of debate. However, recent detailed electron microscopy[5] and *in situ* laser Raman spectroscopy studies[6] are starting to make progress in this area. This lack of detailed knowledge concerning the structure of the active site in heterogeneous catalysts makes it almost impossible to adopt a molecular approach to this subject which is essential if progress is to be made. This is not a disadvantage that is shared by related subject areas of surface science, homogeneous catalysis and theoretical studies, since all of these use a molecular approach. If significant progress is to be made in heterogeneous catalysis then a similar molecular approach has to be adopted. In this paper it is shown that the latest research approaches in the design of heterogeneous catalysts are using a molecular approach and that progress is being made in the understanding of rate enhancement in heterogeneous catalysts. Two systems have been selected as examples of recent work, namely enantioselective hydrogenation using cinchona-modified platinum catalysts and the modification of zeolites with chiral molecules. Both of these examples have been selected since they demonstrate the advantages of rate enhancement in enantioselective catalysis since, in the absence of rate enhancement, the unmodified active sites are not less active than modified sites, and in some cases are more active, and hence the attainment of high enantioselectivities requires the absence of unmodified sites. However, when rate enhancement is observed, then unmodified sites are not a significant source of reaction and do not interfere with enantioselective reactions.

The author has 23 years experience in the study and design of heterogeneous catalysts, particularly oxides and zeolites. His early career involved nine years in ICI in both research and production. In 1984 he left industry for an academic position at the University of Witwatersrand in Johannesburg prior to returning to the UK in 1987 to help establish the Leverhulme Centre for Innovative Catalysis at the University of Liverpool. In 1997 he was appointed as Head of Department and Professor of Physical Chemistry at Cardiff University.

Enantioselective hydrogenation using cinchona-modified platinum

The hydrogenation of α-ketoesters using modified heterogeneous catalysts has been extensively studied, particularly for the reaction of ethyl pyruvate using modified Pt catalysts,[7–9] although recent studies have begun to generalise this system to a broader range of substrates and metals.[10] The reaction was originally described by Orito *et al.*,[11–14] and has been become the most intensively studied heterogeneous enantioselective catalytic reaction. The reason for this interest is that it is viewed by many workers as a model reaction on which to base other enantioselective studies. The approach adopted, *i.e.* the creation of a chiral active site by the adsorption of pure enantiomers onto a metal surface, has also proved successful in the related studies by Izumi[15] for the hydrogenation of β-ketoesters with tartrate-modified nickel catalysts. The early work on this reaction has been extensively reviewed,[7–9,16,17] and consequently only the important features of the reaction will be described here.

Extensive studies have revealed that hydrogenation of α-ketoesters in the presence of cinchona alkaloids as modifiers is best carried out using Pt catalysts (Fig. 1).[9,11–14,18] The Pt can be supported on a diverse range of materials, Al_2O_3, SiO_2, TiO_2, C, and the best results have been obtained using 5%Pt/Al_2O_3.[19]

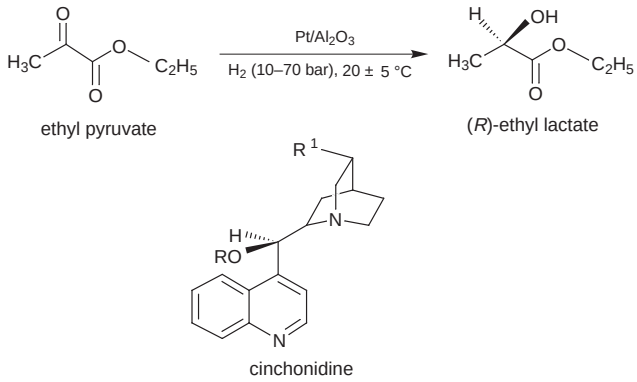

Fig. 1 Hydrogenation of ethyl pyruvate using Pt/Al_2O_3 catalysts modified with cinchonidine.

Interestingly, zeolites have also been successfully used as supports,[20–22] but no advantages for the specific use of microporous materials are apparent when compared with Al_2O_3 or other non-microporous supports. The optimum Pt particle size is considered to be > 2 nm, and catalysts with smaller Pt particle sizes have been shown to be less selective. It is generally agreed that the reason for the structure sensitivity remains a matter for debate. Some researchers[9] consider that the relatively flat low index planes are more suitable for adsorption of the cinchona modifier; however, Augustine *et al.*[23] dispute this and argue that the corner and ad-atoms are the active centres. Evidence in favour of the former viewpoint comes from heat pretreatment of the catalyst, which can be expected to stabilise low index planes, which shows an increase in enantioselectivity.

Most research effort for this reaction has concentrated on the optimisation of the enantioselection, and, specifically, on the design of the chiral modifier for the supported Pt catalyst with ethyl pyruvate as the substrate, and a selection of the results is summarised in Table 1. Early work focused on the method of

modification by cinchona alkaloids and it was recognised that the choice of solvent was important for the attainment of high ee. The highest ee is obtained when acetic acid is used as solvent and the ee was found to increase in the order: ethanol < toluene < acetic acid when either 10,11-dihydrocinchonidine or 10,11-dihydro-*O*-methylcinchonidine were used as modifiers, and ethyl pyruvate or ethyl 4-phenyl-2-oxobutyrate were used as substrates. From this early work it was concluded[16] that the minimal requirements for an efficient modifier for the hydrogenation of α-ketoesters is the presence of a basic nitrogen centre in close proximity to one or more chiral centres and an aromatic ring system, with best results being obtained with planar ring systems, *e.g.* quinolyl or naphthyl. To date it is generally agreed that 10,11-dihydrocinchonidine is the most effective modifier for high pressure hydrogenation of ethyl pyruvate. However, recent extensive studies by Baiker[24] have indicated the efficacy of mechanistic studies for the design of new chiral modifiers in enantioselective hydrogenation that can be used to replace the cinchona alkaloids.

The mechanism by which enantioselection occurs has been a matter of some speculation in recent years, and most recently has become a matter of intense debate.[25,26] Most researchers agree that the cinchona modifier interacts with the metal catalyst surface to form a new enantioselective catalytic site. Augustine *et al.*[23] proposed that the cinchona molecule is adsorbed through the quinoline N atom adjacent to a Pt ad-atom, where the substrate and H coadsorb with the N interacting with a CO group of the substrate. Baiker and coworkers[27–30] have utilised molecular simulations of the interaction between the substrate and the modifier and have suggested that protonated cinchonidine interacts with the oxygen atom of the CO bond that is subsequently hydrogenated, and that this interaction activates the substrate and thereby leads to the observed rate enhancement. An alternative proposal concerning the origin of the enantioselection, the shielding effect model, has been proposed by Margitfalvi and coworkers.[31,32] This model also uses molecular simulations as an integral part of the study. It is proposed that the modifier and the substrate preferentially form a 1:1 complex in solution, and this activated complex is subsequently hydrogenated by adsorbed hydrogen on the metal surface. Recently, we have considered these approaches using molecular simulations,[33] and it is clear that molecular simulation studies are playing a valuable role in aiding the design of new chiral modifiers, but there remains a central problem with this approach, namely that the platinum metal surface is not included in these simulations. Since the interaction between the cinchona and the platinum surface is considered to be crucial, this represents a major flaw. The alternative approach involving a more rigorous quantum mechanics calculation would prove to be too costly in computing time at present, and only relatively simple systems have been studied to date.

One of the most important observations for the Pt/cinchona catalyst system is the observation that the rate of hydrogenation of the α-diketone is significantly enhanced on the addition of the cinchona modifier (Table 2). A rate enhancement is

Table 2 Effect of cinchona modifier on the rate of hydrogenation of ethyl pyruvate with Pt/Al_2O_3 catalysts[a]

support may not be of great significance for this effect. To date, the origin of the rate enhancement has not been determined, partly due to the fact that most studies have concentrated on the

optimisation of enantioselection. It is tempting to link the observation of the rate enhancement effect with the enantioselection that is achieved with this catalyst system. However, the rate enhancement is observed for racemic hydrogenation. For example Blaser *et al.*[19] have shown that aniline, triethylamine and quinuclidine all enhanced the rate of racemic hydrogenation of ethyl pyruvate when added to the Pt/Al_2O_3 catalyst and that there was a relationship between the pK_a of the nitrogen base and the degree of rate enhancement. The rate enhancement observed with cinchonidine is much higher than that predicted by pK_a considerations alone, indicating that other factors are important. Interestingly, Rylander[34] had previously noted that racemic amines could enhance the rate of hydrogenation of ketones. It is possible that the rate enhancement observed in the Pt/cinchona system is similar in origin to that observed in a number of homogeneously catalysed reactions (*e.g.* the enantioselective oxidation catalysts based on Mn–salen complexes[35]). It can be considered that the Pt/cinchona system will be a catalyst where the nature of the active site will be identified at the molecular level in the near future using a combination of experimental and theoretical studies.

Work we have carried out[36] on a related reaction, the hydrogenation of α,β-unsaturated aldehydes, has also shown a rate enhancement effect. We modified the surface of a Cu/Al_2O_3 catalyst with thiophene and this enhanced the rate of formation of the unsaturated alcohol, this being the first example of the catalytic activity of copper being promoted by sulfur. In this case, the thiophene modifier dissociates and the active site is considered to involve the interaction between a sulfur atom and the copper surface, based on detailed spectroscopic study.

Zeozymes: catalysts of the future

In recent years, the use of zeolites as high activity/high selectivity catalysts has received significant interest. The one clear driving force for these studies is that the three dimensional structure of the zeolite and, in particular, the structure of the active site are well known from detailed spectroscopic and diffraction studies. In zeolites all the atoms are on the surface and hence this class of materials enable a link to be formed with the elegant and detailed surface spectroscopic studies on single crystal surfaces, since both approaches allow heterogeneous catalysis to be studied at the molecular level with well-defined systems that can be probed with surface sensitive techniques. For zeolites, since all atoms are on the surface, normal bulk techniques (NMR, FTIR and X-ray diffraction) become surface sensitive techniques. Three distinct approaches are apparent in the recent literature, and these involve (a) using zeolites as supports for homogeneous catalysts or grafting active complexes onto mesoporous materials, (b) encapsulating large homogeneous complexes using a *ship-in-a-bottle* technique, and (c) chiral modification of zeolite surfaces.

(a) The first approach was exemplified by Corma *et al.*[37] for the hydrogenation of prochiral alkenes using Rh and Ni complexes supported on zeolite Y. Enantioselective hydrogenation using homogeneous Rh complexes is well documented,[38] and the rationale for this work was the requirement to find a less expensive heterogeneous route to pharmaceutical chemicals. Corma *et al.*[37] utilised Rh and Ni complexes with a range of ligands derived from proline. The complexes were anchored through silanol groups onto either silica or zeolite Y. The zeolite was prepared by steam calcination at 1027 °C of an 80% exchanged NH_4^+ zeolite Y, followed by treatment with citric acid. The zeolite is described as having a 'supermicropore' system (pore size 1.2–3.0 nm). These catalysts were found to be highly active for the hydrogenation of *N*-acyldehydrophenylalanine derivatives. They observed that the rate of hydrogenation was enhanced when the catalyst was supported on the zeolite compared to the rate observed for the non-supported complex or for the silica supported material, and they suggest that the confinement within the pores of the zeolite may play a role in the observed rate enhancement. However, in other cases, the same group have shown that reactions promoted by zeolite-supported catalysts are slower than those promoted by silica-supported complexes.[39] Hence, this approach cannot be considered to be a general method of securing rate enhancement.

A similar approach has been exemplified in the study of Ti-containing silicates, although in this case the Ti atoms are components of the active site and do not act as a promoter. On the basis of the developments in wider pore zeolites and related materials[40,41] Thomas *et al.*[42–44] have shown that titanium metallocenes grafted onto MCM-41 can act as effective oxidation catalysts with higher activity than Ti-MCM-41 catalysts when the Ti is incorporated into the silicate framework. Thomas *et al.*[42] have based their catalyst design on the concepts of interfacial coordination chemistry, surface organometallic chemistry and shape selective catalysis. However, other researchers[45] have shown that Ti-MCM-41 catalysts can be synthesised with very high activities.

(b) Encapsulation of large complexes within the micropores of zeolites has been pioneered by the studies of Jacobs *et al.*[46,47] The initial examples of this approach[46] involved the encapsulation in zeolites Y and X of iron phthalocyanine complexes, and these were shown to be active for the oxidation of alkanes with H_2O_2 as a mimic for cytochrome 450, the biological oxidation catalyst. Subsequently, complexes of manganese(II) with bipyridene (bpy) have been examined in detail.[47] In solution, the catalytic efficacy of these materials is limited by their catalase activity, *i.e.* their tendency to decompose hydrogen peroxide catalytically. When *cis*-$[Mn(bpy)_2]^{2+}$ complexes are encapsulated within the micopores of zeolite Y and X, however, they can act as effective alkene epoxidation catalysts without complications of competing processes such as self-oxidation or catalase activity. The catalysts are able to epoxidise a broad range of alkenes, and high epoxide selectivities (> 60%) are observed with hex-1-ene, cyclohexene, dodec-1-ene and cyclododecene. Owing to the acidic nature of the zeolites used, the products of the acid catalysed ring opening reactions were observed at extended reaction times. These catalysts are, therefore, further examples of a bifunctional catalyst combining oxidation and acid catalytic functions. The encapsulated *cis*-$[Mn(bpy)_2]^{2+}$ catalysts are remarkably stable, and are found to remain active for up to 1000 cycles for the oxidation of cyclohexene with H_2O_2. The catalyst can also be reused following drying at 47 °C and it is reported that repeated catalyst regeneration is possible, indicating that encapsulation of the *cis*-$[Mn(bpy)_2]^{2+}$ complex reduces the rate of oxidative destruction. The authors report that after repeated regeneration no changes in catalytic activity or spectroscopic properties of the complex could be observed. Electronic, rather than steric, factors were considered to control the reaction of the encapsulated catalysts and the hydrogen peroxide is considered to be activated by the formation of a high-valent manganese species [for example Mn(IV)=O], and it is the oxygen associated with this species that is inserted into the alkene C=C double bond.

Ogunmumi and Bein[48] and Sabater *et al.*[49] have extended the use of encapsulation to prepare heterogeneous catalysts for enantioselective epoxidation. The catalysts are based on the recently developed Jacobson homogeneous oxidation catalyst. Ogunmumi and Bein[48] and Sabater *et al.*[49] have also reported the successful encapsulation of Mn(III) salen complexes into zeolite Y using a *ship-in-a-bottle* approach previously used in the work of Jacobs and coworkers. Assembly of the reagents within the zeolite supercages leads to entrapped complexes that are too large to diffuse out of the zeolite host. The encapsulated complexes were characterised using vibrational and electronic spectroscopies together with ESR spectroscopy to confirm that the Mn(III) salen complex had been formed. The epoxidation of

prochiral alkenes was studied using sodium hypochlorite as oxidant. Bein has reported high ee for the epoxidation of *cis*-β-methylstyrene and there are indications that the encapsulated complex does not leach from the host zeolite. Turnover numbers based on Mn are not high, and the regeneration and reuse of catalysts is an issue that has yet to be confirmed. This approach essentially uses the advances made in homogeneous catalyst systems and it is not anticipated that the encapsulation process can be expected to lead to further enhancement in catalytic performance.

(c) Modification of zeolites by pure enantiomers is the most recent of the approaches to be developed, although clearly it has its basis in the well-studied catalysts for enantioselective hydrogenation based on Pt/cinchona and Ni/tartrate. An initial report on the use of a zeolite as host for chiral induction was by Sundarabubu *et al.*[50] In this study two zeolites NaY and NaX were modified by (−)-ephedrine and modest ee (< 10%) in the photolysis of ketones capable of undergoing the Norrish–Yang reaction. The most important observation related to the nature of the enantiomer that is enhanced in reactions using the two selected zeolites. In NaY, (−)-ephedrine showed enantioselectivity in favour of the (+) isomer of the product; however, the same chiral modifier favoured the (−)-isomer in NaX, although to a lesser extent. This remarkable effect was attributed to differences in the supercage free volume, as this was found to be different for the two modified zeolites.

The concept of modification of zeolite supercages to create the chiral environment required to favour the formation of one of a pair of diastereoisomeric transition states, a necessary condition for enantioselection, has been pioneered in our recent research. We selected chiral dithiane oxides since these were readily available to us with high optical purity, and as they provide a number of heteroatoms to ensure that the modifier is firmly anchored within the zeolite. A surprising early result we obtained is that the dithiane oxides are remarkably stable within the zeolite: they were only decomposed thermally at temperatures > 400 °C, and they were not racemised by adsorption in the zeolite. We selected the dehydration of butan-2-ol as an example of a simple acid catalysed reaction that can in principle demonstrate both enantioselectivity [differentiation between (*R*)- and (*S*)-butan-2-ol] and product selectivity (formation of but-1-ene, *cis*- and *trans*-but-2-ene).

Our initial experiments were carried out using zeolite Y modified with racemic 1,3-dithiane 1-oxide. We found that the dithiane oxide-modified zeolite Y is considerably more active than unmodified zeolite Y by several orders of magnitude, and that this activity was maintained without significant loss over several days. Under our reaction conditions, unmodified zeolite Y only became active at temperatures above 150 °C and required a reaction temperature of 225 °C to achieve 90% conversion, whereas the modified zeolite gave 90% conversion at 115 °C. We have now observed this effect with a number of other dithiane oxides (Fig. 2).[50,51] These early results show that modification of zeolite Y with the dithiane oxide creates a new high activity acid site. As noted previously, it is this observation of rate enhancement that we consider of crucial importance in the design of novel enantioselective catalysts. Since the active sites in the modified zeolite are considerably more active than those of the unmodified zeolite, we believed that the modified zeolite could form the basis of a new enantioselective catalyst. Our initial experiments confirm that this can indeed be observed, and the results are given in Table 4.[50] In these experiments, we reacted racemic butan-2-ol over zeolite Y which had been modified with an enantiomerically enriched dithiane 1-oxide. The chiral acid catalyst is selective for the reaction of one of the enantiomers preferentially, even though both enantiomers are present in equal concentration at the inlet to the reactor.

Modification of zeolite H-Y with dithiane oxide (**I**) leads to the creation of a catalyst that has enhanced activity for the acid

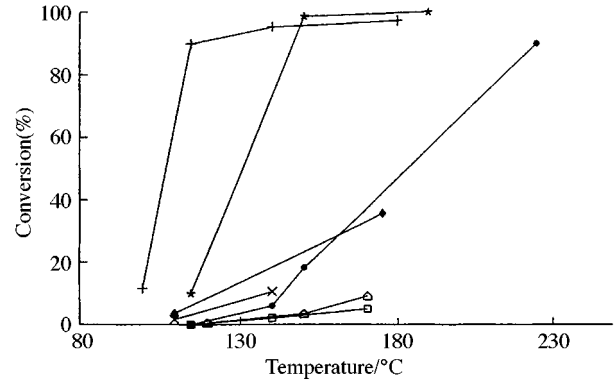

Fig. 2 Effect of temperature on the conversion of butan-2-ol over zeolite Y, key: (●) Zeolite H-Y (LZY 82, Union Carbide), (+) Zeolite H-Y (LZY 82) after modification with 1,3-dithiane 1-oxide, (★) Zeolite H-Y (LZY 82) after modification with 2-methyl-1,3-dithiane 1-oxide, (□) Zeolite H-Y (Crossfield), (X) Zeolite H-Y (Crossfield) with 1,3-dithiane 1-oxide, (⌂) Zeolite H-Y (Crossfield) after modification with 2-phenyl-1,3-dithiane 1-oxide and (◆) H-Y (LZY 82) after modification with 1,3-dithiane, reaction conditions: catalyst (0.3 g) reacted with butan-2-ol (3.2×10^{-3} mol h^{-1}) prevaporised in nitrogen (4.3×10^{-2} mol h^{-1}).

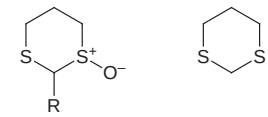
catalysed dehydration of butan-2-ol when compared with the unmodified zeolite or when modified with the corresponding dithiane (**II**). This effect is observed both for samples prepared by addition of the modifier to the synthesis gel and for the post



I **II**

synthesis modification of two different commercial samples of zeolite Y (Crossfield and Union Carbide). When the modifier is added to the synthesis gel, the resulting zeolite contains only a small quantity of the modifier, but the effect is still apparent.[52]

The interaction of alcohols with the acid forms of zeolites has been well studied in recent years, and for butanols it is generally considered that the adsorbed species that is formed initially is a butoxide species adsorbed at the active site that is formed from the dehydration of butan-2-ol. *In situ* FTIR spectroscopy confirmed that, in the present study, a butoxide species is formed on reaction of the butan-2-ol with both the unmodified zeolite and the dithiane oxide modified zeolite.[48] Consistent with the enhanced reactivity observed with the flow reactor studies, the *in situ* FTIR spectroscopy experiments reveal that the alkoxide species is formed at a significantly lower temperature for the dithiane oxide modified zeolite than for the unmodified zeolite.

All these data indicate that when the dithiane oxide is added to the zeolite, a new high activity site is formed, and it was concluded that the degree of rate enhancement observed can be related to the presence of extra-framework aluminium. This must, however, act in combination with the Brønsted acid site of the bridging hydroxy group associated with the zeolite framework aluminium, since the dehydration reaction investigated is catalysed by Brønsted acidity. A number of studies have indicated that a combination of extra-framework (Lewis acid sites) and framework (Brønsted acid sites) aluminium can give enhanced acidity in zeolite catalysts. Haag and Lago[53] showed that steaming zeolites at 500 °C with low levels of water vapour can lead to an increase in the activity of the zeolite for acid catalysed reactions. Mirodatos and Bartemeuf[54] showed that superacid sites could be created in mordenite by a steaming procedure. These effects were subsequently explained by Fritz and Lunsford[55] in terms of the initial dealumination of the zeolite to form non-framework aluminium that imparts, presumably through an electrostatic effect, strong acidity of the

[d] Zeolite Y (Crossfield NaY, ion exchanged with NH_4NO_3 and calcined at 550 °C), modified with (*R*)-1,3-dithiane 1-oxide, 1 molecule per supercage (0.1 g), tested in a convential glass microreactor with racemic butan-2-ol (7.35×10^{-3} mol h^{-1}), prevaporized in a nitrogen diluent (6.7×10^{-3} mol h^{-1}). [e] Zeolite Y (ultrastabilized LZY 82, Union Carbide) modified with (*S*)-2-phenyl-1,3-dithiane,1 molecule per supercage (0.1 g), tested in a convential glass microreactor with racemic butan-2-ol (7.35×10^{-3} mol h^{-1}), prevaporized in a nitrogen diluent (6.2×10^{-3} mol h^{-1}).

remaining framework Brønsted acid sites. This leads to an increase in acidity of the zeolite, and, for simple acid catalysed reactions such as cracking, an enhanced activity is observed. In the present work, the high activity site is considered to be formed by the specific interaction of the dithiane oxide with both the extra-framework aluminium and the Brønsted acid site associated with the framework aluminium (Fig. 3). Supporting

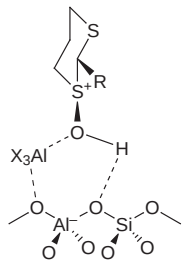

Fig. 3 Schematic representation of the structure of the high activity site formed on addition of 1,3-dithiane 1-oxide to zeolite H-Y (AlX_3 denotes extra-framework aluminium species).

evidence for this proposed model comes from detailed ^{27}Al MAS NMR spectroscopy studies and molecular simulations[56,57] that have shown that the dithiane oxide interacts strongly with the extra-framework aluminium atoms.

The formation of high activity acid sites enables these modified zeolites to be used as enantioselective catalysts, since, although only one active site per supercage is modified, it is many orders of magnitude more active than the remaining unmodified sites. When the dithiane oxide is used in the enantiomerically enriched form, the active sites are able to discriminate between the enantiomers of butan-2-ol. This important effect is achieved by enantioselective rate enhancement, *i.e.* both enantiomers react faster in the chiral environment than in the absence of the chiral modifier, but one reacts faster than the other.

The activation energies for the dehydration of the separate enantiomers over the zeolites doped with the enantiomerically enriched dithiane oxides were found to be identical within experimental error (105 ± 5 kJ mol^{-1}). In addition, it was noted that the enantiomeric discrimination obtained from the reaction of racemic butan-2-ol is higher than that based on the conversions of the separate enantiomers. The apparent inconsistency can be resolved by regarding the modified zeolite as if it were an enzyme (a zeozyme) operating with its active sites saturated with substrate and, due to this saturation, the alcohol–catalyst complexation constant does not appear in the experimental kinetics. The conversions of the separate enantiomers then yield the relative reactivities in the catalytic step, whereas the results using the racemate reflect the enantioselection, not only of the catalytic step, but also of the competitive binding of the substrates. Present indications, supported by molecular modelling studies, are that the latter effect is the larger.[52,56,57]

It is important to note that the reactants and products in this reaction are gas phase. However, the reactant butan-2-ol is present at high partial pressures, and, at the lower temperature used in this study, which is only 12 °C above the boiling point of butan-2-ol, it is possible that condensation may occur in the micropores of the zeolite. This effect would not, however, be expected to contribute significantly to the results obtained at the higher temperatures, where enantioselection is still observed, albeit briefly. We consider that these results provide the first example of a gas-phase enantioselective reaction heterogeneously catalysed by a zeolite. Although the initial approach described here has concerned the design of a catalyst that consumes chiral molecules, the study should be viewed, in effect, as a proof of the concept that a zeolite can be modified so that it preferentially catalyses the reaction of one enantiomer of a chiral substrate in the presence of both. In view of the immense range of microporous zeolites available together with the large number of enantiomerically pure modifiers, we consider that this approach will provide the basis for the generic design of a new type of enantioselective catalysts. As further evidence for this viewpoint, we have recently shown[58] that Cu^{2+}-exchanged zeolites HY modified by chiral oxazolines are highly effective catalysts for the enantioselective aziridination of alkenes employing [*N*-(*p*-tolylsulfonyl)imino)]phenyliodinane (PhI=NTs) as the nitrogen source. (Fig. 4, Table 5) and that

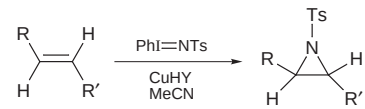

Fig. 4 Aziridination of alkenes using CuHY as catalyst.

the Mn^{3+}-exchanged Al-MCM-41 modified by a chiral salen ligand is an enantioselective epoxidation catalyst using iodosyl benzene as oxidant.[59]

These examples, it is hoped, demonstrate that a molecular approach can be taken to the design of novel high activity/selectivity heterogeneous catalysts. The approach proposed for the design of heterogeneous catalysts is similar in concept to that of the 'ligand accelerated reaction' described by Berrisford *et al.*[60] and exemplified in extensive homogeneous catalytic systems. In addition, it should be noted that the approach detailed in the present paper can also be useful in the design of chiral catalysts supported on different materials, *e.g.* amorphous oxides, organic polymers and dendrimers. In the future it is expected that the approaches outlined herein will become standard and that, in particular, the design of heterogeneous catalysts will involve an interplay between experimental and theoretical studies using catalysts with known structures. The recent work also demonstrates that rate enhancement in heterogeneous catalysis is now being studied at the molecular level, in contrast to the earlier approaches well exemplified in many patents published on this topic.

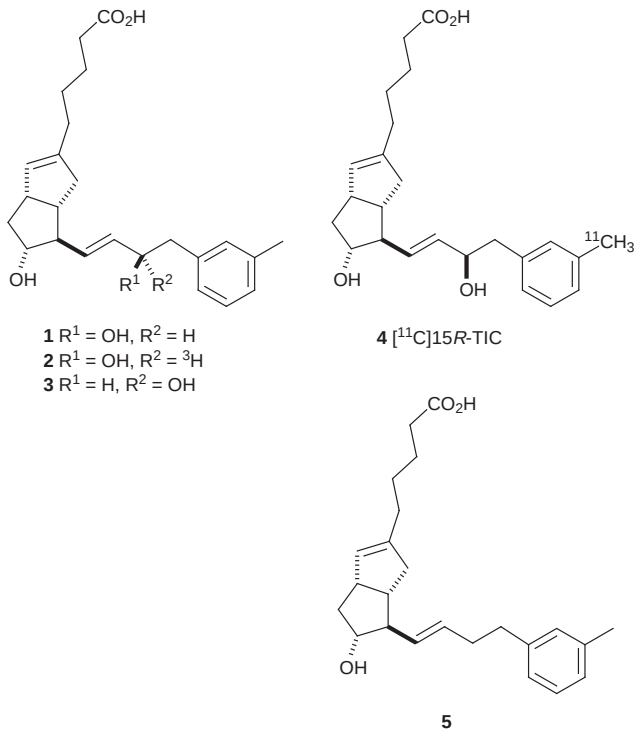
Received (in Cambridge, UK) 30th September 1998, Accepted 7th January 1999

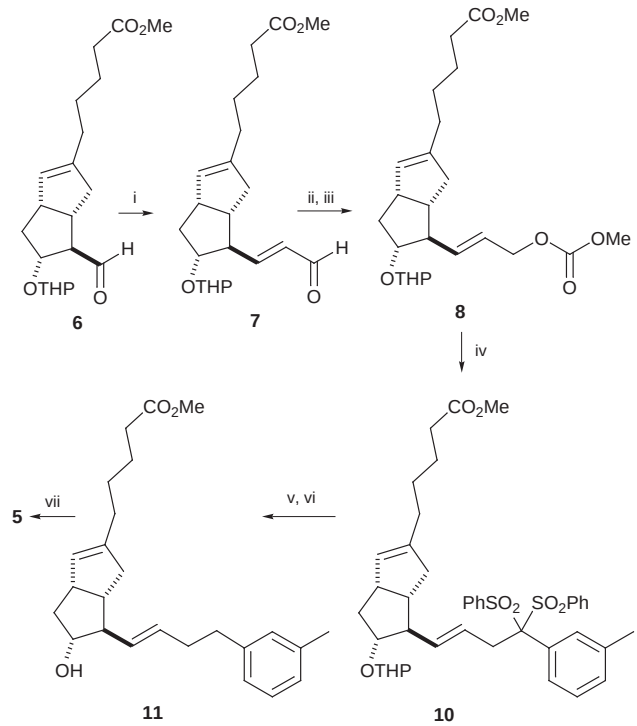
Biologically remarkable 15-deoxy-TIC has been realised by the removal of the C(15) chiral centre in 15*R*-TIC, a stable ligand for a CNS-type prostacyclin receptor (IP_2); this deoxy derivative exhibits ten-fold higher affinity and selectivity than 15*R*-TIC for the IP_2 receptor in correlation with the anti-apoptotic activity for neuronal cells.

In response to the increasing requirement for the development of specific molecular probes for the elucidation of the role of prostaglandin (PG) in brain functions,[1] we have designed (15*R*)-16-(*m*-tolyl)-17,18,19,20-tetranorisocarbacyclin **1** (15*R*-TIC) which has high binding affinity and selectivity for a novel prostacyclin (PGI_2) receptor subtype (IP_2) in the central nervous system (CNS).[2] This was utilised to visualise the specific location of the IP_2 receptor for both *in vitro* and *in vivo* systems by autoradiography of rat brain slices[3] and the positron emission tomography (PET) of a living rhesus monkey[4] using tritium-labelled ligand **2** and ^{11}C-labelled ligand **4**,[5] respectively.

The *R* configuration of C(15) in **1** was surprising, because the configuration of this hydroxy-bearing chiral centre in hormonal PGs is generally *S*.[6] In addition, 15*S*-TIC **3**, a C(15) stereoisomer of **1**, exhibited high binding affinity for both PGI_2 receptors, IP_1 and IP_2, as peripheral and CNS types, respectively.[2,3] These findings led us to speculate that the configuration of hydroxy-bearing C(15) in **1** may not be crucial for the binding with the IP_2 receptor and, therefore, that a common structure capable of more specifically recognising the IP_2 receptor could be hidden between these tolylisocarbacyclin structures, **1** and **3**. Accordingly, our interest has been directed to elucidating the essential structural elements necessary to discriminate between the two receptors, particularly focusing on the elimination of the C(15) chirality. Described herein is the synthesis of a 15-deoxy-TIC derivative with superb biological properties.

The title compound **5**, among other synthesised derivatives, exhibited the highest binding affinity and selectivity for the IP_2 receptor. As outlined in Scheme 1, the synthetic strategy consists of the stepwise construction of the *E*-olefin in the ω side-chain instead of the one-step Julia coupling,[7] because the starting aldehyde **6** is unstable under strongly basic conditions.[8] Thus aldehyde **6**[9] was condensed with (formylmethylene)-triphenylphosphorane in benzene at 80 °C to give (*E*)-α,β-unsaturated aldehyde **7** in 64% yield. Carbonyl reduction of **7** using $NaBH_4$ in MeOH, followed by methoxycarbonylation of the resulting allylic alcohol with $ClCO_2Me$ in the presence of





Scheme 1 *Reagents and conditions*: i, $Ph_3PCHCHO$, benzene, reflux; ii, $NaBH_4$, MeOH; iii, $ClCO_2Me$, DMAP, CH_2Cl_2; iv, $Pd_2(dba)_3$, $CHCl_3$, dppe, *m*-$CH_3C_6H_4CH(SO_2Ph)_2$ **9**, THF, 50 °C; v, Mg, MeOH; vi, TsOH, MeOH; vii, aq. NaOH, MeOH.

DMAP in CH_2Cl_2 gave the allyl carbonate **8** in 91% overall yield. The cross-coupling between the allyl carbonate **8** and the sulfone **9** was conducted at 50 °C in THF in the presence of a catalytic amount of $Pd_2(dba)_3$/dppe (1:2 ratio),[10] giving the sulfone **10** in 97% yield.† Reductive removal of the $PhSO_2$ group in **10** with Mg metal in MeOH and subsequent deprotection of the tetrahydropyranyl group with TsOH in MeOH gave the 15-deoxy derivative **11** in 84% overall yield. Finally, alkaline hydrolysis of **11** afforded the desired 15-deoxy-16-(*m*-tolyl)-17,18,19,20-tetranorisocarbacyclin, referred to as 15-deoxy-TIC **5**, in 94% yield.‡

The binding assay was conducted for the neuronal PGI_2 receptor proteins in frozen tissue sections containing the thalamus and the nucleus tractus solitarius (NTS) as representative of the IP_2 and IP_1 receptors, respectively, using C(15) tritium-labelled 15*S*-TIC ([^{3}H]15*S*-TIC)[2] as a standard radioligand. The 50% inhibitory concentrations of the binding (IC_{50} values) were determined by the degree of displacement of 10 nM [^{3}H]15*S*-TIC bound to each receptor by nonradioactive TIC derivatives. Accordingly, 15-deoxy-TIC **5** binds with the CNS-type IP_2 receptor (IC_{50} value = 3 nM) ten times more strongly than 15*R*-TIC **1** while maintaining the weak binding for IP_1 receptor (IC_{50} value = 1 μM).§ As a result, the binding selectivity for the IP_2 receptor [$IC_{50(IP1)}/IC_{50(IP2)}$] increased by a factor of 10. The importance of the length of the ω side-chain, the tolyl group and 13,14 double bond was clarified by a study of the structure binding affinity relationships. Thus the elimination of the hydroxy group at C(15) markedly enhanced the binding affinity and selectivity.

Since the discovery of 15*R*-TIC **1**,[2] we have pursued the biofunction of various TICs in the brain and developed CNS-specific PGI_2 ligands that exhibit neuronal survival-promoting activity both *in vitro* and *in vivo*.[11] The difference of the potency of the binding affinity between **1** and **5** is actually correlated well with the biological activity. Thus 15-deoxy-TIC **5** showed an inhibitory effect on apoptosis of neuronal cells induced by high oxygen (50%) atmosphere at ten-fold lower concentration than 15*R*-TIC **1** (IC_{50} = 30 and 300 nM, respectively). It should be noted that **5** did not exhibit any significant inhibitory effect on platelet aggregation, up to 400 nM, while PGI_2 derivatives which bind to the IP_1 receptor showed a very potent inhibitory effect at several nM.¶

Overall, we have found the essential structure that has conspicuous biological properties by rational molecular modification. The structural simplification by removal of the C(15) chirality will increase chemical or biological tolerance[12] to give a promising anti-apoptotic agent, particularly for chemotherapy of CNS neurons damaged with oxidative stress and ischemia.[11] Future progress will be reported in due course.

A new and enantioselective indolizidine synthesis by *meso*-epoxide α-deprotonation–transannular N–C insertion

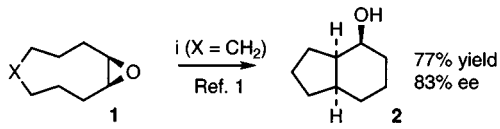
David M. Hodgson* and Lesley A. Robinson

Dyson Perrins Laboratory, Department of Chemistry, University of Oxford, South Parks Road, Oxford, UK OX1 3QY. E-mail: david.hodgson@chem.ox.ac.uk

Received (in Liverpool, UK) 19th November 1998, Accepted 5th January 1999

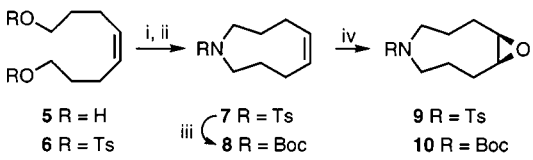
Enantioselective α-deprotonation–rearrangement of *N*-Boc hexahydroazonine oxide 10 using organolithiums in the presence of (-)-sparteine 3 gives the ester 12 in up to 89% ee.

We recently reported the enantioselective α-deprotonation–rearrangement of medium-sized (8-, 9- and 10-membered) cycloalkene-derived achiral epoxides using a secondary organolithium in combination with a chiral ligand such as (−)-sparteine **3**, which gives bicyclic alcohols in good yields and ees (77–84% ee, *e.g.* Scheme 1, X = CH_2).[1] However, only a single functional group is generated in the desymmetrised bicycles. One strategy to enhance the utility of this transformation would be to examine heterocycloalkene-derived achiral epoxides. Here we communicate our preliminary results concerning the synthesis and novel rearrangement chemistry of an azacyclic epoxide of this type (**1**, X = NR).



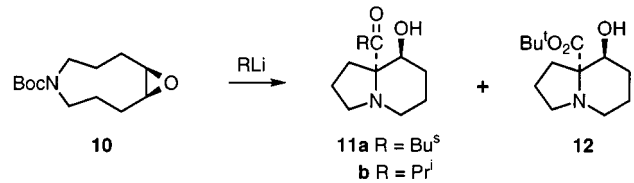
Scheme 1 *Reagents and conditions*: i, Pr^iLi (2.4 equiv.), (−)-sparteine **3** (2.5 equiv.), Et_2O, −98 °C (5 h) to 25 °C (15 h).

An important aspect of the study of transannular reactions of a medium-sized heterocycle concerns the potential problem of preparing the substrate.[2] However, application of methodology[3] used in the synthesis of the azacycloundecene system found in manzamine C led to a highly satisfactory route to the azacyclic epoxide **9** (Scheme 2). Thus, cyclisation under dilute conditions of the ditosylate **6** of the known diol **5** (readily available from cycloocta-1,5-diene)[4] gave the reduced azonine **7** in 62% yield; to the best of our knowledge this is the most efficient cyclisation reported which gives a simple reduced azonine.[2]



Scheme 2 *Reagents and conditions*: i, TsCl (4.9 equiv.), Py, 0 °C (5 h) to 25 °C (15 h), 74%; ii, $TsNH_2$ (1.7 equiv), NaOH (200 equiv.), Bu_4NI (1.4 equiv.), toluene–H_2O, reflux, 5 h, 62%; iii, Na naphthalenide (2.5 equiv.), THF, −78 °C, then HCl(g), then Et_3N (1.5 equiv.), Boc_2O (1.5 equiv.), DMAP (0.1 equiv.), CH_2Cl_2, 25 °C, 64% from **7**; iv, $MeCO_3H$ (1.2 equiv.), Na_2CO_3 (3 equiv.), NaOAc (0.02 equiv.), CH_2Cl_2, 0 °C (10 min) to 25 °C (15 h), 82% (R = Ts), 87% (R = Boc).

Subjection of the epoxide **9**, derived from reduced azonine **7**, to typical asymmetric rearrangement conditions[1] [Bu^sLi (2.4 equiv.) and (−)-sparteine **3** (2.5 equiv.) in Et_2O at −78 °C for 5 h, followed by warming to 25 °C over 15 h, *cf.* Scheme 1] led only to the recovery of starting epoxide **9**, whereas quenching the reaction with D_2O led to essentially complete *o*-deuterium incorporation into the tosyl group of the recovered starting material (64%). An attempt to induce reaction at the epoxide group subsequent to *ortho*-deprotonation using double the quantities of reagents indicated above led to no identifiable products; an alternative protecting group was therefore required. Removal of the tosyl group from **7** using sodium naphthalenide and immediate Boc reprotection of the amine hydrochloride salt gave the reduced azonine **8** (64%). Epoxidation provided **10**, which could potentially undergo deprotonation with an organolithium either α to the epoxide oxygen, or α to nitrogen. Beak has reported a 6-*exo-tet* cyclisation onto an epoxide *via* deprotonation α to NBoc; the deprotonation site was however also benzylic in this case.[5] Beak has also reported that the rate of deprotonation of Boc-protected azacycles decreases on moving from pyrrolidine to piperidine to perhydroazepine.[6] In the event, reaction of the epoxide **10** with Bu^sLi (2.4 equiv. in Et_2O at −78 °C for 5 h, followed by warming to 25 °C over 15 h) led to an inseparable 1 : 1 mixture of epimers (due to the stereogenic centre in the Bu^s group, *vide infra*) of ketone **11a** (48%, 70% based on recovered epoxide **10**, Scheme 3).



Scheme 3

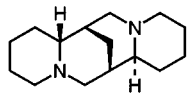
In contrast, reaction of the epoxide **10** with Bu^sLi, under the same conditions but in the presence of TMEDA (2.5 equiv.), led to the formation of ester **12** as the major product (**12** : **11a**, 8 : 1 by ^1H NMR analysis; 74% isolated yield of **12**). Using (−)-sparteine **3** as the ligand in an otherwise identical experiment gave an equal mixture of **11a** and **12** (66% ee for **12**).† Experiments were then carried out to examine the possibility of increasing both the proportion and ee of ester **12** formed from epoxide **10** (Table 1).

Maintaining the reaction at −78 °C for 18 h and then quenching at this temperature gave ester **12** in improved ee (74%, Table 1, entry 1), but the ketone **11a** predominated. However, repeating the same procedure at −98 °C significantly improved the proportion of ester **12** (**12** : **11a**, 5 : 1) and increased the ee of **12** to 79% (entry 2). Using Pr^iLi at −98 °C gave mainly the ester **12** (**12** : **11a**, 10 : 1) and with the highest level of asymmetric induction (89% ee, entry 3),‡ as also observed with our earlier work on cycloalkene-derived epoxides.[1] Using (−)-α-isosparteine **4** as ligand with either Bu^sLi or Pr^iLi slowed the reaction considerably (entries 4 and 5), particularly in conjunction with Bu^sLi; the ees were also reduced compared with the corresponding (−)-sparteine **3** reactions. In an attempt to allow Pr^iLi/(−)-α-isosparteine **4** to completely consume the epoxide **10**, the reaction was left for 40 h at −98 °C (entry 6), but it still remained only 50% complete after this time and no change in the ee of ester **12** was observed. The use of catalytic amounts of ligand was also investigated

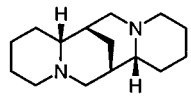
Table 1 Effect of experimental conditions on the yields and enantioselectivities of formation of indolizidine **12** from epoxide **10** using ligand/RLi in Et_2O

Entry[a]	Ligand	RLi	**10** : **11** : **12**[b]	Yield of **12**[c] (%)	Ee of **12** (%)
1[d]	**3**	Bu^{s}Li	0 : 1.6 : 1.0	32 (20)	74
2	**3**	Bu^{s}Li	0.1 : 0.2 : 1.0	58 (50)	79
3	**3**	Pr^{i}Li	0.3 : 0.1 : 1.0	57 (49)	89
4	**4**	Bu^{s}Li	5.0 : 0 : 1.0	14	64
5	**4**	Pr^{i}Li	2.0 : 0.1 : 1.0	29	79
6[e]	**4**	Pr^{i}Li	1.3 : 0.1 : 1.0	40	78
7[f]	**3**	Pr^{i}Li	0.7 : 0.6 : 1.0	36	82
8[f]	**4**	Pr^{i}Li	1.2 : 0.1 : 1.0	33	77
9[e,f]	**4**	Pr^{i}Li	0.4 : 0.2 : 1.0	54	89

[a] Ratio of ligand : RLi : epoxide **10**, 2.45 : 2.4 : 1 and carried out at −98 °C with a reaction time of 18 h unless otherwise indicated. [b] Ratios determined by ^{1}H NMR analysis of the crude reaction mixture. [c] Yield of **12** as measured by ^{1}H NMR analysis using methyl diphenylacetate as an internal standard. Isolated yields given in parentheses. [d] Carried out at −78 °C. [e] Reaction time 40 h. [f] Ratio of ligand : RLi : epoxide **10**, 0.24 : 2.4 : 1.



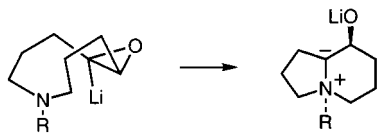
(−)-**3**



(−)-**4**

(entries 7–9) with interesting results. Using 24 mol% (−)-sparteine **3** (10 mol% with respect to Pr^{i}Li), high levels of ee (82%) were still achieved, but the reaction was found to be much slower. In contrast, (−)-α-isosparteine **4** was more effective when used in a catalytic fashion (entry 8), with no apparent change in the ee (compare entry 5). Repeating this last reaction but leaving it for 40 h at −98 °C allowed the reaction to proceed further to completion and also gave a much higher level of ee (entry 9).

The structures of indolizidinols **11** and **12** were assigned by extensive spectroscopic investigations and were later further supported by X-ray crystallographic analysis of ketone **11b**.§ A mechanistic explanation for the formation of the indolizidinols is that they arise *via* lithiation α to the epoxide oxygen to give **13**, followed by transannular reaction using the N lone pair to give an ammonium ylide **14** which undergoes [1,2] migration of the exocyclic N substituent (Scheme 4); direct insertion of the lithiated epoxide into the exocyclic C–N bond is also possible. Incorporation of the organolithium to give the ketones **11** could occur before or after the transannular reaction. The latter



13 **14**

Scheme 4

process seems most likely, since reducing the equivalents of organolithium from 2.5 improves (at the expense of conversion of starting epoxide **10**) the ratio of ester **12** : ketone **11**, and in a separate experiment ester **12** could be quantitatively converted to ketone **11b** using Pr^{i}Li (1.1 equiv., −78 °C for 1 h, followed by warming to 0 °C over 2 h).

Insertion of a lithiated epoxide into a C–N bond has not previously been reported and the present study illustrates an example of this process leading to a new and enantioselective entry to the important indolizidine framework. Further studies on the scope of this process are in progress and will be reported in due course.

We thank the EPSRC for a Research Grant (GR/L39940: postdoctoral support to L. A. R.), the EPSRC National Mass Spectrometry Service Centre for mass spectra and Dr D. J. Watkin and Professor K. Prout (Chemical Crystallography Laboratory, University of Oxford) for assistance with the X-ray structure analysis.

Notes and references

† Ees were determined by GC (Chrompack chirasil-dex 25 m × 0.32 mm ID column; 6 psi, 120 °C). The absolute configurations of the predominant indolizidinol enantiomers are not known but can be tentatively assigned as shown in Scheme 3 by analogy with the selectivity for deprotonation at the *R* configured epoxide stereocentre with (−)-sparteine **3** observed in our earlier medium-ring studies (ref. 1).

‡ Freshly distilled (−)-sparteine (70 mm^3, 0.30 mmol) in Et_2O (1 cm^3) was added dropwise over 0.5 h to a stirred solution of Pr^{i}Li [1.09 mol dm^{-3} in light petroleum (boiling range 40–60 °C); 270 mm^3, 0.29 mmol] in Et_2O (1 cm^3) at −98 °C. The reaction mixture was allowed to stir for 1 h at −98 °C before the epoxide **10** (30 mg, 0.12 mmol) in Et_2O (1 cm^3) was added dropwise over 0.5 h. The reaction mixture was stirred for 18 h at this temperature and then H_3PO_4 (0.5 mol dm^{-3} in water; 1 cm^3) added slowly dropwise. After warming to room temperature the organic layer was removed and the aqueous layer extracted with Et_2O (3 × 5 cm^3). The combined organic extracts were dried ($MgSO_4$) and then evaporated under reduced pressure. Purification of the residue by column chromatography [(SiO_2, 50% Et_2O–light petroleum (boiling range 40–60 °C) → 100% Et_2O] gave the ester **12** (14.8 mg, 49%); $[\alpha]_D^{21}$+48.6 (*c* 0.3 in $CHCl_3$).

Received (in Columbia, MO, USA) 23rd September 1998, Accepted 9th December 1998

YCl_3 reacts with 1 and 2 equiv. of the dipotassium salt of *N,N′*-bis(3,5-di-*tert*-butylsalicylidene)ethylenediamine (K_2salen′) and thf to form the arene soluble complexes, [(salen′)Y(μ-Cl)(thf)]$_2$ and (thf)$_2$K[Y(salen′)$_2$], respectively, which provide comparative structural information on the use of this ligand *vis-à-vis* bis(cyclopentadienyl) ligand sets.

Efforts to extend the range of ancillary solubilizing and stabilizing environments for yttrium and the lanthanide metals beyond the common cyclopentadienyl ligand and its analogs have led to the exploration of alternative, polydentate anionic ligands containing various combinations of oxygen and nitrogen donor atoms.[1] Among the ligands examined have been substituted Schiff base derivatives of *N,N′*-bis(salicylidene)-ethylenediamine (H_2salen), a ligand which has been successfully used with both main group and transition metals.[2–8] Salen derivatives are attractive since they can be prepared and derivatized easily and inexpensively[2] and even bi- and tridentate Schiff bases have been shown to be effective ligands for lanthanides.[3] Initial studies[6] of the di-*tert*-butyl substituted analog *N,N′*-bis(3,5-di-*tert*-butylsalicylidene)ethylenediamine, H_2salen′,[7] suggested that this ligand would be of limited use with the f-elements compared to cyclopentadienyl ligands since synthetic routes using common precursors such as YCl_3 and Y[N(SiMe$_3$)$_2$]$_3$, led to insoluble, presumably oligomeric complexes.[6] Only by use of the specialized silylamide, [N(SiHMe$_2$)$_2$]$^-$,[9] was a fully characterizable complex, (salen′)Y[N(SiHMe$_2$)$_2$](thf) **1** obtained.[6] We report here that by using the potassium salt, K_2salen′, obtained from H_2salen′ and KH, soluble complexes can be obtained directly from YCl_3.

YCl_3 reacts with 1 equiv. of K_2salen′ in thf over a 6 h period to form the arene soluble complex [(salen′)Y(μ-Cl)(thf)]$_2$ **2** which was identified by NMR and IR spectroscopy, elemental analysis,† and X-ray diffraction,‡ Fig. 1. Complex **2** crystallizes from benzene as a thf-solvated asymmetric dimer in which one salen′ ligand adopts a nearly planar orientation [Y(2)] and the other is non-planar.

Both yttrium ions in **2** have seven-coordinate distorted capped trigonal prismatic geometries, but Cl(1) occupies the capping position for the Y(1) trigonal prism and N(3) is the cap for Y(2). The distortions of the trigonal prisms also differ: the dihedral angles of the planes of the trigonal faces are 16.6° for Y(1) and 5.4° for Y(2). The salen′ ligand attached to Y(1) has a 119.8° dihedral angle between the planes of the phenyl rings, whereas the salen′ around Y(2) has a more planar orientation, with an 8.4° dihedral angle. The analogous angle in **1** is 108°.[6] In contrast, (salen′)InCl[8] is a monomer in which the salen′ donor atoms are planar. The monomeric structure may be more favorable for indium since it is less electropositive and *ca.* 0.1 Å smaller than yttrium.

Since **2** is similar to the important general class of bis(cyclopentadienyl) halide precursors [(C$_5$H$_4$R)$_2$Y(μ-Cl)]$_2$, comparison of the structural parameters of the [Y(μ-Cl)]$_2$ unit in **2** with those of the structurally characterized cyclopentadienyl examples in which R = H,[10] SiMe$_3$[11] and PPh$_2$,[12] allows evaluation of the salen′$^{2-}$ ligand set *vs.* two C$_5$H$_4$R$^-$ ligands. As shown in Table 1, the Y–Cl distances in **2** are larger than those

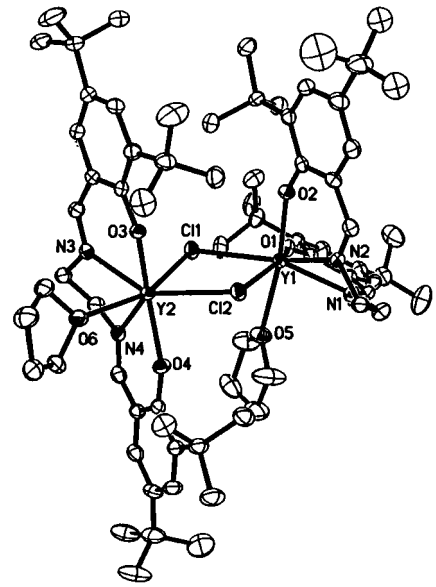

Fig. 1 Structure of [(salen′)Y(μ-Cl)(thf)]$_2$ **2** with thermal ellipsoids drawn at the 50% probability level.

Table 1 Structural data on complexes containing the [Y(μ-Cl)]$_2$ unit

Formula	Coordination number	Y–Cl/Å	Y–Cl–Y/°	Cl–Y–Cl/°	Ref
[(salen′)Y(μ-Cl)(thf)]$_2$	7	2.734(1)–2.759(1)	102.60(3)–103.13(3)	76.34(3)–76.52(3)	This work

[(Me$_3$SiC$_5$H$_4$)$_2$Y(μ-Cl)]$_2$	8	2.684(1) 2.704(1)	98.4(1)	81.6(1)	11
syn-[(Ph$_2$PC$_5$H$_4$)$_2$Y(μ-Cl)]$_2$	8	2.655(2) 2.680(2)	97.19(7) 97.43(7)	82.34(7) 82.99(7)	12
anti-[(Ph$_2$PC$_5$H$_4$)$_2$Y(μ-Cl)]$_2$	8	2.657(2) 2.657(2)	99.30(7)	80.69(7)	12

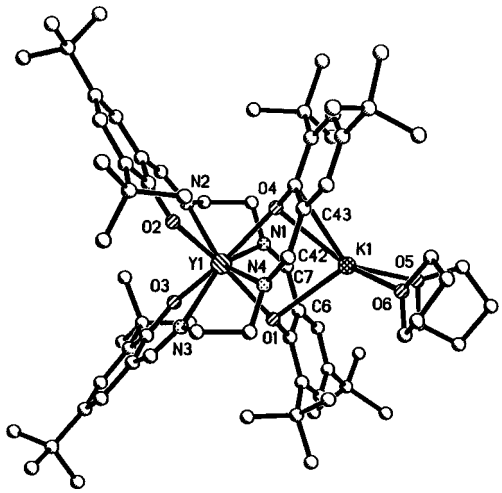

Fig. 2 Ball-and-stick model (for clarity) of $(thf)_2K[(salen')_2Y]$ **3**.

in the $[(C_5H_4R)_2Y(\mu\text{-}Cl)]_2$ complexes, even though **2** is formally seven coordinate and the other complexes are eight coordinate. This difference is accompanied by slightly smaller Cl–Y–Cl angles and slightly larger Y–Cl–Y angles.

Reaction of 2 equiv. of K_2salen′ with YCl_3 also provides an arene soluble product, $(thf)_2K[(salen')_2Y]$ **3**. The coordination environment in **3** (Fig. 2) differs from the 'sandwich' type of coordination which has been postulated for lanthanide complexes containing two disalicylidene-1,2-phenylenediamine ligands.[4] The yttrium in **3** is surrounded by a distorted eight-coordinate square antiprismatic coordination geometry with the N(2) and O(2) of one salen′ ligand and the N(3) and O(3) of the other ligand in one square face and the other donor atoms of the two ligands, N(1), N(4), O(1) and O(4), in the other square face. The dihedral angles between the arene rings in the salen′ ligands are similar: 20.9 and 22.5°. The Y–O distances [2.245(4)–2.356(3) Å] in this eight-coordinate complex are larger than those [2.143(2) and 2.16 Å] in seven-coordinate **2** and six-coordinate **1**, respectively. The Y–N distances [2.556(4)–2.618(4) Å] are also larger than the largest Y–N distances in **2** and **1** [2.492(3) and 2.44 Å, respectively].

The potassium in **3** is coordinated to two thf oxygen atoms at distances of 2.608(6) and 2.683(3) Å and an oxygen atom from each salen′ at 2.720(4) and 2.724(4) Å. The next closest distances involve C(48) [3.141(5) Å] and C(1) [3.180(5) Å], both of which are comparable to the potassium–phenyl carbon distance of 3.191(5) Å in $KBPh_4$.[13] The potassium distances to N(4) [3.245(5) Å], N(1) [3.362(4) Å], C(43) [3.431(5) Å], C(42) [3.434(5) Å], C(6) [3.454(5) Å] and C(7) [3.464(5) Å] are longer, but are within the 3.288(9)–3.534(13) Å range of K-donor atom long distance interactions cited in potassium aryloxide literature.[14] The structure of **3** demonstrates the flexibility of the salen′ ligand: two of these large ligands can be accommodated at one yttrium center and can incorporate a counter-cation to make an arene soluble product. The cyclopentadienyl analog, which would be a $[(C_5H_4R)_4Y]^-$ complex, is not known for yttrium.[15]

These results show that the salen′ ligand is viable both synthetically and structurally for metals the size of yttrium. This ligand can take the place of two cyclopentadienyl ligands in a chloride complex to provide a bridged species with slightly modified structural parameters as well as a bis(salen′) complex which has no cyclopentadienyl analog. Electronically, this salen′ should be quite different from cyclopentadienyl ligand sets and the ramifications of this difference are under investigation.

For support of this research, we thank the Division of Chemical Sciences of the Office of Basic Energy Sciences of the Department of Energy.

Notes and references

† Addition of YCl_3 (975 mg, 5 mmol) to a stirred solution of K_2salen′ (2.69 g, 4.74 mmol, from KH and H_2salen′ in thf) in 70 mL of thf caused the white suspension of K_2salen′ to disappear immediately. A clear yellow solution with white insoluble material began to form. After 6 h, the reaction mixture was filtered and the solvent was removed by rotary evaporation to give an oil. Trituration with hexanes generated a yellow powder and removal of the volatiles by rotary evaporation left **2** as a yellow powder (3.10 g, 90%). $\delta_H(C_4D_8O$, 400 MHz) 8.25 (s, 2H), 7.36 (d, *J* 2.8, 2H), 7.03 (d, *J* 2.4, 2H), 3.89 (br, 4H), 1.45 (s, 18H), 1.25 (s, 18H); $\delta_c(C_4D_8O$, 100 MHz) 169.5, 129.4, 130.5, 63.3, 30.3, 31.9. Not all short C–H···O contacts are hydrogen bonds: the prototypical example of contacts to C=O⁺–H

Thomas Steiner†

Department of Structural Biology, Weizmann Institute of Science, Rehovot 76100, Israel

Received (in Cambridge, UK) 17th November 1998, Accepted 23rd December 1998

Intermolecular contacts between C–H groups and the charged moiety X=O⁺–H show a pronounced negative directionality, *i.e.* short contacts are associated with strongly bent angles; this indicates that these interactions do not represent hydrogen bonds, although they are occasionally short with H···O distances down to 2.5 Å.

After a long period of dispute, it has in recent years become accepted that directional and cohesive C–H···O interactions represent hydrogen bonds.[1,2] Because carbon acidities span a very wide range,[3] the strengths of C–H···O hydrogen bonds cover also a wide range that overlaps at one end with strengths of O–H···O hydrogen bonds,[4] and on the other end it merges with van der Waals interactions.[5] In this context, it is of importance to ask whether *all* short C–H···O contacts are hydrogen bonds, or if there are exceptions. This matter has been addressed by several authors. In particular, short intramolecular C–H···O contacts,[6] short contacts with second-nearest neighbours,[7] compressed C–H···O interactions[8] and inter-anion C–H···O contacts[9] have been mentioned as possibly destabilizing. All these studies, however, remained limited in scope. In the present work, a whole class of short C–H···O contacts that do not represent hydrogen bonds will be presented, and structural consequences of this lack of hydrogen bond nature will be shown. The analytical tool used is the crystal correlation method, which has not been applied for this purpose before.

In hydrogen bonding X–H···A, it is a prerequisite that the acceptor A is a basic entity, and the donor X–H must be at least slightly acidic. Alternatively, in an electrostatic approach, one can give as a basic requirement that the acceptor A must carry a negative partial charge, or at least must have a sterically accessible region of negative charge concentration. This would mean that intermolecular contacts X–H···$A^{\delta+}$ do not fulfill the primary conditions for hydrogen bonding, and even if they occur experimentally, they should not be classified as hydrogen bonds. To look into the matter of intermolecular C-H···O contacts that are not hydrogen bonds, contacts to O atoms of the kind $O^{\delta+}$ are, therefore, a relevant system. Candidates are the O atoms in species like H_3O^+ and $X{=}OH^+$. In the latter, the positive charge need not be localized on the O-atom, but charge delocalization with substantial contribution of the resonance form $X{=}OH^+$ should be sufficient. Examples are systems like $P{=}OH^+ \leftrightarrow P^+{-}OH$, $>N{-}C{=}OH^+ \leftrightarrow >N^+{=}C{-}OH$, and so on.

In crystals, there is not even one example of a short contact X–H···$O^{\delta+}$ formed by an O–H or N–H group.‡ However, relatively short contacts of C–H groups to $O^{\delta+}$ do occur occasionally within frameworks of strong hydrogen bonds and ionic interactions. As an example, the crystal structure of acetamidium nitrate[10] is shown in Fig. 1. A methyl C–H group forms a short contact to a nitrate O atom (H···O = 2.28 Å), which is clearly suggestive of a C–H···$O^{\delta-}$ hydrogen bond. This C–H group also forms an inter-cation C–H···$O^{\delta+}$ contact with H···O = 2.60 Å. When considering only interatomic distances, this contact too might be interpreted as a weak hydrogen bond, and such a view could even be supported by the suitable orientation of the electron lone pair of the protonated amide O atom. On the other hand, when looking at the overall electrostatic situation, and when considering the complete absence of related O/N–H···$O^{\delta+}$ 'hydrogen bonds' in crystals, this C–H···$O^{\delta+}$ interaction would rather be taken as forced by optimization of the strong interionic interctions. In view of such conflicting arguments, further evidence in favour of or against the interpretation as a hydrogen bond is clearly needed.

One of the characterstics of hydrogen bonding is the *directionality*. In optimal geometry, the donor is oriented linearly at the acceptor, and any deviation from linearity incurs an energetic disadvantage. The weaker hydrogen bond types can be easily distorted from optimal geometry so that large deviations from linearity occur frequently, but a statistical preference for linearity is discernible even for the very weak C–H···O hydrogen bonds formed by methyl groups.[11] This property can be used as a test criterion in assessing whether a particular type of intermolecular C–H···O contact is a hydrogen bond or not. In a CSD analysis‡ of intermolecular C–H···$O^{\delta+}$

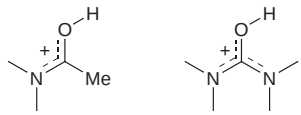
contacts, data quantities sufficient for statistical analysis were found only for the O atoms in OH groups of the cationic fragments **1** and **2**, which represent protonated acetamide and



1 **2**

urea skeletons. In both fragments, the positive charge is delocalized, but this involves only small groups of atoms. Fragments which allow charge dilution over larger atom groups than in urea were generally not considered.

For C–H···O contacts formed by fragments **1** and **2**, the scatterplot of C–H···O angles against the H···O distance is shown in Fig. 2, and some additional information is given in Table 1. The overall appearence of the scatterplot is very different from those obtained for hydrogen bonds. For these, short contacts are associated with relatively linear angles.[1] The shortest contacts in Fig. 2 have H···O distances slightly longer than 2.5 Å, but are all associated with strongly bent angles around 120°. No C–H···O$^{\delta+}$ contact is found which is at the same time short and linear, and relatively linear angles occur only at long distances > 3.0 Å. This could be termed a 'negative directionality', which is clearly incompatible with a hydrogen bond nature of the interaction. In order to compare the typical contact geometry with those of clear C–H···O hydrogen bonds and of C–H···H-C van der Waals contacts, mean distances and angles are listed for H···O < 3.0 Å in Table 2. The van der Waals contacts have isotropic directionality characteristics, associated with a mean C–H···H angle of 128.6°.[11] C–H···O hydrogen bonds are on average more linear than van der Waals contacts, whereas C–H···O contacts of fragments **1** and **2** are more bent, with a mean angle of 121(3)°. This indicates that these C–H···O contacts are neither hydrogen bonds, nor are they of the van der Waals type, but the H atom is rather repelled by the O atom, in a sense pushed out of the way.

A look at Table 1 shows that the data sample is chemically diverse. Most of the C–H···O contacts represent inter-cation interactions, but there are also examples of C–H groups in uncharged molecules. This means that the interaction is not specific to a particular narrow family of molecules, or to cation–cation contacts, but is of more general relevance. Actually, short but bent C-H···O$^{\delta+}$ contacts are found in the CSD also for O-atoms in P = OH$^+$, S = OH$^+$ and H_3O^+ but for these, the data quantities are too small to allow reasonable statistical analysis. It is of importance that the C–H groups involved are all of the very weakly polar types $>CH_2$ and $-CH_3$ (Table 1), for which the unfavourable electrostatic interaction H$^{\delta+}$···O$^{\delta+}$ is expected to be only relatively weak. The more polar kinds of C–H[3,5] apparently avoid short contacts to O$^{\delta+}$ as efficiently as do the strongly polar groups O–H and N–H.

The data in Fig. 2 and Table 2 clearly show that contacts of the kind C–H···O$^{\delta+}$ should not be considered as hydrogen bonds, even though they are occasionally relatively short. It is not the contact distances that lead to this conclusion, but the contact *directionalities*. A look at the data quantities in Table 2 also shows that short C–H···O$^{\delta+}$ contacts are a rare phenomenon when compared to C–H···O hydrogen bonding. There are two important conclusions: (i) not every single short C–H···O contact occurring in crystals is a hydrogen bond, and (ii) considering only contact distances is an unsuitable approach in the analysis of hydrogen bonds, and of intermolecular interactions in general.

The author thanks the Minerva Foundation (Munich) for granting a fellowship to stay at the Weizmann Institute of Science in the research group of Professor Joel L. Sussman.

Functional silica aerogel from metastable lamellar composite

Yizhu Guo and Ana R. Guadalupe*

Department of Chemistry, PO Box 23346, University of Puerto Rico, San Juan, Puerto Rico 00931. E-mail: aguadalu@upracd.upr.clu.ed

Received (in Cambridge, UK) 6th October 1998, Accepted 7th January 1999

A functional aerogel composed of interconnected silica nanoparticles has been synthesized from a metastable lamellar composite based on a novel type of cooperative interaction between silica and surfactant species.

Silica aerogels possess an attractive and unique set of properties, [1,2] including extremely low densities, high surface area, low thermal conductivity and low dielectric permittivity. The pore structure of aerogels is formed by the controlled condensation of small (polymeric or colloidal) primary particles which are usually generated and aggregated by a sol–gel process. [1,3] Typically, an alkoxysilane precursor is used to produce an alcogel in acidic or basic alcoholic solution by a one- or two-step sol–gel process, then the alcogel is subject to air-exchange without destroying the gel structure generally by supercritical drying. A highly pursued goal in aerogel technology is the elimination of the supercritical drying step, because it is the most expensive and risky step in the production of aerogels. While the structure–property relationship of aerogels is readily manipulated through the choice of precursors and polymerization conditions, research in new aerogel chemistry and compositions is necessary for performance improvement and novel applications.[4]

Here we report the synthesis of a functional aerogel from a metastable lamellar surfactant–silica composite, eliminating the intermediate alcogel formation. We demonstrate that the surfactant mesostructure facilitates and stabilizes the formation of monodispersed silica nanoparticles, that aggregate into a highly porous solid. The porous, skeletal structure is maintained after removal of surfactant. This procedure provides a novel non-supercritical drying technique for the production of aerogels and reveals a new aerogel chemistry for functional, highly porous materials.

Bis[(3-triethoxysilyl)propyl]tetrasulfide (SIS, purchased from Petrarch systems) was chosen as the silane precursor. The sulfur chain (–S_4–) in the SIS molecule has been demonstrated to have a high affinity for heavy metals (*e.g.* mercury and silver).[5] Thus, functionalized aerogels would be a potential sorbent for the recovery of heavy metals, as shown for thiol-monolayer modified molecular sieves M41S.[6] The precursor was added dropwise into 5% aqueous sodium dodecyl sulfate (SDS, purchased from Aldrich) solution under vigorous stirring. Then 0.1 M HCl was added dropwise as the catalyst. The composition (molar ratio) of the final solution was SIS : SDS : HCl : H_2O = 1 : 1.5 : 0.05 : 600. A bean curd-like, milky-white gel formed and floated in a clear solution after 2–3 days under ambient conditions. In contrast, no gel formed in the solution without SIS, or a light yellow precipitate formed in the solution without SDS.

Fig. 1 shows the small angle X-ray diffraction patterns of the gel samples dried at room temperature [curve (a)] and at 100 °C for 4 h at atmospheric pressure [curve (b)]. The room temperature-dried gel exhibited well defined (001), (002), and (003) peaks characteristic of lamellar structure, with the largest *d* value of 35.13 Å. By contrast only poorly-defined (001) and (002) peaks were observed for the heated gel, and the *d* value decreased to 28.79 Å, indicating that the lamellar structure of the gel (SDS/SIS sol–gel composite) is thermally unstable.

Fig. 2 shows typical TEM micrographs of the ethanol-washed room temperature-dried SDS/SIS sol–gel composite. It is clear that a three-dimensional highly porous skeleton structure characteristic of aerogel[7] is formed from the SDS/SIS sol–gel composite after removing the surfactant. Closer examination reveals that the network is constructed by interconnected nanoparticles. These nanoparticles are narrowly distributed with a diameter around 38 nm. The aerogel thus prepared exhibited low bulk density (*ca.* 0.2 g cm^{-3}).

A possible mechanism for the SIS aerogel formation from a metastable lamellar SDS/SIS sol–gel composite is proposed in Scheme 1. A high SDS concentration in water leads to a lyotropic lamellar liquid-crystalline phase consisting of bilayer sheets[8] (A). Addition of the hydrophobic silica precursor, SIS, into the aqueous media under vigorous agitation resulted in the formation of SIS droplets promoted and stabilized by the presence of SDS (B). Meanwhile, mediated by Na^+ counter ions, SDS bilayers bend around the SIS droplets.[9,10] Upon closing, these sheets form lamellar vesicles,[11–13] encapsulating the SIS droplets (C). The hydrolysis and condensation (*i.e.* polymerization) of SIS then occurs in these lamellar vesicles. Aggregation of these lamellar droplets is facilitated[9,14–16] by dehydration of the surfactant head groups and an increase in counter ion binding caused by the release of ethanol in the SIS hydrolysis process. Upon aggregation, a bean curd-like gel

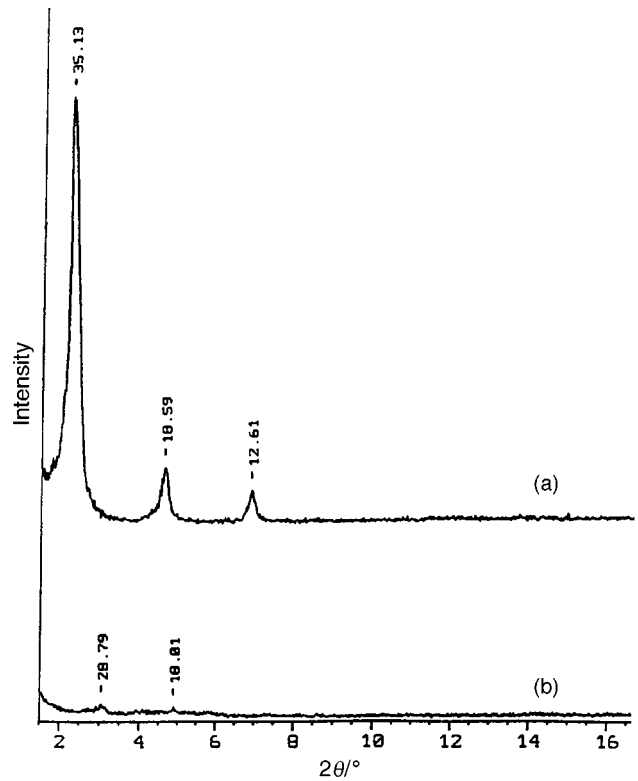

Fig. 1 Small angle X-ray diffraction patterns of the SDS/SIS sol–gel composites dried at room temperature (a) and dried at 100 °C under ambient pressure (b).

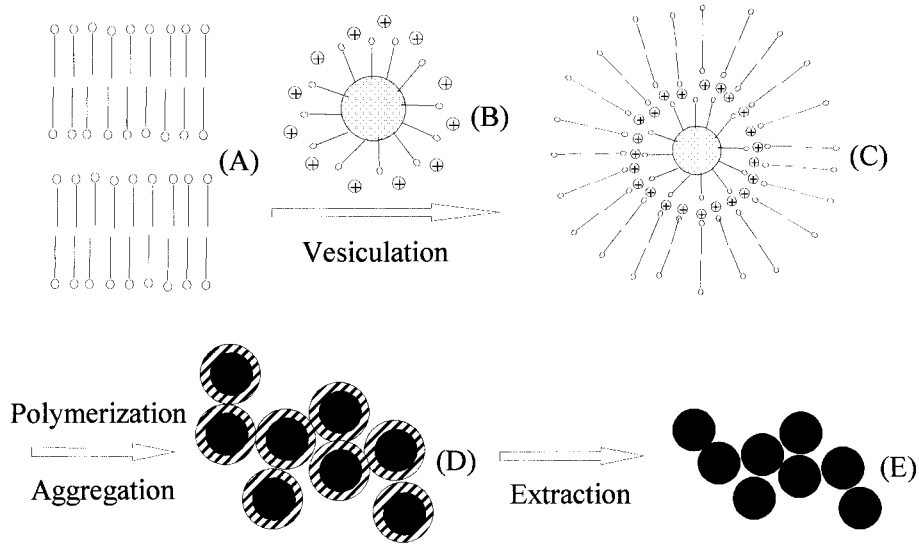

Scheme 1

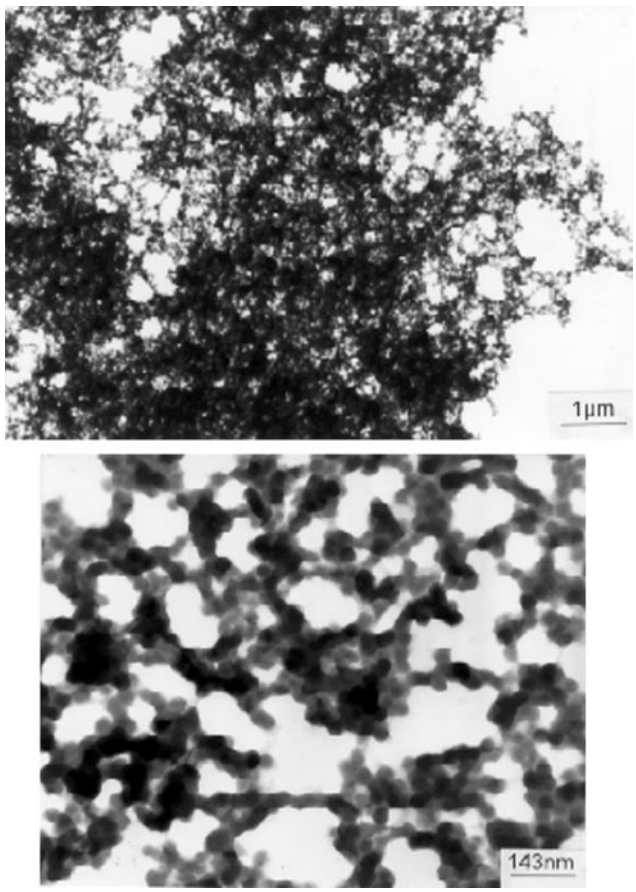

Fig. 2 Transmission electron microscopy micrographs of the ethanol-washed room temperature-dried SDS/SIS sol–gel composite at low (top) and high (bottom) magnifications.

formed (D). At SDS concentrations of ⩾5%, bean curd-like gels are readily formed. A higher concentration (> 10%) results in SDS crystallization. Removal of SDS by alcohol extraction resulted in the SIS aerogel (E), most probably because of the highly hydrophobic interactions among the SIS sol–gel nanoparticles.

In conclusion, we have developed a novel approach for the production of a functionalized aerogel from a surfactant/SIS sol–gel composite. This technique allows atmospheric pressure drying so eliminating expensive and risky supercritical drying. The highly porous characteristics combined with the high affinity of the sulfur chain for heavy metals hold promising and immediate environmental application in the recovery of heavy metals.

A novel protocol for *N*-methyl-γ-amino-β-hydroxy acids from oxazolidinones

G. Vidyasagar Reddy,* G. Venkat Rao and D. S. Iyengar*

Discovery Laboratory, Organic Division – II, Indian Institute of Chemical Technology, Hyderabad-500 007, India. E-mail: iyengar@iict.ap.nic.in

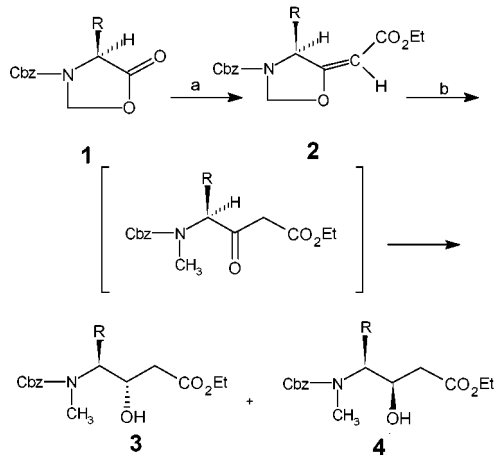
Received (in Cambridge, UK) 29th October 1998, Accepted 18th December 1998

A new two step methodology for *N*-methyl-γ-amino-β-hydroxy acids from oxazolidinones is described

Optically active *N*-methyl-γ-amino-β-hydroxy acids are a class of nonproteinogenic amino acids present in a variety of biologically active compounds, *e.g.* Hapalosin,[1] a multidrug resistance active compound containing 3-hydroxy-4-*N*-methylamino-5-phenylpentanoic acid, and Dolastatine 10,[2] an anticancer compound containing 3-hydroxy-4-*N*-methylamino-5-methylheptanoic acid. Due to their promising biological activity, they have become an interesting class of compounds in the pharmaceutical industry. Although there are methods[3] available for preparation of *syn* and *anti* isomers of γ-amino-β-hydroxy acids, there is no effective method available to make their *N*-methylated analogues. The literature methods[4] of their preparation involves the treatment of *N*-protected-γ-amino-β-hydroxy acid with NaH followed by MeI. However, this method suffers due to competitive reactions such as the β-elimination resulting in the formation of α,β-unsaturated acid derivatives, and pyrrolidinone ring formation. The other problems associated with this method are *O*-methylation and *N*-deprotection, resulting in a complex mixture of products. In view of this, alternative methods have been developed.[5] Herein, we report an elegant, entirely novel, short and efficient protocol for the title compounds involving two new reactions, *viz*. (a) Wittig reaction of oxazolidinones (**1**→**2**) and (b) a reductive process of their corresponding α,β-unsaturated esters (**2**→**3**) (Scheme 1).

N-Cbz-oxazolidinones[6] (**1**) obtained from *N*-Cbz-α-amino acids by the reaction of paraformaldehyde in the presence of catalytic TsOH, were subjected to the Wittig reaction with Ph_3PCHCO_2Et to give α,β-unsaturated esters (**2**) in excellent yields. Since there was no enhancement of the signal in the NOE experiment between the olefinic proton and the methine proton in the ring, the olefin geometry was assumed to be '*E*'.

The reaction of α,β-unsaturated ester **2a** with $NaCNBH_3$–TMSCl under N_2 atmosphere afforded an easily separable mixture of *syn* and *anti* *N*-Cbz-*N*-methyl-γ-amino-β-hydroxy acids **3a** (syrup; $[\alpha]_D^{24}$ −29.4 (*c* 1, MeOH)) and **4a** (syrup; $[\alpha]_D^{25}$ −26.6, (*c* 1, MeOH)) in a ratio of 4:1 in 94% combined yield (Scheme 1).

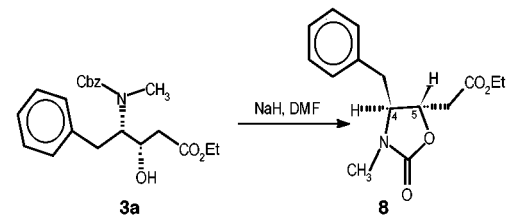


Scheme 1 *Reagents and conditions:* a, Ph_3P=CHCOOEt, toluene, reflux, 3 h; b, $NaCNBH_3$, TMSCl, CH_3CN, N_2, rt, 30 min.

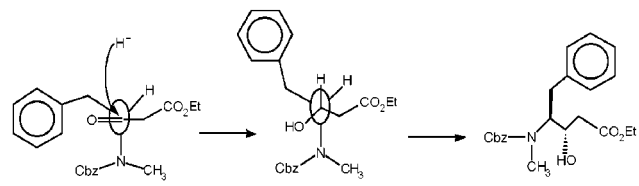
As expected the major isomer **3a** was found to be *syn* from the ^{1}H-NMR of the corresponding oxazolidinone[7] **8** obtained by the treatment of **3a** with NaH in DMF (J = 4.5 Hz for ring protons 4-H and 5-H, Scheme 2), which may be explained by the Felkin–Anh model[8] (Fig. 1). This was further confirmed by converting the minor *anti* isomer **4a** into the known compound **7** (oil; $[\alpha]_D^{25}$ −43.7 (*c* 1, MeOH); lit.[4c] $[\alpha]_D^{25}$ −41.2, (*c* 1, MeOH)) and by comparing specific rotations and spectral data with those of reported values which are found to be in good agreement (Scheme 3).

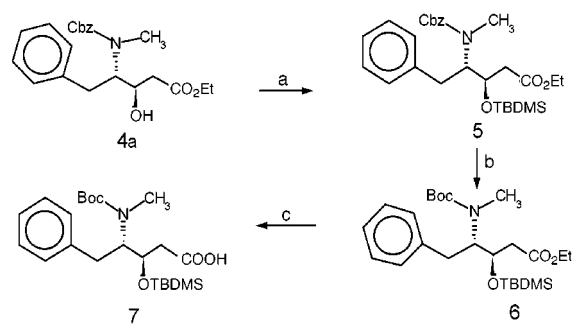
In order to probe the generality of the reaction, the process was further applied to **2b**–**2c.** *N*-Cbz-*N*-methyl-γ-amino-β-hydroxy acids (**3b**,**c**, **4b**,**c**) obtained using this methodology are shown in Scheme 1 (Table 1). All the compounds obtained were fully characterized by spectral data.[9] Important characteristic NMR signals of **3a** [δ_H 2.80 (s, 3H, N-CH_3), 1.30 (t, 3H, J 6.4, CH_3), 4.20 (q, 2H, J 6.4, CH_2)] clearly indicate the *N*-methyl group and ethyl esters. The spectroscopic data and optical rotations are in accordance to those of reported values.

In summary, we report an entirely novel, straightforward and practical methodology for *N*-methyl-γ-amino-β-hydroxy acids,



Scheme 2





Scheme 3 *Reagents and conditions :* a, TBDMSCl, imidazole, DMF, rt, 10 h, 95%; b, 10% Pd–C/H_2, Boc_2O, MeOH, rt, 12 h, 98%; c, 2M NaOH, THF, rt, 4 h, 92%.

Table 1 Preparation of *N*-Cbz-*N*-methyl-γ-amino-β-hydroxy acids from oxazolidinones

		2		**3** and **4**
S. No	R	Yield (%)	$[\alpha]_D^{25}$ [a]	Yield (ratio)[b]
A	$PhCH_2$	96	−13.8	94 (4 : 1)[c]
B	Me_2CHCH_2	94	45.2	92 (3:1)[d]
C	$MeCH_2CHMe$	96	25.6	96 (3:1)[d]

[a] Specific rotations were measured with c = 1 in MeOH. [b] Yield (%) are combined yields. Ratio is [c] based on isolated yield, [d] based on crude ^{1}H-NMR.

key precursors of the potential bioactive molecules and enzyme inhibitors, for the first time. The present methodology enables the synthesis of a variety of *N*-methyl-γ-amino-β-hydroxy acids with ease, and hence offers a practical alternative to the earlier methodologies. Further work is in progress and will be reported in due course.

G. V. S. R. and G. V. R. thank the CSIR (India) for their fellowships.

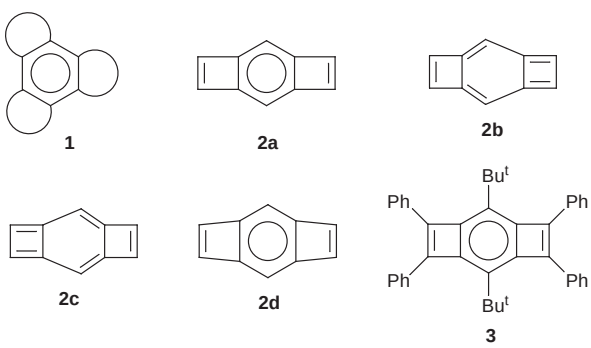
Received (in Cambridge, UK) 23rd December 1998, Accepted 4th January 1999

The X-ray determined structure of the title compound is reported; it was found that the annelated bonds are the longest observed in a benzene derivative [1.540(5) Å]; *ab initio* calculations (at the B3LYP/6-31G* and MP2/6-31G* levels of theory) were used in order to understand the electronic and structural properties of the compound.

Strain imposed on aromatic compounds alters the properties of the aromatic systems. Of particular interest is strain that is imposed in the σ-plane, namely, perpendicular to the π-system. When the strain is imposed in an angular manner (schematically shown in **1**) it causes the localization of the aromatic bonds.[1] When imposed in a linear manner (as in the title compound) the aromatic moiety changes dramatically.[2] However, in the particular case of benzo[1,2:4,5]dicyclobutadiene **2** it was predicted that this system should show two types of isomerism:[3] bond-stretch isomerism (**2a** with D_{2h} symmetry *vs.* **2b** and **2c** with C_{2v} symmetry) and Kekulé isomerism (*i.e.* **2b** *vs.* **2c**). As the title derivative of **2** was prepared some years ago,[4] and the study of its chemical and physical properties has not yielded conclusive answers,[5] and in light of the controversial issue of bond-stretch isomerism,[6] it was decided to characterize the structure crystallographically.

The title compound **3** was made as previously published.[4] Crystals suitable for X-ray analysis of this highly sensitive compound[4] were obtained by careful recrystallization from *p*-xylene. Five data sets of different crystals of different quality and at various temperatures were collected. All of them showed the same features that are presented in Fig. 1 (the essential bonding parameters can be found in the figure caption). In the monoclinic system (space group *C*2/*c*, a = 21.3735(5), b = 6.11890(10), c = 23.4144(6) Å, β = 99.8480(10)°, Z = 4),[7] the molecular structure was found to possess C_2 symmetry with some unexpected bond distances, especially in the central ring. To the best of our knowledge, the C(1)C(2) distance is the longest distance ever found in a benzene ring. The geometry is not expected to be essentially influenced by intermolecular contacts, which are mostly beyond van der Waals contacts; the closest are at H(9B) and H(12A) with 2.22 Å (C–H distances expanded to 1.08 Å).



Although Schulman and Disch[3] predicted unusual structures for **2**, all the structural features of **3** are different than those predicted theoretically. The symmetry of the benzobicyclobutadiene skeleton in **3** is D_{2h}, as in **2a**, but the bond lengths are closer to a hybrid of the two theoretical C_{2v} *isomers* **2b** and **2c**.[8a] However, the annelated bonds in **3** are shorter than the average of the respective bonds in **2b** and **2c**. Also, it looked like the more stable isomer was not the one that was experimentally found.[8b] In order to resolve this dichotomy, we decided to study the issue using *ab initio* calculations on **2** at higher theoretical levels.

GAUSSIAN 94[9] was used. The systems under study were optimized at the B3LYP/6-31G* and MP2/6-31G* theoretical levels, which have been shown to produce reliable structures for small-ring annelated benzene systems.[1c,10] Table 1 summarizes the geometry of the systems obtained at these levels of theory. It was found that there are only two bond-stretch isomers, both possessing D_{2h} symmetry. One is similar to **2a**, and the second one, **2d**, does not correspond to **2b** (or **2c**) but is similar that one found in the crystal structure of **3**. Furthermore, **2d** is theoretically predicted to be 2.4 and 3.7 kcal mol^{-1} (at B3LYP/6-31G* and MP2/6-31G*, respectively) more stable than **2a**.

Table 1 Calculated (B3LYP/6-31G* and MP2/6-31G*) geometries and relative energies of the two isomers of **2**

	Isomer	Level	R_1	R_2	R_3	R_4	ΔE/kcal mol^{-1}
	**2d**	B3LYP/6-31G*	1.3888	1.5641	1.3916	1.4583	−2.4
	2a	B3LYP/6-31G*	1.3944	1.4026	1.5430	1.3456	0
	2d	MP2/6-31G*	1.3898	1.5545	1.3921	1.4587	−3.7
	2a	MP2/6-31G*	1.3943	1.4082	1.5361	1.3456	00

Table 2 Bond-length differences between the calculated geometries of **2d** (at B3LYP/6-31G* and MP2/6-31G*) and **4** and **3**

	X	Level	ΔR_1	ΔR_2	ΔR_3	ΔR_4	Average error
	H (**2d**)	B3LYP/6-316*	−0.023	+0.024	−0.016	−0.013	0.019
	H (**2d**)	MP2/6-31G*	−0.023	+0.015	−0.016	−0.015	0.018
	Vinyl (**4**)	B3LYP/6-31G*	−0.021	−0.011	−0.001	+0.014	0.012

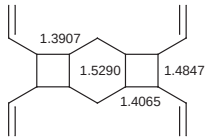

Fig. 2 B3LYP/6-31G* structure of **4** at D_{2d} symmetry (the experimentally found isomer).

Both isomers have been shown to be minima on the potential surface by frequencies calculations.

Although the agreement between the calculated and observed structures is reasonable, we have calculated the structure of the 4,5,9,10-tetraethenyl derivative of **2** (**4**), to see if the alkenyl substitution (that mimics the phenyl substitution in **3**) is responsible for (at least some) of the geometrical differences between the calculated and measured structures. Fig. 2 shows the geometry of **4** (at D_{2h} symmetry)[11] and Table 2 presents an error survey of the studied systems. The numbers in Table 2 suggest that (i) B3LYP/6-31G* and MP2/6-31G* describe the system with about the same accuracy,[12] and (ii) that at least a part of the discrepancy between the measured and calculated structures is due to the substitution. This can be concluded from the fact that the average error values for **4** are 37% smaller than for **2**, and that the sign of the error for different bonds is different.

We are currently studying the issue of interconversion between the two isomers theoretically, and are trying to prepare other derivatives of the title compound that may yield the other bond-shift isomer.

We thank The American – Israeli Binational Science Foundation, the Lise-Meitner-Minerva Center for Computational Quantum Chemistry, the VPR fund at the Technion and the Fonds der Chemischen Industrie for financial support.

11 The discussion presented here for **4** regards the tetraethenyl derivative of isomer **2d**. However, **2a** also has a stable tetravinyl derivative. The two bond-shift isomers (*i.e.* **2a** and **2d**) also have other stable derivatives that show this isomerism, such as the tetrahydroxy and tetracyano derivatives (A. Stanger, unpublished results). These are, however, beyond the scope of this paper.

12 The agreement between the experimental and calculated structures is even better if the experimental σ value (0.005 Å for all the discussed bonds) is considered.

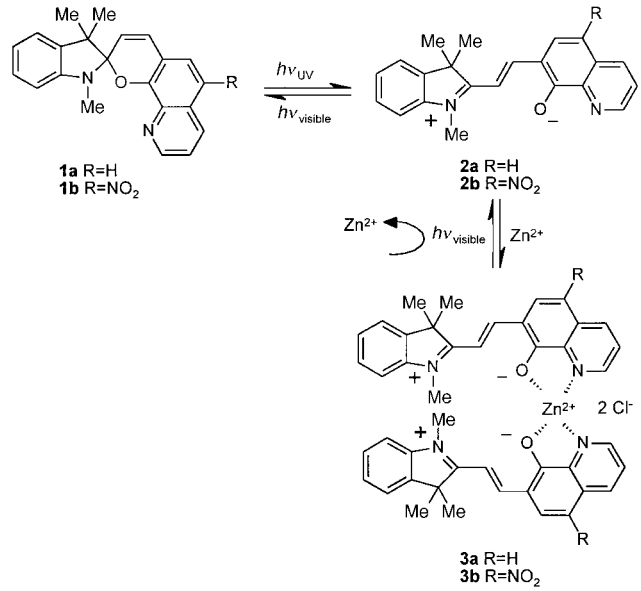
Received (in Columbia, MO, USA) 5th October 1998, Accepted 11th January 1999

The first demonstration of rapid and reversible, photoinduced switching of metal complexation from a quinolinospiropyranindoline–metal complex in aqueous solution is presented.

The design and synthesis of functional molecules with molecular switching characteristics is currently an area of intense activity and tremendous potential significance to the fields of molecular electronics and sensor device fabrication.[1] The development of new materials for application in sensing transducers has traditionally been plagued by non-reversible interactions between the analyte and sensing receptor, a factor resulting in one-time use sensors. Innovative efforts to overcome this problem have typically relied upon the incorporation of both the complexation or recognition site and a light- or potential induced rejection mechanism into a single sensing molecule.[2,3] Spiropyrans[4,5] and spirooxazines[6,7] have shown particular promise in this regard due to the photochemically-mediated interconversion of 'open' and 'closed' forms (*e.g.* **1**⇆**2**) upon exposure to UV or visible light, respectively. The introduction of metal ion complexation sites to take advantage of the spiropyranindoline ⇆ merocyanine interconversion leads to the photoreversible ejection of complexed metal ions.[4] To our knowledge, there are no published accounts of photoreversible metal ion complexation by these compounds in aqueous media. The reason for this is simple: stabilization of the merocyanine isomer in water prevents the photoinduced ejection of trapped metal ions. Photoreversible metal complexation in water is critical to the eventual application of these materials to sensor transducers operated in aqueous systems for environmental monitoring. Here we describe the molecular design issues critical to promoting photoreversible metal complexation for spirobenzopyrans in polar solvents, and present the first demonstration of rapid and reversible, photoinduced switching of metal complexation from a quinolinospiropyranindoline–metal complex in aqueous solution.

Two 8-hydroxylquinoline-derived spiropyranindolines **1a** (R = H)[4,8] and **1b** (R = NO_2),[4] which differ only by the addition of a nitro group *para* to the pyran oxygen, are shown in Scheme 1.

While the denticity of 8-hydroxyquinoline for metal ions is well precedented, our initial expectation was that the stability of the metal/merocyanine complex **3a** would prevent photoisomerization to **1a** with concomitant release of metal ion. Spirobenzopyran **1b** was, therefore, prepared to promote photoreversibility of metal complexation by withdrawing electron density away from the phenolate oxygen and decreasing the denticity of **2b**. Spirobenzopyran **1b** does indeed exhibit significant, photoreversible metal complexation in organic solvents with low polarity, such as tetrahydrofuran. Unfortunately, there is little to no observable reversibility in solvents of higher polarity, such as acetonitrile. The inability to achieve the conversion of **3b** to **1b** *via* irradiation can be explained by the enhanced stabilization of the zwitterionic merocyanine form, **2b**, by the nitro group which serves to delocalize the phenoxide anion in **2b**.[9] This stabilizing effect of the nitro group in **2b** is underscored by the rapid conversion of **1b** in the dark to the colored, merocyanine form **2b** in solvents with dielectric constants higher than that of tetrahydrofuran. Note from Scheme 1 that in addition to the solvent dependent generation of **2** under dark conditions, the concentration of **2** is further enhanced under UV light illumination. Ultimately, the lifetime of any free zinc ions ejected into solution is significantly attenuated due to the rapid recomplexation event, **2b**→**3b**.



Scheme 1 Photoreversible equilibria of quinolinospiropyranindoline (**1a**, R = H) and nitroquinolinospiropyranindoline (**1b**, R = NO_2).

The thermodynamic stability of the closed quinolinospiropyranindoline, **1**, must be enhanced to promote photoreversibility of metal complexation of **3** in polar solvents. The simplest way of doing this is to remove the nitro group *para* to the phenoxide anion, as in **1a**. Evidence for the improved stability of **1a** relative to **1b** is apparent from the colorless solution, indicative of the closed spiropyran, obtained for **1a** in acetonitrile (2.4×10^{-5} M; Fig. 1A, spectrum a). The dark addition of 0.5 equivalents of Zn^{2+} to this solution of **1a** in acetonitrile (Fig. 1A, spectrum b) results in the formation of a bright red complex **3a**, with Zn^{2+} in a 2 : 1 ligand : metal ratio, based upon stoichiometric determinations using the molar ratio absorbance method.

Exposure of a solution of **3a** in acetonitrile to visible light (150 W tungsten flood lamp) causes the temporary ejection of the complexed metal ion, and a transition to the colorless, closed form of the quinolinospiropyranindoline (**3a**→**1a**). Evidence for this shift is shown in Fig. 1A, which shows the effect of exposure of a solution of **3a** to visible light as a function of time.

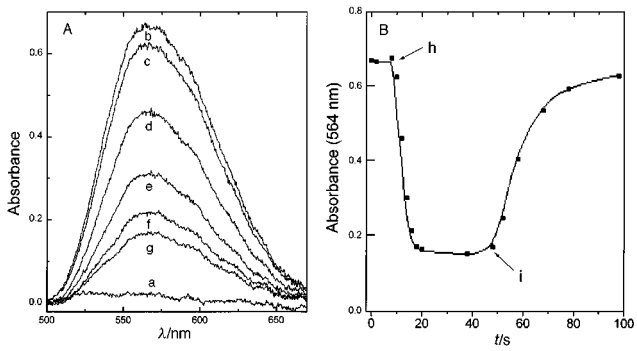


Fig. 1 (A) UV–VIS spectra of 2.4×10^{-5} M **1a** in acetonitrile with (a) no Zn^{2+} added; (b) 1.2×10^{-5} M Zn^{2+} added; and solution (b) after exposure to visible light for (c) 2, (d) 12, (e) 14, (f) 16, (g) 20 s. (B) Switching behavior observed in the absorbance intensity at 564 nm with visible light on at 8 s (h) and off at 48 s (i).

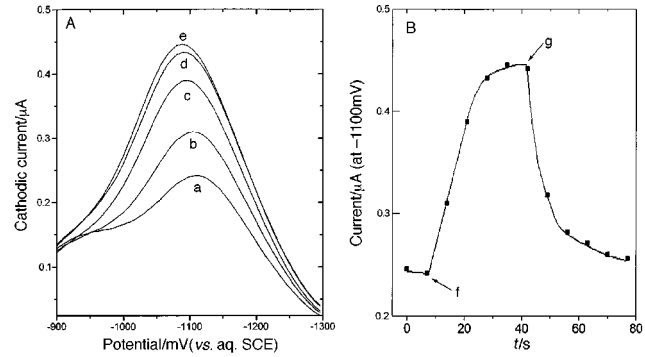

Fig. 2 (A) Cathodic reduction of free Zn^{2+} ions in a 4 : 1 water–acetonitrile solution containing 2.4×10^{-5} M **1a** and 1.2×10^{-5} M Zn^{2+} after exposure to visible light for (a) 0, (b) 7, (c) 14, (d) 21, (e) 28 s. (B) Switching behavior observed in the cathodic reduction of free Zn^{2+} ions in solution with visible light on at 7 s (f) and off at 42 s (g).

This amazing effect can be monitored visually without the aid of a spectrometer, the transition from a strongly colored, red complex to a nearly colorless solution (78% reduction in absorbance at 564 nm, Fig. 1A) indicating that the complex **3a** is undergoing photoisomerization to the closed spirobenzopyran form **1a** and ejecting the complexed Zn^{2+} ion in the process. The photochemically mediated ejection of the metal ion from **3a** is fast, with an 8 s response time following the onset of visible light irradiation (Fig. 1B). Immediately following the cessation of light, the free metal ion is quickly recomplexed (50 s time response) as the equilibrium shifts back to its original state (**1a**→**3a**). In contrast, ejection of Zn^{2+} ion from a solution of **3b** in acetonitrile upon irradiation with visible light is minimal (14%), a result which can be ascribed to the enhanced stability of **2b** in polar solvents, as described above. This rapid switching behavior in the metal complexation properties of spiropyranindoline **1a** is an important step toward the development of molecular devices and sensors.[10]

While UV–VIS spectroscopy monitors equilibria pertaining to the ligand, electrochemistry can be used to monitor equilibria associated with the metal ion. Square wave voltammetry was utilized (1) as a complementary technique to confirm the ejection of metal ions from the merocyanine complex, and (2) to assess the extent of reversible rejection of complexed zinc from both **3a** and **3b** in aqueous solution (a 4 : 1 water–acetonitrile solution was utilized due to solubility constraints). Initially, a control experiment was run on a solution of 1.2×10^{-5} M Zn^{2+} in order to identify the peak position and intensity of the Zn^{2+} cathodic wave (−1100 mV *vs.* aq. SCE). Exposure of the control solution to visible light had no effect on the voltammogram prior to the addition of the spiropyranindolines. Both **1a** and **1b** (2.4×10^{-5} M) led to rapid complexation of Zn^{2+}, resulting in the near elimination of the free Zn^{2+} potential peak. Because of the rapid increase in current associated with the reduction of water, we were unable to identify any cathodic waves corresponding to the reduction of **3a** or **3b**. Unlike the irradiation of **3b** with visible light, which resulted in no change in the free Zn^{2+} cathodic wave at −1100 mV, complex **3a** exhibited an ejection of 8% of the complexed Zn^{2+} ions into the aqueous solution (Fig. 2A). The rate of recomplexation of ejected Zn^{2+} ions in water (Fig. 2B) was nearly twice as fast as that observed in acetonitrile (light on, 14 s response time; light off, 28 s response time, both in an unstirred solution). The attenuation in the extent of photoreversible metal ejection and the more rapid metal ion recomplexation are both indicators of the enhanced stabilization effect water has on the merocyanine form, **2a**, when compared to the solvent, acetonitrile.

In conclusion, we have demonstrated a rapid, switching type mechanism for photoreversible metal complexation by quinolinospiropyranindoline **1a** in aqueous solution. Modifications of these systems designed to enhance the photoreversibility in aqueous media are currently under investigation in our laboratories.

10 In addition to Zn^{2+}, the photoreversibility of complexation by NQSP and QSP was examined using UV–VIS spectroscopy for the following metals: Zn^{2+}, Hg^{2+}, Cd^{2+}, Pb^{2+}, Cu^{2+}, Ni^{2+}, Co^{2+}, Mg^{2+}, Ca^{2+} and Al^{3+}. NQSP in THF exhibited photoreversibility for Hg^{2+}, Cd^{2+}, Pb^{2+}, Mg^{2+}, Ca^{2+} and Al^{3+}, while QSP in THF and MeCN exhibited photoreversibility for only Zn^{2+} and Al^{3+}.

Stereochemical control of *cis*- and *trans*-$TiCl_2$ groups in six-coordinate complexes [(L)$TiCl_2$] (L^{2-} = N_2O_2-donor Schiff base) and reactions with trimethylaluminium to form cationic aluminium species

Jonathan P. Corden, William Errington, Peter Moore* and Malcolm G. H. Wallbridge

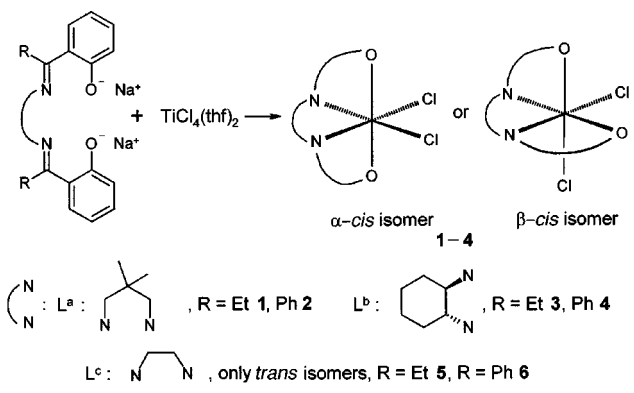
Department of Chemistry, University of Warwick, Coventry, UK CV4 7AL. E-mail: p.moore@warwick.ac.uk

Received (in Cambridge, UK) 29th October 1998, Accepted 7th January 1999

The first example of a *cis*-configuration of the $TiCl_2$ group in a six-coordinate titanium complex [(L)$TiCl_2$], involving a tetradentate N_2O_2-donor Schiff base ligand (L^{2-}), is reported, and reactions of such complexes with trimethyl aluminium have been shown to generate cationic aluminium species.

There is an increasing interest in the use of group 4 metallocenes, and related compounds, such as the chiral bis(indenyl) complexes involving zirconium and hafnium, in combination with aluminium trialkyls or methylaluminoxane (MAO), as alkene polymerisation catalysts.[1–4] The use of other group 4 coordination compounds in such processes may also be possible, and the d^0 metal complexes [(L)MCl_2] (M = Ti, Zr), derived from the disodium salts of the tetradentate Schiff bases H_2L (Scheme 1), is one system being explored,[5] since the zirconium derivative, containing a *cis*-$ZrCl_2$ group, has already been shown to be catalytically active in the presence of an aluminium trialkyl.[6]

The stereochemistry of the MCl_2 group is an important feature of the overall structure with respect to catalytic activity, and therefore it is of significance that to date all reported titanium derivatives [(L)$TiCl_2$] exhibit a *trans*-geometry for the $TiCl_2$ fragment,[7,8] instead of the *cis*-arrangements (Scheme 1) that are analogous to that in the *ansa*-metallocenes. The *cis*-structure is, however, more common with the [(L)MCl_2] complexes of the heavier and larger group 4 elements (M = Zr, Hf),[9,10] and has also been observed with an oxovanadium(IV) species [(L)V(O)OMe].[11] It is significant that even in complexes with the same Schiff base ligand, for example the *N*,*N*'-ethylenebis(acetylacetoiminate) dianion ($acen^{2-}$), the zirconium complex [(acen)$ZrCl_2$] adopts the *cis*-structure, whereas the corresponding titanium compound reverts to the *trans*-geometry.[8,9] Since titanium is the group 4 element that is often used in catalytic reactions, it is desirable to be able to control the stereochemistry at the metal centre. We now report the synthesis of the first *cis*-titanium Schiff base complexes, using easily accessible Schiff bases, together with some reactions of these species with aluminium trialkyls.



Scheme 1

Our present studies on titanium–Schiff base complexes, where we have isolated a series of *trans*-[(L)$TiCl_2$] complexes,[12] have indicated that substantial steric effects within the ligand are required to achieve a folding of the ligand such that it takes up a *cis*-geometry as shown in Scheme 1. Following molecular mechanics and dynamics calculations on [(L)$TiCl_2$] derivatives, it appeared that complexes **1**–**4** should adopt a folded configuration, leading to a *cis*-geometry at the metal centre. The four neutral ligands were prepared in high yield (> 90%) by condensation of the appropriate diamine (using *trans*-cyclohexane-1,2-diamine for L^b) and keto derivatives, and converted to the new metal complexes [(L)$TiCl_2$] (50–60% yield) by the reaction shown in Scheme 1.†

The X-ray structure of [(L)$TiCl_2$] complex **3**‡ (Fig. 1) shows a distorted octahedral arrangement around the titanium centre, with a folded ligand and a β-*cis*-geometry for the complex. The Cl–Ti–Cl angle is 86.9(1)°. The variation in the ligand geometry has little effect on the bond distances involving the metal. The Ti–O and Ti–N distances are *ca.* 1.82 and 2.19 Å respectively, similar to those reported for the numerous *trans*-[(L)$TiCl_2$] complexes,[7,8] while the Ti–Cl distances are all *ca.* 2.35 Å in both the *trans*- and *cis*-derivatives [2.323(2) and 2.391(3) Å in **3**]. Similarities in the spectroscopic data (IR, NMR) between **3** and the other three [(L)$TiCl_2$] complexes **1**, **2** and **4** indicate that these also probably form *cis*-structures, but we are still attempting to obtain suitable crystals to allow definitive X-ray studies to be undertaken.

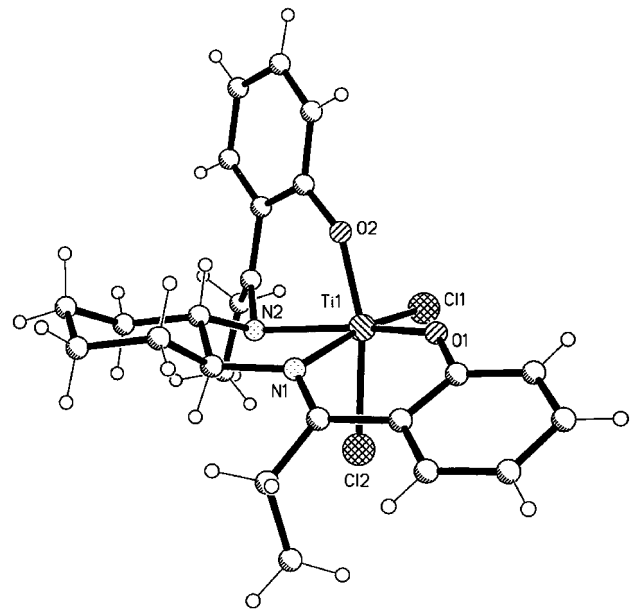


Fig. 1 Molecular structure of **3**. Selected bond lengths (Å) and angles (°): Ti(1)–O(1) 1.796(5), Ti(1)–O(2) 1.827(5), Ti(1)–N(1) 2.186(5), Ti(1)–N(2) 2.205(6), Ti(1)–Cl(1) 2.323(2), Ti(1)–Cl(2) 2.391(3); O(1)–Ti(1)–O(2) 99.5(2), N(1)–Ti(1)–N(2) 76.6(2), N(2)–Ti(1)–Cl(1) 99.67(16); Cl(1)–Ti(1)–Cl(2) 86.89(9).

We have confirmed that the titanium complexes **1**–**4** act as catalysts for the polymerisation of ethene in the presence of MAO, although they are not as active as the *ansa*-titanocenes.§ Since MAO often contains an appreciable quantity of trimethyl aluminium (TMA, ≈15% by weight in the present case) we have investigated the action of TMA on some $[(L)TiCl_2]$ complexes. In a series of ^{1}H NMR experiments we have used titrations with TMA to show that complete reaction is achieved when a molar ratio $[(L)TiCl_2]$: TMA of 1 : 2 is attained. In more detailed experiments on the related *trans*-$[(L^c)TiCl_2]$ complexes, red–brown solids of composition $[\{(L^c)TiCl_2\}\cdot 2AlMe_3]$ were obtained in *ca.* 40% yield by the addition of a hexane solution of TMA to the Schiff base complex (2 : 1 mole ratio) in toluene, and subsequent removal of the solvent. The ^{1}H NMR spectrum of each adduct shows two singlet resonances, with appropriate relative intensities, for the two coordinated $AlMe_3$ molecules (the derivatives with **5** and **6** gave resonances at δ −0.21, −0.41 and −0.34, −0.53 respectively, arising from the methyl groups of the two different $AlMe_3$ molecules) in addition to the resonances from L^c. Thus two different sites for coordination of the TMA are indicated, but we have no definitive evidence to indicate the structures of these species at present. If the initially formed red solution from **5** is allowed to stand, colourless, air-reactive crystals are quickly deposited (yield *ca.* 5%), and these were identified from X-ray data‡ as the unexpected ionic species $[(L^c)(AlMe)(AlMe_2)]^+[AlCl_3Me]^-$ (**7;** Fig. 2). Part of the structure of the cation in **7** resembles the previously reported *neutral* species $[(L^c)AlR']$ [L^c, R = H; R' = Me, Et] which have the metal atom bonded centrally above the N_2O_2 plane.[13,14] In the present case, where the cation is present, the compound contains additionally an $AlMe_2$ fragment bonded symmetrically to two oxygen atoms of the Schiff base. The $[AlCl_3Me]^-$ anion is discrete, with no significant interactions with the cation, and adopts the expected slightly distorted tetrahedral structure. Cationic aluminium alkyl complexes have recently been shown to act as transition metal-free alkene polymerisation catalysts,[15] in addition to the already established cationic group 4 species.[3] The role of the aluminium alkyl as a cocatalyst with group 4 compounds is still the subject of debate, but as a consequence of the present results it is now clear that for some titanium complexes the addition of TMA is capable of generating cationic species of aluminium in solution. It is significant that no titanium atom is present in the cation, but the titanium species is clearly involved in the overall reaction since the $[AlCl_3Me]^-$ anion arises by halide abstraction from the titanium centre. Although we have not yet been able to identify the nature of the titanium species remaining in solution, it is of interest that under our conditions we have not yet observed the formation of any Ti(III) or Ti–Me species, as have been found in other studies involving TMA and the different but closely related complex *trans*-$[(L^c)TiCl_2]$ [(L^c; R = H)].[16]

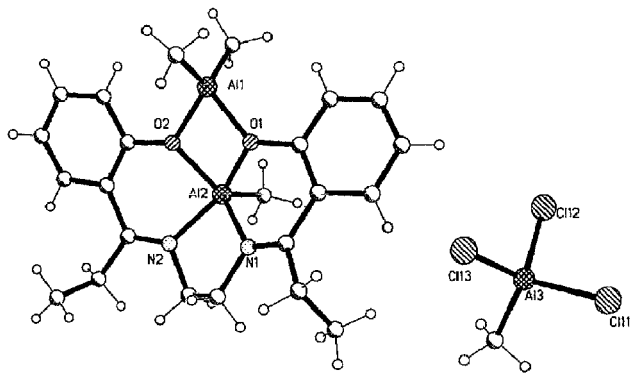

Fig. 2 Molecular structure of **7**. Selected bond lengths (Å) and angles (°): Al(1)–O(1) 1.845(6), Al(1)–O(2) 1.868(6), Al(2)–O(1) 1.873(6), Al(2)–O(2) 1.877(6), Al(2)–N(2) 1.945(7), Al(2)–N(1) 1.960(8); O(1)–Al(1)–O(2) 77.4(2), O(1)–Al(2)–O(2) 76.5(2), O(1)–Al(2)–N(2) 149.6(3), O(2)–Al(2)–N(2) 88.2(3), O(1)–Al(2)–N(1) 88.2(3), O(2)–Al(2)–N(1) 136.2(3), N(2)–Al(2)–N(1) 85.0(3).

We are continuing our studies to determine both the nature of the titanium species remaining in solution, and the effect that variations in the Schiff bases has on the overall reaction involved.

We thank EPSRC for grants in support of this work, the X-ray crystallographic service (University of Wales, Cardiff) for collecting the data on compound **3**, and B.P. Chemicals (Sunbury) for advice (Dr I. R. Little) and collaboration involving a CASE award to J. P. C.

Notes and references

† *Typical procedure*: sodium hydride (2 mol) was added slowly to a solution of the ligand (1 mol) in THF, the suspension was stirred until the evolution of H_2 was complete, and the mixture then refluxed for 2 h. The solution–suspension was cooled to −78 °C and a solution of $[TiCl_4(thf)_2]$ (1 mol) in thf was then added slowly. The resultant suspension was stirred at 50 °C for 5 h, and then filtered through a fine filter stick. The filtrate was evaporated to dryness, and the solid obtained was washed with hot toluene to remove any thf (yield *ca.* 40%). A higher yield (50–60%) can be obtained by extracting the original solid filtered off (mainly NaCl) with toluene. All the new compounds were fully characterised by IR, mass and NMR spectroscopy and elemental analysis.

‡ *Crystal data* for **3**: $C_{24}H_{28}Cl_2N_2O_2Ti\cdot CHCl_3$, M = 614.65, T = 150(2) K, monoclinic, space group $P2_1/c$, a = 16.446(3), b = 9.796(2), c = 18.160(4) Å, β = 111.32(3)°, U = 2725.3(9) Å3, Z = 4, μ = 0.831 mm^{-1}. 12060 reflections (4283 independent) were collected in the range θ 2.29–25.12° using a Delft Instruments FAST TV area detector diffractometer. Final $R1$ = 0.053 and $wR2$ = 0.129.

For **7**: $C_{24}H_{34}Al_3Cl_3N_2O_2$, M = 569.82, T = 230(2) K, orthorhombic, $Pna2_1$, a = 15.7057(15), b = 9.7173(9), c = 19.5089(15) Å, U = 2977.4(5) Å^3, Z = 4, μ = 0.419 mm^{-1}. 5592 reflections (3804 independent) were collected in the range θ 2.09–23.00° using a Siemens SMART CCD area-detector diffractometer. Final $R1$ = 0.074 and w$R2$ = 0.161. Refinement was by full-matrix least squares on F^2 for all data using SHELXL-97.[17] Hydrogen atoms were added at calculated positions and refined using a riding model. CCDC 182/1135. See http://www.rsc.org/suppdata/cc/1999/323/ for crystallographic files in .cif.format.

§ Preliminary polymerisation tests using a 1000-fold excess of MAO with the neutral compounds **1**–**4**, in toluene solution at 23 °C and ethene at 30 psi, show they possess low activities of *ca.* 20–100 (g polymer) (mmol catalyst)$^{-1}$ h^{-1}, while similar runs with several analogous *trans*-$[TiCl_2]$ complexes show a much lower activity (< 1) for these systems.

A formal synthesis of (+)-pyripyropene A using a biomimetic epoxy-olefin cyclisation

Varinder K. Aggarwal,*[a] Paul A. Bethel[a] and Robert Giles[b]

[a] *Department of Chemistry, University of Sheffield, Sheffield, UK S3 7HF*
[b] *SmithKline Beecham, Old Powder Mills, Tonbridge, Kent, UK TN11 9AN*

Received (in Liverpool, UK) 4th November 1998, Accepted 7th January 1999

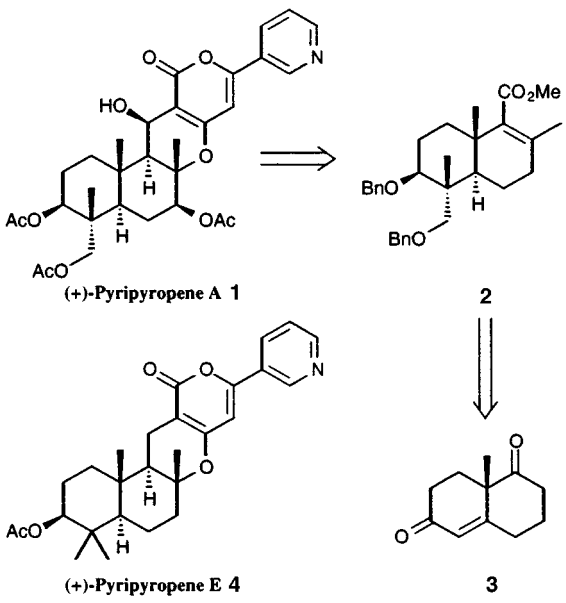
Bicyclic ester 2, a key intermediate in the first total synthesis of (+)-pyripyropene A 1, was synthesised from geraniol in 11 steps, utilising an epoxy-olefin biomimetic cyclisation as the key step.

Pyripyropenes A–L, isolated by Õmura and co-workers[1] from a fermentation broth of *Aspergillus fumigatus*, are the most effective naturally occurring inhibitors of acyl-CoA: cholesterol acyltransferase (ACAT), the enzyme responsible for intracellular esterification of cholesterol. Inhibition of the ACAT enzyme represents a new approach to the prevention and treatment of atherosclerosis and hypercholesterolemia[2] since evidence suggests that ACAT inhibitors may lower plasma cholesterol levels and prevent the accumulation of cholesteryl esters in arterial lesions.

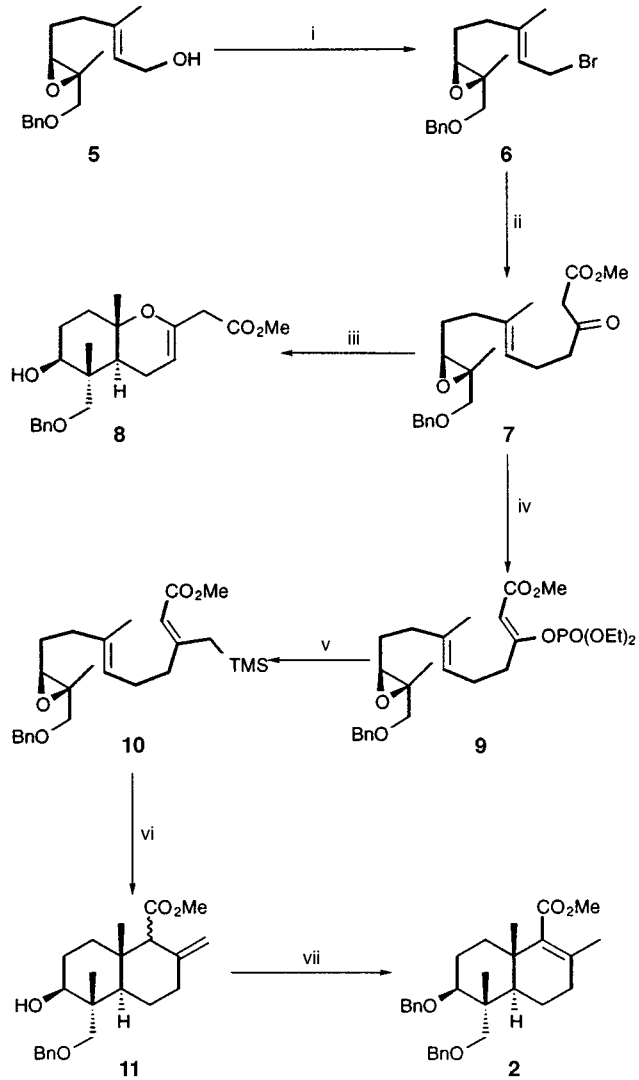
The most active member of the family, (+)-pyripyropene A **1**, was synthesised by Õmura and Smith from (+)-Wieland–Miescher ketone **3** in 19 steps[3] (Scheme 1).

We envisioned a short biomimetic route to the decalin subunit **2**, a key intermediate in the Õmura–Smith synthesis (prepared in 10 steps from **3**), utilising an epoxy-olefin cyclisation[4] of allyl silane **10**. Although a biomimetic polyene cyclisation has been used to prepare the simplest member of the family, pyripyropene E **4**,[5] it was surprising that this strategy had not been adopted for pyripyropene A **1** as the required epoxide contains a neighbouring alcohol group and as such could be easily obtained in enantiomerically pure form by Sharpless epoxidation.[6] Such epoxy alcohols (protected as ethers) have been successfully employed in epoxy-olefin cyclisations.[7]

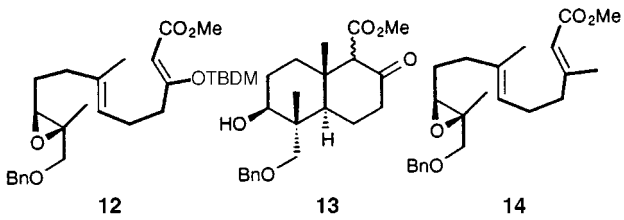
The known allylic alcohol **5**, derived from geraniol in 5 steps,[7] was converted to bromide **6** upon treatment with MsCl/Et_3N followed by LiBr at −78 °C. (Scheme 2).[8] Low temperature and a controlled amount of LiBr were required to minimise opening of the epoxide. The relatively unstable bromide **6** was then employed in the alkylation step with the dianion of methyl acetoacetate[9] to afford β-keto ester **7** in 78% yield. Upon treatment of β-keto ester **7** with $BF_3{\cdot}OEt_2$ in CH_2Cl_2, epoxy-olefin cyclisation ensued but the oxabicycle **8** was formed exclusively.[10] To promote carbon over oxygen cyclisation, the carbonyl group had to be masked or removed and several possibilities were apparent from the literature. (i) Conversion of β-keto ester **7** into the silyl enol ether **12**.[11]



Scheme 1



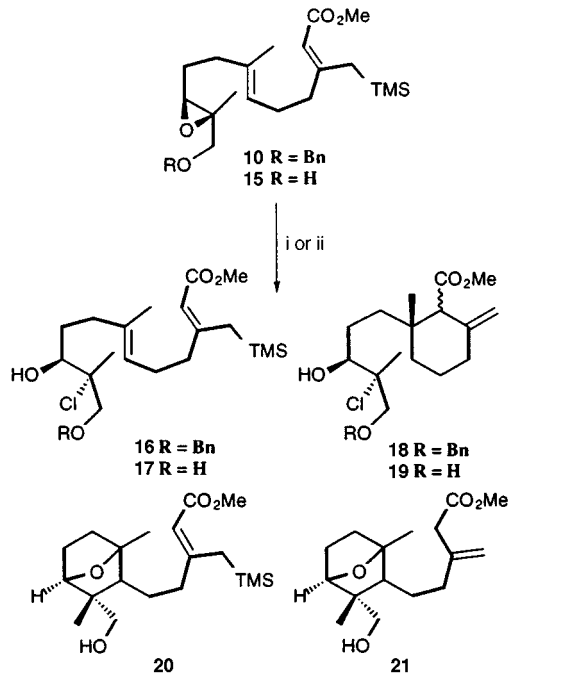
Scheme 2 *Reagents and conditions*: i, MsCl, Et_3N, THF, −78 °C, then LiBr (3 equiv.), acetone, −78 °C, 50 min, 87%; ii, methyl acetoacetate, NaH, Bu^nLi, THF, 0 °C, then **6**, 78%; iii, $BF_3{\cdot}OEt_2$, CH_2Cl_2, 60%; iv, NaH, $(EtO)_2POCl$, Et_2O, 93%; v, $TMSCH_2MgCl$, $Ni(acac)_2$ (cat.), Et_2O, 0 °C, 54%; vi, $BF_3{\cdot}OEt_2$, CH_2Cl_2, 54%; vii, NaH, BnBr, THF, reflux, 51%.



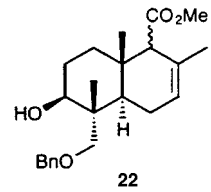
However, cyclisation of this substrate only provided a low yield (26% from **7**) of **13**. (ii) Conversion of β-keto ester **7** into the unsaturated ester **14**.[12] However, it is known that unsaturated esters are poor terminating groups for polyolefin cyclisation.[13] (iii) Conversion of β-keto ester **7** into allylsilane **10**.[14] Weiler had shown that allylsilanes bearing ester groups were sufficiently nucleophilic to undergo epoxy-olefin cyclisation.[14] This route was eventually successful. Thus, conversion of β-keto ester **7** to *Z*-enol phosphate **9** [NaH, $(EtO)_2POCl$, Et_2O] followed by coupling with $TMSCH_2MgCl$ in the presence of nickel(II) bisacetylacetonate furnished the cyclisation substrate, *Z*-allylsilane **10**.

Both the nature of the protecting group on oxygen[15] and cyclisation conditions were critical to the success of the key step. Treatment of the allylsilane **10** with $BF_3{\cdot}OEt_2$ at room temperature gave the required decalin in 54% yield as a 3:2 mixture of epimeric hydroxy esters **11**. In contrast, the use of $SnCl_4$ or $MeAlCl_2$ (Corey's preferred cyclisation catalyst)[4b–d] resulted in chlorohydrins **16** and **18** (Scheme 3). Attempts to cyclise the unprotected epoxy alcohol **15** failed;[16] only mixtures of unidentifiable acyclic and monocyclic products were observed with $BF_3{\cdot}OEt_2$ and the use of $MeAlCl_2$ resulted in the formation of chlorohydrins **17** and **19** as shown in Scheme 3. The use of $SnCl_4$ yielded bicyclic ethers **20** and **21** along with chlorohydrin **17**.

All that remained to complete the formal synthesis was isomerisation of the exocyclic double bond and benzylation of the free alcohol. However, attempts to isomerise the alkene **11** into conjugation with the ester using $RhCl_3$[17] resulted in the formation of the trisubstituted alkene **22** instead.[18] Fortuitously,



Scheme 3 *Reagents and conditions*: i, $MeAlCl_2$, CH_2Cl_2, room temp.; ii, $SnCl_4$, CH_2Cl_2, room temp.



benzylation of alcohol **11** using an excess of NaH in THF and BnBr[19] resulted in concomitant isomerisation of the alkene and provided **2** directly in 51% yield. Decalin **2** was spectroscopically identical[20] to that reported by Ōmura and Smith.[3]

We thank the EPSRC and SmithKline Beecham for a CASE award and Meng Fang Wang for initial studies.

18 From molecular modelling it was found that **22** was lower in energy than the conjugated tetrasubstituted double bond isomer.

19 The optimised procedure required refluxing **11** with NaH (5 equiv.) in THF for 4 h followed by addition of BnBr and refluxing for a further 2 h. Less isomerisation was observed if **11** was refluxed with NaH for a shorter time.

Received (in Columbia, Mo, USA) 28th October 1998, Accepted 11th January 1999

A difunctional Ru(II) complex has been prepared which can be incorporated into synthetic oligonucleotides by means of standard solid-phase methodology and the properties of several oligonucleotide conjugates capable of forming Ru(II)-bridged hairpins have been investigated.

There is continuing interest in the development of oligonucleotide conjugates containing luminescent or redox-active transition metal complexes.[1] These conjugates have been investigated as alternatives to the use of radioactive isotopes for gene sensing, as site specific photonucleases, and as luminescent probes for the study of energy transfer and electron transfer in duplex DNA. In most of the conjugates investigated to date the metal complex is attached post-synthetically to the 5′-end of an oligonucleotide by means of a flexible tether.[2] Flexible tethers[3] and rigid linkers[4] with metal-binding ligands have also been used to modify nucleosides which can be incorporated using standard solid-phase methodology at a specific position in a synthetic oligonucleotide. Hybridization of conjugates with flexible tethers results in the formation of duplexes in which the metal complex may be intercalated, groove bound, or only weakly associated with the duplex. Uncertainty about the location of the metal complex can complicate the interpretation of electron and energy transfer measurements. Our interest in photoinduced electron transfer in duplex DNA[5] led us to undertake the synthesis of oligonucleotide conjugates in which a difunctional metal complex forms a linker connecting two oligonucleotides. We report here the synthesis and spectral properties of the first Ru(II)-linked oligonucleotides which possess complementary sequences capable of forming hairpin structures.

Preparation of synthetic oligonucleotides with a linking metal complex by standard solid state synthesis required the development of a difunctional ligand in which one functional group can be protected and the other activated. Our solution to this problem is outlined in Scheme 1. The difunctional diamidobipyridine ligand dabp (**1a**‡) was prepared from 2,2′-bipyridine-4,4′-dicarboxylic acid following the method developed for the synthesis of analogous arenedicarboxamides.[6] Reaction of this ligand with $[Ru(bpy)_2Cl_2]\cdot 2H_2O$[7] afforded the complex $[Ru(bpy)_2(dabp)]^{2+}$ **2a**, isolated as the PF_6^- salt.[8] Synthesis of the mono-protected complex $[Ru(bpy)_2(DMT\text{-}dabp)][PF_6]_2$ **2b** was best accomplished *via* reaction of the monoprotected dabp ligand **1b** with $[Ru(bpy)_2Cl_2]\cdot 2H_2O$. Repeated efforts to convert **2b** to **2c** using standard conditions led to recovery of **2b**. We found that **2c** is moderately stable when prepared in a glove box, but is rapidly hydrolyzed to **2b** upon exposure to moisture.

The instability of **2c** necessitated a modified protocol for oligonucleotide synthesis. The 3′-segment of the oligonucleotide was prepared according to standard solid phase procedures.[9] After removal of its 5′-DMT protecting group, the column was brought into a dry box and the oligonucleotide coupled with **2c**, using tetrazole as the activator. The column was returned to the automatic synthesizer to complete the synthesis of the oligonucleotide. The coupling efficiency for Ru incorporation, as determined by monitoring release of the dimethoxytrityl cation, was > 95%. Obtained by this procedure were the Ru-linked oligonucleotides dT_4–$Ru(bpy)_2(dabp)^{2+}$–dA_4, dG_3–$Ru(bpy)_2(dabp)^{2+}$–dC_3, and dGCAATTGC–$Ru(bpy)_2(dabp)^{2+}$–dGCAATTGC, **3**–**5**.[10] After removal from the solid support and deprotection the oligonucleotides were purified by HPLC and appear as a single peak on both ion exchange and reverse phase HPLC.[6]

The absorption spectrum of $[Ru(bpy)_2(dabp)]^{2+}$ **2a** displays maxima at 468 nm (ε = 8538 $dm^3\ mol^{-1}\ cm^{-1}$) and 288

(43 550) which are red-shifted with respect to those of $[Ru(bpy)_3]^{2+}$, as previously observed for Ru(II) complexes with a single bipyridine-4,4′-dicarboxamide ligand.[11] The spectra of **3**–**5** have maxima below 300 nm for the nucleobases which overlap the shorter wavelength Ru^{2+} band. The 260 nm bands of **3**–**5**, but not the 468 nm bands exhibit hypochromism. The complex **2a** and conjugates **3**–**5** display a single broad emission band with a maximum at 665 nm, similar to that reported for other Ru(II) complexes possessing a single bipyridine-4,4′-dicarboxamide ligand.[11] The luminescence quantum yields and decay times are summarized in Table 1. The neighboring nucleobases have little effect on the photophysical behavior of the Ru(II) complex, in accord with previous observations for $[Ru(bpy)_3]^{2+}$ covalently attached to oligonucleotides.[3]

Table 1 Emission lifetimes and quantum yields for complexes **2a**, **3**, **4** and **5**

Complex	τ/ns	Φ_e[a]
2a	850	0.013
3	815	0.018
4	790	0.016
5	608	0.019

[a] Values are reported relative to $[Ru(bpy)_3][PF_6]_2$ in water (Φ_e = 0.042) and calculated according to published procedures (J. N. Demas and G. A. Crosby, *J. Phys. Chem.*, 1971, **75**, 991).

Molecular modeling indicates that the conjugates **3**–**5** can adopt low energy hairpin conformations as shown schematically in Fig. 1; however, these conjugates also might form duplexes in which the Ru(II) complexes occupy bulges on opposite strands. In the case of **5** a value of T_M = 50 °C is obtained from the thermal dissociation profile in 0.1 M NaCl. This value is independent of concentration (1.0–5.0 μM). In the case of **4** the observed value of T_M = 50 °C in 1.0 M NaCl is higher than that calculated for either a GGG/CCC duplex [T_M(calc.) = −42 °C] or for two such duplex segments [T_M(calc.) = 20 °C] with no contribution from the Ru(II) linkers and no cooperativity in melting of the two segments.[12] This evidence supports the tentative assignment of a hairpin *vs.* duplex structures for **4** and **5**. The conjugates **3** and **4** have broad thermal dissociation profiles (not shown) and values of T_M (< 20 and 50 °C, respectively, in 1.0 M NaCl) lower than those of the analogous stilbene dicarboxamide-bridged hairpins (T_M = 49 and > 80 °C, respectively, in 1.0 M NaCl).[7] This may reflect a better fit for the stilbene *vs.* Ru(II) linker across the double helix. The broad thermal dissociation profiles for **3**–**5** may reflect multiple conformations for the hairpin loop region as well as the presence of two diastereomeric octahedral complexes.

The preliminary results reported here provide a potentially versatile method for the introduction of a bipyridyl-complexed metal ion at a specific location in a synthetic conjugate. The three conjugates prepared in this study have complementary arms and thus are capable of forming hairpin structures with a bridging metal complex. Whereas the precise structures of these conjugates remain to be established, the metal complex is likely located at the end of a duplex region of a hairpin structure. The excited Ru(II) complex selected for this study is not quenched by nucleobases, however excited state redox potentials can be tuned over a wide range by variation of the nonbridging ligands or metal.[13] Similarly, the use of nucleobase analogs such as 6-oxoguanine or 7-deazaguanine which have low oxidation potentials should increase the driving force for photoinduced electron transfer.[14] In addition, hybridization of metal linked conjugates possessing noncomplementary arms with unlabelled oligonucleotides should position the metal center near a specific location in the unlabelled strand. Thus the availability of difunctional metal complexes which can be introduced into oligonucleotides *via* automated phosphoramidite chemistry serves to extend structural diversity currently available with monofunctional metal complexes.[2–4] The long lifetimes and moderately large fluorescence quantum yields make these Ru(II) complexes particularly well-suited for studies of long range energy and electron transfer.

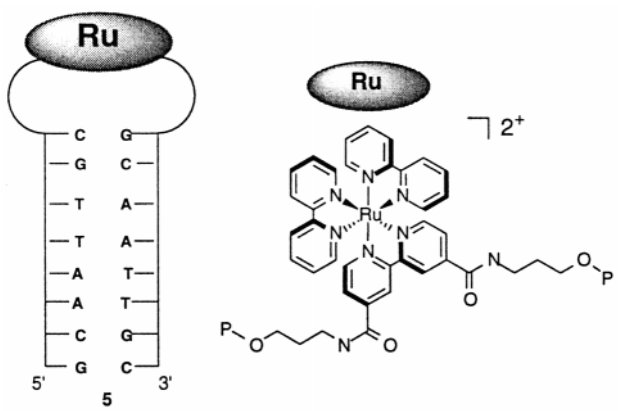

Fig. 1 Schematic structure for the hairpin conformation of **5**.

Predictable solid state structures incorporating the C≡C–H···O$_2$N supramolecular synthon

James M. A. Robinson, Douglas Philp,* Benson M. Kariuki and Kenneth D. M. Harris*

School of Chemistry, University of Birmingham, Edgbaston, Birmingham, UK B15 2TT. E-mail: d.philp@bham.ac.uk

Received (in Cambridge, UK) 23rd November 1998, Accepted 4th December 1998

Terminal alkynes interact with nitro groups in a symmetrically bifurcated manner to form ribbon-like structures in the solid state.

It is widely accepted that although C–H groups are relatively poor hydrogen bond donors, many C–H···O interactions share some of the characteristics of stronger hydrogen bonds that are formed with more conventional hydrogen bond donors such as N–H and O–H.[1] Attempts to quantify donor and acceptor strengths in C–H···O interactions have shown[2,3] that, as expected, the strongest interactions are formed by pairing the most acidic C–H hydrogens, such as Cl_3C–H and C≡C–H, with the best oxygen acceptors, which include P=O and H_2O. Although the oxygens of the nitro group appear to be poor hydrogen bond acceptors when compared to oxygen atoms in other bonding environments, they do participate in other noteworthy interactions such as the polarisation-induced halogeno···nitro motif. In particular, the iodo···nitro supramolecular synthon[4] **1** has been utilised in several recent examples[5] of crystal engineering. Recently, our analysis[6] of the structures of substituted benzene derivatives containing alkynes and/or halogens has suggested that there may be recognition characteristics which are shared between terminal alkynes and halogen atoms. For this reason, we felt that a logical development of the iodo···nitro synthon **1** (Fig. 1) would be the substitution of the iodine by a terminal alkyne to give the synthon **2**, with the expectation that it would retain the novel bifurcated interaction. Furthermore, such studies should provide additional insight into the characteristics of C–H···O hydrogen bonds to nitro groups. Here we describe the crystal structures of 1-ethynyl-4-nitrobenzene **3** and the 1:1 co-crystal [**4**·**5**] of 1,4-dinitrobenzene **4** and 1,4-diethynylbenzene **5**; both structures contain the supramolecular synthon **2**.

Small needle-like crystals of **3** were grown by the slow evaporation of solvent from a solution of **3** in a MeOH–H_2O mixture. However, poor crystal quality, coupled with a tendency for crystal twinning, made structure solution impossible from single crystal X-ray diffraction data. Therefore, the structure was solved from powder X-ray diffraction data using the Monte Carlo method.[7] The crystal structure of **3**† contains (Fig. 2*a*) linear ribbons of **3** which are connected by the alkynyl···nitro motif **2** to create infinite chains of molecules linked by C≡C–H···O hydrogen bonds as the major intermolecular interaction. The two C–H···O distances ($d_{H\cdots O}$ = 2.47 and 2.36 Å) are significantly less than the sum of the van der Waals radii,[8] (Σ_{vdw} = 2.65 Å). The adjacent ribbons of molecules are not coplanar, but are stepped to form corrugated layers. Thus, the aromatic protons of each molecule in a ribbon form a number of minor C–H···O interactions with the nitro groups of the molecules in adjacent ribbons ($d_{H\cdots O}$ range 2.4–2.9 Å).

In order to assess whether the alkynyl···nitro interaction in motif **2** could be used as a robust supramolecular synthon in crystal engineering applications, we attempted a co-crystallisation between two molecular components with the potential to form motif **2**. Whereas the structure of **3** contains *da*··*da* ··*da* interaction arrays based on one molecular component (where *da* is a component containing self-complementary donor and acceptor sites), we aimed to design and construct a structure based on *dd*··*aa*··*dd* arrays using two molecular components (Fig. 1).

Single crystals of [**4**·**5**] suitable for single crystal X-ray diffraction studies were grown by slow evaporation of solvent from a solution of a 1:1 mixture of **4** and **5** in benzene. The crystal structure of [**4**·**5**]‡ (Fig. 2*b*) bears a strong resemblance to that of **3** in that linear molecular ribbons arise from infinite chains of molecules linked by motif **2**. Again, the alkynyl···nitro interaction is not symmetrically bifurcated, with a small difference between the two C–H···O distances ($d_{H\cdots O}$ = 2.54 and 2.61 Å); additional C–H···O contacts ($d_{H\cdots O}$ 2.6–2.7 Å) are also formed between ribbons, as seen for **3**.

The C–H···O distances observed in the alkynyl···nitro motifs in both **3** and [**4**·**5**] are relatively long compared to other C–H···O interactions involving terminal alkynes.[3] This observation can be attributed to the acknowledged poor hydrogen bond accepting properties of the oxygens of the nitro group, although distance alone cannot be a taken as a quantitative indication of the interaction strength. Therefore, we have attempted to further characterise the alkynyl···nitro interaction using infra-red spectroscopy and *ab initio* quantum mechanical calculations.

The difference (denoted $\Delta\nu_{\equiv C-H}$) between the C–H stretching frequency for the 'free' alkyne (as determined for a dilute solution of the alkyne in CCl_4) and for the hydrogen bonded alkyne in the solid gives a qualitative indication of the strength of the C–H···O interaction. Typically, the range in magnitude of $\Delta\nu_{\equiv C-H}$ for alkynyl C–H···O interactions vary from long, and

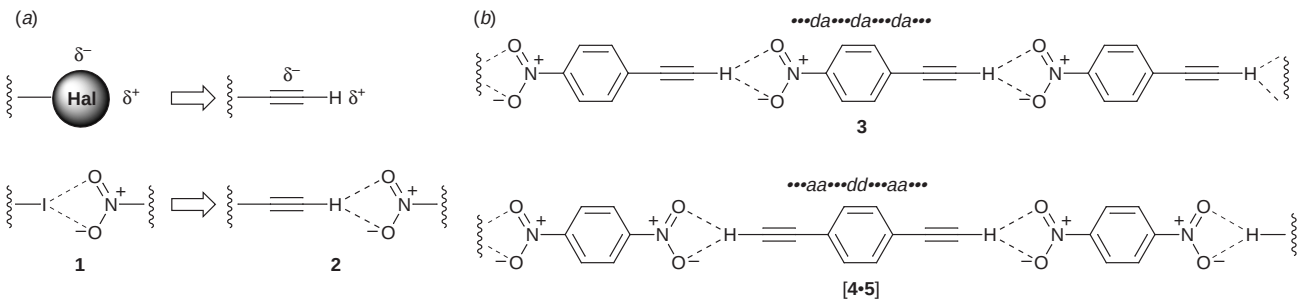

Fig. 1 (*a*) The polarisation pattern found in terminal alkynes is similar to that for halogens. Thus, the established iodo···nitro synthon **1** can be evolved into the alkynyl···nitro synthon **2**. (*b*) The synthon **2** can be used to form linear molecular ribbons, either using one molecular component as in **3** or two components as in [**4**·**5**].

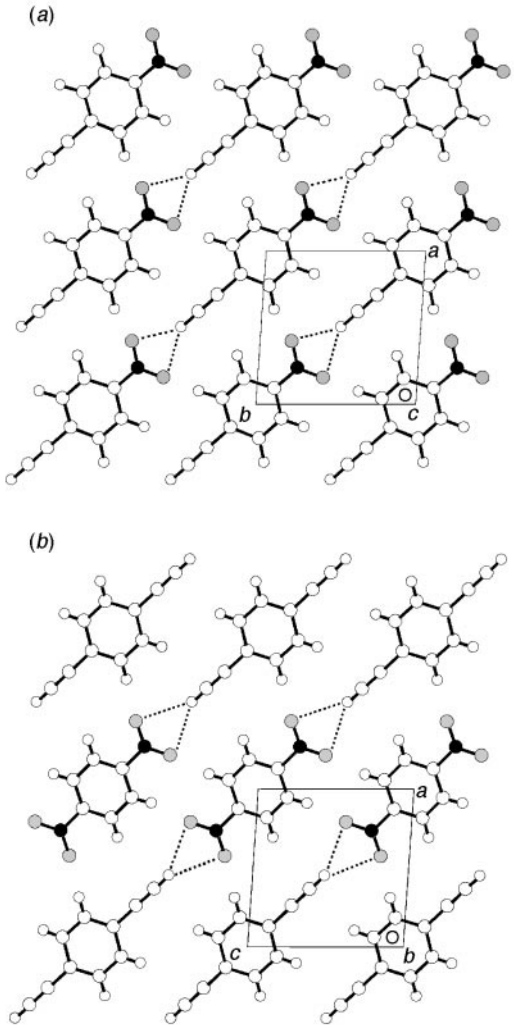

Fig. 2 The crystal structures of (*a*) **3** and (*b*) [**4·5**] both show linear molecular ribbons which are held together by the alkynyl···nitro synthon**2**. The black and shaded spheres represent nitrogen and oxygen atoms respectively; the dotted lines represent C≡C–H···O_2N interactions.

thus presumably very weak, interactions (*ca*. 15 cm^{-1}, $d_{H\cdots O}$ = 2.92 Å)[9] to much shorter, stronger interactions (*ca*. 145-200 cm^{-1}, $d_{H\cdots O}$ < 2.0 Å)[10] with most red-shifts falling[9] in the range 40–100 cm^{-1}. The infra-red spectra for polycrystalline samples of **3** and [**4·5**] obtained from the same batches used for the X-ray diffraction data collections were measured§ in KBr disks. The $\Delta\nu_{\equiv C-H}$ for **3** (57 cm^{-1}) and [**4·5**] (50 cm^{-1}) represents an appreciable red shift of indicative of a moderately strong interaction, which is comparable to alkyne C–H···O interactions which involve supposedly much better oxygen acceptors (such as OH groups).

Ab initio quantum mechanical calculations were performed¶ at the MP2/6-31G(d,p) level using an ethyne–nitrobenzene aggregate as a model system for the alkynyl···nitro interactions. The energy of interaction (ΔE_{int}), corrected for basis set superposition error (BSSE), for the alkynyl···nitro C–H···O_2N interaction was calculated to be −8.0 kJ mol^{-1}. Although this interaction energy is less than that calculated[11] for the alkynyl···water C–H···O interaction (−12.2 kJ mol^{-1}), surprisingly, it is comparable to the estimated[12] interaction energy for the bifurcated iodo···nitro motif (−10 kJ mol^{-1}).

In conclusion, we have demonstrated that, by virtue of common recognition features, halogens and terminal alkynes can be exchanged to create a new supramolecular synthon incorporating a C≡C–H···O_2N interaction which, by FTIR spectroscopy and quantum mechanical calculations, has been shown to possess a significant binding energy.

This research was supported by the University of Birmingham and the EPSRC (Quota award to J. M. A. R. and Postdoctoral Fellowship to B. M. K.). We are grateful to the EPSRC and CCLRC for the award of synchrotron beam-time at the Daresbury Laboratory.

† *Crystal data* for **3**: [$C_8H_5NO_2$], M = 147.13 g mol^{-1}, triclinic, space group $P\bar{1}$, a = 6.8261(8), b = 7.9213(9), c = 7.4743(7) Å, α = 116.581(4), β = 91.556(4), γ = 92.749(9)°, V = 360.5(1) $Å^3$, Z = 2, λ = 1.3 Å, T = 295(2) K. The sample was loaded into a capillary (1.0 mm diameter). Data were measured on the high-resolution powder diffraction station 2.3 at the Synchrotron Radiation Source, Daresbury Laboratory, for a total of 100 min. Data were recorded in the 2θ range 5 to 67° in 0.01° steps. The powder diffraction pattern was indexed using ITO (ref. 13) and the structure was solved by the Monte Carlo method (ref. 7). The geometry of the molecule was restrained during the Rietveld refinement which was carried out using GSAS (ref. 14). Non-hydrogen atom positions were refined with fixed isotropic displacement parameters (0.025 $Å^2$) and hydrogen atoms were placed in calculated positions. Final refinement gave R_p = 0.067, R_{wp} = 0.097.

‡ *Crystal data* for [**4·5**]: [$C_6H_4N_2O_4{\cdot}C_{10}H_6$], M = 294.26 g mol^{-1}, triclinic, space group $P\bar{1}$, a = 7.059(3), b = 7.555(2), c = 6.939(3) Å, α = 91.86(4), β = 93.849(9), γ = 89.669(9)°, V = 369.0(3) $Å^3$, Z = 1, λ = 0.71069 Å, T = 296(2) K, μ = 0.097 mm^{-1}, 1142 independent reflections (R_{int} = 0.065), R = 0.061, wR_2 = 0.155. CCDC 182/1108.

§ Infra-red spectra were recorded on a Perkin–Elmer Paragon 1000 FTIR spectrometer at 293 K. Solid state spectra were recorded as KBr disks. Solution spectra (concentration *ca.* 2 mM) were recorded in CCl_4 in an Aldrich Demountable liquid-cell kit with a pathlength of 0.5 mm. All spectra were recorded at a resolution of 2 cm^{-1}.

¶ *Ab initio* quantum mechanical calculations, including geometry optimisations, were performed using GAMESS (ref. 15) (the version dated 18 May 1997 was used for all calculations). Corrections for BSSE for the optimised coordinates were obtained by the full counterpoise procedure using CADPAC (ref. 16).

Electrodeposition of mesoporous tin films

Adam H. Whitehead, Joanne M. Elliott, John R. Owen* and George S. Attard

Received (in Bath, UK) 10th November 1998, Accepted 12th January 1999

Mesoporous metallic tin has been electrodeposited, from the homogeneous hexagonal mesophase of a series of amphiphilic non-ionic surfactants, with a controllable repeat structure in the range of 5–10 nm.

It has been reported that mesoporous silica may be prepared by a sol–gel route from silicon alkoxides in the presence of a low concentration of a cationic surfactant.[1] Similarly the formation of several mesoporous metal oxides has been reported.[2] It has also been shown that nanostructured silica may be formed in the presence of surfactant concentrations high enough to form homogeneous liquid crystalline mesophases.[3,4] Under these conditions the nanostructure of the silica was a cast of the architecture of the liquid crystalline phase in which it was formed. In other words the liquid crystal phase acted as a direct template for the silica.

There have been very few reports of the formation of nanostructured metals although Attard *et al.* have used a direct templating method to prepare mesoporous platinum as both a powder[5] and coherent film.[6] The platinum film was electrodeposited from a homogeneous hexagonal (H_I) mesophase of a range of octaethylene glycol monoalkyl ethers with aqueous hexachloroplatinic acid. The following work reports on the electrochemical synthesis of mesoporous tin films (H_I-eSn) using a route similar to that employed for platinum. Mesoporous tin could be expected to offer advantageous properties over existing negative electrodes in lithium ion batteries.

Tin was electrodeposited from five electrolytes containing oligoethylene glycol monoalkyl ether surfactants (E1–E5, Table 1) and one electrolyte without surfactant (N1).† After deposition the cells were disassembled and the electrodes bearing the electrodeposited tin (H_I-eSn) were repeatedly washed with *ca.* 200 ml of absolute ethanol to remove the electrolyte. Gravimetric measurements of the deposits revealed that the current efficiency was > 94%, based on the two electron reduction of Sn^{II} to Sn.

Small angle X-ray diffractograms of the tin deposits were recorded over the range 2θ 0.7–3.0° (Cu-Kα radiation), which revealed a single peak for each film prepared from the templating electrolytes E1–E5, but not for the reference electrolyte N1, Table 2. Hence the X-ray peak may be taken to indicate that the templated electrodes possessed a spatially periodic structure with a characteristic repeat distance in the range 5–10 nm which was not an artefact of the X-ray technique. The repeat distance was noted to depend on the type of surfactant used and to be increased by the presence of *n*-heptane. As may be expected, if a direct templating mechanism were operating, the repeat distances of the tin films were similar to those obtained for the respective electrolytes from which they were deposited, Table 2. In addition, the repeat distance for tin deposited from E1 was of the same order of magnitude as that observed for H_I-ePt using $C_{16}EO_8$.[6]

Table 1 Electrolyte compositions

		Electrolyte composition (w/o)		
Electrolyte	Surfactant	0.2 M $SnSO_4$, 0.3 M H_2SO_4	*n*-Heptane	Surfactant
E1	$C_{16}EO_8$	50	0	50
E2	$C_{18}EO_{10}$[a]	50	0	50
E3	$C_{18}EO_{20}$[a]	40	0	60
E4	$C_{16}EO_8$	47	5	48
E5	$C_{18}EO_{10}$[a]	50	3.5	46.5

[a] Nominal surfactant formula.

Table 2 Repeat distances of electrolytes and corresponding tin films based on XRD measurements. Also shown are the second cycle lithium extraction capacities of the films from electrochemical measurements

Electrolyte	Repeat distance of electrolyte/Å	Repeat distance tin film/Å	Lithium extraction capacity/C g^{-1}
E1	58 ± 3	60 ± 6	2510
E2	61 ± 3	66 ± 6	2080
E3	82 ± 4	81 ± 8	2060
E4	63 ± 3	63 ± 5	2570
E5	84 ± 4	85 ± 9	2120
N1	—	—	1260

Transmission electron microscopy (TEM) revealed mesoporosity in the samples, although a regular structure could not be assigned unambiguously, Fig. 1.

Further analysis of tin samples with a loading of 1.2 mg cm^{-2} was undertaken after drying under vacuum at 100 °C for 24 h. The dried samples were used as the working electrodes of non-aqueous electrochemical cells with lithium foil counter and reference electrodes and a 1 M $LiCF_3SO_3$–ethylene carbonate–diethyl carbonate electrolyte.

Using these cells ac impedance measurements were carried out over the frequency range 5 kHz to 5 Hz with a dc bias potential of 2 V *vs.* $Li–Li^+$ and oscillator level of 15 mV p–p.

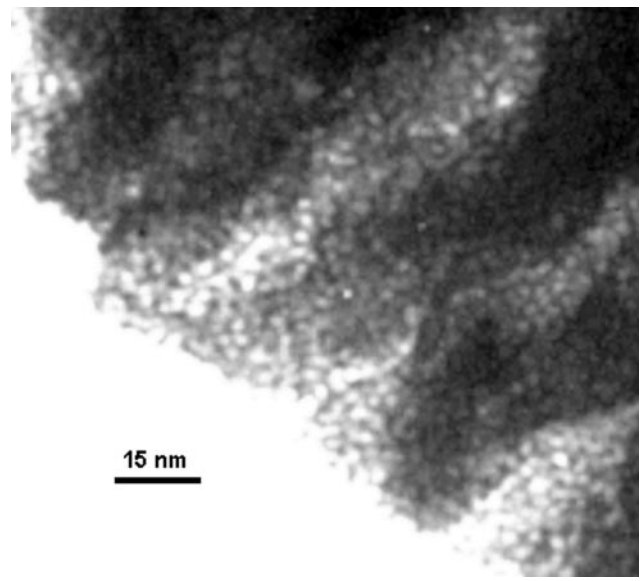

Fig. 1 Typical TEM image of a tin sample deposited from a templating electrolyte (E4).

These measurements showed the tin to act as a blocking electrode at low frequencies, as would be expected in the absence of faradaic reactions. From the values of the electrode capacitance it appeared that the samples prepared from the $C_{16}EO_8$-based electrolytes (E1 and E4), had a surface area 35 ± 10 times greater than that of rolled tin foil (9.0 μF cm^{-2}, Advent metals) of the same geometric surface area. However, an E1 sample dried at 180 °C under vacuum had a surface area enhancement of only 2 ± 1. Such a decrease in surface area may be understood in terms of a reduction in the number of accessible mesopores, which might occur by a surface melting phenomenon at below the bulk melting point of tin (232 °C).[9,10] For comparison tin deposited from the Brij-based electrolytes (E2, E3 and E5) had surface areas only slightly larger than the reference sample (N1), with surface enhancements of 8 ± 3 and 6 ± 2 respectively.

It has been noted previously that the electrochemical alloying of lithium may cause tin to undergo a volume expansion of up to 259%.[11] This expansion and any subsequent contraction, on removal of lithium, tends to create stresses within the tin alloy, leading to disintegration of the structure.[12] As loose tin–lithium particles would not be expected to be in good electrical contact with the bulk of the sample the amount of lithium that may be extracted should give an indication of the extent of pulverisation. It would be expected that extensive mesoporosity would significantly reduce internal stresses during expansion and thus decrease the mechanical degradation of the electrodes.

In order to examine the electrodeposited tin, lithium was inserted and extracted using a pulsed coulometric titration regime,[13] between the potential limits of 0.05 and 0.95 V *vs.* Li–Li^+. The magnitude of the insertion and extraction current densities was 350 μA cm^{-2} (equivalent to 290 mA g^{-1} of tin). The second cycle extraction capacities are shown in Table 2, from which it may be noted that the H_I-eSn samples all showed higher extraction capacities than the non-templated tin (from N1). The samples prepared from the mixed chain length surfactants (E2, E3 and E5) had similar extraction capacities to one another, *ca.* 2100 C g^{-1}. However, the single chain length surfactants (E1 and E4) provided tin samples with the highest extraction capacities, although still below the theoretical maximum of 3570 C g^{-1}.[14] Nevertheless, it may be noted that the H_I-eSn extraction capacities were much higher than those of commercial lithium battery negative electrode materials (coke and graphite) which are typically < 1350 C g^{-1}.[15]

In conclusion mesoporous H_I-eSn films were prepared from a series of templating electrolytes. In addition tin deposited from the $C_{16}EO_8$-based electrolytes (E1 and E4) holds promise for use as a negative electrode material for rechargeable lithium ion batteries.

We thank Mr N. R. B. Coleman and Prof. P. N. Bartlett for their support and advice, and Dr C.G. Göltner for the TEM studies. This work was supported by Southampton Innovations Ltd and the EPSRC.

Notes and references

† Electrodeposition procedure: of the surfactants, octaethylene glycol monohexadecyl ether ($C_{16}EO_8$, > 98% Fluka), had a narrow distribution of both alkyl and oxyethylene chain lengths, whereas the others contained a broader mixture of chain lengths: Brij 76 (average composition of $C_{18}EO_{10}$, Aldrich) and Brij 78 (average composition of $C_{18}EO_{20}$, Aldrich). Templating electrolytes were prepared by mixing the surfactants with an aqueous solution of ≈0.2 M $SnSO_4$ and ≈0.3 M H_2SO_4. E4 and E5 also contained *n*-heptane which was expected to act as a swelling agent, increasing the radii of the cylindrical aggregates of the H_I phase and hence the pore size in the templated electrodeposit. The concentrations of surfactant, aqueous solution and *n*-heptane (Table 1) were chosen such that a H_1 phase of each lyotropic liquid crystal was formed, as verified from the characteristic optical textures when viewed through a polarising microscope.[7]

Although the $C_{16}EO_8$-based electrolytes (E1 and E4) were used at room temperature (22 ± 2 °C) the $C_{18}EO_{10}$-based electrolytes (E2 and E5) required heating to 45 °C, and the $C_{18}EO_{20}$-based electrolyte (E3) to 50 °C, in order to improve ionic conductivity and ensure that a homogeneous H_I phase was formed. All solutions and electrolytes were freshly prepared immediately prior to commencing electrodeposition of tin.

Reference samples were prepared from a non-templating plating electrolyte, N1, with the composition, 0.15 M $SnSO_4$, 0.6 M H_2SO_4, 0.28 M 4-hydroxybenzene sulfonic acid and 0.055 M *p*-cresol.[8] Tin was deposited galvanostatically from N1 with a current density of 5 mA cm^{-2}. Tin was deposited potentiostatically from E1–E5 by applying −100 mV across a two-electrode cell, with a tin counter electrode and copper or gold working electrode of area *ca.* 0.5 cm^2.

Received (in Bristol, UK) 16th December 1998, Accepted 12th January 1999

Thermally stable porous aluminophosphates (ICMUV-3) with P/Al molar ratios in the range 0.15 ⩽ P/Al ⩽ 0.75 and showing continuously adjustable pore sizes from 13 to 37 Å have been prepared through a surfactant-assisted procedure without changing the surfactant length and/or addition of organic expansors.

Since the discovery in 1982 of three-dimensional aluminium phosphates (ALPOs),[1] their chemistry has aroused great interest mainly due to the attainment of microporous structures showing a broad range of physicochemical properties of potential application in fields such as catalysis or molecular sieving.[2,3] Control of pore geometry and diameter are key to many of these applications, especially in the case of those that rely on size or shape selectivity and ready access to pore system. The synthesis of ALPO molecular sieves, as for zeolites, involves the use of organic agents as 'templates'.[4] In this sense, the synthetic strategy developed by Mobil scientists to obtain mesoporous silicas by use of micellar aggregates of surfactants as 'templates',[5] was also seen as very promising for the preparation of aluminophosphates. Thus, Stucky and coworkers[6] were the first to extend the surfactant templating strategy to the synthesis of non-silica-based mesostructures, mainly metal oxides. However, in the case of the ALPO system this method has not been as fruitful as for silica-based materials. Although lamellar[7] and hexagonal MCM-41-type mesostructured ALPOs[8,9] have been prepared through surfactant-assisted synthetic strategies, the preparation of the corresponding mesoporous materials was not possible because their mesostructure collapsed upon calcination during surfactant removal. More recently, the preparation of two thermally stable mesoporous ALPOs using cationic surfactants has been described: Kevan and coworkers[10,11] have reported the synthesis of non-ideal mesoporous aluminophosphates (0.16 ⩽ P/Al ⩽ 0.60) with a constant pore size around 35 Å, and Kuroda and coworkers[12,13] have described the isolation of mesoporous ALPO's showing pore diameters modulated in the range 18–39 Å by changing the chain lengths of the surfactants and using organic cosurfactants as pore expansors.

We report here, a novel method to prepare thermally stable mesoporous aluminophosphates, denoted ICMUV-3, allowing a continuous adjustment of the pore sizes simply by regulation of both the P/Al molar ratio and the water content in the mother-solution.

Mesoporous ICMUV-3 materials have been prepared using cetyltrimethylammonium bromide (CTABr) as surfactant structural directing agent in an aqueous TEA (triethanolamine) medium with a molar ratio in the starting solution Al : *x*P : 0.3CTABr : 3.8TEA : *y*H_2O, (*x* = 0.12–1.5, *y* = 131–185). In a typical sample preparation, Al(OBu^s)$_3$ (5.1 ml, 0.02 mol) was slowly added to liquid TEA (10 ml; 0.075 mol) and heated at 160 °C. After 30 min, the solution was cooled at 120 °C and 2.1 g of CTABr (0.006 mol) added. Then, it was cooled at room temperature and mixed with 43 ml (2.4 mol) of distilled water. The resulting solution (pH$_i$ = 10–11) was then combined with a given amount of diluted phosphoric acid (0.55 mol in 10 ml of water) under vigorous stirring (pH$_f$ = 8–9), and the formation of a white solid was observed. This mesostructured solid was washed with warm water and air dried. In order to obtain the corresponding mesoporous material, the surfactant was thermally removed by stepped treatments under flowing air atmosphere (2 h at 300 °C, 2 h at 400 °C and finally at 500 °C during 2 h). All the samples were analyzed and characterized by X-ray powder diffraction techniques (Seifert 3000TT diffractometer using Cu-Kα radiation), TEM (Philips CM10 instrument operated at 120 kV), electron probe microanalysis EPMA (Philips SEM-515 instrument), N_2 adsorption–desorption isotherms (Micromeritics ASAP2010 analyzer) and ^{27}Al MAS NMR (Varian Unity-300 spectrometer operating at 300 MHz.

EPMA analysis shows that each ICMUV-3 mesoporous sample has a constant and well defined composition, showing in each case a homogeneous distribution of phosphorus atoms in the framework. Hence, monophasic character of the solids can be assumed. In all cases, ICMUV-3 solids have a non-ideal ALPO stoichiometry (P/Al < 1). ^{27}Al MAS NMR spectroscopy for as-synthesized and calcined ICMUV-3 materials show two resonance signals at δ *ca.* 0 and 50. These signals are indicative of six- and four-coordinate metal centers, respectively. A relative intensity increase of the signal assigned to the four-coordinate Al centers is observed as the P/Al ratio increases both in mesostructured and mesoporous solids. Also, an increase of that signal is observed after calcination.

Selected XRD patterns of as-synthesized and mesoporous ICMUV-3 samples are shown in Fig. 1. All solids present at least one very intense peak at low 2θ values (d_{100} = 28–57 Å). It should be remarked that the position of this peak closely follows the variation of the P/Al molar ratio in the solids: the

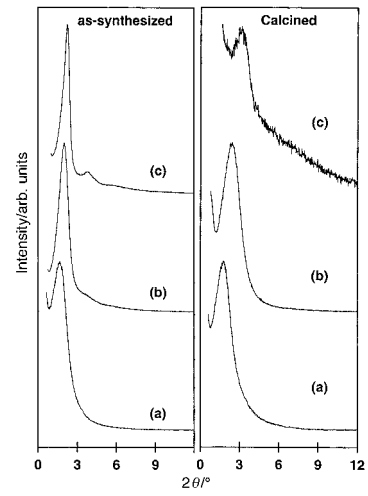

Fig. 1 Representative X-ray powder diffraction patterns of both as-synthesized and porous ICMUV-3 solids; (a) P/Al = 0.17, (b) P/Al = 0.55, (c) P/Al = 0.74.

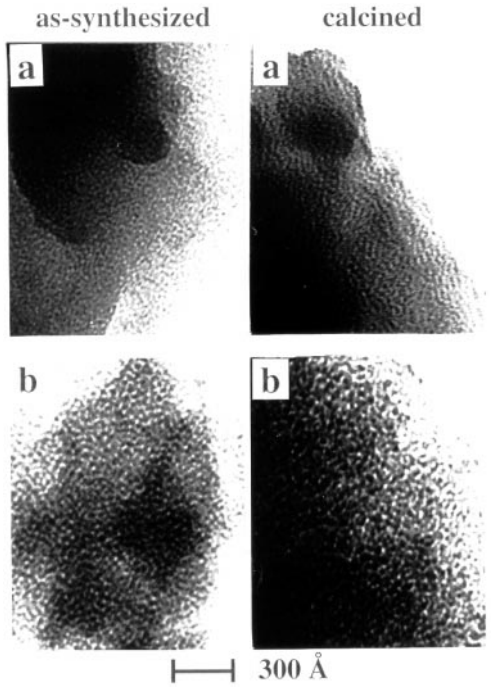

Fig. 2 Typical TEM images of as-synthesized and mesoporous ICMUV-3 solids having a P/Al molar ratio of (a) 0.17 and (b) 0.74.

peak appears at lower *d*-spacing as the P/Al ratio increases. Additionally, as-synthesized ICMUV-3 materials with high phosphorus content (P/Al > 0.4) show XRD peaks that can be assigned to the (110) and (200) reflections assuming an hexagonal MCM-41-type cell.[5] When comparing as-synthesized solids (mesostructured) with the corresponding mesoporous materials, we can see that calcination results in an intensity decrease and a broadening of the XRD peak together with a significant shift towards higher 2θ values. In general, these effects increase as the phosphorus content in the solids does.

Representative TEM images of both as-synthesized and mesoporous ICMUV-3 materials are shown in Fig. 2. On the lines of the XRD observations, it can be noted that while the as-synthesized solids show hexagonal (though disordered) pore distributions, the pore packing motif in the mesoporous materials can be better described as wormhole-like.

All ICMUV-3 aluminophosphates show one well defined step in their N_2 adsorption isotherm. Two different behaviours are, however, observed: while solids with low P/Al ratio present type IV isotherms, materials with high P/Al ratio show type I behaviour. The presence of hysteresis loops in the type IV desorption isotherms, as well as their sharp curvature, suggests the existence of a certain blocking in the pore system of the solids with lower P/Al molar ratio. Similar isotherm curves have been previously observed in aluminas prepared through a related surfactant-assisted procedure.[14,15] As can be seen in Fig. 3, average pore diameters (BJH model) for ICMUV-3 solids seem to agree with XRD data, and a continuous pore size modulation in the 13–37 Å range has been observed. From these data, an almost constant pore wall dimension of 16 Å for all ICMUV-3 solids is obtained.

Besides the pore size adjustment, it is possible to achieve a second and additional tuning by the sole adjustment of the H_2O/TEA molar ratio in the mother-solution, in a similar way we have previously described for pure aluminas.[14] Indeed, for a fixed P/Al molar ratio, such pore size modulation allows us to modify the pore dimensions in a range of *ca.* ± 3 Å by adjusting the H_2O/TEA molar ratio from 34 to 49.

Hence, the synthetic procedure here described has allowed us to obtain porous aluminophosphates with continuously adjustable pore sizes ranging from micro- (13 Å, 480 $m^2\ g^{-1}$) to mesoporous (37 Å, 650 $m^2\ g^{-1}$) by simple adjustment of the P/Al molar ratio in the initial mixture. Though the modulation in pore size is continuous, two groups of materials can be differentiated: those with low phosphorus content, whose behaviour is close to that of pure aluminas, and those with high phosphorus content, which likely approach the conventional behaviour of ALPOs. Mesoporous materials with P/Al ratios corresponding to the second group present a more ordered pore distribution.

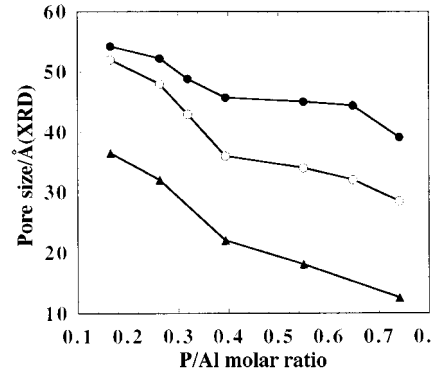

Fig. 3 Evolution of the d_{100} low reflection of both the as-synthesized (●) and porous (○) ICMUV-3 and the average pore size (▲) with the P/Al molar ratio.

We conclude that thermally stable micro/mesoporous aluminophosphates with continuously adjustable pore sizes can be prepared in aqueous/TEA through the surfactant assisted procedure using CTABr. Taking into account the ready formation of stable TEA–Al^{3+} complexes,[14,16] the principal role played by TEA can be postulated as a 'hydrolysis retarding agent'. In this way, its presence in the reaction medium is essential for the isolation of mesostructured ICMUV-3 solids by allowing a satisfactory balance between the two principal processes which take place in solution: the hydrolysis and condensation reactions of aluminium cations in water–phosphoric media and the self-assembling between organic and inorganic moieties.

Unique catalytic properties of Pt and tungstophosphoric acid supported on MCM-41 for the reduction of NO_x in the presence of water vapour

Andreas Jentys,* Walter Schießer and Hannelore Vinek

Vienna University of Technology, Institute for Physical Chemistry, Getreidemarkt 9/156, A-1060 Wien, Austria. E-mail: jentys@tuwien.ac.at; http://www.physchem.tuwien.ac.at/catalysis/

Received (in Cambridge, UK) 6th October 1998, Accepted 21st December 1998

Pt and tungstophosphoric acid supported on MCM-41 type materials show a pronounced increase in the activity during the catalytic reduction of NO_x with propene in the presence water vapour.

To combine the advantages of zeolites[1–4] and oxide based systems,[5,6] we studied the potential of transition metal containing mesoporous molecular sieves with the MCM-41 type structure for the catalytic reduction of NO_x.[7,8] As the acid sites of these materials are only weakly acidic,[9] we also impregnated the catalysts with tungstophosphoric acid ($H_3PW_{12}O_{40}\cdot 6H_2O$) in order to generate strongly acidic sites.[10]

Siliceous mesoporous molecular sieves with the MCM-41[8] type structure, synthesised with $C_{16}TMABr$,[11] were impregnated with aqueous solutions of $PtCl_4$ (Pt/MCM-41),[12] of $H_3PW_{12}O_{40}$ (HPW/MCM-41) and of $PtCl_4$ and $H_3PW_{12}O_{40}$ (Pt + HPW/MCM-41). For comparison Pt/SiO_2 (Degussa Aerosil 200) and Pt/γ-Al_2O_3 (170 $m^2\ g^{-1}$), also prepared by impregnation, were used. The metal and tungstophosphoric acid loading of all catalysts investigated are summarised in Table 1.

The characterisation of the support (MCM-41) was carried out by XRD, N_2 BET and IR spectroscopy.[9] The siliceous MCM-41 type material showed four Bragg reflections (*d*-spacing: 39 Å) and a sharp step in the N_2 isotherm at $p/p_0 \approx 0.4$. The dispersion of the metal, determined by volumetric H_2 chemisorption after reduction for 2 h at 773 K in H_2 (heating rate 15 K min^{-1}), was 64% for the Pt/MCM-41 catalyst. The BET surface areas of Pt/MCM-41 and Pt + HPW/MCM-41 were 1000 and 470 $m^2\ g^{-1}$, respectively.[10]

Catalytic properties were studied in a reaction system using a chemiluminescence NO_x analyser and a gas chromatograph (TCD and FID) to determine the concentrations of the reactants and products. The concentrations of the reactants were 1010 ppm NO, 1010 ppm C_3H_6, 4.9 vol% O_2, 0–8 vol% H_2O (balance He). The reactions reported were carried out at 573 K and at a space velocity of 11 000 h^{-1} ($w/F = 6 \times 10^{-2}$ g s cm^{-3}), the activity reported was measured after 2 h on stream. Before the reaction all catalysts were activated in He at 773 K for 1 h. TPD indicated that at this temperature H_2O was completely removed from the Pt + HPW/MCM-41 catalyst.

A comparison of the activity and selectivity (determined at the temperature of maximum NO_x conversion) is given in Table 1. The use of siliceous mesoporous molecular sieves as the Pt support improved the activity and the selectivity towards N_2 formation compared to Pt supported on dense SiO_2.[6] After the co-impregnation of MCM-41 with Pt and tungstophosphoric acid the activity decreased to a level comparable to Pt/SiO_2 and Pt/Al_2O_3, while MCM-41 based catalysts containing tungstophosphoric acid only showed a significantly lower activity. The main product of these reactions, however, was N_2O, which is characteristic for Pt group metals supported on oxides.[13] Transition metals supported on zeolites, such as Fe/ZSM5, show generally a higher N_2 yield, but are only active above 650 K.[14]

The conversions of NO_x over Pt/MCM-41 and Pt + HPW/MCM-41 at 573 K as a function of the water vapour concentration are compared in Fig. 1. At this temperature, the activity and selectivity of the catalysts in the absence of water vapour were almost identical. With increasing H_2O vapour concentration the activity of Pt + HPW/MCM-41 increased, until a maximum was reached at 2.0 vol% H_2O, where the NO_x conversion was 25% (relative %) higher compared to the water-free reaction conditions. A further increase led to a decrease in the activity; however, even at 8.5 vol% water vapour the activity was 10% higher compared to the water-free reaction conditions. In contrast, for Pt/MCM-41 a continuous decrease in the activity with increasing H_2O concentration was observed.

The activity changed almost instantaneously with the addition of 2.5 vol% water vapour into the gas stream (see Fig. 2). After switching back to water-free reaction conditions the activity immediately returned to the initial value on Pt/MCM-41. On Pt + HPW/MCM-41 it decreased to a constant level, which was 12% above the initial activity, and only after an additional heating for 1 h at 773 K in He could the initial activity be restored.

In contrast to the published results,[3,14,15] this is the first time that a pronounced increase in catalytic activity during the reduction of NO_x with hydrocarbons in the presence of H_2O vapour has been observed. The activity of the Pt + HPW/MCM-41 catalyst is significantly improved in the presence of up to 8.5 vol% water vapour compared to water free reaction conditions, while the activity of Pt/MCM-41 was slightly suppressed in the presence of water vapour.

To elucidate the reason behind these unique catalytic properties, the formation of acidic surface sites resulting from the deposition of tungstophosphoric acid on MCM-41 was

Table 1 Composition and catalytic properties of the catalysts

Sample	Pt (wt%)	Tungstophosphoric acid (wt%)	Max. NO_x conversion (%)	Temp. for max. NO_x conversion/K	Selectivity to N_2[a] (%)
Pt/MCM-41	1.61	0	62	493	35
Pt + HPW/MCM-41 (0 vol% H_2O)	1.61	30	47	543	36
Pt + HPW/MCM-41 (2 vol% H_2O)	1.61	30	51	553	37
HPW/MCM-41 (0 vol% H_2O)	0	30	22	593	32
HPW/MCM-41 (2 vol% H_2O)	0	30	19	593	35
Pt/SiO_2	1.61	0	51	513	29
Pt/Al_2O_3	1.62	0	46	543	34

investigated by following the adsorption of pyridine using IR spectroscopy. The spectra shown in Fig. 3 were normalised to the structural vibrations of MCM-41 between 2100 and 1770 cm^{-1}, the other experimental details are described in ref. 9. After activation in vacuum ($\approx 10^{-6}$ mbar) at 773 K, pyridine was adsorbed with a partial pressure of 10^{-1} mbar at 423 K on Pt + HPW/MCM-41 and on siliceous MCM-41. Subsequently, the tungstophosphoric acid containing sample was hydrated by the co-adsorption of 9×10^{-1} mbar H_2O. The bands at 1449 and 1600 cm^{-1}, present after adsorption of pyridine on MCM-41 and on Pt + HPW/MCM-41, are assigned to hydrogen-bonded pyridine formed on Lewis acid sites. Brønsted acid sites, indicated by the bands at 1540 and 1614 cm^{-1}, were only present on Pt + HPW/MCM-41. After the co-adsorption of H_2O the concentration of Brønsted acid sites on Pt + HPW/MCM-41 increased by about 75%, while the concentration of Lewis acid sites was not affected by the presence of water vapour.

In recent work[16–18] it was shown that hydrated tungstophosphoric acid supported on SiO_2 forms protonated NO species (*i.e.* NOH^+) upon adsorption of NO and that the adsorbed NO is almost completely decomposed (70–100% NO conversion) into N_2 and N_2O ($\approx$ 50% selectivity to N_2) in the presence of O_2 and

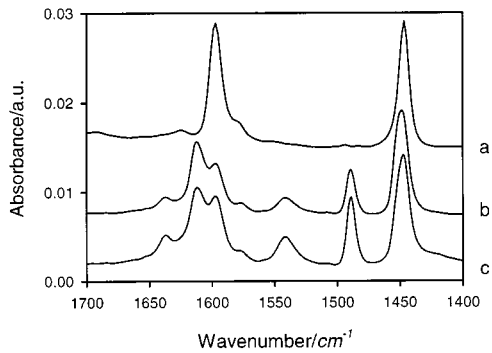

Fig. 3 Difference IR spectra after adsorption of pyridine at 423 K: (a) 10^{-1} mbar pyridine on siliceous MCM-41, (b) 10^{-1} mbar pyridine on Pt + HPW/MCM-41 and (c) 10^{-1} mbar pyridine and 9×10^{-1} mbar H_2O on Pt + HPW/MCM-41.

H_2O around 700 K. This reaction was only observed on hydrated tungstophosphoric acid and, therefore, could be the additional reaction pathway accounting for the improved activity of the Pt + HPW/MCM-41 catalyst in the presence of water vapour.

The reactions reported here however, were carried out at a much lower temperature (573 K), where the NO_x conversion over the Pt-free HPW/MCM-41 catalyst was only 8%. Also, the activity of the HPW/MCM-41 catalyst was not influenced by the presence of water vapour. Therefore, we assume that the direct reaction on tungstophosphoric acid is not the main route contributing to the overall activity in these experiments and that Pt and tungstophosphoric acid are essential to achieve the additional activity observed in the presence of water vapour.

We propose two reaction pathways in order to explain the additional activity observed on the Pt + HPW/MCM-41 catalyst in the presence of water vapour: (i) NOH^+, formed on the hydrated tungstophosphoric acid, disproportionates and the carbonaceous species formed on the Pt clusters react with the O atoms to form CO_2, while N recombines and desorbs as N_2. This reaction mechanism is similar to that described for $C_3H_6/NO/O_2$ reactions, with an additionally proposed reaction pathway for the formation of N^{-}* and O^{-}* on the surface of the hydrated tungstophosphoric acid; (ii) in the other reaction pathway we suppose that C_3H_6 adsorbs on the hydrated tungstophosphoric acid. The C_xH_y species, formed upon adsorption on the Brønsted acid sites, react with NO^{-}* adsorbed on the metal. The presence of highly acidic Brønsted sites on the hydrated tungstophosphoric acid (see Fig. 3) generates additional adsorption sites, which increases the local concentration of hydrocarbons on the perimeter of the metal clusters and thus give rise to the higher activity in the presence of water vapour.

In both mechanisms proposed an additional pathway is described, which is not present on Pt/MCM-41 or on dehydrated Pt + HPW/MCM-41 catalysts. However, at the moment we can not unequivocally decide which of the two routes described is responsible for the catalytic effects observed.

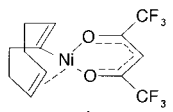
Received (in Cambridge, UK) 28th October 1998, Accepted 15th January 1999

The use of a buffered ionic liquid as a solvent for catalysts known to produce linear dimers from but-1-ene has been explored; this resulted in a significant enhancement of the activity of known catalysts, combined with the retention of both dimer selectivity and product linearity; in addition, the biphasic mode of operation allows easy catalyst recovery and recycle.

The dimerisation and oligomerisation of olefins in the presence of homogeneous Group VIII transition metal catalysts has been studied extensively. With higher olefins, the products typically consist of mixtures of branched isomers. Few catalysts are known which catalyse the linear dimerisation and oligomerisation of C_4-olefins. Linear C_8-olefin dimers are highly-desirable intermediates for the production of C_9-plasticizers, exhibiting better thermal properties than those produced from highly-branched C_8-olefin dimer feedstock (IFP Dimersol, Hüls).

To our knowledge, the best system for producing linear dimers from higher olefins originated from our group in 1979,[1] namely a catalyst based on square planar Ni-*O,O′* chelating systems, with an easily replacable group such as cod, methallyl, allyl, *etc.*, *e.g.* (cod)Ni(hfacac) **1**.



1

The above catalyst is active in organic solvents at > 50 °C, but reaches its maximum activity at 90 °C, with a turnover frequency of 500 h^{-1} with but-1-ene as feedstock. With an overall dimer selectivity of 85%, the selectivity to the linear dimer product is typically as high as 75%. Although the product quality produced by catalyst **1** is of industrial interest, the combination of high ligand costs, low catalyst activity and difficult catalyst recovery from the homogenous reaction mixture, has so far prevented industrial development.

Recently, a new approach has been adopted for catalyst separation and recycling in oligomerisation reactions, involving the use of a solvent known as an ionic liquid, which is simply a salt mixture of melting point below ambient. A well studied example involves salt mixtures of aluminium halides in combination with suitable substituted organic cations such as 1-butyl-3-methylimidazolium or 1-butylpyridinium cations.[2–4]

The oligomerisation of propene and butenes using ionic liquids as catalyst/solvent has been described by Chauvin *et al.*[5–8] These authors used a slightly acidic ionic liquid of the type [cation]X/AlX_3/$AlEtCl_2$ as a solvent for a Ni(II)-catalyst precursor known to produce highly-branched dimer products. Use of the ionic liquid solvent imparted significantly higher activity to highly branched dimer products with high activity. Moreover, the high solubility of the Ni-complex but poor solubility of the olefins produced in the ionic liquid facilitated a simple decantation step allowing complete catalyst separation.

In the case of butene oligomerisation[7] using [Ni-$(MeCN)_6$][BF_4]$_2$ as catalyst, the distribution of butene dimers, typically 39 ± 1% dimethylhexenes, 56 ± 2% monomethylheptenes and 6 ± 1% *n*-octenes, was reported to be independent of the addition of phosphine ligands. Moreover, the product mix was independent of feedstock, with both but-1-ene and but-2-ene yielding the same dimer distribution, with only 6% of the high-value linear dimer.

In the present article, we report the use of slightly acidic 1-butyl-4-methylpyridinium chloroaluminates, buffered with weak organic bases, as solvents for the linear dimerisation of but-1-ene in biphasic mode catalysed by the Ni-complex **1**.

The ionic liquids were initially prepared by mixing 1-butyl-4-methylpyridiniumchloride (4-MBP Cl) with $AlCl_3$. The Ni-catalyst **1** was dissolved in this binary mixture. Additional alkali metal chloride or organic bases were added afterwards to adjust the desired melt composition. The oligomerisation reactions were carried out in a glass autoclave. After the reaction the remaining organic layer was hydrogenated for determination of the linearity of the dimer products (determination of products by GC–MS and comparison with authentic samples).

It was found that **1** is deactivated by basic chloroaluminate ionic liquids ($X_{AlCl_3} < 0.5$) owing to excess free Cl^- anions, which probably block the free coordination sites of the catalyst (Table 1, entry 1). In acidic chloroaluminate ionic liquids ($X_{AlCl_3} > 0.5$) a large number of branched higher oligomers was formed, with only 8% dimer products formed. Clearly, the dimerisation activity of **1** is swamped by the fast cationic oligomerisation reaction initiated by the intrinsic acidicity of the ionic liquid solvent (Table 1, entry 2). Both results fit well to previous observations with other Ni-catalyst in the oligomerisation of monoolefins and are already described elsewhere in some detail.[5]
