A variety of combinatorially linkable units as disposition:† from a giant icosahedral Keplerate to multi-functional metal–oxide based network structures

Achim Müller,* Paul Kögerler and Christoph Kuhlmann

Faculty of Chemistry, University of Bielefeld, Postfach 100131, D-33501 Bielefeld, Germany. E-mail: a.mueller@uni-bielefeld.de

Received (in Cambridge, UK) 22nd February 1999, Accepted 20th April 1999

In polyoxometalate chemistry a large variety of compounds, clusters and solid-state structures can be formed by linking together metal–oxygen building blocks. Interestingly, reactions based on libraries of virtual building blocks can be planned under appropriate conditions, resulting for instance in the high-yield synthesis of inorganic superfullerenes and giant ring-shaped, electron-rich, mixed-valence polyoxomolybdates with nanosized cavities. The latter species can continue to grow and also can be covalently linked together to form chains as well as layered mesoporous compounds with properties relevant for materials science. The largest polyoxometalate cluster obtained on the basis of such a growth process consists of 248 Mo atoms. Remarkably, such giant ring species can also act as hosts for other clusters forming new types of supramolecular compounds.

Introduction

In nature, complex molecular systems like proteins have evolved (*natura naturans*) which are perfectly suited to their functions. These are formed, at least formally, in a sequence of steps principally under dissipative conditions, that is far from thermodynamic equilibrium. The challenge for the chemist is to synthesize correspondingly complex multi-functional molecules also under non-dissipative conditions using one-pot reactions, without the need to separate and purify each single intermediate product. Relevant model reactions have been explored in solutions of simple oxoanions of the early transition metals. Novel types of molecular growth processes including a type of induced cascade and those with feedback effects have been discovered leading to a huge variety of unusual compounds regarding structures and properties.[1] The basis is constituted by a system with a variety of combinatorially linkable polyoxometalate building units either as existing or virtual species (as disposition) which are available on demand in a kind of 'library' depending on the boundary conditions.

† A disposition can be interpreted as the inherent tendency of an object or system (in this case molecules or ions or fragments of these) to act or react under certain characteristic conditions.

Achim Müller, born in Detmold, Germany, studied Chemistry and Physics and obtained his PhD (1965) and his Habilitation (1967) at the University of Göttingen under the supervision of O. Glemser. He is now Professor of Inorganic Chemistry at the University of Bielefeld. His research interests range from problems of molecular physics, vibrational spectroscopy, bioinorganic chemistry, molecular metal chalcogenide complexes and clusters, and supramolecular chemistry to aspects of philosophy of science.

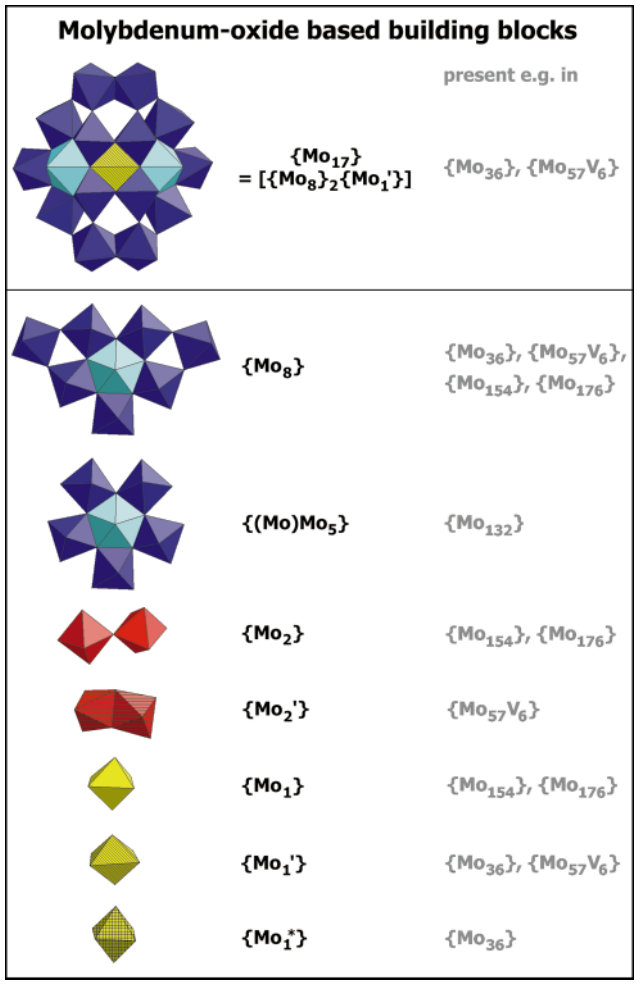
Paul Kögerler, born in Vienna, Austria, studied chemistry at the University of Bielefeld. He received his Diploma in 1996. Currently he is completing his PhD on the magnetism, electronic properties and chemistry of polyoxometalate clusters under the supervision of Professor A. Müller.

Christoph Kuhlmann, born in Gronau, Germany, studied chemistry at the University of Bielefeld. He obtained his Diploma in 1997 and is currently engaged in his PhD work on the synthesis, structure and chemistry of polyoxometalate clusters under the supervision of Professor A. Müller.

In search of an archetypical system with linkable units as disposition: the generation of a superfullerene (giant ball) with more than 500 atoms and icosahedral symmetry as a relevant example

While molecular systems, even relatively large ones, can in principle be generated by successive steps of synthesis and isolation,[2] the formation of extremely large molecular systems, in particular those with unusual structures, properties, together with very high symmetry, *e.g.* those comparable to simple spherical viruses, requires a different method of approach.

If we intend to construct for instance a giant species similar in size and shape to spherical viruses with icosahedral (C_5 C_3 C_2) symmetry, we have to find a reaction system in which pentagonal units can first be generated, then get linked and be placed at the 12 corners of an icosahedron. In the case of polyoxomolybdates these pentagonal units ({(Mo)Mo_5} groups) consist of a central bipyramidal MoO_7 unit sharing edges with five MoO_6 octahedra. The {(Mo)Mo_5} unit is a constituent of the {Mo_8}-type unit abundant in many giant polyoxometalates (see below) in which, apart from the related densely packed {(Mo)Mo_5} unit, two more loosely bound MoO_6 octahedra occur. When linkers in the form of *doubly bridging units* are present in solution, for instance those of the classical $\{Mo^{V}_2O_4\}^{2+}$ type[3] (typically formed in reduced molybdate solutions in the presence of bidentate ligands) that can link these pentagonal units, an icosahedral molecular system with 12 of the mentioned pentagons and 30 of the mentioned linkers is formed. When for example acetate anions act as bridging ligands for the $\{Mo^{V}_2O_4\}^{2+}$ groups, the spherical cluster with the stoichiometry $[Mo^{VI}_{72}Mo^{V}_{60}O_{372}(MeCO_2)_{30}(H_2O)_{72}]^{42-}$ ({Mo_{132}}) results,[4] where the central Mo positions of the {(Mo)Mo_5} pentagons define the 12 corners, and the $\{Mo^{V}_2O_4\}^{2+}$ groups the 30 edges of an icosahedron (in agreement with Euler's well known formula). This corresponds to the formulation $[\{(Mo)Mo_5O_{21}(H_2O)_6\}_{12}\{Mo^{V}_2O_4(MeCO_2)\}_{30}]^{42-}$. Interestingly, the ball-like structure (Fig. 1) is also documented in the crystal structure (space group $Fm\bar{3}$) with cubic closest packed spheres of the salt $(NH_4)_{42}[Mo^{VI}_{72}Mo^{V}_{60}O_{372}(MeCO_2)_{30}$-



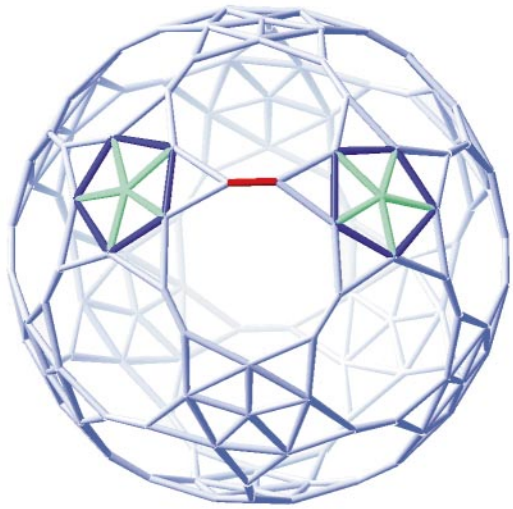


Fig. 1 Schematic representation of the 132 molybdenum atom framework of the Keplerate cluster highlighting its spherical nature. Two pentagonal {(Mo)Mo_5} groups (blue) linked by an {Mo^V–Mo^V} bridge (red) are emphasized.

$(H_2O)_{72}]\cdot xH_2O\cdot yMeCO_2NH_4$ ($x \approx 300$, $y \approx 10$). Remarkably, we are speaking about a molecular system having icosahedral symmetry although it is built up from more than 500 atoms. Despite the large number of normal vibrations the Raman spectrum shows just a few lines because only the A_g and the fivefold degenerate H_g modes are Raman active (Fig. 2).

This molecular system with 60 MoO_6 subunits or 12 related {(Mo)Mo_5} pentagons represents a topological model for

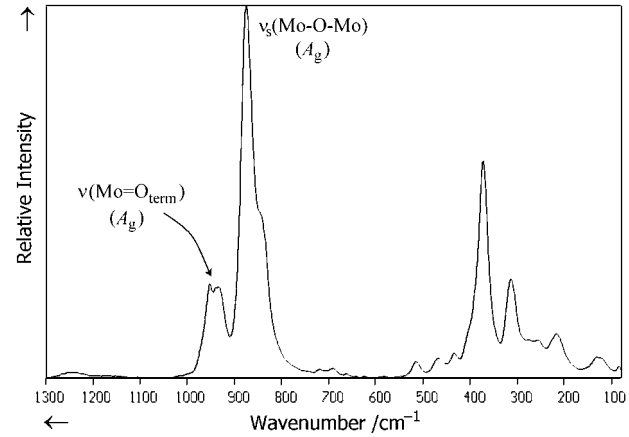

Fig. 2 Raman spectrum of $(NH_4)_{42}[Mo^{VI}_{72}Mo^{V}_{60}O_{372}(MeCO_2)_{30}(H_2O)_{72}]\cdot xH_2O\cdot yMeCO_2NH_4$ ($x \approx 300$, $y \approx 10$) (powder, λ_e = 1064 nm; ν_s stands for breathing).

spherical viruses, *e.g.* the most simple satellite tobacco necrosis virus (STNV) with 60 identical protein subunits (coded only by one gene) or 12 pentagonal capsomers (morphology units), each capsomer consisting of five protomers (for details see ref. 5 and Fig. 3). The wire-frame representation of the {Mo_{132}} cluster species additionally even suggests the structural/topological similarity to the more complex icosahedral virus capsids with a triangulation number of $T = 3$ (Fig. 4) (for details of virus structures and topologies see ref. 5 and 6).

More interestingly, on substituting the bridging acetate ligands by formate groups this smaller ligand allows a special type of organization of the *ca.* 60 encapsulated H_2O molecules: a related hydrogen-bonded cluster as guest system with an 'onion-type' structure which is induced by the peripheral spherical cluster shell (Fig. 5).[7]

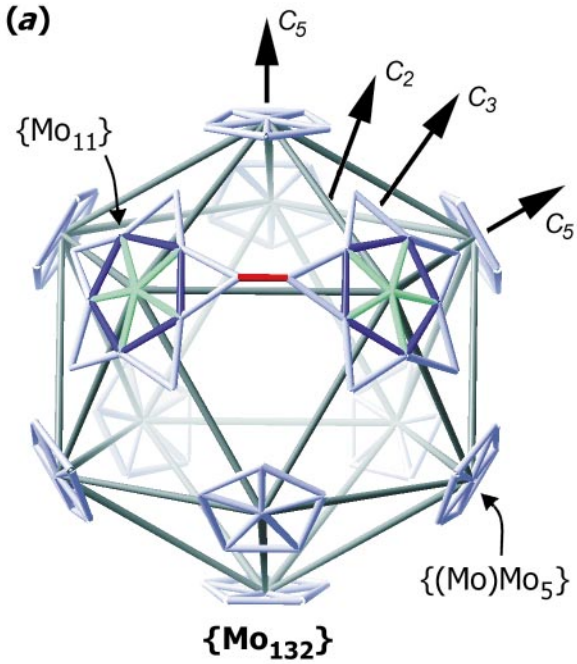
It has been proposed to call the {Mo_{132}}-type cluster a Keplerate corresponding to Kepler's model of the cosmos and his concept of planetary motion, as described in his early opus *Mysterium Cosmographicum*.[8] In accordance with this speculative model, Kepler believed that the distances between the orbits of the planets could be explained if the ratios between the successive orbits were designed to be equivalent to the spheres successively circumscribed around and inscribed within the five Platonic solids. In analogy, the cluster correspondingly shows a spherical shell of terminal oxygen atoms in which an icosahedron spanned by the centers of the 12 {(Mo)Mo_5} pentagons, the Mo atoms of the central MoO_7 bipyramids, is inscribed (see Fig. 1).

We are convinced that this {Mo_{132}}-type cluster will be the starting point for the development of a Keplerate-type chemistry, also due to the fact that these types of species are stable in aqueous solution and allow the encapsulation of different types of guests into the cavity. Furthermore, a collection of the spherically shaped huge clusters is a useful model system for special dynamical aspects of solid-state chemistry, since it enables for instance the investigation of nucleation processes (which are still not understood) but probably also of the first principles of structure-forming processes.

With respect to this fascinating discovery of the giant icosahedral cluster it seems worthwhile to concentrate on general aspects of self-aggregation processes, especially those based on the relevant polyoxometalate library systems (for aspects of combinatorial chemistry see ref. 9). In these systems we can expect reaction pathways which will lead to an extreme variety of unusual molecular systems based on differently linkable virtual units as disposition in solution.

The route to nanoscaled structures

If such unusual species as the mentioned Keplerate can be formed by linking different well defined units as disposition, it



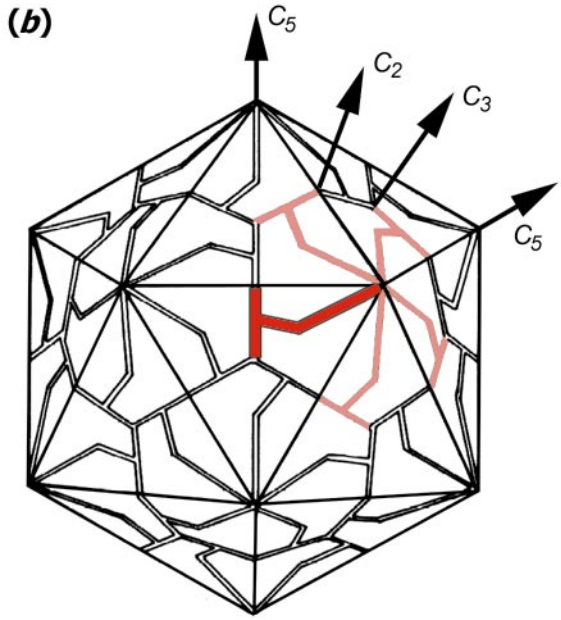


Fig. 3 Schematic representation of the icosahedron spanned by the centers of the {(Mo)Mo_5} subfragments of the {Mo_{132}}-type cluster (*a*) and of the satellite tobacco necrosis virus with triangulation number $T = 1$ (ref. 5) highlighting five of the protomers (red) (*b*). Two {Mo_{11}} units each formed by the {(Mo)Mo_5} groups and the five related Mo centers of the five neighbouring {$Mo^{V}_{2}O_4$}$^{2+}$ bridges are emphasized.

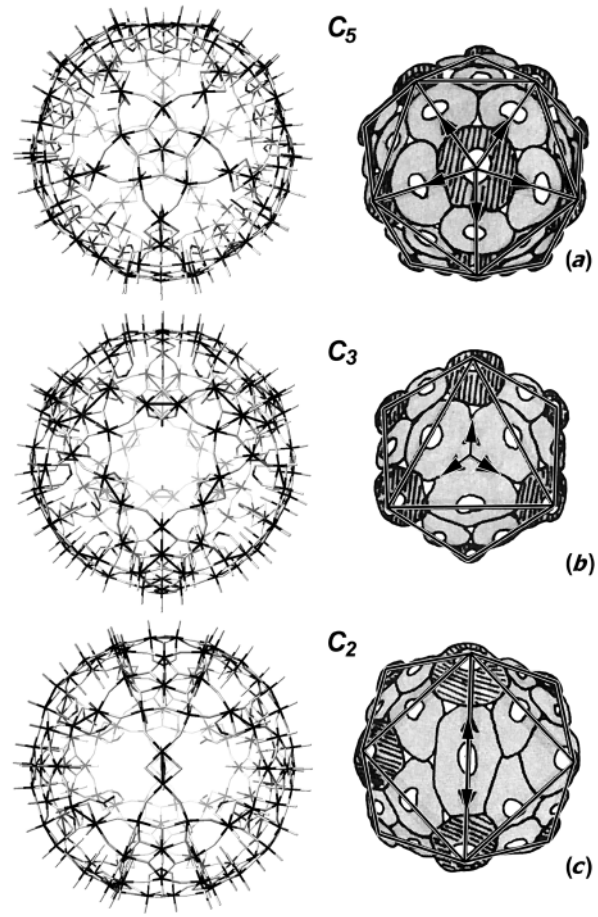

Fig. 4 Illustration of the structure of the {Mo_{132}}-type cluster (left) with perspective views along a fivefold (*a*), a threefold (*b*), and a twofold (*c*) symmetry axis in wire-frame presentations (used due to the structural complexity). For the purpose of comparison, corresponding schematic representations of an icosahedral virus capsid ($T = 3$) with 20 hexagonal and 12 pentagonal capsomers (morphology units) are presented [see ref. 6(*c*)]. In both systems, the C_5 axes cross the centers of the pentagonal units (hatched) (*a*), the C_3 axes cross the midpoint between three units (*b*), and the C_2 axes cross the center of the units (*c*). Whereas (*a*) refers to the centers of both the pentagonal {(Mo)Mo_5} units and the pentagonal capsomers which are located at the 12 corners of an icosahedron (see Fig. 3), (*b*) and (*c*) refer to the {Mo^{V}_{2}} units of the {Mo_{132}}-type cluster and the hexagonal capsomers, respectively.

is worthwhile to have a look at conditions which favour the corresponding emergence of molecular complexity including synthetic routes involving several successive reaction steps.

Optimal conditions for linking of fragments are:

- abundance of a huge variety of linkable units, *i.e.* building blocks and
- the possibility of generation of units (intermediates) with high free enthalpy to drive polymerization or growth processes, *e.g.* by formation of H_2O, of an easy structural change in the building units and blocks, of including hetero elements in the fragments, to form larger units which can be linked in different ways, to control the structure-forming processes by templates, to generate structural defects in reaction intermediates (*e.g.* leading to lacunary structures) in order to remove building units from large intermediates by the presence of appropriate reactants, to localize and delocalize electrons in different ways in order to gain versatility, to control and vary the charge of building parts (*e.g.* by protonation, electron transfer reactions, or substitution) and to limit growth by the abundance of appropriate terminal ligands, of generating fragments with energetically low-lying unoccupied molecular orbitals.

According to our present knowledge these conditions can only be optimally fulfilled in polyoxometalate systems which possess the relevant variety of molecular and electronic configurations, and not *e.g.* in silicate-based systems.

In generating large complex molecular species we have to realize that corresponding natural processes are effected by the (directed as well as non-directed) linking of (a huge variety of) basic and well defined preorganized (or stepwise organized) fragments. An impressive example of this, discussed in almost all textbooks on biochemistry, is the self-aggregation (reconstitution) process of the tobacco mosaic virus (TMV), which is based on preorganized units.[10] *This process more or less meets our strategy in controlling the linking of fragments to form larger units and linking the latter again.* The linking of building blocks containing 17 metal atoms ({Mo_{17}} units) to form cluster anions consisting of two or three of these units provides an archetypical example. The resulting two- or three-fragment

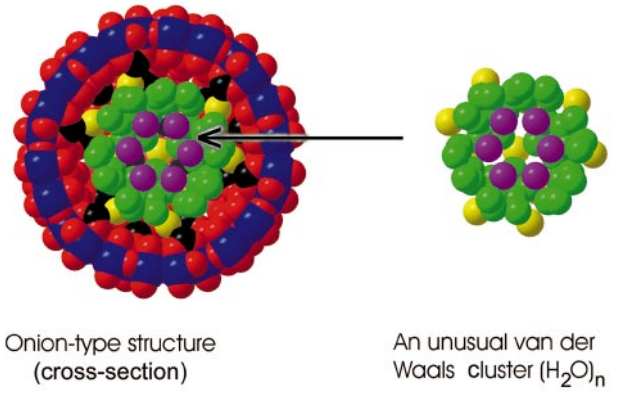

Fig. 5 Cross section through the equator of $[(H_2O)_n \subset Mo^{VI}_{72}Mo^{V}_{60}O_{372}(HCO_2)_{30}(H_2O)_{72}]^{42-}$ allowing a view into the cavity of the cluster shell and highlighting the hydrogen-bonded cluster formed by the encapsulated H_2O molecules (oxygen atoms) (*left*). The different shells spanned by encapsulated H_2O molecules are represented by spheres with different colours [violet shell (radius *ca*. 3.5 Å), green shell (6.2–6.9 Å) and yellow shell (8.2–8.7 Å) (*right*)]. Interestingly, the onion-like structure of the whole anion is completed by the three following outer shells consisting of (1) that of the 72 H_2O and 30 formate ligands coordinated to molybdenum atoms and pointing into the cavity (*ca* 10.5 Å), (2) that of the 132 molybdenum atoms (*ca* 13.1 Å) and (3) that of the terminal 132 oxygen atoms (*ca* 14.7 Å) (Mo centers: blue, O atoms: red, C atoms: black).

clusters are of the $\{Mo_{36}\}$ ($[\{MoO_2\}_2\{H_{12}Mo_{17}(NO)_2O_{58}(H_2O)_2\}_2]^{12-}$ = $[\{Mo_1{}^*\}_2(\{Mo_8\}_2\{Mo_1{}'\})_2]$) or of the $\{Mo_{57}M_6\}$ type (*e.g.* $[\{VO(H_2O)\}_6\{Mo_2(\mu\text{-}H_2O)_2(\mu\text{-}OH)\}_3\{Mo_{17}(NO)_2O_{58}(H_2O)_2\}_3]^{21-}$ = $[\{VO(H_2O)\}_6\{Mo_2{}'\}_3(\{Mo_8\}_2\{Mo_1{}'\})_3]$) (Fig. 6).[11,12]

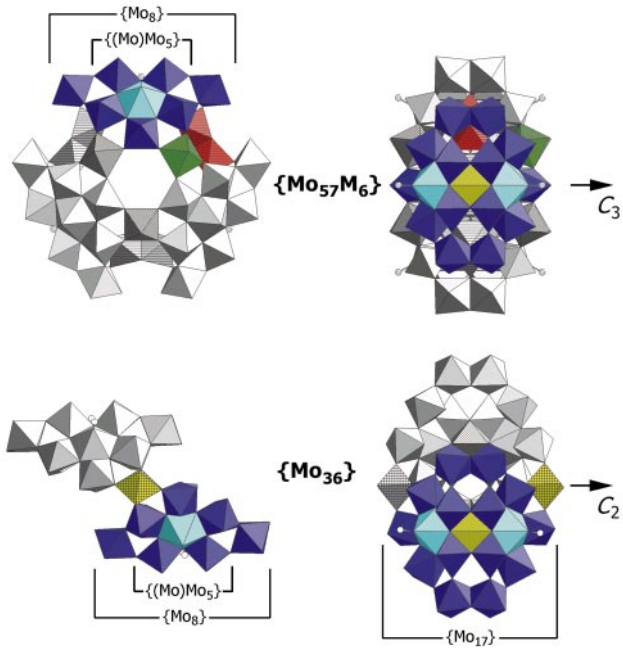

Fig. 6 Polyhedral representation of the $\{Mo_{57}M_6\}$ cluster with its basic building blocks and their constituents along the C_3 (*upper left*) and along one of the three C_2 axes (*upper right*): On the upper right, one $\{Mo_{17}\}$ building block consisting of one $\{Mo_1{}'\}$ and two $\{Mo_8\}$ groups, and on the upper left, one $\{Mo_8\}$ unit is shown in colour. Also shown in colour are one $\{Mo_2{}'\}$ group (built up from two face-sharing octahedra) and one MO_6 unit (green, cross-hatched). For comparison, the polyhedral representations of the $\{Mo_{36}\}$ cluster structure, consisting of two $\{Mo_{17}\}$ building blocks linked by two $\{Mo_1{}^*\}$ units (only one in colour), are shown in the related views, also highlighting one $\{Mo_8\}$ (*bottom left*) and one $\{Mo_{17}\}$ building block (*bottom right*). Of importance is the relation between $\{Mo_8\}$ and the pentagonal $\{(Mo)Mo_5\}$ groups (see text) ($\{Mo_8\}$: blue (central MoO_7 pentagonal bipyramid: cyan), $\{Mo_2{}'\}$: red hatched, $\{Mo_1{}'\}$: yellow hatched, $\{Mo_1{}^*\}$: yellow, cross-hatched).

The structure of the $\{Mo_{17}\}$ unit can furthermore be reduced to two $\{Mo_8\}$-type groups which are symmetrically linked by an $\{Mo_1{}'\}$-type unit. The $\{Mo_8\}$ building block, found in many other large polyoxometalate structures, is itself (as mentioned above) built up by a densely packed pentagonal $\{(Mo)Mo_5\}$ unit, containing a central MoO_7 or $MoO_6(NO)$ bipyramid sharing edges with five MoO_6 octahedra, and two more weakly bonded (sharing only corners) MoO_6 octahedra which can be more easily 'removed'. The pentagonal unit with a high formation tendency is for instance responsible for the formation of structures with icosahedral symmetry like the $\{Mo_{132}\}$-type cluster (for details, see Fig. 1).

With the $\{Mo_8\}$-type building block even very large and unusual clusters can be built up: subsequent to our publication[13] of a 3.5 nm-diameter wheel-shaped metal–oxide based cluster anion containing 154 molybdenum atoms *i.e.* $[Mo_{154}(NO)_{14}O_{448}H_{14}(H_2O)_{70}]^{28-}$ ($\{Mo_{154}\}$) and built up from 14 of the mentioned $\{Mo_8\}$ groups linked by 14 $\{Mo_2\}$- and 14 $\{Mo_1\}$-type units, respectively (Fig. 7,8), it was metaphorically stated in *New Scientist*

"Big wheel rolls back the molecular frontier".[14]

This signifies the enormous interest of modern chemistry to 'leave' the molecular world, characterized by rather small molecules or ions, and to 'proceed' to the meso- or nano-world with a view to discovering and investigating the new inherent phenomena and system qualities.

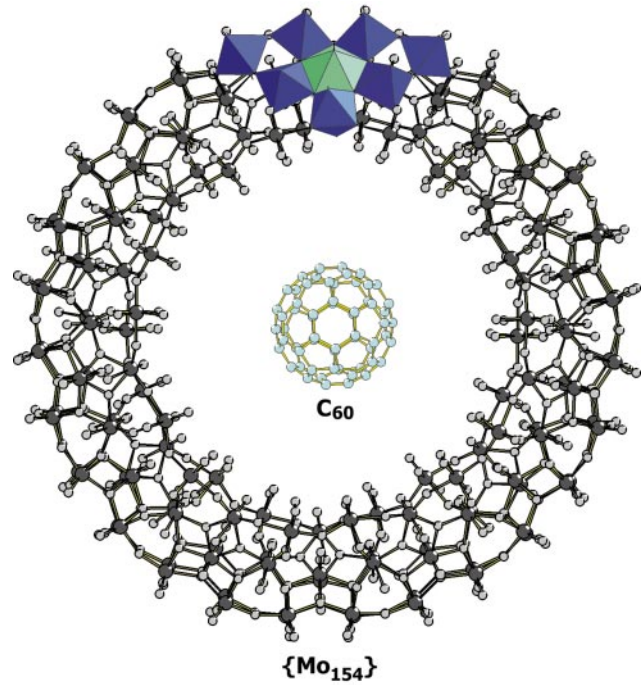

Fig. 7 Ball-and-stick representation of the $\{Mo_{154}\}$-type cluster $[Mo^{VI}_{126}Mo^{V}_{28}O_{462}H_{14}(H_2O)_{70}]^{14-}$ showing one $\{Mo_8\}$ unit (blue) with its central MoO_7 pentagonal bipyramid (cyan) in polyhedral representation. For the purpose of size-comparison, a C_{60} fullerene molecule is shown.

Remarkable is that *using the same reaction type*, i.e. *the acidification of aqueous solutions of the most simple tetrahedral oxoanions of the early transition elements of the type* $MO_4{}^{n-}$, *the resulting products span the three important areas of matter*, from the micro-, through the meso- (or nano-) to the macrostructures, the latter being characterized by crystallinity or translational invariance. In the present case the nano-structures are of particular interest owing to the huge structural variety of the related polyoxometalates. Additional external chemical interventions, *e.g.* those corresponding to the list given above, lead to an even greater structural diversity, for example in the presence of reducing agents (especially those with the possibility of multi-electron transfer), appropriate templates or hetero elements.

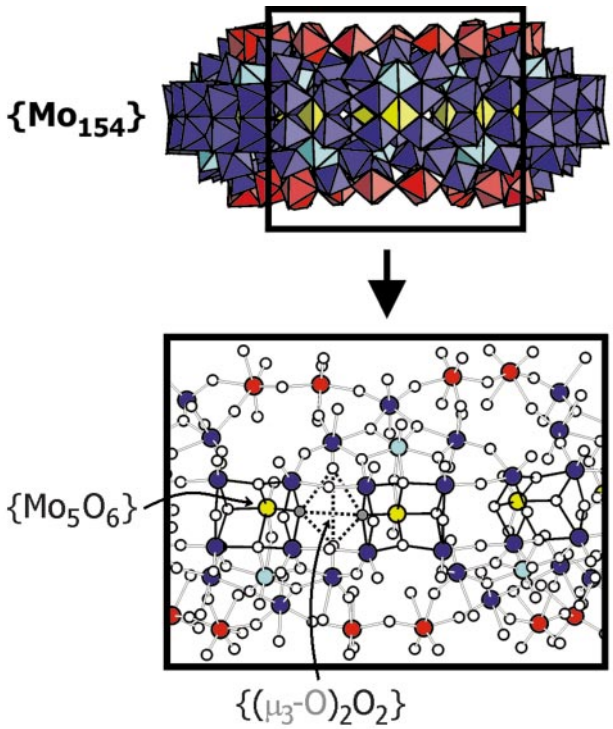

Fig. 8 Polyhedral representation of the tetradecameric $\{Mo_{154}\}$-type cluster with view perpendicular to that depicted in Fig. 7 (*top*) and structural details of cluster compartments in ball-and-stick representation (*bottom*). This representation highlights (1) three of the 14 (incomplete) double-cubane-type compartments each of which is spanned by five Mo centers (Mo–Mo = 3.4–4.0 Å) belonging to $\{Mo_8\}$- as well as $\{Mo_1\}$-type groups and six O atoms (the lowered bond valence sum (BVS) values of the corresponding Mo atoms with an average value of 5.6 prove, besides other experimental data, that two 4d electrons are trapped in each compartment), and (2) one of the 14 $\{(\mu_3\text{-O})_2O_2\}$-type compartments indicated by dotted lines which are located between two double-cubane-type compartments (the two characteristic μ_3-O atoms (dark grey, O–O = 3.07 Å) have an average BVS value of 1.2 indicating a degree of protonation; for details see ref. 34). ($\{Mo_8\}$: blue (central MoO_7 pentagonal bipyramid: cyan), $\{Mo_1\}$: yellow, $\{Mo_2\}$: red).

The use of the above-mentioned fundamental *linkable building units*, *e.g.* in the form of Platonic solids, enables the generation of molecular systems of higher structural variability and versatility compared to arrangements of aggregated metal atoms with spherical symmetry, which lead to pure metal clusters or ligand-stabilized clusters with metal cores. In the present case, the final macroscopic product is the crystalline metal oxide, in the latter, the crystalline metal. Important research in this area has been done by Schmid.[15]

The basic principles of the *one-pot reactions*, mainly those with feedback effects, non-linearity relations and induced cascades (see below), are of relevance for fundamental problems of prebiotic chemistry and conservative self-organization in general. *This is especially valid in the present case with reference to the combinatorially linkable (virtual) units as disposition*. The prebiotic situation is very well reflected by a citation from *Scientific American* that deals with the work of a well-known member of the Santa Fe institute:

> "[Stuart A.] Kauffman's simulations have led him to several conclusions. One is that when a system of simple chemicals reaches a certain level of complexity [...], it undergoes a dramatic transition, or phase change. The molecules begin spontaneously combining to create larger molecules of increasing complexity and catalytic capability. Kauffman has argued that this process of 'autocatalysis'—rather than the fortuitous formation of a molecule with the ability to replicate and evolve–led to life." [16]

On the other hand, one-pot reactions are, in principle, of industrial interest according to Dömling and Ugi's MCR (multi-component reaction)-type studies.[17]

Aspects of self-aggregation, related reaction types and synthesis

Preventing degradation as well as uncontrolled aggregation

The most suitable strategy to guarantee limited growth as well as synthetic aspects in the present case of polyoxometalate chemistry is based on the generation of sufficiently negatively charged fragments (intermediates formed during the aggregation process) enabling growth by avoiding both a possible degradation due to hydrolysis and an uncontrolled aggregation to network-type structures, leading for instance to the formation of the related oxides. This can be attained not only by substituting some metal centers of lower for ones of higher oxidation state or by substituting less positively charged for higher positively charged groups (*e.g.* by exchanging $[Mo(NO)]^{3+}$ for $[MoO]^{4+}$), but also by the (permanent) presence of an appropriate reducing agent or even different types of these. It is of utmost importance to keep the growing molecular system in solution, which can be achieved by avoiding a too high nucleophilicity of the peripheral oxygen atoms, thus preventing aggregation. This is accomplished for instance by the presence of a large number of H_2O ligands which cause the high solubility in protic media and/or terminal doubly bonded oxygen atoms of the O=Mo groups.

In the reaction system MoO_4^{2-}–H_2O–NH_2OH–$(X^VO_4^{3-})$ highly negatively charged species are abundant, for instance the highly soluble ion $[Mo^{VI}_8V^{IV}_4O_{36}(X^VO_4)]^{11-}$ (X = V; As; without protonation); the latter species can be trapped with electrophiles such as the As^{III} centers, resulting in the less soluble stable cluster species $[As^{III}_2Mo^{VI}_8V^{IV}_4O_{36}(As^VO_4)]^{5-}$ with lowered negative charge.[11c,e] Other negatively charged linkable (virtual) fragments as disposition, such as the $\{Mo_{17}\}$ unit which can be 'linked' in different ways by certain electrophilic metal centers (or linkers) such as Fe^{III} or $V^{IV}O^{2+}$, form larger systems, *e.g.* the three-fragment cluster of the $\{Mo_{57}M_6\}$ type with three $\{Mo_{17}\}$ units. A higher nucleophilicity of the fragments and a higher coordination number of the linkers can lead to giant species with a larger number of linked fragments (for the remarkable giant tungstate-based cluster of Pope and coworkers see below).

Spectroscopic detection of stability regions and conditions for further aggregation

The possibility of spectroscopic detection of the mentioned clusters in solution (*e.g.* by means of resonance-Raman spectroscopy) constitutes a good *base when studying conditions for the generation of ever larger species. Stability regions of the clusters can be determined and further possible aggregation processes under different conditions can be recognized upon changing the pH values and redox potentials*. Starting for instance with the above mentioned two-fragment $\{Mo_{36}\}$-type cluster with two $\{Mo_{17}\}$ groups, the three-fragment $\{Mo_{57}M_6\}$-type cluster with three $\{Mo_{17}\}$ groups is formed after adding for instance the strong electrophilic linker $V^{IV}O^{2+}$ under reducing conditions. In solutions containing this cluster, the (more reduced) wheel-shaped cluster $[Mo_{154}(NO)_{14}O_{448}H_{14}(H_2O)_{70}]^{28-}$ ($\{Mo_{154}\}$) forms upon further acidification and reduction ($\{Mo_{154}\}$-type clusters like the pure isopolyoxometalate analogue containing 14 $[MoO]^{4+}$ instead of 14 $[MoNO]^{3+}$ groups turned out to comprise the prototype of the molybdenum-blue species).[18] These clusters can be regarded as tetradecamers that meet D_{7d} symmetry if the hydrogen atoms are excluded and can be formally generated by linking 140 MoO_6 octahedra and 14 $MoO_6(NO)$ or MoO_7 pentagonal bipyramids, forming the building blocks of the $\{Mo_8\}$, $\{Mo_2\}$, and $\{Mo_1\}$ type which are each present in the tetradecameric cluster type 14 times.

Template-driven aggregation: an example

An important strategy often used is that of template-controlled linking especially of relatively small building units (for a review see ref. 19 but also ref. 20). It is for instance possible to link square pyramids built up by five oxygen atoms and a central vanadium atom to form cage systems. The resulting cage, *i.e.* the cluster shell, is formed complementary to the size and shape of the template which is finally encapsulated as guest in the reaction product. The relevant condensation process is initiated by adding negatively charged template ions to an aqueous solution containing vanadate ions in presence of a reducing agent which leads to the formation of polyoxovanadates (IV) or mixed-valent polyoxovanadates (IV,V). A spherically shaped halogenide anion (*e.g.* Cl^-) as template induces the formation of a spherically shaped cage, whereas the presence of the elongated azide anion results in an elongated (stretched) cluster cage (Fig. 9).[19,20] This procedure can also be regarded formally

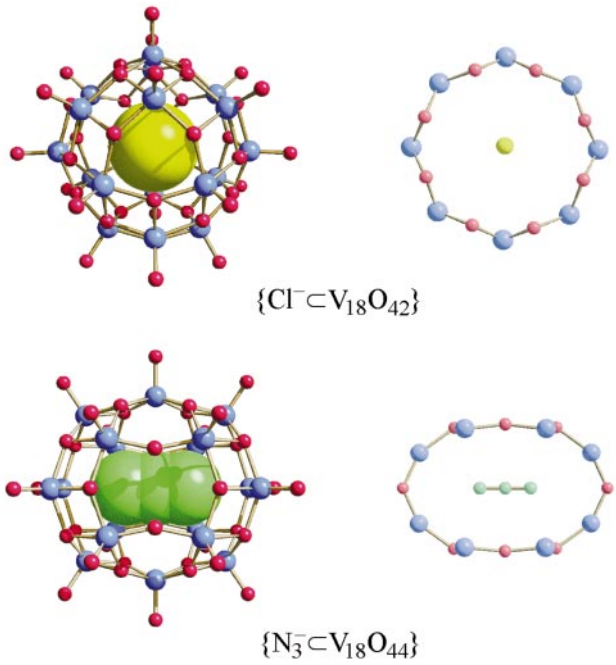

Fig. 9 Representation of the complementarity of the polyoxovanadate shell (host) formed by linking OVO_4 square pyramids (archetypical for the formation of relevant parts of concave host structures) and the encapsulated convex anion (guest) directing the linking as a template.

as a 'slaving' process according to Haken's concept of synergetics:[21] the template 'forces' or 'slaves' the square-pyramidal units to get aggregated in a uniform way. The analogy of the relevant host–guest system, in which the metal–oxygen cluster cage can be regarded as host and the enclosed anion as guest, to the endohedral fullerenes is evident (where in fact metal cations are present as guests). It should be noted that the interaction of the cluster shell with the anion is very weak (but cation stabilized) and consequently the cluster shells may be used as matrices for quasi-isolated anions.[22]

It is furthermore remarkable that all known resulting cluster shells can be regarded as sections of layers of vanadium pentoxide (V_2O_5).[19a,23] (The curvature of the cluster shell is due to the negative partial charges at the peripheral oxygen atoms.) This means that one can describe the cluster cages as being formally cut out from the layers of a crystalline compound.

Of particular interest is the case of *a template, generated in solution in an initial step, directing or determining the subsequent linking processes*: a cubane-type $\{V_4O_4(O_{term})_4\}$ fragment with the stoichiometry of amphoteric $V^{IV}O_2$, obviously primarily formed in solution, induces the formation of a cluster the structure of which has similarity with a segment of the (cubic) NaCl defect structure (Fig. 10).[24]

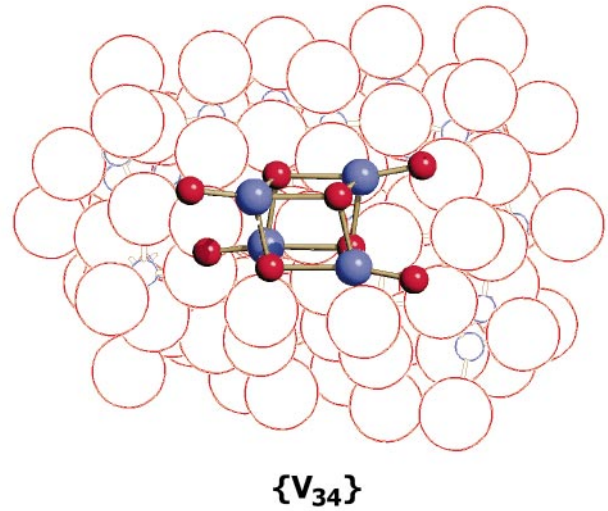

Fig. 10 Structure of the cluster anion $[V_{34}O_{82}]^{10-}$ with the highlighted $\{V_4O_4(O_{term})_4\}$ cubane-type central unit (formed initially in the reaction solution) acting formally as template, as in the case of the clusters of Fig. 9. The $\{V_{34}\}$-type cluster has similarity with a segment of the (cubic) NaCl defect structure (the 'shell' framework in space-filling, the central unit in ball-and-stick representation).

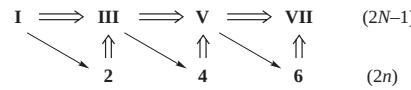
Molecular growth to complexity *via* an induced cascade

During natural evolution the emergence of more complex molecular structures from simpler ones occurred. In this context, basic principles of induced cascade reactions of the type given in Scheme 1 are of special relevance:



Scheme 1

The odd Roman numerals $2N - 1$ signify maturation steps of a molecular system in growth or development and the Arabic numerals $2n$ represent 'reagents' that react only with the special preliminary intermediate $2N - 1$. The 'species' $2n$ can themselves be products of self-assembly processes, but can remarkably be generated template-driven by the corresponding intermediate $2N - 1$. *In the latter case each intermediate* $2N - 1$ *carries information inducing the formation of the subsequent intermediate* $2n$ *(induced cascade-type reaction)* with which it then reacts thus demonstrating an interesting feedback effect.

One example for a growth process according to this model scheme has been investigated in detail: a cluster anion containing 37 molybdenum atoms ($[H_{14}Mo_{37}O_{112}]^{14-}$) is formed *via* intermediates,[25] one of which, the cluster of the type $\{Mo^{V}_{12}Mo^{VI}_{4}\}$ (containing an ε-Keggin-type nucleus capped by four electrophilic $\{Mo^{VI}O_3\}$ groups), can be isolated from the reaction medium[26a] (this $\{Mo_{16}\}$ fragment also resembles the core of other larger clusters with higher symmetry, such as $[XH_nMo_{42}O_{109}\{(OCH_2)_3CR\}_7]^{m-}$ with X = $Na(H_2O)_3^+$: n = 13, m = 9; n = 15, m = 7 or X = MoO_3: n = 14, m = 9; n = 13, m = 10).[26b] After the relevant reduction of the four surface constituents of the type $\{Mo^{VI}O_3\} \rightarrow \{Mo^{V}O_3\}$, the intermediate cluster acts both as nucleophile *and* template in directing the formation of two further electrophilic molybdenum-oxide based intermediates ($\{Mo_{10}\}$ and $\{Mo_{11}\}$). These subsequently react with their template (in a type of symmetry-breaking step) leading finally to the reaction product, the $\{Mo_{37}\}$-type cluster which remarkably has no (higher) symmetry element (Fig. 11). The most interesting aspect is that the former electrophilic $\{Mo^{VI}O_3\}$ groups are transformed into nucleophilic $\{Mo^{V}O_3\}$ ones after they have been attached to the cluster surface. The reduction of units on the cluster surface seems to be (1) the basis of the growth processes investigated here (as the growing system always has a nucleophilic surface)

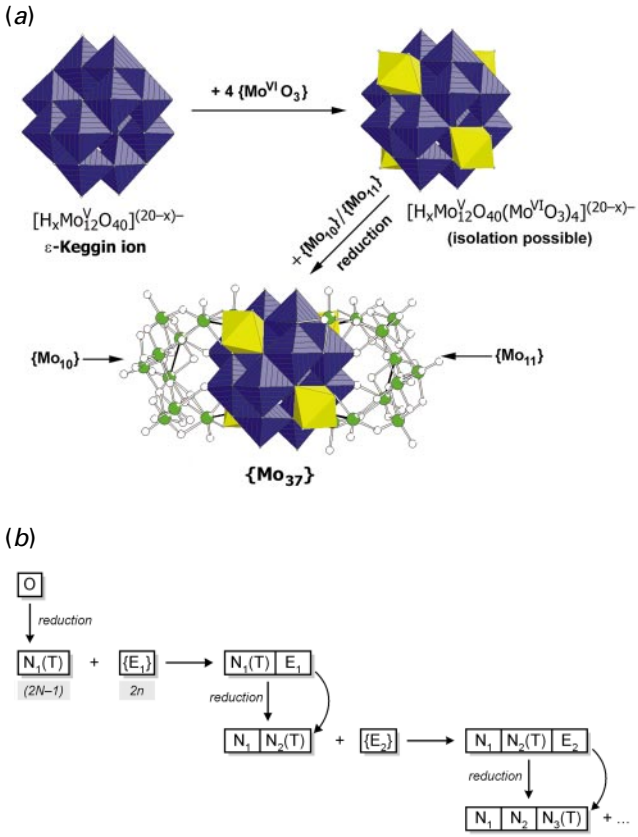


Fig. 11 (*a*) Schematic representation of a molecular growth process based on an induced cascade and molecular symmetry-breaking steps according to the reaction Scheme 1 (see text); the resulting $\{Mo_{37}\}$ cluster remarkably does not show any (higher) symmetry elements. (*b*) Reaction scheme corresponding to the growth process shown in (*a*), demonstrating principally the step-by-step procedure in which nucleophiles (such as the reduced ε-Keggin ion) attract electrophiles (such as $\{Mo^{VI}O_3\}$). Remarkably these can become nucleophiles ($\{Mo^{V}O_3\}$ units) on the surface of the cluster upon reduction. O denotes species at the beginning of a growth process (formally the non-reduced ε-Keggin ion). $N_i(T)$ denotes a nucleophilic intermediate/fragment produced under reducing conditions (of the type $2N-1$ according to Scheme 1, *e.g.* the reduced ε-Keggin ion) with a potential template function for the generation of the electrophilic intermediate E_i (of the type $2n$ according to Scheme 1, *e.g.* the $\{Mo^{VI}O_3\}$ groups).

and (2) the entering point into the world of open systems, since the reduction of the $\{Mo^{VI}O_3\}$ groups at the surface of the cluster can in principle be performed 'externally' by adding an appropriate reducing agent at the right time. It is important to note that these types of integrated constituents (here situated on the surface of a cluster) are more easily reduced than the discrete ones.

Large clusters and the correlated size(form)/complexity(functionality) pair

An increase in the size of a molecular system can *in principle* lead to multi-functionality whereby with increasing size of the system the correlated concept pair, form–function, can correspondingly become more and more important. This should be elucidated by the following examples:

(1) In the case of the mentioned $\{Mo_{57}M_6\}$-type cluster, it is possible to *place* (*or exchange*) *step-wise different* (*para*)-*magnetic centers* M *like* $Fe^{II/III}$ *and* $V^{IV}O^{2+}$ *in the respective linker positions*, thus allowing some control over the cluster's magnetic properties or even the tuning of these.[27] On the other hand the cluster in question exhibits cavities on its periphery. This is of special interest since these *cavities can be filled with positively charged units such as* $[MoO]^{4+}$ *under reducing conditions* (*i.e.* by increasing the nucleophilicity) *and can be emptied again upon oxidation* (Fig. 12). As mentioned earlier,

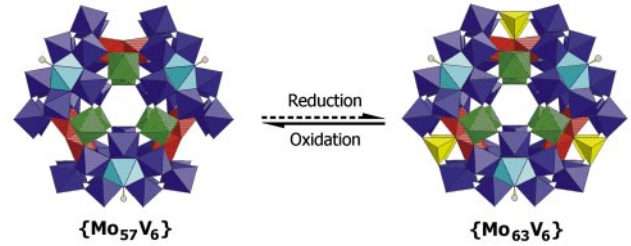

Fig. 12 Quasi-reversible molecular growth $\{Mo_{57}M_6\} \rightarrow \{Mo_{63}M_6\}$ based on a type of switchable sites: six electrophilic $[MoO]^{4+}$ groups (yellow tetrahedra) can (formally) be taken up step-wise under reducing conditions (by the nucleophilic cluster) to form finally the $\{Mo_{63}M_6\}$ cluster, but can be expelled when the latter cluster is oxidized (see text).

this seems to be the basic principle of the growth processes under consideration: aggregation or growth is due to interaction of nucleophilic growing species with electrophilic groups. The reaction, based on a kind of switchable sites, represents a type of model for uptake and release of metal centers in metal storage proteins under redox-active conditions.[25]

(2) A further nice example is presented by the cluster anion $\{Mo_{75}V_{20}\}$.[28] Interestingly, virtual $\{(Mo)Mo_5\}$ pentagons (as disposition) in solutions can be used as basic building blocks in presence of other building blocks to construct spherical species, *e.g.* derivatives of the $\{Mo_{132}\}$-type cluster with its 12 pentagonal $\{(Mo)Mo_5\}$ units. This leads for instance to the mentioned cluster anion which can be described with reference to one of the Archimedean solids, namely the icosidodecahedron with 30 corners and 32 faces. This Archimedean solid is formed by 12 pentagonal and 20 triangular faces built up by 20 V^{IV} and 10 Mo^{VI} centers while ten pentagonal faces of the icosidodecahedron are capped by the $\{(Mo)Mo_5\}$ pentagons (Fig. 13, 14). Besides the remarkable fact that the ten triangles,

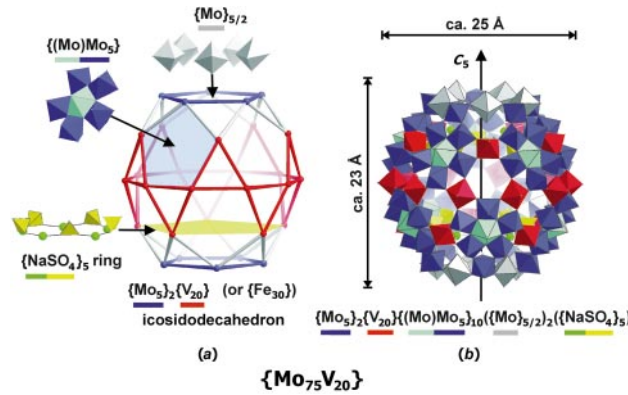

Fig. 13 (*a*) $\{V_{20}Mo_{10}\}$ framework structure of the $\{Mo_{75}V_{20}\}$-type cluster with 30 corners and 32 faces (20 triangles and 12 pentagons) spanned by 20 V^{IV} (red) and 10 Mo^{VI} (blue) centers (the Fe atoms of the related $\{Fe_{30}\}\{(Mo)Mo_5\}_{12}$-type cluster form a less distorted icosidodecahedron). Additional details: (1) one of the $\{(Mo)Mo_5\}$ units capping 10 pentagonal faces (Mo pentagonal bipyramid: light blue, Mo octahedra: dark blue), (2) pentagonal (under-occupied) array built up by the five MoO_6 octahedra capping the other two pentagonal faces (grey), (3) a 'magnetic' ring-shaped band formed by 10 $V^{IV}{}_3$ triangles having common corners (red) and (4) one of the two encapsulated $\{NaSO_4\}_5$-type rings (Na atoms: green, SO_4 tetrahedra: yellow). (*b*) Polyhedral representation of the (approximately) spherical structure of the complete $\{Mo_{75}V_{20}\}$-type cluster.

built up by the 20 V^{IV} centers, form an equatorial paramagnetic ring-shaped band with very strong antiferromagnetic exchange interactions, the cluster opens the doorway for new aspects of supramolecular chemistry because of the abundance of two $\{(NaSO_4)_5\}$-type rings inside the cavity. On the other hand it seems to be clear that the $V^{IV}O^{2+}$ groups should in principle be replaceable by Fe^{III} centers (as in the case of the $\{Mo_{57}M_6\}$-type cluster), which could enable a tuning of magnetic properties. In particular it could result in an isolation of clusters

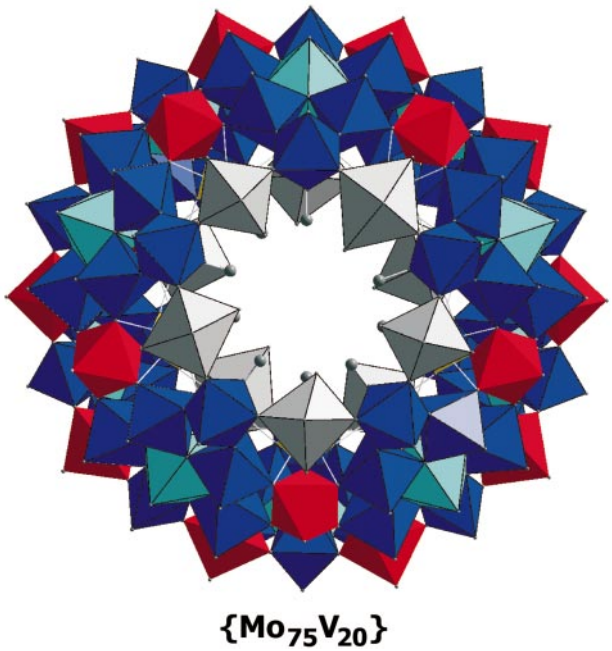

Fig. 14 Polyhedral representation of the $\{Mo_{75}V_{20}\}$-type cluster with a view along the C_5 axis, *i.e.* perpendicular to that depicted in Fig. 13(*b*) (colour code as in Fig. 13).

with an icosidodecahedral base spanned by 30 Fe centers. This for instance would correspond to a derivative of the $\{Mo_{132}\}$ cluster having also 12 $\{(Mo)Mo_5\}$ pentagons but the 30 $\{Mo^{V}{}_2O_4\}^{2+}$ groups replaced by 30 Fe^{III} centers.

(3) The *size/multi-functionality* concept pair can be elucidated very well by means of the giant wheel-type cluster, *e.g.* the tetradecameric $\{Mo_{154}\}$-type cluster and its properties:

1 It exhibits a nanometer-sized cavity, presenting new perspectives for a novel host–guest chemistry.
2 It has an extended hydrophilic inner and outer surface owing to the presence of 70 H_2O ligands.
3 It has a huge surface area which explains in part the high affinity towards adsorbents, such as charcoal or silk.
4 It renders a molecular model for catalytically active metal oxides.
5 The aqueous solution shows further aggregation tendencies: the formation of colloids of 40 nm hydrodynamic radius could be detected by means of dynamic light scattering and scanning electron microscopy.[29]
6 The periphery of the cluster ring shows a rather high electron density.
7 There are 14 uncoupled $\{Mo_5O_6\}$ (incomplete double-cubane) compartments, each of which carries two delocalized 4d electrons (comparable to a so-called electronic necklace, *i.e.* corresponding to an electron-storage system where the uncoupled storage elements are threaded like pearls on a string).[34]
8 It is possible to generate deliberately discrete structural defects on the inner surface of the cluster ring by abstracting positively charged $\{Mo_2\}$ groups using special ligands which have a high affinity to these groups (see below).
9 The ring-shaped units can be linked according to a type of crystal engineering: assembly owing to synergetically induced functional complementarity of distinct surface sites (see below).
10 It is possible to place molecules or replace ligands at different sites of the surface (thereby subsequently changing the properties) and to study direct reactions between the molecules placed inside the cavity.

Relevant compounds containing the ring-shaped units are presented in Table 1.

Table 1 Compounds with nanosized rings: building units (Fig. 8) and bond valence sum values relating to the structures[a]

Compound (with approximate crystal water content)[a]	Building units[b]	Structure	BVS[c] (Mo)	BVS[d] (μ_3-O)	Ref.

[a] Formulae of some earlier reported compounds corrected according to the now accepted type of protonation for compounds with $b = 14$ building units (tetradecameric case) or $b = 16$ (hexadecameric case). [b] The general formula for the discrete pure molybdenum–oxide based unit is $[\{Mo^{VI}{}_2O_5(H_2O)_2\}^{2+}{}_{b-x}\{(Mo^{VI/V}{}_8O_{26}(\mu_3\text{-}O)_2H_m(H_2O)_3Mo^{VI/V})^{(4-m)-}\}_b]^{(2b-bm+2x)-} \equiv [\{Mo_2\}_{b-x}\{Mo_8\}_b\{Mo_1\}_b]^{(2b-bm+2x)-}$ [b = number of building units per set = number of compartments referring to Fig. 8 = number of protonations at the equatorial μ_3-O atoms or in the $\{(\mu_3\text{-}O)_2O_2\}$ compartment (for $m = 1$) = half of the (formal) number of Mo^{V} centers; x = number of defects or missing $\{Mo_2\}^{2+}$ units]. [c] Average BVS value for the Mo centers which span the b incomplete $\{Mo_5O_6\}$-type double cubanes, built up by (parts of) the $\{Mo_8\}$ and $\{Mo_1\}$ units (Fig. 8). The (formal) number of Mo^{V} centers per ring is for all compounds $2b$ (or two per compartment) according to the related constant BVS (Mo) values and other experimental data (see text). [d] Average BVS value for the μ_3-O atoms of the $b = 14$ or 16 $\{(\mu_3\text{-}O)_2O_2\}$-type compartments (Fig. 8), which indicates protonation at the equatorial μ_3-O atoms or within the $\{(\mu_3\text{-}O)_2O_2\}$compartments. The finally accepted value for the number of protons m per compartment is 1 mainly according to the results of the numerous cation analyses. This value corresponds to a disorder of the kind that only one of the two μ_3-O atoms of a compartment is protonated. This situation ($m = 1$) is also more plausible as the other possibility ($m = 2$) leads to a rather small H–H distance in the compartment (compare W. H. Baur, *Acta Crystallogr., Sect. B*, 1992, **48**, 745). [e] Because of the rather high resolution of the crystal structure, Na^+ positions could be determined for the first time, proving their importance for the structure formation. [f] The structure is not sufficiently resolved to calculate reasonable BVS values.

On route to larger and more complex systems: supramolecular and solid-state structures

An aspect of particular interest is the fact that the large ring-shaped synthons can assemble to form chains or layers (Table 1).[34–36] The assembly is based on the replacement of H_2O ligands at $\{Mo_2\}$ units (on rings) by oxygen atoms of terminal Mo=O groups (on other rings), the nucleophilicity of which is increased for instance by introducing electron donating (and the linking-introducing) ligands like $H_2PO_2^-$ at relevant neighbouring sites (Fig. 15). In this case a *layer compound* can be obtained.[36] In addition, as the process is based on reactions at the same type of amphiphilic $\{Mo_2\}$-type O=MoL (L = H_2O, $H_2PO_2^-$) units in different rings, the term synergetically

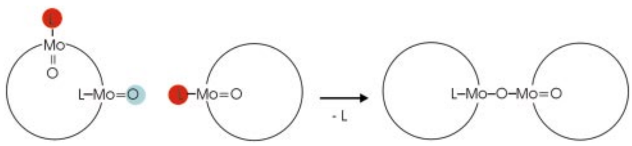

Fig. 15 Schematic representation of the basic assembly principles of ring-shaped cluster units forming the layers with $[Mo^{VI}_{126}Mo^{V}_{28}O_{462}H_{14}(H_2O)_{54}(H_2PO_2)_7]^{21-}$ units. The formation is based on the synergetically induced functional complementarity of the $\{Mo_2\}$-type O=Mo(L) (L = H_2O, $H_2PO_2^-$) sites of their surfaces: each precursor ring contains the corresponding virtual functional complementary O=Mo(H_2O) groups (becoming 'donors' due to the electron-donating $H_2PO_2^-$ replacing H_2O ligands and 'acceptors' without $H_2PO_2^-$ ligands).

induced functional complementarity seems to be justified. The hypophosphoric acid in this case acts both as reducing agent and H_2O-replacing ligand. Linking is in principle also possible by abstracting some $\{Mo_2\}$-type fragments using bidentate ligands, such as the formate anion, from the inner surroundings of the $\{Mo_{154}\}$-type cluster which also causes a higher nucleophilicity at the O=Mo(H_2O) sites of $\{Mo_2\}$ units in the neighbourhood. *Compounds with chains* having interesting electronic properties can be formed in this way (see Fig. 16 and Table 1).[31,34]

An even larger ring-shaped cluster than the tetradecameric $\{Mo_{154}\}$ type with 176 molybdenum atoms ($\{Mo_{176}\}$), *i.e.* with a hexadecameric structure, can be obtained containing correspondingly 16 instead of 14 sets of each of the three mentioned building blocks of the type $\{Mo_8\}$, $\{Mo_2\}$ and $\{Mo_1\}$ (Fig. 17, Table 1).[32,33] Under special reducing conditions the cluster system even starts growing again while two molybdenum–oxide fragments of the type $\{Mo_{36}O_{96}(H_2O)_{24}\}$ cover the cavity of the wheel-shaped cluster like hub-caps, resulting in an $\{Mo_{248}\}$-type cluster (Fig. 18).[37] This is in terms of the number of metal atoms the largest known cluster anion that has been structurally characterized so far. Remarkably the structure of the $\{Mo_{36}O_{96}(H_2O)_{24}\}$-type fragment is nearly identical to a segment of the solid-state structure of the compound Mo_5O_{14} (Fig.19).[38] This offers the possibility to model crystal growth under boundary conditions, especially the related initial nucleation process which is not understood at all. On the other hand,

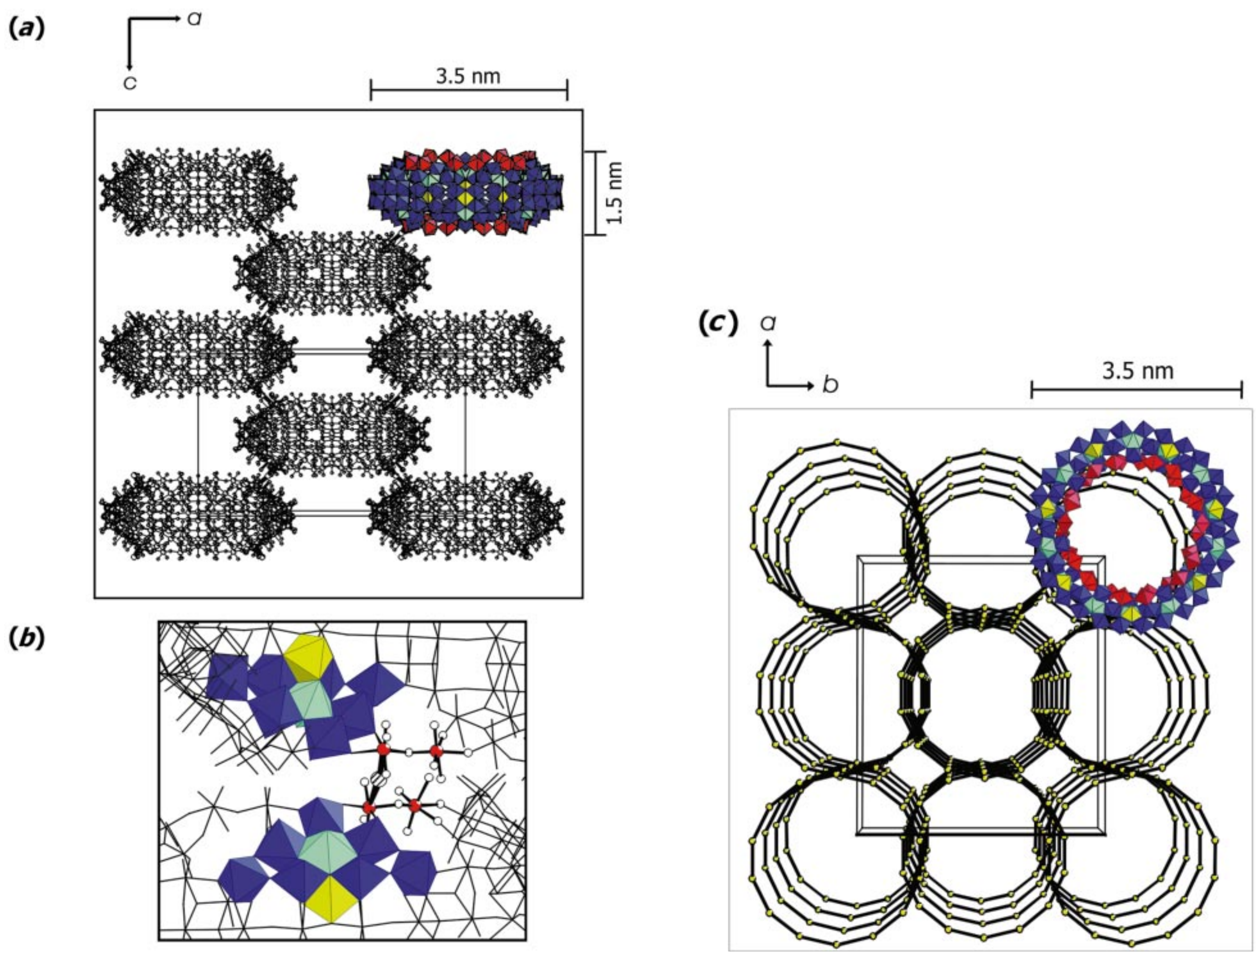

Fig. 16 (*a*) Ball-and-stick representation of the 'packing' of the covalently (in direction of the *b* axis) linked rings in crystals of $Na_{16}[Mo^{VI}_{124}Mo^{V}_{28}O_{429}(\mu_3\text{-}O)_{28}H_{14}(H_2O)_{66.5}]\cdot xH_2O$ ($x \approx 300$) ($\{Mo_{152}\}$) viewed along the crystallographic *b* axis. Each ring is connected to surrounding rings *via* Mo–O–Mo bridges of the O=Mo–O–Mo–OH_2 units, thus forming layer networks parallel to the *ac* plane. One ring is shown as basic unit in polyhedral representation ($\{Mo_2\}$ units: red, $\{Mo_8\}$: blue (central MoO_7 pentagonal bipyramid: cyan), $\{Mo_1\}$: yellow). (*b*) Detailed view of the bridging region between two cluster rings. One $\{Mo_8\}$ unit of each ring together with one $\{Mo_1\}$ unit is shown in polyhedral representation and one $\{Mo_2\}^{2+}$ (= $\{Mo^{VI}_2O_5(H_2O)_2\}^{2+}$) unit per ring in ball-and-stick representation (Mo centers: red). The bridging (disordered) oxygen centers are depicted as large, hatched circles (for clarity, the disorder in the bridging positions is not shown here). (*c*) Perspective view along the crystallographic *c* axis showing the framework with nanotubes which are filled with H_2O molecules and Na^+ cations. For clarity, only one ring is shown completely in polyhedral representation. For the other rings only the centers of the $\{Mo_1\}$ units (yellow) are given and connected. The diameter of the central cavity inside a ring in the crystal is at least 1.9 nm.

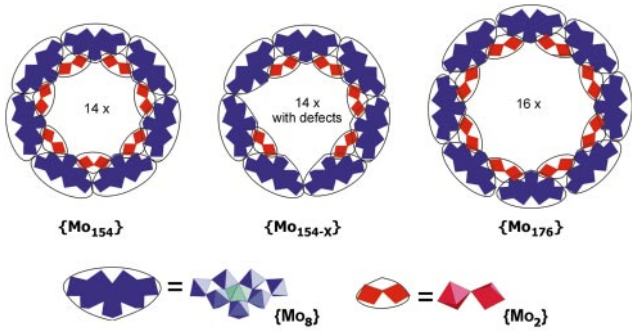

Fig. 17 Schematic comparison of the tetradecameric $\{Mo_{154}\}$- (with and without defects referring to missing $\{Mo_2\}$ groups) and hexadecameric $\{Mo_{176}\}$-type cluster showing the basic $\{Mo_8\}$ and $\{Mo_2\}$ units (the equatorial $\{Mo_1\}$ units are not visible in this representation).

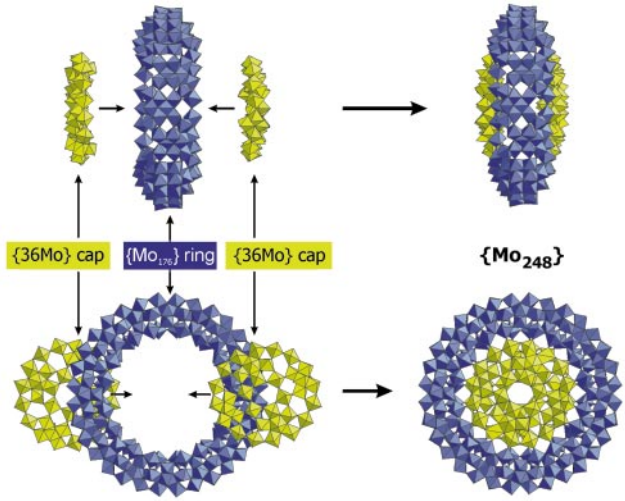

Fig. 18 Schematic representation of the growth process $\{Mo_{176}\} \rightarrow \{Mo_{248}\}$. The structure of one $\{Mo_{248}\}$ cluster can formally be decomposed into one $\{Mo_{176}\}$-type ring (blue) and two $\{Mo_{36}O_{96}(H_2O)_{24}\}$-type hub-caps (yellow).

this type of aggregation has relevance for metal-center assembly in biological systems, in particular in the case of special types of biomineralization in compartments.

In this context important work on large inorganic cluster systems based on copper selenide (*e.g.* $[Cu_{146}Se_{73}(PPh_3)_{30}]$),[39a] silver selenide (*e.g.* $[Ag_{172}Se_{40}(SeBu^n)_{92}(dppp)_4]$),[39b] metal cores (*e.g.* $[Al_{77}\{N(SiMe_3)_2\}_{20}]^{2-}$)[40] and polyoxotungstate systems (*e.g.* $[As_{12}Ce_{16}(H_2O)_{36}W_{148}O_{524}]^{76-}$)[41] should be mentioned, too.

The ring-shaped $\{Mo_{154}\}$-type clusters linked to chains can also act as hosts for smaller polyoxometalate guests, such as the (non-reduced) two-fragment $\{Mo_{36}\}$-type cluster.[42] In this novel supramolecular system the interaction between host and guest, which fits exactly into the cavity of the host, is due to 16 hydrogen bonds as well as the Coulomb interaction mediated by four sodium cations located between the negatively charged host and negatively charged guest (Fig. 20).

Facile and high-yield synthesis of the considered compounds with giant cluster anions

The precipitation and isolation of some of the giant cluster anions, mainly those with high solubility, caused difficulties for generations of chemists in the past, but also during the initial phase of our related investigations. Generations of chemists have for instance tried, without success, to isolate pure compounds or even a few crystals (only amorphous material obtained) from molybdenum blue solutions. These contain *e.g.* highly soluble giant cluster anions of the $\{Mo_{154}\}$ type which can be formed by reducing agents from molybdate solutions

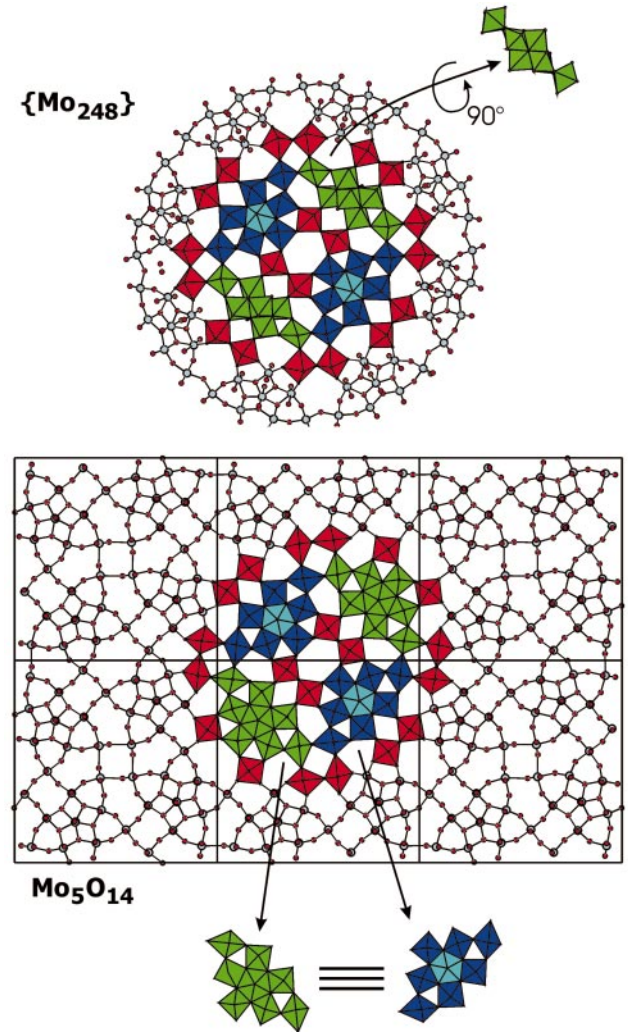

Fig. 19 Structural comparison of the hub-cap motif of the $\{Mo_{248}\}$ cluster and the related segment of the solid-state structure of Mo_5O_{14}. *Above*: schematic representation of one half of the $\{Mo_{248}\}$ cluster with a highlighted $\{Mo_{36}O_{96}(H_2O)_{24}\}$ hub-cap in polyhedral representation. *Below*: structure of Mo_5O_{14} viewed along the *c* axis [see ref. 38(*a*) for details]. Both the hub-caps and the Mo_5O_{14} layer sections each contain four $\{Mo_8\}$ entities surrounding two central $\{Mo_2\}$ units. A central ring of six MoO_6 octahedra is formed by these two $\{Mo_2\}$ units and two MoO_6 octahedra belonging to two opposite $\{Mo_8\}$ entities. Whereas in the case of the Mo_5O_{14} layer section the four $\{Mo_8\}$ entities (two blue; two green) are of the 'usual' type and occur in several of the discussed giant clusters with one central $\{(Mo)Mo_5\}$ pentagon which has two adjacent MoO_6 octahedra, only two of the four $\{Mo_8\}$ entities in the $\{Mo_{248}\}$ hub-caps have that structure. The other two $\{Mo_8\}$ units (in green) consist of a central fragment in which six Mo atoms span an $\{Mo_6\}$ octahedron which is linked to two *trans*-positioned edge-sharing MoO_6 octahedra ($\{Mo_8'\}$ entities). The layers of the solid-state structure of Mo_5O_{14} can be formed by formal superposition of the above-mentioned segment with 36 Mo centers $\{Mo_1\}$: yellow, $\{Mo_2\}$: red).

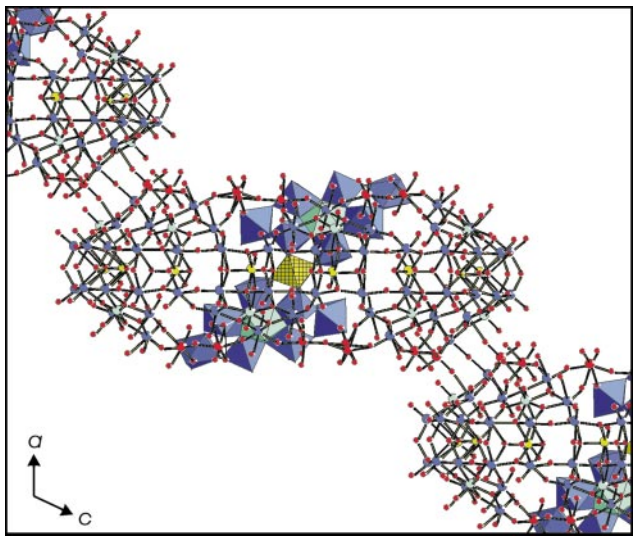
within minutes.[18,31] In the meantime, we have solved this problem: in the presence of a high electrolyte concentration (method of choice) the solubility is tremendously reduced so that the discrete $\{Mo_{154}\}$- and $\{Mo_{176}\}$-type clusters[30,31,33] and also related compounds with chain[31] and layer[36] structures could be obtained in a high-yield within a short time and in pure crystalline form. The same is valid for the $\{Mo_{132}\}$-Keplerate-type compound which can be obtained as very large crystals for which the precipitation is not problematical.

Where are we? Perspectives

Dynamic light scattering experiments on monodisperse solutions containing the $\{Mo_{154}\}$-type cluster show the presence of colloids with a hydrodynamic radius of *ca.* 40 nm which can

(*a*)



(*b*)

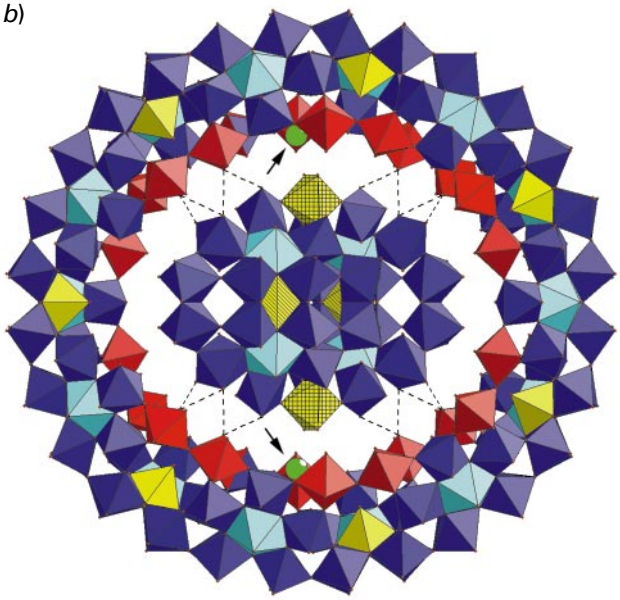


Fig. 20 Some structural details of the novel supramolecular system $\{Mo_{36} \subset Mo_{148}\}$ (occupation of the cavities: *ca.* 20%). (*a*) Part of the chain structure is shown, which is built up by linking ring-shaped cluster units $\{Mo_{148}\}$ (*i.e.* based on the $\{Mo_{154}\}$-type with three missing $\{Mo_2\}$ groups; only the front halves of the rings are shown for clarity). (*b*) View perpendicular to (*a*): the interaction between host and guest is due to 16 hydrogen bonds (dotted lines; O (host) ⋯ O (guest) = 2.744–2.965 Å) and (at least) four sodium cations (green, indicated by arrow, only two Na positions are visible in this perspective view) situated between host and guest. The sodium salt crystallizes in the space group *C*2/*m* (a = 29.425, b = 51.078, c = 30.665 Å, β = 114.85°).

also be isolated and visualized by scanning electron microscopy (Fig. 21).[29] *As the polyoxometalate chemistry covers therefore several orders of magnitude with respect to the number of atoms and the size of the clusters, its nomination as a "Powers of Ten"-type chemistry in accordance with the famous book title seems justified*. Referring to biological systems we are dealing with an order of magnitude comparable in principle to that of the above-mentioned spherical viruses.

Using combinatorially linkable (virtual) building units (as disposition) in solutions of polyoxometalates having library character, the linking of special groups, such as those of the pentagonal $\{(Mo)Mo_5\}$ type, by different types of linker groups or even paramagnetic (open shell) centers, opens new fascinating aspects and possibilities *e.g.* for structural chemistry, supramolecular chemistry, materials science and magneto-chemistry. 'Playing' with pentagons, besides from getting

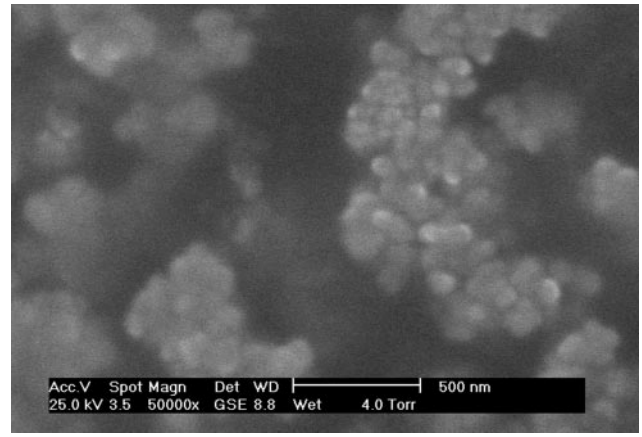

Fig. 21 Scanning electron microscope (Philips ESEM XL30, 25 kV, 3.0 Torr) image showing aggregates with a diameter of *ca.* 500 nm (based on smaller 80 nm particles) which are formed after evaporation of a methanolic solution of $Na_{22}[Mo_{146}O_{442}H_{14}(H_2O)_{58}]\cdot xH_2O$ ($x \approx 250$) (concentration: 0.1 mg ml^{-1}). It is evident that the aggregates tend to form larger arrangements.

several icosahedral-type clusters, is also of interest because of their role in the history of culture and aspects of solid-state physics.[43] Another interesting option is the study of chemical reactions at the surface of giant clusters, *e.g.* to replace H_2O ligands of the wheel-shaped clusters by amphiphilic (head/tail-type) ligands and place paramagnetic centers at the tail inside the cavity while the head replaces H_2O ligands of the parent system. The most interesting challenge will be of course to fill the cavities of the 'opened' ball-type $\{Mo_{132}\}$ cluster (which exists also as lacunary-type system) or through its apertures with a variety of different guests and also to place molecules inside the cavity of the ring- and ball-shaped clusters, which show a different reactivity to the discrete (isolated) ones.

Gold(III)-induced oxidation of glycine†

Juan Zou, Zijian Guo, John A. Parkinson, Yu Chen and Peter J. Sadler*

Department of Chemistry, University of Edinburgh, King's Buildings, West Mains Road, Edinburgh, UK EH9 3JJ. E-mail: P.J.Sadler@ed.ac.uk

Received (in Cambridge, UK) 1st April 1999, Accepted 11th June 1999

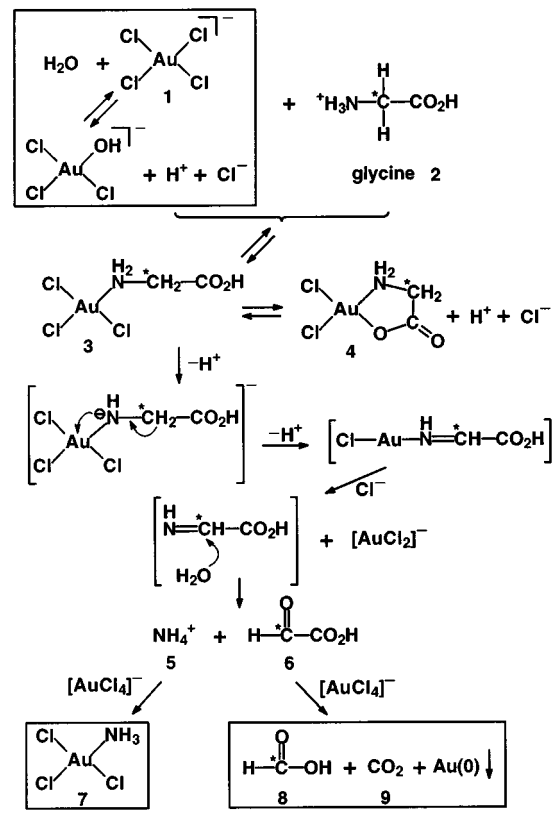
NMR investigations of isotopically-labelled glycine show that Au^{III} induces deamination and subsequent decarboxylation of the amino acid with formation of glyoxylic acid, NH_4^+, formic acid, CO_2 and metallic gold.

Several injectable 1:1 Au(I)–thiolate complexes and an orally-active Au(I)–phosphine complex are used clinically for the treatment of difficult cases of rheumatoid arthritis.[1] Their clinical application is limited, however, owing to severe host toxicity such as kidney damage and blood disorders. The molecular basis for these toxic side-effects of chrysotherapy is poorly understood[2] but recently Gleichmann *et al.*[3] have demonstrated that the oxidation of Au(I) to Au(III) *in vivo* may be responsible for some of the observed toxicity. In inflammatory situations, strong oxidants such as hypochlorite (ClO^-) and hydrogen peroxide (H_2O_2) are potentially available *in vivo* and can oxidise Au(I)–thiolates and Au(I)–phosphines to Au(III).[4] In view of this, and the antitumour activity of some Au(III) complexes,[5] it is important to understand the chemistry of Au(III)–biomolecule interactions. Surprisingly, there are only a few reports of reactions of Au(III) with amino acids, and these have focused on the sulfur-containing amino acids, namely cyst(e)ine and methionine.[6,7,8] Au(III) can cleave the disulfide bond of cystine to give the sulfonic acid[6,7] and can oxidise the sulfur of methionine stereospecifically to the sulfoxide.[8] We report here the first elucidation of the pathway of Au(III)-induced oxidation of the amino acid glycine. The identification of reaction intermediates and final products was made possible by the use of ^{13}C and ^{15}N isotopic labelling and multinuclear NMR spectroscopy.‡ The proposed stepwise oxidation mechanism provides a basis for obtaining further insights into the mechanism of gold drug toxicity.

Reactions of $[Au^{III}Cl_4]^-$ **1** with [^{15}N]glycine [^{15}N] **2** (1:2, starting pH 2.44)§ were monitored by 1D ^1H NMR (data acquired at intervals over a 12 h period) and by 2D [^1H, ^{15}N] HSQC-TOCSY NMR spectroscopy (acquired after 8 h of reaction).[9] On the basis of these results, a mechanism for the reaction of Au(III) with glycine can be proposed (Scheme 1). Initial coordination of Gly to Au(III) *via* the amino group gives $[AuCl_3(Gly\text{-}N)]$ **3** [δ(^1H): CH_2 3.85; δ($^1H/^{15}N$): $^{15}NH_2$ 6.88/2.6], which can undergo chelation to form $[AuCl_2(Gly\text{-}N,O)]$ **4** [δ(^1H): CH_2 3.75; δ($^1H/^{15}N$): $^{15}NH_2$ 6.75/−9.2]. The identification of the O,N-chelate **4** is based on chemical shift arguments compared with analogous Pt(II)–am(m)ine systems.[10] For example, δ(^{15}N) of S,N-chelated Met in [Pt(Hdien-*N*,*N*)(^{15}N-Met-*S*,*N*)] is *ca.* 10 ppm to lower frequency compared to monodentate Met in [Pt(dien)(^{15}N-Met-*N*)].[11] In our case, δ(^{15}N) for $^{15}NH_2$ of coordinated Gly differs by 12 ppm between the monodentate and O,N-chelate Au complexes.

Once formed, the chelate **4** appears to be unreactive. A two-electron transfer from Gly to Au(III) in **3** gives rise to a Au(I)–imine intermediate. Imines with a proton on N are seldom stable and are known to undergo fast hydrolysis to the corresponding aldehyde and NH_4^+.[12] An imine ligand on Au(I) would also be readily displaced by Cl^- and would hydrolyse to give glyoxylic acid **6** [^1H: δ 5.31(s)] with concomitant formation of NH_4^+ **5** [δ 7.09 (d, $^1J_{HN}$ 73 Hz)] and Au(0). The identity of **6** was revealed by further experiments. This species was stable over the pH range 1.45–12.3 and a pH titration gave an associated pK_a of 3.42. ^{13}C–{^1H} DEPT NMR data (CH group, ^{13}C: δ 89.4) suggested assignment to the aldehyde group of glyoxylic acid (lit.,[13] pK_a 3.46 at 298 K, I = 0). NMR spectra of glyoxylic acid recorded at the same pH (^1H: δ 5.36; ^{13}C: δ 173.6 and 89.7) further supported this assignment.

Both the Au(III)– and Au(I)–imine intermediates are too unstable to be observed by NMR during the reactions. The NH_4^+ produced reacts with $[AuCl_4]^-$ to give Au(III)-ammine adducts such as $[AuCl_3(NH_3)]$ **7**. This species was identified by reaction of **1** with $^{15}NH_4Cl$ (1:2, pH 2.98). It gave rise to a major HSQC cross-peak ($^1H/^{15}N$: δ 5.93/−12.9), which exhibited $^1H/^2H$ isotope shift effects[14–16] and chemical shifts very similar to those of **7**. Further substitution of Cl^- ligands by NH_3 is known to be difficult to achieve, and formation of $[Au(NH_3)_4]^{3+}$ requires the use of a large excess (super-saturated solutions) of NH_4^+ together with NH_3 gas.[17] Oxidative decarboxylation of glyoxylic acid *via* further reaction with Au(III) gives rise to formic acid **8**, carbon dioxide **9** and Au(0). This was confirmed by two separate reactions of **1** with glyoxylic acid to give formic acid **8** (^1H: δ 8.20, pH 1.52) and with 2-[^{13}C]Gly **2** to give [^{13}C]**8** (^1H: δ 8.20, $^1J_{CH}$ 218 Hz, ^{13}C: δ 166.4). Therefore formic acid is formed from the aldehyde



Scheme 1

† Reactions of $[Au^{III}Cl_4]^-$ **1** with [^{15}N]glycine as monitored by 1D ^1H NMR and 2D [^1H, ^{15}N] HSQC-TOCSY NMR can be viewed in electronic form, see: http://www.rsc.org/suppdata/cc/1999/1359/.

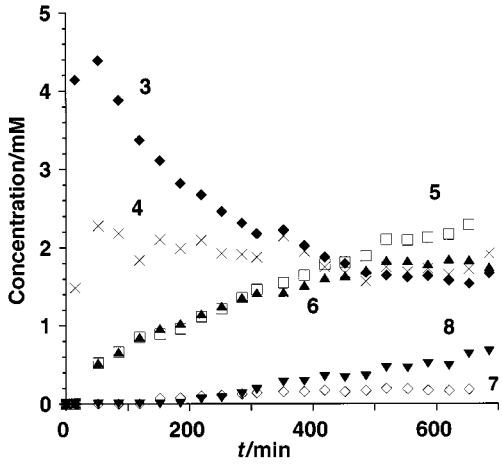


Fig. 1 Concentration *vs.* time profiles for species observed during the reaction of $[AuCl_4]^-$ **1** (15 mM) with [^{15}N]glycine ([^{15}N]**2**) (30 mM) at pH 2.87, 298 K. Concentrations were obtained from peak integrals using TSP as a standard. The profile for free Gly (*ca*. 70% unreacted after 10 h) is not shown.

group of glyoxylic acid. Formic acid can be further oxidised by Au(III) to give Au(0) and carbon dioxide,[18] but this step was not observed in the current study using 2-[^{13}C]Gly, probably due to the slow rate of the reaction at low pH.[18] The variations in concentration of the species observed by NMR during the reaction of **1** with [^{15}N]**2** with time are shown in Fig 1.

Reactions of **1** with [^{15}N]**2** at higher molar ratios gave rise to similar NMR spectra but higher product yields. For example, in the presence of a 10-fold excess of **1**, all [^{15}N]**2** reacted within 14 h. The ^{1}H NMR spectrum of a solution containing **1** and [^{15}N]**2** in a 1 : 2 molar ratio, pH 7.14, recorded after 14 h showed peaks for the CH_2 signal of [^{15}N]**2** at δ 3.56, together with singlets at δ 5.07 (assigned to the CH of glyoxylate) and at δ 8.46 (assigned to formate). The course of the reaction between **1** and **2** at physiological pH§ therefore appears to be similar to that at low pH. However, rapid proton exchange at pH 7[19] made it impossible to carry out a detailed ^{1}H,^{15}N NMR study.

The mechanism in Scheme 1 predicts that the products from the reaction§ of DL-alanine with $[AuCl_4]^-$ should be NH_4^+, pyruvic acid and acetylaldehyde. This was verified by ^{1}H and ^{13}C NMR spectroscopy, although the reaction was slower than that of Gly.

A parallel mechanism has recently been proposed for Fe(III)-assisted oxidative cleavage of a C–N bond.[20] Fe(III)-bound bis(2-pyridylmethyl)aminoacetate (BPG) is transformed into Fe(III)–bis(2-pyridylmethyl)amine *via* an Fe(III)–imine intermediate which undergoes hydrolysis with release of glyoxylic acid. Photodecomposition of complexes such as $[Co^{III}(Gly_3)]$ and $[Co^{III}(Ala_3)]$ have been reported to give rise to dipeptide amides, together with CO_2 and aldehydes.[21] Photoredox transformation of an Fe(III) complex with *N*-(phosphonomethyl)glycine has also been reported, and when irradiated with UV light the Gly derivative decomposes to give formaldehyde, ammonia and a new species containing phosphorus.[22] The reactions with Au(III) studied here were not activated by light.¶

Gold(III)-induced oxidation of Gly and related amino acids may be important in relation to the severe toxicity of gold drugs. It is possible that Au(III) can also deaminate the amino terminus of peptides and proteins. For example, during the reactions of Au(III) with tripeptides GGH and GGG, the formation of colloidal gold is observed together with other unidentified species.[23] Au(III) modification of peptides is likely to influence MHC peptide presentation and T cell recognition systems, allowing gold to have a major influence on the immune system.

We thank the Wellcome Trust (Wellcome Travelling Research Fellowship to J. Z), the Biotechnology and Biological Sciences Research Council, and the Engineering and Physical Science Research Council for their support for this work, the CVCP for an ORS Award to Y. C., Professor A. M. Sargeson (Australian National University) and Dr R. M. Hartshorn (University of Canterbury, New Zealand) for helpful discussion, and Johnson Matthey plc for loan of gold salts.

Notes and references

‡ NMR spectra were recorded at 298 K on a Brüker DMX 500 NMR spectrometer (^{1}H 500.13 MHz, ^{15}N 50.7 MHz), using the procedures described previously.[24] The 1D ^{13}C-{^{1}H} and 2D [^{1}H, ^{13}C] HETCOR NMR spectra were acquired using standard procedures.

§ NMR samples were prepared in 90% H_2O–10% D_2O (600 μl). Fresh solutions of $Na[AuCl_4]\cdot 2H_2O$ (30 mM) and Gly (60 mM) were prepared separately and then mixed in the following molar ratios (Au : Gly) at 298 K: 1 : 1, 2 : 1, 3 : 1, 5 : 1, 8 : 1, 10 : 1, 1 : 2 and 1 : 4. Fresh solutions of DL-Ala and $[AuCl_4]^-$ were mixed in a 2 : 1 molar ratio at 298 K. The concentration of $[AuCl_4]^-$ was 15 mM for all reactions. For reactions at neutral pH, the pH values of the solutions of $[AuCl_4]^-$ and Gly were adjusted separately prior to mixing, and remeasured immediately after mixing.

¶ The same products were observed for the reactions conducted under N_2 and in the absence of light.

Received (in Cambridge, UK) 4th May 1999, Accepted 14th June 1999

A multivalent polymer of vancomycin, synthesized *via* ring-opening metathesis polymerization (ROMP), exhibited significant enhancement of antibacterial activity against vancomycin-resistant enterococci (VRE).

The history of the fight against infectious bacteria centers around the recurring problem of drug resistance. For example, the evolution of MRSA (methicilin-resistant *Staphylococcus aureus*), which resists almost all established antibiotics, is now a serious worldwide problem. Currently the only viable treatment for MRSA is vancomycin. However, VRE (vancomycin resistant enterococci) has emerged, and the possibility of this resistance being transferred to *S. aureus* is a cause of major concern.[1] Although much effort has been put forth to locate new antibiotics, no alternatives to vancomycin-class glycopeptides have been found. Thus, novel strategies to modify the glycopeptides to enhance their potency against VRE are in great demand.

We have been interested in the rapidly growing molecular design principle of multivalent or cluster effects for the enhancement of weak non-bonding interactions.[2,3] Although successful applications of this concept with sugar ligands have been reported, it has not been further generalized to the recognition of complex natural products or peptides.[4] Vancomycin binds to the D-Ala-D-Ala residue of the pentapeptide terminal of a bacterial biosynthetic intermediate through five hydrogen bonds.[5] Since this binding interferes with bacterial peptidoglycan biosynthesis, it is widely believed that strengthening the association could enhance antibacterial activity. We describe herein our preliminary attempts to enhance the potency of vancomycin-class antibiotics against VRE by the formation of vancomycin-based polymers (Fig. 1).

Vancomycin contains a variety of functional groups sensitive to basic, acidic and oxidative conditions,[6,7] which necessitates careful consideration of strategies for both the modification and polymerizations steps. We chose to pursue a ring-opening metathesis polymerization (ROMP) approach. Among the known ROMP catalysts, Grubb's ruthenium catalyst[8] appeared to be well suited, as it is tolerant to polar functional groups, and applications to sugars and protected oligopeptides have appeared. However, deactivation of the catalyst by free amino groups has been demonstrated, and the functional group tolerance of the catalyst to primary amide, carboxylic acids, and phenols has not been fully established.[9]

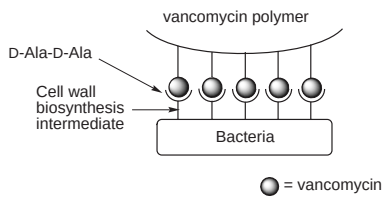

Fig. 1 Schematic presentation of the interaction of a vancomycin polymer with a bacterial cell wall biosynthesis intermediate.

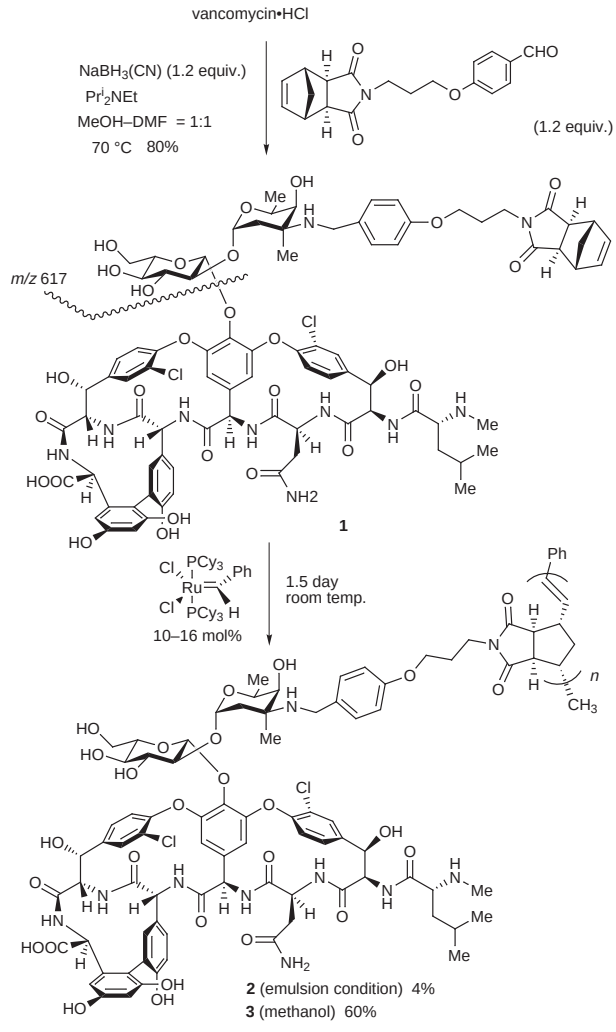
Transformation of vancomycin to a ROMP monomer was accomplished as shown in Scheme 1. An aromatic aldehyde, which was linked to the metathesis-active norbornene unit, was appended onto vancomycin by regioselective reductive amination.[10] ^{1}H NMR and MALDI-TOF mass spectroscopy (*m/z* 1757, M + 1) data[11] were consistent with the structure of monomer unit **1**. The regioselectivity for the amino-sugar portion over the N-terminal secondary amine was further established through a fragmentation analysis of a PSD experiment on the MALDI-TOF mass spectra (*m/z* 617, average mass, see Scheme 1).

The ring-opening metathesis polymerization was investigated under two different sets of conditions. When the polymerization was conducted in aqueous emulsion condi-



Scheme 1

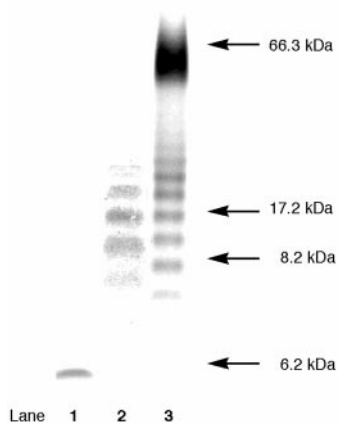


Fig. 2 Electrophoresis of compounds **1**–**3** [16% Tris–Tricine SDS–polyacrylamide gel (silver stained)]: lane 1 = monomer **1**; lane 2 = polymer **3**; lane 3 = polymer **2**.

tions,[12] the reaction was slow and the yield of polymer was only 4%. A significant improvement was observed with MeOH as the solvent in the standard homogeneous system. After 1.5 days reaction time, removal of unreacted monomer and catalyst by reversed phase column chromatography (Cosmosil 75C_{18}-OPN, MeCN–H_2O = 1:2, 1% TFA) afforded 60% yield of polymeric material **3**.[13] Polymerization was evidenced by broadened signals in the ^{1}H NMR spectra, as well as the disappearance of the norbornene olefinic proton signals. Polymer formation was also monitored by SDS-PAGE electrophoresis, which indicated the difference in molecular weight distribution of the two reactions (Fig. 2).

Antibacterial activities of monomer **1** and polymers **2** and **3** were thus evaluated (Table 1). The antibacterial properties of vancomycin were not affected by introduction of the norbornene unit present in **1**. In contrast, polymerization of **1** to **3** resulted in a significant (8 to 60 fold) enhancement of potency agaisnt VREs, with retention of practical MIC values against *S. aureus* and *Enterococci*. The reason for the marked differences in potency between **2** and **3** is not clear at this stage, but may be due either to the polymer weight distributions or to the substructural difference of each polymer. These results suggest that polyvalent polymers may be promising tools in the fight against multi-resistant bacteria.

In conclusion, we have prepared multivalent polymers of vancomycin that displayed significant antibacterial activity enhancement against VRE. Further efforts towards the understanding of this enhancement will be reported in due course.

The authors thank Dr Yoshichika Arakawa, National Institute of Infectious Diseases, and Dr Kiyoshi Nakayama, Daiichi Pharmaceutical Co. Ltd., for antibacterial tests, Dr Masahiro Uritani, Shizuoka University, for SDS-PAGE analysis, and Professor William Moser of IUPUI for helpful discussions and for critiquing the manuscript. This research was partly supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science, Sports and Culture, Japan and a Sasakawa Scientific Research Grant from the Japan Science Society.

13 We believe that monomer **1** was used as a trifuoroacetic acid salt, since the chromatographic purification of **1** was done by a TFA-containing solvent system. Thus, the key to the success in the metathesis polymerization may be the ammonium salt formation of two *sec*-amines in **1**, which prevented the deactivation of catalyst.

Formamides undergo in-plane bimolecular nucleophilic vinylic substitutions (S_N2) by the reaction with (*E*)-alkenyl(phenyl)iodonium tetrafluoroborates: stereoselective synthesis of (*Z*)-vinyl formates

Masahito Ochiai,* Shinji Yamamoto and Koichi Sato

Faculty of Pharmaceutical Sciences, University of Tokushima, 1-78 Shomachi, Tokushima 770-8505, Japan. E-mail: mochiai@ph2.tokushima-u.ac.jp

Received (in Cambridge, UK) 25th May 1999, Accepted 9th June 1999

Reported for the first time is the stereoselective synthesis of (*Z*)-vinyl formates, which involves in-plane bimolecular nucleophilic vinylic substitutions of (*E*)-β-alkylvinyl-(phenyl)iodonium tetrafluoroborates with formamides.

The chemistry of vinyl formates is relatively unexplored, mostly due to the lack of an efficient method for their syntheses. Baeyer–Villiger rearrangement of conjugated enals with H_2O_2 activated with selenium catalysts, *i.e.* SeO_2 and bis(2-nitrophenyl)diselenide, affords vinyl formates.[1] Ring opening of α,β-epoxysilanes with anhydrous formic acid, followed by *anti* β-elimination of silanol, was utilized to create the vinyl formate functionality of *Latia* luciferin.[2] A method for stereoselective synthesis of (*Z*)-vinyl formates is not available. We report herein, for the first time, stereoselective synthesis of (*Z*)-vinyl formates, which involves in-plane biomolecular nucleophilic vinylic substitutions of (*E*)-β-alkylvinyl(phenyl)iodonium tetrafluoroborates **1a**–**c** with formamides (Scheme 1).[3]

The vinyl S_N2 reaction has been considered to be a high-energy pathway and neglected for a long time.[4,5] However, we reported recently that use of aryliodonio groups as a leaving group with very high leaving ability makes possible the vinylic S_N2 pathway; thus, (*E*)-(β-alkylvinyl)iodonium salts **1a**–**c** on exposure to Bu_4NX (X = Cl, Br and I) at room temperature afford the corresponding (*Z*)-vinyl halides stereoselectively with exclusive inversion of configuration in high yields.[6,7] All of the kinetic results, secondary isotope effects, substituent effects of the leaving groups, the solvent effects, the pressure effects as well as stereochemistry of the substitutions firmly establish the in-plane S_N2 mechanism. Interestingly, we found reaction of (*E*)-(β-alkylvinyl)iodonium salts **1a**–**c** with *N*,*N*-disubstituted formamides gives (*Z*)-vinyl formates **2** stereoselectively with inversion of configuration: thus, heating of a solution of (*E*)-dec-1-enyl(phenyl)iodonium tetarfluoroborate **1a** in DMF at 50 °C for 6 h under nitrogen afforded the (*Z*)-vinyl formate **2a**† in a high yield (83%) (Table 1, entry 1). Scheme 2

reaction is highly stereoselective and no formation of the (*E*)-vinyl formate **2f** was detected by GC and 400 MHz ^{1}H NMR. The saturated aldehyde **3a** and the terminal alkyne **4a** were obtained as minor products in 12 and 5% yields.

N,*N*-Diethylformamide and *N*-formyl cyclic amines, *i.e. N*-formyl-pyrrolidine, -piperidine and -morpholine, similarly gave the (*Z*)-vinyl formate **2a** as a major product but with an increased amount of the aldehyde **3a** (entries 2–5). It is noted that the use of aromatic formamides such as *N*-formyl-*N*-methylanilines resulted in reactions almost free of the byproduct **3a** (entries 8–10). In contrast, the reaction course was dramatically changed when sterically demanding *N*,*N*-diisopropylformamide was used and a large amount of dec-1-yne **4a** (52%) was produced *via* elimination. With *N*,*N*-dicylohexylformamide, this elimination is the sole detectable pathway. Acetamides also act as good nucleophiles in this reaction; for instance, treatment of **1a** with *N*,*N*-dimethylacetamide at 50 °C for 6 h afforded stereoselectively (*Z*)-dec-1-enyl acetate in 62% yield, along with formation of **3a** (26%) and **4a** (7%).

The concerted vinylic S_N2 pathways are highly sensitive to the nature of β-substituents of the vinyliodonium salts and are inhibited or retarded when (*E*)-β-*tert*-butylvinyl- **1d** and (*E*)-β-phenylvinyliodonium salt **1e** were used in the reaction with halides.[6,8] This tendency was also kept in the reaction of iodonium salts **1d** and **1e** with DMF at 50 °C, which afforded no S_N2 products **2d** and **2e** (entries 17 and 18). Reaction of the (*Z*)-isomer with DMF resulted in extensive *anti* β-elimination to give **4a** in 80% yield, as reported previously.[6]

Scheme 2 illustrates a possible mechanism for formation of the (*Z*)-vinyl formate **2a** and the aldehyde **3a** from (*E*)-vinyliodonium salt **1a** by the reaction with DMF. Formamide on treatment with alkyl tosylates undergoes exclusive *O*-alkylation with no *N*-alkylation;[9] therefore, it seems reasonable to assume that the oxygen atom of DMF selectively attacks the (*E*)-vinyliodonium salt **1a** to produce the inverted (*Z*)-*O*-vinylimidonium salt **6** (Vilsmeier–Haack salt) *via* the vinylic S_N2 transition state **5**, which was stabilized by delocalization of the nitrogen lone-pair electrons. The hyper-leaving group ability of the phenyliodonio group would be responsible for the vinylic S_N2 reaction.[7] Subsequent attack of water will produce *N*-protonated tetrahedral species **7**, which collapses to **2a** with the ammonio group being released, or *O*-protonated tetrahedral species **8**, which collapses to **3a** with DMF being released.

The formate **2a** and the aldehyde **3a** seem to be kinetic products, since neither isomerization of the double bond of **2a** yielding **2f** nor hydrolysis of **2a** to the saturated aldehyde **3a** was observed under the conditions used. We believe that the ratios of the (*Z*)-vinyl formate **2a** to the saturated aldehyde **3a** might depend on the leaving ability of the ammonio groups, which will increase in the order $HN^+Pr^i_2$ < HN^+Et_2 < HN^+Me_2 < HN^+(Me)Ar. These hypotheses are in a good agreement with the observed ratios shown in Table 1.

Base-induced α-eliminations generating free alkylidene carbenes are a feasible process for β-alkylvinyliodonium salts.[10,11] The α-elimination pathway to yield the alkyne **4a**, which was established by analysis of the deuterium content (88%) of [1-^{2}H]dec-1-yne obtained by the reaction of β-deuterated **1a** with *N*,*N*-diisopropylformamide at 50 °C, would compete with the vinylic S_N2 reaction leading to the formation of **2** and **3**. The ratios of the vinylic S_N2 reaction *versus* the α-elimination shown in Table 1 clearly indicate that sterically demanding *N*,*N*-diisopropylformamide and *N*,*N*-dicyclohexylformamide will lead to steric retardation of the S_N2 pathway, which, in turn, results in formation of a large amounts of the alkyne **4**.

In general, bimolecular nucleophilic substitutions are favoured when a good nucleophile is present; however, formamides with rather low nucleophilicity undergo the vinylic S_N2 reaction under mild conditions. The origin of this unusual reaction is attributable to the hyper-leaving group ability of the phenyliodonio group.

Deprotonated ethylenethiourea as a ligand in an unusual tetrameric gold(I) complex†

Peter G. Jones* and Steffi Friedrichs

Institut für Anorganische und Analytische Chemie, Technical University of Braunschweig, Postfach 3329, 38023 Braunschweig, Germany. E-mail: p.jones@tu-bs.de

Received (in Basel, Switzerland) 24th May 1999, Accepted 13th June 1999

The product of the reaction between $[(etu)_2Au]^+Cl^-$ (etu = imidazolidine-2-thione) and aqueous sodium hydroxide, previously described as $\{(etu)Au\}_2O$, is shown by X-ray analysis to be a tetramer with four gold(I) centres and four deprotonated etu ligands acting as *N*,*S*-donors.

Ethylenethiourea [imidazolidine-2-thione (etu)] is a well known ligand in the chemistry of gold(I); complexes such as $[(etu)_2Au]Cl\cdot H_2O$ were described as long ago as 1928.[1] Also reported[1] was $\{(etu)Au\}_2O$, apparently the product of the reaction between $[(etu)_2Au]Cl$ and aqueous sodium hydroxide. In the light of current knowledge, this complex would be unexpected because of the extremely low affinity of gold(I) centres for oxide ligands; as far as we are aware, there is no established example of such a complex. We have recently begun a study of hydrogen bonding in etu complexes of gold(I),[2] in the course of which we decided to re-examine the previous report.

The reaction between $[(etu)_2Au]Cl$ and aqueous alkalis is not difficult to reproduce; it leads immediately to a white precipitate, which is however practically insoluble in all common solvents. In such cases the slow diffusion of reacting solutions may lead to crystalline material; the careful layering of the three phases aqueous potassium hydroxide (bottom), ethyl acetate (centre) and ethanolic $[(etu)_2Au]Cl$ (top) indeed led to single crystals, albeit extremely small. An X-ray structure determination did however prove possible, exploiting the greater sensitivity of area detector technology.‡

The structure is shown in Fig. 1. It is a tetramer $[Au(etu - H)]_4$, where (etu − H) indicates an ethylenethiourea deprotonated at one nitrogen atom.§ The ligands coordinate through S and the deprotonated N atom, and there are two differently coordinated types of gold centre. Gold atoms Au2 and Au3 lie on twofold axes ½,½, *z* and are linearly coordinated by two nitrogen atoms [Au2–N12 2.04(1), Au3–N22 1.97(1) Å], whereas Au1 lies on a general position and is coordinated by two sulfur atoms [Au1–S1 2.284(4), Au1–S2 2.304(4) Å] in a distorted linear geometry [S–Au–S 169.8(2)°]. As far as we are aware, only one other complex of (etu − H) is known: $[Mo_2(py)_2(O_2CBu^t)_3(etu - H)]$.[3]

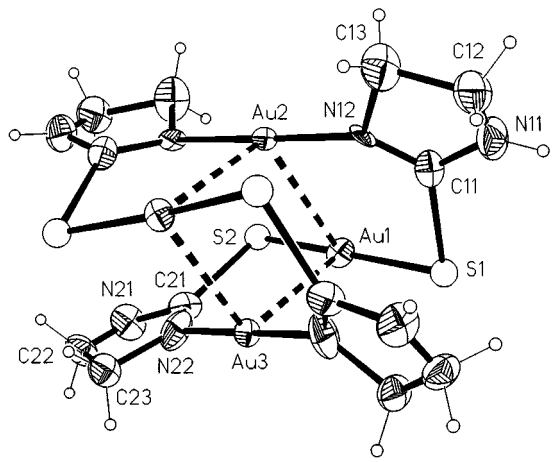

Fig. 1 Structure of the tetramer $[Au(etu - H)]_4$ in the crystal. Only the asymmetric unit is numbered. Ellipsoids represent 50% probability levels; H and S atom radii are arbitrary (see text).

† Dedicated to Professor Reinhard Schmutzler on the occasion of his 65th birthday.

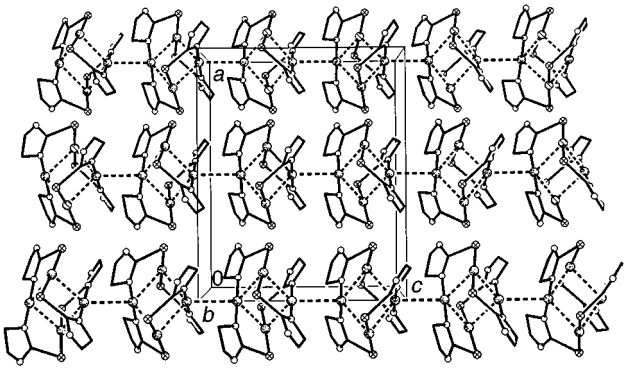

Fig. 2 Packing diagram of $[Au(etu - H)]_4$, showing the formation of chains of tetramers parallel to the *z* axis. Au···Au contacts are indicated by dashed lines. H atoms are omitted.

The tetramer contains a 16-membered ring comprising the gold atoms, all N and S donor atoms, and one C atom of each (etu − H) ligand. Within this ring, the gold atoms are connected *via* short Au···Au contacts Au1···Au2 2.972(1) and Au1···Au3 2.974(1) Å to form a rhombus with angles of 71.28(2)° at Au1 and 108.79(7)° at Au2. A similar arrangement was observed in the gold(I) thioacetate tetramer $[Au(MeCS_2)]_4$.[4] In the current structure, the tetramers are further linked into chains parallel to the *z* axis by contacts Au2···Au3′ 3.176(1) Å (Fig. 2). The non-bonded S···N distances are S2···N12′ 3.23 and S1···N22′ 3.24 Å.

The existence of oxide complexes of Au(I) thus still remains to be demonstrated, whereas the (etu − H) ligand has been found at gold for the first time. Investigations of the reactivity of the (etu − H) tetramer are in progress.

We thank the Fonds der Chemischen Industrie (Frankfurt) for financial support.

Notes and references

‡ X-Ray structure determination: A colourless needle (*ca.* 0.1 × 0.02 × 0.01 mm) was mounted in inert oil on a glass fibre. Data were measured using Mo-Kα radiation on a Bruker SMART 1000 CCD diffractometer. Absorption corrections were based on multiple scans (program SADABS). Structure solution and refinement proved difficult because of pseudo-symmetry; the gold atoms simulate an additional pseudo-mirror plane. The sulfur atoms were refined isotropically because the two components of the double image thus generated are closely adjacent. Otherwise, the structure was refined [as a racemic twin with components 0.54(2): 0.46(2)] anisotropically on F^2 using all reflections (program SHELXL-97[5]). Hydrogen atoms were placed in calculated positions (assuming planarity at nitrogen) and refined using a riding model. An extensive set of restraints

were employed to improve stability of refinement. In view of the severe pseudo-symmetry, bond lengths should be interpreted with caution.

Received (in Columbia, Mo, USA) 17th March 1999, Accepted 20th May 1999

1,2-Bis(trimethylstannyl)tetrafluorobenzene reacts with chlorodimethylaluminium(III) to afford dimeric 1,2-bis-(chloromethylalumino)tetrafluorobenzene the structure of which has been determined by X-ray analysis.

Bidentate aluminium Lewis acids have recently emerged as promising tools for organic reaction catalysis[1] as well as for anion[2] and molecular recognition.[3] Experience gained in boron chemistry indicates that this class of compounds could also prove useful as activators for olefin polymerization with d^0-transition metal catalysts.[4,5] In this latter case, the use of strongly electron withdrawing substituents[6,7] appears to be required in order to yield very stable weakly coordinating anions.[8] As part of our continuing effort[9] in this direction, we now report the synthesis and characterization of dimeric 1,2-bis(chloromethylalumino)tetrafluorobenzene, a bidentate Lewis acid bearing a perfluorinated backbone.

1,2-Bis(trimethylstannyl)benzene has been shown to react with aluminium chlorides to yield 1,2-bis(alumino)benzene complexes.[10] In order to determine if a similar synthetic strategy could be applied to the preparation of perfluorinated systems, bis(trimethylstannyl)tetrafluorobenzene **1**[11] was allowed to react with chlorodimethylaluminium(III) in hexane (Scheme 1).† After 96 h, complete removal of the volatile components afforded a quantitative yield of **2**, which could be crystallized by slow evaporation of the solvent from a hexane solution. The identity of **2** was first inferred from the following salient NMR spectroscopic features.‡ ^{27}Al NMR indicated the presence of a tetra-coordinated aluminium center (δ 150, $\omega_{1/2}$ = 2700 Hz). The ^{19}F NMR spectrum allowed the possibility of fluoride activation[8] to be eliminated since two signals with multiplicity consistent with a AA′BB′ higher order spin system were observed. A high field singlet in both the ^{1}H and ^{13}C NMR spectrum could be assigned to the methylaluminium groups. While EI mass spectrometry allowed the detection of a peak corresponding to 1,2-bis(methylchloroalumino)tetrafluorobenzene, definitive identification of **2** was provided by a single crystal structure analysis (*vide infra*), which revealed its dimeric nature. In this respect, **2** differs from its perprotio analog 1,2-bis(methylchloroalumino)benzene which has been formulated as a monomer.[10] By analogy with the reaction of 1,2-bis(trimethylstannyl)benzene with chlorodimethylaluminium(III),[10] the formation of 1,2-bis(dimethylalumino)tetrafluorobenzene through trimethylstannyl chloride elimination could have been expected. In the present case however, the isolation of **2** is accompanied by formation of tetramethylstannane which was found among the volatile components of the reaction.

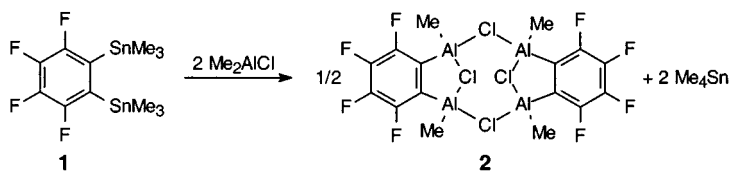
Compound **2** crystallizes in the monoclinic space group $P2_1/c$ with four molecules in the unit cell.§ Important bond length and angles are listed in Table 1. As shown in Fig. 1, the complex approachs C_{2v} symmetry and adopts a conformation reminiscent of a wings-up butterfly. Each aluminium center is tetrahedrally coordinated and lies close to the plane containing its corresponding phenylene ligand [Al(1) 0.129 Å, Al(2) −0.144 Å,Al(3) 0.179 Å, Al(4) 0.018 Å]. There are two types of bridging chlorine atoms in the coordination sphere of each aluminium center. The chlorine atoms Cl(12) and Cl(34) bridge neighboring aluminium centers within the 1,2-bis(alumino)tetrafluorobenzene sub-units. They are thus responsible for the formation of [C_2AlClAl] five-membered rings which approach planarity [Σ(endocyclic angles) 538.32 and 539.33°]. The chloride coordination angles Al(1)–Cl(12)–Al(2) and Al(3)–Cl(34)–Al(4) of 98.25(5) and 99.11(5)° can be compared to the value of 94.83(4)° observed in the structure of the related tin-based bidentate complex 1,2-bis(dimethylchlorostannyl)benzene·HMPA.[12] The Al–Cl bond distances of **2** fall within the narrow range of 2.272(1)–2.300(1) Å with an average value of 2.28 Å. The chlorine atoms Cl(13) and Cl(24) connect the two 1,2-bis(alumino)tetrafluorobenzene sub-units into a symmetrical dimer and form an eight-membered $(AlCl)_4$ ring which adopts a crown conformation. The cofacial tetrafluorophenylene rings are essentially parallel (dihedral angle 6.4°). The distance between their respective centroids is relatively short (3.56 Å) and indicates the presence of an interaction.

In view of the low stability and sometimes explosive behavior of perfluoroaryl aluminium derivatives,[6] the isolation



1 **2**

Scheme 1

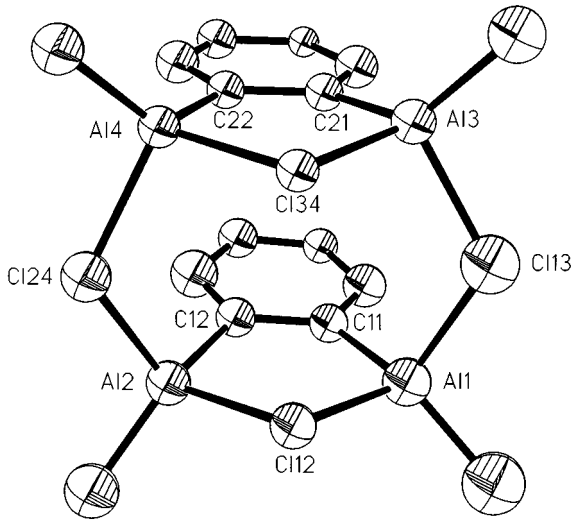


Fig. 1 ORTEP drawing of **2** with 50% probability ellipsoids; H and F atoms omitted for clarity.

of **2** is especially noteworthy. Analogous boron complexes such as 1,2-bis[bis(pentafluorophenyl)boryl]tetrafluorobenzene have been only very recently isolated.[13] Current studies are focussed on the use of 1,2-bis(alumino)tetrafluorobenzene complexes to abstract halides from a variety of substrates.

We thank the Department of Chemistry at Texas A&M University for making this work possible and Dr R. Shröck (Wacker) for the donation of precious chemicals. Financial support from the State of Bavaria/Technische Universität München and the DAAD (Promotionsstipendium, grant to M. T.) is gratefully acknowledged. The purchase of the X-ray diffractometer was made possible by a grant from the National Science Foundation (CHE-9115394); additional support for its purchase was provided by Georgetown University.

Notes and references

† *Synthesis of* **2**: *great caution should be exercised as aluminium complexes with perfluorinated aryl substituents have been reported to spontaneously explode.*[6] Chlorodimethylaluminium (374 mg, 4.04 mmol) was added to a solution of **1** (961 mg, 2.02 mmol) in hexane (5 mL) at room temp. The resulting solution was stirred for four days and filtered to remove traces of insoluble material. Evaporation of the solvent left a white residue that was exposed to a dynamic vacuum for 6 h at 50 °C. This procedure afforded a 95% yield (580 mg) of **2** (mp 79–80 °C). Elemental analysis. Calc. for $C_{16}H_{12}Al_4Cl_4F_8$: C, 31.69; H, 1.98. Found C, 31.05; H, 2.15%.

‡ *NMR data for* **1**, ^{1}H NMR (300 MHz, [$^2H_6$]benzene): δ −0.25 (s, 12 H, CH_3). ^{13}C NMR (75.4 MHz, [$^2H_6$]benzene: δ −8.4 (s, CAl) 126.8 (s, C-1/2) 140.7 (d, $^1J_{CF}$ 241.7 Hz, C-3/6) 152.1 (d, $^1J_{CF}$ 236.6 Hz, C-4/5). ^{19}F NMR (282.2 MHz, [$^2H_6$]benzene, $CFCl_3$ ext.); δ −121.22 (pseudo d, J_{FF} 19.5 Hz, 4 F, F-3/6) −151.88 (pseudo, d, J_{FF} 19.5 Hz, 4 F, F-4/5). ^{27}Al NMR (104.2 MHz, [$^2H_6$]benzene, $AlCl_3 \cdot 6H_2O$ ext.) δ 150 ($\omega_{1/2}$ 2700 Hz).

§ *Crystal and structure determination data for* **2**: X-ray data for **2** were collected at −100 °C on a Siemens SMART-CCD diffractometer using graphite monochromated Mo-Kα radiation (λ = 0.71073 Å). An irregularly shaped colorless plate of **2** *ca.* 0.1 × 0.3 × 0.4 mm in size was selected and mounted on a glass fiber with epoxy. The data were collected using 0.3°-wide ω-scans with a crystal to detector distance of 5.0 cm to yield a sphere (98% complete) of data to a resolution of 0.75 Å (2θ = 56.6°). The data was then truncated, on the basis of intensity statistics, at a resolution of 0.90 Å to yield a sphere (99.8% complete) of data ($2.08 \leqslant 2\theta \leqslant 23.23°$) composed of 19775 reflections (3549 unique, R_{int} = 0.0522). Other key crystallographic parameters are as follows: $C_{16}H_{12}Al_4Cl_4F_{12}$, M = 605.98, monoclinic, space group $P2_1/c$, a = 9.832(2), b = 9.855(2), c = 25.692(6) Å, V = 2484.9(9) Å^3, Z = 4, μ = 0.681 mm^{-1}. The structure was solved by direct methods and refined by full-matrix least squares against F^2 using the SHELXTL/PC (ver. 5.10) package. The refinement converged with residuals of $R1$ ($wR2$) = 0.0359 (0.0779) for 293 refined parameters and 3549 unique reflections [2505 with $I > 2\sigma(I)$].

MIB: an advantageous alternative to DAIB for the addition of organozinc reagents to aldehydes

William A. Nugent

DuPont Company, Central Research and Development, PO Box 80328, Wilmington, DE 19880-0328, USA. E-mail: william.a.nugent@usa.dupont.com

Received (in Corvallis, OR, USA) 14th May 1999, Accepted 10th June 1999

3-*exo*-Morpholinoisoborneol (MIB) catalyzes the addition of organozinc reagents to aldehydes in high enantiomeric excess and provides several advantages over the venerable amino alcohol ligand DAIB.

The addition of organozinc reagents to aldehydes catalyzed by enantiopure β-amino alcohols[1] represents the enantioselective counterpart of the Grignard addition reaction.[2] The extensive research on this transformation has been summarized in review articles.[3] The first ligand to provide high enantioselectivities in such reactions was 3-exo-dimethylaminoisoborneol (DAIB, **1b**) which was developed by Noyori and co-workers.[4] Despite the many alternative β-amino alcohol ligands[5] now available, interest in DAIB has remained remarkably high. Recent studies[6] provide detailed insight into the mechanism of DAIB-promoted additions and new applications of this venerable ligand continue to appear.[7]

While DAIB has enjoyed great success, three factors somewhat limit further extensions of this technology. (i) The most efficient synthesis, that developed by White and co-workers,[8] requires three steps for the conversion of parent amino alcohol **1a** to DAIB. (ii) DAIB is somewhat air-sensitive and slowly decomposes upon storage.[4] (iii) While DAIB-promoted addition of organozinc reagents to aromatic aldehydes proceeds in excellent enantiomeric excess, it has not yet proven possible to obtain similar ees in the case of α-branched aliphatic aldehydes.[4] Here we report that a simple structural modification circumvents these problems whilst retaining the desirable features of DAIB.

(2*R*)-(+)-3-*exo*-Aminoisoborneol (+)-**1a** was prepared by $LiAlH_4$ reduction of *anti*-(1*S*)-(−)-camphorquinone 3-oxime following the literature procedure.[8,9] Treatment of (+)-**1a** with commercial bis(2-bromoethyl) ether in the presence of excess Et_3N resulted in dialkylation of the amine nitrogen (Scheme 1).† Extractive work-up followed by crystallization from hexanes afforded (2*R*)-(+)-3-*exo*-morpholinoisoborneol **2** [(+)-MIB] as transparent crystals, mp 65–67 °C. The enantiomer (−)-MIB was prepared similarly from (−)-**1a**.

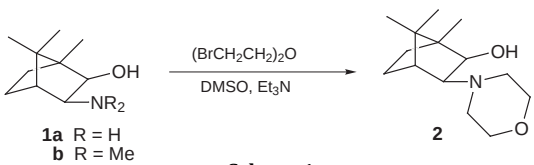
Like DAIB, MIB promotes the enantioselective addition of organozinc reagents to aldehydes (Scheme 2). The addition of Et_2Zn to a series of aldehydes under standard conditions (two-fold excess Et_2Zn in 2:1 hexane–toluene)‡ is summarized in Table 1. The reactions in Table 1 were quenched by addition of Ac_2O which quantitatively converts the intermediate zinc alkoxides to the corresponding acetate esters and allows direct analysis of the product mixture by chiral capillary column gas chromatography.[10] As exemplified by entries 1–4, addition of Et_2Zn to aromatic and heteroaromatic aldehydes proceeded cleanly with enantiomeric excesses similar to those reported using DAIB. Moreover, we were delighted to find that addition of Et_2Zn to several α-branched aliphatic aldehydes (entries 6–10) also proceeded in 97–99% enantiomeric excess. Only in the case of the straight-chain aliphatic aldehyde hexanal did the ee begin to erode. In all cases in Table 1 the major enantiomer of the product had the *R* absolute configuration, thus the sense of chirality obtained from (+)-MIB is the same as that obtained from (+)-DAIB.

Table 1 Enantioselective addition of Et_2Zn to aldehydes catalyzed by (+)-MIB[a]

Entry	Aldehyde	MIB/ mol%	*T*/°C	*t*/h	Yield (%)[b]	Ee (%)[b]
1	Benzaldehyde	2	0	3	98	98
2	*m*-Tolualdehyde	2	0	3	97	98
3	*p*-Fluorobenzaldehyde	5	0	3	98	98
4	3-Furaldehyde	5	0	6	91	97
5	Hexanal	5	0	3	96	91
6	Isobutyraldehyde	5	0	3	94	99
7	Cyclohexanecarboxaldehyde	5	0	3	94	99
8	2-Ethylbutyraldehyde	5	25	18	92	99
9	Cyclopropanecarboxaldehyde	5	0	3	91	98
10	Trimethylacetaldehyde	5	25	24	62	97

[a] All reactions contained aldehyde (3.0 mmol) and Et_2Zn (6.0 mmol) in 2:1 hexane–toluene (9 ml); for details see note ‡. [b] Determined by chiral capillary column gas chromatography on Cyclodex B stationary phase (J&W Scientific); in all cases (*R*)-enantiomer formed preferentially.

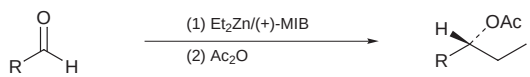
The reduced yield observed for addition of Et_2Zn to the tertiary aliphatic aldehyde trimethylacetaldehyde requires some comment. The limited yield can be traced to competing reduction of the the aldehyde to the zinc alkoxide of neopentyl alcohol which is subsequently acetylated under our reaction conditions (Scheme 3). The formation of minor amounts of BnOH as a side-product of DAIB-catalyzed addition of Et_2Zn to benzaldehyde has been noted by Noyori and co-workers.[11] In our experience, detectable amounts of primary alcohol are invariably formed during addition of organozinc reagents to aldehydes in the presence of β-amino alcohols. This side-reaction is most severe in the case of sterically bulky aldehydes bearing tertiary alkyl substituents. In contrast, for the other aldehydes in Table 1, this reductive pathway occurs to the extent of 2% or less for aromatic and primary aliphatic aldehydes (entries 1–5) and 5% or less for secondary aliphatic aldehydes (entries 6–9).



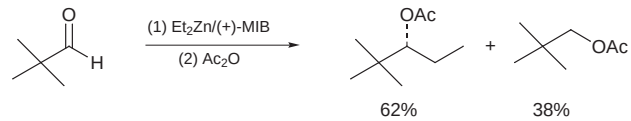
1a R = H
b R = Me

2

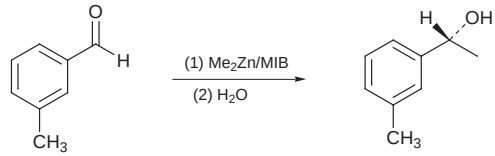
Scheme 1



Scheme 2



Scheme 3



Scheme 4

MIB can also be used to effect the addition of Me_2Zn to aldehydes although longer reaction times are required to compensate for the lower reactivity of this organozinc reagent. Addition of Me_2Zn to *m*-tolualdehyde [18 h, room temperature, 5% (+)-MIB] afforded (*R*)-(+)-1-(*m*-tolyl)ethanol§ in 95% ee and 88% isolated yield after flash chromatography (Scheme 4).

It is also noteworthy that the crystalline nature of MIB imparts greater air-stability as compared with DAIB. A sample of MIB stored under air at ambient conditions for three months showed no degradation of spectroscopic properties nor catalytic performance when compared with freshly prepared material. Given the several advantages of MIB, we suggest that it should be considered as an alternative ligand for reactions where DAIB has previously been utilized.

Notes and references

† *Preparation* of (+)-**2**: Amino alcohol (+)-**1a** (4.53 g, 26.8 mmol) was dissolved in DMSO (25 ml) and Et_3N (10 ml). A solution of di(2-bromoethyl) ether (8.07 g, 90% pure, 31.3 mmol) in DMSO (20 ml) was added dropwise. After 72 h the mixture was added to 250 ml water and 60 ml 1 M NaOH and was extracted into Et_2O (3 × 100 ml). After removal of solvent at reduced pressure the product was taken up in Et_2O, extracted into 1 M HCl (50 ml), released with NaOH, and again extracted into Et_2O. After removal of volatiles, the residue was dissolved in hexanes (4 ml per g of crude product), filtered and cooled to −30 °C to produce **2** (2.95 g, 46%) as a white crystalline solid, mp 65–67 °C. ($C_{14}H_{25}NO_2$: Calc: C, 70.25; H, 10.53; N, 5.85; found: C, 70.18; H, 10.83, N, 5.94%). $\delta_H(C_6D_6)$ 0.69 (s, 3 H), 0.73 (m, 1 H), 0.88 (m, 1 H), 1.04 (s, 3 H), 1.15 (s, 3 H), 1.31 (td, 1 H), 1.52 (m, 1 H), 1.67 (d, 1 H), 1.99 (d, 1 H), 2.13 (br, 2 H), 2.31 (br, 2 H), 3.32–3.42 (m, 5 H total), 3.92 (br d, 1 H); $\delta_c(C_6D_6)$ 11.88, 21.10, 22.19, 27.99, 32.56, 45.35, 46.64, 49.52, 66.82, 73.37, 79.03 (as in the case of **1b**, one ^{13}C resonance is too broad to observe at room temperature); $[\alpha]_D^{25}$ +4.4, (*c* = 2.03, MeOH).

‡ *Typical procedure*: A solution of freshly distilled aldehyde (3.00 mmol), toluene (3.0 ml), internal standard (chlorobenzene or *tert*-butybenzene) and (+)-**2** (14.4 mg, 0.060 mmol) was cooled to 0 °C. After dropwise addition of 1.0 M Et_2Zn in hexane solution (6.0 ml, 6.0 mmol), the mixture was maintained at 0 °C for 3 h. Ac_2O (1.2 ml, 13 mmol) was added and the mixture was allowed to stand overnight prior to capillary column GC analysis on a Cyclodex B stationary phase (J&W Scientific).

§ *Optical rotation* data: $[\alpha]_D^{25}$ +40.5 (*c* = 1.48, EtOH), lit.[12] for (*R*)-enantiomer, $[\alpha]_D^{21}$ +40.4 (*c* 0.530, EtOH), lit.[12] for (*S*)-enantiomer, $[\alpha]_D^{21}$ −41.9 (*c* = 0.500, EtOH).

Asymmetric synthesis of the core cyclopentane of viridenomycin

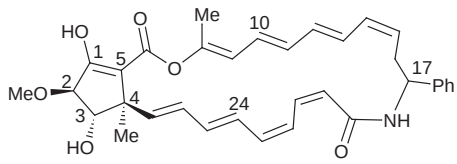
Mark P. Arrington and A. I. Meyers*

Department of Chemistry, Colorado State University, Fort Collins, Colorado 80523-1872, USA.
E-mail: aimeyers@lamar.colostate.edu

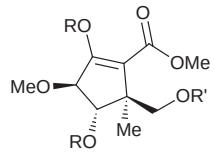
Received (in Corvallis, OR, USA) 20th April 1999, Accepted 28th May 1999

The fully substituted cyclopentene ring with three stereogenic centers has been efficiently constructed for the first time using chiral bicyclic lactams, the insertion of the quaternary center being the key step; ring opening of chiral sulfates to the correct 1,2-dihydroxy substituents also played a major role in reaching 1 in suitable form (18) for further study.

Recently, a natural product was isolated from the culture broth of an actinomycete identified as *Streptomyces gannmycicus*, and upon structure determination, it was found that this compound was identical to viridenomycin, a natural product that had been known for some time, but which had not been structurally characterized.[1] Viridenomycin has been shown to



Viridenomycin



1

act as an antifungal antibiotic, and additionally has prolonged the survival of mice infected with B16 melanoma. It is structurally very similar to the natural product hitachimycin,[2,3] although viridenomycin has not yet been the subject of any reported synthetic efforts. It has, as its core, a highly functionalized cyclopentene ring **1** with three contiguous stereogenic centers, one of which is quaternary. Additionally, the absolute stereochemistry of viridenomycin is still unknown with the stereochemistry at C-17 still in question.

With our interest in chiral, bicyclic lactams as templates for a variety of enantiomerically pure compounds containing quaternary stereocenters, the C-4 position of viridenomycin suggested the possibility of an asymmetric synthesis.

The requisite chiral bicyclic lactam **2** (Scheme 1) was readily prepared by condensation of levulinic acid and enantiomerically pure natural valinol.[4] Treatment of **2** with LDA followed by MeI quench gave a mixture of products, containing primarily the desired α-methyl bicyclic lactam **3a**, in addition to some of the α,α-dimethylated compound **3b**.[5] The latter was only partially separable from the desired compound, so the crude product was simply carried on and directly treated again with LDA. The resulting enolate was quenched with $ClCO_2Me$, giving **3c** with high (> 98%) diastereoselectivity (NMR). Again, the α,α-dimethylated derivative **3b** was difficult to remove, and the mixture of **3b** and **3c** was carried forward. It had been previously observed[6] that acylating agents such as acid chlorides approached the lactam enolate in an *exo* fashion, so an *exo* approach to **3c** was hypothesized for the present transformation. The stereochemistry would be confirmed at a later time.

Reduction of the quaternary lactam ester **3c** with $NaBH_4$ in EtOH furnished the corresponding alcohol **4**, in high overall yield (65%) for the first three steps (**2**–**4**). The alcohol **4** was now easily separable from the accompanying α,α-dimethyl material **3b**. An X-ray crystal structure of alcohol **4** was obtained and confirmed that the hydroxymethyl group in **4** was indeed on the β-face of the molecule. This is the first published example of the lactam enolate of **2** acylating preferentially from the *exo* face. The hydroxymethyl side chain of **4** was transformed to its benzyl ether **5** in 96% yield, and the chiral auxiliary removed by reduction–hydrolysis to yield the cyclopentenone **6** with high efficiency (76%) for the three step process (**5** → **6**).

Studies were undertaken to access the allylic alcohol **7a**, *via* various reducing agents in anticipation of subsequent olefin dihydroxylation, to **9**. Since the benzyl protected hydroxymethyl side chain may be considered larger than the methyl group in **6**, it was expected that reducing agents should approach preferentially from the bottom face of the cyclopentenone **6**, to yield the β-OH group. It was found (Scheme 2) that the highest stereoselectivity could be realized (3.5 : 1) utilizing DIBAL-H[7] to afford **7a**. This modest selectivity was considered acceptable because the major isomer **7a** could be isolated in good (78%) yield, and the undesired α-OH isomer **7b** was also recyclable by oxidizing to the enone **6** with CrO_3 in high (86%) yield.

Repetitive reductions with DIBAL-H produced additional quantities of **7a**. The latter was converted to its *p*-methoxybenzyl (PMB) ether **8**, (KH, PMBCl) in 95% yield. Osmylation proceeded smoothly (90%) to give an inseparable mixture of diastereomeric diols **9** with relatively high (10 : 1) selectivity. The protons at C-2, C-3 (viridenomycin numbering) in **9** were sufficiently discernible in the NMR to determine the level of selectivity. Cyclic sulfate formation was accomplished using the Sharpless technique,[8,9] producing a single isomer (**10**) in

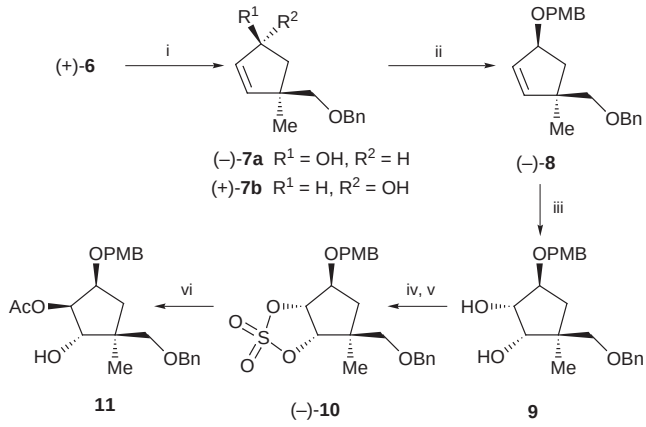
Scheme 1 *Reagents and conditions*: i, LDA, MeI, THF, −78 °C → rt; ii, LDA, $ClCO_2Me$, THF, −78 °C → rt (50 : 1 dr); iii, $NaBH_4$ (7 equiv.), EtOH, 0 °C → rt (65%, 3 steps); iv, NaH, BnCl, DMF, 0 °C → rt (95%); v, Red-Al (6.6 equiv.), THF, −25 °C, 2 d; vi, $NBu_4NH_2PO_4$ (50 equiv.), EtOH–H_2O (1 : 1); vii, KOH (0.1 equiv.), THF (76%, 3 steps).

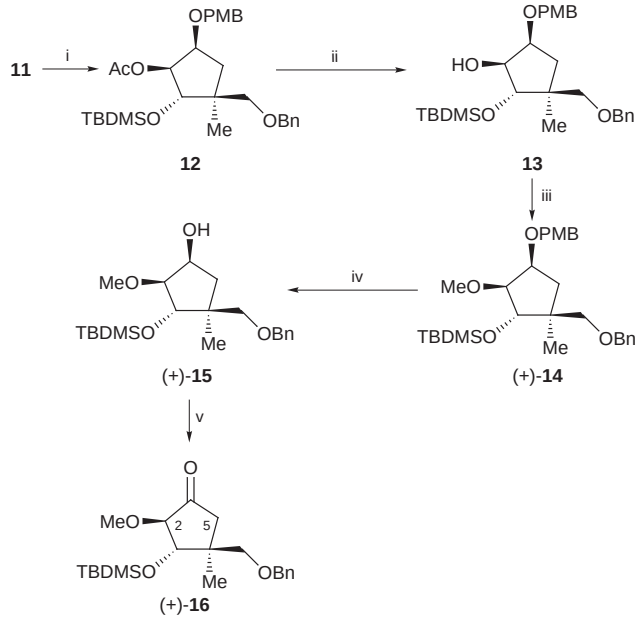


Scheme 2 *Reagents and conditions*: i, DIBAL-H (1.5 equiv.), THF. −78 °C (99%, 3.5:1 dr); ii, KH, (2.2 equiv.) PMBCl, DMF, 0 °C (95%); iii, $K_2OsO_2{\cdot}H_2O$, NMO, acetone–H_2O (3:1) (90%, 10:1 dr); iv, $SOCl_2$, Et_3N, CH_2Cl_2, 0 °C; v, $RuCl_3{\cdot}H_2O$, $NaIO_4$, CCl_4–H_2O–MeCN (1:1.4:1) (85%, 2 steps); vi, CsOAc (5 equiv.), DMF, 40 °C, then H_2SO_4, THF (99%, 9:1 dr).

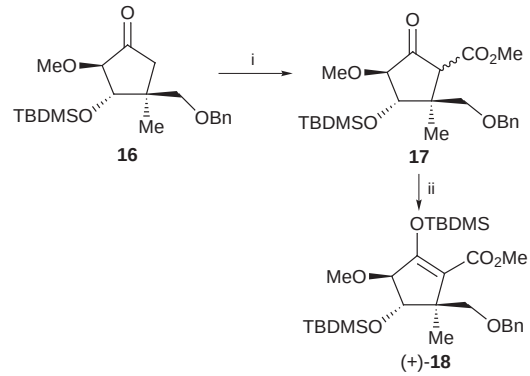
satisfactory (77%) yield for the two steps. Caesium acetate opening of the sulfate **10** occurred with high regioselectivity (10:1) and yield (99%) to furnish the acetoxy alcohol **11** as the major regioisomer. In this case, the regioisomeric products were not separable and thus the mixture was carried forward.

Protection of the alcohol **11** (Scheme 3) was accomplished in excellent yield (96%) with TBDMSCl and imidazole affording the acetate **12** which was removed by K_2CO_3 in MeOH to give a quantitative crude yield of **13**. Methyl ether formation was accomplished on crude **13** in the usual manner to furnish methoxy derivative **14**. At this stage the regioisomeric impurity in **11** obtained by opening the cyclic sulfate was found to be separable and the slightly lower yield of this step (86%) reflects the removal of the undesired isomer.

It was now necessary to remove the PMB ether in **14**. Oxidative cleavage with CAN resulted in several products, thus



Scheme 3 *Reagents and conditions*: i, TBDMSCl, imidazole, DMAP (91%); ii, K_2CO_3, MeOH (100%); iii, NaH (2.5 equiv.), MeI, 0 °C (86%); iv, DDQ (1.3 equiv.), CH_2Cl_2–H_2O (5:1) (93%); v, $(COCl)_2$, DMSO, Et_3N, −78 °C (91%).



Scheme 4 *Reagents and conditions*: i, LDA, HMPA (25 equiv.), $NCCO_2Me$, −78 → −20 °C; ii, TBDNCl, imidazole, DMAP (40%, 2 steps).

the cleavage was performed with DDQ, which quickly removed the PMB group in good yield (93%) and gave the free C-1 alcohol **15**. Mild oxidation under Swern conditions produced the desired ketone **16** (91%).

The enolate of **16** was generated in the presence of HMPA[10] as cosolvent and warmed to −40°C before quenching with NCO_2Me. Enolate formation generated small amounts of the epimerized **16** and elimination products. However, the desired product **17** was the major constituent of the mixture, along with still significant quantities of undesired products. It appears from all of these experiments that the source of epimerization was not initial generation of the incorrect enolate, but was due to facile proton transfer processes after the addition of the electrophile.

Having obtained a quantity of the carboxylated derivative, **17**, attention was turned to isolation of the enol ester **18**, the intended target of this study (Scheme 4). Attempts to silylate **17** gave an enol ether, which was poorly characterized. By combining the two steps from **16** to **18** (no attempt was made to purify the β-keto ester **17**), the crude material was directly silylated and gave an overall yield of **18** of 40%. With the acquisition of **18**, all of the correct regio- and stereo-chemical features have been installed and the substituents at the 4- and 5-positions are in a position to further extend the synthesis to viridenomycin itself.

Further studies are in progress to introduce into **18** the 24-membered polyene ring of viridenomycin.

We are grateful to the NIH for financial support of this work.

Copper zinc oxide catalysts for ambient temperature carbon monoxide oxidation

S. H. Taylor,[a] G. J. Hutchings[a] and A. A. Mirzaei[b]

[a] *Cardiff University, Department of Chemistry, PO Box 912, Cardiff, UK CF10 3TB. E-mail: taylorsh@cf.ac.uk*

Received (in Cambridge, UK) 29th April 1999, Accepted 16th June 1999

Copper zinc oxide catalysts are effective for the ambient temperature carbon monoxide oxidation and display higher specific activity than the current commercial hopcalite catalyst.

The catalytic oxidation of carbon monoxide to carbon dioxide at ambient temperature and pressure is an important process for respiratory protection. In particular, the process is widely adopted by mining industries and has also found applications in deep sea diving and space exploration. Furthermore, new applications for the process such as reducing the deactivation of carbon dioxide lasers and applications for new sensors have been explored. In the last 10 years low temperature carbon monoxide oxidation has received renewed attention since Haruta *et al.* demonstrated that gold, highly dispersed on various oxides, forms catalysts active at sub-ambient temperatures.[1] However, the most widely used catalyst is the mixed copper manganese oxide hopcalite catalyst, $CuMn_2O_4$, first examined in 1921.[2,3] Both the gold based and the copper manganese oxide catalysts are important in terms of their high activity at ambient temperatures. It is the observation of high activity at low temperature which has stimulated significant recent interest in these types of catalysts.[4,5] It is interesting to consider whether other catalysts are capable of sustaining carbon monoxide oxidation at ambient temperature. Here, we present the first results showing that copper zinc oxide catalysts, prepared by co-precipitation, can display much higher activity for reaction than the current commercial hopcalite catalysts.

Catalysts were prepared using a co-precipitation technique under different atmospheres, including air, nitrogen, hydrogen and carbon dioxide. Aqueous solutions of $Cu(NO_3)_2{\cdot}3H_2O$ (0.25 mol l^{-1} Aldrich 99.999%) and $Zn(NO_3)_2{\cdot}6H_2O$ (0.25 mol l^{-1} Aldrich 99.999%) were pre-mixed in a 2:1 ratio. The resulting solution was stirred and heated to 80 °C in a round bottomed flask fitted with a condenser and equilibrated under a gas flow of 20 ml min^{-1} for 5 min. An aqueous solution of Na_2CO_3 (0.25 mol l^{-1} Aldrich 99.999%) was added to the continuously stirred flask until a pH in the range 6.8–7.0 was attained. At this stage the gas flow was passed through the solution and the precipitate allowed to age between 60 and 300 min. After ageing the precipitate was recovered by filtration, washed several times with hot distilled water and dried in air (120 °C for 16 h) and subsequently calcined in static air (550 °C for 6 h) to produce the catalyst. The hopcalite catalyst was also prepared in a similar manner using co-precipitation. The catalysts were characterised by powder X-ray diffraction. and nitrogen adsorption to determine the BET surface area.

The catalysts were tested for CO oxidation using a fixed bed laboratory microreactor. Typically CO (5% CO in He, 5 ml min^{-1}) and O_2 (50 ml min^{-1}) were fed to the reactor at controlled rates using mass flow controllers and passed over the catalyst (100 mg) at 20 °C. The products were analysed using on-line gas chromatography with a 3 m packed Carbosieve column. These conditions are equivalent to a total gas hourly space velocity of 33 000 h^{-1} and CO concentration of 0.45 vol%. Under these conditions the adiabatic temperature rise is < 7 °C and consequently the reactor temperature could readily be maintained isothermally at 20 °C.

All the copper zinc oxide catalysts, irrespective of the preparation atmosphere, showed appreciable activity for the oxidation of carbon monoxide at 20 °C. Blank reactions under the same conditions demonstrated no conversion. All the copper zinc oxide catalysts showed an initial decrease in activity over the first 30 min on line, but after this initial period steady state activity was maintained over the 500 min test period. Representative data for the catalysts prepared in an air atmosphere are shown in Fig. 1. The steady state activity of the aged copper zinc oxide catalysts derived from different atmospheres, and comparison with a copper manganese oxide catalyst are shown in Table 1.

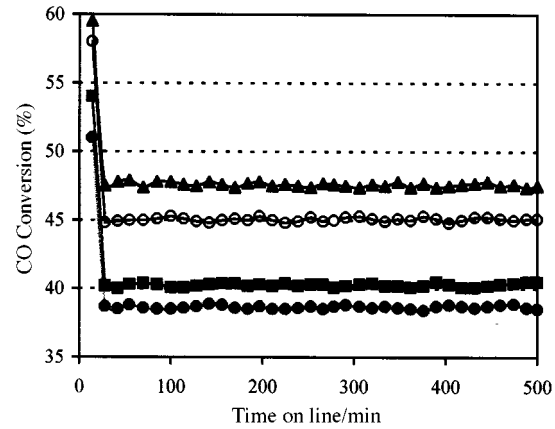

Fig. 1 Carbon monoxide conversion at 20 °C for aged catalysts prepared using air *vs.* time on line (GHSV = 33 000 h^{-1}, 100 mg catalyst, 0.45 vol% CO: Ageing time: (●) 60, (■) 120, (▲) 180 (○) 300 min.

The atmosphere used during co-precipitation has a marked influence on the activity of the copper zinc oxide catalysts. Regardless of ageing time, the general trend in terms of carbon monoxide conversion is air > hydrogen ≈ nitrogen > carbon dioxide. Increasing the catalyst ageing time up to 180 min increased the carbon monoxide conversion over all the copper zinc oxide catalysts. Increasing the ageing time to 300 min resulted in a slight decrease in conversion for the catalyst prepared in an air atmosphere, however, the catalysts prepared under the other atmospheres continued to show an increase in conversion. The catalyst surface areas were of similar magnitude regardless of the preparation atmosphere, however, there is a general increase in surface area as a result of increased ageing time. Although the overall conversion increases with ageing time the specific activity shows a gradual decrease.

Under our reaction conditions comparison of the copper zinc oxide catalyst has been made with the highly active copper manganese oxide catalyst.[6] The copper zinc oxide catalysts aged for < 180 min are all considerably more active than the copper manganese oxide catalysts. For example, the specific activity of copper zinc oxide aged for 60 min is greater than the

Table 1 Steady state activity for ambient temperature carbon monoxide oxidation (GHSV = 33 000 h^{-1}, 100 mg catalyst, 0.45 vol% CO)

Catalyst	Ageing time/min	Preparation atmosphere	Surface area/ $m^2\ g^{-1}$	CO conversion 10^{-16} (%)	Rate/molecules m^{-2}

CuO/ZnO	120	N_2	32	33.2	1.16
$CuMn_xO_y$	120	Air	26	11.8	0.51
CuO/ZnO	180	Air	46	47.5	1.16
CuO/ZnO	180	CO_2	38	25.6	0.76
CuO/ZnO	180	H_2	41	40.2	1.10
CuO/ZnO	180	N_2	40	38.6	1.08
$CuMn_x/O_y$	180	Air	27	20.4	0.84
CuO/ZnO	300	Air	42	45.0	1.20
CuO/ZnO	300	CO_2	40	28.8	0.81
CuO/ZnO	300	H_2	45	42.4	1.06
CuO/ZnO	300	N_2	43	41.4	1.08
$CuMn_xO_y$	300	Air	30	49.5	1.85

corresponding copper manganese oxide catalyst by a factor >3.8. It is only once the copper manganese oxide catalyst has been aged for 300 min that it demonstrates higher activity. The optimum ageing time for the copper manganese oxide catalyst is 720 min showing a specific oxidation rate greater than the best copper zinc oxide by a factor of *ca.* 2.2.

Characterisation of the catalysts by powder X-ray diffraction showed that the preparation atmosphere and ageing process strongly influence the structure of the catalyst precursor. Hydrozincite $[Zn_5(CO_3)_2(OH)_6]$, gerhardite $[Cu_2(OH)_3NO_3]$, malachite $[Cu_2CO_3(OH)_2]$, aurichalcite $[(Cu,Zn)_5(CO_3)_2(OH)_6]$ and rosasite $](Cu,Zn)_2CO_3(OH)_2]$, were all determined and the relationship between preparation conditions and structure is considered to be complex. However, after calcination all the catalysts consisted of CuO and ZnO. The particle sizes of the oxides determined by X-ray line broadening decreased with increased ageing time, this effect was most marked with the catalyst prepared under air and carbon dioxide atmospheres, whilst under nitrogen and hydrogen atmospheres the effect was relatively minor. Temperature programmed reduction using hydrogen indicates that there may be some mixed oxide formation in the calcined catalyst. The catalysts were all similar by transmission electron microscopy, but subtle differences indicate that copper/zinc oxide solid solutions were formed and this is consistent with the evidence from temperature programmed reduction. The origin of the low temperature oxidation activity is unclear, but it appears that the highly dispersed CuO and ZnO, and the presence of solid solution phases formed during the controlled precipitation and ageing process are important.

At this stage no attempt has been made to optimise the activity of the copper zinc oxide catalysts, but it is clear that these catalysts show promising performance for the oxidation of carbon monoxide under ambient conditions. To the best of our knowledge this is the first reported study of copper zinc oxide catalyst prepared by co-precipitation under different atmospheres for the oxidation of carbon monoxide at low temperatures and these systems are now worthy of further investigation.

We thank Chris Kiely and Dave Whittle (University of Liverpool) for electron microscopy and Richard Joyner (Nottingham Trent) for useful discussion.

Evidence for the participation of a high-valent iron–oxo species in stereospecific alkane hydroxylation by a non-heme iron catalyst

Kui Chen and Lawrence Que, Jr.*

Department of Chemistry and Center for Metals in Biocatalysis, University of Minnesota, Minneapolis, Minnesota 55455, USA. E-mail: que@chem.umn.edu

Received (in Bloomington, IN, USA) 1st March 1999, Accepted 10th June 1999

The incorporation of ^{18}O from $H_2{}^{18}O$ into the product of stereospecific alkane hydroxylation by $[Fe^{II}(bpmen)(CH_3CN)_2](ClO_4)_2$–$H_2O_2$ provides the first strong evidence for the participation of a high-valent iron–oxo species in the mechanism of a non-heme iron catalyst.

The mechanisms for stereospecific hydrocarbon oxidation catalysed by iron-containing metalloenzymes have attracted significant interest in the chemical and biochemical communities.[1–3] Discrete high-valent iron-oxo species, formally Fe^V=O, have been proposed as oxidants in these reactions, *i.e.* a $[(Por\cdot)Fe^{IV}=O]^+$ species in alkane and alkene oxidation by cytochrome P450[1] and an $Fe^{IV}{}_2(\mu\text{-}O)_2$ intermediate in methane hydroxylation by methane monooxygenase.[4] In synthetic efforts to mimic these biological catalysts, both heme[5] and non-heme iron complexes[6,7] have been shown to be capable of catalysing alkane hydroxylation. Strong evidence has been obtained for the involvement of high-valent metal–oxo species on reactions involving some heme complexes and H_2O_2 from $H_2{}^{18}O$ exchange experiments,[8–11] but not for corresponding non-heme iron catalysts.[12,13] We have previously reported the first and thus far only example of stereospecific alkane hydroxylation by a non-heme iron catalyst, $[Fe^{II}(tpa)(CH_3CN)_2](ClO_4)_2$ **1** [tpa = tris(2-pyridylmethyl)amine, Fig. 1], in combination with H_2O_2.[7] Reported here are further studies on alkane hydroxylation by H_2O_2 catalysed by a related iron complex, $[Fe^{II}(bpmen)(CH_3CN)_2](ClO_4)_2$ **2** [bpmen = *N*,*N*′-dimethyl-*N*,*N*′-bis(2-pyridylmethyl)ethylene-1,2-diamine, Fig. 1], which exhibits higher catalytic activity. The incorporation of $H_2{}^{18}O$ into the oxidation product provides the first evidence that a non-heme iron catalyst can hydroxylate alkanes stereospecifically *via* a high-valent iron–oxo species.

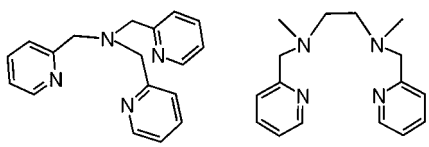

Fig. 1 Tetradentate ligands for non-heme Fe^{II} complexes **1** and **2**.

Complex **2** can be prepared from the reaction of equimolar amounts of $Fe^{II}(ClO_4)_2{\cdot}6H_2O$ and the ligand bpmen[14] in CH_3CN under Ar. Addition of diethyl ether into the CH_3CN solution gives a red solid, which can be recrystallised from CH_3CN–diethyl ether at 4 °C to afford red crystals suitable for crystallographic analysis (Fig. 2).† The crystal structure of **2** shows an iron(II) coordination sphere like that of **1**[15] with two solvent molecules in a *cis* geometry.

The alkane hydroxylation ability of **2** is superior to that of **1**. Under syringe pump conditions in CH_3CN solution in air,[7] 0.7 mM **2** catalyses the oxidation of cyclohexane with 10 equiv. H_2O_2 to afford 5.6(5) turnover (TN) of cyclohexanol and 0.7(2) TN of cyclohexanone within 30 min. The products account for 70% of the oxidant H_2O_2, which is much higher than the 40% conversion exhibited by **1**.[7] The high alcohol/ketone ratio obtained for **2** in air contrasts the much smaller ratios diagnostic of radical chain autoxidation found for other nonheme iron catalysts[6] and suggests the participation of a metal-based oxidant, as proposed in **1**–H_2O_2.[7]

Further mechanistic insight comes from ^{18}O-labeling experiments in the hydroxylation of cyclohexane.‡ With 10 equiv. H_2O_2 in the presence of 1000 equiv. $H_2{}^{18}O$, 18(3)% of the oxygen atom in the cyclohexanol product is ^{18}O-labeled. The complementary experiments with 10 equiv. $H_2{}^{18}O_2$ in the presence of 1000 equiv. H_2O show 84(4)% ^{18}O-labeled alcohol. These results demonstrate that O_2 is not involved in the reaction of **2**–H_2O_2. Furthermore, ^{18}O-incorporation can be significantly affected by the amount of $H_2{}^{18}O$ in the reaction solution. For example, with 200 equiv. $H_2{}^{18}O$, only 13(1)% of the cyclohexanol product is ^{18}O-labeled; and this value decreases further to 5.8(1)% in the presence of 50 equiv. $H_2{}^{18}O$. These observations show that the mechanism of alkane hydroxylation by **2**–H_2O_2 involves an oxidant capable of oxygen atom exchange with H_2O in competition with C–O bond formation.

The **2**–H_2O_2 combination is also capable of stereospecific alkane hydroxylation. The reaction of *cis*-1,2-dimethylcyclohexane with **2**–H_2O_2 affords 4.6(1) TN of *cis*-1,2-dimethylcyclohexanol and no isomeric *trans*-alcohol product. More interestingly, 26(1)% of the *cis*-alcohol product is ^{18}O-labeled when the reaction is carried out in the presence of 10 equiv. H_2O_2 and 1000 equiv. $H_2{}^{18}O$. Therefore, the oxidant responsible for stereospecific alkane hydroxylation can undergo oxygen-atom exchange with H_2O. Since the rate of epimerization of tertiary carbon radicals is quite fast (10^9 s^{-1}),[16] ^{18}O-exchange very likely happens prior to the interaction of the iron-based oxidant and the alkane C–H bond.

A mechanism for alkane hydroxylation by **2**–H_2O_2 combination is proposed based on the recent characterisation of Fe^{III}–OOH intermediates for several non-heme iron complexes

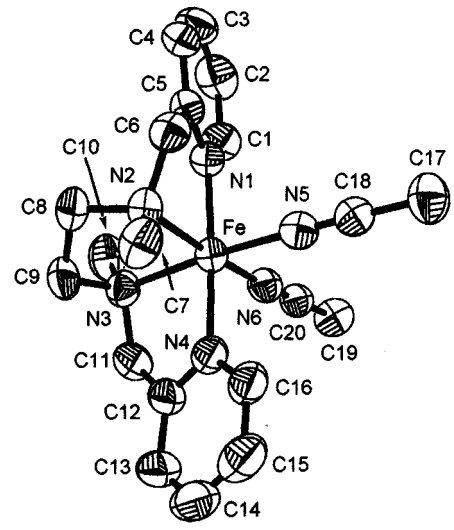

Fig. 2 Thermal ellipsoid plot of complex **2**. Ellipsoids are drawn at the 50% probability level. Hydrogen atoms are omitted for clarity.

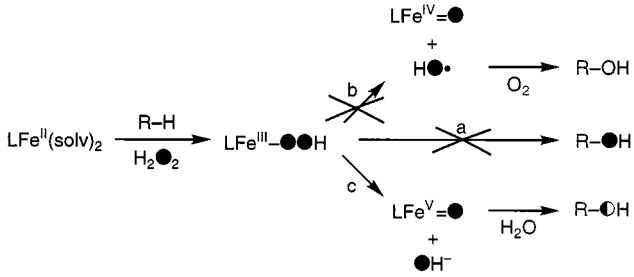

Scheme 1

(Scheme 1).[6j,7,17] Such an intermediate could attack the substrate directly [Scheme 1(a)] or undergo prior O–O bond scission. For the latter cases, homolysis of the O–O bond would afford Fe^{IV}=O and HO· [Scheme 1(b)], while heterolysis would give rise to Fe^{V}=O and HO^- [Scheme 1(c)]. The stereospecificity of *cis*-1,2-dimethylcyclohexane hydroxylation and lack of O_2 involvement in the reaction exclude the participation of hydroxyl radicals.[18] The observation of solvent exchange eliminates the possibility of direct attack of the Fe^{III}–OOH intermediate on the alkane substrate, since solvent exchange could not occur with such a species. The remaining mechanistic option is the heterolysis of the O–O bond to form a formally Fe^{V}=O species analogous to the $[(Por\cdot)Fe^{IV}=O]^+$ species observed for heme peroxidases and proposed for cytochrome P450.[1] Such a species would be capable of solvent exchange, provided its lifetime is long enough.[8–11, 19] Since solvent exchange is indeed observed for the stereospecific oxidation of *cis*-1,2-dimethylcyclohexane, a formally Fe^{V}=O intermediate must be involved in the **2**–H_2O_2 reaction. Complex **2** thus represents the first non-heme iron alkane hydroxylation catalyst for which evidence for a high-valent iron–oxo species has been obtained. Further studies into the nature of this species are in progress.

First η^1-ligated 2,4,6-tri-*tert*-butyl-1,3,5-triphosphabenzene complexes and the remarkable trihydration reaction of *trans*-$[PtCl_2(PMe_3)(P_3C_3Bu^t_3)]$ to *cis*-$[PtCl(PMe_3)(P_3O_3C_3H_5Bu^t_3)]$, containing the novel $CH(Bu^t)PH(O)C(Bu^t)PH(O)CH(Bu^t)P(O)$ ring system

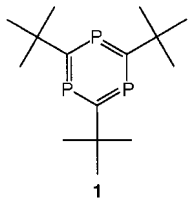
Received (in Cambridge, UK) 10th May 1999, Accepted 9th June 1999

The first examples of η^1-complexes of 2,4,6-tri-*tert*-butyl-1,3,5-triphosphabenzene are described, namely *trans*-$[PtCl_2(PR_3)(P_3C_3Bu^t_3)]$ (PR_3 = PMe_3, PEt_3, PMe_2Ph or $PMePh_2$) and their structures established by ^{31}P and ^{195}Pt NMR spectroscopy. The unusual molecular structure of *cis*-$[PtCl(PMe_3)(P_3O_3C_3H_5Bu^t_3)]$, containing the novel $CH(Bu^t)PH(O)C(Bu^t)PH(O)CH(Bu^t)P(O)$ ring system, which is formed by the trihydration of *trans*-$[PtCl_2(PMe_3)(P_3C_3Bu^t_3)]$ is also reported.

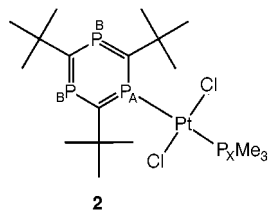
There is considerable current interest in the synthesis and ligating properties of compounds containing P–C multiple bonds.[1–4] Very recently[5,6] synthetic routes have been developed to 2,4,6-tri-*tert*-butyl-1,3,5-triphosphabenzene **1** and its structure and PE spectrum have just been reported.[7]



1

Although η^6-arene transition metal complexes occupy a key position in the development of contemporary organometallic chemistry, heteroarenes of the type EC_5R_5 (E = N, P, As, Sb or Bi) can also form η^1-ligated metal complexes unless bulky substituents such as *tert*-butyl groups in the 2,6-positions disfavour such interactions.[8] To date, no examples of η^1-bonded 2,4,6-tri-*tert*-butyl-1,3,5-triphosphabenzene complexes have been reported and only a handful of η^6-complexes of **1** are known such as the triple decker Sc(I) complex $[Sc_2(\eta^5\text{-}P_3C_2Bu^t_2)_2$ $(\eta^6\text{-}P_3C_3Bu^t_3)]$ the structure of which has been established by X-ray crystallography[9] and $[ML_n(\eta^6\text{-}P_3C_3Bu^t_3)]$, [$ML_n$ = $Mo(CO)_3$, $W(CO)_3$, $Mn(\eta^5\text{-}C_5H_5)$ or Ru(cod)],[10] whose stuctures have been proposed on the basis of NMR spectroscopic studies.

We now describe the first examples of η^1-bonded 2,4,6-tri-*tert*-butyl-1,3,5-triphosphabenzene platinum(II) complexes of the type *trans*-$[PtCl_2(PR_3)(S_3C_3Bu^t_3)]$ (PR_3 = PMe_3 **2**, PEt_3 **3**, PMe_2Ph **4** or $PMePh_2$ **5**) which are formed by treatment of **1**



2

with the appropriate $[PtCl_2(PR_3)]_2$ complex in CH_2Cl_2 or $CHCl_3$ at room temperature. Attempts to make complexes of **1** by direct reaction with a variety of other metal halides such as MCl_4, (M = Ti or Zr), MCl_5 (M = Nb or Ta), CuX (X = Cl or I) were all unsuccessful as were ligand displacement reactions involving $[MCl_2(NCPh)_2]$ (M = Pd or Pt) and $[RhClL_n]$ (L = cyclooctene, n = 2; L = PPh_3, n = 3).

The $^{31}P\{^1H\}$ NMR spectrum of *trans*-$[PtCl_2(PMe_3)(P_3C_3Bu^t_3)]$ **2**, which is typical for all the complexes **2**–**5**, is shown in Fig. 1, and exhibits the characteristic coupling constant data expected for the *trans*-isomer. The ^{195}Pt NMR spectrum exhibits the expected doublet of doublets pattern.† Solution NMR data for the platinum complexes **3**–**5** containing the bulkier phosphines showed that, unlike complex **2**, there was always a significant concentration of the starting $[PtCl_2(PR_3)]_2$ complex present as well as unreacted **1** and several attempts to obtain crystalline complexes invariably led to further disproportionation. Not surprisingly it proved impossible to attach more than one $[PtCl_2(PR_3)]$ fragment to **1**.

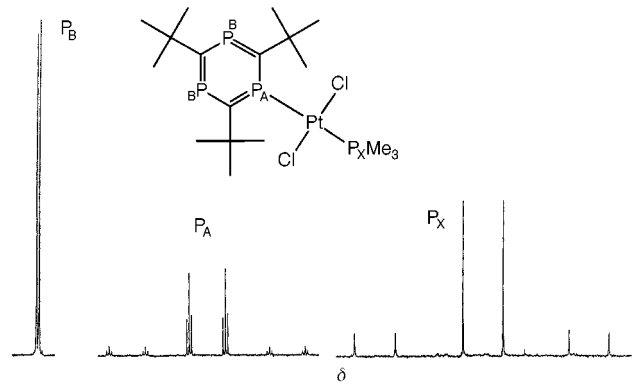


Fig. 1 $^{31}P\{^1H\}$ NMR spectrum of **2**.

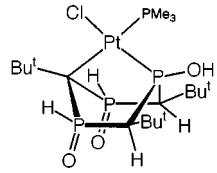
It is interesting to compare the magnitude of the ^1J(PtP) coupling constant to the triphosphabenzene ring in **2** (2418 Hz) with that of the *trans* ligated PMe_3 (2901 Hz) indicating the smaller s-character of the P-lone pair in the triphosphabenzene. In the analogous 2,4,6-tri-*tert*-butyl-1-phosphabenzene[11] complex *trans*-$[PtCl_2(PMe_3)(PC_5H_2Bu^t_3)]$, synthesised in a similar manner, ^1J(PtP) is 2548 Hz, indicating that the presence of additional phosphorus atoms in the aromatic ring reduces the s-character of the P-lone pair electrons.

It has been previously shown that η^1-ligation of phosphaarenes can enhance their reactivity and we observe a remarkable reaction when **2** was recrystallised from CH_2Cl_2 in the air at room temperature. Addition of three water molecules to the coordinated triphosphabenzene ring occurs, together with HCl elimination, to afford the unusual complex $[PtCl(PM_3)\text{-}(P_3O_3C_3H_5Bu^t_3)]$ **6**. The molecular structure of **6**, which was established by a single crystal X-ray diffraction study‡ and is shown in Fig. 2, clearly results from addition of H_2O across each of the unsaturated P–C bonds in **2** in which the H adds to carbon and the OH to phosphorus in accord with the expected



6

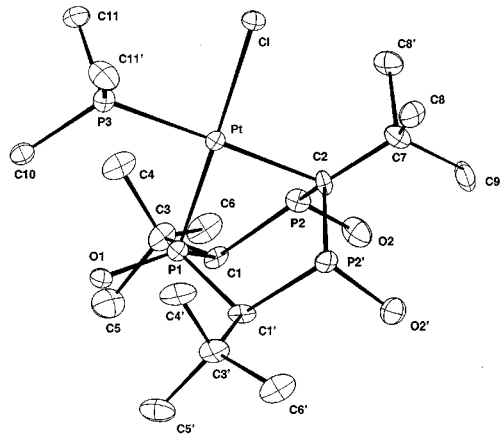


Fig. 2 Molecular structure of **6**. Selected distances (Å) and angles (°): Pt–P(1) 2.224(6), Pt–Cl 2.416(5), Pt–P(3) 2.273(6), Pt–C(2) 2.24(2), P(1)–O(1) 1.479(15), P(2)–O(2) 1.528(12), P(1)–C(1) 1.843(16), P(2)–C(2) 1.777(12), P(2)–C(1) 1.818(15); P(1)–Pt–C(2) 82.6(6), P(1)–Pt–P(3) 96.6(2), C(2)–Pt–P(3) 179.2(6), P(1)–Pt–Cl 178.84(19), C(2)–Pt–Cl 98.6(6), P(3)–Pt–Cl(1) 82.3(2), C(1)–P(1)–C(1′ 97.3(9), C(2)–P(2)–C(1) 109.3(8), P(2)–C(2)–P(2′ 114.6(12) P(2)–C(1)–P(1) 105.6(7)

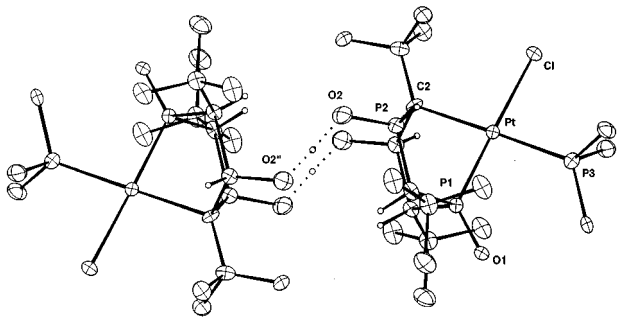

Fig. 3 Dimeric structure of **6**.

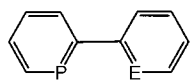
polarity of the bond. The resulting intermediate presumably then undergoes Arbusov-type rearrangement at *two* of the newly formed –P(OH)CHBu^t–centres to produce –PH(O)CHBu^t–ring fragments with the rearrangement at the third phosphorus centre unable to proceed because of ligation of the P atom to Pt. The accompanying loss of HCl and formation of a Pt–C bond leads to the observed product **6**. Mathey, Venanzi and their coworkers,[12–14] have previously noted selective addition of water and methanol to 2-pyridylphosphinines **7** and 2,2′-biphosphinines **8** coordinated to electrophilic metal centres as a result of the partial dearomatisation of the ligand.



E = N **7** or P **8**

Complex **6** shows the following interesting features, (i) the structure consists of a H-bonded dimer; (ii) this H atom lies on a crystallographic twofold axis and was refined to a distance of 2.39 Å between O(2) and O(2)″; (iii) each individual molecule is bisected by a mirror plane through Pt and the ring C and P atoms to which it is bonded; (iv) the ring P–C bond lengths (ranging between 1.78 and 1.84 Å) are elongated compared with those in **1** and are typical for P–C single bonds; (v) the two P(2)=O double bond distances [1.528(12) Å] are similar to that of the formally single P(1)–O bond [1.479(15) Å] for the phosphorus attached to platinum. The structure suggests that the acidic H responsible for the dimeric structure of **6** may be capable of replacement by other cations, or substituted by organic groups, leading to significant structural changes (Fig. 3) and this is currently under study along with other aspects of the ligating behaviour of **1**.

We thank NSERC for a scholarship (for S. B. C.) and EPSRC for their continuing support (to J. F. N.) for phospha-organometallic chemistry.

Received (in Basel, Switzerland) 20th April 1999, Accepted 31st May 1999

[Cp*Co(CO)$_2$] in the presence of PEt$_3$ and MeI catalyses the carbonylation of methanol with initial rates up to 44 mol dm^{-3} h^{-1} before decaying to a second catalytic phase with rates of 3 mol dm^{-3} h^{-1}; [CoI(CO)$_2$(PEt$_3$)$_2$], which is trigonal bipyramidal with axial PEt$_3$ ligands, has been isolated from the final reaction solution.

Ethanoic acid is a bulk chemical of major importance in the polymer, paints and other industries. It is currently mainly manufactured by the carbonylation of methanol in the presence of iodomethane.[1] The first process of this kind used [Co$_2$(CO)$_8$] as the catalyst precursor, but the low activity and selectivity of this system meant that high temperatures and pressures (200 °C, 600 bar) were required and the selectivity to methanol was low.[2]

The discovery that rhodium[3] or iridium[4] based catalysts operate more selectively under much milder conditions (180 °C, 30 bar) led to these processes becoming favoured commercially. However, because of the much lower cost of cobalt than of its two platinum group metal congeners, there would be considerable interest if cobalt based systems that operated with high activity and selectivity under mild conditions could be discovered. In this paper, we report evidence that cobalt based systems can display very high activity and high selectivity.

Fig. 1 shows plots of gas (CO) uptake from a ballast vessel attached to an autoclave at constant pressure by solutions of [Cp*Co(CO)$_2$] under various conditions. [Cp*Co(CO)$_2$] in methanol containing methyl iodide shows relatively low activity but if 10 equivalents of PEt$_3$ are added, a dramatic increase in catalytic activity is observed. The reaction profile shows a very fast initial phase followed by a period with no activity and a further period where the activity is restored but to a level lower than that of the initial phase. This behaviour is reproducible. Addition of water to the system leads to a similar reaction profile, although the overall rates are higher than in the absence of water. The catalyst present during the second phase of the reaction carried out in the presence of water does not appear to be deactivated and the conversion to carbonylation product at the end of the reaction shown in Fig. 2 is *ca.* 41%. Since the major product under these conditions is methyl ethanoate, this represents *ca.* 80% of the methanol being consumed.

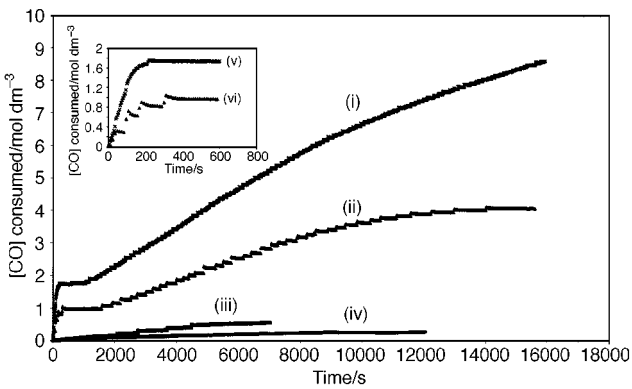

Fig. 1 CO uptake plots for methanol carbonylation reactions catalysed by: (i) [Cp*Co(CO)$_2$–PEt$_3$–H$_2$O; (ii) as (i) but no H$_2$O; (iii) as (ii), but no PEt$_3$; (iv) [Co$_2$(CO)$_8$]; inset: (v) and (vi) early stages of (i) and (ii), respectively.

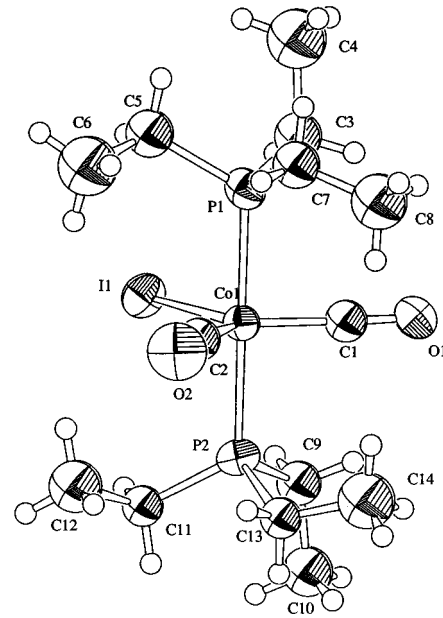

Fig. 2 X-Ray structure and numbering scheme for [CoI(CO)$_2$(PEt$_3$)$_2$]. Important bond lengths (Å) and angles (°): Co(1)–C(1) 1.75(2), Co(1)–C(2) 1.71(2), Co(1)–P(1) 2.208(6), Co(1)–P(2) 2.229(6), Co(1)–I(1) 2.649(3), C(1)–O(1) 1.14(2), C(2)–O(2) 1.17(2); I(1)–Co(1)–C(1) 114.4(7), I(1)–Co(1)–C(2) 118.6(7), I(1)–Co(1)–P(1) 89.5(2), I(1)–Co(1)–P(2) 89.9(2), C(1)–Co(1)–C(2) 127(1), C(1)–Co(1)–P(1) 89.7(7), C(1)–Co(1)–P(2) 89.8(7), C(2)–Co(1)–P(1) 90.5(7), C(2)–Co(1)–P(2) 90.5(7), P(1)–Co(1)–P(2) 179.0(3), Co(1)–C(1)–O(1) 175(1), Co(1)–C(2)–O(2) 173(2). There are two crystallographically distinct molecules in the asymmetric unit cell. The data for only one is reported here. The other is similar, except that only one ethyl group on one phosphine is *anti* to a Co–P bond.

Rates for the two phases of the reaction are presented in Table 1 and it should be noted that the conditions under which these reactions have been carried out are milder than those used for the industrial processes catalysed by rhodium or iridium systems. At 120 °C, the temperature of these studies, rates obtained with [RhCl(CO)$_2$]$_2$ as the catalyst precursor are of the order of 1 mol dm^{-3} h^{-1},[5] 44 times slower than the initial fast phase of the [Cp*Co(CO)$_2$]–PEt$_3$–H$_2$O system. The concentration of cobalt is 30 times that used for the rhodium catalyst so the actual activity of the cobalt system is 1.5 times the rate using rhodium. The high solubility and low cost of the cobalt system mean that it is possible to obtain industrially significant rates using the cobalt based system, even under the mild conditions used in this study.

GLC analysis of the liquid phase at the end of the reactions shows that the major product is methyl acetate, although acetic

[a] p_{CO} = 100 bar, T = 120 °C. Kinetic profiles were obtained using two different Hastelloy C autoclaves with different volumes. Reproducibility between the two reactors was checked by carrying out two identical reactions using identical concentrations. The reproducibility was ±15%. Reproducibility for the same autoclave was ±10%. [b] TOF is defined as the number of mol of CO consumed per mol of catalyst per hour. [c] Initial rate for the second active phase of the reaction. [d] Obtained from a 24 h batch reaction and analysis of the liquid phase products. [e] p_{CO} = 27 bar, but this reaction is zero order in p_{CO}. [f] Substrate added as methyl ethanoate (38.75 cm^3, 3.03 mol dm^{-3}), in ethanoic acid (64.9 cm^{-3}, 6.83 mol dm^{-3}); the reaction is zero order in [MeOH]. [g] Rises to 1.2 mol dm^{-3} as the reaction proceeds and [$RhI_2(CO)_2$]$^-$ forms.[6] [h] Substrate added as methyl ethanoate (23.82 cm^3, 1.83 mol dm^{-3}), in ethanoic acid (109.8 cm^{-3}, 11.4 mol dm^{-3}); the reaction is zero order in [MeOH].

acid is also formed, especially in the system containing added water. Traces of 1,1-dimethoxymethane (the acetal of ethanal) are also observed, but very much less than in the presence of [$Co_2(CO)_8$] based catalysts.

[Cp*Co(CO)$_2$] reacts with *e.g.* PMe_3 to give [Cp*Co(CO)(PMe_3)], which in turn reacts with iodomethane to give [Cp*Co(COMe)I(PMe_3)].[7] Since there is no induction period for the initial phase of the reaction, this suggests that the initial fast step of the carbonylation reaction is catalysed by [Cp*Co(CO)(PEt_3)]/[Cp*Co(COMe)I(PEt_3)]. We have carried out IR studies on a final solution from a reaction carried out in the presence of water [ν_{CO} 1989, 1973 (sh), 1905 cm^{-1}] to try to identify the cobalt species present during the second, slower but more prolonged catalytically active phase, and in addition have isolated a complex from the final reaction solution in the absence of water.

The isolated complex has been characterised by X-ray crystallography‡ as [CoI(CO)$_2$(PEt_3)$_2$], a trigonal bipyramidal complex with axial PEt_3 ligands (Fig. 2). [CoI(CO)$_2$(PEt_3)$_2$] gives rise to the strong peak at 1905 cm^{-1}, together with a weaker peak at 1973 cm^{-1}. The origin of the absorption at 1989 cm^{-1} is unclear, but evidence from other reactions suggests that the species giving rise to it is catalytically active and may be [Cp*Co(CO)I]$^-$. We have not isolated sufficient of [CoI(CO)$_2$(PEt_3)$_2$] to test its catalytic activity but the related [CoI(CO)$_2$(PMe_2Ph)$_2$] is active for methanol carbonylation (Table 1).

The isolation of [CoI(CO)$_2$(PEt_3)$_2$] from a solution containing excess MeI which would be expected efficiently to quaternise PEt_3 to [$PMeEt_3$]I, is surprising. However, we have shown by GCMS that free PEt_3 is present in the catalytic solutions and that the related [CoI(CO)$_2$(PMe_2Ph)$_2$] is formed if [CpCo(PMe_2Ph)CO] is used as a potential catalyst precursor, indicating either that phosphines can migrate between Co atoms without escaping the solvent cage, or that the solution can act as a source of free phosphine.

We conclude that careful design of cobalt based catalysts can give activities and selectivities that are comparable with those of their rhodium based analogues and because of the high solubility and low cost of the catalyst precursor, rates at low temperature can be higher than those currently observed under conditions used for the commercial rhodium or iridium based processes.

We thank BP Chemicals and the EPSRC for a CASE studentship (A. C. M.) and the European Community for support under a TEMPUS programme (A. C. B.). We also thank CATS, the Catalyst Evaluation and Optimisation Service funded by SHEFC for some of the kinetic measurements carried out by G. Schwarz and D. Foster.

Palladium-catalysed formation of maleic anhydrides from CO, CO_2 and alk-1-ynes

Bartolo Gabriele,*[a] Giuseppe Salerno,*[a] Mirco Costa[b] and Gian Paolo Chiusoli[b]

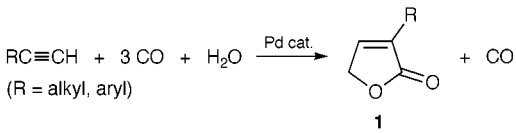
[a] *Dipartimento di Chimica, Università della Calabria, 87030 Arcavacata di Rende, Cosenza, Italy. E-mail: b.gabriele@unical.it; g.salerno@unical.it*

[b] *Dipartimento di Chimica Organica e Industriale, Università di Parma, Viale delle Scienze, 43100 Parma, Italy*

Received (in Liverpool, UK) 8th April 1999, Accepted 20th May 1999

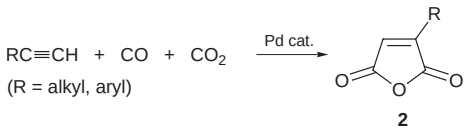
Carbon dioxide causes palladium-catalysed synthesis of unsaturated γ-lactones from alk-1-ynes and CO to shift towards maleic anhydrides.

We recently showed that working in dioxane–water at 80 °C under a 10 atm pressure of CO in the presence of PdI_2 and 10 equiv. of KI leads to catalytic reductive carbonylation of alk-1-ynes with formation of furan-2(5*H*)-ones (Scheme 1).[1] Oxidation of CO to CO_2 accounts for the stoichiometry of the process.



Scheme 1

We now find that in the presence of added CO_2 another catalytic reaction takes place, consisting of the formation of maleic anhydrides according to Scheme 2.



Scheme 2

Table 1 reports the results obtained with and without additional CO_2 pressure. By working under the same reaction conditions which selectively lead to furanones but under an additional 40 atm pressure of CO_2, the product distribution was clearly altered in favour of maleic anhydrides, although the overall reaction rate was decreased.

Both the presence of small amounts of water and the nature of Pd^{II} counterion were essential to the process, only traces of products being obtained under anhydrous conditions or using $PdCl_2$ and 10 equiv. of KCl as catalyst. Decomposition to Pd metal occurred only to a limited extent. In any case, Pd metal was not a catalytically active species for the present reaction, as shown by control experiments.

Table 1 Reactions of alk-1-ynes (100 equiv.) with CO (10 atm), CO_2 and H_2O (200 equiv.) in dry dioxane in the presence of PdI_2 (1 equiv.) and KI (10 equiv.), substrate conc.: 0.5 mmol ml^{-1} dioxane, T = 80 °C

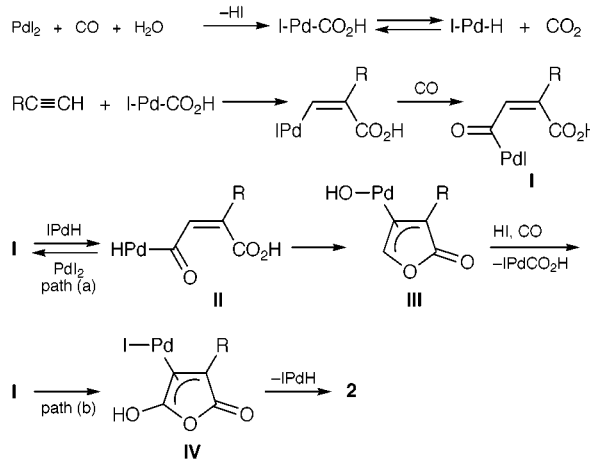
Substrate	$P(CO_2)$/ atm	t/h	Yield (%)[a] 1	2
BuC≡CH	—	15	77[b]	7
BuC≡CH	40	64	32[c]	47
PhC≡CH	—	15	67	traces
PhC≡CH	40	24	30	34

[a] Based on starting alk-1-yne, by GLC. [b] 4-Butyl-2(5*H*)-furan-2-one (8%) was also detected in the reaction mixture. [c] 4-Butyl-2(4*H*)-furan-2-one (10%) was also present in the reaction mixture.

The effect of CO_2 can be rationalised in the following way (Scheme 3; anionic iodide ligands are omitted for simplicity). An I-Pd-CO_2H species,[2] stabilised by iodide ligands, is first generated from PdI_2, CO and H_2O and then inserts the alkyne and CO to give intermediate **I**. At this point two pathways are possible. Formation of furanones requries the intervention of a palladium hydride species,[3] which must derive from decarboxylation[4] of I-Pd-CO_2H, as shown in Scheme 3. Hydride exchange on complex **I** by H-Pd-I[5] followed by reductive cyclization of intermediate **II** leads to allylpalladium complex **III**, whose protonolysis affords **1** with regeneration of the catalytically active species [path (*a*)]. On the other hand, anhydrides can be formed *via* tautomerization of acylpalladium intermediate **I**[6] followed by elimination of Pd^0 and HI or I-Pd-H [path (*b*)]. This reaction is stoichiometric and reoxidation is needed to start a new cycle.[6,7] However, in the presence of an excess of CO_2 I-Pd-H can be reconverted into a catalytically active form. In fact, CO_2 may insert into the palladium hydride bond[8] with formation of either a I-Pd-CO_2H species (which can directly start a new cycle) or a Pd-O(CO)H species, whose protonolysis by HI would afford PdI_2. In both cases no reoxidation is needed and the anhydride cycle can go on. Moreover, in the presence of added CO_2, the decarboxylation equilibrium is shifted to the left and the anhydride cycle becomes competitive with the reduction pathway leading to furanones.

In summary, we have shown that under our conditions CO_2 strongly influences the distribution of products. In the presence of an excess of added CO_2 the resulting concentration of palladium hydride species is reduced in favour of Pd-CO_2H and/or Pd-O(CO)H species, thus minimising furanone formation and allowing the anhydride cycle to run.

The reaction reported here is the first example in which CO and CO_2 are used together for the catalytic formation of unsaturated cyclic anhydrides. The stoichiometric formation of an anhydride from a metallacyclic complex, CO and CO_2 in two steps was described some years ago.[9] In the recently reported



Scheme 3

oxidative cyclization–alkoxycarbonylation of propynylamines carried out in the presence of CO_2, the role of CO_2 in the catalytic cycle was very different (*in situ* generation of a propynyl carbamate, which then underwent cyclization and alkoxycarbonylation).[10]

The authors gratefully acknowledge the Ministero dell'Università e della Ricerca Scientifica e Tecnologica (MURST) for financial support (Progetto d'Interesse Nazionale PIN 9803026360).

Thiazolium-dependent catalytic antibodies produced using a covalent modification strategy†

Fujie Tanaka, Richard A. Lerner* and Carlos F. Barbas III*

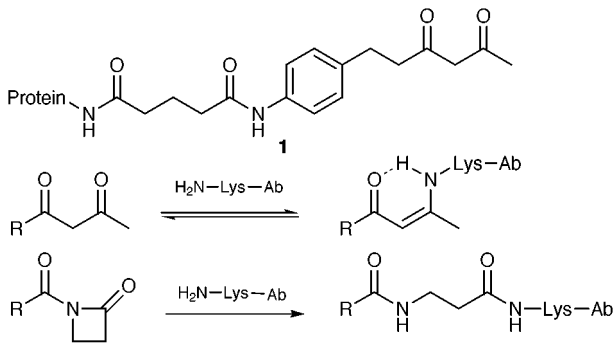
The Skaggs Institute for Chemical Biology and the Department of Molecular Biology, The Scripps Research Institute, 10550 North Torrey Pines Road, La Jolla, CA 92037, USA. E-mail: carlos@scripps.edu

Received (in Corvallis, OR, USA) 23rd March 1999, Accepted 1st June 1999

A thiazolium cofactor was introduced at a unique active site residue within antibodies that were generated by reactive immunization; the modified antibodies catalyzed a new cofactor-dependent reaction.

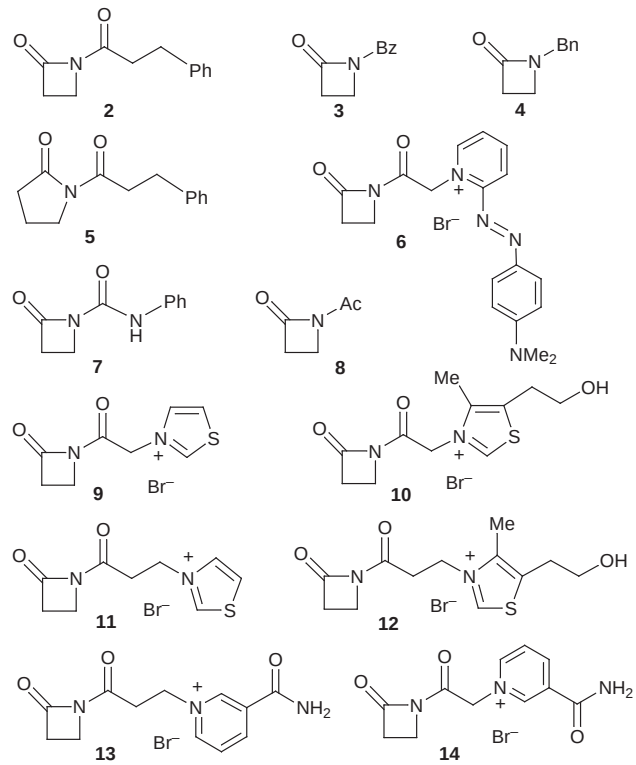
Enzymes effectively extend their catalytic scope by employing cofactors.[1] Consequently, in efforts to create novel cofactor-dependent protein catalysts several strategies have been developed.[2] Herein we report a novel approach which combines the unique features of catalytic antibodies derived from reactive immunization with a strategy for covalent modification that allows for the stable incorporation of a variety of cofactors. We further demonstrate the applicability of this strategy by preparing the first thiazolium-dependent catalytic antibodies.

Antibodies 38C2 and 33F12 were previously generated by reactive immunization with 1,3-diketone **1**.[3] These antibodies possess two key features which make them attractive as model systems for the development of cofactor-dependent catalysts: (i) they have unusually promiscuous active sites capable of binding a large variety of molecules and further transforming them chemically, and (ii) they contain a single highly reactive low pK_a lysine residue in their active site that is essential to their catalytic mechanism. The pK_as of the ε-amino groups of the LysH93 of 38C2 and 33F12 were determined to be 6.0 and 5.5, respectively.[3] Since this reactive lysine is the active nucleophile in Schiff base formation during the aldol reaction, we sought to take advantage of this reactivity and use it as a unique chemical handle for modification of these antibody catalysts. In earlier studies we have demonstrated that many β-dicarbonyl compounds are covalently yet reversibly bound as enaminones by these antibodies.[3] While β-dicarbonyl modified cofactors might be used to decorate the active sites of these antibodies with novel functionalities, we sought to develop a labeling strategy that would be irreversible and compatible with a wide range of cofactor chemistries. We reasoned that β-lactams[4] would form of a stable amide linkage to LysH93 (Scheme 1).



Scheme 1

To test this concept we synthesized a variety of β-lactam derivatives and studied their reactivity towards 38C2. The antibody 38C2 (20–30 μM active site) was first incubated with β-lactams (263 μM) in 5% MeCN– or DMSO–PBS (pH 7.4) at 25 °C. After 15–30 min and 14.5–40 h, the antibody active site was titrated by the addition of pentane-2,4-dione, followed by measurement of the characteristic enaminone absorption at 318 nm.[3] This assay effectively allows us to quantitate modification of the active site. Experiments with compounds **2**, **3** and **4**



suggest that the enhanced reactivity of the β-lactam ring provided by the 1-acyl group present on **2** and **3** is required for reaction with the antibody. The 1-acyl group might also facilitate the reaction by positioning the molecule in the active site of the antibody. The β-lactam ring is in fact required for reactivity since γ-lactam **5**, which contains a stable amide linkage, does not react with the antibody. Although formation of an enaminone upon reaction of the antibody with pentane-2,4-dione is typically complete within 5 min, modification by the β-lactam compounds proceeds in a slow, time dependent fashion.[5] In the case of β-lactam **2**, 95% of the active sites remain unmodified after a 15 min incubation period. After 14.5 h of incubation, only 45% of the active sites remain unmodified. Reaction with these β-lactams was quantitatively inhibited by prior addition of pentane-2,4-dione to the antibody.

In order to determine the stoichiometry of the β-lactam modification, we first used mass spectrometry. The Fab

† Experimental details for the preparation and characterization of **2**–**14**, antibody labeling, characterization, and kinetics are provided as electronic supplementary information, see http//www.rsc.org/suppdata/cc/1999/1383/.

fragment of 38C2 (22 μM) was treated with compounds **2** and **4** (500 μM) for 65 h and the proteins were subsequently purified by gel filtration chromatography. MALDI-TOF mass spectra of the unmodified Fab 38C2, Fab 38C2 treated with **2**, and Fab 38C2 treated with **4** show centroid masses of *m*/*z* 48331, 48534 and 48326, respectively. Given the molecular weight of **2** (*m*/*z* 203), these data indicate that one molecule of **2** is incorporated per molecule of Fab 38C2. The Fab 38C2 was not modified with **4**, as expected based on our active site titration data.

To further support our conclusions, a spectrophotometric assay was also investigated. Violet colored compound **6** was reacted with 38C2 as described above. Absorbance measurements at 566 nm suggest that 65–80%[6] of the antibody was modified with **6.** Titration of this modified antibody by the addition of pentane-2,4-dione verifies that 69% of the active sites were modified. Further, an equivalent loss of aldolase activity from 38C2 was observed. To examine the chemistry by which compound **6** reacts with the active site, **6**-modified antibody 38C2 was treated with 500 mM hydroxylamine at room temperature for 27 h and subsequently purified. Spectrophotometric measurements of the resulting antibody at 566 nm revealed no loss of the chromophore, consistent with the formation of a stable amide linkage. While other active site residues such as tyrosine L41[3*d*] might be candidates for modification, hydroxylamine treatment would be expected to readily deacylate such an ester modification, thereby liberating the chromophore.[5] Additional studies indicated that antibody 38C2 was also covalently modified by compounds **7**–**14**.[7]

We also extended these studies to antibody 33F12, which differs from 38C2 by 18 amino acids. Examination of the rate of modification of 33F12 with 1-acylazetidin-2-ones **2**, **3** and **9** under the conditions described above revealed that antibody 33F12 reacted with these compounds at a rate 70–80% of that observed for 38C2. The studies described above are all consistent with a model wherein 1-acylazetidin-2-ones react with a single amine functionality within the active site of antibodies 38C2 and 33F12. Because of its unique chemical reactivity and structural accessibility, the ε-amino group of LysH93, common to both of these antibodies, is the most likely site for modification.

Given the diverse array of chemistries accessible to the B_1-dependent enzymes,[1,8,9] we chose to study the catalytic activity of antibodies modified with compounds **9** and **10**. We chose α-decarboxylation as a model reaction for the well studied thiamin-dependent enzyme pyruvate decarboxylase.[9] Antibody 38C2 (166 μM) was treated with **9** and **10** (10 mM) in 5% MeCN–PBS at room temperature for 51 and 66 h, respectively, followed by purification by gel filtration chromatography. More than 95% of the active sites were modified as determined by the enaminone assay previously described. Thiazolium-mediated decarboxylation of $PhCOCO_2H$ **15** was studied by HPLC using 40 μM of **9**-modified antibody 38C2 and 500 μM of **15** in 10% DMSO–aqueous buffer [(PBS, pH 7.4)/(200 mM bicine, pH 8.5) = 1:1]. Antibody 38C2 modified with **9** catalyzed the formation of BzOH[10] **16**, whereas unmodified antibody 38C2 and the antibody treated with **10** did not catalyze the reaction. The bulky substituents (Me and $HOCH_2CH_2$ groups) of **10** may present steric barriers to binding of the substrate **15**. When treated with **9,** antibody 33F12 also catalyzed this decarboxylation reaction. The modified antibodies 38C2 and 33F12 displayed typical Michaelis–Menten saturation kinetics; kinetic parameters were as follows: **9**-modified antibody 38C2, k_{cat} 2.1 × 10^{-3} min^{-1} and K_m 5.8 × 10^2 μM; **9**-modified antibody 33F12, k_{cat} 7.8 × 10^{-4} min^{-1} and K_m 2.7 × 10^2 μM. The rates of the antibody catalyzed reactions were compared with the rate of the thiazolium-catalyzed reaction, k_{thz} 1.0 × 10^{-8} μM^{-1} min^{-1}. Antibodies 38C2 and 33F12 modified with **9** therefore yield rate enhancements over thiazolium catalysis alone [$(k_{cat}/K_m)/k_{thz}$] of 370 and 290, respectively. The effective molarity of the cofactor (k_{cat}/k_{thz}) is therefore 0.21 M for 38C2 and 0.078 M for 33F12. These studies suggest that catalysis arises from sequestration of the substrate in proximity to the thiazolium cofactor. The relative hydrophobicity of the active site may also contribute to solvent mediated catalysis of the reaction.[11]

In summary, we have demonstrated that aldolase antibodies 38C2 and 33F12, prepared using reactive immunization, are specifically and covalently modified with a diverse range of 1-acylazetidin-2-ones. We have found that this methodology can be used for the production of novel thiazolium-dependent catalytic antibodies. The attachment system described above should also be useful for the diverse post-translational modification of biological libraries, such as phage displayed antibody libraries[12] which retain LysH93. This would allow for the *in vitro* evolution of cofactor-dependent catalysis. Because reactive immunization selects for catalysts that operate through covalent mechanisms, it presents us with a simple strategy for the generation of diverse antibody combining sites that retain a reactive chemical group in their active site.[3] As we have demonstrated here with aldolase antibodies, the active site remains amenable to labeling with cofactors, thereby providing a handle for extending the scope of catalytic antibodies. Since the chemist is not constrained to select cofactors from nature's pallet, unnatural yet catalytically interesting cofactors can be studied.

This study was supported in part by the NIH [CA27489].

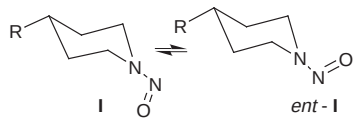
Received (in Liverpool, UK) 3rd March 1999, Accepted 3rd June 1999

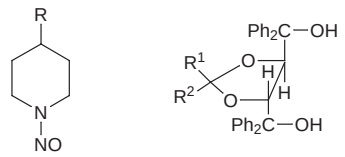
An efficient optical resolution of 4-substituted *N*-nitrosopiperidines achieved by enclathration with chiral diols was evidenced by X-ray crystallography and circular dichroism spectra in solution.

Hindered rotation about the partial double bond between the two adjacent nitrogen atoms in *N*-nitrosamines results in many unusual stereochemical and spectroscopic consequences.[1] In the absence of any improper symmetry axis the molecules of *N*-nitrosopiperidines, derived from symmetric amines, are chiral and may exist in two enantiomeric forms. Interconversion between the enantiomers occurs by rotation about the N–N bond (Scheme 1). The corresponding energy barrier is large enough (23–25 kcal mol^{-1})[2] to permit potential isolation of stereoisomers at ambient temperature.



Scheme 1

The compounds **1**–**4**, owing their chirality solely to restricted rotation of the NO group, would be useful and extremely simple models for studying the chiroptical spectra of the nitrosamino



1 R = H

chromophore. The optical activity of nitrosamines has been the subject of numerous investigations and much speculation in recent years.[3] However, the resolution of racemic compounds devoid of additional functional groups usually poses a serious problem.[4] A method, which has received increasing attention in the last two decades, is the inclusion crystallization of racemates with optically active hosts.[5] This seems to be a promising approach also for our purpose. Recently, we have found that cholic acid crystal matrices show strong chiral recognition ability with the nitrosamines **1** and **2**, making it possible to detect their CD spectra in the solid state.[6] Unfortunately, this technique is restricted to rather small molecules and cholic acid did not form inclusion complexes with **3** and **4**.

Here we present a simple and general procedure for optical resolution of nitrosamines that also makes possible their isolation from the host matrices. We were particularly interested in obtaining easily crystallizing compounds, which stored in the solid state could retain their optical activity for very long periods. The nitrosamines **3** and **4** were among candidates that should satisfy these conditions. With use of (*R*,*R*)-(−)-**5a** and (*R*,*R*)-(−)-**5b** (TADDOLs), easily accessible from (+)-tartaric acid,[7] as the chiral hosts we were able to prepare optically active **3** and **4** in the crystal form and record their CD spectra in solution. The 1:1 complexes of **3** and **4** with **5a** were obtained by cocrystallization of equimolar amounts of the corresponding nitrosamine and the host diol from toluene–hexane. In the case of the diol **5b** and nitrosamine **4**, after choosing the proper component proportion, two types of inclusion compound can be prepared, with mp 109 and 131 °C (guest–host ratio of 1:1 and 1:2, respectively).

Usually separation of the optically active guest from the chiral diol can be accomplished chromatographically or by fractional distillation.[5,8] Obviously neither of these techniques can be used for unstable or rapidly racemising compounds. Taking advantage of the reported strong affinity of **5a**,**b** with secondary amines,[9] we succeeded in liberating of the enclathrated nitrosamines by a competitive complexation of the host diols with piperazine. This was possible because this amine forms a very stable and almost insoluble (in nonpolar solvents) 2:1 complex with **5b**. Therefore after addition of piperazine to a suspension of **4**·2(**5b**) in Et_2O at *ca*. 0 °C, followed by filtration of the precipitated piperazine complex and evaporation of the solvent, the optically active nitrosamine (−)-**4** was isolated; mp 62–63 °C, $[\alpha]_D^{21}$ −67.2 (*c* 1.25, C_6H_6). Compound

Table1 Circular dichroism (CD) data

3·**5b**	T	373 (−2080)
(−)-**4**	CD	373 (−1200)
4·5a	T	372 (1230)
4·**5b**	T	372 (−1880)
4·2(**5b**)	T	371 (−1550)

[a] CD = cyclohexane–dioxane (9:1), T = toluene. [b] Molecular ellipticity in deg cm^2 dmol^{-1}, measured immediately after dissolution of the sample.

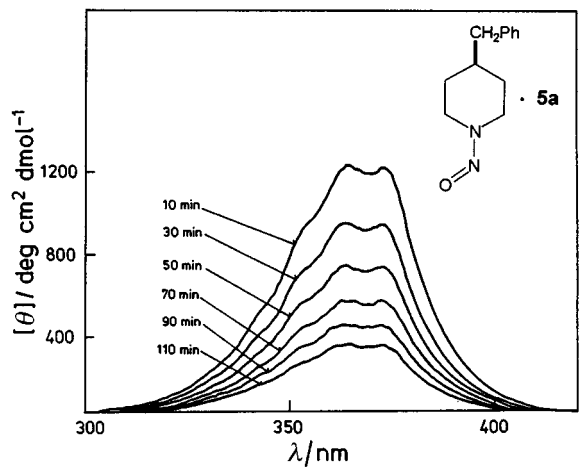

Fig. 1 Decay of the CD signal of **4**·**5a** in toluene at 22 °C.

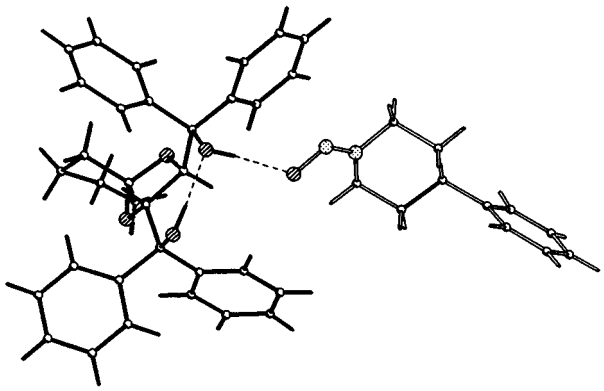

Fig. 2 Molecular structure of the complex **3**·**5b**. Broken lines represent the hydrogen bonds.

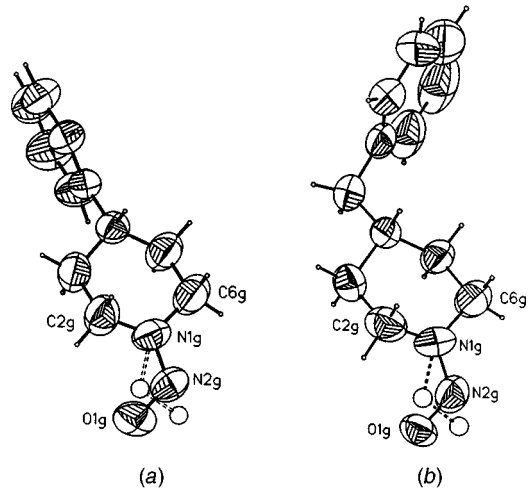

Fig. 3 ORTEP drawings of the guest nitrosamines (*a*) **3** and (*b*) **4** showing their absolute configurations.

(−)-**3** was prepared similarly; mp 66–67 °C, $[\alpha]_D^{21}$ −50.2 (*c* 1, C_6H_6).

The optical activity of the isolated nitrosamines is manifested by their chiroptical spectra in solution. Since the nitrosamine n–π* band does not interfere with the absorption of the phenyl chromophore in **5a**,**b**, the shape of the CD spectra of the complexed and free nitrosamines are essentially the same (Table 1). The CD curves observed in toluene solution show moderately strong Cotton effects corresponding to the nitrosamine n–π* electronic transition near 370 nm, which gradually decrease at room temperature (Fig. 1) due to a rapid racemization of (−)-**3** and (−)-**4**. A comparison of the CD sign of **4**·**5b** with that of **4**·2(**5b**) revealed the same configuration of the guest molecules included in both clathrates. In contrast, the opposite sign and slightly lower CD magnitude of **4**·**5a** to those shown by **4**·**5b** and **4**·2(**5b**) indicates a preferential complexation of the (+)-**4** enantiomer by the host **5a**.

The first order kinetics of the racemization process can be monitored by simple polarimetric measurements and we observed the racemisation half-life $t_{1/2}$ at 22 °C for **3** and **4** of 50 and 45 min, respectively. The calculated activation energy $\Delta G^{\ddagger}$ values of 22.0 and 21.9 kcal mol^{-1} for **3** and **4**, respectively, are comparable to the N–N rotation barrier heights obtained for *N*-nitrosopiperidines *via* NMR measurements.[2]

The X-ray crystallographic analysis of the clathrates **3**·**5b** (Fig. 2) and **4**·2(**5b**) revealed that one enantiomer of the guest nitrosamine was preferentially included in the crystals.† The absolute configurations of the guest molecules can be easily elucidated from the crystal structures of the clathrates and we found that in the case of the complexes **3**·**5b** and **4**·2(**5b**) the *S* configuration is preferred by (−)-**3** and (−)-**4** nitrosamine molecules (Fig. 3). However, a small degree of contamination of the inclusion crystals with the second nitrosamine enantiomer results in disorder of the N–NO group over two positions. A significant excess of the *S* enantiomer was determined from the refinement of the occupancy factors of two NO group positions although the exact enantiomeric ratio could not be determined due to a high correlation between the occupancy factors and dispalacement parameters of the N–NO group *via* the least-squares method. The X-ray structures of the clathrates showed that the piperidine ring in **3** and **4** assumes a chair conformation with the substituent at C-4 occupying the equatorial position. The nitroso oxygen is hydrogen bonded to one of the hydroxy groups of the host diol.

Notes and references

† Diffraction data were obtained on a Kuma KM-4 diffractometer with graphite monochromated Cu-Kα radiation (λ = 1.54178 Å). The structures were solved by direct methods with the program SHELXS-86 (ref. 10). Full-matrix least-squares refinement was carried out with SHELXL-93 (ref. 11). The *N*-nitroso groups in the guest molecules are disordered over two positions. Restraints were imposed on 1-2 and 1-3 distances and the planarity of the *N*-nitrosamino group during structure refinement. The minor components were refined with isotropic displacement parameters. *Crystal data* for **4**·2(**5b**): $2C_{33}H_{27}O_4{\cdot}C_{12}H_{16}N_2O$, M = 1189.44, monoclinic, space group $C2$, a = 35.720(7), b = 8.605(2), c = 23.661(5) Å, β = 117.94(3)°, V = 6425(2) Å^3, Z = 4, D_c = 1.230 g cm^{-3}, μ = 0.632 mm^{-1}, T = 293 K, crystal size 0.4 × 0.4 × 0.05 mm, θ_{max} = 60°, 4792 reflections measured, 4710 unique (R_{int} = 0.029) R_1 = 0.042, wR_2 = 0.107 for 3929 reflections with $I > 2\sigma(I)$ (R_1 = 0.062, wR_2 = 0.114 for all 4710 independent reflections). Aerobic oxidation of α-hydroxycarbonyls catalysed by trichlorooxyvanadium: efficient synthesis of α-dicarbonyl compounds

Masayuki Kirihara,* Yuta Ochiai, Shinobu Takizawa, Hiroki Takahata and Hideo Nemoto*

Faculty of Pharmaceutical Sciences, Toyama Medical and Pharmaceutical University, Sugitani 2630, Toyama 930-0194, Japan. E-mail: kirihara@ms.toyama-mpu.ac.jp

Received (in Cambridge, UK) 6th May 1999, Accepted 8th June 1999

α-Hydroxycarbonyls were efficiently oxidized into α-dicarbonyls using a catalytic amount of trichlorooxyvanadium under an oxygen atmosphere.

α-Dicarbonyl compounds are important materials in synthetic organic chemistry.[1] They have been used as substrates for benzylic acid rearrangement[2] and starting materials for syntheses of heterocyclic compounds.[3] α-Dicarbonyl compounds are frequently obtained by the oxidation of α-hydroxycarbonyl precursors. Due to the sensitivity of the α-dicarbonyl compounds, special reagents and reaction conditions are required to prevent side reactions during the oxidation of the α-hydroxycarbonyls.[1] Although a number of methods have been developed to achieve this transformation, most of them suffer from drawbacks such as the use of stoichiometric amounts of corrosive acids or toxic metallic compounds that generate undesirable waste materials.†

We now describe the chemoselective aerobic oxidation of α-hydroxycarbonyls to α-dicarbonyls catalysed by high valent vanadium.‡

During the course of our study of the oxyvanadium-catalysed cleavage of α-hydroxy ketones, we found that the reaction of 2-hydroxycyclooctanone with a catalytic amount of dichloroethoxyoxyvanadium [$VO(OEt)Cl_2$] in MeCN under an oxygen atmosphere efficiently afforded cyclooctane-1,2-dione.[4]

We further examined the reaction, and found that α-dicarbonyl compounds could be efficiently obtained when trichlorooxyvanadium ($VOCl_3$) was used as the catalyst (Scheme 1).

First, we chose benzoin as the substrate and examined the reaction with several high valent vanadium catalysts in MeCN under an oxygen atmosphere (Table 1). Benzil was obtained in all cases, and the best result was obtained when $VOCl_3$ was used as the catalyst (run 2).

We then examined the reaction of benzoin with a catalytic amount of trichlorooxyvanadium in several solvents (Table 2). As noted in runs 1 and 2, MeCN and acetone are good solvents for this reaction.

The reaction of several α-hydroxy ketones with a catalytic amount of $VOCl_3$ in MeCN under an oxygen atmosphere provided the α-diketones in excellent yields.§ In all cases, the α-diketone was the sole product and no by-products were observed. These results are summarized in Table 3. The reaction

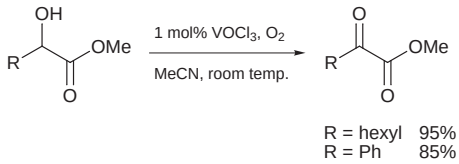
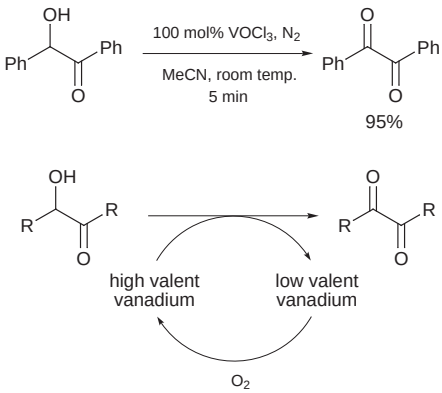


Scheme 2

of benzoin with a catalytic amount of $VOCl_3$ in MeCN in air also gave benzil in good yield (entry 2). It took longer to complete the reaction in the cases of the α-diketones having aliphatic substituents (entries 5–11). Interestingly, alcohols without a carbonyl moiety at their α-position did not react under the same conditions. α-Hydroxy esters were also efficiently oxidized to α-keto esters (Scheme 2).

As mentioned in a previous paper,[4] this reaction is not a simple radical oxidation, because this reaction was not influenced by a radical inhibitor.¶ A stoichiometric amount of $VOCl_3$ reacted with benzoin to afford benzil in the absence of oxygen (Scheme 3). This result means that molecular oxygen acts as a co-oxidant and reoxidizes the low valent vanadium that is formed.

We observed that the color of the reaction mixture was dark yellow at first, and then turned green in most cases. The 'green' of the reaction mixture strongly suggests the presence of V^{IV}



Scheme 3

species. Further study concerning aspects of the mechanism is currently underway.

We would like to express our appreciation to Professor Kan Kanamori, Toyama University, and Dr Yasushi Oda, Kyowa Hakko Kogyo Co., for their useful suggestions.

Notes and references

† We retrieved all the transformations of α-hydroxycarbonyl into α-dicarbonyl using REACCS (MDL Co., Ltd.), and found over 100 methods. Representative reports are cited in ref. 5.

‡ Two other aerobic oxidations of α-hydroxycarbonyls to α-dicarbonyls have been reported (ref. 6).

§ A typical experimental procedure is as follows: a mixture containing the α-hydroxycarbonyls (5.0 mmol), $VOCl_3$ (4.7 μl, 0.05 mmol) and MeCN (50 ml) was stirred at room temperature (or refluxed) under an oxygen atmosphere for 1.5–22.5 h. The mixture was quenched with saturated aq. $NaHCO_3$ and extracted with 20 ml × 3 of EtOAc. The combined organic extracts were washed with saturated aq. NH_4Cl and brine, dried over $MgSO_4$ and evaporated to afford the α-dicarbonyls.

¶ 2,6-di(*tert*-butyl)-*p*-cresol did not interfere with the reaction of $VOCl_3$ with benzoin in MeCN.

Extending the $n = 2$ Ruddlesden–Popper solid solution $La_{2-2x}Sr_{1+2x}Mn_2O_7$ beyond $x = 0.5$: synthesis of Mn^{4+}–rich compounds

Julie E. Millburn, John F. Mitchell* and Dimitri N. Argyriou

Materials Science Division, Argonne National Laboratory, Argonne, Illinois 60439, USA. E-mail: mitchell@anl.gov

Received (in Bloomington, IN, USA) 13th April 1999, Accepted 15th June 1999

Reported herein are the synthesis and room temperature crystal structures of the heretofore unknown, metastable manganites $La_{2-2x}Sr_{1+2x}Mn_2O_{7+\delta}$ ($0.5 \leqslant x \leqslant 0.9$) *via* high temperature ($T = 1650$ °C) quenching followed by low temperature ($T = 400$ °C) annealing to fill oxygen vacancies; this approach enables access to the electronic, magnetic, and structural properties of previously unexplored compositions in this important CMR system.

Mixed-valent manganite perovskites have received considerable attention in recent years, primarily because of the observation of colossal magnetoresistance (CMR) and more generally due to the unusually strong coupling among their lattice, spin, and charge degrees of freedom.[1–3] Although the focus of interest has primarily rested with the pseudocubic $Ln_{1-x}A_xMnO_3$ perovskites (A = Ca, Sr, Ba, Pb, Bi), naturally layered CMR materials have also attracted attention owing to their potential as model systems for low-dimensional physics[4–6] and because they exhibit substantially better low-field magnetoresistance than their three-dimensional perovskite counterparts.[7] Single phase synthesis has only been successfully achieved in the $n = 2$ Ruddlesden–Popper (RP) $La_{2-2x}Sr_{1+2x}Mn_2O_{7+\delta}$ manganite series for doping concentrations in the range $0.3 \leqslant x \leqslant 0.5$. Nonetheless, the structural, electronic, and magnetic phase diagram across this relatively narrow doping region is remarkably rich, displaying ferromagnetism, antiferromagnetism, canted states, spin rotations, and charge ordering.[7–11] Unfortunately, extension of the solid solution towards higher Mn^{4+} concentrations has heretofore proved unsuccessful,[12] with the notable exception of the synthesis of the $x = 1.0$ end member compound, $Sr_3Mn_2O_{7+\delta}$.[13, 14]

Here, we report on the synthesis and room temperature structural data of highly oxidized $La_{2-2x}Sr_{1+2x}Mn_2O_{7+\delta}$ phases with $0.5 \leqslant x \leqslant 0.9$. The importance of these materials for the continuing investigation and understanding of the physics of layered manganites is three-fold. First, they provide prototypes for appraisal of the interplay between aliovalent substitution and vacancy formation. Secondly, they provide models for further assessing the impact of Jahn–Teller distortions in these materials. Finally, they provide experimental data necessary to test theoretical predictions concerning the evolution of the magnetic ground state with dopant concentration.

Polycrystalline samples of $La_{2-2x}Sr_{1+2x}Mn_2O_{7+\delta}$, $0.5 \leqslant x \leqslant 0.9$, were prepared by high temperature, solid state reaction of La_2O_3 (Johnson-Matthey REacton 99.999%, pre-fired at 1000 °C in air for 12 h), $SrCO_3$ (Johnson-Matthey Puratronic 99.994%, dried at 150 °C in air for 12 h) and MnO_2 (Johnson-Matthey Puratronic 99.999%, pre-fired at 425 °C in flowing oxygen for 6 h, then slow cooled at 1 °C min^{-1} to room temperature). Stoichiometric quantities of the starting materials were mixed and fired in air as powders, at 900 °C for 24 h and then 1050 °C for a further 24 h. Samples were then pressed into 13 mm diameter pellets at 6000 lbs and ramped at 5 °C min^{-1} to 1650 °C. After 18 h each compound was quenched directly from the synthesis temperature into dry ice. As is the case for $Sr_3Mn_2O_{7+\delta}$,[2,14] the materials are metastable below 1650 °C and must be rapidly cooled to below 1000 °C to prevent decomposition. The black products were subsequently annealed for 12 h at 400 °C in flowing oxygen. Materials were reground between each firing. The Mn^{4+} content of the as-made and annealed materials was determined by iodometric titration against a standardized potassium thiosulfate solution. For each composition titrations were repeated several times to ensure accurate and consistent results (typically < 2% spread). Approximately 50 mg portions of as-made material were rapidly heated on a thermogravimetric analysis (TGA) balance to 400 °C in flowing oxygen, held at this temperature until no further weight change was observed, then quickly cooled to room temperature. Room temperature time-of-flight (TOF) powder neutron diffraction data were collected for the oxygen annealed samples on the Special Environment Powder Diffractometer (SEPD) at Argonne National Laboratory's Intense Pulsed Neutron Source (IPNS). All crystal structure analysis was performed by the Rietveld method using the GSAS program suite.[15]

The results of the titrations and the room temperature c/a ratio for the annealed samples as a function of x are plotted in Fig. 1. The individual lattice parameters for selected compositions are listed in Table 1. Data included for the $x = 1.0$ composition, $Sr_3Mn_2O_{7+\delta}$, are taken from ref. [13] Within the resolution of the SEPD instrument [$\pm 145° 2\theta$, $\Delta d/d$ (FWHM) = 0.0034] we find no evidence in our samples of the subtle phase separation previously reported for the $x = 0.5$ composition.[4]

Table 1 Room temperature lattice parameters from powder neutron diffraction data for $La_{2-2x}Sr_{1+2x}Mn_2O_7$ ($0.5 \leqslant x \leqslant 0.9$)

x	a/Å	c/Å
0.50	3.87470(3)[a]	20.0031(3)
0.55	3.87035(4)	19.9862(3)
0.60	3.86490(3)	19.9784(3)
0.75	3.84317(5)	19.9968(3)
0.80	3.83533(5)	20.0070(4)
0.90	3.81834(5)	20.0325(5)
1.00	3.79972(5)	20.0959(4)

[a] Numbers in parentheses are esds.

As shown in Table 1, the a lattice parameter monotonically decreases by 1.94% between $0.5 \leqslant x \leqslant 1.0$. In contrast, the c –axis shows a minimum at $x \approx 0.65$. This results in a smooth rise in the c/a ratio with increasing x (Fig. 1), a complete reversal of what is observed with increasing Mn^{4+} concentration in the $0.3 \leqslant x \leqslant 0.5$ region. This transformation in lattice behavior may reflect changes as a function of manganese oxidation state in the nature of d orbital occupation from in-plane to axial. It may also reflect a modification of the A–type magnetic ordering seen in this system at $x \sim 0.5$.[11] Theoretical predictions of the magnetic ground state by Maezono *et al.*,[16] for instance, depend upon a decreasing c/a ratio. In light of the present results, such calculations may require revision.

The as-made materials are found by titration to display an average Mn oxidation state of approximately +3.5 irrespective

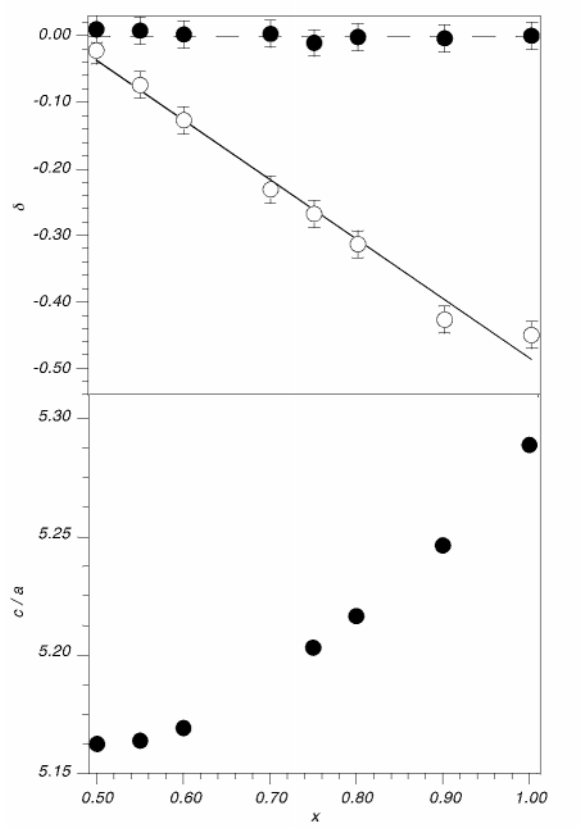

Fig. 1 Oxygen non-stoichiometry, δ, and c/a *vs.* x in $La_{2-2x}Sr_{1+2x}Mn_2O_{7+\delta}$ ($0.5 \leqslant x \leqslant 0.9$). Open circles represent data for the as-made, 1650 °C quenched samples, closed filled that for the low temperature oxygen annealed materials.

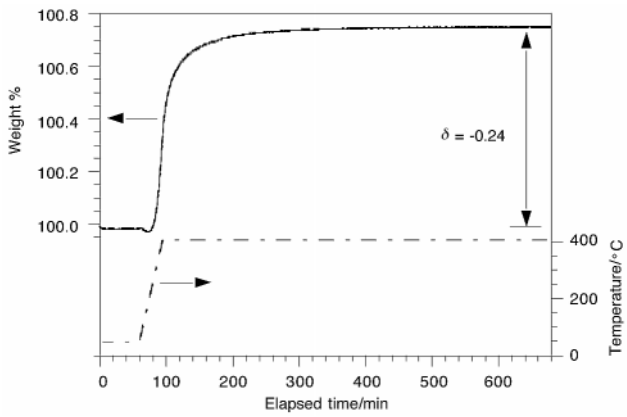

Fig. 2 Thermogravimetric analysis of as-made $La_{0.5}Sr_{2.5}Mn_2O_{7+\delta}$ under a flowing oxygen atmosphere.

of composition. Analogy with $Sr_3Mn_2O_{7+\delta}$[13] suggests this to be a consequence of the formation of oxygen vacancies in the materials during synthesis. Thermogravimetric analysis corroborates this hypothesis; illustrative results for the $x = 0.75$ composition are shown in Fig. 2. The observed weight gain indicates that a substantial quantity of oxygen is incorporated by the sample upon heating. Assuming the end-point corresponds to the stoichiometric material, $La_{0.5}Sr_{2.5}Mn_2O_{7.0}$, then the as-made compound may be formulated as $La_{0.5}Sr_{2.5}Mn_2O_{6.76}$, *i.e.* $\delta = -0.24(2)$. Since, the average manganese oxidation is given by $3 + x + \delta$, this value of δ corresponds to an oxidation state of +3.51(2) in good agreement with the titrimetric result of +3.48(2). Fig. 1 shows the monotonic decrease in δ (or increase in number of oxygen vacancies formed during synthesis) with x that gives rise to the constant, dopant independent Mn oxidation state. Once annealed at 400 °C in oxygen, all the materials are found to be stoichiometric, $\delta = 0.00(2)$. This is corroborated by refinement of the oxygen content in the powder neutron diffraction data: all oxygen site occupancies are unity within error. These findings suggest that the initial synthesis conditions impose an upper limit on the transition-metal oxidation state. In fact, in our experience, $Mn^{+3.5}$ is the maximum mean oxidation state attainable in a layered $n = 2$ manganite system by any high temperature route. Prior attempts to extend the solid solution beyond $x = 0.5$ in this and other $Ln_{2-2x}Sr_{1+2x}Mn_2O_7$ series by conventional high temperature solid state techniques results in the formation of mixed-phase materials.[12]

The use of a two-step procedure such as reported here, in which formation of vacancies within the structure is followed by low temperature oxygen annealing to yield the stoichiometric material, thus seems essential in providing access to compositions containing higher concentrations of Mn^{4+}. Access to these compositions will permit a more complete investigation of the interplay among structure, magnetism, and transport in layered manganites. Full characterization of the temperature-dependent crystallographic and magnetic structure of the compositions prepared here will be reported in a subsequent paper.

The authors thank Simine Short for assistance with the TOF powder neutron diffraction measurements. This work was supported by the U. S. Department of Energy, Basic Energy Sciences–Materials Sciences under contract W-31-109-ENG-38 (JEM, JFM) and W-7405-ENG-36 (DNA).

A novel method for tailoring the pore-opening size of MCM-41 materials

X. Song Zhao,[a] G. Q. (Max) Lu*[a] and X. Hu[b]

[a] *Department of Chemical Engineering, The University of Queensland, St Lucia, Brisbane, Qld 4072, Australia. E-mail: maxlu@cheque.uq.edu.au*

[b] *Department of Chemical Engineering, Hong Kong University of Science and Technology, Clear Water Bay, Kowloon, Hong Kong*

Received (in Cambridge, UK) 26th April 1999, Accepted 21st June 1999

A novel pore tailoring method is proposed by which the pore-opening sizes of MCM-41 materials can be finely tuned without significant loss in pore volume and surface area.

The disclosure of the mesoporous molecular sieve MCM-41[1] has inspired a great deal of interest in catalysis, adsorption/separation and other fields,[2,3] in particular in processing bulk molecules.[4] Most excitingly, a recent study[5] shows that MCM-41 has a comparable cracking activity for long-chain hydrocarbons and even an increased activity for bulky hydrocarbons. This finding further shows the application potentials of MCM-41 in hydrocarbon processing such as in FCC (Fluid Catalytic Cracking) and Friedel–Crafts alkylation. However, for those catalytic reactions over MCM-41 materials studied so far, shape selectivity, which is of paramount importance, has not been observed. Normally, MCM-41 catalysts can lead to the thermodynamic equilibrium of the products owing to the existence of large mesopores.

Although the pore sizes of MCM-41 materials can be varied during synthesis by choosing various surfactants with different carbon chain lengths, the smallest pore size that can be obtained appears to be around 2 nm. It is obviously hard to observe any shape or size selectivity over these materials because the kinetic sizes of most of the products of catalytic reactions are smaller than this. Therefore, fine-tuning the pore diameter of MCM-41 by post modification is desirable and imperative to achieve shape-selective catalytic properties. In this study, we present a preliminary study on a novel pore modification method as schematically shown in Fig. 1. Through selectively removing the surfactant molecules occupied at both ends of the cylindrical pore (step A), we are able to tailor the pore-opening sizes of MCM-41 materials by deposing some modifying reagents such as tetraethylorthosilicate (TEOS) (step B). The main pore body can be protected against modification by the remaining surfactant molecules. In this way, the surface area and pore volume can be largely retained while the pore-opening sizes can be fine-tuned by the number of cycles of step B. Once the template is totally removed (step C), an ink-bottle-like pore-structured MCM-41 material results.

The parent mesoporous silica was prepared from the starting gel composition of 4.5 Na_2O:30 SiO_2:5.6 CTMACl:20 EtOH:2500 H_2O, (CTMACl = cetyltrimethylammonium chloride), at 100 °C for 3 days. The mixture was filtered off and extensively washed with deionized water and acetone to remove any residual ions and surfactants. A typical pore modification run is described as follows. (1) 100 g of the as-synthesized sample were dried at 120 °C overnight before adding to 500 ml of toluene under stirring for 2 h; 1.5 g of acetic acid was then added to the above mixture under stirring for another 2 h. The mixture was filtered off, washed with toluene and dried at 120 ^{0}C. (2) Part of the sample (*ca.* 2 g) was loaded into a chemical vapor deposition (CVD) system[6] and heated to 200 °C. At this temperature, tetraethylorthosilicate (TEOS) was fed from a saturator by high purity helium gas with a flow rate of 50 ml min^{-1} for 18 h. Chemical reaction occurred between surface silanol groups and TEOS *via* SiOH + $Si(OEt)_4 \rightarrow SiOSi(OEt)_3$ + EtOH. (3) The helium carrier gas was then switched to a water saturator to allow the attached $-Si(OEt)_3$ species to hydrolyze to generate new silanol groups for the subsequent modification runs. (4) The modified sample was calcined at 540 °C to remove the remaining surfactant molecules. Samples before and after modification were characterized by physical adsorption of nitrogen, benzene and water vapor, thermogravimetric analysis (TGA), and X-ray diffraction (XRD).

Some preliminary characterization results for a sample whose pore openings had been modified three times using TEOS are given below. Fig. 2 compares the nitrogen adsorption/desorption isotherms of the MCM-41 samples before and after modification, along with their physical adsorption data. The inset to Fig. 2 shows the Haorvath–Kawazoe pore size distribution (PSD) curves. It is seen that the pore-modified MCM-41 sample exhibits a type I isotherm with a small hystersis loop, different from the parent MCM-41 which shows

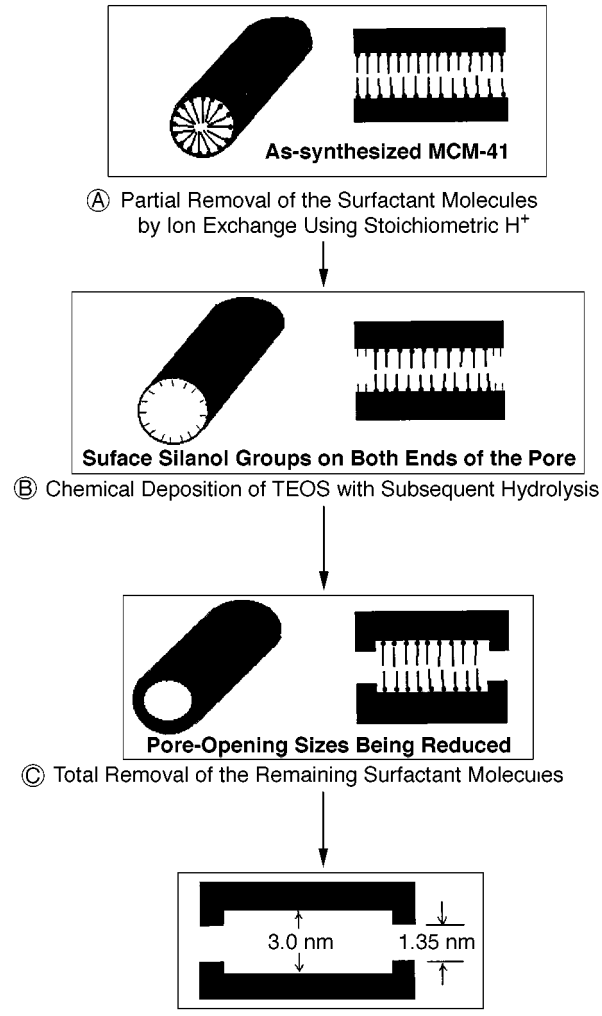

Fig. 1 Schematic model for tailoring the pore-opening size of MCM-41.

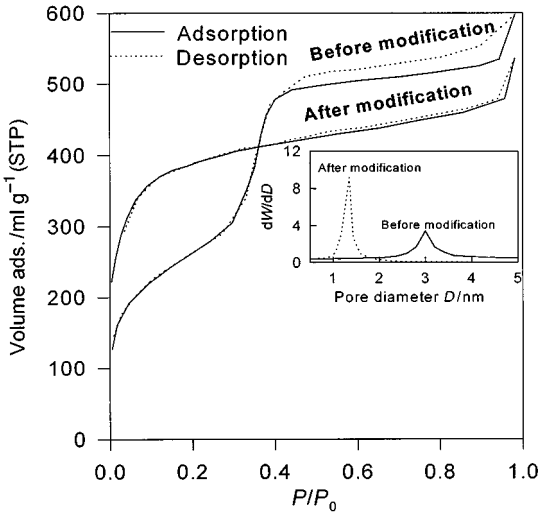

Fig. 2 Nitrogen adsorption/desorption isotherms and other physical adsorption data of the MCM-41 samples before and after pore modification.

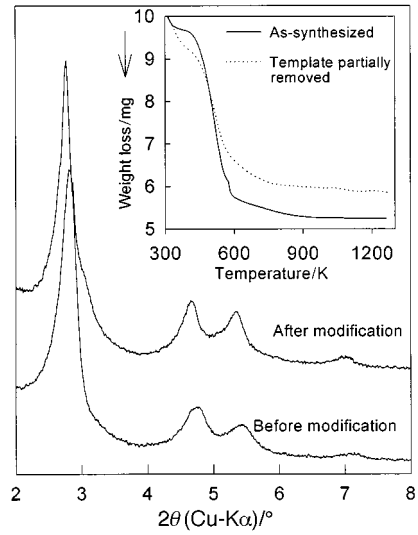

Fig. 3 XRD patterns of MCM-41 samples before and after modification and TGA curves of the parent and the template partially removed MCM-41 sample.

a type IV isotherm. The enhanced adsorption volume in the low relative pressure region indicates that the narrowed pore entrances (to the micropore size) enhanced the adsorption potential near the pore mouth region. The effective pore size, BET surface area, pore volume, benzene and water adsorption capacity had been reduced from 3.0 to 1.35 nm, 1120 to 886 m^2 g^{-1}, 0.86 to 0.69 ml g^{-1}, 8.3 to 6.5 mmol g^{-1} and 39 to 34 mmol g^{-1}, respectively, after three modification runs. These adsorption parameters support our hypothesis shown in Fig. 1 because of the fairly small reduction in porosity after modification (If the whole of the pores were modified, the pore volume would be decreased by about 80%, assuming the thickness of one silica layer to be 0.3 nm). However, the characteristic hysteresis loop for ink-bottle pore structures as documented[7] was not significant on the modified sample, presumably due to the short equilibrium time (60 s) used in our experiments. Further pore structure characterization work, along with shape-selective catalytic properties, are now being undertaken and a full paper will be published soon.

The XRD and TGA data shown in Fig. 3 further confirm our pore modification model. The XRD patterns of the MCM-41 samples before and after modification are essentially identical, demonstrating that the hexagonal pore structure was maintained after modification. The degree of template removal calculated from the TGA curves is *ca.* 15% based on anhydrous silica, indicating that most of the surfactant molecules remained inside the channels after being extracted by acetic acid solution in toluene. The 15% of the removed template is believed to be that occupying both ends of the pore.

To conclude, an effective, novel pore modification method has been proposed and the preliminary characterization data confirm our suggested modification model. This method allows for the tailoring of pore opening sizes of surfactant-templated mesophases without significant loss in pore volume and surface area.

A novel paramagnetic dithiadiazolyl radical: Crystal structure and magnetic properties of *p*-$BrC_6F_4CNSSN^{\bullet}$

Guillermo Antorrena,[a] John E. Davies,[b] Matthew Hartley,[b] Fernando Palacio,[a] Jeremy M. Rawson,*[b] J. Nicholas B. Smith[b] and Alexander Steiner[c]

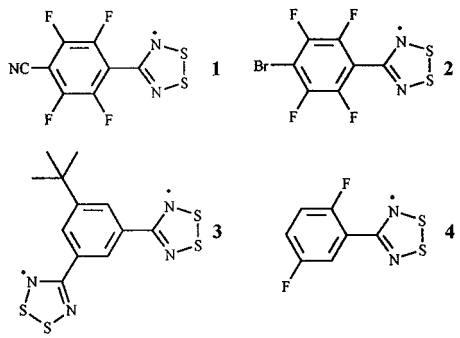
[c] *Department of Chemistry, The University of Liverpool, Crown Street, Liverpool, UK L69 7ZD*

Received (in Cambridge, UK) 11th May 1999, Accepted 8th June 1999

The dithiadiazolyl radical *p*-$BrC_6F_4CNSSN^{\bullet}$ 2 retains its monomeric nature in the solid state; variable temperature magnetic studies on 2 indicate Curie–Weiss behaviour (θ = −27 K) above 60 K with an effective magnetic moment of 1.45 μ_B at room temperature; the absence of long-range magnetic order down to 1.8 K is attributed to the low dimensionality of the magnetic exchange pathway predicted on the basis of the inter-molecular S···N interactions.

The magnetic properties of the dithiadiazolyl radical *p*-NCC_6F_4CNSSN **1** are exceptional.[1,2] The β-phase of this compound is one of a small number of organic magnets and it exhibits a magnetic ordering temperature (36 K) unprecedented for an organic radical.[2] The singly-occupied molecular orbital (SOMO) of **1**, as with other dithiadiazolyl derivatives,[3] is a π-based orbital of a_2 symmetry (nodal at C) and is localised on the heterocyclic ring. Thus, to a first approximation, we may assume that variation of the substituent at C will have only minor effects on the electronic properties of the radical centre. Indeed, because of these negligible electronic effects, one of the most difficult tasks associated with this particular area of chemistry is to overcome the considerable dimerisation energy (*ca.* 35 kJ mol^{-1})[3] associated with these radicals. In **1**, a fortuitous combination of the fluorinated aromatic ring, coupled with strong CN···S interactions effectively compete with the natural tendency for spin-paired dimerisation.[1,2]

Recently, we have concentrated our efforts on a series of fluorinated derivatives, closely related to **1**. Herein, we report the synthesis and structure of *p*-BrC_6F_4CNSSN **2**, which represents only the second example of a dithiadiazolyl radical to retain its paramagnetic nature in the solid state.



Radical **2** was prepared from BrC_6F_4CN using standard synthetic procedures[4] and was purified by vacuum sublimation (10^{-2} Torr, 80 °C), with recovered yields typically 14%, based on *p*-BrC_6F_4CN. Red crystals suitable for X-ray diffraction† were obtained by successive sublimations along a glass tube under dynamic vacuum.

The asymmetric unit (Fig. 1) comprises one molecule of **2** of unexceptional geometry, and with a large twist angle between C_6 and CN_2S_2 rings of 51.8° (*c.f.* α-**1** and β-**1** at 32° and 58°, respectively).[1,2] The majority of dithiadiazolyl radicals are associated *via* a close out-of-plane interaction between the two heterocyclic rings with S···S separations of 2.9–3.1 Å,[5] which facilitates at π*–π* interaction between the singly occupied molecular orbitals (SOMOs) based on each heterocyclic ring, thereby rendering them diamagnetic. In **2** the radicals pack in columns along the crystallographic *a*-axis (Fig. 2), although these out-of-plane contacts are much longer than normal out-of-plane contacts and fall in the range 3.675–3.999 Å, larger than those observed for the bis(dithiadazolyl) radical **3** [3.48(2)–3.61(2) Å][8] and the fluorinated dithiadiazolyl radical **4** [3.544(3) Å].[9] Whilst the molecular structures of **1** and **2** are similar, their solid state structures are different; radical **1** forms a chain-like motif through electrostatic CN···S interactions.[1,2] In the case of **2** the difference in electronegativity between Br and S (0.04) is much less than that observed between S and an sp-hybridised N (2.49) in **1**. Instead electrostatic interactions between S and the heterocyclic sp^2 N (electronegativity

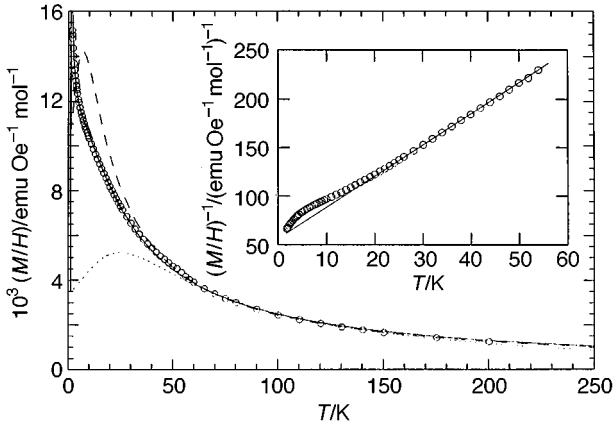

Fig. 3 Variation of M/H as a function of T (○) for **2** and several fits to modified Bonner–Fisher models: Bonner–Fisher with an additional diamagnetic term (·····); Bonner–Fisher considering that only 70% of the molecules contribute to the magnetism (-----) $J = -5.4(1)$ K; and Bonner–Fisher including a linear dependence $J(T)$ term and a paramagnetic term (——).

difference = 1.55) determine the crystal packing. This is manifested in a short intermolecular interaction [S(1)···N(2) 3.175(9) Å] close to the heterocyclic ring plane which links neighbouring molecules into chains along the *c*-axis. Whereas out-of-plane contacts around 3.0 Å lead to essentially diamagnetic solids, this close in-plane approach in **2** leads to retention of paramagnetism (see below).

Variable temperature magnetic susceptibility studies (ac and dc) under different applied magnetic fields were carried out on a microcrystalline sample of **2**. Diamagnetic corrections, were made for the sample holder and sample (Pascal's constants). The effective magnetic moment at high temperature [μ_{eff} = 1.45 μ_B at room temperature] is less than that expected for an $S = ½$ paramagnet and decreases slowly to 1.35 μ_B at 50 K before undergoing a more rapid decrease down to 0.5 μ_B at 1.8 K.

Above 60 K, the magnetic susceptibility follows the Curie–Weiss law with $\theta = -27 \pm 1$ K (Fig. 3, inset), although an extra and unjustified diamagnetic term ($\chi_d \approx -5 \times 10^{-4}$ emu mol^{-1}) must be added in order to explain the low values of μ_{eff}. Using a mean-field approximation, this value of θ would indicate a paramagnetic–antiferromagnetic phase transition at 27 K. However no evidence of long range magnetic order is observed and the linear field dependence of the susceptibility is corroborated at 5 K by a magnetisation *vs.* field plot.

On the other hand, for systems exhibiting low dimensional character (which is strongly suggested by the structure of **2**), a fit of the experimental data to the Bonner–Fisher model for an $S = ½$ Heisenberg chain gives $J = -19 \pm 5$ K and approximately the same χ_d term. This model predicts a broad maximum in χ at $T_{max} = 1.282 \times |J|$ K (24 ± 6 K), as a consequence of short range (low-dimensional) interactions (Fig. 3). However there is no broad maximum in χ observed down to 1.8 K and there is a marked deviation from the Bonner–Fisher model below 60 K. It has not been possible to fit the experimental data satisfactorily by simply including paramagnetic impurities or correction factors due to hypothetical sample degradation (Fig. 3).

These observations indicate a peculiar evolution of the susceptibility as a function of temperature, exhibiting paramagnetic behaviour with antiferromagnetic interactions ($J > 19$ K) in the high temperature range and weaker interactions at low temperatures. However, a surprisingly good fit is obtained throughout the temperature range by incorporating a simple linear dependence of the exchange parameter, J_2 [$J = -(0.31T + 8.2)$] in the Bonner–Fisher model (Fig. 3). In this case, there is no need to use an extra diamagnetic correction, although an additional paramagnetic term (corresponding to 3% of $S = ½$ paramagnetic impurity) is included to explain the large slope of the susceptibility below 10 K.

The absence of a transition to a magnetically ordered state must arise as a consequence of the crystal structure which necessarily precludes propagation of the magnetic exchange interaction throughout the solid above 1.8 K (the limiting low temperature of these measurements). The structure of **2** provides two potential pathways for propagation of the magnetic exchange interaction; either *via* the close in-plane interactions along the crystallographic *c*-axis; and/or *via* the out-of-plane interactions along the crystallographic *a*-axis (Fig. 2). Whilst the intermolecular S···N interactions in β-**1** lead to a diamond-like three-dimensional magnetic exchange pathway,[10] the dimensionality of **2** could, at best, be described as a two-dimensional net with layers separated by half the length (10.213 Å) of the crystallographic *b* axis. Thus the peculiar behaviour of *J* can be ascribed to either structural changes as the temperature decreases,[11] or to the presence of competing ferromagnetic and antiferromagnetic exchange interactions. In the first case, the temperature dependence of *J* will be a direct consequence of the modification of the exchange pathways, whereas in the second case it would just be a mathematical artefact to account for the rising of the magnetisation due to the ferromagnetic interactions. In order to provide a more solid basis to resolve this problem, low temperature structure determinations are in progress.

We would like to thank Ciba-Geigy and the MEC for studentships (J. N. B. S. and G. A., respectively), the Royal Society for an equipment grant (J. M. R.), the CICYT (Grant No. MAT94-043 and MAT97-0951), the British Council and the MEC for their support of international cooperation (J. M. R./F. P.).

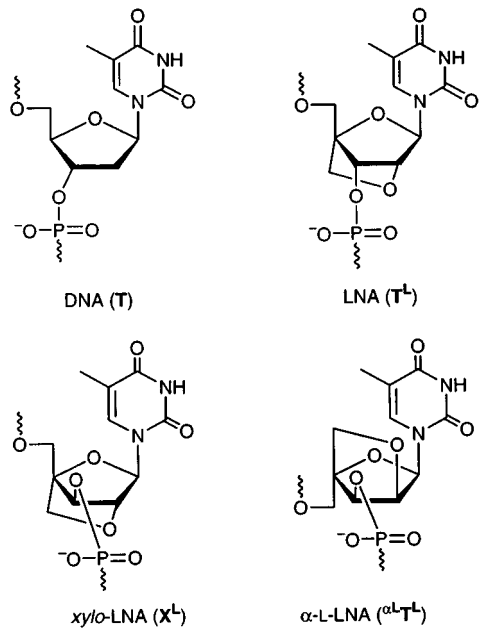
Received (in Cambridge, UK) 21st April 1999, Accepted 3rd June 1999

Synthesis of xylo-LNA containing one 2′-*O*,4′-*C*-methylene-β-D-xylofuranosyl thymine nucleotide monomer and α-L-LNAs containing one or four 2′-*O*,4′-*C*-methylene-α-L-ribofuranosyl thymine nucleotide monomer(s) has been accomplished using phosphoramidite chemistry with pyridine hydrochloride as activator; oligothymidylate α-L-LNA displays strongly enhanced affinity towards complementary RNA.

In a series of papers, Seela *et al.* have synthesized and studied xylo-DNA containing one or more 2′-deoxy-β-D-xylofuranosyl nucleotide(s).[1–4] Compared with the corresponding natural 2′-deoxy-β-D-ribofuranosyl oligonucleotide reference (**T**, thymine

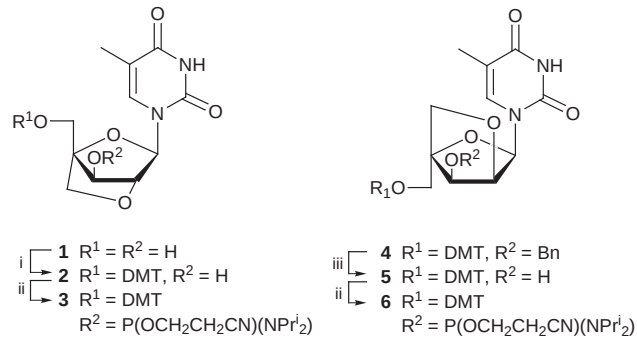


derivatives are shown for all the four different monomers), *xylo*-DNA generally displays decreased thermal affinity towards complementary single stranded DNA.[1–4] We[5–9] and others[10] have recently reported unprecedented thermal stabilities of duplexes involving LNA (Locked Nucleic Acid, $\mathbf{T^L}$)† and complementary single stranded DNA or RNA. Here the first stereoisomers of LNA are introduced, namely *xylo*-LNA ($\mathbf{X^L}$) containing one or more 2′-*O*,4′-*C*-methylene-β-D-xylofuranosyl nucleotide monomer(s), and α-L-LNA containing one or more 2'-*O*,4'-*C*-methylene-α-L-ribofuranosyl nucleotide monomer(s) ($^{\alpha L}T^L$).

Conversion of the thymine *xylo*-LNA nucleoside **1**[11] and the α-L-LNA nucleoside **4**,[12] which both were obtained from D-glucose, into the phosphoramidite building blocks **3** and **6**, respectively, was performed as depicted in Scheme 1. Nucleoside **1** was reacted first with 1.5 equiv. of 4,4′-dimethoxytrityl chloride (DMTCl) in anhydrous pyridine (25 h, room temperature) and then with an additional 1.0 equiv. (21 h, room temperature) to afford the 5′-*O*-DMT-protected *xylo*-LNA nucleoside **2**‡ in 50% yield after column chromatographic separation from the 3′-*O*-DMT isomer (isolated in 29% yield). Interactions (sterical interference and/or hydrogen bonding) between the three substituents at the α-face of the furanose ring are possible explanations for the unusually low reactivity, and low selectivity, towards dimethoxytritylation of the primary hydroxy group of nucleoside **1**. Subsequent phosphitylation of the 3′-hydroxy group afforded in 51% yield the phosphoramidite derivative **3**.§ The 5′-*O*-DMT-protected derivative **5**[12]¶ was obtained in 80% yield by debenzylation of nucleoside **4** and subsequently converted into the phosphoramidite **6** in low yield.‖

The oligomers were synthesized on an automated DNA synthesizer by use of the phosphoramidite approach.[13] Seela *et al.* have reported that the use of 3′-*O*-phosphoramidites in their syntheses of *xylo*-DNA required a ten-fold extension of the standard coupling time. Therefore they applied phosphonate chemistry for oligomerization of 5′-*O*-DMT protected 2′-deoxy-β-D-xylofuranosyl monomers.[3] Analogously, the coupling yield of amidite **3** was only 15% after 10 min coupling time using standard concentrations and 1*H*-tetrazole as activator (sequence 5′-$\mathbf{X^L}T_6$; coupling yields determined spectrophotometrically by the release of the 4,4′-dimethoxytrityl group after each coupling step). This inefficient coupling of **3**, which strongly contrasts with the nearly quantitative coupling of the parent diastereoisomeric LNA amidite,[5–7] is probably caused by steric hindrance during the reaction between the 5′-hydroxy group of 5′-OH-T_6 and the amidite **3**, the latter having three sterically demanding groups oriented towards the α-face of the furanose ring. In an attempt to improve the coupling yield of amidite **3**, syntheses of 5′-$\mathbf{X^L}T_6$ using different activators[14–16] and coupling times were performed (Table 1). These experiments showed that the use of pyridine hydrochloride as activator may indeed allow efficient coupling of sterically very hindered phosphoramidite building blocks. This is an important result as research in this area moves towards bicyclic,[9] tricyclic,[17] functionalized[9] and branched[18] oligonucleotides.

We then turned to the synthesis of the *xylo*-LNA and α-L-LNA sequences **8**–**10** shown in Table 2 using the optimized conditions (pyridine hydrochloride; 10 min coupling time)



Scheme 1 *Reagents and conditions*: i, DMTCl, anhydrous pyridine (50%); ii, Pr^i_2NEt, 2-cyanoethyl *N*,*N*-diisopropylphosphoramidochloridite, anhydrous CH_2Cl_2 (**3**: 51%; **6**: 7%‖); iii, ammonium formate, Pd/C, MeOH (80%).

Table 1 Model syntheses of 5′-$\mathbf{X^L}T_6$

Activator	*t*/min	Yield[a,b] (%)
1*H*-Tetrazole	10 min	15
1*H*-Tetrazole	30 min	31
4,5-Dicyanoimidazole[c]	30 min	71
Pyridine hydrochloride[d]	10 min	> 99

[a] Refers to the coupling yield for amidite **3**. [b] The coupling yield of the unmodified ß-cyanoethyl T-amidite was > 99%. [c] Ref. 14. [d] Ref. 15,16.

Sequence	dA_{14} Complement T_m/°C (ΔT_m/°C)	rA_{14} Complement T_m/°C (ΔT_m/°C)	Mass found $[M - H]^-$	Mass calc. $[M - H]^-$
7 5′-T_{14}	32	28		
8 5′-$T_7\mathbf{X^L}T_6$	19 (−13)	24 (−4)	4221.2	4223.8
9 5′-$T_7(^{\alpha L}\mathbf{T^L})T_6$	32 (±0)	33 (+5)	4225.4	4223.8
10 5′-$T_5(^{\alpha L}\mathbf{T^L})_4T_5$	36 (+1)	46 (+4.5)	4309.0	4307.8

[a] Melting temperatures (T_m values) obtained from the maxima of the first derivatives of the melting curves (A_{260} *vs.* temperature) recorded in medium salt buffer (10 mM sodium phosphate, 100 mM sodium chloride, 0.1 mM EDTA, pH 7.0) using 1.5 mM concentrations of the two complementary strands (assuming identical extinction coefficients for all modified and unmodified thymine nucleotides). Also shown are changes in T_m value *per modification* (ΔT_m) compared with the reference values obtained for **7**.

affording coupling yields of ~99% for amidite **3** and 97–99% for amidite **6**.** Contrary to amidite **6**, consecutive incorporation of amidite **3** resulted in reduced coupling yields (85–97%; sequences not shown). The oligomers **8**–**10** were synthesized in the DMT-off mode and directly ethanol-precipitated after cleavage from the solid support yielding products with > 90% purity as judged from capillary gel electrophoresis.

The results from preliminary binding studies in medium salt buffer are shown in Table 2. The thermal stability of complexes formed between *xylo*-LNA **8**, containing a single $\mathbf{X^L}$ monomer, and complementary single stranded DNA (dA_{14}) and RNA (rA_{14}) was significantly reduced (ΔT_m/mod = −13 and −4 °C, respectively) when compared with the unmodified T_{14} reference **7**. Contrary to this, the binding affinity of α-L-LNAs **9** and **10** was unchanged or slightly improved towards complementary DNA, and strongly increased towards complementary RNA (ΔT_m/mod = +4.5 and +5 °C). The latter results compare closely with our results obtained earlier for the corresponding LNA oligothymidylate sequences.[5] Modeling studies on monomers $\mathbf{X^L}$ and $^{\alpha L}\mathbf{T^L}$ clearly show their furanose conformations to be very different. Thus, whereas $\mathbf{X^L}$ is locked in a 3′-*endo* (N-type) conformation, $^{\alpha L}\mathbf{T^L}$ is locked in a 3′-*exo* (S-type) conformation. The preliminary binding data indicate that the inverted configuration at C-3′ (compared with *e.g.* LNA and DNA) in *xylo*-LNA monomer $\mathbf{X^L}$ causes an unfavorable local disruption of the regular duplex structures. However, the 2′-*exo* conformation of monomer $^{\alpha L}\mathbf{T^L}$ allows the formation of very stable hetero duplexes despite the configuration being inverted at both C-3′ and C-4′. In fact, superimposition of models of the LNA monomer $\mathbf{T^L}$ and the α-L-LNA monomer $^{\alpha L}\mathbf{T^L}$ reveals the possibility of a very close three-dimensional positioning of the thymine moieties and of the C-5′- and C-3′-oxygen atoms for the two monomers existing in locked 3′-*endo* and 3′-*exo* conformations, respectively.

The first LNA stereoisomers, *xylo*-LNA and α-L-LNA, have been synthesized using phosphoramidite chemistry on an automated DNA synthesizer applying extended coupling times and pyridine hydrochloride as activator. This synthetic method should be generally applicable for coupling of sterically hindered phosphoramidite building blocks. α-L-LNA containing one and four α-L-LNA monomers recognized complementary RNA with remarkably increased affinity. Currently, the binding properties of a variety of *xylo*-LNA and α-L-LNA oligomers are being studied in full detail.

The Danish Natural Science Research Council, The Danish Technical Research Council and Exiqon A/S are thanked for financial support. Dr Carl Erik Olsen and Dr Thomas Kofoed are thanked for recording MALDI-MS spectra.

Notes and references

† We have defined LNA as an oligonucleotide containing one or more 2′-*O*,4′-*C*-methylene-ß-D-ribofuranosyl nucleotide monomer(s).

Bis(benzene)chromium: a pre-catalyst for the hydrosilation of ketones and aldehydes, and for the dehydrocoupling of triphenylsilane with primary alcohols†

Franck Le Bideau,[a] Josette Henique,[a] Edmond Samuel*[a] and Ch. Elschenbroich[b]

[a] *Ecole Nationale Supérieure de Chimie de Paris (UMR 7576 CNRS), 11 rue Pierre et Marie Curie, 75231 Paris Cedex 05, France. E-mail: samuel@ext.jussieu.fr*

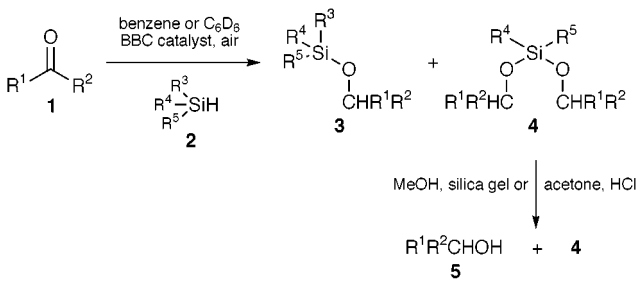
Received (in Basel, Switzerland) 15th February 1999, Accepted 10th June 1999

Bis(benzene)chromium is a valuable pre-catalyst for the hydrosilation of α-aryl carbonyl compounds as well as for the dehydrocoupling between primary alcohols and triphenylsilane.

For a number of years, the catalytic hydrosilation of ketones and aldehydes has been a widely used reaction in organic synthesis, known to be catalysed by a large number of transition metal compounds.[1–6] However, to our knowledge, bis(benzene)chromium (BBC) has never been used for this purpose, and moreover its known catalytic properties have been mentioned only in a very few instances.[7–10]

In this work, we show that under certain conditions, BBC is an active homogeneous catalyst for the hydrosilation of ketones and aldehydes as well as for the dehydrocoupling of primary alcohols with triphenylsilane.

The catalytic reaction was examined using different substrates **1** and a number of silanes **2** (**2**/**1** = 1.2 equiv.) in the presence of neutral BBC (6% mol) in benzene (or benzene-d_6) and under aerobic conditions (Scheme 1). With diphenylsilane and methylphenylsilane, compounds **3** were not stable on silica gel and were converted spontaneously to the corresponding alcohols **5** (MeOH, silica gel or acetone, HCl). The results are summarized in Table 1. It is of note that the hydrosilation reactions were generally clean as judged by the ^{1}H NMR spectra of the crude reaction mixtures. Thus silylenol ether, the main by-product resulting from dehydrogenative silylation, occasionally encountered with other catalysts,[1] was not detected in this case. The formation of polymers was accompanied by an increase in the aromatic signal intensity and the appearance of singlets (corresponding to SiH) in the range δ 5.5–6.0 was observed to a small extent.



Scheme 1

Saturated ketones are not reactive under these conditions. For instance, acetone gave only traces of compound **3** after 24 h at 40 °C in benzene (Table 1, entry 2). On the other hand, and as judged from the ^{1}H NMR spectra of the crude reaction mixtures, with excess acetone (both as solvent and reactant), reaction occurs with total conversion of the silane. We have also attempted the reduction of carbon–carbon multiple bonds but without success, with hydrosilation of 2-cyclopenten-1-one occurring exclusively on the carbonyl function (Table 1, entry 4).

Different silanes were used in the hydrosilation of *para*-anisaldehyde (Table 1, entries 5–8). Ph_3SiH, Me_2PhSiH and Et_3SiH are not effective in this reaction, probably owing to steric hindrance. This can also explain the poor yields for compound **4** obtained with Ph_2SiH_2 (Table 1, entries 1–5). With a less hindered silane (Table 1, entry 6 *vs.* 5), **4** is obtained in 21% yield. Two ethoxysilanes were also examined (Table 1, entries 7 and 8) with success. The formation of **4** is attributed to a redistribution reaction of the silane prior to hydrosilation.[11,12]

In order to gain information about the nature of the species responsible for the catalytic process, *para*-anisaldehyde was reacted with dimethylethoxysilane under argon in the presence of freshly sublimed BBC, by saturating the solution of the aldehyde and the silane in benzene with argon prior to the addition of the arene complex (Scheme 2). No reaction occured after 18 h at room temperature. It follows that although BBC is

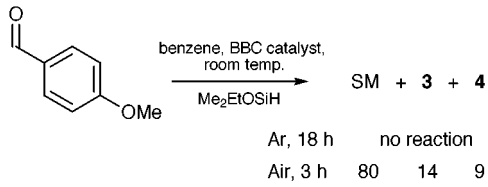

Scheme 2 (SM = starting material)

the catalytic precursor, hydrosilation is thought to proceed by the transient formation of a species generated by the reaction of O_2 with BBC in the presence of trace amounts of water.[13] The mechanism seems therefore to be completely different from the well established Chalk and Harrod oxidative addition process in the case of late transition metal catalyst complexes. Instead it may involve primary electron transfer to yield the radical pair BBC^+ $O_2^{-\cdot}$ and subsequent hydrogen atom abstraction from the silane by the hydroperoxide anion, thereby triggering a radical path for the hydrosilation. This option is currently being tested by means of EPR spectroscopy.

Under the same experimental conditions, primary alcohols led to fast dehydrocoupling in the presence of Ph_3SiH (Scheme 3) with vigorous gas evolution. Yields are of the same order as those reported in the literature for numerous other known catalysts.[14] Propargyl alcohol was thus converted to the corresponding silyl compound with the triple bond remaining intact. This reaction is an alternative, in the case of primary alcohols, to the protection method using bromotriphenylsilane in pyridine.[15]

Scheme 3

It has been demonstrated that BBC can behave as an efficient spin trap[16] and reactions described above provide further support to the hitherto unsuspected usefulness of this well known sandwich compound in organic synthesis.

Notes and references

‡ *Typical procedure* (Table 1, entry 7): Dimethylethoxysilane (1.2 mmol) was added, at room temperature, to a solution of *p*-anisaldehyde (1 mmol) and BBC (0.06 mmol) in benzene (1 mL). After 3 h at 40 °C in the presence of air, the reaction mixture was concentrated. The residue was flash chromatographed affording **3** [light petroleum–diethyl ether (90 : 10)] and then **4** (dichloromethane).

Received (in Cambridge, UK) 20th April 1999, Accepted 15th June 1999

Vanadium oxide catalysts supported on niobia are found to be highly active for ammoxidation of 3-picoline and it is found that the catalytic properties are directly related to the dispersion of vanadia.

Recently, there has been growing interest in the study of niobium-based materials as catalysts in various catalytic transformations.[1–7] Niobium(v) oxide can be used as a support, as a promoter and also as a unique solid acid. There are several advantages of using niobium(v) oxide as a catalyst support for vanadium oxide catalysts. These include the fact that (i) niobium is in the same group of the Periodic table as vanadium and is expected to have similar properties. (ii) Niobium(v) oxide is much more difficult to reduce than vanadium (easy reduction often causes low selectivity in oxidation reaction). (iii) Addition of niobium(v) oxide to a mixture of molybdenum and vanadium oxide improves the activity and selectivity during oxidation, ammoxidation and oxidative dehydrogenation reactions.[6,7]

Nicotinamide is an important chemical compound for the metabolism of human beings and animals, and is used as a food additive. It is usually synthesized by the ammoxidation of 3-picoline to nicotinonitrile and further hydrolysis of the nitrile formed.[8–11] Vanadium oxide catalysts, either unsupported or supported, are generally used for this ammoxidation process. We report here, for the first time, the use of V_2O_5 catalysts supported on niobium(v) oxide for ammoxidation of 3-picoline to nicotinonitrile. The purpose of this work is to determine the degree of dispersion of vanadium oxide supported on niobium(v) oxide and to understand the relation between activity of the catalysts and oxygen chemisorption sites.

Niobium(v) oxide was prepared by calcination of niobium pentoxide hydrate (Niobia HY-340 AD/1227, CBMM, Brazil) in air at 773 K for 4 h. A series of V_2O_5 catalysts with V_2O_5 loadings in the range 2–12 wt% supported on Nb_2O_5 (surface area 55 $m^2\ g^{-1}$) were prepared by impregnation with an aqueous solution containing ammonium metavanadate (Fluka). The catalysts were subsequently dried at 383 K for 16 h and calcined in air at 773 K for 5 h. Oxygen chemisorption was measured by a static method using a Pyrex glass system capable of supporting a vacuum of 10^{-6} Torr. Details of experimental set up have been given elsewhere.[14] Prior to chemisorption measurements, *ca.* 0.250 g of the sample was pre-reduced in a flow of hydrogen (40 ml min^{-1}) at 640 K for 2 h and the catalyst cell was evacuated at the same temperature for 1 h. Oxygen chemisorption uptakes were determined as the difference of two successive adsorption isotherms measured at 640 K.

A down-flow fixed bed reactor operating at atmospheric pressure and made of Pyrex glass was used for testing the catalysts during ammoxidation of 3-picoline to nicotinonitrile. About 2 g of catalyst diluted with an equal amount of quartz grains was charged into the reactor and was supported on a glass wool bed. Prior to introducing the reactant 3-picoline with a syringe pump, the catalyst was reduced at 673 K for 2 h in purified hydrogen flow (40 ml min^{-1}). After prereduction the reactor was fed with 3-picoline, ammonia and air, keeping mole ratio of 3-picoline : H_2O : NH_3 : air at 1 : 13 : 22 : 44 and contact time at 0.6 s. The reaction was carried out at various temperatures ranging from 573 to 683 K. The liquid products obtained (mainly nicotinonitrile) were analysed by gas chromatograph using an OV-17 column. Traces of carbon oxides were also formed during the reaction.

The oxygen chemisorption capacities of various V_2O_5/Nb_2O_5 catalysts are presented along with other information in Table 1. Pure Nb_2O_5 was also reduced under identical conditions and its oxygen uptake was taken into account for the supported catalysts. The results show that oxygen chemisorption capacities are found to increase with increase of vanadia content on niobia (Table 1). However, the dispersion of vanadia (O/V) is found to decrease steadily with increase of vanadia content (Table 1). Dispersion of vanadium oxide is defined as the fraction of total O atoms (determined from oxygen chemisorption) to total V atoms in the sample. The results of oxygen chemisorption results are further supported by powder X-ray diffraction results shown in Fig. 1, wherein a mixed vanadium–niobium oxide such as β-(Nb, V)$_2O_5$ (JCPDS card No: 16-132) was formed at moderately high vanadia content and increases with further increase of vanadia content. This β-(Nb, V)$_2O_5$ phase can be observed with d = 3.77, 3.56 and 3.40 Å for samples containing 10 and 12% V_2O_5 supported on Nb_2O_5 [Fig. 1(d) and (e)]. A decrease in dispersion of vanadia at higher loadings might be due to formation of β-(Nb, V)$_2O_5$.

According to Smits *et al.*,[6] the activity for oxidative dehydrogenation of propane was much reduced for samples containing the β-(Nb, V)$_2O_5$ phase. Wadsley and Andersson[13] also suggested that, in this phase the vanadium is replaced by the niobium present in isolated tetrahedral sites at the junction of blocks of NbO_6 octahedra. Thus the number of surface vanadium species are found to decrease when β-(Nb, V)$_2O_5$ is present in the catalyst.

The conversion and selectivity during ammoxidation of 3-picoline are reported in Table 1. The results show that conversion of 3-picoline increases up to 6% of V_2O_5 and did not

change appreciably at higher loadings. However, the selectivity of nicotinonitrile was found to be independent of vanadia loading in the catalyst. Watling *et al.*[7] also observed a similar trend in the activity for oxidative dehydrogenation (ODH) of propane over V_2O_5/Nb_2O_5 catalysts. They noticed that the rate of propane ODH first increases linearly with vanadia loading up to 6% and then remains constant at higher vanadia loadings. It is worth noting here that this vanadia loading corresponds closely to a theoretical monolayer capacity of V_2O_5 supported on a niobia having a specific surface area of 55 m^2 g^{-1}. This indicates that indeed a monolayer of vanadium oxide is formed at this concentration of V_2O_5 on niobium oxide.

The results of catalytic performance during ammoxidation can be explained by assuming that the active sites are due to vanadium ions at the surface, and the activity and selectivity of this site depends on the number of neighbouring vanadium and niobium ions. According to Smits *et al.*[14] the neighboring vanadium ions provide additional activity, while neighboring niobium ions improve the selectivity. The optimal activity and selectivity is shown a site having both vanadium and niobium as neighbors (V–O–V*–O–Nb).[14] At low vanadium loadings, the possibility of vanadium sites having a vanadium ion as a neighbour are low and thus the catalyst will be selective (Fig. 1) but not very active. The high activity for 6% V_2O_5/Nb_2O_5 catalyst might be due to presence of both vanadium and niobium as neighbors (monolayer loading). At higher loadings of V_2O_5 the activity remains constant due to formation of the new phase *i.e.* β-(Nb, V)$_2O_5$. This can be explained based on the assumption that not all the vanadium present in these catalysts contributes to the formation of mixed oxide phase.

To find the relation between the ammoxidation activity of 3-picoline and the dispersion of vanadia, a plot of 1/*X versus* the number of surface V_2O_5 moles is shown in Fig. 2, where *X* is the rate of picoline molecules converted per second per surface V_2O_5. A linear relationship passing through the origin was obtained, which clearly demonstrates that 3-picoline conversion is directly related to oxygen chemisorption measured at 640 K. As reported elsewhere, in connection with vanadium oxide catalysts supported on alumina[12] and on silica,[15] oxygen is chemisorbed at low temperatures selectively on coordinatively unsaturated sites (CUS), generated upon reduction, having a particular coordination environment. These sites are located on a highly dispersed vanadia phase, which is formed only at low

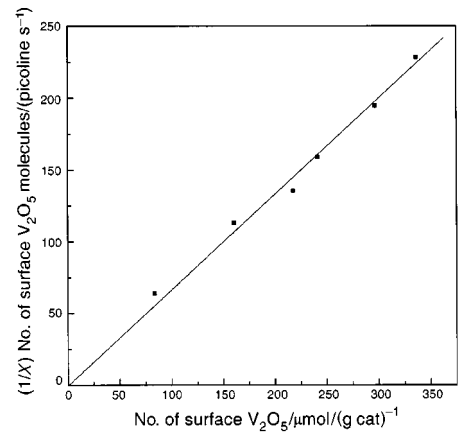

Fig. 2 Relationship between concentration of surface V_2O_5 and the rate of 3-picoline conversion.

vanadia loadings and remains as a 'patchy monolayer' on the support surface. At higher vanadia loadings, a second phase forms, in addition to the existing monolayer, and this post monolayer phase does not appreciably chemisorb oxygen. In light of the above, the correlation observed here, indicates that the catalytic functionality of the dispersed vanadium oxide phase supported on niobium(v) oxide is responsible for the ammoxidation of 3-picoline to nicotinonitrile is located on a patchy monolayer phase and that this functionality can be titrated by the oxygen chemisorption method described in this work.

Thus at low vanadia loadings the active vanadia phase is present in a highly dispersed state. However, at higher vanadia loadings, a mixed oxide containing β-(Nb, V)$_2O_5$ is formed. V_2O_5/Nb_2O_5 catalysts were highly active and selective for the conversion of 3-picoline to nicotinonitrile. The oxygen uptake is found to be directly related to the activity of the catalysts during 3-picoline ammoxidation to nicotinonitrile.

One of us (G. K.) thanks CSIR, New Delhi and T. B. thanks UGC, New Delhi for the award of a Senior Research Fellowships. The authors are also grateful to CBMM, Brasil for providing a hydrated niobia sample.

Received (in Cambridge, UK) 21st April 1999, Accepted 16th June 1999

Made by a nitrile insertion/hydrogen migration process *via* $Ph_2P(O)CH_2Li$ and Bu^tCN, the enamide $Ph_2P(O)CH{=}C(Bu^t)N(H)Li$ and its TMEDA hemisolvate exist as tetrameric and dinuclear arrangements respectively: the novel structure of the starting lithiated phosphane oxide, also in its TMEDA hemisolvated form, is shown to contain Li–C contacts of two distinct types.

Previously we have described the nitrile insertion reaction and subsequent Lewis base-promoted ketimide to azaallyl rearrangement depicted in eqn. (1) (R = H or Pr^n).[1] Here we show

$$RCH_2Li + Bu^tC{\equiv}N \longrightarrow RCH_2(Bu^t)C{=}NLi \xrightarrow{HMPA} RC(H){=}C(Bu^t)N(H)Li{\cdot}HMPA \quad (1)$$

that this dual process can be extended to a functionalised group, R = $Ph_2P(O)$ in the lithiated phosphane oxide $Ph_2P(O)CH_2Li$, and that it can thereby occur without the aid of an external Lewis base. Such lithiated phosphane oxides are widely used as Horner–Wittig reagents[2] for the stereoselective synthesis of alkenes. As such, their metal–ligand bonding is of particular interest since in rare cases intimate C–Li contacts can contribute to the stability of these generally exclusively Li–O bonded molecules. For this reason we determined first the crystal structure of the starting lithiated phosphane oxide in its partially TMEDA-solvated form, $\{[Ph_2P(O)CH_2Li]_2{\cdot}TMEDA\}_2$ **1**, thereby revealing a unique tetranuclear arrangement which has in fact two distinct types of C–Li contact. The products of the nitrile insertion reactions of $Ph_2P(O)CH_2Li$, $\{Ph_2P(O)CH{=}C(Bu^t)N(H)Li\}_4$ **2** and $\{Ph_2P(O)CH{=}C(Bu^t)N(H)Li\}_2{\cdot}TMEDA$ **3**, have also been crystallographically characterised, so giving the first crystal structures of lithiated organophosphorus enamines. We also report some preliminary reactions of **2** which show that it can behave as either a C-based or a N-based nucleophile.

Although earlier attempts to produce crystals of the solvent-free parent compound $Ph_2P(O)CH_2Li$ failed,[3] we have now successfully crystallised its TMEDA hemisolvate **1**.† Despite a high *R* value, the key features of the solid-state structure of **1**‡ are clear-cut. Thus, although formally tetrameric, the centrosymmetric molecular structure of **1** (Fig. 1) is best regarded as a pseudo-dimer, constructed by the dimerisation of two dinuclear units. 'Dimerisation' operates through a strictly planar $(OLi)_2$ ring, a feature common to purely dinuclear lithiophosphane oxide dimers.[4] Each dinuclear unit accommodates two distinct Li atoms within a puckered (POLiOLiC) ring. With respect to individual monomeric (CPOLi) units, the short C26–Li1 contact [2.171(13) Å] within this six-membered ring is intermolecular. A bidentate TMEDA ligand completes the four-fold coordination of Li1. Fused onto the (POLiOLiC) ring is an (OPCLi) chelate ring, made possible by the C13–Li2 contact [2.340(13) Å]. Here, the carbanionic CH_2^- centre functions as

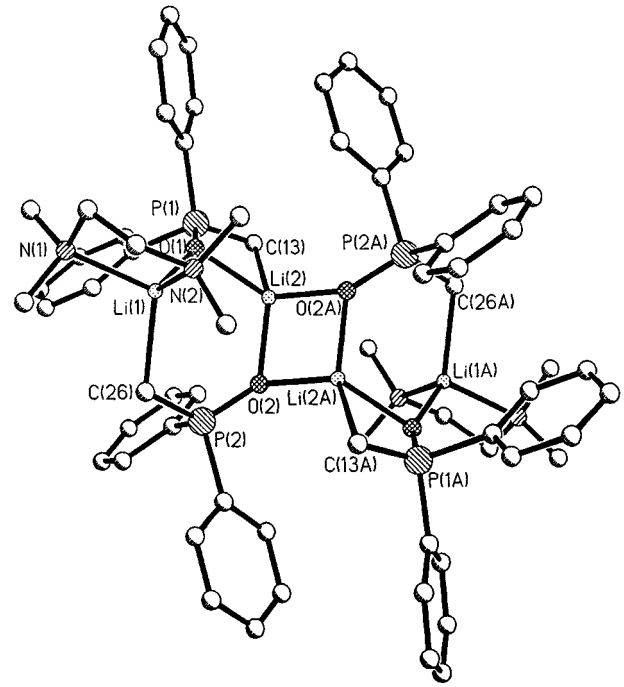

Fig. 1 Molecular structure of **1**. Hydrogen atoms are omitted for clarity.

an internal coordinating centre, to the exclusion of TMEDA (note that in the synthesis of **1** a 3:2 TMEDA:Li ratio was used). Crystallographic confirmation of Li–C contacts in lithiated phosphane oxides has so far been limited to those within (POCLi) chelates in non-solvated $\{Ph_2P(O)CHLiC(H)MeEt\}_4$[3] and to intermolecular ones in the dimer of fully TMEDA-solvated lithio *P*-isopropyl-1,3,2-dioxaphosphorinane 2-oxide[5] (their mean lengths of 2.230 and 2.228 Å, respectively, lie between those found in **1**). Both types of contact are uniquely combined within the structure of **1**, a fact directly attributable to its *partially* solvated nature (*i.e.* with non-solvated and solvated Li sites).

Having an in-built Lewis base function, $Ph_2P(O)CH_2Li$ does not require the participation of a donor solvent to convert to the enamide **2** on addition of nitrile [eqn. (2)]. Accordingly, a

$$Ph_2P(O)CH_2Li + Bu^tC{\equiv}N \longrightarrow \underset{\mathbf{2}}{Ph_2P(O)CH{=}C(Bu^t)N(H)Li} \xrightarrow{TMEDA} \underset{\mathbf{3}}{\tfrac{1}{2}[\{Ph_2P(O)CH{=}C(Bu^t)N(H)Li\}_2{\cdot}TMEDA]} \quad (2)$$

hexane–toluene solvent system was used.† No ketimide intermediate, as detected in the simple alkyl systems [eqn. (1)], is observable here, nitrile insertion and hydrogen transfer (from

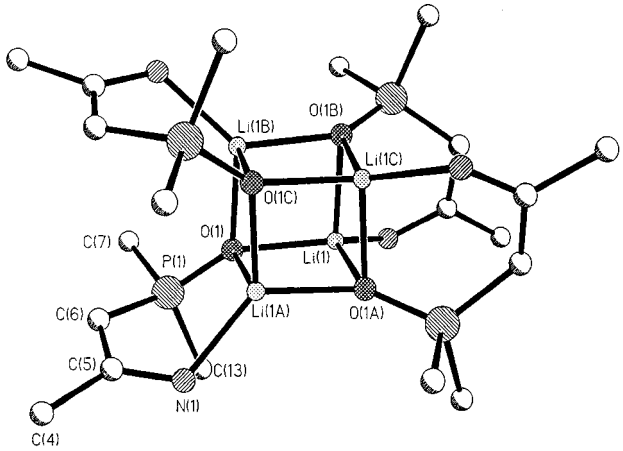

Fig. 2 Molecular structure of **2**. Only the *ipso*-C of Ph and the quaternary C of Bu^t groups are shown. Hydrogen atoms are omitted for clarity.

the CH_2 unit to the N atom) both having occurred. To make the hemisolvated derivative **3**, the same reaction is followed, but TMEDA is added subsequently [eqn. (2)].†

Based on a $(LiO)_4$ pseudocubane core, the molecular structure of **2** (Fig. 2)‡ has N atoms internally donating to the Li ones within (OPCCNLi) chelate rings. The most revealing feature is that relatively long PC⋯C [1.399(5) Å] and short C⋯N [1.310(4) Å] bond lengths within these rings indicate a delocalised arrangement with a high degree of imidoalkyl [RC(H)–C(Bu^t)=NH]$^-$ character, moreso than in the simple lithium azaallyl {Pr^{n}C(H)=C(Bu^t)N(H)Li·HMPA}$_2$ [1] [corresponding lengths: 1.345(3) and 1.390(3) Å]. Accordingly, the Li–N bond in **2** is short [1.958(6) Å; *cf* 2.012 Å (mean) in the latter], reflecting also the relatively strain-free conformation [CNLi angle, 119.2(3)°] of the six-membered chelate ring. No C–Li contacts are therefore necessary, so the *C*(H)*C*(Bu^t) atoms display sp^2 rather than sp^3 hybridisation. The second enamide structure **3** (Fig. 3)‡ is constructed around an asymmetrical, essentially planar $(LiO)_2$ rhomboidal ring. Chelation of Li1 by TMEDA forces the chelating (OPCCN) arms into a *cis* conformation with both N atoms internally donating to Li2: in this way both Li atoms attain (distorted tetrahedral) four coordination. The Li–O bond lengths within the OPCCNLi chelated units are significantly longer [2.075(6) Å] than those involving the TMEDA-solvated Li [1.913(6) Å]. These are counterbalanced by short Li–N(anion) bonds and long Li–N(TMEDA) bonds [1.990(5) and 2.094(7) Å, respectively]. Similarly, the wider bite size of the OPCCN ligand [99.5(1)°; *cf* 88.0(4)° for TMEDA] is offset by narrower O–Li2–O bond angles [94.8(4)° *cf*. 105.9(4)° for OLi1O]. As in **2**, the PC⋯C and C⋯N bond lengths in **3** [1.408(5) and 1.321(5) Å, respectively] suggest that the imidoalkyl canonical form again makes a substantial contribution to the enamide structure, and show therefore that the resonance delocalisation within the OPCCN anion is largely unaffected by the change in aggregation or the introduction of solvation.

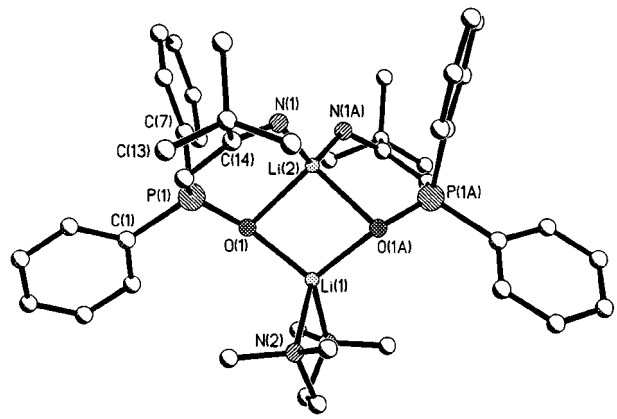

Fig. 3 Molecular structure of **3**. Hydrogen atoms are omitted for clarity.

Finally, quenching the lithium complexes **2** or **3** with suitable electrophiles can give access to new organophosphorus enamines. Related compounds of the type $Ph_2P(O)CH{=}C(R)N(H)R'$, made by nucleophilic addition of amines to 1-alkynylphosphine oxides,[6] are useful precursors to α,β-unsaturated ketimines and ketones. Interestingly, preliminary studies on **2** indicate that methanolysis affords $Ph_2P(O)CH{=}C(Bu^t)NH_2$ but that treatment with methyl iodide affords chiral $Ph_2P(O)CH(Me)$-C(Bu^t)=NH.† This ambi-(N- or C-) nucleophilic behaviour, and the potential uses of the products as unusual new ligands, are being explored further.

Notes and references

† Standard inert-atmosphere Schlenk techniques were used for all syntheses. **1**: Bu^{n}Li (6 mmol in hexane) was added to a suspension of $Ph_2P(O)CH_3$ (6 mmol) in toluene (5 ml) containing TMEDA (3 mmol) at −78 °C. Warming to room temperature gave a yellow precipitate. Hexane was removed *in vacuo* and replaced by toluene (2 ml). Dissolution was achieved by heating the mixture following the addition of more TMEDA (6 mmol). Allowing the solution to cool gradually in a water bath afforded yellow rhomboidal crystals of **1** (yield, 36%; mp decomp. from 90 °C). **2**: $Ph_2P(O)CH_3$ (5 mmol) was suspended in toluene and chilled to −78 °C prior to the addition of Bu^{n}Li (5 mmol in hexane). Warmed to room temperature and treated with Bu^{t}CN (5 mmol) the solution changed from pale to dark yellow. It was then stirred for 30 min before being transferred to a 65 °C water bath and allowed to cool slowly. The solution deposited pale yellow cubic crystals of **2** (yield, 52%; mp decomp. from 175 °C). **3** : the synthesis of **2** was followed to the dark yellow solution stage. TMEDA (5 mmol) was subsequently added. Storing this solution at −30 °C for 4 days produced bright yellow crystals of **3** (yield, 48%; mp decomp. from 167 °C). **1**, **2** and **3** were also characterised by elemental analysis and NMR (^{1}H and ^{13}C) spectral data (to be published in a full paper). The quenched products were also characterised by their ^{1}H NMR spectra.

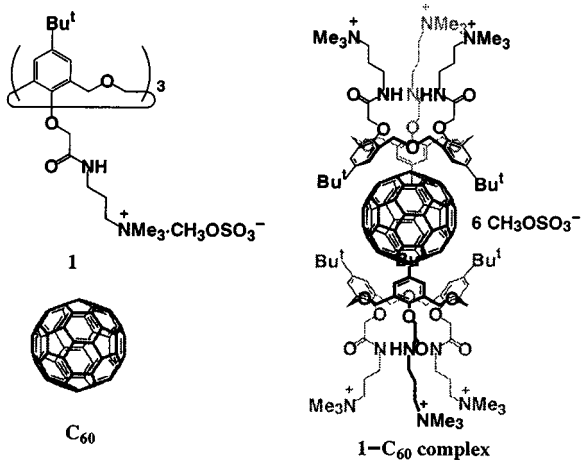
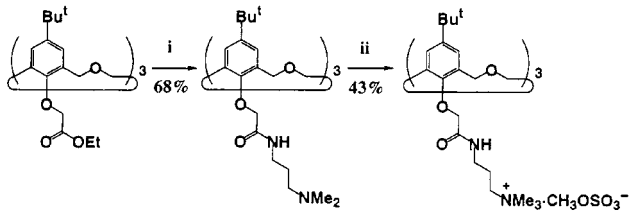
Received (in Cambridge, UK) 14th May 1999, Accepted 14th June 1999

A new water-soluble, cationic homooxacalix[3]arene 1 was synthesized: this homooxacalix[3]arene solubilized [60]fullerene into water and the [60]fullerene–homooxacalix[3]arene complex acted as an efficient DNA photocleavage reagent.

The ready availability of [60]fullerene and its homologues has increasingly invited exploration of their outstanding new physical and chemical properties. Among them, one of the most important applications is medicial use: for example, they act as a singlet oxygen ($^1O_2$) photosensitizer[1,2] to cleave DNA[3–8] and as an inhibitor to suppress HIV protease activity.[9,10] In spite of their high potentials, however, applications have been very limited because of their poor water solubility. Several lines of effort have so far been devoted toward compensation for this drawback, for example, by introduction of water-soluble substituents,[3–6] mixing with water-soluble polymers,[7,11] and solubilization in γ-cyclodextrin (γ-CD)[12] and water-soluble calix[8]arenes.[13] We considered that among these methods, the host–guest method should be superior to others because (i) one can directly use 'unmodified [60]fullerene' which can generate $^1O_2$ more efficiently than other [60]fullerene derivatives,[14] (ii) one can suppress undesired photo-dimerization of [60]fullerene and (iii) dioxygen or substrates can collide with [60]fullerene more efficiently. Recently, we found that homooxacalix[3]arene and its derivatives can include [60]fullerene in their cavities.[15–18] This finding suggests that if a cationic homooxacalix[3]arene can solubilize [60]fullerene into water *via* host–guest interactions, the resultant [60]fullerene–homooxa[3]arene complex should be readily bound to DNA and might act as a DNA photocleavage reagent therein. With these objects in mind, we designed a new water-soluble cationic homooxacalix-[3]arene **1** with a cone conformation.



Water-soluble calixarene **1** was synthesized according to Scheme 1 and identified by ^{1}H NMR, FT-IR and ESI-TOF MS



Scheme 1 *Reagents and conditions*: i, *N*,*N*-dimethylpropane-1,3-diamine, DMAP, NaH, THF–EtOH; ii, Me_2SO_4, THF.

spectroscopic evidence and elemental analysis.† The ^{1}H NMR data are consistent with a cone conformation.

Firstly, the critical aggregate concentration (CAC) of **1** was estimated by surface tension (Wilhelmy method). As shown in Fig. 1, the surface tension of **1** in pure water abruptly decreased at *ca*. 3 mmol dm^{-3}. One can consider, therefore, that compound **1** forms aggregates above this concentration. In the subsequent experiments, we set the concentration of **1** to 0.50 mmol dm^{-3}, where **1** exists discretely in aqueous solution.

[60]Fullerene (solid) was extracted into water containing **1** by sonication (10 min) followed by stirring (3 days).‡ After centrifugation (10 000 rpm, 15 min, 20 °C), the solution was characterized by UV–VIS absorption and ^{13}C NMR spectroscopic methods. The UV–VIS absorption spectrum of the **1**–[60]fullerene complex shows absorption maxima at 264, 341 and 438 nm assignable to solubilized [60]fullerene (Fig. 2). The

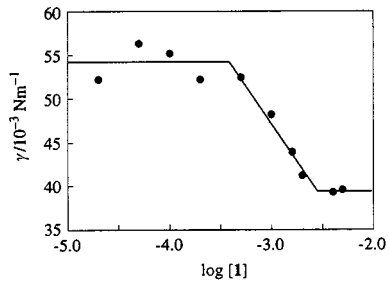


Fig. 1 Plot of surface tension *vs.* concentration of **1** at 25 °C.

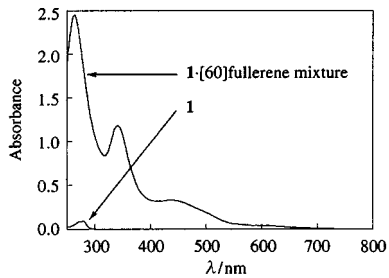

Fig. 2 Absorption spectra of **1** and **1**–[60]fullerene complex in water at 25 °C: [**1**] = 0.50 mmol dm^{-3}.

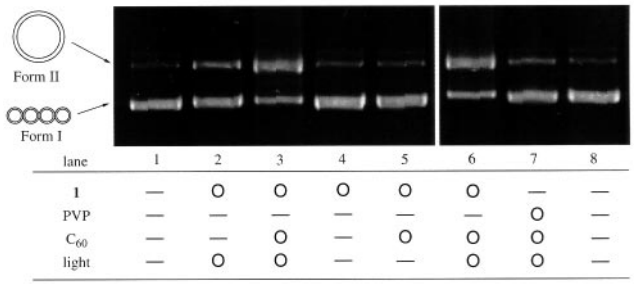

Fig. 3 Agarose gel electrophoretic patterns of DNA nicked by **1**–[60]fullerene complex. The reaction samples contained 93 μmol dm^{-3} of ColE1 supercoiled plasmid. Lanes 1 and 8: no chemicals in distilled water. Lane 2 and 4: 25 μmol dm^{-3} of **1**. Lanes 3, 5 and 6: 25 μmol dm^{-3} of **1** and 12 μmol dm^{-3} of [60]fullerene. Lane 7: 0.9 wt% PVP and 12 μmol dm^{-3} of [60]fullerene. Lanes 1–3 and 6–8: incubated under visible light irradiation at a distance of 10 cm by a 140 W Xe lamp (Sumita LS-140UV) at 25 °C for 6 h. Lanes 4 and 5: incubated in the dark for 6 h. After the addition of 10 mm^3 of 10% SDS solution and loading buffer (Wako) in this order, electrophoresis was performed using 0.9% agarose gel. The gel was stained with 0.3 μg dm^{-3} ethidium bromide and visualized on a UV transilluminator.

^{13}C NMR spectrum of the **1**–[60]fullerene complex shows a new peak (145.90 ppm) due to sp^2 carbon atoms of [60]fullerene. These results consistently support the view that [60]fullerene is solubilized into water by inclusion in **1**. We determined the concentration of solubilized [60]fullerene by elemental analysis of the dried sample obtained by evaporation of this solution. The analytical result shows that the concentration of [60]fullerene in the original aqueous solution was 0.24 mmol dm^{-3}. This indicates the ratio between **1** and [60]fullerene to be 2:1.§ From a dynamic light-scattering measurement (DLS: Otsuka Electronic DLS-7000), the particle size of the **1**–[60]fullerene complex was estimated to be 1.4 nm, which was comparable with the size of the **1**–[60]fullerene 1:2 complex (as simulated by a computational method). These results strongly support the view that the complex does not form large aggregates under the present experimental conditions.

The **1**–[60]fullerene complex was applied to the photocleavage of ColE1 supercoil plasmid. Under dark conditions, DNA was not cleaved even in the presence of these reagents (Fig. 3, lanes 4 and 5). Under visible light irradiation, the **1**–[60]fullerene complex clearly showed DNA-cleaving activity (lane 3). In lane 3, about 65% of supercoiled DNA (form I) was converted to nicked DNA (form II). On the other hand, compound **1** showed a weak DNA-cleaving activity by itself. We consider that 'cationic' **1** is bound to 'anionic' DNA to induce a conformational change in DNA, which facilitates the DNA photocleavage. For comparison, we carried out a control experiment using the poly(vinylpyrrolidone) (PVP)–[60]fullerene system.[7] The DNA-cleaving activity of the PVP–[60]fullerene system (lane 7) was obviously much lower than that of the **1**–[60]fullerene complex (lane 6) under visible light irradiation. Consequently, one can conclude that [60]fullerene included in 'cationic' **1** is transported onto 'anionic' DNA with the aid of electrostatic interactions and cleaves it with the aid of photoirradiation.

How was DNA cleaved by transported [60]fullerene? Foote *et al.*[19] proposed that two mechanisms have to be taken into consideration: type I is the photoinduced electron transfer from the guanine unit to [60]fullerene and type II is the reaction with $^1O_2$ photochemically generated by [60]fullerene. These two mechanisms can be distinguished by comparison of the results of the aerobic conditions with those of the anaerobic ones. We found that there is no significant difference between these two conditions: the yields of form II were 63% under the aerobic conditions, 63% under the anaerobic (N_2) conditions and 66% under the dioxygen-saturated conditions. The results suggest that the mechanism mainly operative in the present DNA photocleavage system is type I, which is basically in line with Foote's results.[19]

In conclusion, the present paper demonstrated that 'cationic' **1** can solubilize [60]fullerene into water and transport it to DNA. Hence, photocleavage can be readily accomplished therein using 'unmodified' [60]fullerene. To the best of our knowledge, this is one of a few successful examples in which 'unmodified' [60]fullerene is directly supplied to DNA. These findings imply, therefore, that the concepts cultivated in host–guest chemistry of [60]fullerene and its homologues are more fruitfully applied to medicinal chemistry.

Communication 9/03872H

Enantiospecific synthesis of a planar chiral bidentate indenyl–alkoxide complex of zirconium using an axially chiral indene ligand

Robert W. Baker* and Brian J. Wallace

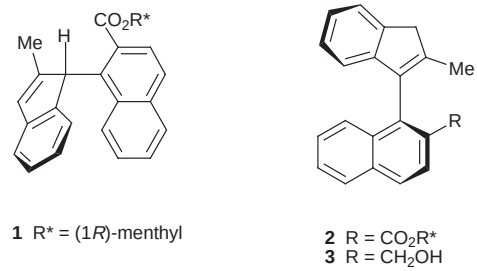
School of Chemistry, The University of Sydney, NSW 2006, Australia. E-mail: r.baker@chem.usyd.edu.au

Received (in Cambridge, UK) 10th May 1999, Accepted 22nd June 1999

The reaction of axially chiral (*M*)-1-(2′-methyl-3′-indenyl)-naphthalene-2-methanol 3 with $Zr(NEt_2)_4$ enantiospecifically provides the planar chiral complex (*P*)-bis(diethylamido)-[1-(2′-methyl-1′-indenyl)naphthalene-2-methoxo]-zirconium 7.

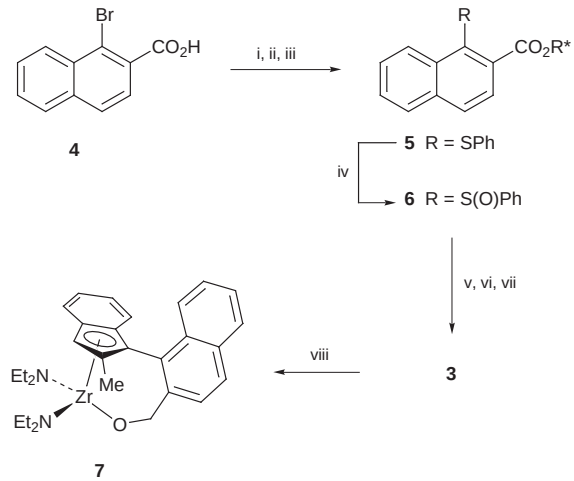
Planar chiral cyclopentadienylmetal complexes feature amongst the more successful stereoselective catalysts. They are usually obtained in enantiomerically pure form through resolution procedures, there being few methodologies allowing asymmetric synthesis. The most common approach[1] designed to avoid resolution utilises cyclopentadienyl ligands containing other stereogenic elements, rendering the faces of the ligand diastereotopic; however, stereoselectivity for the planar chiral element generated during metallation reactions is not guaranteed and separation of diastereoisomers may still be required. An approach extensively employed for 1,2-disubstituted ferrocenes involves the diastereoselective lithiation of complexes containing a chiral *ortho*-directing group.[2] An alternative to this is the enantioselective metallation of ferrocenes with achiral *ortho*-directing groups using a palladium(II) salt with an *N*-protected amino acid,[3] or a chiral lithium amide or an alkyllithium/chiral ligand complex.[2] Two other recently reported methods for the asymmetric synthesis of planar chiral cyclopentadienylmetal complexes are the displacement of chiral auxiliary ligands (L^{ch}) from half-sandwich complexes $Cp^*RuL_2{}^{ch}$ by planar prochiral cyclopentadienylmetals,[4] and the cyclisation of ferrocenyl diazoketones catalysed by chiral rhodium complexes.[5] We have proposed a ligand design whereby a second metal coordination site is constrained to one face of an asymmetrically substituted cyclopentadienyl ring through hindered rotation about the bond between the cyclopentadienyl ring and a naphthalene moiety; formation of chelating complexes using these ligands was anticipated to lead to the enantiospecific generation of a planar chiral cyclopentadienylmetal complex. Towards this objective, we have described approaches to the asymmetric synthesis of precursors to axially chiral chelating fluorene[6,7] and indene[8,9] ligands, employing ligand coupling reactions of sulfoxides. Here we demonstrate the potential of our ligand design with the enantiospecific synthesis of a planar chiral bidentate indenyl–alkoxide complex of zirconium using an axially chiral indene ligand.

We have described previously[9] that the reaction of (1*R*)-menthyl (*R*)-1-(*p*-tolylsulfinyl)naphthalene-2-carboxylate[7] with 2-methylindenyllithium during 30 min at 0 °C provides exclusively the −*ac*-rotamer of (1*R*)-menthyl (*S*)-1-(2′-methyl-1′-indenyl)naphthalene-2-carboxylate **1** in 50% yield and 70% de. The C1–C1′ bond of **1** was shown to be a stable stereogenic element that was conserved during subsequent prototropic shifts to 1-(2′-methyl-3′-indenyl)naphthalenes; thus, treatment of **1** with triethylamine provided **2** in 97% yield and 65% de, while LAH reduction gave **3** in quantitative yield and 70% ee. In order to obtain ligand **3** in enantiomerically pure form, a convenient procedure amenable to operation on a large scale has been developed (Scheme 1). Esterification of 1-bromo-2-naphthoic acid **4** (readily prepared from 2-methylnaphthalene)[10] with (1*R*)-menthol followed by displacement of the bromide with sodium thiophenoxide, furnished the phenylsulfide **5** in 94% overall yield. Oxidation of **5** with dimethyldioxirane, generated *in situ* using OXONE®, provided the sulfoxide **6** as a 58:42 mixture of epimers at sulfur (^{1}H NMR analysis) in 51% yield, accompanied by 46% of recovered **5**.† Reaction of **6** with 2-methylindenyllithium during 40 min at 0 °C furnished **1** and the +*ac*(*R*) isomer of **1**, in a ratio of 44:56, respectively (^{1}H NMR analysis), in 92% combined yield. This mixture was then quantitatively isomerised to a mixture of **2** and the *P*-epimer of **2**, in a ratio of 46:54, respectively,‡ on treatment with triethylamine. Fractional crystallisation, then recrystallisation from hexane solution furnished **2** in > 99% de‡ and 32% yield (maximum theoretical yield 46%). A single-crystal X-ray structure determination on **2**§ establishes the *M* absolute configuration at the chiral axis, which had been previously proposed on the basis of comparisons of CD spectra.[9] The rate of epimerisation of **2** to the *P*-epimer (ultimately affording a 1:1 mixture) has been determined by HPLC analysis in xylenes solution at reflux,‡ providing a barrier to rotation $\Delta G^{\ddagger}_{413}$ = 150.6 kJ mol^{-1}. Reduction of **2** of > 99% de‡ with LAH affords **3** quantitatively with > 99% ee.¶ While the barrier to rotation in **3** has not been determined, it can be anticipated to be higher again than that of **2**.[8]



1 R* = (1*R*)-menthyl

2 R = CO_2R^*
3 R = CH_2OH



Scheme 1 *Reagents and conditions*: i, $SOCl_2$ (15 equiv.), 25 °C, 20 h; ii, (1*R*)-menthol (2 equiv.), pyridine (2 equiv.), CH_2Cl_2, 25 °C, 30 min; iii, PhSNa (1.2 equiv.), DMF, 60 °C, 20 h; iv, OXONE® (3 equiv.), $NaHCO_3$ (5 equiv.), acetone–MeCN–water (20:10:1), 5 °C, 20 h; v, 2-methylindenyllithium (1.3 equiv.), THF, 0 °C, 40 min; vi, NEt_3–toluene (1:1), reflux, 24 h; vii, LAH (5 equiv.), diethyl ether, 25 °C, 1 h; viii, $Zr(NEt_2)_4$ (1 equiv.), toluene, reflux, 16 h.

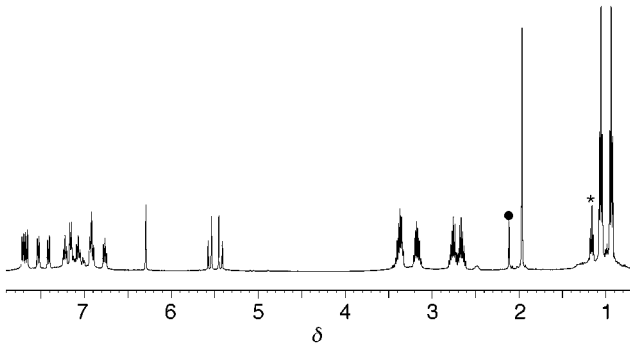


Fig. 1 ^{1}H NMR (400 MHz, C_6D_6) spectrum of complex **7**; unobscured signals of residual toluene and $Zr(NEt_2)_4$ are indicated by • and *, respectively.

With multigram quantities of enantiomerically pure **3** available, we next sought to prepare a bidentate indenyl–alkoxide metal complex[11] in order to demonstrate that the axial chirality of the ligand would indeed translate into planar chirality in the complex without loss of enantiomeric purity.‖ Initial attempts at metallation of **3** through formation of the dilithio species with BuLi, followed by reaction with $ZrCl_4$ in a variety of solvents, failed to produce any of the desired complex. Metallation was readily achieved, however, employing the amine elimination method.[13] Reaction of **3** with 1 equiv. of $Zr(NEt_2)_4$ in toluene solution under reflux for 16 h, followed by removal of the solvent, led to essentially quantitative conversion to the complex **7**,** as evident from inspection of the ^{1}H NMR spectrum of the crude product (Fig. 1).†† In particular, the methylene signal of the indene moiety of **3** (AB pattern centred at δ_H 3.65) is replaced by a singlet at δ_H 6.29 in **7**; the methylene signal of the naphthalenemethanol moiety of **3** (AB pattern centred at δ_H 4.63) is significantly deshielded on formation of **7** (AB pattern centred at δ_H 5.50); and the diastereotopic NEt_2 ligands of **7** appear as two distinct ABX_3 patterns. Consistent with the mononuclear structure proposed for **7**, the high field ^{1}H NMR spectrum of the crude product obtained in the reaction of *rac*-**3** with $Zr(NEt_2)_4$ was identical to that obtained with enantiomerically pure **3**, with additional signals being completely absent. Hydrolysis of complex **7** with dilute HCl solution quantitatively returned ligand **3** with > 99% ee.¶ It follows that complex **7** is also enantiomerically pure and can be assigned *P* absolute configuration (a single descriptor for configuration is used as the atropisomerism of the precursor ligand **3** is considered to be latent in the complex). We are currently examining the expansion of this approach to a wide range of ligands and metal complexes.

Notes and references

† A reaction sequence analogous to that from **4** to **6** was first developed in this laboratory by M. A. Foulkes using the isopropyl esters.

‡ Diastereoisomeric purity was determined by HPLC: a 4.6 × 250 mm column (Zorbax 5 μ silica, Jones) was used with 0.4% ethyl acetate–hexane as eluent at a flow rate of 1.5 ml min^{-1}, detection 254 nm, t_R: 17.4 min for **2** and 20.0 min for the *P*-epimer of **2**.

§ Details of the single-crystal X-ray structure determination of **2** will appear in the full account.

¶ Enantiomeric purity was determined by HPLC: a 4.6 × 250 mm column (Pirkle Type 1A, Regis) was used with 5% propan-2-ol/hexane as eluent at a flow rate of 1.5 ml min^{-1}, detection 254 nm, t_r: 9.5 min for **3** and 10.2 min for *ent*-**3**.

‖ Somewhat related to this work, Pregosin and coworkers[12] have reported that reaction of $Ru(OAc)_2$[(*M*)-6,6′-dimethoxybiphenyl-2,2′-diyl-bis{di(3,5-di-*tert*-butylphenyl)phosphine}] with MeLi affords a planar chiral $RuMe_2$ complex where Ru is coordinated to one phosphine together with an η^6-C_6H_3 moiety from one of the biaryl rings; however, the enantiomeric purity of this complex is not discussed.

** Complex **7** was isolated as an orange viscous oil which, to date, has resisted crystallisation. Consequently, the purity of **7** is dependant on the precision of the stoichiometry of the reaction between **3** and $Zr(NEt_2)_4$, *e.g.* the reaction product shown in Fig. 1 contains *ca.* 5 mol% unreacted $Zr(NEt_2)_4$.

Received (in Bristol, UK) 10th November 1998, Revised manuscript 10th June 1999, Accepted 10th June 1999

The preparation of the first π-conjugated TTF polymer composed entirely of vinylogous, linearly fused TTF moieties has been achieved by oxidative polymerization of 2,5-di(benzylidene)-1,3,4,6-tetrathiapentalene.

Numerous attempts to incorporate TTF into polymeric backbones have been spurred by the exciting solid state properties of TTF molecular conductors and aimed at a combination of the electrical conductivity exhibited by these radical cation salts with the enhanced processability of a polymer matrix.[1] The TTF polymers reported to date consist of essentially independent TTF entities attached to a conjugated polymer backbone or of linear chains composed of segregated TTF units linked through spacer groups *via* σ or π bonds.[1] In spite of the well-known tendency of TTF to form ordered stacks,[2] the interactions between individual TTF units in polymeric matrices are difficult to control in the solid state. Insufficient through-bond and through-space interactions as a consequence of lacking conjugation and structural disorder in TTF polymers may result in low conductivities in the oxidized state.[1]

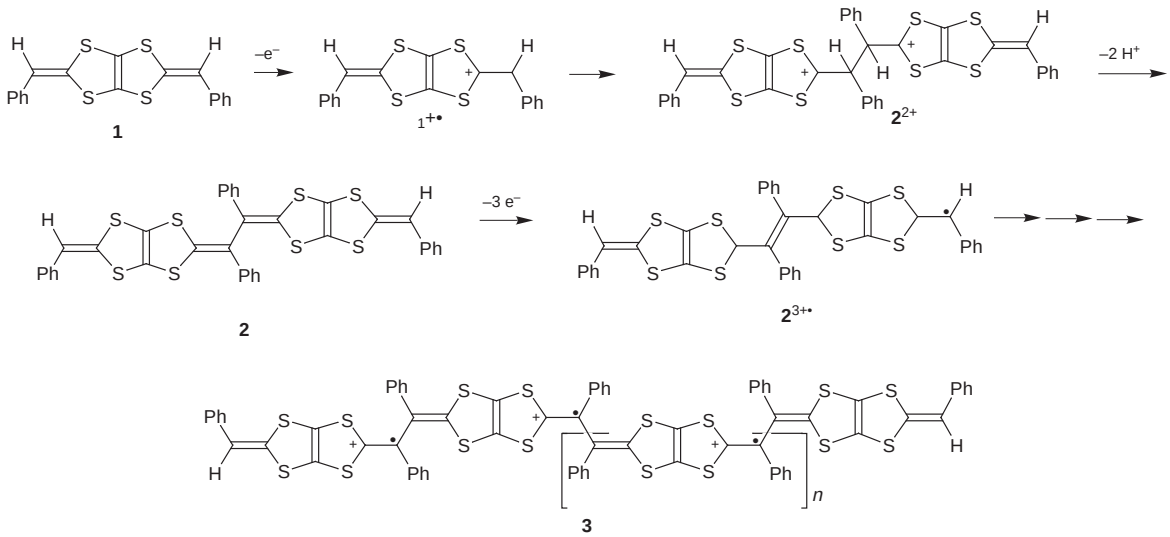
Macromolecular structures composed of fully π-conjugated TTF units could possibly offer an interesting alternative to overcome these inherent drawbacks.[1f,g,3] Linearly annelated TTF entities appear to be particularly promising in that respect, since the radical cation salts of many dimeric, linearly fused TTF derivatives exhibit metallic conductivity.[4] Despite the exceptional solid state properties of molecular conductors based on dimeric TTF donor molecules, the preparation of polymeric analogues has not yet been reported.

Recently, we have disclosed a novel synthetic approach to vinylogous, extended TTF derivatives starting from tetrathiapentalenes as precursors.[5] Here we report the application of this method to the preparation of poly[(dibenzylidene)tetrathiapentalene] (**3**; PDB-TTP), the first conducting polymeric TTF derivative composed entirely of π-conjugated, linearly annelated TTF units.

The synthetic concept is based on the transformation of the tetrathiapentalene (TTP) precursor **1** into the corresponding bifunctional TTF derivative **2**.[5] Owing to its hybrid TTP/TTF character, compound **2** can undergo oligo- and polymerization reactions *via* radical intermediates, a behaviour which contrasts sharply with that commonly known for TTF vinylogues.[6] Suitable substituents, such as the phenyl rings of **1**, enhance the solubility of the monomer and prevent the growing TTF chain from precipitation and thus from an early termination of the polymerization reaction.

The key step of the oxidative polymerization involves the formation of the highly reactive radical $\mathbf{1}^{+\cdot}$ from 2,5-di(benzylidene)-1,3,4,6-tetrathiapentalene (**1**; DB-TTP), which dimerizes with subsequent dehydrogenation to the TTF derivative **2**.[5] The isolation of the stable intermediate **2** confirms that radica–radical coupling of $\mathbf{1}^{+\cdot}$ occurs *via* the benzylic carbon atoms and thus resembles closely the well-known oxidative dimerization of 1,4-dithiafulvenes to vinylogous TTF derivatives.[7] Contrary to ordinary TTF derivatives, however, **2** can be oxidized to the radical trication $\mathbf{2}^{3+\cdot}$ which through subsequent radical dehydrodimerization and oxidation steps, eventually yields a polymer of general formula **3**. The proposed polymerization mechanism is depicted in Scheme 1 and was established by detailed electrochemical investigations performed on **1** and independently synthesized **2**.[8]

Thin films of **3** were prepared on Pt disk electrodes in anhydrous dichloromethane by repeated potential cycling between 0 and + 1.6 V (**1**: 4 10^{-4} M; $Bu^n_4NPF_6$ 0.1M; CH_2Cl_2;



Scheme 1 Redox polymerization of monomer **1**. The counterions have been omitted for clarity, the polymer **3** is shown in a partially oxidized state. For an estimate of *n* see text.

Pt disc electrode ∅ 3 mm; v = 100 mV s^{-1}; 500 cycles) or by potentiostatic electrolysis at + 1.6 V [all potential values *versus* a saturated calomel electrode (SCE)].† The cyclic voltammogram of **1**, recorded during film synthesis, exhibited two irreversible waves (anodic peak potentials *ca.* + 0.8 and + 1.4 V) for the first sweep. Further scans showed the evolution of a new symmetrical redox wave at a less anodic potential (*ca.* + 0.6 V) indicating the formation of a new electroactive species. The peak currents of the latter increased continuously with each subsequent scan thus evidencing progressive deposit growth on the electrode surface.

The electrochemical response of a PDB-TTP film in monomer-free solution. The CV involves a sharp redox wave at a peak potential of *ca.* + 600 mV as well as several coalescing signals between + 900 and + 1500 mV, respectively. For simplicity, the latter will be considered as a single redox wave only. The amounts of charge transferred between 0 to + 700 mV and between + 700 to + 1500 mV are equal, as follows from an integration of the respective peak areas. The symmetrical signal shapes are characteristic of a surface-immobilized reversible redox system and hence in line with the postulated structure **3**.[9]

Results obtained by *in situ* EPR spectro-electrochemistry indicate that each peak potential coincides with a local maximum of the potential-dependent spin density. The relative ratio of the spin populations corresponding to the peak potentials of the first and second redox couple, respectively, is *ca.* 2 : 1. This value, together with the coulometric analysis of the peak areas makes plausible an assignment of the first redox couple to a partial oxidation state **3**, where a linearly extended chain bears one positive charge per vinylogous TTF unit. The removal of further electrons requires the unfavourable localization of positive charges on adjacent dithiole units and occurs in several steps between + 900 and + 1500 mV, where complete oxidation is reached. The resulting increase of the coulombic repulsion shifts the corresponding oxidation potentials towards higher values, simultaneously the number of charge carriers decreases as a consequence of spin recombination.

Continued potential cycling (500 cycles) of films in monomer-free solution between 0 and + 750 mV did not cause any loss in electroactivity, thus demonstrating high stability and pronounced electrochemical reversibility. A switching potential of + 1700 mV reduced the electroactivity by about 50% after 50 scans, presumably as a consequence of overoxidation.

Treatment of **1** with $NOPF_6$ (molar ratio 1 : 1.5) furnished the black, insoluble solid **3** in a yield of 80%, the analytical data of which are in good agreement with the partially oxidized structure **3** containing one counterion per repetitive unit.‡

MALDI-TOF and FAB MS of solid **3** gave intense peaks corresponding to the general formula $m/z = n(354)$ with $z = 1$. Fragments with m/z = 2412 (n = 6), 1416 (n = 4) and 1062 (n = 3) can unambiguously be assigned to structural elements comprising six, four and three monomer units, respectively. These results provide strong evidence for the presence of a linearly extended structure **3**, since the polymerization of **1** (m/z = 356) implies the formal abstraction of two hydrogen atoms per monomer unit within a chain, whereas the two terminal units loose only one hydrogen atom. The lower limit for the average molecular weight of **3** (without counterions) can thus be estimated to amount to at least eight monomer units, corresponding to a molecular weight of 2836 g mol^{-1}. TTF polymers comprising eight monomer units have been described in previous work.[10]

IR spectra of solid **3** exhibit a weak electronic absorption stretching from 3700 to *ca.* 1750 cm^{-1}, a behaviour typical of a semiconductor. Assuming a simple transition between the valence and the conduction band, the corresponding band gap amounts to a value of 217 meV. Intense bands at 1357 and 1248 cm^{-1} closely resemble features characteristic of TTF radical cation salts,[11] and thus corroborate the charged TTF structure **3**. Absorptions at 838 and 557 cm^{-1} confirm the presence of the hexafluorophosphate counterion. EPR spectra of compound **3** display a single, symmetrical line with a width of 6–8 G. The averaged g-factor is 2.0077, the spin density is *ca.* 2×10^{23} spins mol^{-1}. The electrical conductivity, as determined by four-probe measurements on compact samples of **3**, gave values of about 10^{-6} S cm^{-1}. For electrochemically deposited films the conductivities range from 5×10^{-3} to 5×10^{-4} S cm^{-1}. The latter values are among the highest reported to date for polymeric TTF derivatives.[1]

A typical small angle X-ray scattering (SAXS) pattern of compound **3** shows a diffuse scattering background with a sharp superimposed peak at $\boldsymbol{s}$ = 0.44 nm^{-1} and a large bump stretching from 0.6 $nm^{-1} \leqslant \boldsymbol{s} \leqslant$ 1.4 nm^{-1} where s is the modulus of the scattering vector. The observed feature is typical of a partially crystalline polymer comprising an ordered, crystalline phase randomly distributed in an amorphous matrix.[12] The single Bragg peak at $\boldsymbol{s}$ = 0.44 nm^{-1} indicates the presence of a crystalline phase with a d-spacing of 22.6 Å. The large bump of the intensity curve originates from the scattering contribution of both amorphous and crystalline phases. Wide-angle X-ray scattering (WAXS) data show essentially a considerable amorphous background with a few superimposed diffraction peaks in the range $2° \leqslant 2\Theta \leqslant 25°$ and hence support the macromolecular character of **3**.

In conclusion we have presented the synthesis of the first TTF main-chain polymer composed entirely of linearly fused TTF units starting from a tetrathiapentalene precursor. The synthetic approach is unique in its simplicity and contrasts the multistep procedures described in previous work.[1] Attempts to extend the scope of the synthetic approach and to tailor important polymer properties, such as solubility and conductivity by varying the substituents of the monomeric precursors are currently being investigated and will be presented in due course.

Received (in Cambridge, UK) 14th May 1999, Accepted 15th June 1999

A new vanadium–titanium substituted aluminophosphate molecular sieve of MFI structure (VTAPO-5) was synthesized hydrothermally and found to be active and selective in partial oxidation of methanol; catalytic activity depends on the vanadium sites; however, the presence of titanium influences the reactivity of vanadium species during reaction.

Aluminophosphate (AlPO) molecular sieves classified as a new class of microporous crystalline inorganic solids are contemporary to the zeolites. A variety of AlPOs have been reported with a rich diversity of structures.[1,2] They are framework oxides with Al and P in tetrahedral coordination with oxygen. In spite of different structural properties from zeolites, AlPOs also apparently obey Loewenstein's rule with an avoidance of Al–O–Al bonds and thus include framework topologies analogous to zeolites. Although titanium and vanadium substitution is well documented in various topologies,[3–7] very little information on isomorphously substituted Ti and V AlPOs have been reported. Excluding the original patent on synthesis of some titanium containing AlPOs, only the synthesis and characterization of TAPSO-5,[8] and more recently TAPO-5, −11, −31 and –36 have been published.[9–11] Many important issues encountered in the synthesis and application of substituted AlPOs are still unaddressed. Very few reports are available in the literature regarding the catalytic behavior of substituted AlPOs such as TAPOs and VAPOs.

Ulagappan and Krishnasamy[8] found that TAPO-5 and -11 were active in phenol hydroxylation. Also some activity was reported for VAPO-5 and Ti-VPI-5 in the catalytic oxidation of cyclohexane to cyclohexanol using *tert*-butyl hydroperoxide (TBHP). Recently, it has shown that TAPOs of structure types AFI, AEL, ATO and ATS (TAPO-5, -11, -31 and -36 respectively) have comparable activities to titanium silicates (TS-1) in a series of oxidation reactions using dilute H_2O_2 (30 wt%) as the oxidant.[10,11] Vanadium–titanium catalysts, (either supported or impregnated) are widely used in industry for the partial oxidation of hydrocarbons and for the selective catalytic reduction of NO with NH_3. In the literature there are some interesting reports[12] concerning the structural characteristics of coprecipitated VTiO systems and their activity in *n*-butene oxidation for the selective production of acetaldehyde and acetic acid. In a very recent report[13] the nature of vanadium sites in a V/α-Ti phosphate catalyst for the oxidative dehydrogenation of ethane were investigated. Here, we report for the first time, the novel synthesis of vanadium–titanium aluminophosphate-5 (VTAPO-5), which is found to be an active and selective catalyst for the partial oxidation of methanol.

VTAPO-5 was synthesized using a gel composition 0.30 NPr_3 : 0.70 TPAOH : 0.02 TiO_2 : 0.047 V_2O5 : P_2O_5 : 42 H_2O. In a typical synthesis, the calculated amounts of phosphoric acid (85 wt%) and pseudoboehmite, as P and Al sources respectively, were mixed and dissolved in distilled water. Then vanadium and titanium as hydrated oxovanadium(IV) sulfate and titanium isopropoxide, respectively, were introduced dropwise to the homogenous gel under vigorous stirring. A mixture of tripropylamine (NPr_3) and TPAOH (an organic template as structure directing agent), was used to direct the MFI structure type in the VTAPO-5 molecular sieve and was slowly introduced into the gel. Finally the entire gel was further stirred for at least 1 h and transferred into a Teflon-coated stainless-steel autoclave for hydrothermal crystallization. Based on a series of systematic syntheses, pure and highly crystalline VTAPO-5 was synthesized aging the gel directly at 458 K for 200 h. After heating, the autoclave was cooled and solid product was separated by centrifugation and repeatedly washed with distilled water followed by drying at 358 K for 6 h followed by calcination in air at 813 K for 8 h. It was interesting that the systems involving only NPr_3 or TPAOH gave no VTAPO molecular sieve while pure VTAPO was obtained from the gel with a mixture of NPr_3 and TPAOH. Substituted TAPO-5 and VAPO-5 were also synthesized by essentially following a reported procedure,[10,14] using the gel composition TPAOH : 0.04 TiO_2 : P_2O_5 : 40 H_2O : NPr_3 : 0.047 V_2O_5 : P_2O_5 : 40 H_2O respectively.

The samples were characterized by X-ray diffraction (XRD), diffuse reflectance UV-VIS spectroscopy (DRS), Raman spectroscopy and ^{27}Al and ^{31}P MAS NMR. Pore volumes were measured by *n*-butane adsorption and N_2 adsorption methods (BET). Bulk chemical analysis was carried out using inductively coupled plasma atomic emission spectroscopy (ICP). Chemical and physical properties of all samples are given in Table 1.

The XRD patterns of TAPO-5 and VAPO-5 were similar to those reported earlier and confirm the purity of the crystallized product with the XRD pattern of VTAPO-5 being closer to that of pure TAPO-5. Intercalation of vanadium moieties in the framework can be discounted since no change in the basal spacing is observed. Pore plugging as well as evidence for an extraneous phase were checked by *n*-butane and nitrogen adsorption. The measured BET surface area for VTAPO-5 was 304 $m^2\ g^{-1}$ and the void volume was 0.121 ml g^{-1}. The amount

Reaction conditions: Feed = 20% methanol in Ar; 10% O_2 in Ar, reaction temp. = 200 °C; F/W (contact time) = [a] 21400 (0.29 s), [b] 15600 (0.40 s), [c] 9800 (0.64 s); catalyst = 0.2 g; MF = methyl formate; FA = formic acid; nd = not detected.

of *n*-butane adsorbed at STP was 0.114 ml g^{-1}. The DRS UV–VIS spectrum of VTAPO-5 shows a single peak with λ_{max} 232–238 nm and no evident shoulder around 300 nm. This suggested that VTAPO-5 is free from anatase or extraframework species such as titanium or vanadium oxide, in line with the BET and *n*-butane adsorption results. Moreover, in all samples studied, no oxide species were detected by Raman spectroscopy. ^{31}P and ^{27}Al MAS NMR spectra of calcined TAPO-5, VAPO-5 and VTAPO-5 indicate that in all samples the aluminium was present in a tetrahedral environment and octahedral Al was absent as found in pseudoboehmite.[15] The ^{27}Al MAS NMR spectra of TAPO-5 and VAPO-5 show a main peak at δ 32.4 while VTAPO-5 showed a slight shift to δ 34.1. Similar results were obtained from ^{31}P MAS NMR spectra; a single ^{31}P band assigned to framework tetrahedral phosphorus was observed at δ −29.8 for VAPO-5 and TAPO-5 samples whereas VTAPO-5 showed a shift to δ −27.2. The overall characterization results indicates that the novel VTAPO and its analogs TAPO-5 and VAPO-5 are pure and well crystallized.

Previous work indicates that the incorporated metal environment is essentially the same for all substituted AlPO analogs and is quite different from that in metal silicates. However, VTAPO-5 is found to be an active catalyst for the partial oxidation of methanol. The catalytic measurements were carried out in a conventional continuous flow differential reactor system. The typical reaction products were methyl formate, formaldehyde, acetaldehyde dimethyl ether, formic acid, CO and CO_2. Measurement of formic acid was performed by acid–base volumetric analysis while other products were analyzed by gas chromatography. The methanol oxidation reaction results (at steady state) and reaction conditions are summarized in Table 2. The catalytic tests were conducted at 200 °C and measured at different contact times (space velocities) of the feed under differential conditions. TAPO-5 was found to be totally inactive for methanol oxidation at the reaction condition studied except for very low activity observed at higher temperature (> 280 °C). VAPO-5 showed a significant activity. The major products obtained were formaldehyde and CO along with small amount of CO_2 and dimethyl ether. On VTAPO a considerable quantity of methyl formate and acetaldehyde were obtained as major products in addition to CO, formaldehyde, CO_2 and dimethyl ether. For methanol oxidation the product formation is proposed to be accompanied by several known complex equlibrium reactions (1)–(7) (Scheme 1).

With regard to the influence of contact time of the feed on the activity and selectivity, the system clearly showed that increased contact time improves methanol conversion and selectivities to methyl formate, acetaldehyde and CO with a decrease in the selectivity to formaldehyde. Thus, it can be proposed that formaldehyde is the initial product of methanol partial oxidation and is an intermediate species in the production of methyl formate, acetaldehyde and CO while the formation of dimethyl ether and CO_2 are independent of the production of the major products. According to these results, the methanol chemisorbs on vanadium species as a surface methoxy (CH_3O), and depending on the nature of Ti sites present on the surfaces of the catalyst, can react *via* various pathways to form

$$2CH_3OH \rightleftharpoons (CH_3)_2O + H_2O \quad (1)$$

$$CH_3OH + \{O_2\} \rightleftharpoons HCHO + 2H^+ + 2e^- \quad (2)$$

$$CH_3OH + \{O_2\} \rightleftharpoons CO + 4H^+ + 4e^- \quad (3)$$

$$HCHO \rightleftharpoons CO + 2H^+ + 2e^- \quad (4)$$

$$CH_3OH + H_2O \rightleftharpoons CO_2 + 6H^+ + 6e^- \quad (5)$$

$$CH_3OH + H_2O \rightleftharpoons HCO_2H + 4H^+ + 4e^- \quad (6)$$

$$HCHO + CH_3OH \rightleftharpoons [CH_3OCH_2OH] \rightleftharpoons HCO_2CH_3 \quad (7)$$

Scheme 1

acetaldehyde, methyl formate, formaldehyde, dimethyl ether and carbon oxides. While titanium itself is not an active site for the partial oxidation of methanol, VTAPO-5 selectively generates methyl formate and acetaldehyde which are more complex than products generated from pure VAPO-5. Thus titanium plays an important role in catalysis possibly due to strong V–Ti interactions. Verification of the precise reaction mechanism is linked to the measurement of the quantity and nature of the active sites. The fact that titanium modifies the active reaction sites would explain why VAPO-5 does not produce acetaldehyde or methyl formate. Further investigation of the catalytic behavior of VTAPO-5 and analogous VAPO-5 catalysts in various hydrocarbon conversion reactions such as oxidative dehydrogenation and epoxidation are in progress.

Transformations of *fac*-Re(dmbpy)(CO)$_3$(CO$_2$H) in the presence of carbon dioxide (dmbpy = 4,4′-dimethyl-2,2′-bipyridine)

Dorothy H. Gibson* and Xiaolong Yin

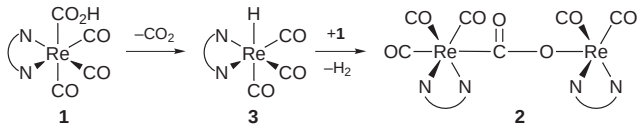
Department of Chemistry and Center for Chemical Catalysis, University of Louisville, Louisville, KY 40292, USA. E-mail: dhgibs01@athena.louisville.edu

Received (in Bloomington, IN, USA) 26th March 1999, Accepted 10th June 1999

Reactions of *fac*-Re(dmbpy)(CO)$_3$(CO$_2$H) 1 or *fac, fac*-Re(dmbpy)(CO)$_3$(CO$_2$)Re(dmbpy)(CO)$_3$ 2 with CO$_2$, in DMSO or DMF containing small amounts of water, lead to the bicarbonato complex, *fac*-Re(dmbpy)(CO)$_3$[OC(O)OH] 4; the formato complex, *fac*-Re(dmbpy)(CO)$_3$(OCHO) 5, is not a major product in any of these reactions.

The proposed intermediacy of metallocarboxylic acids in reductions of CO_2 catalyzed by ruthenium and rhenium polypyridyl complexes[1] has prompted our interest in the synthesis and chemistry of compounds of this type. Previously, the production of formate in the catalytic reactions has been attributed to CO_2 insertion into metal hydrides generated from decarboxylations of metallocarboxylic acids.[1] We recently described the first synthesis of a rhenium acid of this type, *fac*-Re(dmbpy)(CO)$_3$(CO$_2$H) **1**[2] which had been proposed to be an intermediate in electrocatalytic reductions of CO_2 by *fac*-Re(dmbpy)(CO)$_3$Cl.[1] Thermolysis of **1** in dimethyl formamide (DMF) gave the new CO_2-bridged compound, *fac, fac*-Re(dmbpy)(CO)$_3$(CO$_2$)Re(dmbpy)(CO)$_3$ **2**; the reactions could be photoassisted. We suggested that **2** was formed *via* β-hydride elimination from **1**, followed by CO_2 loss, to give *fac*-Re(dmbpy)(CO)$_3$H **3** as an intermediate.[2] Subsequent reaction of **3** with additional **1** was proposed to yield **2** (and hydrogen) as shown in Scheme 1. Since formate was absent from the thermolysis products of **1**, additional reactions of **1** and **2**, with and without CO_2, have been explored because of their relevance to proposed steps in the catalytic processes.[1]

Although the ^{1}H NMR spectrum of **1** can be obtained in DMF-d$_7$ at 0 °C, **1** is labile in this solvent at room temperature and readily converts to **2**.[2] We attempted to follow this transformation by ^{1}H NMR in order to probe for the intermediacy of hydride **3**. A solution of **1** in DMF-d$_7$ was prepared and the spectrum quickly recorded. The spectrum showed none of **3**, but did not correspond exactly to that of **2**[2] either; resonances appeared at the same chemical shift positions as those observed for **2**, but some were broadened (suggesting dynamic behavior) while others were sharp. After 1 h, all resonances had sharpened to those of **2** together with a small amount of a second compound, identified as the bicarbonato complex *fac*-Re(dmbpy)(CO)$_3$[OC(O)OH] **4**.† Importantly, the major features of the spectrum obtained from a sample of **1** after a few minutes in DMF-d$_7$ were reproduced by mixing equimolar quantities of hydride **3** and **1** in this solvent and quickly obtaining the spectrum. The hydride resonance at δ 1.8 had already disappeared by the time the spectrum could be observed, although the spectrum of **3**, alone, can easily be obtained under these conditions. Eventually, the mixture of **3** and **1** afforded **2**, a small amount of formate, *fac*-Re(dmbpy)(CO)$_3$(OCHO) **5**,[2,3] and a small amount of **4**.



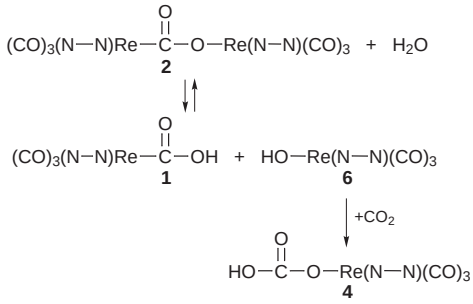
Scheme 1 N–N = 4,4′-dimethyl-2,2′-bipyridine

Compound **1** is more stable in DMSO-d$_6$ and its ^{1}H NMR spectrum can be obtained easily at room temperature. After about 40 min, however, all low field resonances of **1** (dmbpy ring and carboxyl H atoms) became broadened and new resonances that are analogous to those of **2** in this solvent appeared; no resonances for hydride **3** were observed. Compound **2** shows doublets at δ 8.44, 8.34, 7.31 and 7.15 and singlets at δ8.28 and 8.10 in DMSO-d$_6$; the new species showed resonances at all of these positions, but those at δ8.28 and 7.31 were broadened while the others were sharp. After about 2.5 h, all resonances of **1** had disappeared, but the two broadened resonances of the new species were still broadened. Such spectra have been reproduced several times with different samples of **1**; any disturbance (shaking, purging with N$_2$, *etc*.) of samples which have been allowed to stand for 2 h results in immediate transformation of this species to products, primarily **2**. In a separate experiment, a 73% yield of **2** together with 10% of **4** was obtained from a solution of **1** after 2 h standing in DMSO-d$_6$ under laboratory fluorescent lights followed by purging the solution with N$_2$; formate **5** was absent. However, a sample of **1**, dissolved in DMSO-d$_6$ and allowed to stand under laboratory fluorescent lights after purging with CO_2, generated bicarbonato complex **4** in 97% yield after 3 h.

The thermolysis, at ambient temperature, of an equimolar mixture of acid **1** and hydride **3** was followed by ^{1}H NMR spectroscopy in DMSO-d$_6$ in the same manner as for **1** alone. The spectrum was recorded 10 min after dissolving both compounds in the solvent; all resonances of the two substrates were broadened. After 40 min, the carboxyl proton of **1** and the hydride resonance of **3** had disappeared and broadened resonances characteristic of the species formed from **1** alone had appeared. Conversion to **2** occurred slowly, as before; again, formate **5** was not observed.

Other changes in thermolysis samples of **1** in DMSO-d$_6$ accompany changes in the ^{1}H NMR spectra; the initially yellow solutions darken and gas evolution becomes evident after 1.5 h (CO_2 is soluble at these concentrations). As the spectra change to more closely resemble **2**, the solutions become dark orange; with prolonged standing, the solutions become pale yellow and a precipitate of the sparingly soluble bicarbonato complex **4** appears. Thus, it is clear that CO_2 was liberated and available for the eventual production of **4.** Formate **5** was not observed as a product in the reactions conducted in DMSO, although it can be readily formed from hydride **3** and CO_2 in this solvent.[3]

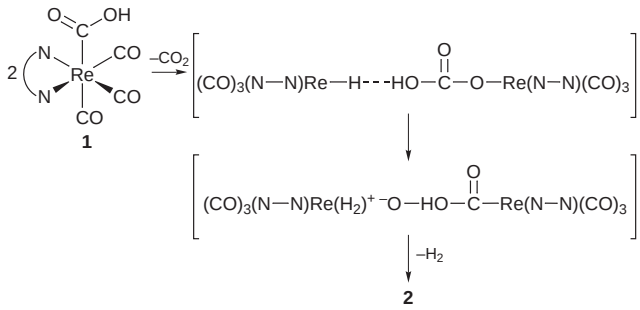
Reactions of **2** were then conducted in DMF-d$_7$ or DMSO-d$_6$ together with 'bone-dry' CO_2[4] in order to provide further clarification. A solution of **2** in DMF-d$_7$ was purged with the CO_2 for a few minutes; during this time, the initially red solution became yellow and a yellow precipitate formed. Further analysis of the solution, and the precipitate, showed that **2** had converted completely to bicarbonate **4**. A similar experiment conducted with **2** in DMSO-d$_6$ showed approximately equal quantities of acid **1** together with **4** after 10 min; formate **5** was formed in only trace quantities in the experiment. Independently, we showed that the hydroxo complex, *fac*-Re(dmbpy)(CO)$_3$(OH)·H$_2$O **6**,[2] was rapidly converted to **4** in quantitative yield upon exposure to CO_2. These results suggest



Scheme 2 N–N = 4,4′-dimethyl-2,2′-bipyridine

that the CO_2-bridged compound **2** exists in these solutions in equilibrium with a small amount of its hydrolysis products, acid **1** and hydroxo complex **6** (generated by adventitious water), and that subsequent conversion of **6** to **4** occurs quickly, and irreversibly, in the presence of CO_2. In DMF-d_7, the conversion of **2** proceeds to **4** rapidly; in DMSO-d_6, a mixture containing **4** and **1** can be observed because **1** is more stable in this solvent. These reactions are shown in Scheme 2. Although not typical of CO_2-bridged complexes of this type,[5] similar hydrolysis of one has been suggested previously;[6] the reverse reaction is facile and well known.[5]

In recent years, both intra- and inter-moleclar interactions between basic transition metal hydrides and H-donor reagents containing N–H or O–H groups have been well documented.[7] These have been described in terms of initial hydrogen bonding between the two species followed by formation of a dihydrogen ligand. A linear H···HO hydrogen bond has been suggested previously;[7d] thus, we suggest the pathway outlined in Scheme 3 for the transformation of **1** to **2**. The precise nature of the intermediate species leading to **2** is not known at present. However, the suggested partial conversion of **1** to **3**, followed by the reaction of **3** with additional **1** and loss of H_2 leading to **2**, is directly analogous to the reactions of other rhenium hydrides with weakly acidic, and protic, substrates. The poor solubility of **1** ensures that free H_2 cannot be spectroscopically observed in our reactions, although gas evolution is evident after the intermediate species develops. Also, the limited solubilities of **1** and **2** prevent low temperature NMR experiments or probes of H-bonding *via* IR spectra of the solutions for further information about the nature of the intermediate species; the existence of the intermediate is clear, however.



Scheme 3 N–N = 4,4′-dimethyl-2,2′-bipyridine

Previous spectral studies of the interactions of hydrides with hydroxylic species have been done in non-polar solvents to avoid competition for the hydroxyl hydrogen.[7] However, the very polar solvents (DMF and DMSO) used with **1** (or **1** and **3**) do not appear to disrupt the association of **1** with **3**. We conclude that it is this strong association with **1** that prevents hydride **3** from being accessible for reaction with CO_2 to form formate **5**.

The behavior of **1** in the presence of CO_2, in solvents and under the not rigorously dry conditions that are typically used in electrocatalytic reactions involving CO_2,[1] casts doubt on the intermediacy of **1** as a precursor to formate in the reactions. We have suggested[2,8] that metal formyl complexes, through the hydrides formed by their degradation, are more likely precursors to formates generated in the reactions. Rapidly in DMF solution, and more slowly in DMSO, acid **1** is transformed to products not identified in the catalytic reactions. Catalytic reactions conducted in acidic media, however, could yield CO as the result of carboxyl cleavage of either **1** or **2**.[1] Efforts are in progress to define the chemical behavior of these reactive compounds further.

Synthesis of highly ordered MCM-41 by micelle-packing control with mixed surfactants

Ryong Ryoo,* Chang Hyun Ko and In-Soo Park

Materials Chemistry Laboratory, Department of Chemistry and Centre for Molecular Science, KAIST, Taejon, 305-701, Korea. E-mail: rryoo@sorak.kaist.ac.kr

Received (in Cambridge, UK) 1st June 1999, Accepted 22nd June 1999

The mesoporous silica molecular sieve MCM-41 can be obtained in a highly ordered form with various pore diameters if micelle packing is suitably controlled with a mixture of *n*-alkyltrimethylammonium bromide and *n*-alkyltriethylammonium bromide according to the length of the C_{12}–C_{22} alkyl groups.

The periodic assemblage between surfactant micelles and inorganic layers is a versatile route to the synthesis of molecular sieves with uniform pore diameters in the mesopore range.[1–6] Previous work on the synthesis of such mesoporous silica molecular sieves referred to as MCM-41 and SBA-15 has revealed that the mesopore diameters can be controlled by using surfactants with different tail lengths and expanding the micelles with suitable organic additives.[2,6–8] Here, we point out that the structural order of the resultant mesoporous materials decreases with changing pore diameter, due to mismatches in the surfactant's head-to-tail packing ratio. We demonstrate that the structural order can be improved remarkably if mixed surfactants of *n*-alkyltriethylammonium bromides [$C_nH_{2n+1}NEt_3Br$ (n = 12, 14, 16, 20 and 22), ATEABr for brevity] and *n*-alkyltrimethylammonium bromides ($C_nH_{2n+1}NMe_3Br$, ATMABr) are used for the synthesis of MCM-41. The optimum mixing ratio can be tuned according to the length of the alkyl groups.

The ATEABr and ATMABr surfactants used for the synthesis of MCM-41 were received from Aldrich or synthesised in our laboratory. The synthesis of ATEABr was carried out by the reaction of 1-bromoalkane with triethylamine in acetonitrile solution under reflux.[9] ATMABr surfactants were synthesised similarly using 1-bromoalkane and trimethylamine, but the reaction was performed in a pressure vessel in order to prevent loss of trimethylamine. Synthesised surfactants were purified twice *via* dissolution in chloroform and subsequent recrystallisation by the addition of ethyl acetate.

The synthesis of the MCM-41 silica was performed in a manner similar to that reported in our previous work,[10,11] except for the use of ATEABr–ATMABr mixtures. An aqueous solution of sodium silicate with Na/Si = 0.5 (2.4 mass% Na_2O, 9.2 mass% SiO_2, 88.4 mass% H_2O) was used as the silica source. The silica source was added dropwise to an aqueous solution of an ATEABr–ATMABr mixture at a given temperature while the solution was stirred vigorously. After continuously stirring for 1 h, the resultant gel mixture was heated for 24 h at 373 K. The mixture after heating was cooled to the same temperature as before the initial mixing, and the pH of the mixture was adjusted to 10 with acetic acid. The mixture after the pH adjustment was heated again for 48 h at 373 K. pH adjustment and subsequent heating was repeated once more before the precipitated MCM-41 product was finally filtered off. The product was washed with EtOH–HCl–H_2O (84.1 : 1.0 : 14.9 mol/mol) and calcined in air at 823 K. The structural order of the product was estimated by its XRD pattern obtained on a Rigaku Miniflex (0.5 kW) instrument using Cu-Kα radiation with 0.01° 2θ step size and 1 s step time.

Fig. 1 shows highly resolved XRD patterns for the C_nMCM-41 samples obtained after optimisation of the starting compositions and mixing temperatures as listed in Table 1. C_n indicates

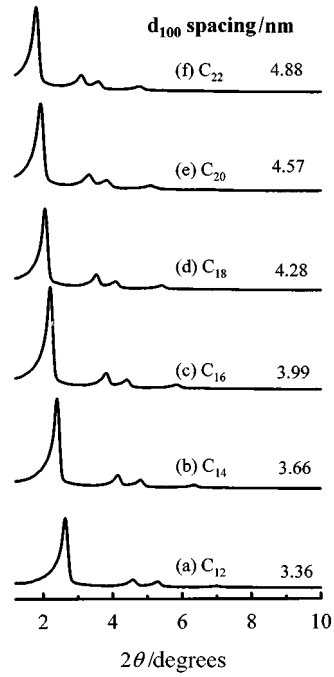

Fig. 1 XRD patterns for high-quality C_nMCM-41 samples obtained by the optimum synthesis conditions given in Table 1: (a) C_{12}, (b) C_{14}, (c) C_{16}, (d) C_{18}, (e) C_{20} and (f) C_{22}MCM-41. Samples were calcined in air at 823 K.

the number of carbon atoms in the alkyl chain of the surfactants. These results show that the optimum ATEABr/ATMABr ratio increased with increasing alkyl chain length in the surfactant. For the synthesis of C_{12} and C_{14}MCM-41, the addition of ATEABr was not beneficial and led to XRD line broadening and loss of intensity. The synthesis of C_{16}–C_{20}MCM-41 by the addition of ATEABr showed a significant improvement of the structural order up to an optimum ATEABr/ATMABr ratio, after which the structural order was progressively lost. The optimum ratio for ATEABr/ATMABr increased from C_{16} to C_{22}MCM-41 so that ATEABr was used as the single surfactant for C_{22}MCM-41. As reported in Table 1, the surfactant concentration and the mixing temperature were also optimised

Table. 1 Optimum conditions for synthesis of MCM-41

	ATMABr	ATEABr	H_2O	
Sample[a]	*x*	*y*	*z*	Mixing temp/K
C_{12}MCM-41	1.0	0.0	400	293
C_{14}MCM-41	1.0	0.0	400	293
C_{16}MCM-41	0.80	0.20	400	303
C_{18}MCM-41	0.66	0.34	400	328
C_{20}MCM-41	0.10	0.90	500	333
C_{22}MCM-41	0.0	1.0	500	338

[a] C_nMCM-41 denotes MCM-41 samples synthesised using a mixture of $C_nH_{2n+1}NMe_3Br$ and $C_nH_{2n+1}NEt_3Br$. The composition of the starting mixture was 4 SiO_2 : x C_nATMABr : y C_nATEABr : 1 Na_2O : z H_2O.

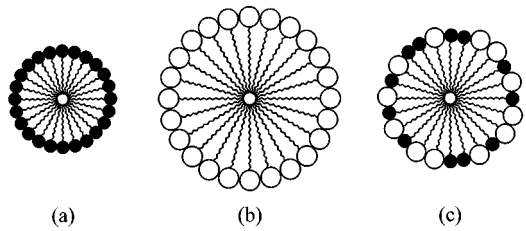

Fig. 2 Schematic models for the cross section of surfactant micelles. (a) The small NMe_3 head group is suitable for short alkyl tails, for the formation of the hexagonal C_{12}MCM-41 mesophase. (b) The large NEt_3 head group for C_{22}MCM-41. (c) The micelle packing in an intermediate case can be controlled with mixed surfactants.

according to the decrease in the solubility of the surfactants as the alkyl group size increases.

An explanation for the change in the optimal ATEABr/ATMABr ratio is depicted in Fig. 2. As Fig. 2(a) shows, small head groups are necessary to form a cylindrical micelle with short alkyl tails in the case of the C_{12} and C_{14}MCM-41 synthesis. If the tail length increases with the same head group, the resultant micelle structures are likely to be those with smaller surface curvatures such as for the cubic *Ia3d* and eventually the lamellar phase. Hence lamellar mesophases are most easily obtained when C_{22}ATMABr is used as a single surfactant for the synthesis of silica–surfactant mesostructures. The head group size should be increased by the substitution with C_{22}ATEABr in order to synthesise the hexagonal mesostructure [Fig. 2(b)]. The highly ordered XRD patterns for C_{16}–C_{20} MCM-41 in Fig. 1 indicate that the use of the ATMABr–ATEABr mixtures is an effective way for controlling the surface curvature of micelles for the hexagonal mesophase [Fig. 2(c)] and probably for the synthesis of other mesophases.

Highly ordered C_{22}MCM-41 can also be obtained using ATMABr as the single surfactant and sodium silicate as the silica source if the pH of the starting mixture is carefully adjusted to 8 before heating, as reported by Namba *et al.*[12] A lamellar or disordered mesophase is obtained if the pH is not adjusted at all, or adjusted after heating. The effect of the pH adjustment is evidence for the mesophase-formation mechanism that takes place co-operatively by the silica source and surfactants.[13] In this mechanism, the silicate anion participates as a part of the head-group moiety of the micelle. The size of the silicate species increases with decreasing pH, and consequently at low pH, the combination of the large silicate species with the small head of the ATMABr surfactant leads to the formation of a large head group that is suitable for the hexagonal mesophase. Thus, the optimum ATEABr/ATMABr ratio for MCM-41 synthesis depends not only on the length of the surfactant tails but also on the pH of the reaction mixture (Fig. 3). The reversibility of the formation of the silica–surfactant mesostructure is an another important factor that affects MCM-41 synthesis. The formation of the hexagonal mesophase at pH 8 is not easily reversed and consequently the synthesis becomes very sensitive to the timing and temperature for the pH adjustment during the silicate polymerisation. On the other hand, the synthesis using C_{22}ATEABr can be performed more easily at sufficiently high pH where the formation of the hexagonal mesostructure is reversible.

The surface curvature of micelles can also be controlled using other mixed surfactant systems such as cationic–neutral[14] and cationic–anionic.[15] For example, it has been reported that the use of ATMABr and poly(oxyethylene) alkyl ethers produced the cubic mesoporous silica molecular sieve MCM-48 in high yield [4.2 SiO_2/surfactant (mol/mol)] by hydrothermal synthesis at atmospheric pressure.[14] Mixed surfactants may be considered for finding mesoporous silica molecular sieves with

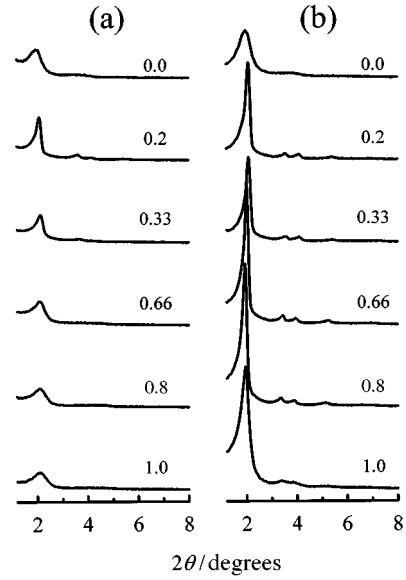

Fig. 3 XRD patterns for MCM-41 synthesised with 4 SiO_2:x C_{18}ATMABr:(1−x) C_{18}ATEABr:1 Na_2O:400 H_2O (mol/mol). Numbers denote the mole number x for C_{18}ATMABr. (a) Product, filtered and dried, after the starting mixture was heated for 24 h at 373 K. (b) Product, filtered and dried, after the pH of the heated mixture in (a) was adjusted to 10 and heated again for 48 h at 373 K.

new structures, as well as improving synthesis procedures for known materials. In addition, the same idea may be used to adjust the surfactant's head group size proportionally to the increase in the diameter of the micelle, when organic additives are used to increase the pore diameter.

An unusual reaction of ethyl 4-bromomethylbenzoate with the carbanion of substituted ethyl acetate

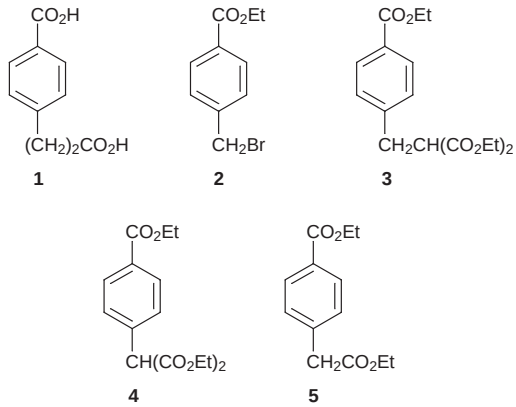
Ramesh C. Anand* and Archana Milhotra

Department of Chemistry, Indian Institute of Technology, Hauz Khas, New Delhi-110016, India.
E-mail: rcanand@chemistry.iitd.ernet.in

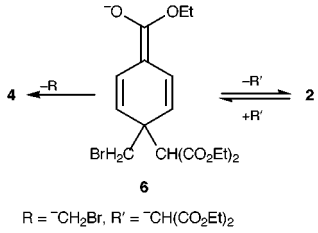
Received (in Cambridge, UK) 18th May 1999, Accepted 11th June 1999

Reaction of ethyl 4-bromomethylbenzoate with the carbanion of substituted ethyl acetate affords nucleophilic aromatic substitution of the bromomethyl group instead of the expected alkylation of the benzylic bromide.

In connection with a project on the synthesis of a natural product, we needed 2-(4-carboxyphenyl)propanoic acid **1** as

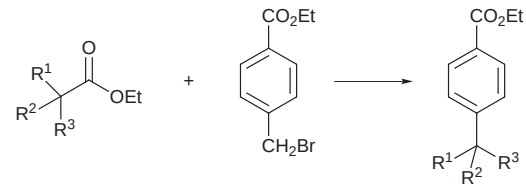


one of the intermediates. A straightforward procedure was employed to prepare this compound by alkylation of ethyl 4-bromomethylbenzoate **2** with the carbanion of diethyl malonate (generated by NaH in C_6H_6) followed by decarboxylation[1] of the resulting alkylated diethyl malonate **3** in aqueous DMSO containing NaCl. The crude product on purification by column chromatography afforded a white crystalline compound as the only product. The ^{1}H NMR and ^{13}C NMR spectra† did not support the expected structure of the diethyl ester of **1**, suggesting the structure to be **5**. In order to further corroborate the structure **5** of the product, it was synthesized by the literature[2] method and was found to be identical with the isolated product **5** of the present reaction (IR, ^{1}H NMR, ^{13}C NMR, mp and TLC). It is likely that an S_NAr mechanism[3] in this case is being preferred over the usual S_N reaction in spite of using a benzylic bromide. Such an S_NAr reaction with *ipso* attack on an aromatic ring having only one ethoxycarbonyl group resulting in the elimination of the bromomethyl group is quite unprecedented under the reaction conditions. Probably the nucleophile is attacking the aromatic carbon carrying the bromomethyl substituent to provide an intermediate **6** (Scheme 1), which in turn may eliminate either $CH_2(CO_2Et)_2$ to give starting compound **2**, or MeBr which may escape as a gas shifting the equilibrium to furnish the product **4**.



Scheme 1

Table 1 Results of reactions with various substituted acetates



Reactant			Product				
R^1	R^2	R^3	No.	R^1	R^2	R^3	Yield[a] (%)
CO_2Et	H	H	**5**[b]	CO_2Et	H	H	63
H	CN	H	**7**[b]	H	CN	H	68
CO_2Et	Me	H	**8**	CO_2Et	Me	CO_2Et	75
Me	CN	H	**9**	Me	CN	CO_2Et	73

[a] The yield of the product is an average of the yields obtained in repeated experiments. The other product obtained from the chromatographic column was the unreacted starting compounds. [b] Isolated product after decarboxylation with NaCl in aq. DMSO (ref. 1).

This type of reaction has also been exhibited by the substituted ethyl acetate carbanions shown in Table 1 (studied so far). A detailed investigation of this reaction is in progress.

Received (in Liverpool, UK) 29th March 1999, Accepted 17th June 1999

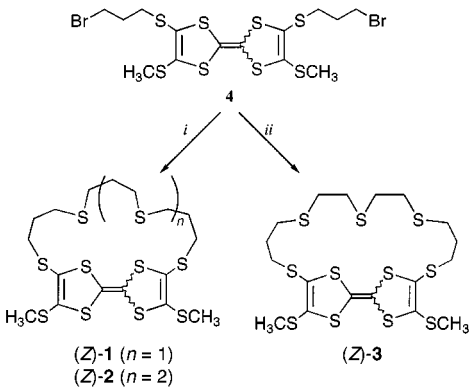
Thiacrown ether TTF derivatives have been synthesized; one of them, whose X-ray molecular structure has been determined, is shown to combine Ag^+ recognition and reversible binding properties as a function of the electrochemical potential applied.

The design of redox-responsive ligands able to recognise cationic guests constitutes an area of active research.[1] In this context, a substantial amount of work has been devoted to the covalent association of a polyether subunit to the tetrathiafulvalene (TTF) moiety.[2,3]

Surprisingly, very few examples of *soft* ligands designed to bind transition metal cations, such as azacrown [4] or thiacrown [5] TTF analogues, have been described. Furthermore, all polythioether-TTFs described so far are poorly soluble, which has precluded any proper characterisation of their metal binding ability.[5]

We now report the synthesis of new sulfur ligands involving various polythioether chains connected to the 2,7-positions of the TTF core, as well as the selective Ag^+ complexing properties of one of them. Receptors **1**–**3**† were prepared (60%, 49% and 52% respectively) under high dilution conditions in DMF, from the [1 + 1] cyclocondensation of compound **4** [4] with suitable ω-dithiole polythioethers,[6] in the presence of caesium carbonate (Scheme 1). Compounds **1**–**3** whose structures were established by 2D NMR (DQF COSY, ROESY, HMQC, HMBC), were obtained as (*Z*/*E*) isomeric mixtures in relative amounts of 60:40 (**1**), 65:35 (**2**), 60:40 (**3**) as determined by ^{1}H-NMR.

X-Ray structural determination of (*Z*)-**1** shows that the increased chain length relative to the previously described thiacrown TTF derivative[5b] considerably decreases the degree of bending of the TTF skeleton (Θ = 16.4°) (Fig. 1). This constitutes a structural prerequisite in order to reach reversible redox processes.



Scheme 1 *Reagents and conditions*: (i) propane-1,3-dithiol (synthesis of **1**), 4-thiaheptane-1,7-dithiol (synthesis of **2**), Cs_2CO_3, DMF; (ii) 3-thiapentane-1,5-dithiol, Cs_2CO_3, DMF.

Binding properties of compounds **1**–**3** were evaluated using different techniques (LSIMS, ^{1}H-NMR and cyclic voltammetry (CV)). LSIMS experiments show that the progressive addition of a silver triflate solution leads to the appearance of a peak corresponding to the formation of the 1:1 complex [**L**-Ag]$^+$. Notably, addition of an excess of Ag^+ results in formation of the additional [**L**-2Ag]$^+$ and [**L**-3Ag]$^+$ complexes in the case of ligands **1** and **2**.

For ligands **1** and **2**, this result may be attributed to the competing Ag^+ binding process between the thiacrown part and both terminal SC=CSCH$_3$ fragments, as observed for the parent tetramethylsulfanyl-TTF.[7]

This observation was confirmed by ^{1}H-NMR titration studies ($CDCl_3$–CD_3CN [1:1]), the signal corresponding to the methylsulfanyl fragments of **1** and **2** being the only one significantly affected by addition of $AgCF_3SO_3$.[8] For macrocycle **3**, the signals which are shifted to lower fields upon titration correspond to the polythioether methylene protons of the (*Z*) isomer only, confirming that in this case complexation preferentially involves the thiacrown cavity. This good Ag^+ binding ability of the polythioether chain in **3** may be attributed to a better orientation of the coordinating S atoms, contrary to compounds **1** and **2** for which insertion of propylene fragments cannot ensure a correct structural environment, as shown by X-ray data (Fig. 1).‡

Interestingly, the Ag^+ titration curves obtained from ^{1}H-NMR shifts for the crown ether methylene protons of **3** exhibit a plateau for 0.6 equiv. of added cation (Fig. 2). This result is in good agreement with the 60/40 ratio of (*Z*)-**3**/(*E*)-**3** isomers, confirming that Ag^+ binding occurs through the (Z)-isomer only. Analysis of these data with the program EQNMR [9] shows that the crown thioether recognition site of (*Z*)-**3** forms a 1:1 complex with Ag^+, with an average stability constant $K°$ = $10^{3.26}$ ($CDCl_3$–CD_3CN [1:1]).

As expected from the quasi-planar character of the TTF skeleton discussed above in the case of **1**, compounds **1**–**3** exhibit two reversible one-electron redox processes, with

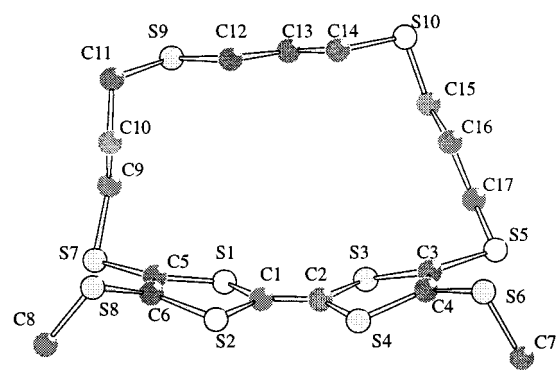


Fig. 1 X-Ray molecular structure of (*Z*)-**1**.

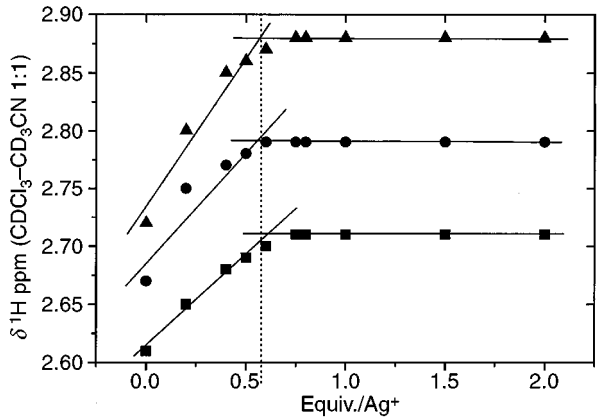

Fig. 2 Proton NMR titration curve of the perturbation of the CH_2S protons of the polythiaether bridge in **3,** upon addition of silver cation.

oxidation potentials similar to those observed for the parent tetramethylsulfanyl-TTF (*e.g.* compound **1**: E_1^{ox} = 0.59 V and E_2^{ox} = 0.89 V *vs*. Ag/AgCl). Whereas no change is observed in CV of compounds **1** and **2** upon addition of Ag^+ and in agreement with the solution NMR study, the progressive addition of controlled amounts of silver triflate to **3** results in a positive shift of E_1^{ox}. This phenomenon is attributed to the electrostatic inductive effect of the crown ether bound metal

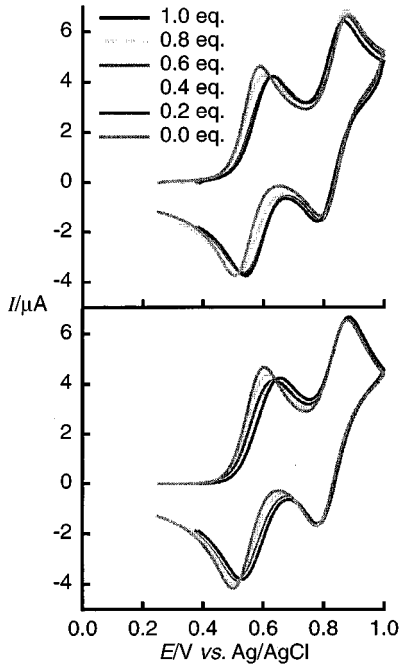

Fig. 3 Experimental (top) and simulated (bottom) cyclic voltammograms of **3** in the presence of increasing amounts of Ag^+. The simulated data were fitted to experimental results for **3** (10^{-3} mol L^{-1} in CH_2Cl_2–CH_3CN [1:1], Bu_4NPF_6 (0.1 mol L^{-1})) at 293 K and 100 mV s^{-1}. All simulations were carried out with the same set of parameters, only the Ag^+ equivalent concentration being changed according to the experimental voltammograms. Charge transfer parameters: $k_s = 3.5 \times 10^{-3}$ cm s^{-1}, $\alpha = 0.5$. Chemical reaction parameters: $K° = 3.35 \times 10^3$ L mol^{-1}, $k_f° = 1.3 \times 10^6$ L mol^{-1} s^{-1} and $K^{\cdot+} = 90$ L mol^{-1}, $k_f^{\cdot+} = 3 \times 10^7$ L mol^{-1} s^{-1}. Diffusion coefficient: $D = 3.6 \times 10^{-6}$ cm^2 s^{-1}.

cation which causes an increase of E_1^{ox} (Fig. 3). The fact that the E_2^{ox} remains unchanged is attributable to the expulsion of the metal ion from the cavity, due to the doubly charged TTF moiety. Values of the binding constant of the Ag^+ complex as a function the redox state of the TTF core in ligand **3** were evaluated using the DIGISIM 2.1® simulation program (BAS Inc.). A strong Ag^+ affinity is found for the neutral ligand (TTF: $K° = 10^{3.53}$) in good agreement with the value determined by ^{1}H-NMR. Oxidation of TTF into $TTF^{\cdot+}$ leads to a decrease of the complexation ability ($K^{\cdot+} = 10^{1.95}$) and to the expulsion of the metal for the dicationic TTF^{2+} state, as shown by the constant E_2^{ox} value ($K^{2+} \approx 0$).

It is noteworthy that no shift of E_1^{ox} has been observed upon addition of a wide variety of groups 1 or 2 or transition metal ions (Na^I, K^I, Cs^I, Mg^{II}, Ba^{II}, Cr^{III}, Ni^{II}, Zn^{II}, Cd^{II}),[10] which illustrates the good selectivity of ligand **3** for Ag^+.

In conclusion, the efficiency in modulation of the trapping properties of ligand **3** has been demonstrated thanks to an unprecedented metal cation binding ability among crown thioether TTF derivatives (neutral TTF state) associated the controllable releasing of the metal cation upon electrochemical oxidation to the dicationic TTF state.

Total synthesis of (+)-rottnestol†

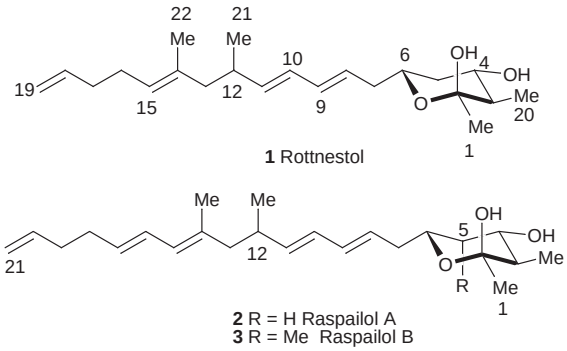
Ivona R. Czuba and Mark A. Rizzacasa*

School of Chemistry, The University of Melbourne, Parkville, Victoria 3052, Australia.
E-mail: m.rizzacasa@chemistry.unimelb.edu.au

Received (in Cambridge, UK) 2nd June 1999, Accepted 18th June 1999

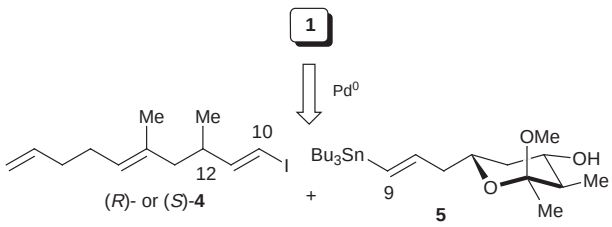
The first total synthesis of the marine metabolite (+)-rottnestol is described.

Marine sponges provide a large range of novel and bioactive metabolites that generally fall into defined chemotaxonomic groups. Recently, some tetrahydropyran containing secondary metabolites have been isolated from sponges that are chemically quite different to compounds that were previously isolated from the same sources. Chemical investigation of the sponge genus *Haliclona* sp., collected around Rottnest Island off the coast of Western Australia, yielded the hemiketal rottnestol (**1**).[1] The structure of **1** was determined using NMR techniques and by comparison to the related compounds, the raspailols A (**2**) and



B (**3**), which were isolated from the sponge *Raspailia* sp. and possess antibiotic activity.[2] However, only small amounts of **1**–**3** were isolated which precluded oxidative degradation to determine the absolute configuration at C12.[1,2] We now report the first total synthesis of each of the possible C12 epimers of **1** which allowed for the assignment of the absolute configuration of this compound.

In designing a synthetic approach to both C12 epimers of **1**, we noted that a pivotal retrosynthetic bond cleavage would be between C9–C10. To generate this linkage, we elected to utilise a Stille cross-coupling protocol because of its remarkable success in constructing diene systems.[3,4] Therefore, coupling between an optically pure C10–C19 fragment **4** and a suitable vinylstannane such as **5** could provide each of the C12 epimers of **1** in a highly convergent manner.



Our approach to the C12 isomers of **1** began with the synthesis of pyran fragment **5** as outlined in Scheme 1. Brown crotylmetallation[5] of the (*S*)-malic acid derived aldehyde **6**[6] followed by silylation provided alkene **7** in good yield. Wacker oxidation[7] using catalytic palladium chloride gave the ketone **8** which upon treatment with camphorsulfonic acid in MeOH afforded the pyran **9** as one anomer. Conversion of the alcohol **9** into an unstable triflate followed by lithium acetylide displacement and silyl group removal provided acetylene **10**. Radical hydrostannylation[8] of **10** in boiling benzene then afforded stannane **5** ready for Stille coupling.

The synthesis of both enantiomers of the sidechain vinyl iodide **4** is outlined in Scheme 2. Addition of but-3-enylmagnesium bromide to methacrolein gave the known allylic alcohol[9]

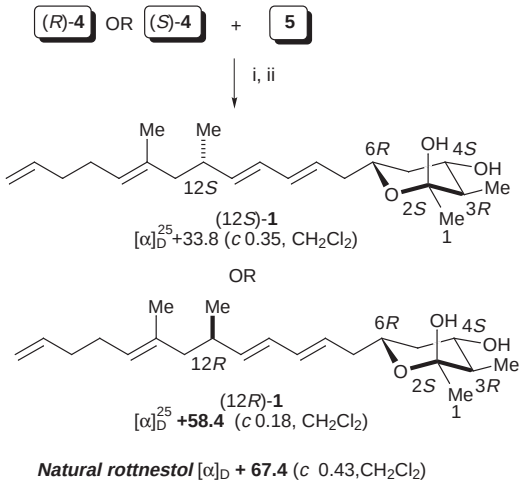
HCl (84%); (iv) (*S*)-methyl mandelate, DCC, 10 mol% DMAP, normal phase HPLC separation (86%); (v) $LiAlH_4$, Et_2O (86%); (vi) Dess–Martin reagent, CH_2Cl_2 (100%) (vii) 7.5 equiv. $CrCl_2$, 1.9 equiv. CHI_3, 6:1 dioxane–THF, rt (71%).

† Dedicated to Professor Robert E. Ireland on the occasion of his 70th birthday.



Natural rottnestol $[\alpha]_D$ **+ 67.4** (*c* 0.43,CH_2Cl_2)

Scheme 3 *Reagents and conditions*: (i) 10 mol% $Pd(MeCN)_2Cl_2$, i-Pr_2NEt, DMF, rt (54–62%); (ii) 5% aq. HCl, THF, 0 °C (55–66%).

which was propionylated to provide ester **11**. Ireland–Claisen rearrangement[10,11] of **11** gave the racemic acid **12** in high yield upon acidic work-up. Resolution of the α-methyl chiral acid **12** was achieved by conversion to the corresponding (*S*)-mandelate esters followed by HPLC separation of the diastereoisomeric (*R*,*S*)- and (*S*,*S*)-mandelates.[11] Reduction of each mandelate ester then gave the optically pure alcohols (*R*)-**13** {$[\alpha]_D^{25}$ +6.5 (*c* 1.0, $CHCl_3$)} and (*S*)-**13** {$[\alpha]_D^{25}$ −6.6 (*c* 1.0, $CHCl_3$)} and the absolute configurations of each were determined by the ^{1}H NMR analysis of the derived (*S*)-MTPA esters.[12,13]‡ Dess–Martin oxidation[14] of (*R*)- and (*S*)-**13** followed by vinyliodination[15] then provided iodides (*R*)- and (*S*)-**4**.

Palladium-mediated coupling of (*R*)- or (*S*)-**4** with stannane **5** proceeded smoothly§ and subsequent acid hydrolysis afforded (12*R*)- and (12*S*)-**1** respectively (Scheme 3). Not surprisingly, (12*R*)- and (12*S*)-**1** could not be differentiated by either ^{1}H or ^{13}C NMR spectroscopy and both were identical to rottnestol in all respects apart from the optical rotation of (12*S*)-**1**.¶ As shown in Scheme 3, (12*R*)-**1** possesses a rotation with the same sign and similar value to that of natural rottnestol[1] while (12S)-**1** had a much lower value. We therefore propose the absolute configuration of rottnestol (**1**) to be 2*S*,3*R*,4*S*,6*R*,12*R*. Application of this approach to the synthesis of the raspailols is now underway.

We thank Dr M. Boyd and Dr J. Beutler of the NCI Maryland, USA for the generous gift of natural rottnestol (**1**) for TLC comparison and copies of the ^{1}H and ^{13}C NMR spectra. This work was financially supported by the Australian Research Council.

Notes and references

‡ For the (*R*,*S*)-MTPA ester (derived from (*R*)-**13** and (*S*)-MTPA) the C1 methylene protons appear as a doublet at δ 4.14 (J = 5.2 Hz) while for the (*S*,*S*)-MTPA ester the same protons appear as well separated doublets of doublets at δ 4.03 (J = 10.8, 6.4 Hz) and 4.24 (J = 10.8, 4.8 Hz): see refs. 12 and 13.

§ Interestingly, the C4-TBDPS ether of **5** and (±)-**4** failed to undergo cross coupling under a variety of conditions.

Catalytic radical acetylation of adamantanes with biacetyl by a cobalt salt under atmospheric dioxygen

Arata Kishi, Susumu Kato, Satoshi Sakaguchi and Yasutaka Ishii*

Department of Applied Chemistry, Faculty of Engineering and High Technology, Research Center, Kansai University, Suita, Osaka 564-8680, Japan. E-mail: ishii@ipcku.kansai-u.ac.jp

Received (in Cambridge, UK) 24th March 1999, Accepted 11th June 1999

Exposure of a mixture of adamantane and biacetyl under O_2 in the presence of $Co(OAc)_2$ (0.1 mol%) in AcOH led to 1-acetyladamantane (47%) and 1,3-diacetyladamantane (20%) as major products along with small amounts of adamantan-1-ol (4%) and adamantan-2-one (3%).

The introduction of an acyl group to alkanes is one of the most difficult transformations in organic synthesis. Until recently, there have been a few reports on the acetylation of cycloalkanes under irradiation of light or by using a radical initiator such as benzoyl peroxide.[1–4] Although the catalytic acetylation of alkanes is of interest and would be more useful in organic synthesis, such a method has not yet been developed. Here, we report the first successful catalytic radical acetylation of adamantanes using biacetyl as an acetylating agent by a cobalt salt under O_2 atmosphere [eqn. (1)].

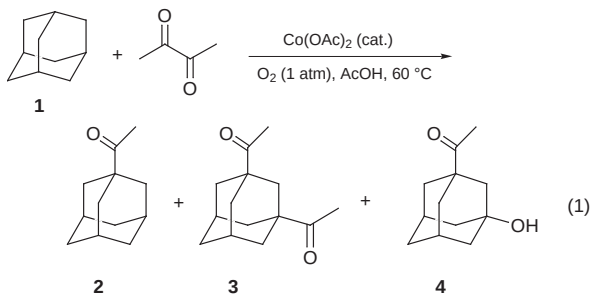

Table 1 shows the results for the acetylation of adamantane **1** with biacetyl under various conditions.† The acetylation of **1** with biacetyl in the presence of $Co(OAc)_2$ (0.1 mol%) and O_2 (1 atm) in AcOH at 60 °C for 2 h gave 1-acetyladamantane **2** (47%), 1,3-diacetyladamantane **3** (20%) and 3-acetyladamantan-1-ol **4** (6%) along with several oxygenated products such as adamantan-1-ol **5** (4%) and adamantan-2-one **6** (3%) (run 1). Photoacetylation of **1** with biacetyl is reported to form **2** in 13.8% under N_2 and 40% under O_2, but no diacetyl compound **3** is formed.[1] Therefore, our reaction provides an efficient catalytic method for the synthesis of acetyl derivatives of **1** which are technically interest compounds. When the acetylation was carried out for 4 h, **3** was obtained in preference to **2** (run 2). Among the solvents examined, AcOH was found to be the best solvent (runs 3 to 5). From the mechanistic point of view, it is important to note that no reaction takes place when a Co^{III} ion was employed in place of the Co^{II} ion (run 6). The reaction proceeded smoothly even in the presence of a very small amount (0.01 mol%) of $Co(OAc)_2$ or $Co(acac)_2$ at 80 °C to give **2** and **3** in satisfactory yields (runs 7 to 9). When the amount of biacetyl was reduced to half (3 equiv.) so that the concentration of biacetyl was halved with respect to O_2, the selectivity to **2** decreased and the amount of partly oxygenated **4** increased (run 10). In the absence of biacetyl, however, no reaction took place and the starting **1** was recovered unchanged (run 11). This fact shows that the aerobic oxidation of **1** is also induced by the presence of biacetyl. The reaction did not take place either in the presence of hydroquinone (0.1 mol%) or in the absence of O_2 (runs 12 and 13). These observations strongly suggest that a radical chain process is involved in the present acetylation, and that molecular oxygen is an essential component to promote the acetylation. Indeed, adamantyl radical, generated *in situ* from 1-bromoadamantane (3 mmol) by the action of Bu_3SnH (3.6 mmol) and AIBN (0.3 mmol) in AcOH (3 ml) reacted with biacetyl (18 mmol) and O_2 (1 atm) at 80 °C for 4 h to form **2** and **5** in 5 and 4% yields, respectively, although it abstracted more easily the hydrogen atom from the Bu_3SnH to give **1** (39%) as the major product. The reaction using benzil in place of biacetyl resulted in the recovery of the starting materials (run 14).‡

Table 1 Acetylation of **1** with biacetyl catalyzed by metal salts[a]

					Yield (%)				
Run	Metal salt (mol%)	Solvent	*t*/h	Conversion (%)	**2**	**3**	**4**	**5**	**6**
1	$Co(OAc)_2$ (0.1)	AcOH	2	94	47	20	6	4	3

10[d]	$Co(OAc)_2$ (0.5)	AcOH	4	98	20	25	16	4	4
11[e]	$Co(OAc)_2$ (0.5)	AcOH	2	no reaction					
12[f]	$Co(OAc)_2$ (0.5)	AcOH	2	no reaction					
13[g]	$Co(OAc)_2$ (0.5)	AcOH	2	no reaction					
14[h]	$Co(OAc)_2$ (0.5)	AcOH	4	no reaction					

[a] **1** (3 mmol) was allowed to react with biacetyl (6 equiv., 18 mmol) in the presence of a metal salt under O_2 (1 atm) in AcOH (3 ml) at 60 °C. [b] Polyfunctionalyzed products and adamantane-1,3-diol were also formed. [c] 80 °C [d] Biacetyl (3 equiv., 9 mmol) was used. [e] In the absence of biacetyl. [f] Hydroquinone (0.1 mol%) was added. [g] Under argon. [h] Benzil was used in place of biacetyl.

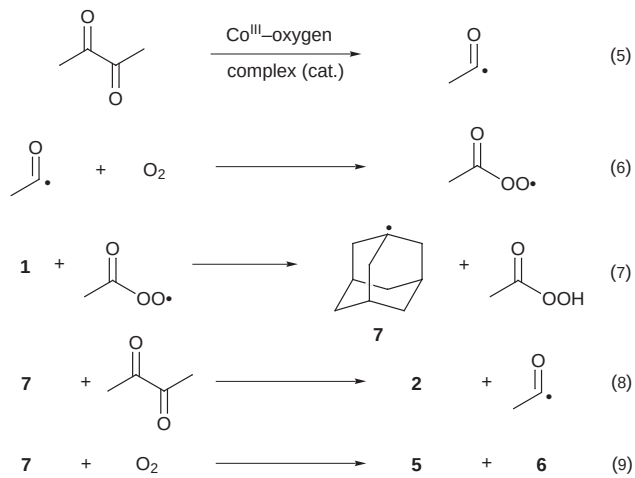
In order to gain insight into the role of cobalt salts in the present reaction, acetylations of **1** with biacetyl by Co^{II} and Co^{III} ions under O_2 (1 atm) at 75 and 80 °C were monitored by GC at appropriate time intervals (Fig. 1). The acetylation of **1** was efficiently catalyzed by Co^{II} at 75 °C, while the reaction with Co^{III} did not take place at all at this temperature. However, when the reaction temperature was raised to 80 °C, the acetylation of **1** by Co^{III} was prompted after an induction period of about 1 h. It is well-known that Co^{III} ions are reduced to Co^{II} ions by organic substrates such as toluene and cyclohexane *via* a one-electron transfer process.§ Therefore, the induction period of about 1 h observed at 80 °C would correspond to the time needed for the formation of Co^{II} by the one-electron transfer to Co^{III} from biacetyl and/or **1**. At 75 °C, however, owing to the difficulty of the electron transfer to Co^{III} from these substrates, no acetylation is induced. Therefore, if the reduction of Co^{III} to Co^{II} is performed by adding an additive like aldehyde, **1** was acetylated by Co^{III} even at 75 °C [eqn. (2)]. These findings indicate that the Co^{II} ion, which reacts easily with O_2 to generate labile dioxygen complexes such as a superoxocobalt(III) or μ-peroxocobalt(III) complex, plays an important role in the present acetylation [eqns. (3) and (4)].[7,8]

$$PhCHO + Co^{III} \longrightarrow PhCO\bullet + Co^{II} + H^{+} \quad (2)$$

$$L_nCo^{II} + O_2 \rightleftharpoons L_nCo^{III}\text{-}O\text{-}O\bullet \quad (3)$$
superoxocobalt(III)

$$L_nCo^{III}\text{-}O\text{-}O\bullet + L_nCo^{III} \rightleftharpoons L_nCo^{III}\text{-}O\text{-}O\text{-}Co^{III}L_n \quad (4)$$
μ-peroxocobalt(III)

Although the mechanistic details are still obscure, the fact that the acetylation did not take place with Co^{II} in the absence of O_2 or with Co^{III} even in the presence of O_2 suggests that a cobalt(III)–oxygen complex is the key species in the present acetylation of **1** with biacetyl. The resulting cobalt(III)-oxygen complex reacts with biacetyl to generate an acetyl radical which is readily trapped by O_2 under the present conditions to form an acetyl peroxyl radical [eqns. (5) and (6)]. The formed acetyl peroxyl radical undergoes hydrogen abstraction from **1** to form an adamantyl radical **7** and peracetic acid [eqn. (7)]. The formed radical **7** would react with biacetyl to give **2** and an acetyl radical which serves as a chain carrier in the reaction [eqn. (8)]. In addition, **7** reacts with O_2 to produce oxygenated products **5** and **6** [eqn. (9)]. Under the present reaction conditions in which O_2 exists in the reaction system, the direct abstraction of the hydrogen from **1** by the acetyl radical may be disregarded, since the rate of hydrogen abstraction from an alkane by acetyl radical is much slower than that of the addition of O_2 to acetyl radical.¶ The acetyl peroxyl radical can also abstract the hydrogen from **1** to form **7** and peracetic acid. It is probable that peracetic acid formed in the reaction is easily subjected to redox decomposition by Co ions to generate a radical species which acts as a radical carrier. In fact, the reaction of **1** (3 mmol) with biacetyl (18 mmol) under the influence of MCPBA (3.6 mmol) and Co^{III} (0.015 mmol) in acetic acid (3 ml) in an inert atmosphere at 60 °C for 1 h afforded **2** with 60% selectivity, although the conversion of **1** was low (5%) probably because of the rapid decomposition of MCPBA by Co ion.



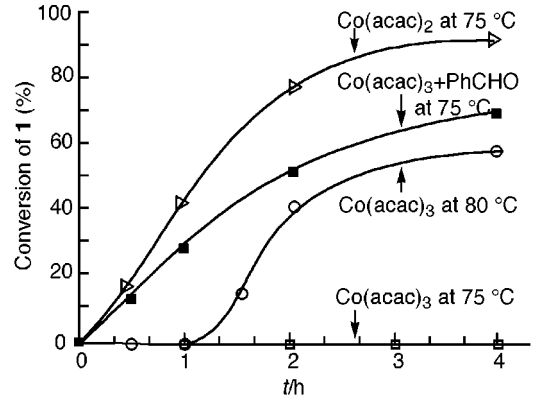


Fig. 1 Time-dependence curves for the conversion of **1** with biacetyl catalyzed by $Co(acac)_2$, $Co(acac)_3$ and $Co(acac)_3$ combined with benzaldehyde in AcOH at 75 or 80 °C. Conditions: **1** (3 mmol), biacetyl (18 mmol), AcOH (3 ml), cobalt salt (3.0×10^{-4} mmol), benzaldehyde (1.5×10^{-2} mmol).

In order to extend the present acetylation to substituted adamantanes, 1,3-dimethyladamantane **8** and **5** were allowed to react with biacetyl under the same reaction conditions as employed for **1** in Table 1, run 3. As expected, **8** was satisfactorily acetylated to the corresponding mono- and diacetyladamantanes in 54 and 21% yields, respectively. Similarly, **5** afforded **4** in 54% yield along with 3,5-diacetyladamantan-1-ol (7%). It is interesting to note that the reaction of **5** with biacetyl did not take place on the hydroxy function, which is different from the usual acetylation procedure using Ac_2O or AcCl, in which the hydroxy group is preferentially acetylated.

This work was partly supported by a Grant-in-Aid for Scientific Research (No.10450337) from Monbusho.

Notes and references

† *Typical reaction*: To a solution of adamantane **1** (3 mmol) and $Co(OAc)_2$ (0.1 mol%) in AcOH (3 ml) was added biacetyl (18 mmol), and the mixture was stirred under O_2 (1 atm) at 60 °C for 2 h. Products were isolated by column chromatography on silica gel with hexane–EtOAc.

‡ Treatment of biacetyl with O_2 in the presence of Co^{II} under these conditions afforded AcOH in 192% (based on Co^{II}), however, benzil was recovered unchanged by the same treatment.

§ The reaction of a Co^{III} ion with cyclohexane (ref. 5) or alkylbenzenes (ref. 6) is known to involve one-electron transfer from the substrate to Co^{III}, yielding a Co^{II} ion and radical cation which readily liberates H^+ to give an alkyl radical.

¶ The reaction of acetyl radical with O_2 is reported to occur very fast [$k = (1.8 \pm 0.5) \times 10^9$ M^{-1} s^{-1}] compared with the hydrogen abstraction from *n*-hexane by acetyl radical ($k \leqslant 5 \times 10^3$ M^{-1} s^{-1}) (ref. 9).

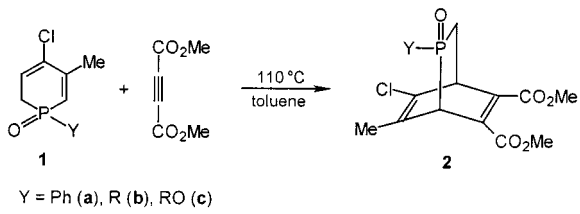
Received (in Cambridge, UK) 1st June 1999, Accepted 22nd June 1999

The reaction of 1-(2,4,6-triisopropylphenyl)-1,2-dihydrophosphinine 1-oxide 1d with dimethyl acetylenedicarboxylate (DMAD) affords, surprisingly, oxaphosphetene 3 instead of the expected Diels–Alder cycloadduct; the unusual reactivity of the trialkylphenylphosphine oxides towards DMAD seems to be of general value.

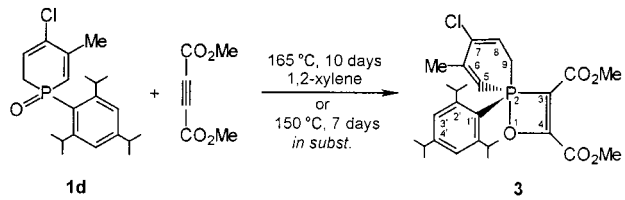
The 1,2-dihydrophosphinine 1-oxides (**1**) with phenyl, alkyl or alkoxy substituents on the phosphorus atom proved to be valuable starting materials in the synthesis of phosphabicyclo-[2.2.2]octadienes **2** that are precursors of low-coordinated fragments, methylenephosphine oxides ($YP(O)CH_2$) useful in the phosphorylation of nucleophiles.[1–4] The cycloadducts (**2**) are obtained by the Diels–Alder reaction of dihydrophosphinine oxides **1** and DMAD (Scheme 1).[1,4] Other dienophiles, such as maleic acid derivatives were also utilised in the synthesis of bridged phosphorus heterocycles.[5,6]



Scheme 1[1–4]

Recently, we have described the preparation of 1-(triisopropylphenyl)dihydrophosphinine oxide **1d** revealing unique properties due to the presence of the sterically demanding P-substituent.[7] We wished to utilise compound **1d** in the synthesis of *P*-(trialkylphenyl)phosphabicyclooctadiene **2d** (**2**, Y = 2,4,6-$Pr^i_3C_6H_2$) that seemed to be promising in the generation of a sterically hindered and hence a relatively stable methylenephosphine oxide (2,4,6-$Pr^i_3C_6H_2P(O)CH_2$).

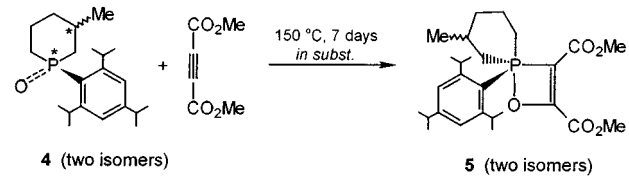
The reaction of **1d** and DMAD in 1,2-xylene at 165 °C (in a bomb) did not lead, however, to cycloadduct **2d**, instead oxaphosphete **3** isomeric with **2d** could be isolated in 76% yield after column chromatography (Scheme 2). Cycloadduct **2** could not be detected, not even in traces. Spiro derivative **3** exhibited a δ_P value of 24.0 ($CDCl_3$). Similar 1,2-oxaphosphetes have never been reported in the literature. The 1,2-oxaphosphetes are, however, well-known intermediates in the Wittig reaction.[8] The structure of product **3** was confirmed by ^{13}C and ^1H NMR,[9] as well as two-dimensional correlation diagrams, such as HMQC and HMPC spectra. Elemental composition of **3** was supported by HRMS.



Scheme 2

This is the first case in which the P=O group of a phosphine oxide reacted with DMAD to furnish the 1,2-oxaphosphete ring. Moreover, the [2+2] cycloaddition was fully selective and the dihydrophosphinine ring of starting material **1d** remained intact.

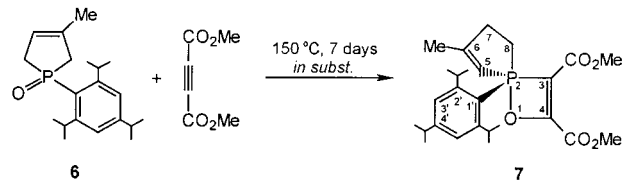
We wished to evaluate if the above [2+2] cycloaddition is of general value for P-heterocycles with a *P*-triisopropylphenyl substituent. Hexahydrophosphinine oxide **4** obtained from **1d** by catalytic hydrogenation was reacted with DMAD at 150 °C in the absence of any solvent, to give oxaphosphete **5** in 58% yield after chromatography (Scheme 3). Starting from the 63–37% diastereoisomeric mixture of **4**, product **5** was also formed as a mixture of two isomers.[10]



Scheme 3

Finally, it was examined if a P-heterocycle with a five-membered ring can be involved in the above type [2 + 2] cycloaddition. The interaction of 1-(triisopropylphenyl)dihydrophosphole oxide **6** and DMAD at 150 °C led again to the corresponding oxaphosphete (**7**). In this case the double-bond of the 2,5-dihydrophosphole moiety was, however, isomerised to afford the 2,3-dihydro hetero ring (Scheme 4). 2,5-Dihydrophospholes are known to undergo double-bond rearrangement on thermal treatment.[11] Product **7** was isolated in 83% yield in a clean reaction. The structure of spiro derivatives **5** and **7**[12] was confirmed by NMR and MS.

It is worth mentioning that the *P*-phenyl analogues of hexahydrophosphinine **4** and dihydrophosphole **6** did not enter into reaction with DMAD at 150–165 °C. This means that the electron-releasing ability of the triisopropylphenyl ring may be responsible for the new type of reactivity of the P=O group.



Scheme 4

To summarise our findings, it can be concluded that the reaction of DMAD with 5- and 6-membered P-heterocycles bearing a triisopropylphenyl substituent on the phosphorus atom affords the corresponding spiro derivative of 1,2-oxaphosphete. This type of [2+2] cycloaddition between the P=O group of tertiary phosphine oxides and the acetylene moiety of DMAD has not been observed previously and is, obviously, the consequence of the presence of the triisopropylphenyl substituent at the phosphorus atom. The reaction under discussion may be of general value and hence the cycloaddition of acyclic trialkylphenylphosphine oxides with DMAD may represent a new entry into the synthesis of *P*-aryl oxaphosphetes.

Future work will be directed towards the possible extension and the theoretical evaluation of the P=O + -C≡C- [2 + 2] cycloaddition reaction.

Thanks are due to FKFP (Grant No.: 363/1999) and OTKA (Grant No.: T029039) financial support.

The gas-phase fragmentation of trineopentylstannyl cation: a rare example of β-methyl migration within a main group organometallic compound

Dainis Dakternieks,* Allan E. K. Lim and Kieran F. Lim

Centre for Chiral and Molecular Technologies, Deakin University, Geelong, 3217 Australia.

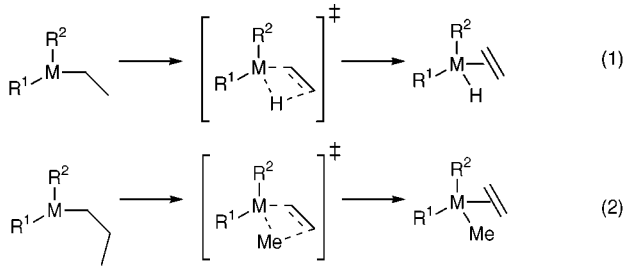
Received (in Cambridge, UK) 19th April 1999, Accepted 21st June 1999

The lowest-energy fragmentation pathway of trineopentylstannyl cation is the first example of β-methyl migration to an organotin compound in the gas-phase; the origin of the migrating methyl groups is confirmed by an isotopic labelling experiment.

The migratory insertion of an unsaturated compound into a transition metal–hydrogen (or carbon) bond is a well established reaction.[1] The β-hydrogen [eqn. (1)] and β-methyl [eqn. (2)]



elimination processes, being microscopic reversals of the insertion process, are of fundamental importance in the many catalytic processes involving transition metals,[2–4] including Ziegler–Natta polymerization.[2]

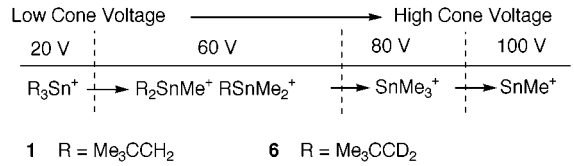
Although these processes are primarily associated with transition-metal organometallic compounds, they are also known to occur within organoaluminium compounds.[5] In particular, trineopentylaluminium dissociates reversibly into $AlMe_3$ and isobutene at 200 °C [eqn. (3)].[6] Whilst the

observations in these early works are now attributed to the β-Me elimination process,[5] to the best of our knowledge, there are no other examples of β-Me elimination in main group organometallic chemistry.

As part of a comprehensive study into the gas-phase fragmentation of organostannyl cations, we investigated the fragmentation of trineopentylstannyl cation $[(Me_3CCH_2)_3Sn]^+$ (**1**), derived from trineopentylstannyl trifluoromethanesulfonate (**2**),† using ESMS. Initially designed as a very mild method of analyzing large biomolecules,[7] ESMS has since been widely used as an investigative tool in organometallic solution chemistry.[8]

While there is still significant debate over the exact nature of the electrospray ionization process,[9] it basically entails spraying the analyte solution into the mass spectrometer source followed by evaporation of the solvent molecules. In-source CID of the analyte ions can be made to occur by increasing the potential difference (cone voltage) across the skimmer cones.[10] This allows analyses to start under *extremely* mild conditions and the energy of the ions analyzed can be gradually increased. Organotin compounds, the halides in particular, have been investigated within several ESMS studies.[11]

Analysis of a solution of **2** in acetonitrile is first performed under mild conditions,‡ at a cone voltage of 20 V. The



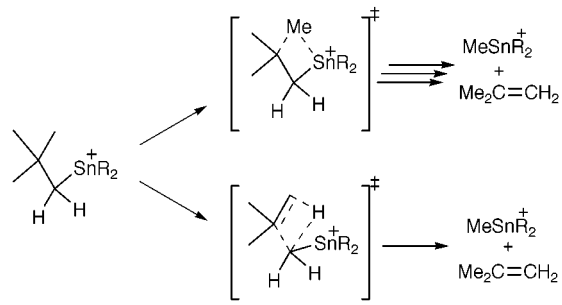
Scheme 1 Observed fragmentation patterns of **1** and **6**.

predominant species observed is the acetonitrile (solvent) adduct, [**1** + CH_3CN], along with a smaller peak corresponding to **1**.§ Increasing the cone voltage to 40 V causes dissociation of the acetonitrile adduct and **1** becomes the main species detected.

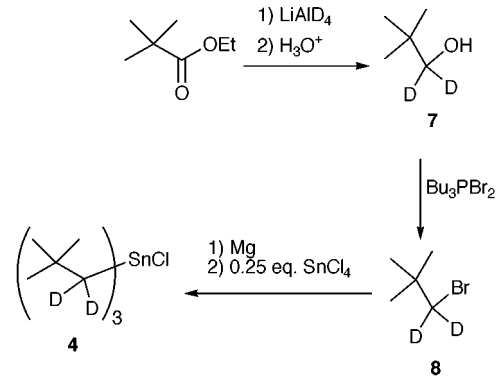
The cation **1** itself remains intact until the cone voltage is raised even further (~60 V), where the onset of fragmentation occurs. The fragmentation pattern observed is summarized in Scheme 1. For each neopentyl group lost, a methyl group remains on tin. No evidence for simple Sn–C bond cleavage was found. The presence of methyl residues on tin in the fragment ions can be rationalized through the two different pathways depicted in Scheme 2. The top pathway is analogous to the β-Me migration process known in transition metal complexes, whereas the bottom pathway resembles a well established[12] hydrocarbon pyrolysis process. Both reaction channels lead to the same products.

To resolve this issue, the deuterated trineopentylstannyl chloride (**4**) was synthesized *via* Scheme 3. The corresponding trifluoromethanesulfonate (**5**) was obtained *via* metathesis of **4** with silver trifluoromethanesulfonate. Subsequently the deuterated trineopentylstannyl cation (**6**) is derived from **5**.¶ In this case, the two different types of hydrogen atom in **6** are distinguished, allowing the discrimination between the two reaction channels.

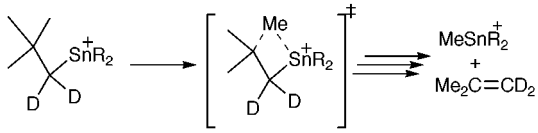
Analysis of an acetonitrile solution of **5** as before, afforded the fragment ions of **6**. The results obtained are depicted in Scheme 1, this time with R being the deuterated neopentyl group. The *m/z* values of the isotope distributions of the fragment ions clearly show that the methyl residues on tin are not deuterium labeled, thus unambiguously identifying the source of the methyl residue as being from the β-position (Scheme 4).



Scheme 2 Possible reaction channels for the fragmentation of **1**.



Scheme 3 Synthesis of deuterated trineopentylstannyl chloride analog **4**.



Scheme 4 Confirmed fragmentation pathway of **6**.

Repeating the ESMS in-source CID analyses on both **2** and **5** using deuterated acetonitrile as solvent and carrier afford the same daughter ions as when normal acetonitrile is used, thus eliminating the possibility that the acetonitrile solvent is the source of the CH_3 groups.

The observed β-Me elimination process is also reproducible under solvent-free (MS/MS) conditions.‖ Selecting and trapping the relevant cations **1** and **6** followed by CID using helium as a collision gas again afforded fragmentation as depicted in Scheme 1.

In conclusion, we believe this is the first report of an unusual β-Me elimination process occurring within an organotin compound. Whilst the observation of complex processes in the gas-phase is not uncommon using conventional (*e.g.* EI or CI) mass spectrometric techniques, it is extremely important to note that the β-Me elimination we observe using ESMS is the first occurring dissociation process to be observed upon gradually raising the cone voltage. This demonstrates that the β-Me elimination observed is the lowest-energy dissociation pathway for this cation, as opposed to being an exotic high-energy process. We suggest that this process occurs *via* β-Me migration to afford a thermodynamically stabilised β-stannyl cation, which then loses isobutene to give the daughter ion. These results would be consistent with known work[13] concerning the importance of the Group 14 β-effect in the reactivities of Group 14 organometallic species.

Notes and references

† **2** was obtained from trineopentylstannyl chloride (**3**) *via* metathesis with silver trifluoromethanesulfonate. **3** was synthesized using literature methods (H. Zimmer, I. Hechenbleikner, O. A. Homberg and M. Danzik, *J. Org. Chem.*, 1964, **29,** 2632.) **3**: $^{119}Sn\{^1H\}$ NMR (111.87 MHz, $CHCl_3$) δ = 126.2; δ_H (299.98 MHz, $CDCl_3$): 1.09 (s, 27H, Me_3C), 1.54 [s, 6H, CH_2Sn, $^2J(^1H,^{119}Sn)$ = 47 Hz]; $^{13}C\{^1H\}$ NMR (75.44 MHz, $CDCl_3$) δ 32.36 (quaternary), 33.27 [CH_3, $^3J(^{13}C,^{119}Sn)$ = 40 Hz], 40.49 [CH_2Sn, $^1J(^{13}C,^{119}Sn)$ = 328 Hz]. ν(KBr)/ cm^{-1}) 2954, 2900, 2860, 1464, 1384, 1364, 1239, 1143, 1113, 1011, 736, 604; mp 110–111 °C [lit. 112.5–113.5 °C].

‡ The following general analysis procedure was used: approximately 100 mg of trineopentylstannyl chloride was combined with one equivalent of silver trifluoromethanesulfonate and stirred in 10 mL of dry CH_2Cl_2 for 15 to 30 min with protection from light. The resultant trineopentylstannyl trifluoromethanesulfonate solution was decanted from the AgCl precipitate and diluted with dry acetonitrile to a concentration of approximately 1 mM for ESMS analysis. ES mass spectra were obtained with a Micromass Platform II single quadrupole mass spectrometer using an acetonitrile mobile phase. Spectra were collected at cone voltages of 20, 40, 60, 80, and 100 V each. All peak assignments were unambiguously confirmed *via* comparison with calculated isotope distributions.

§ In all spectra low intensity peaks corresponding to the $[(R_3Sn)_2Tf]^+$ and (if the solvents used were not absolutely dry) $[(R_3Sn)_2OH]^+$ clusters were observed. MS/MS experiments confirm that the presence of these clusters do not have any bearing on the β-Me migration results observed.

¶ The deuterated trineopentylstannyl cation (**6**) was derived from tris(1,1-dideutero-2,2-dimethylpropyl)stannyl trifluoromethanesulfonate (**5**), which was obtained from tris(1,1-dideutero-2,2-dimethylpropyl)stannyl chloride (**4**) *via* metathesis with silver trifluoromethanesulfonate. The synthesis of **7** was achieved by modifying literature methods (I. Dostrovsky and F. S. Klein, *J. Chem. Soc.*, 1955, 4401; S. Sarel and M. S. Newman, *J. Am. Chem. Soc.*, 1956, **78**, 5416): ethyl trimethylacetate was reacted with $LiAlD_4$ to afford **7** in 61% yield; δ_H (299.98 MHz, $CDCl_3$) 0.87 (s, 9H, Me_3C), 2.03 (s, 1H, OH); $^{13}C\{^1H\}$ NMR (75.44 MHz, $CDCl_3$) δ = 25.91 (CH_3), 32.35 (quaternary), 72.50 (1:2:3:2:1 quintet, CD_2OH, $^1J(^{13}C,^2H)$ = 42 Hz). Using the literature (G. A. Wiley, R. L. Hershkowitz, B. M. Rein and B. C. Chung, *J. Am. Chem. Soc.*, 1964, **86,** 964) method of converting neopentyl alcohol into neopentyl bromide, **7** was converted to **8** in 50% yield; δ_H (299.98 MHz, $CDCl_3$) 1.04 (s, 9H, Me_3C); $^{13}C\{^1H\}$ NMR (75.44 MHz, $CDCl_3$) δ 27.69 (CH_3), 32.00 (quaternary), 47.57 (1:32.00 (quaternary), 47.57 (2:3:2:1 quintet, CD_2Br, $^1J(^{13}C,^2H)$ = 46 Hz); MS (70 eV): *m/z* (%): 57 (100) [$(CH_3)_3C^+$], 137 (11) [$^{79}BrCD_2(CH_3)_2C^+$], 139 (11) [$^{81}BrCD_2(CH_3)_2C^+$], 152 (1) [M^+ containing ^{79}Br], 154 (1) [M^+ containing ^{81}Br]. The Grignard reagent of **8** was formed by reaction of **8** with magnesium turnings in THF. Using this Grignard reagent, the literature procedure (H. Zimmer, I. Hechenbleikner, O. A. Homberg and M. Danzik, *J. Org. Chem.*, 1964, **29,** 2632) for the synthesis of **3** afforded **4** in 18% yield; $^{119}Sn\{^1H\}$ NMR (111.87 MHz, $CHCl_3$) δ 126.8; δ_H (299.98 MHz, $CDCl_3$) 1.09 (s, 27H, Me_3C); $^{13}C\{^1H\}$ NMR (75.44 MHz, $CDCl_3$) δ 31.95 (quaternary), 32.92 [CH_3, $^3J(^{13}C,^{119}Sn)$ = 40 Hz], 39.55 [1:2:3:2:1 quintet, CD_2Sn, $^1J(^{13}C,^2H)$ = 39Hz]. IR (KBr)/cm^{-1} ν 2954, 2900, 2860, 2194 (CD_2), 2133 (CD_2) 1461, 1391, 1364, 1238, 1049, 622; mp 113–114 °C

‖ MS/MS experiments were performed using standard isolation and excitation procedures on mass selected ions generated *via* electrospray ionization using a Finnigan model LCQ (San Jose, CA, USA) quadrupole ion trap mass spectrometer.

Received (in Cambridge, UK) 14th June 1999, Accepted 29th June 1999

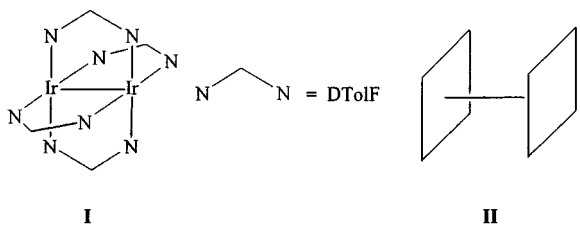
Reaction of $IrCl_3$ with Hhpp in refluxing ethanol (Hhpp = 1,3,4,6,7,8-hexahydro-2*H*-pyramido[1,2-*a*]pyrimidine) yields $Ir_2(hpp)_4Cl_2$, the first paddlewheel complex of Ir^{III}, with a short Ir–Ir distance of 2.495(1) Å, an average Ir–Cl distance of 2.643[6] Å, an Ir_2^{6+} core bridged by four hpp ligands with two axial chlorine atoms, and a double bond between the Ir atoms.

A great deal of understanding has come in the area of multiple bonds between transition metal atoms through the study of dinuclear paddlewheel-type complexes; however, there is very little depth to our knowledge for iridium. Indeed, there is only one paddlewheel complex containing an Ir_2^{4+} core and four bridging anionic ligands, namely $Ir_2(DTolF)_4$ (DTolF = *N*,*N*′-di-*p*-tolylformamidinate) **I**,[1] and the three-step synthesis of this was quite cumbersome. It appears that there are only seven other complexes containing a single bond between divalent iridium atoms that fall within the family of compounds broadly defined by **II**.[1,2]

Dinuclear complexes of iridium(III) are typically edge-sharing or face-sharing bioctahedra and have no metal–metal bonds because of the closed t_{2g}^6 configuration. There are a few complexes in which the short Ir–Ir bond distance is indicative of direct metal–metal bonding, *e.g.* $[Ir_2(\mu\text{-}H)_3H_2(PPh_3)_4]PF_6$,[3] 2.518 Å; $[(Cp^*Ir)_2(\mu\text{-}H)_3]ClO_4$,[4] 2.465 Å, but the close approach may be due to the $(\mu\text{-}H)_3$ bridging. No complex of the paddlewheel type has been reported for trivalent iridium.

It has been shown recently that bridging hpp, the monoanion of 1,3,4,6,7,8-hexahydro-2*H*-pyrimido[1,2-*a*]pyrimidine, stabilizes complexes of the type $M_2(hpp)_4$ (M = V,[5] Nb,[6] Cr,[5] Mo,[5] Ni,[7] and Pd[8]). Additionally, complexes containing an M_2^{6+} core have been made for M = Ru,[9] Re,[10] Mo,[11] and Pd.[8] The complex $[Mo_2(hpp)_4][BF_4]_2$ [11] is the sole example of an Mo_2^{6+} core supported by soft, binitrogen-donor ligands as the bridges and $Pd_2(hpp)_4Cl_2$ [8] is the only example of a single bond between trivalent palladium atoms. As a result, our interest has turned more towards the +3 oxidation state of the transition metals.

For many transition metals (*e.g.* Cr, Co, Ni, Pd, Ru, Rh), simple halide salts are often used as starting materials for the synthesis of a wide variety of paddlewheel complexes, but there is no general pathway for the analogous iridium complexes. Rhenium and osmium paddlewheel complexes are typically synthesized by ligand exchange using $Re_2Cl_8^{2-}$ and $Os_2(O_2CCH_3)_4Cl_2$, respectively, but no similar diiridium starting materials are available. However, one osmium complex, Os_2(hydroxypyridinato)$_4Cl_2$, was synthesized from $OsCl_3$ and the neutral ligand in refluxing ethanol.[12] This same method was tried with $IrCl_3$ and Hhpp and resulted in only the second example of an iridium paddlewheel complex and the first one containing Ir^{III}.



I **II**

Scheme 1

When $IrCl_3$ and Hhpp were stirred in ethanol at room temperature for several hours, no reaction occurred, but heating to reflux overnight resulted in a brown solution containing a small amount of solid.† Removal of the ethanol under reduced pressure left a brown residue, which was dissolved in a minimum amount of CH_2Cl_2. From this solution a dark purple band containing $Ir_2(hpp)_4Cl_2$ **1** (10% yield) was eluted first on a silica gel column with a 10 : 1 CH_2Cl_2–MeOH eluent. Crystals can be readily grown in air by evaporation or diffusion of hexanes into a dichloromethane solution. The solid is air stable and is not decomposed by water, in which it is sparingly soluble.

When an analogous reaction was conducted in toluene, the hot toluene became purple and a dark solid precipitated. Complex **1** was isolated from the toluene filtrate by evaporation. After washing with acetonitrile the yield was reproducibly *ca.* 10%. The dark solid is as yet uncharacterized.

Substitutions in low spin d^6 systems are known to be difficult,[13] and $IrCl_3$ is no exception; this may account for the low yields of $Ir_2(hpp)_4Cl_2$. Additionally it appears that $IrCl_3$ does not react at all with Li(hpp) in refluxing THF or CH_2Cl_2. It is possible that the conditions necessary to activate these reactions also lead to several side products. Clearly a more reactive starting material is desirable, but we have not found one yet as the number of suitable Ir^{III} complexes is rather small.

The structure‡ of **1**, a diiridium unit bridged by four hpp ligands with chlorine atoms bound in the axial positions, is shown in Fig. 1. The Ir–Ir *double* bond distance is 2.495(1) Å and the average Ir–Cl bond distance is 2.643[6] Å. There is no analog with which to make a comparison. The 'nearest kin' is $Ir_2(DTolF)_4$ which contain an Ir_2^{4+} core and a formal Ir–Ir *single* bond of length 2.524(3) Å,[1] a relatively small change of 0.029 Å from the metal–metal distance in **1**.

Compound **1** is paramagnetic with a room-temperature magnetic susceptibility that corresponds to two unpaired electrons. This observation could be accommodated on the basis of the classic molecular orbital ordering, $\sigma^2\pi^4\delta^2\delta^{*2}\pi^{*2}$. However, this is not necessarily the case. We recently reported[8] that $Pd_2(hpp)_4Cl$, which has two more electrons, has the configuration $\pi^4\delta^2\delta^{*2}\pi^{*4}\sigma^2$; the high energy of the σ orbital is traced to the very strong and short Pd–Cl bonds [2.474(4) Å]. In **1**, the Ir–Cl bond lengths are much longer [2.617(4) Å] and therefore the σ orbital will likely be lower in energy, although not necessarily at the bottom. However, as long as the σ orbital is below the π* orbitals, its actual position is not critical and the electronic configuraion of **1** will correspond to a net bond order of 2.

This work suggests several interesting ideas, such as reduction of the Ir_2^{6+} core to Ir_2^{4+} and the question of whether $Rh_2(hpp)_4Cl_2$ as well as $Rh_2(hpp)_4$ can be made. We are pursuing these matters.

We thank Dr Xiaoping Wang for the magnetic measurements and the National Science Foundation for financial support.

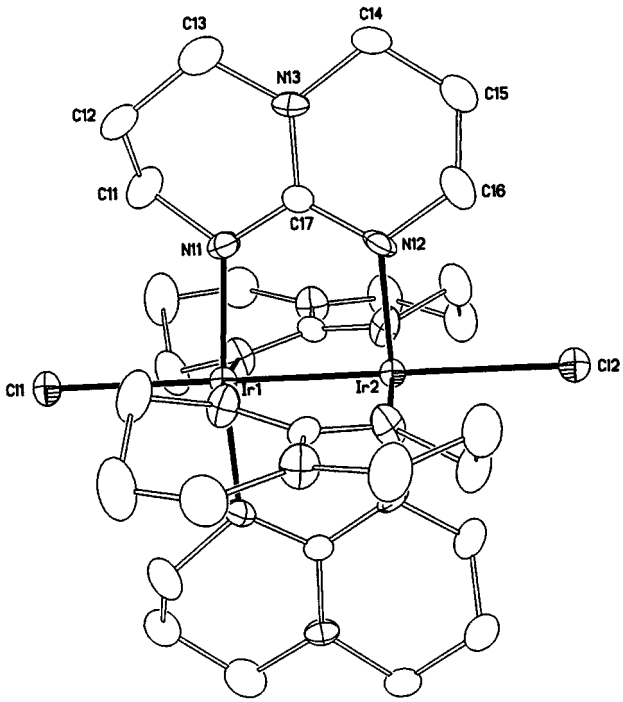


Fig. 1 The molecular structure of $Ir_2(hpp)_4Cl_2$; atoms are drawn at the 50% probability level. Selected bond distances (Å): Ir(1)–Ir(2) 2.495(1), Ir–Cl (av) 2.643[6], Ir–N (av) 2.01[1] Å; N–Ir–Ir–N torsion angle = 11.2(4)°.

Received (in Cambridge, UK) 16th April 1999, Accepted 18th June 1999

The diverse supramolecular chemistry of a rigid, T-shaped single-chain amphiphile, including giant vesicles, spherical and tubular reversed micelles, and gels, is described in comparison to that of rigid-rod amphiphiles of different length.

Classical surfactants are single-chain amphiphiles that consist of a flexible lipophilic chain attached to a hydrophilic head group.[1–5] To better organize their dynamic micellar or vesicular suprastructures, design and synthesis of single-chain amphiphiles with either very short (< 11 Å)[2,4] or very long (rod-coil polymers)[6] rigid-rod subunits have been the subject of recent pioneering reports. Despite the potential importance for modern-day nanotechnology and biophysics, comparable studies with oligomeric rigid-rod single-chain amphiphiles are rare, presumably because of the formidable synthetic challenges involved.[7–9] We have recently considered self-assembly of oligo(*p*-phenylene) amphiphiles (*e.g.* **1**–**4**, Fig. 1) as a possible explanation for the poor binding of rigid-rod guests with either asymmetric (*e.g.* **1**) or hydrophobically mismatched (*e.g.* **3**, **4**) scaffolds to lipid bilayer hosts.[8–11] Here we report self-assembly of 'rigid-T' single-chain amphiphile **1** into giant vesicles ($\mathbf{1_v}$), reversed micelles ($\mathbf{1_m}$), and aqueous gels ($\mathbf{1_g}$) in comparison to amphiphilic oligo(*p*-phenylene) rods of different length (**2**–**4**) that yield vesicles only.

'Rigid-rod' vesicles $\mathbf{1_v}$–$\mathbf{3_v}$ were prepared with entrapped HPTS (8-hydroxypyrene-1,3,6-trisulfonic acid, a water soluble fluorescence probe). To obtain vesicles, fully hydrated mixed micellar solutions containing **1**–**4** (2 mM), octyl D-glucopyranoside (70 mM), HPTS (100 μM), and buffer (5–10 mM $Na_nH_{3-n}PO_4$, 0–100 mM NaCl, pH 6.4) were dialysed at 60–70 °C to remove detergent and external HPTS.[9–11] On the other hand, reversed micelles $\mathbf{1_m}$ were made from a solution of 'rigid-T' amphiphile **1** in biphasic systems composed of a nonpolar solvent (*e.g.* $CHCl_3$, CH_2Cl_2, xylene) and either acidic (pH 1, $\mathbf{1_{m(a)}}$) or basic (pH 13, $\mathbf{1_{m(b)}}$) water with HPTS. After brief sonication, rhythmical shaking (1 h, 1300 rpm), and centrifugation (10 min, < 3000*g*), most of the aqueous layer was a milky, foamlike emulsion. This emulsion was stable for more than two weeks but transformed into a gel ($\mathbf{1_g}$, gel point: 1.0 mg ml^{-1})[12] within 3–5 h after removal of the organic phase containing micellar $\mathbf{1_m}$.

The spectroscopic changes of rigid-rod chromophores **1**–**4** upon self-assembly, namely hypo-/hypsochromism of the ^1L transitions and bathochromic shifts for emission maxima, are listed in Table 1. The effects reached from minor changes for 'rigid T's' ($\mathbf{1_v}$/$\mathbf{1_m}$) to unambiguous H-aggregation[13] for rigid rods $\mathbf{2_v}$ and $\mathbf{3_v}$. This implied herringbone-type packing for self-assembled rods of 30 to 40 Å length with multiple constructive π–π-interactions at least for the latter case. An increased tendency toward herringbones for longer rods may further account for crystallization ($\mathbf{4_c}$) instead of vesiculation of deci(*p*-phenylene) **4** under identical conditions.

Consistent with the spectroscopic trends, differential scanning calorimetry (DSC) gave phase transitions for $\mathbf{1_v}$ but not for $\mathbf{2_v}$, $\mathbf{3_v}$ and $\mathbf{4_c}$. No distinct transitions for $\mathbf{1_g}$ indicated that vesicular $\mathbf{1_v}$ and the (according to cross-polarizing optical microscopy) amorphous crystalline gel strands in $\mathbf{1_g}$ were of different nature. Studies of the presumably involved bilayers with (Fig. 1a) or without (Fig. 1b) interdigitating 'T's' are ongoing to delineate the usefulness of rigid-T vesicles $\mathbf{1_v}$ with

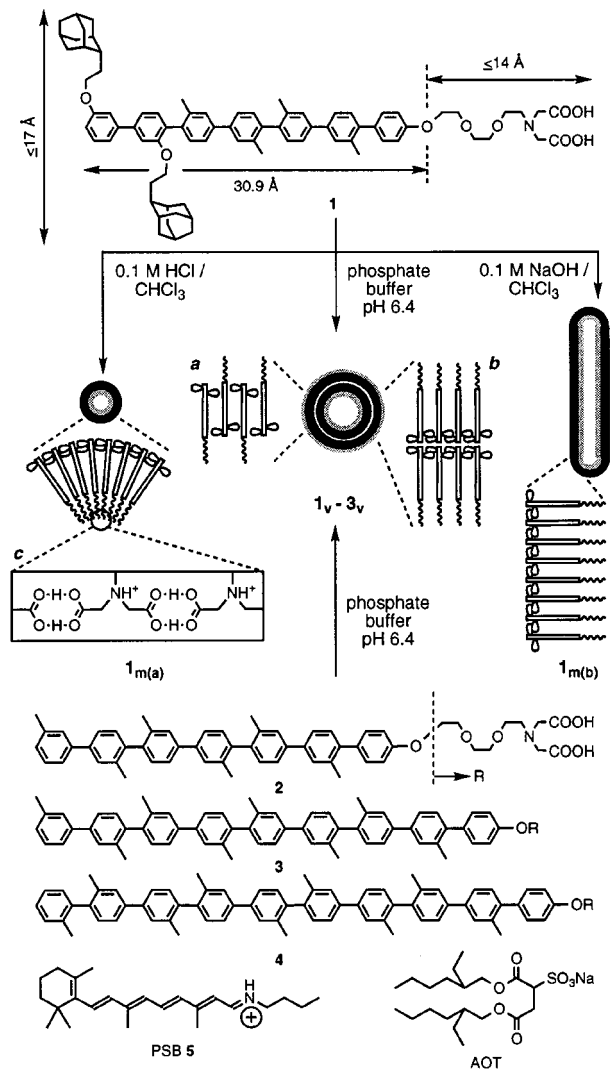

Fig. 1 Structure of oligo(*p*-phenylene)s **1**–**4**, PSB **5**, and AOT; schematic suprastructures for vesicular ($\mathbf{1_v}$–$\mathbf{3_v}$) and micellar ($\mathbf{1_m}$) self-assemblies.

Table 1 Spectroscopic data for self-assembled amphiphilic oligo(*p*-phenylene)s

	1[a]/Å	Micrographs[b]	λ^{e}_{max}/nm ($\Delta\lambda^{e}_{max}$/nm)[c]	λ^{a}_{max}/nm ($\Delta\lambda^{a}_{max}$/nm)[d]	Hypo.[e]
$\mathbf{1_{m(a)}}$	30.9	Micelles	372 (+2)	288 (−2)	0.70
$\mathbf{1_v}$	30.9	Vesicles	375 (+5)	288 (−2)	0.71
$\mathbf{2_v}$	30.9	Vesicles	386 (+19)	274 (−12)	0.43
$\mathbf{3_v}$	39.4	Vesicles	374 (+9)	276 (−10)	0.53
$\mathbf{4_c}$	43.6	Microcrystals	369 (+2)	258 (−28)	0.20

[a] Calculated length of rigid-rod subunit. [b] SEM, phase-contrast and/or fluorescence microscopy. [c] λ^{3}_{max}: emission maxima, $\Delta\lambda^{e}_{max}$: λ^{e}_{max} of self-assembly − λ^{e}_{max} of monomer in THF. [d] λ^{a}_{max}: absorption maxima, $\Delta\lambda^{a}_{max}$: λ^{a}_{max} of self-assembly − λ^{a}_{max} of monomer in THF. [e] Hypochromism (ε^{a}_{max} of self-assembly/ε^{a}_{max} of monomer in THF).

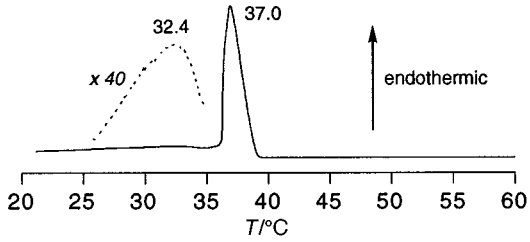

Fig. 2 DSC heating curve of $\mathbf{1_v}$ (scanning rate 1 °C min^{-1}).

T_c = 37.0 °C for applications such as temperature-controlled drug release (Fig. 2).

Optical fluorescence and phase-contrast micrographs contained mainly spherical microparticles for $\mathbf{1_v}$–$\mathbf{3_v}$ and $\mathbf{1_{m(a)}}$ with average diameters that increased with scaffold length and asymmetry ($\mathbf{2_v}$ < $\mathbf{3_v}$ < $\mathbf{1_{m(a)}}$ < $\mathbf{1_v}$, Fig. 3a). Microcrystals were observed for $\mathbf{4_c}$. Perhaps due to better resolution or, more likely, shrinking *in vacuo*, scanning electron microscopy (SEM) revealed nanoparticles for both 'rigid-T' vesicles ($\mathbf{1_v}$, Fig. 3b) and reversed micelles ($\mathbf{1_{m(a)}}$, Fig. 3c). Interestingly, vesicles ($\mathbf{1_v}$) appeared as cavities within precipitated $Na_nH_{3-n}PO_4$ buffer. The additional presence of '8-shaped' besides spherical vesicles implied facile fusion and fission (Fig. 3a/b).

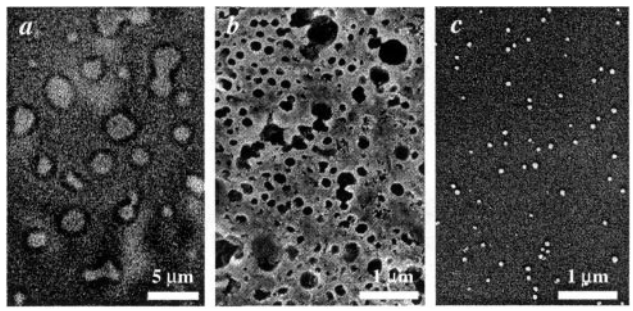

Fig. 3 Representative scanning electron and phase-contrast/fluorescence micrographs for self-assembled **1**–**3**. (a) Fluorescence micrograph for $\mathbf{3_v}$ (diameters: 1.7–3.3 μm). (b) Scanning electron micrograph for $\mathbf{1_v}$ (diameters: 80–260 nm). (c) Scanning electron micrograph for $\mathbf{1_{m(a)}}$ (diameters: 33–73 nm).

Compatibility with the harsh SEM-conditions indicated both stability and high water permeability. The latter was supported for $\mathbf{1_{m(a)}}$ in $CDCl_3$ by a water exchange rate of k = 1.7 ms^{-1} calculated from coalescence of the resonances for intramicellar bulk water (4.78 ppm, ω ([H_2O]/[**1**]) ≈ 100) and extramicellar acidic water (2.18 ppm) at 37.5 °C in the 300 MHz ^{1}H NMR spectra. Extraordinary stability of reversed micelles $\mathbf{1_{m(a)}}$ was further implied by the constant emission intensity of encapsulated HPTS upon dilution of $\mathbf{1_{m(a)}}$. Apparently, the critical micelle concentrations (cmc) of $\mathbf{1_{m(a)}}$ for formation (2 mM) and destruction (< 5 μM) differ significantly. Since rod-shaped **2**–**4** did not self-assemble under identical conditions, the T-shaped structure of **1** seems essential for micellization.[3] However, rapid destruction of $\mathbf{1_{m(a)}}$ by addition of $CuCl_2$, as well as a wormlike morphology for 'basic reversed micelles' $\mathbf{1_{m(b)}}$ (not shown) suggested additional importance of hydrogen bonding in between the hydrophilic iminodiacetate (IDA) termini of **1** for suprastructural organization and stabilization of $\mathbf{1_{m(a)}}$ (Fig. 1c).

Preliminary studies on reversed micelles $\mathbf{1_{m(a)}}$ as biomimetic receptor models revealed that protonated *N*-retinylidene-*n*-butylamine Schiff base (PSB) **5** bound to $\mathbf{1_{m(a)}}$ is not hydrolyzed by intramicellar bulk water.[5] The absorption maximum of PSB **5** surrounded by rigid-rod arene-arrays of the supramolecular host $\mathbf{1_{m(a)}}$ at 456 nm is 16 nm red-shifted compared to that of **5** within conventional AOT reversed micelles.[14] This observation reinforces the potential of $\mathbf{1_{m(a)}}$ as valuable biomimetic receptors. It is in support of the hypothesis that fine-tuning of the absorption of retinylidene Schiff base in bacteriorhodopsins may be governed by aromatic residues in the PSB binding pocket and/or by ring-chain coplanarization of PSB in addition to external point charges.[15]§

In summary, our results imply that single-chain 'rigid-T' amphiphiles are unique surfactants with suprastructural diversity beyond the limitations of comparable rigid-rod amphiphiles. Preliminary results with remarkably stable, water permeable, reversed micelles as biomimetic receptors and catalysts implied potential usefulness of 'rigid-T' amphiphiles in biological, organic and materials chemistry.

This research was supported by NIH (GM56147 (SM) and GM54516 (PDR)), an award from Research Corporation (SM), the donors of the Petroleum Research Fund, administered by the American Chemical Society (SM), Suntory Institute for Bioorganic Research (SUNBOR Grant (SM)), and Georgetown University. The authors thank Drs Naomi Sakai and Richard G. Weiss for discussion, and Dr Robert E. Bachman for access to DSC.

Notes and references

§ The effect of $\mathbf{1_{m(a)}}$ (160 μM in CH_2Cl_2) on the stereoselectivity of cyclopentadiene dimerization (*i.e.* an increasing relative yield of the *exo*-product from 14% to 27%) did not exceed the ordinary influence of reversed micelles.

Received (in Liverpool, UK) 6th May 1999, Accepted 15th June 1999

Ionic liquids based on the 1-butyl-3-methylimidazolium cation have been used as solvents for the preparation in good yield of homoallylic alcohols from tetraallylstannane and a range of aldehydes.

In recent years chemists have striven to develop new synthetic methodologies and techniques which are more environmentally benign, work generally referred to under the title of 'clean technology'. Organostannanes are extremely useful reagents in organic synthesis, but are also notoriously environmentally unfriendly due to the presence of toxic tin residues. There have been a number of attempts to develop cleaner organostannane reagents and reaction conditions. Examples include the development of polymer supported organostannanes,[1] the use of water as solvent,[2] and water-soluble reagents.[3]

Room temperature ionic liquids are attracting increasing interest as environmentally benign reaction media for organic and organometallic synthetic chemistry, for example Friedel–Crafts[4] and hydrogenation reactions.[5] These solvents possess a number of interesting properties, notably their lack of vapour pressure, ease of reuse, lack of flammability, and large accessible temperature range. Furthermore, by alteration of the cation and anion it is possible to adjust the solubility properties of an ionic liquid, for example making it immiscible with water or certain organic solvents. Recent studies on Diels–Alder reactions in ionic liquids based on the 1-alkyl-3-methylimidazolium cation in conjunction with a variety of anions (*e.g.* PF_6^- and BF_4^-) have suggested reactivity patterns similar to those observed in alcoholic solvents.[6,7] Herein we report for the first time the combination of organostannane chemistry and ionic liquid methodology.

The allylation of aldehydes to produce homoallylic alcohols is a useful organic transformation, which has attracted considerable attention in recent years.[8] The most common method is the use of metal–allyl complexes, and one of us (AM) has recently reported the use of tetraallylstannane (**1**) for allylation under very mild conditions (Table 1).[9]

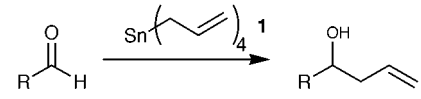
The reaction was found to be most efficient when carried out in MeOH solution. **1** has a number of advantages as a reagent compared with the allyltrialkylstannanes traditionally used for such reactions. In particular, all of the allyl ligands are transferred, leaving the tin by-product in the form of inorganic salt which is much more easily separated from the reaction mixture than organostannane residues resulting from allyltrialkylstannane reactions. Most importantly from a clean chemistry standpoint, as each molecule of **1** will react with four separate aldehyde molecules the reaction is extremely 'atom efficient', since the only reagent atom not incorporated into the product is tin.

The reaction of a range of aromatic and aliphatic aldehydes with **1** was investigated. In a typical experiment, the chosen aldehyde was stirred at room temperature for 16 h with 0.25 equiv. of **1** dissolved in 2 ml of the chosen ionic liquid. The ionic liquids employed were 1-butyl-3-methylimidazolium tetrafluoroborate ([bmim][BF_4]) and hexafluorophosphate ([bmim][PF_6]), which were prepared by literature methods.[10] On completion of the allylation reaction the ionic liquid was observed to be cloudy. Work-up was achieved simply by extraction of the reaction mixture with Et_2O followed by removal of the solvent.† This approach generally allowed isolation of products of excellent purity, unreacted starting material being the only contaminant in some cases, as discussed below. The cloudy residue was assumed to be the tin by-product, and this did not transfer into the Et_2O extracts. The yields obtained are listed in Table 1. Product characterisation was carried out using ^1H and ^{13}C NMR spectroscopy.

As can be seen in Table 1, excluding entry 5 the yields varied from 66–93% depending on the nature of the aldehyde employed. Such values are in good agreement with those previously reported for the equivalent reaction in MeOH solution.[9] Reactions were judged to have gone to completion if the ^1H and ^{13}C NMR spectra showed no signals for the aldehyde group. It should be noted that the small scale on which the reactions were carried out meant that mechanical losses were proportionately quite large, so larger scale preparations would be expected to give higher yields. The allylation of benzaldehyde in [bmim][PF_6] was investigated on a larger scale to confirm this. When 2.50 g of **1** (8.87 mmol) was reacted with 3.765 g of benzaldehyde (35.46 mmol) in 10 ml of ionic liquid, an isolated yield of 5.17 g (96%) of the homoallylic alcohol was obtained.

The reaction was observed to proceed to completion with simple aromatic aldehydes like benzaldehyde (entry 1). Similar behaviour was observed when electron-withdrawing substituents were present (*e.g. p*-Cl, entry 2), and the presence of weakly electron-donating substituents did not appear to hinder the reaction significantly. Thus good yields were obtained in the reactions of tolualdehyde (entry 3) and anisaldehyde (entry 4).

Table 1 Yields of homoallylic alcohol using [bmim][BF_4] and [bmim][PF_6] ionic liquids



Entry	R	Yield (%) [bmim][BF_4]	[bmim][PF_6]
1	Ph	79[a]	82[a]
2	*p*-ClC_6H_4	93[a]	82[a]
3	*p*-MeC_6H_4	80[b]	72[b]

5	*p*-$Me_2NC_6H_4$	0	0
6	Pr	70[b]	70[b]
7	C_5H_{12}	72[b]	74[b]
8	*trans*-PhC=CMe	69[b]	66[b]
9	(*S*)-$Me_2C{=}CH(CH_2)_2CHMeCH_2$	73[b]	78[b]

[a] Isolated yield. [b] NMR yields.

Table 2 Results obtained using recycled ionic liquids

Entry	R	Cycle	Yield (%) [bmim][BF_4]	Yield (%) [bmim][PF_6]
1	Ph	1	79[a]	82[a]
2	Ph	2	82[a]	81[a]
3	Ph	3	78[a]	83[a]

[a] Isolated yield.

When a strongly electron-donating substituent such as Me_2N was present, however, only starting materials were obtained on work-up (entry 5). The greatly reduced reaction rate with electron-donating substituents was also observed in the reactions carried out in MeOH solution.[9]

The presence of significant amounts of unreacted **1** in the organic extracts from the reactions involving simple aliphatic aldehydes suggested that these did not go to completion (entries 6 and 7). No traces of unreacted aldehyde were observed in these cases, but these are probably sufficiently volatile to be lost during work-up. Traces of **1** were also found in the reaction products of *trans*-2-methylcinnamaldehyde (entry 8), suggesting that here too the reaction was incomplete. Yields obtained in all three cases were reasonable despite this.

The product of the (*S*)-(−)-citronellal reaction (entry 9) can contain both *threo*- and *erythro*-isomers. The NMR spectra suggested that any selectivity was modest at best, with peaks corresponding to each isomer being of almost identical intensity. This is perhaps not surprising given the combination of the small size of the methyl group and its distance from the reactive site. Similarly small degrees of selectivity have been reported in the crotylstannationation of citronellal carried out in aqueous solution using (*E/Z*)-Bu_2(MeCH=$CHCH_2$)SnCl.[11]

In general it was found that there was no contamination of the products with tin by-products when the reaction proceeded to completion. This was confirmed by recording ^{119}Sn NMR spectra of the organic products, which indicated that no tin was present in any form. In cases where partial conversion was observed, however, some **1** was found in the organic extracts. No contamination of the products with ionic liquid was observed, however. The reaction between **1** and benzaldehyde was monitored using ^{119}Sn NMR spectroscopy to attempt to determine the fate of the tin residues. A signal corresponding to **1** was observed at −45.8 ppm before addition of the benzaldehyde. This disappeared rapidly when the reagents were mixed, but no further ^{119}Sn signals were observed in either the ionic liquid or the organic product. The reaction was accompanied by the formation of an insoluble white residue, more noticeable than in the preparative experiments due to the lower volume of ionic liquid employed. Attempts were made to identify this species, but it proved to be relatively insoluble in all solvents investigated, and no signals were seen in the ^{119}Sn spectrum. It should be noted that these results contrast strongly with ^{119}Sn investigations carried out on the reaction in MeOH solution, where no insoluble product was observed, and signals were seen in the region −600 to −640 ppm which were assigned to polymeric tin(IV) methoxide species.[9c]

Little difference was found in the yields obtained using the two different solvents. Recycling of the ionic liquid was carried out for the reaction of benzaldehyde following an extremely straightforward protocol.‡ The results gained are shown in Table 2. It can be seen that no decrease in yield was observed in runs carried out using 'old' ionic liquid, and furthermore the products obtained were of the same purity as in the first run. In the case of the recycled $[PF_6]^-$ salt the purification removed all of the cloudy residue, while some cloudiness was observed in the recycled $[BF_4]^-$ salt, but this did not seem to impair the performance of the liquid.

At present the mechanism of the reaction is not clear. Previous studies on the reaction in MeOH have suggested the presence of an eight-membered ring transition state involving both reactants and the solvent.[9] The results presented here do not give any direct clue as to the role of the ionic liquid in this reaction. Further mechanistic investigations are currently in progress.

In conclusion, ionic liquids appear to be excellent solvents in which to carry out allylation reactions using tetraallylstannane. The reaction proceeds most readily with aromatic aldehydes, provided that no strongly electron donating substituent is present. The reaction is less rapid in aliphatic aldehydes, but it should be stressed that all of the investigations reported here were carried out at 15 °C. Allylation of an aldehyde containing a chiral centre gave little evidence for stereoselectivity in the reaction, although the example chosen was relatively unfavourable. Separation of the products from the ionic liquid is very straightforward, as is recycling of the liquid. The latter will be an important concern if ionic liquids are truly to be considered environmentally friendly solvents. Future work will address the reaction of a wider range of substrates, and a mechanistic investigation will be attempted, part of which will be an attempt to identify the insoluble tin by-product of the reaction.

We would like to thank the Royal Society of Edinburgh for the award of a BP Research Fellowship (C. M. G.), the University of Newcastle (A. M.) for financial support, and Dr Phil Dennison for assistance with the ^{119}Sn NMR spectroscopy.

Notes and references

† *Typical procedure for the allylation of alkanals by tetraallylstannane in ionic liquids.* Benzaldehyde (106 mg, 1 mmol) was placed in a 5 ml reaction vial with a spin vane. To this was added 2 ml of [bmim][BF_4] followed by tetraallylstannane (70.7 mg, 0.25 mmol), the septum cap was replaced, and the mixture stirred vigorously at room temperature (typically 15 °C) for 16 h. After this time the mixture was extracted with Et_2O (3 × 10 ml), the organic extracts were combined and dried over anhydrous $MgSO_4$. The Et_2O was removed *in vacuo* to yield a pale oil, 117 mg (79%).

‡ *Recycling of ionic liquids.* After complete reaction and work-up as described above, the ionic liquid could be used with no further treatment. Since this would result in the build-up of tin residues over a period of time, however, the procedure generally employed was to dissolve the ionic liquid in EtOAc (10 ml), and wash with water (2 × 5 ml) and brine (5 ml). Addition of Et_2O (20 ml) caused two layers to form, the lower being essentially pure ionic liquid.

Monomeric magnesium 1-azaallyl and β-diketiminato complexes derived from the bis(trimethylsilyl)methyl ligand: The X-ray structure of the four-coordinate planar magnesium complex [Mg{N(R)C(Bu^t)C(H)R}$_2$] and of [Mg({N(R)C(Ph)}$_2$CH)$_2$]†

Catherine F. Caro, Peter B. Hitchcock and Michael F. Lappert*

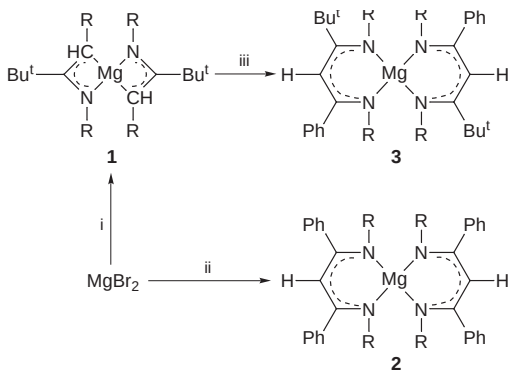
The Chemistry Laboratory, University of Sussex, Brighton,UK BN1 9QJ. E-mail: m.f.lappert@sussex.ac.uk

Received (in Basel, Switzerland) 25th May 1999, Accepted 17th June 1999

Reaction of [K{N(R)C(Bu^t)C(H)R}]$_n$ {[K(LL′)]$_n$} or [Li({N(R)C(Ph)}$_2$CH)]$_2$ {≡ [Li(LL)]$_2$} with magnesium bromide yielded the monomeric, crystalline magnesium complexes [Mg(LL′)$_2$] 1 or [Mg(LL)$_2$] 2, which have been structurally characterised; 1 has the magnesium atom in an unusual planar environment.

Monomeric magnesium complexes containing monoanionic bidentate ligands are rare. Four-coordinate examples have been based upon an alkyl-functionalised pyridyl or a 1,4-diazabutadiene ligand, [Mg{CR$_2$(C$_5$H$_4$N-2)}$_2$][1] or [Mg{N(Bu^t)(CH)$_2$N-(Bu^t)}$_2$][2] (R = SiMe$_3$), while the benzamidinate ligand [N(R)C(Ph)NR]$^-$ has generated a range of solvated monomeric Mg complexes [Mg{N(R)C(Ph)NR}$_2$L$_n$] (L = absent; L = PhCN, n = 1; or L = thf and n = 2).[3] Recent examples of main group metal β-diketiminates include [Al{N(*p*-Tol)C-(Me)C(H)C(Me)N(*p*-Tol)}Cl$_2$][4] (*p*-Tol = *p*-C$_6$H$_4$Me) and [Ba$_3$\{N(R′)C(Me)C(H)C(Me)NR′\}$_3$(NR$_2$)] (R = SiMe$_3$, R′ = C$_6$H$_{11}$).[5] The synthesis and reactions of some alkali metal α,ω-bis(trimethylsilyl)-1-azaallyl and α,β-diketiminates, including their role in preparing unusual transition metal and main group element complexes has been reviewed.[6] We now report the syntheses and structures of the magnesium bis(1-azaallyl) [Mg(LL′)$_2$] **1** (Scheme 1, step i) and bis(β-diketiminate) [Mg(LL)$_2$] **2** (Scheme 1, step ii) and the subsequent reaction of **1** with PhCN to yield the asymmetric β-diketiminato complex [Mg(LL″)$_2$] **3** (Scheme 1, step iii) [LL′ = N(R)C(Bu^t)C(H)R, LL = N(R)C(Ph)C(H)C(Ph)NR, LL″ = N(R)C(Bu^t)C(H)-C(Ph)NR, R = SiMe$_3$].

The new, pale yellow, air-sensitive, readily hydrocarbon-soluble, crystalline solids **1**–**3** gave satisfactory elemental analyses, NMR spectroscopic‡ and X-ray (**1** and **2**)§ data.



Scheme 1 Synthesis of the magnesium bis(1-azaallyl) and β-diketiminates **1**–**3**. *Reagents and conditions*: i, 2 K(LL′), pentane, 16 h, *ca*. 25 °C; ii, [Li(LL)]$_2$, pentane, 16 h, *ca*. 25 °C; iii, 2 PhCN, Et$_2$O, 2 h, −78 °C [LL′ = N(R)C(Bu^t)C(H)R, LL = {N(R)C(Ph)}$_2$CH].

The X-ray molecular structures of crystalline **1** and **2** are shown in Figs. 1 and 2.§ Especially noteworthy is that the centrosymmetric **1** exhibits a very unusual planar coordination geometry around the magnesium centre (*cf.*[1] the distorted tetrahedral geometry in [Mg{CR$_2$(C$_5$H$_4$N-2)$_2$}]). The ligands in **1** are bonded in a *trans*-chelate fashion forming with the magnesium atom a chair skeletal conformation. The angle

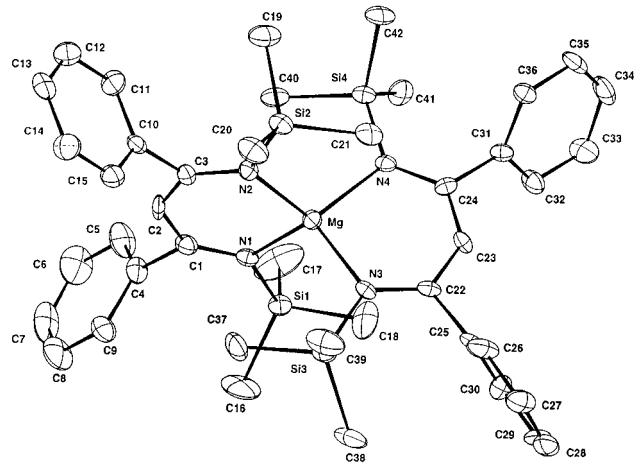

Fig. 2 Molecular structure of **2** with selected bond distances (Å) and angles (°): Mg–N(1) 2.096(8), Mg–N(2) 2.068(8), N(1)–C(1) 1.299(11), C(1)–C(2) 1.432(13), C(2)–C(3) 1.403(13), C(3)–N(2) 1.318(11), C(1)–C(4) 1.499(14); N(1)–Mg–N(2) 99.7(3), N(1)–Mg–N(3) 114.3(3), N(1)–Mg–N(4) 113.6(3), Mg–N(2)–C(3) 117.0(6), Mg–N(1)–C(1) 116.6(7), C(1)–C(2)–C(3) 131.5(9).

between the planes NC(2)C(1) and MgNC(1)N′C(1)′ is *ca.* 46°; the Mg–C(2) distance of 2.408(4) Å is too long for a single bond but lies within the sum of the van der Waals radii. The Mg–N bond of 2.084(3) Å is longer than the terminal Mg–N bonds [1.975(7) Å] in the three-coordinate magnesium amide [Mg(μ-NR_2)(NR_2)]$_2$,[7] but shorter than in the related magnesium complex [Mg{CR_2(C_5H_4N)-2}$_2$] (2.13(1) Å).[1] The N–C and C–C bond lengths lie in between values for single and double bonds; therefore, a degree of π-delocalisation is assumed. 'Ideal' planar magnesium geometry exists in the (tetraphenylporphyrinato)magnesium bis(methyl benzoate) clathrate.[8] Porphyrins are so rigid, that they often form a nearly planar geometry about a metal;[8–10] however, the 1-azaallyl ligand is not rigid and therefore it is very surprising that **1** is planar. This unusual geometry has also been observed for the Group 2 metal compound, [*trans*-Sr(NR_2)$_2$(μ-1,4-dioxane)], where the unexpected stereochemistry about the strontium atom was attributed to agostic intramolecular CH···Sr interactions [Sr···C 3.16(1) Å] with resultant widening of the Si–N–Si angles to 126.4°; the environment about the strontium atom was then best described as quasi-octahedral.[11] The polymeric dialkylmagnesium compound [Mg(CHR_2)$_2$]$_\infty$ is stabilised by intermolecular interactions of 2.535(4) Å between each magnesium atom and a γ-methyl group of a neighbouring Mg(CHR_2)$_2$.[12] In **1**, the closest possible intramolecular contacts (from a methyl group to the magnesium atom) are Mg···H 2.626(3) Å and Mg···C(9) 2.897(3) Å (within the limits of van der Waals forces); however, no significant lengthening of the C(9)–Si(1) bond or distortion of the geometry about the methyl group was observed. The large C(2)–N–Si(2) bond angle of 140.7(3)° in **1** may be due to steric repulsion between the $SiMe_3$ and Bu^t groups as no distortion of the geometry about the Si atoms was observed.

Preliminary first principle AIMPRO (a local density functional, pseudo-potential code[13]) calculations on the whole, isolated molecule, support the planar structure, being 9 kJ mol^{-1} lower in energy than the tetrahedral structure.¶ Such a small energy difference is possibly beyond the accuracy of the code, but indicates the viability of the planar Mg structure. Further calculations will be reported in the full paper. Using the CAChe™ mechanics program, using an enhanced MM2 parametrised force field,[14] we found that the tetrahedral structure is disfavoured by virtue of interligand repulsion between an $SiMe_3$ at the γ-C of one ligand and $SiMe_3$ at N of the other.

Crystalline **2** is the first structurally authenticated example of a simple magnesium β-diketiminate [a macrocyclic bis(ketiminate) is known[15]]. In **2** the magnesium atom is in a distorted tetrahedral environment. The ligands bind η^2 to the magnesium atom through the nitrogen atoms with no observed interactions from the C(1), C(2) or C(3) atoms to the magnesium, as in the related Li complex.[5] Each MgNCCCN skeleton is planar, as also is the case in the isoleptic transition metal Co^{II}, Ni^{II}, Cu^{II} or Pd^{II} compounds,[6,16] and in Sn(LL)Cl. This differs from the situation found in the complexes [Li(LL)]$_2$,[6] [Sn(LL)Me_3][6] or [Al(LL)Me_2][17] in which MLL is boat-shaped, [LL]$^-$ having some η^5- character. It may be that the latter group of complexes favour the boat conformation not only because of their having strong Lewis acid metal sites, but also because the metal is coordinatively unsaturated. Calculations will be reported in the full paper.

The two ligands in **2** are almost orthogonal to one another. The N–C and C–C bond lengths lie in between those for single and double N–C and C–C bonds. This, combined with the coplanarity of each ring, shows that there is a degree of π-delocalisation. The four Mg–N bond lengths in **2** are identical within estimated standard deviations and are similar to values reported for [Mg{N(Bu^t)$(CH)_2$N(Bu^t}$_2$].[2] The monomeric nature of **2** is presumably due to the $SiMe_3$ ligands preventing further attack at the metal centre, demonstrated by the relatively air-stable nature of **2**, as well as its surprising inertness to reaction with small donor molecules (*e.g.* PhCN), metal halides or even protic species.

We are grateful to Dr M. Heggie for the AIMPRO calculations, Professor F. G. N. Cloke for the CAChe™ data and thank EPSRC and FMC Corporation (Bromsgrove and Dr F. Reed) for a CASE award for C. F. C.

§ *Crystal data* for **1** and **2**: data for each of **1** and **2** were collected at 173(2) K on an Enraf-Nonius CAD4 diffractometer in the ω-2θ mode in the range $2 < \theta < 25°$ (**1**) or 23° (**2**). The structures were refined by full-matrix least squares on all F^2 (SHELXL 93).

1: $C_{24}H_{56}MgN_2Si_4$, M = 509.4, orthorhombic space group *Pbca*, a = 10.929(2), b = 17.815(4), c = 16.857(6) Å, U = 3282(2) Å^3, Z = 4, D_c = 1.03 g cm^{-3}, μ(Mo-Kα) = 0.21 mm^{-1}. Final residuals were R_1 = 0.064, for the 1729 with $I > 2\sigma(I)$ and wR_2 = 0.183 for all 2875 reflections.

2: $C_{42}H_{58}MgN_4Si_4{\cdot}C_5H_{12}$, M = 827.74, monoclinic space group $P2_1/c$ (no.14), a = 12.078(4), b = 35.114(8), c = 12.123(3) Å, β = 104.25(2)°, U = 4983(2) Å^3, Z = 4, D_c = 1.10 g cm^{-3} μ(Mo-Kα) = 0.17 mm^{-1}. Final residuals were R_1 = 0.094, for the 2971 with $I > 2\sigma(I)$, and wR_2 = 0.290 for all 6923 reflections. CCDC 182/1320.

¶ AIMPRO is a density functional code using non-conserving pseudopotentials, a wave function basis of atom-centred s,p Gaussians and a charge density fitted to s Gaussians. Three independent Gaussian exponents were used for H (for which the bare Coulomb potential was used), four for C and five each for N, Si and Mg. Geometry optimisation was by conjugate gradient and the local density approximation was employed.

Received (in Cambridge, UK) 1st June 1999, Accepted 22nd June 1999

Heterobifunctional glycopeptide 1 composed of Neu5Acα-(2→3)Galβ(1→4)[Fucα(1→3)]GlcNAc (sialyl Lewis^x) and Lys-Gly-Arg-Gly-Asp-Ser (KGRGDS) having specific activity to bind concurrently with two different types of cell adhesive molecules such as selectins and integrins was synthesised on the basis of a combined chemical and enzymatic strategy.

It has been well documented that many kinds of cell adhesive molecules (CAMs) participate in a variety of biological phenomena such as cell–cell interactions and cell–extracellular matrix (ECM) interactions.[1–6] It should also be noted that collaboration of multiple and complex bindings between different types of cell surface receptors and their ligands greatly contribute to the construction of stable and specific cellular society.

In the present study, we designed a heterobifunctional glycopeptide **1** as a novel and potential glycoligand, because this artificial glycopeptide composed of Neu5Acα(2→3)Galβ≙(1→4)[Fucα(1→3)]GlcNAc (sialyl Lewis^x) and Lys-Gly-Arg-Gly-Asp-Ser (KGRGDS) was supposed to interact with two different types of families of cell adhesive proteins such as selectins and integrins concurrently. This type of synthetic heterobifunctional glycopeptide is strongly expected to become a novel class of antiflammatory and anticancer 'glycodrugs'.[7–9] Kunz *et al*. have reported a significant '*cis*' type interaction of the synthetic RGDS-sialyl Lewis^x with P-selectin as an IC_{50} value of 26 μM. In addition to this type of enhanced affinity of glycoligand with protein, we found an interesting '*trans*' type interaction of a novel glycoligand **1** involving a flexible peptide linker with two different protein receptors. Fig. 1 summarises some plausible mechanisms of '*cis*' and '*trans*' type interactions of glycoligand **1** with cell adhesive proteins.

Scheme 1 indicates a retrosynthetic route for compound **1**. Firstly, a key intermediate **2** was prepared by chemical synthesis from a simple *n*-pentenyl glycoside of *N*-acetyllactosamine **5**[10] and tetrapeptide derivative **4** as starting materials (Scheme 2). The terminal double bond of compound **5** was converted into a carboxy group by treating with potassium permanganate in 87% yield and the active ester of **6** was employed for the coupling reaction with the ε-amino group of Z-lysine to afford **7** in 71% yield. To achieve satisfactory flexibility in the spacer-arm between sialyl Lewis^x and RGDS and versatility in further chemical manipulation, H-Gly-OBn was combined with **7** to give *N*-acetyllactosamine-dipeptide derivative **8** in 83% yield. Consequently, deprotection of the benzyl ester and *O*-acetyl groups of **8** under alkaline conditions was allowed to proceed smoothly and gave compound **3** in 87% yield without racemization. Coupling reaction of the glycopeptide **3** with an unprotected disaccharide moiety with an amino-terminus generated from RGDS derivative **4** was carried out by employing diphenylphosphoryl azide[11] as a selective promoter of the carboxy group of the glycopeptide. A hexapeptide derivative **9** was obtained in 77% yield with no side reaction at the free hydroxy groups of the carbohydrate moiety. Removal of all

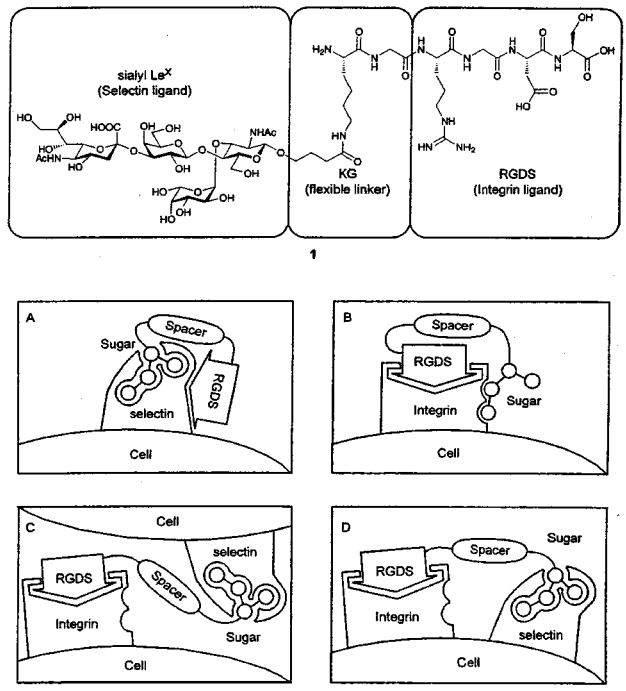

Fig. 1 Chemical structure of **1** and plausible mechanisms of binding of **1** with receptor molecules. (A) and (B) represent cooperative-type '*cis*' interactions, and (C) and (D) represent crosslinking-type '*trans*' interactions (crosslinking by glycopeptide), respectively.

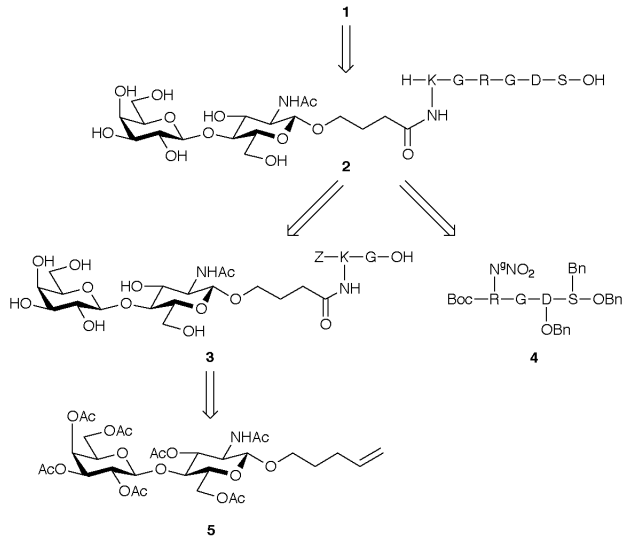
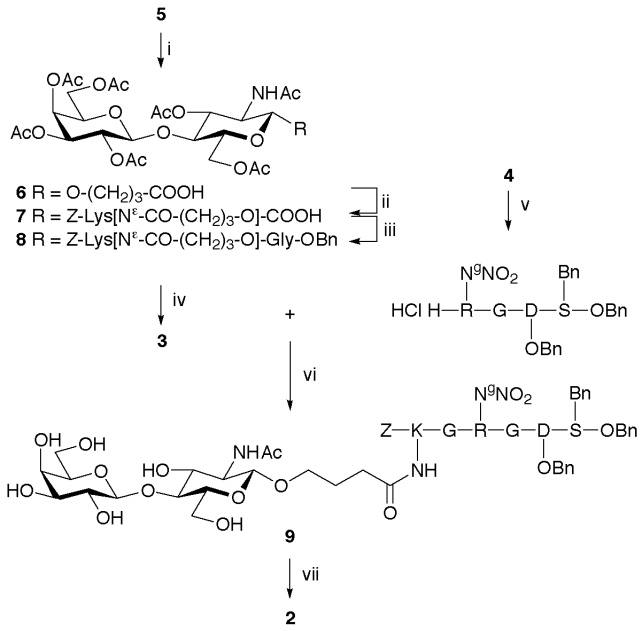


Scheme 1 Retrosynthetic route to cell adhesive glycopeptide **1** (CAGP **1**).

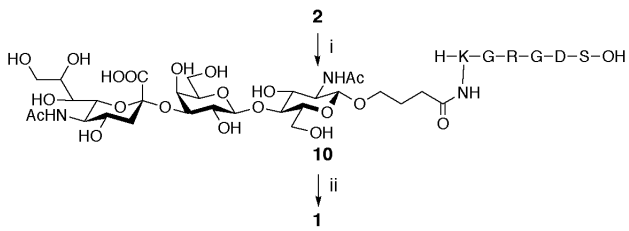


Scheme 2 *Reagents and conditions*: i, $KMnO_4$, AcOH aq., rt, 87%; ii, HONSu, DCC, DMF, 0 °C→rt, then Z-Lys, TEA, DMF–H_2O (9:1), rt, 71%; iii, DPPA, Gly-OBn, TEA, DMF, 0 °C→rt, 83%; iv, NaOMe, dry MeOH, rt, then 1 M NaOH aq., rt, ion exchange resin (Dowex 50W-X8), 87%; v, 2 M HCl–dioxane, 0 °C→rt; vi, DPPA, TEA, DMF, 0 °C→rt, 77% (over all yield from **4**); vii, Pd/C, H_2 gas, MeOH–H_2O, (1:1) rt, 99%.

protecting groups of the peptide moiety of **9** such as benzyl, nitro, and benzyloxycarbonyl groups was performed by standard hydrogenation in the presence of palladium on charcoal to give the intermediate **2** in 92% yield.

Subsequently, the glycopeptide **2** was employed as a substrate for the corresponding glycosyltransferases. It is of interest to examine the substrate specificity of the enzymatic glycosyltransfer reactions against non-natural glycopeptide **2**, since acceptability of synthetic glycoconjugates to the glycosyltransferases depends strongly on the nature of aglycons or supporting backbones.[12] In fact, a synthetic hexapeptide bearing an *N*-acetyllactosamine side chain through an appropriate hydrophobic linker (**2**) was proved to be an excellent substrate both for α(2"→3)sialyltransferase and for α(1→3)fucosyltransferase. The sialylation and fucosylation of compound **2** proceeded smoothly and glycopeptide **1** was isolated by preparative HPLC in 45% overall yield from **2** (Scheme 3).

The effect of hybridisation of the functional carbohydrate and peptide on the '*cis*' type interaction between glycoligand **1** and each protein was investigated by surface plasmon resonance (SPR). As anticipated, compound **1** binds P- and E-selectins more strongly than native sialyl Lewis^x, and association constants of **1** with P- and E-selectins were assumed to be 6.6×10^7 M^{-1} and 4.5×10^5 M^{-1}, respectively. It was also found that **1** inhibited interaction of human integrin β_1 with its monoclonal antibody more effectively than RGDS (IC_{50} = 0.55 mM).



Scheme 3 *Reagents and conditions*: i, **2** (20 mg), CMP-Neu5Ac (25 mg), α-2,3-sialyltransferase (0.3 unit), calf intestine alkaline phosphatase (20 unit), BSA (10 mg), $MnCl_2 \cdot 4H_2O$, Triton CF-54, 50 mM sodium cacodylate buffer (2.0 mL, pH 7.4), 37 °C, 3 d, 80%; ii, **10** (15 mg), GDP-Fuc (10.3 mg), α-1,3-fucosyltranseferase V (10 munit), calf intestine alkaline phosphatase (1 unit), NaN_3, $MnCl_2 \cdot 4H_2O$, 100 mM HEPES buffer (1.0 mL, pH 7.5), 37 °C, 3 d, 56%.

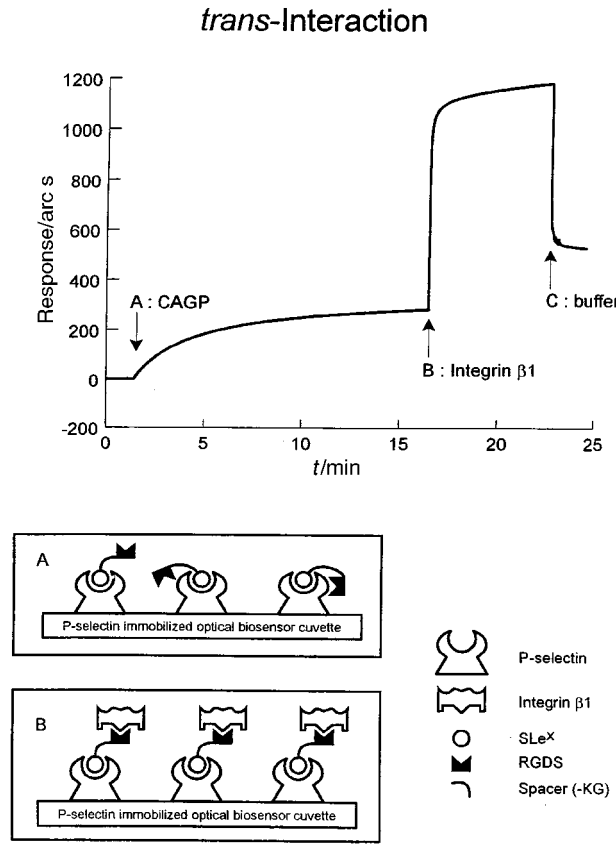


Fig. 2 Crosslinking of selectin and integrin by cell adhesive glycopeptide (CAGP) monitored by SPR method. The first arrow 'A' indicates the time point of the beginning of the injection of cell adhesive glycopeptide (20 μL, 1.3 mg mL^{-1}) to the P-selectin immobilised cuvette. The second arrow 'B' indicates the time point of the injection of integrin β1 (20 μL, 9.1 μg mL^{-1}) to this cuvette. The third arrow 'C' indicates the beginning of the buffer washout (200 μL of phosphate buffer solution). Integrin β1 was found to bind to CAGP-P-selectin complex as indicated by a significant increase in the response unit.

These successful results of cooperative '*cis*' interactions prompted us to examine the artificial crosslinking of selectin and integrin by the synthetic glycoligand. As indicated in Fig. 2, glycopeptide **1** exhibited the specific capacity to bind P-selectin and human integrin β_1 concurrently. We also have evidence that **1** could block the integrin-mediated adhesion of activated T cells to a collagen-coated plate at the same level as inhibition by a monoclonal antibody to integrin. Therefore, it is strongly suggested that synthetic glycopeptide **1** will become an effective practical tool, 'cell adhesive glycopeptide (CAGP)', to modulate immune responses through its inhibitory effect on lymphocyte-endothelial cell interaction.

Ruthenium-catalysed multiple component transformations: one-step stereoselective synthesis of functional dienes from alkynes and carboxylic acids

Jacques Le Paih, Sylvie Dérien and Pierre H. Dixneuf*

Received (in Liverpool, UK) 7th May 1999, Accepted 22nd June 1999

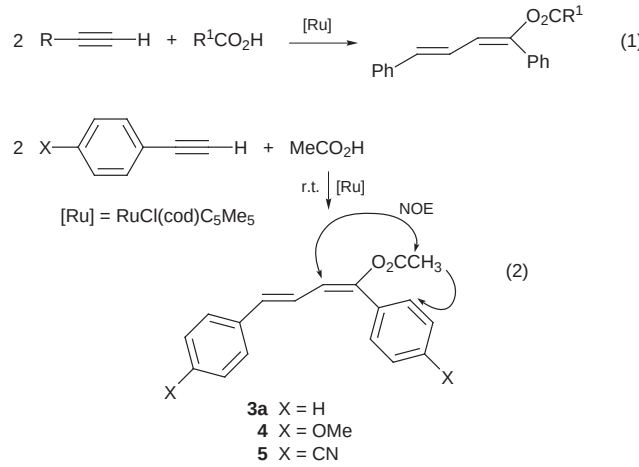
The precatalyst RuCl(cod)C_5Me_5 allows the head-to-head oxidative dimerization of terminal alkynes and the concommittent 1,4-addition of carboxylic acid to afford (1*E*,3*E*)-1-acyloxy-1,3-dienes in one step under mild conditions.

The development of catalysis towards the selective combination of several simple substrates to afford in one step a unique functional molecule in high yield constitutes an important contribution to the discovery of new synthetic methods for environmental impact. These reactions require toxic reagents to be banished, high selectivity and atom economy to avoid costly separations. Multiple component reactions selectively combining several molecules into only one[1,2] *via* the formation of more than two bonds constitute an important challenge for chemists. Recently, ruthenium catalysts, in particular, have been shown to promote the one-step addition of three simple substrates. Representative examples deal with the selective formation of polycyclic compounds,[3] bicyclic phenols,[4] tricyclic hydroquinones[5] or cyclopentenones *via* the catalytic trifunctional Pauson–Khand reaction.[6] The combination of functional arene derivatives with alkene and carbon monoxide *via* the activation of the inert (sp^2)C–H bond has led to aryl ketones.[7] 1,5-Diketones and (*E*)-vinyl chlorides can also be obtained in one step by three component addition of alkyne, unsaturated ketone and water,[8] or NH_4Cl,[9] respectively. The combination of two molecules of acetylene and acrylonitrile has just been achieved by a ruthenium catalyst and affords the heptatrienenitrile.[10]

We have shown recently that the catalyst precursor RuCl(cod)C_5Me_5 promotes the oxidative coupling of C≡C and C=C bonds of alkynes and allyl alcohol to generate either γ,δ-aldehydes[11] or performs the three-component synthesis of methylenetetrahydropyran acetal derivatives.[12] We now report a novel regio- and stereo-selective, three-component catalytic synthesis of functional 1,3-dienes, by one-step combination of two molecules of terminal alkynes and one of carboxylic acid to easily afford (1*E*,3*E*)-1,4-disubstituted-1-acyloxybuta-1,3-dienes [eqn. 1)].

The reaction of 2.5 mmol phenylacetylene with 1.25 mmol acetic acid in the presence of 5 mol% of RuCl(cod)C_5Me_5 (**A**) in 1 mL dioxane affords, after 20 h at room temperature 90% of only the (1*E*,3*E*)-1,4-diphenyl-1-acyloxybuta-1,3-diene **3a** stereoisomer [eqn. (2)]. This reaction corresponds to the highly regioselective head-to-head coupling of terminal alkynes with stereoselective 1,4-addition of the proton and the carboxylate. The stereochemistry of **3a** was established by NMR and NOE experiments.† The addition of $MeCO_2D$ to 2 equiv. of phenylacetylene, catalysed by 5% of **A**, afforded the corresponding PhCD=CH–CH=C(OAc)Ph derivative **3b** and showed the selective 1,4-addition of acetic acid to the conjugated diene skeleton.

The efficiency of the reaction drastically depends on the nature of the solvent. After 15 h the previous reaction leading to **3a**, performed at room temperature led to 37, 41, 49, 75 and 77% phenylacetylene conversion in toluene, CH_2Cl_2, MeCN, THF and dioxane, respectively. The corresponding addition of acetic acid to *p*-methoxyphenylacetylene and *p*-cyanophenylacetylene led to 85% of **4** and 81% of **5**, but after 42 and 0.5 h,



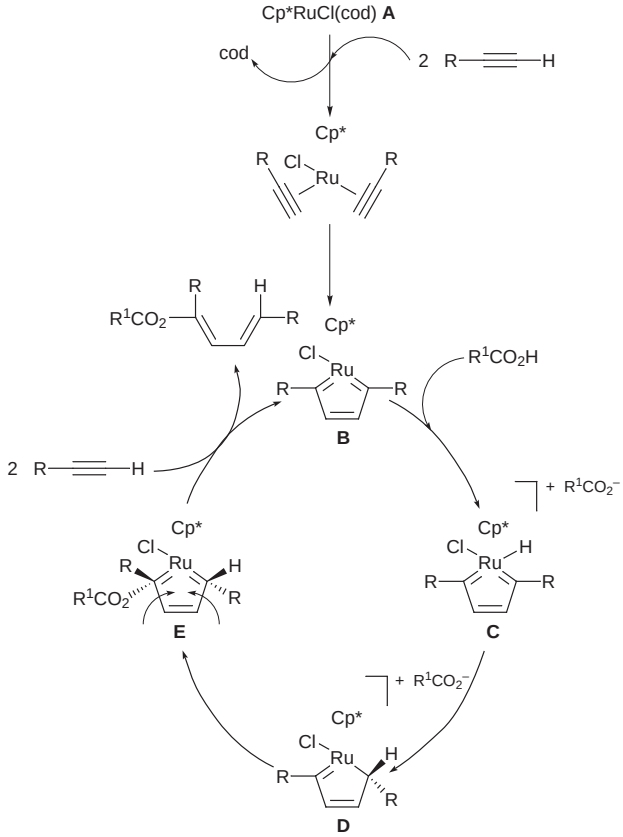
respectively, at room temperature [eqn. (2)], showing that an electron-withdrawing group on the phenyl ring drastically favours the reaction. The reaction also proceeds with alkylacetylenes but with a lower efficiency as hex-1-yne and oct-1-yne are transformed, under the **3a** formation conditions, into (1*E*,3*E*)-RCH=CH–CH=C(OAc)R **1** (R = Bu^n, 20%) and **2** (R = C_6H_{13}, 40%).

A variety of carboxylic acids have been added to phenylacetylene in the presence of catalyst **A** at room temperature and the corresponding dienes **6** were obtained (Scheme 1). It thus appears that strong carboxylic acids give a low yield of diene (**6a**: 30%), and the weaker acids ($pK_a > 4$) afford quantitative yields after 16–18 h of catalytic reaction at room temperature (**6d**–**6f**).

It has been shown recently that RuCl(cod)C_5R_5 precursors react with terminal alkynes to give, after cod ligand displacement, a complex resulting from the head-to-head, oxidative coupling of two molecules of alkyne at the ruthenium site[10,13,14] to give either a bis-carbene derivative[13,14] or, when a phosphine ligand is coordinated, a ruthenacyclopentadiene.[10] Moreover, we have shown that the addition of two equivalents of phenylacetylene to precursor **A** led to the formation and isolation of the metallacycle **B**, with a bis-carbene structure

	R^1	*t*/h	Yield (%)
a	$CHCl_2$	15	30
b	CH_2CN	18	85
c	H	20	62
d	CH_2OMe	18	95
e	Ph	16	98
f	Bu^t	16	91

Scheme 1 *Reaction conditions*: alkyne (2.5 mmol), catalyst **A** (0.125 mmol), acid (1.25 mmol), dioxane (1 ml), stirred at room temperature for various reaction times (15–20 h).



Scheme 2

(Scheme 2) which was previously obtained *via* a different route.[14] Consequently, Scheme 2 provides a possible mechanism leading to the formation of dienes **3**–**6**. Protonation of bis-carbene intermediate **B** can lead to the species **D**, *via* known carbene ligand insertion into a M–H bond.[15] The direct protonation of the carbene atom of **B** to afford **D** in one step cannot be ruled out. The species **E** arising from carboxylate addition to **D** is expected to generate (1*E*,3*E*)-dienes **3**–**6**. In support of this mechanism we have shown that the isolated complex **B** catalyses the formation of **3a** under conditions reported in Scheme 1 and that the substitution of acetic acid by NaO_2CMe in THF does not lead to any transformation of either phenylacetylene or complex **B**.

The above catalytic reaction represents a new example of multiple component addition of type 2A + B → C, performed under mild conditions with atom economy. It offers potential for the stereoselective preparation of functional dienes by 1,4-addition to the ruthenacycle intermediate resulting from oxidative coupling of two alkyne molecules at the ruthenium centre.

The authors are grateful to Dr Christian Bruneau for helpful discussions and MENRT for the award of a thesis grant to J. L. P.

Received (in Liverpool, UK) 30th April 1999, Accepted 18th June 1999

***N*-methylpyridinium ylide complexes obtained from alkoxycarbene complexes of chromium and *N*-methyldihydropyridines easily insert successively a CO ligand to give α-alkoxy chromium acyl complexes, then a tethered triple bond and two additional CO groups to yield bicyclic butenolides.**

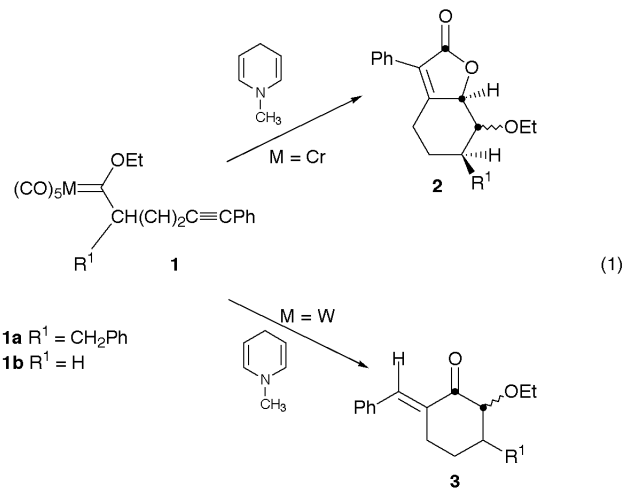
The use of stoichiometric amounts of transition metal complexes for the synthesis of organic compounds can only be acceptable if elaborate molecules are obtained and if, ideally, most of the ligands around the metal center can be incorporated in the final products. As examples of such reactions we can cite those involving Fischer carbene complexes for the cyclopropanation of olefins,[1] and for the synthesis of phenols[2] and pyrrolinones[3] from alkynes. As far as the balance of the metal ligands in these reactions is concerned, whereas only one CO ligand is used in the first case to form the carbene group which is then transferred to the double bond, two CO ligands of $M(CO)_6$ are incorporated in the two latter examples, one for the formation of the starting carbene complexes, the other one for the formation of respectively a phenol and a lactam.

The purpose of this communication is to describe for the first time a straightforward, room temperature triple insertion of CO groups from $Cr(CO)_6$ *via* carbene complexes, providing finally polycyclic polyoxygenated compounds *without* the need of external CO.[4]

The starting carbene complexes, containing either a tethered triple or double bond, were prepared from $Cr(CO)_6$ and $W(CO)_6$ *via* known routes.[5,6] Interaction of **1a** (M = Cr, R^1 = CH_2Ph) (2.02 g, 4.2 mmol) in CH_2Cl_2 (110 ml) at −10 °C, with an excess (3 equiv., 0.84 ml) of a mixture of 1,2 and 1,4 *N*-methyldihydropyridines in CH_2Cl_2 (10 ml) gave after 12 h at room temperature, the tetrahydrobenzofuranones **2a** (0.95 g, 65%) as a 77:23 mixture of two diastereoisomers which could be separated by fractional crystallization into an oil for the major isomer and white crystals (mp 153 °C) for the minor one. The microanalysis confirmed the insertion of two CO groups in the organic ligand of complex **1a**.† Both the IR spectrum (νCO, 1751 cm^{-1}, νC=C, 1662 cm^{-1}) and the ^{13}C NMR spectrum (δ CO, 172.9 and δ C≡C, 161.2 and 124.9) were in agreement with the presence of a butenolide. The fitting of the various carbon atoms was established by extensive NMR spectroscopy. The structure of the minor stereoisomer could finally be assessed by an X-ray analysis (Fig 1).‡ It confirmed the reduction of the starting carbene complex, the insertion of the triple bond and of two CO ligands and also established the stereochemistry of the various substituents with respect to H-7a, the hydrogen at the ring junction. The stereochemistry of the major product could be assessed by ^1H–^1H COSY and NOE experiments: in both compounds, the benzyl group is equatorial and *trans* with respect to H-7a.

Complex **1b** (M = Cr, R^1 = H) behaved similarly and led to a 10:1 mixture of diastereoisomers **2b**, the less abundant being obtained as white crystals, mp 90 °C. Its structure and thus the relative stereochemistry was again established both by NMR and by X-ray crystallography.§

When the same reaction was carried out on complex **1a** (M = W, R^1 = CH_2Ph), then the course of the reaction was different: product **3a** was isolated in 62% yield as a 2:1 mixture of isomers which were separated by silica gel chromatography. The NMR data of the minor isomer (yellowish crystals, mp 78 °C) confirmed the presence of a low field singlet at δ 7.70, of two diasteretopic hydrogens of an ethoxy group and of a carbonyl group, δ CO 200.7, belonging to a cyclohexenone.¶ Confirmation of structure **3** arose again from an X-ray analysis (Fig. 2).‡ As far as the mechanism of these transformations is concerned, we had already established that alkoxycarbene



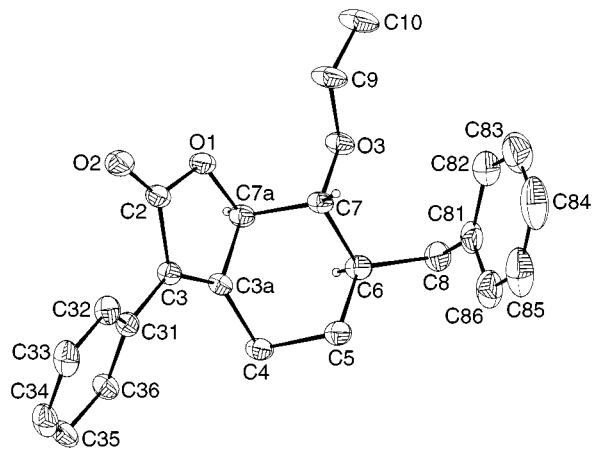


Fig. 1

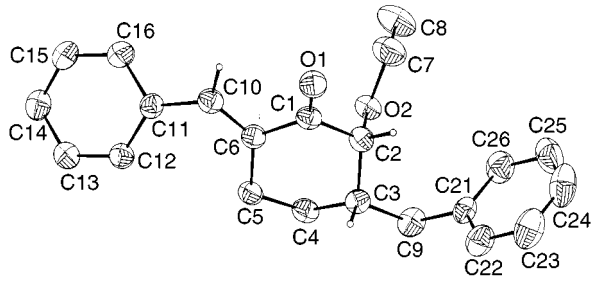

Fig. 2

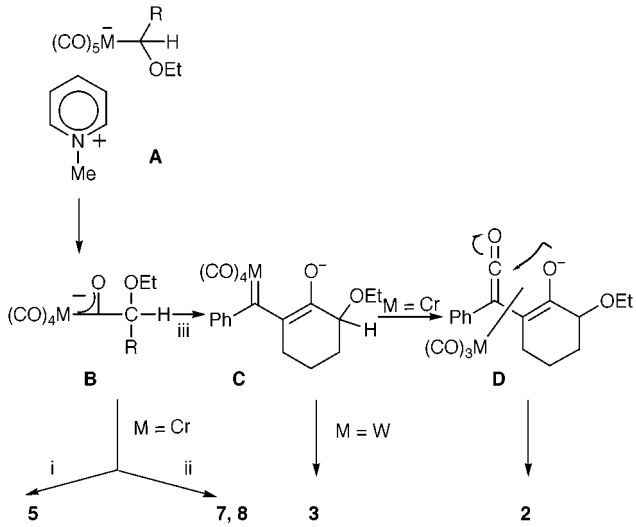
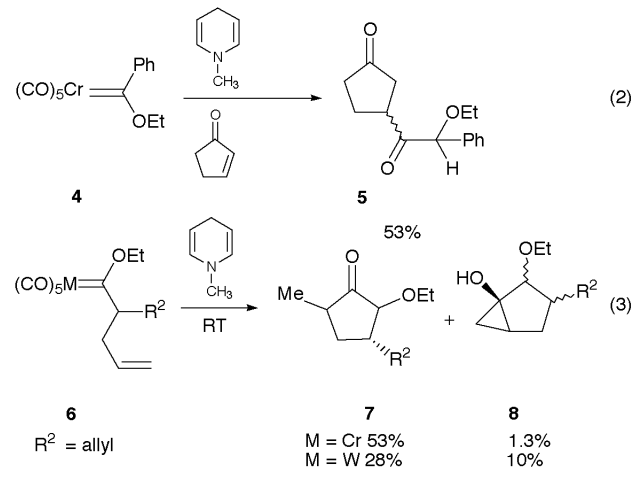


Scheme 1 i, R = Ph; ii, R = $(CH_2)_2CH{=}CH_2$; iii, R = $(CH_2)_3C{\equiv}CPh$.

complexes of chromium and tungsten were reduced by *N*-methyldihydropyridines into pyridinium metallates **A** (Scheme 1).[7]

Two sets of reactions allowed the assessement of the origin of **2** and **3** starting from the intermediate **A**: first, the reaction of **4** with *N*-methyldihydropyridines in the presence of cyclopent-2-en-1-one led to the 1,4 dicarbonyl compound **5** in 53% yield. This confirmed the formation of an ethoxy acyl metallate **B** from **A** and its addition to the conjugated ketone.[8–10]



Second, reaction of complex **6** containing a tethered double bond led to a mixture of two possible products, **7** as the result of its intramolecular cyclopropanation by the oxycarbene function of **B**, and **8**, as the result of its insertion in the metal acyl bond of **B**.

If instead the R group in **A** and **B** contains a triple bond, then its insertion into the metal–carbon double bond of the oxycarbene complex **B** leads to a new carbene complex **C**: in the case of tungsten, no further reaction but protonation takes place giving **3**.

In the case of chromium, an additional CO insertion occurs leading to a ketene complex **D**. A nucleophilic intramolecular interaction between the oxygen atom and the central carbon of the ketene function, a reaction which has been well established in the case of aminocarbene complexes, will then give the lactone **2**.[3,10]

Thus, starting from $M(CO)_6$, and depending on the nature of the metal, either two (M = W) or three CO groups (M = Cr) were inserted leading to elaborate, functionalized molecules.This result confirms again the higher propensity of chromium to induce the insertion of carbonyl ligands and demonstrates for the first time that up to three carbonyl ligands of $Cr(CO)_6$ can be used as successive building blocks.

Diels–Alder and Michael addition reactions of indoles with masked *o*-benzoquinones: synthesis of highly functionalized hydrocarbazoles and 3-arylindoles

Ming-Fang Hsieh, Polisetti Dharma Rao and Chun-Chen Liao*

Department of Chemistry, National Tsing Hua University, Hsinchu, Taiwan 300. E-mail: ccliao@faculty.nthu.edu.tw

Received (in Cambridge, UK) 1st June 1999, Accepted 16th June 1999

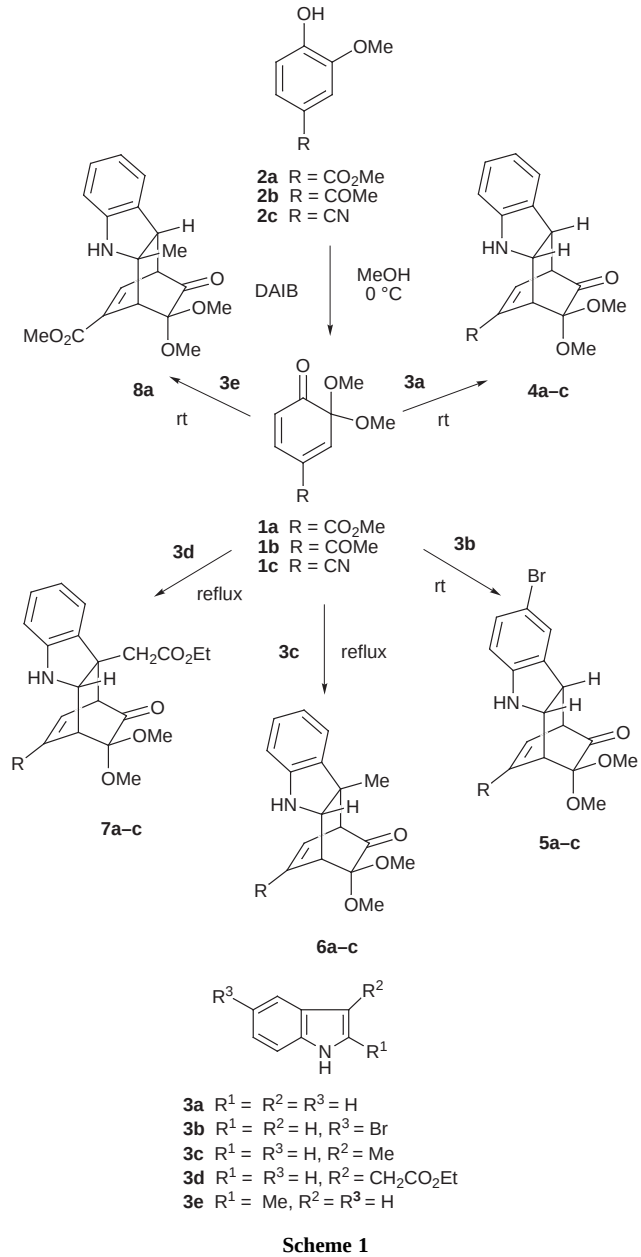
Highly functionalized hydrocarbazoles and 3-arylindoles are prepared from commercially available 2-methoxyphenols and indoles.

The chemistry of indole[1] has been extensively investigated because of the wide-spread occurrence of its skeleton as a basic structural unit of various types of natural products with interesting and useful physiological properties.[2] It is well-known that indole behaves as an enamine towards electrophiles and undergoes Michael addition to electron-deficient alkenes.[1] In contrast, its dienophilic behavior has been reported only on a few occasions.[3–8] Indoles have been found to react as dienophiles in formal [4 + 2] cycloaddition reactions with 3,6-disubstituted 1,2,4,5-tetrazines,[3] tetrachlorothiophene 1,1-dioxide,[4] isoprene,[5] buta-1,3-diene,[5] cyclohexa-1,3-dienes[6] and quinodimethanes.[7] Indole magnesium salts were found to undergo facile cycloaddition reactions with 2-phenylsulfonyl-1,3-dienes.[8] However, indole participates in other types of cycloadditions as an electron-rich alkene.[1]

Masked *o*-benzoquinones (MOBs) are one of the most readily accessible types of cyclohexa-2,4-dienones with immense synthetic potential.[9,10] MOBs have been shown to be efficient dienes and they have been extensively used in this capacity in our laboratory.[9] Following our studies on Diels–Alder reactions of furans with MOBs,[11] we turned our attention to indoles. It was envisioned that if indoles could react with MOBs by cycloaddition, easy access to a variety of potentially useful hydrocarbazoles could be achieved. On the other hand, if indoles add to MOBs by a Michael addition a facile synthesis of highly substituted 3-arylindoles could be achieved. Accordingly, the reactions of selected MOBs **1a**–**c**, generated from phenols **2a**–**c** with a variety of indoles, were examined. We herein report that indoles **3a**–**e** undergo Diels–Alder or Michael addition to MOBs **1a**–**c** depending on the reaction temperature and substitution pattern, to furnish Diels–Alder adducts **4**–**8** or aromatized Michael adducts **9**–**11** in good yields.

In order to avoid their dimerization, MOBs were usually generated *in situ* from the corresponding 2-methoxyphenols in the presence of a reactive dienophile at a suitable temperature using (diacetoxyiodo)benzene (DAIB) in MeOH. Since indoles are known to react with DAIB,[12] an alternative procedure needed to be developed. Consequently, **1a**–**c** were generated from **2a**–**c** in MeOH by adding DAIB (1.0 equiv.) at 0 °C in MeOH and then an indole derivative was added. After the addition of an indole derivative, the temperature was elevated either to room temperature or to reflux (Schemes 1 and 2, Table 1).[13]

3-Methylindole (**3c**) reacted efficiently only at reflux to furnish the Diels–Alder adducts **6a**–**c** and products which could result *via* Michael addition were not descernible. The reactions of **3d** with **1a**–**c** were found to be sluggish and only Diels–Alder adducts **7a**–**c** were obtained in poor yields. At both room temperature and reflux, 2-methylindole (**3e**) underwent Michael addition to MOBs **1b** and **1c** followed by aromatization of the adducts to provide compounds **11b** and **11c** exclusively in excellent yields. Intriguingly, indole (**3a**) underwent cycloaddition at room temperature to furnish Diels–Alder adducts **4a**–**c** and Michael addition at reflux temperature to afford aromatized Michael adducts **9a**–**c** in good yields. 6-Bromoindole exhibited the same behavior as indole albeit with low efficiency.



Scheme 1

The gross structures of all the products were determined by their IR, ^{1}H and ^{13}C NMR, DEPT, low- and high-resolution mass spectral analysis. The majority of these products provided satisfactory elemental analyses. The regioselectvity of the Diels–Alder reactions was determined by ^{1}H–^{1}H decoupling

experiments in all cases. Their stereoselectivity was predicted to be as shown based on our earlier results with furans[11] and is confirmed in the case of the adduct **7b** by its single crystal X-ray diffraction analysis.[14] Since in all cases the reactions furnished adducts resulting from *endo*-addition, these cycloaddition reactions appear to have followed all the ground rules of Diels–Alder reactions. On the other hand, the Michael addition appears to be highly regioselective. In all cases, only 1,6-addition took place. This result was confirmed by the NMR spectra of the aromatic Michael adducts **9**–**11** and by single crystal X-ray analysis in the case of **10a**.[14]

The exclusive cycloaddition of 3-substituted indoles **3c**,**d** and exclusive Michael addition of 2-methylindole to MOBs at both temperatures is probably due to steric factors. The dual reactivity of indoles lacking substituents needs to be understood. It was reasoned that the initially formed Diels–Alder adducts rearrange to the observed products **9**–**11** at high temperature. In order to test this hypothesis, the Diels–Alder adduct **4a** was refluxed in MeOH in the presence of indole and AcOH but only a complex mixture of products which contained no trace of **9a** was obtained. Hence an alternative mechanism, with **9**–**11** being produced *via* a Michael addition–aromatization sequence, is proposed. This concept has also gained support from the substitution pattern required for the success of these reactions. The presence of electron-withdrawing groups on C-4 of MOBs is essential for the success of these reactions. On the other hand, the presence of electron-withdrawing substituents on the 2- or 3-position of indole prevents both cycloaddition and Michael addition.

In conclusion these reactions are mechanistically interesting and help unravel a new class of dienes that can force indoles to act as dienophiles. These reactions provided easy access to a variety of multifunctional tetracyclic compounds and 3-aryl-indoles whose synthesis is otherwise difficult. The Diels–Alder adducts of indoles could potentially be useful starting materials in the total synthesis of indole monoterpenoid alkaloids and ellipticine-type compounds with antitumor activity.

We thank the National Science Council (NSC) of Taiwan, R.O.C for financial support. One of us, (P. D. R.) thanks NSC for a postdoctoral fellowship.

Received (in Cambridge, UK) 1st March 1999, Accepted 20th April 1999

A few years ago, the remarkable catalytic activity of lanthanide ions for the hydrolysis of nucleic acids was discovered. With Ce^{IV}, DNA was hydrolysed under physiological conditions. For RNA hydrolysis, the last three lanthanide ions (Tm^{III}, Yb^{III}, and Lu^{III}) are superb. Furthermore, artificial restriction enzymes for site-selective scission of DNA and RNA, essential tools for the future biotechnology, have been prepared by using the lanthanide complexes. The present article emphasizes the mechanistic aspects of the catalyses of these metal ions. Both DNA hydrolysis and RNA hydrolysis involve the cooperation of acid catalysis (by metal ion and/or metal-bound water) and base catalysis (by metal-bound hydroxide). The magnitudes of contributions of these catalyses, as well as the positions where they work, are primarily governed by the relative height of the energy-barrier for the formation of the pentacoordinated intermediate and that for its breakdown. The following conclusions have been obtained on the basis of various kinetic and spectroscopic evidence: (1) for the hydrolysis of both DNA and RNA, the catalytically active species are dinuclear hydroxo-clusters, (2) Ce^{IV} enormously activates DNA and promotes the formation of the pentacoordinated intermediate, and (3) the catalysis for RNA hydrolysis is mainly ascribed to the promotion of breakdown of the pentacoordinated intermediate.

Introduction

Non-enzymatic hydrolysis of DNA and RNA has attracted much interest, mainly because it is essential for further developments in biotechnology, molecular biology, therapy, and related fields.[1] In current biotechnology, the DNA of bacteria and viruses is manipulated using naturally-occurring enzymes. In the near future, however, we must deal with the DNA of higher animals and plants in order to widen the scope of applications. Is the currently employed technology directly applicable there? The answer is 'No'. First, the genomes of higher species are so large that the sequence-specificity of the restriction enzymes found in nature is too low to cut them solely at the desired site (most of them recognize a specific sequence composed of 4 or 6 DNA-bases).[2] Second, there are no natural enzymes showing sufficient sequence-specificity in RNA scission. Thus, artificial enzymes, which selectively hydrolyse DNA and RNA at the target position with a desired specificity, are crucially important. They may also be valuable tools for therapy, regulation of cell-growth, and other applications.

In order to prepare these artificial enzymes, catalysts for the scission of DNA and RNA are necessary. However, the phosphodiester linkages in DNA are enormously stable, and (until recently) could not be hydrolysed without using natural enzymes.[3,4] Non-enzymatic hydrolysis of RNA was also difficult. Several years ago, however, the remarkable catalytic activity of the lanthanide ions was discovered, and both DNA and RNA were for the first time hydrolysed at reasonable rates under physiological conditions.[5–7] The Ce^{IV} ion is the most active for DNA hydrolysis,[8,9] whereas Tm^{III}, Yb^{III} and Lu^{III} (the last three lanthanide ions) are quite effective for RNA hydrolysis.[10] The acceleration by these metal ions is as large as 10^8–10^{12} fold. Interestingly, these enormous activities are restricted to the lanthanide ions. Furthermore, artificial enzymes

Professor Makoto Komiyama was born in 1947 in Utsunomiya, Japan. After graduated from the University of Tokyo, he entered the Graduate School of this University, where he got his Ph.D. in 1975. After working in the USA as a postdoctoral fellow for Professor Myron L. Bender at Northwestern University, he got the position of Assistant Professor at the University of Tokyo in 1979. In 1987, he became an Associate Professor at the University of Tsukuba, and, since 1992, has been a full Professor of the University of Tokyo. His research areas involves bioorganic and bioinorganic chemistry (especially DNA and RNA hydrolysis), host–guest chemistry (cyclodextrins), functional polymers, and others. He received Awards for Young Scientists from the Chemical Society of Japan, the Japan IBM Science Award, an Award from the Rare Earth Society of Japan, and the Inoue Prize for Science.

Dr Naoya Takeda was born in 1968 in Chiba, Japan. Following his undergraduate education at the University of Tokyo, he obtained his Ph.D. from the University in 1998 under the supervision of Professor M. Komiyama. After working as an assistant staff member at the National Institute for Advanced Interdisciplinary Research, he is currently doing his postdoctoral work as a JSPS Research Fellow at the University of Tokyo. His research interests include bioorganic and bioinorganic chemistry.

Professor Hidemi Shigekawa was born in 1955 in Hiroshima, Japan. After graduated from the University of Tokyo, he entered the Graduate School of the University, and got a position of Assistant Professor there in 1980. After getting his Ph.D. in 1986, he worked at the Brook Haven National Laboratory (1987–1988) using the synchrotron radiation source, as a Postdoctoral Fellow for Dr J. Rowe of Bell Labs. In 1989, he became a lecturer at the University of Tsukuba, and has been an Associate Professor there since 1993. His main research is in the field of surface science using scanning tunneling microscopy and related techniques. He was awarded the Paper Award from the Surface Science Society of Japan in 1991 and 1998.

for site-selective scission of DNA and RNA were prepared by conjugating the lanthanide complexes to DNA oligomers (the sequence-recognizing moieties) (Fig. 1).[11,12] The DNA and

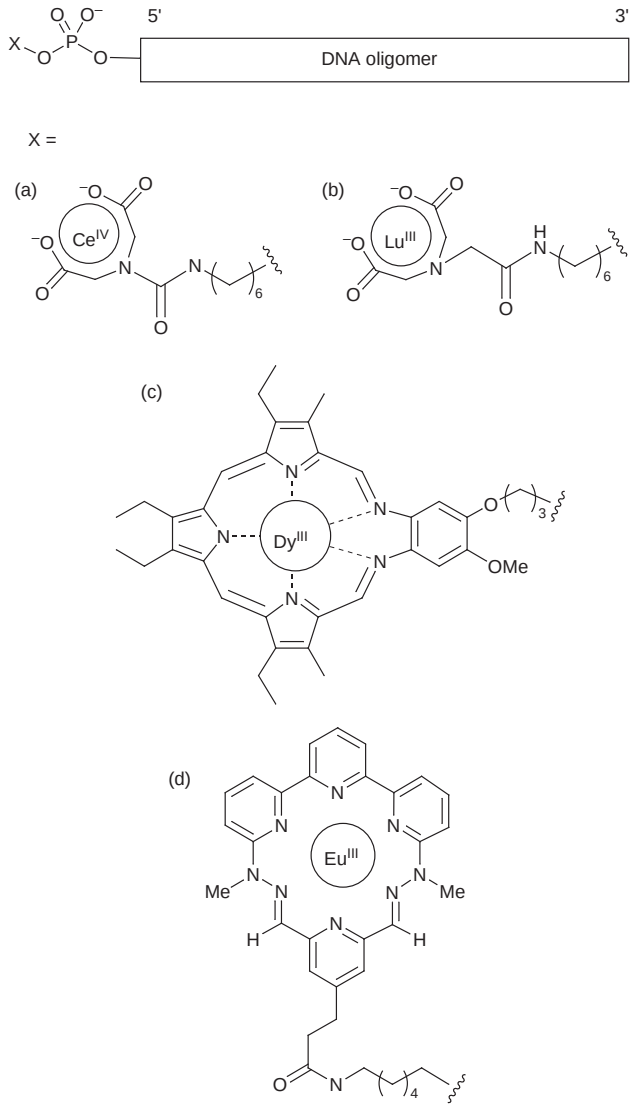

Fig. 1 Typical artificial enzymes for sequence-selective scission of (*a*) DNA and (b)–(d) RNA.

RNA fragments, obtained *via* scission, can be transformed into substrates for enzymatic manipulation. The synergy between lanthanide catalysis and biotechnology is straightforward.[13] A new era is imminent.

This paper focuses on the mechanistic aspects of the lanthanide catalysis for the hydrolysis of DNA and RNA. The following points are clarified on the basis of various kinetic and spectroscopic evidence: (a) what are the catalytically active species?, (b) where do the catalyses work in the course of the reactions?, and (c) why are the lanthanide ions highly active? The mechanisms of the catalyses for DNA and RNA are compared with each other, and also with those for the RNA hydrolysis by dinuclear complexes of non-lanthanide ions. The conclusions obtained here should pave the way to the rational design of still more active catalysts and also to versatile applications of these novel catalyses.

1 DNA hydrolysis by Ce^{IV}

1.1 Survey of the previous studies

The following features of Ce^{IV}-induced DNA hydrolysis have been already documented.[9]

(1) The DNA scission proceeds totally *via* the hydrolysis of phosphodiester linkages, without concurrent oxidative cleavage of the deoxyribose residues.

(2) At pH 7 and 50 °C, the half-life of the phosphodiester linkage in DNA is reduced to a few hours. The acceleration by Ce^{IV} is more than 10^{11} fold.

(3) The catalytically active species is formed from tetravalent Ce ion(s).

(4) Molecular oxygen is not necessary for the catalysis. Only when Ce^{III} salts (*e.g.* $CeCl_3$) are used as the catalysts, is molecular oxygen required to oxidize Ce^{III} to the catalytically active Ce^{IV}.

(5) The rate of DNA hydrolysis is almost constant from pH 2 to pH 8.5.

(6) The nucleic acid bases do not directly participate in the catalysis (the rate of DNA hydrolysis is almost independent of them).

(7) The reaction is accompanied by a notable D_2O solvent isotope effect (k_{H_2O}/k_{D_2O} = 2.2–2.4), showing a rate-limiting proton-transfer.

1.2 The rate-limiting step for DNA hydrolysis

The hydrolysis of DNA proceeds as a two-step reaction (Fig. 2). In the first step, a nucleophile (*e.g.* hydroxide ion) attacks the phosphorus atom, forming a pentacoordinated intermediate. In the second step, the 5′-OH of 2′-deoxyribonucleotide is removed from the phosphorus atom through the scission of the P–O bond [in non-enzymatic hydrolysis, the P–O(3′) scission can also take place]. In order to accelerate the whole reaction, the catalysts must promote the rate-limiting step. Unfortunately, however, it was not known which step is rate-limiting. Thus, the DNA analogues in Fig. 3, which possess better leaving groups

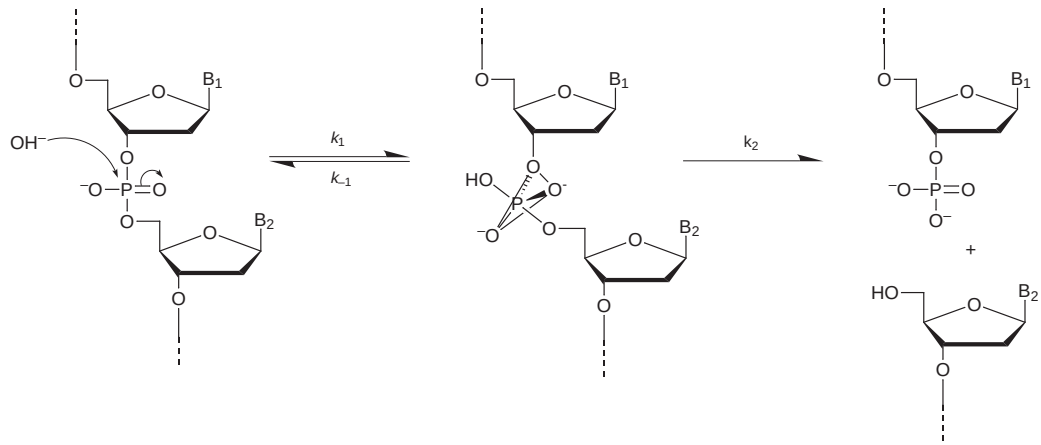

Fig. 2 The reaction pathway of DNA hydrolysis.

than DNA, were prepared as probes, and their hydrolysis rates were compared with the value for the native DNA.[14]

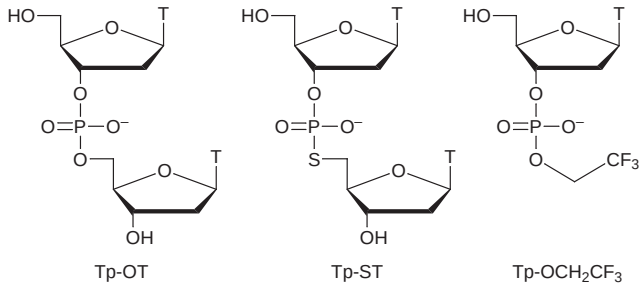

Fig. 3 DNA analogues possessing better leaving groups, as the probes of the rate-limiting step.

(1) Ce^{IV}-induced DNA hydrolysis. When the 5′-O atom of the thymidine in thymidylyl(3′–5′)thymidine (Tp-OT) is replaced with an S atom (the leaving group is changed from T-O^- to T-S^-), the dinucleotide analog (Tp-ST) is hydrolysed by Ce^{IV} around 1000 fold faster than is Tp-OT. The rate constants are 1.7×10^1 and 2.0×10^{-2} h^{-1}, respectively, when $[Ce^{IV}]_0$ = 10 mM at pH 7 and 30 °C. Similarly, the hydrolysis of Tp-OCH_2CF_3 is 75 fold faster than that of Tp-OT. The rate of hydrolysis monotonically increases with decreasing pK_a of the leaving group (the pK_as of T-SH, CF_3CH_2OH, and T-OH are around 11, 13, and 15, respectively). Apparently, the second-step (the scission of the P–O bond) is rate-limiting [the energy diagram is presented by the solid line in Fig. 4(*a*)]. If the first step were to be rate-limiting, the analogues should be hydrolysed at the same (or comparable) rate as Tp-OT.[15]

By using this result, the rate constant k_{obs} for the overall reaction in Fig. 2 is expressed by eqn. (1). The reaction involves the pre-equilibrium formation of the pentacoordinated intermediate.

$$k_{obs} = k_1k_2/k_{-1} \quad (1)$$

Accordingly, the hydrolysis of DNA is accelerated by (a) the increase in k_2 (promotion of the second-step) and/or (b) the increase in k_1/k_{-1} (stabilization of the pentacoordinated intermediate, with respect to the initial state). The activation free energy for the whole reaction ($\Delta G^{\ddagger}$) is the sum of ΔG_1 (the difference between the initial state and the pentacoordinated intermediate) and $\Delta G_2^{\ddagger}$ (the difference between the intermediate and the second-energy barrier).

The trivalent lanthanide ions also hydrolyse DNA, although the activities are far smaller (> 10^3 fold) than that of Ce^{IV}. Here, the second step is also rate-limiting. In contrast, non-lanthanide ions such as Mg^{II}, Zn^{II}, Co^{II}, Al^{III}, and Fe^{III} show no measurable catalysis under the same conditions.

(2) Alkaline hydrolysis. DNA is so stable that it is not hydrolysed at measurable rates even in highly alkaline solutions (*e.g.* in 1 M NaOH at 50 °C). Thus, the direct evaluation of the shape of the energy diagram using the probes in Fig. 3 has been unsuccessful.

However, the following argument shows that the energy diagram is almost symmetric, with respect to the position of the pentacoordinated intermediate: see the dotted line in Fig. 4(*a*). In the forward reaction of DNA hydrolysis, hydroxide ion is the nucleophile and the alkoxide ion of 5′-OH is the leaving group. In the backward reaction, the hydroxide ion and the alkoxide ion exchange positions. Since the pK_as of the conjugate acids of the hydroxide ion and the alkoxide ion are almost the same, their potentials as nucleophiles and the leaving groups are comparable.

1.3 Which step is promoted by the Ce^{IV} ion?

The Ce^{IV} ion accelerates DNA hydrolysis by 10^{11} fold or more, and thus the second step of the reaction must be promoted by this magnitude [see the energy diagrams in Fig. 4(*a*)]. Nevertheless, this step still remains rate-limiting in the whole reaction. Apparently, the first step is also accelerated by the Ce^{IV} ion to a similar (or greater) degree (otherwise, this step should become rate-limiting). The difference in the activation free energies between these two steps is not large. The pentacoordinated intermediate should also be stabilized by the metal ion.

As described later, the catalysis by Ce^{IV} is mainly ascribed to the decrease in ΔG_1, which is associated with the activation of the DNA. Note that the decrease in ΔG_1 necessarily lowers the height of the second barrier (with respect to the initial state), since $\Delta G^{\ddagger} = \Delta G_1 + \Delta G_2^{\ddagger}$.

1.4 Catalytically active species for the DNA hydrolysis

The Ce^{IV} ions form complex metal hydroxide gels when the pH is greater than 4. These heterogeneous systems are inappropriate for detailed kinetic analysis. However, it has been found that homogeneous mixtures can be obtained under highly acidic conditions (pH < 2.5).[16] Significantly, these mixtures have almost the same catalytic activity as the metal hydroxide gel (the hydrolysis of single-stranded DNA at pH 2 is only a few

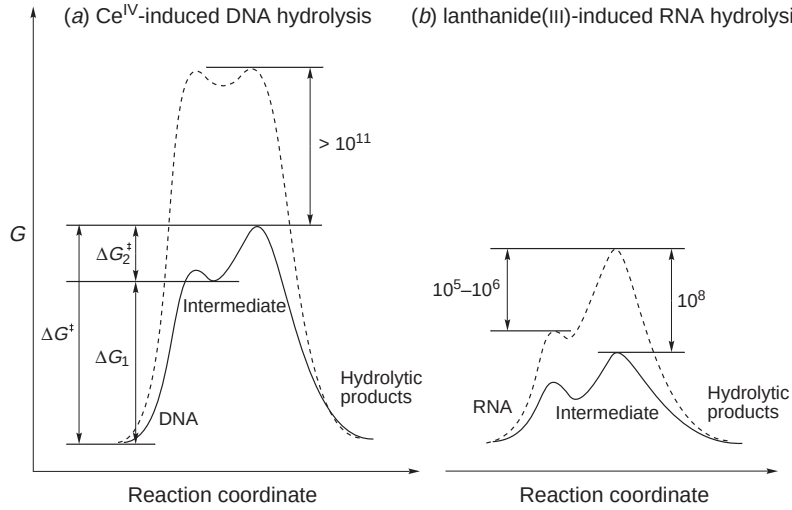

Fig. 4 Energy diagrams for (*a*) Ce^{IV}-induced DNA hydrolysis and (*b*) lanthanide(III)-induced RNA hydrolysis. The dotted lines show the diagrams for the corresponding alkaline hydrolysis.

fold slower than that at pH 7). Moreover, the concentrations of all the Ce^{IV}-derived species therein can be calculated using the equilibrium constants in the literature.[17] Thus, the catalytically active species for DNA hydrolysis in these homogeneous solutions have been investigated.[18,19]

(1) Hydrolysis of cyclic adenosine 3′,5′-monophosphate (cAMP). The hydrolysis of cAMP has many common features with DNA hydrolysis. First, both reactions are enormously (10^{11}–10^{12} fold) promoted by Ce^{IV}.[20] Second, the catalytic activity of Ce^{IV} is far greater than that of any other catalyst. Thirdly, both of the reactions proceed *via* the attack by OH^- (or H_2O) as external nucleophile. The six-membered cyclic phosphodiester in cAMP is activated by strain and is much more readily hydrolysed than the non-cyclic linkage in DNA. A variety of fundamental information on Ce^{IV}-induced DNA hydrolysis can be obtained from cAMP hydrolysis.[18]

In the reaction mixtures, six equilibria [eqn. (2)–(7)] hold.[17]

$$Ce^{IV} + H_2O \overset{K_{1,1}}{\rightleftharpoons} [Ce^{IV}(OH)]^{3+} + H^+, \quad pK_{1,1} = 1.1 \quad (2)$$

$$Ce^{IV} + 2H_2O \overset{K_{1,2}}{\rightleftharpoons} [Ce^{IV}(OH)_2]^{2+} + 2H^+, \quad pK_{1,2} = 0.3 \quad (3)$$

$$2\,Ce^{IV} + 2H_2O \overset{K_{2,2}}{\rightleftharpoons} [Ce^{IV}_2(OH)_2]^{6+} + 2H^+, \quad pK_{2,2} = 3.6 \quad (4)$$

$$2\,Ce^{IV} + 3H_2O \overset{K_{2,3}}{\rightleftharpoons} [Ce^{IV}_2(OH)_3]^{5+} + 3H^+, \quad pK_{2,3} = 4.1 \quad (5)$$

$$2\,Ce^{IV} + 4H_2O \overset{K_{2,4}}{\rightleftharpoons} [Ce^{IV}_2(OH)_4]^{4+} + 4H^+, \quad pK_{2,4} = 3.5 \quad (6)$$

$$6\,Ce^{IV} + 12H_2O \overset{K_{6,12}}{\rightleftharpoons} [Ce^{IV}_6(OH)_{12}]^{12+} + 12H^+, \quad pK_{6,12} = 15.4 \quad (7)$$

Thus, the equilibrium concentrations of all the Ce^{IV}-derived species (Ce^{4+}, $[Ce^{IV}(OH)]^{3+}$, $[Ce^{IV}(OH)_2]^{2+}$, $[Ce^{IV}_2(OH)_2]^{6+}$, $[Ce^{IV}_2(OH)_3]^{5+}$, $[Ce^{IV}_2(OH)_4]^{4+}$, and $[Ce^{IV}_6(OH)_{12}]^{12+}$) are evaluated by using the $K_{1,1}$, $K_{1,2}$, $K_{2,2}$, $K_{2,3}$, $K_{2,4}$, and $K_{6,12}$ values. As depicted in Fig. 5, the pH–rate constant profile (the

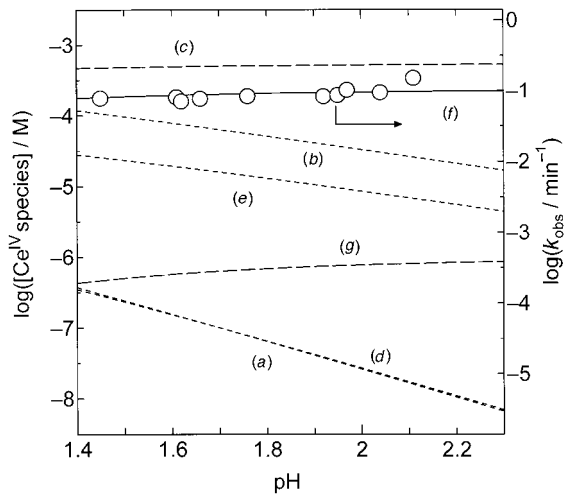

Fig. 5 The pH–rate constant profile for the cAMP hydrolysis by $Ce(NH_4)_2(NO_3)_6$ (10 mM) at 30 °C. The open circles are the experimental points. The equilibrium concentrations of the Ce^{IV}-derived species, calculated by using the *K* values in eqn. (2)–(7), are presented by the curved lines: (*a*) Ce^{4+}, (*b*) $[Ce^{IV}(OH)]^{3+}$, (*c*) $[Ce^{IV}(OH)_2]^{2+}$, (*d*) $[Ce^{IV}_2(OH)_2]^{6+}$, (*e*) $[Ce^{IV}_2(OH)_3]^{5+}$, (*f*) $[Ce^{IV}_2(OH)_4]^{4+}$, (*g*) $[Ce^{IV}_6(OH)_{12}]^{12+}$.

open circles) fits reasonably well the theoretical lines for the concentrations of $[Ce^{IV}(OH)_2]^{2+}$ [line (*c*)], $[Ce^{IV}_2(OH)_4]^{4+}$ [line (*f*)], and $[Ce^{IV}_6(OH)_{12}]^{12+}$ [line (*g*)]. These three species are the candidates for the catalytically active species. Note that the shapes of these lines are unanimously determined by the *K* values, whereas their positions (with respect to the right-hand side ordinate) can be moved vertically by changing the catalytic rate constants of the corresponding species.

In Fig. 6, the hydrolysis rate is plotted *vs.* $[Ce^{IV}(NH_4)_2(NO_3)_6]_0$

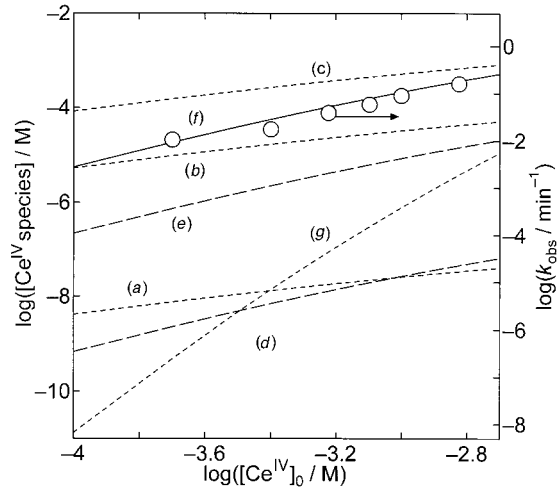

Fig. 6 The plots of the rate of cAMP hydrolysis *vs.* $[Ce(NH_4)_2(NO_3)_6]_0$ at pH 2.0 and 30 °C. The open circles are the experimental points, whereas the curved lines show the equilibrium concentrations of the corresponding species (see Fig. 5).

$(NO_3)_6]_0$. The experimental points agree well with the theoretical lines for $[Ce^{IV}_2(OH)_2]^{6+}$ [line (*d*)], $[Ce^{IV}_2(OH)_3]^{5+}$ [line (*e*)], and $[Ce^{IV}_2(OH)_4]^{4+}$ [line (*f*)]. Thus, only $[Ce^{IV}_2(OH)_4]^{4+}$ satisfies the results in both Figs. 5 and 6. This tetracationic bimetallic hydroxo cluster is the active species for the remarkable hydrolysis of cAMP.

(2) DNA hydrolysis. The Ce^{IV}-induced DNA hydrolysis has been analyzed in acidic solutions (pH 1.5–2.5) at 50 °C, exactly as described above for the cAMP hydrolysis.[19] It has been concluded that $[Ce^{IV}_2(OH)_4]^{4+}$ is also the active species. Of all the Ce^{IV} ions in the mixtures, only a small portion (20–30%) forms this bimetallic hydroxo-cluster (most of the rest exists as $[Ce^{IV}(OH)_2]^{2+}$), yet this species governs the whole reaction. Its catalytic activity is overwhelmingly greater than those of the other species. The cooperation of the two Ce^{IV} ions in the cluster is strongly indicated (*vide infra*).

From the viewpoints of biological and other practical applications, DNA hydrolysis at around pH 7 is the most important. In these mixtures, $[Ce^{IV}_2(OH)_4]^{4+}$ further aggregates, forming complicated gels. The bimetallic hydroxo clusters in the gels are the active species for DNA hydrolysis.

1.5. Activation of DNA by the Ce^{IV} ion

Why is Ce^{IV} ion highly effective for DNA hydrolysis? Why are the phosphodiester residues significantly activated by this metal ion? Do its f-orbitals play a significant role in the catalysis? In order to answer these questions, core-level photoelectron spectroscopy,[21] as well as EXAFS (extended X-ray absorption fine structure) and XANES (X-ray absorption near edge structure) measurements[22] were carried out. To simplify the analysis, diphenyl phosphate (DPP) was used as the specimen, in place of DNA.[23]

(1) Enormous electron-withdrawal from the phosphate by Ce^{IV}. Fig. 7 presents the core-level spectra for the 2*p* orbitals of the phosphorus atom of DPP in various lanthanide complexes. The electron-withdrawal by the metal ions from the phosphodiester linkage (and thus from the phosphorus atom), if any, is observed as the increase in the binding energy. It has been found that the binding energy of the orbitals in the Ce^{IV} complex is considerably greater than those for the complexes with La^{III}, Eu^{III}, Lu^{III}, and other non-lanthanide ions. Appar-

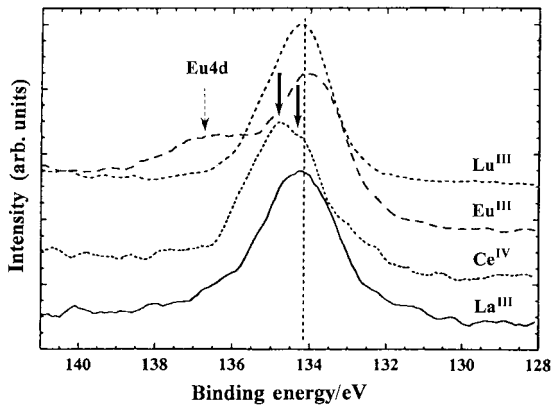

Fig. 7 Core-level spectra for the P2p orbital of DPP in the La^{III}, Ce^{IV}, Eu^{III}, and Lu^{III} complexes. $[Lanthanide\ ion]_0 / [DPP]_0 = 10$. The two bold arrows correspond to the P_H and P_L in Fig. 9.

ently, the Ce^{IV} ion exceeds the other metal ions in electron-withdrawing activity, and exceptionally promotes the electrophilicity of the phosphodiester linkage. The superiority of Ce^{IV} for the activation of DNA has been for the first time spectroscopically studied.

According to the L_3-XANES spectroscopy, 0.67 electrons exist in the 4f-orbitals of the Ce ion in the Ce^{IV}–DPP complex (these orbitals should be empty, if the Ce were to be really tetravalent). Upon complex formation, the electrons flow into the 4f-orbitals from the surroundings. In the DPP complexes of Ce^{III} and other lanthanide(III) ions, however, the corresponding electron-transfer to the metal(III) ions is not observed. The enormous activity of Ce^{IV} for DNA hydrolysis is primarily ascribed to the dominant electron-accepting activity, which is derived from the stability of its trivalent state. The lanthanide(III) ions cannot efficiently accept the electrons from DNA, since their divalent states are too unstable.

(2) Mixing of the orbitals of the phosphodiester linkage with those of Ce^{IV}. The electron-transfer from the phosphate to the Ce^{IV} ion occurs, at least partially, through the hybrid orbitals, which are formed from the 4f-orbitals of Ce^{IV} and the orbitals of the phosphorus atom (and/or of the oxygen atom) in the phosphate residue.[24] Consistently, a new energy state, related to this hybrid 4f-orbitals, appears near the Fermi level, when the Ce^{IV}–DPP complex is formed (Fig. 8). Neither free

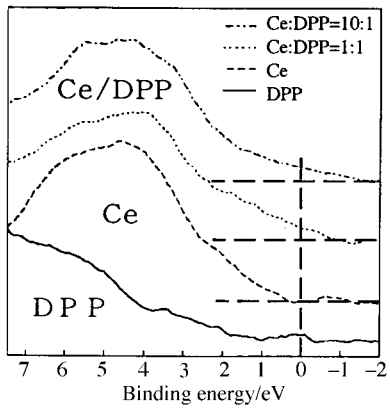

Fig. 8 X-Ray photoelectron spectra near the Fermi level.

DPP nor the Ce^{IV} hydroxo cluster (without DPP) has any energy-state density at this level. Since the 4f-orbitals of Ce^{IV} are lower in energy than those of the lanthanide(III) ions, and, at the same time, are widely spreading in space, they can efficiently interact with the orbitals of the phosphate. This mixing of the orbitals (as well as the resultant electron-transfer) would be still more efficient in the transition state, and decrease the activation free energy for the DNA hydrolysis.

(3) Structure of the Ce^{IV}–phosphate complex. According to detailed analysis of the core-level spectra, the phosphodiester is simultaneously coordinated to two Ce^{IV} ions, and enormously activated. As depicted in Fig. 9, the P2p signals of DPP in the

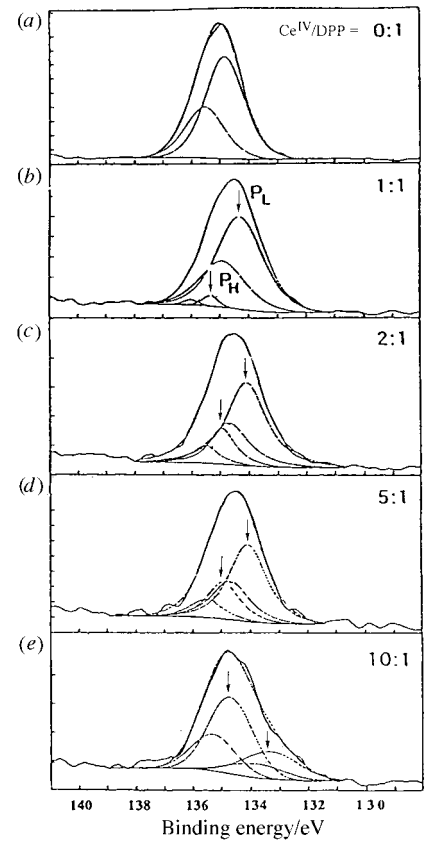

Fig. 9 Core-level spectra of the P2p orbital of DPP in the Ce^{IV}–DPP mixtures of different molar ratios. The peaks P_H and P_L correspond to the doublet signals of higher and lower binding energies.

Ce^{IV} complexes are composed of two components (P_H and P_L: each of the peaks is further split into a spin doublet). When the Ce^{IV} : DPP ratio is 1 : 1, the peak P_L of lower energy is predominant (b). Here, the phosphodiester linkage is bound to one Ce^{IV} ion and is only slightly activated (DNA hydrolysis hardly takes place). As the Ce^{IV} : DPP ratio increases [Fig. 9(*c*)–(*e*)], the intensity of P_H (of higher energy) gradually increases. This signal corresponds to DPP which is coordinated to two Ce^{IV} ions in the hydroxo cluster and is exceptionally activated by 'two-metal activation' (see Fig. 11). Consistently, the remarkable DNA hydrolysis occurs when Ce(IV) exists in excess to DNA.

These arguments are further substantiated by the EXAFS spectra in Fig. 10. In the absence of DPP [Fig. 10(*a*), (*b*)] the Ce^{IV} ions form metal hydroxo clusters (and the gel as their aggregates). Accordingly, the signal for the Ce–Ce distance is clearly observed at 3.6 Å (the position designated by the broken line). The signal at around 2.0 Å is for the Ce–O distance. Upon addition of DPP, the Ce–Ce signal rapidly weakens and is virtually nil at a Ce : DPP ratio of 1 : 1 [Fig. 10(*c*)]. Since the 1 : 1 Ce^{IV}–DPP complexes exist independently from each other (without mutual aggregation), the Ce–Ce signal is absent. When the Ce^{IV} : DPP ratio is > 1, however, the Ce–Ce signal appears again and gradually increases with increasing Ce : DPP ratio [Fig. 10(*d*), (*e*)]. Here, two Ce^{IV} ions are simultaneously interacting with one DPP molecule, and located in close

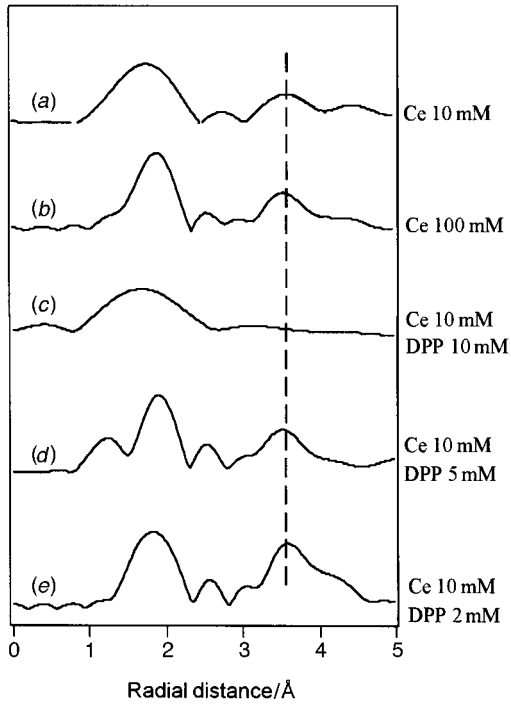

Fig. 10 EXAFS spectra for the Ce^{IV}–DPP systems.

proximity. Thus, these two Ce^{IV} ions are bound to each other, giving rise to the Ce–Ce signal.

1.6 Proposed mechanism for the DNA hydrolysis

The proposed mechanism is schematically depicted in Fig. 11. First, the phosphate residue is coordinated to the two Ce^{IV} ions in $[Ce^{IV}_2(OH)_4]^{4+}$ (the apparent association constant between Ce^{IV} and TpT is 10^3 M^{-1} at pH 2 and 50 °C).[9] As the result, the electrons of the phosphate are strongly withdrawn by the Ce^{IV} ions. Furthermore, the orbitals of the phosphate are mixed with the 4f-orbitals of Ce^{IV}, and form new hybrid orbital(s). These two factors greatly activate the phosphodiester linkage for the nucleophilic attack.

Then, the phosphate is attacked by the hydroxide ion coordinated to one of the two Ce^{IV} ions. According to the potentiometric titration, each of the Ce^{IV} ions releases three protons from its coordinated water to the aqueous phase, when the pH is increased from 0 to 4 (no proton is released above pH 4). Although this metal-bound hydroxide ion is a rather weak nucleophile, the phosphate is so activated (as described above) that the reaction can efficiently proceed. Furthermore, the hydroxide ion is located at quite a suitable position for the nucleophilic attack (the two Ce^{IV} ions in the bimetallic cluster have many coordinated water molecules, and at least one of them is placed appropriately for the purpose). Finally, the positive charges, accumulated in the Ce^{IV} hydroxo cluster (and also in the hydroxide gel as their aggregates), stabilize the negatively-charged transition state of DNA hydrolysis (the transition state is more negatively charged than the initial state, and is stabilized to a greater extent by the adjacent positive charges). Because of these factors, the pentacoordinated intermediate is efficiently formed.

In the breakdown of the intermediate, the water bound to Ce^{IV} functions as an acid catalyst. With this catalysis, the alkoxide ion of the 5′-OH of the 2′-deoxyribonucleotide (which is otherwise very unstable) can be promptly removed from the phosphorus atom. The large coordination number of the Ce^{IV} ions in the bimetallic cluster is favorable for the catalysis, exactly as described above for the first-step of DNA hydrolysis. The notable D_2O solvent isotope effect (see the Section 1.1) is associated with this proton transfer.

These arguments are supported by the fact that the activity of Ce^{IV} for DNA hydrolysis is substantially enhanced by cooperation with Pr^{III}.[25] When the Ce^{IV} : Pr^{III} ratio is 2, the activity is 10 fold greater than that of the Ce^{IV} ion (the Pr^{III} itself is virtually inactive under the reaction conditions employed). The catalysis occurs in the mixed hydroxo clusters, formed from these two metal ions in the reaction mixtures. Presumably, the Pr^{III} ion in this mixed cluster provides its metal-bound water as the acid catalyst, and promotes the second-step of DNA hydrolysis (the removal of the 5′-OH of 2′-deoxyribonucleotide). Under the reaction conditions (around pH 7), the Pr^{III}-bound water mostly remains undissociated ($pK_a \sim 9$),[26] and is superior as an acid catalyst to the Ce^{IV}-bound water. Although the $[Ce^{IV}(H_2O)_n]^{4+}$ ion is intrinsically a very strong acid (the pK_a for the first deprotonation is around 0),[26] it loses three protons at pH 0–4, and is only a weak acid at pH 7.[27]

On the $CeCl_3$-induced DNA hydrolysis under air, a mechanism, in which a hydrogen peroxide-like species (formed by the reduction of O_2 with the Ce^{III}) functions as the nucleophile, was proposed.[8b] However, this mechanism is unlikely, since Ce^{IV} salts satisfactorily hydrolyse DNA even in the complete absence of O_2.[8a,9] The role of O_2 is only to oxidize the Ce^{III} to the catalytically active Ce^{IV}, and not to provide the nucleophile. The nucleophile comes from the water.

2 Lanthanide(III) ion-induced hydrolysis of RNA

Since RNA has the 2′-OH of ribose as an intramolecular nucleophile towards the phosphorus atom, RNA is far more promptly (10^5–10^6 fold) hydrolysed than is DNA. Yet, non-enzymatic hydrolysis of RNA under physiological conditions is not easy (in order to hydrolyse RNA within an hour, for example, the catalyst must accelerate the reaction by 10^7-fold or more). Although a number of catalysts have been proposed,

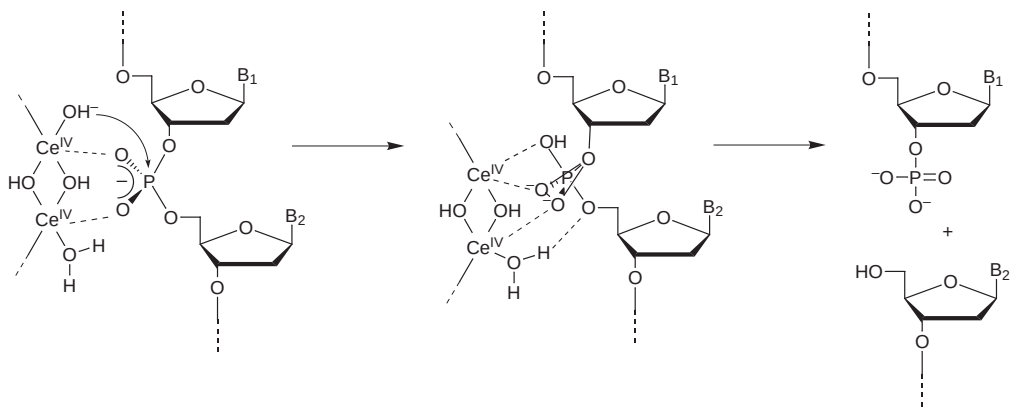

Fig. 11 Proposed mechanism of the Ce^{IV}-induced DNA hydrolysis [the P–O(5′) scission is presented here, although the P–O(3′) scission can also occur (see ref. 15)].

none of them exceeds (or is even comparable with) the lanthanide(III) ions in activity.

The catalytic activity of the lanthanide(III) ions at pH 7 monotonically increases with increasing atomic number.[10] With the last three (Tm^{III}, Yb^{III}, and Lu^{III}), RNA hydrolysis is completed within a few minutes at pH 7 and 30 °C. Interestingly, Ce^{IV}, which is the best for DNA hydrolysis, is not so active for RNA hydrolysis (its activity is comparable with that of Tb^{III}).

2.1 Catalytic species for RNA hydrolysis

The solvolysis chemistry of Nd^{III} is well known [eqn. (8) and (9)].[28] Thus, the Nd^{III}-induced hydrolysis of adenylyl(3′-5′)adenosine (ApA) has been kinetically analyzed in detail.[10] In

$$Nd^{III} + H_2O \overset{K_{1,1}}{\rightleftharpoons} [Nd^{III}(OH)]^{2+} + H^+ \quad pK_{1,1} = 9.4 \quad (8)$$

$$2Nd^{III} + 2H_2O \overset{K_{2,2}}{\rightleftharpoons} [Nd^{III}_2(OH)_2]^{4+} + 2H^+ \quad pK_{2,2} = 13.9 \quad (9)$$

the reaction mixtures, there exist three Nd^{III}-derived species: free Nd^{3+}, $[Nd^{III}(OH)]^{2+}$, and $[Nd^{III}_2(OH)_2]^{4+}$. The equilibrium concentration of each species can be calculated by using the $K_{1,1}$ and $K_{2,2}$ values.

As shown in Fig. 12, the logarithm of the rate of RNA hydrolysis steeply increases with increasing pH, up to pH 8, and

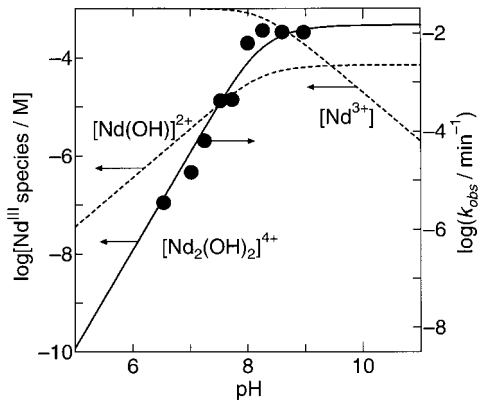

Fig. 12. The pH dependence of the rate of ApA hydrolysis by $NdCl_3$ (1 mM) at 30 °C. The closed circles are the experimental points, whereas the curved lines show the equilibrium concentration of the Nd^{III}-derived species.

then attains a plateau. The experimental points fit well the theoretical line showing the equilibrium concentration of $[Nd^{III}_2(OH)_2]^{4+}$ (the solid line). This bimetallic cluster is the active species for RNA hydrolysis (its formation is accompanied by the release of two protons, as shown by eqn. (9), and thus the pH–rate constant profile is so steep). This conclusion is further supported by the dependence of hydrolysis rate on the initial concentration of $Nd^{III}Cl_3$. In order to hydrolyse RNA efficiently, the bimetallic structure is essential. This finding is totally consistent with the fact that $[Ce^{IV}_2(OH)_4]^{4+}$ is the active species for Ce^{IV}-induced DNA hydrolysis.

2.2 Why does the activity of the lanthanide(III) ion at pH 7 increase with increasing atomic number?

The pH–rate constant profiles for all the lanthanide(III) ions have similar shapes, and are composed of (a) a steep straight line at lower pH and (b) a plateau at higher pH (see Fig. 13). The straight line corresponds to the formation of the active species $[Ln^{III}_2(OH)_2]^{4+}$ (Ln = lanthanide ion), whereas its formation is completed in the plateau.

As the atomic number increases, these profiles gradually shift towards the lower pH side. Accordingly, the concentration of the active species at pH 7 increases in this order. For example, Lu^{III} exists mostly as the bimetallic active species ($[Lu^{III}_2(OH)_2]^{4+}$) at pH 7. As the result, this metal ion is quite

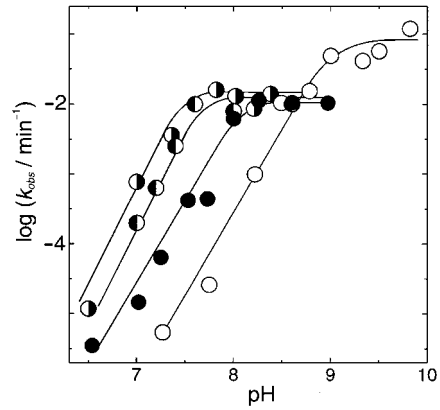

Fig. 13 The pH dependence of the rate of ApA hydrolysis by various lanthanide(III) chlorides (1 mM) at 30 °C: (○) La^{III}, (●) Nd^{III}, (◑) Tb^{III}, (◐) Lu^{III}. Only the typical results are presented here, since the shapes of the profiles for all the lanthanide(III) ions are similar and their positions monotonically shift towards lower pH side with increasing atomic number.

active for RNA hydrolysis in neutral solutions. For La^{III}, however, only a small fraction takes the active form at pH 7. Thus, Tm^{III}, Yb^{III}, and Lu^{III} are superior to the others, when the RNA hydrolysis is carried out under physiological conditions. In alkaline solutions, even the La^{III} ion mostly takes the active form and is sufficiently active.[29]

2.3 The rate-limiting step for RNA hydrolysis

When the 5′-O atom in RNA is replaced with a sulfur, the rate of alkaline hydrolysis of the corresponding phosphodiester linkage is increased by 10^5–10^6 fold.[30] Exactly as discussed in DNA hydrolysis (Section 1.2), the removal of the 5′-OH of the ribose from the phosphorus atom is rate limiting. Similarly, the lanthanide ion-induced RNA hydrolysis involves a rate-limiting removal of the 5′-OH.[10,31]

Based on these results, the energy diagrams are depicted in Fig. 4(*b*). The lanthanide(III) ions primarily accelerate the second step (the removal of the 5′-OH). At the same time, however, the first step (the intramolecular attack by the 2′-OH towards the phosphorus atom) is also promoted, to some extent ($> 10^{2-3}$ fold), so that the second-step remains rate-limiting (the RNA hydrolysis is accelerated by 10^8 fold). It is noteworthy that the first barrier in the alkaline hydrolysis of RNA is much lower than that in DNA hydrolysis [compare Fig. 4(*a*) with 4(*b*)]. The intramolecular attack by the 2′-OH is enormously efficient compared with the intermolecular reaction in the latter. Furthermore, the second barrier in the RNA hydrolysis (corresponding to $\Delta G_2^{\ddagger}$) is considerably higher than the first barrier (the rate difference is 10^5–10^6 fold). This is in contrast with the symmetric energy diagram in the DNA hydrolysis. The RNA hydrolysis involves the formation of a 2′,3′-cyclic monophosphate of the ribonucleotide as the first product, and a considerable strain is induced on the formation of this five-membered ring phosphate. The cyclic phosphate is much more reactive than RNA, and is rapidly hydrolysed to the 2′- or 3′-monophosphate as the final product.

2.4 Proposed mechanism of the RNA hydrolysis

First, the phosphodiester linkage in RNA is coordinated to the lanthanide(III) ion in the bimetallic cluster $[Ln^{III}_2(OH)_2]^{4+}$. In the following intramolecular nucleophilic attack by the 2′-OH towards the phosphorus atom, the hydroxide ion, bound to the metal ion(s), functions as the general base catalyst. Alternatively, the 2′-OH is directly coordinated to the metal ion, and its dissociation to alkoxide ion is facilitated.

In the breakdown of the resultant pentacoordinated intermediate, the metal-bound water (or the metal ion itself)

functions as the general acid catalyst. The water bound to the lanthanide(III) ions has a pK_a of around 8–9, which should be further decreased in the bimetallic clusters through the electron-withdrawal by the second metal(III) ion. This is quite appropriate for the present acid catalysis, since the RNA hydrolysis is carried out at around pH 7 (when the apparent activities of various acid catalysts are compared with each other at a predetermined pH, the activity increases as the pK_a gets closer to the pH).[31] The acid catalysis cooperates with the base catalysis in the hydroxo clusters, resulting in the prompt hydrolysis of RNA (Fig. 14).

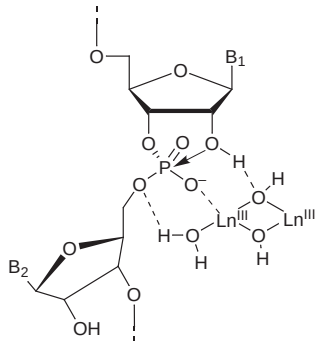

Fig. 14 Proposed mechanism of the lanthanide(III)-induced RNA hydrolysis.

3 DNA hydrolysis *vs.* RNA hydrolysis

What factor makes the Ce^{IV} ion the best for DNA hydrolysis? Why does RNA hydrolysis choose the lanthanide(III) ions? The energy diagrams in Fig. 4 give us some tips on these subjects. The energy diagram for the uncatalysed (alkaline) hydrolysis of DNA is virtually symmetric, and the heights of the first barrier and the second barrier are almost the same [the dotted line in Fig. 4(*a*)]. Under these conditions, the primary requirement for efficient catalysis is to *lower the energy barrier of the first step* (otherwise, the first barrier governs the rate of the whole reaction, no matter how much the second step is promoted). Second, the catalyst must stabilize the pentacoordinated intermediate with respect to the initial state [see eqn. (1)]. The Ce^{IV} ion satisfactorily fulfils these requirements, through the activation of the DNA by both (a) withdrawing the electrons from the phosphate in the 'two-metal activation' (Fig. 7 and 9) and (b) mixing its f-orbitals with those of the phosphate (Fig. 8). The second barrier is lowered with respect to the initial state, mainly because ΔG_1 is decreased. In contrast, the lanthanide(III) ions cannot activate DNA to such an extent that they are rather poor for DNA hydrolysis.

In uncatalysed hydrolysis of RNA [Fig. 4(*b*)], however, the second energy barrier is far higher than is the first energy barrier (10^5–10^6 fold difference in the reaction rate), as described in Section 2.3. Here, the promotion of the second step should directly accelerate the whole reaction (until it becomes lower than the first barrier). The promotion of the first step is not as essential as is the case in DNA hydrolysis. The lanthanide(III) ions are suitable for the acid catalysis in the second step, since they have many (8 or 9) coordinated water molecules and their pK_a values are close to the pH of the reaction mixtures (*vide ante*).[32]

4 From lanthanide ions to non-lanthanide ions

Soon after the remarkable catalysis by the lanthanide ions was discovered, many laboratories attempted to hydrolyse DNA and RNA by using non-lanthanide ions.[1] These catalysts, if available, should be useful for various practical applications (especially *in vivo*). It has been established that RNA can be hydrolysed by these metal ions, if two (or more) of them satisfactorily cooperate in dinuclear (or multi-nuclear) complexes (to date, there are no non-lanthanide complexes which can hydrolyse DNA of various sequences and structures).[33] In order to place the metal ions appropriately, various ligands have been designed. The control of acid/base properties of the metal ions (and of the water bound to them) is also important. For example, Zn^{II} ion itself is virtually inactive for RNA hydrolysis at pH 7. Mono-nuclear Zn^{II} complexes also exhibit poor activity. However, di- and tri-nuclear Zn^{II} complexes of pyridine-based ligands efficiently hydrolyse RNA (Fig. 15).[34,35] By attaching these zinc(II) complexes to DNA oligomers, sequence-selective artificial ribonucleases have been synthesized.[36]

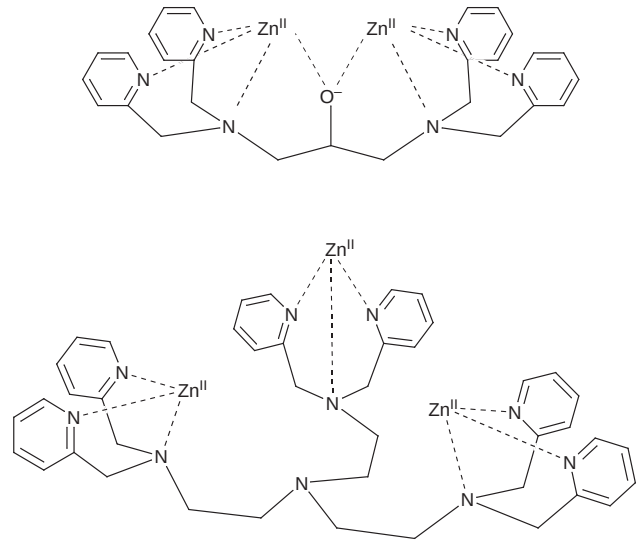

Fig. 15. Di- and tri-nuclear Zn^{II} complexes for RNA hydrolysis.

The lanthanide ions spontaneously form multi-nuclear clusters under physiological conditions, even in the absence of specific ligands. Two or more lanthanide ions are appropriately placed in these clusters, where bimetallic (or multi-metallic) synergism efficiently takes place. The 4f-orbitals activate the phosphates through orbital–orbital interactions. Furthermore, the acid/base properties of the coordinated water on the lanthanide ions are suitable for the catalysis at pH 7. Finally, the positively-charged reaction field, provided by the clusters, stabilizes the negatively-charged transition states for the hydrolysis of DNA and RNA. The combination of these factors gives rise to the remarkable activities of the lanthanide ions.

Conclusions

A few years ago, it was found that the lanthanide ions hydrolyse DNA and RNA under physiological conditions, and we have obtained useful tools to manipulate DNA and RNA without using naturally-occurring enzymes. However, the mechanistic details of these remarkable catalyses were not clear. In the present study, the following important conclusions have been obtained on the mechanisms of these catalyses.

(1) Tetracationic bimetallic hydroxo clusters are the active species ($[Ce^{IV}_2(OH)_4]^{4+}$ for DNA hydrolysis and $[Ln^{III}_2(OH)_2]^{4+}$ for RNA hydrolysis).

(2) The Ce^{IV} ion notably activates the phosphodiester linkages in DNA to nucleophilic attack, through (a) electron-withdrawal from the residues and (b) mixing its 4f-orbitals with their orbitals. As a result, the formation of the pentacoordinated intermediate is remarkably promoted.

(3) The catalysis for RNA hydrolysis is mainly ascribed to the acceleration of the breakdown of the pentacoordinated intermediate. The activity at pH 7 increases with increasing atomic number of the lanthanide(III) ion, since the concentration of the

active species (the bimetallic hydroxo cluster) increases in this order.

(4) In the lanthanide-induced hydrolysis of both DNA and RNA, the breakdown of the pentacoordinated intermediate is rate limiting.

These findings are valuable for the design of still more advanced catalysts for the hydrolysis of DNA and RNA, as well as artificial enzymes for site-selective scission of them. What should be clarified next is (1) what is the real nature of the orbital-mixing between the Ce^{IV} ion and the phosphate? and (2) how big a contribution is made to DNA activation by each of the electron-withdrawal and the orbital-mixing? In order to solve these problems, quantum-chemical analyses are under way. The application of lanthanide catalysis to biotechnology, molecular biology, and therapy are also currently being attempted.

2 The scission site of a restriction enzyme, which recognizes a sequence of 6 DNA bases, appears every 4^6 DNA bases (in average). If the DNA of the human beings, composed of more than 10^9 DNA bases, is treated with this restriction enzyme, the scission occurs at more than 10^5 sites.

3 The half-life of the phosphodiester linkage in DNA at pH 7 and 30 °C is estimated to be 200 million years. Although the linkage in RNA is much more reactive than that in DNA, its half-life is still 1000 years or so.

4 Supercoiled DNA, which is activated by strain and other factors, was reportedly cleaved *via* the hydrolytic pathway: L. A. Basile, A. L. Raphael and J. K. Barton, *J. Am. Chem. 15 The electrophilicity of the phosphorus atom is not much altered by the O → S substitution, since the substitution of non-bridging oxygen in the phosphate to sulfur hardly affects the rate of hydrolysis. In Tp-OCH_2CF_3, the perturbation on the phosphorus atom is still smaller. In the Ce^{IV}-induced hydrolysis of Tp-OT, the P–O(3′) bond and the P–O(5′) bond are cleaved at almost the same rates (the resultant 5′- and 3′-monophosphates of thymidine are rapidly hydrolysed to thymidine as the final product, and thus are not much accumulated: see ref. 9). In the hydrolysis of Tp-ST and Tp-OCH_2CF_3, the P–S bond and P–O(5′) bond are exclusively cleaved.

16 Homogeneous hydrolysis of DNA at pH 7 by Ce^{IV}–saccharide complexes was reported: A. Kajimura, J. Sumaoka and M. Komiyama, *Carbohydr. Res.*, 1998, **309**, 345.

32 The Brønsted relationship indicates that the intrinsic activity of acid catalysts increases with decreasing pK_a. However, the concentration of the active species (in the acidic form) at a predetermined pH decreases in this order. Thus, the net efficiency of the catalysis, determined by (the intrinsic activity of active species) × (the concentration of active species), takes the maximum when the pK_a is close to the reaction pH (see M. L. Bender, R. J. Bergeron and M. Komiyama, *The Bioorganic Chemistry of Enzymatic Catalysis*, Wiley, New York, 1984, ch. 6.

33 Some of the complexes in ref. 4 were proposed to be active for the hydrolysis of non-supercoiled DNA.

Received (in Cambridge, UK) 14th May 1999, Accepted 23rd June 1999

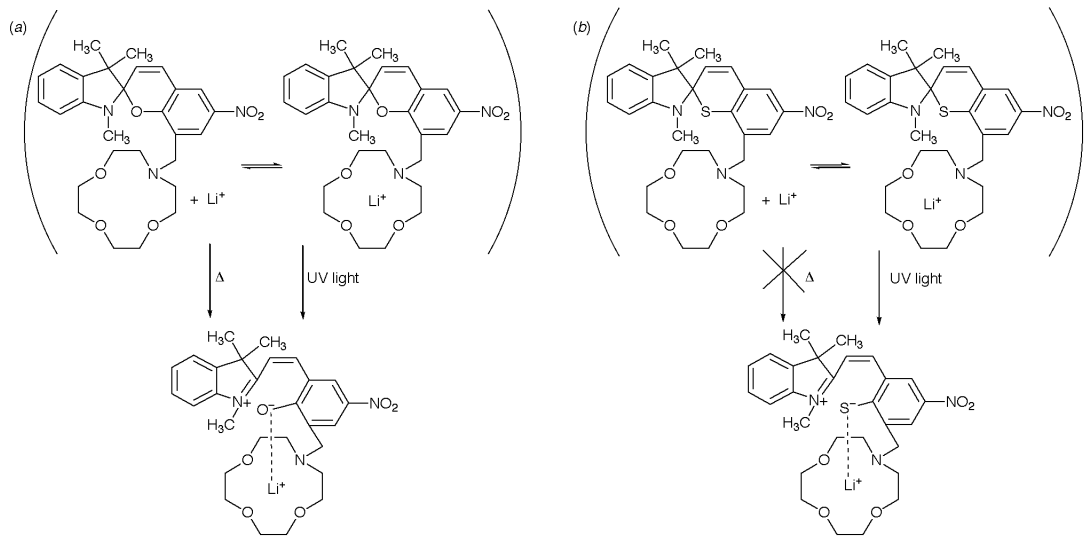
A spirobenzothiapyran derivative bearing a monoaza-12-crown-4 moiety affords significant thermal stability enhancement in the UV light induced colored merocyanine form of its photochromic moiety by metal-ion complexation of its crown ether moiety, although the complexation hardly induces the isomerization without photoirradiation.

Spirobenzopyrans[1] and spirobenzothiapyrans[2] are well-known photochromic compounds that isomerize to their corresponding merocyanine forms under UV light, and *vice versa* under visible light or heat. Such kinds of compounds have been studied extensively in view of photochromic devices.[3] However, the application of spirobenzothiapyrans to photochromic devices does not seem to be very easy due to the poor thermal stability of their open colored form. In our previous studies[4] on spirobenzopyrans bearing a monoazacrown ether moiety, we found that the spiropyran ring opening was facilitated by metal ion complexation of the crown ether moiety in the presence of metal ions. This resulted in the spiropyran ring opening even without UV light irradiation [Scheme 1(*a*)]. This finding prompted us to design spirobenzothiapyrans bearing a crown ether moiety, which we call crowned spirobenzothiapyrans, expecting facilitation of the thiapyran ring opening by metal ion complexation of the crown ether moiety. This in turn may allow the resulting spirobenzothiapyrans to be applicable for photochromic devices. Here we report preliminary results on significant stabilization of the photoinduced open colored isomer of a crowned spirobenzothiapyran in the presence of alkali metal ions, especially Li^+.

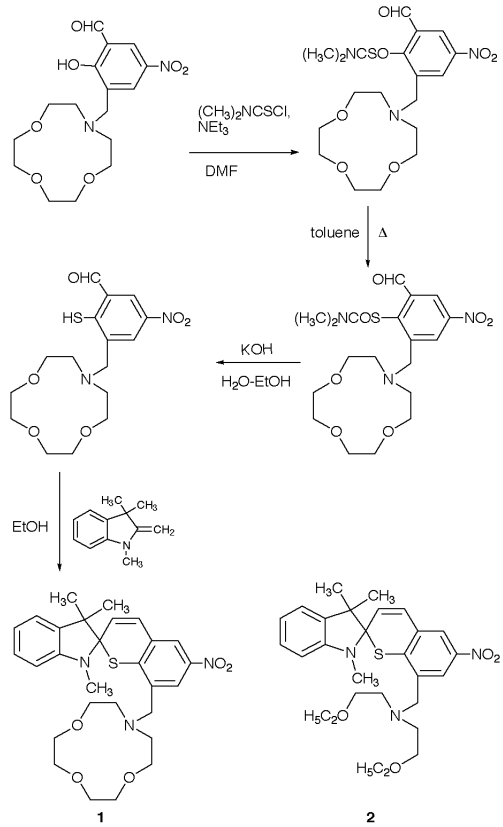
The synthesis of crowned spirobenzothiapyran **1** was carried out in accordance with Scheme 2. The conversion of the phenolic hydroxy group of crowned nitrosalicylaldehyde[4a] to the corresponding thiol group was attained by the reaction with $(CH_3)_2NCSCl$ at 0–25 °C in the presence of NEt_3, by refluxing in toluene, and by hydrolysis with KOH.[2d] The crowned thiosalicylaldehyde was then reacted with 2-methylene-1,3,3-trimethylindoline in refluxing EtOH to yield the spirobenzothiapyran bearing a monoaza-12-crown-4 moiety, **1**, which was purified by recrystallization from EtOH after preparative gel-permeation chromatography.† For comparison, we also synthesized a spirobenzothiapyran derivative bearing an oligooxyethylene moiety, **2**, in a similar way to **1**.

Absorption spectra of **1** and **2** were measured in MeCN in the presence and absence of an alkali metal perchlorate. The spectra of **1** and **2** were hardly changed by adding an equimolar amount of Li^+, Na^+, and K^+, unless irradiated by UV light. This means that isomerization to their merocyanine form by the thiapyran ring opening cannot proceed by metal ion complexation of their crown ether ring under dark conditions [Scheme 1(*b*)]. This isomerization behavior of **1** is very different from that of the spirobenzopyran bearing a monoaza-12-crown-4 moiety, the pyran ring of which can be opened readily by metal ion complexation even without UV light irradiation[4] [Scheme 1(*a*)], probably due to the polarity increase induced by the metal ion binding.

It should be noted that irradiation of 365 nm UV light‡ on the **1** solution containing Li^+ causes a drastic change in the absorption spectrum (Fig. 1). On the other hand, hardly any significant spectral change was observed in the **1** solution without any metal ion and with an equimolar amount of K^+. The Na^+ addition afforded only a slight spectral change (Fig. 1). Definitely, the metal ion complexing ability of the crown ether



Scheme 1



Scheme 2

moiety of **1** stabilizes the colored merocyanine isomer that is formed only on UV light irradiation, owing to the polarity enhancement. It is worth noting that the stabilization is highly selective for Li^+. In addition to the selective Li^+ binding with a monoaza-12-crown-4 moiety of **1**, some interaction between the thiolate anion and Li^+ complexed by the crown ether moiety probably contributes to the stabilization of the colored merocyanine isomer of **1,** as is the case with the Li^+ complex for merocyanine form of crowned spirobenzopyran (Scheme 1).[4c] This Li^+-specific stabilization of the photoinduced colored form of **1** is also supported by photochromism for a model compound carrying a linear oligooxyethylene moiety instead of a crown ether moiety, **2**. Since the linear oligooxyethylene moiety of **2** cannot bind a metal ion very powerfully, the presence of a metal

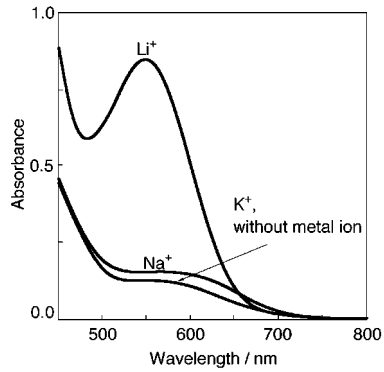


Fig. 1 Absorption spectra of crowned spirobenzothiapyran **1** under UV irradiation in the absence and presence of an alkali metal ion. **1** and alkali metal perchlorate: 2×10^{-4} mol dm^{-3} in acetonitrile.

ion, even Li^+, scarcely induced such UV light-induced isomerization to the open colored isomer as seen in the **1** system.

In order to elaborate the thermal stability of the open colored form of crowned spirobenzothiapyran **1** in MeCN, thermal decoloration of the **1** solution in the presence or absence of Li^+ was followed at room temperature by turning off UV the light.§ In the absence of Li^+, the thermal isomerization back to the spiropyran form was complete within 5 s. On the contrary, the thermal back-isomerization in the presence of Li^+ was very sluggish even by visible light irradiation, the half-life of the UV-induced merocyanine isomer being about 2 min. This again proves the Li^+ complexation-induced high stability of the colored merocyanine form in crowned spirobenzothiapyran **1**.

In conclusion, the crowned spirobenzothiapyran **1** exhibits characteristic photochromism as follows: i) the isomerization of **1** to its corresponding colored merocyanine form does not proceed even in the presence of any crown ether complexing metal ion, unless otherwise irradiated by UV light; ii) the Li^+-selective complexation of the crown ether moiety facilitates UV light induced isomerization (thiapyran ring opening) dramatically; and iii) the metal ion complexation stabilizes the colored merocyanine isomer thus formed to a great extent. Thus the photochromic crown ether seems to be promising for applications such as photochromic devices.

‡ The UV light, obtained by passing light of a 250 W Hg lamp through a light filter (wavelength 363.25 nm, $\Delta\mu/2$ 9.5 nm, transmittance 0.53), was introduced to the cell compartment of a spectrophotometer by using a glass fiber guide and was irradiated on the quartz cell containing a solution. The absorption spectra were therefore taken, while irradiating the measurement cell in the perpendicular direction to the measuring incident light.

§ The thermal coloration was followed by measuring the absorbance at 550 nm after UV light irradiation for 1.5 min.

Formal synthesis of roseophilin

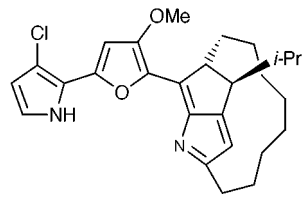
Jeremy Robertson* and Richard J. D. Hatley

Dyson Perrins Laboratory, South Parks Road, Oxford, UK OX1 3QY.
E-mail: jeremy.robertson@chemistry.oxford.ac.uk

Received (in Cambridge, UK) 14th June 1999, Accepted 23rd June 1999

A thirteen step route to the tricyclic ketopyrrole core of roseophilin is presented in which the final step consists of a Paal–Knorr pyrrole synthesis that proceeds with *in situ* oxidation.

The intriguing structure of roseophilin, a cytotoxic antibiotic isolated from *Streptomyces griseoviridis* as disclosed by Seto in 1992,[1] has stimulated significant synthetic interest[2] culminating in Fürstner's elegant total synthesis of the racemate[3] and its analogues.[4] Our group has also been active in this area[5] and in this communication we outline a concise synthesis of the tricyclic ketopyrrole right hand half (±)-**10**. This route was

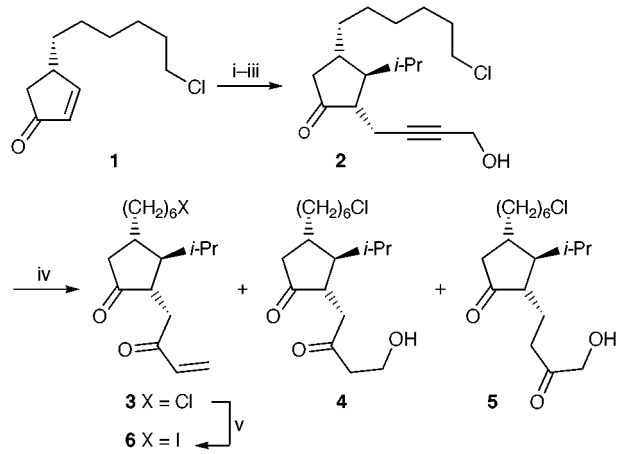


Roseophilin

designed to be easily tailored to provide access to either enantiomer of roseophilin as well as being sufficiently flexible that a range of roseophilin analogues could be prepared for biological evaluation.

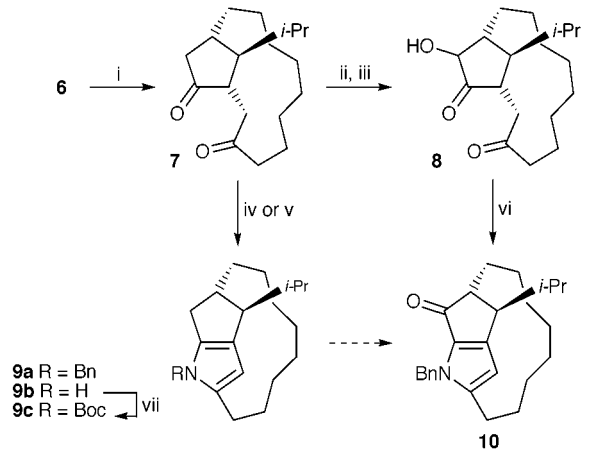
At the outset of our investigations towards tricycles such as **10** we elected to form the pyrrole ring in the final step so that the energetic drive towards aromaticity would serve to override the adverse strain inherent in these molecules. In this respect our synthetic concept differs fundamentally from those of Fürstner,[2d,3,4] Fuchs,[2b,c] and Terashima.[2f] Our second guiding principle was to construct the thirteen membered ring by a free radical macrocyclisation[6] since our own studies[5a] had shown that bicyclo[10.2.1]pentadecenones could be obtained by this method.

Radical macrocyclisation precursor **6** was constructed in five steps from cyclopentenone derivative (±)-**1**[7] (Scheme 1) starting with conjugate addition[8] of *i*-PrMgCl which proceeded in essentially quantitative yield provided excess TMSCl (4.0 equiv.) was used to trap the enolate and Et_3N was added to the reaction mixture prior to aqueous work-up. Generation of the lithium enolate from the intermediate silyl enol ether, trapping with propargylic iodide (propargyl = prop-2-ynyl) **11**[9] and desilylation with fluorosilicic acid[10] afforded 1°-alcohol **2**. Yadav's procedure for converting 1°-propargyl alcohols into vinyl ketones[11] was unsuccessful when applied to this substrate as the hydrogen sulfide used in the work-up led to thiol adducts that could not be processed further. Eventually we found that treatment of alcohol **2** with $Hg(OAc)_2$ in acetic acid containing water (1.0 equiv.) then work-up after 30 min with dilute hydrochloric acid gave much improved results, a mixture being obtained consisting of the desired enone **3**, β-hydroxy ketone **4**, and the regioisomeric hydrolysis product **5** (4.5:1:1.5 respectively). These compounds were readily separable and the 1,4-adduct **4** could be dehydrated efficiently (MsCl, Et_3N, cat. DMAP; 93%) to give an acceptable overall yield of the radical precursor **6** after Finkelstein reaction.



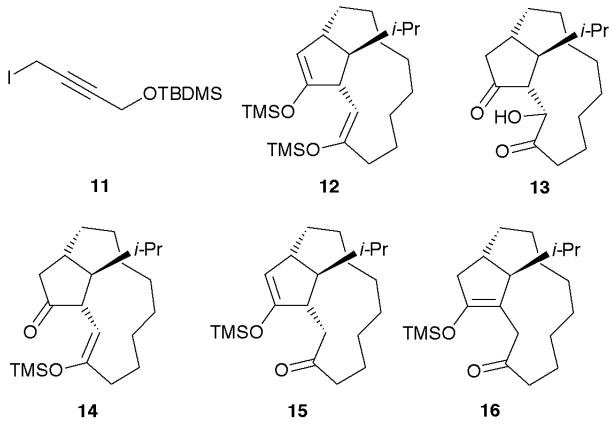
Scheme 1 *Reagents:* i. *i*-PrMgCl, CuI, LiCl, TMSCl, THF (96–99%); ii. MeLi then DMPU, **11**, THF (62%); iii. H_2SiF_6, aq. CH_3CN (96%); iv. $Hg(OAc)_2$, H_2O, AcOH then 5% aq. HCl (59% → **3**); v. NaI, butanone (88%).

The radical macrocyclisation required high dilution (2.5 mM) and slow addition (7 h) of the tin hydride in order to minimise direct reduction but enone hydrostannylation products could not be avoided. Work-up with thiophenol[12] facilitated isolation of the crystalline macrocyclic diketone **7** (Scheme 2) whose identity was confirmed by X-ray crystallography.[13] The *N*-benzyl pyrrole **9a** was formed straightforwardly but direct access to the *N*-unsubstituted analogue **9b** gave an indication of the strain in this system and forcing conditions were required (*cf.* ref. 14). Unfortunately we were unable to effect direct α-oxidation of either **9a** or the *N*-Boc analogue **9c** even though studies on compounds lacking the macrocyclic linking chain gave promising results.[15]



Scheme 2 *Reagents:* i. Bu_3SnH, AIBN, PhH (35–50%); ii. LDA, THF, −50 → 0 °C then TMSCl (55%, partial hydrolysis on SiO_2); iii. dimethyldioxirane (0.1 M in acetone), CH_2Cl_2 then aq. H_2SiF_6, CH_3CN (80%); iv. $BnNH_2$, AcOH, EtOH, 50 °C (60%); v. $(Me_3Si)_2NH$, Al_2O_3, 150 °C (sealed tube) (86%); vi. $BnNH_2$, AcOH, EtOH, 55 °C then 2 M aq. HCl, MeOH (25%); vii. KH, Boc_2O, THF (75%).

This problem proved insurmountable therefore we embarked on an attempt to effect oxidation prior to pyrrole formation which required a method for discriminating between the two carbonyl groups in diketone **7**. Treatment with LDA (1.1 equiv.) at −78 °C with an *in situ* TMSCl quench resulted in the sole formation of the doubly silylated compound **12** with a



11 **12** **13**

14 **15** **16**

corresponding recovery of starting material. Furthermore, oxidation of bis-silyl enol ether **12** by MCPBA was selective for the macrocyclic position giving α-hydroxy ketone **13** in 70% isolated yield. An attempt to effect selective mono-desilylation[16] of **12** merely returned starting material.

Selective mono-silylation in the five-membered ring proved to be a challenging task as kinetic enolate formation with an *external* TMSCl quench led predominantly to silyl enol ether **14**. However a reasonable product ratio in favour of silyl enol ether **15** could be attained under equilibrating conditions although this compound could not be obtained free of the regioisomer **16** (3–4 : 1 ratio). This mixture was treated with dimethyldioxirane[17] to give, after desilylation, α-hydroxy ketone **8** (containing *ca*. 20% of the inseparable regioisomer). Overall yields for **7** → **8** were generally around 45% either with or without purification of the intermediate silyl enol ether mixture.

The final step, Paal–Knorr pyrrole synthesis from a 1,4-diketone bearing an unprotected α-hydroxy substituent, had no immediate precedent. Heating compound **8** with benzylamine in ethanolic acetic acid proved insufficient to drive the reaction to completion but, after consumption of the starting material, addition of 2.0 M hydrochloric acid in methanol was effective in delivering a pyrrole product. However this product did not contain a hydroxy group; in fact the ring closure was accompanied by an unexpected oxidation to afford a compound with spectroscopic data exactly matching those reported by Fürstner for the ketopyrrole **10**.

This route to ketopyrrole **10** not only stands as a formal total synthesis of (±)-roseophilin but opens the way to an enantiospecific synthesis because treatment of commercially available (4*R*)-(*tert*-butyldimethylsilyl)oxycyclopentenone[18] with 6-chlorohexylcuprate[5*a*] followed by elimination of the silyloxy group is expected to yield (*R*)-**1** from which a single enantiomer of roseophilin would follow. Currently we are optimising a new synthesis of the pyrrolylfuran left hand half and will report on this and our progress towards an enantiospecific total synthesis of roseophilin in due course.

We wish to thank the EPSRC for a studentship (RJDH), the EPSRC Mass Spectrometry Service Centre for exact mass measurements, Dr David J. Watkin for obtaining the X-ray structure of diketone **7**, and the Chemical Database Service at Daresbury.[19]

One-pot synthesis of γ-lactams in a reaction cascade from α,β-unsaturated imines, CO and ethylene catalysed by $Ru_3(CO)_{12}$†

Daniel Berger and Wolfgang Imhof*

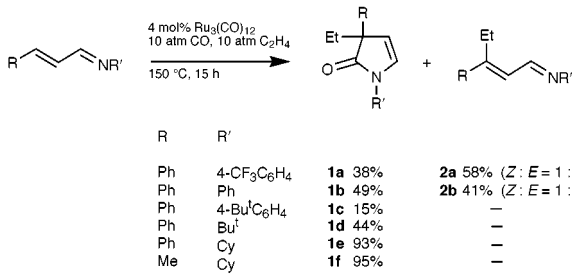
Institut für Anorganische und Analytische Chemie, August-Bebel-Str. 2, 07743 Jena, Germany. E-mail: cwi@rz.uni-jena.de

Received (in Cambridge, UK) 23rd April 1999, Accepted 22nd June 1999

The formation of 1,3-dihydropyrrol-2-one derivatives in moderate to excellent yields may be achieved by sequential insertion of CO and ethylene into C–H bonds of 1-azadienes catalysed by $Ru_3(CO)_{12}$; thus two new C–C bonds and a new center of asymmetry at C3 are produced *via* an intramolecular aldol condensation-like cyclization.

C–H activation reactions induced by transition metal compounds have aroused considerable interest as models for the initial steps of catalytic transformations of the ligands, *e.g.* in C–C coupling reactions. Thus in the past years inter- as well as intramolecular C–H activation reactions have been thoroughly reviewed.[1] In our recent work we investigated the reaction of aromatic imines towards $Fe_2(CO)_9$ which proceeds *via* C–H activation steps and subsequent intramolecular hydrogen migration reactions towards suitable acceptor sites in the ligand, producing di- or trinuclear iron carbonyl complexes.[2] On the other hand, it has been shown previously that aromatic imines may react with CO and/or a wide variety of olefins in the presence of catalytic amounts of $Ru_3(CO)_{12}$ to give the respective substitution products.[3] The C–C coupling reaction selectively takes place in the position *ortho* with respect to the imine substituent, and thus similar C–H activation steps to the ones which we observed in the stoichiometric reactions of the same ligands with $Fe_2(CO)_9$ may well be the initial steps of these catalytic reactions. The reaction of acyclic α,β-unsaturated imines with $Ru_3(CO)_{12}$ yields ruthenium carbonyl complexes, the formation of which also includes C–H activation steps, whereas treatment with $Fe_2(CO)_9$ produces (η^4-azadiene)$Fe(CO)_3$ complexes.[4,5]

Here we report the catalytic synthesis of γ-lactams, namely 1,3-dihydropyrrol-2-one derivatives, from α,β-unsaturated imines, CO and ethylene (Scheme 1).[6] From Scheme 1 it can be seen that variation of the organic substituent at nitrogen leads to different product distributions. Obviously CO and ethylene compete for the azadiene. In the case of the least electron donating organic moieties at the imine nitrogen, in addition to the pyrrol-2-one derivatives **1a** and **1b** two other compounds, **2a** and **2b** respectively, are formed in which one molecule of ethylene has inserted into the C–H bond at the β-carbon atom of the 1-azadiene. If R′ is *p*-$CF_3C_6H_4$ then **2a** is the main product



R	R′		
Ph	4-$CF_3C_6H_4$	**1a** 38%	**2a** 58% (*Z* : *E* = 1 : 2.5)
Ph	Ph	**1b** 49%	**2b** 41% (*Z* : *E* = 1 : 1)
Ph	4-$Bu^tC_6H_4$	**1c** 15%	–
Ph	Bu^t	**1d** 44%	–
Ph	Cy	**1e** 93%	–
Me	Cy	**1f** 95%	–

Scheme 1

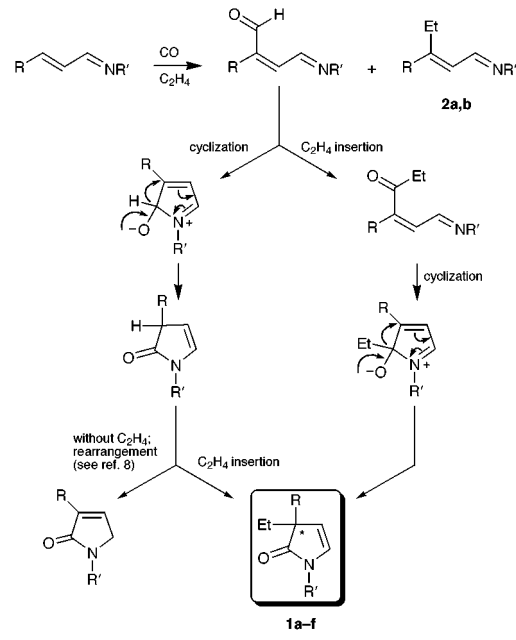
of the reaction. *Z* and *E* isomers are formed as can be demonstrated by IR and NMR spectroscopy. If the imine nitrogen and thus the whole π-system of the azadiene is nucleophilic enough the 1,3-dihydropyrrol-2-one derivatives **1c–f** are formed selectively. In these cases CO is obviously preferred for the first catalytic C–C coupling reaction. In the case of **1c** and **1d** the yields are quite low, presumably because of the higher steric demands of the *tert*-butyl groups. If the organic substituent at nitrogen is cyclohexyl the reaction produces **1e** and **1f** in nearly quantitative yield, so the steric as well as the electronic properties of the azadiene in those cases are ideal. Whether the starting material was cinnamaldehyde or croton aldehyde has no significant effect on the product distribution or the yield.

The formation of **1a–f** obviously proceeds *via* the catalytic incorporation of CO into the C–H bond at the β-carbon atom of the azadiene, followed by a nucleophilic attack of the imine nitrogen lone pair towards the aldehyde carbon closing the pyrrole ring. Compounds **1a–f** are then produced by a second catalytic C–C bond formation reaction by inserting one molecule of ethylene into the C–H bond *ortho* to the new carbonyl group in the 2-position of the pyrrole system (Scheme 2). By this reaction also a new chiral carbon atom at C3 is formed. This reaction sequence seems to us to be more reasonable than the other possibility, which would be for the intramolecular aldol condensation-like cyclization reaction to take place after the insertion of ethylene. If this were the reaction mechanism an ethyl group would have to be transferred from the carbonyl carbon atom to C3 of the pyrrolone system (Scheme 2). In addition, the reaction pathway we propose corresponds very well to the literature, in which C–C coupling



Scheme 2

reactions of olefins in the position *ortho* with respect to carbonyl groups have been reported using acetophenone derivatives as the starting material.[7] Parallel to our work Murai and coworkers very recently published a very similar reaction of azadienes with CO to yield the isomeric 1,5-dihydropyrrol-2-one derivatives.[8] They proposed a reaction mechanism in which as an intermediate a 1,3-dihydropyrrole-2-one derivative is formed which then isomerises to give the thermodynamically more stable 1,5-dihydropyrrol-2-one derivative (Scheme 2). Obviously in our reaction the second catalytic reaction of the pyrrol-2-one intermediate with ethylene to give **1a–f** is much faster than the rearrangement reaction, which we never observed. So this reaction offers the opportunity of selectively synthesising the thermodynamically less stable 1,3-dihydropyrrol-2-ones and in the same reaction building up a new center of chirality. Since γ-lactams are very interesting compounds with respect to pharmaceutical purposes,[9] the selective synthesis of 1,5-dihydropyrrol-2-one derivatives as reported by Murai as well as the synthesis of 1,3-dihydropyrrol-2-one derivatives we describe herein may both be useful synthetic strategies to achieve the selective synthesis of both isomers.

In the ^{1}H-NMR spectra of **1a–f** the most significant features are the two pyrrole hydrogen atoms at C4 and C5 which both give rise to doublets by coupling with each other in the range of δ 5.5 to 5.9 and δ 6.5 to 7.1, and the multiplet structures representing the CH_2 protons of the ethyl group attached to the new chiral center at C3 which clearly indicate that these two hydrogen atoms are diastereotopic. In the crystal structure determination of **1f** both enantiomers are observed to be statistically disordered in the lattice.[10] The bond lengths and angles show the values expected for a 1,3-dihydropyrrol-2-one. In addition, a quite strong intramolecular hydrogen bond is observed between the carbonyl oxygen atom and the methine hydrogen atom of the cyclohexyl substituent, which may be responsible for the downfield shift of the resonance of this hydrogen atom in the ^{1}H-NMR spectra of **1e** and **1f** at about δ 3.9 and the observation of five different CH_2 resonances for the cyclohexyl substituent in the ^{13}C-NMR spectrum of both compounds.

In conclusion we may say that the procedure described above allows the selective synthesis of 1,3-dihydropyrrol-2-one derivatives in a one-step synthesis. These compounds are produced *via* a reaction mechanism including two catalytic C–C bond formation reactions as well as the formation of a new center of chirality. Investigations on the reactivity of chiral azadienes in order to achieve diastereoselective reactions or reactions using catalysts derived from $Ru_3(CO)_{12}$ by substituting one or more CO groups by chiral ligands to achieve enantioselective reactions are under way and we will report these in due course.

Use of scandium tris(trifluoromethanesulfonate) as a Lewis acid catalyst in supercritical carbon dioxide: efficient Diels–Alder reactions and pressure dependent enhancement of *endo*:*exo* stereoselectivity

R. Scott Oakes, Toby J. Heppenstall, Najam Shezad, Anthony A. Clifford and Christopher M. Rayner*

School of Chemistry, University of Leeds, Leeds, UK LS2 9JT. E-mail: chrisr@chem.leeds.ac.uk

Received (in Liverpool, UK) 20th May 1999, Accepted 15th June 1999

The Diels–Alder reaction between various acrylates and cyclopentadiene in supercritical CO_2 are catalysed by scandium tris(trifluoromethanesulfonate); optimisation of CO_2 density leads to increased *endo*:*exo* selectivities compared to those obtained in conventional solvents.

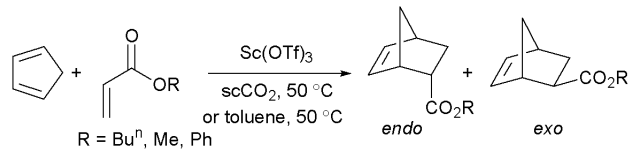
The use of supercritical carbon dioxide ($scCO_2$) as an environmentally friendly non-toxic alternative to common organic solvents is an area of significant current interest.[1] Alongside the environmental aspects, $scCO_2$ also has additional benefits as a reaction medium, such as its ready availability, ease of removal and disposal and/or recycling. Other advantages which are particularly relevant for carrying out reactions in $scCO_2$ are: fine control of solvent properties by changes in temperature and pressure (*vide infra*); the ability to homogenise reaction substrates, electrically neutral metal complexes and gases like oxygen and hydrogen; enhanced diffusion rates; and potential for product processing.[2]

More recently, it has become apparent that there are more significant benefits to carrying out reactions in $scCO_2$. In our own laboratories we have recently reported that dramatic enhancements of diastereoselectivity are possible compared to those obtained in conventional solvents, simply by switching to $scCO_2$ and optimising the pressure and hence density of the reaction medium.[3] We have also recently shown that it is possible to fine tune the *endo*:*exo* selectivity of the Diels–Alder reaction between cyclopentadiene and methyl acrylate by controlling the density of the reaction medium by varying the temperature and pressure of the $scCO_2$.[4] It proved possible to change the *endo*:*exo* ratio from approximately 3:1 to 4:1. Whilst such a variation could be effected by changing solvent in a liquid phase reaction, it was of interest that similar variations could also be achieved in the same solvent, simply by altering its density. Such levels of selectivity and the slow rate of reaction were however of limited preparative value, and hence further investigations were warranted.

It is well known that Lewis acids catalyse Diels–Alder reactions and can improve their rate and stereoselectivity.[5] However, examples of conventional Lewis acid catalysis in $scCO_2$ are very limited.[6] It is known that fluorinated organometallic complexes have enhanced solubility in $scCO_2$, a factor we have recently exploited in the development of new C–C bond forming processes in $scCO_2$ using palladium sources such as $Pd(OCOCF_3)_2$.[7] We reasoned that related Lewis acidic complexes should also be capable of enhancing the rate and stereoselectivity of a Diels–Alder reaction such as that described above. Initial results of these studies are described below.

To follow on from our previous work, we decided to investigate catalysis of the Diels–Alder reaction between a variety of acrylates and cyclopentadiene (Scheme 1). Our initial studies concentrated on using *n*-butyl acrylate as dienophile as this was particularly convenient for product isolation and purification.

Scandium tris(trifluoromethanesulfonate) is widely used as a Lewis acid in a variety of reaction media.[8] Owing to its fluorinated nature, we believed it would also be suitable for use



Scheme 1

in $scCO_2$. Initial results were encouraging. The reaction went to completion within 15 h at 50 °C, whereas the uncatalysed reaction was only 10% complete after 24 h under otherwise very similar conditions. In addition, a significant increase in *endo*:*exo* selectivity was observed as is common for Lewis acid catalysed Diels–Alder reactions.[5] We found that 6.5 mol% $Sc(OTf)_3$ catalyst gave good results, with no significant improvement at greater catalyst loading. In a conventional solvent such as toluene, an equivalent reaction gave a ratio of 10:1 *endo*:*exo* stereoselectivity. Changing to a significantly more polar solvent such as chloroform only had minimal effect on the selectivity (11:1 *endo*:*exo*). In $scCO_2$ at the same temperature (50 °C), variation of pressure (Fig. 1) allowed us to optimise the selectivity of this process,[9] with a maximum of 24:1 *endo*:*exo* being achieved, which is a considerable improvement, and further confirms our previous findings that significant enhancements of diastereoselectivity can be obtained by carrying reactions out in $scCO_2$ and optimising by varying the pressure and hence density of the reaction medium. Similar observations were observed with both phenyl and methyl acrylates, with *endo*:*exo* selectivities improving from 2:1 (toluene) to >8:1 ($scCO_2$, 1.09 g ml^{-1} density), and 4:1 (toluene) to >10:1 ($scCO_2$, 1.12 g ml^{-1} density) respectively.

It is of interest to note that, as was observed in our previous work, as pressure increases, the stereoselectivity rises to a maximum, and then begins to decrease. Note that this maximum

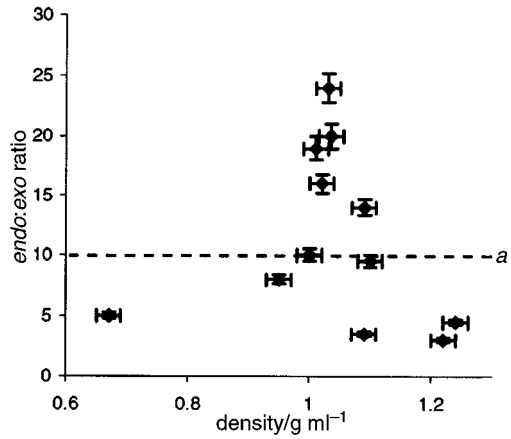


Fig. 1 Pressure dependent enhancement of *endo*:*exo* selectivity for Diels–Alder reaction between *n*-butyl acrylate and cyclopentadiene in $scCO_2$ catalysed by $Sc(OTf)_3$ at 50 °C. [a] 10:1 *endo*:*exo* selectivity observed in toluene at atmospheric pressure added for comparison.

occurs above the critical density of the medium and so is unlikely to be associated with clustering of molecules as is often proposed for effects observed around the critical point in near-supercritical fluids.[10] These new observations are consistent with the 'potential tuning' effect proposed in our previous paper[4] where the optimisation of the position and number of nearest neighbour solvent molecules with respect to a particular transition state was used to explain such a phenomenon. In such a case, an effect is observed which can be likened to a state of resonance between the solvent and reagents leading to an optimal selectivity for the reaction.

This work has now demonstrated the potential of Lewis acid catalysed reactions in $scCO_2$, and shown that enhanced rates and selectivities are possible. We are now further studying the origin and potential of this effect with respect to Diels–Alder reactions and other Lewis acid mediated reactions. The results of these studies will be reported in due course.

We are very grateful to the following members of the Leeds Cleaner Synthesis Group and their respective companies for funding and useful discussions: Dr Andrew Bridge, Rhône-Poulenc Rorer; Dr Mike Loft, Glaxo Research and Development; Julie MacRae, Pfizer Central Research; Dr William Sanderson, Solvay Interox; and Dr Ken Veal, SmithKline Beecham Pharmaceuticals.

9 Apparatus used is as previously described in ref. 3. *Typical procedure*: scandium tris(trifluoromethanesulfonate) (95 mg, 0.18 mmol, 6.5 mol%) was placed in a pressure vessel which was then sealed and charged to 50 bar pressure with CO_2. Agitation and heating was commenced, and a period of 20 min allowed for equilibration of conditions. *n*-Butyl acrylate (270 μl, 3.0 mmol) was injected into the system and the pressure increased to 80 bar. Cyclopentadiene (500 μl, 6.0 mmol, freshly cracked monomer) was injected and the pressure increased to the desired level. After 15 h, agitation and heating was stopped and the pressure released through a trap of diethyl ether (25 ml). The system was cleaned by further diethyl ether washes (2 × 1 ml). Filtration through Celite followed by solvent removal yielded the crude product mixture from which diastereomeric ratios were measured by ^{1}H NMR. Conversions were typically > 90%, and isolated yields > 80%. Density calibration was achieved by metering known amounts of carbon dioxide into the reaction vessel under standard reaction conditions (including reagents) using an ISCO 100D programmable syringe pump. Knowing the amount of carbon dioxide, the reactor volume and by observing the pressure, a calibration curve can be plotted for density versus pressure at constant temperature.

Facile and general syntheses of 3- and/or 5-substituted 7*H*-pyrazolo[4,3-*e*]-1,2,4-triazolo[4,3-*c*]pyrimidines as a new class of potential xanthine oxidase inhibitors†

Tomohisa Nagamatsu* and Takayuki Fujita

Received (in Cambridge, UK) 7th May 1999, Accepted 24th June 1999

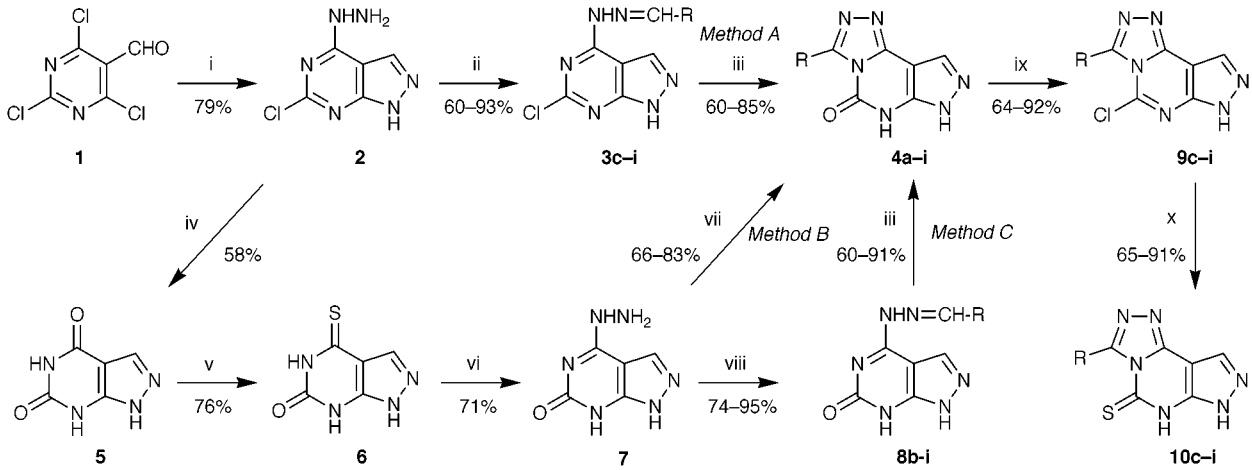
Convenient syntheses of 3- and/or 5-substituted 7*H*-pyrazolo[4,3-*e*]-1,2,4-triazolo[4,3-*c*]pyrimidines as a new class of potent xanthine oxidase inhibitors, involving the oxidative cyclisation of 4-alkylidenehydrazino- or 4-arylmethylidenehydrazino-1*H*-pyrazolo[3,4-*d*]pyrimidines with 70% nitric acid as the key step, are described.

As part of our studies on the synthesis[1] and biological evaluation[2] of novel fused pyrimidines, we initiated investigations aiming at designing new xanthine oxidase (XO) inhibitors. Among the fused purines prepared, the angular type purine analogues, 7*H*-1,2,4-triazolo[3,4-*i*]purines have been recently investigated for their potential XO inhibitory activities.[3] Allopurinol is known to inhibit XO[4] and is now widely employed in treatment of gout and hyperuricemia resulting from uric acid.[5–7] Although XO inhibitory activities have recently been discovered in some synthetic compounds,[8–10] no clinically effective XO inhibitors for the treatment of hyperuricemia have been developed since allopurinol was introduced for clinical use in 1963.[4] Herein, we report a facile strategy for general syntheses of the title compounds as a new class of potent XO inhibitors.

We have elucidated that 5-substituted 7*H*-1,2,4-triazolo[3,4-*i*]purines, especially the 5-oxo or 5-thioxo derivatives,[3] showed more potent bovine milk XO inhibitory activities than allopurinol. In contrast, few synthetic ways to prepare 7*H*-pyrazolo[4,3-*e*]-1,2,4-triazolo[4,3-*c*]pyrimidines, which are analogous to them, have been reported in the literature[11,12] or in patents[13] and several derivatives have been synthesized. However, none of the 5-substituted derivatives have been prepared up to now.

Our synthetic approach to the title compounds **4a**–**i** involved the preliminary synthesis of 6-chloro-4-hydrazino-1*H*-pyrazolo[3,4-*d*]pyrimidine (**2**) (79% yield) through the reaction of 2,4,6-trichloropyrimidine-5-carbaldehyde (**1**)[14] with anhydrous hydrazine (4 equiv.) in 2-methoxyethanol at 0 °C, followed by the reaction of **2** with an appropriate aldehyde (1.2–1.5 equiv.) in DMF at room temperature to yield the corresponding hydrazones **3c**–**i** in 60–93% yields as shown in Scheme 1.‡ In the light of this multiple step synthesis, a one-pot oxidative cyclisation starting from **3c**–**i** would be really attractive. Indeed, heating the hydrazones **3c**–**i** thus obtained with 70% nitric acid (*ca.* 5 equiv.) in DMF at 100 °C afforded the desired 3-substituted 7*H*-pyrazolo[4,3-*e*]-1,2,4-triazolo[4,3-*c*]-pyrimidin-5(6H)-ones (**4c**–**i**) accompanied with hydrolytic dechlorination in 60–85% yields (*Method A*).§ On the other hand, heating compound **2** with concentrated hydrochloric acid (50 parts) under reflux gave oxypurinol **5** (58% yield), which was confirmed by direct comparison with an authentic sample.[15] Then, treatment of the 4-thioxo derivative **6**, obtained by thiation of **5** according to the previously reported procedure,[15] with hydrazine monohydrate (17 equiv.) in ethanol under reflux afforded the 4-hydrazino derivative **7** in 71% yield. Compound **7** was subsequently cyclised to the corresponding **4a**,**b** (66–83% yields) by stirring with appropriate triethyl orthoesters (5 equiv.) in trifluoroacetic acid at room temperature (*Method B*).¶ Further, treatment of **7** with an appropriate aldehyde (1.5 equiv.) in DMF at room temperature gave the corresponding hydrazones **8b**–**i** in 74–95% yields. The intramolecular cyclisation of **8b**–**i** to the corresponding **4b**–**i** was also accomplished by

† Details of bovine milk xanthine oxidase inhibition by **4** and **10** are available from the RSC web site, see http://www.rsc.org/suppdata/cc/1999/1461/



a R = H; **b** R = Me; **c** R = *n*-C_7H_{15}; **d** R = Ph; **e** R = 4-F-C_6H_4; **f** R = 4-Cl-C_6H_4; **g** R = 4-Me-C_6H_4; **h** R = 4-MeO-C_6H_4; **i** R = 4-O_2N-C_6H_4

oxidation using 70% nitric acid (*ca.* 1.2 equiv.) in 60–91% yields in a similar manner as above (*Method C*).

In addition, we tried to prepare the 5-thioxo derivatives **10c**–**i**. Thus the key starting materials, 5-chloro derivatives **9c**–**i**, were readily prepared by refluxing the appropriate 5-oxo derivatives **4c**–**i** with phosphoryl chloride (100 parts) in 64–92% yields.‖ Then, thiation by reaction of **9c**–**i** with thiourea (1.2 equiv.) in butan-2-ol under reflux afforded the corresponding 5-thioxo derivatives **10c**–**i** in 65–91% yields.**

In conclusion, we accomplished the facile and general syntheses of not only oxypurinol **5** and 3- and/or 5-substituted 7*H*-pyrazolo[4,3-*e*]-1,2,4-triazolo[4,3-*c*]pyrimidines (**4** and **10**) as a new class of potential XO inhibitors but also 6-chloro-4-hydrazino-1*H*-pyrazolo[3,4-*d*]pyrimidine (**2**), which was an useful intermediate. The compounds (**4** and **10**) exhibited 100–760 fold more potent bovine milk XO inhibitory activities than that of allopurinol† and did not show any appreciable inhibition against the proliferation of T-cell acute lymphoblastic leukemia (CCRF-HSB-2). Further investigation of the present synthetic and XO inhibitory study is in progress and will be reported in detail shortly.

We are grateful to the SC-NMR Laboratory of Okayama University for 200 MHz ^{1}H NMR experiments. This work was partly supported by Grant-in-Aid for Scientific Research (C) (No. 09680570) from the Ministry of Education, Science, Sports and Culture, Japan.

Notes and references

‡ All new compounds **2**, **3c**–**i**, **7** and **8b**–**i** exhibited satisfactory elemental combustion analyses and mass and ^{1}H NMR spectral data consistent with structures indicated, and showed mps over 300 °C except for **3c** (mp 250 °C).

§ *Typical procedure*: A solution of **3c** (0.3 g, 1.02 mmol) with 70% nitric acid (0.5 ml, 5.55 mmol) in DMF (30 ml) was heated at 100 °C for 1 h. After the reaction was complete, the solution was concentrated to dryness *in vacuo* and treated with MeOH to afford the crystals **4c** (75%), which were collected by filtration and recrystallized from a mixture of DMF and EtOH. Other derivatives **4d** (85%), **4e** (72%), **4f** (71%), **4g** (67%), **4h** (61%) and **4i** (60%) were prepared in a similar manner to **4c** and recrystallized from a mixture of DMF and EtOH or water. The compounds **4c**–**i** showed mps above 300 °C, respectively. δ_H[60 or 200 MHz, $(CD_3)_2SO$] for **4c**: 0.86 (3H, t, *J* 6.54), 1.30 (8H, br s), 1.50–1.80 (2H, m), 2.50–2.95 (2H, m), 8.53 (1H, s), 12.41 (1H, br s), 13.50 (1H, br); for **4d**: 7.40–7.70 (3H, m), 7.90–8.35 (2H, m), 8.68 (1H, s), 12.60 (1H, br s), 13.60 (1H, br); for **4e**: 7.37 (2H, dd, *J* 8.82, 9.06), 8.22 (2H, dd, *J* 8.82, 5.88), 8.66 (1H, s), 12.59 (1H, br s), 13.65 (1H, br); for **4f**: 7.62 (2H, d, *J* 8.60), 8.17 (2H, d, *J* 8.60), 8.70 (1H, s), 12.62 (1H, br s), 13.66 (1H, br s); for **4g** (CF_3CO_2D): 2.54 (3H, s), 7.51 (2H, d, *J* 8.76), 8.03 (2H, d, *J* 8.76 Hz), 8.94 (1H, s); for **4h**: 3.85 (3H, s), 7.10 (2H, d, *J* 8.76), 8.12 (2H, d, *J* 8.76), 8.64 (1H, s), 12.60 (1H, br s), 13.50 (1H, br); for **4i**: 8.39 (4H, br s), 8.69 (1H, s), 12.70 (1H, br s), 13.60 (1H, br).

¶ *General procedure*: A solution of **7** (0.2 g, 1.2 mmol) with an appropriate triethyl orthoester (6 mmol) in trifluoroacetic acid (3 ml) was stirred at room temperature for 1 h. After the reaction was complete, the deposit was collected by filtration and recrystallized from DMF to yield the corresponding **4a** (mp > 300 °C, 66%) and **4b** (mp > 300 °C, 83%). δ_H[200 MHz, $(CD_3)_2SO$] for **4a**: 8.34 (1H, s), 8.62 (1H, s), 12.58 (1H, br s), 13.60 (1H, br s); for **4b**: 2.40 (3H, s), 8.54 (1H, s), 12.46 (1H, br s), 13.57 (1H, br s).

‖ All new compounds **9c**–**i** exhibited satisfactory elemental combustion analyses and mass and ^{1}H NMR spectral data consistent with structures indicated, and showed mps over 300 °C except for **9c** (mp 150 °C).

** *Typical procedure*: A solution of **9c** (0.3 g, 1.02 mmol) with thiourea (93 mg, 1.22 mmol) in Bu^{s}OH (15 ml) was heated under reflux for 1 h. After the reaction was complete, the solution was concentrated to dryness *in vacuo* and treated with EtOH to afford crystals of **10c** (mp 260–261 °C, 65%), which were collected by filtration and recrystallized from a mixture of DMF and water. Other derivatives **10d** (81%), **10e** (71%), **10f** (71%), **10g** (74%), **10h** (91%) and **10i** (77%) were prepared in a similar manner to **10c** and recrystallized from a mixture of DMF and EtOH or water. The compounds **10d**–**i** showed mps above 300 °C. It is noteworthy that the compounds **4**, **9** and **10** were reasonably stable in acid or alkali solution due to the substituents at the 5-position on the rings. δ_H[60 or 200 MHz, $(CD_3)_2SO$] for **10c**: 0.90 (3H, t, *J* 6.30), 1.31 (8H, br s), 1.55–2.10 (2H, m), 2.64–3.08 (2H, m), 8.63 (1H, s), 14.0 (1H, br), 14.38 (1H, br); for **10d**: 7.50–7.64 (3H, m), 8.10–8.30 (2H, m), 8.84 (1H, s), 14.0 (1H, br s), 14.35 (1H, br s); for **10e**: 7.40 (2H, dd, *J* 8.84, 8.90), 8.25 (2H, dd, *J* 8.84, 5.54), 8.75 (1H, s), 14.01 (1H, br), 14.37 (1H, br); for **10f**: 7.63 (2H, d, *J* 8.57), 8.20 (2H, d, *J* 8.57), 8.81 (1H, s), 14.01 (1H, br), 14.38 (1H, br); for **10g**: 2.40 (3H, s), 7.35 (2H, d, *J* 7.92), 8.10 (2H, d, *J* 7.92), 8.75 (1H, s), 13.90 (1H, br), 14.40 (1H, br); for **10h**: 3.85 (3H, s), 7.09 (2H, d, *J* 8.82), 8.14 (2H, d, *J* 8.82), 8.75 (1H, s), 14.0 (1H, br), 14.55 (1H, br); for **10i**: 8.41 (4H, br s), 8.77 (1H, s), 13.75 (1H, br), 14.25 (1H, br).

Received (in Cambridge, UK) 25th May 1999, Accepted 22nd June 1999

Hydrogenation of nitrobenzenes bearing aldehyde-containing substituents over heterogeneous platinum or palladium catalysts gives medium and/or large heterocyclic amines as a result of simple or dimeric cyclisation in moderate to good yields; a range of heteroatoms can be incorporated into the macrocycles, enhancing their potential as ligands.

The preparation of cyclic amines by hydrogenation of nitroaldehydes or nitroketones over platinum metal catalysts has been well established in the case of 5- and 6-membered heterocycles.[1] Recently the synthesis of a 17-membered cyclic amine has been reported in good yield (66%) by hydrogenolysis of a Cbz-protected aminoaldehyde with subsequent hydrogenation of the resulting cyclic iminium salt.[2] The reactions were carried out at relatively high dilution (4×10^{-3} M) in methanol using moderate amounts of a palladium hydroxide catalyst precursor (3.7×10^{-4} g atom of Pd) relative to substrate (2.3×10^{-1} mmol).

The above chemistry prompted us to explore a general synthesis of medium and large heterocycles based on the ready availability of nitrobenzenes bearing aldehyde-containing side chains **2** and **3** from hydroformylation[3] of the related nitroalkenes **1** (Scheme 1).[3,4] Good regio-control for the terminal aldehydes **2** can often be attained using the bulky bisphosphite ligand, BIPHEPHOS.[5] Use of triphenylphosphine or hydroformylation of allylic ethers[6] led to greater amounts of branched-chain aldehydes **3** but in all cases facile chromatographic separation of the branched and linear aldehydes was possible. The nitroaldehydes were reacted with hydrogen in methanol over 10% Pd/C and/or PtO_2 catalysts (Scheme 2). Standard conditions involved 1 atm H_2, ambient temperature, with Pd (5.6×10^{-5} g atom) for reaction on *ca.* 0.4 mmol scale with substrate concentration of 4.8×10^{-3} M. Larger amounts of Pt (3×10^{-4} g atom) were used, comparable with that described by the Japanese workers.[2] The results are summarised in Table1.

The monomeric compounds **5** and the dimeric compounds **6** were separated from any polymeric material and isolated in pure form by chromatography. Structures were assigned by ^{1}H and ^{13}C NMR spectroscopy and by electrospray (ESI) mass spectroscopy. Three representative products, the monomer **5n** as its *N*-benzoyl derivative and the dimers **6a** and **6g**, were fully characterised by single crystal X-ray structure determination.† Careful examination of the total product mixture by both adsorption chromotography and HPLC failed to show any evidence for the formation of trimers or other oligomers.

The yields of cyclic products obtained from *ortho*-substituted nitrobenzenes varied both with ring size and the pattern of heteroatom incorporation in the side chain. No clear trends emerged other than that in general compounds containing oxygen as the only heteroatom in the side chain gave lower yields of medium ring compounds, 9–11 membered (0–36%, entries 4–6, 8–10) than larger ring compounds, 13–22 membered (36–75%, entries 1, 4, 5, 9, 10, 13–15). Introduction of other heteroatoms had a marked influence. Reaction of compound **4b** containing sulfur in the side chain led only to an 8-ring monomer (entry 2) and two compounds **4f** and **4j** containing nitrogen in the side chain surprisingly gave only 9- and 11-membered ring compounds (entries 7 and 12). Introduction of ethyleneoxy units into the side chain in general led to improved yields over compounds containing carbon chains of similar lengths, *cf.* reactions of **4k** and **4l** (entries 13–15) with those of **4m** and **4n** (entries 16–18).

The *meta*- and *para*-substituted compounds **4o**–**4s** in all cases gave higher yields of dimeric compounds (entries 19–23).

An attempt was made to influence the yields of products by the addition of potential templating compounds to the reactions. Reactions of the compound **4i** were carried out with additives as summarised in Table 2.

Addition of the heavy metal salts Ag(OTf) and $La(OTf)_3$ dramatically influenced the ratio of products and resulted in exclusive formation of the eleven-membered heterocycle **5i** although the overall recovery of non-polymeric products was reduced. Energy minimisation calculations for interaction of one silver ion with the monomer **5i** and for two silver ions with the dimer **6i** were carried out.[7] The energy of the preferred conformation of the free monomer is similar to that of the preferred conformation when bonded to silver whereas serious distortion of the preferred conformation of the dimer is required in order to attain the conformation most suitable for bonding to two silver ions. Addition of glycine to the reaction had no effect on the yield or product distribution, perhaps not surprising as aqueous methanol was the reaction solvent.

The compounds have potential for use as novel ligands[8–10] and as constituents in molecular switching devices[11,12] and these applications are being evaluated.

Received (in Cambridge, UK) 6th May 1999, Accepted 22nd June 1999

Zn(II) carboxylate salts of ethylene-methacrylic acid copolymer undergo coordination-structural change by applying low pressure including atmospheric pressure at temperatures above 60 °C; the structure transforms from six-coordinate to four-coordinate, as the applied pressure increases from 0 to 3 MPa.

Ethylene-methacrylic acid copolymers neutralized with metal cation (E-MAA-*x*M, see Fig. 1) are representative ionic polymers (so-called ionomers which are defined as polymers functionalized with a small amount of pendant ionic groups).[1–3] The ionic groups are frequently phase-separated from the host hydrophobic polymer matrix to form ionic aggregates, resulting in physical properties superior to the host polymer. Therefore, E-MAA-*x*M, in general, consists of three phases of amorphous polyethylene, crystalline polyethylene, and ionic aggregation regions and hence undergoes a transitional change around 60 °C (T_i) (loss of order inside the ionic aggregations, according to our proposal[4]) and the melting of crystalline polyethylene region near 90 °C (T_m). E-MAA-60Zn is one of the most popular ionomers which have been marketed as wrapping sheets for foods, and plastics for golf balls and sport shoes by Du Pont since 1964.[5] In E-MAA-*x*Zn, it is known that the Zn(II) carboxylate salts can take either four-coordination or six-coordination structures, dependent on temperature or humidity,[6–9] but we have found that the coordination structure is changed with applied low pressure between 0 and 3 MPa above 60 °C. The present letter communicates this wonderful and unique transformation of the coordination structure in E-MAA-60Zn under low pressure including atmospheric pressure.

E-MAA-60Zn was supplied from Du Pont-Mitsui Polychemicals Co. Ltd. (Tokyo), where MAA content in E-MAA is 5.4 mol% and its degree of neutralization by Zn(II) cation is 60%; E-MAA is ACR-1560 of Du Pont-Mitsui Polychemicals Co. Ltd. and E-MAA-60Zn pellets were prepared by a melt reaction of E-MAA with a stoichiometric quantity of zinc oxide in an extruder.[10] The 10–30 μm thick films for IR measurements were prepared by compression-molding the pellets at 130 °C under 19.6 MPa.

The films obtained were annealed in a vacuum oven at 130 °C for 2 h under reduced pressure with a rotary pump (around 6.7×10^{-4} MPa because of a leak in the oven), and then cooled to room temperature at a rate of about 3 °C min^{-1}. After storing for more than 30 d at room temperature, this sheet was used as the starting sample in the following IR measurements. Differential scanning calorimetric measurements were made for the starting sample at a heating rate of 10 °C min^{-1} by use of a Seiko Denshi SSC-5000 calorimeter. The data showed an annealing peak near 52 °C, corresponding to the transition temperature of ionic aggregates (T_i) and the melting peak (T_m) of crystalline polyethylene regions near 88 °C, being well consistent with the previous data.[4]

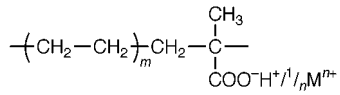

Fig. 1 Chemical structure of ethylene-methacrylic acid copolymer neutralized partially with metal cation (E-MAA-*x*M, MAA content = 5.4 mol%, M: metal cation, *x*: degree of neutralization in %).

IR spectra were measured with a Perkin-Elmer 1640 FT-IR spectrometer in the following two measuring procedures, where each trace was taken as the average of 16 scans at a resolution of 4 cm^{-1}.

(E-1) IR spectra under low pressures below 0.101 MPa: IR spectra were measured by use of a commercial gas cell (GL Sciences Co., Tokyo, Type GC-KBr) equipped with a hand-made heater. The starting film was placed in the gas cell two KBr windows and the pressure was controlled with N_2. Then, IR spectra were recorded at different temperatures.

(E-2) IR spectra under high pressures above 0.101 MPa: Under a pressure controlled by N_2 in an autoclave, the starting film was heated to 130 °C above T_m and annealed for 2 h, and then cooled to room temperature at a rate of about 3 °C min^{-1}. IR spectra were recorded at 30 °C.

Fig. 2(a) shows IR spectra of the starting E-MAA-60Zn in the wave number range from 500 to 2500 cm^{-1} at 30 °C. There are observed three characteristic peaks near 1624 and 1538 cm^{-1}, and near 1585 cm^{-1}, which have been assigned as antisymmetric stretching vibrations of COO$^-$, [ν_{as} (COO$^-$)], in six-(octahedral) coordination structure and that in four-(tetrahedral) coordination structure, respectively[6,7] (Coleman *et al.*[7] assumed that the 1536 and 1565 cm^{-1} bands are assigned to the six-coordination structure, and the 1537 and 1620 cm^{-1} bands to an acid salt structure, but here we assigned the bands at 1538 and 1624 cm^{-1}, and the weak band at 1565 cm^{-1} which is

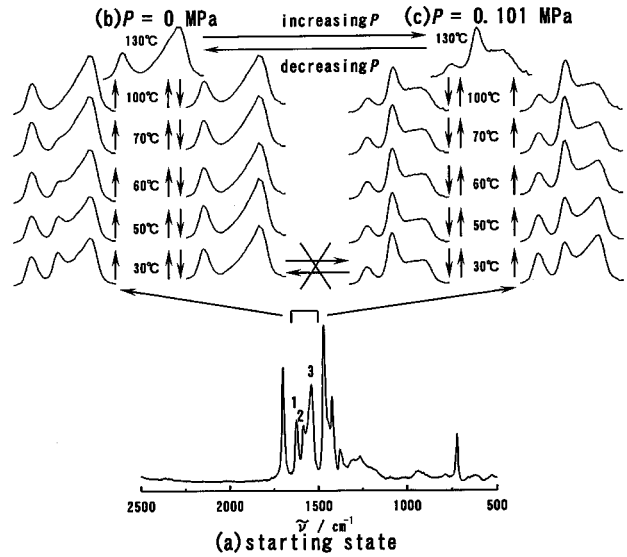

Fig. 2 IR spectrum in the wavenumber range from 500 to 2500 cm^{-1} (a), and variation of antisymmetric stretching vibration of COO$^-$ [ν_{as}(COO$^-$)] with temperature under P = 0 (b) and P = 0.101 MPa (atmospheric pressure) (c). 1 : 1624 cm^{-1}, 2 : 1585 cm^{-1} and 3 : 1538 cm^{-1} in (a).

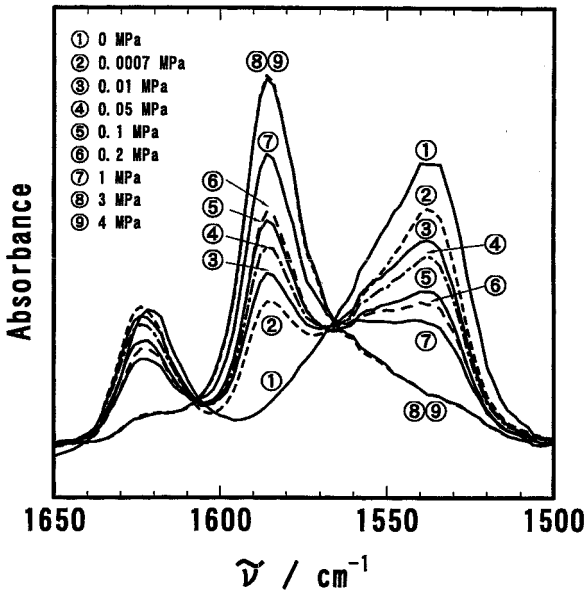

Fig. 3 Variation of antisymmetric stretching vibrations of COO^- [$\nu_{as}(COO^-)$] with pressure (P) at 30 °C. IR spectra were recorded at 30 °C for the samples cooled from the molten state of 130 °C under different constant pressures (P). The IR spectra (the coordination structure) are almost the same as those at 130 °C.

superimposed on the two bands, all to a six-coordination structure, because both structures are principally in six-coordination, and actually there would be a complicated distribution of the coordination structure over various structures from the six-coordination to the acid salt coordination). Fig. 2(b) and (c) show changes in the characteristic peaks of ν_{as} (COO^-) with varying temperature from 30 °C under two pressures [P = 0 (b) and P = 0.101 MPa (atmospheric pressure) (c) which is estimated about 0.137 MPa at 130 °C by the gaseous state function], where the measurements were done by use of the gas cell (E-1). When the starting sample is heated at P = 0, the ν_{as} (COO^-) band at 1585 cm^{-1} begins to be weakened from around 60 °C and disappears at 130 °C above T_m (88 °C), and as a result, only the bands at 1624 and 1538 cm^{-1} are seen at 130 °C. The IR spectra at 130 °C, exhibiting the two bands at 1624 and 1538 cm^{-1}, are unchanged during cooling to 30 °C. On the other hand, as temperature increases under P = 0.101 MPa, the 1585 cm^{-1} band becomes markedly intensified, accompanying the decrease of the 1624 and 1538 cm^{-1} bands, and becomes predominant at 130 °C. When P = 4 MPa, only the band at 1585 cm^{-1} was seen at 130 °C and the two bands at 1624 and 1538 cm^{-1} virtually disappeared, as described later. Consequently, these IR data indicate that the Zn(II) carboxylates in E-MAA-60Zn are in six-coordination at P = 0 and mostly in four-coordination when $P \geq 3$ MPa. At 130 °C, as P increases from 0, the coordination structure of the Zn(II) carboxylate undergoes a reversible transformation from a six-coordinate to a four-coordinate structure whose transformation rate was too fast to be detected on the present IR measurements. At 30 °C, the coordination structure, of course, is not changed with P, but when the temperature is elevated above 60 °C, it begins to be controlled by P again.

To examine the coordination structure under higher pressure above atmospheric pressure, we made IR spectral measurements at 30 °C for E-MAA-60Zn which was cooled to room temperature, after annealing at 130 °C for 2 h under different constant pressures of N_2 by use of an autoclave (E-2); the results are shown in Fig. 3, where the spectrum for P = 0 is that in Fig. 2 which was measured by use of the gas cell (E-1). Of course, the coordination structure at 30 °C copies that at 130 °C, as already described in Fig. 2. When P = 0 at 130 °C, the $\nu_{as}(COO^-)$ band appears near 1624 and 1538 cm^{-1}, corresponding to the six-coordinate structure, but as P increases, the two bands become weaker, and the 1585 cm^{-1} band is stronger, being predominant when $P \geq 3$ MPa. This pressure-dependent change was scarcely affected by the cooling rate from 130 °C. In Fig. 3, the pressure-dependent IR spectra for three $\nu_{as}(COO^-)$ bands show two isosbestic points near 1610 and 1570 cm^{-1}. The existence of two isosbestic points suggests that the structural transformation results from an equilibrium change between four- and six-coordination structures.

The pressure-dependent change in the coordination structure found in this work was also observed under Ar gas and the results were almost identical to those under N_2. Therefore, it was concluded that the coordination structure of Zn(II) carboxylate in E-MAA-60Zn is dependent on P at higher temperatures above around 60 °C. It has been reported that the coordination structure in some metal complexes is changed by adduct formation of gas molecules such as O_2 or under very high pressure,[10–13] but it is certainly surprising that the coordination structure changes with low pressure around atmospheric pressure. This novel finding, moreover, appears to have some significance in nature; for example it reminds us of relationships between physiological activity and coordination structure of some metal complexes in biological systems, and speaking boldly, physiological anomalies in deep sea, high mountains and cosmic space. Further studies are progressing for pressure-dependent coordination structures of metal complexes in various ionomers and also common metal complexes, for example pure metal alkyl carboxylates, in our laboratories and will be published elsewhere in the near future. In ethylene ionomers such as E-MAA-*x*M, the appearance and features of the pressure-dependent coordination structure seem to change sensitively depending on the host polymer, metal cation, its degree of neutralization and ion content.

The authors very much thank Professor Y. Sugi and Y. Kubota, Faculty of Engineering, Gifu University, for permitting us the use of an autoclave and their kind encouragement, and also Professor J. Uemura, Institute for Chemical Research, Kyoto University, for his valuable discussions and encouragement.

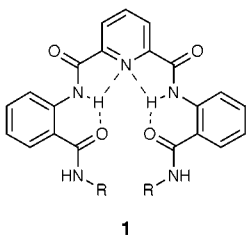
Received (in Columbia, MO, USA) 5th January 1999, Accepted 3rd June 1999

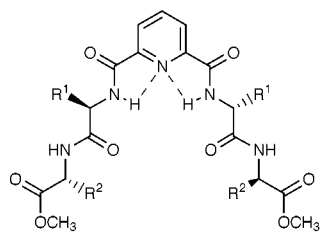
A series of peptide dimers of 2,6-carbamoylpyridine have been isolated and their solid-state structures evaluated for the formation of strands motifs and lamellar architecture.

Many fibrous proteins found in nature (*e.g.* silks) have a significant amount of β-sheet structure which leads to lamellar architectures in the solid state.[1,2] The desirable physical properties associated with these proteins, such as high tensile strength, are proposed to result, in part, from their β-sheet structures.[1,2] Most attempts to duplicate these structural properties in synthetic systems have been hindered by difficulties in controlling secondary and tertiary peptide structures.[3] One useful approach to organize peptide structure is to incorporate a rigid template into the peptide backbone.[4,5] Our laboratory,[6] and that of Hamilton,[7] have been exploring the use of 2,6-bis[(2-carbamoylphenyl)carbamoyl]pyridine templates (**1**) to nucleate synthetic helices. Compounds with **1** have an inherent twist that results from the two appended phenyl rings being disposed on opposite faces of the planar 2,6-bis(carbamoyl)pyridine unit. We have found that replacing the phenyl groups with peptides would yield more planar compounds containing chiral clefts (**2**). In this design, direct intramolecular interactions between appended peptides are not possible; however intermolecular hydrogen bonding can occur to form supramolecular β-strands with antiparallel arrangements of peptides. We report herein our structural findings for a small family of peptide dimers.

Four dipeptides were synthesized that include all possible combinations of alanine and valine **2**(X,Y). Valine and alanine were chosen for their differing propensities to form β-sheets in proteins as shown by statistical[8] and thermodynamic studies.[9] Each pendant peptide arm was synthesized using standard DCC coupling protocol for Boc-protected amino acids.[10] Species **2**(X,Y) were obtained by treating THF solutions of the deprotected peptides with 2,6-bis(chlorocarbonyl)pyridine. All new compounds gave satisfactory FTIR, ^{1}H and ^{13}C NMR, FAB-MS, and elemental data.



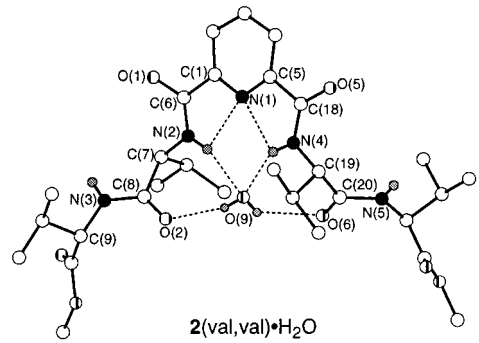
1



2(ala,ala): $R^1 = R^2 = CH_3$
2(val,val): $R^1 = R^2 = CH(CH_3)_2$
2(ala,val): $R^1 = CH_3$, $R^2 = CH(CH_3)_2$
2(val,ala): $R^1 = -CH(CH_3)_2$, $R^2 = CH_3$

NMR data in $CDCl_3$ obtained for the four peptide dimers suggest that the compounds are C_2 symmetric in solution. The chemical shift for the 2,6-carbamoylpyridine protons are observed at *ca.* 8.5 ppm which is indicative of intramolecular hydrogen bonding (*i.e.* $N–H_{amide}\cdots N_{py}$).[11] Moreover, the chemical shifts of these protons are sensitive to the presence of water. For **2**(val,ala), the resonance for these proton shifts downfield by 0.20 ppm with the addition of 1 equiv. of H_2O. Furthermore, the observed temperature dependence of the 2,6-carbamoyl protons of **2**(val,ala) in the presence of water ($\Delta\delta/\Delta T = -0.012$ ppm K^{-1}) is significantly greater than that under anhydrous conditions ($\Delta\delta/\Delta T = -0.0017$ ppm K^{-1}). Variable temperature ^{1}H NMR data also show that the chemical shift of the water present in **2**(val,ala) has a large temperature dependence of ($\Delta\delta/\Delta T = -0.0345$ ppm K^{-1}. Taken together these NMR data suggest the **2**(val,ala)·H_2O adduct forms *via* multiple hydrogen bonds.[12]

The solid state structures of **2**(val,ala)·H_2O and **2**(val,val)·H_2O were examined by single-crystal X-ray diffraction methods and agree with the structures suggested from solution studies. Both compounds crystallize in non-centrosymmetric space groups: **2**(val,ala)·H_2O in the tetragonal space group $P4_12_12_1$† and **2**(val,val)·H_2O in the orthorhombic space group $P2_12_12_1$.‡ The compounds have similar 'V'-shaped molecular structures with a guest water molecule residing in the chiral cleft formed by the two appended peptides [see Fig. 1 for **2**(val,val)·H_2O]. Species **2**(val,ala)·H_2O has exact C_2-symmetry where the axis bisects the pyridine ring and coincides with N(1) and O(9) of the water molecule. N(2)–H(2) of the carbamoyl moieties are involved in H-bonding between the pyridyl nitrogen [N(2)···N(1), 2.724(7) Å]. The guest water molecule also H-bonds to the internal valine carbonyl oxygens of each peptide as indicated by the heavy atom O(9)···O(2) distance of 3.097(7) Å. Compound **2**(val,val)·H_2O is not C_2-symmetric in the crystalline state; however, it also interacts with its guest water molecule through four H-bonding interactions: (i) O(9) H-bonds to carbamoyl N–H groups with N(2)···O(9) and N(4)···O(9) distances of 3.054(16) and 2.931(16) Å; and (ii) the water hydrogens H-bond to the appended peptides through the



2(val,val)•H_2O

Fig. 1 Molecular structure of **2**(val,val)·H_2O. Selected distances (Å) and dihedral angles (°): N(2)–O(9) = 3.053(16); N(4)–O(9) = 2.928(15); C(30)–O(2) = 3.206(15); O(9)–O(2) = 2.830(16); O(9)–O(6) = 2.697(16); N(2)–C(7)–C(8)–N(3) = 136.3; N(4)–C(19)–C(20)–N(5) = 124.2; C(6)–N(2)–C(7)–C(8) = −130.9; C(18)–N(4)–C(19)–C(20) = −113.5.

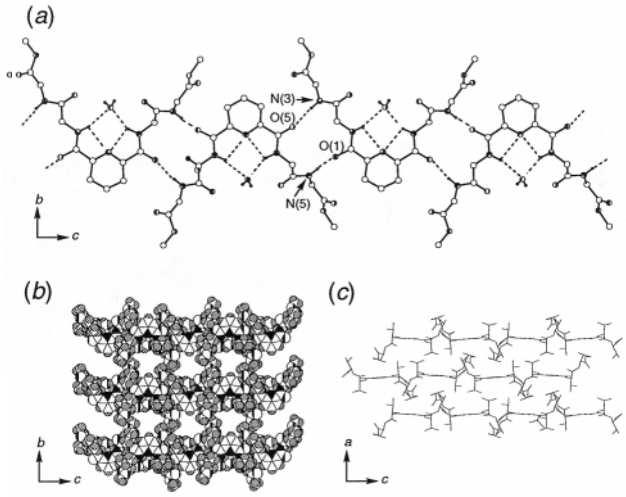


Fig. 2 Crystal lattice architecture in **2**(val,ala)·H_2O. (*a*) intermolecular hydrogen bonding network formed within antiparallel β-sheet (viewed along crystallographic *a*-axis, isopropyl groups removed for clarity), (*b*) lamella structure viewed in the *a*,*b* plane and (*c*) *a*,*c* plane. Chloroform solvent molecules removed for clarity.

internal valine carbonyl oxygens where heavy atom O(9)···O(2) and O(9)···O(6) distances are 2.830(15) and 2.698(15) Å.[13]

Although similar in molecular structure, **2**(val,val)·H_2O and **2**(val,ala)·H_2O have significantly different lattice architectures. Strand motifs are the dominant structural element found in the lattice of **2**(val,val)·H_2O. Individual strands are formed by an antiparallel arrangement of molecules connected by a network of intermolecular H-bonds which runs parallel to the crystallographic *c*-axis. Molecules within a strand have four intermolecular H-bonds, two bonds to each of its two nearest neighbors at distances of N(3)···O(5) = 2.860(16) and O(1)···N(5) = 2.970(18)Å [Fig. 2(*a*)]. The nearly coplanar positioning of the N(3)–H and C(6)–O(1) vectors (RMS planar deviation 0.064 Å) offers a favorable geometric arrangement for the formation of strands.

The strand motif in **2**(val,val)·H_2O resembles antiparallel β-strands (sheets) observed in proteins. The strands in this synthetic system have dihedral angles that are similar to the ψ (136°) and ϕ (−139°) angles found in protein antiparallel β-sheets.[14] The ψ angles for the internal valine in the molecular structure of **2**(val,val) are 136.2 and 124.2°, while those for ϕ are −130.9 and −113.5° (see legend to Fig. 1). These strand motifs assemble to produce sheets that lie in the crystallographic *b*,*c*-plane [Fig. 2(*b*)]. Note that each layer has an open framework which is formed by the interactions of peptides in neighboring strands. In **2**(val,val)·H_2O, the resultant open spaces within a layer are partially occupied by chloroform molecules. The arrangement of sheets within this crystal lattice is a lamellar structure [Fig. 2(*c*)].

In contrast to **2**(val,val)·H_2O, **2**(val,ala)·H_2O associates with neighboring molecules to form a three-dimensional network of hydrogen bonds which has neither strands nor a lamellar structure. Moreover, each molecule in the lattice of **2**(val,ala)·H_2O is involved in only two intermolecular H-bonds.[15] A possible explanation for the differences between the lattice architecture of **2**(val,ala)·H_2O and **2**(val,val)·H_2O is the magnitude of the molecular dihedral angles ψ and ϕ. In **2**(val,ala)·H_2O, the angles are ψ = −133.6° and ϕ = 118.6°, approximately 180° different than found for **2**(val,val)·H_2O (*vide supra*).

The β-strand formation observed in **2**(val,val)·H_2O and absent in **2**(val,ala)·H_2O is consistent with the results found in proteins, where valine and alanine confer different propensities for sheet formation. Moreover, β-sheets are often found in the interior of proteins where side chains engage in hydrophobic interactions with other units of secondary structure.[16] These interactions lead to alternating positioning of side chains that results in a 'tongue and groove' structure as observed in the lattice of **2**(val,val)·H_2O [Fig. 2(*c*)]. However, in **2**(val,ala)·H_2O the side chains do not permit the same long-range interactions, therefore an alternative lattice structure is adopted. The small size of **2**(val,val)·H_2O in comparison to proteins makes it particularly notable that antiparallel strand formation and lamellar structure is observed. Extension of this design to other peptide systems is currently under investigation.

We thank the NIH for financial support.

The complete and irreversible conversion of a *cis* carbon-substituted thiiranium ion into the *trans* isomer

Lucia Pasquato* and Giorgio Modena

Centro CNR Meccanismi di Reazioni Organiche (CMRO) and Dipartimento di Chimica Organica, Università di Padova, via Marzolo 1, 35131 Padova, Italy. E-mail: pasquato@chor.unipd.it

Received (in Liverpool, UK) 18th March 1999, Accepted 23rd June 1999

***t*-2-*tert*-Butyl-*t*-3-phenyl-*r*-1-methylthiiranium 1 isomerizes into the more stable (32.3 kJ mol^{-1}) *t*-2-*tert*-butyl-*c*-3-phenyl-*r*-1-methylthiiranium 2 in a complete and irreversible process (monitored by proton NMR at −30 °C) *via* an open benzylic carbenium ion.**

Thiiranium ions, the bridged intermediates in the addition of sulfenyl derivatives to alkenes,[1,2] are known to be among the most stable of the iranium ion family with respect to the isomeric open carbonium ions.[1,2] Isolation of these cyclic species[3] and their characterization in the solid state by X-ray structural determination[4–6] and in solution mainly by NMR spectroscopy[7,8] together with theoretical *ab initio* calculations[6,9] have provided detailed information on their structure.

Thiiranium ions are responsible for the complete *anti* stereospecificity of the additions of sulfenyl halides to alkenes. Few exceptions are known† and they concern, mainly, those alkenes having electron-donor substituents. For example, in the sulfenylation of vinyl ethers the thiiranium ion may be in equilibrium with the open carbonium ion stabilized *via* the mesomeric oxonium ion.[12]

Recently, we began to investigate the chemistry of stable and isolated thiiranium ions for mechanistic[8,13,14] as well as for synthetic reasons.[15] Bulky substituents at the ring carbons stabilize the ions, whereas phenyl substituents activate the α-carbon toward nucleophilic reactions. Here we report that we could observe, for the first time, the unexpected complete isomerization of the *t*-2-*tert*-butyl-*t*-3-phenyl-*r*-1-methylthiiranium **1** hexachloroantimonate into the *t*-2-*tert*-butyl-*c*-3-phenyl-*r*-1-methylthiiranium **2** hexachloroantimonate.

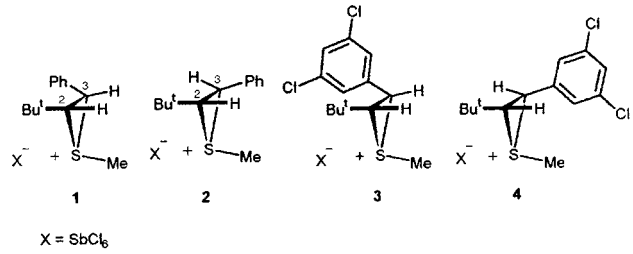
The *t*-2-*tert*-butyl-*c*-3-phenyl-*r*-1-methylthiiranium **2** hexachloroantimonate was prepared by reaction of (*E*)-3,3-dimethyl-1-phenylbut-1-ene with 1 equiv. of methylthio(bismethylthio)sulfonium hexachloroantimonate in CH_2Cl_2 at −20 °C.[14] Only the isomer having the phenyl ring *cis* to the *S*-methyl group is formed.[14] When we attempted the synthesis of the *t*-2-*tert*-butyl-*t*-3-phenyl-*r*-1-methylthiiranium **1** hexachloroantimonate by adding the same electrophile to the (*Z*)-3,3-dimethyl-1-phenylbut-1-ene at −20 °C, only the *trans* isomer **2** was obtained. The reaction repeated in CD_2Cl_2 and monitored by ^{1}H-NMR at −20 °C confirmed the exclusive formation of the *trans* thiiranium ion **2**.

However, the addition of CH_3SCl in CH_2Cl_2 at −78 °C to (*E*)- and (*Z*)-3,3-dimethyl-1-phenylbut-1-ene is completely stereoselective and hence the corresponding thiiranium ions must be the intermediates.

Indeed, when the reaction of the (*Z*)-alkene with $Me_3S_3SbCl_6$ was carried out at −50 °C in an NMR tube we could observe the slow formation of the *cis* thiiranium ion **1**.‡ The reaction is complete in about 30 min. Very diagnostic are the doublets relative to protons 2-H and 3-H which in the *trans* isomer are at 4.38 and 5.56 ppm respectively (*J* 12.0 Hz) whereas in the *cis* isomer 2-H and 3-H are doublets at 4.52 and 5.65 ppm (*J* 10.14 Hz). Also, the *S*-methyl group shows a singlet at 2.95 ppm in the *cis* isomer and at 2.16 ppm in the *trans* isomer.

Raising the temperature gradually up to −30 °C we observed the quantitative isomerization of the *cis* isomer **1** into the *trans* one ($t_{1/2}$ is about 2 h) without detecting any significant amount of (*Z*)-alkene suggesting that the isomerization occurs on the thiiranium ion itself, likely *via* a ring opening–ring closure process as depicted in Scheme 1.§

To confirm the hypothesis of Scheme 1, *i.e.* that the observed isomerization is due to an equilibrium between thiiranium ion and the corresponding carbonium ion, we prepared the *t*-2-*tert*-butyl-*t*-3-(3,5-dichlorophenyl)-*r*-1-methylthiiranium **3** hexachloroantimonate and the *t*-2-*tert*-butyl-*c*-3-(3,5-dichlorophenyl)-*r*-1-methylthiiranium **4** hexachloroantimonate, where the phenyl group is substituted by the more electronegative 3,5-dichlorophenyl residue, by addition of methylthio(bismethylthio)sulfonium hexachloroantimonate to (*Z*)- and (*E*)-1-(3,5-dichlorophenyl)-3,3-dimethylbut-1-enes¶ in CH_2Cl_2 at −60 °C.

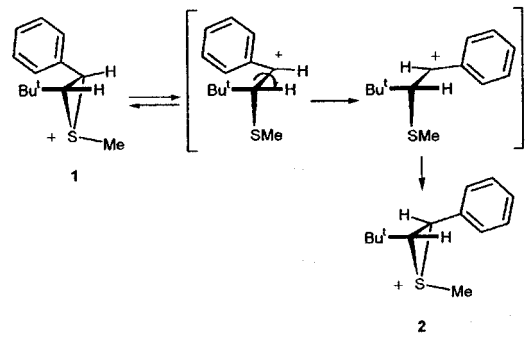


Scheme 1

As expected thiiranium ion **3** is much more stable than the homologous **1** in CD_2Cl_2. At 0 °C the compound is stable for more than 12 h.‖

Independent information on the relative stability of thiiranium ions **1** and **2** has been obtained by *ab initio* calculation.** Optimization at the RHF/3-21G*//RHF-3-21G* level gives an energy difference of 32.3 kJ mol^{-1} between the most stable *trans* and the *cis* isomer. The stronger steric interaction between the phenyl ring and the *cis tert*-butyl group in the ion **1** with respect to the steric interaction between the phenyl ring and the *S*-methyl group in the *trans* ion **2** may be responsible for the calculated energy difference.

In the optimized geometry relative to the *trans* thiiranium ion **2** the S–C(3) bond is 1.991 Å whereas the S–C(2) bond is 1.870 Å. The same bonds in the *cis* ion **1** are 1.855 and 1.884 Å respectively. The C(2)–C(3) bonds in the two isomers **1** and **2**



Scheme 2

are similar being 1.463 and 1.488 Å respectively. Very likely the *cis* interaction between the phenyl and the S–Me group in the ion **2** is minimized by stretching the S–C(3) bond. The much greater steric interaction between the *tert*-butyl and the *cis* phenyl moieties in the *cis* ion **1** is removed very efficiently by breaking the S–C(3) bond due to the presence of the phenyl ring which stabilizes the α positive charge in the open carbonium ion. Rotation around the C(2)–C(3) bond and closure to the *trans* ion **2** complete the rearrangement process (Scheme 1). The energy difference between the two ions ensures an irreversible reaction.

In conclusion, we have reported the isomerization of the *t*-2-*tert*-butyl-*t*-3-phenyl-*r*-1-methylthiiranium ion **1** to the more stable *trans* isomer **2** *via* an open benzylic carbonium ion. The different stability of these ions (32.3 kJ mol^{-1}) makes the process irreversible. Efforts are in progress in our laboratories to find suitable thiiranium ions to study the different reactivity modes of *cis* carbon-substituted thiiranium ions with respect to *trans* ones.

The authors thank Professor Vittorio Lucchini and Dr Alessandro Bagno for performing *ab initio* calculations.

Notes and references

† It has been reported that sulfenyl halides add stereospecifically to (*E*)- and (*Z*)-but-2-ene in the temperature range −34 to +146 °C (ref. 10). The corresponding thiiranium ions may be independently synthesized and they react with nucleophiles at −20 °C to give the non-isomerized adducts. However, a mixture of *erythro* and *threo* products, whose composition is independent of the starting thiiranium ion, is formed if the thiiranium ion salts are kept for some time at +20 °C (ref. 11).

‡ $\delta_H(CD_2Cl_2$, 200 MHz, −50 °C) 0.92 (9H, s, Bu^t); 2.95 (3H, s, Me), 4.52 (1H, d, *J* 10.14), 5.65 (1H, d, *J* 10.14), 7.45 (5H, m, Ph). $\delta_C(CD_2Cl_2$, 62.9 MHz, −50 °C) 23.46, 27.31, 33.88, 63.96, 75.02, 124.91, 127.42, 128.55, 129.14.

§ The stability of the (*Z*)-alkene was independently checked in CD_2Cl_2 in the range −30 to +25 °C by ^{1}H NMR.

¶ Both isomers were obtained from the corresponding alkyne prepared following the procedure reported in ref. 16. The (*Z*)-isomer was then obtained by hydroboration with catecholborane (ref. 17); the (*E*)-alkene was prepared by photochemical isomerization of the (*Z*)-isomer.

‖ The rather large difference in reactivity observed between *cis* thiiranium ions **1** and **3** is not unexpected since the reaction may be compared to a carbonium ion formation process from a neutral substrate. The difference in sigma values for phenyl and 3,5-dichlorophenyl is 2 × 0.37 which applied to a unimolecular process having rho values of −4 leads to an estimate value for the reactivity ratio of 10^{-3}.

Coordination and oxidation of phosphine selenides with iodine: from cation pairs $[(R_3PSe)_2I^+]_2$ to (iodoseleno)phosphonium ions $[R_3PSeI]^+$ existing as guests in polyiodide matrices

Emma Seppälä, Frank Ruthe, Jörg Jeske, Wolf-W. du Mont* and Peter G. Jones

Institut für Anorganische und Analytische Chemie, Technische Universität Braunschweig, Postfach 3329, D-38023 Braunschweig, Germany. E-mail: w.du-mont@tu-bs.de

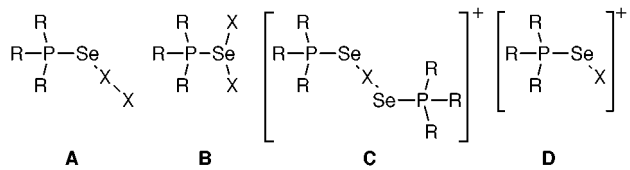
Received (in Basel, Switzerland) 23rd April 1999, Accepted 21st June 1999

An X-ray crystallographic study of adducts of trialkylphosphine selenides with > 1 equivalent of diiodine reveals that solid $Bu^t_3PSeI_3$ consists of cation pairs $[(Bu^t_3PSe)_2I^+]_2$ intercalated between I_5^- layers and that solid $R_2R'PSeI_7$ (R = Bu^t or Pr^i, R′ = Pr^i) contains $[R_2R'P–Se–I]^+$ cations with weak secondary I···I interactions to polyiodide networks.

Phosphine selenides $R_2R'P{=}Se$ are known act as donors towards dihalogen molecules, providing 1:1 adducts $R_2R'PSeX_2$.[1–7] *Molecular* structures have been determined for $R_2R'PSeI_2$ (type **A**, R, R′ = Ph, NMe_2, NEt_2,[3] and R = Bu^t, R′ = I[4]) and R_3PSeBr_2 (type **B**, R, R′ = NMe_2, C_6H_{11},[5] R = Bu^t, R′ = Pr^i or Bu^t[2,7]). Bromo- and iodo-selenophosphonium ions (type **D**) have been postulated as cations in ionic 1:1 adducts of phosphine selenide and dihalogen.[6] The first X-ray crystallographically characterised purely *ionic* solid 1:1 adduct was $(Pr^i_3PSe)_2I^+$ I_3^- **1a** (type **C**).[7] NMR spectra, however, suggest that in solutions of such 1:1 adducts equilibrium mixtures of several species are present.[2,6,7] Solutions prepared from $R_2R'P{=}Se$ (**2a**: R, R′ = Pr^i; **2b**: R = Bu^t, R′ = Pr^i; **2c**: R, R′ = Bu^t) and various amounts of I_2 always exhibit only one averaged ^{31}P NMR line accompanied by satellites arising from $^1J(^{77}Se,^{31}P)$, which decreases with increasing amounts of iodine. In CD_2Cl_2 solution, couplings $^1J(^{77}Se,^{31}P)$ are smaller than in C_6D_6 solution. Addition of < 5% of I_2 to $R_3P{=}Se$ leads to severe broadening and a slight downfield shift of the ^{77}Se NMR doublet. With larger amounts of I_2, as in the pure '1:1 adducts', the ^{77}Se resonances become too broad to be detected. This indicates kinetic lability of $R_3PSe–I_2$ systems and equilibration by exchange reactions that are fast on the ^{31}P and ^1H NMR time scales.

Such an equilibrium mixture is 'frozen' in solid $Bu^t_3PSeI_2$ **1c** [consisting of *molecular* $Bu^t_3PSe–I–I$ and *ionic* $(Bu^t_3PSe)_2I^+$ I_3^-].[2,7]

The transition from the molecular adduct $Bu^t_3PSeI_2$ to the cationic species $(Bu^t_3PSe)_2I^+$ is completed by adding slightly more iodine to solutions of **1c**. This leads to the solid compound $(Bu^t_3PSe)_2I^+$ I_5^- **3**. Cations with linear Se–I–Se arrangements that are well separated from each other and from the counter anions, are known from Se_6IAsF_6 and from related Se-coordinated $[L_2I]^+$ [L = *N*-methylbenzothiazole-2(3*H*)-selone].[8] Compound **3**, however, consists of *pairs* of cations $[(Bu^t_3PSe)_2I^+]_2$ [Fig. 1(a), (b)] intercalated into channels emerging from the corrugated structure of the polymeric I_5^- counter anion. The polymeric I_5^- ion creates channels between adjacent layers that offer suitable space for *pairs* of cations. Within these pairs, Se···Se contacts are shorter than the van der Waals radii; these cation pairs are well separated from the anionic network.



Scheme 1 Structural alternatives of phosphine selenide halogen adducts.

Use of an *excess* of iodine on $[I(py)_2]^+$ $[I_3]^-$ is known to provide solid $[I(py)_2]^+$ $[I_7]^-$.[9] Pr^i_3PSe **2a** and $Bu^t_2Pr^iPSe$ **2b** on reaction with excess iodine, however, do not form higher polyiodides of $(R_3PSe)_2I^+$ cations, but instead provide compounds of the composition $R_2R'PSeI_7$ **4a**, **4b** that represent the first examples of $[R_3PSeI]^+$ cations (type **D**). ^{31}P NMR spectra of these compounds exhibit, in comparison with **1a**, **1b**,[7] further decreased coupling constants $^1J(^{77}Se, ^{31}P)$, which are now similar to that of the type **B** molecular adduct $Pr^i_3PSeBr_2$, which contains a P–Se single bond.[7] The higher iodine content of $R_2R'PSeI_7$, compared with $(Me_2N)_3PSeI_4$ and $(Morph)_3PSeI_5$,[10] leads to improved separation of the $[R_2R'PSeI]^+$ cations of **4a** and **4b** from the surrounding weakly donating polyiodide networks.

Rather long cation–anion I···I distances in **4a** and **4b** (between 324.8 and 330 pm) correlate well with the shortest yet observed (P)–Se–I bonds (256.3–257.8 pm) in their $[R_2R'P–Se–I]^+$ cations.

The slight steric differences between the alkyl groups of the cations of **4a** and **4b** lead to quite different long-range order of their polyiodide anion structures. In solid **4b** (Fig. 2), one iodide anion [I(3)] bridges two of the $R_2R'PSeI^+$ cations and is in further contact with three I_2 molecules [*d*(I–I) 274–275 pm within the I_2 units], one of which [I(4)–I(5)] contacts the other I^- anion [I(6)]. I(6) is in contact with five I_2 molecules; of these, I(11)–I(12) is the only *terminal* I_2 molecule (Fig. 2). In solid **4a** (Fig. 3), one I^- [I(9)] is surrounded by two cations [$Pr^i_3P(1)$–Se(1)–I(1) and $Pr^i_3P(2)$–Se(2)–I(4)] and four I_2 molecules (when one I···I_2 distance of 368 pm is included), two (five-coordinated) I^- are in contact with one cation [I(7) with $Pr^i_3P(3)$–Se(3)–I(22), I(11) with $Pr^i_3P(4)$–Se(4)–I(5)] and four I_2 molecules, and the fourth I^- [I(20)] is surrounded by five I_2 molecules (Fig. 3).

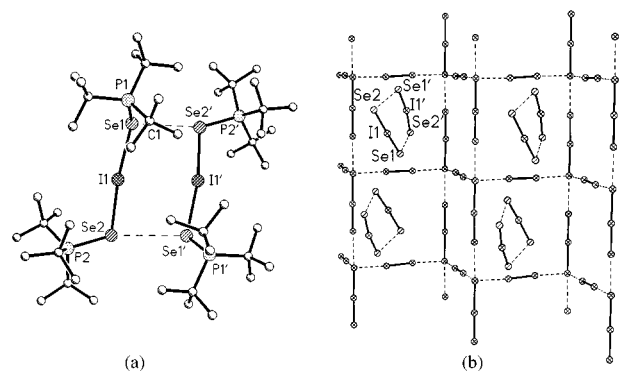


Fig. 1 (a) Cation pairs of **3**, selected bond lengths (pm) and angles (°): I1–Se2 273.7(1), I1–Se1 276.7(11), P1–Se1 218.6(2), P2–Se2 219.0(2), Se1···Se2′ 367.9(1), Se2–I1–Se1 170.3(3), P1–Se1–I1 112.6(7), P2–Se2–I1 111.5(7) (symmetry operator for generating equivalent atoms: −x, 1 + y, 0.5 − z); (b) Layer structure of **3**: Bu^t_3P groups omitted.

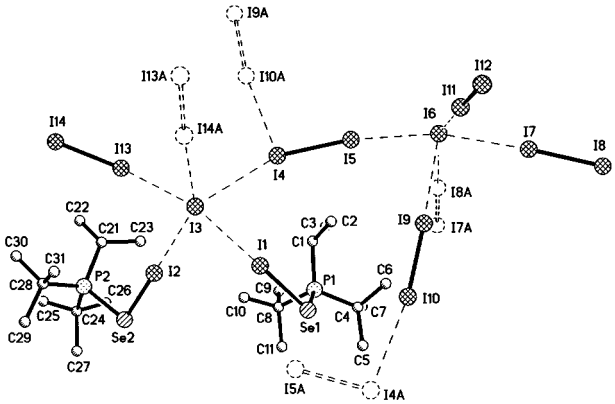

Fig. 2 Structure of **4b**, selected bond lengths (pm) and angles (°): I1–Se1 256.4(6), P1–Se1 223.5(1), I1···I3 330.2(4), I2–Se2 256.7(6), P2–Se2 223.7(1), I2···I3 324.8(5), P1–Se1–I1 102.1(3), P2–Se2–I2 101.6(4). Broken circles indicate atoms of other asymmetric units.

$[R_2R'P–Se–I]^+$ cations are also related to the rare class of alkane and arene selenenyl iodides R–Se–I[11–13] and with the (iodoseleno)imidazolium cation R^+–Se–I [*d*(Se–I) 259.1(5) pm] reported by Kuhn *et al.*[14] Compared with uncharged R–Se–I species,[11,13] all Se–I distances of the cations in **4a** and **4b** are slightly longer, which can be readily explained by the n → σ* nature of their anion-to-cation donor–acceptor interactions involving σ* orbitals of covalent Se–I bonds. We expect that the use of counter anions of low nucleophilicity will permit syntheses and studies of the electrophilicity of a larger number of stable (halogenoseleno)phosphonium ions of type **D**.

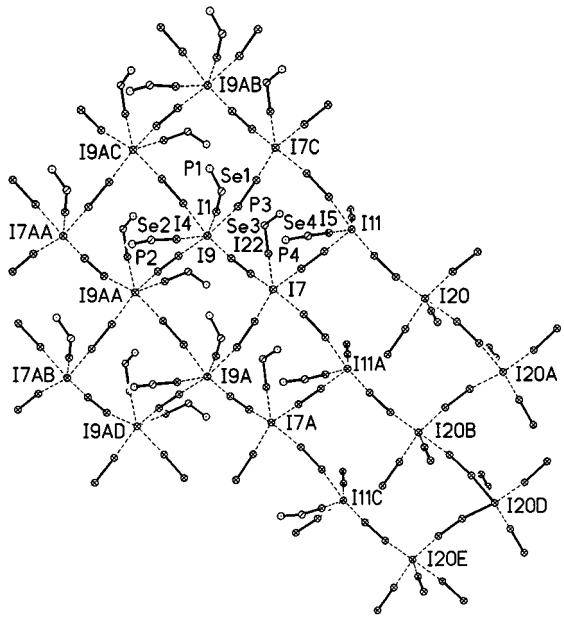

Fig. 3 Topology of I···I interactions within **4a**, selected bond lengths (pm) and angles (°): I1–Se1 256.3(2), P1–Se1 222.6(4), I1···I9 326.7(2), I4–Se2 256.4(2), P2–Se2 222.8(4), I4···I9 328.6(1), I22–Se3 257.1(2), P3–Se3 220.7(5), I22···I7 330.9(2), I5–Se4 257.8(2), P4–Se4 222.1(4), I5···I11 328.5(2), P1–Se1–I1 99.9(1), P2–Se2–I4 99.9(1), P3–Se3–I22 100.3(3), P4–Se4–I5 99.2(1); Pr^i groups omitted.

Received (in Cambridge, UK) 22nd April 1999, Accepted 25th June 1999

The synthesis and characterization of a novel three-dimensional gallium phosphatooxalate is described; the structure consists of GaO_4 tetrahedra and GaO_6 octahedra linked by phosphate and oxalate groups to form two-dimensional sheets between which are GaO_4N square pyramids, generating tunnels in which the monoprotonated 4,4′-bipyridine molecules reside; ^{71}Ga MAS NMR confirms the presence of four-, five- and six-coordinate Ga atoms.

Open-framework materials have been the subject of intense research owing to their diverse structural chemistry and potential applications as ion-exchangers, catalysts and adsorbents.[1–3] Many of these materials are synthesized in the presence of an organic amine as structure-directing agent.[4–7] The organic moieties are usually accommodated in the structural voids, and in some cases can be removed by calcination or other treatments. In addition to the use of organic templates for preparing large-pore 3-D networks, the incorporation of organic multidentate ligands into the structure also creates a new route to open-framework materials. Advantages of using multidentate components can be realized by the enhancement in the thermal stability of the structure and the efficacy of rational design of crystalline solids through their coordinating propensities and geometries.[8] Recently, many research activities have focused on the synthesis of inorganic/organic hybrid materials; we have synthesized some interesting three-dimensional organically templated iron and indium phosphates.[9,10] There is equal interest in synthesizing 3-D GaPOs containing large apertures. Here, we report the synthesis and structural characterization of an inorganic/organic hybrid material, $[Ga_5(OH)_2(C_{10}H_9N_2)(C_2O_4)(PO_4)_4]\cdot 2H_2O$ **1**. Its unique framework structure is built up from three different types of gallium–oxygen polyhedra, oxalate and phosphate groups, forming channels in which the monoprotonated 4,4′-bipyridine molecules are located. ^{71}Ga solid state NMR has been applied to study the different coordination environments for gallium.

In a typical hydrothermal synthesis, a mixture of Ga_2O_3, 2-methylpiperazine, 4,4′-bipyridine, $C_2H_2O_4\cdot 4H_2O$, H_3PO_4 and H_2O in a molar ratio of 1 : 3 : 3 : 5 : 5 : 444 was sealed in a Teflon-lined acid digestion bomb and heated at 165 °C for 3 days under autogeneous pressure followed by slow cooling at 10 °C h^{-1} to room temperature. The resulting product consists of pale yellow plate-shaped crystals of **1** obtained in 69% yield based on Ga. A suitable pale yellow crystal was carefully selected for structure determination by single-crystal X-ray diffraction.† The product is monophasic as judged by the total consistency of its powder X-ray diffraction pattern with that simulated from the atomic coordinates derived from the single-crystal X-ray study. Elemental analysis confirmed its stoichiometry. (Anal. Found: C, 13.89; H, 1.44; N, 2.70. Calc.: C, 13.81; H, 1.45; N, 2.68%.) We have also carried out retro-syntheses and replaced 2-methylpiperazine with tetramethylammonium hydroxide; the resulting products are either monophasic with a very low yield or a mixture of **1** and a small amount of unidentified orange side product. Thermogravimetric analysis data in air for **1** showed a broad weight loss in several overlapping steps which begins gradually at 180 °C, has a maximum rate at *ca*. 450 °C and is incomplete by 975 °C. The final decomposition product is mainly $GaPO_4$ (JCPS: 31-0546). The weight loss in the initial step can be attributed to the loss of water molecules in the structural channels. The framework structure is stable up to 350 °C in air, as indicated from powder X-ray diffraction.

The three-dimensional framework of **1** consists of anionic sheets made of GaO_4 tetrahedra and GaO_6 octahedra connected *via* coordinating PO_4^{3-} and $C_2O_4^{2-}$ anions, and bridging GaO_4N square pyramids that interlink the sheets. The layer constructed from phosphates, oxalate and two types of Ga–O polyhedra in the *bc*-plane is shown in Fig. 1. Each GaO_4 tetrahedron is coordinated to four phosphate tetrahedra of which two connect one GaO_4 and two GaO_6 polyhedra in the same sheet while the other two connect one GaO_4, one GaO_6 and the bridging GaO_4N. Oxalate anions act as bis-bidentate ligands to two Ga(1) and form dimers of GaO_6 octahedra.

The coordination by the oxalate leads to a distorted octahedron for Ga(1), as indicated by the wide range of Ga–O bond lengths [1.887(3)–2.057(4) Å] and the O–Ga–O bond angle [81.5(1)°] subtended by the oxalate group. Connectivity between the dimers is *via* $P(1)O_4^{3-}$ and GaO_4N. Bond-valence calculations indicate that the bridging atom, O(11), between GaO_6 and GaO_4N is a hydroxo oxygen. The Ga(1)–O(11)–Ga(3) bond angle is 134.9(2)°. GaO_4N square pyramids, positioned in between the layers, join the GaO_6 and $P(2)O_4^{3-}$ from different layers, generating two types of tunnels parallel to the [001] direction (Fig. 2). Monoprotonated 4,4′-bipyridine cations are accommodated in the 12-membered void while the water molecules are located in the 8-membered channel. Ga(3) sits on a twofold axis and is bonded to four oxygens in the basal plane [Ga–O 1.869(4) Å (2×), 1.943(4) Å (2×)] and one nitrogen at the vertex [Ga–N 2.024(7) Å]. The two rings of 4,4′-bipy are twisted at an angle of 35.1°.

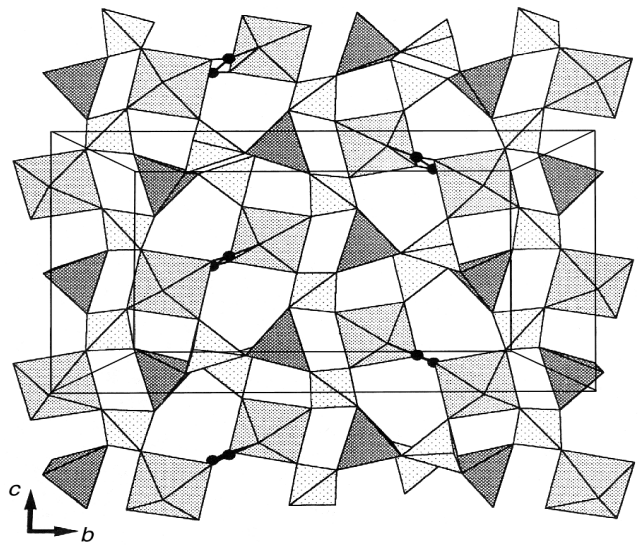

Fig. 1 Section of a sheet in **1** showing the connectivity among the Ga–O polyhedra, phosphate and oxalate anions. GaO_6 octahedra are medium grey, GaO_4 tetrahedra are dark grey and PO_4 tetrahedra are light grey. Solid circles are the carbon atoms of oxalate groups.

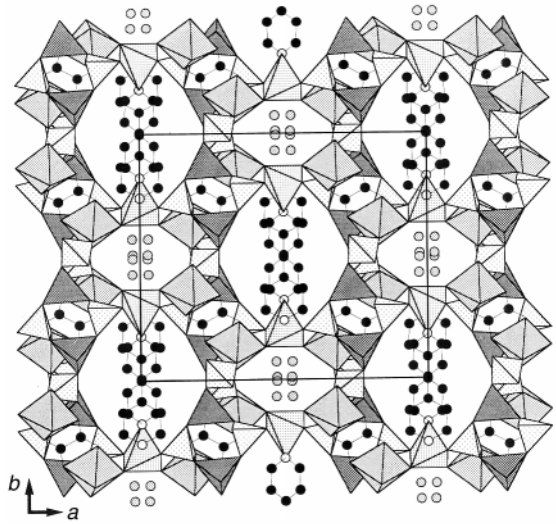

Fig. 2 Structure of **1** viewed along the [001] direction. Polyhedra with decreasing shading: GaO_4 tetrahedra, GaO_6 octahedra, GaO_4N square pyramids and PO_4 tetrahedra. Solid circles, C atoms; open circles, N atoms; stippled circles, water oxygen atoms.

The most interesting structural feature of **1** is the presence of GaO_6 octahedra, GaO_4N square pyramids and GaO_4 tetrahedra. In other microporous gallium phosphates, most frameworks are composed of some combinations of four-, five- or six-coordinate gallium atoms and PO_4 tetrahedra. $Rb_2[Ga_4(HPO_4)(PO_4)_4]\cdot 0.5H_2O$ and $GaPO_4$-14 are the other two examples in which gallium atoms have mixed four-, five- and six-coordination.[11,12] Because there is little known on solid state Ga NMR owing to intrinsic experimental difficulties,[13] it would be of great interest to investigate the correlation between the ^{71}Ga NMR of **1** and the structure. Fig. 3 shows the ^{71}Ga NMR spectrum (I = 3/2, ν = 121.84 MHz) with spinning rate of 12000 Hz and a single 45° pulse (a hard B_1 = 120 kHz is used). Chemical shifts were measured relative to the $[Ga(H_2O)_6]^{3+}$ ion in a gallium nitrate solution. Because there is a linear correlation between ^{27}Al and ^{71}Ga NMR chemical shifts in isostructural Al and Ga compounds,[14] the resonances at δ 116.4 and 94.0 correspond to tetrahedrally and octahedrally coordinated gallium, respectively. Interestingly, an additional resolved band at δ 66.8 is evident. We can compare the NMR spectrum of **1** with the ^{71}Ga MAS NMR of $[Ga_4(C_{10}H_9N_2)_2(PO_4)(H_{0.5}PO_4)_2(HPO_4)_2(H_2PO_4)_2(H_2O)_2]\cdot H_2O$ **2**,[15] where X-ray structure analysis shows only octahedral and tetrahedral gallium.Two bands at δ 94.0 and 116.4 were observed for **2**, while no band below δ 90 is evident. Therefore, we conclude that the resonance at δ 66.8 corresponds to the five-coordinate gallium (GaO_4N square pyramid). To our knowledge solid state NMR of five-coordinate gallium has not been documented previously. The splitting in the band at δ 116.4 reflects the residual line shape originated from the second order quadrupolar interaction associated with the large electric field gradient (efg) in the GaO_4 unit. By contrast, both GaO_6 and GaO_4N moieties show relatively smaller efg values. The large upfield shift for five-coordinate gallium is believed to be due to the strong shielding by directly bonded nitrogen.

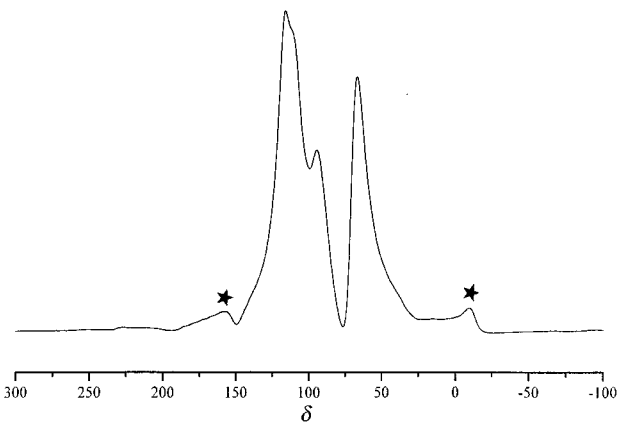

Fig. 3 ^{71}Ga MAS NMR spectrum for **1**. Asterisks denote spinning side bands.

In summary, this work illustrates that a novel gallium phosphatooxalate with a framework structure is synthesized hydrothermally and structurally characterized by single-crystal X-ray diffraction and ^{71}Ga MAS NMR spectroscopy. There is a good correspondence between the NMR spectrum and the structure.

We thank the Institute of Chemistry, Academia Sinica, National Science Council, and Chinese Petroleum Corp. for support, and Ms. F.-L. Liao and Prof. S.-L. Wang at the National Tsing Hua University for X-ray intensity data collection.

Notes and references

† X-Ray intensity data were collected on a Siemens SMART CCD diffractometer in 1271 frames with ω scans (width 0.30° and exposure time of 20 s per frame).

Crystal data for $[Ga_5(OH)_2(C_{10}H_9N_2)(C_2O_4)(PO_4)_4]\cdot 2H_2O$: monoclinic, space group $C2/c$, a = 18.3430(2), b = 15.9372(4), c = 9.1019(2) Å, β = 90.867(1)°, U = 2660.5(1) Å^3, Z = 4, M_r = 1043.74, D_c = 2.606 g cm^{-3}, μ(Mo-Kα) = 53.5 cm^{-1}, λ = 0.71073 Å, graphite monochromator, crystal dimensions 0.135 × 0.045 ×0.009 mm. Of the 2902 unique reflections collected ($2\theta_{max}$ = 56°, R_{int} = 0.0466), 2187 reflections were considered observed [$F_o > 4\sigma(F_o)$] after empirical absorption correction ($T_{min/max}$ = 0.826/0.942). Bond-valence calculations indicated that both Ga atoms are trivalent, O(11) had a valence sum of 1.24, and all other phosphate oxygens had values close to 2. The value for O(11) indicates that it is a hydroxo oxygen. The H atom was found in difference Fourier maps. Two lattice water sites, O(w1) and O(w2), were located in the structural tunnel. Both water oxygens initially showed very large thermal parameters. If the occupancy of O(w) is refined, the site occupancy factors obtained are 0.56(2) for O(w1) and 0.45(2) for O(w2), indicative of a half occupancy of the water of crystallization. The water hydrogens were not located. The 4,4′-bipyridine ligand acts as a monodentate ligand to Ga. To balance charge, the N atom which is not coordinated to Ga is protonated. The H atom which appears to be disordered over two positions, which are symmetry related by a twofold axis, is not included in the refinement. All other H atoms in 4,4′-bipyridine were located. Least-squares refinement (240 parameters) was performed with anisotropic thermal parameters for all non-hydrogen atoms and fixed isotropic thermal parameters (U = 0.05 Å^2) for all H atoms. $(\Delta\rho)_{max,min}$ = 0.79, −0.97 e Å^{-3}. The reliability factors converged to $R1$ = 0.0410, $wR2$ = 0.0921 and S = 1.072.

Highly selective catalysts for conversion of ammonia to nitrogen in gasified biomass

Robert Burch* and Barry W. L. Southward

Catalysis Research Centre, Department of Chemistry, University of Reading, Whiteknights, Reading, UK RG6 6AD. E-mail: r.burch@reading.ac.uk

Received (in Cambridge, UK) 21st May 1999, Accepted 29th June 1999

Almost zero emissions of NO_x can be achieved in the catalytic combustion of simulated biomass mixtures containing substantial amounts of ammonia by use of a heteropolyacid catalyst.

Renewable energy sources, such as biomass, will be of increasing importance in the future as part of a strategy to lower the total emissions of CO_2. Recently, the combustion of biomass-derived gas (biogas) for combined heat and power generation has been studied.[1–3] However, conventional flame combustion processes create problems because biogas contains significant quantities of NH_3 (600–4000 ppm) in addition to fuel components (CO, H_2, CH_4) and on combustion the NH_3 is largely converted into NO_x. Catalytic combustion may overcome this problem but until now the selectivity for the conversion of NH_3 to N_2 is unsatisfactory, typically < 70%.[2,4] Here, we describe a newly discovered process for removing NH_3 from biogas with almost zero production of NO_x.

The novel solution to the selective oxidation of NH_3 in a biogas fuel which we have discovered is to differentiate the feed components on the basis of their chemical properties. The crucial discovery is that ammonia, being a basic molecule, can be differentiated from carbon monoxide and hydrogen by using a catalyst which contains acidic sites, to preferentially adsorb the ammonia. Combination with redox sites allows the selective oxidation of ammonia to nitrogen.

The catalyst selected was 12-tungstophosphoric acid, $H_3PW_{12}O_{40}$ (ex Acros, hereafter denoted HPW). It is a heteropoly acid material based upon the Keggin unit structure.[5] Such materials are well known for their strong and uniform acid sites arising from the charge balancing protons associated with the Keggin unit anion. In addition they also possess strong redox properties arising from surface and bulk electron transfer processes.[5]

Catalyst testing was performed in a standard quartz flow microreactor described previously[6] at a gas hourly space velocity (volume of reactants per volume of catalyst per hour) of 250 000 h^{-1}. The reaction mixture comprised 6.0% CO, 4.0% H_2, 0.5% O_2, 1050 ppm NH_3, and balance He. Product analysis was by mass spectrometry (Hiden DSMS) with NO_x emissions and residual NH_3 levels being confirmed using an external NH_3 oxidation reactor (with independent oxygen supply) coupled with a NO_x chemiluminescence detector (Signal series 4000). The partial salts of HPW were prepared by reflux of the parent acid with varying stoichiometries of KNO_3 (Analar ex Aldrich) to produce $K_{2.06}H_{0.94}PW_{12}O_{40}$ (hereafter KHPW) and $K_{2.66}H_{0.34}PW_{12}O_{40}$ (hereafter KPW) using a standard exchange process.[5] Temperature-programmed desorption of NH_3 was performed by saturation of the sample at 150 °C in 1% NH_3–He followed by purging in He. The sample was then ramped at 12 °C min^{-1} and the evolved species monitored by mass spectrometry.

Fig. 1 illustrates the NH_3 TPD profile of HPW. The strong and uniform acidity of the material is demonstrated by the single, sharp combination of desorption peaks at *ca.* 600 °C. These comprise H_2O, NH_3, N_2 and NO, the latter at two orders of magnitude lower concentration. This was a significant result since it demonstrated that NH_3 may be fixed on the Brønsted

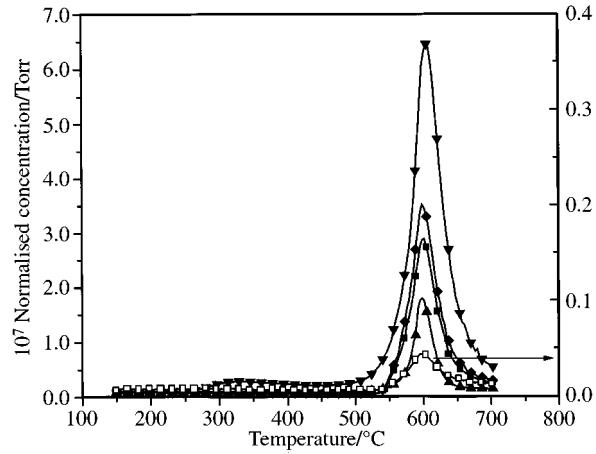

Fig. 1 NH_3 TPD results for HPW. Key: (□) NO (*m/z*) 30, (▲) N_2 (*m/z* 28), (▼) H_2O (*m/z* 18), (◆) NH_3 (*m/z* 17, corrected for H_2O contribution), (■) NH_3 (*m/z* 16).

acid sites of HPW and then converted into N_2 and H_2O by an internal reaction with labile oxygen from the Keggin anion. This reaction is presumed to proceed *via* the condensation of NO with NH_3, a proposal which is supported by temperature programmed reaction of a NO–CO–H_2 mix (1050 ppm 6.0%:4.0%) over NH_3 pretreated HPW. This yielded N_2 as the only product with peak N_2 production occurring at *ca.* 600 °C, the dissociation temperature of the NH_4–Keggin unit complex.[7] The amount of N_2 produced was consistent with a catalytic reaction between the NO and NH_3.

Fig. 2 shows the reaction of HPW pre-treated with NH_3 and then heated in the full reaction mixture. The results show that this material displays little or no catalytic function at temperatures below the NH_4^+ dissociation temperature. However, simultaneous with the onset of NH_4^+ dissociation there is a

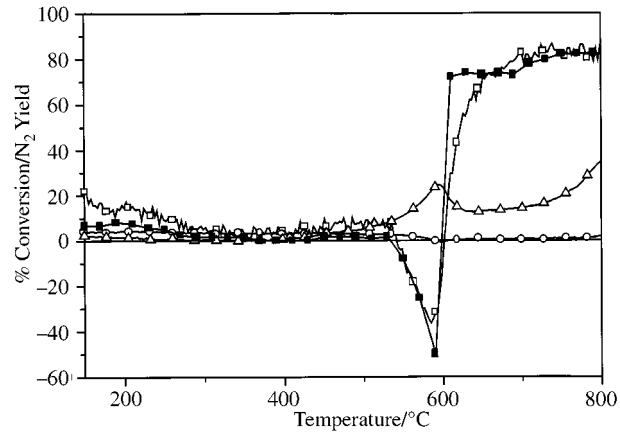

Fig. 2 Conversion profiles for simulated biomass stream over HPW. (6.0% CO, 4.0% H_2, 0.5% O_2, 1050 ppm NH_3 balance He). Key: (□) NH_3 conversion by MS (△) H_2 conversion by MS, (○) CO conversion by MS, (■) % N_2 yield by NO_x chemiluminescence.

sharp evolution of NO_x, as reflected in the negative N_2 production.

After this initial burst of NO_x, the catalyst then becomes active and highly selective for N_2 production, giving *ca.* 85% conversion of NH_3 and 100% selectivity to N_2. There is no measurable production of NO, NO_2, N_2O or HCN, and the nitrogen mass balance from both the mass spectrometry and NO_x analysis is 100% within experimental error. At the same time as we observe this very high conversion of ammonia, we see that the conversion of CO is $< 1\%$ and there is $< 20\%$ conversion of H_2 in the temperature range 600–750 °C.

These data for ammonia oxidation are consistent with an 'internal selective catalytic reduction' mechanism which can be summarised as follows. The Keggin unit oxidises the adsorbed NH_3 (trapped as NH_4^+) to NO_x using labile oxygen from the anion. The NO_x formed is retained briefly as part of the anion, and reacts with an NH_3 molecule to give N_2 and H_2O. The Keggin unit then re-oxidises by reaction with gas phase oxygen. This last step further accounts for the high chemical specificity of the process as it limits the concentration of active oxygen to react with CO and/or H_2. The rapid turnover between the proton and NH_4^+ states also prevents over reduction and collapse of the Keggin unit through dehydration,[8] with the result that the HPW is stable over the course of 6 h.

The requirement for protonic sites for the reaction was confirmed by the synthesis and testing of full and partial salts. The results in Fig. 3 show that, in comparison with the parent acid, KHPW displays a smaller NO_x formation (negative) peak and a lower activity, which increases gradually with temperature. KPW shows no negative NO_x peak and then an increasing level of N_2 production with temperature. For both the full and partial salts (KPW and KHPW) the activity for ammonia conversion to N_2 is much lower than for the HPA over most of the temperature range from 600–800 °C. The lower activity at *ca.* 600 °C is consistent with the requirement for acid sites to adsorb NH_3.

In conclusion, we have developed a strategy for the selective conversion of NH_3 from biomass-derived gases into N_2 by selective oxidation in competition with a large excess of CO and H_2. The key feature is the use of a catalyst which contains acid sites, to differentiate ammonia from CO and H_2, and redox properties, to oxidise the adsorbed species. Heteropoly acid catalysts have been used to demonstrate that the concept is viable and provides a novel way to overcome the NO_x formation associated with the direct combustion of biogas.

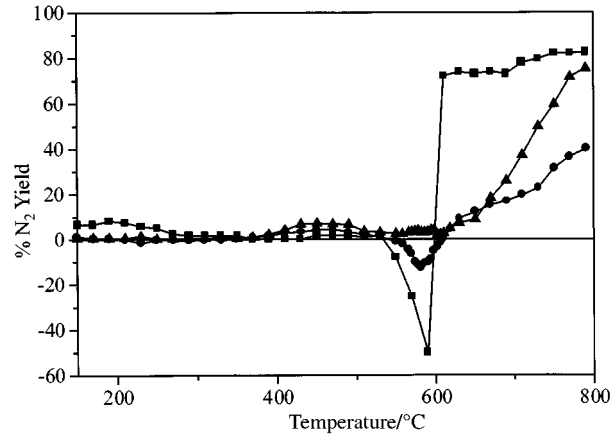

Fig. 3 N_2 production profiles for HPW and its salts. (6.0% CO, 4.0% H_2, 0.5% O_2, 1050 ppm NH_3 balance He). Key: (■) HPW ($H_3PW_{12}O_{40}$), (●) KHPW ($K_{2.06}H_{0.94}PW_{12}O_{40}$), (▲) KPW ($K_{2.66}H_{0.34}PW_{12}O_{40}$).

We are pleased to acknowledge the financial support of Alstom, DTI, and EPSRC through the FORESIGHT Challenge initiative. Helpful discussions with colleagues at Reading (Mr Matthieu Amblard), Cranfield University (Mr J. J. Witton, Professor B. Moss, Mr J. M. Przybylski, and Dr E. Noordally) and at Alstom (Mr M. Cannon) are gratefully acknowledged.

[$PdCl_2$($dppfO_2$-*O*,*O*′)]: a simple palladium(II) complex with a rare tetrahedral structure

Jeremy S. L. Yeo, Jagadese J. Vittal and T. S. Andy Hor*

Department of Chemistry, National University of Singapore, 3 Science Drive 3, Singapore 117543. E-mail: chmandyh@nus.edu.sg

Received (in Cambridge, UK) 19th May 1999, Accepted 1st June 1999

Single-crystal X-ray diffraction analysis of $PdCl_2$($dppfO_2$) [$dppfO_2$ = 1,1′-bis(oxodiphenylphosphoranyl)ferrocene] shows a rare tetrahedral geometry at a d^8 metal centre; physical and spectroscopic characterisations indicate a paramagnetic species.

The coordination and catalytic chemistry of 1,1′-bis(diphenylphosphino)ferrocene (dppf) has been reviewed.[1] There are ample examples in the recent literature that demonstrate the significance of this diphosphine ligand.[2] Like other phosphines, it can be readily oxidised to its mono- and di-oxide forms.[3] The structure of the latter, 1,1′-bis(oxodiphenylphosphoranyl)ferrocene ($dppfO_2$) is of interest to a number of groups, notably those of Hor,[3b] Pilloni,[3c] Postel[3d] and Hashmi.[3e] Phosphine oxides in general have attracted attention in view of their weak coordinating ability[4] and their function as co-catalysts,[5] crystallisation aids,[6] *etc*. The chemistry of Ph_3PO, the most familiar phosphine oxide, is well established.[4] The coordination ability of some diphosphine oxides[7] is also known, although less so for $dppfO_2$.[3] Our interest in Pd^{II}–dppf chemistry stems from the rich catalytic activities shown by many dppf complexes of Pd(II).[2b–h] Some of these complexes are susceptible to oxidation in solution and the decomposition product is generally assumed to be chiefly free $dppfO_2$.[3a] There is hitherto no report on the coordination chemistry of $dppfO_2$ with Pd(II) although such complexes with other diphosphine oxides are known.[7] Herein, we report the isolation of a simple Pd(II)–$dppfO_2$ complex with a rare mononuclear tetrahedral Pd(II) centre which, to our knowledge, has not been reported in the literature. It is well known that d^8 platinum metals overwhelmingly favour square planar structures and only Ni(II) forms a significant number of tetrahedral complexes.

Addition of $dppfO_2$ to [$PdCl_2(MeCN)_2$] in CH_2Cl_2 gives [$PdCl_2$($dppfO_2$-*O*,*O*′)] **1** in 81% yield.† This complex was originally obtained as a by-product in the reaction of [$Pd_2(dppf)_2(\mu\text{-}S)_2$] with COS. Its isolation contrasts with an earlier unsuccessful attempt to crystallise a palladium-containing triphenylphosphine oxide complex.[8] The IR spectrum of **1** (CH_2Cl_2) exhibits two strong ν(P–O) peaks at 1260 and 1269 cm^{-1}. The ^{31}P NMR spectrum in CD_2Cl_2[9] shows a broad peak at δ 34.0 and a minor resonance at δ 47.2, tentatively assigned to [$PdCl_2$(μ-$dppfO_2$)]$_2$. Upon standing for a week, this solution decomposes readily to give predominantly free $dppfO_2$ (δ 28.2). The electronic spectrum shows two bands at 20 264 [$^3T_1(F) \rightarrow {}^3A_2(F)$] and 26 900 cm^{-1} [$^3T_1(F) \rightarrow {}^3T_1(P)$], similar to that of a typical tetrahedral nickel(II) complex.[10] The magnetic moment[11] (2.48 μ_B) is lower than that of a typical Ni(II) tetrahedral complex (*ca.* 3.2 μ_B) but still consistent with paramagnetic Pd(II) with two unpaired electrons. The cyclic voltammogram shows a reversible one-electron couple with $E_{1/2}$ = 0.410 V (*vs.* [$FeCp_2$]$^+$–[$FeCp_2$]). Similar behaviour has been reported for $PdCl_2$(dppf) (0.430 V)[2a] and $dppfO_2$ (0.573 V).[3a] The remote possibility of an internal electron transfer that generates Pd(I) and Fe(III) is thereby eliminated. Similar observations were reported for some Cu(II)–$dppfO_2$ complexes[3f] and point to an oxygen-donating $dppfO_2$ ligand coordinated to a paramagnetic Pd(II) centre. The rarity of the postulated structure merited a crystallographic analysis.‡ This confirmed a mononuclear neutral complex with a chelating $dppfO_2$ and two terminal chlorides (Fig. 1). The near-ideal tetrahedral geometry at the Pd(II) centre is exemplified by the large intra- and inter-ligand angles [O1–Pd1–O2, Cl1–Pd1–Cl2 and O–Pd–Cl angles of 104.3(3), 120.4(2) and 107.8° (av.), respectively]. The dihedral angle between the {PdO_2} and {$PdCl_2$} planes (84.2°) also reflects a tetrahedral rather than a 'distorted square-planar' description. O-donation leads to lengthening of the P–O bonds (av. 1.512 Å) compared to those in $dppfO_2$ (1.495 Å[3]). This is also consistent with a stronger P–C (C_5 plane) bond (av. P–C 1.772 Å) compared to those in [$PdCl_2$(dppf)] (av. P–C 1.804 Å[2d]). There is little geometric distortion of the ferrocenyl C_5, moieties, the C_5 rings being planar with tilts of 3.6(7)° and torsional twist of < 2° (close to mirror symmetry). C1–P1 and C6–P2 deviate slightly from the mean plane by +0.12 and +0.008°, respectively.

The analogous $NiCl_2$($dppfO_2$) complex can be obtained only in poor yields from $NiCl_2 \cdot 6H_2O$ and $dppfO_2$ in propan-2-ol at room temperature or under reflux. Attempts to synthesise the platinum analogue have been unsuccessful. This is not surprising in view of the even stronger preference of Pt(II) for square planar coordination. The tetrahedral geometry of **1** is probably imposed by the large bite angle as a consequence of the sterically demanding chelating ring in $dppfO_2$. Its isolation demonstrates, for the first time, that tetrahedral Pd(II) is sustainable even in a mononuclear structure in which the metal centre is not constrained by neighbouring metal moieties.

[$PdCl_2$(dppf)] is probably the most well known dppf complex and finds extensive uses in catalysis (*e.g.* Grignard synthesis,[2b–d] hydrodehalogenation,[2f] *etc*.). Although this catalyst has demonstrated superior activity in many situations,[2d,e] in certain cases, its effectiveness is poor[2b,c] and reasons for this are

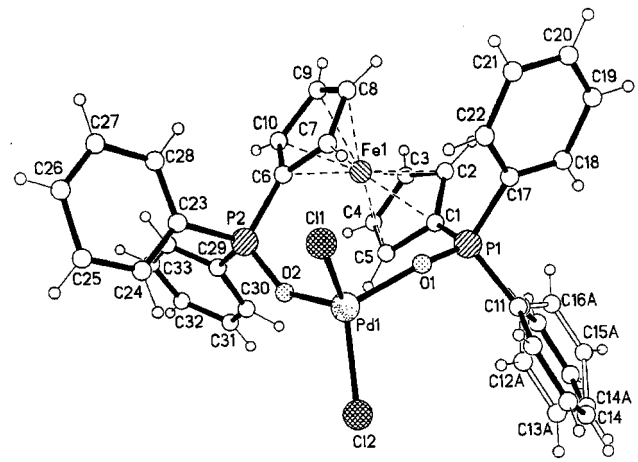

Fig. 1 Molecular structure of [$PdCl_2$($dppfO_2$-*O*,*O*′)]. Selected bond lengths (Å) and angles (°): Pd(1)–O(1) 1.974(8), Pd(1)–O(2) 1.968(7), Pd(1)–Cl(1) 2.222(4), Pd(1)–Cl(2) 2.204(3), P(1)–O(1) 1.495(9), P(2)–O(2) 1.529(6), P(1)–C(1) 1.780(9), P(1)–C(11) 1.781(10), P(1)–C(17) 1.781(9), P(2)–C(6) 1.764(11), P(2)–C(23) 1.785(13), P(2)–C(29) 1.791(10), O(1)–Pd(1)–O(2) 104.3(3), Cl(1)–Pd(1)–Cl(2) 120.4(2), O(1)–Pd(1)–Cl(1) 100.2(3), O(1)–Pd(1)–Cl(2) 112.7(3), O(2)–Pd(1)–Cl(1) 110.8(3), O(2)–Pd(1)–Cl(2) 107.3(2), P(1)–O(1)–Pd(1) 158.3(6), P92)–O(2)–Pd(1) 139.9(5).

presently not well understood. It is commonly accepted that $PdCl_2$(dppf) loses its catalytic efficiency after losing its phosphine ligand (in the form of $dppfO_2$) *via* $PdCl_2(dppfO_2)$. Isolation of **1** and its reasonable stability suggested that the current perception is not necessarily correct. The loss of activity rather may be linked to the geometric changes for Pd(II) upon oxidation of its dppf ligand. For example, we have recently demonstrated that C–C coupling and hydride transfer[2g,h] occur very efficiently on a planar Pd(II) core. Oxidative addition of tetrahedral Pd(0) gives a Pd(II) intermediate which must be geometrically rigid[12] for effective reductive elimination to occur. Loss of such rigidity could adversely affect the catalytic efficiency. Oxidation of the phosphine ligand also leads to a change in bite angle which would have an effect on catalytic activities.[13]

The authors acknowledge the National University of Singapore (NUS) for support (Grant RP 960664/A). We thank G. K. Tan for assistance in X-ray analysis, Y. P. Leong for assistance in the preparation of this manuscript and the technical staff of the department for professional support. Discussions with Y. K. Yan and Z. H. Loh are much appreciated. Notes and references

† *Synthesis* of [$PdCl_2$($dppfO_2$-*O*,*O*′)]: addition of $dppfO_2$ (0.074 g, 0.126 mmol) to a CH_2Cl_2 solution (40 cm^3) of [$PdCl_2(MeCN)_2$] (0.032 g, 0.125 mmol) resulted in a brown suspension that was stirred for 12 h. Filtration and concentration gave an orange solution. Layering of hexane on this solution gave red crystals of **1**, which were collected and washed with hexane and Et_2O (yield 81%). Found: C, 53.42; H, 4.02; Cl, 10.17. Calc. for $C_{34}H_{28}Cl_2O_2P_2FePd$: C, 53.47; H, 3.70; Cl, 9.28%.

‡ *Crystallographic data*: $C_{34}H_{28}Cl_2FeO_2P_2Pd$ **1**: M = 763.65, crystal dimensions: 0.33 × 0.18 × 0.13 mm, monoclinic, space group *Cc* (no. 9), a = 10.0444(2), b = 19.4070(3), c = 16.3157(1) Å, β = 91.340(2), V = 3179.58(8) $Å^3$, Z = 4, μ(Mo-Kα) = 1.321 mm^{-1}. 7985 reflections measured, 4010 unique (R_{int} = 0.0297), final $R1$ and $wR2$ values 0.0679 and 0.2104 for 3799 independent reflections [$I \geqslant 2\sigma(I)$] and 344 parameters. The data collection was performed at 295 K on a Bruker SMART CCD area-detector by the ω-scan method, within the limits $2.1 \leqslant \theta \leqslant 25.0°$. The data were corrected for absorption using an empirical method (SADABS[14a]) and the structure was solved by direct methods and refined by full-matrix least squares (SHELXTL[14b]). One of the phenyl rings (C11–C16) attached to P(1) was found to be disordered. Two disorder models (occupancies 0.7/0.3) were included in the least-squares refinements. Individual isotropic thermal parameters were refined for the major disorder component and common isotropic thermal parameter was refined for the other ring. Both the rings were treated as regular hexagons. Riding models were used to place all the hydrogen atoms in their idealized positions. CCDC 182/1307. $Mn^{II}(N_3)_2$(pyrazine). A 2-D layered structure consisting of ferromagnetically coupled 1-D $\{Mn(\mu\text{-}1,1\text{-}N_3)_2\}_n$ chains

Jamie L. Manson, Atta M. Arif and Joel S. Miller*

Department of Chemistry, University of Utah, 315 S. 1400 E., Salt Lake City, UT 84112-0850, USA. E-mail: jsmiller@chemistry.utah.edu

Received (in Bloomington, IN, USA) 20th April 1999, Accepted 21st June 1999

$Mn(N_3)_2$(pyz) (pyz = pyrazine) consists of ferromagnetically coupled linear chains of $\{Mn(N_3)_2\}_n$ comprised of μ-1,1-azido bridges together with μ-pyz ligands to afford 2-D planar layers.

In the last decade several families of molecule-based magnets have emerged,[1] including examples that exhibit ordering temperatures, T_c, in excess of 300 K.[2,3] For the latter high-T_c materials, both diamagnetic (cyanide) and paramagnetic ligands (tetracyanoethylene, TCNE) have been used to organize transition metal centers into 3-D networks. To better interpret magnetic properties of complex 3-D solids, reduced-dimensional structures, *i.e.* 1- and 2-D, are preferred to develop the necessary theoretical models. Recently, we have exploited the coordination chemistry of the dicyanamide ligand, $[N(CN)_2]^-$, which has produced a rich variety of polymeric architectures[4] with T_c values as high as 47 K.[5]

The azido ligand, N_3^-, unlike cyanide can bond two metal ions symmetrically either μ-1,1 through a terminal nitrogen which typically couple spins ferromagnetically, or μ-1,3 through both terminal nitrogens which couple spins antiferromagnetically.[6] Several monomeric,[7] dimeric[8] and polymeric[9] species typically with combinations of azido and pyridine-type ligands have been utilized to assemble a plethora of framework structures. $NMe_4[Mn(N_3)_3]$ is the only material where the metal coordination sphere contains only 1,3-N_3^- bridging ligands,[9a] while the others possess μ-1,3- or a mixture of μ-1,1- and μ-1,3-azido linkages, *i.e.* there are no characterized examples of polymeric solids that consist solely of μ-1,1-N_3^- bridging units. Hence, expecting ferromagnetic coupling, we sought to synthesize and structurally and magnetically characterize the first such example. Herein, we report the crystal structure and magnetic properties of $Mn^{II}(N_3)_2$(pyz), **1** (pyz = pyrazine).

The reaction of $MnCl_2$, NaN_3 and pyrazine in aqueous media leads to the formation of yellow plates of $Mn(N_3)_2$(pyz)† suitable for single crystal X-ray diffraction.‡ Each Mn^{II} ion is octahedrally coordinated to four different N_3^- ligands and two axial pyrazine ligands. In turn, each N_3^- ligand is μ-1,1-bound to two Mn^{II} metal centers. The MnN_6 octahedron is markedly distorted, with Mn–N_{azido} distances ranging from 2.198(12) to 2.270(14) Å (averaging 2.235 Å) and two equivalent Mn–N_{pyz} distances of 2.299(4) Å while *cis*-N–Mn–N angles range from 80.1(4) to 101.2(5)°. The Mn^{II}–N bond distances found for the MnN_4 equatorial plane are typical of azide coordination while the longer Mn–N_{pyz} distances are similar to those found in $Mn[N(CN)_2]_2$(pyz).[4b] The N–N distances of the azido ligand range from 1.091(18) to 1.248(17) Å (averaging 1.170 Å) and reflects typical double bond character, and as such, N(1)–N(2)–N(3) and N(4)–N(5)–N(6) bond angles are 178.5(14) and 179.4(13)°, respectively. Interestingly, the azide ligands do not reside within the Mn–N–Mn–N plane but form angles of 19.2(8) and 15.4(7)°. The solid consists of 1-D $\{Mn(N_3)_2\}_n$ linear chains linked *via* μ-pyz ligands to afford an extended 2-D layered network, Fig. 1, with intranetwork Mn···Mn separations of 3.412 (*via* azide) and 7.385 Å (*via* pyz) while the shortest internetwork Mn···Mn separation is 8.412 Å.

The magnetic susceptibility of **1** was measured between 2 and 300 K in a 1 kOe dc field upon warming. Above 10 K the data can be least-squares fit to the Curie-Weiss expression, $\chi \propto g/(T - \theta)$, with $g = 2.037(1)$ and $\theta = 5.51(3)$ K, Fig. 2, indicative of ferromagnetic coupling between the Mn^{II} metal sites joined *via* the μ-1,1-N_3^- ligands. The Lande-g value is in good agreement with the literature.[9c] χT has a value of 4.63 emu K mol^{-1} at 300 K, slightly larger than the expected value (4.38 emu K mol^{-1}) for isolated $S = 5/2$ Mn^{II} ions and due to ferromagnetic coupling increases gradually upon cooling to *ca.* 50 K. Below this temperature, χT increases to a maximum value of 9.7 emu K mol^{-1} at 5 K due to rapidly increasing ferromagnetic correlations between adjacent spin carriers. Upon cooling to 2 K, χT decreases quickly due to interchain antiferromagnetic interactions through the bridging pyrazine ligands. To determine the exchange parameters *via* each bridge type, χT was fit to the $S = 5/2$ Fisher chain model, $\chi_{1\text{-}D}$,[10] [eqn. (1)] in conjunction with an additional mean-field correction term, χ_{MF}, [eqn. (2)] assuming $z = 2$,[11] where N is Avogadro's number, μ_B is the Bohr magneton, k_B is the Boltzmann constant and z is the number of nearest neighbours. The best least squares fit parameters gave $g = 2.037(3)$, $J/k_B = 0.61(4)$ K, and J'/k_B

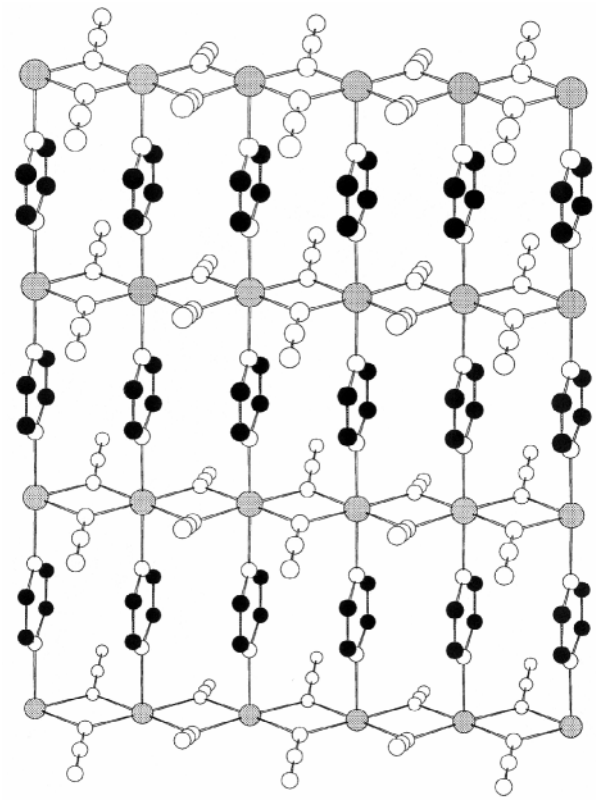

Fig. 1 Crystal structure of $Mn(N_3)_2$(pyz) showing a single 2-D layer. The shaded, open and filled spheres represent Mn, N and C, respectively. Hydrogen atoms have been omitted for clarity.

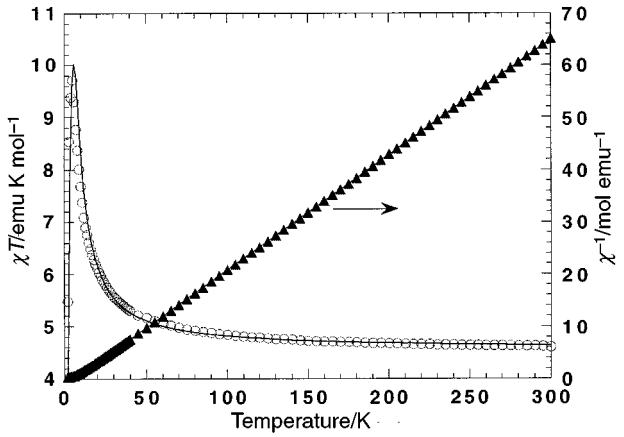

Fig. 2 Temperature-dependence of χT (○) and the reciprocal molar magnetic susceptibility, χ^{-1} (▲) for $Mn(N_3)_2(pyz)$. The heavy line denotes the theoretical fit of the data to eqn. (1) and (2).

$= -0.24(3)$ K for ferro- and antiferro-magnetic interactions *via* the azide and pyrazine ligands, respectively.

$$\chi_{1-D} = \frac{Ng^2\mu_B{}^2S(S+1)}{3k_BT} \bullet \frac{1+u(K)}{1-u(K)};$$

$$\text{where } u(K) = \coth K - 1/K \text{ and } K = \frac{2JS(S+1)}{k_BT} \qquad (1)$$

$$\chi_{MF} = \frac{\chi_{1-D}}{[1-\chi_{1-D}(2zJ'/Ng^2\mu_B{}^2)]} \qquad (2)$$

Weak ferromagnetic coupling is anticipated when the Mn–N–Mn bridge angles are appreciably less than 103–104°.[12] These angles are 97.9(5) and 101.2(5)° for **1** and hence suggest ferromagnetic coupling. Bridge angles approaching 105° give rise to strong ferromagnetic coupling due to accidental orthogonality of the magnetic d_{yz} orbital as shown by EHMO (extended Huckel molecular orbital) calculations.[13] By comparison, Mn–N–Mn angles of 104.6 and 101.0°, respectively, lead to J/k_B = 3.5 K for the dinuclear complex $(N_3)_2[Mn(terpy)_2]_2(X)_2$ (terpy = 2,2′:6′,2″-terpyridine; X = ClO_4^-, PF_6^-)[14] and 13.8 K for the alternating chain compound $[Mn(bipy)(N_3)_2]_n$.[13] A significantly reduced angle of 84.2° was reported for 2-D $[Ni(N_3)_2(tmeda)]_n$ (tmeda = *N*,*N*,*N*′,*N*′-tetramethylethylenediamine) which yielded antiferromagnetic exchange (−9.9 K) *via* the μ-1,1-N_3^- bridge.[15]

A broad maximum indicative of short-range antiferromagnetic ordering was observed at 2.7 K using low field $M(T)$ ($H_{dc} \leq 50$ Oe) and ac susceptibility measurements. For low dimensional solids, the actual ordering temperature lies below the maximum as elucidated by Fisher[10] from plots of $d\chi T/dT$, and for $Mn(N_3)_2(pyz)$, $T_N \approx 2$ K. Specific heat measurements are better suited to unambiguously identify T_N and are in progress. According to ac susceptibility, $\chi''(T)$ is frequency independent suggesting a non-glassy ground state. A shallow minimum at 3 K was observed in $\chi''(T)$, with the onset of spontaneous magnetization near 2 K and suggests the presence of a weak ferromagnetic ground state.

Isothermal magnetization experiments performed at 2 K show behavior typical of a soft ferromagnet as coercivity was not observed. Below *ca*. 6 kOe, the magnetization rises rapidly where a decrease in slope occurs, reaching a saturation magnetization, M_s, of 23530 emu Oe mol^{-1} at 50 kOe. This value is comparable, although slightly reduced, to the expected value of 27925 emu Oe mol^{-1} for isolated S = 5/2 ions.

The authors gratefully acknowledge the ACS-PRF (Grant #30722-AC5) and the U.S. Department of Energy (Grant #DE-FG03-93ER45504) for support of this work.

Communication 9/03406D

A facile reaction of Sb_2S_3 with $[CpCr(CO)_3]_2$: formation of a novel tetrachromium complex $[CpCr(CO)_3]_4(Sb_2S)$

Lai Yoong Goh,*[a] Wei Chen[b] and Richard C. S. Wong[b]

[b] *Department of Chemistry, University of Malaya, 50603 Kuala Lumpur, Malaysia*

Received (in Cambridge, UK) 6th May 1999, Accepted 1st July 1999

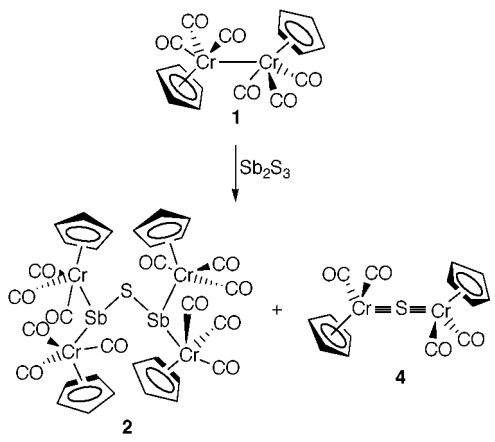
The reaction of $[CpCr(CO)_3]_2$ with Sb_2S_3 under mild reaction conditions led to the isolation of $[CrCp(CO)_2]_2S$ 4 and the new tetrachromium complex $[CpCr(CO)_3]_4(Sb_2S)$ 2, which has been characterized *via* a single crystal X-ray diffraction analysis.

Our earlier work has demonstrated the role of the 17-electron $CpCr(CO)_3$· species in the cleavage of the pnictogen tetrahedra P_4 and As_4,[1] and of mixed element P_4X_3 (X = S, Se) cages,[2] to generate complexes possessing a variety of geometries and structures. This communication reports the results from an extension of the investigation to Sb_2S_3.

In comparison to the organotransition metal complexes of the lighter elements of Group 15, those of antimony are scarce.[3] Most of the reported complexes derived from the reactions of the trihalo compounds SbX_3 or their alkyl derivatives, *e.g.* $RSbX_2$, R_2SbX, R_3Sb, $MeC(CH_2Sb)_3$ and $(Bu^tSb)_4$, with the anions of metal carbonyls, metal carbonyl clusters or cyclopentadienylmetal carbonyl fragments, as well as neutral transition metal fragments.[4] A few unique reactions generated antimony ligands from the reactions of elemental antimony with $[CpMo(CO)_3]_2$,[5] of the nortricyclic Zintl ion Sb_7^{3-} with $Ni(CO)_2(PPh_3)_2$[6] and of $S_8(Sb_2F_{11})$ with $Fe(CO)_5$.[7]

The reaction of $[CpCr(CO)_3]_2$ **1** with 6 mol equiv. of Sb_2S_3 in toluene under ultrasonication at ambient temperature for 48 h, led to the isolation of $[CpCr(CO)_3]_4(Sb_2S)$ **2** (19.3%), $[CpCr(CO)_2]_2(Cr{\equiv}Cr)$ **3** (5.8%) and $Cp_2Cr_2(CO)_4S$ **4** (46.6%) from the product mixture.† The tetrachromium complex **2** has been characterized spectroscopically‡ and by a single crystal X-ray diffraction analysis.§ Thermolysis of **2** at 80 °C, monitored by proton NMR spectral analysis, showed total degradation after 2 h to give **4** (28%), $Cp_4Cr_4S_4$ **5** (13%) and an insoluble as-yet-unidentified precipitate.

The reaction is represented in Scheme 1. In view of the facile dissociation of **1** into the 17-electron $CpCr(CO)_3$· monomeric species,[8] it is conceivable that the reaction proceeds *via* the attack of this reactive radical moiety on the ribbon-like polymeric structure of Sb_2S_3, cleaving the interlocking SbS_3 and SSb_3 tetrahedra in the structure,[9] producing the Cr_4Sb_2S complex **2** together with the Cr≡S≡Cr complex **4**, into which **2** also degrades under thermolytic conditions. Such reactions of Sb_2S_3 with an organometallic fragment under the mild conditions as utilised here is unprecedented, demonstrating the efficiency of the $CpCr(CO)_3$· species in the cleavage of the antimony–sulfur bonds of the polymeric structure of Sb_2S_3, as in the case of the cage molecules of the lighter elements of Groups 15/16.[1,2]



Scheme 1

An ORTEP plot of **2** is shown in Fig. 1. The molecule possesses an approximate C_2 symmetry with a butterfly configuration about the central sulfur atom. Each of the Sb atoms is coordinated to one S and two Cr atoms which form the base of a trigonal pyramid [angles ranging from 98.5(1) to 115.07(9)° at Sb1 and 98.8(1) to 114.83(9)° at Sb2]. Each Cr atom in turn is coordinated to one Cp ring and three CO ligands in a four-legged piano stool configuration. The Cr_2SbS fragments in the molecule belong to the electron precise pyramidal EM_2Y type[3c] [E = Sb, M = the 17-electron $CpCr(CO)_3$ fragment, Y = S]; the structure can be envisaged as the product of 'fusion' of two such units with the extrusion of a S atom, resulting in a bent Sb–S–Sb bridge [angle 93.9(3)°]. The Sb–Cr bond distances in **2** (2.837–2.849 Å) are longer than those found in $[\{Cr(CO)_5\}_3(\mu_3\text{-}Sb)]^-$ (2.624–2.636 Å)[10] and in $[Sb(Fe(CO)_4)_3\{Cr(CO)_5\}]^-$ (2.638 Å).[11] The Cr–Sb–Cr angles (115.07, 114.83°) are smaller than those in $[\{Cr(CO)_5\}_3(\mu_3\text{-}Sb)]^-$ (118.9, 122.2°).[10]

The new complex **2** is the first example of a transition metal complex containing a 'bare' antimony–sulfur bridging ligand with each antimony atom bonded to two metal atoms. The only other reported instance of such antimony–sulfur ligands, *viz.* the Sb_2S_6 ligand in the cationic cluster $[Fe_2(Sb_2S_6)(CO)_6]^{2+}$ is bonded to the Fe atoms only *via* its six S atoms.[7] The closest analogues to **2** are complexes containing an organoantimony–sulfur ligand, $\{(CO)_4Cr\}_n[(Ph_2Sb)_2S]$ and

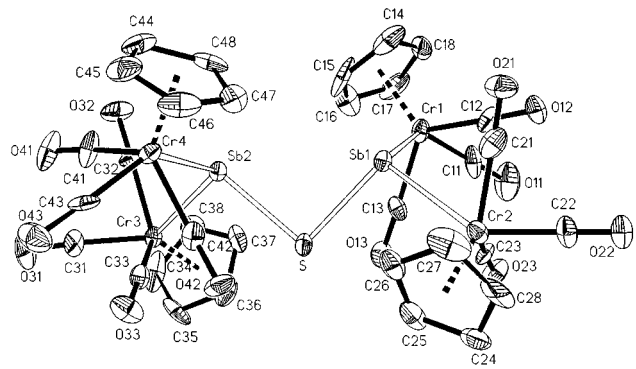


Fig. 1 Molecular structure of **2**. Selected bond lengths (Å) and angles (°): Sb1–S 2.466(5), Sb2–S 2.449(4), Sb1–Cr1 2.837(3), Sb1–Cr2 2.849(3), Sb2–Cr3 2.842(3), Sb2–Cr4 2.849(3), $Cp_{centroid}$–Cr 1.828–1.843; Sb1–S–Sb2 93.9(2), S–Sb1–Cr1 106.96(12), S–Sb1–Cr2 98.53(12), Cr1–Sb1–Cr2 115.07(9), S–Sb2–Cr3 98.82(12), Cr3–Sb2–Cr4 114.83(9), Cp–Cr–CO 112.4–125.0.

$\{(CO)_5Cr\}_n[(Ph_2Sb)_2S]$ (n = 1 or 2, depending on whether one or both Sb atoms are linked to Cr carbonyl fragments). Compared to **2**, the crystallographically characterized $\{(CO)_4Cr\}[(Ph_2Sb)_2S]$ complex possesses an Sb–S–Sb angle of 96.7(5)° and a Sb–Cr distance of 2.598(3) Å, much shorter than in **2**.[4l] Somewhat related parallels are the Mn⋍E⋍Mn 'inidene' complexes $[(MeCp)(CO)_2Mn]_2As_2E^-$ (E = S, Se)[12] and the ruthenium complex $(Cp^*Ru)_2(As_2S)_2$, the core structure of which consists of a Ru_2As_4 octahedron in which two edges are bridged by sulfur atoms.[13]

Notes and references

† *Experimental procedure*: a deep green suspension of $[CpCr(CO)_3]_2$ **1** (100 mg, 0.25 mmol) and Sb_2S_3 powder (503 mg, 1.48 mmol) in toluene (20 ml) was ultrasonicated at ambient temperature for 48 h. The resultant orange–green reaction mixture was filtered through Celite (2 × 1 cm disc, *ca.* 1.5 g) and concentrated to *ca.* 20 ml. The filtrate was absorbed onto Celite (*ca.* 2 g) and concentrated to dryness before loading onto a silica gel column (2 × 10 cm) prepared in *n*-hexane–toluene (1:1). Elution gave four fractions: (i) a brownish green eluate in *n*-hexane–toluene (1:1, 25 ml), which on concentration gave deep green crystals of $Cp_2Cr_2(CO)_4S$ **4** (43 mg, 0.11 mmol, 46.6% yield). (ii) A deep green eluate in *n*-hexane–toluene (1:1, 10 ml), from which was obtained lustrous deep green crystals of the starting dimer **1** (23 mg, 0.057 mmol, 23.0% recovery). (iii) A dark green eluate in *n*-hexane–toluene (1:2, 20 ml) which yielded fine dark green crystalline $[CpCr(CO)_2]_2$ **3** (5 mg, 0.014 mmol, 5.8% yield). (iv) A dark brown eluate in THF (15 ml), which on concentration yielded fine black crystalline $Cp_4Cr_4(CO)_{12}Sb_2S$ **2** (26 mg, 0.024 mmol, 19.3% yield). Elemental analyses. Calc. C, 35.56; H, 1.85; Cr, 19.26; O, 13.33; Sb, 22.59; S, 2.96. Found: C, 35.0; H, 2.27; Cr, 19.03; Sb, 22.88; S, 2.95%.

‡ *Selected spectroscopic data*: ^{1}H NMR (100 MHz, C_6D_6): δ 4.52 (s, η^5-Cp). ^{13}C NMR (100 MHz, C_6D_6): δ 89.61 (η^5-Cp). IR (cm^{-1}, Nujol): ν(CO) 1986s, 1954m, 1901vs; other bands, 1066vw, 1025vw, 840w, 722w. MS (EI, 70 eV): *m/z* 622 $[Cp_2Cr_2(CO)_4Sb_2S]$, 468 $[Cp_2Cr_2(CO)_4Sb]$, 417 $[CpCr(CO)_2Sb_2]$, 346 $[Cp_2Cr_2(CO)_4]$, 295 $[CpCr(CO)_2Sb]$, 149 [CpCrS].

§ *Crystal data* for $C_{32}H_{20}O_{12}SCr_4Sb_2$ **2**: M_r = 1080.04, monoclinic, space group $P2_1/c$, a = 20.181(5), b = 12.400(4), c = 15.209(8) Å, β = 106.26(3)°, V = 3653.7(24)° Å^3, D_c = 1.963 g cm^{-3}, Z = 4, $2\theta_{max}$ = 24.99°, Mo-Kα = 0.71073 Å, ω-scan, T = 300 K. From 6413 reflections, 2446 were observed [$I > 2\sigma(I)$]. Lorentz-polarization and absorption corrections were applied (empirical), μ = 53.073 cm^{-1}, transmission$_{max./min.}$ = 99.93/61.12. The structure was solved by the direct method (SHELXS86) and refined on F^2 (SHELXL93). All non-hydrogen atoms (except C38 and C47) were refined anisotropically; C38 and C47 were refined isotropically as their temperature factors became non-positive. H atoms were generated geometrically and were allowed to ride on their respective carbon atoms. The final R and wR {w = $[\sigma^2(F_o^2) + (0.0139P)^2]^{-1}$ where $P = 1/3(F_o^2 + 2F_c^2)$} are 0.0836 and 0.1011, respectively, for 450 variables. The maximum residual peak is 0.945 e Å^{-3}. Diffraction-quality crystals of **2** were obtained as brownish black polyhedra from a saturated solution in THF after a week at −28 °C. A selected crystal was coated in epoxy glue, and X-ray diffraction measurements were made on a CAD4 diffractometer. CCDC 182/1303. Reversible metal-directed assembly of clusters of vesicles

Edwin C. Constable,*[a] Wolfgang Meier,[b] Corrinne Nardin[b] and Stefan Mundwiler[a]

[a] *Institut für Anorganische Chemie, Spitalstrasse 51, CH-4056 Basel, Switzerland. E-mail: constable@ubaclu.unibas.ch*

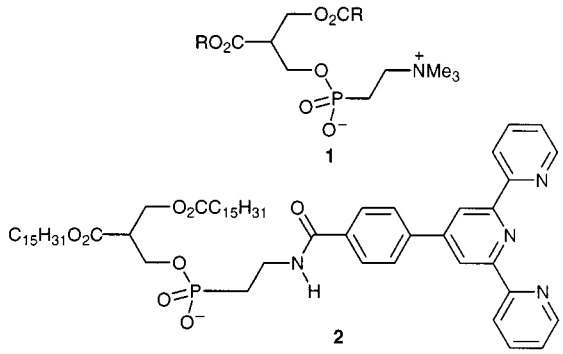
[b] *Institut für Physikalische Chemie, Klingelbergstrasse 80, CH-4056 Basel, Switzerland*

Received (in Cambridge, UK) 11th June 1999, Accepted 2nd July 1999

A terpy-functionalised phospholipid has been incorporated into lecithin vesicles and iron(II)-directed aggregation processes have been studied.

Self-assembly is a powerful methodology in supramolecular chemistry that allows the efficient formation of complex multidimensional structures from simple building blocks.[1] Much effort has been devoted to understanding the basic physical chemistry of self-assembled monolayers (SAMs), vesicles and micelles.[2] We have recently commenced a programme in which structural motifs with known self-assembly or molecular recognition paradigms are functionalised with metal-binding domains[3–5] and have described the formation and metal-initiated aggregation of SAMs bearing pendant 2,2′:6′,2″-terpyridine (terpy) motifs.[5] Here, we show that the introduction of a small amount of a terpy-functionalised phospholipid into 'normal' phospholipid vesicles leads to metal-initiated clustering and the formation of aggregates.

Hydrogenated L_α-lecithin **1** (a mixture of phospholipids with 31% R = $C_{16}H_{33}$, 59.75% R = $C_{18}H_{37}$, 5.71% R = $C_{20}H_{41}$ and 3.07% R = $C_{22}H_{45}$, average molecular mass 557 Da) was used as the host. A vesicle stock solution at a L_α-lecithin concentration of 10 mg cm^{-3} (1.8×10^{-2} M) was prepared;† the average vesicle mass was 3×10^7 g mol^{-1} corresponding to 54 000 molecules per vesicle and they have a mean hydrodynamic radius R_h of 54 nm and radius of gyration R_G of 51 nm as determined by dynamic and static light scattering.[6]‡ This gives $\rho = R_G/R_h = 0.944$ which is close to the theoretical value of $\rho = 1.0$ for hollow spheres.[7] The terpy-functionalised phospholipid **2** was prepared as previously described[5] and a 3 wt% amount added to the stock solution of the lecithin to give a total concentration of **2** of 3.29×10^{-4} M. The experimentally measured R_h and R_G were unchanged by the addition of the functionalised compound **2**, indicating no fundamental changes in the solution behaviour of **1** at this level of doping with **2**. The doping corresponds to an average of 970 molecules of **2** per vesicle. Freeze fracture replication transmission electron microscopy[8] revealed the presence of dispersed vesicles [Fig. 1(a)].



The free ligand **2** forms a typical purple iron(II) complex $[Fe(\mathbf{2})_2]^{2+}$ with a characteristic MLCT absorption maximum at 576 nm. Assuming that K_1 and K_2 for the formation of ML and ML_2 complexes are similar to those for terpy itself,[9] even with large excesses of iron, the 1:1 species is not of importance at *ca.* 0.1 mM ligand concentrations. The addition of aqueous $FeSO_4 \cdot 7H_2O$ to the modified vesicle solution resulted in a purple colour (λ_{max} 577–584 nm), indicating that the terpy is still available for coordination and that an $\{ML_2\}$ species is formed. Titration of aqueous Fe^{2+} into the stock solution reached a maximum absorbance at 582 nm at an M:**2** ratio of 0.7:1, compatible with the speciation calculations above and strongly suggesting that all of the terpy groups are on the *outer* surface of the vesicle.

The results of dynamic light scattering measurements as the iron(II) salt as titrated into the modified vesicle solution are presented in Fig. 2. The measured R_h increases smoothly past the 1:2 Fe^{2+}:**2** equivalence point until an Fe^{2+}:**2** ratio of *ca.* 4.5:1 is reached. After this point a rapid increase in the measured hydrodynamic radius occurs followed by precipitation of a violet solid when $[Fe^{2+}]$ reaches 1.76 mM. A control experiment with the stock solution in the absence of **2** showed

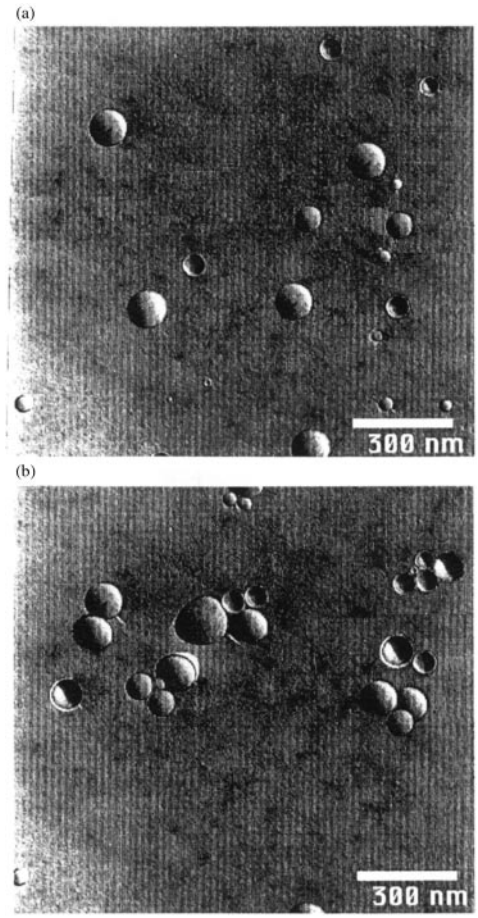


Fig. 1 (a) Freeze fracture electron micrograph of vesicles obtained with lecithin **1** (1.8×10^{-2} M) and **2** (3.29×10^{-4} M). No clustered vesicles are observed. (b) Freeze fracture electron micrograph of an identical vesicle solution after treatment with aqueous iron(II) sulfate to give an Fe^{2+}:**2** ratio of 4.5:1.

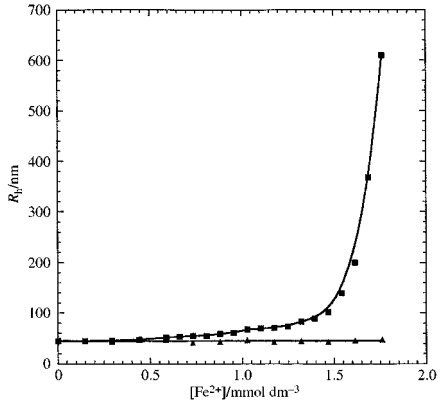

Fig. 2 Measured hydrodynamic radius of vesicles as a function of aqueous iron sulfate concentration. The data presented refer to the hybrid **1** + **2** vesicles (■) and to a control experiment with **1** alone (▲).

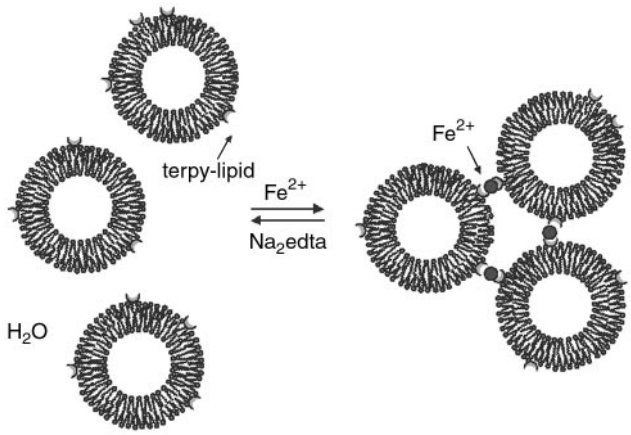
that the addition of the iron salt had no effect on the parent vesicles (Fig. 2). The aggregation process proved to be reversible, and the addition of a 100-fold molar excess of $Na_2(H_2edta)$ at 40 °C resulted in the discharge of the violet colour and restoration of the light scattering characteristics of the vesicle solution. At an Fe^{2+}:**2** ratio of 4.5:1, light scattering gave R_G = 108 nm and R_h = 106 nm consistent with an aggregation of the vesicles into clusters (see later). Metal-initiated transformation into giant vesicles can be rejected on the basis of the reversibility of the process upon addition of edta.

We propose that an aggregation process is occurring (Scheme 1) in which the surface terpy ligands are coordinating to the iron(II) centres. The low dilution of **2** within individual vesicles means that inter-vesicle coordination is favoured and each



Scheme 1 Proposed iron(II) induced aggregation process of modified vesicles.

coordination event will clip two vesicles together. The high Fe^{2+}:**2** ratios needed before precipitation occurs represent the statistical factors involved in bringing two ligands together. The dimensions indicate an average aggregation state of 3.1 ± 1.1 vesicles in the clusters at a ratio of Fe^{2+}:**2** of 4.5:1 and an increase in size as the amount of iron is increased. It has previously been reported[10] that biotin-functionalised vesicles may be aggregated into clusters through interaction with streptavidin, but the approach we present here utilises a remarkably simple metal–ligand recognition process for the aggregation.

Direct evidence for the aggregation comes from cryomicroscopy. Fig. 1(b) shows a freeze fracture electron micrograph of the material at a ratio of Fe^{2+}:**2** of 4.5:1. At this concentration, microscopy reveals that only a very few single vesicles are present, the majority being aggregated into clusters.

In conclusion, we have shown that iron(II) salts may be used to assemble modified vesicles into clusters in a reversible process. We are currently investigating the extension of the chemistry to other metal ions with the aim of introducing specific redox, magnetic or photophysical properties into the aggregates.

We thank the University of Basel and the Schweizerischer Nationalfonds for financial support.

Notes and references

† **1** was deposited on the wall of a glass vessel by evaporation of a 1.8 M $CHCl_3$ solution and then hydrated in doubly distilled water to give a multilamellar liposome dispersion. This was repeatedly frozen in liquid nitrogen and thawed, followed by repeated extrusion through Nanopore filters of 100 nm pore size to form unilamellar vesicles.

‡ The results of the static and dynamic light scattering were obtained by extrapolation to zero concentration of vesicles by dilution of the stock solution with doubly distilled water. This indicates that the vesicles and the vesicle clusters are stable under these conditions of dilution.

Received (in Columbia, MO, USA) 3rd June 1999, Accepted 30th June 1999

Silver benzenesulfonate is an example of a layered 'inorgano–organic' solid where the inorganic component is comprised of sulfonate-bridged silver(I) centers and the organic moiety is a phenyl group; the resulting network of silver ions forms a planar hexagonal array incorporating a previously unobserved six-fold metal-bridging mode for the sulfonate ion.

Currently, there are numerous well studied examples of 'inorgano–organic' lamellar solids.[1] This term is used to describe layered solids containing a planar backbone, comprised solely of inorganic elements, which also incorporate organic moieties as covalently bound pendant groups. Organic derivatization of inorganic layers couples the skeletal rigidity of the inorganic lamellae with the structural diversity inherent to organic functionalization. The result can be a new compound with markedly different properties (solubility, intercalation, exfoliation) from the parent inorganic backbone. The principal sub-groups of complexes in this class include metal phosphonates,[2] and perovskite halides.[3] Whereas examples of lamellar networks with phosphonate groups abound,[2] lamellar 'inorgano–organic' systems employing sulfonates are virtually unknown.[4,5] Silver benzenesulfonate is a two-dimensional network from which the phenyl groups protrude from both sides. The resulting phenyl–silver(sulfonate)–phenyl trilayer then assembles by dispersive forces between the phenyl groups. The network of Ag–Ag bonds forms a nearly perfect hexagonal grid. Each Ag^{I} in the structure has nine atoms at less than van der Waals contact distances and each SO_3 group caps six different Ag^{I} centers. The observed η^6-coordination mode of the sulfonate group to metals is unprecedented.

Silver benzenesulfonate **1** may be generated by the addition of aqueous sodium benzenesulfonate to a solution of $AgNO_3$ in water. Concentration of this solution results in the precipitation of **1**, in very good yields, as a light gray solid.‡ Elemental analyses confirmed a 1 : 1 stoichiometry of Ag^{I} to benzenesulfonate. Diffusion of isopropyl ether into a MeOH solution of **1** resulted in the growth of extremely thin plate-like crystals suitable for an X-ray diffraction analysis.§

Silver benzenesulfonate forms a two-dimensional infinite array wherein the Ag^{I} centers are bridged by SO_3 groups to form layers and the phenyl moieties of the sulfonates protrude into the interlayer region (Fig. 1).[6] The asymmetric unit contains a single disordered silver benzenesulfonate unit. The interlayer distance, defined as the perpendicular distance between the layers of Ag^{I} ions, is 15.23(2) Å. The thickness of an individual lamella, defined as the region containing solely the Ag, S and O atoms, is 3.87(2) Å. The difference between these two values, 11.36(2) Å, constitutes the gallery height in the complex. Adjacent layers in the complex are slightly offset by 1.32(2) Å in a direction between the *a* and *b* axes. The benzenesulfonate has its major axis oriented *ca.* 14° off the normal to the plane containing the silver atoms. The interlayer phenyl group is disordered between two positions situated 81° apart about the major axis of the ring. NMR shows that at room temperature this disorder is dynamic.[7] The nearest distance between phenyl groups is 5.20(1) Å.[8] The structure is representative of the bulk phase as PXRD data was indexed to the same unit cell.[9]

The structure of **1** is extremely unusual both with respect to the coordination of the Ag^{I} ions and the mode of coordination of the sulfonate groups to the metals. Each Ag^{I} ion is nine-coordinate (Fig. 2) with a coordination sphere comprised of six sulfonate oxygen atoms [from six different sulfonate groups, Ag–O distances range from 2.42(1)–2.56(1) Å] and three bonds to other Ag ions [Ag–Ag 2.915(1) Å].[10] The geometry at each Ag^{I} may be considered as a distorted octahedron of oxygen donors, with three silver donors approaching in a trigonal plane bisecting the octahedron.[11] Congruently, the SO_3 groups must form bonds to six different Ag ions, each oxygen coordinating to two silver centres.[12] The six Ag–O distances span a smaller range than observed for the five Ag–O interactions in AgOTs [2.391(6)–2.700(3) Å].[4] Interestingly, the network of Ag–Ag

Note the hexagonal arrangement of the silver(I) centers and the nonavalent coordination mode, and the μ_6-sulfonate groups.

interactions forms a nearly perfect hexagonal grid reminiscent of graphite.[13,14] The hexagons are completely planar with the observed angles around the Ag periphery averaging to 120.0(1)° [the three different angles are 114.83(3), 116.12(3) and 128.79(3)°]. Each Ag hexagon is capped by an SO_3 group and the mean distance across a hexagon is 6.01(30) Å. The solely inorganic component of this structure, the $AgSO_3$ lamellae, possess almost hexagonal symmetry. The phenyl groups, however, cannot adopt this high symmetry necessitating a distortion in the overall structure to a triclinic, albeit pseudo-hexagonal, space group.[15] DSC–TGA analyses of a sample of silver benzenesulfonate revealed the sample to be completely stable to 139.7 °C at which point a reversible endothermic transition was observed in the DSC. A second non-reversible endothermic transition was observed at 198.2 °C followed by an exothermic transition with an onset temperature of 253.4 °C corresponding to loss of 43.9% of sample weight.

Silver(I) is a notoriously pliant ion with respect to its coordination sphere. Coordination numbers ranging from two to four are common[10] but examples of five- and six-coordinate Ag^I have also been observed.[16] Even in this light, the structure of **1** is remarkable. Silver benzenesulfonate possesses a fascinating structure both from the macroscopic viewpoint, the lamellar motif, and from the microscopic perspective, the highly unusual nine-coordinate Ag^I as well as a novel six-fold bridging mode for a coordinating sulfonate.The question of structure-directing effects (Ag–O *versus* Ag–Ag) in the silver sulfonate family will be resolved upon consideration of other derivatives.

Notes and references

‡ **1**: To a solution of $AgNO_3$ (1.44 g, 8.50 mmol) in H_2O (20 mL) was added a solution of sodium benzenesulfonate (1.53 g, 8.50 mmol) in H_2O (50 mL). A clear solution resulted which was concentrated to *ca.* 10 mL. A gray solid precipitated which was vacuum filtered, washed with cold water (2 mL) and dried. Yield: 1.78 g (6.72 mmol, 79%) CP MAS SS ^{13}C NMR (75 MHz) δ 144.1 (quat. arom), 127.5 (tert. arom). C, H analyses: calc. C, 27.19, H, 1.90: obs. C, 26.82, H, 1.84%. Diffusion of isopropyl ether into a MeOH solution of **1** gave plate-like crystals suitable for an X-ray analysis.

§ *Crystal data* for **1**: $C_{12}H_{10}Ag_2S_2O_6$, M = 530.06, colorless plates, triclinic, space group $P\bar{1}$, a = 5.1596(8), b = 5.1979(8), c = 15.296(2) Å, α = 86.75(2), β = 84.56(2), γ = 61.00(2)°, V = 357.2(1) Å^3, Z = 2, D_c 2.464 g cm^{-3}, R = 0.037, R_w = 0.043 and GOF = 1.27 for 161 parameters using 1540 [$F_o > 2.5\sigma(F_o)$] reflections. Mo-Kα radiation (λ = 0.71073 Å), μ(Mo-Kα) 3.05 mm^{-1}. Data collection temp. −100 °C. The data was collected on a Siemens SMART CCD diffractometer using the ω scan mode ($3 < 2\theta < 57.3°$) and solved using the NRCVAX suite of programs.[17] An initial refinement was attempted in $P\bar{1}$. The discovery from this of the $PhSO_3$ molecule disordered over two equally occupied positions then led us to consider the $P1$ space group. We were able to refine the structure (without disorder) in $P1$ to a residual $R_1(R_w)$ of 0.045 (0.063). However, under $P1$, strong correlations between parameters, non-positive definite thermal parameters, unacceptable C–C bond distances, higher residuals and an inconsistency with the NMR dynamics studies convinced us to accept the 50:50 disordered $P\bar{1}$ structure. The O and C atoms are all 50% occupied. The hydrogens were all placed in calculated positions. The partially occupied atoms in close contact (C1, C1a and C4, C4a) were refined isotropically. This structure was corroborated by CP MAS ^{13}C and ^2H SS NMR studies to be reported in detail elsewhere. CCDC 182/1311.

5 Sulfonates have been employed as H-bond acceptors in the generation of layered guanidinium sulfonates. Interestingly, in these complexes the sulfonate group forms six H-bonds much like the sulfonates herein form six-coordinate covalent bonds, see: V. A. Russell, C. C. Evans, W. Li and M. D. Ward, *Science*, 1997, **276**, 575; J. A. Swift, A. M. Pivovar, A. M. Reynolds and M. D. Ward, *J. Am. Chem. Soc.*, 1999, **121**, 5887; V. A. Russell, M. C. Etter and M. D. Ward, *J. Am. Chem. Soc.*, 1994, **116**, 1941.

6 Tetranuclear Ag^I clusters bridged by succinates have been previously observed, A. Michaelides, V. Kiritis, S. Skoulika and A. Aubry, *Angew. Chem., Int. Ed. Engl.*, 1993, **32**, 1495.

7 From CP MAS ^{13}C and ^2H solid state NMR, a model for the dynamics about the twofold axis of the phenyl ring consistent with the disorder was determined.

8 For a comparison with the structure of $Zr(O_3PPh)_2$, see: M. D. Poojary, H.-L. Hu, F. L. Campbell III and A. Clearfield, *Acta Crystallogr., Sect. B*, 1993, **49**, 996.

9 PXRD data of a bulk sample of silver benzenesulfonate was indexed to the following triclinic cell: a = 5.1564, b = 5.1956, c = 15.3099 Å, α = 86.785, β = 84.582, γ = 61.149°, V = 357.62 Å^3.

10 Moore and coworkers have recently performed a comprehensive search of the Cambridge Structural Database to quantify occurrences of metal ion geometries, see: D. Venkataraman, Y. Du, S. R. Wilson, P. Zhang, K. Hirsch and J. S. Moore, *J. Chem. Educ.*, 1997, **74**, 915. Their results, which are available at http://sulfur.scs.uiuc.edu, indicate Ag^I primarily occurs in linear, trigonal or tetrahedral coordination modes. No examples of nine-coordinate Ag^I are known. The Ag–Ag distances reported here are all significantly less than the van der Waals contact distance for Ag–Ag of 3.40 Å.

11 The most common geometry for nine-coordinate species, primarily observed for nonahydrated lanthanide complexes, is a tricapped trigonal prism, see F. A. Cotton and G. Wilkinson, *Advanced Inorganic Chemistry*, John Wiley, Toronto, 5th edn., 1988, p. 17. The present structure would fit this description if the two sulfonate groups bonded to each silver(I) were in an eclipsed orientation.

12 In a review of triflate binding, a listing of observed coordination modes of R–SO_3 to metals does not include the six-fold bridging mode observed here. See: G. A. Lawrance, *Chem. Rev.*, 1986, **86**, 17.

13 H. Zabel and S. A. Solin, *Graphite Intercalation Compounds I*, Springer Series in Material Science 14, Springer, Berlin, 1990.

14 Based upon the structural similarity to graphite, the prospect that the network may be a conductor was entertained. However, EPR spectra revealed a noiseless signal to 77 K, indicative that all the electrons were highly localized and the material is not a conductor.

15 For a hexagonal unit cell, the symmetry requirements are: $a = b$, $\alpha = \beta = 90$, $\gamma = 120°$. The observed unit cell parameters, with doubling of γ, are slight distortions from these conditions.

Towards multifold cycloswitching of biphotochromes: investigation on a bond-fused dihydroazulene/vinylheptafulvene and dithienylethene/dihydrothienobenzothiophene

Received (in Liverpool, UK) 19th April 1999, Accepted 14th June 1999

The concept of molecular switching within a *cyclic* four-stage process is introduced on the basis of two structurally fused photochromic systems (A–D). The synthesis of 1,8a-dihydro-2,3-bis(2,5-dimethyl-3-thienyl)azulene-1,1-dicarbonitrile (open/closed A) is described; irradiation with UV light leads to an equilibrium of open/open B, open/closed A and closed/closed C, whereas B is thermally rearranged to A by ring closure of the vinylheptafulvene substructure.

The photochromes dihydroazulene (**DHA**)/vinylheptafulvene (**VHF**)[1] and dithienylethene (**DTE**)/dihydrothienobenzothiophene (**DHB**)[2] are based on all-carbon cyclizations, which differ in the number of participating bonds. **DHA/VHF** uses a five-bond and **DTE/DHB** a three-bond cyclization. The light-induced reversible isomerization reactions between open and closed forms have been intensively studied,[3] both systems were also optimized for multimode switching, *e.g.* redox-switch,[1e,2b] fluorescent switch.[1d,2d] From a mechanistic point of view both systems differ in that **DHA/VHF** has a photochemical forward and a thermal back-reaction, whereas in **DTE/DHB** both isomerizations occur photochemically.

There are no reports of biphotochromic systems containing both systems structurally condensed and therefore strongly coupled as shown in Scheme 1.[4] Photochrome **A**, for example, which contains **DTE** and **DHA** substructures fused by a common double bond, represents an energy minimum on a closed circuit established by the four photochromes **A**–**D**. A manifold of independent switching arises, which is likely to be controlled by substituents or functional units. Multimode switches, as shown in Scheme 1, are of interest for information handling at the molecular level.[2c,3,5] Here we report on the synthesis of the open/closed **A** ($R^1 = R^2 = CH_3$) and demonstrate the reversible interconversion of **A** into isomers **B** and **C**.

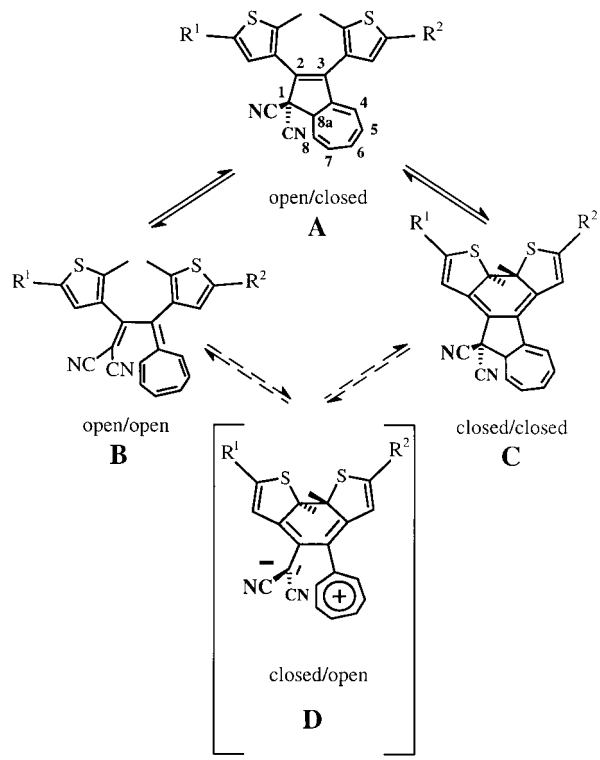
The synthesis[6] of **A** is shown in Scheme 2; the synthetic and analytical details will be published elsewhere.

(*Z*)-1,2-Bis(3-thienyl)ethenes[2a] are known to form stable atropisomers with perpendicular arrangement of ethene and thiophene substructures thus leading to three stereoisomers (a *meso* form with mirror symmetry and two enantiomeric forms with C_2 symmetry). Isomer **A** may give rise to eight stereoisomers consisting of four enantiomeric pairs of diastereomers due to the additional chiral center at C-8a.[1a,f] The ^{1}H-NMR at −50 °C (Fig. 1, top) reveals a 2 : 1 mixture of two atropisomers indicated by four pairs of singlets due to the thiophene's methyl groups: δ (stereoisomer 1) = 1.68, 1.80, 2.38, 2.46; δ (stereoisomer 2) = 1.77, 2.00, 2.34, 2.45. At room temperature the ^{1}H-NMR displays broadening of the methyl signals which is in agreement with fast equilibrating rotational isomers. We assume that the π–π repulsion of the neighbouring thiophenes favors the two stereoforms with pseudo-C_2 symmetry leading to two diastereomeric forms due to the chiral center at C-8a.

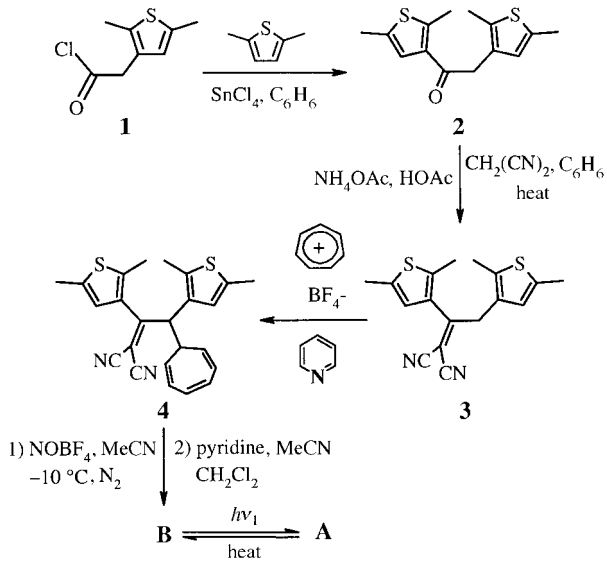
UV/Vis spectroscopy gives a detailed insight into the photochromic behaviour; the photochemically induced rearrangement was also monitored by IR (not shown) and ^{1}H-NMR. Irradiation of **A** in THF-d_8 at room temperature (quartz NMR tube, 254 nm[7a]) leads to a new compound, the structure of which is assigned to **C**. The methyl singlets at δ 1.90, 2.02, 2.20 and the doublet at δ 2.25 prove that only one isomer is formed (Fig. 1, bottom). Since the photochemical electrocyclization occurs in a conrotatory mode,[2] only one of the two pseudo-C_2 symmetric conformers will lead to the final product.

Irradiation of **C** with light $\lambda \geqslant 450$ nm[7b] restores the original spectrum of **A** completely. This clearly demonstrates the retroelectrocyclization of the 1,2-dihydrobenzene moiety of dihydrothienobenzothiophene **C**. Under the conditions of the ^{1}H-NMR experiment we could find no evidence for the formation of photochrome **B** under irradiation. This is due to the fast thermal back-reaction of the **VHF** substructure in **B** to the **DHA** form in **A**.

Irradiation with UV light, either steady-state (254, 313 or 366 nm) or pulsed (248, 308 or 354 nm),[1c] of **A** in non-polar solvents, *e.g.* cyclohexane (Fig. 2) and methylcyclohexane (MCH), leads to new strong absorption bands with maxima at



Scheme 1 Concept of a four-step cyclic process of biphotochromic compounds. The notation 'open/closed' for isomer **A** refers to the dithienyl moiety being in its 'open' state and the dihydroazulene moiety in a 'closed' one. This nomenclature is equally applied to forms **B**, **C** and **D**.



Scheme 2 Synthesis of open/closed **A**.

300, 360 and 480 nm within 10 ns. When the UV light is removed, the 300 nm peak slowly disappears and the visible band becomes less intense and is red-shifted to 510 nm. The latter findings are characteristic for **VHF** chromophores, which thermally revert back, reaction **B** → **A**.[1c] For comparison and reference, typical long wavelength absorption bands of chromophores **DHA**, **VHF**, **DTE** and **DHB** in various solvents are as follows: **DHA**:[1] 320–380 nm; **VHF**:[1] 410–470 nm; **DTE**:[2] 250–450 nm; **DHB**:[2] 420–820 nm.

Similar changes within 10 ns were observed for **A** in PhMe and polar solvents, *e.g.* DMF, MeCN, MeOH or EtOH, at room temperature, where after a few seconds or some minutes only the intense 360 nm band, in addition to the broader band centered at *ca.* 500 nm, were observed and no further spectral changes occur on heating. This is in agreement with the formation of **C** in the photochemical forward step. Note that the photochemical **A** → **B** forward and thermal **B** → **A** backward steps take place in all solvents. By irradiation with visible light ($\lambda \geqslant 450$ nm), **A** is completely restored.

Kinetic measurements quantify the solvent effects of the thermal ring closure. They follow a first order rate process. The corresponding pre-exponential factor (A), the activation energy (E_a) and the relaxation time ($\tau_{B\rightarrow A}$) at room temperature are given in Table 1. The activation parameters are similar, but they clearly demonstrate the trend that the more polar the solvent is, the faster the thermal rearrangement proceeds.

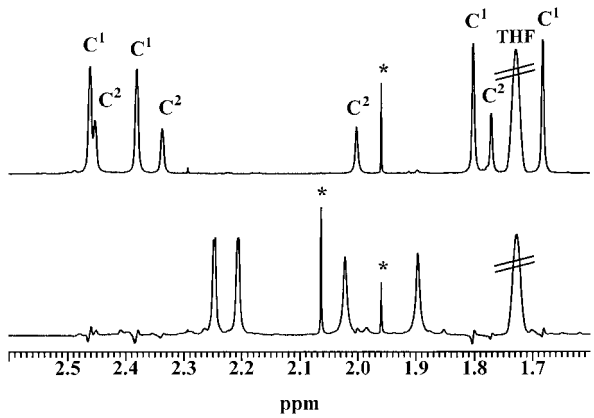


Fig. 1 Irradiation experiments of **A** in THF-d_8 (3.8×10^{-3} mol dm^{-3}) monitored by ^{1}H-NMR spectroscopy (−50 °C), representing the methyl signals. Top: precursor isomer **A** before irradiation; C^1,C^2 = methyl groups of the two conformers. Bottom: **A** after irradiation at room temperature (254 nm) for 5 h (photoconversion: *ca.* 50%) and subtraction of the upper spectrum (subtraction spectrum is shown). * = Unidentified signals.

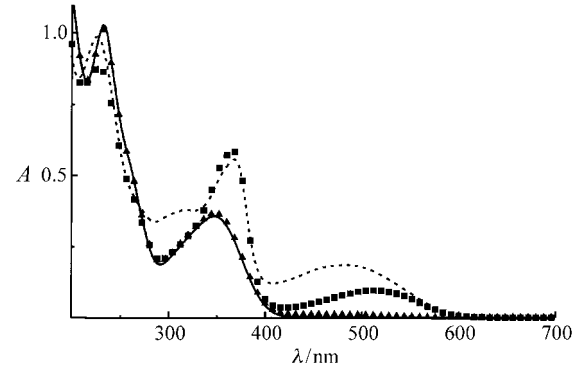

Fig. 2 Reversible irradiation of **A** in cyclohexane (4.4×10^{-5} mol dm^{-3}) at room temperature: **A** prior to (—) and after irradiation at 254 nm (----), after thermal relaxation (■) and after subsequent irradiation with visible light ($\geqslant 450$ nm), where **A** is restored (▲).

Table 1 Pre-exponential factor A, activation energy E_a and relaxation time $\tau_{B\rightarrow A}$ for the thermal ring-closure reaction[a]

Solvent	$A/10^{10}$ s^{-1}	E_a/kJ mol^{-1}	$\tau_{B\rightarrow A}$ s[b]	Temperature range/°C
MCH	20	82	1100	25–95
PhMe	1	70	130	25–110
DMF	100	78	30	25–130
MeCN	1	66	30	25–70
EtOH	0.5	64	25	0–70

[a] Obtained from Arrhenius plots, detection wavelength 475 nm and excitation wavelength λ_{exc} = 308 nm. [b] At 25 °C.

To summarize, both open/open **B** and closed/closed **C** are rapidly formed on irradiating open/closed **A**. **B** is thermally rearranged to **A,** and **C** can photochemically be reverted into **A**. Closed/open **D** has not yet been observed in the system with the substitution pattern $R^1 = R^2 = CH_3$. Appropriate donor and acceptor groups at the **DTE/DHB** moiety (R^1: acceptor subtituent; R^2: donor substituent) would make its formation likely.

Received (in Cambridge, UK) 16th March 1999, Accepted 18th June 1999

$AlPO_4$ and BPO_4 catalyse the conversion of 3-methylbutan-2-one to isoprene in high yields *via* 2-methylbut-2-en-1-ol as an intermediate.

Isoprene is an important monomer for the stereoselective polymerisation to 1,4-*cis*-polyisoprene which is used in the manufacture of synthetic rubber. Isoprene is currently obtained from naphtha cracking but in recent years there has been continued interest in the identification of new synthetic routes. One interesting possibility is the dehydration of 2-methylbutanal which is available as a result of the commercialisation of the low pressure hydroformylation of butene.[1] BPO_4 has been shown to be an effective catalyst[2–4] for this reaction and can give 60–70% yield at high conversion, but deactivation can be rapid. Recently, we have shown[5] that BPO_4 can be readily reactivated using a simple high temperature treatment, thereby making these catalysts more suitable for industrial application. However, together with isoprene, 3-methylbutan-2-one is formed as a major by-product with both phosphate catalysts and this, at present, limits the commercial applicability of the process. Here we demonstrate that 3-methylbutan-2-one can be readily converted to isoprene using BPO_4 and $AlPO_4$ as catalysts. Furthermore, we demonstrate that isoprene and 3-methylbutan-2-one formation from 2-methylbutanal are linked by a common intermediate, 2-methylbut-2-en-1-ol. These results indicate that by recycling the 3-methylbutan-2-one by-product the overall yield of isoprene can be increased by $\geqslant$10% for both BPO_4 and $AlPO_4$ catalysts.

Boron phosphate (P:B = 1) was prepared by heating phosphoric acid (93 ml, 85%) with boric acid (100 g) at 60 °C for 1 h. Water (100 ml) was then added and the mixture was refluxed for 5 h and then dried (110 °C, 16 h) and calcined (350 °C, 4 h). The product was confirmed to be the cristabolite form of BPO_4 by X-ray diffraction. Aluminium phosphate (Al:P = 1) was prepared by the slow addition of aqueous ammonia (40 vol%, 5 °C), with continuous stirring, to an aqueous solution containing equimolar quantities of $AlCl_3$ and phosphoric acid (0.985 mol l^{-1}, 5 °C). Aqueous ammonia addition was continued until pH = 7.0 was attained. The white precipitate was aged (18 h, 20 °C) and collected by filtration, washed several times with propan-2-ol, dried (24 h, 120 °C) and calcined (3 h, 800 °C). Powder X-ray diffraction showed that the catalyst was a mixture of the cristabolite and tridymite phases of $AlPO_4$. Both these solids were screened (200–250 mesh), and pelleted and sieved (600–1000 μ) prior to use as catalysts. The phosphates were investigated as catalysts for the dehydration of 2-methylbutanal and isoprene was observed as the major product in agreement with our previous results.[5] For both BPO_4 and $AlPO_4$ the only by-product was 3-methylbutan-2-one which was formed at *ca.* 18–20% yield. In a separate set of reactions 3-methylbutan-2-one [0.67 ml (g catalyst)$^{-1}$ h^{-1}] was reacted over the phosphate catalysts (0.3 g) using a standard laboratory microreactor with nitrogen as a diluent (24 ml h^{-1}). Products were analysed using GC and satisfactory mass balances were obtained for all data presented. The results for BPO_4 at 325 °C and $AlPO_4$ at 400 °C are shown in Fig. 1. $AlPO_4$ required a higher reaction temperature than BPO_4 to observe a significant conversion level. Both catalysts convert 3-methylbutan-2-one to isoprene with high selectivity (80–95%) and at reasonable conversion levels. The catalyst performance was found to be very stable and, significantly, no appreciable deactivation was observed.

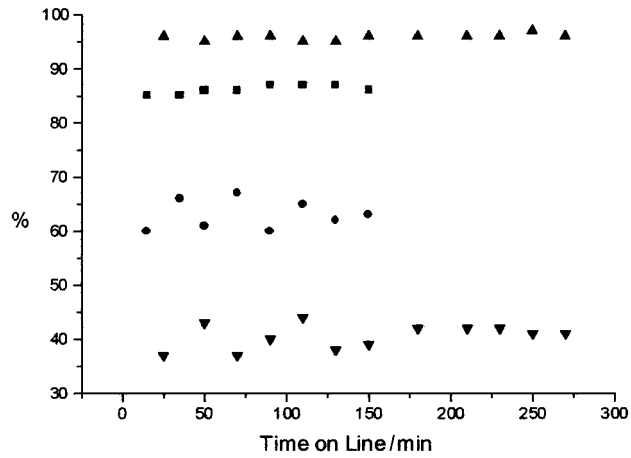

Fig. 1 Reaction of 3-methylbutan-2-one over (a) BPO_4 at 325 °C [(▼) conversion, (▲) isoprene selectivity] and (b) $AlPO_4$ at 400 °C [(■) conversion, (●) isoprene selectivity].

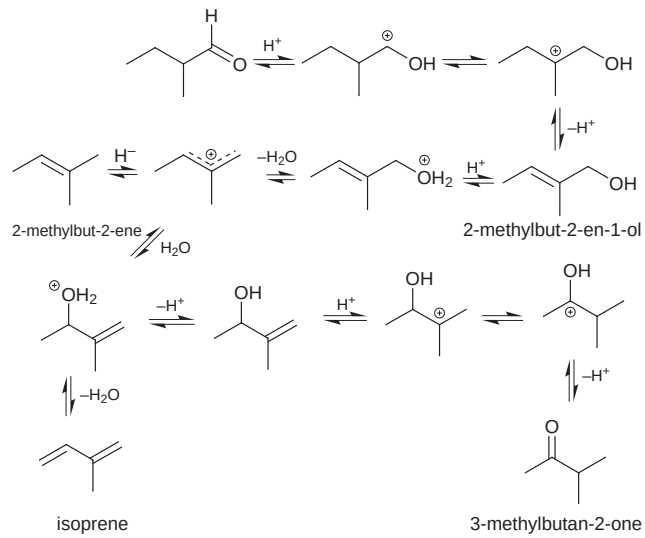

Scheme 1 Proposed mechanism for the conversion of 2-methylbutanal and 3-methylbutan-2-one to isoprene.

† Present address: Department of Chemistry, Cardiff University, PO Box 912, Cardiff, UK CF1 3TB.

‡ Present address: BNFL Ltd, Springfields Works, Salwick, Preston, UK PR4 0XJ.

The observation that both 2-methylbutanal and 3-methylbutan-2-one could be converted to isoprene with these catalysts prompted us to consider the reaction mechanism for these catalytic processes. We believe that 2-methylbut-2-en-1-ol is a central intermediate in the conversion of 2-methylbutanal into both isoprene and 3-methylbutan-2-one (Scheme 1). To test this proposal, 2-methylbut-2-en-1-ol was synthesised by reduction of 2-methylbut-2-enal with sodium borohydride in MeOH. 2-Methylbut-2-en-1-ol was then reacted [0.67 ml (g catalyst)$^{-1}$ h^{-1}] in a nitrogen diluent (24 ml min^{-1}) over BPO_4 (0.3 g) at 110 and 300 °C. At these temperatures, 2-methylbut-2-ene was a major product (*ca.* 10–40%) but in addition isoprene (37%), 2-methylbutanal (10%) and traces of 3-methylbutan-2-one were also observed and the conversion increased from 87% at 110 °C to 99% at 300 °C (Table 1). These results support the proposal that 2-methylbut-2-en-1-ol is a key intermediate in the conversion of 2-methylbutanal into both isoprene and 3-methylbutan-2-one.

This study indicates that the yield of isoprene from the dehydration of 2-methylbutanal, using $AlPO_4$ and BPO_4 catalysts, can be significantly enhanced if the major by-product, 3-methylbutan-2-one, is reacted over the same phosphate catalyst under the same reaction conditions. It is anticipated that this can be done *via* a recycle step and yield increases of *ca.* 10% for BPO_4 (from 72 to 82 at 325 °C) and 16% for $AlPO_4$ (from 56 to 72% at 400 °C) can be expected.

Table 1 Conversion of 2-methylbut-2-en-1-ol over BPO_4[a]

		Selectivity[b]		
T/°C	Conversion	2MBA	2MBE	I
110	87	12	49	39
300	99	25	47	10

[a] BPO_4 (0.3 g), 2-methylbut-2-en-1-ol [0.67 ml (g catalyst)$^{-1}$ h^{-1}], N_2 (24 ml min^{-1}. [b] 2MBA = 2-methylbutanal; 2MBE = 2-methylbut-2-ene; I = isoprene.

Oxidative C(sp³)–C(sp³) bond cleavage reaction of an isopropyl group to give an acetyl group upon O_2-treatment of a labile cationic ruthenium species, $[Tp^{iPr}Ru(dppene)(OH_2)]^+$†

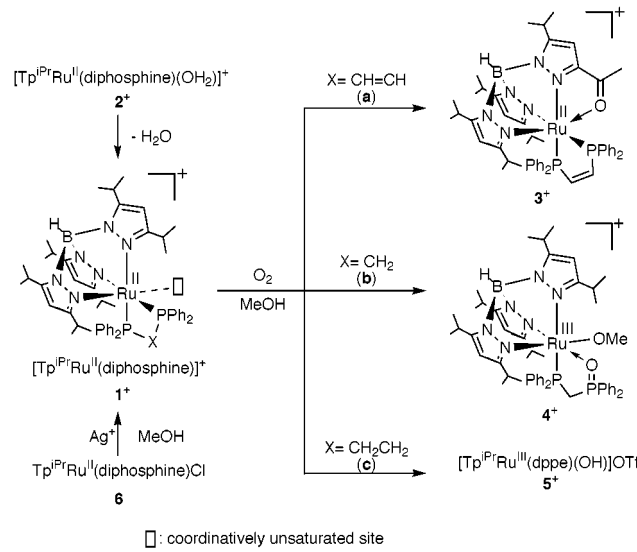
Received (in Cambridge, UK) 25th May 1999, Accepted 28th June 1999

Exposure of a cationic aquoruthenium(II) complex, $[Tp^{iPr}Ru(dppene)(OH_2)]^+$ [Tp^{iPr} = hydrotris(3,5-diisopropylpyrazolyl)borato; dppene = 1,2-bis(diphenylphosphino)ethene], to O_2 at ambient temperature results in oxidative cleavage of the C(sp³)–C(sp³) bond in an isopropyl group in the Tp^{iPr} ligand to give an acetyl functional group.

Oxygenation reactions mediated by a transition metal species are involved as key steps in organic synthesis and metabolic reactions, and selective aerobic oxygenation of hydrocarbyl functional groups has long been a challenging research target.[1] Transition metal–O_2 adducts have been studied extensively as pivotal intermediates of oxygenation reactions but the adducts may be too reactive to be isolated and they frequently oxidize external or internal functional groups including hydrocarbyl substrates. In contrast to a considerable number of C–H and C(sp²)=C(sp²) bond oxygenation reactions induced by O_2-treatment of a transition metal complex,[2] oxygenation of saturated C(sp³)–C(sp³) bond has few precedent examples.[3] During the course of our systematic synthetic study on dioxygen complexes coordinated by hydrotris(pyrazolyl)borato ligands (Tp^R),[4] we observed an oxidative cleavage reaction of a C(sp³)–C(sp³) bond in a ruthenium complex.

We attempted the synthesis of a ruthenium–dioxygen complex bearing the Tp^{iPr} ligand [Tp^{iPr} = hydrotris(3,5-diisopropylpyrazolyl)borato] by O_2-treatment of a coordinatively unsaturated cationic ruthenium(II) species, $[Tp^{iPr}Ru(diphosphine)]^+$ **1**$^+$ [diphosphine = Ph_2P–X–PPh_2: X = CH=CH (**a**: dppene), CH_2 (**b**: dppm), CH_2CH_2 (**c**: dppe)], which should be formed from labile cationic aquo complexes, $[Tp^{iPr}Ru(diphosphine)(OH_2)]^+$ **2**$^+$.[5,6] Exposure of the aquo complexes **2**$^+$ to O_2, however, did not afford the desired product but instead resulted in three different types of oxygenation reactions giving complexes **3**–**5** depending on the structure of the diphosphine ligand (Scheme 1).[7]

Stirring a methanol solution of the dppene complex **2a**OTf[5] (OTf = trifluoromethansulfonate) under an O_2 atmosphere (1 atm) at room temperature gave a mixture containing the red–brown diamagnetic complex **3**OTf (20 % isolated yield) as a major product. The three inequivalent 4-pz-H signals (^{1}H NMR)‡ indicated an unsymmetrical structure but **3**OTf could not be identified by the spectroscopic data alone. In addition, single crystals suitable for X-ray crystallography were not obtained. The coordinatively unsaturated species **1**$^+$ may be generated by an alternative method, *i.e.* dechlorination of the corresponding chloro complex **6** by the action of a Ag salt. Treatment of **6a** with $AgBF_4$ under O_2 atmosphere afforded **3**BF_4 showing spectroscopic properties† similar to those of the OTf salt and its molecular structure was determined by X-ray crystallography [Fig. 1(a)].‡ The most striking structural feature was formation of the acetyl group (C15–C14–O1) resulting from oxygenation of an isopropyl group in the Tp^{iPr} ligand proximal to the metal center, and coordination of the acetyl oxygen atom to the metal center leads to a distorted octahedral coordination geometry [N11–Ru1–N21 93.0(2)°, N11–Ru1–N21 77.8(2)°, N21–Ru1–Ru31 85.2(2)°, Ru1–P1 2.271(2) Å, Ru1–P2 2.297(2) Å, Ru1–O1 2.118(5) Å, Ru1–N11 2.051(5) Å, Ru1–N21 2.123(5) Å, Ru1–N31 2.180(7) Å]. In accord with the structure, a singlet signal at δ_H 1.66 (3H) assignable to the coordinated acetyl group was observed. The acetyl oxygen atom came from O_2 molecule as revealed by a labeling experiment using $^{18}O_2$. When the reaction was carried out in propan-2-ol, formation of methanol was detected by GLC analysis of the solution phase and, therefore, the removed methyl group should be converted to methanol. Thus interaction of the coordinatively unsaturated species **1a**$^+$ with O_2 resulted in unprecedented oxidative cleavage of the C(sp³)–C(sp³) bond in an isopropyl substituent under mild reaction conditions.



Scheme 1

In order to examine the generality of the oxygenation reaction, related diphosphine complexes **1b** and **1c**$^+$ were exposed to O_2. Although oxygenation of a hydrocarbyl group

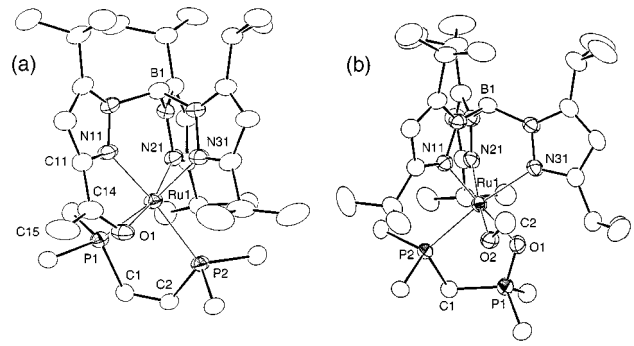


Fig. 1 Structures of the cationic parts of the oxygenated products, **3**BF_4 (a) and **4**PF_6 (b), drawn at the 30% probability level. For the phenyl groups only *ipso* carbons are shown for clarity and the acetyl part in **3**$^+$ is shaded.

did not occur, other types of oxygenation reactions were observed. Dechlorination of **6b** with $AgPF_6$ in MeOH under an O_2 atmosphere produced the red–brown paramagnetic complex **4**$^+$,† and its FD-MS data [*m/z* 998: Tp^{iPr}Ru(dppm)(OMe)(O)] suggested occurrence of oxygenation. X-Ray crystallography [Fig. 1(b)]‡ revealed that complex **4**$^+$ was a cationic ruthenium(III) complex with a 5-oxa-2,4-diphospharuthenacyclopentane structure resulting from oxygenation of one of the two phosphorus atoms in the dppm ligand, and the sixth coordination site was occupied by the methoxo ligand coming from the reaction solvent. In this case, an active oxidizing species bonded to the metal center should be trapped by the neighboring phosphorus atom to release strain of the four membered Ru–P–C–P ring in **2b**$^+$. Finally, treatment of the dppe complex **2c**PF_6 with O_2 resulted in one-electron oxidation of the ruthenium center coupled with deprotonation of the aquo ligand to give a hydroxo–Ru(III) complex **5**PF_6,† which was characterized by X-ray crystallography,‡ but no ligand oxygenation was observed. Complex cation **5**$^+$ is octahedral with a η^1-hydroxo ligand and it should be noted that the Ru–O distance [2.158(5) Å] is comparable to that in the cationic aquoruthenium(II) complex **2c** [2.148(8) Å] [5] but significantly longer than that in the Ru(II) analogue, Tp^{iPr}Ru(dppe)(OH) [2.067(4) Å].[8]

Thus O_2-treatment of the labile aquo–Ru(II) complexes **2**$^+$ resulted in oxidative C–C bond cleavage (dppene: **3**$^+$) or P-oxidation (dppm: **4**$^+$) or oxidation of the metal center (dppe: **5**$^+$) depending on the nature of the diphosphine ligands. The present oxygenation reactions should consist of complex multi-step reaction sequences, and several plausible mechanisms involving a combination of O–O homolysis, Ru–O homolysis, H-abstraction, ·OH-addition, epoxidation, *etc*. can be depicted. Although no other species could be isolated and further study is needed for clarification of the mechanisms, we propose a Ru(III)–η^1-superoxo species, [Tp^{iPr}Ru^{III}(dppe)(η^1-O_2^-)]$^+$, as a likely intermediate on the basis of the following consideration. In **1**$^+$, the chelating κ^3-Tp^{iPr} and κ^2-diphosphine ligands are tightly bound to the Ru center and the sixth coordination site originally occupied by the aquo ligand in **2**$^+$ is the only accessible coordination site. Coordination of an O_2 molecule, therefore, is feasible only in η^1-fashion (η^1-superoxo species). Because the oxygenation was observed only in alcohols, subsequent hydrogen abstraction from the solvent may lead to a hydroperoxo intermediate, which should induce oxidative C–C cleavage. In addition, the alcohol should also act as a reducing agent to regenerate a Ru(II) species like **3**$^+$. The Ru(II) system is in sharp contrast to the Rh(I) system, which undergoes oxidative addition of an O_2 molecule (two-electron oxidation process), and many (η^2-O_2)Rh(III) complexes were prepared by this method.[9] For elucidation of the mechanism of the O-atom transfer step, further experiments are now under way.

In summary, we reported oxidative C(sp^3)–C(sp^3) bond cleavage reaction induced by O_2-treatment of the coordinatively unsaturated Ru(II) species **1**$^+$. The present study revealed that such a highly active oxidizing species can be generated by simple exposure of a precursor **1**$^+$ to O_2 at ambient temperature. It is also notable that the reaction pathway is dependent on the electronic and structural features of the diphosphine ligand (*e.g.* strain of the diphosphametallacyclic structure and electron-donating ability of the diphosphine ligand).[10]

We are grateful to the Ministry of Education, Science, Sports, and Culture of the Japanese Government for financial support of this research (Grant-in-Aid for Scientific Research: No. 08102006).

Remarkably stable self-assembled monolayers of new crown-ether annelated tetrathiafulvalene derivatives and their cation recognition properties†

Haiying Liu, Shenggao Liu and Luis Echegoyen*

Department of Chemistry, University of Miami, Coral Gables, FL 33124, USA. E-mail: echegoyen@miami.edu

Received (in Columbia MO) 26th May 1999, Accepted 23rd June 1999

Bis-thioctic ester derivatives of crown-ether annelated tetrathiafulvalenes (TTFs) form extremely stable self-assembled monolayers (SAMs) on gold electrodes and can recognize alkali metal ions by cyclic voltammetry.

The first TTF-functionalized SAMs, reported by Yip and Ward, were relatively unstable upon electrochemical probing and cycling.[1] Very recently a novel TTF compound containing four thiol groups was reported, which formed very robust SAMs on gold, and these were stable after repeated voltammetric cycling.[2] The use of such multiple anchoring sites provides very strong adherence of the compound to the metal surfaces, especially if the sulfur atoms are present within the same ring structure, in which case they exhibit a chelate effect.[3] For these reasons, the use of thioctic acid derivatives to anchor SAMs on metal surfaces has received considerable recent attention.[4] In addition, thioctic acid (1,2-dithiolane-3-valeric acid) is commercially available and easy to incorporate into a wide variety of structures *via* simple condensation reactions, as reported in the present work.

The incorporation of crown-ether groups into SAMs and their use as potential metal ion sensors were first reported almost simultaneously last year by Moore *et al.*[5] and by Flink *et al.*[6] In one case they prepared simple 12-crown-4 and 15-crown-5 derivatives with appended single chains terminated in a thiol group, and impedance spectroscopy was used to monitor ion binding events on the surface.[6] The other group reported crown-annelated TTF derivatives which also contained single alkyl chains terminated in thiol groups.[5] This work exploited the direct electrochemical response of the surface-confined crown-TTF groups to measure the effect of ion complexation, similar to previously reported work in homogeneous solution by Hansen *et al.*[7] However, these SAMs were apparently not very stable under various conditions and the electrochemical responses observed were very weak and poorly resolved.[5] Here we report the preparation of two bis-thioctic ester derivatives of crown-annelated TTFs, which form remarkably stable SAMs on gold and show very clear and reversible surface-confined electrochemistry and anodic shifts upon binding with alkali metal ions.

Compounds **1a**–**c** were directly synthesized in high yield by reacting the corresponding bis-alcohols with thioctic acid in CH_2Cl_2 in the presence of 1,3-dicyclohexylcarbodiimide (DCC) and 4-pyrrolidinopyridine or 4-(dimethylamino)pyridine (DMAP).[8] The corresponding crown-annelated TTF bis-alcohol precursors were prepared in reasonable yields following literature procedures.[9] The mono-alcohol precursor to prepare **1d** was obtained by reducing one of the ester groups of diester-EDT-TTF.[9b,10] It should be stressed that the synthetic method reported here to prepare crown-ether annelated tetrathiafulvalene derivatives with disulfide groups attached by reacting thioctic acid with derivatives of TTF incorporating hydroxy group(s) is general, straightforward and gives high yields.

dipped into 5 mM THF solutions of the corresponding bis-thioctic ester compounds **1a**–**d** for 24 h to form the corresponding SAMs.[11] After washing these with clean THF and allowing them to dry in air, these SAM modified electrodes were placed into 0.1 M Bu_4NPF_6–THF (or 0.1 M Bu_4NPF_6–CH_2Cl_2) and their cyclic voltammograms (CVs) recorded.[12] Fig. 1 shows the

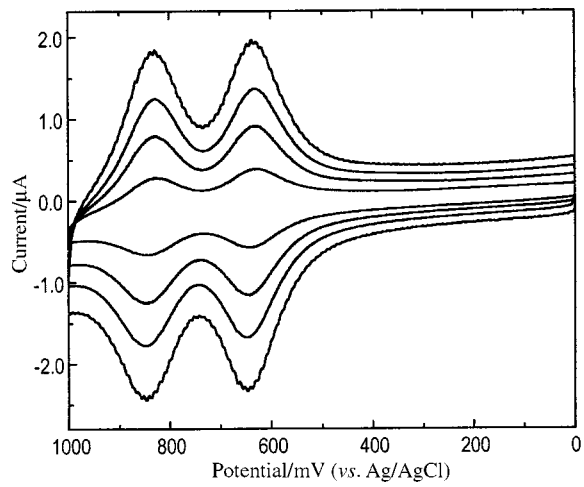

Fig. 1 Cyclic voltammetric analysis of the SAMs of **1a** in THF solution containing 0.1 M Bu_4NPF_6 at different scan rates: 100 (smallest current), 250, 400 and 600 mV s^{-1} (largest current).

† Data for compounds **1b**–**d** are available from the RSC web site, see http://www.rsc.org/suppdata/cc/1999/1493/

Table 1 Electrochemical data for the SAMs of the disulfides in THF solution containing 0.1 M Bu_4NPF_6 *vs.* an aqueous Ag/AgCl reference electrode

SAMs of compound	$E_{1/2}^1$/V (ΔE_p/mV)	$E_{1/2}^2$/V (ΔE_p/mV)	Coverage[a]
1a	0.64 (12)	0.85 (5)	1.15
1b	0.62 (20)	0.80 (15)	0.33
1c	0.65 (25)	0.90 (15)	1.58
1d	0.73 (58)	0.96 (70)	2.21

[a] In units of 10^{-10} mol cm^{-2}.

variable scan rate dependence of the CVs for SAMs of **1a** on gold in a THF-electrolyte solution. Both TTF-based oxidations are clearly observed and reversible, and their currents increase linearly with the scan rate, indicative of surface-confined behavior (Fig. 1).

This behavior is also evident from the Gaussian shapes of the peaks and the small potential difference between the anodic and cathodic peaks, 12 mV for the first oxidation at $E_{1/2}$ = +0.64 V (*vs.* an aqueous Ag/AgCl reference electrode and at v = 100 mV s^{-1}) and 5 mV for the second oxidation at $E_{1/2}$ = +0.85 V, see Table 1. Essentially identical behavior was observed for **1b**, **1c** and **1d**, but the SAMs of **1d** were much more unstable upon repeated potential cycling, with an 80% decrease in current after four cycles between 0 and +1.1 V. The potentials for the TTF-based oxidations are summarized in Table 1.

The SAMs derived from compounds **1a**, **1b** and **1c** were remarkably stable, exhibiting almost the same current response even after more than 100 potential scan cycles. Perhaps more impressively, these SAMs retained their stability over the course of several days, apparently indefinitely. In our hands, these are the most stable SAMs with which we have ever worked.

The effect of adding alkali metal ions to the THF solutions (typically 5 mM of MPF_6, with M = Li^+, Na^+ or K^+) varied for the different compound–M^+ combinations. The largest anodic shift was observed for **1b**–Na^+, and these cyclic voltammetric results are presented in Fig. 2.

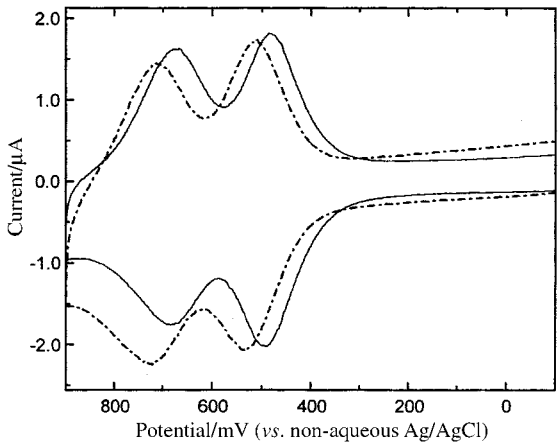

Fig. 2 Cyclic voltammetry of the SAMs of **1b** in THF solution containing 0.1 M Bu_4NPF_6 in the absence (solid line) and in the presence (dotted line) of 5.0 mM $NaPF_6$ at a scan rate of 400 mV s^{-1}. A non-aqueous Ag/AgCl containing 0.1 M Bu_4NPF_6 in THF was used as a reference electrode. Thus the potential axis is different from that in Fig. 1.

The first oxidation process was anodically shifted by 60 mV in this case, while the second oxidation was also shifted anodically, by 55 mV. This behavior is somewhat in contrast to that previously reported for crown-annelated TTF compounds in homogeneous solution, for which the first oxidation is shifted anodically, but the second remains unchanged, presumably due to electrostatically-induced decomplexation of M^+ following the first oxidation to form TTF^+–crown.[7] Either surface aggregation or cooperativity effects between neighboring crown rings on the SAMs could account for the different behavior observed here. The effects of the alkali metal ions tested on the CVs of **1a** and **1b** are summarized in Table 2.

Table 2 Shifts (mV) of redox potentials of the SAMs of **1a** and **1b** upon addition of alkali metal ion salts

Metal ion salt (5.0 mM)	SAMs of **1a**		SAMs of **1b**	
	$E_{1/2}^1$	$E_{1/2}^2$	$E_{1/2}^1$	$E_{1/2}^2$
$LiPF_6$	0	0	0	0
$NaPF_6$	+10	0	+60	+55
KPF_6	0	0	+20	+30

Note that Li^+ showed no effect on either of the crown compounds, while Na^+ showed the largest effect with both SAMs. K^+ induced a smaller anodic shift than Na^+, and only with **1b**. As expected, **1c** did not exhibit any cation-induced effects, since there is no crown ether ring present in the structure. All of these results indicate that the cation-induced shifts result from complexation between the crown rings and the metal ions.

In summary, electrochemically active SAMs have been prepared which are almost indefinitely stable and show promise as potential thin-film sensors for electrochemically inactive metal ions. Further work is underway to improve the selectivity properties of these SAMs.

12 All electrochemical experiments were performed using a BAS-100W system. Electrolyte solutions were prepared from recrystallized materials using spectroscopic grade solvents and purged with argon prior to use. A three-electrode configuration was used with a Ag/AgCl reference electrode and a platinum wire as the counter electrode. The geometric areas of the gold electrodes were calculated from the slopes of the linear plots of cathodic peak current *vs.* the square root of the scan rate obtained for the diffusion-controlled reduction of $Ru(NH_3)_6^{3+}$ [ref. 4(*b*)]. We employed a diffusion coefficient of 7.5×10^{-6} cm^2 s^{-1} (at 25 °C in 0.1 M NaCl). Typical values for the geometric area of the electrodes varied from 0.01 to 0.02 cm^2. Surface coverages of the SAMs of TTF derivatives were calculated by integration of the current during the first scan.

Opposite influence of calf thymus DNA on the rate of substitution of ethylenediamine, by thiourea, in the complex cations $[Pd(bpy)(en)]^{2+}$ and $[Pd(bromazepam)(en)]^{2+}$ (bromazepam = 7-bromo-1,3-dihydro-5-(2-pyridyl)-2*H*-1,4-benzodiazepin-2-one)

Received (in Cambridge, UK) 4th June 1999, Accepted 29th June 1999

Calf thymus DNA inhibits the substitution of ethylenediamine, by thiourea, in $[Pd(bpy)(en)]^{2+}$ and catalyses the same reaction in $[Pd(bromazepam)(en)]^{2+}$ (bromazepam = 7-bromo-1,3-dihydro-5-(2-pyridyl)-2*H*-1,4-benzodiazepin-2-one); this kinetic effect can be related to the different binding modes of the two complexes to the biopolymer.

Inclusion in receptors such as cyclodextrins[1] as well as interactions with micelles[2] or polyelectrolytes[3] alter, often to a large extent, the physical properties and the reactivity of the interacting molecules. DNA can also, thanks to a variety of non-covalent interactions with small molecules,[4] produce these effects.[5] We report here an example in which calf thymus DNA exerts an opposite influence on the reactivity of the two similar palladium(II) complexes $[Pd(bpy)(en)](PF_6)_2$ and $[Pd(bromazepam)(en)](BF_4)_2$ (bromazepam = 7-bromo-1,3-dihydro-5-(2-pyridyl)-2*H*-1,4-benzodiazepin-2-one). For comparison, we report also the effect of DNA on the reactivity of $[Pd(en)_2]Cl_2$ and $[Pd(Me_4en)(py)_2](PF_6)_2$.

$[Pd(bromazepam)(en)](BF_4)_2$ was obtained by treating $[Pd(en)Cl_2]$[6] with $AgBF_4$ (ratio 1 : 2) in acetone, and then adding the corresponding amount of bromazepam. $[Pd(Me_4en)(py)_2](PF_6)_2$ was prepared by heating $[Pd(Me_4en)Cl_2]$, suspended in water, in the presence of an excess of pyridine. After dissolution of the complex, the product was obtained as a yellow precipitate by addition of NH_4PF_6. $[Pd(Me_4en)Cl_2]$,[7] $[Pd(bpy)(en)](PF_6)_2$[8] and $[Pd(en)_2]Cl_2$[6] were prepared by literature methods. Calf thymus DNA (Sigma) was purified as previously described.[9]

The complexes $[Pd(N–N)(en)]^{2+}$ (N–N = bpy or bromazepam) react with thiourea according to reaction (1). The nature of

$$[Pd(N–N)(en)]^{2+} + 2\ tu \longrightarrow [Pd(N–N)(tu)_2]^{2+} + en \quad (1)$$

the reaction products, isolated from water, was established by elemental analysis and ^1H NMR. The kinetics of ligand substitution, by thiourea, were followed spectrophotometrically, in the range 310–370 nm, at 25 °C. Under pseudo-first-order conditions with respect to the complex, the rate of reaction (1), which occurs in one observable step, is related to thiourea concentration by law (2). A good linear trend with zero

$$k_{obs} = k_2[tu]^2 \quad (2)$$

intercept, over the whole thiourea concentration range investigated, is obtained on plotting the k_{obs} values against the square of the thiourea concentration $[tu]^2$. If the reaction is monitored in the presence of calf thymus DNA ([DNA]/[Complex] = 6), the same rate law is observed; however DNA induces opposite changes in the rate of the reactions. Fig. 1 shows that, using the same experimental conditions ($I = 2.2 \times 10^{-2}$ mol dm^{-3} by addition of NaCl or $NaNO_3$; pH = 7 by using phosphate buffer; T = 25 °C), while the substitution of ethylenediamine in $[Pd(bpy)(en)]^{2+}$ is inhibited, the same reaction in $[Pd(bromazepam)(en)]^{2+}$ is accelerated. This kinetic effect can be related to the mode of interaction of the complexes with DNA. $[Pd(bpy)(en)]^{2+}$ intercalates to the double helix.[9,10] $[Pd(bromazepam)(en)]^{2+}$ binds externally, either docking in one of the grooves or simply electrostatically. No changes in the absorption spectrum of the latter complex nor any increase in the DNA viscosity are observed upon interaction. In addition, the increase in thermal denaturation temperature of the double helix, in the presence of $[Pd(bromazepam)(en)]^{2+}$ (1.4 ± 0.2 °C),† is much smaller than expected for a dicationic intercalator.[9] Intercalation protects the reaction centre from nucleophile attack making $[Pd(bpy)(en)]^{2+}$ unreactive; only the non-intercalated portion of this complex participates in the reaction and the

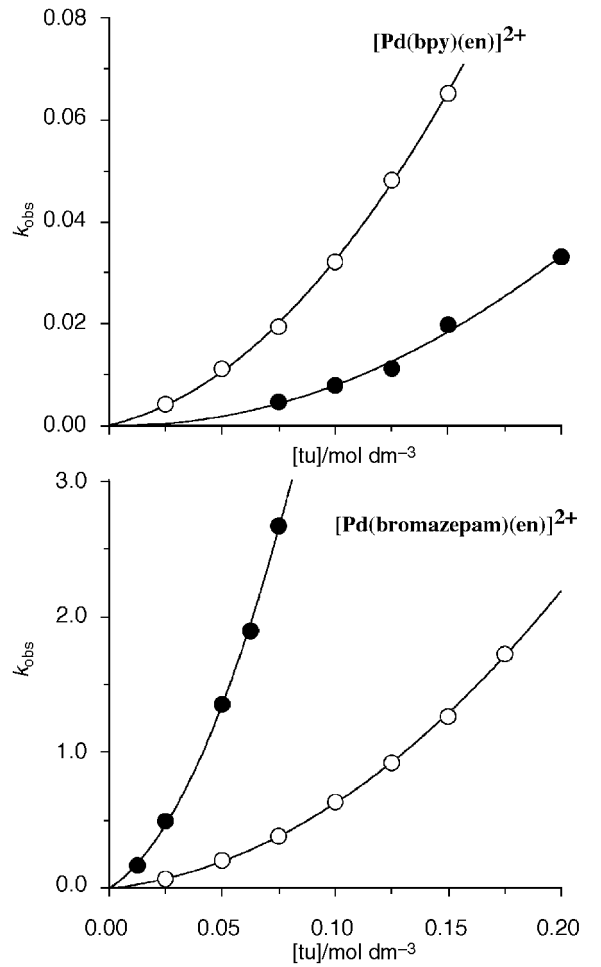

Fig. 1 Plot of k_{obs} against [tu] for reaction (1) (○) in the absence and (●) in the presence of DNA; 1.0×10^{-3} mol dm^{-3} phosphate buffer (pH 7) and 2.1×10^{-2} mol dm^{-3} NaCl or $NaNO_3$; T = 25 °C.

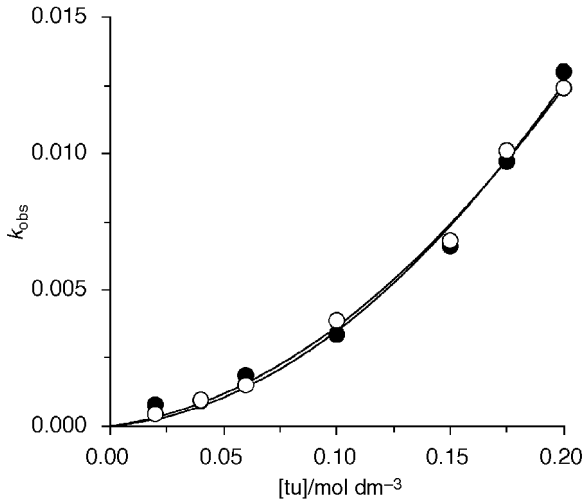

Fig. 2 Plot of k_{obs} against [tu] for reaction of $[Pd(Me_4en)(py)_2]^{2+}$ with thiourea (○) in the absence and (●) in the presence of DNA; 1.0×10^{-3} mol dm^{-3} phosphate buffer (pH 7) and 2.1×10^{-2} mol dm^{-3} NaCl or $NaNO_3$; T = 25 °C.

decreased concentration of one of the two reactants accounts for the decrease in the rate of substitution. In principle, an increase in the local concentration of the reagents can explain the catalytic effect of DNA; owing to its cationic nature [Pd(bromazepam)(en)]$^{2+}$ concentrates around DNA and if we assume that, for some reason, thiourea interacts with the biopolymer accumulating around it, enhanced concentration of the two reacting species would account for the observed acceleration in rate. More likely the observed catalytic effect is electronic in origin; the NH_2 hydrogen atoms of en are acidic[11] enough to interact with the DNA phosphate groups and so hydrogen bounding could stabilise the reaction intermediate with monodentate ethylenediamine. Kinetic data for the reaction of thiourea with $[Pd(en)_2]^{2+}$ and $[Pd(Me_4en)(py)_2]^{2+}$ corroborate this hypothesis. Both complexes bind externally to the double helix; however, while DNA catalyses the substitution of en, the rate of reaction for the latter complex, where no hydrogen atoms are available for interaction, is practically unaffected by the presence of the biopolymer (Fig. 2).

In conclusion, our data show that the observed kinetic effect of DNA on the reactivity of a small molecule can, in principle, be used as an indicator of its binding mode to the biopolymer.

Financial support from MURST and CNR is acknowledged.

The influence of A-cation disorder on the Curie temperature of ferroelectric $ATiO_3$ perovskites

Derek C. Sinclair[a] and J. Paul Attfield*[b]

[a] *Department of Engineering Materials, University of Sheffield, Mappin Street, Sheffield UK S1 3JD*
[b] *Department of Chemistry, University of Cambridge, Lensfield Road, Cambridge, UK CB2 1EW. E-mail: jpa14@chem.ac.uk*

Received (in Oxford, UK) 7th May 1999, Accepted 28th June 1999

The ferroelectric Curie temperature T_C in $ATiO_3$ perovskites is shown to increase linearly with the size variance of the A-site cation mixture [A = (Ba, Sr, Ca)] and this effect accounts for the unusual T_C variation in the $Ba_{1-x}Ca_xTiO_3$ system.

$BaTiO_3$ is a ferroelectric perovskite widely used in capacitors, thermistors and piezoelectric devices. The Curie temperature above which $BaTiO_3$ changes from being tetragonal and ferroelectric to cubic and paraelectric is T_C = 403 K.[1] The ferroelectricity arises from displacements of the Ti atoms towards one of the octahedrally coordinating oxygen atoms along the *c*-axis. A complete solubility exists between $BaTiO_3$ and $SrTiO_3$, and T_C decreases across the series to a value of 110 K for $SrTiO_3$.[2] This trend was ascribed to a cation size effect, in which the smaller Sr ion causes a reduction in the average radius of the A cation site and stabilises the cubic $ATiO_3$ structure to lower temperatures. By contrast, in the $Ba_{1-x}Ca_xTiO_3$ system, T_C rises from 403 K to a maximum value of 410 K at x = 0.08 before dropping to 391 K at the solid solution limit of x = 0.24.[3] This variation is not consistent with the above size effect.

It has recently been shown that the electronic and structural phase transition temperatures of several perovskite-type materials vary with the mean size and the size mismatch of the cations on the A-site.[4,5] Size is parameterised by the mean A-cation radius, $\langle r_A \rangle$, and A-site size mismatch is described by the statistical variance in the distribution of the radii, σ^2:

$$\sigma^2 = \langle r_A^2 \rangle - \langle r_A \rangle^2$$

σ^2 is defined for a mixture of many cations, but in a binary system such as A = $(Ba_{1-x}M_x)$, it reduces to:

$$\sigma^2 = x(1-x)(r_{Ba} - r_M)^2$$

and hence σ^2 varies quadratically with x. At a constant $\langle r_A \rangle$, the temperatures of the ferromagnetic metal to paramagnetic insulator transition in $AMnO_3$ perovskites (at which colossal magnetoresistances are observed),[6] and the superconducting critical transitions in A_2CuO_4 and ABa_2CuO_7 decrease linearly with increasing σ^2.[5,7] However, the orthorhombic–tetragonal structural transition in the A_2CuO_4 materials shows a strong linear increase with σ^2.[5] Here, we present the first systematic study of the influence of A site disorder on the properties of $BaTiO_3$-based ferroelectric perovskites.

Six (Ba, Sr, Ca)TiO_3 compositions (Table 1) were chosen to give a constant $\langle r_A \rangle$ = 1.454 Å but variable σ^2. $\langle r_A \rangle$ and σ^2 were calculated using standard values of nine-coordinate ionic radii.[8] 10 g samples were prepared by mixing appropriate quantities of $BaCO_3$, $SrCO_3$, $CaCO_3$ and TiO_2 (all 99.99+% pure) which were ground in an agate mortar and pestle with acetone for 15 min, fired in Pt foil boats at 1000 °C for 12 h, then reground for 15 min before refiring at 1200 and 1350 °C. Regrinding and refiring at 1350 °C for 12 h was repeated six times. The powders were milled in a planetary ball mill for 5 min rather than a mortar and pestle for the final three cycles. This lengthy preparative procedure was necessary as it is known to be difficult to homogenise low levels of alkaline earth dopants in $BaTiO_3$ powders.[9]

Table 1 Starting and EPMA analysed compositions for six $(Ba_{0.90+0.45x}Sr_{0.1-x}Ca_{0.55x})TiO_3$ samples and their A site cation size variances

Starting composition	Analysed formula[a]	σ^2/Å^2
$Ba_{0.900}Sr_{0.100}TiO_3$	$Ba_{0.91(3)}Sr_{0.09(3)}Ti_{1.0(4)}O_3$	0.0023
$Ba_{0.909}Sr_{0.080}Ca_{0.011}TiO_3$	$Ba_{0.90(2)}Sr_{0.09(2)}Ca_{0.01(2)}Ti_{1.02(2)}O_3$	0.0028
$Ba_{0.918}Sr_{0.060}Ca_{0.022}TiO_3$	$Ba_{0.92(1)}Sr_{0.06(1)}Ca_{0.02(1)}Ti_{1.02(2)}O_3$	0.0032
$Ba_{0.927}Sr_{0.040}Ca_{0.033}TiO_3$	$Ba_{0.93(1)}Sr_{0.04(1)}Ca_{0.03(1)}Ti_{1.02(2)}O_3$	0.0037
$Ba_{0.936}Sr_{0.020}Ca_{0.044}TiO_3$	$Ba_{0.94(1)}Sr_{0.02(1)}Ca_{0.04(1)}Ti_{1.02(2)}O_3$	0.0041
$Ba_{0.945}Ca_{0.055}TiO_3$	$Ba_{0.95(1)}Ca_{0.05(1)}Ti_{1.03(1)}O_3$	0.0047

[a] Formulae were calculated by normalising to Ba + Sr + Ca = 1.

The samples were characterised by electron probe microanalysis (EPMA), using a Cameca SX51 microprobe, and powder X-ray diffraction on a Stoe STADI/P diffractometer. The L_α line of Ba and the Kα line of Sr, Ti and Ca were used for the cation analysis, by employing calibration standards of $BaTiSi_3O_9$, $SrTiO_3$ and $CaSiO_3$ and the oxygen contents were calculated by difference. The EPMA showed the samples to be homogeneous with compositions consistent with the starting formulae (Table 1). The room temperature diffraction patterns were obtained with monochromated Cu-Kα_1 radiation and were all fully indexed in the tetragonal space group *P*4*mm*. A linear variation of lattice parameters with σ^2 is observed (Fig. 1), however, the cell volumes for all samples (64.10 ± 0.09 Å^3) were the same within error and showed no significant variation with σ^2.

The ferroelectric Curie temperatures, T_C, were found from permittivity and calorimetric measurements. Pellets for the permittivity experiments were cold pressed and fired overnight at 1350 °C in air. Impedance was measured between 25 and 180 °C over the frequency range 10–10^7 Hz with an applied voltage of 100 mV using a 4192 Hewlett Packard impedance analyser. Data obtained at fixed frequency of 1 kHz showed sharp permittivity *vs*. temperature profiles for all the samples, with no apparent broadening of the ferroelectric transition, T_C values were extracted from the permittivity maximum obtained

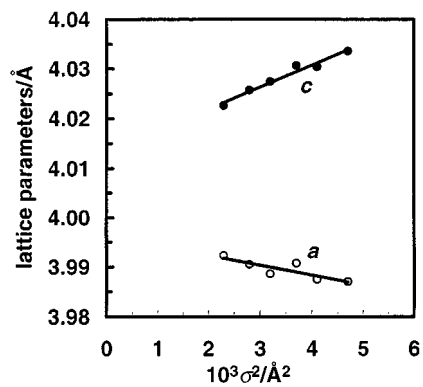

Fig. 1 Variation in the tetragonal lattice parameters of the $ATiO_3$ samples with σ^2 at 300 K.

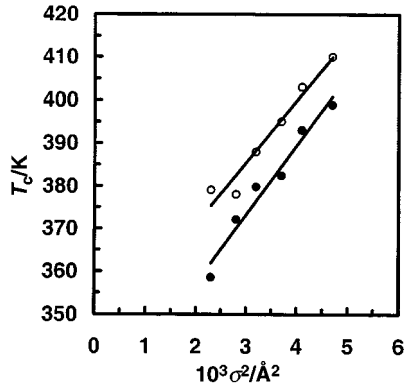

Fig. 2 Variation in T_C with σ^2. Open and filled circles correspond to data obtained from permittivity and DSC measurements, respectively.

on a heating cycle. Such values are dependent on the thermal history of the sample, as $BaTiO_3$-based materials show hysteresis on thermal cycling, so calorimetric measurements were used to confirm the T_C variation. Powdered samples were thermally cycled between 0 and 180 °C in a Polymers Lab differential scanning calorimeter at a heating rate of 10 °C min^{-1} and T_C values were extracted from the peak maximum associated with the endotherm in the cooling cycle. The two sets of T_C values are plotted *vs.* σ^2 in Fig. 2. A detailed analysis of the microstructure and electrical properties of the samples, which are sensitive to microstructural effects such as grain size and pellet density,[9] will be reported elsewhere.

The two sets of T_C values both show a strong linear increase with increasing A-cation size variance, σ^2, although the calorimetric values are systematically lower than those obtained from permittivity measurements. Linear fits to the permittivity and DSC results give slopes of $dT_C/d\sigma^2$ = 14500(400) and 16000(300) K Å^{-2}, and T_C^0 values (by extrapolation to σ^2 = 0) of 341(3) and 325(3) K, respectively, with fitting errors in parentheses. To estimate the contribution of cation size disorder to T_C in the $Ba_{1-x}Ca_xCa_xTiO_3$ series, the reported T_C values are shown together with disorder-corrected T_C^0 values in Fig. 3. These were calculated in the first approximation by extrapolating from T_C to σ^2 = 0 assuming a constant $dT_C/d\sigma^2$ = 15 000 K Å^{-2}, although a slight variation in $dT_C/d\sigma^2$ is expected across the series by comparison with other systems.[4] The resulting T_C^0 values show a near-linear fall with x comparable to the behaviour of T_C in the $Ba_{1-x}Sr_xTiO_3$ series.[2]

These results show that the ferroelectric transition temperature in doped $BaTiO_3$ materials is strongly influenced by

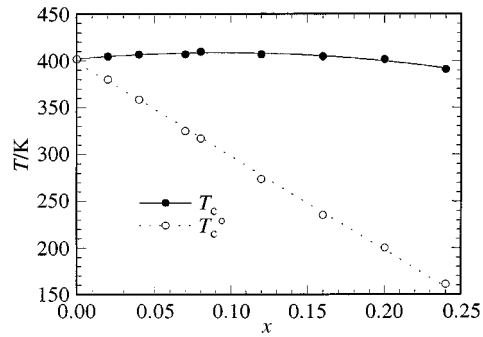

Fig. 3 The variation of T_C (from ref. 3) and the disorder corrected T_C^0 in the $(Ba_{1-x}Ca_x)TiO_3$ series.

both the average A cation size $< r_A >$ and the size variance σ^2. These effects initially oppose one another in substituted $(Ba_{1-x}M_x)TiO_3$ series where Ba is replaced by smaller M = Sr or Ca cations. As x increases, the decreasing $< r_A >$ *reduces* T_c but the increasing σ^2 *raises* T_C. The former reduction is essentially linear with $< r_A >$, as evidenced by the T_C^0 variation in Fig. 3, in apparent contrast to the size dependence of the previously studied electronic transitions, which decrease quadratically with $< r_A >$.[4,6] The linear increase of T_C with σ^2 is in keeping with the observed variation of the structural transition in A_2CuO_4 materials. Reducing $< r_A >$ in the $ATiO_3$ perovskites leads to tilts and rotations of the TiO_6 octahedra that destabilise the ferroelectrically ordered phase, whereas the local disorder associated with increasing σ^2 enables the ferroelectric distortions in the TiO_3 network to occur more easily and thereby stabilises the ferroelectric phase. This is supported by the data in Fig. 1, which show a divergence of the tetragonal a and c parameters as σ^2 increases.

The observed $dT_C/d\sigma^2 \approx$ 15 000 K Å^{-2} in our $ATiO_3$ series is smaller than the value of ≈50 000 K Å^{-2} found for the A_2CuO_4 structural transition,[5] which involves rotations but not distortions of the CuO_6 octahedra. However, $dT_C/d\sigma^2$ is comparable to the reported magnitudes of ≈20 000 K Å^{-2} for the metal–insulator transition in $AMnO_3$ perovskites.[4,6] This is accompanied by the formation of Jahn–Teller distortions of the MnO_6 octahedra *above* the transition,[10] whereas Ti displacements of comparable magnitude occur within the TiO_6 octahedra *below* the ferroelectric transition in $ATiO_3$ materials. Hence, the magnitude of $dT_C/d\sigma^2$ appears to be related to the degree of structural distortion occurring at the transition.

In conclusion, the ferroelectric–paraelectric transition temperature of $ATiO_3$ materials shows a strong linear increase with A-cation size variance. The σ^2 effect opposes the influence of the average A cation size and may be useful in stabilising ferroelectric phases to higher temperatures. In the $(Ba_{1-x}Sr_x)TiO_3$ series, the size effect dominates, so T_C falls with increasing x. However, Fig. 3 shows that the much greater σ^2 contribution in the $(Ba_{1-x}Ca_x)TiO_3$ series effectively cancels out the $< r_A >$ effect, leading to almost constant T_C values up to the observed maximum x = 0.24.

The authors thank James Marr and Susan Geddes for assistance with sample preparation, Dr Alison Coats for EPMA analysis and Dr Corrie Imrie and Brian Paterson for assistance with DSC measurements.

Received (in Basel, Switzerland) 7th May 1999, Accepted 13th June 1999

Thermolysis of $Fe_2(CO)_6(\mu\text{-}PPh_2)(\mu\text{-}C_2Bu^t)$ affords the binuclear alkenyl complex $Fe_2(CO)_5(\mu\text{-}PPh_2)(\mu\text{-}o\text{-}Ph_2PC_6H_4C{=}CHBu^t)$ and the trinuclear arene complex $Fe_3(CO)_4(\mu_3\text{-}o\text{-}PhPC_6H_4PPh)\{\mu_3\text{-}C(Bu^t)CCH{=}CBu^t\text{-}\eta^6\text{-}C_6H_5\}$ both resulting from a number of novel transformations including C–C bond formation and C–H and C–P bond cleavage and reformation.

Binuclear iron triad acetylide complexes such as $M_2(CO)_6(\mu\text{-}PPh_2)(\mu\text{-}C{\equiv}CR)$ have recently been exploited as novel precursors for the synthesis of multimetallic polycarbon materials *via* intermolecular coupling of alkynyl ligands.[1–4] For example, thermolysis of $Ru_2(CO)_6(\mu\text{-}PPh_2)(\mu\text{-}C{\equiv}CR)$ (R = Ph, Bu^t) affords several tetraruthenium clusters with C_4 chains formed by head-to-head or head-to-tail ynyl coupling, the nature of which depends on the acetylide substituent.[1,2] Similarly, in a remarkably specific, high yield reaction, the diiron complex $Fe_2(CO)_6(\mu\text{-}PPh_2)(\mu\text{-}C{\equiv}CPh)$ has been shown independently by ourselves[3] and Mays and coworkers[4] to undergo head-to-head carbon–carbon coupling generating the unusual tetrairon cluster $Fe_4(CO)_8(\mu\text{-}PPh_2)_2(\mu_4\text{-}C{\equiv}CPh)_2$ in which the face capping acetylides are linked through the tetrairon core by a short [1.596(4) Å] carbon–carbon contact. In an effort to extend this chemistry to other polycarbon systems we have studied the analogous thermolysis of $Fe_2(CO)_6(\mu\text{-}PPh_2)(\mu\text{-}C{\equiv}CBu^t)$ **1**. To our surprise, we have discovered that this leads to two new complexes formed *via* unprecedented transformations including carbon–carbon bond formation, and carbon–hydrogen and carbon–phosphorus bond cleavage and reformation. We describe herein the characterisation of these novel compounds $Fe_2(CO)_5(\mu\text{-}PPh_2)(\mu\text{-}o\text{-}Ph_2PC_6H_4C{=}CHBu^t)$ **2** and $Fe_3(CO)_4(\mu_3\text{-}o\text{-}PhPC_6H_4PPh)\{\mu_3\text{-}C(Bu^t)CCH{=}CBu^t\text{-}\eta^6\text{-}C_6H_5\}$ **3**.

Heating a toluene solution of **1** at 140 °C for 30 h resulted in a gradual darkening of the solution and disappearance of **1** as shown by IR spectroscopy, and led after chromatography to the isolation of orange $Fe_2(CO)_5(\mu\text{-}PPh_2)(\mu\text{-}o\text{-}Ph_2PC_6H_4C{=}CHBu^t)$ **2** (35%) and green $Fe_3(CO)_4(\mu_3\text{-}o\text{-}PhPC_6H_4PPh)\{\mu_3\text{-}C(Bu^t)CCH{=}CBu^t\text{-}\eta^6\text{-}C_6H_5\}$ **3** (10%) (Scheme 1). Spectroscopic data† and X-ray crystallography‡ established full details of the molecular structures and the nature of the coupled organic fragments.

Complex **2** (Fig. 1) is binuclear, the diiron centre being bridged by phosphido and alkenyl ligands. The latter carries the *tert*-butyl substituent at the β-carbon as expected, while the α-carbon is attached to the *ortho*-position of a 2-diphenylphosphino–C_6H_4 group and is *cis* to the Bu^t substituent. The diphenylphosphido functionality is coordinated to Fe(1) as a two-electron ligand. The two phosphorus ligands subtend an angle of 159.39(4)° at Fe(1) accounting for the relatively large phosphorus–phosphorus coupling constant of 75 Hz and the unique alkenyl proton lies *endo* to the phosphido bridge. While the structural features of the alkenyl group are similar to those of related diiron μ-alkenyl complexes the formation of a 2-diphenylphosphino–C_6H_4 substituent at C_α is quite unex-

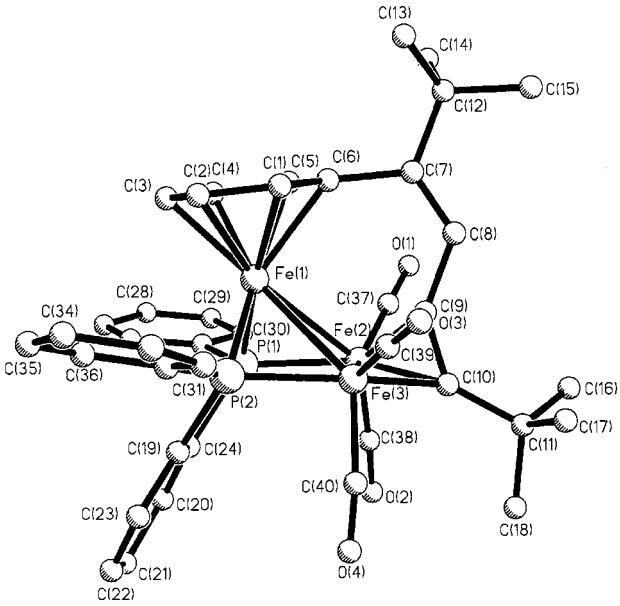

Fig. 2 Molecular structure of **3** with selected bond lengths (Å): Fe(1)–Fe(2) 2.696(2), Fe(1)–Fe(3) 2.689(3), Fe(2)–Fe(3) 2.438(2), Fe(1)–P(1) 2.184(4), Fe(1)–P(2) 2.191(4), Fe(2)–P(1) 2.165(4), Fe(3)–P(2) 2.155(4), Fe(1)–C(1) 2.119(14), Fe(1)–C(2) 2.097(13), Fe(1)–C(3) 2.104(12), Fe(1)–C(4) 2.089(11), Fe(1)–C(5) 2.142(12), Fe(1)–C(6) 2.156(12), Fe(2)–C(9) 2.020(11), Fe(3)–C(9) 1.982(12), Fe(2)–C(10) 2.041(11), Fe(3)–C(10) 2.034(11), C(1)–C(2) 1.412(18), C(2)–C(3) 1.374(18), C(3)–C(4) 1.411(18), C(4)–C(5) 1.398(17), C(5)–C(6) 1.461(17), C(1)–C(6) 1.433(17), C(6)–C(7) 1.490(17), C(7)–C(8) 1.294(16), C(8)–C(9) 1.469(16), C(9)–C(10) 1.335(16).

pected. Formally the new hydrocarbyl ligand can be derived from **1** by loss of CO and addition of PPh_3 across the alkynyl ligand. Indeed **2** is an isomer of $Fe_2(CO)_5(PPh_3)(\mu\text{-}PPh_2)(\mu\text{-}C{\equiv}CBu^t)$ **4**.[5] The latter is formed upon addition of PPh_3 to **1** under benzene reflux and we have now shown in a separate experiment that **4** cleanly converts to **2** in refluxing toluene. This may imply that upon thermolysis of **1**, PPh_3 is released which subsequently reacts with **1** to afford **2**.

The structure of trinuclear **3** (Fig. 2) is quite unprecedented and highly unusual for an Fe_3 cluster. It consists of a triiron core, one edge of which [Fe(2)–Fe(3) 2.438(2) Å] is significantly shorter than the other two [Fe(1)–Fe(2) 2.696(2), Fe(1)–Fe(3) 2.689(3) Å]. One face of the cluster is capped by an *ortho*-phenylenebis(phenylphosphido) bridge,[6] while the second is spanned by a new enyne ligand namely 2,2,7,7-tetramethyl-3-phenylocta-3-en-5-yne. The acetylinic triple bond acts as a four-electron donor, binding in perpendicular fashion to the short iron–iron vector, while the phenyl ring is coordinated as an η^6-ligand to Fe(1). The average iron–carbon (2.118 Å) and carbon–carbon (1.415 Å) bond lengths for the η^6-ligand fall within the ranges associated with mononuclear iron–arene complexes.[7] All bonds to the substituted aryl carbon C(6) are elongated with respect to the other carbons in the ring, an effect probably due to the strain imposed on the hydrocarbyl ligand to maximise metal–alkyne bonding. Two iron centres also bear two carbonyls giving the cluster the expected 48-electron count. Although there is no crystallographic plane of symmetry, the molecule has an approximate plane containing Fe(1)C(3)C(6)C(7)C(8)C(9)C(10) and bisecting Fe(2)–Fe(3) and P(1)–P(2) hence accounting for the relatively simple NMR data.

While the precise mechanism of formation of **2** and **3** from **1** is unknown, the nature of the new ligands and the nuclearity of **3** imply key bond breaking and bond making processes: (i) P–C(Ph) cleavage of a $\mu\text{-}PPh_2$ bridge and scavenging of released phenyl groups by phosphido and hydrocarbyl ligands; (ii) addition of a C–H bond of a phenylphosphine across a coordinated triple bond—we believe that this observation is unprecedented; (iii) head-to-head coupling of acetylide ligands and intermolecular condensation at binuclear metal centres; (iv) coupling of PPh_2 and PPh fragments *via* orthophosphination of a phenyl ring to afford a six-electron donor $PhPC_6H_4PPh$ ligand in **3**; (v) loss of carbonyl groups and η^6-coordination of an aryl substituent to afford a carbonyl free iron atom. Again, we are unaware of any comparable reacton.

We are currently examining the thermal and photochemical transformations of other binuclear phosphido bridged acetylides to gain further insights into the factors governing these novel processes.

We are grateful to the National Research Council of Canada and the Natural Sciences and Engineering Research Council for financial support of this work.

Resolution of coupled electron transfer–ion transfer processes at liquid/liquid interfaces by visualisation of interfacial concentration profiles

Jie Zhang, Christopher J. Slevin and Patrick R. Unwin*

Department of Chemistry, University of Warwick, Coventry, UK CV4 7AL. E-mail: P.R.Unwin@warwick.ac.uk

Received (in Cambridge, UK) 10th June 1999, Accepted 23rd June 1999

A powerful approach for investigating heterogeneous electron transfer (ET) reactions at liquid/liquid (oil/water) interfaces is described and illustrated with studies of the reactions between $IrCl_6^{2-}$ or $Fe(CN)_6^{3-}$ in an aqueous phase and decamethylferrocene (DMFc) or ferrocene (Fc) in 1,2-dichloroethane (DCE).

ET reactions that occur at the interface between two immiscible electrolyte solutions (ITIES) are of considerable fundamental and industrial interest,[1] as well as representing a simple, useful analogue of redox processes that occur across cell menbranes.[2,3] Surprisingly, ET kinetics at ITIES are still poorly understood[4] and difficult to investigate unambiguously, because conventional electrochemical methods measure a total current flow which does not discriminate between ET and coupled ion transfer (IT).[5–7] To circumvent this problem, differential cyclic voltabsorptometry was recently combined with UV-VIS spectroscopy, to determine whether the products of an ET process crossed the interface.[8] A similar, earlier approach,[9,10] employed fluorescence as the spectroscopic probe. An *in-situ* EPR cell has also recently been developed to detect and monitor paramagnetic species produced as a result of ET at ITIES.[11]

While spectroscopic methods have provided improved insights into ET at liquid/liquid interfaces, they necessarily place demands on the types of reactants and products that can be studied.[12] Here, we describe a novel approach for investigating ET kinetics at ITIES, based on microelectrochemical measurement at expanding droplets (MEMED)[13,14] which, we show, allows all of the reactant and product distributions adjacent to the interface to be visualised. In this way, not only can the kinetics of the ET reaction be determined, but the extent to which the products are involved in coupled IT processes can readily be identified.

In the MEMED technique,[13,14] the ITIES is created by flowing a feeder liquid through a fine capillary tip (100–200 μm internal diameter), so that droplets form and grow periodically in a second receptor phase, immiscible with the first, analogous to the dropping mercury electrode[15] or electrolyte dropping electrode.[16,17] In contrast to these methods, however, MEMED determines the individual concentration profiles of products or reactants extending from the droplet surface into the receptor phase using a probe ultramicroelectrode (UME), positioned adjacent to the capillary. In the studies here, we used a 1 or 0.5 μm radius Pt disc working electrode held at a potential to detect a specific reactant or product by local diffusion-limited electrolysis. The current for the species of interest was recorded as a function of time, as droplets grew towards the tip, and converted to a concentration-distance profile.

We consider the redox reaction between Fc or DMFc (which we denote as Fc′) in DCE and either $IrCl_6^{2-}$ or $Fe(CN)_6^{3-}$ in the aqueous phase (denoted by Ox_{aq}):

$$Fc'_{DCE} + Ox_{aq} \xrightarrow{k} Fc'^{+} + Red_{aq} \quad (1)$$

where k is a first-order rate constant for the heterogeneous reaction. The objective was to determine k and identify whether the products (particularly Fc'^{+}) crossed the interface, by recording the concentration profiles for all four species in eqn. (1). This was achieved by expanding a DCE droplet containing Fc′ into an aqueous phase containing Ox and recording the Ox and Red profiles with the UME in the aqueous phase. Subsequently, an aqueous droplet, containing Ox, was expanded into the DCE phase and the profiles for Fc′ and Fc'^{+} recorded in DCE.

In all experiments, the potential across the interface was established by using the potential-determining ClO_4^- ion in each phase.[18] Fig. 1 and 2 show the concentration profiles for the reactants and products in the receptor phase for the reaction between $IrCl_6^{2-}$ and either Fc or DMFc. The concentrations have been normalised with respect to the bulk reactant concentrations, $[IrCl_6^{2-}]^*$ or $[Fc']^*$, and plotted against the separation, d, between the probe and droplet surface. The initial driving force for the reactions is governed by the difference in the formal potentials of the $IrCl_6^{2-}/IrCl_6^{3-}$ couple and the Fc′/Fc'^{+} couple, $\Delta E°$, and the relative potential drop, $\Delta\phi$, across the ITIES. This was determined by measuring the difference in the half-wave potentials, $\Delta E_{1/2}$, of the reversible couples in the two phases *versus* saturated calomel (SCE) reference electrode in the aqueous phase:

$$\Delta E_{1/2} = \Delta E° + \Delta\phi \quad (2)$$

For the $IrCl_6^{2-}$–Fc reaction $\Delta E_{1/2}$ was *ca.* 0.40 V, while for the $IrCl_6^{2-}$–DMFc reaction $\Delta E_{1/2}$ was *ca.* 0.70 V. These are

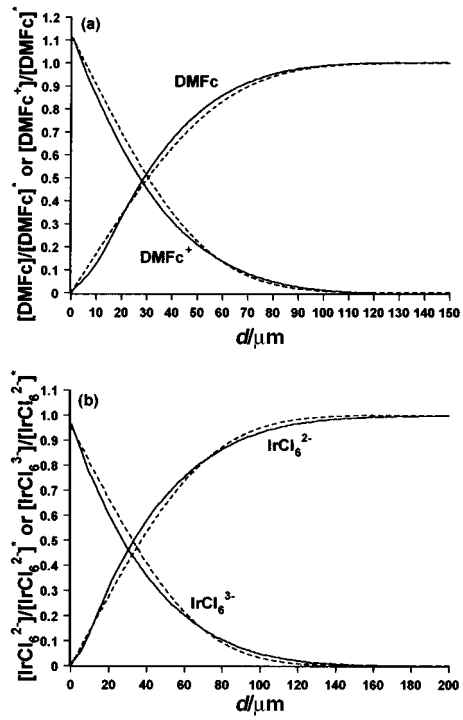

Fig. 1 Normalised concentration profiles (solid lines) of the reactants and products in the DCE (a) and aqueous (b) receptor phases for the reaction between DMFc (DCE) and $IrCl_6^{2-}$ (aqueous). Drop times and final sizes were (a) 5.54 s and 0.96 mm, and (b) 6.32 s and 1.00 mm. The theoretical profiles (dashed lines) are for a transport-controlled reaction, with no transfer of the product ions.

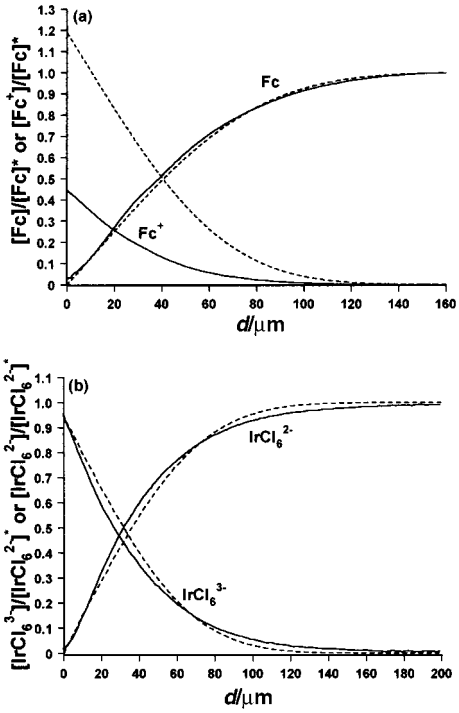

Fig. 2 Normalised concentration profiles (solid lines) of the reactants and products in the DCE (a) or aqueous (b) receptor phase for the reaction between Fc (DCE) and $IrCl_6^{2-}$ (aqueous). Drop times and final sizes were (a) 5.54 s and 0.96 mm, and (b) 6.32 s and 1.00 mm. The theoretical profiles (dashed lines) are for a transport-controlled reaction, with no transfer of the product ions.

relatively large driving forces and consequently the $IrCl_6^{2-}$ and $IrCl_6^{3-}$ profiles in both cases indicate that the reaction is transport-controlled ($k > 0.1$ cm s^{-1}), with the concentration of $IrCl_6^{2-}$ falling to zero at the surface of the droplet. There is generally good agreement between the experimental and theoretical profiles, calculated based on the following convective–diffusion equation, which applies close to the interface of the expanding droplet:[13,14]

$$\frac{\partial c_i}{\partial t} = D_i \frac{\partial^2 c_i}{\partial r^2} - \frac{q}{2\pi}\left(\frac{1}{r^2} - \frac{1}{r_o^2}\right)\frac{\partial c_i}{\partial r} \qquad (3)$$

D_i and c_i are the diffusion coefficient and concentration of the reactant, i = R, or product, i = P, in the receptor phase, respectively. The spherical coordinate, starting at the centre of the drop, is denoted by r; q is the volume flow rate, and r_o is the (time-dependent) drop radius.

The interfacial boundary condition is:

$$r = r_o: \quad -D_R \frac{\partial c_R}{\partial r} = D_P \frac{\partial c_P}{\partial r} = k c_R \qquad (4)$$

where R and P are, respectively, $IrCl_6^{2-}$ and $IrCl_6^{3-}$ for the aqueous receptor phase or Fc′ and Fc′$^+$ for the DCE receptor phase. Eqn. (4) assumes that neither the product nor the reactant in the receptor phase partition into the droplet. Semi-infinite no-flux boundary conditions apply at a long distance from the ITIES. Measured values of $D_{IrCl_6^{2-}} = 6.8 \times 10^{-6}$ cm^2 s^{-1} and $D_{IrCl_6^{3-}} = 7.5 \times 10^{-6}$ cm^2 s^{-1} were employed to calculate the concentration profiles.

The DMFc and DMFc$^+$ profiles (Fig. 1) for the DCE receptor phase also show a good fit to a transport-controlled process, with $k > 0.1$ cm s^{-1}, calculated using $D_{DMFc} = 7.5 \times 10^{-6}$ cm^2 s^{-1} and $D_{DMFc^+} = 6.0 \times 10^{-6}$ cm^2 s^{-1}. The excellent agreement between the DMFc$^+$ experimental and theoretical profiles indicates that DMFc$^+$ does not cross the ITIES under the defined experimental conditions, and that charge neutrality must be maintained by ClO_4^- transfer from the aqueous phase to the DCE phase. In contrast, while the Fc profile in Fig. 2 indicates that the $IrCl_6^{2-}$–Fc reaction is clearly transport-controlled, the Fc$^+$ profile indicates a substantial loss of Fc$^+$ which can be attributed to transfer across the interface from the DCE to the aqueous phase.[5]

The reaction between $Fe(CN)_6^{3-}$ and DMFc was also investigated. Although DMFc was proposed as an ideal electron donor for ET studies at ITIES,[6] earlier investigations concluded that no ET reaction could be observed between DMFc and $Fe(CN)_6^{3-}$ at the DCE/aqueous interface.[6] In this study, DMFc and DMFc$^+$ were measured in a DCE receptor phase, while forming an aqueous droplet containing $Fe(CN)_6^{3-}$. The results clearly showed that an ET reaction occur between $Fe(CN)_6^{3-}$ and DMFc, evidenced by a decrease in DMFc and formation of DMFc$^+$ close to the interface. The process was characterised by a first-order heterogeneous reaction rate constant of $(2.0 \pm 0.2) \times 10^{-3}$ cm s^{-1}. The smaller rate constant with $Fe(CN)_6^{3-}$ compared to $IrCl_6^{2-}$ as the electron acceptor can be attributed to a lower driving force, $\Delta E_{1/2} = 0.086$ V.

In summary, MEMED is a promising technique for studying ET reactions at ITIES. Determining all of the reactant and product distributions adjacent to the ITIES allows interfacial ET kinetics to be determined unambiguously, and the nature of any coupled IT processes is revealed.

We thank the EPSRC (GR/L15074) and Zeneca for support. J. Z. also gratefully acknowledges scholarships from the ORS scheme and the University of Warwick. Helpful discussions with Dr John Atherton and John Umbers (Zeneca Huddersfield Works) are much appreciated.

Received (in Cambridge, UK) 7th April 1999, Accepted 23rd June 1999

Two porphyrins were attached to the cyclic decapeptide Gramicidin S and its analogs *via* the side chain amide bonds and the solvent-dependent molecular structure was characterized by various spectroscopic methods.

Since the elucidation of a natural system with a number of tetrapyrroles,[1] such porphyrin assemblies have attracted much attention. To understand the function of the multi-porphyrin systems, many porphyrin arrays with different linker architecture have been studied as models.[2] So far, the porphyrin units have often been connected by tight linkers which determine their distance and orientation.[2b–d] However, a peptide-linked porphyrin array may be interesting because of its likeness to the natural system with a flexible peptide moiety.[3] The flexible linker may afford a porphyrin array wherein structural changes reflect its surroundings such as solvents.

Gramicidin S [*cyclo*(-Val-Orn-Leu-D-Phe-Pro-)$_2$, GS, Fig. 1] is a natural cyclic decapeptide with a pair of antiparallel β-sheets and two β-turns.[4] GS has often been modified without changing its rigid cyclic conformation in various solvents.[4b,c] The incorporation of porphyrins to the Orn residues facing each other may afford a defined porphyrin dimer. Here we report the syntheses and the spectroscopic characterisation of the porphyrin array attached on this rigid cyclic decapeptide and its analogs.

The cyclic decapeptides with side chain Z-protection (**1a**, **2a** and **3a**) were synthesized *via* the cyclisation–cleavage method on the oxime resin in 74–84% yield.[4c] After Z-deprotection with H_2–Pd/C, 5-(*p*-carboxyphenyl)-10,15,20-tritolylporphyrin (2 equiv.) was coupled with PyBOP–HOBt in 70–84% yield. The products with two porphyrins (**1b**, **2b** and **3b**) were characterized with FAB-HIMS and ^{1}H NMR (1D and 2D) spectra.

In the ^{1}H NMR spectrum of **2b** in DMSO-d_6, the α-amide NH signals appeared at δ 8.93 (D-Phe), 8.80 (Leu), 8.50 (Orn) and 7.30 (Val) at 303 K (data not shown). Both the chemical shifts and their temperature dependency (−8.3, −2.6, −4.5 and −2.0 ppb K^{-1}, respectively) were close to those of GS.[4c] These facts suggested the intramolecular hydrogen bonding between the NH and CO groups of Leu and Val residues (see Fig. 1), *i.e.* the conformational similarity of **3b** to GS. The attachment of porphyrins on the Orn positions did not change the peptide conformation. Such phenomena were also confirmed in the ^{1}H NMR study in $CDCl_3$.

The striking feature of the ^{1}H NMR spectrum of **2b** was that the tolyl groups of porphyrins appeared as two sets of doublets, δ 8.06/7.61 (4H each) and δ 7.79/7.23 (8H each) [Fig. 2(*a*)]. The methyl signals of the tolyl groups also appeared as two sets, δ 2.66 (6H) and 2.39 (12H). Compared with the monomeric porphyrin [Fig. 2(*b*)], apparently four tolyl groups among six in **2b** were high field shifted probably because of the ring current effect of the other porphyrin. The tolyl group near the other porphyrin (10-position, the inner tolyl groups in Fig. 3) may be high field shifted, but those at the 15- and 20- positions may be not. The tolyl signals at δ 7.79 and 7.23 were broad at 303 K [Fig. 2(*a*)] and were sharp at 333 K (data not shown), which implied restricted rotation of the porphyrin ring along the porphyrin–peptide axis. The signals of the 10- and 20-positions might be averaged and showed a broadened signal in the higher field. These facts suggest that the two porphyrins are spatially close. Fig. 3 shows the molecular structure of **2b** (bis-zinc complex) built by CAChe® MM2, adopting the crystal structure for the peptide moiety.[4a,5] This model also suggests that the two porphyrins are spatially close, and moreover, the left-twisted chiral orientation of the porphyrins (see below).

In CH_2Cl_2 **1b**, **2b** and **3b** (1.6 μM concentration, determined by the amino acid analysis) showed strong CD signals (data not shown), for instance **2b**, $[\theta]_{min}$ and $[\theta]_{max}$ at 424 and 416 nm ($[\theta]_M$ = −168 000 and 97 000 deg cm^2 dmol^{-1}, respectively). These CD signals were assigned to the split Cotton effects *via* the exciton coupling of the two porphyrins.[6] The (−+) sign of the couplets indicated the left-twisted orientation of the porphyrins, which was also suggested by the CAChe® calculation (Fig. 3). The intensity of the CD signals were **1b** < **2b** > **3b**. The drastic difference between **2b** (Orn) and **3b** (Lys) suggested that the flexible Lys side chains caused the loose structure of **3b**.

The Cotton effect for the porphyrins on GS was solvent-dependent (Fig. 4). The CD spectra of **2b(Zn$_2$)** in toluene (1.6 μM) showed a split Cotton effect at 435, 427 and 418 nm ($[\theta]_M$ = −951 000, 1275 000 and −234 000 deg cm^2 dmol^{-1}). The CD signals were weaker in other solvents, for instance in MeOH, $[\theta]_{430}$ = −803 000 and $[\theta]_{422}$ = 594 000 deg cm^2 dmol^{-1}. The intensity of the Cotton effect was in the order toluene > MeOH > trimethyl phosphate > TFE > CH_2Cl_2 > pyridine. These facts may indicate that the two

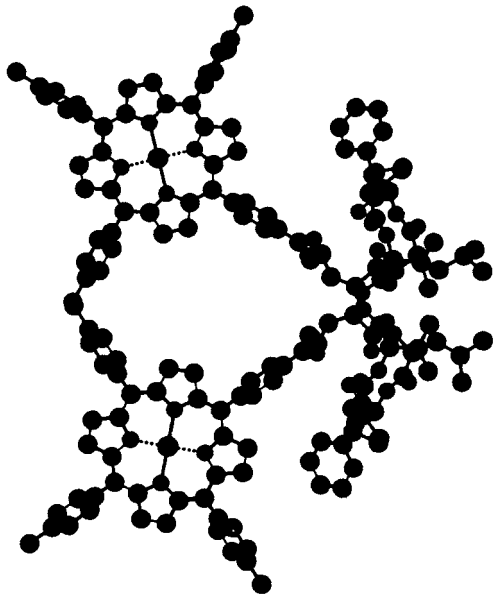

Fig. 3 CAChe® MM2 generated structure of **2b(Zn$_2$)**.

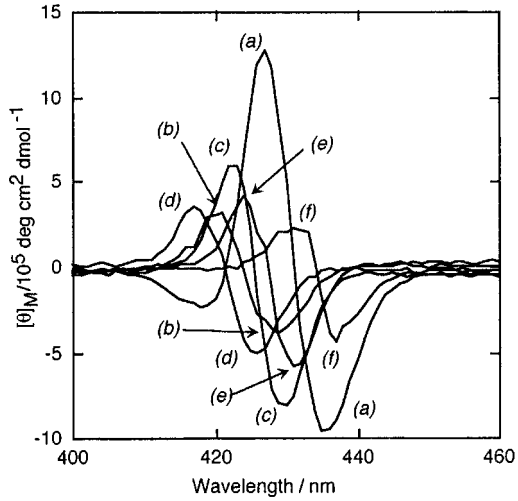

Fig. 4 CD spectra (1.6 μM for peptide) of **2b(Zn$_2$)** in (*a*) toluene, (*b*) CH_2Cl_2, (*c*) MeOH, (*d*) TFE, (*e*) trimethyl phosphate and (*f*) pyridine.

porphyrins in **2b(Zn$_2$)** were in close proximity in toluene, and the distance differed in the solvents. The different assembling ability of porphyrins in these solvents might cause different CD in the solvents, probably because of the different stabilization effect of the solvent for the π–π interaction. The details of the π–π interaction of the porphyrins are not clear yet, however, an electrostatic model may account for the tendency for porphyrin assembly in nonpolar solvents.[7] The UV spectra also supported the different orientation of the two porphyrins in these solvents. The λ_{max} of **2b(Zn$_2$)** in toluene (424 nm) was a little red-shifted from that of zinc tetratolylporphyrin (421 nm), which might be interpreted by the edge-to-edge interaction of the two π-systems.[8] However, such a shift of the λ_{max} was not observed in the other solvents investigated in the CD study, probably because of the weak interaction of the porphyrins.

Anyway, the porphyrins on GS showed different CD, *i.e.* different orientations in various solvents. This interesting fact was further confirmed by steady-state fluorescent spectrometry.[2a,3a] For this purpose, **2b(FbZn)** with one free-base porphyrin and one zinc porphyrin was synthesized. GS with different side-chain protection (Z and Fmoc) was synthesized in the same way as **2a**. After selective Z-deprotection by TFA–thioanisole–*m*-cresol (75% yield),[9] 5-(*p*-carboxyphenyl)-10,15,20-tritolylporphyrin was coupled using PyBOP–HOBt (quantitative). Then, Fmoc was removed with piperidine and zinc 5-(*p*-carboxyphenyl)-10,15,20-tritolylporphyrinate was coupled. After HPLC purification, **2b(FbZn)** was isolated in 60% yield (2 steps), and characterized with FAB-HIMS, HPLC and ^{1}H-NMR. The visible spectrum of **2b(FbZn)** (data not shown) was close to the average of **2b** (bis free-base) and **2b(Zn$_2$)**, suggesting no interaction of the two porphyrins in **2b(FbZn)** in the Q-state. However, the Soret band was somewhat broadened, suggesting a weak interaction in the B-state.[2a]

Upon exciting **2b(FbZn)** in toluene at 552 nm, the emission appeared at 608, 655 and 723 nm with an intensity ratio of 14:58:28. The ratio of ε_{552} of **2b** (bis free-base) and **2b(Zn$_2$)** was 40:60, *i.e.* 40% of the excitation light at 552 nm was absorbed by the free-base component of **2b(FbZn)** and 60% by the zinc porphyrin. From the comparison with the fluorescence spectra of **2b** (λ_{em} = 655, 719 nm, 74:26) and **2b(Zn$_2$)** (λ_{em} = 608, 652 nm, 46:54), intramolecular quenching of the excited state zinc porphyrin by the free-base porphyrin was suggested. The energy transfer from excited Zn porphyrin to free-base smoothly occurred intramolecularly, because these two porphyrins were in close proximity. The quenching efficiency was calculated to be *ca.* 82%. The same experiment performed in CH_2Cl_2 showed that 65% of the energy of the excited zinc porphyrin in **2b(FbZn)** was quenched by the free-base porphyrin. This semi-quantitative fluorescence experiment might suggest that the orientation of porphyrins differs in solvents, as suggested by CD and UV spectroscopy. However, the different energy transfer efficiencies in toluene and in CH_2Cl_2 could be due to a single solvent effect, as one of the reviewers pointed out.

We thank Professor Hideo Akisada at Kyushu Kyoritsu University for CD measurements. The molecular modeling study was partially done by Dr Masako Fujiwara at JOEL, which is gratefully acknowledged.

Catalytic enantioselective addition of enol silanes to ketomalonate mediated by C_2-symmetric bisoxazoline Lewis acid complexes

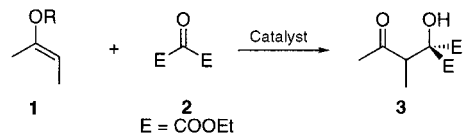
Frank Reichel, Xiangming Fang, Sulan Yao, Marina Ricci and Karl Anker Jørgensen*

Center for Metal Catalyzed Reactions, Department of Chemistry, Aarhus University, DK-8000 Aarhus C, Denmark. E-mail: kaj@kemi.aau.dk

Received (in Cambridge, UK) 22nd March 1999, Accepted 22nd June 1999

A catalytic enantioselective addition reaction of silyl enol ethers to ketomalonate in the presence of C_2-symmetric copper(II) bisoxazolines as catalysts is presented; the reaction has been studied for different ligands and substrates under various reaction conditions and proceeds in good yield and with ee's > 90% and a procedure for the preparation of an optically active hydroxy acid is shown.

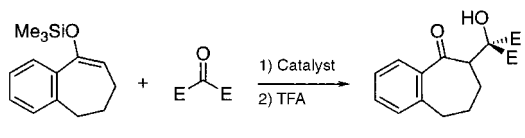
C_2-Symmetric copper(II) bisoxazoline Lewis acid complexes have proven to be highly enantioselective catalysts for a variety of different organic reactions. Such reactions include addition to dicarbonyl compounds[1] where they promote Diels–Alder,[2] hetero-Diels–Alder,[3] Mukaiyama aldol[4] and carbonyl ene reactions.[3a,5] Recently, it has been shown that copper(II) bisoxazolines can catalyze the reaction of ketomalonate with conjugated dienes leading to chiral CO_2 synthons and 1,4-disubstituted cyclohex-2-enes in good yields and ee's > 90%.[1b,6] It was proposed that the reaction proceeded *via* a five-membered ring intermediate with ketomalonate coordinated to the metal center through the reacting carbonyl and one of the two ester carbonyls.[6] This communication presents the first catalytic enantioselective addition of silyl enolates **1** to ketomalonate **2** with high ee in the presence of C_2-symmetric bisoxazoline Lewis acid complexes as the catalysts [eqn. (1)].



(1)

1 **2** (E = COOEt) **3**

Thus, the preparation of highly functionalised molecules such as **3** is achieved in high enantiomeric purity. Compound **3** may be regarded as the starting point for the preparation of valuable compounds such as β-keto and β-hydroxy esters or polyhydroxylated compounds.[7] It should also be mentioned that Evans *et al.*[8] in a very recent paper showed that copper bisoxazolines can also catalyze the enantioselective Michael addition of silylketene acetals to alkylidene malonates. Thus, we were prompted to present our recent results for the reaction outlined in eqn. (2).

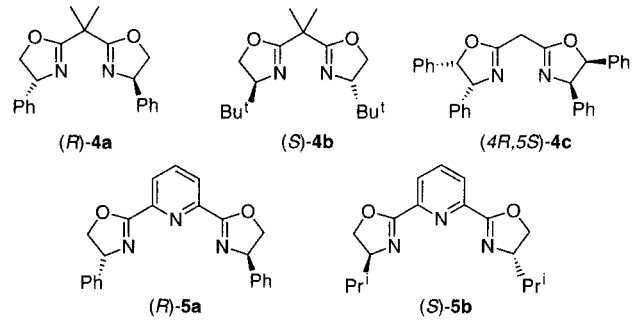


(2)

1a **2** **3a**

The reaction of the silyl enol ether **1a** with ketomalonate **2** has been investigated in order to study the potential of the bidentate and tridentate bisoxazoline-type ligands **4a–c**, **5a**,**b** in combination with $Cu(OTf)_2$ and $Zn(OTf)_2$ as the Lewis acid as enantioselective catalysts.† The yield and ee of **3a** are presented in Table 1.

The results in Table 1 show that both copper(II) and zinc(II) as the Lewis acids in the combination with the various ligands **4a–c**, **5a**,**b** are able to catalyze the reaction of the silyl enol ether



1a with ketomalonate **2**. However, the yield and ee of **3a** are very dependent on the Lewis acid and ligand applied. The highest yields and ee's are obtained with the (*R*)-**4a**-$Cu(OTf)_2$ and (4*R*,5*S*)-**4c**-$Cu(OTf)_2$ (entries 2, 4), where 99 and 94% isolated yield, and 67 and 70% ee, respectively, are obtained. Applying the same ligand, but changing the Lewis acid to zinc(II) leads to a reduction in both yield and ee of **3a** (entry 1). It is notable that changing the chiral ligand from the phenyl-substituted bisoxazoline (*R*)-**4a** to the *tert*-butyl-substituted (*S*)-**4b** and $Cu(OTf)_2$ as the Lewis acid leads to a significant reduction in the ee of **3a** as only 1% ee is obtained (entry 3). The application of the tridentate bisoxazoline ligands **5a**,**b** gives only moderate yield of **3a** accompanied with very low ee's (entries 5,6).

The promising results for the reaction of the silyl ether **1a** with ketomalonate **2** prompted us to investigate the influence of the choice of anions, solvents and temperature on the reaction course. The results are presented in Table 2 and it appears that the reaction is dependent on the solvent, temperature and anion. A fast reaction takes place at room temperature with high isolated yield and 77% ee in Et_2O as the solvent (entries 1–3), while at −10 °C longer reaction times are required to achieve good yield and the best results are obtained in Et_2O and Bu^{t}OMe where 86 and 83% ee are obtained, respectively (entries 5, 6). Changing the anion to hexafluoroantimonate causes a dramatic decrease in ee of **3a** (entry 7). Reducing the reaction temperature to −78 °C improves the ee up to 93% (entry 8). The chiral ligand (4*R*,5*S*)-**4c** is also a promising ligand and similar good yield and high ee are obtained as using (*R*)-**4a**-$Cu(OTf)_2$ as the catalyst (entries 9, 10).

Table 1 The reaction of silyl enol ether **1a** with ketomalonate **2** in the presence of the chiral ligands **4a–c**, **5a**,**b** in combination with $Cu(OTf)_2$ and $Zn(OTf)_2$ as Lewis acid in CH_2Cl_2 at room temperature

Entry	Catalyst	Yield[a] **3a** (%)	Ee[b] (%)

[a] Isolated yield. [b] Determined by chiral HPLC.

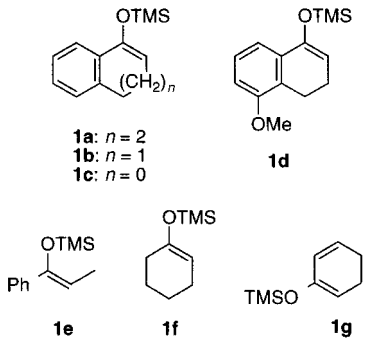
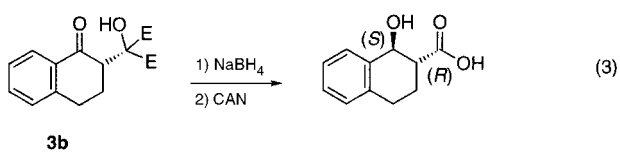
The reaction has been studied for a series of silyl enol ethers **1a**–**g** reacting with ketomalonate **2** in the presence of (*R*)-**4a** in combination with $Cu(OTf)_2$ or $Zn(OTf)_2$ and the results are presented in Table 3.



The reactions generally proceed with high isolated yields for the various substrates; for the cyclic aromatic silyl enol ethers **1a**,**b**,**d**, high ee's were obtained (Table 3, entries 1, 3, 6), whereas for the five membered analogue **1c**, the ee is reduced to 58% (entry 5). Furthermore, it appears from the results for **1b**,**c** that zinc(II) also can be used as the Lewis acid, however the ee is lower in these reactions (entries 2, 4). For the aromatic acyclic silyl enol ether **1e** the reaction proceeds also very well with very high isolated yield and ee (entry 7). The cyclic aliphatic silyl enol ether **1f** reacts also smoothly with ketomalonate **2** in the presence of (*R*)-**4a**-$Cu(OTf)_2$ as the catalyst giving the corresponding adduct in good yield and with up to 60% ee (entry 8), whereas the conjugated silyl enol ether **1g** only leads to the corresponding product in moderate yield and ee by using (*R*)-**4a**-$Cu(OTf)_2$ as the catalyst, while high yield and a racemic compound is obtained when (*R*)-**4a**-$Zn(OTf)_2$ is the catalyst (entries 9, 10).

The potential of the reaction is shown by the reduction, followed by oxidative cleavage of the ester groups in **3b** [eqn. (3)] giving the corresponding hydroxy acid in good yield and maintaining the ee obtained in the catalytic step.[9a] These reactions lead also to an assignment of the absolute configuration of the chiral center formed in the catalytic reaction.[9b]



3b (3)

In conclusion we have presented a novel catalytic enantioselective addition reaction of different silyl enol ethers to ketomalonate catalyzed by copper(II) bisoxazoline complexes giving highly functionalized optically active compounds.

This work was made possibly by a grant from The Danish National Research Foundation.

Table 3 The reaction of silyl enol ethers **1a**–**g** with ketomalonate **2** in the presence of (*R*)-**4a**-$Cu(OTf)_2$ or (*R*)-**4a**-$Zn(OTf)_2$ (10 mol%) as the catalyst in Et_2O as the solvent

Notes and references

† *Representative procedure*: $Cu(OTf)_2$ (18.1 mg, 0.05 mmol) and the ligand (*R*)-**4b** (17.6 mg, 0.0525 mmol) were placed in a flame dried Schlenk tube and dried under high vacuum for 1–2 h. Et_2O (1.5 ml) was added and the suspension was stirred for 1 h. Subsequently **2** (76 μl, 0.5 mmol) was added and the mixture was placed in a dry ice–acetone bath and after 30 min **1a** (232 mg, 1.0 mmol) was added. Stirring was continued for 75 h followed by addition of TFA–CH_2Cl_2 (10%, 1 ml). After 30 min TLC showed completion of hydrolysis and the solvent was removed. The residue was purified by FC (20% EtOAc in light petroleum) to afford **3a** (147 mg, 0.44 mmol, 88%) as a colourless oil with 93% ee, determined by chiral HPLC using a Chiralcel OJ column (5% Pr^iOH in hexane, 0.7 ml min^{-1}); $[\alpha]_D^{rt}$ −23.6 (*c* 0.008 g ml^{-1}, $CHCl_3$). δ_H 7.72 (dd, *J* 8.2, 1.1, 1H, arom.), 7.41 (dt, *J* 8.8, 1.5, 1H, arom.), 7.29 (t, *J* 7.2, 1H, arom.), 7.20 (d, *J* 7.1, 1H, arom.), 4.40 (br s, 1H, OH), 4.34–4.20 (m, 4H, CH_2), 3.86 (dd, *J* 11.0, 3.8, 1H, C(O)CHC), 3.12–2.86 (m, 2H, CH_2), 2.17–1.64 (m, 4H, CH_2), 1.28 (t, *J* 7.1, 3H, CH_3), 1.14 (t, *J* 7.1, 3H, CH_3) δ_C 204.4, 170.2, 169.0, 141.6, 137.9, 132.5, 129.9, 129.0, 126.7, 81.3, 62.7, 62.6, 53.5, 32.8, 25.0, 23.7, 14.1, 13.9.

Covalent adhesion; organic reactivity at a solid–solid interface through an inter-bead Diels–Alder reaction†

Iain P. Thomas, James A. Ramsden, Tibor Z. Kovacs and John M. Brown

Dyson Perrins Laboratory, South Parks Road, Oxford, UK OX1 3QY. E-mail: john.brown@chemistry.ox.ac.uk

Received (in Liverpool, UK) 26th February 1999, Accepted 18th June 1999

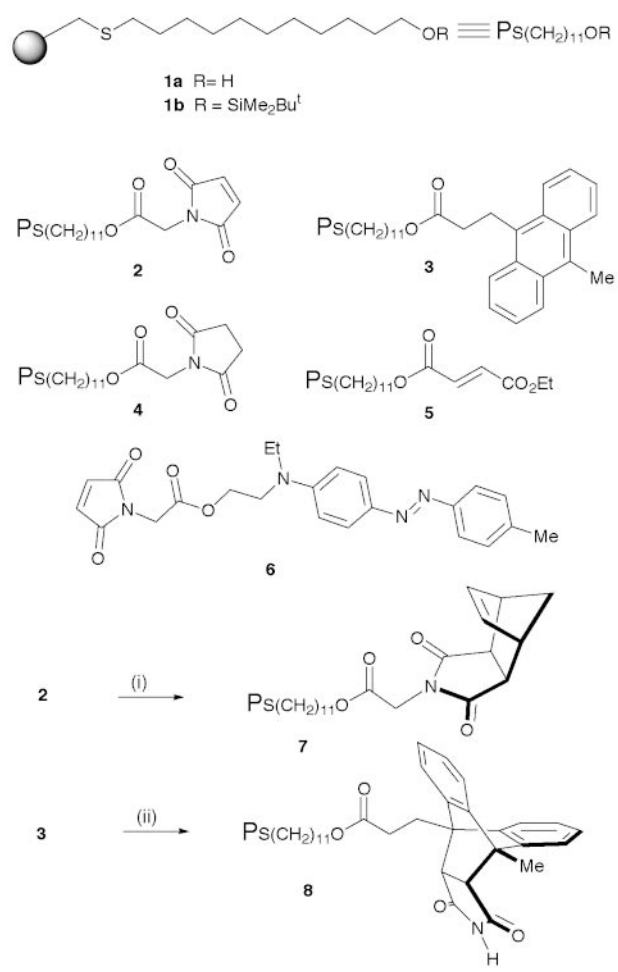
Polystyrene resin beads carrying respectively maleimide and anthracene groups attached to extended side-chains adhere to one another in a manner consistent with an inter-bead cycloaddition reaction.

We reported earlier on the synthesis of modified polymers based on cross-linked polystyrene where *ca.* 60% of the arene rings bore a long alkyl side-chain possessing terminal functionality.[1] The quality of ^{13}C NMR spectra observed for the solvent-swollen polymer and in particular the high degree of mobility deduced from the ^{13}C T_1 relaxation times indicated a fluid-like polymer where the functional groups were readily accessible. In addition, their effective concentration is in the 2–2.5 mM region. This led us to consider the possibility for reaction at the interface between two polymers of this type, each carrying a different reactive entity. There are interesting precedents for employing an intermolecular Diels–Alder reaction as a probe for the reaction environment, or immobilisation;[2] the reaction is a formal addition to give a single product, and it is relatively insensitive to solvent polarity.[3]

Synthesis of the desired polymers was accomplished according to Scheme 1. For the dienophilic component, the maleimide functionality was introduced in a one-step sequence whereby the alcohol **1a** was reacted with *N*-(chlorocarbonylmethyl)maleimide, giving **2**.[4] First attempts at forming a polymer-linked diene involved attachment of chlorodimethylcyclopentadienylsilane[5] (in the expectation of forming a regiochemically defined product) but were not quantitative. A more successful approach involved reaction of alcohol **1a** with 9-(2-chlorocarbonylethyl)-10-methylanthracene[6] from which resin **3** was obtained. For control experiments, the saturated succinimide **4** and fumarate ester **5** were synthesised using related methods. A staining procedure was adapted by synthesis of the dienophilic dye **6** prepared from Disperse Red 1 which was shown to selectively stain the resin diene **3** bright red[7] (1% solution, 1 h, THF), and to leave the dienophilic resin **2** unaffected under the same conditions. It was confirmed by ^{13}C NMR that the desired polymers had been synthesised without significant side-reactions and also that the staining procedure introduced an insignificant number of additional linkages into resin **3**. It were further confirmed by ^{13}C NMR that diene resin **3** reacted with maleimide to form the adduct **8** and dienophile resin **2** reacted with cyclopentadiene to form the adduct **7**. Both cycloadditions were complete by ^{13}C NMR. Since there is a rapid intermolecular Diels–Alder reaction between maleimide and 9,10-dimethylanthracene,[8] these polymer-bound entities provided a suitable test for investigation of interfacial reactivity.

Solvent effects on the aggregation of resin beads were explored first. Alcohol **1a** and its silyl ether **1b** were suspended in a range of solvents; the former aggregated in toluene or cyclohexane, the latter in ethanol (weakly) or DMF, indicating the inverse relationship between functional group polarity and disposition to aggregation in a given solvent. Further experiments demonstrated that all the resins **2**, **3** and **5** possessing unsaturated chains were aggregated in cyclohexane and fully dispersed in DMF. On this basis a protocol for the desired inter-bead Diels–Alder reaction was established. Approximately equal quantities of stained resin **3** and resin **2** were briefly sonicated together and then stood in toluene or cyclohexane. After 20 h there was considerable aggregation which persisted on transfer to suspension in DMF. On standing longer the degree of aggregation increased after the same treatment, and after an extended period agglomeration was observed.

Two more quantitative approaches were then attempted. Samples of resins **2** and **3** were mixed by sonication as before, centrifuged together for a defined period (0–75 min, 6500 rpm), suspended in the minimum quantity of DMF (centrifugation was not necessary in order to observe the described phenomena, but shortened the timescale). After completion the suspension was transferred to water on a microscope slide, causing considerable dispersal of aggregates, and observed by microscopy. The following observations were made, facilitated by the staining of the diene with maleimide **6** before reaction.



Scheme 1 *Reagents*: (i) neat cyclopentadiene, rt, 3 d; (ii) xs. maleimide, C_7H_8, rt, 6 d.

† A colour version of Fig. 1 is available as supplementary data from the RSC web site, see http://www.rsc.org/suppdata/cc/1999/1507/

Table 1 Analysis of bead–bead contacts after centrifugation in DMF and resuspension in water

	No. of beads		No. of contacts							
t/min	Diene **3**	Dienophile **2**	**3**–**3**	**2**–**2**	**2**–**3**	Total beads	No. in aggregation	Total contacts[a]	Statistical **2**–**3**	Actual **2**–**3**
0	213	445	43	54	96	658	273	193	0.438	0.497
30	700	1051	77	109	449	1751	780	635	0.480	0.707
75	703	1119	233	155	832	1822	1006	1220	0.487	0.682

[a] Includes single and multiple contacts.

(a) The extent of aggregation and the average size of aggregates increased with time; without mechanical intrusion the proportion of **2**:**3** (heterotopic) contacts was significantly higher than statistical, the proportion of **2**:**2** and **3**:**3** (homotopic) contacts likewise significantly lower than statistical expectation. Results are recorded in Table 1.

(b) When either resins **2** or **3** was subjected to the same treatment separately, no aggregation phenomena were observed.

(c) The nature of the interface was distinct for **2**:**3** contacts when compared to **2**:**2** or **3**:**3** contacts. For the latter, the point of contact was not defined, so that two or three beads made visible rolling movements, the stable state of most trimers being triangular. In contrast, association between beads **2** and **3** occurred at a fixed point and the interaction was stable (Fig. 1). Alternating linear tetramers were observed, but rarely higher states of linear aggregation. These aggregates could move freely maintaining their inter-bead vectors. By carrying out the staining procedure *after* inter-bead reaction, it was verified that heterotopic interactions (**2**:**3**) were uniquely responsible for the distinctive stable linear trimers and tetramers.

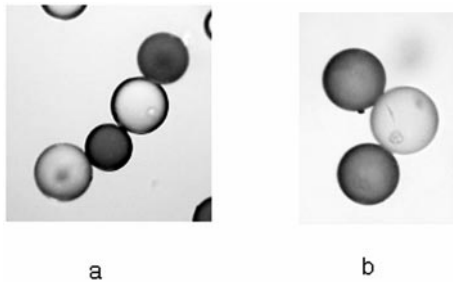


Fig. 1 Reaction of diene beads **3**, stained with Disperse Red to 1% of accessible functionality (dark spheres), with dienophile **2** in DMF (light spheres). Aggregates were located by microscopy after dispersal in water.

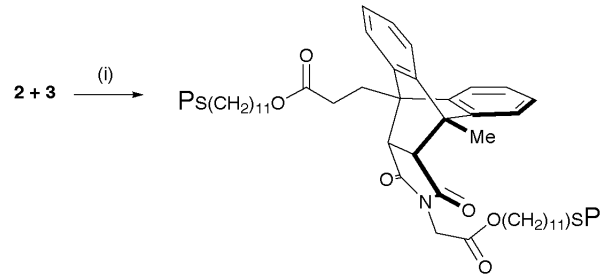
(d) Aggregates were not observed in control experiments involving the succinimide-capped resin **4** together with resin **3**, where complete dispersal to individual beads was observed on transfer to a polar medium.

(e) Aggregates formed in DMF were not broken down by exposure to maleimide (1 M in DMF, 20 min).

Although these aggregates were robust enough to be mechanically manipulated, their fragility is evident from the loss of adhesion after evaporation of all solvent DMF and attendant shrinkage of the beads.

Although the definitive explanation must await further studies at the nanochemical level, these experiments are best interpreted through the operation of a cycloaddition reaction occurring between diene and dienophile on separate beads, in the manner of Scheme 2. The beads remain undistorted, so that the extent of reaction is small. For a hard contact of a pair of beads 10^5 nm diameter in a solvent (DMF) of molecular volume 0.13 nm^3, the contact area is 7500 nm^3, with respectively 7×10^3 diene and 8×10^3 dienophile moieties in the surface segment. With long alkyl chains attached to an spatially irregular polymer backbone the surface of the bead will be rough at molecular dimensions, permitting reaction over a greater surface area than this. Since the activation free energy of the retro-Diels–Alder reaction is about 190 kJ mol^{-1},[10] each cycloaddition provides an interparticle bond of strength 3×10^{-19} J. Many bonding events are likely to be necessary to overcome shear forces.



Scheme 2 Suspend in DMF, sonicate 1–2 min, centrifuge 0–75 min, 5000 rpm.

There are few precedents for a well-defined reacting system with the components confined to different surfaces. A reasonable analogy can be made with the work of Sasaki and Maeda,[11] who studied peptide–peptide interactions with one component bound to magnetic polystyrene beads and the other bound to 5 μm controlled pore glass beads. Recent work of Whitesides and co-workers has been concerned with surface adhesion of micromachined objects through controlled hydrophobic or hydrophilic character of surfaces.[12] Our aims are to develop these present observations and define the scope and limitations of solid–solid interfacial chemistry.

We thank EPSRC for an award under the ROPA Scheme. Dr Colin Bain and Mr Peter Breed made helpful comments. We thank referees for valuable comments.

Catalytically self-threading polyrotaxanes

Dönüs Tuncel and Joachim H. G. Steinke*

Department of Chemistry, Imperial College of Science, Technology and Medicine, South Kensington, London, UK SW7 2AY. E-mail: j.steinke@ic.ac.uk

Received (in Cambridge, UK) 14th April 1999, Accepted 24th June 1999

A mainchain polyrotaxane is formed in which polymerisation and rotaxane formation occur simultaneously, due to the presence of the catalytically-active self-threading macrocycle cucurbituril.

Exerting increasing architectural control in the synthesis of polymers is key to the development of new materials.[1] This has been exemplified in the case of dendrimers where for the first time truly single entity synthetic polymers have been prepared.[2] The convergent approach in particular highlights how a well-established synthetic concept from one area of chemistry (protection/deprotection chemistry) can have a tremendous impact on another one (polymer synthesis). In a similar vein we describe in this communication a unique route for the synthesis of structurally perfect mainchain polyrotaxanes (Fig. 1).

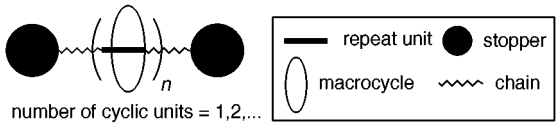

Fig. 1 A perfect polyrotaxane.

Polyrotaxanes represent a relatively recent addition to the repertoire of polymer architectures. Seminal work by Gibson,[3] Stoddart,[4] Harada[5] and Wenz,[6] and more recently Kim,[7] has produced a wealth of polyrotaxane structures and identified key synthetic parameters.[8] Earlier work was limited to the statistical synthesis of mainchain polyrotaxanes, but the current state-of-the-art uses directed (templated) strategies applied to the synthesis of mainchain, sidechain and hyperbranched polyrotaxanes and polypseudorotaxanes.[9,10] Perfect linear mainchain and networked polyrotaxanes have also been prepared, albeit in the solid-state only.[11]

Here we would like to add to the repertoire of polyrotaxane syntheses. In our approach polymerisation and rotaxane formation occur simultaneously to yield a perfectly threaded polyrotaxane due to the presence of cucurbituril, a macrocycle that catalyses 1,3-dipolar cycloadditions. Cucurbituril has also been used recently by Meschke *et al.* as the statistically threaded macrocyclic component in an interfacial condensation polymerisation.[12]

There are principally three ways in which to ensure that each polymer repeat unit is threaded by an integer number of cyclic units: (i) to polymerise a preformed rotaxane monomer, (ii) to select a polymer backbone that can bind strongly and selectively to a suitably chosen macrocycle, or (iii) to ensure that during the polymerisation step each added monomer contains an integer number of cyclic units. We opted for the third alternative by employing cucurbituril as macrocyclic component (Fig. 2). It was established by Mock *et al.*[13] in the 1980s that cucurbituril is capable of catalysing 1,3-dipolar cycloadditions in an enzyme-like fashion (Fig. 2).

The bond forming process requires the complexation of an ammonium azido and an ammonium alkyne compound to each of the carbonyl-fringed portals of cucurbituril. Complexation is accompanied by the displacement of solvent molecules from the hydrophilic interior of the macrocycle. The resulting complex is slightly strained. The release of this strain is responsible for the catalytic effect of cucurbituril on the cycloaddition reaction leading to an acceleration by a factor of 10^5.[14]

We decided to utilise this intriguing reaction for the synthesis of polyrotaxanes since each cycloaddition reaction catalysed by cucurbituril not only leads to a chemical bond but also to the self-threading of the macrocyclic catalyst. From a polymer synthesis point of view this means that each additional repeat unit added to a polymer chain is inevitably accompanied by the threading of exactly one cyclic unit.

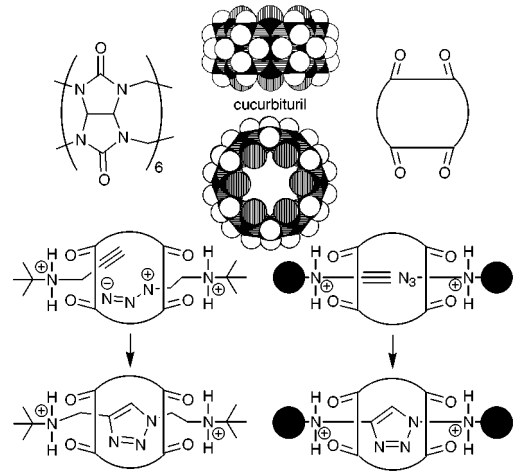

Fig. 2 1,3-Dipolar cycloaddition catalysed by cucurbituril.

Cucurbituril was synthesised according to a literature procedure.[15] The required diazide and dialkyne monomers have been synthesised efficiently as shown in Fig. 3. Monomer A was synthesised by treating **1** with propargylamine (propargyl = prop-2-ynyl), followed by formation of the dihydrochloride salt in 86% overall yield. The synthesis of monomer B also started from **1**, reacting first with 2-aminoethanol. Subsequent treatment with $SOCl_2$, followed by substitution with sodium azide and formation of the dihydrochloride salt gave monomer B in 4 steps and 39% overall yield.

The preparation of model compounds synthesised from monomer A and B with 2 equivalents of a corresponding *tert*-butylamine-derived mono-azido and mono-alkyne compound in the presence of cucurbituril yielded [3]rotaxanes in 88% and 67% yield respectively (for NMR see Fig. 5). The correspond-

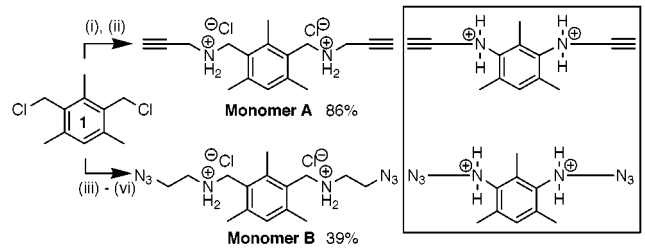

Fig. 3 Synthesis of monomers A and B. (i) $NH_2CH_2C{\equiv}CH$, neat, 0 °C → rt, 16 h, 100% (crude), (ii) 1 M HCl in Et_2O, rt, 86%, (iii) $NH_2CH_2CH_2OH$, neat, 5 h, 150–160 °C, 66%, (iv) $SOCl_2$, $CHCl_3$, 5 h, rt, 70%, (v) NaN_3, H_2O, 75 °C, 16 h, 87%, (vi) 1 M HCl in Et_2O, rt, 96%.

ing [2]rotaxane, first prepared by Mock *et al.*[14] was obtained in 76% yield. Polymerisation was carried out at room temperature by dissolving equimolar amounts of monomer A and monomer B in acidified water followed by the addition of 2 equivalents of cucurbituril (Fig. 4).

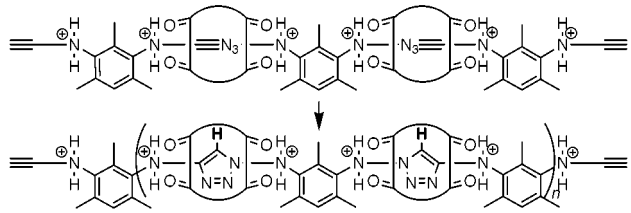

Fig. 4 Synthesis of a perfect mainchain polyrotaxane.

The reaction was followed by ^{1}H-NMR. Comparison of the relative intensities of the triazole proton to phenyl proton indicated the formation of possibly dimers (ratio 1 : 2) within the first 24 h of the reaction. After an additional 24 h the ratio had changed to a value close to 1 : 1. Longer reaction times had no bearing on the reaction outcome. Precipitation of the aqueous solution into acetone resulted in a white precipitate which was filtered, washed and dried *in vacuo* (yield: 68%). ^{1}H- and ^{13}C-NMR (^{13}C data of the corresponding carbon in brackets) are in agreement with the proposed structure. The crucial appearance of the triazole proton is documented in Fig. 5 and compared with a [3]rotaxane[16] and [2]rotaxane model compound (*vide infra*).

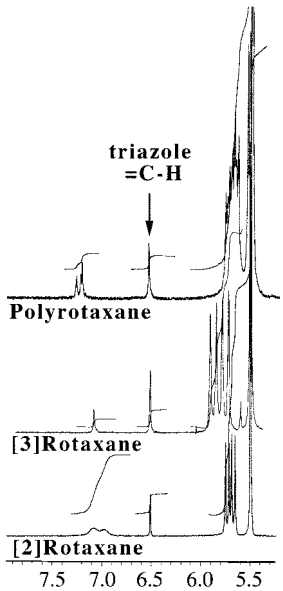

Fig. 5 ^{1}H-NMR overlay of the triazole region of the polyrotaxane and a [3][16] and [2]rotaxane model compound.

The triazole proton located inside the cavity of cucurbituril has a chemical shift of 6.54 ppm (122.7 ppm) which is further confirmed through the model [2]rotaxane and [3]rotaxane (Fig. 5). In an unprotonated triazole model compound the same proton appears at 7.52 ppm (120.8 ppm) and is shifted even further downfield in the same compound at 8.56 ppm (130.5 ppm) upon its diprotonation (formation of the dihydrochloride salt). Furthermore in the absence of cucurbituril polymerisation has not been observed. GPC data in DMF were obtained after anion exchange (Cl^- to PF_6^-) gave a M_n value of 5100 and a M_w value of 9000 based on polystyrene standards. MALDI-TOF showed very broad peak clusters and the reason for this is not known. Peak maxima are spaced by about *m/z* 1350 (molar masses of the repeat units are 1324.14 and 1386.17) with an average value close to 6000. ^{1}H-NMR allows an estimate of the molecular weight by comparing the integration of the triazole proton with the one located on the benzene ring. A ratio of 0.9 (triazole) to 1 translates into a molecular weight of about 13000. We have not been able to precisely establish the charge state of the polyrotaxane in our ES-MS measurements. Indications so far are of a molar mass of about 10000. Finally small angle light scattering measurements were attempted but have been unsuccessful because a reliable d*n*/d*c* value could not be obtained (maybe due to concentration dependent aggregation effects). Additional evidence for the formation of a polyrotaxane was also found in its solubility behaviour. Cucurbituril and the polyrotaxane are both soluble in acidic aqueous media, but *only* cucurbituril dissolves in a saturated solution of sodium chloride as shown by Kim.[17] Dissolution of cucurbituril in water through the presence of a sodium salt requires accessibility of the carbonyl portals to which sodium cations are complexed. This has become impossible (*vide infra*) once cucurbituril has been incorporated into a mainchain polyrotaxane architecture.

We have presented the first solution synthesis of a perfect mainchain polyrotaxane. Investigations are in progress to reveal mechanistic details of the polymerisation itself and to apply our approach to more complex polymer architectures.

We would like to thank the EPSRC for providing an IPSI project studentship for D. T. Thanks are also due to Dr Welham of the University of London ULIRS service for running MALDI-TOF spectra, Dr Ball for providing us with ES mass spectrometry data and the EPSRC RAPRA service for GPC characterisation data.

Received (in Cambridge, UK) 1st April 1999, Accepted 30th June 1999

X-Ray single crystal diffraction studies of TDAE·C_{60} were performed at low temperature and its crystal structure could be solved and analysed on the basis of diffraction data obtained at 7–11 K.

The discovery of organic ferromagnetism in TDAE·C_{60} by Allemand *et.al.*,[1] where TDAE is tetrakis(dimethylamino)-ethylene, with a transition temperature of about 16 K aroused considerable interest in this compound, since it has the highest T_c of any known molecular ferromagnet without transition metal atoms. A number of possible models, such as itinerant ferromagnetism, superparamagnetism, spin-glass like ground state, and spin-canted weak ferromagnetism have been proposed [1–6] to explain its magnetic behavior at low temperatures. However, despite intensive studies of TDAE·C_{60}, a detailed crystal structure based on single crystal diffraction data has not been published until now. The first structural characterization of TDAE·C_{60} crystals was conducted on X-ray powder diffraction data by Stephens *et.al.*,[7] on the basis of which it has been shown that TDAE·C_{60} is a 1:1 charge-transfer complex and that the structure has a *C*-centered monoclinic unit cell. The space group was determined as *C2/m* (or non-centric subgroups *Cm* and *C*2). However, a more recent X-ray study of single crystals suggests a space group of symmetry *C2/c* with a doubling of the unit cell size in the *c*-direction and with TDAE shifted along the *b*-axis by about 0.02 Å perpendicular to the *c*-axis.[6] A determination of the crystal structure at room temperature is complicated because, as is well known, in most materials based on fullerenes the C_{60} molecules rotate rapidly or have orientational disorder at room temperature. In TDAE·C_{60} crystals the fullerene molecules also rotate at room temperature and freeze out below 150 K,[6] so it is hard to localize carbon atom positions of the molecule in this temperature range.

We have carried out an X-ray single crystal diffraction study of TDAE·C_{60} compound at low temperatures down to 7 K. As was shown by EPR measurements the freshly grown, unannealed single crystals are found to be ordered antiferromagnetically below 10 K[6,8] and do not show a ferromagnetic transition.

For crystal growth we used the diffusion method, originally developed in the 1970s for the crystallization of organic charge-transfer salts.[9] C_{60} (Hoechst, gold grade) and TDAE (Aldrich, 95% pure) were used without further purification. The solvent (toluene) was distilled under argon atmosphere and transferred into a glove-box (O_2 concentration < 1 ppm). A toluene solution of C_{60} (2 mg ml^{-1}) and a mixture of toluene and TDAE (3:1) were prepared inside the glove-box and poured separately into the two compartments of a growing cell separated by fritted glass. The cell was carefully closed and maintained at 8 °C. After six months the crystal growth was completed. The cell was then transferred back to a glove-box, and the crystals were extracted from it, washed with hexane and dried.

The full set of diffraction patterns for structural analysis were obtained using a Weissenberg type X-ray imaging plate at 160, 30, 7 and 11 K. The structure was solved and refined based on the space group *C*2/*c* for the set of data obtained at 7 K. The same structural parameters were used as initial values for analyzing the intensity arrays collected at other temperatures.

The crystal structure for TDAE·C_{60} at 160 K shows the presence of significant molecular disorder, with rapid oscillation of the carbon atoms of the C_{60} molecules around the *b*-axis. This is expressed by the large values of the thermal coefficients for the atoms. Even at the lowest temperatures, the values of B_{eq} remain high, which testifies to the presence of some degree of disorder in the structure. It seems that the degree of orientational ordering depends on the cooling time below 50 K and structural parameters with relatively low thermal coefficients were obtained for data collected at 11 K after cooling at that temperature for about 4 h.‡

There are four chemically equivalent $C_{60}\cdot C_2(NC_2H_6)_4$ units per unit cell. Projections of the structure along the *b* and *c* crystallographic axes are shown in Fig. 1. The packing of the unit cell shows that C_{60} anions are located at inversion centers with the coordinates (0.5, 0, 0), (0, 0.5, 0), (0.5, 0, 0.5) and (0,

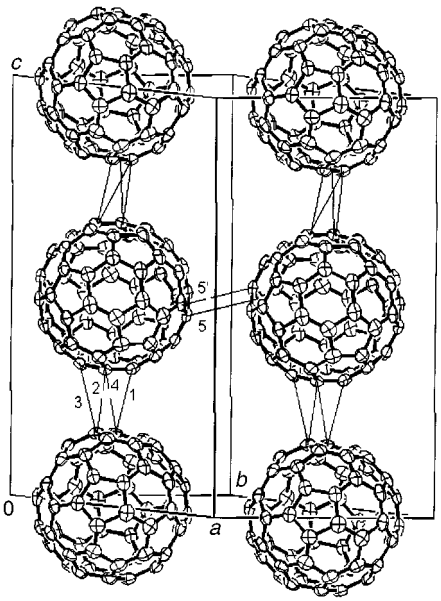

Fig. 2 Shortest $C_{60}\cdots C_{60}$ contacts along the [001] and [1$\bar{1}$0] directions: (1) C(16)–C(16') = 3.369(6), (2) C(24)–C(24') = 3.082(6), (3) C(24)–C(28') = 3.373(4), (4) C(16)–C(24') = 3.479(4), (5,5') C(3)–C(14') = 3.471(4) Å.

0.5, 0.5). The centers of gravity of the C=C double bonds of the TDAE units are at the two-fold axes and the molecules are located at positions (0, −0.0022, 0.25), (0, 0.0022, 0.75), (0.5, 0.4978, 0.25) and (0.5, 0.5022, 0.75), with the double bonds parallel to the *c*-axis.

The C_{60} molecules form a chain along the *c*-axis with the shortest distance between molecular centers equal to 9.915 Å at that temperature. There are several short contacts between adjacent fullerene molecules along the chain: 3.082(6), 3.369(6) and 3.373(4) Å. The intermolecular separation between C_{60} molecules within the *ab* plane is 10.223 Å and there is a short contact [3.471(4) Å] in the [1$\bar{1}$0] crystallographic direction, while in the [110] direction all distances are more than 3.60 Å. The $C_{60}\cdots C_{60}$ type short contacts are shown by dashed lines in Fig. 2.

The C–C bonds in the six-membered rings (6:6) of the C_{60} molecule vary from 1.369(5) to 1.409(5) Å, and in the five-membered rings (5:6) they fall in the range 1.433(4)–1.490(4) Å. In the previous reports[10–16] it was noticed that on going from the neutral molecule C_{60} to the C_{60}^{n-} (n = 1–6) anions, the mean 6:6 ring junction bond length tends to increase [1.355(9) Å (for C_{60})[12] → 1.389(3) Å (C_{60}^{-})[13] → 1.399(2) Å (C_{60}^{2-})[10]], while the mean 5:6 bond tends to decrease [1.467(21) → 1.449(3) → 1.446(2) Å].§ The trend of increasing 6:6 bond lengths and descreasing 6:5 bond lengths in the series C_{60} → C_{60}^{n-} with increasing n is consistent with successive additions of electrons to the t_{1u} LUMO of C_{60}.[10,16] The mean 6:6 and 5:6 bond lengths in TDAE·C_{60} are 1.389(5) and 1.453(5) Å, respectively. These values are close to those of C_{60}^{-} and also C_{60} in the molecular complexes [Fe(C_5H_5)$_2$]C_{60} [1.387(6) and 1.450(6) Å][14] and TPDP(C_{60})$_2$(CS_2)$_4$ [1.381(6) and 1.451(6) Å].[11]

Two symmetrical parts of the TDAE molecule are twisted about the C=C double bond and the dihedral angle between the planes formed by the symmetrically equivalent N–C–N group of atoms is equal to 41.7°. The central C–C bond length is 1.408(6) Å, and distances from the central C atoms to the N atoms of the N(CH_3)$_2$ groups are equal to 1.372(3) and 1.369(3) Å. The N–C type bond lengths within the N(CH_3)$_2$ groups are 1.454(4)–1.461(3) Å. The obtained configurations of TDAE are in reasonable agreement with predictions,[17] which testifies to a charge state of TDAE of +1. There are several short distances between atoms of C_{60} molecule and methyl groups of TDAE. The two contacts, 3.401(4) and 3.482(4) Å, show that there is close interaction between C_{60} and TDAE.

Low temperature X-ray single crystal diffraction studies have allowed access to detailed structural characteristics of an unannealed sample of TDAE·C_{60}. On the basis of this analysis it has been shown that there are very short contacts (3.082 Å) between adjacent C_{60} molecules along the chain of fullerene molecules as well as the presence of close interactions between C_{60} and TDAE.

Unexpected polymeric string formation between Ag(I) and a homoleptic thioether cage: synthesis and crystal structure of [R,R′-S_6tricosane] and {[Ag(R,R′-S_6hexacosane)]TsO}$_\infty$

Roger Alberto,*[a] Daniela Angst,[a] Ulrich Abram,[b] Kirstin Ortner,[b] Thomas A. Kaden[c] and August P. Schubiger[a]

[a] *Center for Radiopharmacy, Paul Scherrer Institute, CH-5232 Villigen, Switzerland. E-mail: ariel@aci.unizh.ch*

[c] *Department of Inorganic Chemistry, University of Basel, CH-5067 Basel, Switzerland*

Received (in Basel, Switzerland) 29th April 1999, Accepted 13th June 1999

The large cavity homoleptic thioether cages [R,R′-S_6tricosane] (1-hydroxymethyl-9-methyl-3,7,11,15,18,22-hexathiabicyclo[7.7.7]tricosane) (1) and [R,R'-S_6hexacosane] (1-hydroxymethyl-10-methyl-3,8,12,17,20,25-hexathiabicyclo-[8.8.8]hexacosane) (2) have been synthesized and the structures of 1 and of the complex {[Ag(2)]TsO}$_\infty$ have been elucidated, the latter showing a polymeric string structure with Ag^+ coordinated by three different cages.

The radionuclide ^{111}Ag has excellent decay properties for applications in radioimmunotherapy.[1] For applications of the labile Ag(I) in organisms, this metal center has to be efficiently shielded in order to prevent transchelation from cancer specific antibodies to serum proteins. For this purpose, a number of thia- and thia-aza macrocycles of various ring size providing high selectivity and/or stability have been prepared for Ag(I).[2–6] However, although the corresponding silver complexes are of relatively high thermodynamic stability,[7] Ag(I) was found to transchelate rapidly to other coordinating sites in serum. Ligand exchange at d^{10} metal centers often occurs *via* an associative or interchange associative mechanism.[8] Only efficient shielding of Ag^+ might allow the protection of Ag(I) against incoming ligands. We therefore prepared thio-cages with large cavities in order to encapsulate Ag^+ and to profit from the well known high kinetic stability of the corresponding metal complexes.[9]

Although a number of homoleptic thio-cages have been published, their coordination chemistry is far less well investigated than that of their aza- or thia-aza-homologues. The only structurally characterized inclusion complex of a homoleptic thio-cage is that of Co(II) and ligand **4**. Additionally, a similar structure of the Co(III) complex with ligand **3** has been concluded from ^{1}H NMR measurements.[10,11] We have prepared the two cages **1** and **2** by a novel route and investigated their coordination chemistry with Ag(I) (Scheme 1).

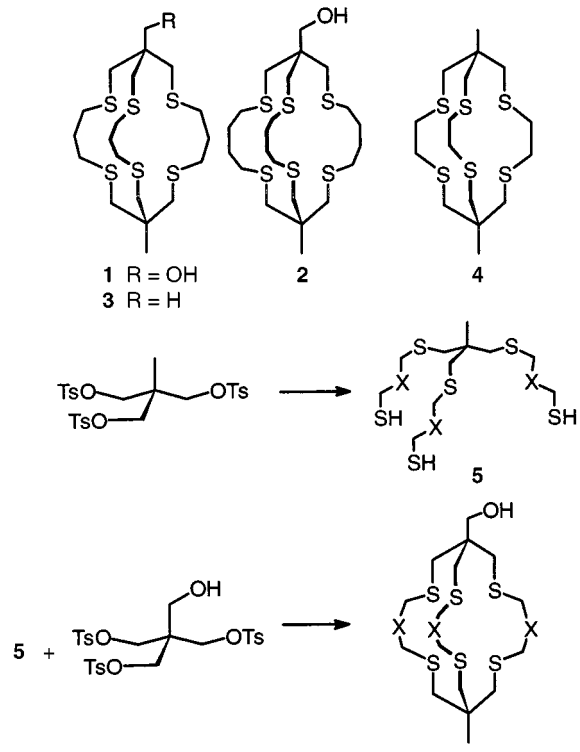
The syntheses presented here are principally different from published methods but also involve adaption of the conventional synthesis for macrocyclic thioethers with a Cs_2CO_3 mediated ring closure step.[11] The -SH groups are located on the larger fragment of the [1+1] bicyclisation, whereas the leaving groups are on the small cap. The yields for such bicyclisations are relatively high and reach up to 30%. The hydroxymethyl groups have been attached to allow subsequent covalent binding of **1** or **2** to proteins. Ligand **3** was prepared according to the same procedure. Reaction yield, rate of formation and behaviour of **3** are very similar to **1**. ^{1}H NMR data of **3** are in full agreement with the published ones.[10]

Structure optimization of **1** by simple molecular modelling calculations predicts a structure with predominant *exo*-orientation of the lone pairs which is confirmed by the X-ray structure of **1** (Fig. 1).[12]

The structure of **3** was determined as well. The basic framework of the two ligands is essentially the same, showing that the influence of the functional group is negligible in regard to the orientation of the lone pairs.

Although no X-ray structure of a metal complex with **1** has been described to date, the ^{1}H NMR spectrum of the Co(III) complex of **3** clearly shows the metal center to be encapsulated.[13] Since Co(III) forms highly inert complexes, rapid transchelation between different donors, resulting in a fully symmetrical ^{1}H NMR spectrum, can be excluded (even on the NMR timescale). Thus, **1** and **3** are able to reorganize their conformation from *exo*- to *endo*-sulfur lone-pairs, as required for inclusion of the metal. Obviously, the relatively small Co(II) ion is able to penetrate a 16-membered ring of **1** and to coordinate additionally to the sulfur atoms of the bicyclic backbone (oxidation to Co(III) was done after inclusion). The highly symmetrical ^{1}H NMR spectrum rationalizes an octahedral coordination geometry.

Ag(I) is much larger than Co(II) (ionic radii 129 *vs*. 89 pm) and probably not able to penetrate the formal 16-membered ring in **1**. This assumption is supported by the X-ray structure of the Ag(I) complex with [16]aneS_4 recently published.[14] This ligand coordinates only through one sulfur to Ag(I) resulting in a three dimensional polymer. In contrast, the X-ray structure analysis of [Ag([18]aneS_6)]$^+$ clearly demonstrated that, when the ring is enlarged, the Ag^+ can slip inside and the ligand wraps around it.[15]



Scheme 1

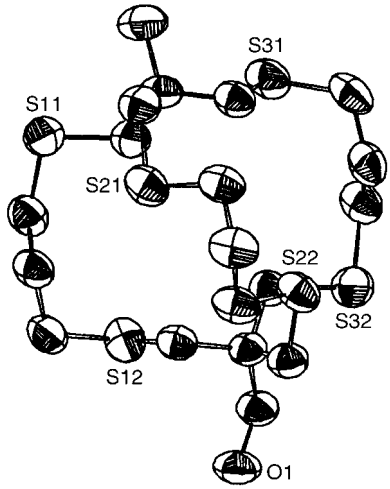


Fig. 1 ORTEP plot of (1-hydroxymethyl-9-methyl-3,7,11,15,18,22-hexathiabicyclo[7.7.7]tricosane) (**1**).

We have enlarged the propylene backbone in **1** to butylene in **2**. Molecular modelling calculations gave a reasonable coordination geometry for $[Ag(\mathbf{2})]^+$ without significant steric interactions between hydrogen atoms from the backbone or from the cap. The ^{1}H NMR of **2** shows 6 signals. Complexation with different Ag^+ salts shifts the resonances by about 0.1 ppm towards lower field but leaves the pattern unchanged. The exhibition of 6 different H's indicates either an inclusion of the metal ion (pseudo-symmetry retained) or a fast fluxionality between different coordination sites.

Several modes of external coordination can be expected, *i.e.* by one, two, three or four sulfur atoms from one ring in the bicyclic ligand which is known in the literature for tridentate thio crowns where Ag^+ is found to bind at least to two different macrocycles.[16] X-Ray structure analysis exhibits an unexpected polymeric string structure (Fig. 2). Three cages are coordinated to one Ag(I) center by one thioether ligand atom. Thus, each cage is coordinated to three Ag^+ atoms. The distorted tetrahedral geometry around the Ag^+ center is completed by the coordination of one counter-ion (tosylate).[17] The highly symmetrical ^{1}H NMR spectrum thus comes from a fast exchange between the different coordinating sites.

Monodentate coordination only is unexpected. Analysis of the solid state structure of **1** or calculated models of **2** reveals that preorganization could favour bidentate external coordination by two sulfur atoms from two different backbones under formation of a six-membered chelate in **1** or in **2**. Six-membered chelates with Ag(I) and sulfur are disfavoured compared to five-membered rings.[18] Indeed, the Cambridge Crystallographic Database does not contain any Ag(I) complex with a six-membered thioether chelate. However, a number of crown thioethers with propylene backbones were found to coordinate in a monodentate fashion to Ag(I) resulting in comparable polymeric structures as in $[Ag(\mathbf{2})]^+$.[5,14,16]

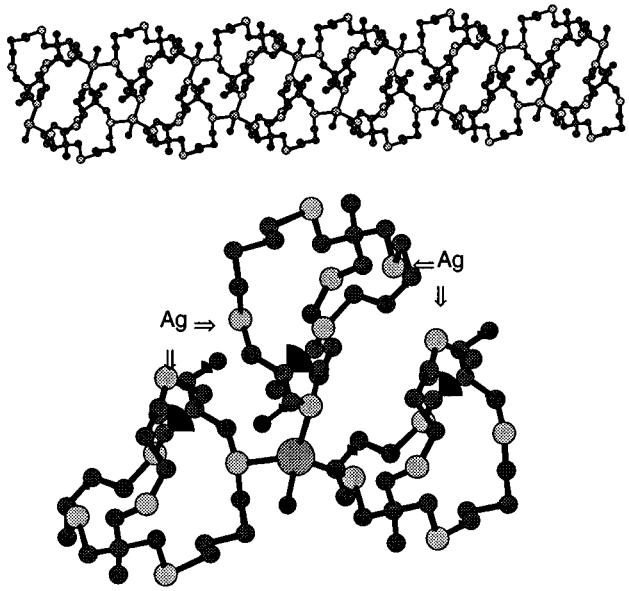

Fig. 2 Part of the polymeric string structure of $\{[Ag(\mathbf{2})]TsO\}_\infty$. The coordinated tosylate anions are omitted for clarity (above). Excerpt of the structure, depicting three cages coordinated to one Ag^+ (below).

To exclude the possibility that the product is a kinetic intermediate and to overcome high reorganization energies for the encapsulation, we exposed $[Ag(\mathbf{2})]^+$ to ultrasound or microwave heating. In neither case was it possible to obtain a 1:1 complex of Ag^+ encapsulated in cage **2**.

In the case of radioactive ^{111}Ag, where the metal concentrations are extremly low, similar behaviour was not observed. Chromatographic investigations (the only possible analytical method) exhibits only free $^{111}Ag^+$, demonstrating the low ability of a monodentate thioether to compete with coordinating solvents.

Although thio-cages can kinetically stabilise labile metal centers, their coordination chemistry, in particular with late transition metals, is not routine. The steric requirements and the electronic properties of a metal center demand a perfectly tailored framework of backbones and donor atoms.

Structural isomerization of cyclopropane: a new mechanism through propylidene

Holger F. Bettinger,[a] Jonathan C. Rienstra-Kiracofe,[a] Brian C. Hoffman,[a] Henry F. Schaefer III,[a] John E. Baldwin[b] and Paul v. R. Schleyer*[a]

Received (in Corvallis, OR, USA) 4th March 1999, Accepted 20th May 1999

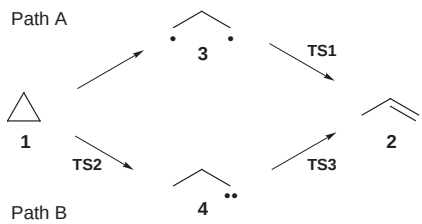
***Ab initio* coupled cluster methods indicate that the isomerization of cyclopropane to propene (E_a = 64–66 kcal mol^{-1} experimentally) might involve two different mechanisms: the barrier for the newly proposed pathway through propylidene is only slightly higher ($\Delta E^{\ddagger}$ = 66.6 kcal mol^{-1}) than that of the traditional trimethylene route ($\Delta E^{\ddagger}$ = 64.2 kcal mol^{-1}).**

Even though cyclopropane (**1**) and propene (**2**) have comparable thermodynamic stabilities (8 kcal mol^{-1} in favor of **2**),[1] a remarkably high activation energy of approximately 65 kcal mol^{-1} hampers their interconversion.[2–9] Both concerted and stepwise mechanisms have been considered for this isomerization.[3,5,10–14] The stepwise pathway (A in Scheme 1) involving trimethylene (**3**) has generally been favored since Benson[11] presented arguments against a concerted reaction: his estimated barrier for such a process was significantly higher than the activation energy determined experimentally.[5] However, the most recent computational study purported to have located a transition state 'connected to cyclopropane and propylene without an intermediate.'[14] We examine another path (B in Scheme 1) involving carbene **4** as an intermediate which apparently has not been considered for the parent rearrangement, although carbene pathways have been implicated in more elaborate systems.[15]

The singlet biradical **3** is assumed to be involved in the geometrical and the 'optical' (*i.e.* enantiomeric) isomerization of appropriately labeled cyclopropanes,[16–30] but has only been observed recently *via* femtosecond laser spectroscopy. The extremely rapid ring closure to **1** limits the lifetime of **3** to 120 fs.[29]

Although the [1,2]-H shift *via* **TS1** is the rate determining step in the **1** → **2** isomerization *via* **3**, the **3** to **2** rearrangement has not been studied as comprehensively as the **1** ⇌ **3** process. A barrier of approximately 5 kcal mol^{-1} was estimated for the **3** → **2** [1,2]-H shift.[13] This was based both on the experimental finding that the structural isomerization of **1** at 480 °C is approximately an order of magnitude slower than the **1** ⇌ **3** process (ΔE_a = 3.7 kcal mol^{-1})[31] and on the theoretical barrier of less than 1 kcal mol^{-1} for the **3** → **1** reaction.[18–20]

Fan *et al.*[13] recently computed pathway A (Scheme 1) at various levels, but found good agreement with the experimental activation energies for the overall **1** → **2** reaction (64–66 kcal mol^{-1})[2–9] only at UB3LYP/6-31G**//UMP2/6-31G** (66.1 kcal mol^{-1}). However, the **3** → **2** barrier *via* **TS1** was 9.5 kcal mol^{-1}, indicating that the computed energy of the trimethylene intermediate might be somewhat too low. Doubleday obtained a zero point corrected barrier of 6.9 kcal mol^{-1} for the **3** → **2** [1,2]-H shift reaction at MR-CISD//CASSCF(4,4).[22] Dubnikova and Lifshitz[14] reported a transition structure at UB3LYP/cc-pVDZ which is very similar to Doubleday's TS1 for the **3** → **2** reaction; however, their intrinsic reaction coordinate (IRC) computation was not able to locate intermediate **3** and was said to connect **TS1** to **1** and **2** directly.[14] This result is the only evidence in favor of a concerted process, but may be an artifact due to the inadequacy of density functional methods for closed shell biradicals.



Scheme 1 Ring opening of cyclopropane (**1**) *via* trimethylene (**3**) (Path A) or propylidene (**4**) (Path B) to propene (**2**).

We now propose a new possibility. Our *ab initio* data† suggest a carbene mechanism (path B in Scheme 1) involving propylidene (**4**) to be competitive energetically to the traditional trimethylene (**1** → **3** → **2**) pathway A.

A transition state (**TS2**, 66.6 kcal mol^{-1} above **1**) for the endothermic ring opening of **1** leads directly to propylidene (**4**, Fig. 1). The carbene obtained from this reaction is in conformation **4a** (66.5 kcal mol^{-1}), where the divalent carbon center is stabilized by the adjacent C2–C3 bond through hyperconjugation and by interaction with the methyl CH bond (analogous stabilizations have been reported for related carbocations).[34,35] Isomer **4b**, oriented in a conformation favoring CH hyperconjugation, is slightly lower in energy (1.5 kcal mol^{-1}). The [1,2]-H shifts in acyclic alkylcarbenes are well known to be very facile.[36–38] Indeed, only an very small barrier (0.07 kcal mol^{-1} *via* **TS3**), which disappears after the CCSD/DZP ZPVE correction, is predicted for the **4b** → **2** rearrangement.

In addition to **TS1**, Doubleday obtained a structure very similar to **TS2** previously at the CASSCF(4,4) level.[22] However, his intrinsic reaction coordinate (IRC) computation at CASSCF(4,4) with a modified 6-31G* basis set indicated that his **TS2**-like transition structure connects **3** and **4**. In contrast to Doubleday's report, our CASSCF(4,4)/TZ2P IRC clearly shows that **TS2** is not connected to **3** but rather joins **1** to **4a**

Table 1 Relative energies, zero-point corrected relative energies (in parentheses), and zero-point vibrational energies of C_3H_6 stationary points.

Species	CCSD/DZP	CCSD/TZ2P	CCSD(T)/TZ2P[a]	ZPVE[b]/ kcal mol^{-1}
1	0	0	0	52.1
2	−7.2 (−8.7)	−8.4 (−9.9)	−9.2 (−10.7)	50.6
4a	70.9 (68.2)	69.8 (67.1)	69.2 (66.5)	49.4
4b	69.3 (65.6)	68.8 (65.1)	68.7 (65.0)	48.4
TS1	79.7 (73.9)	78.6 (72.8)	70.0 (64.2)	46.3
TS2	72.0 (68.9)	71.1 (68.0)	69.7 (66.6)	49.0
TS3	70.9 (66.3)	69.7 (65.1)	68.8 (64.2)	47.5

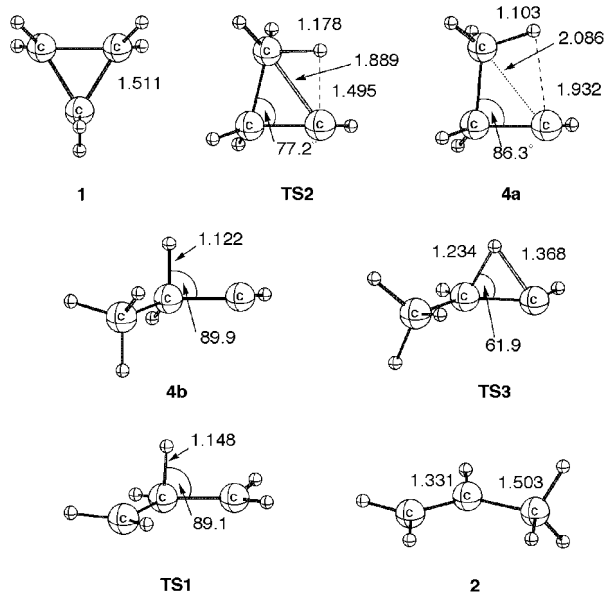

Fig. 1 Geometries of C_3H_6 stationary points optimized at the CCSD/TZ2P level of theory. All distances are in Å, all angles in degrees.

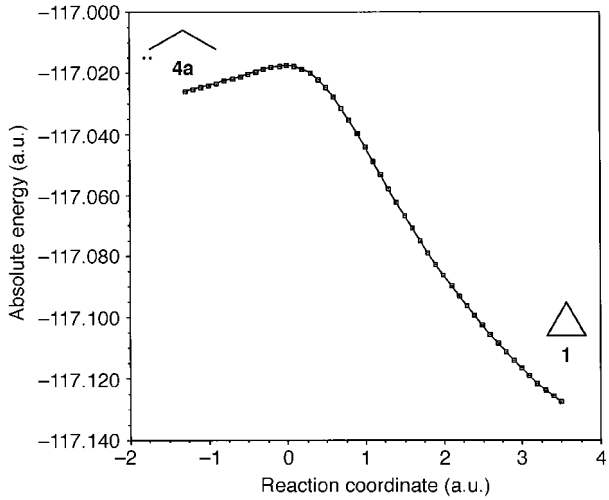

Fig. 2 The intrinsic reaction coordinate for the propylidene (**4a**) to cyclopropane (**1**) reaction *via* **TS2**.

(Fig. 2). The dominating initial mode along the path towards **1** is the migration of the H atom approximately in the ring plane. This motion is accompanied by a shortening of the C1–C3 distance and a decrease of the C1–C2–C3 angle leading ultimately to **1**.

We restricted our investigation to the highest point along path A, *i.e.* the transition structure (**TS1**) for the [1,2]-H shift from **3** to **2**. The analyses of the CCSD wave function (small T_1 diagnostic value of less than 0.02) as well as that of CISD (the Hartree–Fock configuration has a coefficient of 0.93) indicate that **TS1** should be computed reliably using coupled cluster methods. We find that **TS1** is 64.2 kcal mol^{-1} above **1**, and therefore 2.4 kcal mol^{-1} lower in energy than **TS2**. This difference is significantly smaller than that reported by Doubleday [5.5 kcal mol^{-1} in favor of **TS1**] at the MRCI/VTZ(2d,p)//CASSCF(4,4)/VTZ(2d,p) level. Our more extensive computations suggest that the carbene mechanism for the rearrangement of **1** to **2** has a zero-point corrected barrier of 66.6 kcal mol^{-1} which agrees with the barrier deduced experimentally (64–66 kcal mol^{-1}).[2–9] Hence, the carbene pathway might compete energetically with the trimethylene mechanism (64.2 kcal mol^{-1}). As experimental data have been discussed traditionally in terms of the latter mechanism,[5,11] additional investigations of the rearrangement of appropriately labeled cyclopropanes to propenes are desirable.

This work was supported by the U.S. Department of Energy.

Notes and references

† This study employed double-ζ and triple-ζ basis sets augmented with one [DZP, α_p(H) = 0.75, α_d(C) = 0.75] or two [TZ2P, α_p(H) = 1.5 and 0.375, α_d(C) = 1.5 and 0.375] sets of polarization functions. Single point energy computations at the CCSD(T)/TZ2P level employed the CCSD/TZ2P geometries.[32] In addition the geometry of **TS2** was optimized with the complete active space SCF method and the TZ2P basis set [CASSCF(4,4)/TZ2P] (ref. 33). Harmonic vibrational frequencies were computed *via* finite differences of analytic gradients at CCSD/DZP, and, for **TS2**, *via* analytic second derivatives at CASSCF/TZ2P.

Synthesis and properties of a novel phosphodiester analogue, nucleoside boranophosphorothioate

Jinlai Lin and Barbara Ramsay Shaw*

Paul M. Gross Chemical Laboratory, Department of Chemistry, Duke University, Durham, North Carolina 27708-0346, USA. E-mail: brs@chem.duke.edu

Received (in Corvallis, OR, USA) 8th February 1999, Accepted 28th April 1999

The first boranophosphorothioate [$(RO)_2P(S)(BH_3)^-$] mimic of a phosphodiester compound, dithymidine boranophosphorothioate, has been synthesized; while it is water soluble, this new analogue is more lipophilic and nuclease resistant than natural nucleoside phosphodiesters [$(RO)_2P(O)(O)^-$] and phosphorothioates [$(RO)_2P(S)(O)^-$].

Novel oligonucleotide analogues are currently attracting attention as probes in biochemistry and molecular biology[1] and as possible therapeutic agents against cancer and viral diseases.[2] An impressive variety of these analogues[3] have been developed as potential therapeutic drugs for 'antisense' and 'antigene' targeting of specific genes to modulate their expression.[4] Of these modified oligonucleotides, the nucleoside phosphorothioates[5] and nucleoside boranophosphates[6] (Fig. 1) are among the most promising because they are resistant to nucleases and support RNase H induced cleavage[7] of the complementary messenger RNA. Nearly a dozen phosphorothioate oligonucleotides are now in clinical trials.[8] By structurally combining the phosphorothioate and boranophosphate backbones, we have created a new phosphodiester analogue, the boranophosphorothioate, $[S{=}P{-}BH_3]^-$, wherein the two nonbridging oxygen atoms of a phosphodiester group are replaced with a sulfur atom and borane group.

Here, we report the first example of a novel boranophosphorothioate compound, specifically the dithymidine boranophosphorothioate, its synthesis and properties.

The general procedure for the synthesis of dinucleoside boranophosphorothioates is outlined in Scheme 1. 5′-*O* Fluorenylmethoxycarbonyl (Fmoc)-thymidine[9] was phosphitylated with $(Pr^i_2N)_2PCl$ catalyzed by DMAP to give **1**. Phosphite **1** was treated *in situ* with 3′-*O*-acetylthymidine and tetrazole in DMF to give **2**. To the above mixture, 4-nitrophenol and tetrazole in DMF were added to yield **3**, which was then treated with excess $BH_3{\cdot}SMe_2$ complex to afford the phosphite–borane **4** with ^{31}P NMR signal at δ_P 116.6 (br). Dry **4** was reacted with Li_2S to give **5** (broad ^{31}P NMR signal at δ_P 161.0) which was converted to **6** with conc. NH_4OH–MeOH (1 : 1) at room temperature. The crude mixture was purified by ion-exchange column chromatography on QA-52 (HCO_3^-) cellulose to give **6** as the ammonium salt and isolated by HPLC. The overall yield of dithymidine boranophosphorothioate **6** (T^SpBT) was about 28%. Successful separation of the two diastereomers (R_P and S_P) of **6** was achieved by reverse-phase HPLC. The first eluted isomer T^SpBT I (**6a**) and the second eluted isomer T^SpBT II (**6b**) were characterized by ^{31}P and ^1H NMR.[10] The Li_2S method used above should be applicable to the synthesis of other boranophosphorothioates including $[^{35}S{=}P{-}BH_3]^-$ phosphodiesters.

In oligodeoxynucleotides (ODN), the replacement of a nonbridging oxygen atom in the natural phosphodiester linkage by S^-, Me or BH_3^- imparts resistance to nucleases that cleave DNA.[6f,g,11] For instance, the non-ionic methylphosphonates (Me-ODN) are highly resistant[11c] to phosphodiesterases; the

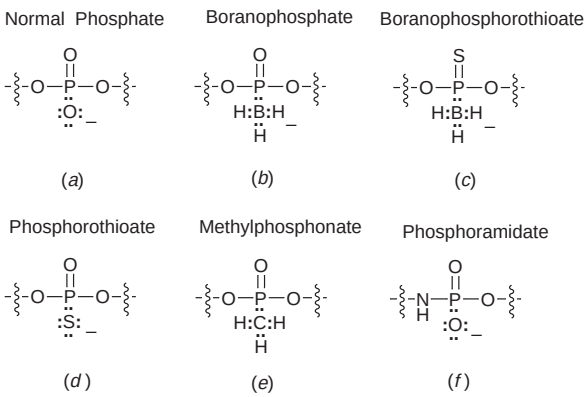

Fig. 1 Structurally and/or electronically similar internucleotide linkages and their abbreviations: (*a*) normal phosphate [O=P–O$^-$], (*b*) boranophosphate [O=P–BH$_3^-$], (*c*) boranophosphorothioate [S=P–BH$_3^-$], (*d*) phosphorothioate [O=P–S$^-$], (*e*) methylphosphonate [O=P–Me], (*f*) phosphoramidate. Placement of the negative charge does not necessarily reflect the actual spatial location of charge in the molecule.

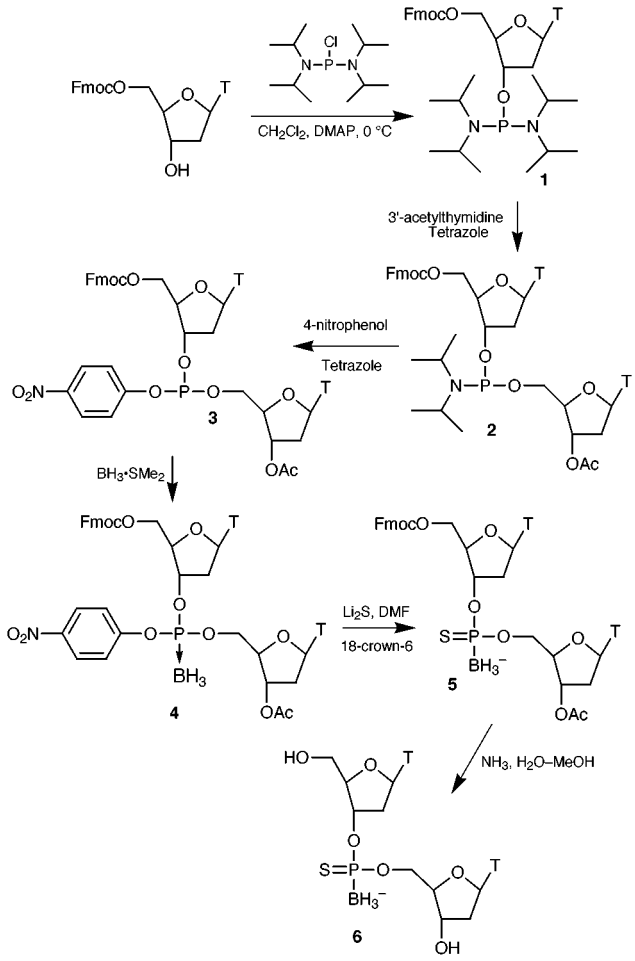

Scheme 1

Table 1 Special properties of $[S{=}P{-}BH_3]^-$ backbone relative to natural and other phosphodiester backbone analogues

Property	$[O{=}P{-}O]^-$	$[O{=}P{-}S]^-$	O=P–Me	$[O{=}P{-}BH_3]^-$	$[S{=}P{-}BH_3]^-$
Nuclease resistance	—	+	++	+	++
Lipophilicity	—	+	+++	+	++
RNase H activity	+	+	—	+	N.D.

anionic phosphorothioates (S^--ODN) can be hydrolyzed by phosphodiesterase I, but with a much lower rate[11d] than O^--ODN. Boranophosphates (BH_3^--ODN) are even more resistant[6g] to certain phosphodiesterases than S^--ODN. This nuclease resistance, together with the ability to form stable duplex structures with DNA or RNA, has led to broad trials of S^-- and Me-ODN as agents for regulating gene expression *in vitro* and *in vivo*.[4] By combining aspects of both the charged $[O{=}P{-}S]^-$ and the non-ionic O=P–Me into a $[S{=}P{-}BH_3]^-$ hybrid phosphodiester linkage, it was anticipated that the resulting compound may exhibit greater nuclease resistance and other unique or potentially useful properties. The BH_3 moiety in $[S{=}P{-}BH_3]^-$ is isoelectronic with oxygen and isosteric with the Me group in O=P–Me, but imparts a negative charge to the backbone, like S^- in $[O{=}P{-}S]^-$. By virtue of the larger volume of the BH_3 group and its lack of lone pair electrons, we expect that $[S{=}P{-}BH_3]^-$ oligonucleotides should be more lipophilic than $[O{=}P{-}S]^-$ oligonucleotides. The new $[S{=}P{-}BH_3]^-$-ODN, which is a hybrid backbone of S^--ODN and BH_3^--ODN, has some special properties summarized in Table 1.

The boranophosphorothioate group is very stable towards basic or acidic hydrolysis. The diastereomers, T^Sp^BT I and T^Sp^BT II, were each dissolved in 100 mM AcOH–NH_4OH pH 3 or pH 11 buffer and incubated for 24 h at 37 °C. No hydrolyzed or degraded products were detected *via* HPLC.

The boranophosphorothioate internucleotide linkage in dimer **6** is quite stable towards cleavage by both snake venom phosphodiesterase (SVPDE) and bovine spleen phosphodiesterase (BSPDE). Under conditions where the natural dithymidine phosphate (TpT) was > 99% cleaved by SVPDE, both T^Sp^BT I and T^Sp^BT II were > 99% stable. Similarly, with BSPDE, while TpT was > 96% cleaved, T^Sp^BT I and T^Sp^BT II were > 98 and 97% stable, respectively.

The $[S{=}P{-}BH_3]^-$ dimers carry a full negative charge and are water soluble, yet are intermediate between normal phosphates and methylphosphonates in lipophilicity. In partitioning experiments,[12] T^Sp^BT was 320- and 18-fold more lipophilic than natural TpT and Tp^BT (dithymidine boranophosphate) accordingly.

The $[S{=}P{-}BH_3]^-$ nucleotidic linkage is the only non-bridging disubstituted chiral phosphodiester with a negative charge. This property coupled with ready synthesis of isotopic $[^{35}S{=}P{-}BH_3]^-$ compounds from Li_2S^* ($S^* = {}^{35}S$) could make this linkage very useful for elucidating the stereochemical course of phosphoryl and nucleotidyl transfer reactions and at the same time probing whether one or two non-bridging oxygens are necessary in these reactions.

To summarize, we have synthesized a totally new type of modified phosphodiester analogue, in which the two non-bridging oxygen atoms of a phosphodiester group have been replaced with a sulfur atom and borane group. The analogue has been placed in a nucleic acid and the resulting dithymidine boranophosphorothioate diastereomers shown to be stable under a broad range of pH conditions and highly resistant to enzymatic cleavage relative to natural DNA. Based on partitioning into octanol, the boranophosphorothioates may exhibit a greater membrane permeability than the O-oligonucleotides, yet maintain nuclease resistance like the methylphosphonates. The novel combination of high lipophilicity, reasonable water solubility and nuclease resistance could be extremely useful for drug design;[13] the $[S{=}P{-}BH_3]^-$ linkage instead of $[O{=}P{-}O]^-$ may enable the compounds to penetrate the plasma membrane and to enter cells.

Thus, synthesis of the first $[S{=}P{-}BH_3]^-$ phosphodiester analogue offers the possibility of preparing an entirely new and intriguing class of compounds, including modified nucleotides and nucleic acids. Their similarity to natural nucleic acids and unique properties such as high lipophilicity and resistance to enzymatic cleavage, in conjunction with their potential utility as molecular probes for the study of stereochemical aspects of enzymatic and nonenzymatic reactions and as carriers of ^{10}B in boron neutron capture therapy (BNCT)[14] for the treatment of cancer, make the $[S{=}P{-}BH_3]^-$ linkage a promising candidate for further mechanistic, diagnostic and therapeutic applications.

We thank Drs Dmitri S. Sergueev, Vladimir Rait and Zinaida Sergueeva and Mr Kaizhang He for their suggestions and help. This work was supported by grants 1R01-GM57693-01 from NIH and DE-FG05-97ER62376 from DOE to B. R. S. and is in partial fulfillment of requirements (J. L.) for a PhD at Duke University.

ChemComm

A novel two-electron mixed-valence Ir(II)–Ir(0) complex

Alan F. Heyduk and Daniel G. Nocera*

Department of Chemistry, Massachusetts Institute of Technology, 6-335, 77 Massachusetts Avenue, Cambridge, MA 02139-4307, USA. E-mail: nocera@mit.edu

Received (in Bloomington, IN, USA) 26th March 1999, Accepted 24th June 1999

An Ir^{II}–Ir^{0} mixed-valence complex, $Ir_2\{MeN[P(OEt^{F3})_2]_2\}_3Cl_2$ (OEt^{F3} = OCH_2CF_3), has been prepared by treatment of $Ir_2Cl_2(cod)_2$ with 3 equiv. of $MeN[P(OEt^{F3})_2]_2$; donor ligands ($CNBu^t$ and PEt_3) add to the binuclear core, which provides a novel platform for the multielectron activation of small molecule substrates.

Few ligand systems are able to support the intramolecular disproportionation of a symmetric binuclear metal core. The bis(difluorophosphino)methylamine (dfpma) ligand,[1] $CH_3N(PF_2)_2$, therefore, is distinguished by its ability to drive the conversion of binuclear $Rh^{I}(\mu\text{-}X_2)Rh^{I}$ (X = Cl, Br or I) dimers to two-electron mixed-valence X_2Rh^{II}–Rh^{0} complexes.[2] When a long-lived excited state can be incorporated into the electronic structure of the two-electron mixed-valence center, controlled multielectron photoreactivity may be achieved.[3] For instance, we have recently accomplished a four-electron photoreaction among discrete molecular species, for the first time, by using a dσ* excited state to interconvert among $Rh(0,0)_2(dfpma)_3(L)_2$, $Rh(II,0)_2(dfpma)_3X_2(L)$ and $Rh(II,II)_2(dfpma)_3X_4$ (L = PF_3, η^1-dfpma or PPh_3).[4] By spanning reduced LRh^{0}–$Rh^{0}L$ and oxidized X_2Rh^{II}–$Rh^{II}X_2$ brethren, the X_2Rh^{II}–$Rh^{0}L$ complex sustains the multielectron reactivity of the Rh_2 dfpma system. This multielectron design strategy is general as long as a two-electron mixed-valence complex can be stabilized with respect to its symmetric congener.

With the understanding that M^{n+2}–M^{n} complexes are a keystone to multielectron photoreactivity, we sought to expand the concept of two-electron mixed valency to other transition metals. Our initial attempts focused on iridium, for which Ir^{0}–Ir^{II} cores are unknown.[5] Efforts to use the dfpma ligand to develop a parallel chemistry to that of Rh, however, were met with frustration as mixtures of Ir^{I} monomers and various oligomerization products were obtained. Introduction of more sterically demanding OR substituents on P could avoid these problematic reactions while providing us with the additional flexibility of tuning the electronic properties[6] of the two-electron mixed-valence core by R substitution. As we now report, an excursion into Ir chemistry with the bidentate diphosphazane, $MeN[P(OEt^{F3})_2]_2$ (OEt^{F3} = OCH_2CF_3), successfully afforded two-electron mixed-valence compounds and not the oligomers that plague Ir dfpma chemistry.

Addition of $HOEt^{F3}$ to a cold Et_2O solution of $MeN(PCl_2)_2$[1,7] and NEt_3 results in the formation of $MeN[P(OEt^{F3})_2]_2$ in good yields.[8] $Ir_2Cl_2(cod)_2$ was treated with 3 equiv. of the ligand in CH_2Cl_2 at room temperature. The solution immediately turned yellow and then slowly darkened to orange–brown. Over several days, a fine green powder precipitated from the reaction solution. Single crystals of the compound, which analyzes as $Ir_2\{MeN[P(OEt^{F3})_2]_2\}_3Cl_2$ (**1**),† were obtained from saturated CH_2Cl_2 solutions of **1** at 22 °C.

X-Ray diffraction analysis of **1** reveals the unsymmetrical coordination sphere of the Ir^{0}–Ir^{II} binuclear core displayed in Fig. 1.‡ In a structural departure from Rh–dfpma chemistry, two of the three bidentate ligands adopt a bridging coordination mode with the third ligand binding as a chelate. The Ir^{0} center possesses a trigonal bipyramidal coordination geometry that is typical for d^9 metals composing a binuclear core.[2,9] Two equatorial sites of the Ir^{0} center are coordinated by phosphites from the bridging $MeN[P(OEt^{F3})_2]_2$ ligands with the third equatorial site occupied by one end of a chelating $MeN[P(OEt^{F3})_2]_2$ ligand. The other end of the chelating ligand resides at an axial coordination site of the Ir^{0} center. The apical position of the square pyramid that defines the coordination geometry about the neighboring Ir^{II} center is reciprocally capped by the Ir^{0} center. Two *cis*-equatorial sites are occupied by phosphites from the bridging ligands, while the other two equatorial sites are occupied by chloride ligands. An Ir–Ir bond distance of 2.7871(8) Å is typical of singly bonded binuclear iridium complexes.[10]

Although **1** shows little solubility in non-coordinating solvents, the 16-e^- Ir^{II} center readily receives donor ligands at its open coordination site, rendering more soluble derivatives. Addition of $CNBu^t$ or PEt_3 to suspensions of **1** in CH_2Cl_2 results in the rapid dissolution of the solid to form bright yellow solutions.† Pale yellow crystals of the $CNBu^t$ (**2**) and PEt_3 (**3**) derivatives were obtained upon the addition of pentane to reaction solutions that had been concentrated by solvent evaporation. Ligand occupation of the vacant axial site of the Ir^{II} center of **1** is confirmed by an X-ray crystal structure of **2**.‡ Excepting changes along the P_{ax}–Ir^{0}–Ir^{II}–L axis, the X-ray crystal structure of **2**, is very similar to that of **1**.

As determined from ^1H and ^{31}P NMR spectroscopy, the solid state coordination geometries of **1**–**3** are preserved in solution. Whereas the methylene protons of the ligand's OCH_2CF_3 group are not well resolved, two distinct resonances in a 2 : 1 ratio are observed for the methyl groups of both the bridging and chelating $MeN[P(OEt^{F3})_2]_2$ ligands. The integration ratios for the protons of $CNBu^t$ and PEt_3 in **2** and **3**, respectively, compared to those of the proton resonances of $MeN[P(OEt^{F3})_2]_2$ establish the incorporation of only one ligand into the diiridium coordination sphere. The ^{31}P NMR spectra presented in Fig. 2 reveal congruent solution structures for **1**–**3**. Two signals at δ *ca.* 46 and 95 are maintained in each of the spectra, consistent with the preserved equatorial arrangement of phosphites in **1**–**3**. The resonance at δ 46 is assigned to the P(5) phosphite of the Ir^{0} equatorial plane and the resonance at δ 95

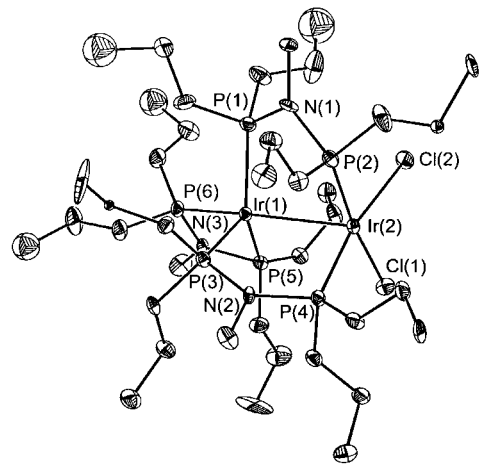

Fig. 1 ORTEP representation of **1**, with fluorine atoms omitted for clarity. Thermal ellipsoids are drawn at the 25% probability level.

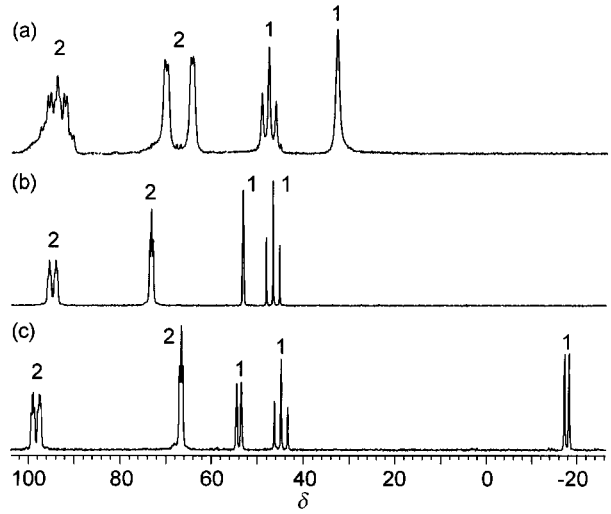

Fig. 2 ^{31}P NMR (121.488 MHz) of the two-electron mixed-valence compounds (a) **1**, (b) **2** and (c) **3** in CD_3CN, referenced to an external 85% H_3PO_4 standard. The relative integration values are indicated for each phosphorus resonance.

is consistent with the P(2)/P(4) equatorial phosphites coordinated to the Ir^{II} center. Conversely, differences are observed for the resonance associated with the axial phosphite [P(6)]. The high frequency shift of the P(6) resonance from δ 32.7 in **1** to δ 52.5 and 53.3 in **2** and **3**, respectively, is in accordance with the structural perturbations induced by the presence of the donor ligand in the axial coordination site of Ir^{II}. The observed increase in the Ir^0–P_{ax} bond distance [*d*(Ir(1)–P(6)) = 2.238(6) Å in **2** *vs* *d*(Ir(1)–P(6)) = 2.206(4) Å in **1**] upon coordination of the donor ligand is expected to result in decreased $Ir^0 \rightarrow P_{ax}$ π-backbonding and consequently a shift of the axial phosphite resonance to higher frequency. The $^3J(P_{ax},PEt_3)$ coupling for **3**, and its absence in **1** and **2**, follows logically from the coordination of a phosphorus donor ligand along the metal–metal bond. The only other significant difference in the three spectra of Fig. 2 is the collapse of the resonances at δ 64.7 and 70.5 of **1**, assigned to the remaining Ir^0 phosphites [P(1) and P(3)], to give triplet signals at δ 72.5 and 66.0 for **2** and **3**, respectively.

Initial investigations of the reactivity of the Ir^{II}–Ir^0 compounds suggest a facile oxidative-addition chemistry. Suspensions of **1** in CH_2Cl_2 yield homogeneous, yellow solutions upon the introduction of H_2, I_2, HCl and $PhICl_2$. As exemplified by the reaction between **1** and $PhICl_2$, the addition products are consistent with the presence of an $Ir^I \rightarrow Ir^{III}$ dative bond, with both metals assuming an octahedral coordination geometry. The NMR spectrum of the isolated product, $Ir_2\{MeN[P(OEt^{F3})_2]_2\}_3Cl_4$, shows that the coordination of the bridging and chelating phosphites remains unchanged. In contrast to **1**, reactions of **2** and **3** with strong oxidants proceed sluggishly and not at all with H_2. This arrested reactivity of the latter complexes suggests that ligand dissociation should precede the oxidative-addition of substrates when the diiridium core is coordinatively saturated.

Previous reactivity studies of bimetallic complexes indicate that the presence of two-electron mixed valence cores inhibit oxidation–reduction chemistry.[11] Thus, our observation that the mixed-valence Ir^{II}–Ir^0 core undergoes facile redox conversions is noteworthy. Current investigations are continuing to explore the structure, spectroscopy and reactivity of the Ir^{II}–Ir^0 compounds and their addition products.

The authors thank Dr William M. Davis for assistance with the solution of the X-ray crystal structures. The National Science Foundation Grant CHE-9817851 funded this research.

† *Experimental Procedures:* **1**: in a nitrogen atmosphere, 734 mg (1.51 mmol) of $MeN[P(OEt^{F3})_2]_2$ was added to a solution of 331 mg (0.493 mmol) of $Ir_2Cl_2(cod)_2$ (Strem) dissolved in 15 mL of CH_2Cl_2. The mixture was stirred at room temp. for 24 h during which a dark precipitate formed. A green powder precipitated from solution over several days. The solid was collected by filtration, washed with 5 mL of C_6H_6 and three 5 mL aliquots of pentane and then dried *in vacuo* to yield 590 mg (62%) of the analytically pure product. $C_{27}H_{33}Cl_2F_{36}Ir_2N_3O_{12}P_6$; found: C, 17.06; H, 1.65; N, 2.29; P, 9.63; requires: C, 16.92; H, 1.74; N, 2.19; P, 9.70%. ^{1}H NMR (CD_3CN, 300 MHz, TMS) δ 2.576 (t, 10.5 Hz, 3 H), 2.763 (s, 6 H), 4.0–5.5 (m, 24 H). ^{31}P NMR (CD_3CN, 121 MHz, 85% H_3PO_4) δ 32.710 (s), 47.665 (dd, 299, 292 Hz), 64.702 (m), 70.509 (m), 94.002 (m). UV–VIS (CH_2Cl_2) λ_{max}/nm (ε/dm^3 mol^{-1} cm^{-1}): 271 (11 400), 348 (1090), 402 (1480), 509 (140).

2: in an N_2 atmosphere, a few drops of $CNBu^t$ were added to a suspension of **1** (201 mg, 0.105 mmol) in 8 mL of CH_2Cl_2 at room temperature. The solution immediately turned yellow and all the solid dissolved. After a few hours the solvent volume was reduced to 2 mL and 10 mL of pentane was added. Cooling the solution to −35 °C over 24 h resulted in the formation pale yellow crystals exhibiting a plate morphology. Yield 155 mg (74%). $C_{32}H_{42}Cl_2F_{36}Ir_2N_4O_{12}P_6$; found: C, 19.30; H, 2.18; N, 2.86; requires: C, 19.22; H, 2.12; N, 2.80%. ^{1}H NMR (CD_3CN, 300 MHz, TMS) δ 1.510 (s, 9 H), 2.494 (dd, 12.3, 9.0 Hz, 3 H), 2.730 (dt, 9.0, 3.6 Hz, 6 H), 4.15−4.95 (m, 24 H). ^{31}P NMR (CD_3CN, 121 MHz, 85% H_3PO_4) δ 46.056 (t, 290 Hz), 52.509 (s), 72.530 (t, 75.4 Hz), 93.960 (dm, 290 Hz). UV–VIS (CH_2Cl_2) λ_{max}/nm (ε/dm^3 mol^{-1} cm^{-1}): 302 (13 400).

3: in an N_2 atmosphere, PEt_3 (19 mg, 0.160 mmol) was added to **1** (102 mg, 0.053 mmol) in 10 mL of CH_2Cl_2 at room temperature. The solution immediately turned yellow and all the solid dissolved. The solution was concentrated and 10 mL of pentane was added. Cooling to −35 °C overnight caused a yellow microcrystalline solid to precipitate from solution. Yield 87 mg (81%). $C_{33}H_{48}Cl_2F_{36}Ir_2N_3O_{12}P_7$; found: C, 19.58; H, 2.55; N, 2.12; requires: C, 19.22; H, 2.12; N, 2.80%. ^{1}H NMR (CD_3CN, 300 MHz, TMS) δ 1.230 (dt, 13.2, 7.6 Hz, 9 H), 2.114 (dq, 7.4, 7.5 Hz, 6 H), 2.559 (dd, 11.7, 8.7 Hz, 3 H), 2.648 (m, 6 H), 4.040 (m, 2 H), 4.29–4.87 (m, 18 H), 5.010 (m, 4 H). ^{31}P NMR (CD_3CN, 121 MHz, 85% H_3PO_4) δ: −18.189 (dd, 205 Hz, 18.8 Hz), 44.238 (t, 288 Hz), 53.340 (d, 208 Hz), 65.967 (t, 71.4 Hz), 97.496 (dm, 291 Hz).

‡ *Crystal data*: **1**: $C_{27}H_{29}Cl_2F_{36}Ir_2N_3O_{12}P_6$, M = 1912.65, monoclinic, space group $C2/c$, a = 22.6597(5), b = 12.8038(2), c = 40.1310(6) Å, β = 92.4210(10)°, U = 11632.8(4) Å^3, Z = 8, D_c = 2.184 g cm^{-3}, T = 183(2) K, μ = 4.996 mm^{-1}, $wR2$ = 0.1441 (8322 independent reflections), $R1$ = 0.0669 [$I > 2\sigma(I)$]. C(8), C(14) and the CF_3 group of C9 were disordered between two positions. The fluorine atoms on C(5) and C(7) were placed in an idealized, tetrahedral geometry.

2: $C_{32.5}H_{43}Cl_3F_{36}Ir_2N_4O_{12}P_6$, M = 2042.28, monoclinic, space group $P2_1/n$, a = 13.0879(2), b = 54.4519(9), c = 18.4318(3) Å, β = 101.1890(10)°, U = 12885.9(4) Å^3, Z = 8, D_c = 2.105 g cm^{-3}, T = 183(2) K, μ = 4.558 mm^{-1}, $wR2$ = 0.1787 (18440 independent reflections), $R1$ = 0.0892 [$I > 2\sigma(I)$]. The asymmetric unit contains two chemically identical, but crystallographically different molecules; the CF_3 groups were generated in an idealized, tetrahedral geometry then refined anisotropically. Isopropyl *tert*-butyl ether from crude acetone streams

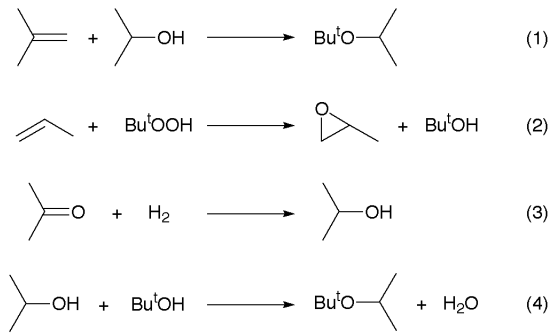
John F. Knifton,* Pei-Shing E. Dai and John M. Walsh

Shell Chemical Company,PO Box 1380, Houston, TX 77251-1380, USA. E-mail: jfknifton@shellus.com

Received (in Bloomington, IN) 19th March 1999, Accepted 22nd June 1999

Isopropyl *tert*-butyl ether may be prepared from crude acetone streams through a combination of selective hydrogenation and *tert*-butyl alcohol etherification.

Methyl *tert*-butyl ether (MTBE) has in recent years been under severe environmental pressure[1] and refiners have been examining alternative gasoline blending stocks, including *tert*-amyl methyl ether (TAME), ethyl *tert*-butyl ether (ETBE), *etc*.[2,3] Of the fuel ethers seriously being considered, isopropyl *tert*-butyl ether (IPTBE) has the triple advantages[3] (see Table 1) of (i) highest octane blending values, (ii) lowest oxygen content and (iii) low vapor pressure. However, until now the only route to IPTBE was through the acid-catalyzed etherification of isobutene (oftentimes in short supply) with isopropyl alcohol (propan-2-ol, IPA) [eqn. (1)].[4,5] We have developed an alternative route to IBTBE from crude acetone streams, making it a co-product of propylene oxide (PO) manufacture. Propylene epoxidation with *tert*-butyl hydroperoxide produces PO plus *tert*-butyl alcohol commercially [eqn. (2)], with significant quantities of acetone as a secondary by-product.[6] We have demonstrated,[7] and report herein, that IPTBE can be made in good yield *via* (i) selective hydrogenation of the crude acetone (Me_2CO) by-product stream to give isopropanol [eqn. (3)] and (ii) isopropyl alocol etherification with the *tert*-butyl alcohol co-product to yield IPTBE plus water [eqn. (4)].



Typically, low-value acetone by-product streams from propylene oxide manufacture comprise 20–80% Me_2CO, but also contain significant quantities of MeOH, *tert*-butyl alcohol (tBA), and allyl *tert*-butyl peroxide (ATBP), as well as detectable quantities of HCO_2H, AcOH, plus their ester derivatives, such as *tert*-butyl formate (tBF).[6] Selective hydrogenation of a 61.7% acetone stream in a continuous, upflow, reactor system containing a nickel, copper, chromium bulk-metal catalyst (72% Ni), at 160 °C, is illustrated in Table 2. Near quantitative (99%) acetone conversion levels are achieved at liquid hourly space velocities (LHSVs) of 0.5, with IPA as the major product. Selectivity to IPA is typically in the range of 76–80 mol%. Critical features of this selective hydrogenation are (i) catalyst activity may be sustained for extended periods without loss of performance and (ii) any ATBP or *tert*-butyl hydroperoxide fractions present in this crude acetone feed are quantitatively converted to more innocuous alcohols, *e.g. tert*-butyl alcohol, without causing catalyst deactivation.

Table 1 Typical properties of fuel ethers[a]

	MTBE	ETBE	TAME	IPTBE
Octane blending value (R + M)/2	110	112	105	113
Oxygen content (wt%)	18.2	15.7	15.7	13.8
Vapor pressure neat Rvp (37.8 °C)	7.8	4.0	2.5	2.5

[a] Data taken from references 2 and 3.

Etherification of the IPA intermediate with added tBA to give IPTBE [eqn. (4)] has also been demonstrated in continuous, upflow, reactor systems using three classes of acidic, large-pore, zeolites:[7] Zeolite Beta, transition metal-modified β-zeolites, and dealuminized Y-zeolites.

IPTBE is typically generated in near quantitative molar selectivities (on the basis of IPA converted) in the crude liquid products under mild etherification conditions. Fig. 1 illustrates IPTBE syntheses from the crude IPA stream of Table 2, plus added tBA (IPA:tBA mole ratio 1:1.6), using an acidic β-zeolite catalyst (80% Beta, 20% alumina binder, in $\frac{1}{16}$″ diameter extruded form), over a reactor temperature range of 40 to 100 °C. At 60–80 °C the estimated IPA conversion level is moderate (*ca*. 12%) and the crude liquid effluent comprises 7–8 wt% IPTBE. However, IPTBE molar selectivity on the basis of tBA converted is below 50% with this crude feedstock, due to

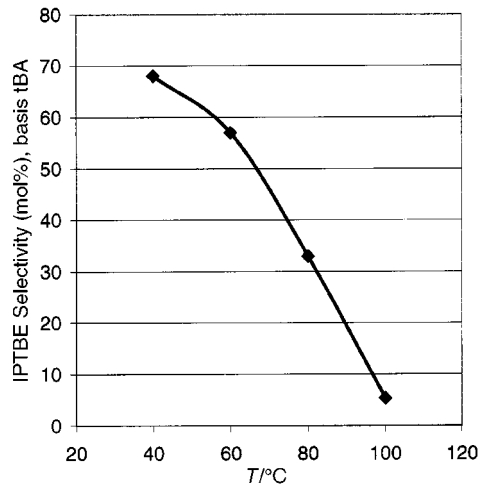

Fig. 2 Pure IPA etherification to IPTBE with tBA.

competing tBA dehydration and oligomerization to isobutene and diisobutene, as well as the formation of smaller quantities of MTBE through etherification. It is noteworthy, nevertheless, that the β-zeolite catalyst does maintain etherification activity and good IPTBA molar selectivity with this crude hydrogenated Me_2CO feedstock for extended periods.[7]

Very similar product distributions were realized when using transition metal-modified β-zeolite catalysts—particularly β-zeolites modified with platinum, palladium, and nickel. These data are illustrated in Table 3 for the non-aqueous product fraction, when starting with the same crude IPA feed stream of Table 2, but adding additional tBA (IPA:tBA molar feed ratio 1:5.8). The transition metal-modified β-zeolites were selected for study here, on the basis of our earlier observations that they provide superior performance in related service, *e.g.* MTBE production from Bu^{t}OH–MeOH mixtures,[8] as well as in ETBE synthesis.[9] Significantly poorer etherification performance was generally realized with the dealuminized Y-zeolites.[7]

Liquid-phase IPTBE synthesis from IPA–tBA mixtures [eqn. (4)] is essentially thermoneutral—see Table 4—in contrast to IPTBE from isobutene [eqn. (1)].[4,5] Isolating and purifying (99%) the intermediate IPA from Table 2, and running etherification with close to stoichiometric quantities of tBA, provides measurably higher IPTBE selectivities over this temperature range (see Fig. 2, IPA:tBA feed ratio 1:1.6) and fewer competing reactions. However, etherifications conducted much above 100 °C lead to the formation of diisopropyl ether as a dominant product.[10]

Continuing improvements in this technology are under investigation, particularly in the area of an integrated, one-step, route to C-3 ethers from crude acetone streams plus tBA.[11]

The authors wish to thank Mr Melvin Stockton for experimental excellence.

Received (in Basel, Switzerland) 23rd April 1999, Accepted 21st June 1999

Two different tren-capped porphyrins—in which the two metals, iron and copper, are more or less off-centered—are shown to be efficient catalysts for the reduction of O_2 to H_2O; surprisingly, their iron-only complexes are shown to be even more effective 4e$^-$ catalysts when adsorbed on a graphite electrode.

The biological reduction of dioxygen to water is an essential reaction that produces energy in the mitochondria. The protein that drives this reaction, the cytochrome *c* oxidase (C*c*O), is the terminal enzyme of the respiratory chain. Additionally, this reaction is coupled with proton translocation across the inner membrane, for the synthesis of ATP.[1] The design and synthesis of new functional analogs is absolutely critical for the understanding of the structural features required for this reaction. This area has been reviewed several times[2] and in particular through the application of 'cofacial metallodiporphyrin' models.[3] The first biomimetic model of C*c*O with a copper complex covalently bound above the porphyrin in a well-defined geometry was reported five years ago.[4] In 1995, the X-ray analysis of bovine heart oxidase[5] revealed that the Cu_B was 4.5 Å from the Fe_{a3} and 1 Å away from the normal axis of the heme iron position. These observations led us to design the 'Arbor' porphyrins,[6] a new series of biomimetic models based on tren [tris(2-aminoethyl)amine] capped porphyrins and for which we have already pointed out that the secondary amino groups could be crucial for the interaction with dioxygen.[7] Since the description of the 'Arbor' porphyrins, several compounds closely related to them have recently appeared in the literature but in both cases with a tri-alkylated cap.[8,9] Until a few months ago,[10] the only biomimetic models having catalytic activity were a cobalt(II) porphyrin associated with a copper(I) triazacyclononane[11] and a copper(I) imidazole-picket iron(II) porphyrin.[12] We report herein our observations about the reduction reaction of dioxygen catalyzed by two different, but still related, model compounds (Scheme 1), for which the relative position of the two metal centers is precisely tuned. The coordination site of the copper ion is highly dependent on the number of 'linker arms' which attach the tripodal cap to the porphyrin core. Compound **4** was obtained by grafting the tren molecule on a chloroacetamido picket porphyrin, leading to a ligand in which the cap is more off-centered and closer to the porphyrin than in model **3** (where a Michael acceptor was used). To the best of our knowledge, this is the first series of two Fe/Cu model complexes differing only in the relative position of copper *vs*. iron, achieved in this work not only by the use of two different linkers but also by a specific strategy that consists in using a non-protected tren molecule.

The synthetic routes to the two different final complexes are shown in Scheme 1. The atropisomer $\alpha\alpha\alpha\alpha$ of the *meso*-(tetra-*o*-aminophenyl)porphyrin (TAPP)—or its singly acetylated derivative—was acylated by either chloroacetyl chloride or acryloyl chloride. These acylations lead to either the three chloroacetyl or the four acryloyl picket porphyrins, which are eventually used in the iron insertion reaction. The capping reaction is carried out on the iron complexes, before copper insertion, to avoid any possible cross-metallation. Then, an excess of nitrogenous base (1,2-dimethylimidazole) is added to stabilize the iron(II) as a five coordinate complex. By combining two crucial structural features: a) the distance between the two coordination sites and b) the off-centering of the two metals, it might be possible to know if one of these two compounds is more efficient than the other one for O_2 electroreduction.

Among the four possible ligands that could be synthesized (3 or 4 linkers and one or two methylene groups), the two studied complexes **3** and **4**‡ (which are the most different compounds in terms of Fe–Cu distance and relative positions of the two metal centers) were found to be active catalysts for the four electron reduction of dioxygen in aqueous solution. This has been assessed by rotating ring-disk voltammetry. Experiments have been performed at pH = 6.86 ($HPO_4^{2-}/H_2PO_4^-$ buffer), an acidity level close to the physiological pH at which cytochrome

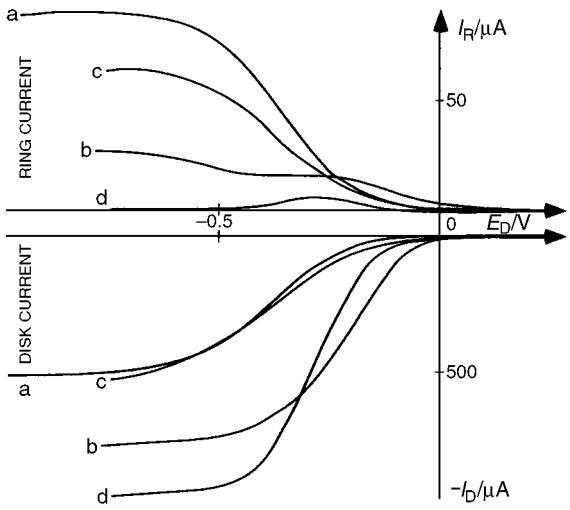

Fig. 1 Rotating ring-disk voltammetry for O_2 reduction; graphite disk impregnated with **1** or **3**. pH = 6.86; N_r = 250 rpm; reference: SCE; $P(O_2)$ = 1 atm; potential of the platinum ring-electrode: 0.8 V. a: bare graphite electrode. b,c: first and third consecutive voltammogram after coating with **3** (4C2FeCu). d: after coating with **1** (4C2Fe).

c oxidase operates; however, as dicobaltbisporphyrins require acidic media for the 4e$^-$ reduction, the catalytic efficiencies of **3** and **4** have also been tested at low pH (0.1 M $HClO_4$).

As illustrated for **3** (Fig. 1), models **4** and **3** have identical effects on the reduction of O_2 at pH 6.86, when adsorbed on the graphite disk. The reduction waves for the first scan (curve b) begin at −0.1 V and have almost the same limiting current. From comparison with the dioxygen reduction on a bare edge-plane graphite electrode (curve a), it can be concluded that the number of electron exchanged per O_2 molecule is 2.8. The production of H_2O_2 is detected at the platinum ring (ring current, curve b) almost immediately at the beginning of O_2 reduction, which means that the two and four electron reduction processes occur simultaneously. A second and third scan with the same electrode (curve c) show that the catalyst is degraded, as proved by the lower reduction current. When the electrode is in contact with an aqueous acidic solution (0.1 M $HClO_4$), O_2 reduction starts at a higher potential (0.1 V); the 4e$^-$ process occurs also under these conditions but the catalytic efficiency is lost more rapidly than in the neutral medium. The number of electrons for the electrocatalytic reduction of O_2, measured as described above, is only apparent as the catalyst is degraded during the reduction. Surprisingly, changes in the structure of the molecule do not seem to significantly affect the activity of these models of cytochrome *c* oxidase. The first hypothesis which explains the loss of activity could be the leaching of copper from its rather labile complex. The second could be the decoordination of the fifth ligand of the iron. These two structural features have been presented as essential to the catalytic activity in related biomimetic models.[11] However, catalysts **1** and **2**, the respective analogs of **3** and **4** without copper, cleanly catalyze the 4e$^-$ reduction, as shown for **1** in Fig. 1 (curve d). This simple test has never been reported even for close structural models bearing imidazole pickets.[8,12]

These experimental observations led us to several conclusions. Firstly, the loss of activity that occurs during the O_2 reduction is not due to the decoordination of the copper ion in contact with aqueous media as the iron-only compounds are even more efficient catalysts. The second conclusion derived from this study is that the fifth ligand does not need to be covalently bound to the porphyrin.

The fact that the iron catalysts are efficient for the reduction of dioxygen to water excludes the formation of a μ-peroxo intermediate between iron and copper atoms as a prerequisite for O_2 activation, as it has been postulated.[1a,d] However, it is compatible with a peroxo derivative, probably protonated.[2b] In the case of the enzyme, Yoshikawa *et al*. have suggested that this hydroperoxo complex is formed by addition of a proton delivered by Tyr 244.[13] In the case of the present model compounds, whether the proton transfer from the solution to the peroxo entity is mediated by the tren cap, or these secondary amino groups stabilize the hydroperoxo complex, are questions that could not receive proper answers in this preliminary work.

In conclusion, this new series of catalysts are efficient and selective for the electroreduction of dioxygen to water, without copper in the tripodal cap. This is in favor of the formation of a hydroperoxo complex rather than a μ-peroxo complex. Surprisingly, these results seem to be in contradiction with what has already been reported for related model compounds.[9] This difference of reactivity could be explained by structural differences; more explicitly, the existence of secondary amino groups in our compounds. These are certainly protonated when the compounds are in an aqueous environment at pH 6.86. Indeed, it would be of great interest to know if iron-only models such as the imidazole picket porphyrin of Holm[8] or its analog with an intramolecular nitrogen base described by Collman[12] are also efficient 4e$^-$ catalysts or not. It should however be stressed that these conclusions have been reached by the observation of molecules adsorbed on a graphite electrode in contact with water, a situation different from the environment of the active site of the enzyme. This study is presently in progress with other new molecules, to investigate if these tren-capped porphyrins represent a particular case or if this unexpected reactivity is general for iron–copper cytochrome *c* oxidase models.

An efficient synthesis of CMP-3-fluoroneuraminic acid

Michael D. Burkart, Stéphane P. Vincent and Chi-Huey Wong*

Department of Chemistry and The Skaggs Institute for Chemical Biology , The Scripps Research Institute, 10550 N. Torrey Pines Road, La Jolla, CA 92037, USA. E-mail: wong@scripps.edu

Received (in Corvallis, OR, USA) 27th April 1999, Accepted 23rd June 1999

CMP-3-fluoroneuraminic acid, a useful mechanistic probe for sialyltransferases, has been efficiently synthesized using recent fluorination and phosphorylation techniques from a sialic acid glycal.

Sialic acids displayed on the surface of mammalian cells are involved in many cell–surface interactions including cell–cell recognition processes, cell adhesion, and viral receptor recognition.[1,2] Sialyltransferases are the enzymes responsible for transfer of sialic acid from cytidine 5′-monophospho-*N*-acetylneuraminic acid (CMP-Neu5Ac) to a growing oligosaccharide, often terminating the series at the non-reducing end.[3] We recently synthesized the nucleotide phosphate sugars of fucose and galactose fluorinated α to the anomeric carbon that demonstrated significant competitive inhibition against the respective fucosyl- and galactosyl-transferase enzymes. These results, together with isotope studies, are indicative of substantial oxocarbenium ion transition state structure.[4,5] The effect of fluorine is attributed to its strong electron-withdrawing nature which destabilizes formation of positive charge within the carbohydrate ring. Though several substrate analog inhibitors have recently been designed to effectively inhibit α(2,6)-sialyltransferase,[6–9] a cationic transition state structure has not yet been demonstrated in mechanistic studies. Only solvolysis of CMP-Neu5Ac has been shown to display a finite sialyl cation species.[10] Additionally, *N*-acetyl-3-fluoroneuraminic acid (3F-Neu5Ac) alone serves as a competitive inhibitor of bacterial and viral sialidases.[11–13] Therefore, a fluorinated CMP-Neu5Ac derivative would be expected to inhibit sialyltransferases as a non-reactive mechanism-based inhibitor if the enzyme catalyzes formation of a cationic transition state species in the donor glycon. Such inhibition by a fluorinated substrate analog would extend the cationic transition state phenomenon to sialyltransferase enzymes, as has been demonstrated with other glycosyltransferases. Here we describe the synthesis of cytidine 5′-monophospho-*N*-acetyl-3-fluoroneuraminic acid **1**, which employs a fluorine subsituent α to the anomeric carbon on the neuraminic acid, and demonstrate its competitive inhibition of α(2,6)-sialyltransferase in the presence of CMP-Neu5Ac.

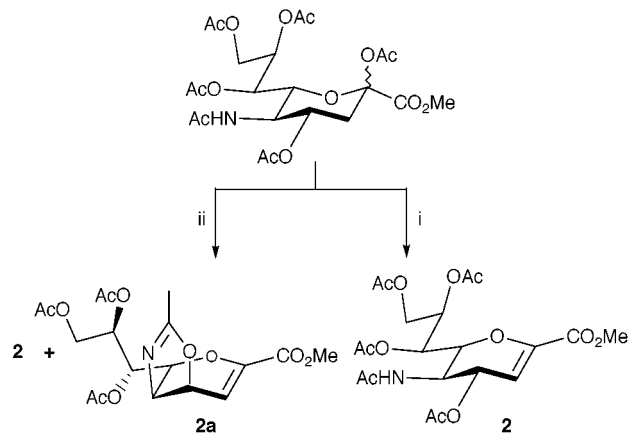
Previous syntheses of *N*-acetyl-3-fluoroneuraminic acid have relied upon fluorination of the glycal of peracetyl-*N*-acetylneuraminic acid methyl ester **2** with XeF_2–BF_3•OEt_2[12] or molecular fluorine.[13] The reported overall yield of this method gives less than 20% of the fluorinated monosaccharide in several steps from the sialic acid methyl ester. With the recent development of a one-pot, high-yielding fluorination technique using F–TEDA–CH_2Cl•$2BF_4$ (Selectfluor), the 2-hydroxy-3-fluoro protected monosaccharide **3** is available in 80% yield from the glycal.[14] Unlike previous methods, the fluorinated product retains all protecting groups from the glycal starting material, leaving a deprotected hydroxy at the anomeric position that is ready for selective chemical modification. This technique uniquely solves problems associated with the synthesis of **1**, as 3F-Neu5Ac is not a substrate of CMP-Neu5Ac synthase (EC 2.7.7.43), which converts Neu5Ac and cytidine-5′-triphosphate to CMP-Neu5Ac.[15] Hence, synthesis of the fluorinated CMP-Neu5Ac derivative must proceed *via* chemical methods. Conveniently, an improved synthesis of CMP-Neu5Ac and its conjugates was recently published enumerating a four step strategy from the 2-OH protected monosaccharide.[16] Combination of these two techniques with a new method to synthesize the glycal are reported here to synthesize **1**.

The known protected sialic acid glycal **2** was prepared directly from the peracetylated neuraminic acid (Scheme 1).[17] The described procedure utilizing TMSOTf in MeCN[18] led generally to a mixture of glycal **2** (65%) along with the 2,3-dehydro-4,5-oxazoline **2a**.[19,20] We found that the use of a catalytic amount of PPh_3HBr[21] in place of TMSOTf gave **2** in nearly quantitative yield (96%) without detectable cyclized product.

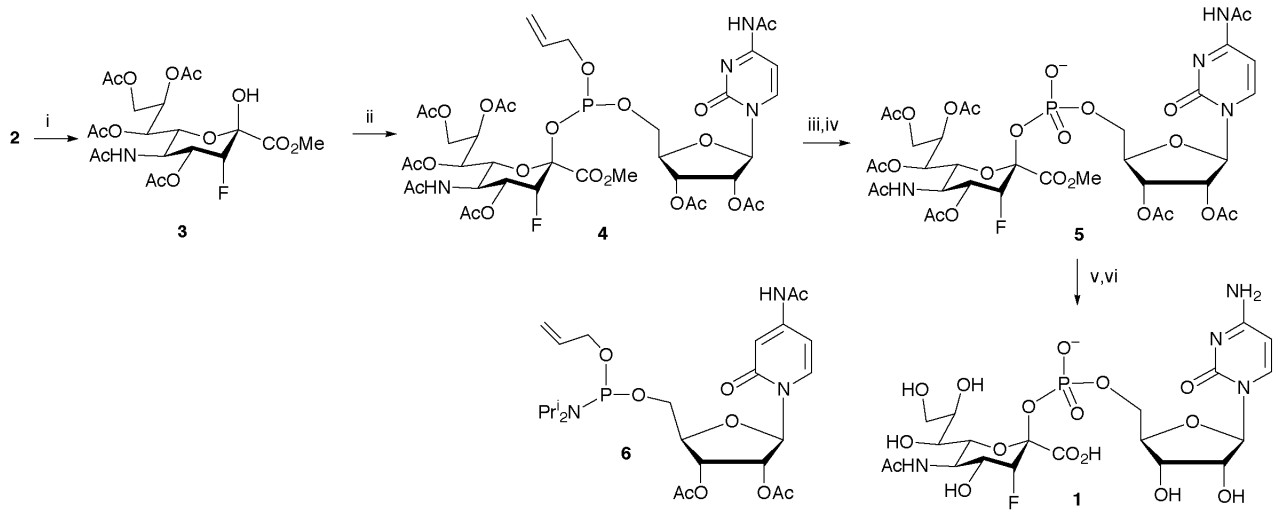
The glycal **2** was fluorinated with F–TEDA–BF_4 following the general glycal fluorination procedure in DMF and H_2O (Scheme 2).[14] Purification by silica gel chromatography yields **3** in 80% yield (3 : 1 F_{ax}/F_{eq}). The 2-*O*-acetylated derivative of this molecule and the fully deacetylated 3-fluoro-Neu5Ac have been previously characterized and were demonstrated to contain β anomeric configuration based upon no ^{13}C–^{19}F coupling between C1 and F3.[13] For this reason as well as an established anomeric effect for sialic acid[22] and the yield of only one stereoisomer from this reaction, we concluded **3** to be in the pure β form.

Compound **3** (F_{ax}) was condensed with phosphoramidite **6**[16] in MeCN followed by quench with Et_3N. The product was purified by Dowex LH-20 size-exclusion chromatography in MeCN to give the protected phosphite **4** in 54% yield.[23] Anomeric stereochemistry was determined to retain β configuration by ^{13}C–^{19}F coupling between C1 and F3 (0 Hz) and by the chemical shift of H3 deviating less than 0.1 ppm from **3**. Anomerization is well known to give rise to significant chemical shift at H3.[24] Furthermore, only one stereochemical isomer was isolated.

The phosphite **4** was oxidized to the phosphate with *tert*-butyl hydroperoxide and deprotected with $Pd(PPh_3)_4$ and Pr^i_2NH. Silica gel chromatography gave **5** in 72% yield.[25] Deprotection of the methyl ester with NaOMe in MeOH was followed by immediate size-exclusion chromatography in water. The product was deacetylated with 1 M NaOH and subsequently purified



Scheme 1 *Reagents and conditions*: i, PPh_3HBr, MeCN, 96%; ii, TMSOTf, MeCN.



Scheme 2 *Reagents and conditions*: i, Selectfluor, DMF–H_2O (3 : 1), 60 °C, 80%; ii, **6**, 1*H*-tetrazole, MeCN, −78 °C→room temp., 60%; iii, Bu^{t}OOH, Et_3N; iv, $Pd(PPh_3)_4$, Pr^i_2NH, 72% for 2 steps; v, NaOMe, MeOH; vi, NaOH, 80% for 2 steps.

by aqueous size-exclusion chromatography to provide **1** in 80% yield over two steps.[26]

Compound **1** was assayed as an inhibitor of α(2,6)-sialyltransferase (Calbiochem, San Diego, CA) using standard radioisotopic assay procedures. These results show that **1** competes with CMP-Neu5Ac for the enzyme with K_i = 5.7 ± 1.2 μM.[27] Compared to the K_m for CMP-Neu5Ac of 15 μM, this result is consistent with a transition state structure containing considerable oxocarbenium ion characteristic.[5]

Urea–picoline *N*-oxide (4:2) cocrystal: an unusual channel inclusion compound

Veneta Videnova-Adrabińska* and Elżbieta Janeczko

Institute of Inorganic Chemistry and Metallurgy of Rare Elements, Wrocław University of Technology, 23 Smoluchowskiego St. 50 370 Wrocław, Poland. E-mail: veneta@ichn.ch.pwr.wroc.pl

Received (in Oxford, UK) 26th April 1999, Accepted 28th June 1999

The crystal structure of urea–picoline *N*-oxide cocrystal reveals urea channel formation in which two independent picoline *N*-oxide molecules are stacked with their charge-transfer axes aligned approximately at 60° toward the crystallographic *b*-axis.

In the classical urea inclusion compounds[1–3] the host structure comprises an extensive hydrogen-bonded array of urea molecules, giving rise to parallel chains (with an internal diameter of 5.3–5.7 Å) within which the guest molecules are densely packed. The X-ray structural characterisation confirmed that the vast majority of urea inclusion compounds are incommensurate, that is no small integers m and n exist to satisfy $mc_h = nc_g$, where c_h and c_g are the host and guest repeat distance along the channel axis. Unusual inclusion compounds are formed by urea and sebaconitrile[4] (6 urea:1 guest) and undecane-2,10-dione (9 urea:1 guest),[5] in which additionally hydrogen-bond interactions appear between the host and the guest molecules. Urea also forms many inclusion compounds with the incorporation of other molecular species as additional building blocks of their hydrogen-bonded host lattices as for example halides and pseudohalides, planar oxoanions, dihydrogen orthoborate $BO(OH)_2$ and allophanate ion $NH_2CONHCO_2^-$, spirocyclic pentaborate anion $[B_5O_6(OH)_4]^-$, and tetra-*n*-propylammonium halides.[6] Thus far, with the exception of urea inclusion complexes with trioxane,[7] undecan-5-one[8] and with certain short-chain α,ω-dihaloalkanes and dicarboxylic acids,[9] virtually all urea inclusion compounds are incommensurate, where the repeat distance of host and guest along the channel is a common factor, and the guest molecules pack within van der Waals contact of each other. In some cases, particularly at low temperatures, the host structure becomes slightly distorted from the conventional hexagonal tunnel structure, but the repeat length along the channel axis is uniformly close to the standard value of 11.0 Å.[2] If a guest species cannot be accommodated by the conventional hexagonal channel, it is ordinarily not included within urea,[10] and either separate phases or specific cocrystals[11] are formed. Recent reviews[12,13] summarise the present level of understanding of the structural and dynamic properties of urea and thiourea channel inclusion compounds.

We now report the X-ray single crystal structure† of a novel channel inclusion compound formed by urea and picoline *N*-oxide molecules (4 urea:2 guest). Nice transparent rectangular plates of significant sizes were obtained by the slow evaporation method from a methanol solution of urea and picoline *N*-oxide (T_m 146–148 °C).‡ The crystal structure comprises two independent picoline *N*-oxide molecules, each lying on a mirror plane, and four independent urea molecules forming host channels in which the guests are imbedded. The IR spectra§ of the crystal are qualitatively different from the spectra of the substituents and reflect the formation of a hydrogen-bonded network, substantially different from that in the urea crystal. The splitting of the ring C–C and C–H modes in the regions 1450–1500 cm^{-1}, 1150–1250 cm^{-1}, 1000–1050 cm^{-1} and 750–760 cm^{-1}, as well as of the CH_3 stretching and deformation modes (3000–3130 cm^{-1} and 1370–1460 cm^{-1}), reflects the presence of two independent picoline *N*-oxide molecules. On the other hand, the significant changes (band broadening, multiplication and wavenumber shift) observed in the regions of νNH_2 and δNH_2 modes (3450–3000 and 1600–1700 cm^{-1}) are consequential to the hydrogen-bond modification in the new channel arrays. However, the most spectacular changes are observed in the region 750–500 cm^{-1}, where several new bands appear, each of which is doubly split. This region is not well understood now and requires further investigation, but it very probably has something to do with the formation of hydrogen bonds toward the picoline O21 oxygen atom.

The 1D hydrogen-bonded arrays are extended explicitly through $N–H_{syn}\cdots O{=}C$. Each pair of urea molecules assigned as U1–U3 and U2–U4 (related *via* screw rotation along the *z*-axis) form hydrogen-bonded ring motifs $R_2^2(8)$ which are further propagated to form molecular tapes running along the *a*-crystallographic axis. Distortions from planarity allow for mutual topological, geometrical and sterical adaptation and recognition of the hydrogen-bond donor and acceptor sites, left unused in the tape formation, in order to zip each two neighbouring tapes at 1/2a, 3/2a, 5/2a, *etc.* *via* four $N–H_{anti}\cdots O$ bonds with the resultant formation of a strongly folded 2D hydrogen-bond arrangement of the host lattice (see Chart 1a).

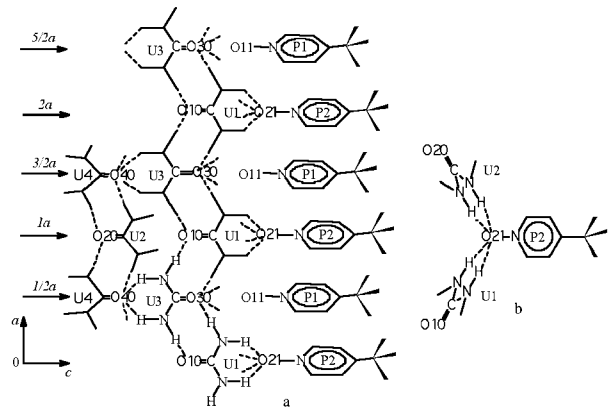

Chart 1

The dihedral angle between the zipped tapes is *ca.* 120°. The fourfold accessibility of O30 and O40 for hydrogen bonds is a rare phenomenon, so far noted only in urea crystals. This fact suggests that the two electron pairs on the urea oxygen are delocalised on a cone surface. The four hydrogen bonds toward the urea O30 and O40 adapt a pyramidal configuration. The other two oxygens O10 and O20 from U1 and U2 are imbedded in the tapes and are not accessible for additional hydrogen bonds.

The two independent picoline *N*-oxide molecules assigned as P1 and P2 are stacked in the host channels of urea with a repeat distance of 3.55 Å between the aromatic ring planes and densely fill the empty space. However, the bound mechanism toward the host lattice is diverse for the guests P1 and P2. Four $N–H_{anti}$ donors from U1 and U2 project the O21 atoms located on P2 in order to form four hydrogen bonds with a pyramidal configuration (see Chart 1b). The dihedral angle between the planes of two pairs of hydrogen bonds toward O21, donated by U1 and U2 is 120°. Thus, each two neighbouring tapes are hinged on the P2 molecules at 1a, 2a, 3a *etc.*, completing the 3D hydrogen-bonded network (Chart 1 and Table 1). The three-dimensional

N10–H2(N10)···O21	2.994(5)	2.25(4)	*x*, *y*, *z* 2 − *x*, *y*, *z*

crystal structure can be considered as consisting of urea channels running along the *a*-axis, in which the P2 molecules are hydrogen-bond fixed perpendicularly to the urea chains, padlocking large cavities where the other guests P1 are simply trapped. Despite the similar geometry of both guest molecules, the topology of the host lattice dictates different including mechanism and the P1 molecules intercalate (at 1/2a, 3/2a *etc*.) between the P2 molecules residing the empty spaces in between. The acceptor site O11 on the P1 molecule is imbedded in the O10 and O20 electron rich environment, lacking free hydrogen-bond donors. However, neither the repulsive forces between the P1 guests and U host lattice nor the dipole–dipole interactions between the P1 and P2 are strong enough to overcome the hydrogen bond interactions confining the cavity size. So, the P1 molecules, though not specifically bonded to the host, are only free to some librational motions. The sublimation process in the temperature range 100–140 °C may be explained with a partial breaking of the hydrogen bond lattice and leaving of the P1 molecules. As a result of this unusual channel inclusion mechanism, both guest molecules P1 and P2 are aligned almost in the same way in the host lattice (see Fig. 1). Their charge-transfer (CT) axes are directed approximately at 60° toward the optical *b*-axis, which is very close to the optimal molecular orientation for bulk phase-matching in the *mm*2 space group.[14] The crystal passes positively a second harmonic generation test yielding a signal 1.5 times higher than that of urea.

Single-electron reduction of C_{60} with a carbon radical: formation of the Crystal Violet cation–fulleride ion salt†

Toshikazu Kitagawa,* Yangsoo Lee and Ken'ichi Takeuchi*

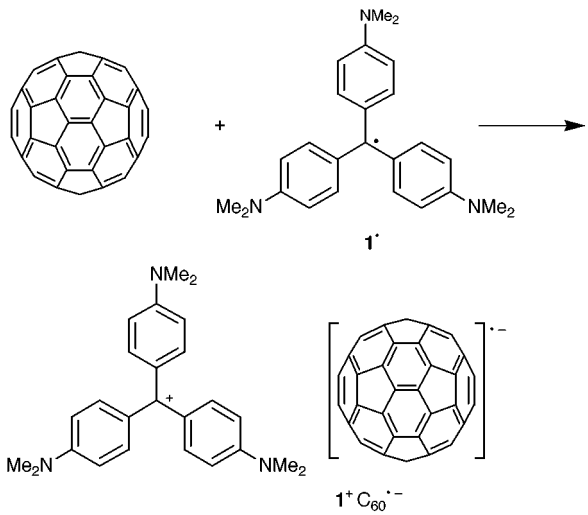
Department of Energy and Hydrocarbon Chemistry, Graduate School of Engineering, Kyoto University, Sakyo-ku, Kyoto 606-8501, Japan. E-mail: kitagawa@scl.kyoto-u.ac.jp

Received (in Cambridge, UK) 17th May 1999, Accepted 5th July 1999

Whereas many carbon radicals are known to add to C_{60}, the reaction of Crystal Violet radical $\mathbf{1}^{\bullet}$ with C_{60} resulted in single-electron transfer, leading to a carbocation–carbanion salt $\mathbf{1}^{+}C_{60}^{\bullet-}$: the product was isolated as microcrystalline powder and was characterized by EPR, VIS-NIR and NMR spectroscopy.

The addition of radicals to buckminsterfullerene (C_{60}) to give fullerenyl radicals constitutes a well-known and characteristic reaction. The addition of reactive carbon-centered radicals, such as alkyl, benzyl and haloalkyl radicals and some heteroatom-centered radicals, to C_{60} has been reported to produce $RC_{60}^{\bullet}$ as well as multiple-addition fullerenyl radicals.[1] The high affinity of C_{60} toward radicals has been demonstrated by its ability to absorb up to 34 methyl radicals,[2] 15 benzyl radicals,[2] 11 phenyl radicals,[3] and 16 perfluoroethyl radicals.[4] Another possibility in the reaction of an alkyl radical with C_{60} is electron transfer from the radical to C_{60}. Such a reaction, which, to the best of our knowledge, has not been reported, would be expected to occur if the reducing power of the radical is sufficiently strong to reduce C_{60}. We report herein the single-electron reduction of C_{60} with the Crystal Violet radical $\mathbf{1}^{\bullet}$ and the isolation of the product $\mathbf{1}^{+}C_{60}^{\bullet-}$ as a solid (Scheme 1).

For stoichiometric single-electron transfer from a carbon-centered radical $R^{\bullet}$ to C_{60} without a subsequent redox or chemical process, the following requirements must be fulfilled. First, the oxidation potential of $R^{\bullet}$ must be more negative than the first reduction potential of C_{60} (−1.09 V *vs.* Fc/Fc^{+}),[5] but not more negative than the second reduction potential (−1.48 V *vs.* Fc/Fc^{+}).[5] Considering the effective delocalization of the positive charge in $\mathbf{1}^{+}$ over three nitrogen atoms, one would expect that the corresponding radical $\mathbf{1}^{\bullet}$ would be readily oxidized. Cyclic voltammetry for $\mathbf{1}^{+}I^{-}$ indicates that the $\mathbf{1}^{\bullet}/\mathbf{1}^{+}$ redox couple has a potential of −1.19 V *vs.* Fc/Fc^{+} in PhCN, which is midway between the first and second reduction potentials, thus allowing a complete single-electron reduction to give $C_{60}^{\bullet-}$ but no further electron transfer to C_{60}^{2-}.[6] Secondly, the ions produced by the electron transfer, R^{+} and $C_{60}^{\bullet-}$, should be sufficiently stable so as not to react with each other. Although carbocations and carbanions have a strong tendency to combine to form neutral molecules, we have earlier reported that a highly stabilized carbocation with a $pK_{R^{+}}$ of 7.29–13.6 and a carbanion whose conjugate acid has a pK_a of 5.7–5.9 can, in fact, coexist in solution and in the solid state, without cation–anion coordination.[8] The reported $pK_{R^{+}}$ of $\mathbf{1}^{+}$ (9.36[9]) and the pK_a of the conjugate acid of $C_{60}^{\bullet-}$ (3.4–9.0[10]) led to the prediction that these ions are sufficiently stable to allow the formation of a stable salt, $\mathbf{1}^{+}C_{60}^{\bullet-}$, rather than a neutral radical, $\mathbf{1}$–$C_{60}^{\bullet}$. In addition, the formation of such a bond would be severely hindered, because of the repulsion between the aromatic rings of $\mathbf{1}^{+}$ and the fullerene cage.



Scheme 1

Radical $\mathbf{1}^{\bullet}$ can be quantitatively generated by the reduction of the Crystal Violet cation $\mathbf{1}^{+}$ with zinc.[11] Unlike the unsubstituted triphenylmethyl radical, this radical does not dimerize but persists in solution.[12] All the procedures for the preparation of $\mathbf{1}^{+}C_{60}^{\bullet-}$ and spectroscopic analysis of the product were carried out under degassed conditions using a glass apparatus connected to a high-vacuum line ($< 10^{-4}$ mmHg). The apparatus contains two chambers, one for the preparation of $\mathbf{1}^{\bullet}$ and the other for the reduction of C_{60}. The two chambers are separated by a sintered glass frit, and to the latter is connected a tube or a cell for spectroscopic analysis of the product. In a typical experiment, $\mathbf{1}^{\bullet}$ was prepared by the treatment of anhydrous Crystal Violet iodide (2.05 mg) with zinc powder (93 equiv.) in 0.1 ml of pyridine. The zinc iodide was precipitated as the pyridine complex by diluting the reaction mixture with hexane (1.2 ml). The resulting red solution of $\mathbf{1}^{\bullet}$ was then transferred to the other chamber, which contained a CS_2 solution (5 ml) of C_{60} (2.86 mg, 0.97 equiv.). The salt $\mathbf{1}^{+}C_{60}^{\bullet-}$ was immediately precipitated from the mixed solution as red–brown microcrystalline powder, which was collected on the sintered glass frit and washed three times with small amounts of CS_2. Elemental analysis of the crystals[13] showed a nitrogen content of 3.50%, a value close to that calculated for $\mathbf{1}^{+}C_{60}^{\bullet-}$ (3.84%), consistent with the 1:1 molar ratio of the Crystal Violet moiety and the C_{60} component.

The EPR spectrum for a powder sample showed a broad single line (g = 1.999, peak-to-peak width 2.9 mT at 20 °C). The signal intensity, relative to a known amount of external standard, 4-hydroxy-TEMPO, indicated that the solid contained 90 ± 10% of the theoretical amount of unpaired spins. A THF solution of the solid material showed spectra typical of the fullerene anion (Fig. 1). A broad signal (peak-to-peak width *ca.* 9 mT) with a superimposed spike (peak-to-peak width 1 mT, g = 2.000) was observed at room temperature; the former became narrower with decreasing temperature. These observations are all in agreement with the behavior of the $C_{60}^{\bullet-}$ signal reported earlier.[14,15]

A ^{1}H NMR spectrum, taken in CD_2Cl_2, showed the presence of $\mathbf{1}^{+}$ and the corresponding alcohol **1**–OH in 41:59 molar ratio.

† Experimental details and the ^{1}H NMR data for $\mathbf{1}^{+}C_{60}^{\bullet-}$ are available as supplementary data from the RSC web site, see http://www.rsc.org/suppdata/cc/1999/1529/

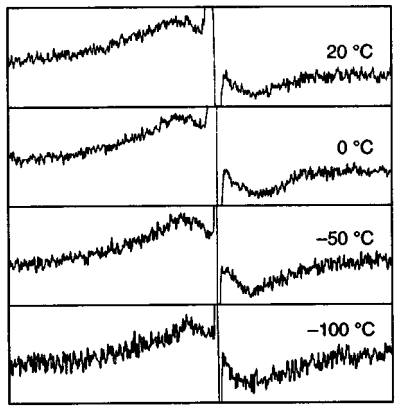


Fig. 1 X-Band EPR spectra of $\mathbf{1}^{+}C_{60}^{\bullet-}$ in THF recorded at 0.6 mW microwave power, 0.4 mT modulation and 50 mT sweep width.

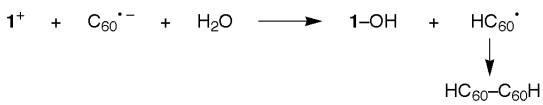
The signals of $\mathbf{1}^{+}$ were significantly broadened, probably due to the paramagnetism of $C_{60}^{\bullet-}$. Hydrolysis by a trace amount of water in the solvent appears to be responsible for the formation of alcohol, indicating that the salt $\mathbf{1}^{+}C_{60}^{\bullet-}$ is extremely moisture-sensitive. This is in contrast to the fact that the other Crystal Violet salts, *e.g.* $\mathbf{1}^{+}Cl^{-}$, are stable in water. The difference may be explained by the higher basicity of $C_{60}^{\bullet-}$ compared with Cl^{-} and the dimerization of the resulting radical $HC_{60}^{\bullet}$ (Scheme 2).[16]



Scheme 2

The VIS-NIR spectrum of a THF solution of $\mathbf{1}^{+}C_{60}^{\bullet-}$ exhibited absorption maxima which were characteristic of $\mathbf{1}^{+}$ and $C_{60}^{\bullet-}$ at 593 and 1074 nm, respectively (Fig. 2). The latter absorption band had a substructure identical with that reported for $C_{60}^{\bullet-}$.[15,17] Based on the molar absorptivity of $\mathbf{1}^{+}$ at 593 nm (1.05×10^{5} M^{-1} cm^{-1}) and assuming a 1 : 1 composition of $\mathbf{1}^{+}$ and $C_{60}^{\bullet-}$,[18] the molar absorptivity of $C_{60}^{\bullet-}$ at 1074 nm was calculated to be 1.96×10^{4} M^{-1} cm^{-1}, which is comparable with reported values of $1.20–2.00 \times 10^{4}$ M^{-1} cm^{-1}.[15c,17] The observed absorption line shape is in agreement with the sum of the independently measured absorptions of $\mathbf{1}^{+}$ and $C_{60}^{\bullet-}$. No significant decay of absorbance was observed, indicating the absence of charge recombination. Charge-transfer type interaction is also unlikely, since no absorption band indicative of a charge-transfer complex was observed.

The above experiments clearly demonstrated that C_{60} undergoes single-electron reduction by an electron-rich, sterically protected radical $\mathbf{1}^{\bullet}$. The product, $\mathbf{1}^{+}C_{60}^{\bullet-}$, is stable both in solution and in the solid state, providing a new isolated carbocation–carbanion salt. Thus, the possibility of electron-transfer in the reaction of organic radicals to C_{60} has been demonstrated as an alternative to the addition to C_{60}, which is usually observed for reactive radicals.

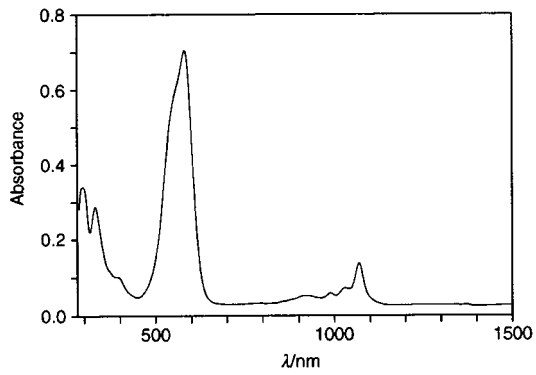


Fig. 2 VIS–NIR absorption spectrum of $\mathbf{1}^{+}C_{60}^{\bullet-}$ in THF at 25 °C.

Synthesis and characterization of 'calixsalens': a new class of macrocyclic chiral ligands

Zengmin Li and Chet Jablonski*

Received (in Corvallis, OR, USA) 4th January 1999, Accepted 7th June 1999

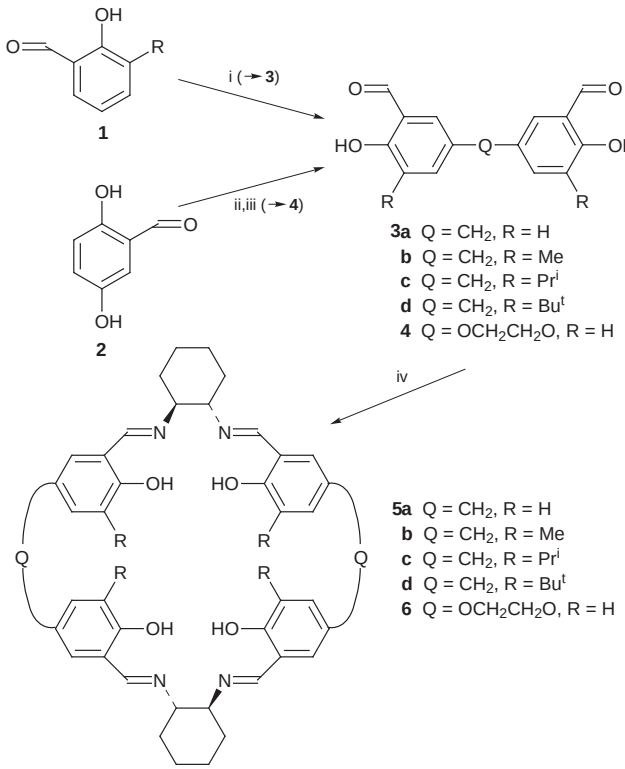
Template directed reaction of dialdehydes and (*R*,*R*)- or (*S*,*S*)-1,2-diaminocyclohexane affords a practical route to chiral, metal-free macrocyclic salen dimers which have a novel calixarene-like structure and show catalytic activity for enantioselective epoxidation of unfunctionalized alkenes in the presence of Mn^{III}–NaOCl (aq.).

Chiral Schiff base ligands are efficient chiral auxiliaries for a wide range of enantioselective epoxidations.[1] Our search strategy for new asymmetric catalysts, particularly for asymmetric epoxidation of unfunctionalized alkenes,[1–4] has focussed on development of chiral macrocycles bearing two salen-based metal binding sites[5] which can act co-operatively[6a,7] within an enzyme-like chiral cavity. This approach is based on the expectation that non-covalent interactions,[8] which are the sole determinants of stereochemical outcome for enantioselective reactions of unfunctionalized substrates,[2a,9] can be maximized within a chiral host–guest paradigm.[6] The macrocycles reported herein are simple chiral salen dimers (Scheme 1) containing two tetradentate metal binding sites coupled by one- or four-atom linking groups which determine ring size.

The 26- or 32-membered salen macrocycles **5** and **6** were synthesized by template-induced cyclization (Scheme 1) of *trans*-(*R*,*R*) or *trans*-(*S*,*S*)-1,2-diaminocyclohexane and an appropriate dialdehyde (**3a**–**d** or **4**), prepared from the corresponding aldehydes.[10] Three products, identified as the dimer **5d** (*m/z* 893), along with the corresponding trimer (*m/z* 1339) and tetramer, were isolated from condensation of dialdehyde **3d** and *trans*-(*R*,*R*)-(−)-1,2 diaminocyclohexane. Two major products were obtained from cyclization of **3a**–**c** with the (*R*,*R*)-diamine. The higher TLC R_f product in each case was confirmed to be macrocyclic dimer **6a**–**c** (*m/z* 668, 725 and 837). Relatively simple and similar ^{1}H NMR spectra of the dimer and the corresponding trimer or tetramer suggested a highly symmetric structure. ^{13}C NMR revealed seven low field signals assigned to the four equivalent imine C=N carbons and six of the twenty-four aromatic carbons of **5a**–**d**. Consistent with overall D_2 symmetry, four (**5a**), five (**5b**) or six (**5c**,**d**) high field ^{13}C NMR signals were observed for the remaining carbon atoms.

A single crystal X-ray study† of **5a**·DMF confirms the D_2 symmetric structure (Fig. 1) inferred from solution spectroscopy. The four benzene rings of **5a**·DMF form a well-defined cavity and adopt a 1,3-dialternate conformation with a striking calixarene-like[11] structure, hence we have introduced the name 'calixsalen' to describe these macrocycles. The two opposing face-to-face benzene rings are nearly coplanar and lie 7.57 Å apart and, as a consequence of the preferred 1,3-dialternate conformation, the hydroxy groups are twisted away from the 'salen' plane so that hydrogen-bonding between adjacent OH groups is precluded.

In contrast, the ambient temperature 500 MHz ^{1}H NMR spectrum of the 32-membered salen macrocycle **6**, obtained as a single TLC band from cyclization of **4** with the (*R*,*R*)-diamine (*cf.* Scheme 1), showed four imine signals (8.12, 8.10, 8.09 and 8.07 ppm) in a ratio of 2:4:8:30 which were assigned to four slowly-interconverting conformers. NMR and mass spectral (*m/z* 761) evidence are consistent with the dimeric structure **6**. ^{13}C NMR showed two imine carbon signals (164.74, 164.51 ppm) in an approximate ratio of 10:30 corresponding to the two most stable conformers. Eleven pairs of ^{13}C resonances for the two major conformers, tentatively assigned as the D_2 symmetric 1,3-alternate and C_2 symmetric 1,2-alternate conformers in slow exchange, were observed. Although a maximum of eleven ^{13}C resonances are expected for the D_2 symmetric 1,3-alternate conformation, the 1,2-alternate or any of the remaining



Scheme 1 *Reagents and conditions*: i, $(CH_2O)_3$, H_2SO_4, AcOH, 70 °C; ii, NaH, $(TsOCH_2)_2$; iii, HCl; iv, 1,2-diaminocyclohexane, $Ba(ClO_4)_2$, MeOH–THF.

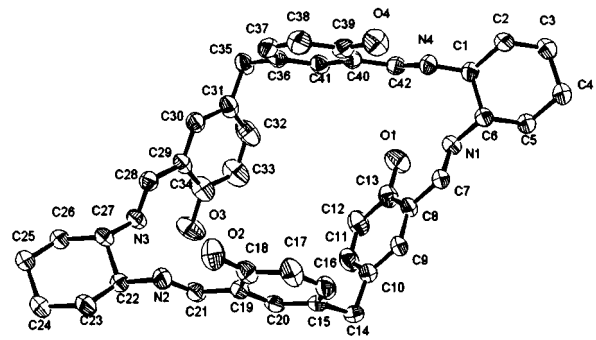


Fig. 1 ORTEP representation (30% ellipsoids) for **5a**·DMF (DMF and hydrogen atoms removed for clarity).

conformations should show a total of 22 resonances. We conclude that some degree of flexibility, made possible by the ethylene glycol links, establishes a second, time-average C_2 axis. Warming to 55 °C results in collapse of the two ^{13}C imine resonances into a single peak at 165.04 ppm, possibly as a result of 1,3-alternate ↔ 1,2-alternate exchange which becomes fast on the NMR time scale.

Although the solid state conformation of **5a**·DMF appears ill-disposed to provide two tetradentate salen coordination sites, reaction with Mn^{III} salts is facile. Addition of a solution of $Mn(OAc)_3$ to solutions of the salen dimers **5** or **6** caused an immediate colour change from yellow to deep brown. An electrospray mass spectrum of a methanolic solution of the dark brown product obtained by treatment of **5d** with $Mn(OAc)_3$ showed strong peaks at *m/z* 1093 [(**5d** −4H)Mn_2·2MeOH·CH_2O]$^+$, 1063 [(**5d** −4H)Mn_2·2MeOH]$^+$, 1045 [(**5d** −4H)Mn_2·HCO_2H]$^+$, 999 [(**5d** −4H)Mn_2]$^+$ and 893 [**5d**]$^+$, consistent with the formation of a bimetallic complex.

Preliminary tests of the brown Mn^{II} macrocyclic salen complexes as catalysts for the epoxidation of styrene, the most challenging enantioselective version of this type of reaction thus far,[12] were conducted at room temperature (23 °C) using NaOCl (aq) as terminal oxidant (Scheme 2). Both ring-opened chloromethyl ether and epoxide products were obtained with modest enantioselectivity (Scheme 2) in methanolic solvent. Chemoselectivity responds to the steric requirements of the R groups**.** For example, *tert*-butyl substituted macrocycle **5d** gave epoxide : chloro ether in the ratio 100 : 3 but only one product (85–87% chemical yield), identified as 1-phenyl-1-chloro-2-methoxy ethane by mass spectrometric analysis and comparison of NMR data with 1-phenyl-1-methoxy-2-chloroethane (obtained through direct chlorination of styrene in MeOH), was isolated in the presence of unsubstituted dimer **5a** or **6**. Interestingly, both epoxide and chlorinated products (chloro ether or chlorohydrin) in a ratio of 10 : 1 are obtained with catalyst **5b** (R = CH_3).

The ring opened products obtained were uniquely *anti*-Markownikoff, hence Scheme 2 may have some important synthetic applications.[13] Reversed regioselective chlorination of alkenes has previously been observed in alkoxychlorination of allylamines with Wacker type catalysts[14] but Markownikoff addition was found for all other alkenes tested.

Unlike mononuclear salen catalysts,[2a] the enantioselectivity of the macrocyclic Mn^{III}–calixsalen systems reported in this work appears unrelated to the steric requirements of the R groups on the *ortho* position of the phenol in the salen frame (Scheme 2). We therefore speculate that the observed enantioselectivity is controlled by host–guest intra-cavity interactions.

The dimanganese complex isolated from ligand **5d**, which unlike that from **5a** was soluble in CH_2Cl_2, allows direct comparison of the enantioselectivity of the bimetallic calixsalen complexes reported in this work with the well characterized Jacobsen catalysts. Aqueous NaOCl oxidation of styrene in the presence of the brown dimanganese complex of **5d** in CH_2Cl_2 gave only epoxide product with 52% ee in 63% isolated chemical yield at 25 °C. This result compares favourably with the best value of 59% ee at 23 °C in CH_2Cl_2 for a mononuclear Mn^{III} salen catalyst reported by Jacobsen.[12]

The new borate $[CPh_3]^+[CN\{B(C_6F_5)_3\}_2]^-$ and the anionic isocyanoborate complex $[Ni\{CNB(C_6F_5)_3\}_4]^{2-}$ are readily accessible in one-pot reactions and act as a highly efficient activators for metallocene polymerisation catalysts; turnover numbers of up to 53 000 s^{-1} appear to be the highest reported so far for ethene polymerisation catalysts.

The basicity of the counter anion X^- in cationic metal alkyl complexes $[L_nMR]^+X^-$ is known to be one of the most important factors that determine the ability of these complexes to act as catalysts for the polymerisation of alkenes.[1,2] Research has been directed at reducing the nucleophilicity of such anions as far as possible, for example by increasing steric hindrance in borate and aluminate anions, such as $[B(C_6F_4SiR_3)_4]^-$, $[MeB(2\text{-}C_6F_4C_6F_5)_3]^-$, $[FA1(2\text{-}C_6F_4C_6F_5)_3]^-$,[3] or by using halogenated carboranes such as $[CB_{11}H_6Cl_6]^-$ and $[CB_{11}HF_{11}]^-$.[4,5] Since the synthesis of such anions requires a very substantial preparative effort, for practical purposes $[B(C_6F_5)_4]^-$ and $[MeB(C_6F_5)_3]^-$ are most widely used.

An alternative strategy for reducing the nucleophilicity of borate anions is to distribute the negative charge over more than one boron atom. Such borate anions can be made by reacting $B(C_6F_5)_3$ with anions which can act as bridging groups. Thus the reaction of $B(C_6F_5)_3$ with KCN in Et_2O followed by treatment with Ph_3CCl in CH_2Cl_2 gives rise to $[CPh_3]^+[(C_6F_5)_3B–CN–B(C_6F_5)_3]^-$ **1** (Scheme 1). The synthesis is best conducted as a one-pot procedure.

As an activator for metallocene-based polymerisation catalysts, compound **1** has several practical advantages over the commonly employed $[CPh_3][B(C_6F_5)_4]$.[6] The synthesis of $[B(C_6F_5)_4]^-$ requires the use of hazardous LiC_6F_5 which is prone to detonate on warming above −20 °C;[7] yields of $Li[B(C_6F_5)_4]$ tend to be variable, $[CPh_3][B(C_6F_5)_4]$ is frequently very difficult to crystallise and purify and is air sensitive. By contrast, $B(C_6F_5)_3$ is commercially available and can be made by safe alternative routes,[8] it is readily converted into **1** in high yield, the product crystallises very easily, and we found that crystalline **1** can be exposed to air for weeks without any visible signs of deterioration.

The crystal structure of **1** is shown in Fig. 1.† The anion is related to the borohydride $[H_3B–CN–BH_3]^-$ but gives a slightly higher ν_{CN} stretching frequency (**1**: 2305 cm^{-1}; $[CN(BH_3)_2]^-$: 2260 cm^{-1}).[9] The serendipitous formation of $[Ph_3B–CN–BPh_3]^-$ has also been reported (ν_{CN} 2255 cm^{-1});[10] this anion was however found to be prone to dissociation into BPh_3 and $[Ph_3BCN]^-$. The higher Lewis acidity of $B(C_6F_5)_3$ evidently makes such a dissociation less facile.

Another type of anion with even more extensively delocalised charges is represented by metal complexes of the isocyanoborate anion, accessible from $B(C_6F_5)_3$ and metal cyanides. For example, the reaction with $K_2[Ni(CN)_4]$ gives off-white microcrystalline $K_2[Ni\{CNB(C_6F_5)_3\}_4]$ which on treatment with Ph_3CCl in dichloromethane affords orange **2a** (ν_{CN} 2234 cm^{-1}) (Scheme 1), while metathesis with $[HNMe_2Ph]Cl$ leads to colourless crystals of $[HNMe_2Ph]_2[Ni\{CNB(C_6F_5)_3\}_4]\cdot Me_2CO$ **2b** (ν_{CN} 2239 cm^{-1}). The crystal structure confirms the square geometry of the anion in **2a** (Fig. 2).†

The suitability of **1** and **2a** as activators for metallocene polymerisation catalysts was tested at 1 bar and under pressure at temperatures up to *ca*. 100 °C using *rac*-$Me_2Si(indenyl)_2ZrMe_2$ **3** and Cp_2ZrMe_2 **4** as standard test metallocenes. The results are collected in Table 1; for comparison the literature data for other high-activity catalysts have also been included.

Activity tests at 1 bar are frequently used to assess catalyst performance, and short reaction times are thought to prevent mass-transport limitations.[3] However, exposing mixtures of **1** and **3** to ethene at 1 bar resulted in the instantaneous formation of polymer films on the surface of the rapidly stirred liquid which impeded feed gas diffusion. Higher pressure was therefore employed to reduce mass transport problems. At 7 bar ethene pressure and 5 μmol **1** at a starting temperature of 20 °C in toluene, a significant reaction exotherm raised the temperature to > 60 °C, and ethene polymerisation was found to be so rapid that after about 2 min gas take-up stopped because the

autoclave was filled with swollen polymer. Polymerisations in a 5-l autoclave at the reduced activator concentration of 6.7×10^{-8} M and an initial temperature of 60 °C proceeded so rapidly that the rate of feed gas delivery could not keep pace with gas consumption; the pressure dropped to *ca*. 2 bar and only recovered after 4 min when the amount of polymer formed prevented effective gas take-up. Under these conditions, a turnover number of 53 000 s^{-1} was observed. This figure represents a lower limit estimate and is to our knowledge the highest activity for an ethene polymerisation catalyst reported in the literature so far. Mixtures of **4** and **2a** also showed a good activity of $>10^6$ g PE {(mol Zr) h bar}$^{-1}$.

The activity of a catalyst may be due to several factors: (i) the ligand influence on the rate of chain propagation, (ii) the concentration of active centres generated by the activator, (iii) the position of the equilibrium between active species and dormant states, (iv) the rate of irreversible deactivation of the active centre. When assessing catalysts, it is often tacitly assumed that (i) is the most important factor, and hence the search for new catalysts concentrates on ligand design.[11] The results reported here show that at least equally large variations in catalyst activity are achieved by varing the mode of activation: under closely comparable conditions, activation of **3** with **1**/$AlBu^i_3$ gives a catalyst which is 36 times more active than **3**/MAO (entries 5 and 6).[12]

Ligand properties of 1*H*-diphosphirenes and diphosphirenylium salts towards iron carbonyl fragments

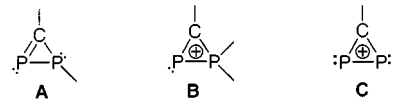
Didier Bourissou, Yves Canac, Heinz Gornitzka, Antoine Baceiredo and Guy Bertrand*

Laboratoire d'Hétérochimie Fondamentale et Appliquée, UPRESA-5069-CNRS, Université Paul Sabatier, 118 route de Narbonne, F-31062 Toulouse Cédex, France. E-mail: gbertran@ramses.ups-tlse.fr

Received (in Cambridge, UK) 14th June 1999, Accepted 7th July 1999

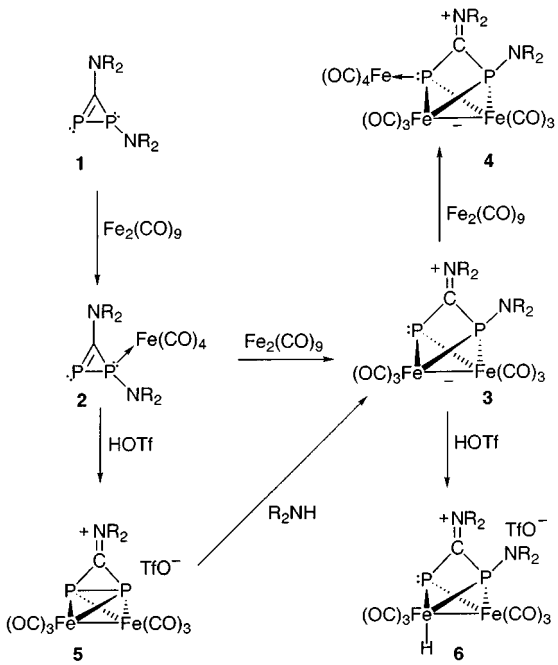
Treatment of η¹-[1,3-bis(diisopropylamino)-1*H*-diphosphirene]tetracarbonyl iron 2 with trifluoromethanesulfonic acid affords the binuclear [3-diisopropylaminodiphosphirenylium salt] iron complex 5, which reacts with diisopropylamine giving the opened binuclear iron complex 3.

The chemistry of phosphorus-containing three-membered rings has attracted considerable attention over the last 15 years.[1] In the diphosphorus-containing series,[2] the 1*H*-diphosphirenes **A**[3] and diphosphirenium salts **B**[4] were discovered in the early 1990s. More recently, we have described the synthesis and reactivity of P-functionalized 1*H*-diphosphirenes **A** and diphosphirenylium salts **C** (Scheme 1) as tungsten carbonyl complexes.[5] Here, we report the ligand behavior of heterocycles **A** and **C** towards iron carbonyl fragments, including the unprecedented cleavage of the P–P bond of the ring framework.



Scheme 1 1*H*-diphosphirene **A**, diphosphirenium cation **B** and diphosphirenylium cation **C**.

The η¹-iron tetracarbonyl complex **2** was readily obtained in 85% yield by treatment of **1** with 1 equiv. of $Fe_2(CO)_9$ (Scheme 2). The end-on coordination of the σ³-P was unequivocally established by comparing the spectroscopic data for **2**† with those of the related η¹-tungsten pentacarbonyl complexes.[5,6]



Scheme 2 R = Pr^i, Tf = CF_3SO_2.

Addition of 1 equiv. of $Fe_2(CO)_9$ to **2** afforded the binuclear complex **3**, which was isolated in 42% yield as red crystals. The low-field AB system (δ 125.5 and 122.4, J_{PP} 85 Hz) observed in the ^{31}P NMR spectrum for **3** strongly suggests that the three-membered ring has been opened, although the value of the J_{PP} coupling constant remains large. The cleavage of the P–P bond was confirmed by an X-ray diffraction study‡ (Fig. 1), the P···P distance (P1–P2 2.62 Å) being much longer than that of a classical P–P single bond (2.20–2.35 Å).[7] The structure of **3** consists of a 1,3-diphosphorus chain bridging a metal–metal bonded $Fe_2(CO)_6$ unit (Fe1–Fe2 2.61 Å), both phosphorus atoms being bonded to both iron atoms (P1–Fe1 2.21 Å, P1–Fe2 2.22 Å, P2–Fe1 2.29 Å, P2–Fe2 2.33 Å).[8] The N2P1C1N1P2 skeleton is perfectly planar (maximum deviation from the best plane: 0.036 Å), and the C1–N1 bond length [1.298(9) Å] is in the range expected for a CN double bond, implying that the positive charge has shifted to the nitrogen atom. P1 can be regarded as a typical phosphido phosphorus atom, while P2 is a three-coordinate phosphorus atom with a strongly pyramidal geometry (sum of the angles: 243.3°) suggesting its potential for coordination of an additional transition-metal fragment. Indeed, when **3** was treated with an excess of $Fe_2(CO)_9$ in THF solution, after two days at room temperature, the trinuclear complex **4** was isolated as red crystals in 70% yield (Scheme 2). The spectroscopic data observed for **4** are very similar to those of **3**,† and the structure of **4** has been confirmed by an X-ray diffraction study.‡ The introduction of the $Fe(CO)_4$ fragment on P2 does not result in dramatic geometric modifications. In

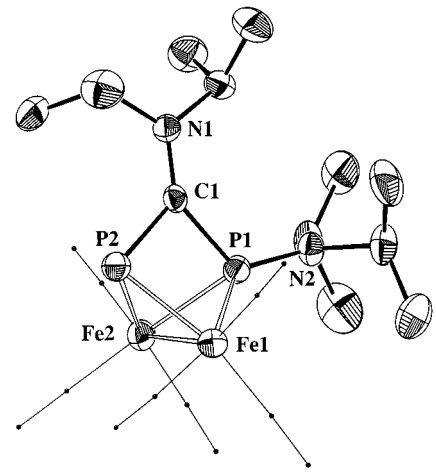


Fig. 1 Thermal ellipsoid diagram (30% probability) of **3** showing the atom numbering scheme. All the carbonyl groups have been omitted, and the isopropyl groups have been simplified. Selected bond lengths (Å) and angles (°): C(1)–N(1) 1.298(9), C(1)–P(1) 1.811(7), C(1)–P(2) 1.841(7), P(1)–N(2) 1.671(7), P(1)–Fe(1) 2.206(2), P(1)–Fe(2) 2.222(2), P(2)–Fe(1) 2.294(3), P(2)–Fe(2) 2.329(3), Fe(1)–Fe(2) 2.613(2); N(1)–C(1)–P(1) 137.9(6), N(1)–C(1)–P(2) 130.4(5), P(1)–C(1)–P(2) 91.4(3), C(1)–P(1)–N(2) 121.1(3), C(1)–P(1)–Fe(1) 94.1(3), C(1)–P(1)–Fe(2) 87.9(2), N(2)–P(1)–Fe(1) 134.3(2), N(2)–P(1)–Fe(2) 131.3(3), Fe(1)–P(1)–Fe(2) 72.31(8), C(1)–P(2)–Fe(1) 90.5(2), C(1)–P(2)–Fe(2) 84.0(2), Fe(1)–P(2)–Fe(2) 68.81(1).

particular, the P···P distance is still long (2.58 Å), and the N2P1C1N1P2 fragment remains planar with the supplementary iron centre Fe3 in the same plane (maximum deviation from the best plane: 0.044 Å). Therefore, in contrast to that observed in the coordination sphere of tungsten (end-on coordination *via* both phosphorus lone pairs of **1**),[5] the binuclear iron complex **3** formally results from the insertion of a $Fe_2(CO)_6$ fragment into the P–P bond of **1**, which leaves a phosphorus lone pair available for coordination to a third metal fragment.

Surprisingly, treatment of the 1*H*-diphosphirene mononuclear complex **2** with 2 equiv. of trifluoromethanesulfonic acid at −78 °C led to the diphosphirenylium binuclear complex **5**§ (Scheme 2). The presence of a $Fe_2(CO)_6$ fragment in **5** was unambiguously established from the mass spectrum [*m/z* 454 (M^+) and 426 ($M - CO)^+$], while the cationic three-membered ring structure was apparent from the high-field ^{31}P NMR (s, δ −139.8) and low-field ^{13}C NMR (t, δ 218.2 J_{PC} 93.1 Hz) signals. Interestingly, **5** was not formed when the binuclear iron complex **3** was reacted with trifluoromethanesulfonic acid. Instead, protonation of an iron centre occurred leading to the iron carbonyl hydride **6**.†

Although the mechanism of the reaction of **2** with triflic acid remains obscure, it is quite clear that the formation of the binuclear complex **5** involves a metallic disproportionation process. To achieve an 18-electron configuration for each iron atom in **5**, the three-membered ring must act as a six-electron ligand (*via* the P=P bond and the lone pair of both phosphorus atoms). This coordination mode is similar to that observed in [*cis*-$P_2Bu^t_2$]·[$Fe_2(CO)_6$],[9] but it necessarily implies that in **5** both phosphorus centres have an unusual inverted tetrahedral geometry.[10]

Finally, we investigated the reactivity of this new diphosphirenylium salt complex. Using diisopropylamine, the neutral binuclear complex **3** was obtained in quantitative yield. Therefore, nucleophilic attack occurs at the highly electrophilic phosphorus atom as observed for the tungsten complexes,[5] but simultaneous cleavage of the P–P bond is observed for the iron complex.

Satisfactory elemental analyses have been obtained for compounds **2**, **3** and **4**.

‡ *Crystallography*: data for **3** and **4** were collected at low temperatures using an oil-coated shock-cooled crystal[11] on a Stoe-IPDS with Mo-Kα (λ = 0.71073 Å) radiation. The structures were solved by direct methods using SHELXS-97[12] and refined with all data on F^2 using SHELXL-97.[13] All non-hydrogen atoms were refined anisotropically. The hydrogen atoms of the molecules were geometrically idealized and refined using a riding model. A numerical absorption correction was employed, min./max. transmissions for **3** are 0.4325/0.5682 and for **4** 0.7035/0.8889. Refinement of an inversion twin parameter[14] [x = 0.49(2), where x = 0 for the correct absolute structure and +1 for the inverted structure] confirmed a racemic twinning of **3**.

Synthesis of a cyclodextrin azo dye [3]rotaxane as a single isomer

Michael R. Craig,[a] Tim D. W. Claridge,[a] Michael G. Hutchings[b] and Harry L. Anderson*[a]

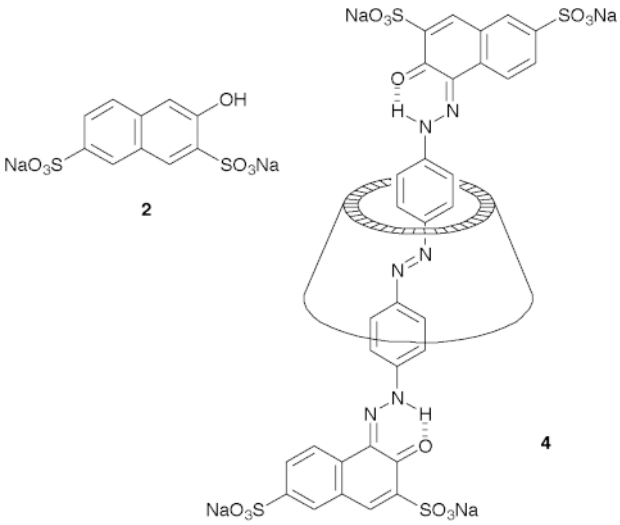
[a] *Department of Chemistry, University of Oxford, Dyson Perrins Laboratory, South Parks Road, Oxford, UK OX1 3QY. E-mail: harry.anderson@chem.ox.ac.uk*

[b] *BASF plc, PO Box 4, Earl Road, Cheadle Hulme, Cheshire, UK SK8 6QG*

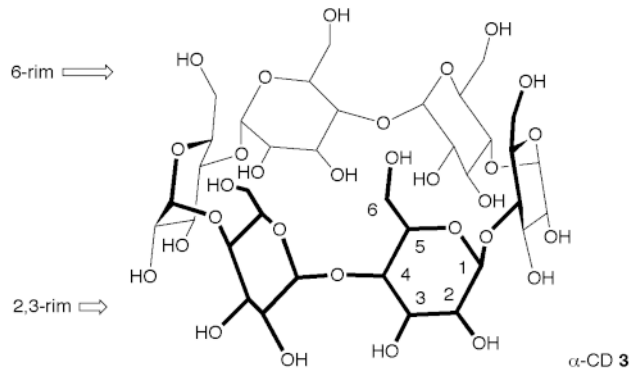
Received (in Liverpool, UK) 29th March 1999, Revised 28th June 1999, Accepted 30th June 1999

Azo coupling between 2,6-dimethylphenol and aqueous 4,4′-bis(diazonio)azobenzene chloride in the presence of α-cyclodextrin yields an azo dye [3]rotaxane as a single stereoisomer, with the 2,3-rims of both cyclodextrins pointing outwards.

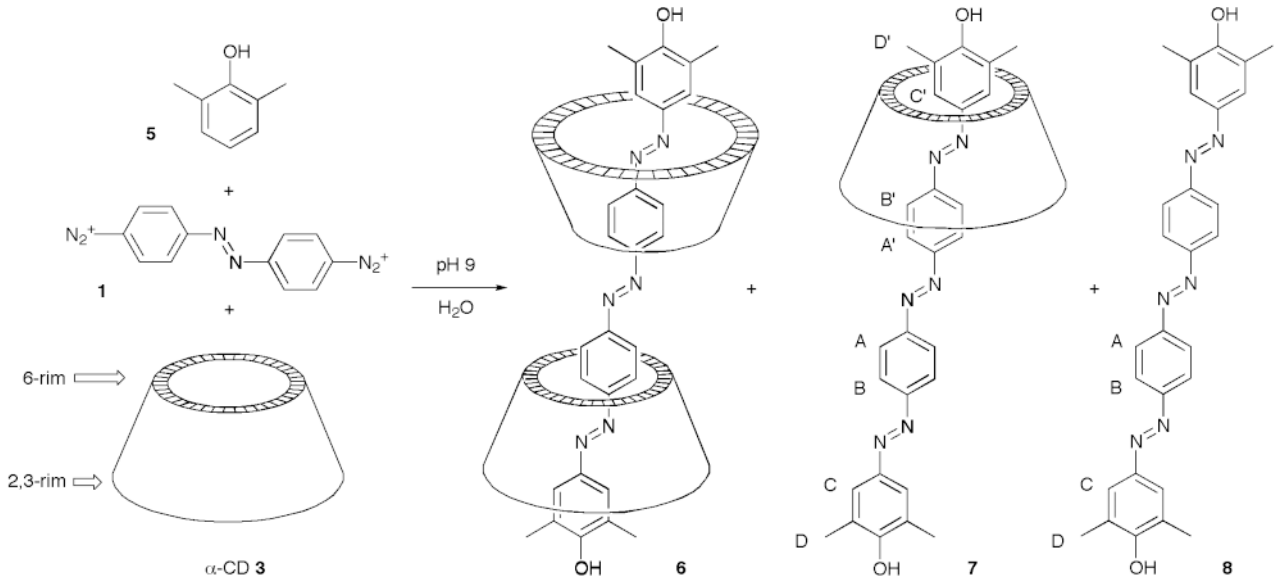
As part of a project on the encapsulation of chromophores,[1] we recently reported[1b] that reaction of 4,4′-bis(diazonio)azobenzene chloride **1** with aqueous β-naphthol **2** in the presence of



α-cyclodextrin (α-CD) **3** yields the azo dye [2]rotaxane **4**. Here we present the unexpected discovery that, when this reaction is carried out using 2,6-dimethylphenol **5** instead of β-naphthol **2**, the main product is the [3]rotaxane **6** (Scheme 1). The [2]rotaxane **7** and the unencapsulated dye **8** are also formed. To the best of our knowledge this is the first report of a cyclodextrin [3]rotaxane[2] (previous [3]rotaxanes have been made from crown ethers[3] and cyclophanes;[1a,c,4] polyrotaxanes have also been prepared using cyclodextrins[5]). α-Cyclodextrin has a narrow 6-rim (with primary OH groups) and a wider 2,3-rim (with secondary OH groups). There are three possible relative orientations of the cyclodextrin units in **6**, but, remarkably, this [3]rotaxane is formed as a single stereoisomer.



The three products of the reaction shown in Scheme 1 were separated by column chromatography on silica, eluting with 25% aqueous ammonia–butanone–*n*-propanol (1:1:1). Traces of [2]rotaxane **7**, dumbbell **8** and free α-CD **3** can be removed from the [3]rotaxane **6** by ultrafiltration; **6** is retained by a cellulose ultrafiltration membrane (1000 nominal molecular weight limit†), whereas the other components wash through.



Scheme 1

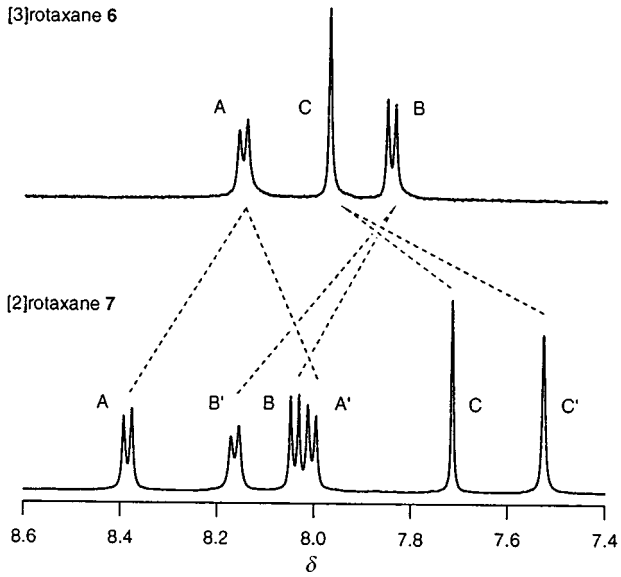


Fig. 1 Aromatic regions of the ^{1}H NMR spectra (DMSO-d_6, 340 K, 500 MHz) of [2]rotaxane **7** and [3]rotaxane **6**.

The isolated yields of **6** and **7** are 12 and 9%, respectively, and the [3]rotaxane can be prepared on a 0.5 g scale using this technique.

The [2]rotaxane and [3]rotaxane were thoroughly authenticated by ^{1}H and ^{13}C NMR, and mass spectrometry.‡ Their ^{1}H NMR spectra were assigned using 2D techniques. The aromatic regions of these spectra are shown in Fig. 1. In the [2]rotaxane, all the resonances of the azo dye dumbbell are split, as expected, due to the inequivalence of the rims of the cyclodextrin, leading to six aromatic signals (H_A–H_C are nearer the 2,3-rim and H_A–$H_{C'}$ are nearer the 6-rim). This type of splitting is not observed in the spectra of the [3]rotaxane, which has only three aromatic resonances (H_A–H_C). This shows that the two α-CD units are either 6-rim-to-6-rim or 2,3-rim-to-2,3-rim; these possibilities were distinguished using 1D gradient NOESY experiments. Strong NOEs are observed from the methyl protons (H_D) to positions on the 2,3-rim of the α-CD (H-3, OH-3 and OH-2), proving that it is the 6-rim-to-6-rim isomer, as depicted in Scheme 1. The reasons for exclusive formation of this isomer are being investigated. Surprisingly, NOE experiments on the [2]rotaxane, in DMSO-d_6, show that it prefers the conformation shown in Scheme 1, with the 6-rim near the end of the chromophore. The two methyl signals, H_D and $H_{D'}$, are almost coincident, and cannot be selectively inverted, however when both methyl resonances are inverted, the dominant NOEs are to H-6, H-6′ and H-5; an NOE is also observed to H-3, but it is about half as large as those to H-6, H-6′ and H-5. Strong NOEs are also observed from $H_{C'}$ to H-6, H-6′ and H-5, whereas H_C shows only a weak NOE to H-3 (about four times smaller than those from $H_{C'}$ to H-6, H-6′ and H-5). The cyclodextrin shuttles rapidly along the dumbbell on the NMR timescale at room temperature, but it shows a distinct preference for the A′–D′ end near the 6-rim.

Yoshida has shown that azo dyes derived from 2,6-dimethylphenol do not easily slip through the cavity of α-CD,[6] but we were initially uncertain as to whether this end-group would be large enough to yield a stable rotaxane. No unthreading[3f,7] of **6** and **7** has been observed in solution at temperatures up to 100 °C, but when **6** was heated to 120 °C in DMSO-d_6 for a week, ^{1}H NMR showed about 15% of the material unthreaded to give **7** and α-CD **3**. This corresponds to a unimolecular rate constant for unthreading of about 10^{-7} s^{-1} and a free energy barrier ($\Delta G^{\ddagger}$) of 147 kJ mol^{-1} at 120 °C, which indicates that the half-life for unthreading at room temperature is probably more than 10^5 years.

This direct route to a [3]rotaxane encapsulated azo dye, in one step from readily available materials, will facilitate investigations into the consequences of chromophore encapsulation, and into the photochemistry of these rotaxanes.[8]

Communication 9/02494H

A conjugated triple strand porphyrin array

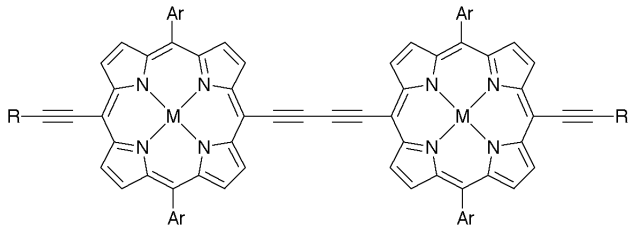
G. Scott Wilson and Harry L. Anderson*

Department of Chemistry, University of Oxford, Dyson Perrins Laboratory, South Parks Road, Oxford, UK OX1 3QY. E-mail: harry.anderson@chem.ox.ac.uk

Received (in Liverpool, UK) 17th May 1999, Accepted 30th June 1999

A conjugated tetrapyridylporphyrin dimer has been synthesised, which binds two metalloporphyrin dimers to form a triple strand array; formation of this supramolecular assembly holds both components in planar conformations, increasing the conjugation.

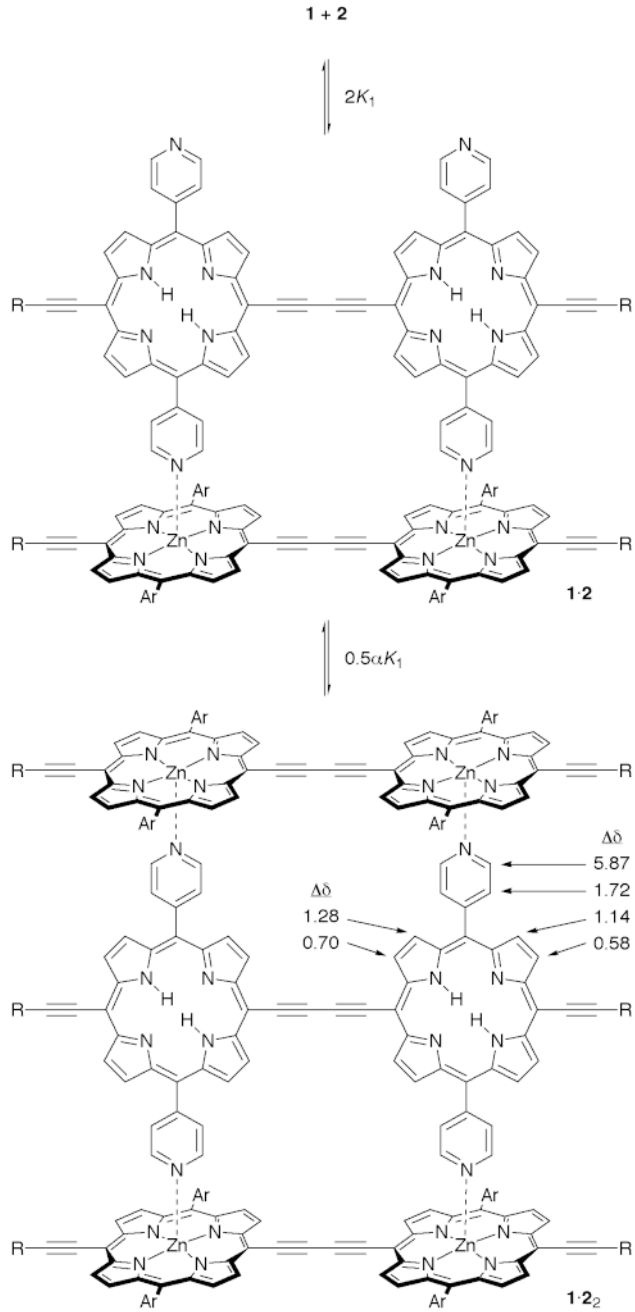
The unusual electronic and optical properties of conjugated porphyrin oligomers make them appealing materials for a variety of potential applications.[1] We are interested in controlling the behaviour of these materials through the formation of non-covalent arrays.[2] Self-assembly offers a way of controlling the conformation, and thus indirectly controlling the π-overlap and conjugation. The reversible formation of multi-strand arrays could also be used to control the synthesis of these covalent units, *via* template-directed coupling and even self-replication. Here we present the synthesis of a conjugated tetrapyridylporphyrin dimer **1**, which binds a zinc porphyrin dimer **2**[3] to form double and triple strand arrays (Scheme 1), changing the conformation and conjugation of both components.



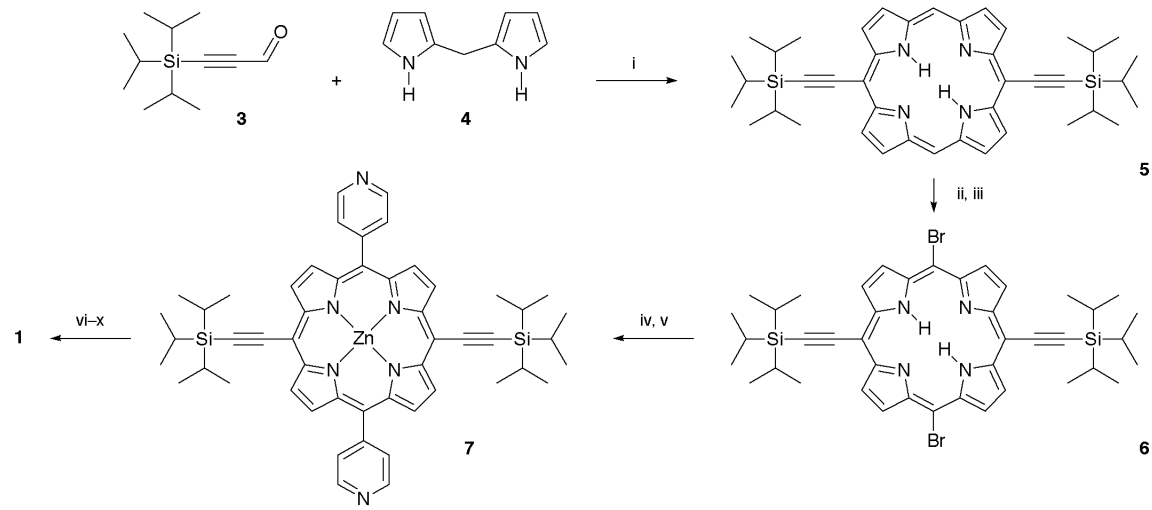
1 M = H_2, Ar = 4-pyridyl, R = Si(*n*-C_6H_{13})$_3$
2 M = Zn, Ar = 3,5-$Bu^t_2C_6H_3$, R = Si(*n*-C_6H_{13})$_3$

The key intermediate in the synthesis of tetrapyridylporphyrin dimer **1** is 5,15-bis(4-pyridyl)-10,20-bis(triisopropylsilylethynyl)porphyrin **7** (Scheme 2). Attempts to prepare **7** by condensation of pyridine-4-carbaldehyde and *meso*-alkynyl dipyrromethanes, and also by reaction of acetylenic aldehydes with *meso*-pyridyl dipyrromethane, were unsuccessful.[4] We eventually prepared **7** using *meso*-bromination[5] and Stille coupling,[2d,6] as shown in Scheme 2. *meso*-Bromination of 5,15-dialkynylporphyrins is difficult due to competing β-substitution and alkyne addition. The electron-withdrawing alkynes deactivate the porphyrin ring towards bromination, but this effect can be overcome by inserting an electropositive metal into the macrocycle.[5a] Bromination of free-base **5**, or its zinc complex, with NBS gave complex mixtures of products, whereas the magnesium complex reacted cleanly at both *meso*-positions, to give the dibromoporphyrin **6**. Stille coupling with 4-(trimethylstannyl)pyridine worked efficiently with the zinc complex of **6**, giving **7** in 83% yield. Triisopropylsilyl groups were used to protect the alkynes during the synthesis of **7**, and were subsequently changed to trihexylsilyls in **1**, to increase the solubility. Compound **1** was prepared from **7** by protecting group manipulation and Glaser–Hay coupling.[7]

UV-visible titrations showed that dimers **1** and **2** form a stable 1 : 2 complex in CH_2Cl_2. When ligand **1** is added to **2**, the spectrum evolves with several sharp isosbestic points, indicating clean formation of the **1**·$\mathbf{2}_2$ complex (Scheme 1). The titration has a well defined end-point at 1 : 2 stoichiometry and the stability constant of **1**·$\mathbf{2}_2$ is too high to determine accurately ($\alpha K_1^2 \approx 10^{16}$–$10^{19}$ M^{-2}). The UV-visible spectrum of **1**, the **2**·(pyridine)$_2$ complex (scaled ×2) and **1**·$\mathbf{2}_2$ are compared in



Scheme 1 Coordination of **1** and **2** gives **1**·**2** and **1**·$\mathbf{2}_2$. Selected complexation induced shifts are marked on **1**·$\mathbf{2}_2$, in ppm up-field relative to free **1** (equilibrium constants: $\alpha = 1.8 \pm 0.3$ and $K_1 \approx 10^8$–10^9 M^{-1} in CH_2Cl_2 at 298 K).



Scheme 2 *Reagents and conditions:* i, $BF_3{\cdot}OEt_2$, then DDQ, 31%; ii, MgI_2, 97%; iii, NBS then TFA, 59%; iv, $Zn(OAc)_2$, 92%; v, 4-(trimethylstannyl)pyridine, Pd_2dba_3, PPh_3, LiCl, PhMe, 83%; vi, TBAF (2 equiv.), 97%; vii, LiHMDS then $(n\text{-}C_6H_{13})_3SiCl$ (1 equiv.), 26%; viii, CuCl, TMEDA, CH_2Cl_2, air, 91%; x, TFA, 94%.

Fig. 1(*a*)–(*c*). If the conformations of dimers **1** and **2** were to remain unchanged when they form **1**·$\mathbf{2}_2$, then spectrum (*c*) would be the sum of spectra (*a*) and (*b*); clearly this is not the case. Formation of the triple strand array is accompanied by an increased splitting in the Soret band (B_x and B_y) and an increased red-shift in the Q_x band, both of which indicate increased conjugation, due to increased planarity. The absorption bands at 460 and 680 nm, which decrease when **1** and **2** bind together, can be attributed to less conjugated conformations with large porphyrin–porphyrin dihedral angles.

^{1}H NMR titrations (in CD_2Cl_2 or $CDCl_3$ at 298 K) confirm that **2** forms a 2:1 complex with **1**. When up to half an equivalent of ligand **1** is added to **2**, the system is in slow exchange. Sharp well-resolved signals are observed for free **2** and for the **1**·$\mathbf{2}_2$ complex, but there is no sign of **1**·**2**, nor of free **1**. Complete assignment of the ^{1}H NMR spectrum of **1**·$\mathbf{2}_2$ was made possible by the observation of NOEs from one of the β-pyrrole doublets to the trihexylsilyl end groups. The selected complexation-induced shifts marked on Scheme 1 support the proposed triple-strand geometry. When more than half an equivalent of **1** is added to **2**, the system goes into fast exchange. An equilibrium is established between **1**·$\mathbf{2}_2$ and **1**·**2**, which shifts gradually towards **1**·**2** as the concentration of **1** is increased. Analysis of this binding isotherm shows that the cooperativity coefficient α is 1.8 ± 0.3. The fact that there is positive cooperativity ($\alpha > 1$) confirms that formation of the **1**·**2** complex tends to hold the ligand unit **1** in a coplanar conformation, increasing its affinity for a second molecule of **2**.

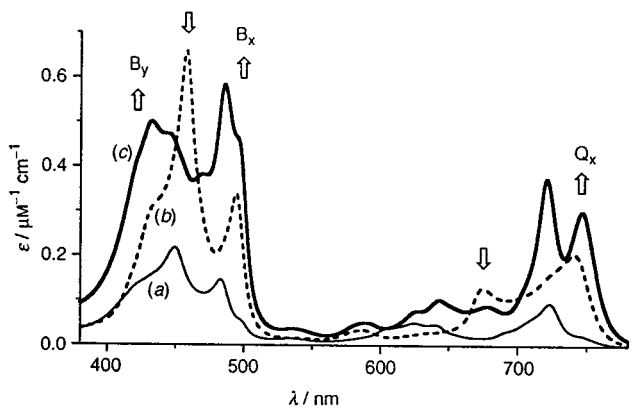


Fig. 1 Electronic absorption spectra of (*a*) **1**, (*b*) the **2**·(pyridine)$_2$ complex and (*c*) **1**·$\mathbf{2}_2$ in CH_2Cl_2. Spectrum (*b*) was recorded in the presence of excess pyridine and is scaled ×2 to facilitate comparison with (*c*). Arrows highlight regions of increased or decreased absorption in the **1**·$\mathbf{2}_2$ complex.

There has been some debate about the conformational properties of alkyne-linked conjugated porphyrin dimers such as **1** and **2**.[1b,2a,3,8] The results reported here demonstrate that these dimers explore a range of torsional angles in solution, and that non-covalent self-assembly can be used to hold them co-planar, to maximise the electronic coupling. A detailed analysis of the ^{1}H NMR and electronic spectra of structures such as **1**, **2** and **1**·$\mathbf{2}_2$ may enable us to elucidate the distribution of dihedral angles. The ability to control this conformational equilibrium should result in materials with enhanced non-linear optical behaviour.

Synthesis of the first complex with acetonine as ligand: the first crystal structure of an acetonine derivative

José Vicente,* María Teresa Chicote, Rita Guerrero and M. Carmen Ramírez de Arellano†

Grupo de Química Organometálica,‡ Departamento de Química Inorgánica, Facultad de Química, Universidad de Murcia, Apartado 4021, Murcia, 30071 Spain. E-mail: jvs@fcu.um.es

Received (in Cambridge, UK) 15th June 1999, Accepted 8th July 1999

The complex $[Au(acetonine)_2]ClO_4$ (3·ClO_4) (acetonine = 2,2,4,4,6-pentamethyl-2,3,4,5-tetrahydropyrimidine) is obtained by bubbling NH_3 through an acetone solution containing equimolar amounts of $NaClO_4$ and [AuCl(tht)] (tht = tetrahydrothiophene); the crystal structure of 3·ClO_4 was determined by X-ray crystallography.

We have recently reported the synthesis of $[Au(NH_3)_2]Cl$ (**1**·Cl) by reacting [AuCl(tht)][1] (tht = tetrahydrothiophene) with NH_3 in acetone (Scheme 1).[2] The reaction of **1**·Cl with $TlCF_3SO_3$ or $AgClO_4$ gives, respectively, **1**·CF_3SO_3 or **1**·ClO_4. The latter two complexes react with acetone to give the first acetiminogold(I) complexes $[Au(NH{=}CMe_2)_2]X$ (**2**·CF_3SO_3,[3] **2**·ClO_4, Scheme 1) while **1**·Cl neither reacts with acetone nor with $NaClO_4$ in acetone, probably due to its low solubility in this solvent. In an attempt to prepare **1**·ClO_4 in a one-pot reaction, using $NaClO_4$ instead of $AgClO_4$, we bubbled NH_3 through an acetone solution containing equimolar amounts of [AuCl(tht)] and $NaClO_4$. However, a suspension formed from which a small amount of **1**·Cl was removed, and from the resulting solution the complex $[Au(acetonine)_2]ClO_4$ (**3**·ClO_4) (acetonine = 2,2,4,4,6-pentamethyl-2,3,4,5-tetrahydropyrimidine) was isolated in 88% yield (Scheme 1).

Acetonine was first characterized by Bradbury *et al.*[4] in 1947, based on its molecular refraction and its reduction and hydrolysis products. It has been reported to form among the decomposition products of acetimine $NH{=}CMe_2$,[5] but it is most frequently obtained from the reaction of acetone with ammonia; many attempts to improve its synthesis have recently been reported (most of them patents). Thermal or photochemical activation, as well as a wide variety of catalysts have been used.[6–13] Acetonine finds its main use in its reaction with acetone to give 2,2,6,6-tetramethyl-4-oxopiperidine (triacetonamine)[9,11,14–17] which is an attractive intermediate for the synthesis of pharmaceutical products, pesticides, photostabilizers for polymers *etc.*[18] With so much work devoted to acetonine and its derivatives we were rather surprised to find that neither a single acetonine complex of any element nor X-ray studies on acetonine itself or any substituted acetonine had been reported.

In the reaction of NH_3, [AuCl(tht)] and $NaClO_4$ leading to **3**·ClO_4, neither **1**·ClO_4 nor **2**·ClO_4 were detected. We have independently proved that these two complexes react with acetone solutions of NH_3 to give **3**·ClO_4 (Scheme 1) which could explain their absence among the reaction products, if they were formed. These results suggest that acetonine forms from the reaction of NH_3 with acetone and replaces tht in [AuCl(tht)]. The displacement of Cl^- by ClO_4^- (from [AuCl(tht)] or from the possible intermediate [AuCl(acetonine)], or even from the non-isolated **3**·Cl) is crucial in the formation of **3**·ClO_4 because, as mentioned above, in the absence of $NaClO_4$, [AuCl(tht)] and NH_3 react in acetone to give **1**·Cl. It is likely that in the latter reaction the insolubility of **1**·Cl prevents the substitution of NH_3 by acetonine to give **3**·Cl or [AuCl(acetonine)]. This and previous studies,[2,3] show the complexity of acetone solutions of NH_3 from which it is possible to isolate coordination compounds with NH_3, $NH{=}CMe_2$ and acetonine ligands.

The crystal structure of **3**·ClO_4 was determined by X-ray crystallography (Fig. 1).§ The structure consists of centrosymmetric $[Au(acetonine)_2]^+$ cations and perchlorate anions forming a chain through hydrogen bonds [N2···O2 3.26(1) Å, H2···O2 2.46(4) Å, N2–H2···O2 157(5)°]. In Fig. 1 the packing diagram along the *c* axis and the hydrogen bonds are shown. Although the gold atoms are in a chain there are no aurophilic interactions (Au···Au 5.921 Å). In the acetonine ring the C2–C1–N1–C4–N2 fragment is planar (mean deviation 0.0052 Å) and makes an angle of 44.7° with the C2–C3–N2 plane. The Au–N bond distance found in **3**·ClO_4 [2.040 (5) Å] is similar to those found in **2**·CF_3SO_3[3] [2.017(5), 2.018(2) Å] or other complexes containing Au–N(sp^2) bonds (range 1.985–2.07 Å).[19,20] The bond distances in the acetonine rings are similar to those found in compounds with the same hybridization and bond order.[21] ^1H and ^{13}C NMR spectra of **3**·ClO_4 show that the coordination of the gold center to the iminic nitrogen atom is maintained in solution, as no chiral centers seem to be present and one pair of Me groups show a change of chemical shift upon complexation [$\delta(Me)_{complex} - \delta(Me)_{acetonine}$] greater [0.57 ppm; asigned to methyls on C(6)] than the other one [0.09 ppm; asigned to methyls on C(4)].¶

Fully substituted cyclooctatetraenes assembled by the [4 + 4] cross coupling of two different diene units: a shunting strategy of Wilke's metallacyclopentadiene coupling mechanism†

Yoshihiko Yamamoto, Tatsuya Ohno and Kenji Itoh*

Department of Molecular Design and Engineering, Graduate School of Engineering, Nagoya University, Chikusa, Nagoya 464-8603, Japan. E-mail: itohk@apchem.nagoya-u.ac.jp

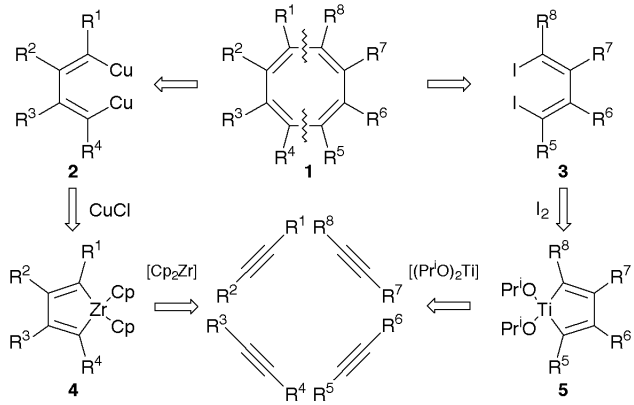
Received (in Cambridge, UK) 8th June 1999, Accepted 1st July 1999

The first regio- and chemo-selective synthesis of fully substituted cyclooctatetraenes from two or three different alkynes was achieved using the cross-coupling between 1,4-dicuprabuta-1,3-dienes and 1,4-diiodobuta-1,3-dienes.

Since Reppe's historical discovery of his cyclooctatetraene (COT) synthesis from acetylene,[1] the nickel-catalyzed cyclotetramerization of alkynes leading to COTs has been extensively studied from both synthetic and mechanistic points of view.[2] The catalytic reactions, however, are generally limited to the parent and terminal acetylenes, and the reaction of monosubstituted alkynes gave the 1,2,4,6-, 1,2,4,7- and 1,3,5,7-substituted isomers depending on the alkyne employed rather than on the nature of the catalyst. Moreover, the concomitant formation of other oligomers and polymers of alkynes is also a problem for the catalytic methods.

Forty years after Reppe's discovery of the Ni-catalyzed COT synthesis,[1] Wilke proposed a fascinating mechanism: two nickelacyclopentadienes generated from four molecules of acetylene couple together to form COT.[3] Based on this proposal, we postulated that highly substituted COTs **1** might be chemo- and regio-selectively synthesized if the selective coupling between two different independently prepared metallacycles is possible. In order to realize such an idea, the cross-coupling of 1,4-dicuprabuta-1,3-dienes **2** with 1,4-diiodobuta-1,3-dienes **3** was investigated instead of the direct coupling of the parent metallacyclopentadiene counterparts **4** and **5** (Scheme 1).[4] The vinylcopper reagents **2** can be prepared by the transmetallation of the corresponding zirconacyclopentadienes **4** as reported by Takahashi and coworkers.[5] The bifunctional electrophile, diiodides **3**, can be readily obtained from the corresponding titanacyclopentadienes **5** and iodine according to the Tamao–Sato procedure.[6]

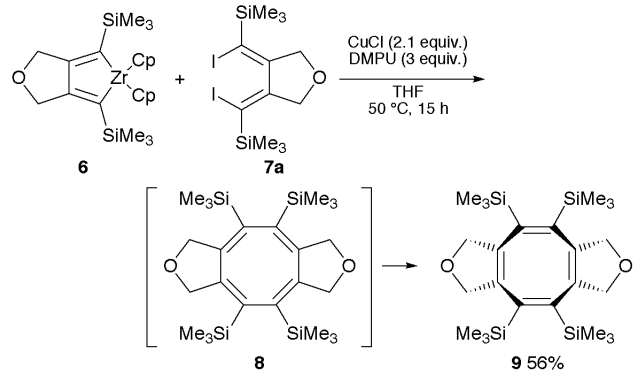
At the outset, we examined the coupling of an isolated bicyclic zirconacyclopentadiene **6**[7] with a cyclic diiodide **7a**.



Scheme 1

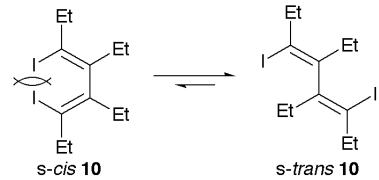
† Experimental and spectral data for **9** and **12a–f** are available from the RSC web site, see http://www.rsc.org/suppdata/cc/1999/1543/

Interestingly, both diene units **6** and **7a** were prepared from a common precursor, 4-oxa-1,7-bis(trimethylsilyl)hepta-1,6-diyne. In the presence of 3 equiv. of 1,3-dimethyl-3,4,5,6-tetrahydro-2(1*H*)-pyrimidone (DMPU), equimolar amounts of **6** and **7a** were treated with 2.1 equiv. of CuCl in THF at 50 °C for 15 h. The usual work-up followed by chromatographic separation gave a symmetrically substituted coupling product **9**[8] in 56% yield (Scheme 2). Its structure was confirmed based on the following spectral data: in its ^{1}H NMR spectra, only one singlet of the four trimethylsilyl groups was observed at δ 0.27, indicative of **9** having a highly symmetrical structure. This was also supported by its ^{13}C NMR spectra, in which only two sp^2 signals were observed at δ 116.3 and 143.3 together with a signal of the trimethylsilyl groups and a signal of the methylene carbon α to the ether oxygen at δ −0.6 and 70.1, respectively. Nonaromatic COT is known to exist in a tub shape rather than in a planar structure.[9] This is also true for **9**; the expected **8** isomerized to the thermodynamically more favorable tub-shaped isomer **9**. This was deduced by the absorption of its methylene protons α to the ether oxygen being observed as a couple of doublets with a geminal coupling constant J = 16.5 Hz.



Scheme 2

The cyclic structure of **7a** plays a critical role in the present coupling; an acyclic diiodide **10** gave no coupling product under the same reaction conditions. This is attributed to the conformational flexibility of its butadiene moiety. The diiodobutadiene moiety fixed as the s-*cis* form in **7a** is required for the cross coupling, whereas acyclic **10** may mainly exist in the s-*trans* form in order to avoid steric repulsion between the two iodine atoms (Scheme 3).



Scheme 3

Based on these results, we next examined the generality of this approach (Table 1). According to established methods,[5] unstable zirconacycles[10] were converted into the corresponding dicopper reagents **11a**–**d** without isolation. In the presence of DMPU, the diiodide **7a** was reacted with **11a**[11] at ambient temperature for 1 h to afford the desired coupling product **12a**[8] in high yield (88%). In the same manner, a cyclic dicopper **11b** derived from deca-2,8-diyne gave a tricyclic product **12b**[8] in 52% yield. In contrast, the coupling of a tetraphenyl-substituted dicopper **11c** required higher temperature. The reaction of **11c** with **7a** was carried out at 50 °C for 1 h to afford **12c**[8] in 56% yield. Similarly, an unsymmerical dicopper **11d**, prepared from hex-3-yne and oct-4-yne, gave the corresponding unsymmetrical COT **12d**[8] in 79% yield. In addition to the furan derivative **7a**, a cyclopentane **7b** and a pyrrolidine **7c** can be used as the diiodide units. The reaction with dicopper **11a** gave **12e**[8] and **12f**[8] in 65 and 41% yields, respectively.

Table 1 Cross coupling of dicoppers **11a**–**d** with diiodides **7a**–**c**[a]

Dicopper	Diiodide	Conditions	Product and yield[b]
 **11a**	 **7a**	rt, 1 h	 **12a** 88%
 **11b**	**7a**	rt, 1 h	 **12b** 52%
 **11c**	**7a**	50 °C, 1 h	 **12c** 56%
 **11d**	**7a**	rt, 1 h	 **12d** 79%
11a	 **7b**	50 °C, 20 h	 **12e** 65%
11a	 **7c**	rt, 20 h	 **12f** 41%

[a] Zirconacyclopentadiene (1 mmol), **7** (0.5 mmol), CuCl (2.1 mmol), DMPU (3 mmol), THF (5 ml). [b] Isolated yields based on **7**.

In addition to the furan derivative **7a**, a cyclopentane **7b** and a pyrrolidine **7c** can be used as the diiodide units. The reaction with dicopper **11a** gave **12e**[8] and **12f**[8] in 65 and 41% yields, respectively.

In conclusion, we successfully developed a novel strategy to assemble fully substituted COTs by imitating Wilke's coupling mechanism of two metallacyclopentadiene moieties for the prototype Ni-catalyzed COT synthesis. This approach allows us to synthesize fully substituted unsymmetrical COTs with complete chemo- and regio-selectivity from 1,4-dicuprabuta-1,3-dienes and 1,4-diiodobuta-1,3-dienes as different diene units.

We gratefully acknowledge financial support in the form of a Grant-in-Aid (09305059 and 10132222) from the Ministry of Education, Science Sports and Culture, Japan.

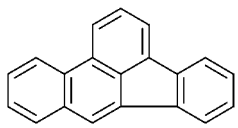
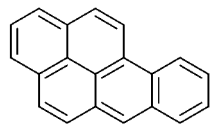
Received (in Cambridge, UK) 18th May 1999, Accepted 29th June 1999

A 2-D double-strand helical complex with a strand of polycyclic aromatic hydrocarbons and a strand of silver(I) perchlorate has been isolated and crystallographically characterised.

Polymetallic helical complexes are of special interest because of their structural similarities to nucleic acids. They are also intrinsically interesting for their potential applications in the fields of supramolecular chemistry, asymmetric catalysis, and nonlinear optical materials.[1–3] Very often, these helicates are prepared by the coordination of metal ions to tailored polydentate organic strands, such as oligopyridines and some optically active organic ligands, in which nitrogen or oxygen atoms always serve as binding units along the strand.[1–6] In contrast, we report an unprecedented 2-D double-strand helical polymer synthesized from a polycyclic aromatic hydrocarbon (PAH), benzo[*e*]acephenanthrylene (bpa), and silver(I) perchlorate. It was proven in our earlier studies that metal complexes with planar PAH ligands have a tendency to form decker-like or multilayer architectures.[7–9] To our surprise, the planar bpa can lead to the formation of a helical structure with a sheet network. Here we present our results showing how the bpa molecules are self-assembled and wrapped about the flexible silver(I) ions to construct a unique double-strand helical architecture. Some physicochemical properties of the complex are also discussed.



benzo[*e*]acephenanthrylene (bpa)



benzo[*a*]pyrene (L)

The reaction of bpa with $AgClO_4$ in toluene leads to formation of the complex $[Ag_4(bpa)_3(ClO_4)_4]$ **1**.† The X-ray structural determination‡ reveals a two-dimensional framework constructed from cation–π interactions of Ag^I with bpa. While there are two crystallographically independent Ag^I cations, both of them have a similar pseudotetrahedral environment comprising two C=C π-bonds from two aromatic groups and two oxygen atoms from two perchlorate anions (taking the C=C group as one ligand) (Fig. 1). The Ag–O and Ag–C distances range from 2.402(6) to 2.69(1) Å, and 2.412(6) to 2.755(6) Å, respectively. The next closest contact between silver and carbon is 2.867(8) Å, well beyond the limits from 2.40 to 2.76 Å observed in the reported silver(I) aromatic complexes.[7] On the other hand, the aromatic ligand also involves two different coordination modes, one displaying μ-di-η^2 coordination with two metal ions above and below the aromatic plane, and the other exhibiting a μ-tri-η^2 motif with three metal centers on the same side of the aromatic plane. Furthermore, these aromatic ligands are coordinated to the silver(I) ions by wrapping about them to construct a double-helical chain with the silver(I) perchlorate groups in one strand and the μ-tri-η^2 aromatic ligands in the other (Fig. 2). The period of the helix is equal to the crystallographic *a* axis (14.11 Å). In addition, each μ-di-η^2 bpa moiety functions as a linkage bridging two adjacent helical chains *via* the Ag^I ions. This results in extended interactions of the double-strand helical chains to form the two-dimensional framework shown in Fig. 3.

The most significant structural feature presented here is the interesting arrangement of bpa molecules and unusual coordination of the silver ions forming a unique helical structure. As established in the literature,[2] for most helicates the governing factor of the structure is that the organic ligand is shaped into one strand and contains several binding units, such as N or O, along the strand allowing the recognition and coordination of the metal ions. By comparison, the organic strands in complex **1** are self-assembled *via* π–π interactions at the overlapped portion of two adjacent μ-tri-η^2 bpa molecules, with a shortest interplanar separation of 3.52 Å. On the other hand, the flexible silver(I) ions, linked by perchlorate anions, exhibit a special spiral structure, being bound both to these stacked aromatic strands forming the helical chains and to the μ-di-η^2 bpa molecules exhibiting a sheet framework. Such a structural feature, to the best of our knowledge, has not been described before. There is only one example in the literature describing a helical structure of a polycyclic aromatic hydrocarbon, $[Ag_4(L)_2(ClO_4)_4(toluene)_2]$ (L = benzo[*a*]pyrene), where no stacking interactions were observed along the organic strand, and the double-helical chains are formed by aromatic π–π interactions *via* interweaved strands of polycycles.[7]

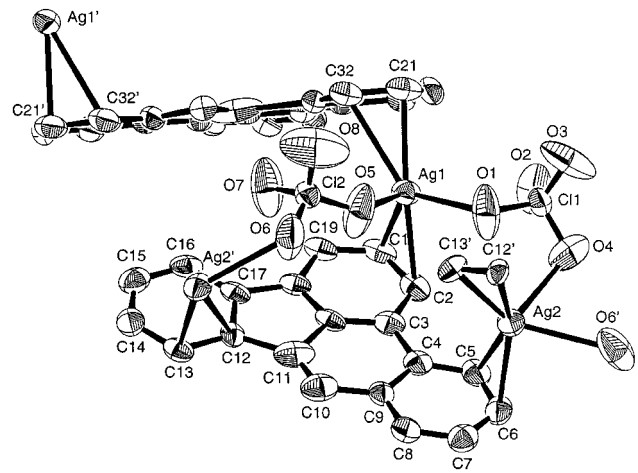


Fig. 1 Structure and partial labeling of $[Ag_4(bpa)_3(ClO_4)_4]$. Selected bond lengths (Å) and angles (°): Ag(1)–O(1) 2.452(7), Ag(1)–O(5) 2.402(6), Ag(1)–C(1) 2.502(6), Ag(1)–C(2) 2.555(6), Ag(1)–C(21) 2.446(7), Ag(1)–C(32) 2.720(7), Ag(2)–O(4) 2.69(1), Ag(2)–O(6) 2.532(8), Ag(2)–C(5) 2.622(7), Ag(2)–C(6) 2.454(6), Ag(2)–C(12) 2.755(6), Ag(2)–C(13) 2.412(6); O(1)–Ag(1)–O(5) 77.2(2), O(1)–Ag(1)–C(1) 125.0(3), O(1)–Ag(1)–C(21) 106.0(3), O(5)–Ag(1)–C(1) 118.9(3), O(5)–Ag(1)–C(21) 105.6(3), C(1)–Ag(1)–C(21) 116.8(2), O(4)–Ag(2)–O(6) 72.5(2), O(4)–Ag(2)–C(6) 104.7(3), O(4)–Ag(2)–C(13) 110.5(3), O(6)–Ag(2)–C(6) 86.3(3), O(6)–Ag(2)–C(13) 130.0(3), C(6)–Ag(2)–C(13) 135.2(3).

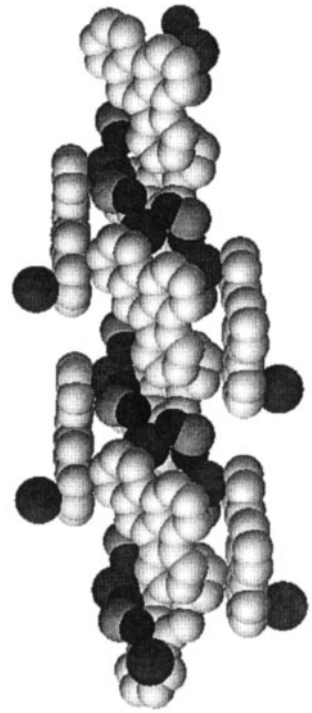

Fig. 2 Space-filling model of the double-strand helical structure of **1**.

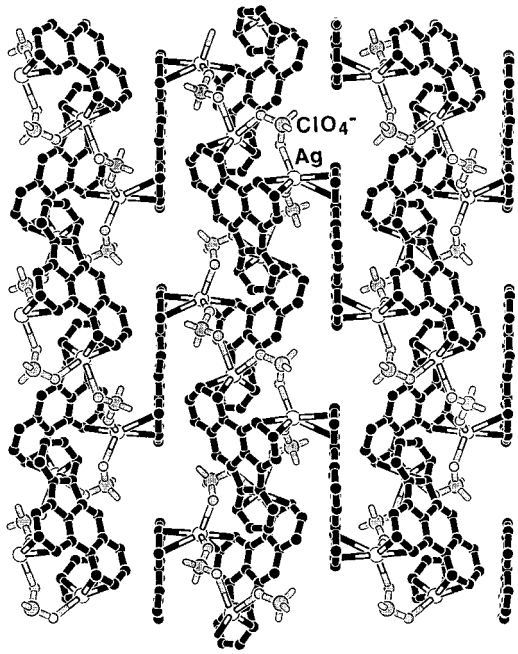

Fig. 3 Two-dimentional sheet framework of **1**.

The compound is soluble in most common organic solvents. It is reasonably stable in ambient daylight for 1 week, but shows slight moisture sensitivity under atmospheric conditions. The UV–VIS absorption spectrum of the free ligand bpa in toluene (2.5×10^{-4} M) displays an intense absorption around 350 nm, indicative of a $\pi \rightarrow \pi^*$ transition.[10] Upon complexation to Ag(I), the transition does not change significantly, probably due to the dissociation of the complex in solution. The electrical conductivity of the complex and its free ligand bpa was measured *via* the silver-coated two-probe technique with compacted pellets and showed that complex **1** displays semiconducting behavior with a σ value of 1.1×10^{-4} S cm^{-1}, whereas the bpa free ligand is non-conducting at room temperature.

It is obvious that helicates can sometimes be obtained from non-stranded polycyclic aromatic hydrocarbons through stacking interactions. Although structural control in this new system is rather difficult compared with the conventional polydentate strand-like organic ligands,[1,2] once structural control and molecular programming have been significantly explored and improved, the very interesting motifs isolated may broaden our insight into the helicate research field and introduce a novel perspective in the area of supramolecular chemistry. Further studies are directed toward the development of the structure-predicting process in this area with the aim of exploring the intrinsic nature and design of other novel helicate frameworks.

This work was partly supported by a Grant-in-Aid for Science Research [Nos. 10440201 and 10016743 (priority areas)] from the Ministry of Education, Science, Culture and Sports, Japan.

Notes and references

† To a solution of benzo[*e*]acephenanthrylene (25.2 mg, 0.1 mmol) in 1 ml of toluene was added $AgClO_4$ (84 mg, 0.4 mmol). After about 20 min of stirring, the resultant colorless solution was introduced into a 7 mm diameter glass tube and layered with *n*-hexane as a diffusion solvent. The glass tube was sealed under Ar and wrapped with aluminium foil. After standing at room temperature for 3 days yellow brick-like crystals were obtained (calc. for $C_{60}H_{36}Cl_4Ag_4O_{16}$: C, 45.39; H 2.27. Found: C, 44.96; H, 2.31%). **CAUTION:** Perchlorate salts of metal complexes with organic ligands are potentially explosive. Suitable care should be taken during the synthesis.

Solid-phase synthesis of pyrrolidines employing a cyclisation–cleavage strategy

Richard C. D. Brown* and Martyn Fisher

Department of Chemistry, University of Southampton, Highfield, Southampton, UK SO17 1BJ.
E-mail: rcb1@soton.ac.uk

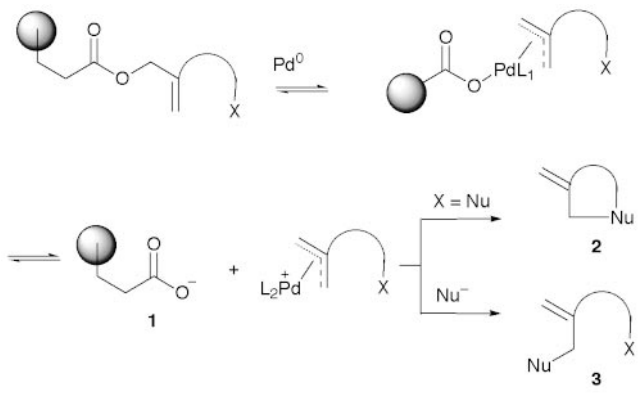
Received (in Liverpool, UK) 20th May 1999, Accepted 28th June 1999

The solid-phase synthesis of several pyrrolidines has been realised utilising imino-Sakurai and palladium-catalysed cyclisation–cleavage reactions as key steps.

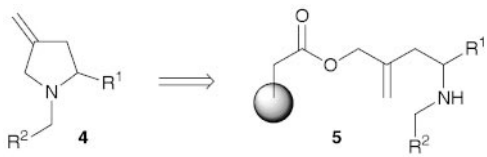
The development of solid-phase combinatorial and multiple parallel synthesis methods has stimulated considerable interest in the design of new linkers and cleavage strategies which are suitable for the release of small molecules from the solid support.[1–4] Linkers or cleavage conditions which activate a polymer-bound molecule towards nucleophilic cleavage can be particularly useful providing an additional point of variability in the released compounds,[4] or allowing the formation of a ring upon cleavage.[4,5] Here we describe the development of a novel nucleophile-cleavable linker that is sufficiently robust to survive a multi-step reaction sequence, yet can be cleaved under mild conditions with incorporation of a nucleophile.

Several linkers which rely upon the palladium-catalysed cleavage of allylic systems have been reported, releasing carboxylic acids or amines (through an intermediate carbamic acid) from the resin.[6–9] We imagined that a reversed allylic linker would provide a mild means of generating electrophilc π-allyl palladium species which could be trapped with heteroatom- or carbon-centred nucleophiles to release cyclic **2** or acyclic **3** products from the solid phase (Scheme 1).

In order to demonstrate the viability of a palladium-catalysed cyclisation–cleavage reaction we chose to investigate the solid-phase synthesis of pyrrolidines **4** (Scheme 2).[10,11] A key intermediate is the homoallylic amine **5** which could be derived from the reaction of a resin-bound allylic nucleophile with an imine.[11–13] The presence of an ester group in the linker meant that the reactivity of the allyl metal component would have to be attenuated, leading us to consider the use of an allylic silane as the immobilised nucleophile.



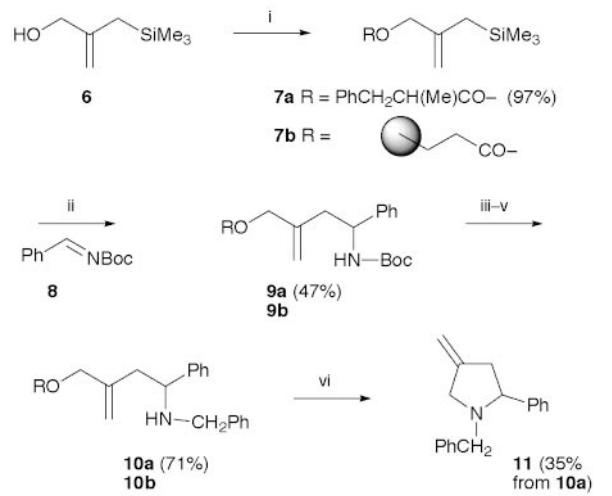
Scheme 1



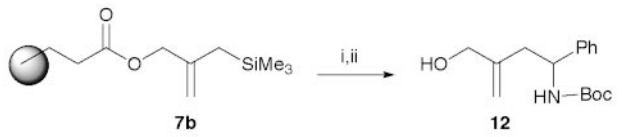
Scheme 2

Before attempting any solid-phase work the analogous solution chemistry was investigated (Scheme 3). 2-Hydroxymethyl-3-trimethylsilylpropene **6** was esterified with 2-methyl-3-phenylpropanoyl chloride to give the allylic silane **7a**. Addition of **7a** to the preformed *N*-acyl imine **8** provided a satisfactory yield of the homoallylic amine **9a**. Attempted cyclisation of either the Boc-protected homoallylic amine **9a** or the corresponding deprotected primary amine failed using 10 mol% $Pd(acac)_2$ with 15 mol% diphenylphosphinoethane (dppe). However, deprotection and reductive alkylation of **9a** provided secondary amine **10a** which when subjected to the same cyclisation conditions afforded the desired pyrrolidine **11** in 35% yield. Although some of the yields in the solution pyrrolidine synthesis were rather low, we were sufficiently satisfied with the overall approach to carry out further optimisation on the solid phase.

Solid phase synthesis of pyrrolidine **11** started with a carboxyethylated polystyrene resin† **1** which was prepared in three steps from Merrifield resin. The 2-hydroxymethyl-3-trimethylsilylpropene **6** was immobilised under standard carbodiimide coupling conditions using an excess of DMAP to prevent the well-known side reaction leading to a resin-bound *N*-acylurea. The imino-Sakurai reaction required some optimisation, turning out to be the most challenging step in the solid-phase reaction sequence. The effect of changing several reaction parameters including reaction time, amount of *N*-acylimine and the amount of Lewis acid was investigated. The efficiency of the reaction was measured by reduction of the ester linkage followed by purification of the cleaved alcohol **12** and quantification (Scheme 4). Our results are shown in Table 1. Optimum conditions required a large excess of the *N*-acylimine **8** and an excess of $BF_3{\bullet}OEt_2$ relative to the resin-bound allylsilane **7b** (entry 7), providing significantly better yield of the homoallylic amine than was achieved in the analogous reaction in solution.



Scheme 3 *Reagents and conditions*: i, 1,3-diisopropylcarbodiimide, DMAP, CH_2Cl_2, **1**; or 2-methyl-3-phenylpropionyl chloride, CH_2Cl_2, pyridine; ii, $BF_3{\bullet}OEt_2$, CH_2Cl_2; iii, TFA, CH_2Cl_2; iv, PhCHO, AcOH, CH_2ClCH_2Cl; v, $Me_4NB(OAc)_3H$, CH_2ClCH_2Cl; vi, $Pd(acac)_2$, dppe, THF, Δ.



Scheme 4 *Reagents and conditions*: i, **8**, BF_3•OEt_2, CH_2Cl_2; ii, $LiBH_4$, MeOH (1 equiv.), THF.

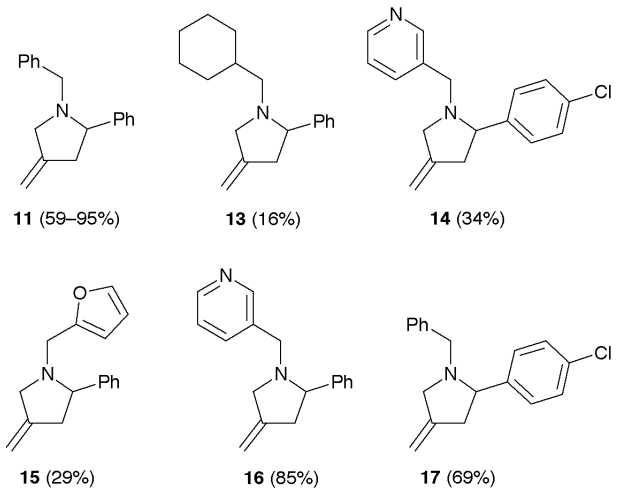
Table 1 Effect of reaction parameters on yield

Entry	Molar ratio[a] of *N*-acylimine **8**	Molar ratio[a] of BF_3•OEt_2	Reaction time/h	Yield[a] (%)
1	8	12	12	16
2	8	4	12	25
3	15	8	12	61
4	15	8	28	49
5	23	8	12	70
6	23	8	3	70
7	23	4	3	70

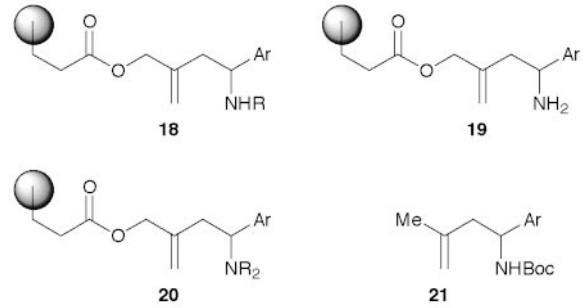
[a] The yield represents the amount of purified isolated alcohol **12** relative to the loading of the carboxylated resin **1**. Molar ratios are also based upon the loading of the carboxylated resin **1**.

Removal of the carbamate protecting group from **9b** and a two-step reductive alkylation using benzaldehyde gave the resin-bound cyclisation precursor **10b**, which was also quantified by reductive cleavage from the resin. Initial attempts to perform the cyclisation–cleavage reaction of **10b** gave the desired heterocycle **11** in low yield, even when a large quantity of palladium complex was employed. However, efficient catalytic cyclisation-cleavage was achieved by employing a three-fold excess of the dppe ligand relative to palladium (10 mol% based upon the loading of the carboxylated resin **1**), returning an excellent yield of the desired pyrrolidine **11**.‡

In order to demonstrate the scope of the palladium-catalysed cyclisation–cleavage reaction, pyrrolidines **11** and **13**–**17** were synthesised.§ In all instances the desired pyrrolidine was obtained, furthermore the purity of the crude product, except in the case of **13**, was judged to be high by inspection of the ^1H NMR spectra. Notably, the crude pyrrolidines **11**, **13**–**17** were



cleaner than their acyclic precursors which were released from the resin by reductive cleavage of **18** using $LiBH_4$. This significant result suggests that the cyclisation–cleavage reaction acts as an in-built quality control step, favouring the release of



the desired product over the release of by-products from earlier steps. To test this theory further, several of the possible by-products from the deprotection–reductive alkylation sequence **9b**, **19** and **20** were subjected to the cyclisation–cleavage reaction conditions. No significant quantity of material was released from any of the resins **9b**, **19** or **20**. Interestingly, treatment of the resin **9b** recovered from the attempted palladium-catalysed cleavage with $LiBH_4$ in THF afforded a reduced product **21** in 80% yield rather than the expected allylic alcohol **12**.

In summary, the viability of a palladium-catalysed cyclisation–cleavage reaction has been demonstrated by the solid-phase synthesis of pyrrolidines **11** and **13**–**17**. This strategy should also be amenable to the solid-phase synthesis of other heterocyclic and carbocyclic compounds. Intermolecular palladium-catalysed nucleophilic cleavage, using $LiBH_4$ as a source of hydride, is also possible releasing substituted propene derivatives such as **21**.

We wish to thank the Royal Society for a University Research Fellowship (R. C. D. B.), and the EPSRC for a QUOTA studentship (M. F.). We wish to acknowledge the use of the EPSRC's Chemical Database Service at Daresbury.[14]

Notes and references

† Merrifield resin was heated with the sodium salt of diethyl malonate at 60 °C for 14 h. Hydrolysis was carried out in refluxing THF–2 M KOH (9:1). Finally, decarboxylation in THF–HCl gave the desired carboxyethylated polystyrene **1**.

‡ Yields have been calculated based on the loading of the carboxylated polystyrene resin **1**.

§ All reactions were carried out on at least a 50 μM scale with respect to the loading of the carboxylated polystyrene resin **1**. All products were purified by flash chromatography and gave satisfactory analytical data.

Pyrolysis reactions of 4-nonafluorobiphenyl prop-2-enyl ether: a remarkable rearrangement reaction

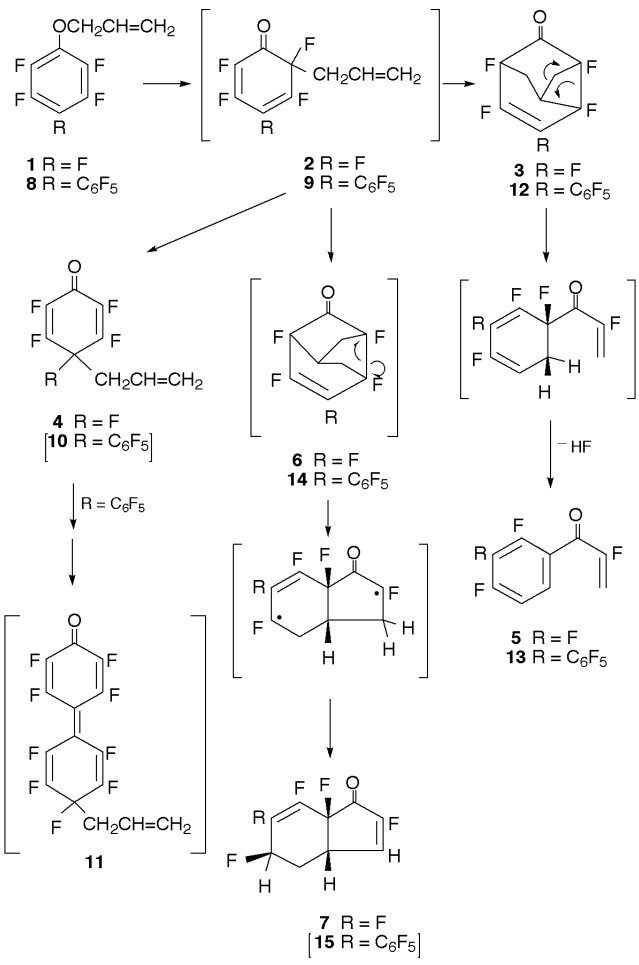
Andrei S. Batsanov, Gerald M. Brooke,* Darren Holling and Alan M. Kenwright

Chemistry Department, Science Laboratories, South Road, Durham, UK DH1 3LE.
E-mail: g.m.brooke@durham.ac.uk

Received (in Liverpool, UK) 21st April 1999, Accepted 9th July 1999

The formation of the unexpected bicyclic compound 16 *via* the pyrolytic isomerisation of 4-nonafluorobiphenyl prop-2-enyl ether 8 can be rationalised by invoking the intermediacy of a rare retro-cyclisation reaction of the internal Diels–Alder adduct 12 (from the Claisen intermediate 9) to a tethered ketene 18, recyclisation *via* the alternative mode to 17 and its subsequent transformation.

In some earlier work[1] the thermolysis of pentafluorophenyl prop-2-enyl ether **1** *in vacuo* at 137–141 °C over 13 days was shown to give **3**, one of the two possible intramolecular Diels–Alder adducts from the intermediate Claisen rearrangement compound **2**. Under FVP conditions at 365 °C and 0.05 mmHg through a silica tube packed with silica wool, **1** gave the cyclohexa-2,5-dienone **4** *via* **2** followed by a classical Cope rearrangement,[2] while under even more forcing conditions at 440 °C and 0.001 mmHg the fluorovinyl compound **5** was isolated, formed by the decomposition of **3** and loss of HF.[3] In a separate FVP experiment at 480 °C and 0.05–0.1 mmHg, **1** was also shown to be converted into the bicyclic compound **7**, the formation of which was rationalised by invoking the decomposition of the other possible intramolecular Diels–Alder adduct **6**, formed from **2**.[4] All these reactions are summarised in Scheme 1 which also shows the original objective of the present work: namely, the investigation of the pyrolysis of the closely related 4-nonafluorobiphenyl prop-2-enyl ether **8** to ascertain whether **10**, an expected intermediate from the Claisen rearrangement intermediate **9**, would undergo two further possible rearrangements to give the novel isomer **11**; to our knowledge, no Cope rearrangement has ever been described in which one moiety in a 3,3-sigmatropic reaction is an aromatic ring. In the event, no isomerisation of **8** to either **10** or **11** occurred, but a much more interesting rearrangement reaction was discovered.



Scheme 1

The starting ether **8**, readily accessible from 4-hydroxynonafluorobiphenyl,[5] was subjected to FVP at 350 °C and 0.01 mmHg as before to give a complex mixture of products among which was **12** (13% isolated yield), the structure of which was determined by X-ray crystallography† (Fig. 1). When the pyrolysis of the ether **8** was carried out at 420 °C and 0.01 mmHg, more than 90% of the crude product was shown by ^{19}F NMR spectroscopy to contain three major products in the proportions shown, which were separated by chromatography on silica using light petroleum (bp 40–60 °C)–Et_2O (95 : 5 v/v): 4-hydroxynonafluorobiphenyl (46%); the fluorovinyl compound **13** (24%) (identified unequivocally by ^{1}H, ^{19}F and ^{19}F–^{19}F COSY NMR spectroscopy); and a compound isomeric with the starting material, possessing a CHF functionality (readily identified by ^{1}H NMR spectroscopy as a doublet, $J_{H,F}$ 49 Hz) (30%). Not all of the ^{1}H and ^{19}F NMR characteristics of this latter product were in agreement with the expected bicyclic

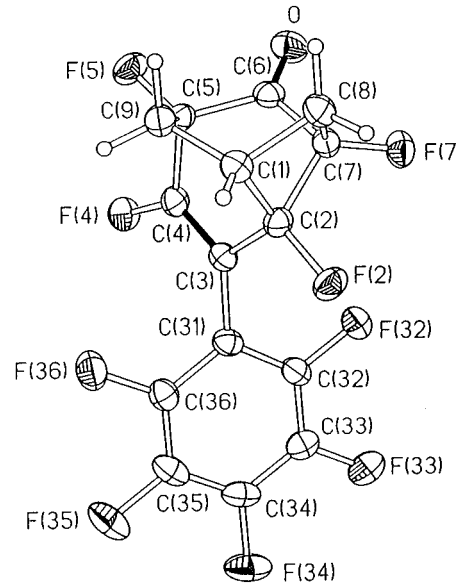


Fig. 1 Molecular structure of **12** (50% displacement ellipsoids; double bonds shown in black).

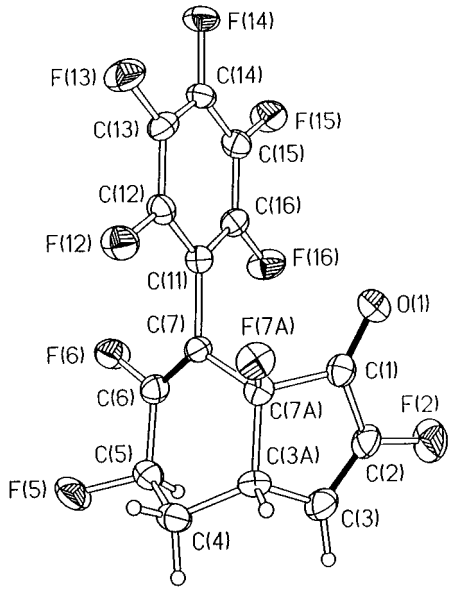

Fig. 2 Molecular structure of **16** (50% displacement ellipsoids; double bonds shown in black).

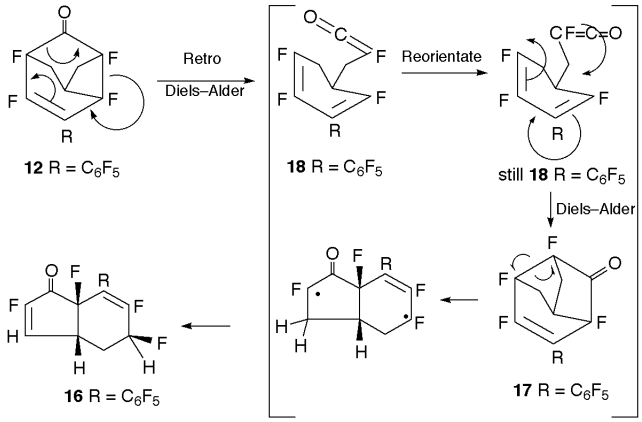
compound **15** which would have been formed if the Diels–Alder adduct **14** had been produced directly from the Claisen intermediate **9** by analogy with the mechanism proposed earlier for the formation of **7** from **1** *via* **2** and then **6**. The material was shown by X-ray crystallography† to have the structure **16** (Fig. 2) which enabled all the NMR data to be rationalised.

The formation of compound **16** (a racemate, but having the enantiomeric structure shown in Scheme 2 when formed from **12** with the configuration given), isomeric with the starting material **8**, poses an intriguing mechanistic problem since the Diels–Alder adduct **14** must not have been formed from **9** during the reaction; the precursor to **16** has to be **17**, the basic skeleton of which is identical with **14** but having the alkenic F and R groups interchanged. The formation of the unexpected intermediate tricyclic compound **17** can be rationalised most simply on the basis of a retro-Diels–Alder reaction of **12** to give the cyclohexa-2,4-dienylmethyl fluoroketene **18**—a very rare[6] reaction type—followed by the alternative intramolecular Diels–Alder cyclisation as shown in Scheme 2. Intermolecular (4 + 2) π reactions of ketenes to form six-membered *carbocyclic* rings[7] are uncommon, but an intramolecular process of this type has been recorded.[8]



Scheme 2

The present work begs the question: *why* do the complex molecular dynamics involved in the rearrangement of **12** to **17** take place in preference to the direct formation of **14** having the same basic carbon skeleton? We have no real answer to this question but models show that the formation of structures **6**[4] and **14** from **2** and **9** respectively are sterically more demanding than for the formation of compounds **3** and **12**, which were isolated under milder conditions. Consequently, even the formation of **7** is likely to proceed *via* this new molecular rearrangement reaction.

Received (in Oxford, UK) 17th June 1999, Accepted 2nd July 1999

Highly dispersed titanium oxide species on silica prepared by the sol-gel method catalyse selective epoxidation of propene by molecular oxygen upon photoirradiation.

Propene epoxidation is of industrial importance. The mixed oxide of Ti and Si has been recognized as a catalyst for the epoxidation of olefins with hydroperoxides and is employed industrially to produce propene oxide (PO) from propene.[1] TS-1, titanium-containing crystalline silica, is known to catalyse epoxidation of propene using H_2O_2.[2] However, employing oxygen as oxidant would be the most economical way of carrying out the oxidation.[1] The discovery of catalysts for the epoxidation of propene by molecular oxygen is highly desirable. One of the most promising systems for this reaction should be photocatalysis on silica-supported systems, since PO was obtained as a product over Nb/SiO_2,[3] Mg/SiO_2 and even over bare amorphous silica[4,5] with significant selectivity. However, the PO yield in these systems was still low, and it is not clear whether the reaction proceeds catalytically or not.

In the present study, we prepared highly dispersed titanium oxide species on silica by two methods, impregnation and sol-gel methods, and examined their photocatalytic activity for propene epoxidation using molecular oxygen.

Amorphous silica was prepared from $Si(OEt)_4$ by the sol-gel method followed by calcination in a flow of air at 773 K for 5 h.[6] The bulk titanium oxide employed was a Japan Reference Catalyst (JRC-TIO-4; equivalent to P-25). A silica-supported titanium oxide sample containing 0.1 mol% Ti (Ti/Ti + Si), referred to as T/S(0.1), was prepared by the impregnation method.† A TiO_2–SiO_2 mixed oxide sample containing 0.34 mol% Ti, T-S(0.34), was prepared by the sol-gel method.‡ The Ti content was determined by inductively coupled plasma (ICP) measurements. A diffuse reflectance UV-VIS absorption spectrum of the sample *in vacuo* was recorded at room temperature with a JASCO V-570 spectrophotometer after the same pretreatment as for the photoreaction test.

Before the photoreaction, the samples were heated in air up to 673 K, and then evacuated. Subsequently the samples were treated with 100 Torr oxygen (1 Torr = 133.3 N m^{-2}) at 673 K for 1 h, followed by evacuation at 673 K for 1 h.§ The photooxidation of propene was carried out in a closed reaction vessel made of quartz (123.6 cm^3) for 2 h. The temperature of the catalyst bed was elevated by *ca.* 20 K from room temperature by the photoirradiation. The reactants were propene (100 μmol, 15 Torr) and oxygen (200 μmol, 30 Torr). The catalyst (200 mg) was spread on the flat bottom (12.6 cm^2) of the vessel. A 200 W Xe lamp was used as the light source. Products in the gas phase and products desorbed by photoirradiation for 1 h were analyzed separately by gas chromatography, followed by analysis of the desorbed products by heating at 573 K. The results presented here are the sum of each product yield. The products were propene oxide (PO), propanal (PA), acetone (AC), acrolein (AL), acetaldehyde (AA), alcohols (MeOH, EtOH and Pr^iOH), hydrocarbons (ethene and butenes; HC) and CO and CO_2 (CO_x).

Fig. 1 shows diffuse reflectance UV-VIS spectra of the samples. Bare silica showed no large absorption band [Fig. 1(*a*)], while bulk TiO_2 showed a large absorption band below the band gap [Fig. 1(*d*)]. Both T/S(0.1) and T-S(0.34) exhibited a narrow band centred at *ca.* 210 nm [Fig. 1(b),(*c*)] which is assigned to the ligand-to-metal charge transfer band of highly dispersed tetrahedral titanium species.[7] This means that T/S(0.1) and T-S(0.34) consist of predominantly highly dispersed tetrahedral titanium species on silica.

Table 1 shows the results of photooxidation of propene by molecular oxygen on the samples. Bare silica (entry 1) exhibited almost the same conversion (1.53%) and propene oxide selectivity (22.3%) as previously reported.[4,5] The conversion to CO_x was not significant. Other major by-products are AC, AL and AA. Bulk TiO_2 (entry 2) showed high photooxidation activity; the conversion of propene was 14.1% when irradiated for 1 h (half of the standard irradiation time). However, the

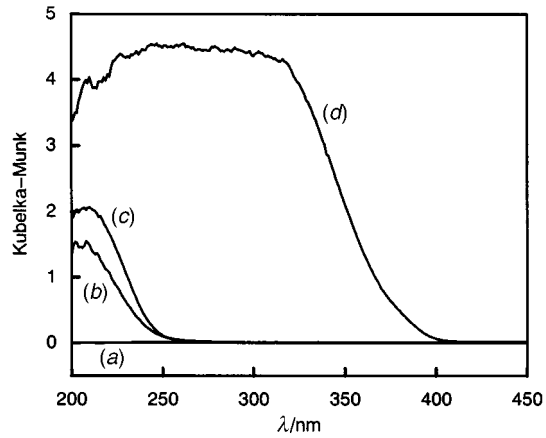

Fig. 1 Diffuse reflectance UV-VIS spectra of (*a*) silica, (*b*) T/S(0.1), (*c*) T-S(0.34) and (*d*) TiO_2.

Table 1 Results of the photooxidation of propene

Entry	Sample	BET surface area/ $m^2\ g^{-1}$	Irradiation time/h	Conversion of propene (%)	PO yield (%)	Selectivity (%)							
						PO	PA	AC	AL	AA	Alcohol	HC	CO_x
1	SiO_2	558	2	0.7	0.2	27.1	1.4	26.7	8.9	16.8	6.0	8.8	4.3
2	TiO_2	34	1	14.1	0.0	0.0	0.0	1.3	0.0	0.8	0.0	1.7	96.2
3	T/S (0.1)	477	2	9.1	3.7	40.8	3.3	11.3	4.2	24.5	3.6	2.3	10.0
4	T-S (0.34)	423	2	9.2	5.3	57.5	2.7	5.8	1.2	21.1	0.0	5.1	6.6

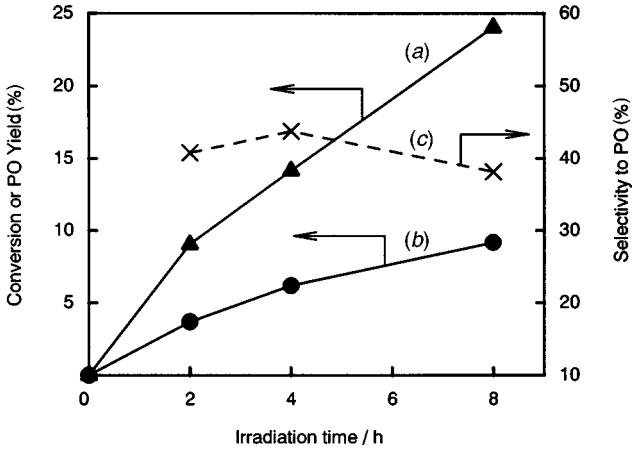

Fig. 2 Time course of (*a*) propene conversion, (*b*) PO yield and (*c*) PO selectivity in the photooxidation of propene by molecular oxygen on T/S(0.1).

major product (96.2%) was CO_x; no propene oxide was observed.

On the other hand, the silica-supported titania sample T/S(0.1) (entry 3) exhibited higher selectivity to PO (40.8%) than bare silica and bulk TiO_2. The conversion of propene on T/S(0.1) was much higher than on bare silica, while selectivity to CO_x was considerably lower than bulk TiO_2. Therefore, it was found that dispersed titanium oxide on silica has a moderate ability to produce PO from propene and molecular oxygen upon photoirradiation.

T-S(0.34) prepared by the sol-gel method showed almost the same conversion as T/S(0.1); therefore, an accurate comparison of product selectivity was allowed. Obviously the PO selectivity on T-S(0.34) was higher than that on T/S(0.1); it was also higher than the selectivities previously reported in the literature.[3–5] The conversion to CO_x was also suppressed more than that of T/S(0.1). It is thus indicated that T-S(0.34) has excellent properties for this photoepoxidation; sol-gel methods should be advantageous for producing active sites for selective photoepoxidation of propene using molecular oxygen.

Fig. 2 presents the time course of propene conversion, PO yield and PO selectivity in the photooxidation on T/S(0.1). The conversion of propene and yield of PO increased with increasing irradiation time. The selectivity was not affected significantly by the conversion at least until a conversion of 24.1%. After 8 h photoirradiation, the yield of PO achieved was 9.2% of the initial amount of propene. The amount of PO produced was 9.2 μmol, and the calculated amount of titanium ions in the reactor was 3.33 μmol. Even if all the titanium ions were active sites, the turnover number¶ would be 2.8, indicating that the photoepoxidation of propene on titanium oxide species on silica proceeded catalytically. This is the first report of the catalytic photooxidation of propene to propene oxide by molecular oxygen.

In conclusion, highly dispersed titanium oxide species were found to catalyse the photooxidation of propene to propene oxide by molecular oxygen at room temperature. The selectivity to propene oxide on titanium oxide species on silica was affected by the preparation method; the sol-gel method was superior to conventional impregnation methods. Titania–silica prepared by the sol-gel method in the present study showed higher selectivity to propene oxide than those previously reported in the literature. It is expected that fine-tuning of the preparation method, the amount of titanium oxide and the reaction conditions should further enhance their activities.

This work was supported by a Grant-in-aid from the Ministry of Education, Science, Art, Sports and Culture, Japan.

Notes and references

† Calcined silica was impregnated by aqueous solutions of ammonium titanyl oxalate, dried at 383 K for 12 h and calcined at 773 K in a flow of air for 5 h.

‡ A mixture of $Si(OEt)_4$, EtOH, H_2O and HNO_3 (1, 3.8, 1, and 0.085 mol, respectively) was stirred at 353 K for 3 h and cooled down to room temperature. An Pr^iOH solution of titanium isopropoxide was added dropwise and stirred at 293 K for 2 h, followed by very slow addition of an aqueous solution of HNO_3 [1 and 0.085 mol respectively, the amount of this acid solution was equivalent to that of $Si(OEt)_4$ used]. Two weeks later, the obtained gel was heated at a rate of 0.2 K min^{-1} up to 338 K and dried for 5 h. After drying for an additional 5 h at 373 K, the TiO_2–SiO_2 mixed oxide was obtained by calcination at 773 K in a flow of air for 8 h.

§ This treatment temperature was lower than that of the previous reports (refs. 4,5) because low temperature (673 K, even room temperature) was found to be sufficient to activate the sample.

¶ Turnover number is defined as (the amount of produced PO)/(the amount of catalytic active sites).

Intramolecular C–H···O hydrogen bonding reduces cation complexation strength in a fluorescent crown ether

Stephen L. De Wall, Eric S. Meadows, Leonard J. Barbour and George W. Gokel*

Received (in Columbia, MO, USA) 6th April 1999, Accepted 20th May 1999

Complexes of the fluorescent crown ether, *N,N*-bis(9-anthrylmethyl)-4,13-diaza-18-crown-6, with NaI_3 and KSCN reveal the presence of intramolecular C–H···O hydrogen bonds that appear to control conformation and lead to reduced cation binding affinity.

For more than a decade, the fluorescent properties of macrocycles have proved fascinating.[1] A hope has been that fluorescent residues appended to macrocycles would afford lariat ethers[2] that could function as cation sensors.[3] Indeed, de Silva and de Silva demonstrated 'fluorescent signaling' in *N*-(9-anthrylmethyl)aza-15-crown-5 and -18-crown-6 nearly 15 years ago.[4] Anthracene has proved particularly popular as the fluorescent element. It has, for example, been incorporated into crowns and cryptands used as probes of phospholipid membrane fluidity.[5] It has been attached to one crown, to two crowns, and *via* the 9- and 10-positions of a single molecule to a macrocycle to afford proton sensors.[6] Two anthracenes incorporated into a macrocycle[7] and two anthracenes attached to a crown afforded a crown–cryptand photoswitch.[8] Anthracene has also been incorporated as the fluorescent element for sensing Cu^{2+} ions[9] and D-glucosamine.[10] Very recently, Kubo, Ishige and Sakurai have prepared and studied *N,N′*-bis(9-anthrylmethyl)-4,13-diaza-18-crown-6 **1** for use as a fluorescent cation sensor. In the latter case, some cation binding selectivity and cation-induced fluorescence change were observed, but the results were generally modest. This is surprising for such a widely used and strongly fluorescent residue. We now report the first solid state structures of **1** bound by either Na^+ or K^+. Intimate C–H···O hydrogen bonding between the sidearm and macrorings clearly decrease the ability of **1** to form stable cation complexes and, in turn, diminish their utility as sensors.

Compound **1** was prepared by heating commercial 9-chloromethylanthracene, 4,13-diaza-18-crown-6,[11] and Na_2CO_3 in MeCN for 72 h. Crystallization from toluene afforded **1** as yellow needles (68%, mp 195–196 °C).[12] Kubo and co-workers report **1** in 90% yield as yellow needles (from $CHCl_3$) having mp 189–190 °C. The NaI_3 complex of **1** was isolated from a mixture of **1** and NaI (1:1) in THF that was not protected from the air. The rhombohedral crystals obtained (dark yellow to brown) had the stoichiometry **1**·NaI_3·$(THF)_2$ and decomposed on melting, presumably with loss of THF, at *ca.* 215 °C. A projection of the complex is shown in Fig. 1.

There are several notable features about this complex. First, the macroring is in the D_{3d} conformation, as expected. The average Na^+–O distance is 2.46 Å and the Na^+–N distances are 3.03 and 2.92 Å. These values are typical for diaza-18-crown-6 Na^+ complexes. The sidearms are in the *anti* conformation, one being above, and the other below, the mean plane of the macroring heteroatoms. The *anti* orientation of the anthryl sidearms effectively excludes the anion from the cation's solvation sphere. It is especially interesting that the two (disordered) THF molecules (normally excellent donors) found in the crystal lattice do not coordinate the cation. Since the macroring is essentially planar, it is reasonable to expect the apical position(s) to be occupied by donor groups. Either I_3^- or THF or a combination of the two could fill the void above and below the macrocycle but neither does. Instead, the space is filled by anthracene.

There are two especially close contacts between C–H bonds and electronegative elements. The first involves the hydrogen atoms on anthracene's 1-position (α-position). The C···O distances are 3.54 (θ = 152.7°) and 3.58 Å (θ = 156.7°). If the aromatic C–H bonds are 0.95 Å long, this makes the average H-bond distance ~2.7 Å from the nearest macroring oxygen atom. The second type of close contast is a C···I interaction observed between one (but not the other) of the anthracene 2-positions (β-positions) and the proximal terminus of I_3^- (3.79 Å) and has a C–H–I bond angle of *ca.* 140°. In contrast, the shortest distance between Na^+ and any iodine atom or either THF oxygen is ⩾6 Å. There are also anthracene–crown C···N contacts apparent in both structures (3.17–3.39 Å range) but the contact angles (113–117°) make their overall importance unclear.

The K^+ complex of **1** was isolated from a mixture of **1** and KSCN (1:1), dissolved in $CHCl_3$–EtOH (1:1 v/v). The colorless, rhombohedral crystals had the stoichiometry **1**·KSCN·$(EtOH)_2$. Interactions analogous to those observed in the Na^+ complex of **1** are apparent here. The average K–O distance for the macroring contacts is 2.73 Å and the average K–

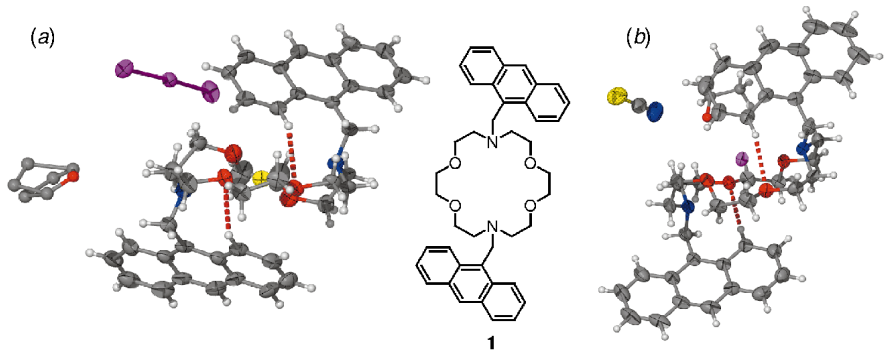

Fig. 1 Solid state structures of **1** complexed by (*a*) NaI_3 and (*b*) KSCN. In each case, one of two disordered solvent molecules has been deleted for clarity. Dotted lines indicate C–H···O contacts. Thermal ellipsoids are shown at 50% probability.

N distance is 3.20 Å. We also note a contact between the oxygen of one EtOH molecule and K^+ (K–O) that is 2.71 Å, essentially identical to the macroring K–O interactions. The anthracene C–H to macroring oxygen contacts (C···O, similar to those observed for **1**·Na^+) are 3.58 (θ = 177.5°) and 3.63 Å (155.5°). Carbon-3 of one anthracene is 4.12 Å from the sulfur atoms of SCN^- and the C–H···S angle is 151.3°.

Other data are worthy of note. The transannular N↔N separation in **1**·NaI_3 is 5.93 Å and in **1**·KSCN is 6.11 Å. The latter value is similar to those reported for other K^+ complexes of diaza-18-crown-6 derivatives.[13] In contrast, the transannular span for the Na^+ complex is considerably larger than the value of 5.10 Å reported for *N*,*N*′-bis(2-hydroxyethyl)-4,13-diaza-18-crown-6.[13]

Kubo *et al.*[14] have titrated **1** with either Na^+ or K^+ and used fluorescence changes to determine complexation constants. They have found that in MeOH–$CHCl_3$ (9 : 1 v/v), log K_s (Na^+) for **1** is 2.70 and log K_s (K^+) is 3.29. They do not report values in the more commonly used solvent: anhydrous MeOH. The poor solubility of **1** in MeOH prevented us from measuring log K_s in this solvent.

Several observations clearly indicate that unusual interactions occur in the Na^+ and K^+ complexes of **1**. One of the most obvious is the low cation binding constant. In anhydrous MeOH solution, *N*,*N*′-dibenzyl-4,13-diaza-18-crown-6 (**2**) was found to have the following cation complexation constants: log K_s (Na^+) = 2.72 and log K_s (K^+) = 3.38. It is well known that cation complexation constants diminish with increasing polarity of the solvent.[15] It is expected, therefore, that complexation constants determined in a $CHCl_3$–MeOH mixture would be greater than in more polar MeOH. In fact, the binding constants are *lower* by a small factor (1.2- to 1.4-fold). This suggests that in MeOH, log K_s would be significantly lower for **1** than for **2**.

In previous studies, we found a clear correlation between the complexed cation's coordination number and the metal–heteroatom donor group distances.[13] As the coordination number increased, the M^+–O distance increased. Indeed, our data correlated well with the values published by Shannon.[16] Thus, metal-ion-to-oxygen distances for six-coordinated Na^+ and K^+ should be, respectively, 2.42 and 2.78 Å. (Considering the EtOH interaction in **1**·KSCN, the latter value could be 2.86 Å). In fact, the average distances observed are, respectively, 2.47 and 2.73 Å. The predicted M^+–N distances are 2.52 and 2.62 Å for Na^+ and K^+. The observed average distances are 2.97 and 3.20 Å. The M^+–O distances are approximately as expected for six-coordinated Na^+ and K^+, but the M^+–N lengths are remarkably long. This suggests that the cation's interaction with macroring nitrogen is weaker than expected and may be compensated by other, less obvious interactions.

The most remarkable feature of these two structures is the short C–H···O contacts observed between the anthracene α-hydrogen and a proximate macroring oxygen. Desiraju has recently discussed the occurrence of such interactions.[17] The four close contacts observed for the interaction noted above are in the range (designated *D*) of 3.54–3.62 Å and exhibit C–H···O angles from 152.7–177.5°. Desiraju has noted that '*D* values span the range 3.00–4.00 Å' and has further stated that 'linear bonds ($150 < \theta < 180$°) are structurally significant.' Clearly, all of these putative contacts fall within the 'significant' range by both criteria. Moreover, the molecules that possess these remarkable contacts are unusually poor cation binders. The excellent fluorescent potential of the anthryl residue should thus be weighed against its potential to interfere with complexation when considered as the sensor element in fluorescent signaling cation complexers.

We thank the NIH (GM-36262) and the NSF (CHE-9805840) for grants that supported this work. We are also grateful for an American Chemical Society fellowship, funded by Procter and Gamble, to E. S. M. We appreciate helpful discussions with Professors Nigam Rath and Jonathan Steed.

1- and 2-Naphthylmethyl sidearms of isomeric bibracchial lariat ethers significantly affect alkali metal cation complexation

Eric S. Meadows, Stephen L. De Wall, Leonard J. Barbour and George W. Gokel*

Bioorganic Chemistry Program and Department of Molecular Biology and Pharmacology, Washington University School of Medicine, 660 S. Euclid Avenue, Campus Box 8103 St. Louis, MO 63110 USA.

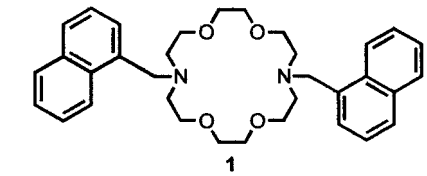
Received (in Columbia, MO) 20th April 1999, Accepted 23rd June 1999

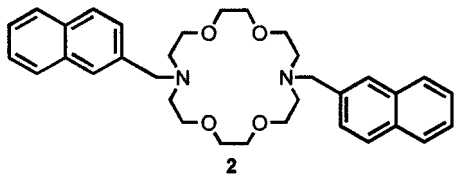
Derivatives of 4,13-diaza-18-crown-6 having benzyl or isomeric naphthylmethyl sidearms have significantly different solid state structures and show differences in cation complexation strengths.

During the more than three decades since Pedersen reported the first crown ethers,[1] these remarkable cation binders have been studied in exquisite detail. Numerous structural studies have established their conformations when unbound or when complexed by a variety of alkali and alkaline earth metal cations as well as by numerous other cationic and even neutral species. The now well-established chemistry of macrocycles[2] is exhibiting utility in the development of supramolecular systems.[3] As more complicated structures are designed, unanticipated properties occasionally emerge. Understanding such unusual effects is critical for achieving the desired properties in supramolecular structures that incorporate crowns as modules. We have recently reported the first definitive evidence for arene participation in the complexation of sodium and potassium cations.[4] In a second study, the indolylethyl sidearms[4] that bound Na^+ or K^+ were replaced by 9-anthrylmethyl.[5] In the latter case,[5] the intercession of C–H···O hydrogen bonding affected complexation geometry and cation binding strength. We now report the results of a study involving isomeric aromatic sidearms and the effect they have on complexation geometry and cation binding strength.

N,*N*′-Bis(1-naphthylmethyl)-4,13-diaza-18-crown-6, **1**, and its isomer *N*,*N*′-bis(2-naphthylmethyl)-4,13-diaza-18-crown-6, **2**, were prepared by alkylation (48 h reflux) of diaza-18-crown-6[6] using either 1-chloro- or 2-bromomethylnaphthalene in $CH_3CH_2CH_2CN$ in the presence of KI and Na_2CO_3. Compound **2** was obtained as a thick yellow oil that crystallized from hexanes and then EtOH to give light yellow prisms (76%, mp 92–93 °C).[7]



1



2

Kubo and coworkers have recently reported the preparation of **1** as part of a program to develop fluorescent cation sensors.[8] The fluorescent properties of **1** allowed them to determine cation complexation constants. They reported that log K_s values in anhydrous MeOH for Na^+ and K^+ complexation by **1** were 2.09 and 3.27, respectively. This compares with binding constants determined for *N*,*N*′-dibenzyl-4,13-diaza-18-crown-6 (**3**) as follows: log K_s (Na^+) = 2.68 and log K_s (K^+) = 3.38. There is a 1.3-fold difference in the K^+ binding constant but a larger, ~4-fold, difference in the Na^+ binding constant. We have independently determined the binding constant for **1** and find log K_s (Na^+) to be 2.32 ± 0.26. While this 1.7-fold difference is more in line with related compounds, K_s is still lower than expected. A complexation constant determination for previously unreported **2** gave a log K_s value of 2.68 ± 0.10. For calibration, **3** was re-examined and log K_s (Na^+) was found to be 2.71, identical within experimental error to the previously reported value (see above) and to the binding constant for **2**.

Although the complexation constant differences are not major, the variation between isomers **1** and **2** is striking. We thus determined the solid state structures of the two Na^+ complexes in the hope that differences observed there might help to account for the binding variation. The structures of **1**·Na^+ and **2**·Na^+ are shown in Fig. 1(*b*),(*d*). Kubo and coworkers have reported the structure **1** in the absence of any cation (not shown).[8a] The previously unreported structure of **3**·NaI is shown in Fig. 1(*a*). For comparison, the structure we reported a number of years ago for **3**·KSCN is shown in Fig. 1(*c*).[9]

It is worth noting at the outset that the reported structure[8a] of uncomplexed **1** (not shown) is similar to many other unbound 18-membered macrocycles. The conformation of **1** is planar and the methylene groups adjacent to each macroring nitrogen atom are rotated inward in a typical free macrocycle conformation. The naphthyl groups are clearly turned away from the macroring. Kubo comments that 'the naphthalene ring of [**1**] is close to the N atom of the crown ether; the distance between C1 and N1 is 2.505 Å, shorter than the sum (3.05 Å) of their van der

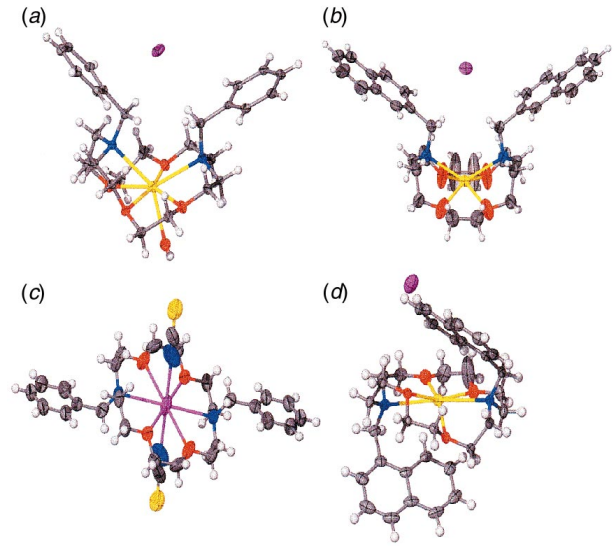


Fig. 1 (*a*) Structure of dibenzyl sodium complex, **3**·NaI. (*b*) Structure of bis(2-naphthyl) sodium complex, **2**·NaI. (*c*) Structure of **3**·KSCN (see ref. 9). (*d*) Structure of bis(1-naphthyl) sodium complex, **1**·NaI.

Waals radii.'[8a] The authors note only that intramolecular charge transfer between these atoms may be favorable.

The structures of **2** and **3** complexing NaI are both unusual but identical in essential features. In both cases the macrocycle is bowed upward with the nitrogen atoms at the peaks. This contraction reduced the N↔N separation from ~5.5–6 Å to ~4.5 Å. Likewise, the sidearm methylenes are separated by 4.02 Å and the sidearm methylene hydrogens across the ring from each other are separated by 2.76 Å and 3.41 Å, respectively. The *syn* 2-naphthyl residues mirror each other through a symmetry plane that intersects Na^+ and I^-. The bowed macroring conformation is also observed for the bis(benzyl)crown complex, **3**·NaI.

The **3**·NaI complex [Fig. 1(*a*)] differs significantly from the structure of **3**·KSCN [Fig. 1*c*)]. In the latter, the macrocycle is in the expected D_{3d} conformation, the M^+–O and M^+–N contacts are as expected, and the apical positions are occupied by SCN anions. In fact, the structure of **3**·KSCN is typical of 18-membered ring crown complexes that lack sidearms.

In contrast to the situation with **2**·NaI [Fig. 1(*b*)], the isomeric complex **1**·NaI [Fig. 1(*d*)] has an *anti*, rather than *syn*, arrangement of the 1-naphthyl sidearms. Although the macroring is far from planar, the N↔N separation is a more typical 5.9 Å. One of the naphthalene α-hydrogens is separated from the nearest macroring oxygen atom by only 2.67 Å (C···O distance = 3.56 Å). The adjacent β-hydrogen is 2.99 Å from the adjacent macroring nitrogen atom and that C–H is only 3.31 Å from iodide. These close contacts suggest significant C–H···X hydrogen bonding interactions.[10] The presence of C–H···O contacts in complexes of **1** and their absence in complexes of **2** may help to account for differences in cation binding strengths observed for these isomeric host molecules. The arene-sidearm to ring C–H···O contacts observed for **1** correspond well with those noted for the structurally related anthrylmethyl derivative previously reported.[5]

The dibenzyl- and dinaphthyldiaza-18-crown-6 derivatives reveal unexpected complex structures. The **1**·NaI complex does not appear to be stabilized by π-stacking interactions but rather by a variety of C–H···X contacts that define sidearm and, in turn, macroring conformation. The **1**·NaI complex exhibits the geometry noted above and **1** also exhibits reduced cation binding affinity, a pattern observed in previous studies from this laboratory.[5,11] Two factors may contribute to the decreased binding ability of **1** compared to **2** or **3**. First, complexes of **1** may require more complete desolvation of the cation than do complexes of **2** or **3** because of the 1-naphthyl sidearms' steric requirements compared to either benzyl or 2-naphthyl. Second, the C–H···O interactions that we observe in the complex of **1** may be able to organize the naphthyl sidearms over the macrocycle in the unbound state, therefore blocking access by the cation. It seems reasonable that both cation binding and release may be directly affected by these sidearm interactions. Our previous study of the 9-anthrylmethyl sidearmed compound,[5] which is closely related to **1**, shows a similar result for a similar geometrical situation. Ultimately, resolution of the contributory factors will require a thermodynamic study so that entropic and enthalpic contributions to ΔG and, in turn, to K_s can be appreciated. For now, it is important to note that such significant differences in conformational and binding behavior occur with isomeric host molecules.

We thank the NIH (GM-36262) and the NSF (CHE-9805840) for grants that supported this work. We are also grateful for an American Chemical Society Division of Organic Chemistry fellowship, funded by Procter and Gamble, to E. S. M.

Multiple morphologies of aggregates from block copolymers containing glycopolymer segments

Zi-Chen Li, Yu-Zeng Liang and Fu-Mian Li*

Department of Polymer Science and Engineering, College of Chemistry, Peking University, Beijing 100871, China. E-mail: fmli@chemms.chem.pku.edu.cn

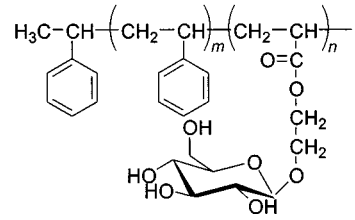
Received (in Cambridge, UK) 25th June 1999, Accepted 6th July 1999

Multiple morphologies of aggregates (micelle-like spheres, vesicles, tubules) from well-defined polystyrene-*b*-poly[(2-β-D-glucopyranosyloxy)ethyl acrylate] (PS-*b*-PGEA) diblock copolymers in diluted aqueous solutions were observed by transmission electron microscopy.

Block copolymers have been investigated vigorously as building units for highly ordered molecular aggregates. It has been shown that when diblock copolymers are dissolved in a solvent which is selective for one of the blocks, colloidal size aggregates or micelles can form as a result of the association of the insoluble blocks.[1–3] Recent reports on rigid-coil diblock copolymers reveal that highly asymmetric diblock copolymers can self-assemble into highly ordered supramolecular architectures with special optical and electrical or encapsulation properties.[4,5] Ordered aggregates from other types of diblock copolymers have also been reported by Armes *et al.*[6] Amphiphilic AB block copolymers are a very important type of block copolymer that show various applications in which the combination of hydrophobic and hydrophilic properties of these materials may be utilized. It has been shown recently by Eisenberg *et al.* that special amphiphilic block copolymers can form stable aggregates of variable morphologies, namely, spheres, rods, vesicles *etc.*, in aqueous solution. Polystyrene (PS) based copolymers, PS-*b*-poly(acrylic acid) (PS-*b*-PAA), PS-*b*-poly(ethylene oxide) (PS-*b*-PEO) and PS-*b*-poly(4-vinylpyridine) (PS-*b*-P4VPy) with various compositions have been extensively investigated.[7] Several factors, including the copolymer composition, the initial copolymer concentration and the nature of the common solvent, have been found to be essential to control the aggregate morphologies. The morphologies are normally studied by observation with a transmission electron microscope (TEM).

In the recent past, increasing attention has been paid to synthetic polymers substituted with pendant saccharide moieties (so called glycopolymers) as biological recognition signals.[8–10] Studies on the synthesis of block copolymers containing glycopolymers as hydrophilic segments and the aggregates formed therefrom in aqueous media are few, especially for block copolymers with controlled molecular weight and narrow molecular weight distribution.[11–13] Recent developments in atom transfer radical polymerization (ATRP) have made it possible to synthesize well-defined block polymers very easily.[14] By using this initiation system, we have successfully synthesized a series of well-defined amphiphilic block copolymers with PS as the hydrophobic block and poly(2-β-D-glucopyranosyloxy)ethyl acrylate) as the hydrophilic one (PS-*b*-PGEA).[15]† The aim of our study is to use these amphiphilic copolymers to construct ordered molecular aggregates and then to use them as models for the study of cell–lectin interactions. Here, we report our preliminary results on the multiple morphologies formed from these amphiphilic block copolymers in aqueous media. The block copolymers used in this study are summarized in Table 1.

To study the aggregation behavior of these new block copolymers in water, a known amount of the completely dried block copolymer sample was dissolved in a common solvent of the two blocks, such as DMF, dioxane *etc.*, to obtain solutions



PS-*b*-PGEA

with different concentrations (0.5–5 wt%). While vigorously stirring the solution, water was added at a rate of 0.2–0.3 wt% every 10 s. When *ca.* 6 wt% of water was added, the clear solution became turbid. The addition of water was continued until 25 wt% of water had been added. Then the sample was put into a dialysis bag (molecular weight cut: 10000) and dialyzed against distilled water for 4 days to remove the organic solvents. To observe the morphologies of these aggregates under TEM, one drop of the diluted suspension was put onto a carbon-coated copper grid, and was negatively stained with uranyl acetate. The observation was conducted with a JEOL 100 CXII transmission electron microscope operated at 100 kV.

Multiple morphologies of aggregates from these PS-*b*-PGEA block copolymer are obtained by using different solvents or changing the initial copolymer concentration. When DMF was used as solvent, small spheres were observed for a large range of initial copolymer concentration for these three PS-*b*-PGEA diblock copolymers as listed in Table 1. One of the typical pictures is shown in Fig. 1(*a*). It can be seen that the spheres are of low polydispersity and their average diameters are *ca.* 25 nm. The small spheres belong to the normal 'crew cut' micelles.[7] The largest initial copolymer concentrations of PS_{88}-*b*-$PGEA_4$, PS_{101}-*b*-PGEA7 and PS_{55}-*b*-$PGEA_9$ in DMF that form spheres in water are 2.5, 3.2 and 4.0 wt% respectively. Above these concentrations, large compound micelles coexisted with the crew cut micelles that were normally observed.

Vesicles were obtained for these three PS-*b*-PGEA block copolymers in other solvents. Fig. 1(*b*) shows a typical example of the vesicular structure obtained from PS_{88}-*b*-$PGEA_4$ in dioxane. The vesicular nature is evidenced by a higher transmission in the center of the aggregates than around their periphery in the TEM pictures. When the initial concentration of PS_{88}-*b*-$PGEA_4$ is within the range of 2.0–4.0 wt%, predominant

Table 1 A summary of the molecular weight, polydispersities and copolymer compositions of PS-*b*-PGEA

Copolymers[a]	GEA content/ mol%	M_n[b]/ g mol^{-1}	M_w/M_n[b]
PS_{88}-*b*-$PGEA_4$	4.3	9 700	1.18
PS_{101}-*b*-$PGEA_7$	6.5	13 000	1.28
PS_{55}-*b*-$PGEA_9$	14.1	8 300	1.24

[a] Degree of polymerization of polystyrene block was determined by GPC; PGEA chain length was determined by measuring the ^{1}H NMR spectra of the copolymer precursor in $CDCl_3$. [b] As determined by GPC in DMF (RI detector, calibrated with polystyrene standards).

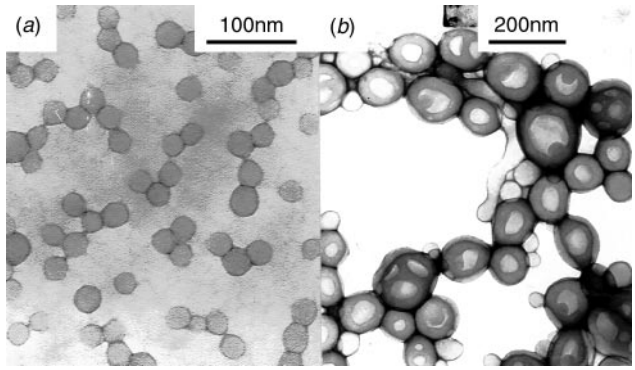


Fig. 1 TEM pictures of (*a*) PS_{101}-*b*-$PGEA_7$ aggregates in DMF (the initial copolymer concentration was 2.0 wt%) and (*b*) PS_{88}-*b*-$PGEA_4$ aggregates in dioxane (the initial copolymer concentration was 3.0 wt%).

vesicular structures were detected, however, there were also a few small spheres and occasionally short cylinders. Most of the vesicles are single-room and coexist with some two- or multiple-room ones. The sizes of the vesicles are very polydisperse with the outer diameters ranging from 100 to 200 nm. The vesicles formed from PS_{55}-*b*-$PGEA_9$ in dioxane (3.5 wt%) were irregular in shape and coexisted with tubular aggregates as shown in Fig. 2(*a*). The overall sizes of vesicle vary very much. The outer diameter ranges from 100 to 300 nm. PS_{101}-*b*-$PGEA_7$ did not yield vesicles in dioxane, however, it formed primarily single-room vesicles in dioxane–DMF (1 : 1, v/v, 2.5–4.0 wt%). The outer diameter of the vesicles ranges from 250 to 500 nm. The present results indicated that the sizes of the vesicles were sensitive to the solvent and the initial copolymer concentration, however, the wall thickness of the vesicle was very uniform and independent of the size of vesicles.

More interestingly, PS_{55}-*b*-$PGEA_9$ also formed tubular structures in dioxane as shown in Fig. 2(*c*). The wall thickness of the tubules is equal to the wall thickness of the vesicles [Fig. 2(*a*)]. The tubular aggregates have not been found for the other two PS-*b*-PGEA copolymers. When the initial copolymer concentration in dioxane is 2.5–3.0 wt%, vesicles are predominate, and when the concentration is 3.0–4.0 wt%, tubules coexisted with vesicles. The morphologies shown in Fig. 2(*b*) are the intermediate shape of vesicles and tubules, which can usually be obtained from a 3.5 wt% dioxane solution. This suggests the transition of morphologies from vesicles to tubules upon increasing the initial copolymer concentration.

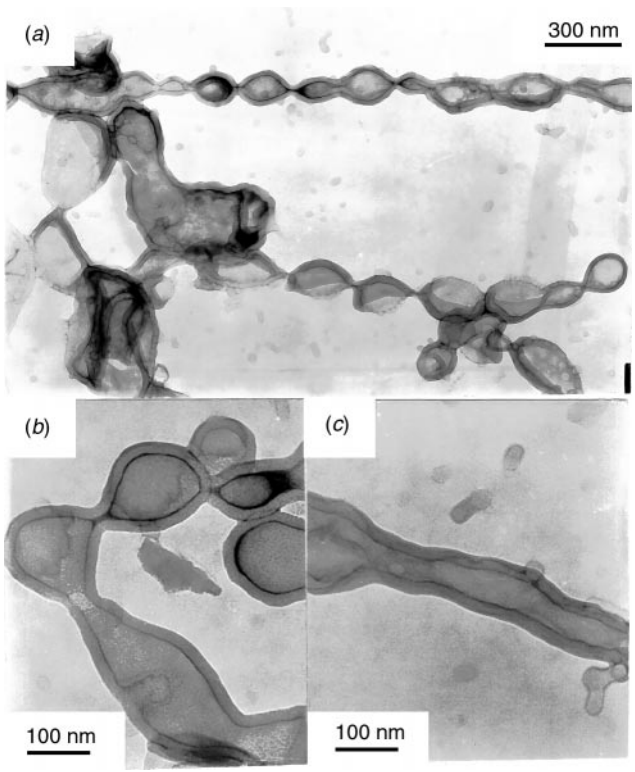

Fig. 2 TEM pictures of PS_{55}-*b*-$PGEA_9$ aggregates in dioxane. The initial copolymer concentrations were (*a*) 2.5, (*b*) 3.5 and (*c*) 4.0 wt%.

Besides the above-mentioned morphologies, other aggregates of PS-*b*-PGEA, such as large compound micelles (LCMs) and large compound vesicles (LCVs) were also observed. Their diameters range from 100 nm to 2 μm. It is also worth noting that the spheres and vesicles formed from the present block copolymers tend to connect with each other. This might be caused by hydrogen bond interactions between the PGEA blocks that constitute the outer surface of the aggregates.

In conclusion, PS-*b*-PGEA belongs to a novel class of amphiphilic AB block copolymers, exhibiting interesting aggregation behavior in aqueous medium. Several morphologies of aggregates, such as micelle-like spheres, vesicles and tubules have been observed from PS-*b*-PGEA block copolymers with different compositions. The morphologies are also found to be dependent on the solvent, and the initial copolymer concentration. These aggregates will be used as models to study cell–lectin recognition.

We wish to thank the National Natural Science Foundation of China and the Ministry of Education of China for financial support.

Notes and references

† PS-*b*-PGEA was synthesized as follows: First, styrene was polymerized with 1-phenylethyl bromide, CuBr and 2,2′-bipyridine in chlorobenzene at 110 °C for 20 h (conversion was about 90%) and the bromo-terminated polystyrene (Br-PS) was isolated by precipitation from MeOH. The dried sample was then used as a macroinitiator for the polymerization of the second monomer. In the second step, the OH protected monomer [2-(2′,3′,4′,6′-tetra-*O*-acetyl-β-D-glucopyranosyloxy)ethyl acrylate (AcGEA)] was polymerized with a pre-determined amount of CuBr, 2,2′-bipyridine and the macroinitiator to obtain the block copolymers, PS-*b*-PAcGEA. The precursor block copolymer was deprotected to the target amphiphilic block copolymer by treatment with a dilute solution of freshly prepared MeONa in a mixed solvent of anhydrous MeOH and $CHCl_3$ at room temperature. The final product was further purified by extraction with cyclohexane and water repeatedly to remove the homopolymers. IR and NMR analysis confirmed the quantitative deprotection without any degradation of the polymer main chain.

Photochemical reaction of *ortho*-formylbenzyltrialkylstannanes for the generation of α-oxy-*o*-quinodimethane

Hiroshi Sano,* Daisuke Asanuma and Masanori Kosugi

Department of Chemistry, Faculty of Engineering, Gunma University, Kiryu, Gunma 376-8515, Japan.

Received (in Cambridge, UK) 18th June 1999, Accepted 6th July 1999

Irradiation of *o*-formylbenzyltrialkylstannanes in benzene gives α-trialkylstannoxy-*o*-quinodimethanes which are trapped with dienophiles at room temperature to afford cycloadducts with high stereoselectivities, while the corresponding silane and germane gave a different type of *o*-quinodimethane and moderate stereoselectivities in cycloadditions.

o-Quinodimethane intermediates are a useful synthetic tool for the synthesis of condensed cyclic compounds and numerous methods for the generation of the intermediates have been developed.[1] We previously reported new methods for the generation of *o*-quinodimethanes from tin precursors utilizing the high leaving ability of the tributylstannyl cation and radical.[2] In the course of our studies, we focused our attention on the photochemical generation of *o*-quinodimethane intermediates utilizing the characteristics of Group 14 organometallic compounds, since it is known that facile generation of α-hydroxy-*o*-quinodimethanes was achieved by irradiation of *o*-tolualdehyde *via* a photoenolisation process involving a 1,5-hydrogen shift.[3] We present here our investigation on the photoreactions of *o*-formylbenzyltrialkyl-stannanes, -silane and -germane in the presence of dienophiles.

The tin precursors **1c**,**d** were easily prepared from *o*-methylbenzyl alcohol in two steps by a method previously reported,[2b] and the corresponding timethylsilyl and tributylgermyl derivatives **1a**,**b** were prepared in a similar way. First, these precursors were irradiated in a benzene solution at room temperature to give the corresponding *o*-quinodimethane intermediates, which were trapped *in situ* with dimethyl fumarate (Scheme 1 and Table 1).

Table 1 Photoreaction of **1** with dienophiles

1	Dienophile	Cycloadduct	Yield(%) (**2**:**3**)
1a	Dimethyl fumarate	**2a** + **3a**	35 (71:29)
1b	Dimethyl fumarate	**2b** + **3b**	45 (53:47)
1c	Dimethyl fumarate	**2c** + **3c**	36 (>99:1)
1d	Dimethyl fumarate	**2d** + **3d**	48 (>99:1)
1d	Dimethyl maleate	**2d** + **3d**	35 (>99:1)
1e	Methyl vinyl ketone	**2e** + **3e**	38 (>99:1)
1f	Methyl acrylate	**2f** + **3f**	21 (>99:1)
1g	*N*-methylmaleimide	**2g** + **3g**	25 (>99:1)
1h	*N*-phenylmaleimide	**2h** + **3h**	51 (>99:1)

It has been reported that cycloaddition of α-hydroxy-*o*-quinodimethane with dimethyl fumarate gave the corresponding cycloadduct as a mixture of two stereoisomers (1,2-*cis* and 1,2-*trans*) in a 74:26 ratio.[4] Compounds **1a**,**b** also showed similar selectivities. When **1a** was irradiated with dimethyl fumarate, the cycloadduct having a trimethylsilyl group on the benzylic position was isolated as a mixture of two stereoisomers in a 71:29 ratio; **1b** gave a similar result. In these reactions, it is obvious that a 1,5-hydrogen shift proceeds upon photolysis to give *o*-quinodimethane intermediates (**A** in Fig. 1) followed by trapping with the dienophile to afford the cycloadducts **2a**(+**3a**) and **2b**(+**3b**) , respectively.

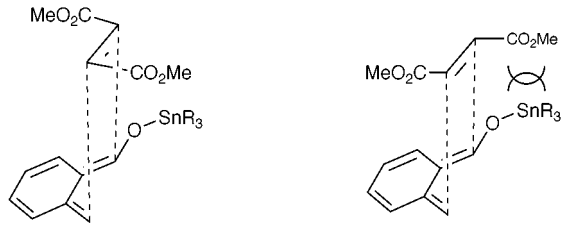
In the case of stannanes **1c**,**d**, however, the corresponding cycloadducts **2c**(+**3c**) and **2d**(+**3d**) involved no stannyl groups and the stereoselectivity was extremely high.[5] In a control experiment, it was observed that when 1-hydroxy-4-tributylstannyl-1,2,3,4-tetrahydronaphthalene was irradiated under similar conditions, most of the compound was recovered without loss of the stannyl group. This observation suggests that the formation of **2c**(+**3c**) and **2d**(+**3d**) does not proceed *via* an α-hydroxy-α′-trialkylstannyl-*o*-quinodimethane such as **A** in Fig. 1. The plausible reactive intermediate would be α-trialkylstannoxy-*o*-quinodimethane **B** (Fig. 1) .

That is, it is conceivable that a 1,5-shift of the stannyl group proceeded to give **B**,[6] which was trapped with the dienophile to give 2,3-dimethoxycarbonyl-1-trialkylstannoxy-1,2,3,4-tetrahydronaphthalene followed by destannylation to give the hydroxy compounds.[7] Furthermore, the present high stereoselectivities in the cycloadditions can be rationalized by supposing the existence of the intermediate **B**. When **B** approaches the dimethyl fumarate, the 1,2-*cis endo* addition **C** would be a favored pathway, since the 1,2-*trans exo* addition **D**

$R^1 = SiMe_3$, $GeBu_3$ — **A**

$R^1 = SnMe_3$, $SnBu_3$ — **B**

Fig. 1 The structure of *o*-quinodimethanes generated from the silane and geramane (**A**) and the stannane (**B**).



C D

Fig. 2 Transition states for the cycloaddition of *o*-quinodimethane with dimethyl fumarate: 1,2-*cis endo* addition (**C**); 1,2-*trans exo* addition (**D**).

suffers from steric repulsion between the trialkylstannyl group and the ester group (Fig. 2).

We next examined the photoreaction of *o*-formylbenzyltributylstannane with various dienophiles, as shown in Table 1. It is noted that the cycloadditions proceeded with exclusive formation of the 1,2-*cis* isomers in all cases. That dimethyl maleate gave the same cycloadduct (2,3-*trans*) as in the case of dimethyl fumarate could be explained by the following facts. It is known that dimethyl maleate isomerizes to dimethyl fumarate under irradiation conditions, and it is also known that dimethyl fumarate is a more reactive dienophile than dimethyl maleate in Diels–Alder reaction.[8]

In summary, we have shown that the generation of α-trialkylstannoxy-*o*-quinodimethanes was achieved *via* 1,5-shift of the stannyl group by irradiation of *o*-formylbenzyltrialkylstannanes, and the stereoselectivities of the cycloadditions with dienophiles were extremely high, whereas other precursors without a stannyl group undergo a 1,5-hydrogen shift and showed moderate selectivities in the cycloadditions.

Received (in Oxford, UK) 16th April 1999, Accepted 9th July 1999

A new type of crystal packing with μ_6-bridged squarate anions has been found in the structure of $Mn_2(OH)_2(C_4O_4)$ 1 during magnetic and X-ray single crystal diffraction measurements performed over a wide range of temperatures; the unit cell parameters for the crystal remain remarkably unchanged in the interval from 10 to 120 K.

We are currently investigating the use of solvothermal synthesis to generate materials with extended metal–ligand networks,[1] particularly ones displaying cooperative magnetic effects. As part of this study we have prepared $Mn_2(OH)_2(C_4O_4)$ **1** from the hydrothermal reaction of NaOH, $H_2C_4O_4$ and $MnCl_2$ at 220 °C. A study of the magnetic behaviour of this compound‡ is consistent with canted antiferromagnetic ordering below 32 K (Fig. 1). Compound **1** obeys the Curie–Weiss law in the paramagnetic region, and fitting the data in the range $70 \leqslant T/K \leqslant 300$ gives a Weiss constant of −52(1) K. Below 32 K a very small but significant spontaneous magnetisation of 13 cm^3 G mol^{-1} is observed, which corresponds to a canting angle φ_m = 0.03° for a two-sublattice model. This type of ordering can be caused by either single ion anisotropy or antisymmetric exchange coupling.[2] The former is a product of the interaction of spin–orbit coupling with a low-symmetry crystal field whilst the latter is also caused by spin–orbit coupling and is due to its modification of the exchange interaction. The weakness of spin–orbit coupling in octahedral high-spin Mn(II) means that canting is rare for this ion in comparison to those such as high-spin Co(II) which display large spin–orbit couplings. Both single-ion anisotropy and antisymmetric exchange have been invoked to account for the observed spin canting in Mn(II) phthalocyaninate[3] and $Mn(CO_3)$[4] respectively. Although the single ion anisotropy for Mn(II) is generally small[5] the distorted Mn environment (see below) and unusual yellow colour of this material are evidence for its existence. Regardless of the magnitude of any single ion anisotropy, the presence of crystallographic inversion centres in the solid state between hydroxy bridged manganese(II) ions means that the axes of anisotropy will be collinear. This precludes single-ion anisotropy as the source of spin canting, unless there is significant structural change accompanying the magnetic phase transition. Therefore it was important to obtain structural data at a temperature as close to the magnetic phase transition as possible. In order to follow possible structural changes during the magnetic phase transition, we collected single crystal X-ray data§ for **1** at 120, 40, 20 and 10 K (well below T_c) using an *Fddd* diffractometer.[6]

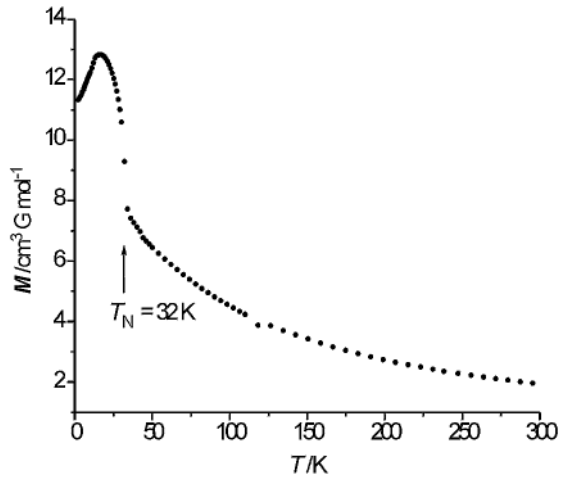

Fig. 1 The static magnetic susceptibility of a powdered sample of **1** in an applied field of 100 G in the temperature range 2 to 300 K.

† Electronic supplementary information (ESI) available: magnetic susceptibility measurement results; crystal data at various temperatures. See http://www.rsc.org/suppdata/cc/1999/1561

Squarate complexes of transition metals are well known, not least as materials with unusual magnetic and optoelectronic properties. The new interest in these compounds arose with the development of crystal engineering of organometallic compounds.[7] It was found that the structures of metal squarates contain a complex network of hydrogen bonds, usually there are channels in the structure, $C_2O_4^{2-}$ dianions form stacks and the coordination of the first row transition metals is close to octahedral with squarate ligands in mutually *trans* positions. Depending on the stoichiometry the squarate can be a terminal, μ- or μ_4- bridged ligand. In a recent review,[8] three types of aqua squarates were analyzed and their structural relationship was discussed.

The structure of **1** is remarkably different from those of the aqua squarates, which are chemically closely related to **1**. As in all previously known squarates of Mn the metal center has an octahedral coordination (Fig. 2), but in **1** the octahedron is severely distorted. The coordination mode is unusual: there are not two or four, but three μ-squarate ligands, which are not in the usual mutual *trans* positions but occupy the adjacent vertices (fac) of the octahedron. The squarate dianions occupy special positions in the center of symmetry and adopt the usual geometry for $C_4O_4^{2-}$ with delocalized C–C and C–O bonds and almost perfect D_{4h} symmetry. The slight difference in C–O bond lengths is the result of different crystal environments and bonding for O(1) and O(2). Indeed, atom O(1) is μ-bridged between two Mn atoms and O(2) is bonded to one Mn atom and accepts a hydrogen bond from the hydroxy group. Therefore each squarate dianion in structure **1** is connected to 6 metal atoms and is a μ_6-ligand. We are not aware of any other observations of such bonding of squarate anions.

In spite of the unusual coordination, the squarate anions in **1** maintain the usual tendency to form stacks. In **1** the stacks are formed along the short *a* axis and the distance between the planes of the anions is about 3.1 Å. The angle between the planes of the anions in adjacent stacks is 35.2°. The Mn(OH) chains are located between the stacks (Fig. 3).

As mentioned above, the aqua squarate complexes of transition metals usually have a number of hydrogen bonds. Complex **1** contains just one independent H atom and the cations and anions have to be linked together by Mn–O bonds.

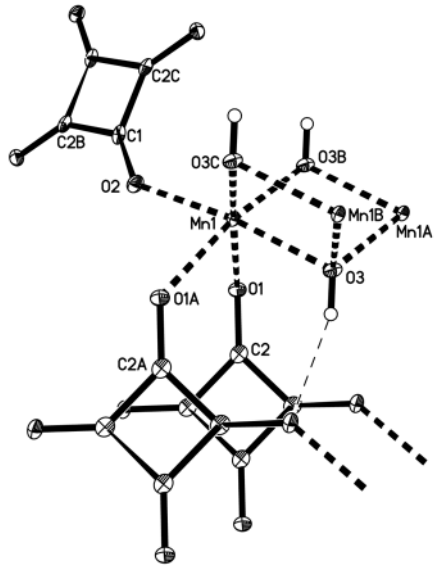

Fig. 2 Fragment of the crystal packing of **1** showing the coordination of the metal atom (thermal ellipsoids are at 70% probability level). Bond lengths (Å) at 10 K: Mn(1)–O(1) 2.3653(9), Mn(1)–O(1A) 2.264(1), Mn(1)–O(2) 2.1374(7), Mn(1)–O(3) 2.1820(7), Mn(1)–O(3B) 2.1132(9), Mn(1)–O(3C) 2.1297(8), O(1)–C(2) 1.2617(9), O(2)–C(1) 1.252(1), C(1)–C(2′) 1.467(1) and C(1)–C(2″) 1.468(1).

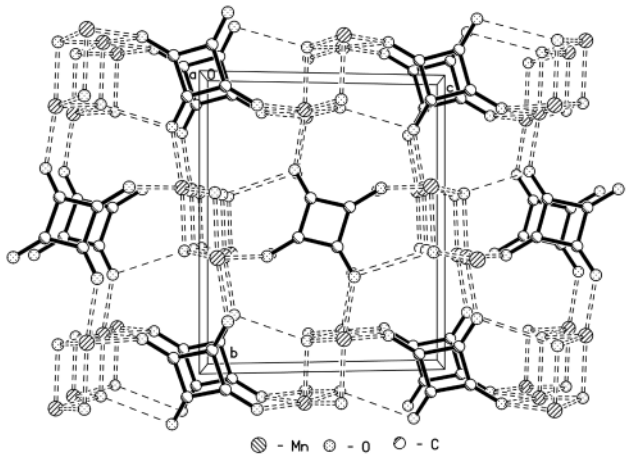

Fig. 3 Crystal packing of **1** (view along *a*). H-atoms omitted for clarity. Mn–O bonds are shown as double-dashed and H-bonds as single-dashed lines.

The only hydrogen bond in the structure links the hydroxy group with the O(2) carbonyl oxygen atom of the squarate anion. The result is a much closer crystal packing of **1** without substantial channels or cavities. This fact is probably the reason for the remarkable thermal behaviour of compound **1**: the crystal is virtually 'unshrinkable' from room temperature down to 10 K: in this range the unit cell volume changes from 295.5(1) to 292.9(1) Å^3—less than 1%.

At all temperatures studied the Mn–O, O–C and C–C distances are constant in the range 2–3σ. There is a slight tendency towards the contraction of the shortest Mn···Mn distance from 3.2055(6) Å at 120 K to 3.1974(6) Å at 10 K, and the Mn(1)–O3–Mn(1B) angle from 96.18(7)° to 95.72(2)°. These changes happen progressively across the whole range of temperatures studied and obviously are the result of thermal contraction rather than of a structural phase transition.

Since there is no apparent change in the symmetry of the crystallographic unit cell on passing through the magnetic phase transition, we can draw the conclusion that the source of the canting is an antisymmetric exchange interaction. Importantly this shows that **1** may be used as a model system in which the canting can unequivocally be ascribed to one type of anisotropy. Many of the types of magnetic behaviour which are the subject of considerable current interest, such as single molecule magnets, metamagnets and spin-flop phases, canted ferro- and antiferromagnets, are caused by different sources of anisotropy. Hence we hope that the title compound will provide an insight into antisymmetric exchange that can be used as a component in much-needed reliable magnetostructural correlations.

Financial support from EPSRC is gratefully acknowledged.

Topological control in coordination polymers by non-covalent forces

Gemma Guilera and Jonathan W. Steed*

Department of Chemistry, King's College London, Strand, London, UK WC2R 2LS. E-mail: jon.steed@kcl.ac.uk

Received (in Columbia, MO, USA) 20th April 1999, Accepted 23rd June 1999

Reaction of Zn^{2+} salts with the terephthalate dianion results in a herringbone motif coordination polymer; the orientation of the terephthalate spacer ligands and the coordination geometry about the Zn^{2+} ion is crucially dependent on hydrogen bonding to ancillary ligands; replacement of coordinated water with ethylenediamine results in marked changes to the polymer orientation without disruption of the fundamental features of the material.

A key objective in the emerging field of crystal engineering is the control and manipulation of weak interactions in order to tune the properties of the bulk material.[1–6] Potential applications of such studies include the preparation of new non-linear optical materials, design of porous solids with novel inclusion or reactivity properties (*e.g.* for use in separation science and heterogeneous catalysis, particularly in stereo- or enantiospecific synthesis) and new sensor materials and coatings.[7–11] The vast majority of current work centres around the controlled assembly of donor and acceptor building blocks (particularly involving hydrogen bond acid–base pairs, *e.g.* nucleobases[12]) in order to generate an entirely 'supramolecular polymer', *i.e.* a material held together solely by non-covalent interactions. While such systems can be remarkably robust,[12] such an approach is fundamentally limited by the intrinsic strength of the constituent interactions, which are markedly weaker than covalent or ionic bonds, although our recent work has focussed on the importance of such interactions.[13–16] With this in mind, we have begun a programme of research aimed at the construction of molecular coordination polymers of low dimensionality in which mechanical strength is imparted by strong coordinate bonds, while admitting scope for weaker, lateral interactions which might enable the material to be tuned in the same way as in more conventional crystal engineered solids. We now report the results of simple, proof of principle studies, which demonstrate how an inherently robust coordination polymeric framework may be manipulated by weak interactions.

In attempting to prepare coordination polymers we were struck by the utility of avoiding the need for counter anions which must *inter alia* disrupt the solid state packing and give rise to additional cation–anion interactions which might be difficult to control.[17] Accordingly we have chosen to examine the reactions of divalent metal cations with the terephthalate dianion, (tph^{2-}, **1**) in the expectation of generating a neutral polymeric material. We chose initially relatively labile Zn^{2+} (as nitrate or acetate salts) in the hope of generating reaction products under thermodynamic control. The structure of zinc acetate itself, $Zn(O_2CMe)_2{\cdot}2H_2O$, consists of two essentially bidentate acetate ligands and two water molecules engaging in intra- and intermolecular hydrogen bonding interactions.[18] We reasoned that replacement of acetate with terephthalate would result in an analogous structure consisting of both a polymer chain and ancillary aqua ligands which would exert additional control over the polymer geometry by means of strong hydrogen bonding interactions. Consistent with expectation, an excellent yield of crystalline material of stoichiometry $[Zn(tph)]{\cdot}2H_2O$ **2** was deposited within 24 h. This material was characterised by low temperature X-ray crystallography† (100 K) and proved to consist of the desired coordination polymer, Fig. 1. The compound consists of approximately tetrahedral

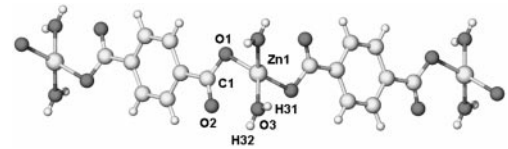

Fig. 1 XSeed[21] view of the coordination polymer $[Zn(H_2O)_2(\mu\text{-}O,O'\text{-}tph)]_\infty$ **2**. Selected bond lengths (Å): Zn(1)–O(1) 2.0049(15), Zn(1)–O(2) 2.5500(16), Zn(1)–O(3) 1.9855(18) Å.

Zn^{2+} centres linked by a herringbone pattern of tph^{2-} spacers aligned approximately along the crystallographic *a/c* diagonal. The tph ligands are essentially monodentate with Zn–O(1) 2.0049(15) Å, however the Zn–O(2) distance of 2.5500(16) Å suggests a non-negligible interaction with the uncoordinated oxygen, which may be described as a semi-chelating coordination mode.[19] The two water molecules within the coordination sphere of the metal cation engage in two distinct hydrogen bonded interactions, which, together, are responsible for the conformation of the polymer. In the crystallographic *b* direction, perpendicular to the direction of chain propagation, the metal cations stack precisely on top of one another and are linked in an eight membered hydrogen bonded ring [R_2^2 (8) in graph set notation[20]] involving the water hydrogen atom H31 attached to O3 and the coordinated oxygen atoms of the tph ligand, Fig 2(a). In addition, lateral hydrogen bonds involving the second unique water hydrogen atom H32 and the uncoordinated terephthalate oxygen atoms link one chain to those adjacent in R_2^2 (12) hydrogen bonded sets, Fig. 2(b). The aryl

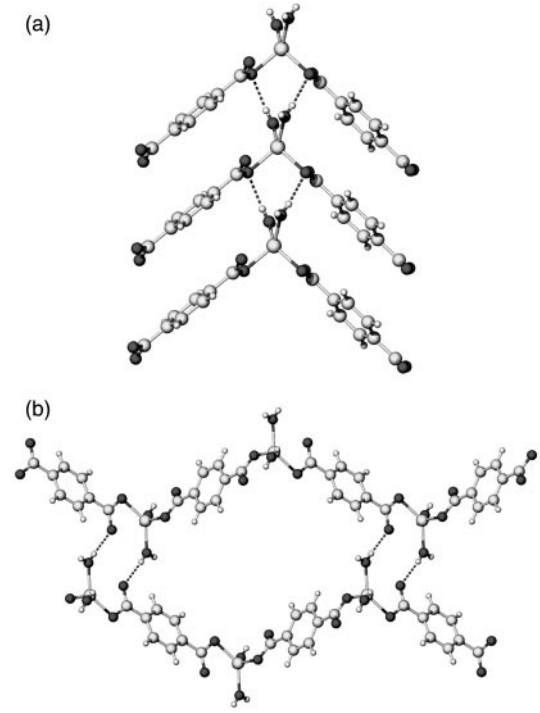

Fig. 2 (a) Stacking of $[Zn(H_2O)_2(\mu\text{-}O,O'\text{-}tph)]_\infty$ **2** in the *b* direction *via* R_2^2 (8) hydrogen bonded sets,[20] O···O 2.776(2) Å, (b) lateral R_2^2 (12) motifs which link one polymeric chain to those adjacent, O···O 2.699(3) Å.

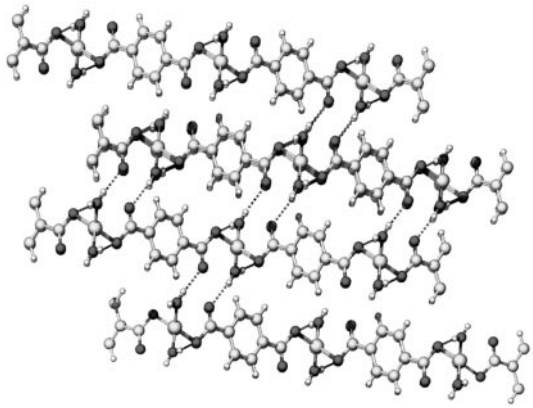

Fig. 3 Crystal packing in **2**.

rings of the tph ligands stack in an offset fashion perpendicular to the *b* direction, *ca.* 3.7 Å apart. The overall crystal packing is shown in Fig. 3.

Clearly the presence of two labile water molecules within the Zn^{2+} coordination sphere, playing only an indirect part in the polymeric chain, suggests that they might be replaced by other ligands with different hydrogen bonding characteristics. This should influence, *via* hydrogen bonding, the geometry of the coordination polymer. Hence we carried out the reaction of Zn^{2+} salts with Na_2tph in the presence of 1 equivalent of ethylenediamine (en). This resulted in the formation of an exactly analogous coordination polymer, $[Zn(en)(\mu\text{-O,O'-tph})]_\infty$ **3**, in which the two water molecules have been replaced by a single, chelating en ligand. Fascinatingly, the X-ray crystal structure of this material† reveals the same essential features of the coordination geometry and herringbone packing of the polymer observed in **2** despite the greatly different characteristics of the en ancillary ligand. As in **2**, the Zn^{2+} centres stack precisely along the crystallographic *b* direction. However, in **3** there is no possibility of the propagating R_2^2 (8) hydrogen bonded links because of the steric bulk of the ethylene spacer and this is reflected in the dramatic expansion of the crystallographic *b* axis from 5.00 to 7.25 Å. One of the amine protons on each donor atom is thus unable to take part in any hydrogen bonding. The NH_2 functions are, however, capable of engaging in lateral interactions from one chain to another in the same fashion as **2** to give twelve-membered hydrogen bonded rings, Fig. 4. The most obvious consequence of the reduction in inter-chain connectivity is the dramatic reorientation of the aryl groups of the tph ligands such that in **3** they are approximately parallel with the crystallographic *b* direction, as opposed to perpendicular, as in **2**. This has the curious consequence both of disrupting the π-stacking interactions seen for **2** *and* changing the coordination mode of the tph ligands from 'semi-chelating', to entirely unidentate, with a non-bonded Zn–O(2) distance of 2.931(3) Å, compared to 2.5500(16) Å in **2** and a shortening of the Zn–O(1) bond length to 1.947(3) Å. Since it is the non-coordinated tph oxygen atom O(2) which is involved as a hydrogen bond acceptor in both cases it is clear that the accommodation of the lateral hydrogen bonds plays a much more significant role in determining the overall structure than factors such as weak interactions of O(2) with the zinc centre and π-stacking.

The key to the future potential of this system clearly lies in the robustness of the one dimensional coordination polymeric chain and its ability to tolerate other ancillary ligands. In order to explore the phase space of the Zn^{2+}–tph^{2-} system a large variety of reactions between these two components were set up with mole ratios of 1 : 1 up to 1 : 4 in a range of solvents and with a range of Zn^{2+} salts. Compound **2** was formed in excellent yield in every case (as determined by solid state IR spectroscopy and measurement of unit cell dimensions) except for one occasion in which the reaction of hydrated zinc acetate with Na_2(tph) in water in a 1 : 1 ratio gave a mixture of **2** and a further product of formula $[Zn(H_2O)(tph)]_\infty$ **4**. Compound **4** is a highly cross-linked polymer involving coordination of all four tph oxygen atoms, each to a different trigonal bipyramidal Zn^{2+} centre (aqua ligand equatorial). The structure is based on a ladder arrangement of puckered eight-membered $Zn_2O_4C_2$ rings. Thermogravimetric analysis of **2** indicates stepwise loss of the two aqua ligands at 168 and 192 °C, respectively, suggesting the possible conversion of **2** into **4**. Full details of this system will be reported fully in a separate paper.

We thank the EPSRC and King's College London for funding of the diffractometer system and the Nuffield Foundation for the provision of computing equipment. Grateful acknowledgement is also given to the ULIRS Thermochemistry service at UCL.

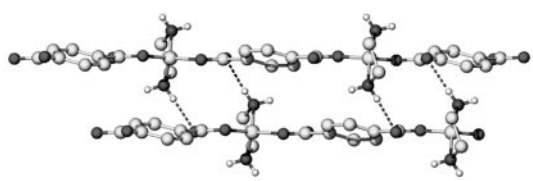

Fig. 4 Lateral R_2^2 (12) motifs in $[Zn(en)(\mu\text{-O,O'-tph})]_\infty$ **3**, N···O 2.984(5) Å (CH hydrogen atoms omitted for clarity). Note the second NH proton does not take part in any hydrogen bonds.

Spectra and temperature dependent decay rates of emission from $[Mn(15\text{-crown-}5)(H_2O)_2]^{2+}$ ions anchored by a network of O–H···Br···H–O bonds in two- and one-dimensional supramolecular arrays of $\{[Mn(15\text{-crown-}5)(H_2O)_2][TlBr_5]\}_n$ 1 and $\{[Mn(15\text{-crown-}5)(H_2O)_2]Br_2\}_n$ 2 demonstrate the potential efficacy of manganese(II) ions as luminescent probes for supramolecular dynamics.

The good response of the manganese(II) $^4T_1(^4G)$ state to changing ligand field strength and symmetry as well as the high sensitivity of luminescence techniques, such as time resolved luminescence spectroscopy, make the $Mn^{2+}[^4T_1(^4G)\rightarrow{}^6A_1]$ emission attractive as a potential diagnostic tool for coordination characteristics of divalent metal ions.[1,2] Besides classical four- and six-coordinate oxide and halide species,[3] $Mn^{2+}[^4T_1(^4G)\rightarrow{}^6A_1]$ emission was recently shown to occur in well defined seven- and eight-coordinate environments[4] thereby expanding the range of Mn^{2+} coordination environments accessible by luminescence techniques. Herein we demonstrate the diagnostic efficacy of the $Mn^{2+}[^4T_1(^4G)\rightarrow{}^6A_1]$ emission by probing the behaviour of coordinated H_2O in response to thermal tuning of the structural rigidity of $[Mn(15\text{-crown-}5)(OH_2)_2]^{2+}$ cations anchored in two- and one-dimensional supramolecular arrays of $\{[Mn(15\text{-crown-}5)(H_2O)_2][TlBr_5]\}_n$ **1**[4] and $\{[Mn(15\text{-crown-}5)(H_2O)_2]Br_2\}_n$ **2**.[5]

Compounds **1**[4] and **2**[5] were prepared as described previously, whilst compound **3** was obtained by a procedure similar to that used for **2** but with D_2O and CH_3OD replacing H_2O and CH_3OH respectively. X-Ray analysis‡ shows compound **1** to be composed of two-dimensional corrugated sheets of $[TlBr_5]^{2-}$ anions and $[Mn(15\text{-crown-}5)(OH_2)_2]^{2+}$ cations cross-linked *via* O–H···Br hydrogen bonds (Fig. 1). The symmetry at the seven-coordinate manganese centre is crystallographically imposed C_{2h} with the two symmetry related aqua ligands lying on the mirror plane. The 15-crown-5 component is disordered, having four resolved symmetry-imposed partially overlapping orientations. The $[TlBr_5]^{2-}$ dianion has crystallographic C_{2v} symmetry, adopting a slightly distorted trigonal bipyramidal geometry; the equatorial Tl–Br bonds subtend angles of 116.43(5), 116.43(5) and 127.15(10)° and the axial bonds an angle of 175.36(9)°, and there is a very marked asymmetry between the axial [2.883(2) Å] and the equatorial [2.540(2) and 2.552(3) Å] bond lengths. The anion geometry observed here {the first reported structural characterisation of $[TlBr_5]^{2-}$} differs markedly from that observed in the only two reported examples of the closely related anion $[TlCl_5]^{2-}$, both of which are slightly distorted square pyramidal with only small asymmetries in the bond lengths.[6] A $[Br\cdots TlBr_4]^{2-}$ species was reported recently.[7]

In contrast, the structure of **2** comprises one-dimensional chains of $[Mn(15\text{-crown-}5)(OH_2)_2]^{2+}$ cations linked by pairs of O–H···Br hydrogen bonds to the Br^- anions.[5]

In the light of these structural results, it was interesting to determine if this difference in structural rigidity would translate into contrasts in the ability of H_2O to quench $Mn^{2+}[^4T_1(^4G)\rightarrow{}^6A_1]$ emission from the $[Mn(15\text{-crown-}5)(H_2O)_2]^{2+}$ cations of **1** and **2**. The excitation and luminescence spectra of dihydrates **1** and **2** were too weak to measure reliably on the LS5B spectrometer.§ We thus sought to prepare deuterates of **1** and **2**, namely $[Mn(15\text{-crown-}5)(D_2O)_2][TlBr_5]$ and $[Mn(15\text{-crown-}5)(D_2O)_2]Br_2$, since D_2O vibrations are much less effective quenchers. However, impracticably large amounts of the CH_3OD–CH_2Cl_2 mixed solvent system were required for the deuteration of **1** and thus its synthesis was abandoned. Crystals of $[Mn(15\text{-crown-}5)(D_2O)_2]Br_2$ **3** are readily prepared and upon microscopic examination were found to have a morphology similar to that of **2**. The emission and excitation spectra of seven-coordinate manganese(II) in $[Mn(15\text{-crown-}5)(D_2O)_2]^{2+}$ are shown in Fig. 2(b). These are the first pure spectra for seven-coordinate Mn^{2+}; the excitation spectrum reported in ref. 4 is contaminated by transitions of the sensitizing $MnBr_4^{2-}$ anion.

Comparison of the spectra of $[Mn(15\text{-crown-}5)(D_2O)_2]^{2+}$ [Fig. 2(b)], $[Mn(12\text{-crown-}4)_2]^{2+}$ [Fig. 2(c)], classical $[MnBr_4]^{2-}$ [Fig. 2(d)], $[MnBr_3]^-$ [Fig. 2(a)] and the previously reported[8] absorption spectrum of species $[MnBr(Me_6tren)]^+$ reveals major variations in emission and excitation/absorption spectral profiles for Mn^{2+} ions in coordination numbers 7, 8, 4, 6 and 5 respectively. Luminescence techniques may thus be informative in probing such common Mn^{2+} coordination sites[9] in a wide range of materials including phosphors,[3] polymers,[10] industrial minerals,[11] biomolecules and potential MRI contrast agents for which the behaviour of the Mn–OH_2 linkage is crucial.[12]

To establish whether the decay rates of $Mn^{2+}[^4T_1(^4G)\rightarrow{}^6A_1]$ emission from the seven-coordinate Mn(II) centre in [Mn(15-

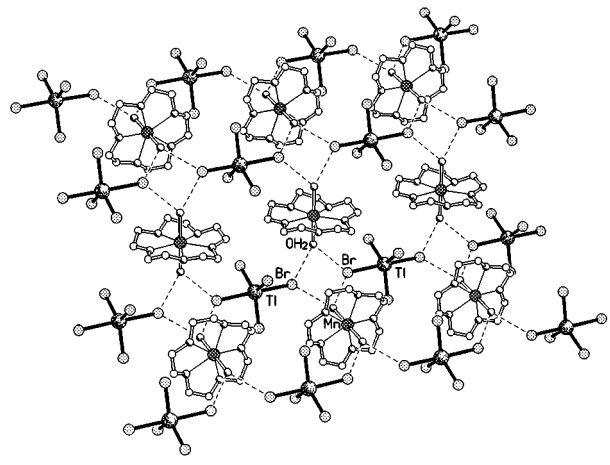

Fig. 1 Part of one of the corrugated hydrogen bonded sheets of $[TlBr_5]^{2-}$ anions and $[Mn(15\text{-crown-}5)(H_2O)_2]^{2+}$ cations in the structure of **1**. The O···Br distances are all 3.25 Å.

crown-5)$(H_2O)_2]^{2+}$ are sensitive enough to allow the detection of dynamic supramolecular lattice events we compared the luminescence decay dynamics of compounds **1**–**3**. The absorption energy of the broad $Mn^{2+}[^4T_1(^4G)\leftarrow{}^6A_1]$ transition ($\lambda_{max} \approx 520$ nm) of [Mn(15-crown-5)$(H_2O)_2]^{2+}$ [Fig. 2(b)] overlaps well with the second harmonic of Nd:YAG lasers (532 nm). Our powerful Nd:YAG laser§ was thus used to directly excite the $Mn^{2+}[^4T_1(^4G)]$ energy level in complexes **1**–**3**; a broad emission centered at *ca.* 590 nm [Fig. 2(b)] was observed in each case. The temperature dependence (10–320 K)§ of this emission revealed remarkable similarities between the behaviour of the more rigid two-dimensional hydrate **1** and that of the one-dimensional deuterate **3**, with both of these differing dramatically from the behaviour of the one-dimensional hydrate **2**. For $T < 100$ K, compounds **1** and **3** exhibit similar double exponential luminescence decay kinetics with a common minor short-lived temperature independent emission (component A) decaying at *ca.* 1×10^3 s^{-1}. The major emission comes from a marginally temperature dependent and much longer-lived component (decay rate is *ca.* 7×10 s^{-1} at 10 K) with phonon type thermal barriers of *ca.* 2.1×10^2 and 2.7×10^2 cm^{-1} for **1** and **3** respectively. By sharp contrast, compound **2** exhibits temperature independent perfectly double exponential decay behaviour for $T < 160$ K. Besides the common minor component A (decay rate *ca.* 1.1×10^3 s^{-1}), compound **2** features a major very short-lived emission (decay rate *ca.* 7.0×10^3 s^{-1}).

These observations we believe can be rationalised as follows: the sharply contrasting behaviour between the two one-dimensional compounds **2** and **3** is due to the more efficient quenching of the $Mn^{2+}[^4T_1(^4G)\rightarrow{}^6A_1]$ emission by H_2O in **2** compared to the weak quenching action of D_2O in **3**. The similarity of the behaviour of **1** and **3** however, can be explained by considering the rigidity of the two-dimensional O–H···Br···H–O bonds in **1** which hinders the vibrational motions of the coordinated H_2O molecules of [Mn(15-crown-5)$(H_2O)_2]^{2+}$. At low temperature vibrational restrictions in **1** appear to be so severe that the normal quenching effect of the aqua ligands is stopped and hence the similarity in the decay behaviour of hydrate **1** and deuterate **3**. The thermal barrier of *ca.* 210 cm^{-1} is in this case the energy needed to distort the lattice of **1** and allow some vibrational freedom for the H_2O molecules which triggers quenching of the $Mn^{2+}[^4T_1(^4G)\rightarrow{}^6A_1]$ emission by those coordinated H_2O molecules. To our knowledge, this is the first example of thermal tuning of the luminescence quenching action of H_2O molecules, in particular, one in which supramolecular manipulations are employed.

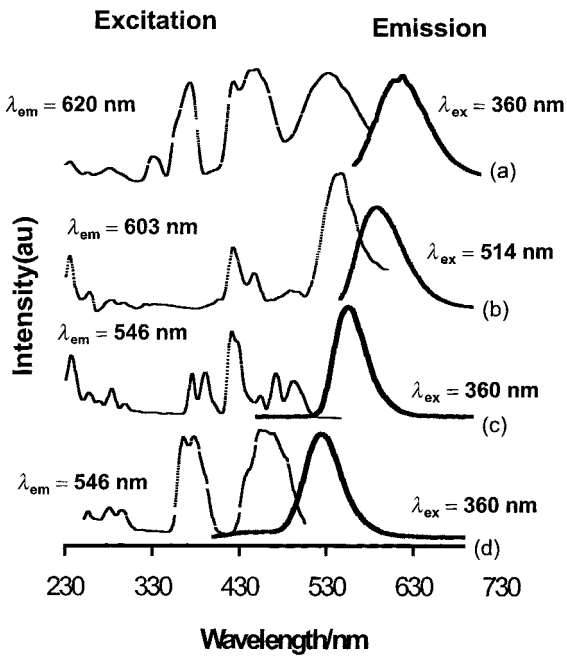

Fig. 2 Excitation and emission spectra of manganese(II) in (T_d = delay time; T_g = gating time): (a) six-coordination, $[NMe_4][MnBr_3]$ (293 K; T_d = 1.00 ms, T_g = 1.00 ms); (b) seven-coordination, $[\{Mn(15\text{-crown-}5)(D_2O)_2\}Br_2]_n$ **3** (77 K; T_d = 0.01 ms, T_g = 5.00 ms); (c) eight-coordination, $[Mn(12\text{-crown-}4)_2][NMe_4]_2[MnBr_4]_x[ZnBr_4]_{2-x}$ (77 K; T_d = 12.0 ms, T_g = 0.5 ms); (d) four-coordination, $[NMe_4]_2[MnBr_4]$ (293 K; T_d = 1.00 ms, T_g = 1.00 ms).

We thank the University of the West Indies (UWI) for a demonstratorship to HONR and the Inter-American Development Bank-UWI development programme (R&D Project #29) for funds used to purchase the powerful Nd:YAG laser and the helium refrigerator. We also thank the TMRU (UWI) for use of the LS5B luminescence spectrometer and Mr S. Logan for help with setting up the laser induced luminescence facilities.

‡ *Crystal data*: **1**: $[C_{10}H_{24}O_7Mn][TlBr_5]$, M = 915.2, orthorhombic, space group *Pmma* (no. 51), a = 15.879(3), b = 10.122(3), c = 7.109(1) Å, V = 1142.5(5) Å^3, Z = 2 (the cation and anion have crystallographic C_{2h} and C_{2v} symmetries respectively), D_c = 2.660 g cm^{-3}, μ(Mo-Kα) = 163.6 cm^{-1}, $F(000)$ = 842, T = 293 K; yellow blocks, 0.40 × 0.33 × 0.30 mm, Siemens P4/PC diffractometer, ω-scans, 1102 independent reflections. The structure was solved by direct methods and, because of the severe disorder (see text) only the oxygen atom of the aqua ligand and the manganese, thallium and bromine atoms were refined anisotropically using full matrix least squares based on F^2 to give R_1 = 0.054, wR_2 = 0.132 for 850 independent observed absorption corrected reflections [$|F_o| > 4\sigma(|F_o|)$, $2\theta \leqslant 50°$] and 92 parameters. Full structural details of compound **2** will be reported elsewhere.[5] CCDC 182/1305. See http://www.rsc.org/suppdata/cc/1999/1565/ for crystallographic files in .cif format.

§ Luminescence and excitation spectra were recorded using a LS5B Perkin Elmer Fluorescence spectrometer that is essentially similar to the one described earlier.[13] The luminescence decay rates were measured using a Continuum Powerlite 8000 YAG laser and an electronic and computational set up which was described previously.[13] The Powerlite 8000 YAG laser generates *ca.* 600 mJ pulses (5–8 ns) of the second harmonic at 532 nm but minimum light intensities required to obtain decay curves of satisfactory signal:noise ratios were used. Variable temperature measurements (8–320 K) were done using an APD Cryogenics Inc. CSW-202 Displex helium refrigerator system with the sample in contact with cryocon conducting grease.

Received (in Oxford, UK) 14th May 1999, Accepted 23rd June 1999

The reorganisation energy associated with the end groups may be used to influence the localisation behaviour of cyanines; thus, the 1,3-bis(ruthenocenyl)allylium cation is markedly unsymmetrical in the crystal structure of its hexafluorophosphate salt, with the positive charge localised on one ruthenium, whereas the analogous iron species is delocalised and has approximate C_5 symmetry.

Concepts of resonance lead to the expectation that typical polymethine cations or anions (cyanines) should have symmetrical structures, intermediate between two unsymmetrical extreme resonance structures [Figure 1(a)]. Numerous reported crystal structures[1] confirm that typical cyanines are indeed symmetrical delocalised systems with equalised C–C bond lengths. However, extrapolation of the properties of a typical cyanine to infinite chain length[2] affords a one-dimensional zero-band-gap material, which should be subject to a Peierls distortion.[3] If the end groups can stabilise the overall positive or negative charge, this distortion is predicted to result in a bond-alternated structure resembling *one* of the extreme structures in Fig. 1(a); the two structures are now related by an equilibrium arrow.[4–7] To date the only experimental evidence for a Peierls-distorted cyanine is for the compound shown in Fig. 1(b); the solution structure was shown to be unsymmetrical by comparison of its IR and UV–VIS–NIR spectra with those of symmetrical delocalized shorter chain homologues.[8]

Although previous studies have distinguished between end groups which stabilise the overall charge and those which do not,[7] the possibility of different charge-stabilising end groups controlling the length at which localisation occurs does not seem to have been discussed in detail. It has been noted[8,9] that Peierls-distorted cyanines are analogous to class II mixed-valence compounds, whilst typical cyanines are analogous to class III species. The placement of a compound in the Robin and Day classification[10] depends on the interplay of the electronic coupling between the two extreme localised structures, V, and the vertical reorganisation energy of Marcus theory, λ.[11] In a polymethine, V will be influenced by the length and planarity of the polymethine chain, whilst λ will have contributions from interconverting the end groups (for example: the Me_2N^+= and Me_2N– geometries in a cyanine such as that in Fig. 1(a); analogous to the Ru^{II} and Ru^{III} coordination geometries in the mixed-valence Creutz–Taube ion[11]), as well as from the polymethine bridge itself, where the sense of the bond-length alternation must be inverted. In a typical cyanine, the end group effect is limited to changing a few bond lengths. We chose to investigate the Group 8 metallocenes as end groups with potentially different reorganisation energy characteristics: a carbocation α to a metallocene is stabilised through resonance contributions from the [(η^6-fulvene)(η^5-cyclopentadienyl)-metal] cation,[12] which has significantly different geometry from the parent metallocene,[13] especially when the metal is ruthenium[14] or osmium.[15]

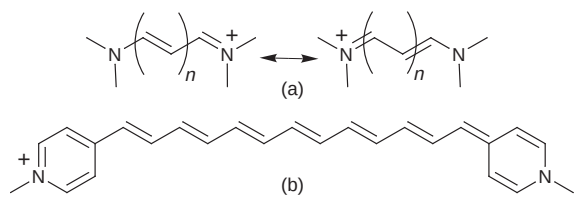

Fig. 1 Representations of (a) the extreme unsymmetrical resonance structures for a typical cyanine and (b) the Peierls-distorted cyanine reported by Tolbert and Zhao.[8]

We synthesised a range of 1,3-bis(metallocenyl)allylium salts, $[Mc(CH)_3Mc']^+[X]^-$ {Mc = Mc′ = ferrocenyl (Fc), **1**; Mc = Mc′ = 2,3,4,5,1,2,3,4-octamethyl-1-ferrocen-1-yl (Fc″), **2**; Mc = Mc′ = ruthenocenyl (Rc), **3**; Mc = Fc, Mc′ = Rc, **4**; X = PF_6, **a**; X = BF_4, **b**}. Single crystal X-ray diffraction showed the cations in **1a**‡ and **2a**[16] to be essentially symmetrical with equalised C–C bonds in the allylium bridges, as might be expected by analogy with the previously described structure of closely related cyclopentadienyl(1,3-diferrocenyl-1-ylium-pentalenyl)iron tetrafluoroborate.[17] In contrast, we found the structure of **3a**‡ to be much less symmetrical (Fig. 2), although the packing diagrams for **1a** and **3a** are rather similar. The structural parameters for the Ru1 ruthenocene are similar to those for previously reported examples of ruthenocene-stabilised carbocations; *i.e.* it is essentially fully distorted to an [(η^6-fulvene)(η^5-cyclopentadienyl)ruthenium] cation structure. Thus, the Ru1–C11 bond length of 2.381(3) Å may be compared with 2.270(3) Å for the corresponding distance in $[Cp^*Ru(\eta^6\text{-}C_5Me_4CH_2)]^+[BPh_4]^-\cdot CH_2Cl_2$ **5**;[14] similarly the Ru1–C_{ring} distances fall in the range 2.089(2)–2.234(2) Å, whilst those for **5** fall in the range 2.066(3)–2.274(3) Å. In the $[Rc(CH)_3Rc]^+$ cation of **3a**, the α-carbon C11 is bent towards Ru1 such that the C10–C11 bond makes an angle of 38.2° with the C6–10 plane; the corresponding angle in **5** is 40.4°. The dimensions of the Ru2 ruthenocene are typical for a 'normal' ruthenocene; thus, the Ru2–C_{ring} distances for **3a** fall in the range 2.167(2)–2.194(3) Å, whilst those for *E*-1,2-dimethyl-1,2-diruthenocenylethylene[18] and ruthenocene itself[19] fall in the

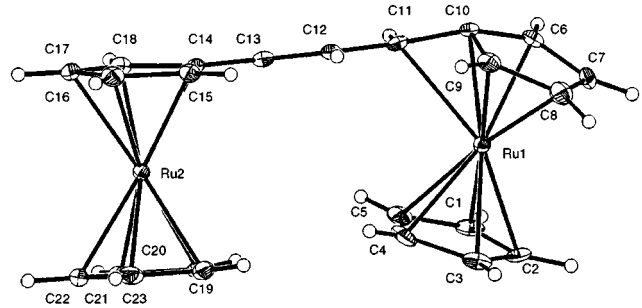

Fig. 2 View of the $[Rc(CH)_3Rc]^+$ cation in the crystal structure of its hexafluorophosphate salt, **3a**, showing the atomic numbering scheme; non-hydrogen atoms are represented by 50% thermal ellipsoids, whilst hydrogen atoms are shown as spheres of arbitrary radius.

† Present address: Inorganic Chemistry Laboratory, University of Oxford, South Parks Road, Oxford, UK OX1 3QR.

ranges 2.171(3)–2.216(3) and 2.181(2)–2.188(2) Å respectively. The α-carbon, C13, is *not* bent towards Ru2 and the Ru2–C13 distance is 3.237(3) Å. The structure of **3a** also shows considerable bond length alternation in the allylium bridge; the C(11)–C(12) bond length is 1.443(4) Å, whilst the C(12)–C(13) bond length is 1.343(4) Å.[20]

The structure of **3a** is the first crystal structure of a nominally symmetrical cyanine adopting an unsymmetrical bond-alternated structure. Indeed, the only previously reported Peierls-distorted cyanine is the much longer species shown in Fig. 1(b). One question that now arises is whether the unsymmetrical structure of the cation in **3a** is due to solid-state (crystal-packing) effects. However, *all* previous cyanine structures *are* symmetrical, despite a great variety of counterions and packing motifs. Moreover, the similarity in the packing of **1a** and **3a** suggests the differences in molecular structure are due to internal electronic, rather than external crystal-packing, effects.[21] We believe that the origin of these electronic effects is the larger reorganisation energy of the ruthenium system; the structural differences between ruthenocene and [(η^6-fulvene)-(η^5-cyclopentadienyl)ruthenium] cation are much greater than for the analogous iron species. To further investigate this question we studied the **3** cation in solution.[22] Symmetrical and unsymmetrical forms of cyanines are expected to have vibrational modes of different energies; calculations support this expectation for $[NH_2(CH)_nNH_2]^+$ (n = 19, 25).[23] The differences should be most readily detected in the stretches associated with the multiple bonding of the polymethine bridge. **3a** (1609 cm^{-1} in KBr, 1598 cm^{-1} in CH_2Cl_2) and **3b** (1603 cm^{-1} in KBr, 1603 cm^{-1} in CH_2Cl_2) both show a strong IR band which we assign to the multiple bond stretch; neither ruthenocene nor [(η^6-fulvene)(η^5-cyclopentadienyl)ruthenium] cations[24] show absorptions in the same region. The same band is also present in Raman spectra (1609 and 1601 cm^{-1} for **3a** in KBr and CH_2Cl_2, respectively). The insensitivity of the band to the counter ion, or the medium, implies that the structure of the **3** cation is the same in crystals of both its tetrafluoroborate and hexafluorophosphate salts, and in CH_2Cl_2 solution. Moreover, the IR evidence implies that the structure of the **3** cation most closely resembles that of the **4** cation (1598 cm^{-1} in KBr for **4a**), which is unsymmetrical both formally and electronically (according to ^1H–^1H coupling constants), and is somewhat different from those of the **1** (1558 and 1558 cm^{-1} for **1a** in KBr and CH_2Cl_2 respectively) and **2** (1538 and 1542 cm^{-1} for **2a** in KBr and CH_2Cl_2 respectively) cations (which have been shown to be symmetrical in the crystal structures of their hexafluorophosphate salts).

In conclusion, we believe that the large reorganisation energy associated with the ruthenocene / [(η^6-fulvene)(η^5-cyclopentadienyl)ruthenium] system has enabled us to characterise a bond-alternated cyanine at an unprecedentedly short chain length. We have presented the first crystal structure of a Peierls-distorted bond-alternated cyanine; vibrational spectroscopy suggests the cyanine is also unsymmetrical in solution. Control of the reorganisation energy in this way may be a useful design principle for the synthesis of other charge-localised cyanines, which have potential optical and electronic applications.

Support from the National Science Foundation and Air Force Office of Scientific Research (AFOSR) at Caltech is gratefully acknowledged. The research described in this paper was performed in part by the Jet Propulsion Laboratory (JPL) California Institute of Technology, as part of its Center for Space Microelectronics Technology and was supported by the Ballistic Missile Defense Initiative Organization, Innovative Science and Technology Office through an agreement with the National Aeronautics and Space Administration (NASA). We thank Kenneth Calgren for his assistance with Raman measurements and Dr Paul Roussel for assistance with low temperature NMR experiments.

Notes and references

‡ Single crystals of **1a** and **3a** were grown by layering dichloromethane solutions with diethyl ether. Diffraction data were acquired at 85 K using an Enraf-Nonius CAD-4 diffractometer, employing Mo-Kα radiation (0.71073 Å). Structures were solved by direct methods using SHELXS97;[25] full-matrix least-squares refinement on F^2 against all reflections was carried out using SHELXL97.[25]

Crystal data: for **1a**, $C_{23}H_{21}F_6Fe_2P$, M = 554.07, orthorhombic, a = 14.420(3), b = 12.267(2), c = 24.062(5) Å, V = 4256.3(14) $Å^3$, space group *Pbcn*, Z = 8, μ = 1.499 mm^{-1}, 9150 reflections measured, 3752 unique (R_{int} = 0.034); the final R indices (for all data) were $R1$ = 0.101 and $wR2$ = 0.1327. Fourier maps revealed disorder, whereby there is a minor alternative orientation of the cation related to the major orienation by rotation about an axis perpendicular to the plane of the bridging group and passing through the central atom of the bridge. However, this could not be satisfactorily modelled and is, therefore, not included in the reported structure.

For **3a**; $C_{23}H_{21}F_6PRu_2$, M = 644.51, monoclinic, a = 26.409(6), b = 15.004(3), c = 11.970(3) Å, β = 113.83(2)°, V = 4338.6(17) $Å^3$, space group $C2/c$, Z = 4, μ = 1.526 mm^{-1}, 10256 reflections measured, 3818 unique (R_{int} = 0.014); the final R indices (for all data) were $R1$ = 0.0238 and $wR2$ = 0.0491.

20 The bond length alternation in **1a** is insignificant, although the large values for the appropriate bond lengths [1.469(10) and 1.461(10) Å] are artefacts of unmodelled disorder in the structure.
21 The inherently unsymmetrical **4a** is isomorphous with **3a**.[16]
22 The **3** cation appears symmetrical on the NMR timescale at room temperature [as does the cation shown in Fig. 1(b)]; low temperature studies (to –85 °C, 500 MHz for ^1H and 125 MHz for ^{13}C) also give no unambiguous evidence for localisation. UV–VIS solvatochromism studies are also inconclusive; symmetrical **1** and **2**, and unsymmetrical **4** all show similar behaviour to **3**.

Received (in Cambridge, UK) 16th June 1999, Accepted 8th July 1999

Synthesised from its homonuclear components in the presence of the Lewis base TMEDA, the title heteronuclear alkoxide crystallises in an unsolvated TMEDA-free form; its novel breastplate-like $Li_4K_4O_8$ cage structure, which undergoes an exchange process in arene solution as determined by dynamic NMR spectroscopic studies, displays a planar K_4 arrangement in marked contrast to the tetrahedral K_4 arrangement found in homonuclear $[(Bu^tOK)_4]$.

The chemistry of metal alkoxides has gained greater significance in recent years primarily because of the demand for technologically important oxide materials: metal alkoxides serve as excellent precursors to oxide-based electronic and ceramic materials by sol–gel and MOCVD processes.[1,2] Group 1 alkoxides command additional attention due to their role in two-component 'superbases',[3] epitomised by 'BuLi·Bu^{t}OK', which are utilised widely in synthetic chemistry. As part of our continuing development of hetero-s-block metal chemistry, we have a particular interest in synthesising alkoxides that contain a mixture of Group 1 metals. Having recently reported the octalithium–dipotassium mixed oxide–alkoxide $[(Bu^tOLi)_6(Bu^tOK)_2(Li_2O)\cdot 2TMEDA]$,[4] the cage structure of which is built around an O^{2-} core, we subsequently directed our efforts towards synthesising a pure, oxide-free, analogue. These studies have afforded the new solvent-free heterometallic tetralithium–tetrapotassium alkoxide, $[(Bu^tO)_8Li_4K_4]$, **1**. Herein we report its synthesis, novel molecular structure, and dynamic NMR spectral data in arene solution.

Whilst many bimetallic alkoxides containing an alkali metal in combination with a less electropositive (p- or d-block) metal have been synthesised by direct reaction of the component homonuclear alkoxides,[5] this strategy has not been used previously as an entry into mixed alkali metal alkoxides. We have found it to be successful here for the synthesis of **1**. To elaborate, in a Schlenk tube under an argon atmosphere, a mixture of Bu^{t}OLi (4 mmol) and Bu^{t}OK (2 mmol) in toluene (5 ml) solution was heated to 70–80 °C for 20 min. On cooling to room temperature, the solution was treated with dried TMEDA (4 mmol) and stirred for 2 h. All solvent was then removed *in vacuo* to leave an oily pale yellow residue. Almost complete dissolution was achieved by the subsequent addition of hexane (5 ml). After filtering, the resulting solution was cooled to −26 °C for 48 h, at which time colourless crystals of **1** were obtained (yield, based on consumption of Bu^{t}OK, 65%). These crystals can be distinguished from their homonuclear components by a simple melting point analysis (*i.e.*, 242 °C, *cf.*, Bu^{t}OLi, decomp. > 250 °C;[6] Bu^{t}OK, 256–258 °C[7]). The synthesis of **1** proved reproducible on changing the Bu^{t}OLi: Bu^{t}OK reaction stoichiometry to 1 : 1 to match that found in the crystal. It is noteworthy that no TMEDA is present in **1** even though it was available in the reaction mixture. This contrasts with the situation encountered in the aforementioned $[(Bu^tOLi)_6(Bu^tOK)_2(Li_2O)\cdot 2TMEDA]$, and its rubidium relative $[\{(Bu^tOLi)_5(Bu^tORb)_4(Li_2O_2)\cdot 2TMEDA\}_\infty]$.[8] The compositions and structures of these solvates are presumably largely dictated by the templating action of their core dianion, O^{2-} or O_2^{2-}. An alternative structure building principle must operate in the absence of such templates; hence it is no surprise that the metal stoichiometry in **1** (4Li : 4K) is very different to that in the mixed-anion alkoxides (8Li : 2K or 7Li : 4Rb). Why such oxygen-based contaminants, and different ones at that, appear in the TMEDA solvates but not in **1** when the same routine 'inert-atmosphere' conditions were used in all three cases is not clear at present. Less efficient drying and degassing, leading to adventitious moisture or oxygen participation, is an obvious possibility, but more complex chemistry may be at work. In this regard, it is germane to note that the formation of another heterometallic oxo-alkoxide of potassium, $[(Pr^iO)_{10}(O)K_4Zr_2]$,[9] is thought to involve C–O bond scission from Pr^{i}OM units.

Possessing exact crystallographic C_s (*m*) symmetry, the molecular structure of **1**† (Fig. 1) displays a distinctive breastplate-like, sixteen vertex $Li_4K_4O_8$ core (Fig. 2). The crystallographic mirror plane runs through Li(1), Li(2), O(1), O(2), O(3), O(4) in the body of the cage, and C(1), C(4), C(7),

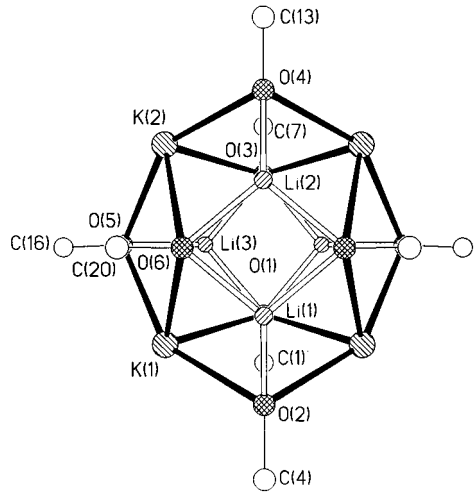

Fig. 1 Molecular structure of **1** with unique atoms labelled (not methyl C). Hydrogen atoms and methyl C atoms have been omitted for clarity. Bonds to K are filled, to Li hollow, to C single line.

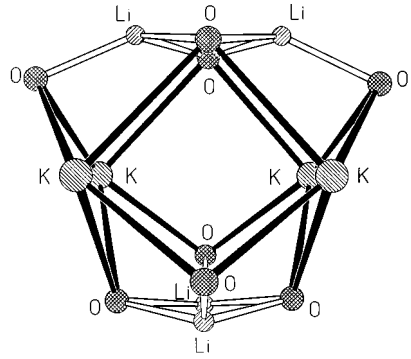

Fig. 2 Sixteen-vertex $O_8Li_4K_4$ 'breastplate' core of **1**.

C(10) outside the body. The molecular symmetry is essentially D_{2d} (42*m*), with Fig. 1 viewed along the S_4 axis. There are 14 MOMO faces: 8(LiOKO), 4$(KO)_2$ and 2$(LiO)_2$ types. The Li(3)O(1)Li(3A)O(3) 'neck' and Li(1)O(6)Li(2)O(6A) 'waist' rings lie almost orthogonal to each other. A plane of $4K^+$ cations occupies the 'midriff' position. These large cations form the apex of tetragonal pyramidal KO_4 coordination polyhedra. The smaller Li^+ cations form the apex of trigonal pyramidal LiO_3 coordination polyhedra. Half of the O centres [O(2)O(4), O(5)O(5A)] coordinate to 3 metal cations (1Li/2K), while the other half [O(1)O(3), O(6)O(6A)] coordinate to 4 metal cations (2Li/2K). The alkyl foliage completes the structure.

Intriguingly, whilst **1** is formally a 1:1 stoichiometric composite of lithium *tert*-butoxide and potassium *tert*-butoxide, it has a unique structure not made from contiguous fragments of the homonuclear structures $[(Bu^tOLi)_6]$[10] and $[(Bu^tOK)_4]$.[7] From a comparison with the homonuclear structures the major reorganisation behind the heterometallic construction has taken place at the 'softer' K^+ centres. First, together they make up a K_4 plane. Second, they occupy the higher (four) coordinate sites which are organised asymmetrically in two short and two long K–O bonds (mean values: 2.463 Å and 2.815 Å, respectively). This contrasts markedly with the tetrahedral K_4 arrangement and symmetrical μ_3-K–O bonding (mean length, 2.623 Å) found in the cubane $[(Bu^tOK)_4]$. Furthermore, there are no planar $(KO)_n$ rings in **1** like those observed in other cocomplexes of potassium *tert*-butoxide such as $[\{(cyNLi)_3Sb\}_2(Bu^tOK)_3{\cdot}x$-(toluene)][11] or $[\{[PhN(H)]_2(Bu^tO)LiNaK{\cdot}(TMEDA)_2\}_2]$.[12] There has been only one previous report of a planar K_4 substructure in the aforementioned $[(Pr^iO)_{10}(O)K_4Zr_2]$,[9] but this is not strictly analogous as here the four cations are fixed in place by an O^{2-} ligand at its centre. Contrary to the situation for K^+, the Li^+ cations have not had to compromise from their optimum μ_3-bonding role adopted in $[(Bu^tOLi)_6]$ in forming heterometallic **1** [range of Li–O bond lengths, 1.815(3)–1.919(3) Å]. This reflects the 'harder', more strongly polarising character of the smaller alkali metal. Given the strength of Li–O bonding it is perhaps surprising that a larger fragment of $[(Bu^tOLi)_6]$ has not been retained in **1**, *cf.* the tetrameric unit in $[(Bu^nLi{\cdot}Bu^tOLi)_4]$[13] and the hexameric unit in $[(Bu^tOLi)_{10}(LiOH)_6]$.[14] The fact that **1** formally contains only dimeric $(Bu^tOLi)_2$ fragments suggests that the Lewis base TMEDA may be involved in the mechanism of the reaction without appearing in the final product. Another factor in the construction of **1** is the coordinative flexibility of the alkoxide ligands. Exclusively μ_3-bonded in the homonuclear precursors, they exhibit both μ_3- and μ_4-bonding modes here. Following the expected trend, the μ_4-O centres form longer bonds (mean: to Li, 1.915 Å; to K, 2.875 Å) than their μ_3-O counterparts (mean: to Li, 1.811 Å; to K, 2.643 Å).

The ^{1}H NMR (400 MHz) spectrum of **1** in [$^2H_8$]toluene solution at 295 K reveals two singlet resonances (at 1.25 and 1.31 ppm) in a 1:1 ratio. Assuming the sixteen-vertex cage structure is retained these resonances can be assigned to the two distinct types (μ_3- or μ_4-bonded) of butoxide ligand present (there are four of each type). This receives support from the corresponding ^{13}C NMR (100.6 MHz) spectrum which shows a pair of CH_3 (36.09 and 36.55 ppm) and a pair of $(CH_3)_3C$ resonances (66.79 and 67.11 ppm). A variable-temperature ^{1}H NMR study reveals only one resonance at elevated temperatures with coalescence occurring at 312(±1) K, while the two resonances remain distinct but progressively broaden at lower temperatures down to 183 K. This data is consistent with the exchange of Bu^tO^- ligands between three-coordinate and four-coordinate sites. From the limiting chemical shift difference of 27(±2) Hz, a rate constant k of 60 s^{-1} can be estimated[15] for the uncoupled exchanging protons: this corresponds to a free energy of activation, $\Delta G^{\ddagger}$, of 65.9 kJ mol^{-1}. The variable-temperature spectra also contain trace amounts of an unknown protic impurity (having chemical shifts of 1.54 and 1.50 ppm at 273 K) which is not involved in the dynamic process.

Perhaps the most interesting aspect of **1** is its remarkable structural similarity to a series of heterobimetallic Group 15–Group 1 or Group 11 imido cage species (*e.g.*, $[\{As_2(N\text{-}Cy)_4\}_2Na_4]$);[16] this development, which will be elaborated upon in a full account of this work, may have its origin in the isoelectronic relationship between RO^- and RN^{2-}.

Finally, in view of the relationship of Bu^tOK to the superbasic reagent '$BuLi{\cdot}Bu^tOK$' as alluded to earlier, it will be of future interest to probe the interaction of BuLi with the new heterometallic alkoxide.

We thank the EPSRC for financial support.

Received (in Liverpool, UK) 15th February 1999, Accepted 9th July 1999

The mixed-metal carbonylate cluster $[Pd_6Ru_6(CO)_{24}]^{2-}$ was used as a single-source precursor in the synthesis of a highly active hydrogenation catalyst (stoichiometry PdRu) which has been characterised by electron microscopy and X-ray absorption spectroscopy: PdRu readily hydrogenates alkenes and naphthalene (the latter predominantly to *cis*-decalin) under mild conditions

Bimetallic nanoparticle catalysts occupy a position of high prominence in modern heterogeneous catalysis, especially for reactions of petrochemical significance.[1–3] Published reports[4–9] on such catalysts, typified by Pt–Re, Ir–Sn, Pt–Ru, Ag–Ru and Cu–Ru, reveal that enhanced catalytic performance apparently arises from the synergy between the component elements at the nanoscale which is absent in solid solutions of the two bulk metals.

In this communication we show that a single-source, mixed-metal cluster carbonylate precursor yields (by gentle thermolysis) a uniform distribution of discrete nanoparticles (*ca*. 17 Å diameter) of a Pd–Ru bimetallic catalyst encapsulated within the pores (*ca*. 30 Å diameter) of mesoporous silica. This catalyst is highly active in the hydrogenation of linear alkenes and significantly more so than two other bimetallic catalysts also prepared from single-source carbonylate precursors, Ag_3Ru_{10}[7] and Cu_4Ru_{12}.[9] Moreover, the Pd–Ru catalyst described here is capable of hydrogenating naphthalene under relatively mild conditions.

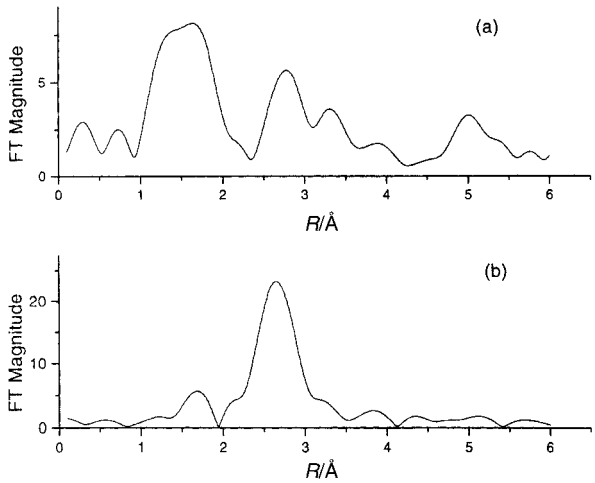

Fig. 1 (a) Fourier transform of the Pd K-edge EXAFS data (effectively a radial distribution function) for the mixed-metal carbonylate ion $[Pd_6Ru_6(CO)_{24}]^{2-}$ precursor dispersed inside the mesopores of the MCM-41 silica. (b) The corresponding transform for the dispersed precursor after gentle thermolysis (see text). The resulting cluster (see Fig. 2) has an average metal–metal (Pd–Ru and Pd–Pd) distance that peaks at 2.73 Å and the average co-ordination number is 5.3.

† Electronic supplementary information (ESI) available. See http://www.rsc.org.suppdata/cc/1999/1571.

The anionic molecular precursor $[Pd_6Ru_6(CO)_{24}]^{2-}$, **1**, was synthesised as described[10] previously; and isolated as its NEt_4^+ salt. This particular precursor was selected for a variety of reasons including its solubility, stoichiometry, adsorbability at, and dispersion across, the silanol rich[11,12] interior surfaces of the mesoporous silica support (MCM-41), as well as the ease with which it sheds its cloak of carbonyl groups during mild thermal treatment. Of prime importance also was our wish to design a bimetallic catalyst in which a metal (Pd) that readily takes up hydrogen is juxtaposed with one (Ru) that has a strong tendency to bind arenes. A Pd–Ru catalyst should therefore function effectively in the hydrogenation of aromatic molecules.

The methodology for its preparation and encapsulation into the mesopores is essentially that used in our earlier work[7,9] on Ag–Ru and Cu–Ru bimetallic nanocrystals. Retention of the structural integrity of the mixed-metal cluster carbonylate inside the mesoporous silica was deduced from *in situ* spectroscopic analysis, both infra red[9] (Nujol mull) and X-ray absorption using a specially designed cell.[13,14] The respective data sets showed the same structural features as those of the cluster when dispersed in homogeneous solution (tetrahydrofuran as solvent). The characteristic IR absorption peaks were somewhat broadened and slightly shifted (*ca*. 3 cm^{-1}) to lower energy upon encapsulation. Precise structural information (Ru–Ru, Pd–Pd and Ru–Pd distances and associated co-ordination numbers), retrieved from EXAFS analyses for Ru and Pd K-absorption edges, was in good accord with that obtained from the single-crystal X-ray structure[10] of Et_4N^+ salts of the anion **1**.

When the encapsulated carbonylate **1** was heated (10^{-4} Torr) for 1 h, at 180 °C, the sample changed colour from brown to

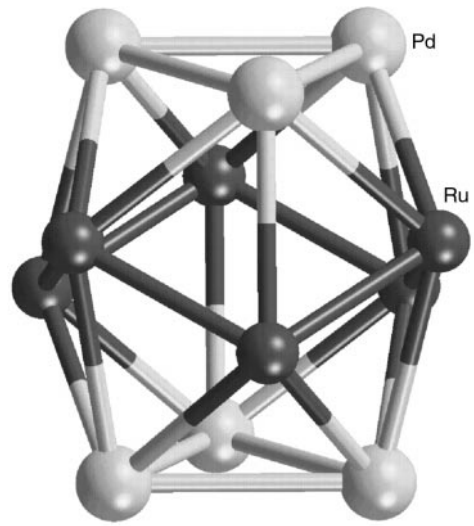

Fig. 2 Schematic diagram of the Pd_6Ru_6 cluster derived from an EXAFS analysis of the Ru and Pd K-edge X-ray absorption spectra (it is difficult to distinguish scattering by Pd atoms from that by Ru atoms).

Table 1 Hydrogenation of olefins—comparison of catalysts

Substrate (mass/g)	Catalyst	Solvent	Reaction time/h	Residual H_2 pressure/bar	Conv. (%)	TOF/ h^{-1}	Product distribution (mol%)

	Cu_4Ru_{12}/MCM-41	CH_3CN	8	18	0.8	2	—	—	100
		Hexadecane	8	20	0			No Reaction	

Reaction conditions: catalyst = 20 mg; T = 373 K; starting H_2 pressure = 20 bar; solvent ≈ 55 g; [a] 200 ppm of sulfur was added in the form of benzothiophene.

black; the IR carbonyl stretching region gradually disappeared; and the atomic structure of the mixed-metal cluster, as seen by details of the XANES and EXAFS, changed dramatically (Fig. 1). High-resolution transmission electron microscopy (HRTEM) revealed[15] that the Pd–Ru bimetallic nanoparticles were of uniform size (*ca*. 17 Å diameter) and spatially well distributed within the pores of the siliceous support.

The catalytic performance in alkene hydrogenation of the Pd–Ru nanoparticles is compared in Table 1 with those of similarly prepared (and sized) Cu_4Ru_{12} bimetallic nanoparticles. The kinetics of hydrogenation of hex-1-ene and dodec-1-ene reveal that the Pd_6Ru_6 catalysts showed a higher selectivity for n-hexane (or n-dodecane) than Cu_4Ru_{12}. The Pd_6Ru_6 catalyst is more active than Cu_4Ru_{12} for the hydrogenation of hex-1-ene (≈2 times) and dodec-1-ene (≈2.5 times). For comparison, a monometallic Ru_6 cluster was encapsulated in MCM-41 and a Pd/MCM-41 catalyst was prepared following a literature procedure,[16] and both were tested for the hydrogenation of hex-1-ene employing the same reaction conditions. It is very clear from Table 1 that the bimetallic catalysts are far superior in performance (% conversion) than their monometallic analogues and more importantly yield a higher selectivity for hydrogenated products, suggesting a possible synergism between the two bimetallic nanoparticles. The Pd_6Ru_6 catalyst was more effective than Cu_4Ru_{12} in the hydrogenation of naphthalene and higher conversions were obtained when acetonitrile was used as a solvent. Other solvents such as hexadecane showed a lower preference for the production of *cis*-decalin. The solid catalyst may be recycled without any significant decrease in activity or selectivity. This was done by filtering off the solvent–product mixture and recharging the Parr reactor with fresh material[17] (see Table 1 for reaction conditions). Unsurprisingly,[1–3] the introduction of ≈200 ppm of sulfur in the reaction mixture completely poisons the catalyst.

Surveys by electron-stimulated energy dispersive X-ray emission[17] of the Pd–Ru nanocatalyst particles after their use in four consecutive test runs showed that there was no segregation of the two components of the bimetallic catalyst. Moreover, annular dark field (*Z*-contrast) high-resolution microscopy showed[15] that there was no evidence of coalescence or sintering of the nanoparticles during catalytic use. Guided by energy-minimisation procedures[18] using density-functional theory computations, we have arrived at the EXAFS model for the structure of the bimetallic cage shown in Fig. 2.

We thank Professor C. R. A. Catlow for invaluable assistance. We also thank the EPSRC for a rolling grant to J. M. T., a ROPA award funding S. B. and a regular one to B. F. G. J., the Commissioners of the 1851 Royal Exhibition for an award to R. R., the European Commission for a grant to S. H., and the Royal Society and Peterhouse for a Research Fellowship to D. S. S. G. S. was funded partly by J. M. T.'s rolling grant and the CCRL Daresbury Laboratory, to whom we are grateful.

Received (in Oxford, UK) 10th March 1999, Accepted 5th July 1999

Highly mono-dispersed CdSe–CdS core–shell nanoparticles have been prepared by a novel method in which [Cd{Se_2CNMe(^{n}Hex)}$_2$] (250 °C for 30 min) and [Cd{S_2CNMe(^{n}Hex)}$_2$] (250 °C for a further 30 min) are thermolysed in tri-*n*-octylphosphine oxide (TOPO) in a 'one pot' synthesis; the core–shell structure has been characterized by electronic spectroscopy, photoluminescence, X-ray diffraction and electron microscopy (SAED, SEM and TEM).

Unique physical and chemical properties due to quantum confinement effects have been reported for a wide range of semiconductor nanoparticles.[1–6] Whilst many studies have focused on the relationship between particle size and optical behavior, the control of the surface chemistry is still a challenge to chemists. The presence of localized surface trap sites (defects) due to the high surface-to-volume ratio has made surface modification a necessity. Passivation of the surface has been achieved by organic ligands such as thiopyridine,[7] thiolates,[8] and 2,2′-bypyrimidine.[9] Core–shell structures such as Si–SiO_2,[10] CdS–$Cd(OH)_2$,[11] CdSe–ZnS,[12] CdSe–ZnSe,[13,14] CdS–HgS–CdS[15] and CdSe–CdS[16–18] are examples of inorganic passivation. These systems normally show an increase in photoluminescence efficiency and reduced fluorescence lifetimes.

We report the synthesis of a CdSe–CdS core–shell structure using the precursors [Cd{Se_2CNMe(Hex)}$_2$] and [Cd{S_2CNMe(Hex)}$_2$] for the CdSe core and CdS shell, respectively.† In a typical synthesis, [Cd{Se_2CNMe(Hex)}$_2$] (0.8 g) was dissolved in tri-*n*-octylphosphine (TOP) (15 ml). This solution was then injected into hot (250 °C) tri-*n*-octylphosphine oxide (TOPO) (20 g) and kept at this temperature for 30 min to give CdSe. To prepare the core–shell structure a solution of [Cd{S_2CNMe(Hex)}$_2$] (0.5 g) in TOP (10 ml) was injected into the deep red reaction mixture. The reaction was allowed to proceed for a further 30 min and the resulting solution was cooled to *ca*. 70 °C. Methanol was then added and a flocculant precipitate formed which was separated by centrifugation. CdS and CdSe nanocrystals were also synthesized as described previously.[19]

The absorption spectra for CdS, CdSe and CdSe–CdS nanoparticles are shown in Fig. 1.‡ The band edge (652 nm; 1.90 eV) of the CdSe–CdS structure is red shifted (22 nm, 0.02 eV) as compared to the CdSe nanocrystals (630 nm; 1.96 eV). This red shift is indicative of the formation of the core–shell structure. The overall shape of the spectrum is similar to that of CdSe, however a slight sharpening of the features at 535 and 613 nm is observed which may suggest a narrower size distribution. Photoluminescence (PL, λ_{ex} = 400 nm) shows an emission maximum close to the absorption band edge in both CdSe (585 nm) and the core–shell (622 nm) nanocrystals (Fig. 1), an observation consistent with the observed absorption spectra. The intensity of the emission maximum is considerably increased in the core–shell structure as compared to the parent materials.[10–17]

The X-ray diffraction pattern‡ of CdSe–CdS shows broad peaks along the (110), (103) and (112) planes which are assigned to the hexagonal phase of CdSe (Fig. 2) suggesting that the diffraction is predominantly due to the CdSe core. The sharp X-ray pattern§ indicates epitaxial growth of the shell. This also accounts for the slight shift in the peaks to higher 2θ values in the core–shell structure since the epitaxy requires that the lattice parameters are the same for both core and shell and hence will be between those for CdS and CdSe, as is observed. Similarly, in the SAED,‡ a pattern intermediate between that for CdS and that for CdSe was observed, as expected (Fig. 2). The reflections for the (002), (100) and (101) planes shown in the hexagonal CdS diffraction pattern are not visible in the CdSe and CdSe–CdS patterns owing to broadening of the peak in the region 2θ

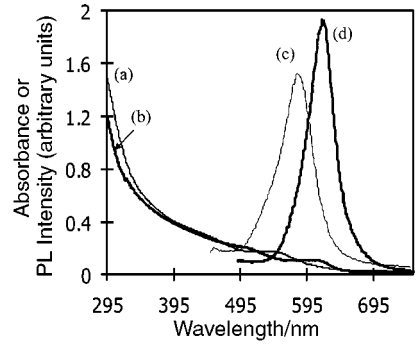

Fig. 1 Absorption spectra of (a) CdSe–CdS, (b) CdSe and photoluminescence spectra (λ_{ex} = 400 nm) of (c) CdSe, (d) CdSe–CdS.

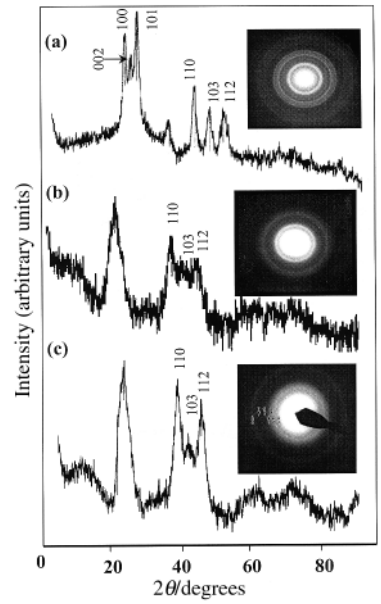

Fig. 2 XRD and SAED patterns showing the hexagonal phase for (a) CdS, (b), CdSe and (c) CdSe–CdS.

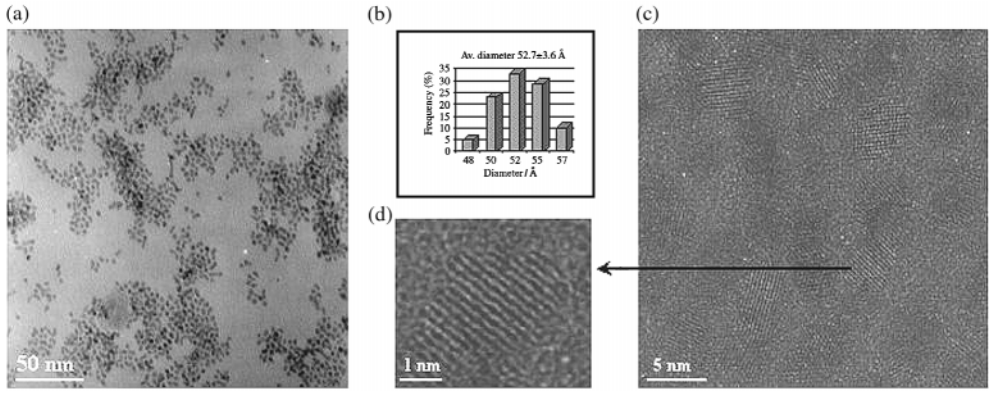

Fig. 3 CdSe–CdS core–shell nanocrystals: (a) TEM image, (b) particle size histogram, (c) HRTEM image, (d) HRTEM image of a single quantum dot (*ca.* 5.3 nm in diameter).

≈ 20–25°. The X-ray data may be consistent with a core–shell structure or with the formation of a composite but the composite would give blue shifts in the emission and absorption maxima. A red shift clearly shows the presence of the core–shell structure.

TEM images‡ show well defined, spherical CdSe–CdS particles (Fig. 3) with an average size of 53 ± 3.6 Å. The average size of the bare CdSe nanoparticles is 45 Å which indicates an increase of 8 Å due to the CdS shell in the core–shell nanoparticles. The crystallinity of the core–shell structure is confirmed by an HRTEM image (Fig. 3) which shows clear lattice fringes for the CdSe core (hexagonal phase).

HRTEM‡ showed lattice spacings intermediate between those for CdSe and CdS as is observed by SAED and X-ray patterns. As expected, no interface can be observed by HRTEM between the CdSe core and the CdS shell. The EDAX pattern and ICP analysis‡ confirmed the presence of Cd, Se and S in the CdSe–CdS nanoparticles. The peak for phosphorus in each case was due to the capping of the particles by TOPO which was further confirmed by a shift in the IR band (from 1146 to 1120 cm^{-1}, P=O) for TOPO.

Highly monodispersed CdSe–CdS core–shell nanoparticles have been prepared by a novel route involving thermolysis in TOPO using $[Cd\{Se_2CNMe(^nHex)\}_2]$ and $Cd\{S_2CNMe(^nHex)\}_2]$ as single molecule precursors in a one-pot synthesis. This route is a simple and convenient route to produce reasonable quantities of high quality, monodispersed core–shell nanoparticles. The precursors are easy to synthesize and store and give high yields of TOPO capped quantum dots.

P. O'B. is the Sumitomo/STS Professor of Materials Chemistry. We thank the EPSRC for a grant supporting work on single molecule precursors for quantum dots. N. R. is supported by a Royal Society/FRD development program between ICSTM and UZULU.

Notes and references

† The compounds were prepared by adaptations of the literature method[20,21] and fully characterised by NMR, mass spectometry, microanalysis and IR spectroscopy.

‡ A Philips PU 8710 spectrophotometer was used to perform the optical measurements for which the samples were placed in silica cuvettes (1 cm path length). For photoluminescence spectroscopy a Spex FluoroMax instrument with a xenon lamp (150 W) and a 152 P photomultiplier tube as a detector was used to measure the photoluminescence of the particles. Measurements were carried out on samples with an optical density of 0.1 at 400 nm, also the excitation wavelength. Good spectra were obtained with the slits set at 2 nm and an integration time of 1 s. The samples were placed in quartz cuvettes (1 cm path length). X-Ray diffraction studies were performed using secondary graphite-monochromated Cu-Kα radiation (40 kV) on a Philips X'Pert Materials Research Diffractometer (MRD, R. Sweeney, IC). Measurements were taken using a glancing angle incidence detector at an angle of 3°, for 2θ values in the range 20–60° in steps of 0.04° with a count time of 1 s. For electron microscopy a JEOL 2000 FX MK 1 electron microscope operated at 200 kV with an Oxford Instrument AN 10000 EDS analyser was used for the conventional TEM (transmission electron microscopy) images. Selected area electron diffraction (SAED) patterns were obtained using a JEOL 2000 FX MK2 electron microscope operated at 200 kV. The samples for TEM and SAED were prepared by placing a drop of a dilute solution of sample in toluene on a copper grid (400 mesh, agar). The excess solvent was wicked away with a paper tip and the sample allowed to dry completely at room temperature. EDAX (energy dispersion analytical X-rays) was performed on samples deposited by evaporation on glass substrates using a JEOL JSM35CF scanning electron microscope. ICPAES analyses (Cd, Se, S) were recorded on an ARL instrument, Geology Department, Imperial College.

§ The X-ray diffraction pattern of the CdS particles gave peaks with the following observed *d* values (% relative intensity, *hkl*): of 3.55 Å (76, 100), 3.35 Å (52, 002), 3.16 Å (100, 101), 2.06 Å (43, 110) and 1.90 Å (26, 103) corresponding to the hexagonal cadmium sulfide *cf.* 3.57 Å (62, 100), 3.36 Å (91, 002), 3.16 Å (100, 101), 2.45 Å (29, 102), 2.07 Å (48, 110) and 1.90 Å (50, 103) {ASTM}. For CdSe: 3.50 Å (100, 002), 2.13 Å (80, 110), 1.84 Å (50, 112) and 1.96 Å (48, 103) corresponding to the hexagonal phase *cf.* 3.51 Å (70, 002), 2.15 Å (85, 110), 1.83 Å (50, 112) and 1.98 Å (70, 103) {ASTM}. For the CdSe–CdS core–shell: 3.50 Å (100, 002), 2.15 Å (85, 110), 1.83 Å (66, 112), 1.98 Å (60, 103) corresponding to the hexagonal phase *cf.* 3.51 Å (70, 002), 2.15 Å (85, 110), 1.83 Å (50, 112) and 1.98 Å (70, 103) {ASTM}.

Dynamic combinatorial libraries of pseudo-peptide hydrazone macrocycles

Graham R. L. Cousins, Sally-Ann Poulsen and Jeremy K. M. Sanders*

Cambridge Centre for Molecular Recognition, University Chemical Laboratory, Lensfield Road, Cambridge, UK CB2 1EW. E-mail: jkms@cam.ac.uk

Received (in Cambridge, UK) 21st May 1999, Accepted 5th July 1999

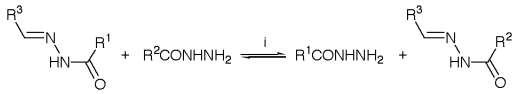
Combinatorial libraries of pseudo-peptide hydrazone macrocycles are formed from amino acid-derived building blocks equipped with hydrazide and aldehyde functionalities; a series of experiments confirm that hydrazone formation is reversible and that the libraries are genuinely dynamic.

Dynamic combinatorial libraries (DCLs) are emerging as interesting systems for the identification of new catalyst, host and guest molecules.[1] In a DCL the connections between building blocks are reversible and in flux: they may be covalent or non-covalent, and are continuously being made and broken. The composition of a DCL is dependent on the environment, in that the addition of a template which selectively binds one member may bias the equilibrium towards that member. Many different reversible reactions have been proposed for the purpose of DCL generation, but none has yet been shown to be ideal.[1–3] Here we report that transimination of hydrazones, a reaction that occurs at room temperature in the presence of a mild acid catalyst (Scheme 1),[4] is a promising candidate for the generation of DCLs. Relative to simple imines (Schiffs bases), hydrazides are expected to have the advantage of greater stability and the potential for peptide-like hydrogen bonding.[5]

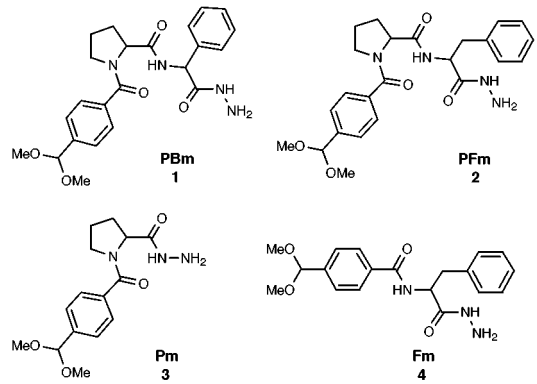
The amino acid-derived building blocks **1**–**4**, each comprising a protected aldehyde moiety and a hydrazide functionality on an amino acid core, were synthesised by standard routes.† Proline features prominently in these monomers because its frequent occurrence in protein β-turns[6] led us to expect that it would give a propensity for the formation of macrocyclic products. Phenylalanine and phenylglycine, components of the other monomers, possess 'chemically inert' side chains, ideal for preliminary investigations.

Cyclisation of the monomers **Fm**, **Pm**, **PFm** and **PBm** is performed by the addition of 50 μl of TFA to a 5 mM solution of monomer in CH_2Cl_2; TFA catalyses both dimethoxy acetal deprotection to the free aldehyde and hydrazone exchange (Scheme 2).‡ The low concentration of monomer directs formation of cyclic oligomers; linear polymers are likely to be formed at higher concentrations. Electrospray mass spectrometry (ES-MS) analysis of reaction solutions of any one of **Pm**, **PFm** or **PBm** reveals the formation of a range of oligomeric macrocyclic species.§ After 2 h there is no evidence of free protected or deprotected linear monomer, and more significantly, no evidence for linear oligomeric products. Under these conditions **Pm** affords cyclic dimer through to cyclic heptamer; cyclic dimer to cyclic nonamer are observed for **PBm**, and finally **PFm** exhibits cyclic dimer through to cyclic hexamer. Monomer **Fm** showed no formation of identifiable oligomeric species; all of the monomer was consumed but the products were largely insoluble and presumably polymeric.

Combinatorial libraries of great diversity are rapidly achieved by the treatment of a solution of two or more monomers with TFA. For example, a solution of **PBm** and **PFm**, when treated with TFA, yields a library of 75 readily



Scheme 1 *Reagents and conditions*: i, Dilute acid.

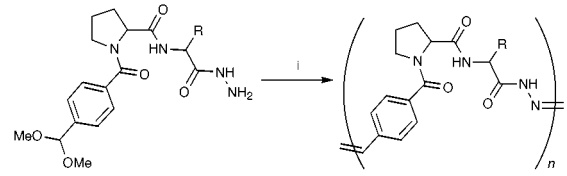


detected macrocyclic species; other products may well be formed in lower concentrations. Importantly, all possible combinations of monomers are detected from cyclic dimer through to cyclic undecamer. Cyclic oligomers of hexamer and above are observed as the doubly-charged species in the range *m/z* 200–2000, and gratifyingly, hexamers, octamers and decamers of odd numbers of each of the two monomers exhibit unique doubly-charged masses, which interdigitate between those signals due to the mono-charged cyclic trimers, tetramers and pentamers respectively (Fig. 1).

The cyclisation of **Pm**, **PFm** and **PBm** in the presence of TFA gives a very diverse macrocyclic library; for example, 14 out of the 15 possible tetramer compositions are detected by ES-MS. In this experiment > 30 product compositions are identified within the sensitivity range of the spectrometer, including dimers, trimers, tetramers and pentamers. These spectra underestimate the number of products formed: doubly charged higher oligomeric species are not observed, perhaps because as the number of possible products increases, their concentration may decrease. This analysis also neglects sequence isomers, which are not detectable by conventional MS.

Mixing experiments performed with monomers **Fm** and **Pm** highlighted the role played by proline in inducing the formation of cyclic species. **Fm** under the cyclisation conditions does not afford any detectable cyclic species, but when **Pm** is introduced mixed cyclic species are observed as well as homo-**Pm** cyclic species. Thus, **Fm** may be incorporated into DCLs but will not stand alone in pseudo-peptide macrocycle formation.

The dynamic reversibility of hydrazone formation is illustrated by two simple experiments. If solutions of macrocycles generated from two different monomers, and containing no free monomer, are mixed, then libraries of the mixed macrocyclic species are observed. The final composition is identical to that observed by mixing the monomers prior to treatment with TFA. It follows that the mixed cyclic species must be the result of



Scheme 2 *Reagents and conditions*: i, TFA, CH_2Cl_2, RT.

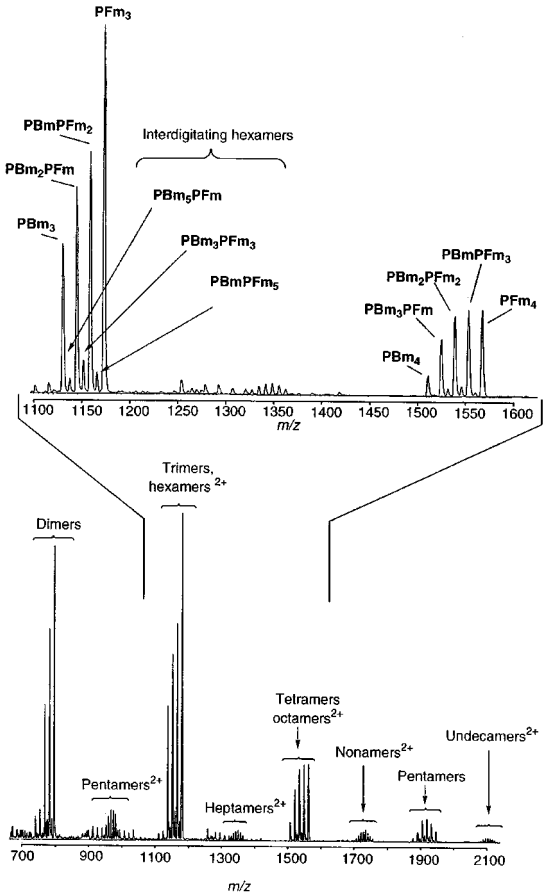


Fig. 1 ES-MS spectrum for the mixed cyclisation of **PBm** and **PFm**.

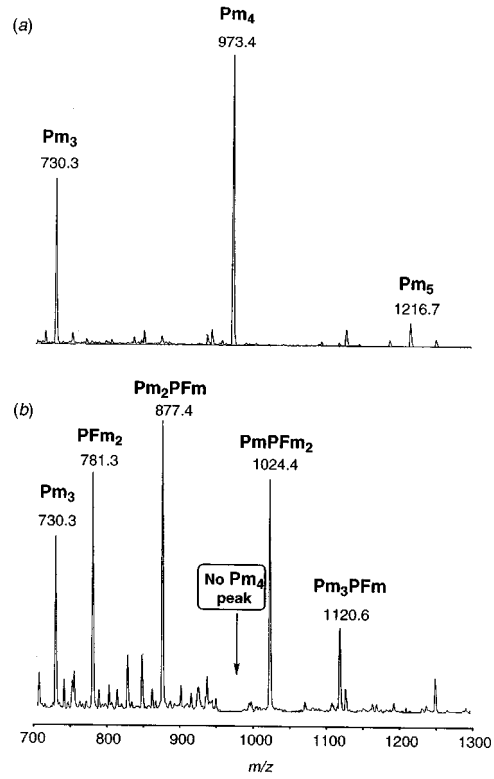

Fig. 2 (*a*) ES-MS spectrum demonstrating cyclisation of **Pm** in the presence of TFA after 2 h. (*b*) ES-MS spectrum of the same reaction mixture recorded 4 h after **PFm** was added. Note the absence of a peak at *m/z* 973 for $\mathbf{Pm}_4$.

homo-oligomer fragmentation and subsequent hydrazone formation. More elegantly, in a second experiment, **Pm** was cyclised in the presence of TFA. To the solution containing preformed macrocyclic **Pm** oligomers was added a 5 mM solution of **PFm**. ES-MS analysis showed the preferential formation of mixed products, with complete loss of *m/z* 973 ($\mathbf{Pm}_4$) and 1216 ($\mathbf{Pm}_5$), present in the solution prior to the addition of **PFm** (Fig. 2). Indeed $\mathbf{Pm_4}$ is the only tetramer not observed in the three monomer library. This preference for mixed species is in marked contrast to the self-sorting of homo-oligomers that we previously observed in relatively rigid alkaloid-derived libraries under transesterification conditions.[3]

The ability to 'switch off' the reaction is of fundamental importance to the success of any DCL. Two separate cyclisation solutions, one of **PFm** and the other of **PBm**, were each treated with 1.5 equiv. of Et_3N relative to the amount of TFA. The solutions were stirred for 15 min before being combined. ES-MS analysis after 2 h showed no formation of mixed cyclic species, demonstrating that in the absence of acid no exchange of hydrazones occurs. Even after 36 h no mixed products are observed. Upon addition of an excess of TFA the exchange reaction is restarted and within a few hours the same distribution of cyclic products is observed as if the reaction had been initiated from a mixture of two protected monomers.

These results demonstrate the applicability of hydrazone chemistry to the generation of DCLs. In conjunction with amino acid-derived building blocks, this chemistry allows for the rapid, and potentially automated, generation of libraries of pseudo-peptide macrocycles which are under thermodynamic control. The mild conditions of hydrazone exchange offer reason to be optimistic that efficient template binding will bias the libraries to receptors with good binding characteristics. The rewards may include a rapid evolution of pseudo-peptide macrocycles as catalysts and host or guest molecules.

We thank the BBSRC, Royal Society and Ethyl Corporation (UK) for financial support, M. Simpson for preliminary experiments and P. Lukeman and S. Rowan for helpful discussions.

Notes and references

† Monomers were synthesised from carboxybenzaldehyde dimethoxy acetal, Cbz-proline and commercially available amino acid methyl esters using standard peptide chemistry. The notation is derived from the single letter notation for amino acids with **B** assigned to phenylglycine.

‡ The general procedure for cyclisation experiments entailed dissolution of monomers in freshly distilled CH_2Cl_2 and the addition of 50 μl of TFA. All were carried out on a 5–10 mg scale at a concentration of 5 mM. The reactions were stirred at room temperature for 2 h before ES-MS analysis. This deprotection–cyclisation chemistry is compatible with a range of solvents including DMSO and MeCN and aqueous mixtures of these solvents.

§ Electrospray mass spectra were recorded on a Micromass Quattro-LC triple quadrapole apparatus fitted with a *z*-spray electrospray source. The electrospray soucre was heated to 100 °C and the sampling cone voltage (V_c) was 65 V. Samples were prepared by removal of 200 μl of crude reaction mixture and dilution in 200 μl of THF. Samples were introduced into the mass spectrometer source with an LC pump (Shimadzu LC-9A LC pump) at a rate of 4 μl min^{-1} of MeCN–H_2O (1:1). Calibration was performed using protonated horse myoglobin. Scanning was performed from *m/z* 300 to 2100 in 8 s and several scans were summed to obtain the final spectrum which was processed using MassLynx V3.0 software.

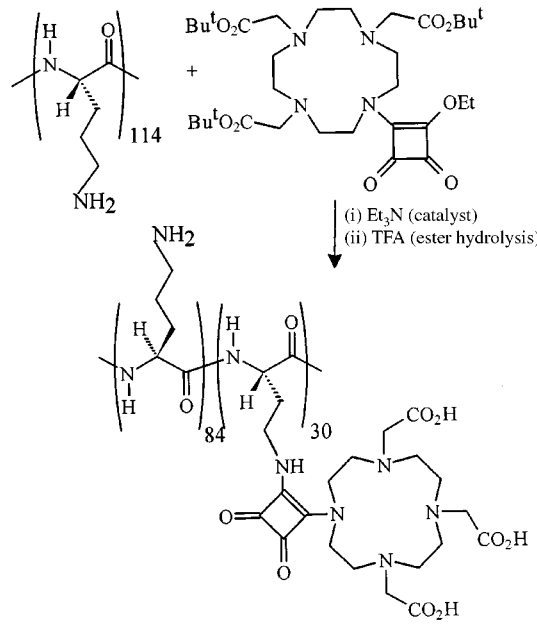
Received (in Basel, Switzerland) 18th January 1999, Accepted 14th June 1999

The ability of the paramagnetic macromolecular complex $(GdDO3ASQ)_{30}$-Orn_{114} to enhance the water proton relaxation rate has been found to be a function of pH; this behaviour is related to the structural changes occurring in the polypeptide upon protonation of the side-chain NH_2 groups.

Magnetic resonance imaging (MRI) is a powerful diagnostic technique based on the acquisition of images which are topological representations of NMR parameters, including the T_1 and T_2 of water protons. Contrast agents (CAs) for MRI are mainly represented by Gd(III) chelates whose high paramagnetism causes a marked increase of the water proton relaxation rates in the bodily regions where they distribute.[1–3] The effectiveness of a Gd(III) complex as a CA is measured by the relaxivity, r_{1p}, which represents the net increment of the water proton relaxation rate in a 1 mmol l^{-1} solution of the paramagnetic solute. The development of a second generation of Gd(III) based CAs stems from systems endowed either with higher relaxivities or with an improved ability to act as reporters of their biochemical environment. Among the various possibilities, the availability of a pH-sensitive Gd(III) chelate appears particularly interesting since it is known that increased glycolytic activity may cause a significant pH decrease in the extracellular region of certain tumours.[4] At the magnetic fields usually employed in MRI (0.5–1.5 T) the relaxivity of a Gd(III) chelate is mainly determined by the molecular reorientational time τ_r.[5] Thus a means of assaying pH may be pursued by designing systems whose molecular mobility is a function of pH. It is well established that the structures of poly(amino acid)s like polylysine and polyornithine are strongly dependent upon the pH of the solution. In fact, at acidic pHs, the repulsion among positively charged amino groups induces the occurrence of a highly flexible structure whereas at basic pHs the formation of intra-chain hydrogen bonds yields the formation of an α-helix resulting in an overall rigidity of the macromolecular system.

On this basis a novel macromolecular system has been recently synthesised, containing thirty Gd(III) chelates bound to a poly(amino acid) chain made of 114 ornithine residues. Since it has been recently reported that squaric esters readily react with amines,[6] we exploited this finding by using the squaric acid moiety as a linker between the tetraazamacrocyclic structure of DO3A and the amino groups of the polyornithine chain (Scheme 1).[7] In addition to acting as linker between the poly(amino acidic) chain and the DO3A ligand, the squaric acid moiety may participate in the coordination of the Gd(III) ion through the oxygen atom of the carbonyl group. Such a reaction scheme has some advantage with respect to that previously reported for $(GdDTPA)_n$-Lys_m.[8] In fact, the synthesis of the latter system implies the use of the bifunctional DTPA bis-anhydride which leads to undesirable intra- and inter-molecular cross-linking reactions with a consequent reduction of the thermodynamic stability of the metal complexes.[9] The use of a monoreactive chelate derivative allows a controlled and specific activation of the amino groups in the poly(amino acid) macromolecule.

At acidic pH the unreacted amino groups in $(GdDO3ASQ)_{30}$-Orn_{114} are protonated and highly hydrated, thus they tend to stay as far apart as possible. The paramagnetic moieties too maintain a relatively high degree of mobility along the lateral chain of each substituted ornithine and the molecular reorientation of the complex only in part 'feels' the large size of the whole macromolecule. The progressive deprotonation of the $-NH_3^+$ groups occurring with the increase of pH induces a 'rigidification effect' due to the formation of intramolecular hydrogen bonds between adjacent peptidic linkages. The progressive changes in the overall structure of $(GdDO3ASQ)_{30}$-Orn_{114} are reflected in the relaxivity parameter as shown in Fig. 1. At pH < 4 r_{1p} has a constant values of *ca.* 23 mM^{-1} s^{-1} which is about five times higher than the r_{1p} value normally found for related monomeric Gd(III) complexes. The increase of the pH of the solution causes a linear increase of r_{1p} which reaches the value of 32 mM^{-1} s^{-1} at pH 8. Further increase of pH above this value does not cause any change in the observed relaxivity. To check that the observed behaviour is a con-



Scheme 1

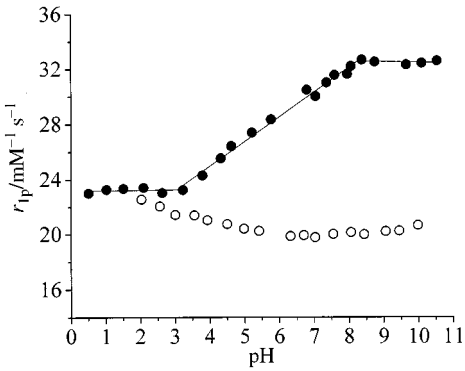


Fig. 1 pH dependence of r_{1p} values for $(GdDO3ASQ)_{30}$-Orn_{114} (●) and $(GdDO3ASQ)_{50}$-Orn_{50} (○). The latter system has been chosen because its molecular weight is similar to that of $(GdDO3ASQ)_{30}$-Orn_{114}.

sequence of a change in τ_r, the $1/T_1$ dependence on the Larmor frequency (ω_0) (NMRD profile) has been measured at three pH values (Fig. 2). The shape of the NMRD profile of Gd(III) chelates, as measured on a field-cycling relaxometer over the frequency range from 0.01 to 50 MHz, is determined by a number of parameters including the number of water molecules in the inner coordination sphere, the molecular reorientational time (τ_r), the exchange lifetime of the coordinated water (τ_m), the electronic relaxation time (τ_s), and the Gd-bound water proton distance (r).[5] The NMRD profiles of paramagnetic macromolecular systems show a characteristic hump in the 20–35 MHz region whose height is determined by the relative ratio of τ_s to τ_r.[10] In fact, in the low frequency range r_{1p} is determined primarily by τ_s whose value, being field dependent, increases steadily with ω_0 causing an increase of the observed r_{1p}. As τ_s becomes longer than τ_r, the observed r_{1p} is determined by the latter parameter and the $1/T_1$ dispersion takes place. As shown in Fig. 2, a significant increase in the height of the relaxivity peak in the 20–35 MHz region occurs as the pH of the solution passes from 4.5 to 8.5. This behaviour is consistent with an increase of τ_r with pH. Furthermore, the increase in pH also induces an increase in relaxivity at low magnetic field strength. Such behaviour, which is reminiscent of that observed upon formation of macromolecular adducts between a paramagnetic Gd(III) chelate and HSA,[2] has been accounted for in terms of an additional contribution to the overall relaxivity arising from water molecules surrounding the complex and those belonging to the hydration layers of the macromolecule. We take this finding as further evidence of structure formation in the polypeptide chain upon deprotonation of the -NH_3^+ side chain groups.

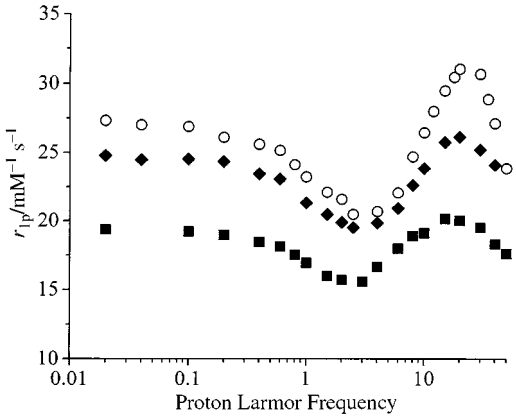

Fig. 2 $1/T_1$ NMRD profiles (298 K) of $(GdDO3ASQ)_{30}$-Orn_{114} (1 mM) at pH 4.5 (■), 7 (◆) and 8.5 (○) respectively.

The role of the free amino groups on the macromolecule in determining the dependence of r_{1p} upon the pH of the solution is clearly assessed by compairing the pH dependence of r_{1p} for $(GdDO3ASQ)_{30}$-Orn_{114} and r_{1p} of a related system containing no free NH_2 groups (Fig. 1). Such a system has been obtained by following an analogous procedure to that used for $(GdDO3ASQ)_{30}$-Orn_{114} but with a higher DO3A ester : poly-(amino acid) ratio.[7] Clearly, the lower r_{1p} values shown by the saturated conjugate indicate that, in this system, the chelates moieties undergo larger motions than in $(GdDO3ASQ)_{30}$-Orn_{114}. It is likely that the steric requirements of the bulky chelates do not allow the poly(amino acid) chain to adopt, at basic pHs, a compact α-helix structure as occurs for the partially substituted derivative. Rather, the flexibility of the main chain is transfered to the side-chains bearing the paramagnetic chelates which, in turn, are responsible for the partial 'quenching' of the relaxivity potentially expected for systems of this size.

In summary $(GdDO3ASQ)_{30}$-Orn_{114} is an interesting macromolecular MRI agent whose high relaxivity is made strongly pH dependent through structural changes which limit the internal mobility of the chelate moieties. The pH range at which r_{1p} changes fits better the physiological values than that recently observed for another macrocyclic Gd(III) complex whose pH-dependent r_{1p} is the result of variations in its hydration sphere.[11] Furthermore it appears to provide an alternative MRI route to recently reported procedures for the determination of the extracellular pH of tumours based on ^1H, ^{19}F or ^{31}P probe molecules, known to have pH-dependent MR properties which titrate in the physiological range.[12,13]

Notes and references

‡ Synthesis of $(GdDO3ASQ)_{30}$-Orn_{114}. The triester (1,4,7,10-tetraazacyclododecane-1,4,7-triacetic acid, tri-*tert*-butyl ester) is reacted with diethyl squarate in ethanol, overnight at room temperate (RT) to yield the DO3A5Q ligand. The synthesis of the polyornithine conjugate is pursued by reacting the latter compound and the poly(amino acid) (at the molar ratio of *ca.* 30 : 1) at RT for 72 h in ethanol (in the presence of triethylamine as catalyst). Finally hydrolysis of *tert*-butyl ester groups is carried out with TFA. The complexation was carried out by adding a stoichiometric amount of $GdCl_3$ to the aqueous solution of the polyornithine conjugate at neutral pH and at RT. The eventual excess of free Gd(III) ions is easily removed by centrifugation of the solution brought to basic pH. All new compounds exhibited satisfactory spectral and elemental analysis. The CD spectra between 200 and 250 nm of $polyOrn_{114}$ and of $(GdDO3ASQ)_{30}$-Orn_{114} appear similar, indicating that the conformation of the polypeptide backbone is unaltered upon partial conjugation of lateral amino groups to squaric acid moieties.

Received (in Cambridge, UK) 25th June 1999, Accepted 9th July 1999

We present an approach to fabricate very large, soluble, self-contained metallosupramolecular entities employing a template-directed strategy based on charged nanoparticles: consecutive deposition of negatively charged macromolecules and positively charged metallosupramolecular coordination polyelectrolytes is exploited to assemble the metallosupramolecular components on the nanoparticles.

Self-assembly provides an efficient approach to create large supramolecular architectures through non-covalent interactions, bypassing problems associated with stepwise covalent synthetic methodologies.[1] In recent years, metal ion mediated self-assembly has been intensely investigated as a means to construct complex structures. Two dominant metallosupramolecular architectures can be identified. The first involves closed, self-contained (solution) architectures of well-defined shape and nanometer size with a small number of components, a representative example being the cage-type architectures of polytopic bipyridine ligands, 6-PhHat and Cu^{I} or Ag^{I} ions.[2] The other class consists of infinite solid-state architectures, as in crystals of 1,2-di(4-pyridyl)ethane and Fe^{II} ions.[3] Complementarity and metal ion–ligand interactions are the dominating assembly principles for the spatial organization of the components.

Metal ion containing assemblies are expected to exhibit novel physicochemical properties such as optical, magnetic, electrochemical and catalytic functions, similar to a variety of proteins bearing multi-metal active sites.[4] In order to integrate active functional units into operating molecular based materials and devices, existing assembly methodologies have to be improved and new methods need to be developed. To date, it has not been possible to construct metallosupramolecular assemblies that bridge the gap between closed cage-type structures (few components) and extended solid-state architectures (infinite number of components). Here, we present a template-directed strategy to fabricate metallosupramolecular entities that contain a very large, yet finite, number of components which remain in solution. To achieve this goal, two types of interaction that operate on two different length scales are utilized. At the molecular level, metal ion mediated interactions generate the supermolecules. Primarily electrostatic interactions effect self-assembly of single layers at the mesoscopic level. The concept of template-directed self-organization is analogous to biological processes; for instance, spontaneous assembly of protein segments along an RNA strand generates the tobacco mosaic virus.[5]

Terpyridine transition metal ion complexes were found to present an array of interesting electronic, photonic, magnetic and reactive properties.[6] Recently, Kurth *et al.* showed that metal ion mediated self-assembly of the ditopic ligand 1,4-bis(2,2′:6′,2″-terpyridin-4′-yl)benzene with transition metal ions results in the formation of metallosupramolecular coordination polyelectrolytes (MEPE).[7] Using the layer-by-layer technique, consecutive deposition of the positively charged MEPE and oppositely charged polyelectrolytes results in well-defined multilayers.[8] This facile method relies on electrostatic interactions of oppositely charged macromolecules. The resulting films present a periodic architecture of active supramolecular components. Thin films with functional components and a well-defined architecture provide an interesting class of advanced materials or devices with tailored properties.

Here, we extend this concept to produce self-contained, yet large metallosupramolecular entities by using nanometer-size templates, namely nanoparticles. In contrast to the previously mentioned methods, this approach offers the following advantages: (i) a large number of active components can be assembled in an easy and inexpensive way; (ii) different functional units can be easily combined within one layer or along the radial direction in order to tailor the properties of the final entity; (iii) the final entity remains in solution (in contrast to crystalline solids); and (iv) the total number of components is readily controlled through the size of the template and the number of layers deposited. A simplified scheme of our approach is shown in Fig. 1.

As templates we employed cetyltrimethylammonium-stabilized, positively charged polystyrene (PS) latices with an average diameter of 73 ± 14 nm (determined from light scattering).[9] Consecutive adsorption of sodium polystyrene-

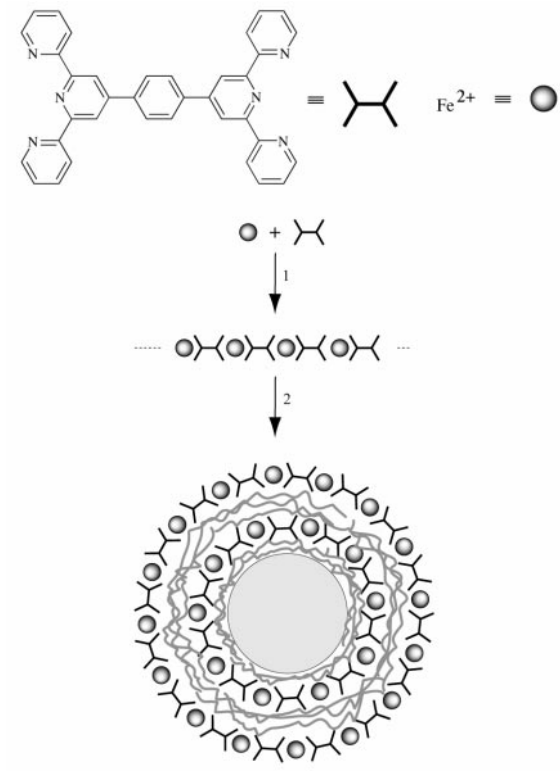

Fig. 1 Two different types of interactions at two different length scales are operative in generating giant, self-contained metallosupramolecular entities (bottom). Metal ion coordination is operative at the molecular level to produce the supermolecules (step 1). Electrostatic interactions are employed to assemble single layers of charged macromolecules on charged nanoparticles at the mesoscopic length scale (step 2). Using PS latices with a diameter of 73 nm, each layer contains approximately 7600 metal ions and ligands; multilayer sheaths with a total of 53 000 components per nanoparticle were created by consecutive deposition of PSS and Fe^{II}–MEPE. The counterions are omitted for clarity; the configurations of the polymers are simplified and the molecules are not drawn to scale.

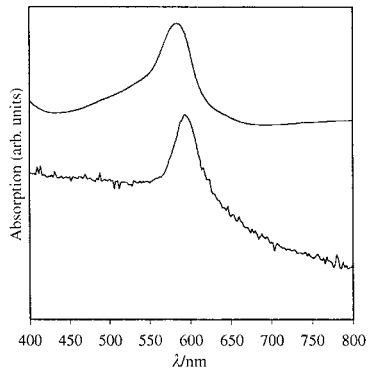

Fig. 2 UV/vis absorption (arbitrary units) spectrum of Fe^{II}–MEPE in aqueous solution (top) and of the coated Fe^{II}–MEPE nanoparticles (bottom). The UV/vis spectrum of the Fe^{II}–MEPE coated nanoparticles was corrected for particle background scattering.

sulfonate (PSS) and Fe^{II}–MEPE results in multilayers on the PS latices.[10] Repeated centrifugation and washing of the PS latices removes excess polyelectrolyte.

Evidence for the deposition of PSS/Fe^{II}–MEPE multilayers on the PS latices is obtained by visual inspection: upon deposition, the PS latices turn blue, the characteristic color of Fe^{II}–MEPE. A representative UV/vis absorption spectrum of the coated PS latices and of Fe^{II}–MEPE in aqueous solution is shown in Fig. 2. The band at 583 nm is characteristic of the Fe^{II}–terpyridine complex; it is associated with a metal-to-ligand charge transfer transition. In the case of the coated PS latices, this band is observed at 593 nm.The red shift is attributed to the different polarity within the multilayer polyelectrolyte film and is characteristic of PSS/Fe^{II}–MEPE layers.

Layer-by-layer growth is confirmed by successful recharging of the particle surface with each deposition cycle. The neat PS latices have a positive ζ-potential of +60 mV. Deposition of PSS reverses the sign of the ζ-potential (approximately −42 mV). Subsequent deposition of Fe^{II}–MEPE results in a positive ζ-potential (app. +18 mV).[11] The ζ-potential for deposition of 14 PSS/Fe^{II}–MEPE layers is summarized in Fig. 3. Alternating ζ-potentials are characteristic of regular multilayer growth on colloidal templates.[12]

Additional evidence for the adsorption of Fe^{II}–MEPE on the particles is provided by energy dispersive X-ray analysis measurements, which clearly show the presence of Fe^{II} on the Fe^{II}–MEPE/PSS-coated particles. Preliminary TEM experiments reveal that PS latices coated with PSS/Fe^{II}–MEPE multilayers have a rougher surface than the uncoated nanocolloids. This is attributed to the linear, rigid-rod type shape of Fe^{II}–MEPE.

A single metallosupramolecular component consisting of one ligand and one metal ion occupies roughly a surface area of 1.2 × 1.8 nm^2. Based on the surface area of *ca.* 17 000 nm^2 per nanoparticle, one particle can accommodate approximately 7600 metallosupramolecular components in one layer. Since up to 7 Fe^{II}–MEPE layers were assembled, a total of 53 000 metal

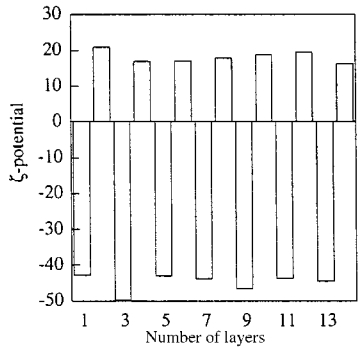

Fig. 3 ζ-potential of alternating layers of PSS (negative values) and Fe^{II}–MEPE (positive values) on PS latices. Alternating ζ-potential values confirm layer-by-layer growth of PSS/Fe^{II}–MEPE multilayers on colloidal templates.

ions and ligands are confined on a single particle. This number can be readily increased, simply by carrying out extra deposition cycles.

Due to the non-covalent nature of the coordination bond, the metal ion–ligand union is labile and subject to exchange processes. Adding chelating agents, like phenanthroline or salicylic acid, to a solution of Fe^{II}–MEPE results in discoloration of the solution. This is due to disassembly of the Fe^{II}–terpyridine bond. In contrast to the solution species, PSS/Fe^{II}–MEPE multilayers show a much greater stability under these conditions: no color change was detected by UV/vis spectroscopy even after prolonged exposure to chelating agents. Apparently, the adsorption of the charged macromolecules at multiple contact points reduced the degrees of freedom of the Fe^{II}–MEPE to such an extent that removal of a single component becomes strongly hindered.

The template-directed approach based on nanoparticles presented here opens a novel entry to stable dispersed metallosupramolecular entities with a large number of active components. Ongoing research in our laboratories suggests that this approach is generally applicable to the construction of other 'giant', dispersed metallosupramolecular entities. Due to the facile and efficient layer-by-layer method, different active components can be assembled in each layer, thus opening avenues to construct complex functional materials and devices (*e.g.* with vectorial properties). The fact that these entities remain in solution makes them potential candidates for various technological applications. Stimulus-responsive ligands could trigger the release of the metal ions, similar to neuronal action.[13] After removal of the template, the remaining shell constitutes an internal, separated micro-compartment.[14] Motion of the shell may be induced by electrochemical switching of the metal ion coordination geometry. In addition, the permeability of the shell may be controlled with an electrochemical stimulus.

This study was supported by the Max-Planck-Society. Helmuth Möhwald is acknowledged for valuable discussions. The authors thank Christa Stolle and Markus Schütte for the preparation of Fe^{II}–MEPE.

Lithium naphthalenide induced reductive cleavage of α,β-epoxy ketones: an efficient procedure for the preparation of β-hydroxy ketones

Renata Jankowska,[a] George L. Mhehe[b] and Hsing-Jang Liu*[a]†

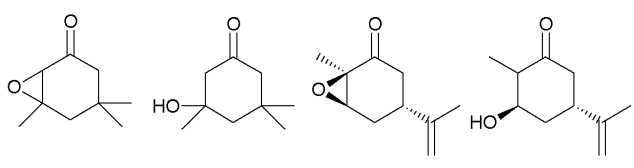
Received (in Cambridge, UK) 10th June 1999, Accepted 6th July 1999

Lithium naphthalenide presents itself as a mild and efficient reagent for the cleavage of α,β-epoxy ketones to give the corresponding β-hydroxy ketones in good yields.

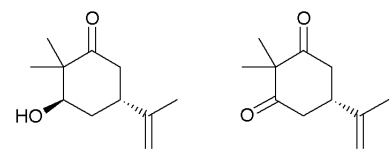
β-Hydroxy ketones and the closely related 1,3-diol group are important functionalities, which are found in prostaglandins,[1] taxol and congeners,[2] and many other interesting natural products. β-Hydroxy ketones are commonly prepared by an aldol condensation reaction[3] or by reductive cleavage of an α,β-epoxy ketone. The aldol process proved to be highly useful for the preparation of 'acyclic' β-hydroxy ketones. For cyclic β-hydroxy ketones, however, this method cannot be generally applied efficiently due to the lack of stereo- and regio-control in general, side reactions such as the intermolecular aldol, and further reactions (*e.g.* dehydration) of the desired products. Many reagents have been found to be effective for the reductive cleavage of α,β-epoxy ketones, which are readily accessible from conjugated enones and allylic alcohols with stereocontrol and possible asymmetric induction, including alkali metal in liquid ammonia,[4] zinc in acetic acid,[5] samarium diiodide,[6] aluminium amalgam,[7] chromous salts in alcohol,[8] organoselenium borate complex,[9] sodium hydrogen telluride,[10] sodium iodide in conjunction with sodium acetate,[11] and the combination of palladium, formic acid and triethylamine.[12] It has also been shown that the reductive cleavage can be carried out electrochemically.[13] The yields of the desired β-hydroxy ketones, however, are often inconsistent by the use of many of the existing procedures. This is mainly because of the intrinsic instability of the β-hydroxy ketone system which may undergo facile dehydration or retro-aldol reaction even under weakly acidic or basic conditions at somewhat higher temperature over somewhat longer reaction time. Herein we describe an efficient and apparently general procedure for the reductive cleavage of α,β-epoxy ketones to the corresponding β-hydroxy ketones under very mild conditions, which minimize the side reactions.

The new procedure, which is operationally simple, makes use of lithium naphthalenide (LN) as the reducing agent. This reagent, which can be easily prepared as a stable stock solution by mixing equal parts of lithium metal and naphthalene in THF at room temperature,[14] was found to be highly effective for the selective cleavage of the α,β-epoxy ketone system.‡ In a typical experiment, a solution of epoxy ketone **1** (49 mg, 0.32 mmol) in THF (2 ml) was added to a 0.34 M solution of LN in THF (2.8 ml) at −78 °C. The resulting solution was stirred at −78 °C under an atmosphere of argon for 10 min. Then water (1 ml) was added, and the resulting solution was allowed to warm up to room temperature, diluted with water (4 ml) and extracted with Et_2O (15 ml). Usual work-up of the ethereal solution gave the β-hydroxy ketone **2** in 78% yield after flash chromatography on silica gel (prewashed with a 1% solution of Et_3N in hexanes), eluting with a 15% solution of EtOAc in hexanes containing a small amount of Et_3N (5 drops in 100 ml of solution). The generality of this procedure is evident from the results obtained for a number of α,β-epoxy ketones examined (Table 1). In all cases, products were obtained in synthetically useful yields, many of which are superior to those obtained using other reducing agents. For example, the reduction of epoxide **3** derived from (*R*)-carvone was found to be ineffective with samarium diiodide.[6] With lithium in liquid ammonia, it gave only 35% yield of the desired product **4**.[4b] In the present case with LN, a considerably higher yield of **4** (62%) was realized. As another example, many attempts previously made to introduce the β-hydroxy ketone moiety to steroidal compounds often met with undesirable results.[4c,d,8] Again, by the use of LN under the described conditions, two isomeric steroidal epoxy ketones (entries 8 and 9) were readily reduced to the corresponding β-hydroxy ketones.

In light of its generality, operational simplicity, good yield in product formation, and the mild reaction conditions under which many functional groups are known to be unaffected towards LN,[14] the aforementioned procedure promises to be a method of choice for the synthesis of β-hydroxy ketones *via* reductive cleavage of the corresponding epoxy ketones. As illustrated by the following experimental results, this procedure can be extended to facilitate the preparation of α,α-disubstituted β-hydroxy ketones *via* alkylation of the ensuing enolate produced from the reductive cleavage of the epoxy ring and of 2,2-disubstituted 1,3-diones by subsequent oxidation. Treatment of epoxy ketone **3** with LN in tetrahydrofuran under the standard conditions (*vide supra*) for 30 min, followed by addition of MeI (5 equiv.) and warming up to room temperature resulted in the formation of β-hydroxy ketone **5** in 70% yield.



1 **2** **3** **4**



5 **6**

When hydroxy ketone **5** was subjected to oxidation [PCC (5 equiv.), CH_2Cl_2, 20 °C, 8 h], diketone **6** was formed in 78% yield.

We are grateful to the Natural Sciences and Engineering Research Council of Canada and the University of Alberta for financial support and to the University of Dar-Es-Salaam for granting a sabbatical leave to G. L. M.

Table 1 Reductive cleavage of α,β-epoxy ketones with lithium naphthalenide to the corresponding β-hydroxy ketones

Entry	α,β-Epoxy ketone[a]	*t*/min	Product	Yield[b] (%)	Entry	α,β-Epoxy ketone[a]	*t*/min	Product	Yield[b] (%)
1		10		78	6		20		88
2		15		78					
3		15		71	7		60		65[d]
4		30		62[c]	8		30[e]		77
5		25		68	9		30[e]		87

[a] The α,β-epoxy ketones used for the present study were prepared by treatment of the corresponding enones with LiOH (0.5 equiv.), 30% H_2O_2 (1.5–2.0 equiv.) in MeOH (4 ml per 1 mmol of enone) at room temperature for 0.5–2 h. [b] Yields are for isolated products. [c] An inseparable mixture of two diastereomers was obtained in a ratio of 11 : 1. The stereochemistry of these compounds remains to be determined. [d] A single stereoisomer was obtained. Its stereochemistry remains to be determined. [e] In each of these cases, 4 equiv.of LN was used.

Notes and references

‡ The reductive cleavage of epoxides derived from alkenes with aromatic radical anions has been studied previously by Bartmann (ref. 15) and Cohen *et al*. (ref. 16). To the best of our knowledge, however, this procedure has never been applied to α,β-epoxy ketones to facilitate the preparation of 1,3-ketols.

Nickel-catalysed enantioselective hydrovinylation of styrenes in liquid or supercritical carbon dioxide

Andreas Wegner and Walter Leitner*

Max-Planck-Institut für Kohlenforschung, Kaiser-Wilhelm-Platz 1, 45470 Mülheim an der Ruhr, Germany. E-mail: leitner@mpi-muelheim.mpg.de

Received (in Cambridge, UK) 16th June 1999, Accepted 14th July 1999

Compressed (liquid or supercritical) CO_2 is an environmentally benign reaction medium for the highly efficient regio-, chemo- and enantio-selective nickel-catalysed hydrovinylation of styrenes and it allows for catalyst recycling and selective removal of the product from the reaction mixture.

The formation of carbon–carbon bonds is a fundamental operation in synthetic organic chemistry. There is a great demand for catalytic C–C coupling reactions that allow a high level of chemo-, regio- and stereo-selectivity and can be carried out under environmentally friendly conditions. A very efficient catalytic carbon–carbon bond forming reaction is the transition metal catalysed co-dimerisation of alkenes with ethene yielding 3-substituted but-1-enes (hydrovinylation).[1] The hydrovinylation reaction is particularly intriguing because both starting materials are incorporated entirely in the product and the resulting double bond can be used for further transformations to highly functionalised molecules. Wilke *et al.* introduced the (η^3-allyl)nickel(II) complex **3** (containing a unique chiral 1,2-substituted 1-azaphospholene ligand) as a catalyst precursor for the asymmetric hydrovinylation of aromatic olefins (Scheme 1).[1,2] Complex **3** catalyses the enantioselective hydrovinylation of styrenes at extremely high rates and with unrivalled chemo-, regio- and enantio-selectivity, but it needs to be activated by an excess of highly flammable $Et_3Al_2Cl_3$. Furthermore, the reaction requires temperatures below −60 °C and the use of toxicologically disreputable CH_2Cl_2 as a solvent.

In order to overcome these drawbacks, we investigated the hydrovinylation with complex **3** in liquid and supercritical CO_2 as an alternative solvent.[3,4] The reaction proceeded smoothly using $Et_3Al_2Cl_3$ as the co-catalyst, but ees were disappointingly low (Table 1). We also observed some corrosion of the stainless steel high pressure reactor under these conditions, and therefore tried to replaced the aggressive Lewis acid by weakly co-ordinating anions which are easier to handle and non-corrosive under the reaction conditions. Unfortunately, no catalytic activity was observed using TfO^- or $[Al(O(CH_2)_2C_6F_{13})_4]^-$ as co-catalysts. The use of $[Al(OC(Ph)(CF_3)_2)_4]^-$ led to an active catalytic system but reactivity and stereoselectivity were low. Finally, we were pleased to find that the use of tetrakis[3,5-bis(trifluoromethyl)phenyl]borate (BARF) yields a catalytic system that is comparable to $Et_3Al_2Cl_3$ in activity and chemoselectivity but gives far better ees.† The use of BARF activates **3**, increases the thermal stability of the catalyst, and provides sufficient solubility of the active species in liquid and supercritical CO_2,[5] thus allowing the reaction to proceed close to and beyond the critical point of pure CO_2 (T_c = 31 °C, P_c = 73 atm, d_c = 0.468 g cm^{-3}). The 4-substituted styrenes **1b**,**c** were also successfully reacted with ethene in liquid and supercritical CO_2 to yield **2b**,**c** in high yield and with high ee. We note that **2c** is a key intermediate in a potential route to the non-steroidal anti-inflammatory drug Ibuprofen™.[1]

[a] For standard reaction conditions see note †. [b] Determined by GC analysis. [c] Fraction of **2** in product mixture. Typical by-products were 2-phenylbut-2-enes and hydrovinylation products of **2**. [d] Reaction time 30 min. [e] Reaction time 50 min.

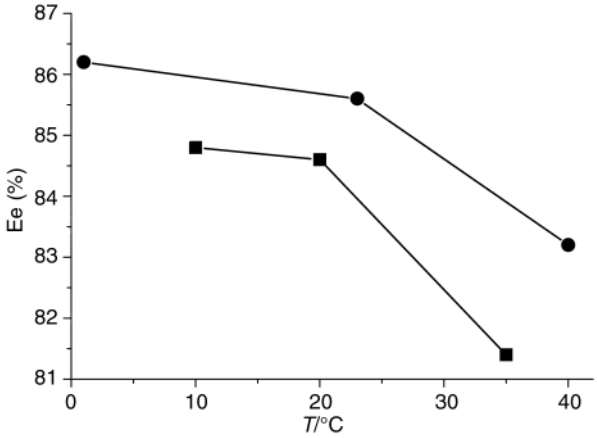

Fig. 1 Enantiomeric excess of **2a** obtained from hydrovinylation using the **3**–NaBARF catalyst in (●) CO_2 and (■) CH_2Cl_2 at different temperatures.

In hydrovinylation, the positive 'BARF effect' on the thermal stability of catalyst is not limited to $scCO_2$ as a solvent.[6] This anion can also be used as co-catalyst with **3** for the hydrovinylation of **1a** in CH_2Cl_2 and, at temperatures above 0 °C, proves to be superior to $Et_3Al_2Cl_3$ in terms of enantioselectivity (84.8 *vs.* 70.2% at 1 °C) with similar chemo- and regioselectivities. However, a comparison of the solvents CO_2 and CH_2Cl_2 reveals that enantioselectivity is generally better in CO_2 (Fig. 1). Chemoselectivity for **2a** is also considerably higher in CO_2 at elevated temperatures; 57.2% selectivity for **2a** are observed in CH_2Cl_2 at 35 °C compared to 74.9% in $scCO_2$ at 40 °C, with complete conversion in both cases.

In $scCO_2$, the catalyst formed from **3** and NaBARF exhibits remarkable stability as demonstrated in an experiment at 40 °C where a **1a**:Ni ratio of 10 000:1 was used (Fig. 2). With an initial turnover frequency of greater than 1300 h^{-1}, a total turnover number of 5000 (corresponding to 50% conversion) was achieved. This result is quite remarkable because previously reported turnover numbers for other nickel-catalysed reactions in the presence of $scCO_2$ were below 22.[7] A catalyst formed from [Ni(cod)$_2$] and PEt_3 was found to be highly susceptible to ligand oxidation in $scCO_2$, resulting in the formation of nickel carbonyls and the corresponding phosphinoxides.[7c] In the experiment shown in Fig. 2, the desired product **2a** was formed with extremely high chemoselectivity and no other products could be detected by NMR or GC analyses. The ee of 79.8% was only slightly lower than in experiments leading to complete conversion of **1a**.

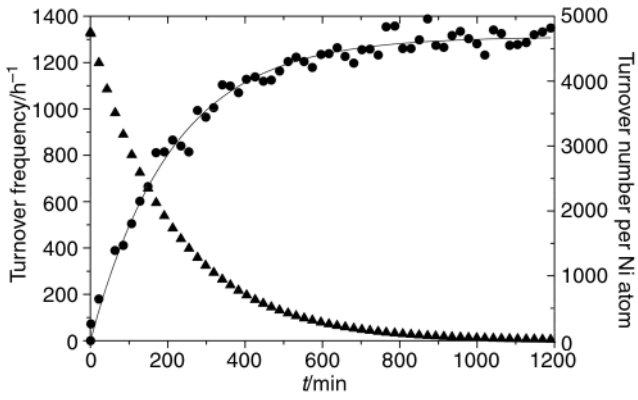

Fig. 2 (●) Turnover number of hydrovinylation of **1a** in the presence of **3**–NaBARF (**1a**:Ni = 10.000) in CO_2 at 40 °C. (▲) Turnover frequencies, derived from the first derivative of the least-squares fit of the turnover number data.

Another intriguing feature of our new procedure for hydrovinylation is the difference in product distribution of the condensate collected from the cold trap and the residue in the high pressure vessel. If the reactor was vented at temperatures above T_c of pure CO_2, the trap content was considerably enriched with **2a** (*e.g.* 81.0 *vs.* 60.5% in the residue) and contained less of the by-products formed from isomerisation and hydrovinylation of **2a**. This finding indicates that it is possible to remove **2a** selectively from the reaction mixture with CO_2. Additionally, the catalyst can be easily recycled after venting and removal of all volatiles *in vacuo*. At a reaction temperature of 22 °C, the ee was minimally reduced (from 83.4% at the beginning down to 79.8%), but some loss in activity was observed (from > 99% conversion down to 33% conversion of **1a**) in four subsequent runs.

In summary, we obtained highly promising results performing enantioselective nickel-catalysed hydrovinylation in liquid and supercritical CO_2. The attractive prospects for catalyst recycling and selective removal of the product encourage our ongoing efforts to explore CO_2 as a solvent for enantioselective catalysis.

This work was supported by the Max-Planck-Gesellschaft, the Deutsche Forschungsgemeinschaft (Gerhard-Hess-Programm) and the Fonds der Chemischen Industrie. We thank Professor G. Wilke for his encouragement in this project and for stimulating discussions.

Notes and references

† In a typical experiment, a stainless steel high pressure reactor (V = 27 cm^3) equipped with thick-wall glass windows, a PTFE stirring bar, a bore hole for a thermocouple, and needle and ball valves was charged with NaBARF (33.4 mg, 35.5×10^{-3} mmol) under argon. A dosing unit containing a solution of **3** (5.4 mg, 6.3×10^{-3} mmol) in **1a** (450 mg, 4.37 mmol) was connected to the reactor through the closed ball valve and pressurised with CO_2 (7.1 g). The reactor was filled through the needle valve with ethene (1.1 g, 39.3 mmol) and CO_2 (14.6 g) using a compressor. The reaction mixture was then warmed to 40 °C, while the dosing unit was heated to 60 °C. Opening the ball valve started the reaction, which was allowed to proceed for 15 min. The reactor contents were then vented through a trap cooled to −55 °C. The products were collected separately from the trap and the reactor by extraction with Et_2O or acetone and analysed by GC and NMR.

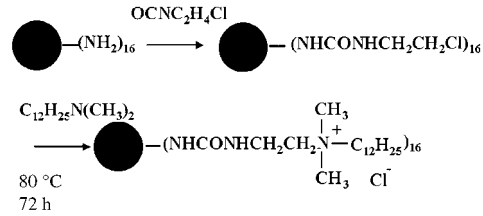
Received (in Columbia, MO, USA) 11th June 1999, Accepted 6th July 1999

Dimethyldodecylammonium chloride functionalized poly(propylene imine) generation 3 dendrimers have been synthesized and proven to have strong antibacterial properties.

The novel architecture of dendrimers[1–6] provides a very high number of functional groups in a compact space. Thus, it is reasonable to expect that these novel molecules will play a major role in materials whose performance depends on high local concentration, such as drugs or antimicrobial agents. Presently, there are few reports in this field. In this work, DSM Astramol™ poly(propylene imine) (PPI) dendrimers have been successfully used to synthesize dendritic biocides, which are shown to be over two orders of magnitude more potent than their small molecule counterpart, *n*-dodecyltrimethylammonium chloride (DTAC), against *Escherichia coli*.

Quaternary ammonium compounds (QACs) have been widely used as disinfectants. They are effective biocidal agents when they possess an alkyl chain with at least eight carbon atoms. Although the exact mechanism of their antimicrobial action is still unclear, it is mostly attributed to cell membrane disruption, their ability to increase cell permeability, and their possible effects on proteins.[7] Since biocidal action requires interactions with the cell membrane, it will be influenced by both the size of the molecules and the functional group density. Larger molecules tend to have a lower permeation rate through the cell membranes, and thus are less efficient. Therefore, dendritic biocides need to counterbalance the negative side of their bulkier size to be very effective. The antibacterial actions against Gram-positive and Gram-negative bacteria are also different since they have different cell structures. The purpose of this study was to synthesize novel dendritic biocides by converting the surface groups of dendrimers to quaternary ammonium functionalities and to test their biocidal capability. The target biocides not only carry 16 quaternary ammonium groups per molecule but also possess a polycationic structure, which is well-known to increase the permeability of cell membranes and thus aid the killing process.[8]

Commercially available poly(propylene imine) (PPI) dendrimers were used in this study. These dendrimers are well-characterized by various techniques.[9–11] The purity of PPI dendrimers has also been investigated by electrospray mass spectrometry.[12] To synthesize these dendritic biocides, the peripheral primary amine groups of PPI generation 3 dendrimers [DAB-dendr-$(NH_2)_{16}$] were reacted with 2-chloroethyl isocyanate to yield pendent chloroethyl groups.[13,14] Urea protons (CO-NH-CO) were observed at δ 6.72 (^{1}H NMR, $CDCl_3$) and carbonyl carbons (CO-NH-CO) were observed at δ 158.7 (^{13}C NMR, 15% in $CDCl_3$). The modified dendrimers were subsequently quaternized by dimethyldodecylamine to give the dimethyldodecylammonium chloride functionalized dendrimers (Scheme 1).[15] A five-fold excess of dimethyldodecylamine was used to facilitate the reaction and to prevent inter-



Scheme 1 Synthesis of dimethyldodecylammonium chloride functionalized PPI generation 3 dendrimers (the filled circle represents a complete dendrimer molecule except for the end groups).

dendrimer quaternization. Two different carbons in the methyl groups were clearly identified with ^{13}C NMR. The methyl groups connected directly with nitrogen were observed at δ 51.1 while the methyl carbon in the dodecyl groups was observed at δ 13.8. FTIR analysis also showed C–H saturation at 2930.4 cm^{-1}, C=O at 1639.9 cm^{-1}, N–H bend at 1562.3 cm^{-1} and N–H stretch at 3297.9 cm^{-1}. The final product was obtained as a yellow solid in 70% yield. It is very soluble in alcohol and $CHCl_3$, and slightly soluble in water. Although MALDI data for a similar amphiphilic dendrimer structure have been published,[2] our effort to collect MALDI-TOF data was not successful, probably because the sample was extremely hygroscopic and the hydrophobic chains were hard to ionize. The nomenclature used is D3C1NC12, which denotes dimethyldodecyl (C12) ammonium (N) chloride (C1) functionalized PPI generation 3 dendrimers (D3).

The antibacterial properties of D3C1NC12 against Gram-negative *E. coli* were determined by a bioluminescence method.[16–18] Bioluminescence is observed under normal growth conditions for the recombinant *E. coli* strain TV 1048. Whenever the bacteria are in a biocidal environment, the light-off response corresponds to the toxic effect of the biocide.[19] Fig. 1 shows typical data for the bioluminescence experiment. The result is expressed as the sample bioluminescence normalized to a control (without biocide) *vs.* time. The reduction of luminescence quantitatively shows the antibacterial properties of the

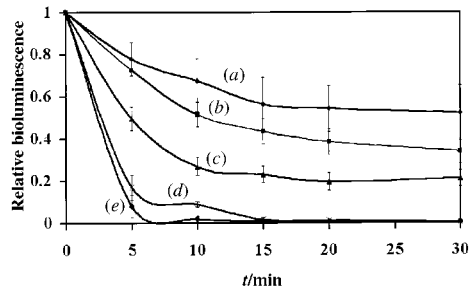


Fig. 1 Time course of the relative bioluminescence of *E. coli* in contact with D3C1NC12: (*a*) 4, (*b*) 8, (*c*) 12, (*d*) 16 and (*e*) 20 μg ml^{-1}. The temperature of experiments was maintained at 30 °C, the optimal temperature for the growth of strain TV 1048. The dendrimer biocides were added to bacterial suspensions with an optical density at 600 nm at 0.2. The data shown are the average of three experiments.

† Current address: Illinois Institute of Technology, E1 Room 117, 10 West 32nd Street, Chicago, IL 60616 USA.

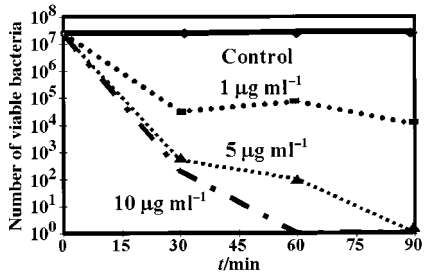

Fig. 2 Biocidal effect of D3C1NC12 on *S. aureus* in suspension tests (10% Tween 80 was used as a neutralizer).

sample. At 4 μg ml^{-1}, the dendrimer inhibited the growth of *E. coli*, but the bacteria could adjust to the environmental stress and survive. At higher concentrations (20 μg ml^{-1}), the bioluminescence decreased very rapidly and was reduced to an undetectable level in 15 min, indicating a strong biocidal effect. In the control experiment, the bioluminescence of the bacteria did not change significantly (5%) if the same concentration of pure PPI generation 3 dendrimers was added (data not shown).

To quantify the level of the biocidal effect of the cationic dendrimer and to compare it to its small molecule counterpart, the *n*-dodecyltrimethylammonium chloride (DTAC) EC_{50} value was determined. EC_{50} is defined as the concentration of the compound which causes a 50% reduction of the bioluminescence in a certain time period. EC_{50} concentrations were determined by interpolation of the bioluminescence against concentration curves at a specific time. A lower EC_{50} indicates a more toxic compound. The EC_{50} of D3C1NC12 is about 12 μg ml^{-1} at 5 min while the EC_{50} of DTAC is about 2000 μg ml^{-1}. The dendrimer architecture increases the potency of DTAC against *E. coli* over 100 times.

Conventional linear or branched polymeric QACs have been investigated for many potential applications.[20–23] Interestingly, it is not enhanced efficiency but low toxicity to humans and the absence of foaming that are often cited as their special features.[7] Compared to conventional linear or branched polymers, dendrimers offer a large number of functional groups in a compact space. These chemical functionalities of the dendrimer biocides are presumably exposed on the surface, while a significant portion of them will be trapped on the interior of random-coil linear polymers. Therefore, the increased potency of dendritic biocides results from their novel dendritic architecture. These biocides could possibly achieve enhanced antimicrobial properties along with low toxicity and the absence of foaming. QACs are not very effective on Gram-negative bacteria such as *E. coli* because they have a complex outer membrane structure that effectively keeps out the antibacterial agents. The combination of their high functional group density and increasing permeability due to their polycationic structure allow dendritic biocides to reach and disrupt cell membranes and eventually lead to cell death. This explanation is supported by the analysis of the bioluminescence data, which give a dilution coefficient of 1.8. The dilution coefficient is similar to the reaction order in chemical kinetics. It represents the change in activity brought about by different concentrations. The higher the dilution coefficient, the more rapidly the antimicrobial agent loses its activity. The dilution coefficient of the novel dendrimer biocides falls into the range of conventional QACs (1–2.5), implying a similar mode of action.[24]

To verify that the biocidal effects of D3C1NC12 were not bacteria dependent, its antibacterial properties against Gram-positive *Staphylococcus aureus* were investigated by suspension tests.[25] Fig. 2 shows that D3C1NC12 inhibited the growth of *S. aureus* at levels as low as 1 μg ml^{-1} and effectively killed them at 10 μg ml^{-1} in 60 min. Similar results have been reported for DTAC.[7] This demonstrates the strong potency of dendritic biocides on typical Gram-positive *S. aureus*.

We have demonstrated that it is feasible to synthesize highly potent dendrimer-based antibacterial agents. The novel dendritic biocides are over two orders of magnitude more potent than their small molecule counterparts against Gram-negative bacteria. They are also very effective against Gram-positive bacteria. The dendritic architecture greatly enhances the effectiveness of common quaternary ammonium disinfectants.

The authors would like to acknowledge Dr Prasad Dhurjati (University of Delaware), Tina K. Van Dyk and Dr Robert LaRossa (DuPont Company) for the use of *E. coli* strain TV1048 and Steve Bai (University of Delaware) for assistance with NMR.

Unique polymers *via* radical diene cyclization: polyspironorbornanes and their application to 193 nm microlithography

Robert P. Meagley, Dario Pasini, Linus Y. Park and Jean M. J. Fréchet*

Department of Chemistry, University of California, Berkeley, CA 94720-1460, USA.
E-mail: frechet@cchem.berkeley.edu

Received (in Corvallis, OR, USA) 25th March 1999, Accepted 23rd June 1999

The design of novel alkylated norcamphor derivatives that undergo cyclopolymerization is explored; the resulting polymers incorporate suitable functional groups for chemical amplification and show excellent imaging characteristics under lithographic exposure at 193 nm.

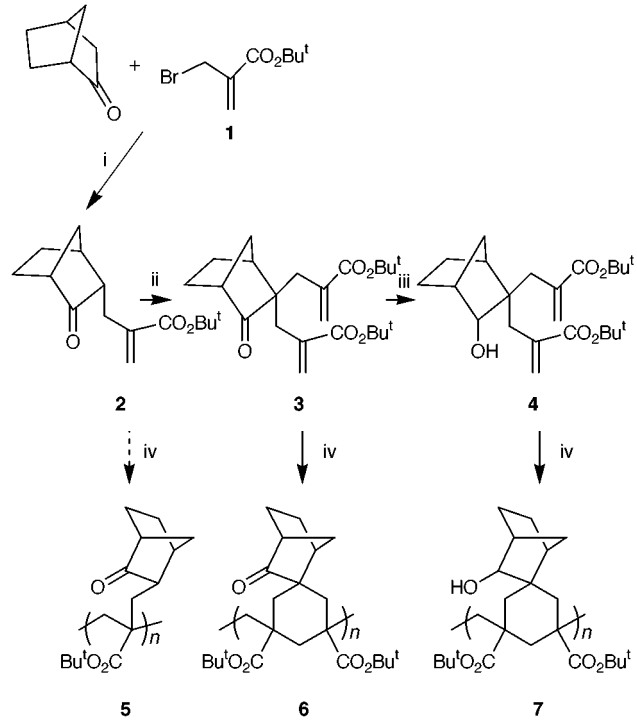
The rapid advance in the miniaturization of microelectronic devices requires the development of new imageable polymeric materials for 193 nm microlithography.[1] Highly sensitive, chemically amplified resists for 248 nm microlithography were described in the early 1980s,[2] and have been used commercially for more than a decade. They operate on the basis of acid-catalyzed deprotection of a polymer in a process that renders the final product soluble in aqueous base.[3] The next generation of resists for 193 nm lithography requires much structural redesign to obtain optical transparency at 193 nm while preserving the etch resistance normally afforded by aromatic rings.

Acrylic and methacrylic acids[4] have been suggested for this application due to their good transparency but their dry-etch resistance is limited. Since a high carbon to hydrogen (C/H) ratio is required to confer etch resistance[5] to the polymeric structure, several carbon-rich, chemically amplified resist materials have recently been described.[6,7] Here, we present a novel synthetic approach for the construction of carbon-rich polymers *via* the cyclopolymerization[8] of suitably modified difunctional monomers.

In earlier work, Marvel *et al.*,[9] and later Mathias *et al.*,[10] have described the free radical polymerization of diacrylates to afford soluble cyclopolymers with virtually complete cyclization. We have now designed bifunctional acrylic-like monomers, incorporating both (i) *tert*-butyl esters as imageable functionalities for chemical amplification, and (ii) carbon-rich cage moieties for etch resistance. A suitable commercially available building block is racemic norcamphor. It can be alkylated *via* its enolate using *tert*-butyl 2-(bromomethyl)acrylate **1** to give the monosubstituted product **2** in good yield (Scheme 1).† This alkylation, as shown by 2D ^{1}H NMR spectroscopy, proceeds diastereoselectively, the *endo* face of the norbornene structure being less sterically hindered and more suitable for reaction with the bromide. The disubstituted monomer **3** could also be obtained under the same reaction conditions, although incomplete conversion of the starting monosubstituted camphor derivative **2** into **3** was observed, probably due to attack of the alkylating agent on the more sterically hindered *exo* face.

Isolation of pure monomer **3** required careful purification of the crude product by flash column chromatography. The structure of **3** was determined by standard spectrometric techniques and confirmed by X-ray crystallographic analysis. The ketone functionality of **3** could be selectively reduced with KBH_4 in MeOH to afford alcohol monomer **4** in good yields.

Monomers **3** and **4** undergo smooth cyclopolymerization under free-radical conditions in deoxygenated solvents to give the cyclopolymerized products **6** and **7**, respectively (in up to 88% yield after precipitation from MeOH). The resulting polymers were soluble in a variety of organic solvents, and IR and NMR spectroscopic analyses revealed the absence of residual alkene groups in the two polymers, thus confirming that virtually complete cyclization had been achieved. Interestingly,



Scheme 1 *Reagents and conditions*: (i) NaOBu^t, THF, 0 °C, 70%; (ii) **1**, NaOBu^t, THF, 0 °C, 50%; (iii) KBH_4, MeOH, 0 °C, 50%; (iv) AIBN, solvent, 70 °C, 30 h.

the monosubstituted camphor derivative **2** did *not* polymerize under standard free radical conditions, probably as a result of the extreme steric hindrance that adjacent camphor derivatives would experience within the backbone of polymer **5**.

Differential scanning calorimetry analysis of polymers **6** and **7** showed no transitions below the decomposition temperature of the polymer, which occurs at *ca.* 240 °C and results from the thermolysis of the *tert*-butyl esters. Thermogravimetric analysis data for the polymers were in close agreement with the observed and calculated weight losses for the thermolysis of the *tert*-butyl ester functionalities. As can be seen in Table 1, variations in

Table 1 Cyclopolymerization of monomers **3** and **4** under free radical conditions

[a] Molecular weights determined by size exclusion chromatography relative to polystyrene standards. [b] Polydispersity index.

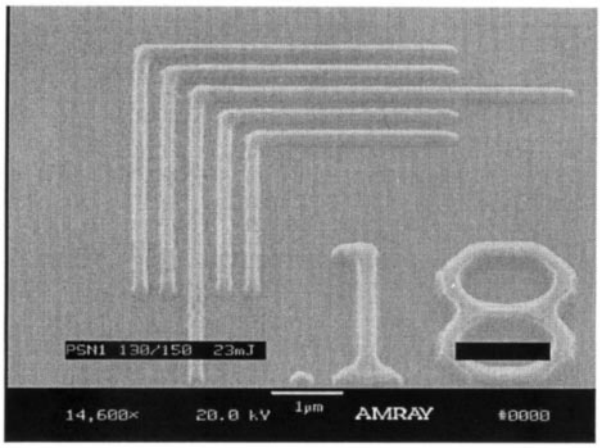

Fig. 1. Electron micrograph of 180 nm nested features obtained from films of polymer **6** and a photoacid generator after exposure to a 193 nm stepper.

monomer or initiator concentrations, solvent, or the use of dodecanethiol as a chain transfer agent,[11] brought about considerable variations in the molecular weight distribution. Control of molecular weight is useful for such polymers since low molecular weight polymers are often desirable for lithographic applications at 193 nm.

Camphor-derived polymers **6** and **7** produced high quality films on silicon wafers. Nevertheless, the absorbance of films of polymer **6** at 193 nm (A = 0.66 per μm of film thickness) was found to be relatively high. The corresponding polymer **7**, free of ketone or olefin moieties, showed a greatly reduced absorbance at 193 nm (A = 0.23 μm^{-1}). Films prepared from polymer **6** bearing ketone functionalities and 10 wt% of a photoacid generator[12] showed clearing doses in the order of 10 mJ cm^{-2}. Similar films prepared from polymer **7** and 5 wt% photoacid generator required doses of *ca.* 15 mJ cm^{-2}. This confirms that the removal of the somewhat basic ketone functionalities, in addition to lowering the absorbance of the films, contributes to enhance the photospeed of the corresponding resist formulations. Images with feature sizes of 0.18 μm (Fig. 1) and lower could be obtained. This study demonstrates the feasibility and flexibility of a cyclopolymerization protocol that allows the rapid adjustment of 'carbon density' within the polymeric structure for applications such as nanolithography. All of these bis-olefinic monomers cyclopolymerize readily and preliminary experiments suggest they can also be used in copolymerizations with a variety of co-monomers. We are currently pursuing further optimization of the fundamental design of these materials as well as of their imaging properties.

Funding by SEMATECH is acknowledged with thanks. This work was carried out in collaboration with Professor C.G. Willson at the University of Texas-Austin. We thank Professor Willson and his group, as well as Dr J. Byers of SEMATECH and the IBM Almaden Lithography Group, for assistance in the 193 nm imaging experiments.

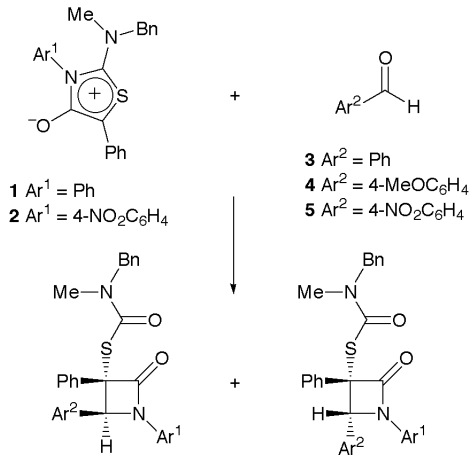
Received (in Liverpool, UK) 28th May 1999, Accepted 9th July 1999

A novel and simple method has been developed to obtain penem analogs with biologically interesting functionalities, which combines aromatic aldehydes with thioisomünchnones, a readily available class of mesoionic heterocycles.

Mesoionics, five-membered aromatic heterocycles that cannot be represented by Lewis forms not involving charge separation, constitute a large and heterogeneous family of masked dipoles.[1] Their [3 + 2] cycloadditions have proven to be a fertile methodology, often encompassing the preparation of naturally-occurring products.[2] The versatility of these synthons can be exemplified in the case of 1,3-thiazolium-4-olates (thioisomünchnones) which have been converted into six-,[3] five-[4] and three-membered[5] functionalized rings by reaction with different dipolarophiles.

In contrast to what was expected, the reactions of 2-aminothioisomünchnones, such as **1** and **2**, with aromatic aldehydes yielded β-lactams, which have hitherto been unknown for this type of mesoionics. These condensations were conducted in anhydrous benzene at reflux and gave rise to a monocyclic β-lactam skeleton in moderate to good yields and without by-products (Scheme 1, Table 1). Besides the crucial importance of β-lactams as antimicrobial agents,[6] monocyclic azetidin-2-ones are potential inhibitors of elastase enzymes.[7] An additional feature of the structures arising from the above-mentioned coupling is the presence of a sulfur-containing side chain, the structural motif encountered in other penem antibiotics such as penicillins and cephalosporins.[8]



Scheme 1

Table 1 Synthesis of β-lactams **6**–**11**

Mesoionic	Aldehyde	*t*/h	Yield (%)[a]		*cis*:*trans*[b]
1	**3**	4	**6a** (41)	**6b** (34)	65:35
1	**4**	10	**7a** (54)	**7b** (20)	70:30
1	**5**	3	**8a** (—)[c]	**8b** (30)	59:41
2	**3**	1	**9a** (35)	**9b** (25)	57:43
2	**4**	6	**10a** (29)	**10b** (20)	60:40
2	**5**	1	**11a** (42)	**11b** (25)	58:42

[a] Yields of the pure isolated *cis* and *trans* isomers. [b] The *cis*:*trans* ratio was determined by ^{1}H NMR (400 MHz). [c] Not isolated.

In every case, β-lactams were formed as a mixture of *cis*- and *trans*-isomers (with respect to the orientation of aryl substituents at C-3 and C-4) and the *cis*:*trans* ratio was established by ^{1}H NMR of crude samples.† Individual diastereomers could be separated either by fractional crystallization or preparative chromatography. Furthermore, the structure of compound *cis*-**7a** was unequivocally confirmed by single-crystal X-ray diffraction analysis (Fig. 1).‡

A plausible rationale to account for the formation of β-lactams is shown in Scheme 2. The tandem process involves first a [3 + 2] cycloaddition in which thioisomünchnone plays the role of the dipole to produce a transient cycloadduct which undergoes a spontaneous C–N bond cleavage, followed by a rearrangement under the reaction conditions. The first step may also be rationalized assuming the stereoelectronic effect provided by the lone pair of the *N*,*N*-dialkylamino nitrogen *via* an intramolecular elimination. The pyramidal configuration of this nitrogen may bring the lone-pair orbital into an *anti* disposition with the leaving group, which competes favorably with the alternative carbon–sulfur scission. The resulting zwitterionic intermediate would largely be stabilized by resonance effects of the substituents on the charged atoms. The

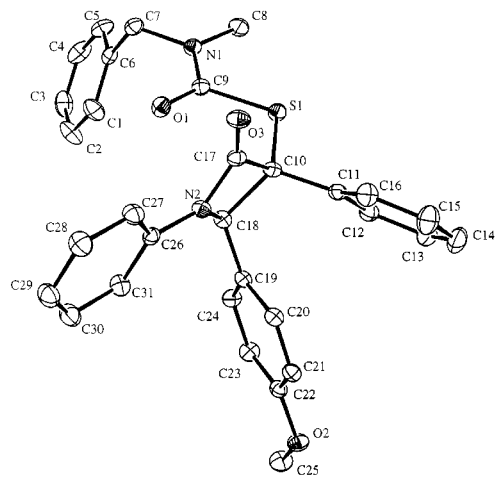


Fig. 1 Solid-state structure of compound **7a**.

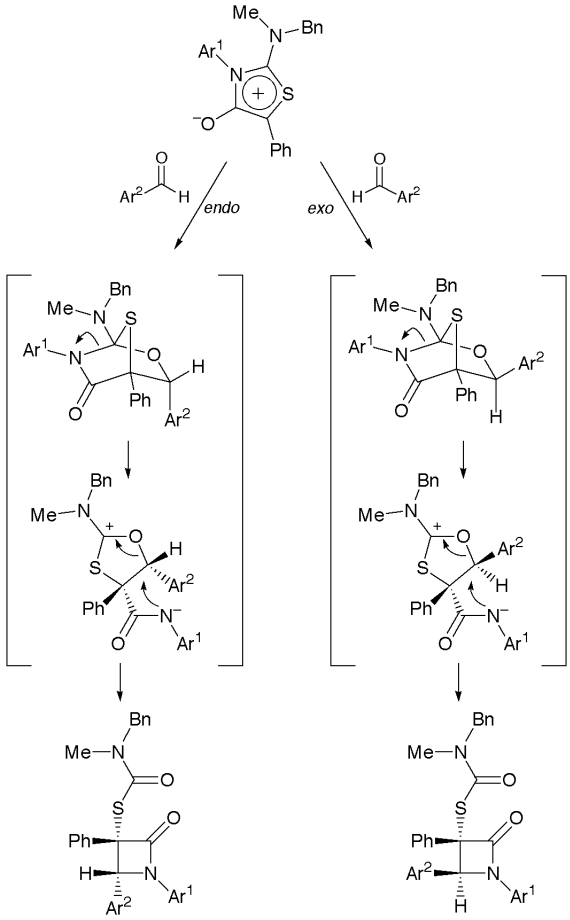
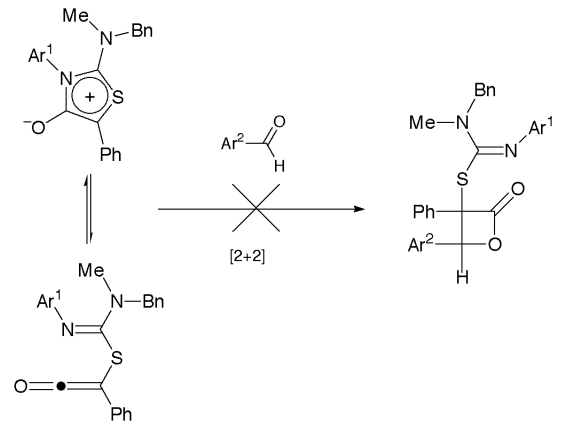


Scheme 2

formation of *cis*- and *trans*-diastereomers results from *exo* and *endo* approaches to the mesoionic ring.

It is fair to say that another mesoionic system, 1,3-oxazolium-5-olate, denoted colloquially as münchnone and containing an azomethine ylide dipole, also affords β-lactams by reaction with imines.[9] This formal [2 + 2] cycloaddition has been rationalized assuming that münchnones exist in equilibrium with their ketene-type valence tautomers, which would ultimately be the reactive species. However, there is no spectroscopic evidence of such tautomers, albeit this might be accounted for by a weak equilibrium in solution or a very short lifetime of the latter species. Since β-lactams have now been obtained from thioisomünchnones, for which putative valence tautomers would otherwise lead to a different four-membered ring (Scheme 3), the hypothesis of ketene reagents for münchnone cycloadditions should be revisited. In fact, it is also plausible for a stepwise reaction mechanism combining a [3 + 2] cycloaddition and rearrangement to afford the desired β-lactams. Even though further studies are required, our results represent a step in a direction that has been overlooked. It thus seems likely that münchnones do not behave like ketenes, a belief held for almost three decades.



Scheme 3

To sum up, a concise and novel approach to β-lactams has been developed. The strategy may provide an exciting and growing interest in mechanistic and synthetic chemistry with mesoionic systems.

Efficient ruthenium–TEMPO-catalysed aerobic oxidation of aliphatic alcohols into aldehydes and ketones

Arné Dijksman, Isabel W. C. E. Arends and Roger A. Sheldon*

Laboratory for Organic Chemistry & Catalysis, Department of Biotechnology, Delft University of Technology, Julianalaan 136, 2628 BL Delft, The Netherlands. E-mail: secretariat-ock@stm.tudelft.nl

Received (in Liverpool, UK) 30th March 1999, Accepted 3rd June 1999

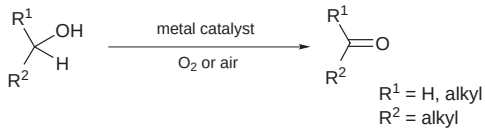
The combination of $RuCl_2(PPh_3)_3$ and TEMPO affords an efficient catalytic system for the aerobic oxidation of a broad range of primary and secondary (aliphatic) alcohols at 100 °C, giving the corresponding aldehydes and ketones, respectively, in >99% selectivity in all cases.

The oxidation of primary and secondary alcohols into their corresponding aldehydes and ketones, respectively, plays a central role in organic synthesis.[1] Traditionally, such transformations have been performed with stoichiometric quantities of inorganic oxidants, such as chromium(VI) compounds.[2] The quest for effective catalytic systems that use clean, inexpensive primary oxidants, such as molecular oxygen or hydrogen peroxide, *i.e.* a 'green method' for converting alcohols to carbonyl compounds on an industrial scale, remains an important challenge.[3]

Ruthenium compounds have been extensively investigated[4] as catalysts for alcohol oxidations using a variety of primary oxidants, *e.g.* iodosobenzene,[5] *N*-methylmorpholine *N*-oxide,[6] *tert*-butyl hydroperoxide,[7] hypochlorite,[8] bromate[9] or a combination of oxygen and an aldehyde.[10] Ruthenium compounds, *e.g.* $RuCl_2(PPh_3)_3$,[11a] trinuclear ruthenium complexes[11b] and Ru-hydrotalcite,[11c] have also been shown to catalyse the oxidation of alcohols using oxygen as the sole oxidant, but the scope was generally limited to activated alcohols, *i.e.* allylic and benzylic alcohols.

A few ruthenium-based systems for the catalytic aerobic oxidation of non-activated aliphatic alcohols (Scheme 1) are known.[12] For example, ruthenium complexes in combination with hydroquinone as cocatalyst,[12b,c] and tetrapropylammonium perruthenate (TPAP), either as such[12d] or supported on an ion exchange resin,[12e] catalyse the reaction in Scheme 1. Two heterogeneous ruthenium catalysts, the improved Ru/Co-hydrotalcite[12f] and Ru/CeO_2,[12g] have also been described. Besides ruthenium, a few other metals, *e.g.* palladium,[13] cobalt[14] and copper,[3,15] have also been shown to catalyse the reaction in Scheme 1. However, all reported systems require relatively large quantities of catalyst (5–10 mol%) and/or additives, *i.e.* cocatalyst (10–20 mol%) and drying agents (2 equiv.), to achieve their activity.

The stable free radical 2,2′,6,6′-tetramethylpiperidine *N*-oxyl (TEMPO) catalyses the oxidation of alcohols by positive halogen compounds, *e.g.* hypochlorite, hypobromite and trichloroisocyanuric acid.[16,17] In this reaction, the corresponding oxoammonium salt is the active oxidant. The hydroxylamine, which is formed, is reoxidised by the positive halogen compound. Alternatively, the use of TEMPO in combination with copper salts and oxygen as primary oxidant was reported by Semmelhack.[18] However, this system was effective only with easily oxidised benzylic and allylic alcohols, simple primary and secondary alcohols being largely unreactive.



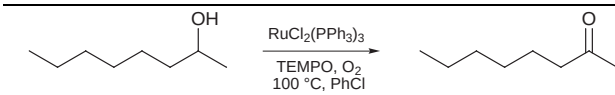
Scheme 1

Based on the various systems described above, we reasoned that the combination of ruthenium and TEMPO would likely lead to an efficient catalytic system for the aerobic oxidation of alcohols. For our initial experiments, we selected octan-2-ol as the test substrate and allowed it to react in PhCl with catalytic quantities of $RuCl_2(PPh_3)_3$ in the presence of TEMPO and oxygen. The results of these studies are collected in Table 1.

A typical reaction was carried out as follows: octan-2-ol (15.0 mmol; 1.96 g), *n*-hexadecane (internal standard; 3.0 mmol; 0.69 g), $RuCl_2(PPh_3)_3$[19] (0.225 mmol; 215.7 mg) and TEMPO[20] (0.675 mmol; 105.5 mg) were dissolved in 30 ml of PhCl and heated in a high-pressure reactor (10 bar) under a nitrogen atmosphere to 100 °C. The nitrogen atmosphere was replaced by a continuous stream (10 ml min^{-1}) of an oxygen–nitrogen mixture (8:92; v/v) and the mixture was stirred for 7 h. Octan-2-ol conversion and octan-2-one selectivity were determined using GC-analysis (50 m × 0.53 mm CP-WAX 52 CB column).

As can be seen from Table 2, $RuCl_2(PPh_3)_3$ alone is a poor catalyst for the oxidation of octan-2-ol to octan-2-one (entry 1). On the other hand, addition of TEMPO, which itself is not active as catalyst, to $RuCl_2(PPh_3)_3$ leads to a substantial increase in activity (entry 2). The use of PhCl as solvent is not essential and was chosen merely to simplify the GC analysis. Toluene can also be employed and even better results were obtained in neat octan-2-ol (entry 4). In this case, the same absolute conversion (15 mmol) was achieved within 1 h compared to the 9–16 h needed in PhCl (entries 2 and 3). Other ruthenium compounds were also tested. $RuCl_3$ gave lower rates and $RuCl_2(bipy)_2$ and $RuCl_2(DMSO)_4$ were completely unreactive. The turnover frequency (TOF) of our system in the oxidation of octan-2-ol is 9 h^{-1} and is superior to the most active ruthenium system

Table 1 Aerobic ruthenium–TEMPO catalysed oxidation of octan-2-ol[a]



Entry	Substrate : catalyst ratio	*t*/h	Conversion (%)[b]	Selectivity (%)[b]
1[c]	67	7	10	> 99
2	67	7	95	> 99

12[d]	$4\text{-}MeC_6H_4CH_2OH$	$4\text{-}MeC_6H_4CHO$	4	100
13[d]	$4\text{-}O_2NC_6H_4CH_2OH$	$4\text{-}O_2NC_6H_4CHO$	7	68

[a] *Reaction conditions:* 15 mmol substrate, 1.5 mol% $RuCl_2(PPh_3)_3$, 4.5 mol% TEMPO, 30 ml PhCl, 10 ml min^{-1} O_2–N_2 (8:92; v/v), P = 10 bar, T = 100 °C. [b] Conversions based on GC results (selectivity >99% in all cases) using *n*-hexadecane as internal standard. [c] 2 mol% $RuCl_2(PPh_3)_3$, 5 mol% TEMPO and O_2 atmosphere. [d] 1 mol% $RuCl_2(PPh_3)_3$ and 3 mol% TEMPO. [e] O_2 atmosphere.

described in the literature, *i.e.* TPAP,[12d] which in our hands gave a TOF of 5.5 h^{-1} for octan-2-ol.

The use of $RuCl_2(PPh_3)_3$–TEMPO as catalyst for the aerobic oxidation of alcohols was then applied to a range of representative alcohols. As can be seen from Table 2, octan-1-ol is oxidised selectively into octanal (entry 2). TEMPO not only accelerates the oxidation of octan-1-ol, but also completely suppresses the over-oxidation of octanal to octanoic acid. Attempted oxidation of octanal under the same reaction conditions, in the presence of TEMPO, gave no reaction in one week. On the other hand, without TEMPO octanal was converted completely to octanoic acid within 1 h. Besides primary alcohols, secondary, cyclic, allylic and benzylic alcohols also undergo smooth oxidation (selectivity in all cases >99%) into the corresponding ketones and aldehydes (entries 3–13).

In competition experiments, the Ru–TEMPO system displayed a selectivity for primary *versus* secondary alcohols. When an equimolar mixture of octan-1-ol and octan-2-ol was used, 80% of the octan-1-ol was converted, in 7 h, to octanal, whereas only 10% of the octan-2-ol was oxidised to octan-2-one. For an equimolar mixture of BnOH and PhMeCHOH, after 3 h, respectively 90 and 5% conversion was obtained. The preference for primary alcohols is analogous to results obtained with other ruthenium systems, which involve an oxidative dehydrogenation mechanism.

In summary, we have discovered that $RuCl_2(PPh_3)_3$–TEMPO is an effective catalyst for the aerobic oxidation of non-activated aliphatic alcohols and a broad range of other alcohols to aldehydes and ketones, thus providing an environmentally benign method for these synthetically important transformations. To the best of our knowledge this is one of the most reactive catalysts reported to date for the aerobic oxidation of (aliphatic) alcohols. We are currently investigating the mechanistic details of this interesting catalytic system.

We gratefully acknowledge IOP (Innovation-Oriented Research Program) for financial support and Johnson Matthey Inc. for their donation of $RuCl_3$ hydrate.

Making cyclic RNAs easily available

Miriam Frieden, Anna Grandas and Enrique Pedroso*

Departament de Química Orgànica, Facultat de Química, Universitat de Barcelona, Martí i Franquès 1-11, 08028 Barcelona, Spain. E-mail: pedroso@admin.qo.ub.es

Received (in Cambridge, UK) 17th June 1999, Accepted 13th July 1999

A simple solid-phase procedure allows cyclic oligoribonucleotides to be obtained as long as the linear precursor attached to the support has a 2′-deoxyribonucleoside or a 2′-*O*-methylribonucleoside at the 3′-end.

Some of the smallest oligoribonucleotides with known biological activity are cyclic molecules. For instance, c(GG) is an activator of cellulose synthase in *Acetobacter xilinum*,[1] and c(UU) and c(AU) are inhibitors of the DNA dependent RNA polymerase of *E. coli*.[2] At the other end of the scale, large cyclic RNAs are formed in the splicing processes of ribonucleic acids in certain organisms[3] and viroids have circular single stranded RNA as their genomic material.

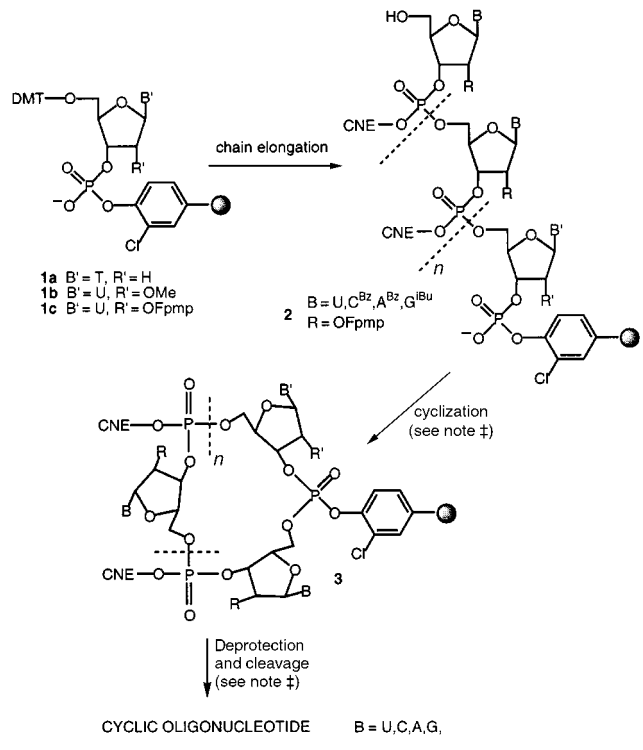
The structure of cyclic RNAs has been determined either by X-ray diffraction[4] or by NMR[5] only for very small molecules. Cyclic RNAs may be useful models for the study of a variety of RNA structural motifs,[6] such as hairpin loops, which could bring new insights into the structure–function relationship of ribonucleic acids.

In spite of their wide potential applications, few efforts have been dedicated so far to the development of chemical methods for the preparation of cyclic oligoribonucleotides. The synthesis of cyclic dinucleotides[7] and tetranucleotides[8,9] has been reported using the phosphotriester[7,8] or the H-phosphonate[9] methods in solution, whereas a solid-phase method has been employed for the preparation of cytidine homooligomers.[10] Larger cyclic RNAs have been obtained either by template-directed chemical[11] or enzymatic[12] ligation, and by rolling circle transcription and self-processing of circular DNA oligonucleotides encoding hairpin ribozymes.[13]

We have recently described a straightforward solid-phase procedure for obtaining small to medium-sized cyclic oligodeoxyribonucleotides.[14] The main advantage of the method is that, after the cyclization and cleavage reactions, non-cyclized chains, polymers and other by-products remain attached to the solid matrix. Therefore, fairly pure crude products are obtained, regardless of the size of the circles and the sometimes low cyclization yields. Scheme 1 shows the key steps in the extension of this methodology to the preparation of cyclic RNA. Synthesis of the ribonucleotide-resin **1** and chain elongation by the phosphite-triester approach using 2-cyanoethyl (CNE) phosphoramidites yields the oligonucleotide-resin **2** which, upon cyclization with 1-mesitylenesulfonyl-3-nitro-1,2,4-triazole (MSNT), affords **3**. After oximate cleavage of **3** and deprotection the cyclic RNA is obtained.

The choice of a suitable 2′-OH protecting group is the most crucial decision in RNA synthesis. It is well documented that the last step of the synthesis must be the deprotection of the 2′-hydroxy functions to avoid strand cleavage or 3′–5′ to 2′–5′ migration of the phosphodiester linkages.[15] The commonly used TBDMS group was discounted because of its lack of stability towards the oximate cleavage treatment.[16] Early elimination of the TBDMS group of the ribonucleoside directly attached to the support may result in the above mentioned undesirable side reactions.

For this reason, we turned our attention to the acid-labile 1-(2-fluorophenyl)-4-methoxypiperidin-4-yl group (Fpmp),[17] whose stability to oximate was confirmed using 2′-*O*-Fpmp-uridine (data not shown). However, to our surprise, the first attempts to prepare small cyclic RNAs (2- to 6-mer) employing the Fpmp group were completely unsuccessful: very low yields and impure crude products were obtained. We reasoned that the key difference with respect to cyclic DNA synthesis was the presence of the bulky 2′-*O*-Fpmp group at the 3′-end of **2** that may be hindering the cyclization reaction. In order to test the validity of this assumption, three nucleotide resins **1** having differently hindered phosphate groups were prepared as previously described[14] on an NH_2-TentaGel™ resin, **1a** (B′ = T, R′ = H), **1b** (B′ = U, R′ = OMe) and **1c** (B′ = U, R′ - OFpmp), and their homogeneity was assessed by gel-phase ^{31}P NMR.† On these nucleotide-resins a series of dinucleotides were assembled, cyclized, cleaved and deprotected.‡ Nucleoside sequences, yields and mass spectrometric data are indicated in Table 1 (entries 1 to 5). These results clearly indicate that the lowest yields were obtained when the nucleotide-resin **1c** was employed (entries 4 and 5). In fact, c(UU) could not be isolated from the complex crude mixture, whilst the rest of the cyclic dinucleotides were easily purified by C18-HPLC chromatography and unequivocally characterized by mass spectrometry and enzymatic digestion.[14] Particularly striking is the difference in yield between the two syntheses of c(UT) [= c(TU)] (entries 3 and 4): much lower yield was obtained from the most hindered resin **1c** than from **1a**, thus demonstrating that steric hindrance in the vicinity of the 3′ terminus phosphate of linear precursor **2** plays a key role. Nevertheless, comparing the results of entries 4 and 5 we can assert that the rest of the chain has a non-negligible effect. Most probably, it hinders the dinucleotide in attaining a reactive conformation.



Scheme 1

Table 1 Synthesized cyclic oligoribonucleotides

Entry	Oligonucleotide-resin	Cyclic oligonucleotide	Crude yield (%)	Purity (%) (HPLC)	Mass spectrometry	
					calc.	found
1	T-T-**R**	c(TT)	50	>90	608.09	608.29[b]
2	T-U_{OMe}-**R**	c(TU_{OMe})	43	>90	624.08	624.20[b]

11	UAGCA-U_{OMe}-**R**[a]	c(UAGCAU_{OMe})	4	80[d]	1934.26	1932.84[c]

[a] Ribonucleosides were 2′-*O*-Fpmp protected. [b] Electrospray MS. [c] MALDI-TOF MS. [d] Estimated by PAGE.

The synthesis of some larger circles was undertaken to further evaluate the possibilities of the method. Several cyclic oligoribonucleotides were obtained at the 1–2 μmol scale from resins **1a** and **1b**. Results are shown in Table 1 (entries 6 to 11). The cyclic products were submitted to Sephadex G-10 gel filtration and HPLC or PAGE purification, and were characterized as above.

Yields of crude products are generally lower than those typically obtained in the synthesis of cyclic DNA. The low yield obtained for c(U_5T) (entry 8) and the difference in yield between the two cyclic tetramers (entries 6 and 7) reflect the difficulty in getting high and reproducible yields in the cyclization reaction with MSNT. A 2′-*O*-methylribonucleotide at the 3′ end of the linear precursor seems to have a negative effect on the cyclization yield of the hexamers (entries 10, 11), which was not observed for a dinucleotide (entry 2). The homogeneity of the crude products detached from the resin is also slightly lower than in cyclic DNA synthesis. However, a major HPLC peak or PAGE band is always obtained, thus allowing easy purification of the circle and showing that the key advantage of the method is preserved.

In conclusion, cyclic RNA can be obtained provided that the linear precursor attached to the support has a 2′-deoxyribonucleoside or a 2′-*O*-methylribonucleoside at the 3′ end. Such single modification in the sequence of the cyclic RNAs should have little relevance for many purposes. For instance, enzymatically circularized hammerhead ribozymes containing non-nucleoside linkers have been shown to display increased biological activity and reduced divalent metal ion requirement.[18]

Work is in progress to prepare larger, 'all-ribonucleoside' cyclic RNAs by circumventing the problem of the steric hindrance at the 3′ end phosphate.

This work was supported by the Ministerio de Educación (DGES, grant PB97-941) and the Generalitat de Catalunya (Centre de Referència de Biotecnologia and SGR98-1).

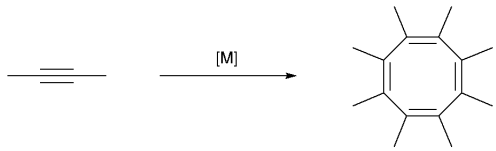
Received (in Cambridge, UK) 8th April 1999, Accepted 6th July 1999

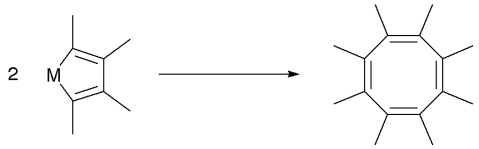
Treatment of zirconacyclopentadienes with 2 equiv. of CuCl at room temperature and with 1 equiv. of NBS at −78 °C selectively afforded cyclooctatetraene derivatives in good yields.

The cyclo-coupling reaction of acetylene to give cyclooctatetraene [eqn. (1)] was discovered by Reppe using the $NiBr_2$/CaC_2 system.[1] For this reaction, the mechanism most generally accepted involves the coupling of two nickellacyclopentadienes for the formation of cyclooctateteraenes.[2]



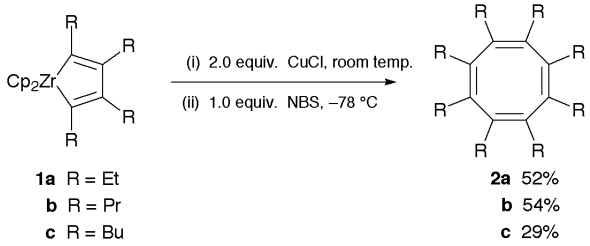
(1)

However, to the best of our knowledge, there is no report of the formation of cyclooctatetraenes from two metallacyclopentadienes [eqn. (2)].[3] This prompted us to investigate the formation of cyclooctatetraene derivatives from zirconacyclopentadienes.[4]



(2)

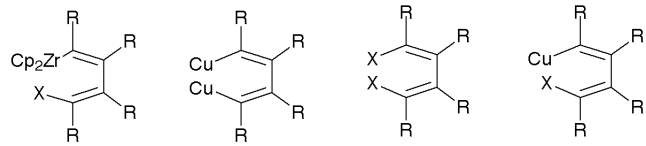
Here we report the first example of cyclooctatetraene formation from metallacyclopentadienes. Sequential treatment of zirconacyclopentadiene with 2 equiv. of CuCl and 1 equiv. of NBS afforded cyclooctatetraenes as described in Scheme 1.†



Scheme 1

A typical procedure is as follows. Tetraethylzirconacyclopentadiene **1a** in THF was treated with 2 equiv. of CuCl at room temperature for 1 h. After the mixture was cooled to −78 °C, 1 equiv. of NBS was added, and the resulting mixture was stirred for 3 h at −78 °C. The product, octaethylcyclooctatetraene **2a**, was obtained in 52% yield.

In order to prepare the cyclooctatetraenes from zirconacyclopentadienes, we designed two reactions, namely, (i) a coupling reaction of **4** with **5** and (ii) a coupling reaction of two molecules of **6**. Reaction of **4** with **5** did not give **2**, and it was not a clean reaction. As already reported,[5] the complex **3** produced cyclobutadienes in good to high yield when it was treated with CuCl. Therefore, the formation of **6** has been

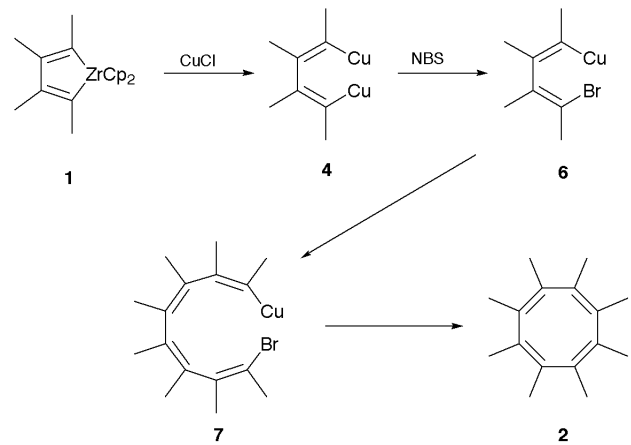


3 X = I or Br **4** **5** X = I or Br **6** X = I or Br

proposed although **6** was not detected. In the reaction a dimer of the cyclobutadienes, tricyclo[4.2.0.$0^{2,5}$]octa-3,7-diene, was obtained as the major product at room temperature. Only a trace amount of cyclooctatetraene was detected in this reaction. This suggested that at room temperature the intramolecular coupling of **6** was faster than the intermolecular coupling. However, we expected that the reaction rate of the intramolecular coupling of **6** would be significantly decreased at low temperature due to steric crowding. In this case, the intermolecular coupling would be the major reaction. Since transmetalation of the Zr–C bond of **3** to a Zr–Cu bond requires room temperature conditions, the complex **6** could not be formed from **3** at low temperature. Therefore, we used monobromination of **4** with 1 equiv. of NBS to produce **6** at low temperature, since it proceeds at −78 °C.

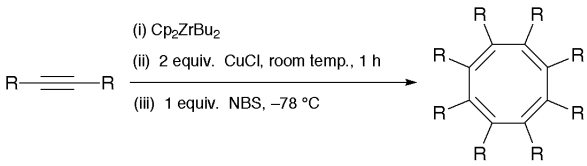
A mixture of tricyclooctadienes and cyclooctatetraenes was obtained as expected when the reaction was carried out at −30 °C. Reflux of the mixture of the two products in THF did not change the ratio. This clearly indicates that rearrangement of tricyclooctadienes to cyclooctatetraenes did not occur. As shown in Scheme 1, cyclooctatetraenes were obtained in good yield at −78 °C as the major product. An X-ray study was carried out to verify the structure of **2b**.‡

On the basis of these results, the following mechanism is plausible (Scheme 2). In the first step, transmetallation of



1 **4** **6** **7** **2**

Scheme 2



Scheme 3

zirconacyclopentadiene with CuCl gives dicopper intermediate **4**. Addition of 1 equiv. of NBS to **4** leads to monobromination at −78 °C giving **6**. The intermediate **6** undergoes intermolecular coupling to form **2** *via* **7**.

It is noteworthy that the formation of cyclooctatetraene derivatives can be performed in one pot from the starting acetylene as follows. For example, to a mixture of 1 mmol of Cp_2ZrCl_2 and 5 ml of THF was added 2 mmol of BuLi at −78 °C. The mixture was stirred for 1 h at −78 °C and then 2 mmol of hex-3-yne was added. The reaction mixture was gradually warmed to room temperature and tetraethylzirconacyclopentadiene **1a** was formed. The same procedure described above for **1a** can then be used (Scheme 3).

High-yield synthesis of a chiroporphyrin by hydrogen bond-directed cyclisation

Céline Pérollier,[a] Jacques Pécaut,[a] René Ramasseul,[a] Robert Bau[b] and Jean-Claude Marchon*[a]

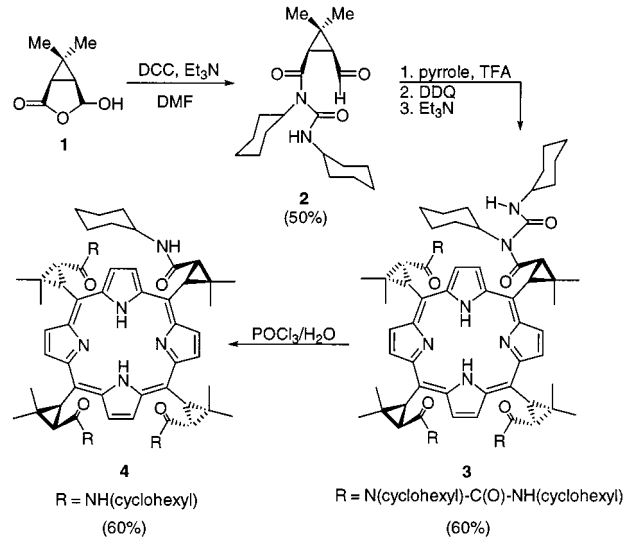
Received (in Basel, Switzerland) 24th May 1999, Accepted 29th June 1999

A new chiroporphyrin is prepared in 60% yield using complementary intramolecular hydrogen-bonding interactions between *N*-acylurea substituents to direct the cyclisation of the tetrapyrrolic intermediate; similar hydrogen-bond assistance by carboxylic acid functions is suggested for cyclisation of hydroxymethylbilane to uroporphyrinogen I.

Esters and disubstituted amides of (1*R*, 3*S*)-(−)-2,2-dimethyl-3-formylcyclopropane-1-carboxylic acid **1** [also called (1*R*, *cis*)-caronaldehyde or biocartol][1,2] are valuable building blocks for the synthesis of porphyrins bearing chiral *meso*-cyclopropyl groups. These chiroporphyrins are obtained as the D_2-symmetric α,β,α,β atropisomer exclusively by classical condensation reaction between the formyl group and pyrrole in modest yield (2–20%). We have shown recently that their manganese(III) complexes are competent catalysts in the asymmetric epoxidation[3] and aziridination[4] of aromatic alkenes. We have also found that the ruthenium(II) and cobalt(III) complexes of tetramethylchiroporphyrin (derived from the methyl ester of **1**) display multipoint binding of axial ligands such as alcohols,[5] amines[6] and amino alcohols:[7] in addition to the metal–ligand interaction, the host–guest bonding array involves two convergent ester carbonyl groups which act as hydrogen bond *acceptors* on each face and are instrumental in ligand enantioselection. In order to obtain a new type of chiroporphyrin bearing both hydrogen bond *donors* and *acceptors*, we have now synthesized the *N*-acylurea **2** by reaction of **1** with DCC, and the corresponding chiroporphyrin. To our surprise, the amphoteric nature of **2** led to an unprecedented high yield of chiroporphyrin **3** (60%), presumably by directing cyclisation of the porphyrinogen intermediate *via* intramolecular hydrogen bonding.

Compound **2** was previously obtained as a side-product (18%) in esterification reactions of **1** catalyzed by DCC–DMAP, and it has been characterised as an *N*-acylurea on the basis of its ^{1}H and ^{13}C NMR spectra.[1] Without competing alcohol or amine reactant, reaction between **1**, 1.2 equiv. of DCC and 1.2 equiv. of Et_3N in DMF, followed by workup and purification by silica gel chromatography (CH_2Cl_2–EtOAc 9 : 1) affords **2** in 50% yield (Scheme 1). The structure assignment was confirmed by X-ray crystallography† (Fig. 1). Notable features of the stereochemistry of **2** are the planarity of the disubstituted amide and urea moieties, and the near orthogonality of the two corresponding planes. The urea is flanked by two sterically bulky cyclohexyl substituents, yet its C11–O12 group is able to interact with the N13–H group of a neighbouring molecule in the crystal, resulting in a chain of strong head-to-tail N–H···O=C–N–H···O=C hydrogen bonds (N13A···O12, 2.889 Å; H13···O12, 1.937 Å; N13A–H···O12, 170.6°) along the *c* axis. There is no hydrogen bond to the amide carbonyl group C8–O9.

After the classical condensation reaction between **2** and pyrrole, subsequent aromatisation of the porphyrinogen intermediate[8] with DDQ and neutralisation with Et_3N, the purple color and nearly clean porphyrin UV–visible spectrum of the reaction mixture came as a surprise. In fact, the D_2-symmetric free base porphyrin **3** was obtained in an unprecedented yield of 60% after purification by silica gel chromatography with CH_2Cl_2–MeOH mixtures. For comparison, a similar condensation reaction carried out on the related *N*-ethyl-*N*-phenyl amide of **1** led only to a 12% yield of chiroporphyrin.[9] Isolation of the abundant porphyrinogen intermediate of **3** was attempted, but this compound was still contaminated with linear oligopyrrole side-products after silica gel chromatography and single crystals could not be obtained. Crystals of the nickel(II)-substituted derivative of **3** were successfully grown from a DMSO solution.



Scheme 1

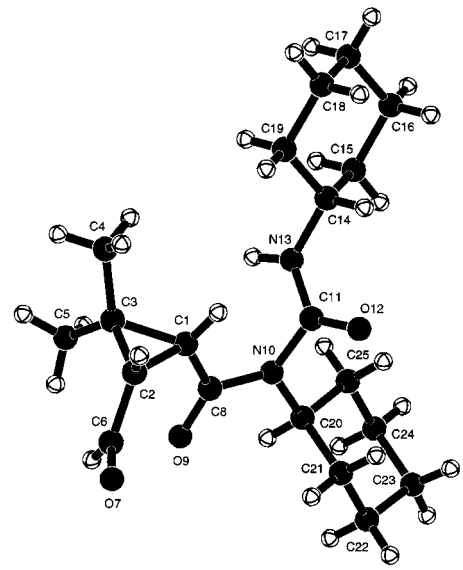


Fig. 1 Molecular structure of **2** showing the planar amide (C1–C8–O9–N10–C11–C20) and urea (N10–C11–O12–N13–C14) moieties, and the near orthogonality of the two corresponding planes (dihedral angle around N10–C11: 76.4°).

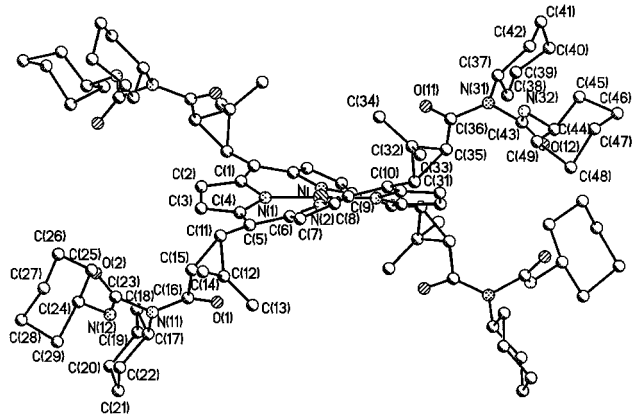

Fig. 2 ORTEP view (30% probability) of the molecular structure of Ni-**3** showing the conformations of the *N*-acylurea substituents with inward oriented amide carbonyl (O1, O11) and urea N–H (N12, N32) groups, and the absence of intramolecular hydrogen bonds.

The X-ray structure of Ni-**3**† (Fig. 2) shows a highly ruffled α,β,α,β porphyrin with inward oriented amide carbonyl and urea N–H groups, and indicates that the distance between two opposite α or β substituents is too large to allow any intramolecular hydrogen bonding interaction. However, examination of a molecular model of the porphyrinogen intermediate suggests that conformations in which the opposite *meso* groups on each face are close enough to allow double hydrogen bonding between the urea N–H donor and amide C=O acceptor groups[10] are accessible. We conclude that the self-complementary nature of the *N*-acylurea substituent of **2** leads to a preorganised, quadruply hydrogen-bonded tetrapyrrole intermediate in which the close proximity of the two reactive end groups directs intramolecular cyclisation[11] and leads to a high yield of porphyrinogen [Fig. 3(*a*)].

The carboxylic acid function is another classical example of self-complementary hydrogen-bonding groups, and it is tempting to speculate that the carboxylic acid substituents on the β-pyrrolic positions of porphobilinogen may serve the function of

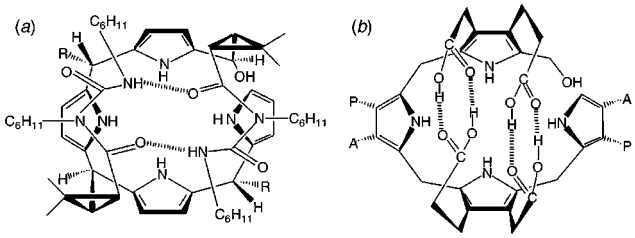

Fig. 3 (*a*) The conformation of the tetrapyrrole intermediate, preorganised by hydrogen bonding between self-complementary *N*-acylurea substituents, which leads to a high yield of porphyrinogen and to a 60% yield of **3**. For the sake of clarity, only the H-bonding pattern on the top face is shown, and each of the two H-bonded *meso* substituents on the bottom face is abbreviated as R. (*b*) Proposed hydrogen-bond assistance by carboxylic acid functions in the cyclisation of hydroxymethylbilane to uroporphyrinogen I. For the sake of clarity, the double hydrogen bond between each of the opposite acetic (A) and propionic (P) substituent pairs on the lower face has been omitted.

directing the spontaneous macrocyclisation of the hydroxymethylbilane tetrapyrrole to uroporphyrinogen I [Fig. 3(*b*)].[12]

Finally, the high yield synthesis of **3** from a readily accessible *N*-acylurea derivative of **1** makes this macrocycle a convenient precursor of other chiroporphyrins, as exemplified by the preparation of the tetra-*N*-cyclohexylamide **4** by $POCl_3$-induced cleavage of the ureido groups,[13] which will be described elsewhere.

exo-Glycal approaches to *C*-linked glycosyl amino acid synthesis

Andrew D. Campbell,[a] Duncan E. Paterson,[a] Tony M. Raynham[b] and Richard J. K. Taylor[a]*

[a] *Department of Chemistry, University of York, Heslington, York, UK YO10 5DD. E-mail: rjkt1@york.ac.uk*
[b] *Roche Discovery Welwyn, Welwyn Garden City, Hertfordshire, UK AL7 3AY*

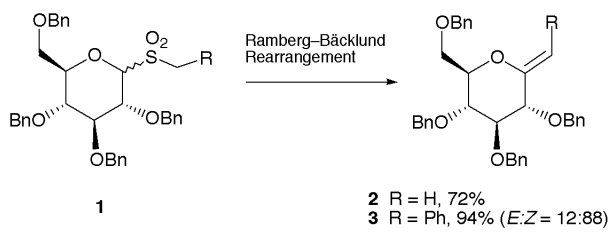
Received (in Cambridge, UK) 22nd June 1999, Accepted 8th July 1999

Two novel routes to *C*-linked glycosyl amino acids are described; the first involves elaboration of an *exo*-glycal and subsequent Ramberg–Bäcklund rearrangement of a sulfone intermediate to give, after functional group manipulation, a protected *C*-glycosyl serine, while the second uses hydroboration–Suzuki coupling of the same *exo*-glycal to produce ultimately the corresponding *C*-glycosyl asparagine analogue.

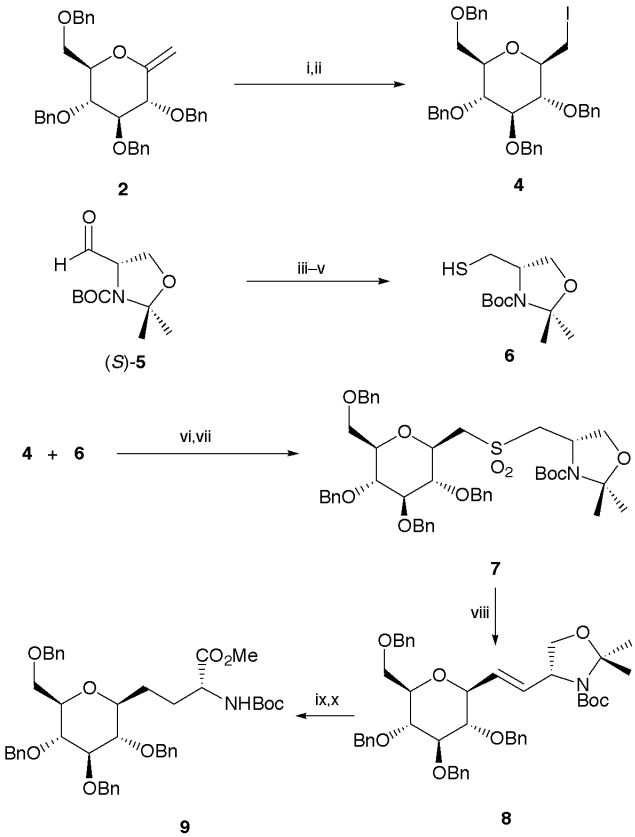
Glycopeptides and glycoproteins are of great current interest from the viewpoints of structure elucidation, molecular recognition, biological function and chemical synthesis.[1] Replacement of the glycosidic oxygen by carbon gives the corresponding *C*-glycoside analogues (glycopeptidomimetics), compounds which are particularly valuable for biological studies because of their hydrolytic stability. The recent publications in this area[1,2] prompt us to disclose our own results. We have recently established that the Ramberg–Bäcklund rearrangement of *S*-glycoside dioxides provides a versatile route to di-, tri- and tetra-substituted *exo*-glycals[3] which are themselves useful intermediates for the preparation of more elaborate *C*-glycosides.[4] Scheme 1 illustrates this methodology with a glucose-derived sulfone: the Meyers variant[5] of the Ramberg–Bäcklund rearrangement is used to convert the sulfones **1** directly into the corresponding *exo*-glycals **2** or **3** without competing 1,2-glycal formation. We have gone on to apply this methodology to the synthesis of *C*-linked disaccharides such as β,β-*C*-trehalose and methyl *C*-gentiobioside.[6]

We now report the application of this methodology to the construction of *C*-linked glycopeptidomimetics. Initial studies (Scheme 2) were concerned with the synthesis of the *C*-glucosyl serine analogue **9**. The key starting material, iodide **4**, was readily prepared from *exo*-glycal **2** by stereoselective 9-BBN hydroboration–oxidation[7] followed by iodination.[6] Thiol **6** was the required coupling partner. We were surprised to discover that this useful building block had not been reported previously but it was easily obtained from the Garner aldehyde (*S*)-**5**[8] by reduction followed by Mitsunobu displacement using thioacetic acid and then treatment with sodium methoxide.† Alkylation of thiol **6** using iodide **4** followed by oxidation of the resulting sulfide produced sulfone **7** {$[\alpha]_D$ −30.1 (*c* 0.57, $CHCl_3$) [HRMS (FAB+): Found: 838.3601. $C_{46}H_{57}NO_{10}SNa$ requires 838.3608 (0.9 ppm error)]}. This sulfone was then treated under Chan's tandem halogenation–Ramberg–Bäcklund conditions[5b] to produce the *E*-alkene **8** (*J* 15.6 Hz) in 37% unoptimised yield. Alkene reduction was efficiently achieved using diimide generated *in situ* and the amino acid was unmasked using a one-pot hydrolysis–oxidation procedure.[9] Diazomethane esterification gave the target *C*-glycosyl serine derivative **9** {$[\alpha]_D$ −8.2 (*c* 1.45, $CHCl_3$) [HRMS (FAB+): Found: 762.3614. $C_{44}H_{53}NO_9Na$ requires 762.3618 (0.6 ppm error)]}.

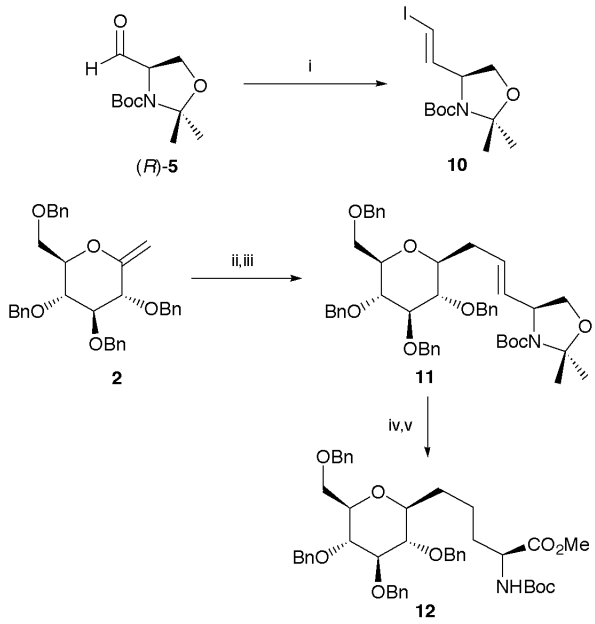
The second target was the *C*-glycosyl asparagine analogue **12** depicted in Scheme 3. In principle, this compound could be made *via* the methodology outlined in Scheme 2 simply by using the higher homologue of iodide **4**[6] or of thiol **6**. However, we decided to investigate an alternative approach based on the Suzuki coupling procedure developed by Johnson and Johns[10] but not previously applied to *C*-glycosyl amino acid synthesis (Scheme 3). For this route we required vinyl iodide **10** which has been described but *via* a rather lengthy route.[11] An improved route to **10** was developed: treatment of the Garner aldehyde (*R*)-**5**‡ with $CHI_3/CrCl_2$[12] produced **10** exclusively as the *E*-isomer {$[\alpha]_D$ −80.8 (*c* 1.76, $CHCl_3$); lit.,[11] −75.3 (*c* 1.9, $CHCl_3$)}. Hydroboration of *exo*-glycal **2** followed by Suzuki coupling with vinyl iodide **10** gave alkene **11** in moderate yield but with complete control over 'anomeric' configuration and alkene geometry (*J* 15.5 Hz). Diimide reduction followed by treatment with Jones' reagent and then diazomethane, as before,



Scheme 1



Scheme 2 *Reagents and conditions*: i, 9-BBN, then H_2O_2, NaOH; ii, PPh_3, imidazole, I_2, 80% (ref. 6); iii, $NaBH_4$; iv, PPh_3, diisopropyl azodicarboxylate, AcSH; v, NaOMe, 38% for 3 steps; vi, K_2CO_3, MeCN–MeOH, reflux; vii, MCPBA, Na_2HPO_4, 66% for 2 steps; viii, CBr_2F_2, KOH–Al_2O_3, Bu^{t}OH, 60 °C, 37%; ix, $TsNHNH_2$, NaOAc, 85 °C, 82%; x, Jones' reagent (1 M), then CH_2N_2, 60%.



Scheme 3 *Reagents and conditions*: i, CHI_3, $CrCl_2$, THF, 60%; ii, 9-BBN; iii, **10**, $PdCl_2(dppf)\cdot CHCl_3$, aq. K_3PO_4, DMF, 48%; iv, $TsNHNH_2$, NaOAc, 85 °C, 78%; v, Jones' reagent (1 M), then CH_2N_2, 56%.

gave the protected *C*-glycosyl amino acid **12** in good yield. All data correlated well with those reported in a previous synthesis of **12** by Dondoni *et al.*[2a] {*e.g.* $[\alpha]_D$ +6.25 (*c* 0.8, $CHCl_3$); lit.,[2a] +6.2 (*c* 0.7, $CHCl_3$) [HRMS (FAB+): Found: 776.3783. $C_{45}H_{55}NO_9Na$ requires 776.3775 (1.2 ppm error)]} and thus confirmed the expected[7,10] β-selectivity of the hydroboration step.

In summary, we have devised two new, versatile routes to glycopeptidomimetics which join together the individual sugar and amino acid units to produce exclusively β-stereoisomers at the 'anomeric' centre. We have also established that the Ramberg–Bäcklund rearrangement of *S*-glycoside dioxides is a general procedure which can be utilised for the synthesis of *exo*-glycals,[3] *C*-linked disaccharides,[6] and now in this work, *C*-linked glycosyl amino acids. We are currently optimising the above procedures and extending the methodology to more challenging targets.

We are grateful to the BBSRC and the University of York for studentships (A. D. C. and D. E. P., respectively). We would also like to thank Roche Discovery Welwyn for CASE support (A. D. C.).

Unusual chromatic properties observed from polymerized dipeptide diacetylenes

Qun Huo, Shaopeng Wang, Aurélien Pisseloup, Deepali Verma and Roger M. Leblanc*

Center for Supramolecular Science and Department of Chemistry, University of Miami, PO Box 249118, Coral Gables, FL 33124, USA. E-mail: rml@umiami.ir.miami.edu

Received (in Columbia, MO, USA) 1st June 1999, Accepted 1st July 1999

The chromatic properties of a few dipeptide polydiacetylenes were found to change dramatically with very slight structural variations of dipeptides, leading to the proposal of a non-coplanar packing model to explain the chromatic behavior of polydiacetylenes.

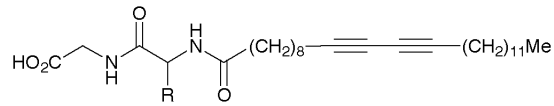
In 1993 Charych *et al.* reported the development of a direct colorimetric detection method of influenza virus based on the chromatic change of polydiacetylene Langmuir–Blodgett films.[1] This work provided a new possibility for diagnostic applications, and the chromatic property of polydiacetylenes has caused extensive attention since then. However, up until now, the precise molecular mechanism of the blue to red color change or transition remains unclear.

At the present time, it is generally accepted that the chromatic difference is based on the difference in the effective π-electron delocalization length along the polymer backbone. The blue form of polydiacetylene, which absorbs light at around 640 nm in the red region, is believed to have a more effective π-electron conjugation length, whereas the red form of polydiacetylene, which absorbs light at around 540 nm in the blue region, has a shorter π-electron conjugation length.[2] However, conflicting explanations for what causes the difference of the effective π-electron conjugation length have been put forward. A model which was generally accepted during the past years attributes the less effective π-electron conjugation of red form polydiacetylenes to conformational disorder or the entangling of the side chains.[3] However, this side chain disorder model is facing more and more challenges from new experimental observations. Recent investigations by FT-IR, electron diffraction[4] and atomic force microscopy[5] have shown that the side chains of red form polydiacetylenes are actually also in an ordered conformation.

Cheng and Stevens reported that the chromatic properties of polydiacetylene liposomes functionalized with amino acids such as Glu, Gln and His as polar moieties were affected by the pH of the aqueous solution.[6] The chromatic change upon pH value variation is attributed to the repulsive Coulombic interactions developed on the surface due to ionization of the amino acid head groups. As a result, the head groups must rearrange themselves to a staggered non-coplanar packing to accommodate the new charge distribution. The staggered non-coplanar packing of diacetylene lipids leads to the formation of a non-linear red form polydiacetylene backbone when irradiated, yet the alkyl chains attached to polydiacetylene backbone remain in their well-ordered conformation.

In the meantime, our recent study of hydrogen bonding effects on the polymerization and chromatic properties of a triaminotriazine diacetylene lipid has led us to the same conclusion.[7] In order for two different diacetylene lipids to attain stable intermolecular hydrogen bonding, the two lipids were packed into a staggered non-coplanar packing mode in the mixed monolayer, leading to the observation of only red form polydiacetylene films.

We now report experimental evidence which further supports this mechanism. Four dipeptides, GlyGly, AlaGly, ValGly and PheGly, were attached to pentacosa-10,12-diynoic acid (PDA) through solid phase peptide synthesis. The four dipeptide



PDA-GlyGly-OH R = H
PDA-AlaGly-OH R = Me
PDA-ValGly-OH R = Pr^i
PDA-PheGly-OH R = Bn

diacetylene lipids have the same molecular skeleton structure, except that they have different hydrophobic side groups on the second amino acid residue. While PDA-GlyGly-OH has no side group, PDA-AlaGly-OH has a methyl side group, PDA-ValGly-OH has an isopropyl side group and PDA-PheGly-OH has a benzyl side group. The surface pressure–area isotherm measurements have shown that the four lipids formed stable monolayers at the air-water interface (Fig. 1). The limiting molecular areas of PDA-GlyGly-OH, PDA-AlaGly-OH, PDA-ValGly-OH and PDA-PheGly-OH are 23, 32, 36 and 40 $Å^2$ $molecule^{-1}$, respectively, which are proportional to the size of the second amino acid side groups in the dipeptides.

The dipeptide Langmuir films were irradiated with UV light (254 nm) at a surface pressure of 20 mN m^{-1} on a pure water subphase (pH 5.80). The *in situ* UV-Vis absorption spectra of the monolayers with different irradiation times are presented in Fig. 2. Tremendous chromatic differences were observed from the four polymerized dipeptide lipid monolayers, despite the very slight structural differences between these molecules. While the PDA-GlyGly-OH monolayer exhibits a typical blue absorption band with a maximum absorption around 640 nm, the polymerization of PDA-AlaGly-OH, PDA-ValGly-OH and PDA-PheGly-OH monolayers leads to the appearance of polymer absorption bands at 570 (purple form), 535 (red form) and 525 nm (red–yellow form), respectively.

The only difference between these peptide amphiphiles is the size of the hydrophobic side groups on the second amino acid residue. It has been reported previously that dipeptide GlyGly derivatized lipids with single hydrophobic alkyl chains tend to form β-sheet structures at the air-water interface, due to strong

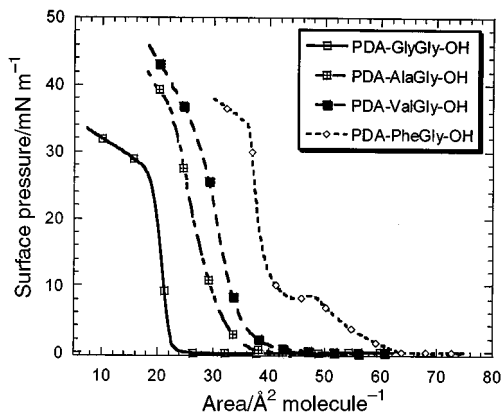


Fig. 1 The surface pressure–area isotherms of the dipeptide diacetylene lipids at the air-water interface.

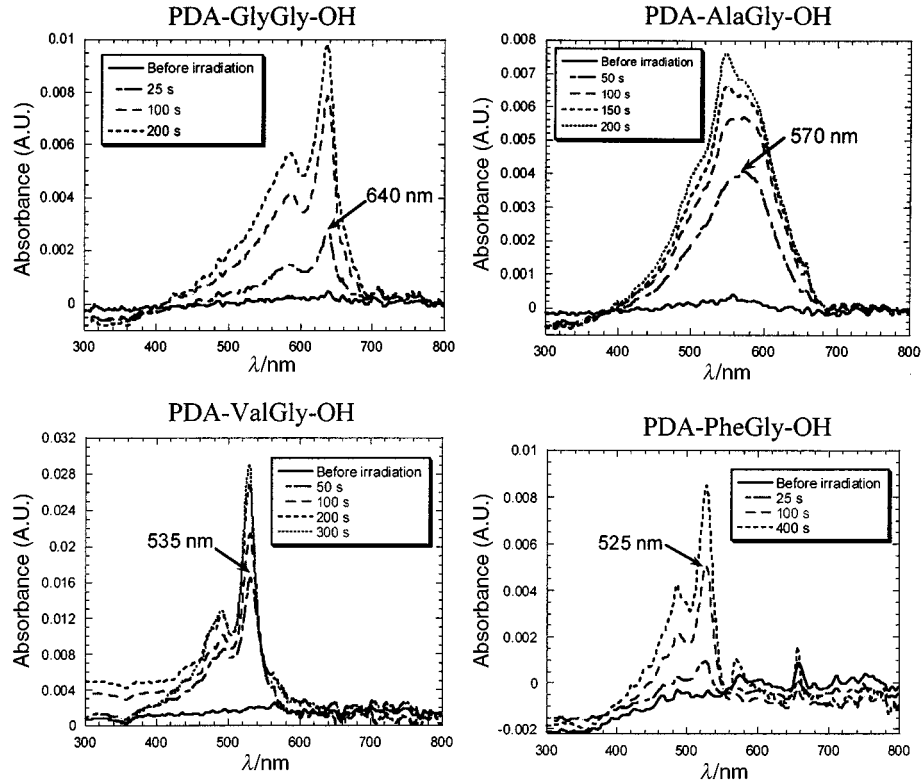

Fig. 2 The UV-Vis absorption spectra of polymerized dipeptide diacetylene monolayers with different irradiation times.

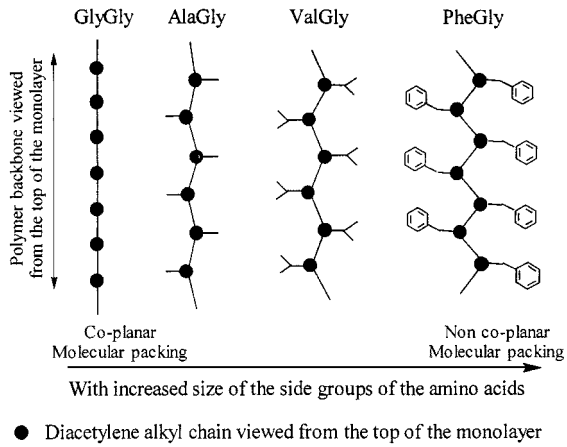

Fig. 3 An illustration of the decreased linearity of the polydiacetylene backbone due to the non-coplanar packing of diacetylene lipids with the increased size of the side groups on the dipeptides.

hydrogen bonding between the GlyGly polar moieties.[8] We believe that the PDA-GlyGly-OH lipids also formed a β-sheet structure at the air-water interface and the lipid alkyl chains are packed in a coplanar mode. As a result, the polymerization of the coplanar diacetylene groups leads to the formation of a linear blue form polydiacetylene backbone, as shown in Fig. 3.

In the case of PDA-AlaGly-OH, due to the presence of a methyl group as a side group on the dipeptide, steric hindrance does not allow the formation of a perfect β-sheet structure. The PDA-AlaGly-OH lipids are obliged to adopt a staggered non-coplanar packing mode. With this staggered non-coplanar packing of diacetylene lipids, the photoirradiation leads to the formation of a non-linear zigzag red form polydiacetylene backbone, as illustrated in Fig. 3. With increased size of the side groups on the amino acid residues, as in the case of PDA-ValGly-OH and PDA-PheGly-OH, the linearity of the polymer backbone is further decreased, leading to a shift of the absorption band towards lower wavelength.

Theoretical calculations have shown that very slight rotations around the C–C bonds of the polymer backbone (5°) are enough to produce a dramatic decrease in the π–π electron conjugation length.[9] When the non-coplanar packed monolayer is polymerized, the C–C single bonds must rotate away from the linear backbone to accommodate the non-coplanar packing of the lipids. Even a slight deviation of lipids from coplanar packing may introduce enough rotations of C–C bonds to produce large chromatic differences, as observed from the four dipeptide lipids. In the meantime, the alkyl side chains attached to the polymer backbone remain in their well-ordered conformation without being disturbed by the slight structural change of the polydiacetylene backbone.

Electrochemically controlled self-complexation of cyclodextrin–viologen conjugates

Armen Mirzoian and Angel E. Kaifer*

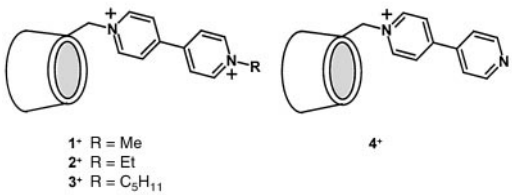
Center for Supramolecular Science and Department of Chemistry, University of Miami, Coral Gables, FL 33124-0431, USA. E-mail: akaifer@umiami.ir.miami.edu

Received (in Columbia, MO, USA) 21st May 1999, Accepted 6th July 1999

Self-complexation of cyclodextrin–viologen conjugates can be controlled electrochemically through changes in the oxidation states of the viologen subunits as well as chemically when competing water-soluble hosts or guests are added to solutions of the conjugates.

The phenomenon of intermolecular self-complexation has attracted considerable interest in supramolecular chemistry.[1,2] A compound must possess suitably located complementary (host and guest) sites to recognize itself and form intermolecular complexes in solution. Depending on the spatial relationship between the host and guest sites of the self-complementary monomer units, different superstructures can be predicted, from cyclic dimers to polymer-like, extended acyclic ones.[3–5] Of course, intramolecular self-complexation is also possible in molecules with enough flexibility.[6] Here we report the first example of electrochemically-driven,[7] intermolecular self-complexation. Specifically, we describe a series of cyclodextrin–viologen conjugates that exhibit remarkable intermolecular self-recognition triggered by the two-electron reduction of their viologen subunits.

We have recently reported on the binding interactions between the hosts β-cyclodextrin (β-CD) and its heptakis(2,6-*O*-dimethyl) analog (DM-β-CD) and a series of viologens (*N*,*N*′-disubstituted 4,4′-bipyridinium derivatives) designed to enhance their water solubility in any of their three oxidation states.[8,9] We have shown that while the oxidized forms of the viologen derivatives are not bound by the CD hosts, the two-electron reduced forms give rise to very stable inclusion complexes.[9] The intermediate one-electron reduced forms are only weakly bound by β-CD. Based on these findings, we reasoned that compounds containing covalently linked β-CD and viologen subunits should undergo self-complexation upon two-electron reduction. Therefore, we prepared the series of cyclodextrin–viologen conjugates $\mathbf{1}^{2+}$–$\mathbf{3}^{2+}$ by alkylation of their precursor $\mathbf{4}^{+}$.[10]



As anticipated, the electrochemical behavior of $\mathbf{1}^{2+}$–$\mathbf{3}^{2+}$ is dominated by the two reversible, one-electron reductions of their viologen residues.[11] Fig. 1 (solid line) shows a typical voltammogram for $\mathbf{2}^{2+}$ in 0.5 M phosphate buffer (pH = 7) solution. Half-wave potential values for $\mathbf{1}^{2+}$–$\mathbf{3}^{2+}$ and $\mathbf{4}^{+}$ are collected in Table 1. In aqueous media the cathodic voltammetric behavior of most viologens is affected by the precipitation on the electrode surface of their more hydrophobic, reduced forms.[12–14] In contrast, the CD–viologen conjugates $\mathbf{1}^{2+}$–$\mathbf{3}^{2+}$ exhibit (at concentrations around 1 mM) two reversible voltammetric reduction waves, free from any precipitation effects, due to the solubilizing effect of the appended CD moieties. On the other hand, we found that the electrochemical behavior of the CD–viologen conjugates is strongly concentration dependent. The second reduction wave of $\mathbf{1}^{2+}$–$\mathbf{3}^{2+}$ broadens and shifts to more positive potentials (Fig. 1, dotted line) at concentrations above 1 mM. In control experiments, other highly water-soluble viologens lacking covalently appended CD residues did not show this type of concentration dependent behavior.[15] Furthermore, the changes observed in the second reduction waves of $\mathbf{1}^{2+}$–$\mathbf{3}^{2+}$ at concentrations above 1 mM are similar to those observed for water-soluble viologens in the presence of added β-CD.[9] We thus conclude that compounds $\mathbf{1}^{2+}$–$\mathbf{3}^{2+}$ undergo intermolecular self-complexation upon two-electron reduction of the viologen subunit (Scheme 1). The intermolecular character of these self-complexation processes is clearly evidenced by the observed concentration dependence. To further verify that the presence in the same molecule of viologen and β-CD subunits is responsible for self-complexation, we performed several experiments using independent guest or host molecules. Fig. 2 shows the voltammetric behavior of a solution containing 7.3 mM $\mathbf{3}^{2+}$ (solid line) clearly

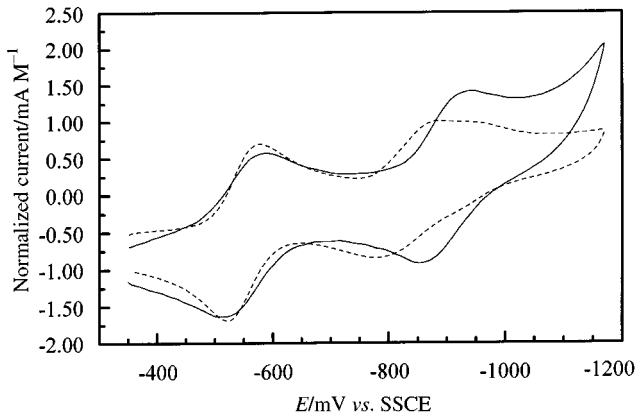


Fig. 1 Normalized cyclic voltammograms (0.1 V s^{-1}) of 0.15 (solid line) and 6.7 mM solutions of $\mathbf{2}\cdot Cl_2$ in 0.5 M pH 7 phosphate buffer.

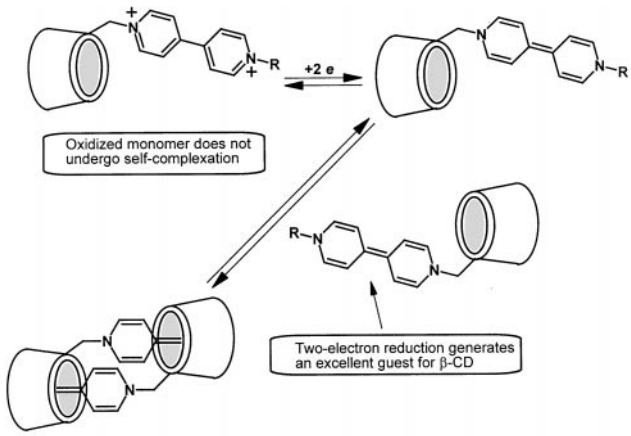
Table 1 Half-wave potentials ($E_{1/2}$) and peak-to-peak splittings (ΔE_p) measured for the cyclodextrin–viologen conjugates in 0.5 M phosphate buffer (pH 7) solution

Cationic compound	$E_{1/2}^1$/V (ΔE_p/mV)[a]	$E_{1/2}^2$/V (ΔE_p/mV)[b]
$\mathbf{1}^{2+}$	−0.573 (80)	−0.933 (90)[c]
$\mathbf{2}^{2+}$	−0.555 (60)	−0.911 (65)[d]
$\mathbf{3}^{2+}$	−0.524 (65)	−0.934 (75)[e]
$\mathbf{4}^{+}$	−0.908 (70)[f]	—

[a] Half-wave potentials for the first one-electron reduction of the bipyridinium subunit (V^{2+}/V^{+}). The value in parenthesis represents the potential difference between the cathodic and anodic peak potentials measured by cyclic voltammetry at a scan rate of 0.100 V s^{-1}. [b] Same for the second one-electron reduction of the bipyridinium subunit (V^{+}/V). [c] 1.2 mM. [d] 0.15 mM. [e] 7.3 mM (potential data for the free compound obtained after adding excess of competing guest). [f] 0.22 mM.



Scheme 1

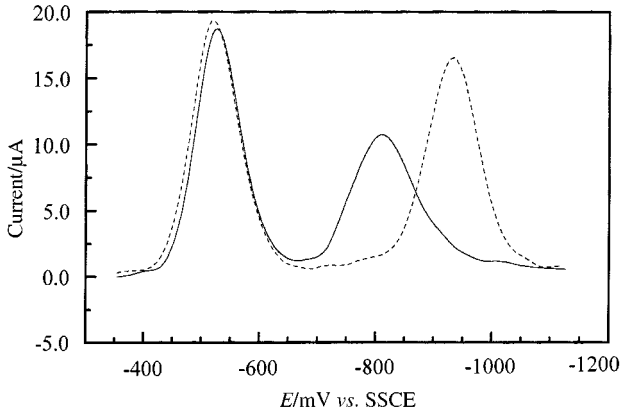


Fig. 2 Square wave voltammograms of a 7.3 mM solution of **3**·Cl_2 in 0.5 M pH 7 phosphate buffer in the absence (solid line) and presence (dotted line) of 8.7 mM adamantane-1-carboxylic acid (ACA). Data recorded using a potential step of 4 mV, pulse amplitude of 25 mV, and frequency of 15 Hz.

exhibiting the broadening and anodic shifting of the second reduction wave which is associated with the self-complexation of the reduced form **3**. Addition of adamantane-1-carboxylic acid, an excellent guest for β-CD hosts,[16] has a profound effect on the second reduction wave (dotted line), which returns to the potential region and to the appearance that it had at concentrations ⩽1 mM. Thus, adamantane-1-carboxylic acid disrupts self-complexation by competing with the reduced viologen subunits for the available CD cavities.

Similarly, voltammograms of the investigated CD–viologen conjugates exhibit large changes in the presence of heptakis(2,6-*O*-dimethyl)-β-cyclodextrin (DM–β-CD). In this case, the addition of the DM–β-CD host leads to a greater anodic shift for the second reduction waves of $\mathbf{1}^{2+}$–$\mathbf{3}^{2+}$, as the added host increases the CD-bound fraction of the reduced viologen subunits (voltammograms not shown). Thus, the observed voltammetric results clearly reveal that the self-complexation of the CD–viologen conjugates upon two-electron reduction (**1**–**3**) can be disrupted by addition of competing CD guests or free CDs. Based on previous electrochemical and spectroscopic studies on the complexation of CD hosts with the viologen guests we estimate the association constant of observed intermolecular complexes to be 10^3 to 10^4 M^{-1}.[17]

A final issue that must be addressed is the mode of assembly exhibited by the CD–viologen conjugates. Are they interacting face-to-face to yield dimeric structures (as shown in Scheme 1) or face-to-tail to produce oligomeric aggregates formed by a larger number of monomers? An unequivocal answer to this question will require additional physicochemical characterization of fully isolated reduced complexes. This task has proven to be a very difficult one due to extreme air sensitivity of the reduced viologen species.[11] Park and coworkers,[10c] however, demonstrated formation of face-to-face dimers in solution upon photochemically-induced, one-electron reduction of related CD–viologen conjugates. Our data also suggest face-to-face dimerization, since face-to-tail complexation should yield bulky insoluble aggregates in solution, which we have never observed, upon two-electron reduction of the viologen moieties. Entropic considerations similarly suggest that formation of small cyclic dimeric complexes is more favorable than aggregation to yield large assemblies.

In summary, we have prepared a series of three CD–viologen conjugates that exhibit concentration-dependent voltammetric behavior. This behavior is clearly indicative of intermolecular self-complexation upon two-electron reduction of the pendant viologen subunits.

The authors are grateful to the National Science Foundation (to A. E. K., CHE-9633434) for the generous support of this work.

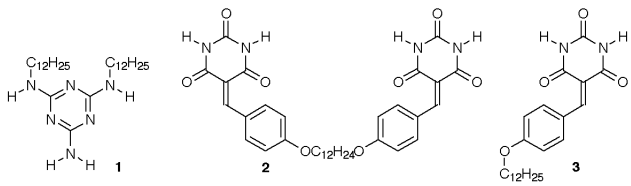
Received (in Columbia, MO, USA) 6th April 1999, Accepted 1st June 1999

Barbituric acid and melamine derivatives self-assembled into highly ordered structures from the molecular scale (~ 3 Å) to geometric patterns on a macroscale (~ 0.5 mm).

Supramolecular self-assembly is a fascinating process in which hierarchical organization from the molecular level to the mesoscale and macroscale is spontaneously established. Mesoscale ordered domains have been observed before,[1] but formation of well-defined patterns up to the macroscale is rare. Given knowledge of chemical functionalities, it is widely accepted that one cannot accurately predict the spontaneously organized structures by design, from intuition, or from physical principles. Here we attempt to understand the relationship between self-assembled structures and molecular functionalities using SEM, TEM, X-ray, and IR spectroscopy. Hydrogen bonding has long been employed as a powerful tool to organize molecules in the solid state[2] and on air/water interfaces.[3] H-bonded networks in barbituric acid and melamine systems[4] are intriguing because of their structural resemblance to the base pairs of DNA. We synthesized new derivatives of barbituric acid and melamine which formed highly organized molecular self-assemblies exhibiting order from the molecular scale (0.3 nm) to the macroscale (0.5 mm). This shows that macrostructures and macropatterns may be controlled by molecular functionalities.

The melamine and barbituric derivatives **1** and **2** were studied, along with **3** with a single barbituric acid for



comparison. Supramolecular assemblies were prepared by mixing **2** and **1** in a molar ratio of 1:2 in dried DMF (~ 0.2–1 mM), followed by heating the solution to 50 °C for 24 h.[5] Samples were prepared by simply drop-casting the homogeneous solution onto various substrates such as glass, carbon, gold and germanium. These substrates were chosen to meet the requirements of various analytical techniques, for example, gold and carbon for electron microscopy and germanium for infrared spectroscopy.

The $\mathbf{2}\cdot\mathbf{1}_2$ supramolecular system was linked with six complementary H-bonds (~ 30 kcal mol^{-1}), which is the minimum number that nature requires to precisely transfer information from DNA to RNA (triplet base pairs or codons).[6] The formation of our supramolecular self-assemblies is driven primarily by the interplay of encoded six H-bonds, and secondarily by hydrophobic chain–chain interactions, π–π interactions, and functional group–substrate interactions. The zigzag H-bond network in the $\mathbf{2}\cdot\mathbf{1}_2$ system was verified with IR measurements carried out in the internal (total) reflection at the center of the flat surface of a Ge hemisphere. First, the shifts of carbonyl, amide, and amino infrared bands confirm the formation of six-fold zigzag H-bonds between **2** and **1**.[7] Secondly, the carbonyl vibrations at the 2,6-position (1675 cm^{-1}) of the barbituric acid are insensitive to polarization because of their structural arrangement. However, the carbonyl vibrations at the 4-position (1733, 1705 cm^{-1}; *para* to ylidine substitution) are strong in p-polarization but weak in s-polarization. This polarization effect proves that the 4-position C=O bond is mostly perpendicular to the surface, suggesting that the extended H-bonded networks are parallel to the surface. Finally, the low CH_2 vibration frequencies (υ = 2916 and υ_s = 2849 cm^{-1}) indicate that the hydrocarbon chains are highly crystalline;[8] this order is rather long range (> μm) as shown by the constant CH_2 vibrational frequencies when the IR beam is changed from grazing incidence (75°) to near-normal incidence (20°). While **2** is replaced with **3**, no such long-range order was observed; both CH_2 vibration frequencies incresed by ~ 5 cm^{-1} from 75 to 20°, indicating that the alkyl chains become more disordered away from the Ge substrate.

Bright-field transmission electron microscopy (TEM) indicated that these systems consist of layered structures with very long, linear 'ribbons' (width = ~ 322–644 Å) as the secondary building blocks. High-resolution TEM and electron diffraction (Fig. 1) revealed that the layered structure had four different periodicities of d = 2.6, 3.7, 4.0 and 4.6 Å in the plane of the substrate. Small-angle X-ray diffraction of $\mathbf{2}\cdot\mathbf{1}_2$ on silicon yielded the first-order Bragg diffraction peak at 2θ = 1.334°, which proved that $\mathbf{2}\cdot\mathbf{1}_2$ formed multilayers with a d-spacing of c = 66.2 Å along surface normal. This value agrees quite well with a d-spacing of c = ~ 65 Å generated from a 3D molecular model. These results also support the IR observation that the $\mathbf{2}\cdot\mathbf{1}_2$ system is a layered structure with extended H-bonded networks parallel to the substrate surface. The TEM and X-ray results are consistent with the proposed supramolecular structure illustrated in Fig. 2. Fig. 2(*a*) describes that the distance between barbituric acids or melamines is 9.8 Å[9] and their nearest neighbor in the next sheet is 4.3 Å away at an angle of 70°. This packing (Fig. 2) of the extended H-bond networks can explain all the observed d-spacing values;[10] they are (1) the periodicity along the H-bond network $d(1,-1) = a \sin 60° =$ 4.6 Å, and (2) the stacking distance between H-bond networks $d(1,1) = b \sin 32.5° =$ 4.0 Å and between phenyl rings in **2**

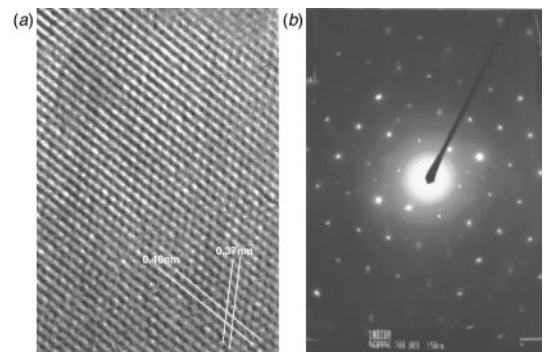


Fig. 1 (*a*) A high-resolution TEM image of the $\mathbf{2}\cdot\mathbf{1}_2$ multilayer supramolecular self-assembly on a carbon-coated copper grid. The four d = 2.6, 3.7, 4.0 and 4.6 Å. (*b*) An electron diffraction pattern of the same $\mathbf{2}\cdot\mathbf{1}_2$ system confirms the d-spacing values of 2.6, 3.7, 4.0 and 4.6 Å.

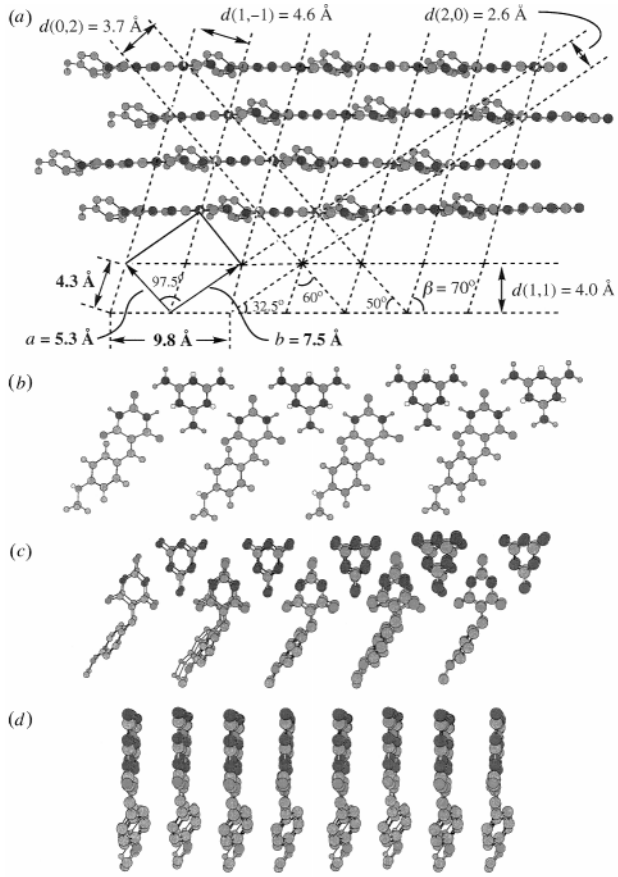

Fig. 2 (*a*) Proposed **2**·**1**$_2$ crystal lattice structure which explains the observed *d*-spacing values. (*b*) Side view of the H-bond networks, *d*(1,−1) = 4.6 Å. (*c*) Stacking along the phenyl ring direction, *d*(0,2) = 3.7 Å. (*d*) End view of H-bond networks, distance between H-bond sheets is *d*(1,1) = 4.0 Å.

d(0,2) = 3.7 Å, and *d*(2,0) = 2.6 Å. Molecular modeling of steric interactions between the 2,6-position oxygen atoms and the *ortho* position hydrogen atoms on the phenyl ring gives a dihedral angle between these two stacking planes of 49° [Fig. 2(*a*),(*c*)]. This angle corresponds to the 50° angle observed in high-resolution TEM between *d*(0,2) = 3.7 Å phenyl–phenyl planes and *d*(1,1) = 4.0 Å barbituric–melamine planes.

In Fig. 3(*a*), we observed that the amplified molecular information was expressed as very long straight lines with a line width between 3 and 4 μm and a length exceeding 0.1 mm. Furthermore, the amplified molecular information stored in the chemical units also generated well-defined angular structures of 60 and 70° through intermolecular interactions. These features may result from much interplay of secondary interactions including the H-bond, ribbon packing, and the alkyl chain interaction/tilt. When we substituted **3** for **2**, no such pattern was observed [Fig. 3(*b*)]. This fact suggests that the template effect from the gold substrate is not a dominant factor in the formation of these specific geometric structures because **3** has all the chemical functional groups that **2** has. Furthermore, these lines are hierarchical and built from smaller dot-like units (0.5–2 μm) which are also observed in the SEM image. The SEM micrograph clearly shows that there is a strong tendency to form such long-range ordered patterns that are governed by the information encoded in the molecular structures. These results imply that molecular building blocks can be programmed to spontaneously assemble into prescribed structures according to a molecular blueprint, a process needed in materials by design. In the **2**·**1**$_2$ system, we have employed H-bonding interactions and hydrophobic associations to generate microscale straight lines and angles on gold surfaces. The ability to generate pattern on the microscale through tuning of the molecular functionality is important because it allows formation of unique structures without utilizing external lithographic tools.

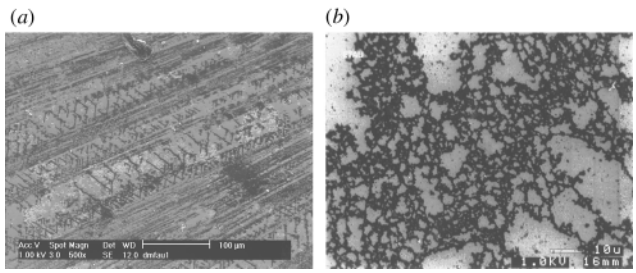

Fig. 3 (*a*) SEM images of **2**·**1**$_2$ systems on gold surfaces. The **2**·**1**$_2$ self-assemblies are darker, and they form extremely long lines (> 0.5 mm) and micron-size angles. These geometric features are constructed from secondary plate-like units, which are also observed in the micrograph. (*b*) The SEM image of the **3**·**1** system on gold surfaces shows random network structures. Note that the **3**·**1** system has all the functionalities of the **2**·**1**$_2$ system. The only difference is that the two barbituric acid groups are linked together in the **2**·**1**$_2$ system.

In conclusion, we have demonstrated that molecular design can lead to order on the microscale, mesoscale, and macroscale. The results show that H-bonding effects are the major driving forces in our systems, compared to hydrophobic interactions and van der Waals forces. The perfect match of six pairs of H-bonds induces the system to spontaneously organize into highly ordered hierarchical architectures manifested as micro-wide straight lines with 60 and 70° angles.

Synthesis, structure and inclusion properties of 1,4,15,18-tetrahydro-1,4,15,18-tetraoxodibenzo[*b*,*h*]tetraphenylene†

Xiao-Ping Yang,‡ Da-Ming Du,§ Qi Li,¶ Thomas C. W. Mak‖ and Henry N. C. Wong*

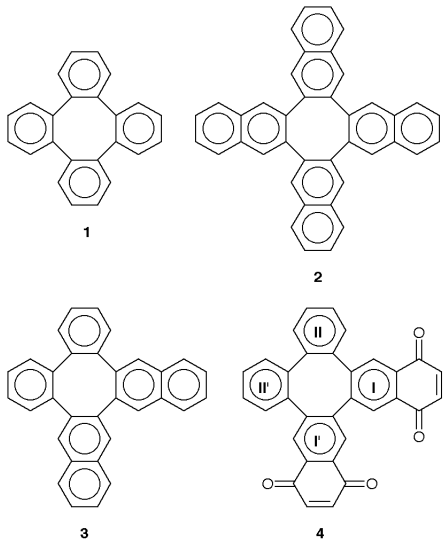
Department of Chemistry, The Chinese University of Hong Kong, Shatin, New Territories, Hong Kong, China

Received (in Cambridge, UK) 24th May 1999, Accepted 24th June 1999

The new host molecule 1,4,15,18-tetrahydro-1,4,15,18-tetraoxodibenzo[*b*,*h*]tetraphenylene forms inclusion complexes with specific guest molecules, exhibiting two distinctly different types of host lattices whose construction is dictated by intermolecular, face-to-face π··π interactions between benzoquinone rings across inversions centres.

Recent advances in crystal engineering[1] have generated a large variety of fascinating supramolecular frameworks which rely on non-covalent bonding interactions[2,3] for their self-organization. The geometry of the π-stacking motif is of particular interest since Burley and Petsko[4] have identified two important orientations for aromatic–aromatic interactions, namely face-to-face and edge-to-face interactions, in their survey of protein crystal structures.[5]

Our investigation of the host–guest chemistry of tetraphenylene **1**[6] and its benzo-fused derivatives, *e.g.* **2**[6d] and **3**,[6c] revealed that a secondary molecular C_2 axis passing through the



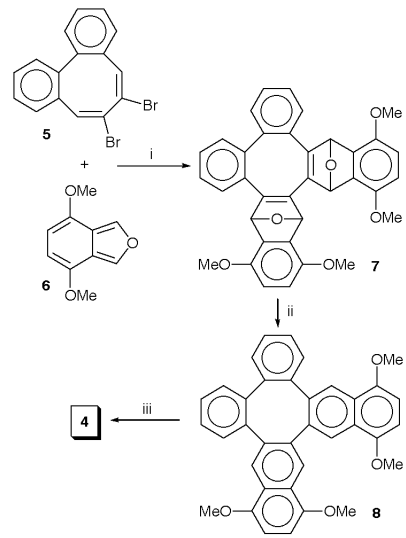
centres of a pair of opposite carbon–carbon single bonds, which gives tetraphenylenes their twisted shapes, would be a prerequisite component of inclusion behaviour.[6a,b,7] In order to substantiate this presumption and to enhance the inclusion capacity of the otherwise non-polar tetraphenylenes, namely **1**, **2** and **3**, we decided to undertake the design of a functionalized oxo derivative of **3**. Here we report the synthesis and "guest-specific" clathrate inclusion property of 1,4,15,18-tetrahydro-1,4,15,18-tetraoxodibenzo[*b*,*h*]tetraphenylene (**4**).

As can be seen in Scheme 1, the synthesis of bis-quinone **4** began with dehydrobromination of the known dibromide **5**[8] with Bu^{t}OK in the presence of freshly generated 4,7-dimethoxyisobenzofuran (**6**).[9] This reaction presumably proceeded through a cyclodienediyne intermediate[8] which underwent intermolecular Diels–Alder reaction with the reactive isobenzofuran **6**. In this way, **7** was obtained in 53% yield as the major product after careful chromatographic separation. Low-valent titanium deoxygenation[10] of **7** then produced the tetramethoxy compound **8** in 79% yield. On oxidation with silver(II) oxide and nitric acid in dioxane, **8** was smoothly converted to the desired product **4** in 60% yield.

A mixture of toluene–xylene–mesitylene (1:1:1 v/v/v) was added to a solution of **4** in CH_2Cl_2, and the resulting solution allowed to stand at room temperature for several days, after which crystals of **4**·$C_6H_3Me_3$ appeared in the form of yellow prisms. Slow evaporation of a solution of **4** in hexane–EtOAc (1:1 v/v) yielded yellow plate-like crystals of **4**·C_6H_{14}. Recrystallisation of **4** in EtOAc–AcOH (1:1 v/v) gave yellow prismatic crystals of **4**·AcOH. Yellow crystals of **4**·C_6H_{12} in the form of prisms were obtained from evaporation of a solution of **4** in cyclohexane–EtOAc (1:1 v/v).

Host **4** exhibits selective inclusion behaviour toward aromatic solvents: it does not form any crystalline adduct with either pyridine or benzene, and it selectively includes mesitylene from an equivolume mixture of toluene–*p*-xylene–mesitylene, forming a 1:1 crystalline complex. Among potential guests of the aliphatic type, only *n*-hexane and AcOH (as a hydrogen-bonded cyclic dimer) have been found to form 1:1 crystalline inclusion compounds with **4**. In the case of saturated ring systems, cyclohexane readily forms a 1:1 complex with **4**, but THF does not.

X-Ray analysis** has shown that the 1,4,15,18-tetrahydro-1,4,15,18-tetraoxodibenzo[*b*,*h*]tetraphenylene host molecule (**4**) has normal molecular dimensions and exhibits structural features common to the four inclusion compounds: a crystallographic C_2 axis†† passes through the midpoints of two opposite



Scheme 1 *Reagents and conditions:* i, Bu^{t}OK, THF (53%); ii, $TiCl_4$, $LiAlH_4$, Et_3N, THF, reflux (79%); iii, AgO, HNO_3, dioxane (60%).

Table 1 Selected structural parameters of inclusion complexes of 1,4,15,18-tetrahydro-1,4,15,18-tetraoxodibenzo[*b*,*h*]tetraphenylene (**4**)

	Dihedral angle between rings (°) in host molecule		Intermolecular π··π interaction between pair of adjacent benzoquinone rings	
Inclusion complex	I–I′	II–II′	*d*, interplanar spacing/Å	*D*, centroid-to-centroid distance/Å
4·Mesitylene	56.1	62.7	3.476	3.728
4·Hexane	67.1	63.3	3.581	3.909
4·Acetic acid	73.2	65.0	3.426	3.926
			3.508	3.825
4·Cyclohexane	69.7	65.3	3.441	3.883

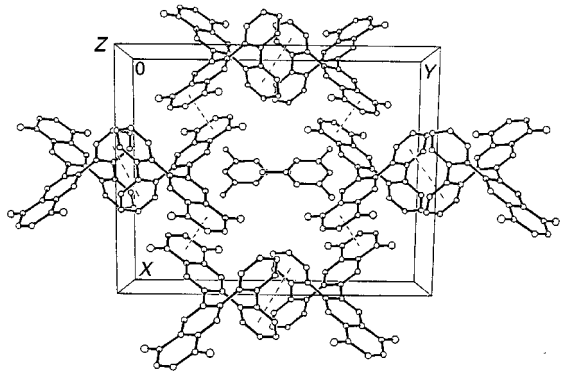

Fig. 1 Crystal structure of **4**·mesitylene (1:1) showing the packing of mesitylene guest molecules arranged in a zigzag column along an open channel running parallel to the *c* axis. The centroid-to-centroid distances between pairs of π··π interacting rings are represented by broken lines.

carbon–carbon single bonds in the central cyclooctatetraene ring, which is tub-shaped with C–C and C=C bonds alternating around it. The naphthoquinone rings I and I′ and the benzene rings II and II′ are disposed alternately above and below the mean plane of the molecule, and the dihedral angles between pairs of rings of the same kind are listed in Table 1. The resulting molecular configuration of **4** enables it to function as an efficient host for a wide range of guest molecules.

Complexes **4**·$C_6H_3Me_3$ and **4**·C_6H_{14} are isostructural with the same host framework and differ only in regard to the enclosed guest molecules. As shown in Fig. 1, the host molecules are connected by intermolecular face-to-face π··π interactions[11] between pairs of centrosymmetrically-related benzoquinone rings to form a zigzag chain running parallel to the [1 0 1] direction. The contact between these rings is described by two geometric parameters, namely the interplanar spacing *d* and the centroid-to-centroid distance *D*, as listed in Table 1. In an analogous manner, similar but much weaker π··π interactions between benzene rings across inversion centres (d = 4.341, D = 4.389 Å) give rise to another type of zigzag chain running parallel to the *c* axis. The three-dimensional host lattice resulting from these two systems of inter-connected chains contains open channels running parallel to the *c* axis, which accommodate the mesitylene guest molecules in a zigzag fashion.

Compounds **4**·AcOH and **4**·C_6H_{12} have essentially the same type of sandwich-like crystal structure although they belong to different space groups. In each case the host molecules are linked by π··π interactions between benzoquinone rings across centres of symmetry to form an infinite chain. Such chains are aligned side by side to constitute a layer, but there is no significant interaction between them. The chains are orientated in different directions, [0 1 $\bar{1}$] in **4**·AcOH and [1 0 $\bar{1}$] in **4**·C_6H_{12}, and the separations between adjacent chains are almost equal, being 8.19 and 8.13 Å, respectively.

In **4**·AcOH, two centrosymmetrically-related guest molecules are linked by a pair of O–H··O hydrogen bonds to form a cyclic dimer, in which all non-hydrogen atoms are almost coplanar (mean deviation 0.026 Å). These dimers are accommodated in voids and sandwiched between layers of host molecules whose mean planes correspond to the (100) series of planes. In a similar manner, the disordered cyclohexane guest molecules in **4**·C_6H_{12} are sandwiched between pairs of host layers that match the (010) planes. The difference in size of the guest molecules is reflected in the interplanar spacings of the host layers, which are 8.83 and 9.65 Å, respectively.

Dinuclear lanthanum complex catalyzes the hydrolysis of a phosphate diester with unprecedented speed

Paul E. Jurek and Arthur E. Martell*

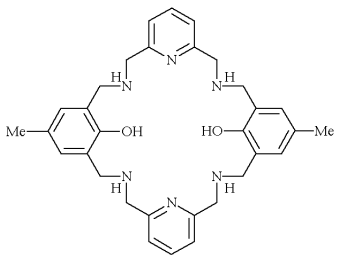
Department of Chemistry, Texas A and M University, College Station, Texas 77842-3012, USA.
E-mail: martell@mail.chem.tamu.edu

Received (in Bloomington, IN, USA) 23rd October 1998, Accepted 12th July 1999

The dihydroxo dilanthanum macrocyclic complex hydrolyzes bis(*p*-nitrophenyl) hydrogen phosphate (BNP) with a remarkably high rate constant and a unique third-order dependence on the concentration of the dinuclear complex.

Restriction endonucleases are enzymes that hydrolyze the phosphate diester bonds of DNA with great specificity and high turnover numbers.[1] A small molecule that could recognize a specific DNA sequence and catalyze the rapid hydrolysis of the phosphate diester bond would be an invaluable research tool. Multinuclear metal complexes have been known to hydrolyze phosphate diesters[2] and are models for a number of phosphodiesterases that contain multinuclear active sites.[3] This work reports a defined dinuclear lanthanum(III) complex that can hydrolyze a phosphate diester (BNP) with unprecedented speed. This complex also has the unique feature that the hydrolysis of BNP is third-order with respect to the concentration of the dinuclear La^{3+} complex, $[LLa_2]$.

The ligand L was synthesized according to literature procedures.[4] Potentiometric experiments were performed by



L

means of a well-defined method[5] to determine stability constants for the mono- and di-nuclear La^{3+} complexes (Table 1). The pK_a of a water bound to the mononuclear complex [LLa] is 11.15, while the pK_a of a water bound to the dinuclear complex $[LLa_2]$ is 7.75. The fact that the pK_a is lowered by 3.40

Table 1 Stability constants for the formation of mono- and di-nuclear La^{3+} complexes with the ligand L. T = 35 °C, μ = 0.10 M KCl, 3:1 EtOH–H_2O solution pK_as of L, under the same conditions: 12.95, 12.84, 8.24, 7.39, 5.76 and 4.38

Equilibrium	Log K

$[LLa_2(OH)_2][H]/[LLa_2(OH)]$	10.03
$[LLa_2(OH)_3][H]/[LLa_2(OH)_2]$	11.17

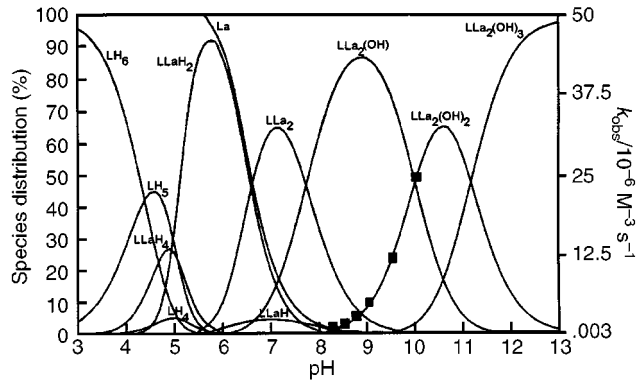

Fig. 1 Species distribution diagram for a system containing a 1:2 ratio L to La^{3+}. Observed third-order rate constants are denoted by (■).

pH units implies that the water is bridging the two La^{3+} ions. The pK_a of the second water bound to the dinuclear complex is 10.03, so this water also forms a bridge between the two La^{3+} ions.

In Fig. 1 the prevalence of the various dinuclear μ-hydroxy species can be seen. In the pH range 6–8 the rate constants are easily measurable, but relatively small in magnitude. The graph clearly shows that the rate constants follow the formation of the dinuclear dihydroxo complex $[LLa_2(OH)_2]$. When $[LLa_2]_{TOT}$ = $[BNP]_{INIT}$ = 0.5 mM, it would take 5.0 days for one turnover at pH 7.[6] It would take only 27 min for one turnover at pH 9 and a mere 6 min at pH 10. It is not clear why the dihydroxo complex is more effective than the monohydroxo complex $[LLa_2(OH)]$. There is at least one other example in the literature of a dinuclear macrocyclic complex where the active catalyst for hydrolyzing BNP is the dihydroxo complex and not the analogous monohydroxo species.[2a] The reason may simply be that the second hydroxo ligand is better positioned for nucleophilic attack than the initial hydroxo complex that forms.

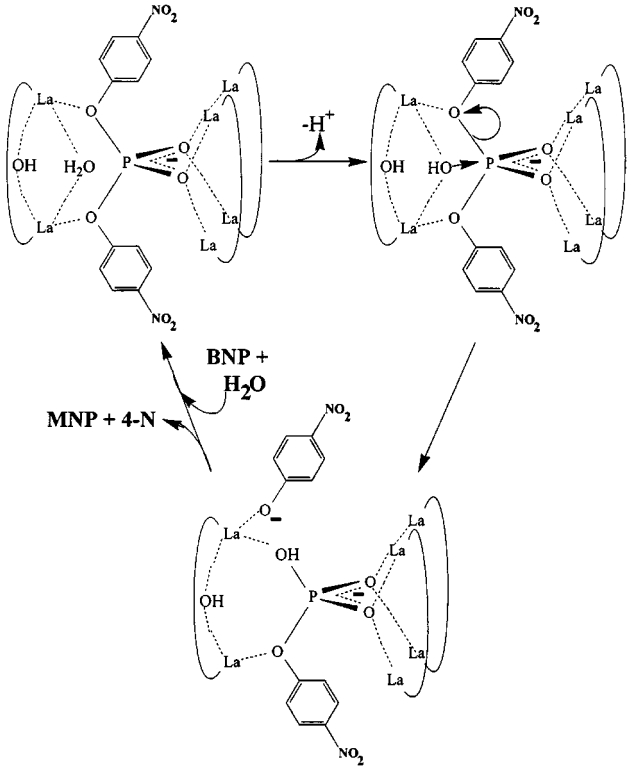
Within the concentration range studied, the reaction is first-order with respect to $[BNP]_{INIT}$. However, analysis of the data in Table 2 shows that the reaction is an unusual third-order with respect to the concentration of the dinuclear species $[LLa_2]_{TOT}$. Consequently, the rate law is given by eqn. (1).

$$\text{Rate} = k_{obs}[LLa_2]^3_{TOT}[BNP]_{INIT} \quad (1)$$

A reaction may appear to have an unusual catalyst dependence if there is an unexpected equilibrium at the concentration at which the kinetic trials were measured as opposed to the

Table 2 Dependence of the rate of BNP hydrolysis on the concentration of $[LLa_2]_{TOT}$

pH	$[LLa_2]_{TOT}$/M	$[BNP]_{INIT}$/M	Rate/10^8 M s^{-1}
8.25	0.000728	0.000531	24
8.25	0.000486	0.000539	7.3
8.25	0.000244	0.000518	0.81



Scheme 1 Proposed mechanism for BNP hydrolysis by $[LLa_2(OH)_2]$. For simplicity, the ligand has been drawn as a curved line and the coordinated hydroxides of the two rightmost $[LLa_2(OH)_2]$ species were not included.

concentration at which the potentiometric experiments were performed. To test this hypothesis the stability constants were measured over a large concentration range. The stability constants at various concentrations agreed to within experimental error. Thus this aggregation of three $[LLa_2]$ molecules, required to satisfy the third-order rate law dependence, occurs only in the presence of substrate.

A proposed mechanism is shown in Scheme 1. Two dinuclear La^{3+} complexes coordinate the partially negatively charged phosphate oxygens. The third dinuclear La^{3+} complex coordinates both ester groups and attacks the phosphorus center with one of its bridging hydroxide nucleophiles. A *p*-nitrophenolate group (4-N) is displaced and the monophosphate ester (MNP) is generated. The products are displaced and the $[LLa_2]$ complex molecules coordinate another incoming substrate. The active catalyst $[LLa_2(OH)_2]$ is regenerated by the loss of a proton from a coordinated water. Hydrolysis is fast because there are three dinuclear La^{3+} complexes withdrawing electron density from the phosphorus center. This makes that phosphorus center extremely susceptible to nucleophilic attack from the coordinated hydroxide nucleophile.

This work describes the formation of the first defined dinuclear La^{3+} complex capable of hydrolyzing phosphate diesters. The catalysis occurs at such an unprecedented rate that it takes only 6 min for one turnover at pH 10. The rate constant *versus* pH profile clearly shows the most efficient catalyst is the dinuclear dihydroxo complex $[LLa_2(OH)_2]$. The unique third-order dependence on $[LLa_2]_{TOT}$ is the most probable reason for the high rate constants that are observed. The high rate constants and third-order concentration dependence holds much promise for future work of hydrolyzing DNA on a practical time scale.

6 A k_{cat} value of 0.0004 s^{-1} was measured at pH 7.0 by using $[LLa_2]_{TOT}$ = 5.0 mM and $[BNP]_{INIT}$ = 0.5 mM. The rate enhancement over spontaneous hydrolysis is 1.2×10^7. A k_{cat} value at pH 10.0, with the concentrations just described, is too fast to measure by our method. By extrapolation, it calculates to $k_{cat} = 0.32\ s^{-1}$ which is one turnover every 3–4 s. This is a rate enhancement of 1.2×10^8.

Combinatorial and rapid screening approaches to homogeneous catalyst discovery and optimization

Robert H. Crabtree

Yale Chemistry, PO Box 208107, 225 Prospect St., New Haven, CT 06520-8107, USA

Received (in Bloomington, IN, USA) 3rd February 1999, Accepted 29th March 1999

Rapid screening and combinatorial chemistry are expected to influence the way homogeneous catalysts are discovered and developed.

Homogeneous catalyst discovery owes at least as much to empirical testing as to mechanistic understanding, because structure/function relationships are either obscure or not readily predictable for most catalysts. Once an initial lead catalyst has been identified—either in current experimental work in one's own laboratory or in the literature—incremental changes in the ligand set, often guided by simple mechanistic considerations, are then made to bring the activity, selectivity or scope of the catalyst up to useful levels. Since each new potential catalyst is normally separately prepared and purified, then assayed, progress is relatively slow. In our own early studies, an iridium catalyst that is highly active for the hydrogenation of tri- and tetra-substituted alkenes was only found after a year, even though only 6–12 complexes were assayed. Activity proved to be poor in then-standard solvents and only when a weakly coordinating solvent, CH_2Cl_2, was used did high activity emerge.[1] At that time CH_2Cl_2 was considered inadvisable for homogeneous hydrogenation because of its oxidising character. This emphasizes the point that a new catalyst may need to be assayed under non-standard conditions, where rapid screening methods could prove useful.

Robert H. Crabtree was educated at New College Oxford with Malcolm Green, studied for his PhD with Joseph Chatt at Sussex University and spent four years in Paris at the Natural Products Institute of the CNRS, the French national laboratory.

In 1977 he came to the US as an Assistant Professor at Yale, where he is now Professor of Chemistry. He has been A. P. Sloan Foundation Fellow and Dreyfus Teacher-Scholar, received the ACS and RSC prizes for organometallic chemistry and is past Chair of the Division of Inorganic Chemistry of ACS. He has also received the Mack Award in Chemistry, Ohio State University, been an H. C. Brown Lecturer at Purdue University, Esso Distinguished Lecturer at the University of Toronto, Albright and Wilson lecturer at Warwick University, and visiting Professor at the University of Toulouse.

He has been involved in C–H activation chemistry, including oxidative addition and mercury photosensitized pathways and more recently, C–F bond activation. In hydride chemistry, he contributed to the development of dihydrogen complexes, including the development of physical methods for their detection, and developed the chemistry of hydrogen bonding in inorganic chemistry. He discovered halocarbon and HF complexes. Early work on hydrogenation led to a homogeneous hydrogenation catalyst with useful properties. He has also been involved in the bioinorganic chemistry of nickel and manganese, most recently in functional modelling of photosynthetic water oxidation.

With the advent of combinatorial chemistry,[2] a new strategy is currently emerging that may accelerate the pace of homogeneous catalyst discovery and development. It combines parallel synthesis of a broad range of catalysts, the catalyst library, with a rapid and preferably parallel assay, the rapid screen. When perfected, this procedure is expected to greatly accelerate the rate at which catalysts are discovered or improved although the area is still in its earliest phases. Another potential advantage of making screening much easier is that complexes that do *not* appear promising candidates can also be assayed, leading to the possibility that unexpected classes of catalyst may be found. One recent example,[3] discovered by conventional means, shows that an important class of catalyst for alkene polymerization long escaped discovery in spite of intense activity in the field, in this case because, being based on a late metal, it defied expectations based on what later proved to be oversimplified mechanistic arguments. For a decade or more in the development of alkene polymerization catalysis, it was thought that commercially useful polymer molecular weights in alkene polymerization would only be obtained with early metal catalysts. Late metals were considered to be too prone to β-elimination and would therefore only form oligomers at best. In spite of intense activity in the polymerization area, highly active late metal complexes were only discovered very recently. They prove to have usefully different properties from their early metal counterparts. This example shows how the influence of inappropriately generalised mechanistic ideas can sometimes hold back advance in catalysis research by creating artificial conceptual barriers to innovation.

Combinatorial ideas have already made a strong impact in drug discovery, are becoming established in organic chemistry, and are now beginning to enter homogeneous catalysis. In addition to speeding catalyst discovery and development they are likely to change homogeneous catalysis in a number of ways. The convenience of polystyrene-bead-based combinatorial solid phase synthesis and on-bead testing of catalysts may emphasize the area of supported homogeneous catalysis.[4a] Solid phase organic synthesis (SPOS) allows certain types of reactions to be carried out particularly easily, including ones not possible in solution, so we may be led to envisage ligands not currently in the lexicon of the catalysis chemist.

Combinatorial chemistry

Combinatorial chemistry involves three steps: the rapid parallel synthesis of a library of many compounds of related structure, the parallel testing of these compounds for a desired property by an appropriate assay, and the identification of the compounds, called 'hits', that show the best desired properties. In this way, chemical structural diversity can be thought of as a multi-dimensional space probed by the combinatorial method. Once an initial hit has been identified in the initial broad library, a new library may be constructed that probes a smaller region of diversity space around the intial hit. Combinatorial chemistry

can therefore be considered as an artificially accelerated evolution process but with human rather than natural selection as its motor.

Merrifield's[4b] solid phase synthesis of polypeptides (1963) on polystyrene beads was the first step on the road to the new ideas. In a Merrifield synthesis, the growing polypeptide chain is anchored to a polystyrene bead and extended one amino acid residue at a time using appropriate reagents; final cleavage gives the desired polypeptide. The method can readily be automated. The advantage of the solid phase is that the steps can be pushed to high yield using an excess of reagents and the growing polypeptide can be separated at each step simply by filtering the beads and washing. The availability of this procedure led to the concept of replacing a specific amino acid residue reagent, as is normally used in a specific chain-extension step, by a mixture of reagents, leading to a mixture of compounds in the final product. By having fixed amino acid residues at most sites but variable residues at a few sites, an unprecedentedly large degree of diversity could be obtained rather easily within a class of closely related polypeptides. Suitable procedures were then developed to assay for the desired ligand binding properties and identify which sequence is responsible for binding.

The next conceptual step was the recognition by Bunin and Ellman[5] that the same sort of diversity could be created by SPOS for non-peptide organic compounds, where the substituent groups on a central motif were permuted. The method was first applied to benzodiazepines, where four different substituents could be independently varied.

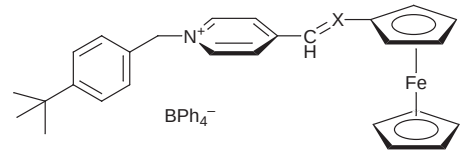
From this, it is a short step to the idea of creating a diverse library of potential ligands on a set of beads, binding a reactive metal complex to the supported ligand and assaying the resulting bead for catalytic activity. This and related ideas are being developed at the moment, both in academia and in such industrial companies as Symyx.[6]

Rapid screening of catalysts

High throughput screening (HTS) in the pharmaceutical industry became so efficient by the early 1990s that it made the synthesis of drug candidates the rate determining step in the drug discovery process and directly encouraged the adoption of combinatorial synthesis.[7] In the catalyst area, neither HTS methods nor combinatorial synthesis had been applied until very recently, so both have had to be developed together.

Assays reported to date can be either parallel or non-parallel: in a parallel assay, all the data are collected at one, but in a non-parallel assay, each data point is obtained independently, one at a time, by conventional methods. It is clearly more efficient to screen a combinatorial catalyst library with a parallel HTS screen than with conventional GC or HPLC, although the availability of automatic sampling could modify this conclusion. Continuous assays have the advantage of allowing monitoring of a reaction in real time; others require some action to be taken to gather the data, such as taking a sample, in which case the method is discontinuous. Methods are also likely to vary in their quantitative value, going from a purely qualitative indication to a detailed quantitative analysis of all species present. They also vary very considerably in sophistication going from low to high tech. The former are generally easier to apply but the latter will be advantageous for automation. There will probably eventually be a hierarchy of such HTS assays, but the initial screen is likely often to be that for activity, because without sufficient activity, no catalyst, however selective, is likely to be useful.

Perhaps the simplest is our own continuous, parallel assay[8] based on a reactive dye **1** that bleaches when a catalytic reaction, such as hydrosilation, takes place. The assay is carried out in a glove bag or glove box on a Teflon block drilled with 70 reaction wells. This allows us to continuously monitor a large set of catalysts until a 'hit' (the most active catalyst) is registered by the dye bleaching in one of the reaction wells. We needed a dye that would not have potentially interfering reactive groups, hence the choice of a ferrocenyl group as electron donor and of a pyridinium as acceptor; the bulky benzylic tail is needed to make the dye conveniently soluble. When the reactive C=C or C=N bond is saturated, the electronic connection between donor and acceptor is broken and the absorption coefficient of the material drops by a factor of *ca*. 100. The starting dye must absorb intensely [ε(EtOAc) = 12 600, **1a**; 5200, **1b**] so as to mask any catalyst color and to be a sensitive indicator. Some quantitative data can be obtained: an initial bleaching time, t_i, corresponds to the first observable color change relative to a control well and a final time, t_f, corresponds to complete bleaching. Other work indicated that t_i corresponds to *ca*. 40% dye conversion and t_f to *ca*. 95%. A long induction time therefore translates to a long t_i, and high activity after induction to a short value of $t_f - t_i$. Recording the data proved possible using a digital camera.



1a X = CH
1b X = N

As an initial test, we applied the method to a library of conventional catalysts, some of which were known to be active while others had never been considered for hydrosilation. The results showed that such well known species as $RhCl(PPh_3)_3$ are very active catalysts for **1**–Ph_2SiH_2, but, unexpectedly, that among the most active of all was a palladacycle never previously tried for hydrosilation. For reasons that are not yet clear, the dyes are activated substrates and react much faster than conventional ones, like stilbene, but the relative order of activity of different catalysts seems to be preserved between dye-substrates and conventional ones. Controls demonstrated that catalyst, silane and substrate are all required for reaction to occur. Fig. 1 shows the result of a typical run.

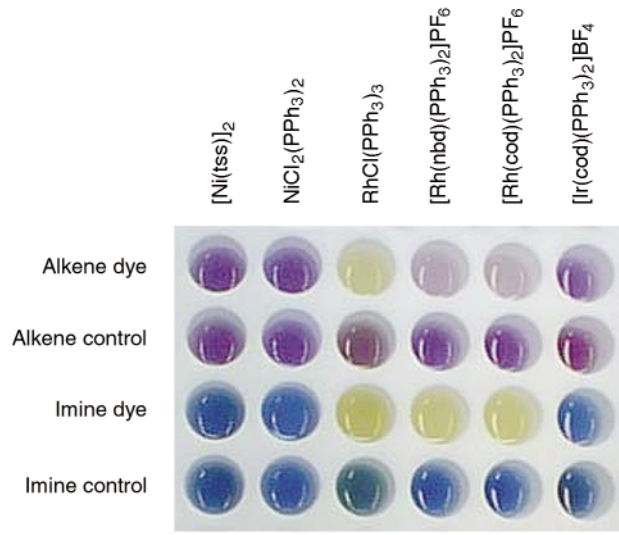


Fig. 1 Results of a typical run using the dyes **1a**,**b** to screen the catalysts identified in the figure for hydrosilation with Ph_2SiH_2.

The heat output of a catalytic reaction has been used by several groups as a continuous, parallel assay for activity. For example, Morken and coworkers[9] used an IR camera to record heat output. This was used to assay a simple polypeptide catalyst library on polystyrene beads that catalysed an exothermic ester hydrolysis in one case and in another the catalysts were homogeneous Mn, Cr and Co complexes for epoxide

opening. Each hit appeared as a bright spot on the image (Fig. 2) as the result of that bead having a temperature estimated to be *ca*. 1 °C above that of the reaction medium. Some differentiation of the spots by relative intensities was possible. Heterogeneous catalyst arrays can be analyzed in the same way.[10]

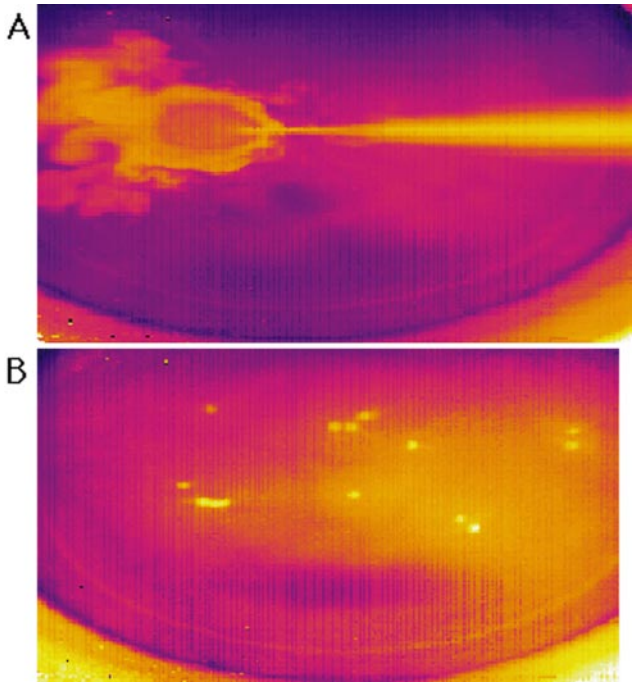

Fig. 2 Results of Morken's IR camera screening method. The more highly catalytically active beads appear bright because of the heat output from the reaction. (A) Thermographic image during addition of acetic anhydride to a chloroform mixture of ethanol, triethylamine and polystyrene bead-supported 4-aminopyridine. (B) As in (A), but after 15 s, showing bright beads. The illustrations were kindly provided by Professor Morken.

Hartwig and coworkers[11] have reported an interesting discontinuous fluorescence screen in which a series of forty conventional homogeneous $Pd(dba)_2$ + L (L = phosphine and diphosphine) catalysts were assayed for activity for coupling of an aryl halide with an alkene (Heck reaction). The aryl halide component was grafted onto cross-linked polystyrene and catalytically coupled with a soluble alkene bearing a powerfully fluorescent coumarin group (Fig. 3). At the end of the catalytic

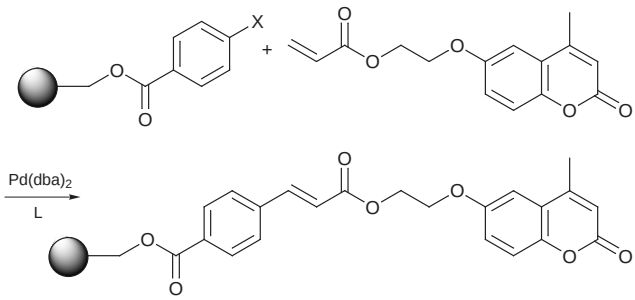

Fig. 3 The principle of Hartwig's[11] fluorescence screen of forty conventional homogeneous $Pd(dba)_2$ + L (L = phosphine and diphosphine, dba = dibenzylidene acetone) catalysts for activity in coupling of an aryl halide with an alkene (Heck reaction).

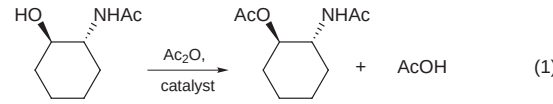
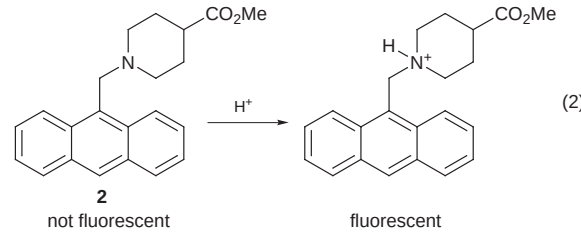
reaction the polymer beads were isolated by filtration and their fluoroescence assayed visually as low, moderate or high. Greater catalyst activity for a conventional homogeneous reaction using the same catalyst was shown to correlate quite well with the catalysts that gave the strongest fluorescence in the rapid assay. For example, the L = PBu^t_3 catalyst was identified as one of the most active.

Copeland and Miller[12] have proposed a method in which the catalytic reaction of eqn. (1) was followed by fluorescence: the acid released in the acyl transfer step protonates the dye precursor **2** [eqn. (2)] and turns on the fluorescent response.





Using an automated fluorescent plate reader allowed quantitative, parallel intensity data to be obtained in solution on a 96-well plate, allowing comparison in triplicate of seven catalysts at three different loadings. The data were good enough to allow the kinetics to be followed. As described in more detail below, the same method was also applied to assaying a small catalyst library on polystyrene beads.

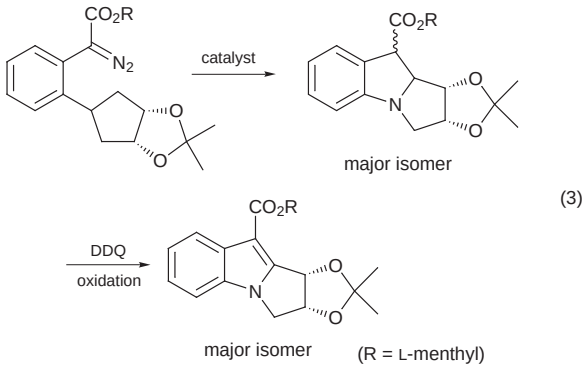
In an extremely sophisticated continuous parallel assay, proposed by Senkan,[13] resonance-enhanced multi-photon ionization techniques were used in connection with the evaluation of a heterogeneous catalyst library. A big advantage is that the method allows the products to be directly analyzed and selectivity data to be obtained. Catalyst libraries have also been evaluated by the conventional discontinuous, non-parallel methods of GC and HPLC.[14]

Asymmetric reactions pose special problems because a catalyst may be efficient only for one class of substrate but mediocre for others. To help solve this problem, Kagan[15] has proposed a discontinuous screening of the products from the reduction of multiple substrates from a one-pot reaction. The results for borane reduction of seven ketones with a chiral oxazaborolidene catalyst, where enantiomeric excesses were highly substrate-dependent, were comparable to those from conventional single substrate reactions on the individual ketones, suggesting only limited cross-talk took place between parallel reactions. Assay was by HPLC analysis with a chiral column.

Libraries of catalysts

A wide variety of methods[2] have been used for implementing combinatorial strategies in other fields but we will only discuss methods that have been applied to transition metal chemistry. The types of libraries that can be considered are just as varied as the types of assays. Libraries, which may be soluble or polymer-bound, may consist of preformed catalysts or of ligands that are active without metal ions or are converted to the catalytically active form by loading a suitable metal-containing precursor *in situ*. Catalysts can be highly solvent-sensitive, so varying the solvent can be useful. A study by Burgess *et al.*[16] illustrates the use of HTS to identify the best ligand/metal/solvent combination for a carbene insertion into a C–H bond [eqn. (3)]. In all, seven different metal ions, five chiral ligands and four solvents were studied using HPLC with an autosampler for determination of the diastereoisomer ratio. Each distinct combination was run in one well of a 96-well microtitre plate. Silver ion, previously not generally considered as a suitable catalyst, was shown to be very effective.

Having described the principal known catalyst assays, we move to the types of catalyst libraries that have been considered to date. These can be soluble or polymer-bound and either conventional or combinatorial. Although using a rapid parallel



(3)

assay with a large combinatorial library is ultimately likely to be the most effective strategy for catalyst discovery, semiclassical approaches like conventional screening of combinatorial libraries or rapid screening of conventional catalysts are likely to be useful in certain situations.

A set of conventional homogeneous metal catalysts, such as was used in a study discussed above,[8] constitutes one of the simplest soluble libraries, and can be useful when the best combination of metal and ligand type is sought in the initial stage of an investigation. Once these have been chosen, the natural next step would be to vary the ligand set using parallel synthesis. Solid phase organic synthesis (SPOS) being so widely used for polymer-bound library synthesis, many catalysts are likely to be most conveniently synthesized on beads. Extensive literature on SPOS is available[17] but some discussion is appropriate here. Merrifield's original 2% cross-linked styrene–divinylbenzene copolymer is one current recognized standard, because it swells in many organic solvents, thus allowing reagents access to the interior of the bead, yet it does not dissolve and has substantial thermal stability. The material is partially chloromethylated to form the base resin used in SPOS. The level of chloromethylation determines the maximum achievable loading of the resin. A linker is normally employed to provide the starting point for the organic synthetic steps proper and to introduce a spacer group so that the reactive functionality is held somewhat apart in space from the polymer itself. The organic synthesis then proceeds on the linker. High yields are required in each step if good overall yields are to be obtained. Many standard organic reactions have been found to go well on solid phase and an excess of reagents can often be used to drive these reactions to high yield. Finally, the product may be cleaved from the resin, if a cleavable linker has been chosen, or used directly on-bead, although full characterization may not be possible if this alternative is chosen. Other related resins, such as Wang resin,[2] have also proved useful in catalysis studies.

A small library of four purely organic peptide-like catalysts has been assayed for acyl transfer catalytic activity with Miller's fluorescence assay [eqn. (1) and (2)].[12] In this case, the catalyst and the sensor were both grafted onto a Wang resin, each bead containing only a single type of catalyst. Once exposed to the substrates, acid was formed within the individual beads by the catalytic reaction. The resulting fluorescence [eqn. (2)] was detected visually with a microscope. Similar relative activities were observed between soluble and bead-bound versions of the same catalyst.

While not catalytic, Jacobsen's[18] combinatorial syntheses of a peptide-like library having metal-ligating properties illustrates how standard[2] 'split-and-pool' techniques can be used to introduce diversity into a ligand library. In such a synthesis, different batches of beads receive different initial residues in the first step of a parallel synthesis, and are then pooled together. The beads are then split so each batch can be subjected to a synthesis step that attaches a different residue in the second position. The beads are once again pooled and the procedure repeated until all the residues have been added. The final pool contains beads that have every permutation of possible sequences. The Still[19] encoding procedure was used by which a covalently bond organic tagging compound was grafted onto each type of bead to allow the ligand present on that bead type to be identified *via* MS detection of the tag after cleavage. Finally, the beads were assayed for their ability to bind Ni(II) *vs.* Fe(III). Colorimetric detection of metal binding provided the required assay.

Solid phase synthesis of a ligand and loading a metal to make a catalyst precursor poses no particular difficulty, but cleavage of a reactive catalyst from the bead is not likely to be possible without degradation of the complex, so it is likely that the ligands will be characterized on an aliquot of the bead sample before metal binding and catalysts will normally be assayed on-bead. For a valid comparison of two bead-catalysts for activity, it is not necessary to know exactly how many of the purported active sites really are active, but all the beads in the study must have approximately the same proportion of active sites. That beads that prove to be most active contain active sites is certain, but it may be very hard to rule out the possibility that one of the inactive or barely active beads would have been extremely active if the desired complex had been formed as intended. At a severely practical level one could say that this does not matter—a catalyst that cannot be made is not of practical interest. On a theoretical level, however, such an outcome would severely perturb any structure–activity relationships one was hoping to extract and therefore lead to erroneous conclusions. From the point of view of improving our understanding of catalysis, these structure–activity relationships are likely to be the most important general points that emerge from combinatorial catalysis and it remains to be seen how reliable these will be. Direct comparison of bead catalyst data with data from the solution analogues will not necessarily give reliable information, because we will not know whether to ascribe any deviation to improper synthesis of the active catalyst on the bead or to catalyst–polymer interactions.

One technical problem that can be readily addressed is the possibility of slow diffusion of the catalytic reagents into and products out of the bead could mask activity differences. To distinguish such differences between catalysts we need the catalyst turnover, not the diffusion steps, to be rate-limiting. This is most readily achieved, we find, by limiting the loading of the resin. Instead of using commercially chloromethylated resin, we therefore have made our own; the appropriate level may need to be determined for each case. This problem may be general. We also need a solvent that efficiently swells the polymer to allow rapid substrate access and product departure; the observed rate needs to reflect the rate of the catalytic and not the diffusion steps.

Assuming we use a suitable assay for picking the bead-bound catalyst with the properties that best correspond to what is needed, we are faced with a significant choice: do we try to make a homogeneous analogue of the successful catalyst or do we continue to use the bead-bound version in later work. The advantage of the homogeneous version is that it can be fully characterized and it is more amenable to full mechanistic studies. The successful ligand may be much harder to make by conventional methods than by SPOS, however, but this problem is unlikely to be serious. The most severe problem is that the activity and selectivity of the catalyst may well be very different in going from the bead-bound to the soluble forms; many examples of big differences in chemistry between soluble and polymer phase are known. As an example of a typical difference that might be expected to affect catalytic activity, a polymer-bound catalyst is unlikely to be as easily able to dimerize as a soluble version, and it may also interact with the linker or backbone polymer in some way. Not enough is known to be able to tell how big a problem this will prove to be, but it is already clear that solution and bead-bound catalysts do show significant differences. A significant dependence on the nature of the

polymer support and differences between bead-bound and the corresponding homogeneous catalyst in solution have already been seen for Jacobsen's epoxidation catalyst.[20] On the other hand, Hoveyda studied this specific problem and found generally good agreement between the selectivities of bead-bound and solution phase catalysts in the particular case studied.

We have prepared a diverse monophosphine library[21] of the type **P**–C_6H_4PRR' (**P** = polymer) on cross linked polystyrene by the route shown in Fig. 4 and loaded it with [M(diene)-

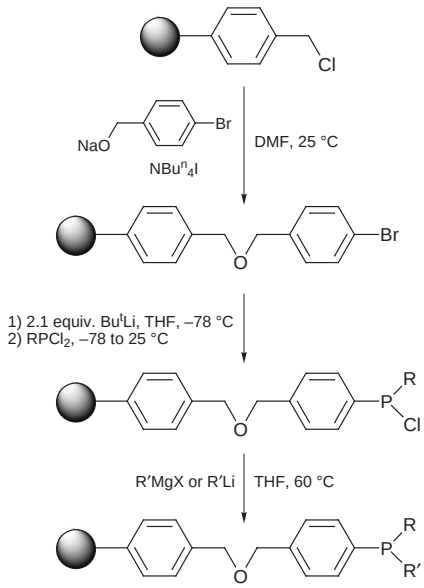


Fig. 4 The synthetic route to the generalized phosphine library of ref. 21.

$(py)_2]PF_6$, (M = Rh, Ir; py = pyridine). The two resulting sublibraries were assayed for hydrosilation activity with dyes **1a**,**b** following the prior[8] procedure to find the best supported catalysts. The resulting activities followed a different phosphine dependence for Ir *vs*. Rh and for alkene dye *vs*. imine dye, so catalysts selective for either alkene or imine could be identified. Structure/activity trends were weakly marked. The best catalyst of all had M = Ir, R = Ph and R′ = 1-naphthyl, but only rapidly reduced the alkene dye and the Rh analogue was rather slow for both dyes, an unexpected combination given the other trends seen. A combinatorial search may be particularly useful in situations such as this were the existence of ill-defined trends makes it hard to design a good catalyst.

Limitations

These methods are likely to have a number of significant limitations. Not all catalytic problems will be readily susceptible to the rapid screening-combinatorial approach. Bead-bound catalysts may also differ strongly from their soluble analogues in certain cases, making correlations between the two types of systems very difficult. Bead bound catalysts are difficult to characterize, and so one may not always be able to tell for sure why any particular bead-catalyst is poorly active—it could be that the catalyst is inherently poorly active or that the intended complex was not properly formed on the bead or that a catalyst dimerization only possible in free solution is required for activity. Careful controls and reliable analysis of the materials for metal content will be needed. Different solvents are expected to swell the polymer to different extents, resulting in rate differences that are unrelated to what would be seen in solution. We typically check, for example, that the unmodified starting resin does not take up metal and act as a catalyst in the absence of covalently attached ligand groups and that typical high activity resins have similar metal analyses to medium and low-activity resins. Even more than in traditional catalyst work, care will be needed in interpreting the results of combinatorial studies.

Combinatorial methods are unlikely to displace traditional characterization and mechanistic work. Indeed, these methods may enrich mechanistic studies by making structure–activity relationships available over a much wider range of structures than is usual in traditional studies. They may also help correct mechanistic misconceptions based on examining too small an amount of data.

Combinatorial methods could potentially be applied to any inorganic, organometallic, or bioinorganic problem where a suitable assay can be devised. For example, functional modelling of enzyme active sites has proved very challenging by traditional approaches. They also seem suitable for determining what coordination or organometallic structures can bind, or selectively bind, particular classes of ligand; in many cases, these ligands could be covalently bound to dyes for easy visualization. This approach might also help in determining the resting state of catalysts. For example, in hydrosilation, the silane might be tagged with a red dye and the alkene with a blue one. In such a case, catalyst beads that bound silane but not alkene would be red, silane but not alkene, blue, and if both were bound the beads would be expected to appear purple.

Future developments

There are already initial indications that other areas of inorganic chemistry than homogeneous catalysis are also likely to benefit from combinatorial methods. Mallouk *et al.*[22] have shown how they can be applied to finding electrochemical oxidation catalysts, for example, and they have also been used for materials synthesis, such as finding a superior luminescent material.[23]

Although the area of combinatorial chemistry and rapid screening is very new as applied to inorganic chemistry, it has already made a significant impact. The challenge now is to develop methods to apply it to a variety of problems to see how widely they are applicable. Care will be needed to characterize the resulting materials and to check the reliability of the data obtained by comparison with traditional approaches on selected materials. There are so many different ways these ideas could be embodied, that the effort will require ingenuity combined with a close attention to practicality and care in interpretation.

Acknowledgements

I am grateful to the US Dept. of Energy, Catalytica Corp. and Mitsubishi Oil Co. for funding, Jennifer Loch, Alyssa White, Matthew Torres and Alan Cooper for unpublished data and the other coworkers mentioned in the citations for their work on the problem.

Lanthanide organometallic chemistry based on the porphyrinogen skeleton: acetylene and ethylene bridging praseodymium and neodymium $\eta^5:\eta^1:\eta^5:\eta^1$-bonded to *meso*-octaethylporphyrinogen

Elisa Campazzi, Euro Solari, Rosario Scopelliti and Carlo Floriani*

Received (in Basel, Switzerland) 19th May 1999, Accepted 8th July 1999

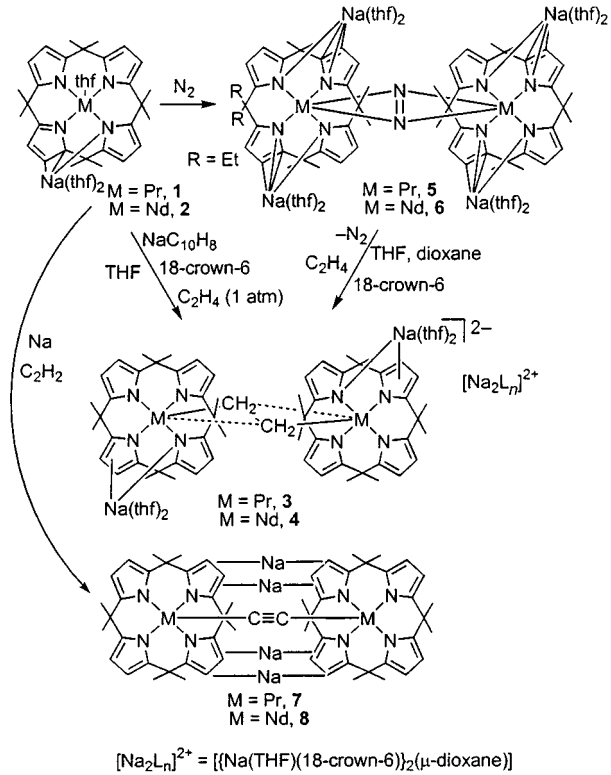
The reaction of *meso*-octaethylporphyrinogen–lanthanide complexes, [{($\eta^5:\eta^1:\eta^5:\eta^1$-$Et_8N_4$)M}Na(thf)$_2$] [M = Pr, Nd], with $NaC_{10}H_8$ in an ethylene or acetylene atmosphere leads to the isolation of dimeric species, where the metals are bridged by the $[C_2H_4]^{2-}$ and $[C_2]^{2-}$ anions.

Porphyrinogen tetraanions provide a unique binding cavity for electron deficient metals, *e.g.* early transition metals.[1] Such metals can exploit the $\eta^5:\eta^3:\eta^1$ bonding mode of each of the pyrrolyl anions according to the metal charge and electronic requirements. In addition, the electron-rich pyrrolyl anions can function as binding countercations in the structure.[1,2] Although the organometallic chemistry of divalent lanthanides[3] is largely confined to Sm(II)[4–6] and, to a lesser extent, Yb(II)[7] and Eu(II),[3] and based on cyclopentadienyl ligands,[4,5] it has been possible, using *meso*-octaethylporphyrinogen as an ancillary ligand, to generate the oxidation state (II) for lanthanides which are usually not available in this oxidation state,[8] and to make them very reactive in the presence of appropriate substrates.

The reduction of complexes **1**[9] and **2**[9] with sodium metal in the presence of 18-crown-6 led to the isolation of the dimetalla-ethane-like skeleton, where each lanthanide ion is supported by the porphyrinogen tetraanion. It is important that the reaction is carried out in the presence of 18-crown-6 because of its beneficial effect on crystallization and the higher stability of the ethylene complex in case of the ion-separated form. A particularly interesting synthetic route to complexes **3** and **4**† is the replacement of N_2 by ethylene from complexes **5**[9] and **6** (Scheme 1).[9] Such a replacement was successful when it was carried out in the presence of 18-crown-6. The solvation of the alkali countercations, though often neglected, can be, in some of the polynuclear compounds like those reported here, a determining factor on the energetics of the reaction. Complexes **3** and **4** have been obtained under such experimental conditions (see synthetic procedures) which rule out any reversible binding of ethylene to the metal in complexes **3** and **4**.

The structure of the anion in complex **4**‡ is shown in Fig. 1 along with selected structural parameters. The porphyrinogen moieties display a saddle-shaped conformation with the metals being $\eta^5:\eta^1:\eta^5:\eta^1$ bonded to them. The solvation of the two sodium cations linked to the dimetallic tetraanion is provided by two adjacent pyrrole moieties, which act, at the same time, as η^5 ligands for the lanthanide and η^1 for the sodium and *vice versa*; solvation is completed by two THF molecules.[2] The other sodium cations are bonded together by a dioxane, and they both complete their coordination spheres with an 18-crown-6 and a THF molecule. The C–C bond distance [C37–C37′, 1.49(2) Å] tells us that the original ethylene has been converted into a 1,2-dimetalla-ethane moiety. The M–C bond distances [M–C37, 2.497(7); M–C25, 2.790 Å][10] however, when compared with those of olefin complexes from the literature,[5,10] leave the possibility of assuming a μ-$\eta^2:\eta^2$-bonding mode for the bridging $[C_2H_4]$ fragment. The metals in complexes **3** and **4** are in the oxidation state (III) according to the magnetic moments, which are very close to those of the starting complexes **1** and **2**.

When the same synthetic method was applied to the reaction of **1** and **2** in the presence of acetylene, deprotonation of the substrate occurred instead of reduction of the metal, leading to **7**† and **8** (Scheme 1). The resulting acetylido complex **7**‡ is shown in Fig. 2 with selected structural parameters. The dimer



Scheme 1

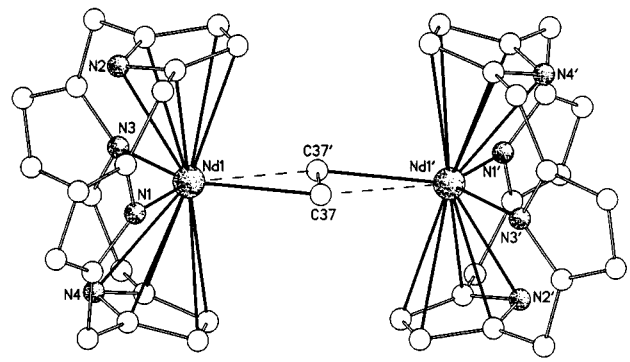


Fig. 1 A view of complex **4**. Selected bond distances (Å): Nd(1)–η^5(Pyr)$_{av}$ 2.584(4), Nd(1)–η^1(Pyr)$_{av}$ 2.564(7), Nd(1)–C(37) 2.497(7), Nd(1)–C(37′) 2.790(7), C(37)–C(37′) 1.49(2). η^5(Pyr)$_{av}$ indicates the centroid. Prime indicates a transformation of $-x, -y, -z$. (*meso*-Ethyl groups omitted for clarity).

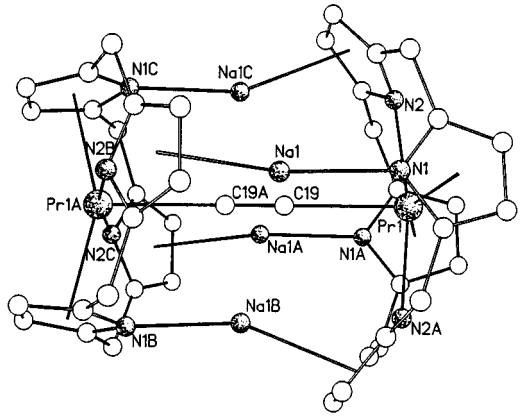

Fig. 2 A view of complex **7**. Selected bond distances (Å): Pr(1)–η⁵(Pyr) 2.492(1), Pr(1)–η¹(Pyr) 2.408(2), Na(1)–η⁴(Pyr) 2.612(2), Na(1)–η¹(Pyr) 2.376(2), Pr(1)–C(19) 2.670(4), C(19)–C(19A) 1.250(8). η⁵(Pyr) indicates the centroid. Letters A, B and C indicate symmetry operations of $-x + 1/2$, $-y + 1/2$, z; y, $-x + 1/2$, $-z + 1/2$; $-y + 1/2$, x, $-z + 1/2$, respectively. (*meso*-Ethyl groups omitted for clarity).

has C_4 symmetry and the porphyrinogen, in the saddle-shaped conformation, displays an $\eta^5:\eta^1:\eta^5:\eta^1$ bonding mode. The two metal–porphyrinogen moieties are bridged by the C_2^{2-} μ-$\eta^2:\eta^2$-bonded anion [C–C, 1.250(8) Å]. The rather long M–C bond distances [2.670(4) Å][11] account for the high coordination number of the metals when bonded to the *meso*-octaalkylporphyrinogen tetraanion.[1,2] The C_2^{2-} anion is an appropriate spacer determining the cavity inside which are bound four Na cations, which are sandwiched by the two metalla-porphyrinogen moieties.[2d] Each Na is alternately bonded η^1 and η^4 to the two metalla-porphyrinogens, which assure complete solvation of all four alkali metal cations without the help of any additional solvent.[2]

The methodology reported in this paper represents a new entry into the organometallic chemistry of lanthanides for a number of issues: (i) the use of non-conventional ancillary ligands; (ii) the possibility to exploit the high reactivity of transient Ln(II) derivatives, *i.e.* for those metals which are not stable in this oxidation state; and (iii) the possibility to form M–C σ bonds readily directly from olefins and alkynes.

Notes and references

† *Synthesis of* **4**. The addition of 18-crown-6 (2.61 g, 9.87 mmol) to a sky-blue suspension of **2** in THF (130 cm³) caused the formation of a sky-blue solution. The addition of sodium metal (0.124 g, 5.38 mmol) under a C_2H_4 atmosphere did not cause any change until a small amount of naphthalene was added (0.172 g, 1.34 mmol). After 2 h a green suspension was obtained and was kept at room temperature until the complete disappearance of sodium metal. The solvent was evaporated to 10 cm³, then pentane (40 cm³) was added (5.3 g, 44%). Crystals appropriate for X-ray analysis were obtained from refluxing THF in the presence of a small amount of dioxane. (Found: C, 60.15; H, 8.25; N, 4.28. **4**·(18-crown-6)$_2$(THF)$_8$(dioxane), $C_{134}H_{220}N_8Na_4Nd_2O_{22}$ requires C, 60.15; H, 8.29; N, 4.19%). μ_{eff} = 3.18 μ_B at 298 K. The magnetic susceptibility was measured with an MPMS5 SQUID susceptometer. Complex **4** was obtained equally well from the reaction of **6** with ethylene in the presence of 18-crown-6. *Synthesis of* **7**. Sodium metal (0.089 g, 3.85 mmol) was added to a yellow suspension of **1** (2.94 g, 3.48 mmol) in THF (130 cm³) under an acetylene atmosphere. The sodium reacted within 24 h at room temperature. Some white solid was filtered out and the solvent evaporated to dryness. The solid residue was collected using pentane (2.20 g, 72%). (Found: C, 61.40; H, 7.54; N, 6.23. **7**·4THF, $C_{90}H_{128}N_8Na_4Pr_2O_4$ requires C, 61.43; H, 7.33; N, 6.37%). μ_{eff} = 2.61 μ_B at 298 K. Crystals for X-ray analysis were obtained from refluxing benzene, as **7**·4C_6H_6.

Catalyst poisoning by methyl groups

Peter Albers,*[a] Hubert Angert,[a] Günter Prescher,[a] Klaus Seibold[a] and Stewart F. Parker[b]

[a] *Degussa-Hüls AG, P.O. Box 1345, D-63403 Hanau, Germany. E-mail: Dr_Peter.Albers@degussa.de*
[b] *ISIS Facility, Rutherford Appleton Laboratory, Chilton, Didcot, UK OX11 0QX*

Received (in Cambridge, UK) 23rd June 1999, Accepted 12th July 1999

Palladium catalysts which showed premature deactivation under technical conditions were studied by means of inelastic incoherent neutron scattering (INS) spectroscopy revealing the cause of the poisoning to be a surface-bound methyl group.

During investigations on deactivation phenomena on catalysts from various industrial applications, macroscopic samples (many kilograms each) of spent palladium catalysts were isolated because of their peculiar behaviour. These catalysts were used for the partial hydrogenation of C=C structures in the ring systems of aromatic and polyaromatic molecules and for the hydrogenation of C=O groups to C–OH groups of functionalized aromatic and polyaromatic systems.† Conventional analytical methods for catalyst characterisation did not give any clear evidence for the presence of coke, inorganic contaminants or chemical poisons (carbon monoxide, sulfidic species) which are the most common causes of premature deactivation. Hydrogen absorption/desorption isotherms did not reveal anomalous properties or atypical hysteresis effects compared to literature data,[1,2] nor did electron microscopy studies show any unusual particle growth or sintering effects. When comparing the compositions of active and deactivated catalysts by elemental analysis, there was no correlation between the total amount of residual carbonaceous species and the catalytic activity. Surface spectroscopy by means of energy dispersive X-ray microanalysis, time-of-flight secondary ion mass spectrometry, and X-ray photoelectron spectroscopy did not result in the identification of any critical surface contamination involved. The signals of residual amounts of adsorbed solvent molecules were observed predominantly.

Vibrational spectroscopy has been extensively used for the characterisation of surface species on metal single crystal surfaces[3] and supported metal catalysts.[4] However, finely divided metal particles of catalysts absorb electromagnetic radiation from the infrared through the visible. As a result, Raman spectroscopy, using either visible or near-infrared excitation, and infrared spectroscopy were both unsuccessful. This problem could uniquely be circumvented by the use of inelastic neutron scattering spectroscopy. For neutrons the scattering is determined by the total scattering cross-section and the amplitude of vibration. For palladium the large mass (106.4 u) and small cross-section (4.48 barns, 1 barn = 1×10^{-28} m^2) mean that the palladium is largely transparent to neutrons. In contrast, the incoherent scattering cross-section for hydrogen is huge (79.90 barns) and together with its light mass (1.007 u) has the result that the scattering is dominated by hydrogenous motions.

The normalized INS spectra‡ of a deactivated catalyst before and after extraction with acetone (24 h, afterwards dried *in vacuo*) are shown in Fig. 1 together with the spectrum of the corresponding active catalyst after extraction with acetone under exactly the same conditions. In its original condition—as obtained from the technical application—the catalyst surface is still covered by a variety of adsorbed species consisting of polyaromatic molecules which are mainly residual amounts of solvent molecules [Fig. 1(a)]. After extraction, the broad background due to these solvent molecules or other adsorbed organic species is removed from the spectrum but a series of strong, sharp peaks remain [Fig. 1(b)] which are completely absent on the corresponding active catalyst [Fig. 1(c)]. Note that the same peaks are present in the "as-received" sample before clean-up.

The most striking feature of the spectrum is its simplicity: there are remarkably few bands. This implies either a highly symmetric structure with many degenerate modes or a small molecule. The intense 302 cm^{-1} feature suggested a methyl torsion, so a model consisting of a methyl group in an on-top site (see inset in Fig. 2) was used as the basis for a CLIMAX[5] analysis of the spectrum. The excellent fit shown in Fig. 2 was obtained. The quality of the fit is not dependent on the precise geometry of the model; small changes in bond angles or distances do not make any significant difference. The critical factors are the number of atoms and their spatial arrangement, thus a surface methylene group gives a different pattern. The only modification necessary was to increase the mass of the outer Pd atoms by a factor of 10 (*i.e.* to 1060 u) to mimic the

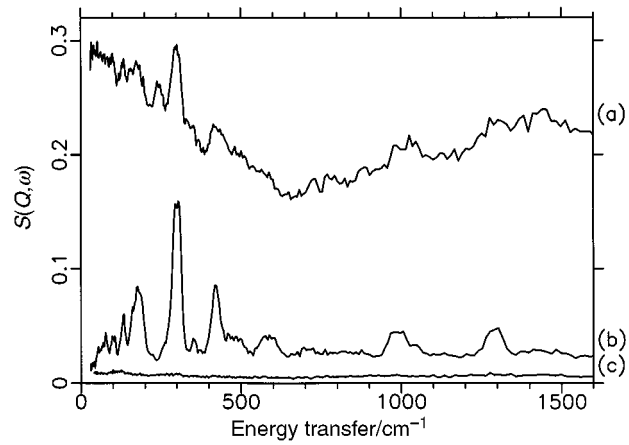

Fig. 1 INS spectra of palladium catalysts. Deactivated catalyst before (a) and after (b) extraction. Active catalyst after extraction (c).

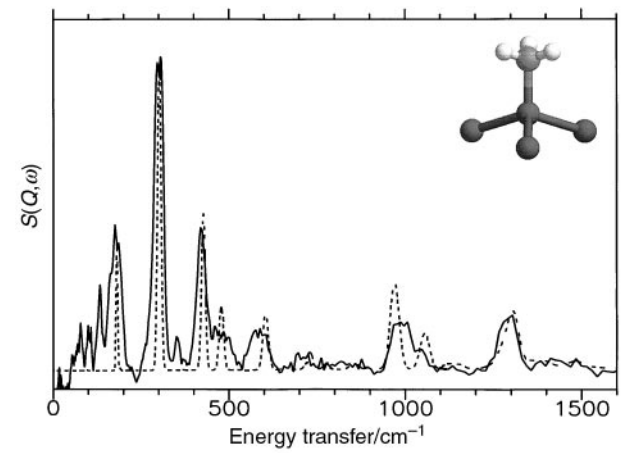

Fig. 2 Comparison of the INS spectrum of the deactivated catalyst (solid line) and the results from the CLIMAX analysis of the spectrum (dashed line).

inertia of the catalyst surface. Only the band at 179 cm^{-1} was affected by this procedure. Table 1 lists all the observed bands and their assignments as well as some literature comparisons.[6–10] The assignments for the fundamentals are taken from the literature. It should be noted that the frequencies for the methyl vibrations differ significantly from those typical of organic molecules, this is well documented. The assignments for the overtones and combinations come from the CLIMAX fit. The assignment to surface bound methyl groups is also supported by a recent density functional calculation[11] that indicated CH_3 on Pd(111) was stable to dehydrogenation and preferentially adsorbed in the on-top site, as observed here. Additional computer simulation experiments on the spectral features of ethyl, methylidyne, methylene and ethylidyne groups revealed that the only fit with reasonable quality and chemically reasonable frequencies was obtained for a surface methyl group.

The sharpness of the peaks suggests that the methyl groups are bound to the topmost atomic layer of the catalyst and the intensities suggest that macroscopic amounts of CH_3–Pd species are present. Comparing the normalized intensities of the CH_3–Pd signals for several deactivated samples showed an excellent correlation of these intensities with the degree of catalyst deactivation. The large quantity of bound methyl groups presumably caused a modified surface polarity by their sp^3 centres inhibiting the adsorption of sp^2 type reactants on the catalyst surface and, therefore, significantly lowered the catalyst performance by a surface blocking effect. The CH_3–Pd species at the surfaces of the deactivated catalysts were observed to be quite stable in air and quite resistant to repeated solvent extraction or hydrogenation/dehydrogenation experiments under ambient conditions.

It seems remarkable that on the surfaces of finely divided, deactivated catalysts from large scale technical applications very well defined, simple molecular structures can reproducibly be found at a macroscopic scale which hitherto have only been detected in surface science experiments on metal single crystals. This example illustrates that the gap[12] between surface science and technical catalysis, which is considered to complicate the translation of results from experiments on low surface area materials at low pressures on the one hand into the field of applied catalysis on high surface area materials at ambient or high pressures on the other, may, in some cases, not be as large as is believed.

We would like to express our gratitude to the Rutherford Appleton Laboratory for access to the neutron beam facilities of ISIS. Degussa-Hüls AG is thanked for support of the measurements.

Notes and references

† The hydrogenation reactions were carried out in conventional gas/liquid reactor systems with suspended catalyst and internal recycle at temperatures between 60 °C and 90 °C, hydrogenation pressures between 1.5 and 3 bar. At reactant concentrations of 10–15% the degree of hydrogenation was adjusted to 60–70% yielding product concentrations of about 7–10% of hydrogenated products for further processing. The spent catalyst samples exhibited less than 10% of their regular hydrogenation activity. Usually they show excellent activity over extended times of use under varying conditions.

‡ 25 g samples of the palladium catalysts were put into thin walled aluminium cans which were evacuated to 10^{-6} mbar to remove volatile adsorbed species. INS spectra were recorded at 20 K using the INS spectrometer TFXA (Time Focused Crystal Analyzer) at the ISIS pulsed neutron scattering facility (Rutherford Appleton Laboratory, Chilton, UK).

Received (in Cambridge, UK) 9th June 1999, Accepted 5th July 1999

The Grubbs' catalyst, $(PCy_3)_2RuCl_2$(=CHPh), generates persistent radical anions on treatment with π-acceptors such as *p*-benzoquinones and a remarkably wide range of dienes and even simple alkenes.

In the course of an investigation of the metathesis polymerisation of several norbornadiene derivatives catalysed by $(PCy_3)_2RuCl_2$(=CHPh) (**1**), we have noted[1] that 2,3-bis(ethoxycarbonyl)norbornadiene is slow to react even though it polymerises rapidly using $RuCl_3{\cdot}nH_2O$ as catalyst. Dias and Grubbs[2] previously remarked on the reluctance of 2,3-bis(trifluoromethyl)norbornadiene to polymerise, so there is here a hint that those dienes which are also Michael acceptors may chelate to **1** in the di-*endo* mode *via* a charge transfer interaction which retards normal initiation and/or propagation. Furthermore there is a very recent report[3] that **1** is also a very good catalyst for methyl methacrylate polymerisation. This led us to conclude that **1** may be capable of reducing a variety of π-acceptors in solution to radical anions. We therefore decided to investigate, by EPR analysis, the presence of radical anions generated from strong π-acceptors such as tetrahydro- (**2**), tetrafluoro- (**3**), tetrachloro- (**4**) and dichlorodicyano-*p*-benzoquinone (**5**).

When 0.5 cm^3 of a (1–5) $\times$ 10^{-3} M solution of **1** in CH_2Cl_2 is mixed with 0.5 cm^3 of a solution of the of π-acceptor [(5–10) $\times$ 10^{-2} M] in the same solvent under argon at room temperature, EPR spectra are observed which persist for many hours.† Each diene generates a different EPR spectrum centred close to the free spin value, (g ~ 2.005, typical of radical anions) and bearing no resemblance to Ru^{III}-centred EPR signals in general[4] or to Ru^{III}-bound alkenes in particular.[5]

Using **2** we observed immediate strong well-resolved EPR signals (Fig. 1) that decay over a period of hours. The spectrum consists of a triplet of triplet of triplets, arising from coupling to three pairs of spin ½ nuclei, presumably the protons H_A and H_B (see **I**) together with the ^{31}P nuclei of the catalyst.

The EPR spectrum from **3** under these conditions is complex; on preliminary analysis, two distinct overlapping patterns of six and eight lines suggesting the existence of more than one radical species. When **1** is replaced by (phen)$Ru(CO)_2Cl_2$ (**6**) as donor, however, addition of **3** gave a weak simple 1:2:1 triplet which was stable over several hours (Fig. 2). By way of contrast, the addition of Grubbs' catalyst **1** to **4** generated a very strong doublet, while with **6**, **4** generated only a very intense singlet. The behaviour of **6** with benzoquinone is different in nature from anything so far observed in this work. The initial weak complex signal evolves into a relatively intense five-line metal-centred signal due to coupling to two equivalent N atoms from the phen ligand, similar to those found previously[6] for electrochemically generated Ru-centred radical anions.

The most striking result occurred on addition of norbornadiene **7** to **1**. An intense sharp triplet (Fig. 3) is observed, which decays only by some 50% over 24 h. We believe this signal can be explained by delocalisation of unpaired spin over *one* alkene moiety, as represented by **I**.

On treatment with **1**, norbornene and cyclopentene afford similar but much weaker triplets, while benzonorbornadiene gives a similar triplet following on the disappearance of an initial short-lived doublet of around the same g value. We are, as yet, unable to assign these spectra.

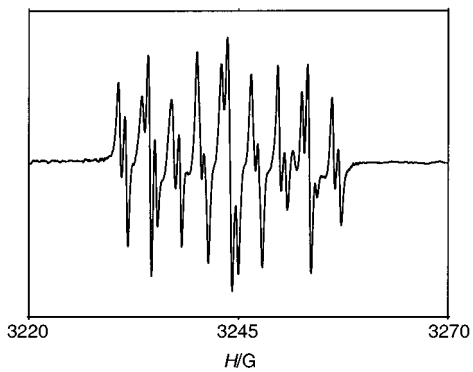

Fig. 1 EPR spectrum of Grubbs' catalyst **1** (1×10^{-3} M) with benzoquinone **2** (1×10^{-1} M), recorded in CH_2Cl_2 at 20 °C, showing the 1:2:1:2:4:2:1:2:1 triplets. g = 2.0048; A_1 = 4.8 G, A_2 = 1.6 G, A_3 = 0.4 G.

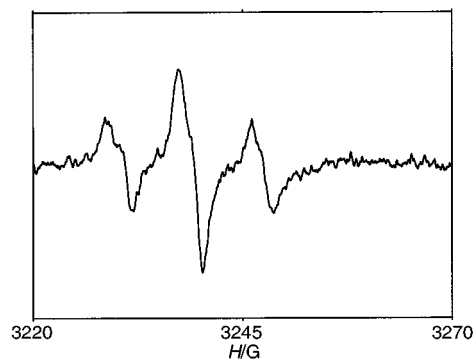

Fig. 2 EPR spectrum of **6** (5×10^{-3} M) with tetrafluorobenzoquinone **3** (5×10^{-2} M), recorded in CH_2Cl_2 at 20 °C. g = 2.0075; A = 8.6 G.

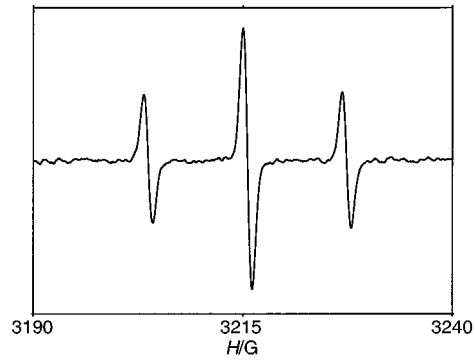

Fig. 3 EPR spectrum of **1** (1×10^{-3} M) with norbornadiene **7** (2×10^{-1} M), recorded in CH_2Cl_2 at 20 °C. g = 2.0064; A = 12.0 G.

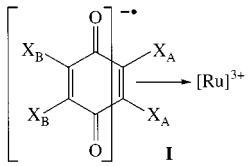


I

The presence of **2**, **3** or **4** enhances the activity of the Grubbs catalyst without changing the *cis* content of the polynorbornadiene (16%) as found using **1** alone. Similar results have also been obtained[7] when **4** is used as a cocatalyst with mesityl-$Mo(CO)_3$ for phenylacetylene and norbornene polymerisations.

Several major points arise from this work.

(i) Species **1** is remarkably effective at forming radical anions even from simple olefins.

(ii) The spectrum generated by treatment of **2** with **1** indicates the loss of equivalence of the four protons in the benzoquinone radical anion,[8] a consequence of the η^2-binding of **2** to the Ru^{II} centre as in **I**. Following π-donation from the coordinated C=C moiety, electron transfer takes place from the ruthenium cation to the uncoordinated C=C group. In this way the inequivalence of the X_B and X_A sets in Fig. 1 and 2 is explained; in Fig. 2, indeed, the F_A set is seen to be EPR silent.

(iii) The mechanism of initiation and perhaps even propagation of the metathesis reaction involves radical anions even for simple alkenes in accordance with eqns. (1) and (2). In support

$$\mathbf{1} + \text{alkene} \rightarrow [\mathbf{1}\text{–}\eta^2\text{-alkene}] \quad (1)$$

$$[\mathbf{1}\text{–}\eta^2\text{-alkene}] + \text{alkene} \rightarrow [\mathbf{1}\text{–}\eta^2\text{-alkene}]^{\bullet+} + [\text{alkene}]^{\bullet-} \quad (2)$$

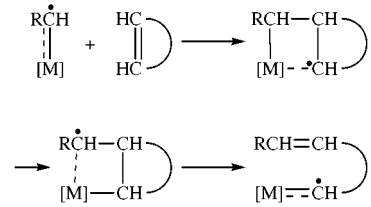
of this we note that norbornadiene, which may act *in lieu* of two alkene molecules and chelate as in **I**, generates a more intense signal than norbornene and also initiates polymerisation far more efficiently. This suggests that in metathesis the substrate itself may act as a cocatalyst by virtue of radical anion formation, as supported by the cocatalytic effect noted above for quinones **2, 3** and **4**. While there is evidence for involvement of anion radicals in the initiation step, we do not know whether this extends to the [2 + 2] cycloaddition propagation step. Should this prove to be so, it raises very fundamental questions about the exact theoretical nature (concerted or otherwise) of the key step.‡

(iv) Not only is the EPR technique now seen as a valuable novel probe in metathesis reactions but it can also be employed for a wide variety of organometallic systems and other catalytic processes where the presence of suitable π-acceptors may also act as important promoters. With the objective of identifying, *via* detailed assignment of their spectra, the radical anions observed in this work, we plan experiments to replace by ^2H both olefinic H atoms and the α-H atom of the carbene ligand. We also intend to examine the behaviour of more recent analogues of **1**, which lack the phosphine ligands.[9] The elucidation of the nature and reactivity of the radical anions involved should assist in the design of improved catalysts for metathesis.

Notes and references

† EPR spectra were recorded at X-band frequencies in liquid CH_2Cl_2 at room temperature. No signals were observed from solutions of **1** in the absence of added substrates.

‡ We have now found that **1** polymerises α-methylstryrene and simultaneously generates EPR-active species. This information, together with the knowledge that Grignard reagents also catalyse free radical addition polymerisation (ref. 10) and metathesis polymerisation of norbornene (ref. 11), suggests a novel mechanism based on metalla-radicals.



We believe that a metalla-carbenium ion mechanism is responsible when the most acidic metathesis catalysts are used, but the new metalla-radical scheme applies using **1** or when Mg-based catalysts (Grignard reagents) are active.

Received (in Cambridge, UK) 4th June 1999, Accepted 15th July 1999

Phosphine functionalised carbosilane dendrimers have been synthesised and their palladium complexes used as catalysts in the allylic alkylation reaction performed in a continuous flow membrane reactor.

Since Vögtle and co-workers synthesised branched structures in 1978,[1] much research has been devoted to the synthesis and investigation of dendrimeric molecules.[2] One of the main applications of dendrimers[2h,i] is in catalysis,[3] allowing easy recycling of the homogeneous catalyst by means of nanofiltration.[4] Here we report the synthesis of phosphine functionalised carbosilane dendrimers and their use as catalysts in a continuous process.

We have chosen carbosilane dendrimers[5] as a backbone for our catalytic system because of their catalytic inertness. A previous report describes the synthesis of these dendrimers.[6] The second generation dendrimer is a white solid and crystals suitable for X-ray analysis were grown from a diethyl ether–methanol solution.‡ The structure (Fig. 1a) shows that the molecule crystallised with all the bonds in a zigzag conformation. This dendrimer has a calculated molecular volume of 2414 Å^3, which is anticipated to be large enough for separation from a reaction mixture by nanofiltration.

The phosphine functionalised carbosilane dendrimers were synthesised by hydrosilylation of the double bonds of the various generations (G_0, G_1, G_2) with chlorodimethylsilane or dichloromethylsilane followed by reaction with lithium methyldiphenylphosphine–TMEDA[7] (Scheme 1).§ All the phosphine functionalised dendrimers were obtained as wax-like solids. Characterisation by ^{1}H and ^{31}P-{^{1}H} NMR and MALDI-TOF MS shows that the P-functionalised dendrimers were obtained in at least 95% purity. The dendrimer with seventy-two phosphine groups could not be prepared, probably because of surface congestion.

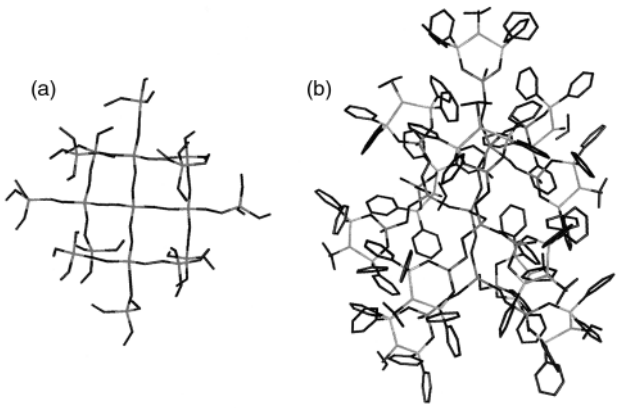

Fig. 1 Crystal structure of the second generation dendrimer (a) and a modelled structure of the Pd(allyl) complex of **8** (b). Hydrogens and counterions have been omitted for clarity. [See Electronic Supplementary Information (ESI) for a colour version of this figure (Si in red, C in dark blue, Pd in green, P in yellow)].

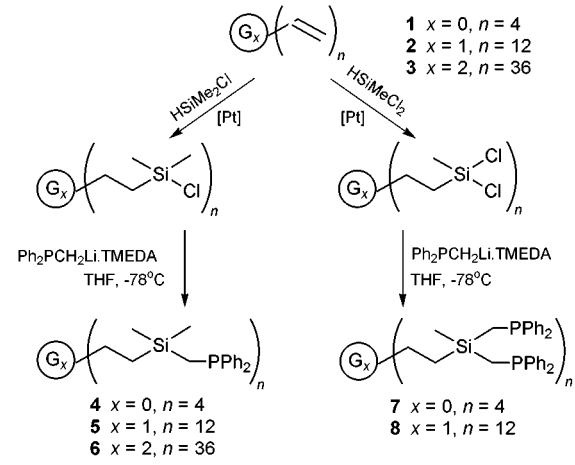
† Electronic supplementary information (ESI) available: full colour version of Fig. 1. See http://www.rsc.org/suppdata/cc/1999/1623/

Dendrimers **7** and **8** have four and twelve endgroups, respectively, each containing a chelating bidentate phosphine ligand. The endgroups of dendrimers **4**, **5** and **6** contain monodentate phosphine ligands. Allylpalladium complexes of these dendrimers were synthesised by reaction with [(η^3-C_3H_7)PdCl]$_2$. According to ^{1}H and ^{31}P-{^{1}H} NMR the phosphine dendrimers **7** and **8** co-ordinate in a bidentate way resulting in well defined Pd complexes, while the monodentate phosphine dendrimers give rise to a mixture of products.

All the Pd(allyl) dendrimer complexes were used as catalysts in the allylic alkylation reaction of allyl trifluoroacetate and sodium diethyl methylmalonate yielding diethyl allylmethylmalonate. The reaction was first carried out *via* a batch process. All the dendrimeric catalysts showed a very high activity. Using a substrate–Pd ratio of 2000 the yield after 30 min was over 80%, and only small differences in reaction rates were observed for the different catalysts.¶ The fact that the activity did not decrease with increasing generation indicates that all active sites act as independent catalysts. From molecular modelling (Fig. 1b) it was clear that indeed all the Pd(allyl) groups reside at the outer surface of the dendrimer and should be easily accessible to



Scheme 1 Synthesis of phosphine functionalised carbosilane dendrimers.

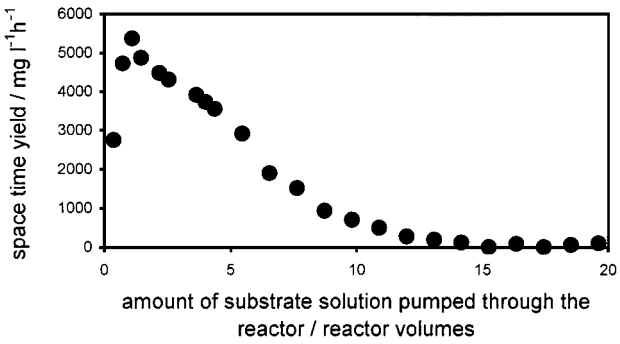


Fig. 2 Space time yield *versus* amount of solvent pumped through the reactor of the continuous allylic alkylation reaction in a membrane reactor.‡‡

the nucleophile. Addition of a second portion of substrate after nearly full consumption of the sodium diethyl methylmalonate (over 90%) showed that the catalyst remained active.

These novel dendrimeric catalysts were studied in a continuous process using a membrane reactor.‖ A solution of allyl trifluoroacetate and sodium diethyl methylmalonate in THF (including *n*-decane as an internal standard) was pumped through the reactor. The allylpalladium complex of the largest dendrimer with bidentate phosphines (**8**) was used as a catalyst.**

In Fig. 2 the space time yield is plotted as a function of the amount of solvent (expressed in reactor volumes) pumped through the reactor. The reaction started immediately after addition of the catalyst and reached its maximum space time yield after one reactor volume. The space time yield slowly dropped to zero after *ca.* 15× the reactor volume of substrate solution had been pumped through the reactor. Regarding the size of the catalyst, this decrease was unexpectedly rapid. The retention in the membrane reactor of the second generation dendrimer (molecular volume: 2414 Å^3), which is much smaller than the Pd catalyst (calculated molecular volume: ≈7600 Å^3 (Fig. 1)), was determined to be 98.1%. Using this number the decrease in catalyst activity is calculated to be only 25% after flushing the reactor fifteen times. The observed decrease in catalyst activity is therefore ascribed to decomposition†† of the palladium compound and not to loss of the dendrimeric catalyst. This is in agreement with the observation that samples taken from the product flow were not catalytically active, indicating that no active catalyst had gone through the membrane.

In conclusion, carbosilane dendrimers functionalised with diphenylphosphine groups at the periphery have been synthesised and characterised. Palladium complexes of these dendrimers have been used as catalysts in the allylic alkylation reaction. It has been shown that these dendrimeric catalysts can be used in a continuous process using a membrane reactor. Current work is aiming at the enhancement of the stability of these catalysts, and the exploration of these systems in other reactions.

This work was supported in part (A. L. S.) by the Council for Chemical Sciences of the Netherlands Organisation for Scientific Research (CW-NWO).

Received (in Cambridge, UK) 29th June 1999, Accepted 14th July 1999

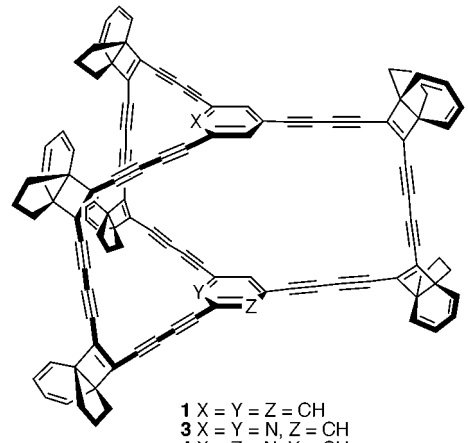
(1,3,5)Pyridinophanes having [4.3.2]propellatriene units were synthesized as precursors to macrocyclic polyyne $C_{58}H_4N_2$; diazafullerene anion $C_{58}N_2^-$ was detected in the laser desorption mass spectrum of the pyridinophanes.

Increasing interest has been focused on heterofullerenes, in which one or several carbon atoms of the fullerene cage are replaced by heteroatoms. Regarding azafullerenes, Wudl and Hirsch reported mass spectral detection of monoazafullerene cation $C_{59}N^+$, which was generated by the fragmentation of precursors manipulated from C_{60}.[1] Subsequently, isolation of its stable derivatives such as $C_{59}NH$, $C_{59}NR$ (R = $CHPh_2$, Ar) was reported from the same groups.[2] Rao reported the formation of azafullerenes $C_{59}N$ to $C_{56}N_4$ together with nitrogen-containing carbon clusters such as $C_{70}N_2$, $C_{59}N_6$, $C_{59}N_4$ and $C_{59}N_2$ in the soot produced by contact arc vaporization of graphite in the presence of N_2 or NH_3.[3] The closed shell azafullerenes having an even number of nitrogen atoms, $C_{60-n}N_n$ (n = 2, 4 and 6), are isoelectronic with the di-, tetra- and hexa-anions of C_{60}, respectively, and are predicted to be reasonably stable.[4] However, selective formation of such azafullerenes has not been achieved so far experimentally.

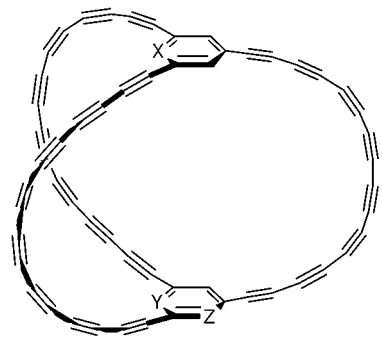
Recently we synthesized (1,3,5)cyclophane **1** fused by [4.3.2]propellatriene units, as precursors to polyyne-bridged macrocycle $C_{60}H_6$ **2**.[5] The laser-desorption mass spectra of **1** exhibited not only the negative ion corresponding to $\mathbf{2}^-$ but also C_{60} ions in both positive and negative modes. Rubin obtained similar results using a cyclobutenedione derivative related to **1**.[6] The formation of C_{60} from **2** can be explained in terms of the zipping-up cyclization of the polyyne chain accompanying the loss of hydrogen atoms.[7] As an extension of this method to the synthesis of azafullerenes, we report here the synthesis of pyridinophane **3** and its regioisomer **4** which would serve as precursors to polyyne $C_{58}H_4N_2$ **5** and **6**, respectively.[8] We detected the $C_{58}N_2$ anion in the laser desorption mass spectrum of **3** and **4**.

The Corey–Fuchs ethynylation[9] of dichloroformylpyridine **7**[10] afforded **8** which was converted to triethynylpyridine **9**† by the Sonogashira coupling[11] with trimethylsilylacetylene (Scheme 1). Tris(bromoethynyl)pyridine **10** derived from **9** by treatment with NBS and $AgNO_3$ was coupled with mono-(triisopropylsilyl)-protected diethynyl[4.3.2]propellatriene **11**[5] using Pd^0–Cu^I catalyst[12] to afford the tripod **12**.† After removal of the protective group, oxidative coupling of **13** under high-dilution conditions gave a mixture of pyridinophanes **3** and **4**† as a light-sensitive yellow solid.[13]

The positive mode laser desorption time-of-flight mass spectrum of **3** and **4** exhibited only indane fragments. Fig. 1 shows the negative mode laser desorption mass spectrum of **3** and **4**. The prominent peak due to $\mathbf{5}^-$ and $\mathbf{6}^-$, *i.e.* $C_{58}H_4N_2^-$, was observed at *m/z* 728 together with those of $C_{58}H_4N_2$(indane)$^-$ at *m/z* 846 and $C_{58}H_4N_2$(indane)$_2^-$ at *m/z* 964 formed by the successive loss of the indane fragments. More importantly, as shown in the inset of Fig. 1, the peak due to the $C_{58}N_2$ anion was indeed observed at *m/z* 724, albeit in relatively low



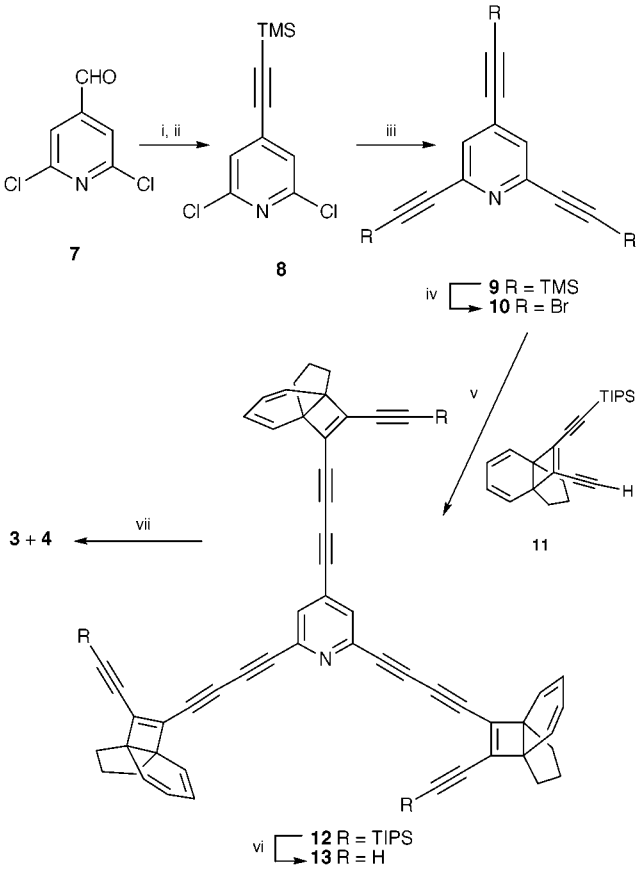
1 X = Y = Z = CH
3 X = Y = N, Z = CH
4 X = Z = N, Y = CH



2 X = Y = Z = CH
5 X = Y = N, Z = CH
6 X = Z = N, Y = CH

intensity, which represents the first observation of diazafullerene formed in a size selective manner. It seems likely that the conversion of $C_{58}H_4N_2^-$ to $C_{58}N_2^-$ takes place in a stepwise fashion, since intermediate species such as $C_{58}H_3N_2^-$ and $C_{58}H_2N_2^-$ were detected. Observation of such dehydrogenation from the aromatic pyridine derivative $C_{58}H_4N_2^-$ manifests itself as the fullerene-like structure of the $C_{58}N_2$ anion.[14]

A relatively high yield of C_{60}^- was reported for the transformation of $C_{60}H_6$ to C_{60}.[5,6] The relatively inefficient conversion of $C_{58}H_4N_2$ to $C_{58}N_2$ in the present work is ascribed to the thermodynamic and kinetic lability of diazafullerene.[4] Indeed, Fig. 1 shows a strong peak due to CN^- which must be extruded from $C_{58}N_2$ or its precursors. Moreover, anions $C_{57}N^-$ and C_{56}^- formed by the loss of neutral CN from $C_{58}N_2^-$ are detected as shown in the inset of Fig. 1, even though it is well-documented that the internal temperature of negative ions is relatively low.[15]



Scheme 1 *Reagents and conditions*: i, CBr_4, PPh_3, CH_2Cl_2, 0 °C, 76%; ii, LDA, THF, 0 °C, then Me_3SiCl, 89%; iii, trimethylsilylacetylene, $Pd(PPh_3)_4$, CuI, Pr^i_2NH, THF, 73%; iv, NBS, $AgNO_3$, acetone, 77%; v, $Pd(dba)_3{\cdot}CHCl_3$, CuI, pentamethylpiperidine, benzene, 61%; vi, Bu_4NF, AcOH, THF; vii, $Cu(OAc)_2$, pyridine, 12%.

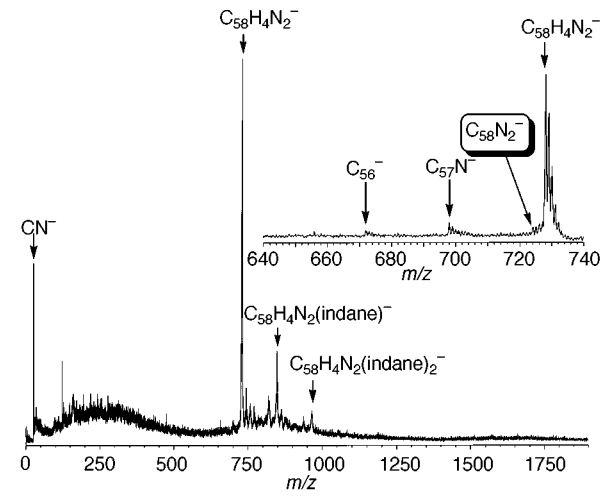


Fig. 1 Negative mode laser desorption time-of-flight mass spectrum of **3** + **4**. Liquid paraffin was used as a matrix and the third harmonic of a Nd:YAG laser (355 nm, typically 3 MW cm^{-2} with a 7 ns duration) was employed for simultaneous desorption and ionization.

In summary, we synthesized pyridinophanes **3** and **4** which served as precursors to polyyne $C_{60}H_4N_2$ **6** and **7** and detected diazafullerene anion $C_{58}N_2^-$ in the laser desorption mass spectrum of **3** and **4**.

This work was supported by Grants-in-Aid from the Ministry of Education, Science, Sports and Culture of Japan. The authors are grateful to Professor Aihara for providing us with his results on the estimation of the kinetic stability of azafullerenes.

Novel oxo-peroxo molybdenum(VI) complexes incorporating 8-quinolinol: synthesis, structure and catalytic uses in the environmentally benign and cost-effective oxidation method of methyl benzenes: $Ar(CH_3)_n$ (n = 1, 2)

Ratna Bandyopadhyay,[a] Sudeb Biswas,[a] Subhadra Guha,[b] Alok K. Mukherjee[b] and Ramgopal Bhattacharyya*[a]

[b] *Department of Physics, Jadavpur University, Calcutta-700032, India*

Received (in Cambridge, UK) 3rd June 1999, Accepted 14th July 1999

A hitherto unknown distorted pentagonal bipyramidal complex, $[MoO(O_2)(QO)_2]$, very efficiently catalyses homogeneous liquid phase oxidation of methylbenzenes, *viz.* toluene and *o*- and *p*-xylenes to benzoic acid, phthalic acid and *p*-toluic acid respectively, using H_2O_2 and O_2 as oxidants.

Oxo-peroxo molybdenum complexes[1] catalytically oxidise a variety of organic substrates,[2] *viz.* alkenes, alcohols, amides and nitro compounds *etc.*, *via* homogeneous as well as heterogeneous routes.[3] However, homogeneous liquid-phase hydrocarbon oxidation is rare.[4] In this communication, besides reporting two new oxo-peroxo molybdenum(VI) compounds, *viz.* $MoO(O_2)_2{\cdot}2QOH$ (**1**) and $[MoO(O_2)(QO)_2]$ (**2**) (QOH = 8-quinolinol),† and elucidating the structure of **2** by X-ray crystallography,‡ we also report and substantiate that **2** is the catalyst precursor and **1** the active catalyst in the homogeneous and selective oxidation of toluene, *o*-xylene and *p*-xylene to benzoic acid, phthalic acid and *p*-toluic acid respectively, under very mild conditions, with an impressive yield and turnover number and smooth catalyst recovery technique. This can be regarded as one of the most inexpensive, environmentally benign and industrially feasible methods of oxidising methylbenzenes (which are very important by-products in coal-tar distillation and petroleum cracking) to the corresponding carboxylic acids, which have many uses in the chemical and pharmaceutical industries.

The structure of **2** consists of discrete monomeric units of $[MoO(O_2)(QO)_2]$ (QO = 8-quinolinolate anion), and disordered CH_2Cl_2 molecules held in the lattice. The geometry around the Mo atom can be best described as distorted pentagonal bipyramidal (Fig. 1) with the axial sites being occupied by the oxo (O5) and a phenolate oxygen (O1) ligands. The other phenolate oxygen (O2), two N atoms (N1,N2) of the bidentate QO^- ligands and the η^2-peroxo moiety (O3,O4) define the equatorial plane with the Mo atom being displaced by 0.175(1) Å from the equatorial plane towards the oxo oxygen. The two essentially planar five-membered chelate rings (Mo, O1, C8, C9, N1 and Mo, O2, C17, C18, N2) are approximately orthogonal to each other,‡ the dihedral angle between the least square planes through the ring atoms is 81.0(1)°. The bond distance and angles (Fig. 1) correspond well to those of other seven coordinate molybdenum oxo-peroxo complexes.[5]

Empirically **1** contains two atoms of oxygen and two atoms of hydrogen more than **2**. During crystallization or oxidation the yellow solution of **1** changes to orange and displays a UV-Vis spectrum which is identical to that of **2**; **2** is actually deposited from this orange solution. When in isolation **2** reacts with an excess ($Mo:H_2O \approx 1:4$) of H_2O_2 to yield **1** (this is also observed under a UV-Vis probe). Analytical and infrared data (see Notes and references) indicate that **1** may be formulated as $MoO(O_2)_2{\cdot}2QOH$ (**1**) or $MoO(O_2)(QO)_2{\cdot}H_2O_2$ (**1a**). However, preliminary rate data show that the conversion of **1** to **2** at room temperature is rather slow which is not compatible with its formulation as **1a**. Moreover, when **1** (but not **2**) is treated with $FeCl_3$ solution, a deep green colour appears instantaneously due to the formation of $[Fe(QO)_3]$. Also, the $\{MoO(O_2)_2\}$ moiety is formed readily.[6] Hence, it appears that, albeit putatively, **1** is correctly formulated. Interestingly, **1** reacts§ with toluene to give benzoic acid (72%), with *o*-xylene to give phthalic acid (55%) and with *p*-xylene to give *p*-toluic acid (61%) (all were confirmed using the undepressed mixed melting point, and the superimposability of the IR and NMR spectra with those of the respective authentic acids as well as their methyl esters), with **2** produced also. The reaction with toluene is shown by eqn. (1) as

$$MoO(O_2)_2{\cdot}2QOH + C_6H_5{-}CH_3 + O_2 \rightarrow C_6H_5COOH + [MoO(O_2)(QO)_2] + 2H_2O \quad (1)$$

a representative case. These observations led to the prediction that **2** may be the catalyst precursor and **1** the active catalyst in the oxidation of methylbenzenes. This has been excellently verified by observing that **2** in a catalytic concentration furnishes the same oxidations (Table 1) in refluxing acetonitrile in the presence of H_2O_2 and a brisk bubble of dioxygen/air. The yield is reduced when only H_2O_2 is used as the oxidant, and trace when exclusively O_2 is used. The data in Table 1, suggest that the catalytic process may be shown as Scheme 1. Table 1 shows that the use of an excess of H_2O_2 imparts a negative effect on the catalytic oxidation, even in the double additive case. The reason for this is at present obscure. When H_2O_2 is used as the sole oxidant, it may undergo disproportionation ($H_2O + O_2$) under the catalytic influence of **2**, and the O_2 produced is utilized to drive the reaction in a similar fashion as in the twin reagent case. This hypothesis is supported by the fact that the process needs a much greater amount of H_2O_2 than is necessary in the double additive method.

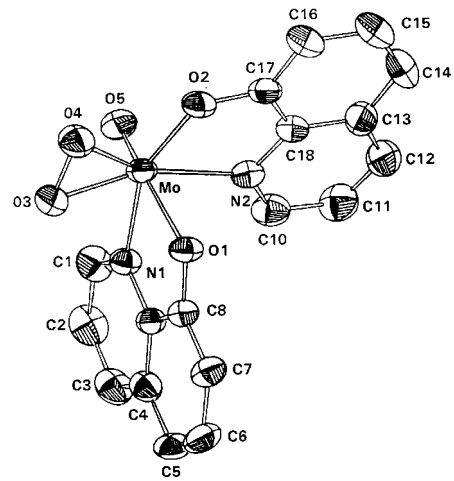

Fig. 1 An ORTEP view of $[MoO(O_2)(QO)_2]$ **2** with selected bond distances (Å) and angles (°): Mo–O1, 2.037(3); Mo–O3, 1.933(3); Mo–O5, 1.685(3); Mo–N2, 2.269(3); Mo–O2, 1.993(3); Mo–O4, 1.925(3); Mo–N1, 1.441(4); O3–Mo–O4, 43.86(13); O2–Mo–N2, 75.36(12); O1–Mo–N1, 74.87(11); O1–Mo–O5, 156.25(14); O3–Mo–N2, 159.72(13).

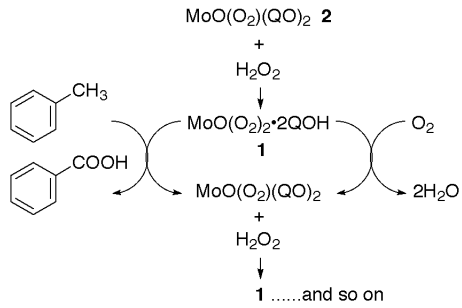
Table 1 Oxidation of methylbenzenes by H_2O_2 and O_2 catalysed by $[MoO(O_2)(QO)_2]$[a]

Substrate[b]	Time/h	Oxidant[c]	Product[d]	Yield[e] (%)	Turnover no.[f]
$C_6H_5CH_3$ (A)	6	H_2O_2 (0.038) + O_2	 (D)	95	1310
A	10	H_2O_2 (0.076)	D	72	1019
A	10	H_2O_2 (0.190) + O_2	D	15	21
o-$C_6H_4(CH_3)_2$ (B)	6	H_2O_2 (0.038) + O_2	 (E)	76	1047
B	10	H_2O_2 (0.076)	E	55	757
p-$C_6H_4(CH_3)_2$ (C)	6	H_2O_2 (0.038) + O_2	 (F)	88	1221
C	10	H_2O_2 (0.076)	F	60	832

[a] **2** is the catalyst precursor (1.15×10^{-5} moles used in each case), while **1** is the active species. No oxidation occurs without using **2** (or **1**, though much less efficiently). [b] 0.016 mol used in each case. [c] Figures in parentheses indicate mol of H_2O_2. Rate of flow of O_2 = one bubble per second. [d] See footnote ¶. [e] Based on mol of substrates used. Temp = reflux, solvent = acetonitrile. [f] Is defined here as the ratio of the number of mol of product obtained to the number of mol of catalyst used, in 1 batch.



Scheme 1

It is extremely satisfying to note that the recovered catalyst in the double additive process can be used again to oxidize a new batch of the corresponding methylbenzenes showing similar catalytic efficiency, but from the third batch onwards the efficiency falls to a marked extent. Interestingly no oxidation occurs if benzoquinone is added to the reaction medium, and a 98% yield (*vs.* 30% without AIBN) is obtained after only 3 h reflux when using AIBN [azobis(isobutyronitrile)], indicating that the oxidation proceeds *via* a radical mechanism. All these aspects will be detailed in due course.

Data collection for X-ray crystallography was done from RSIC, Bose Institute, Calcutta. We thank the Alexander von Humboldt-Foundation, Germany for the donation of the IR spectrophotometer used and UGC and CSIR, New Delhi, for financial support.

Notes and references

† **1** was synthesised by dissolving MoO_3 in 30% H_2O_2 and adding an acetic acid solution of QOH at 1:2 molar ratio. Yield 80%. IR (KBr) ν/cm^{-1}: (Mo=O) 960; (O–O) 860, 910(sh);[7] (O–H) 3080 (b, H-bonded); Electronic spectrum of **1**, λ/nm: {QOH → $MoO(O_2)_2$ CT} 355, {O_2^{2-} → Mo(VI) LMCT} 375 (sh). **2** was obtained by slow crystallization of **1** from CH_2Cl_2–hexane or CH_3CN–Et_2O, yield 60%. IR (KBr) ν/cm^{-1}: (Mo=O) 945; (O–O) 920; vibrations of QO^- comparable to those of $[MoO_2(QO)_2]$[8] where QO^- is bidentate;[9] electronic spectrum, λ/nm: {QO^- → Mo(VI) LMCT} 400;[10] {O_2^{2-} → Mo(VI) LMCT} 375 (sh). Satisfactory elemental analyses (C,H,N,Mo) were obtained for all the isolated complexes.

‡ *Crystal data* for **2**: $[MoO(O_2)(QO)_2]$, $C_{19}H_{14}Cl_2N_2O_5Mo$, M = 517.16, orange, triclinic, space group $P\bar{1}$, a = 9.791(1) Å, b = 10.643(1) Å, c = 10.964(2) Å, α = 117.70(2)°, β = 90.14(1)°, γ = 105.08(1)°, V = 966.5 (3) Å^3, T = 293(2) K, Z = 2, λ = 0.71093 Å, D_c = 1.777 g cm^{-3} D_m = 1.73 g cm^{-3}, μ(Mo-Kα) = 0.990 mm^{-1}. 3359 observed [$I > 2\sigma(I)$] reflections. Enraf Nonius CAD4 diffractometer. Mo-Kα, R_1 = 0.0414, wR_2 = 0.1190 and GOF on F^2 = 1.099. Structure solved and refined by Patterson (SHELXS86) and successive Fourier and full matrix least squares (SHELXL93) methods. CCDC 182/1330. See http://www.rsc.org/suppdata/cc/1999/1627/ for crystallographic files in .cif format.

§ In three different experiments **1** (0.05 g; 0.15 mmol) and (a) toluene (0.01 g; 0.11 mmol), (b) *o*-xylene (0.012 g; 0.11 mmol) and (c) *p*-xylene (0.012 g; 0.11 mmol) were separately dissolved in acetonitrile (15 ml), refluxed for 4 h and then cooled. In the case of toluene the resulting mixture was evaporated to dryness, the mass extracted with diethyl ether and the extract shaken with aqueous bicarbonate. On acidifying the aqueous layer, benzoic acid was obtained. In the cases of *o*- and *p*-xylenes the respective products separated out on standing the solutions after CH_3CN reflux.

¶ **2** and (a) toluene, (b) *o*-xylene, (c) *p*-xylene were separately dissolved in acetonitrile (15 ml) and 30% H_2O_2 (4 ml; 38 mmol) was added. The resulting solution was refluxed for 6 h under bubbling dioxygen, cooled, acetonitrile expelled, aqueous remains treated with diethyl ether and the separated catalyst filtered from the aqueous solution. The ether extract was treated with aqueous bicarbonate and the aqueous layer was acidified to obtain benzoic acid. For phthalic acid (b) and *p*-toluic acid (c), after evaporating off the CH_3CN the aqueous layer was subjected to CH_2Cl_2 extraction to separate the catalyst. The aqueous portion was then concentrated using a rotary evaporator to get the respective acids. All the acids obtained were chromatographically and analytically pure.

An uncommon bonding mode of a familiar ligand: a molybdenum complex with a four-electron donor chelating η^3-PPh_3 ligand, and its structural determination using synchrotron radiation

Tan-Yun Cheng, David J. Szalda† and R. Morris Bullock*

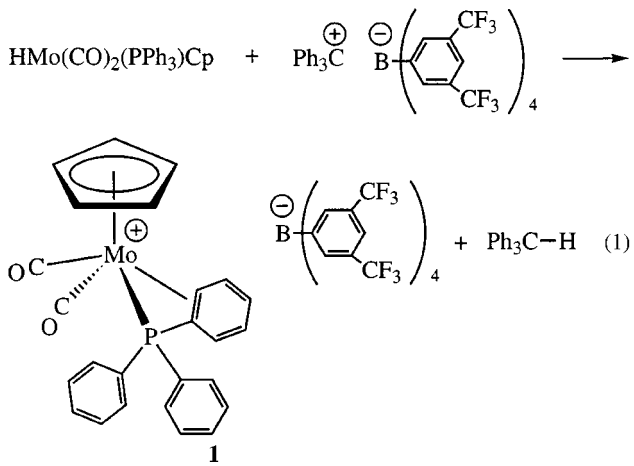
Chemistry Department, Brookhaven National Laboratory, Upton, New York 11973-5000, USA. E-mail: bullock@bnl.gov

Received (in Bloomington, IN, USA) 15th June 1999, Accepted 8th July 1999

A crystallographic study using synchrotron radiation shows that a C=C bond of one phenyl group of a PPh_3 ligand bonds to Mo in $[Cp(CO)_2(PPh_3)Mo]^+$, resulting in an unusual bonding mode in which PPh_3 functions as a chelating four-electron donor ligand.

The triphenylphosphine ligand occupies a prominent role in organometallic chemistry and homogeneous catalysis. The traditional mode of bonding of PPh_3 is as a two-electron donor through the lone pair on the phosphorus atom. We have prepared a new complex in which PPh_3 functions as a chelating four-electron donor ligand, with a C=C bond of one phenyl group bonding to the metal. A structural determination by X-ray crystallography was carried out using synchrotron radiation. Weak C–F···H–C interactions are found between C–F groups on the $BAr'_4{}^-$ [Ar′ = 3,5-bis(trifluoromethyl)phenyl] counterion and ligand C–H groups on the cationic molybdenum complex.

Hydride transfer from $Cp(CO)_2(PPh_3)MoH$ to $Ph_3C^+BF_4^-$ gives $Cp(CO)_2(PPh_3)MoFBF_3$.[1] In this reaction and many others reported by Beck and co-workers, the 16-electron metal cation resulting from removal of hydride is captured by a weakly coordinating counterion such as BF_4^-.[2] We recently measured the kinetics of this and several related hydride transfer reactions using stopped-flow techniques.[3] We have found that a completely different product results when hydride abstraction from $Cp(CO)_2(PPh_3)MoH$ is carried out using a counterion that is much more weakly coordinating than BF_4^-. Reaction of $Ph_3C^+BAr'_4{}^-$ with $Cp(CO)_2(PPh_3)MoH$ at −30°C led to the isolation of a new complex (**1**) in 84% yield [eqn. (1)].[4]



1

The ^{13}C NMR spectrum of **1** at −60 °C exhibits a doublet (J_{CP} = 29 Hz) at δ 81.5 and another doublet (J_{CP} = 12 Hz) at δ 90.0. These resonances are assigned as the *ipso* and *ortho* carbons of one of the C=C bonds of the Ph ring. The significant upfield shift of these carbons from the other aromatic carbons (δ 120 –135) suggests that one C=C bond of the ring is coordinated to the molybdenum, as indicated in eqn. (1).

Remarkable progress has been made recently in the design and utility of large, weakly coordinating counterions.[5] A serious drawback often encountered is the difficulty of obtaining single crystals that are large enough and that diffract well. Initial attempts to obtain a crystal structure of **1** using a conventional X-ray diffractometer suffered from an insufficient number of observed data to enable a complete refinement. The use of a high intensity source of X-rays, such as a synchrotron, can provide sufficient scattering to obtain a reliable structural determination. The crystal structure of **1** was successfully solved and refined[6] using data collected from a beamline at the National Synchrotron Light Source at Brookhaven. A significant advantage of using a synchrotron source of X-rays is that small crystals are suitable; the crystal we used had dimensions of 0.02 × 0.08 × 0.08 mm. The use of synchrotron radiation may offer advantages for single crystal diffraction studies of other complexes of large, weakly coordinating counterions, as well as other complexes for which only small crystals suitable for diffraction can be obtained.

The ORTEP diagram in Fig. 1 shows that the Mo is located out of the plane of the arene ring. The distortion of the PPh_3 ligand is evidenced by the acute Mo–P–C(31) angle of 73.0(3)°, compared to angles of 117.8(3)° and 131.3(4)° for the other two Mo–P–C bonds. The dihedral angle between the Mo–C–C plane and the plane of the phenyl ring is 62°. The bond distances of the Ph ring bonded to Mo show some evidence of localization of C=C and C–C bonds. Similar structural parameters were found

in other M(η^2-arene) complexes, such as Cp*(PMe_3)Rh(η^2-phenanthrene),[7] Cp*(NO)Ru(η^2-naphthalene),[8] and $[(NH_3)_5Os(\eta^2$-naphthalene)$]^{2+}$.[9] An η^2-C=C bond of a *p*-tolyl group was shown to be bound to tungsten in a series of bimetallic compounds where the *p*-tolyl group was part of a bridging alkylidene in a W[μ-C(*p*-tolyl)(R)]Pd moiety.[10]

In several previously reported examples where a metal bonds to the phenyl group of a $PPhR_2$ ligand, the CH bond of the arene interacts with the metal in an η^2-CH agostic[11] interaction, rather than the η^2-C=C bonding found here. Structurally characterized phosphine complexes with agostic C–H interactions include $Pd(PPh^tBu_2)_2$,[12] $RhHCl(SiCl_3)(PPh_3)_2$,[13] $RuCl_2(PPh_3)_3$,[14] and $PdI_2(PPhMe_2)_2$.[15] These η^2-CH agostic complexes have conspicuous structural differences that contrast with η^2-arene complexes: the metal is normally nearly coplanar with the arene ring (dihedral angle of < 15° between M–C–C and arene planes) and the M–P–C angles are typically 111–114° rather than the acute Mo–P–C(31) angle of 73.0(3)° noted above. Although it has been suggested[11] that $[Rh(PPh_3)_3]^+$ [16] has an agostic interaction, its structural features (Rh–P–C angle of 75.6(5)°; dihedral angle of 59° between Rh–C–C and arene planes) are much more similar to those found in **1**. Accordingly, we suggest that $[Rh(PPh_3)_3]^+$ [16] has an η^2-arene interaction, rather than agostic, and we believe that these structural criteria will be diagnostic in distinguishing between agostic and η^2-arene interactions in other complexes. Other than complex **1** reported here and $[Rh(PPh_3)_3]^+$ which we interpret as having an η^2-CH arene interaction, we are not aware of other examples where a PPh_3 ligand bonds to a metal as a four-electron donor in an η^3-bonding mode. There are, however, examples of η^2-C=C bonds in Ru complexes with chelating diphosphine ligands BINAP[17] or MeO-BIPHEP.[18] These diphosphines are bridged by substituted-biphenyl groups.

The structural determination of **1** reveals a series of weak C–F···H–C interactions, with over twenty F···H distances in the range of 2.6–3.0 Å. The presence of F···H–C interactions[19] has been observed in a variety of compounds recently,[20] though their assignment as hydrogen bonds is not without controversy.[21]

Although **1** was isolated as a pure solid, it decomposes slowly at room temperature (several days in CD_2Cl_2 solution or a few months as a solid). The weak C=C bond of **1** is readily and cleanly displaced by ligands such as CH_3I and H_2O. Further spectroscopic and structural studies of these compounds will be reported.

This research was carried out at Brookhaven National Laboratory under contract DE-AC02-98CH10886 with the US Department of Energy and was supported by its Division of Chemical Sciences, Office of Basic Energy Sciences. We thank Dr. Jonathan C. Hanson for assistance with the use of Beamline X7B at the National Synchrotron Light Source.

Wavelength dependent photochemistry of an iron–arene organometallic photoinitiator: a quantitative study of the photoreactivity†

Vladimír Jakúbek and Alistair J. Lees*

Department of Chemistry, State University of New York at Binghamton, Binghamton, New York 13902-6016, USA. E-mail: alees@binghamton.edu

Received (in Bloomington, IN, USA) 18th May 1999, Accepted 12th July 1999

The quantitative photochemistry of the widely used cationic photoinitiator complex, [CpFe(η⁶-isopropylbenzene)]PF_6, has been investigated in several different solvents as a function of exciting wavelength in the 355–683 nm region; the photoefficiency results reveal that the system exhibits a strong wavelength dependence following excitation into its ligand field (LF) manifold and that the photochemistry does not occur solely from the lowest lying LF triplet excited state.

In recent years the [CpFe(η⁶-arene)]X system (Cp = η^5-C_5H_5; arene = benzene, toluene, hexamethylbenzene, naphthalene, anthracene, pyrene; X = BF_4, PF_6, SbF_6, AsF_6, CF_3SO_3) has been shown to be an effective cationic photoinitiator in the polymerization of epoxides,[1] dicyanate esters,[2] pyrrole,[3] styrene,[4] dioxolenes[5] and acrylates.[4,6] Consequently, complexes such as [CpFe(η⁶-ipb)]PF_6 (ipb = isopropylbenzene) are used widely in industrial polymerization processes, including the manufacture of printed circuit boards[7] and other coating applications.[8] A number of detailed studies of the photochemistry of [CpFe(η⁶-arene)]X have been carried out and the influence of several parameters (substitution on Cp ligand and nature of arene, counter ion and solvent) on the photoefficiency have revealed that the reactivity involves arene dissociation *via* an initial ring slippage mechanism.[1,9]

Despite the importance of this system our knowledge of the quantitative photochemistry has been restricted. All investigations to date have employed excitation at 436 nm to avoid any light absorption by the entering ligand. At this wavelength the lowest lying ligand field (LF) absorption manifold is populated and it has been assumed that the quantum efficiency for intersystem crossing is unity and that the reactivity occurs exclusively from a lowest energy LF triplet state (a^3E_{1g}).[9a] Recently we have developed a photokinetic procedure that enables one to study in detail the wavelength dependence of the photoreactivity in systems where there are inner filter absorbances.[10] Here, we report an investigation of [CpFe(η⁶-ipb)]PF_6 in various solvents; quantitative results have been obtained over a wide range of excitation wavelengths and they clearly show that the photochemistry does not occur solely from the lowest energy triplet excited LF state.

The UV-visible absorption spectrum of [CpFe(η⁶-ipb)]PF_6 in dichloromethane is shown in Fig. 1a and irradiations have been performed at 355, 458, 488, 514, 632 and 683 nm. Excitation in the 458–514 nm region results in population of the lowest lying LF singlet band (a^1E_{1g}).[9] Excitation at 355 nm results in population of an upper lying LF singlet band ($^1E_{2g}$) and may also involve some absorption into the long-wavelength tail of a higher lying ligand-to-metal charge transfer (LMCT) transition.[9,11] Excitation at 632 and 683 nm directly populates the LF triplet excited state of the complex (a^3E_{1g}),[9a] notwithstanding the extremely low absorbance in this region (in acetone, λ_{max} = 650 nm, ε = 3.2 M^{-1} cm^{-1}).

Fig. 1b illustrates UV-visible absorption spectra that have been recorded during the 458 nm photolysis of [CpFe(η⁶-ipb)]PF_6 in deoxygenated acetone solution containing an excess concentration (0.05 M) of scavenging phen (phen = 1,10-phenanthroline) ligand. Photolysis experiments have been performed at 355 and 683 nm with a Nd:YAG laser (the latter excitation wavelength utilized a Raman shift of the laser line), at 458, 488 and 514 nm with an Ar^+ laser and at 632 nm with a He–Ne laser. The spectral sequence depicted in Fig. 1b is representative of those obtained at any of the excitation wavelengths studied and in each case the reaction involves an exceptionally clean conversion to the $[Fe(phen)_3]^{2+}$ photoproduct (λ_{max} = 510 nm), according to eqn. (1).[9a] It was determined that the photochemistry was uncomplicated by any thermal processes or secondary photoreactions under these experimental conditions.

$$[CpFe(\eta^6\text{- ipb})]PF_6 \xrightarrow[0.05\ M\ phen]{h\nu} [Fe(phen)_3]^{2+} + ipb + PF_6^- + Cp^- \quad (1)$$

Absolute photochemical quantum efficiencies (ϕ_{cr}) have been obtained for the arene dissociation reaction of [CpFe(η⁶-

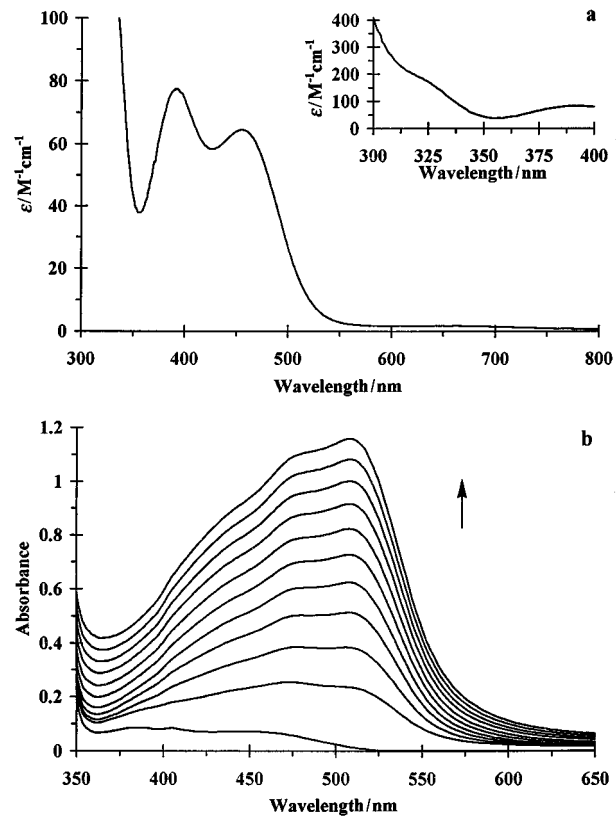

Fig. 1 (a) UV-visible absorption spectra of [CpFe(η⁶-ipb)]PF_6 in dichloromethane at 293 K. (b) UV-visible absorption spectral changes accompanying the 458 nm photolysis of 1 × 10^{-3} M [CpFe(η⁶-ipb)]PF_6 in deoxygenated acetone containing 0.05 M phen at 293 K. Spectra are depicted following 1 min time intervals; initial spectrum was recorded prior to irradiation.

† Dedicated to the memory of Dr Stephen J. Fuerniss who died suddenly on October 31, 1998.

Table 1 Absolute photochemical quantum efficiencies (ϕ_{cr}) for the arene dissociation reaction of [CpFe(η^6-ipb)]PF_6 in various solutions following excitation at several wavelengths[a,b]

1,2-Dichloroethane	0.25(0.02)	0.21(0.001)	0.22(0.002)	0.17(0.002)		0.051(0.002)

[a] Errors estimated at ±5%; values in parentheses represent the standard deviations from at least five measurements. [b] phen Concentration is 0.05 M in each case. [c] Value was not obtained due to solvent absorption.

ipb)]PF_6 following excitation at each of the above irradiation wavelengths. These values were determined by our previously reported procedure which accounts for inner filter effect absorbances due to the entering ligand.[10] Such a method is much more accurate than the procedure used earlier (in which ϕ_{cr} values were obtained over a small percentage of reaction[9c]) and it has also facilitated measurement of ϕ_{cr} data at both short and long excitation wavelengths. When phen is present in excess concentration it is understood to act solely as a scavenging ligand and not affect the reaction kinetics.[9c] For each excitation wavelength, the predicted linearity of the data, according to the photokinetic procedure,[10] was indeed observed in plots of $\ln[(A_t - A_\infty)/(A_0 - A_\infty)]$ *versus* $\int_{t_0}^{t_i}[(1 - 10^{-A_{tot}})/A_{tot}]dt$, where A_0, A_t and A_∞ are the absorbance values of the photoproduct at 510 nm during the irradiation, and A_{tot} is the total absorbance at various irradiation times t. This confirms that there is only one light step in the photochemistry. Time-resolved absorption spectra obtained for this system have also indicated that the initial photochemistry is extremely rapid (picosecond timescale) and that subsequent ligand scavenging is a much slower dark process ($k_{bimol} \approx 10^5$–10^8 M^{-1} s^{-1}).[1,9b]

The determined absolute photochemical quantum efficiencies for the arene dissociation reaction of [CpFe(η^6-ipb)]PF_6 are shown in Table 1. In each case, the phen concentration was kept constant and in excess (0.05 M) in order to make a fair comparison across all of the excitation wavelengths. The ϕ_{cr} results reveal strong dependence on the exciting wavelength for each solvent studied. The arene dissociation reaction clearly proceeds very efficiently following excitation in the 355–514 nm region into either of the two lowest lying LF singlet states, whereas this process is much less effective upon long-wavelength excitation in the 632–683 nm region following direct population of the LF triplet state. The observed wavelength dependence of ϕ_{cr} demonstrates unequivocally that the reaction does not occur solely from the lowest energy triplet level. If the quantum efficiency for intersystem crossing from the lowest lying singlet excited state (a^1E_{1g}) to the triplet reactive state (a^3E_{1g}) was unity[9a] then the determined ϕ_{cr} values would represent the processes from the lowest energy triplet state and would be independent of excitation wavelength. One possibility is that in the [CpFe(η^6-ipb)]PF_6 complex the lowest lying singlet (a^1E_{1g}) and triplet (a^3E_{1g}) LF states have distinct photoreactive pathways. Recently, independent photochemical routes occurring from lowest energy singlet and triplet excited states have been identified in $W(CO)_5$(py) and $W(CO)_5$(pip) (py = pyridine, pip = piperdine),[12] $W(CO)_4$(en) (en = ethylenediamine)[13] and $CpMn(CO)_3$.[14] Another possibility is that the photoreactivity arises exclusively from the singlet level (a^1E_{1g}) and the long wavelength photochemistry proceeds *via* thermal activation from the triplet (a^3E_{1g}) state.

Additionally, the ϕ_{cr} results in Table 1 show a significant solvent dependence for each excitation wavelength with higher ϕ_{cr} values being obtained in more polar solvents. The lower ϕ_{cr} values in solvents with low relative permittivities are understood to be caused by ion-pair formation of [CpFe(η^6-ipb)]$^+$ PF_6^- and the subsequent participation of the counter ion in the photochemical mechanism. Previously, time-resolved experiments have indicated that the close interaction of the counter ion results in a separate pathway involving a longer lived ring slipped (η^4-arene) reaction intermediate.[9b,c] Such long lived intermediates give additional opportunity for the arene ligand to undergo a reverse ring slippage ($\eta^4 \rightarrow \eta^6$), thereby lowering the ϕ_{cr} values. Currently, a number of solvent effects on the photochemical mechanism are under further investigation.

This study represents the first one in which the photochemistry of the [CpFe(η^6-arene)]X system has been investigated quantitatively at different excitation wavelengths. The results illustrate that the photoreaction is extremely efficient in the UV and visible regions, particularly if polar solvents are employed. Moreover, it is noteworthy that the photochemistry can be effectively performed throughout the visible spectrum making it possible to use a variety of laser excitation sources; indeed, the triplet state can be populated directly at 683 nm. The wavelength dependence of the photochemistry reveals that the reactivity does not solely derive from the lowest triplet state, as previously assumed. The strong wavelength dependence in this system will certainly have a major influence on future photoinitiator applications in coatings and moldings, in holography and lithography, in the manufacture of liquid-crystal display devices and protective films for optical devices, and in dentistry.[1–8]

We are grateful to the US DOE (Grant DE-FG02-89ER14039) for support of this research.

Received (in Basel, Switzerland) 17th May 1999, Accepted 5th July 1999

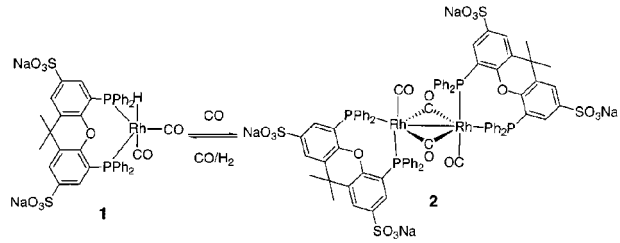
A highly regioselective supported aqueous phase hydroformylation catalyst is presented that is completely and conveniently separated from the products and reused in numerous consecutive catalytic cycles.

Hydroformylation is one of the mildest and cleanest methods to produce aldehydes and is therefore widely applied in the petrochemical industry. The cleanest and most important industrial hydroformylation process is the aqueous biphasic process, developed by Ruhrchemie, affording a straightforward separation of the organic products from the catalyst. The applicability of this system, however, is strictly limited to substrates that are slightly water soluble, such as propene and but-1-ene.[1] The industrial hydroformylation of higher olefins is carried out in a single, organic phase and the catalyst is separated by distillation, which may result in catalyst decomposition. Distillation techniques are not suitable for the production of heavier products or fine chemicals because of the high boiling points of the products.

An interesting novel concept of catalyst immobilisation is the supported aqueous phase catalyst (SAPC).[2] In this system the catalyst is immobilised in a thin water layer adhered within the pores of a high-surface-area silicate.[3] Using this system higher alkenes can be converted at a relatively high rate without metal leaching. The regioselectivity, however, towards the linear aldehyde of the reported systems thus far is very low and surprisingly little has been reported on the recyclability and stability of these systems.[4] Virtually all SAP hydroformylation catalysts described in literature are based on rhodium, cobalt or platinum/nickel complexes with TPPTS as the ligand.[5,6] Only in a single case were sulfonated diphosphines examined.[7] Diphosphines with a large P–M–P bite angle have a beneficial influence on the regioselectivity of homogeneous hydroformylation catalysts.[8,9] We recently reported on the synthesis of a water-soluble ligand with a large bite angle: the disodium salt of 2,7-bissulfonate-4,5-bis(diphenylphosphino)-9,9-dimethylxanthene (Sulfoxantphos) (**A**) and its use in biphasic hydroformylation reactions.[10] The high regioselectivity obtained with this ligand stimulated us to investigate its performance as an SAPC.

It was shown that the rhodium hydride HRh(**A**)$(CO)_2$ (**1**), the precursor to the active species in hydroformylation reactions, was formed quantitatively under a CO–H_2 (1:1) atmosphere in DMSO-d_6.[10] When **1** is exposed to 1 bar of CO it completely transforms to the rhodium dimer [Rh(**A**)(CO)(μ-CO)]$_2$ (**2**) (Scheme 1), which was isolated and characterised by means of NMR, FT-IR and FAB-MS.[11] The ^{31}P NMR spectrum of **2** is consistent with an AA′BB′XX′ spin system ($^1J_{RhP}$ = 129, 135, 155 and 164 Hz, $^2J_{RhP}$ = 8 Hz, $^1J_{PP}$ = 18 Hz, $^3J_{PP}$ = 2 and 5 Hz, see Fig. 1). The equilibrium between **1** and **2** can be forced completely to either side by changing the hydrogen pressure.[12] A similar experiment in D_2O revealed that the formation of both **1** and **2** is much slower under aqueous conditions. The *in situ* formation of **2** on CPG-240 was, however, clearly observed using NMR techniques.‡

† Electronic Supplementary Information (ESI) available: experimental details. See http://www.rsc.org/suppdata/cc/1999/1633/



Scheme 1 Equilibrium between rhodium hydride and carbonyl-bridged dimeric species.

Both the novel Rh(**A**)/SAPC and the known Rh(TPPTS)/SAPC were studied in the hydroformylation of oct-1-ene.§ Rh(**A**)/SAPC is very selective towards the linear aldehyde; a linear to branched aldehyde ratio of 40:1 was obtained. This is an increase in regioselectivity, compared to Rh(TPPTS)/SAPC, of a factor of at least 10 (Table 1, entries 1 and 11). This proves that **A** plays a key role in the regulation of the regioselectivity in the hydroformylation of immobilised homogeneous catalysts.

The rate of hydroformylation of oct-1-ene using Rh(**A**)/SAPC at 80 °C in toluene as the co-solvent was found to be low (*ca.* 1 turnover per hour; Table 1, entries 1 and 2). When the catalysis was performed in pure oct-1-ene, however, the rate increased to a turnover rate of 15 per hour (Table 1, entry 1 and 3). Interestingly, this large concentration dependence was not found for Rh(TPPTS)/SAPC (Table 1, entries 11 and 12). We also found a 5-fold increase on performing the catalysis at 100 °C (turnover rates of 55 and 160 per hour, entries 9 and 13). Under optimised conditions the activities of Rh(**A**)/SAPC and Rh(TPPTS)/SAPC are competitive while the high selectivity of the former catalyst is retained.

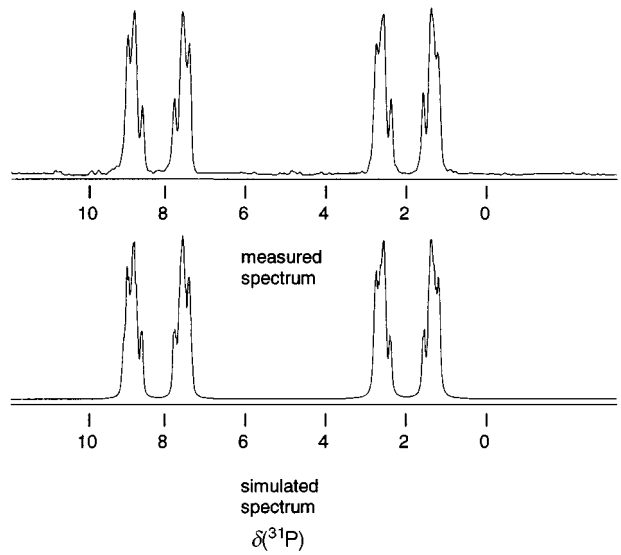


Fig. 1 Observed and calculated ^{31}P NMR spectrum of [Rh(Sulfoxantphos)(μ-CO)(CO)]$_2$ **2**.

Table 1 Results from the hydroformylation of oct-1-ene at 80–100 °C and 50 bar $CO–H_2$ (1:1).

Entry	Catalyst [cycle][a]	Conversion after 24 h (%)	TOF[b]	Linear to branched ratio[c]	Alkene isomerisation[c] (%)	Linear aldehyde[c] (%)
1	Rh(**A**) [1]	7	1	38	1.9	95.6
2	Rh(**A**) [2]	28[d]	1	44	5.7	92.2
3	Rh(**A**) [3][e]	14	15	46	5.0	93.0
4	Rh(**A**) [4][e]	14	14	42	8.7	89.2
5	Rh(**A**) [5][e]	12	14	40	8.5	89.3
6	Rh(**A**) [6][e]	10	13	40	7.7	90.0
7	Rh(**A**) [7][e]	24[f]	10	39	7.3	90.3
8	Rh(**A**) [8][g]	37	44	31	7.0	90.1
9	Rh(**A**) [9][g]	46	55	31	4.1	92.9
10	Rh(**A**) [10][g]	48	55	27	5.8	90.7
11	Rh(TPPTS) [1]	20	15	3	7.4	67.2
12	Rh(TPPTS) [2][e]	3	30	3	12.3	67.2
13	Rh(TPPTS) [3][g]	17	160	3	7.3	70.5
14	Rh(TPPTS) [4][g]	90[f]	146	2	52.6	33.9

[a] Ligand to rhodium ratio is 10 for Rh(**A**) and 20 for Rh(TPPTS), catalysis performed at 80 °C and 50 bar $CO–H_2$ in 15 ml toluene as a co-solvent using 1 ml of oct-1-ene. [b] Average turnover frequencies were calculated as (mol aldehyde/mol catalyst)$^{-1}$ h^{-1}. [c] Determined by means of GC analysis using decane as an internal standard. [d] Conversion after 96 h. [e] Catalysis performed in 15 ml oct-1-ene at 80 °C. [f] Conversion after 72 h. [g] Catalysis performed in 15 ml oct-1-ene at 100 °C.

The product/catalyst separation efficiency of the SAPCs was examined on performing recycling experiments (Table 1). Rh(**A**)/SAPC could be recycled numerous times without deterioration of the catalyst performance (entries 1–10). The selectivity towards the linear aldehyde remained high during all experiments and the decrease in rate of hydroformylation was very small (at 100 °C we even observed a small increase in rate in successive runs).¶ This indicates that ligand **A** retains the rhodium quantitatively on the support which is confirmed by rhodium analysis on the product by means of ICP-AES. No traces of rhodium were detected in the product phase of any of the SAPC experiments (detection limit 1 ppm). In contrast, Rh(TPPTS)/SAPC showed a drop in catalyst performance after three catalytic runs (Table 1, entries 11–14). In the fourth cycle, over 50% of the oct-1-ene isomerised and the linear-to-branched ratio decreased to 2. The Rh(**A**)/SAPC is thus far more robust then the TPPTS based SAPC; Rh(**A**)/SAPC could be recycled over at least three weeks, showing no deterioration of the catalyst performance whereas under similar conditions Rh(TPPTS)/SAPC showed a strong reduction in hydroformylation performance after three days.

Importantly, Rh(**A**)/SAPC is stable in the absence of substrate as it can be transformed into the dimer [Rh(**A**)(μ-CO)(CO)]$_2$ which is stable over weeks when properly stored under 1 bar of CO. The reversible switching between the catalytically active species **1** and the stable dimeric species **2** did not influence the catalytic performance in at least four consecutive runs.‖

We can conclude that the introduction of rigid bidentate diphosphines with a large 'natural' bite angle in the supported aqueous phase catalysis improves the regioselectivity towards the linear aldehyde enormously compared to the SAPCs known thus far. Moreover, the application of Sulfoxantphos in SAP catalysed hydroformylation gives rise to a significant improvement of the sustainability of the system. To the best of our knowledge this supported aqueous phase catalyst is the first example of an immobilised homogeneous catalyst that is highly selective and robust and shows no metal leaching in numerous consecutive catalytic runs.

This work was sponsored by the Innovation Oriented Research Program (IOP-katalyse). We thank J. Elgersma for performing the Rh analyses.

Notes and references

‡ For more experimental details see Electronic Supplementary Information (ESI).

§ The recycling experiments were performed as follows. A stainless steel 50 ml autoclave, equipped with a mechanical stirrer, a substrate vessel, a cooling spiral and a sample outlet, was charged with 1 g of SAPC containing (1) 1×10^{-4} mol **A**; (2) 1×10^{-5} mol Rh(acac)(CO)$_2$ and (3) 4% (m/m) water on CGP-240 in 10 ml toluene. The suspension was incubated for 1 h at 80 °C under 20 bar $CO–H_2$ (1:1). A mixture of 1 ml oct-1-ene and 1 ml decane in 3 ml toluene was added and the $CO–H_2$ pressure was brought to 50 bar. The mixture was stirred for 24 h. The autoclave was cooled to 15 °C and the pressure was reduced to 2 bar. With the small overpressure the liquid was slowly removed from the catalyst with a 1.2 mm syringe. After the catalyst was washed with 5 ml toluene, 10 ml of toluene was added and the pressure was brought to 20 bar. Finally the mixture was heated to 80 °C and the next cycle was performed.

¶ We also observed this increase in rate of hydroformylation in successive catalytic runs in the biphasic Rh(**A**) system (ref. 10). We suggest that at this temperature the remaining catalytically inactive species are slowly transformed into the active form (the inactive species is most probably the carbonyl bridged rhodium dimer).

‖ The procedure described above is extended as follows. After a catalytic run was performed the reaction medium was cooled to 90 °C the $CO–H_2$ (1:1) pressure was removed and 20 bar of CO was introduced. The mixture was slowly cooled to 20 °C and stirred for 4 h. The liquid was subsequently removed from the catalyst by means of a syringe. The catalyst was washed with CO-saturated toluene and the next cycle proceeded after the reaction mixture was pressurised with 50 bar of $CO–H_2$.

Protein film cryovoltammetry: demonstrations with a 7Fe ([3Fe–4S] + [4Fe–4S]) ferredoxin

James P. McEvoy and Fraser A. Armstrong*

Inorganic Chemistry Laboratory, Department of Chemistry, Oxford University, South Parks Road, Oxford, UK OX1 3QR. E-mail: fraser.armstrong@chem.ox.ac.uk

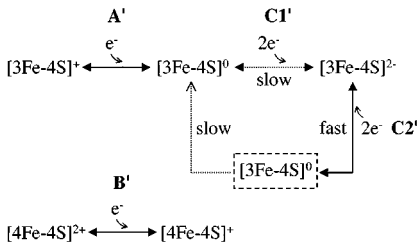
Received (in Cambridge, UK) 22nd April 1999, Accepted 29th June 1999

Low-temperature protein film voltammetry, demonstrated here by studies of Fe–S clusters in the 7Fe ferredoxin from *Thermoplasma acidophilum*, offers a novel way to investigate active site redox reactions, allowing resolution of complex transformations and transient states, and providing an immediate and sensitive gauge of solvent effects.

Protein film voltammetry (PFV) is proving to be a powerful method of investigating biological redox-active sites.[1,2] The protein sample is adsorbed onto a suitable electrode surface as an electroactive film, and its electron transfer and coupled processes are probed as functions of potential and time. Signals obtained from a minuscule quantity of sample (monolayer coverage or less, equating to pmol cm^{-2}) lead to the detection and characterization of labile active sites and deconvolution of complex reaction sequences. The potential may be cycled at rates > 100 V s^{-1}, accessing coupled reactions occurring on the sub-millisecond time scale. Here we report an important extension of PFV in which the sample is easily and reversibly transferred to a cryosolvent. Details of redox chemistry are revealed across a wide sub-zero temperature range, and transient states can be trapped at slow (< 100 mV s^{-1}) scan rates. The approach draws together several areas, notably cryoenzymology,[3] enzymes in organic solvents[4] and cryovoltammetry.[5]

We demonstrate the concept with experiments on a 7Fe ferredoxin (Fd). These proteins contain a [3Fe–4S] and a [4Fe–4S] cluster, and have been extensively characterized. They display distinctive voltammetry with a unique combination of characteristics, both simple and complex, that can be identified and correlated with behavior established under more conventional conditions.[6–10] The ferredoxin from *Thermoplasma acidophilum* (*Ta*),[11] MW *ca.* 16 kDa, which also contains a single Zn atom, is related structurally to the previously studied ferredoxin isolated from *Sulfolobus acidocaldarius*.[9,10,12,13]

The redox reactions of interest are shown in Scheme 1. The [4Fe–4S] cluster undergoes only one redox transition (2+/+), referred to in PFV as signal B′, while the [3Fe–4S] cluster exhibits more complex behavior. The '+' and '0' oxidation levels (whose interconversion gives rise to signal A′) are well characterized[8,9,14] and a further two electrons are taken up in a chemically reversible process (signal C1′) to produce an unusual all-Fe(II) cluster.[10] It has been shown[13] that this hyper-reduced state is capable of undergoing a rapid and reversible two-electron–two-proton oxidation (signal C2′), the immediate oxidized product of which reverts to the normal '0' state within a second at 273 K unless re-reduced within this time. The C′ signals are due to *cooperative* two-electron transfers (as revealed by the narrow voltammetric peak shapes),[15] making it likely that this novel cluster reaction involves disulfide coupling instead of Fe-based redox transitions.



Scheme 1 Redox transitions of the [3Fe–4S] and [4Fe–4S] clusters in *Thermoplasma acidophilum* ferredoxin. The transition between alternative states of $[3Fe–4S]^0$ is also shown, with the metastable form capable of very rapid $2e^-$–$2H^+$ transfer indicated by the dashed box. Proton transfers are not included.

Fig. 1 shows voltammograms, scan rate 20 mV s^{-1}, obtained from a film of *Ta* Fd formed on a pyrolytic graphite edge (PGE) electrode in aqueous solution[16] and then transferred to a cell containing 70% v/v methanol–water (pH* = 7.4 at 273 K[17]), the temperature of which could be varied down to 188 K.[3a] The potential range engages only the $[3Fe–4S]^{+/0}$ couple, to provide the simplest test of the system. At 273 K the oxidation and reduction peaks of signal A′ are nearly symmetrical and the reduction potential $E^{\circ\prime}$ is −297 ± 10 mV, compared with −250 mV obtained under the same conditions in aqueous electrolyte. Experiments with 60% v/v ethane-1,2 diol–water gave similar results with $E^{\circ\prime}$ = −276 mV. The electroactive coverage, *ca.* 55 × 10^{-12} mol cm^{-2} based on geometric electrode area, is as expected for a very densely packed monolayer on an ideal flat surface.[1b] As the temperature is lowered, $E^{\circ\prime}$ increases (linearly with temperature, as expected), the peak separation increases to reflect slower interfacial electron transfer, and the peaks broaden slightly. In the limit of a Nernstian system, half-height peak widths should decrease from 83 mV at 273 K to 60 mV at 198 K.[15] However, the expected sharpening was not observed even if a very slow scan rate (2 mV s^{-1}) was used; reductive and oxidative peak widths at 273 K were 86 and 90 mV respectively, with peak separation 7 mV, whereas at 198 K these broadened

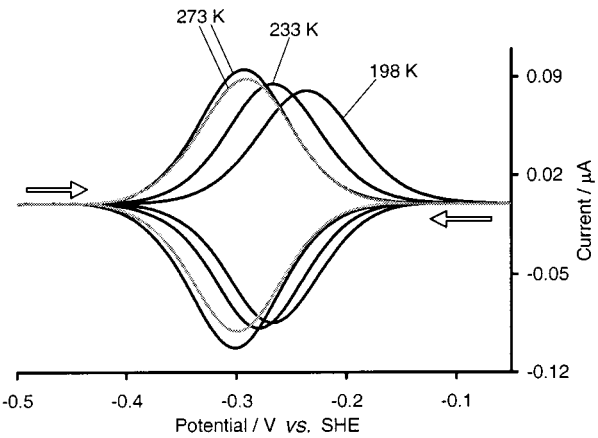


Fig. 1 Background-subtracted cyclic voltammograms obtained from a single film of *Thermoplasma acidophilum* ferredoxin adsorbed on a PGE electrode (coated from ice-cold aqueous solution) and transferred to a 70 : 30 methanol–water electrolyte, showing the temperature dependence of the $[3Fe–4S]^{+/0}$ couple. Each scan was conducted at 20 mV s^{-1} and started from the oxidative limit. The film was cooled from 273 to 233 and then to 198 K, before re-warming to 273 K (final voltammogram shown in grey). The cell solution (pH* = 7.4 as measured at 273 K) contained 0.1 M NaCl, 20 mM HEPES buffer and 200 μg ml^{-1} polymyxin B sulfate. Chunky arrows indicate the direction of scanning.

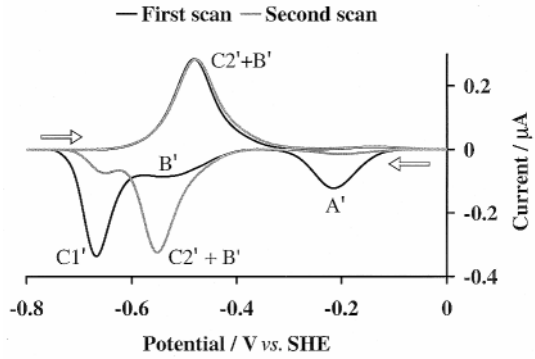

Fig. 2 Background-subtracted cyclic voltammograms showing the first cycle (black) and the second (grey) obtained from a film of *Thermoplasma acidophilum* ferredoxin (coated from aqueous solution) adsorbed on a PGE electrode in 70:30 methanol–water electrolyte at 198 K. The scan was conducted at 40 mV s^{-1} and started from an oxidative poise. The cell solution, pH* = 5.0 as measured at 273 K, contained 0.1 M NaCl, 20 mM acetate buffer and 200 μg ml^{-1} polymyxin B sulfate. Arrows indicate direction of scanning.

slightly to 90 and 96 mV, with a modest 23 mV peak separation.[18] Warming to 273 K almost completely restores the voltammetry measured at the start of the experiment (*ca.* 1 h previously).[19]

Fig. 2 shows the voltammetry obtained across a wide potential range, engaging all the redox couples shown in Scheme 1 to provide a more demanding test. The solution acidity (pH* = 5.0 at 273 K) parallels conditions used to reveal the novel cooperative two-electron couple at ambient temperatures in aqueous electrolyte.[13] In the first cycle, started from an oxidative poise, the reduction peaks correspond to $[3Fe–4S]^{+/0}$ (A′ is at a higher potential than in Fig. 1 because pH* is below p*K*[16]), $[4Fe–4S]^{2+/+}$ (B′, somewhat broader than A′), and $[3Fe–4S]^{0/2-}$ (C1′, narrow and intense). The A′:B′:C1′ peak area ratio is 1:1.1:1.8, close to that expected. The subsequent oxidative scan is dominated by one large signal in the position expected for a superposition of B′ and C′. Notably, the oxidation peak of signal A′ has almost vanished; the second reductive scan also reveals very little A′ and is dominated instead by the new couple C2′. As reported recently, the immediate product of two-electron oxidation of $[3Fe–4S]^{2-}$ is an alternative '0' state which cannot be oxidized rapidly to $[3Fe–4S]^{+}$. Poising for sufficient time at potentials higher than the $[3Fe–4S]^{+/0}$ couple restores almost completely the voltammetry of the first cycle. At 245 K this requires *ca.* 3 min, whereas at 273 K the metastable '0' species is too short-lived to be detected below 1 V s^{-1}.[13]

The behavior of this system therefore mimics that observed in fast-scan experiments at ambient temperatures in pure aqueous media. We conclude that extremely small samples of protein, immobilized on an electrode, can be introduced conveniently and reversibly into cryosolvents—in effect, an instantaneous microscopic dialysis—and studied at low temperatures. Convoluted and multi-step redox reactions are retarded to allow deconvolution and detection of intermediates at conventional scan rates. Other proteins respond similarly well to this technique, and we are currently extending its application to enzymes.

We are grateful to Professors Richard Cammack and Dieter Oesterhelt for providing a sample of *Thermoplasma acidophilum* ferredoxin, and Dr Michael Honeychurch for helpful discussions. This research was supported by the UK Engineering and Physical Sciences Research Council, and by the Royal Society.

16 The methodology was based on that described in ref. 6. Polymyxin B sulfate (200 μg ml^{-1}) was present as co-adsorbate in both the aqueous electrode-coating solution and the cryosolvent cell solution (usually 70% v/v methanol; Prolabo > 99%) with 0.1 M NaCl buffered by HEPES at pH* 7.4 or acetate at pH* 5.0. The aqueous saturated calomel reference electrode (SCE) with internal salt bridge was held in a Luggin side arm filled with cryosolvent but maintained at room temperature with a water jacket. Values of pH and pH* [see: ref. 3(*a*), and R. G. Bates, *Determination of pH: Theory and Practice*, Wiley, New York, 1973] were measured with glass pH electrode at 273 K, without corrections. Cell anaerobicity was maintained by purging with Ar. Temperatures were controlled by immersing the cell compartment in a stirred ethanol bath, to which was added dry ice or frozen ethanol, and measured (±1 K) with a thermometer after 10 min equilibration. Background currents were subtracted using an in-house analysis program (Dr H. A. Heering).

17 Measurements of the $[3Fe–4S]^{+/0}$ couple between pH* 4 and 9 (recorded at 273 K) showed that, over the full temperature range studied, the p*K* for protonation of $[3Fe–4S]^{0}$ remains significantly lower than the pH* used in measuring the voltammetry for Fig. 1, thus ruling out the possibility that $E^{\circ\prime}$ varies trivially as a result of pH* changes. Values obtained were: at 273 K (aqueous) p*K* = 5.6, at 273 K (70% v/v methanol) p*K* = 6.7, at 198 K (70% v/v methanol) p*K* = 6.8 (an apparent value since pH* is measured at 273 K).

18 The peak broadening observed as the temperature is lowered is not due to increased uncompensated resistance (*iR*); like irreversible electrode kinetics, *iR* effects are associated with large increasaes in peak separation. See: L. Roullier and E. Laviron, *J. Electroanal. Interfacial Electrochem.*, 1983, **157**, 193.

19 Peak potentials were completely restored although peak areas were *ca.* 10% smaller than measured at the start of the experiment.

A fluorescent probe for the detection of NAD(P)H

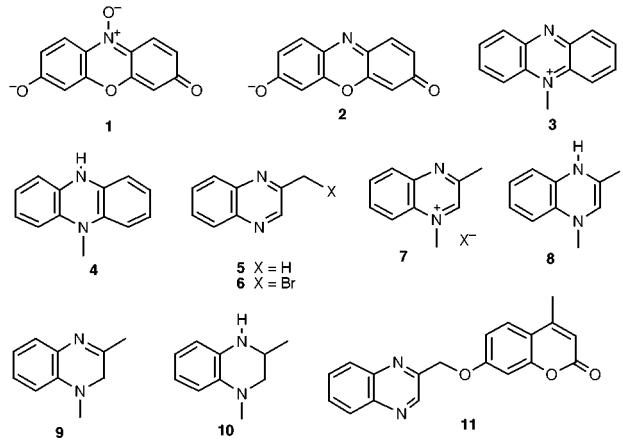
Carl A. Roeschlaub, Nicola L. Maidwell, M. Reza Rezai and Peter G. Sammes*

Molecular Probes Unit, Department of Chemistry, School of Physical Sciences, UNIS, Guildford, Surrey, UK GU2 5XH. E-mail: p.sammes@surrey.ac.uk

Received (in Cambridge, UK) 22nd June 1999, Accepted 16th July 1999

NAD(P)H may be monitored by using reduction to release the fluorophore umbelliferone from a precursor conjugate with a quinoxalinium salt.

NADH and its phosphate ester NADPH are ubiquitous reducing agents in nature. In rapidly proliferating cervical cancer cells the turnover of NAD(P)H is greater than in normal cells and thus it can be used as a general biological marker for cancer.[1] A potential fluorescent probe for the detection of these aberrant cells has been described[2] that uses the reduction of the weakly-fluorescent dye resazurin **1** to the fluorescent derivative



resorufin **2**. A disadvantage of this system is that direct reduction of resazurin to resorurufin does *not* occur and the reaction has to be 'catalysed' by an electron carrier such as phenazinium methosulfate **3** or an enzyme such as diaphorase.[3] The mechanism of this reduction has been investigated[2] and, for the catalyst phenazinium methosulfate, shown to proceed *via* initial formation of the dihydrophenazine derivative **4**, which is extremely unstable and rapidly undergoes further redox reactions.

NAD(P)H is also co-produced by a number of enzyme-based redox systems, such as glucose-6-phosphate dehydrogenase[4] and is used in a number of enzyme linked immunosorbent assays (ELISA).[5] In these assays a catalyst has also to be used, often another enzyme such as diaphorase, to act as the electron carrier in conjunction with either resazurin, reduced to the fluorescent resorufin,[3] or of a leuco-dye, such as a tetrazolium salt, which is reduced to the corresponding, highly coloured formazan.[6]

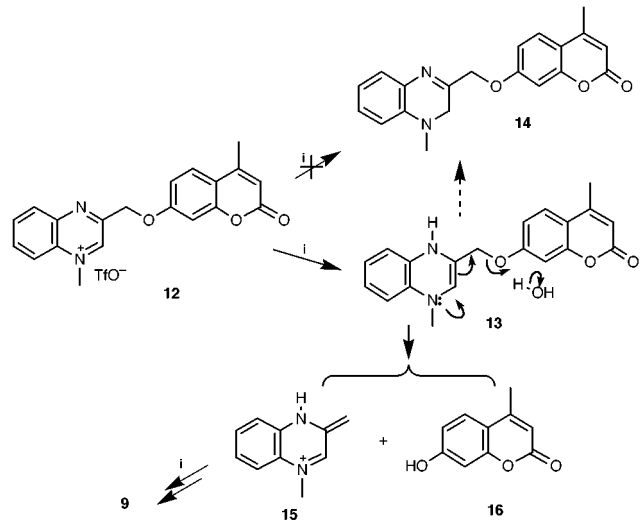
In order to avoid the need for these two-component systems involving an electron carrier, conjugation of a masked fluorophore to a reducible heteroaromatic system was considered, in which the reduction would unmask the fluorophore. After studying several systems we focused on use of derivatives of the quinoxalinium system. 2-Methylquinoxaline **5** was found to react regioselectively with methylating agents, such as MeI and MeOTf, to produce the corresponding 1,3-dimethylquinoxalinium salt **7**.† Reduction of these salts with NADH at pH 7.5 rapidly produces a dihydro compound. Whilst mechanistic studies with NADH predict that this will be the 1,4-dihydro isomer **8**,[7] this was not obtained since it efficiently tautomerises to the 1,2-dihydro isomer **9,** isolated in high yield (> 90%). In contrast to the dihydrophenazine **4,** the dihydroquinoxaline **9** is relatively stable, although, upon exposure to air it is oxidised to give a variety of highly coloured products. It is to be noted that both **4** and **8** are both formally anti-aromatic and this undoubtedly contributes to their chemical reactivity. Reduction of the salt **7** can also be effected with $NaBH_4$, although with an excess of this reagent, over-reduction to give the tetrahydroquinoxaline **10** was observed. None of **10** was observed upon reduction of **7** with NADH.

Because of its bimolecular nature, the rate of reduction of the quinoxalinium salt **7** by NADH is concentration dependent. At concentrations in the micromolar range the reduction takes several hours to complete but at millimolar concentrations reaction is complete within seconds.

In order to generate a useful fluorescent probe, 2-methylquinoxaline **5** was brominated at the methyl group, using NBS, and the bromomethyl compound **6** then conjugated with umbelliferone **16** to produce the derivative **11**. Methylation of this base with MeOTf afforded the triflate salt **12**. Neither of the compounds **11** nor **12** showed any significant fluorescence.

Reduction of the salt **12** with NADH was effected by adding a solution of the salt to a stirred solution of NADH at pH 7.5 and immediately re-measuring the emission spectrum. A signal corresponding to that of free umbelliferone **16** formed almost immediately. That this was due to liberated umbelliferone **16** was also confirmed by TLC and direct isolation; in a quantitative experiment > 85% **16** could be extracted from the solution. In the absence of NADH no formation of umbelliferone **16** was observed, confirming that the liberation was a direct consequence of reduction by NADH.

The fate of the quinoxalinium moiety has also been explored. Reduction is assumed to give, initially, the 1,4-dihydro intermediate **13**. Rather than tautomerising, in the manner observed for the conversion of the unsubstituted quinoxalinium salt (**7** to **8** to **9**), to give **14**, which has not been observed, elimination of umbelliferone occurs to give the quinoxalinium



Scheme 1 *Reagents and conditions*: i, NADH, pH 7.5.

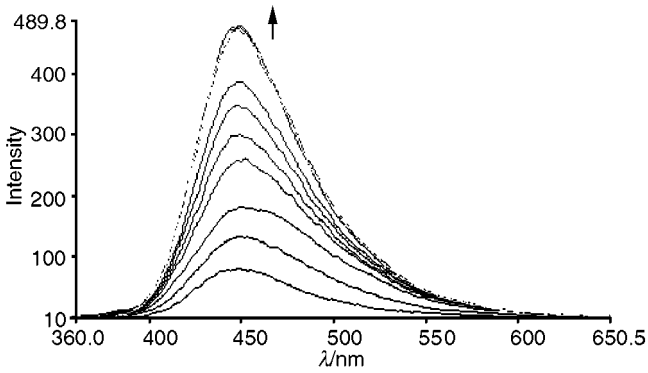


Fig. 1 Increase in emission with time; scans at 2 min. intervals; maximum reached in < 24 min. See text for conditions.

tautomer **15**, which then reforms the quinoxalinium species **7**, followed by a second NADH reduction step to produce the imine **9**, which has also been isolated and characterised (see Scheme 1).

Fig. 1 shows the results of a typical reaction. The increase of umbelliferone **16** fluorescence is obtained by mixing a solution of the salt **12** at 1×10^{-4} mol dm^{-3} with NADH at 1×10^{-3} mol dm^{-3} in TRIS buffer at pH 7.5, taking aliquots at 2 min intervals and diluting 100-fold in buffer (to give a sample at 1×10^{-6} mol dm^{-3}) before measuring the fluorescence spectrum, (λ_{ex} 350 nm), monitoring the umbelliferone emission peak at λ_{em} 450 nm. Under these conditions reduction is observed in under 24 min. Control fluorescence measurements on pure umbelliferone, in the presence of 1 equiv. of the imine **7,** indicate that release of the umbelliferone from the salt **12** is quantitative.

We thank the EPSRC for support of this work and the EPSRC National Mass Spectrometry Service Centre, Swansea, Wales, for accurate mass measurements.

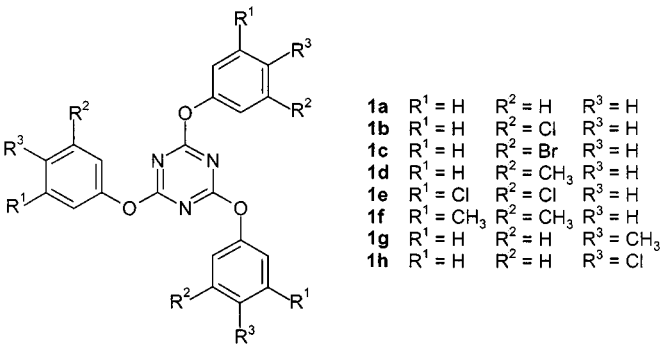
Received (in Cambridge, UK) 7th June 1999, Accepted 16th July 1999

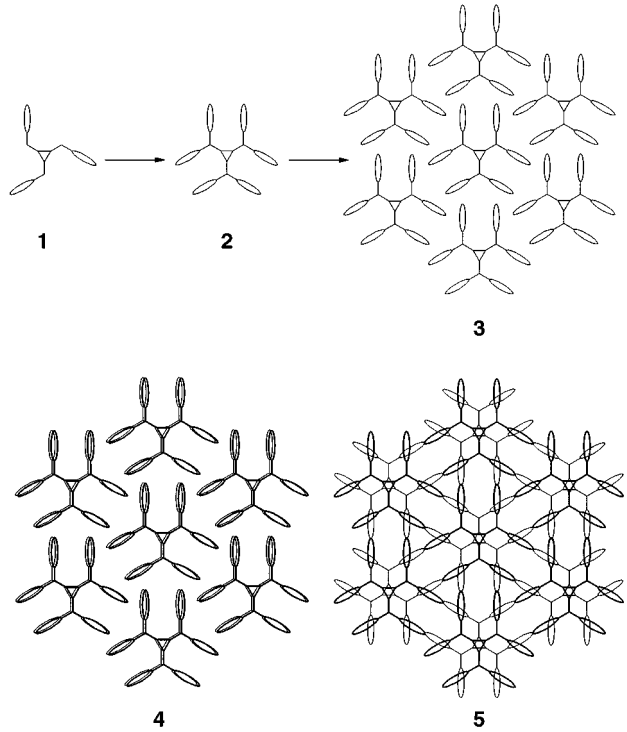
The ability of CH_3 groups to form helical chains of C–H···π interactions with phenyl rings leads to polar stacking of trigonal octupolar networks in a substituted triazine, and therefore to three-dimensional non-centrosymmetry.

Structural control in the third dimension continues to be one of the most sought-after goals in crystal engineering.[1,2] We have recently reported that a family of *sym*-triaryloxytriazines **1** lend themselves well, *via* dimeric Piedfort units (PU) **2**, to the adoption of trigonal two-dimensional networks **3** (Scheme 1).[3] This disymmetric network stacks in a parallel or anti-parallel fashion to give, respectively, **4** and **5**. Arrangement **4** meets the requirements of crystalline octupolar nonlinear optical (NLO) behaviour[4] and is seen in compound **1a**. A number of other derivatives **1b-f** crystallise in arrangement **5**, that is, they do not display Second Harmonic Generation (SHG). The undesirable anti-parallel stacking in these cases may be attributed to the steric bulk of Cl, Br and CH_3 substituent groups located in the *meta* position of the phenoxy rings.



We had explored variations in the *meta* substituent, arguing that tampering with the *ortho* H-atoms of the phenoxy rings would disturb the formation of the PU itself, while the *para* H-atom was needed for the C–H···π interactions that are implicated in the formation of trigonal network **3**.[3] Here, we show that 2,4,6-tris(4-methylphenoxy)-1,3,5-triazine **1g** adopts a non-centrosymmetric packing because the *para* CH_3 substituent can form C–H···π interactions with an orientation that sustains three-dimensional chirality.

Single crystals of **1g** suitable for X-ray diffraction (non-centrosymmetric space group *R*3*c*) were grown from slow evaporation of an *o*-xylene solution.† The molecules are positioned on three-fold axes and retain their molecular symmetry in the crystal. Successive *c*-glide related molecules are stacked and are interconnected by C–H···O (*D*, 3.57 Å, *d*, 2.64 Å; *θ*, 143°)‡ and C–H···N (3.46 Å, 2.43 Å, 160°) hydrogen bonds to form the D_3-symmetric PUs. The trigonal assembly of D_3-PUs generates an octupolar network structure parallel to (001) as shown in Fig. 1.



Scheme 1

The *para* CH_3 groups participate in C–H···π interactions[5] (*D*, 3.60 Å, *d*, 2.77 Å; *θ*, 133°) that link interlayer D_3-PUs. This ability of the CH_3 groups to form C–H···π interactions coupled with fact that the C–H vectors are bent with respect to the plane of the trigonal network allows these groups to link with molecules in the third dimension.[6] Fig. 2 shows that the C–H···π interactions are arranged around 3_1 and 3_2-axes and that they extend to the third dimension in a helical manner. Any two adjacent helices have opposite handedness, but the chains of C–H···π interactions always run along [001]. Thus all C–H···π helices have the *same* polarity. Consequently, successive layers are compelled to stack in an eclipsed manner leading to bulk non-centrosymmetry.

It is of interest to note that, in triazines **1b**–**f**, the peripheral aryloxy rings are inclined perpendicular to the central heterocyclic ring (with an inclination angle of 89–92°) whereas they are inclined at a much shallower angle in **1g** (67°).§ The C–H···O and C–H···N bonds become shorter and linear with such flattening and as such are more effective. Additionally, the central rings in **1g** are stacked at a separation of 3.30 Å. This is much shorter when compared to the stacking found in triazines **1a**–**f** (3.6–4.0 Å). In summary, the CH_3 groups not only maintain the eclipsed stacking of the layers but also reinforce

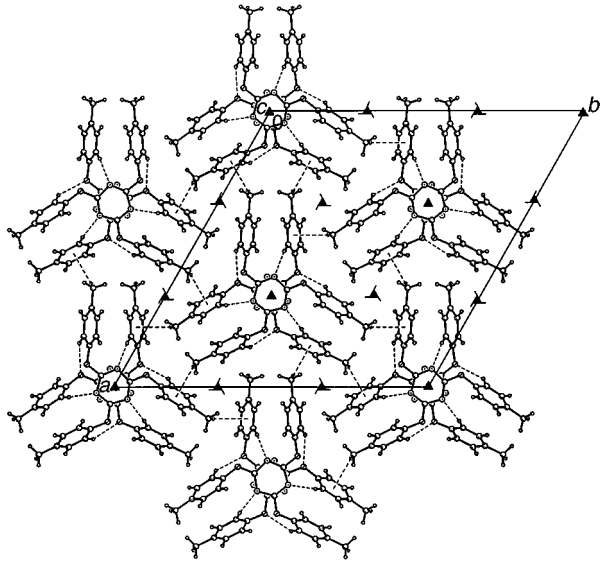


Fig. 1 Octupolar trigonal network structure in **1g**. The 3-fold, 3_1- and 3_2-axes are indicated. Notice the C–H···O and C–H···N hydrogen bonds within a D_3-PU. Notice that the C–H···π interactions extend to the third dimension in a helical manner around 3_1- and 3_2-axes.

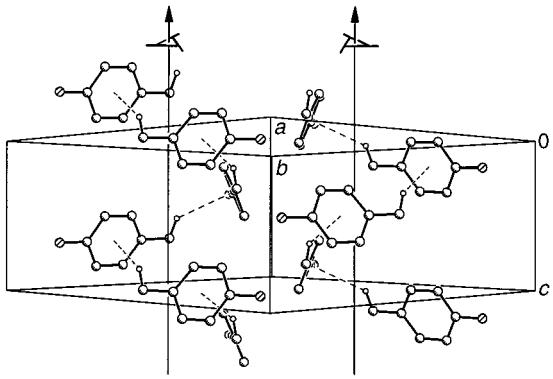

Fig. 2 Helical arrangement of C–H···π hydrogen bonds in triazine **1g** (several atoms deleted). Note that the two helices have opposite handedness but that they run in the same direction, [00$\bar{1}$].

other interactions which are important for effective three-dimensional packing.

The non-centrosymmetric nature of **1g** was confirmed by a powder SHG signal at 1.064 μm which is ~1 × KDP. Due to the weak donor property of the methyl group, the quadratic hyperpolarisability of **1g** may be assumed to be very close to that of **1a**. Indeed there is evidence for the equivalence of the unsubstituted and *para*-methyl substituted aromatic rings towards quadratic effects in NLO.[7] One can further infer[8] a rough estimate of the crystalline *d* susceptibility, assuming the oriented gas model[9] with optimal cos(3θ) projection factors corresponding to a fully eclipsed stacking,[8] and assuming a cubic order Lorentz–Lorentz local field correction factor of 3.5 corresponding to a realistic value of 1.6 for the index of refraction. This simplified model is known to be reliable and leads in the present case to a magnitude of 120×10^{-9} esu comparable to that of *N*-4-nitrophenyl-L-prolinol, a prototype crystal often used as a standard.[10] The comparatively modest powder SHG signal of **1g** may be related to absence of phase-matching at the 1.06 μm fundamental wavelength used by us. Alternatively, a noticeably small average grain size may prevent any benefit from a cumulative phase-matching in a non-resonant configuration considering that the coherence length must be significantly larger than the grain size.

The structure of **1g** is also important from a different perspective. Usually, Cl and CH_3 groups can be interchanged with no structural change when these groups contribute merely to the close packing.[11] However, in this case the corresponding chloro triazine **1h** forms an entirely different structure that is stabilised by trimeric Cl_3 supramolecular synthons.[3] This emphasizes the fact that the CH_3 and Cl groups in **1g** and **1h** respectively play structurally distinct roles and that they are involved in interactions specific to the functional groups.

This work demonstrates that the weak C–H···π interactions may be employed to achieve third dimensional control of a crystal structure, which leads in the present case to an interesting physical property, namely crystalline octupolar NLO with a remarkably large estimated *d* coefficient. In tribenzylisocyanurate[12] and in **1a**, bulk non-centrosymmetry was not designed and is not easily extendable to other examples. This is not so in the present case, where the preferred C–H···π interactions clearly discriminate in favour of a polar packing. Our continued interest in this family of compounds stems from their transparency in the blue region and from their possible utilization in unphase-matched thin film configurations for short pulse NLO.[8]

Received (in Liverpool, UK) 2nd June 1999, Accepted 14th July 1999

A new positive photocatalytic system comprising an organic dye within the micropores of a titanium zeolite is able to effect the catalytic dihydroxylation of alkenes using water and molecular oxygen as reagents; the dye acts as an antenna to absorb the energy of visible light, generating hydroxyl radicals from water; subsequently, the OH˙ radicals react with olefins in the presence of oxygen to form allylic hydroperoxides that in the presence of the Ti atoms of the zeolite promote the epoxidation of the alkene.

Photocatalysis applies the energy of light to effect chemical reactions. The energy of a blue photon (λ = 400 nm) is 71 kcal $\times$ mol^{-1}, enough to overcome most of the activation barriers of chemical reactions. Compounds considered chemically inert, such as water, may become reactive under photocatalytic conditions.

Up to now, photocatalysis has been almost exclusively limited to the degradation of pollutants in aqueous media,[1] but *positive* photocalysis being applied to the synthesis of organic compounds is more scarce.[2] Herein, we report a positive photocatalytic system that comprises 2,4,6-triphenylpyrylium ion (TP^+) encapsulated within the voids of tridirectional large-pore zeolites that absorbs visible light, transforming it into chemical energy. A second Ti catalytic site located in the walls of these molecular sieves promotes oxidation of an alkene using as reagent the hydroperoxides generated *in situ* in the photochemical process (Fig. 1).

Zeolites are crystalline aluminosilicates whose structure contains strictly uniform cavities and channels of molecular dimensions called micropores.[3] The zeolite host cooperates in the success of the overall process, playing several crucial roles. Thus, TP^+ is not stable in H_2O where it undergoes rapid hydrolysis to 1,3,5-triphenylpent-2-ene-1,5-dione. This prevents the direct use of this sensitizer in aqueous media. In contrast, when encapsulated inside the cages of zeolites (TP-Z), the confined space provided by the host impedes the reaction of the heterocycle because it involves bulkier intermediates that simply would not fit in. As result, when entrapped inside the zeolite micropores TP^+ is completely stable in the presence of

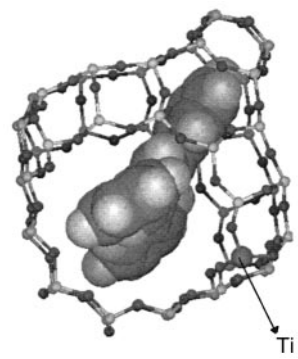

Fig. 1 Molecular modeling structure of TP,Ti-Zeolite bifunctional photocatalyst. The bulky TP^+ acting as light harvester is entrapped inside the zeolite cavities. The Ti atoms are bonded to the framework of the zeolite.

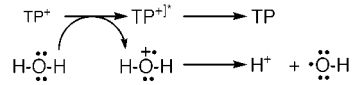


Scheme 1

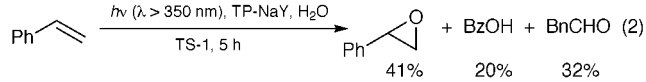
H_2O. In addition, the zeolite pores provide a polar reaction medium favorable for the initial photoinduced electron transfer between TP^+ excited state and water (Scheme 1). This oxidation transforms inert water into chemically agressive hydroxyl radicals. Evidence for the formation of OH˙ in this system has been previously obtained by laser flash photolysis.[5] In addition, trapping of OH˙ by 5,5-dimethyl-1-pyrroline *N*-oxide leads to a persistent N-centered radical detectable by conventional EPR spectroscopy.

Normally, OH˙ radicals would destroy any organic photosensitizer. However, in the case of the TP-Z system, the restricted reaction cavity prevents this OH˙ attack. In fact, no bleaching of TP^+ was observed after an operation time of 100 h. Furthermore, the final product of the OH˙ chemistry in the TP-Z irradiation of pure water is H_2O_2, indicative of OH˙ coupling [eqn. (1)].

(1)

Eqn. (1) is well-established in the γ-radiolysis of H_2O[6] but never occurs when there are alternate waste channels for OH˙ radicals. Fig. 2 shows an illustrative time-conversion plot for the concentration of H_2O_2 under these conditions.

The ability of TP-NaY sensitizer to generate a constant concentration of H_2O_2 has been exploited here for the epoxidation of styrene using titaniumsilicalite (TS-1) as co-catalyst, whereby styrene oxide is formed [eqn. (2)]. However,



(2)

the low photostationary concentration of H_2O_2 determines that the epoxidation step takes hours. This allows the occurrence of concomitant photochemical reactions leading to by-products (mainly benzoic acid and 2-phenylacetaldehyde).

This limitation was overcome by using TP-Z as a continuous source of OH˙ radicals to generate *in situ* organic hydroperoxides formed through hydrogen abstraction and subsequent trapping of the carbon-centered radical by O_2. Thus, when cyclohexene was present during the irradiation of a H_2O–MeCN slurry with TP-Z photocatalyst, 3-hydroperoxycyclohexene was formed (Scheme 2). This was confirmed by addition of PPh_3 after the photocatalytic irradiation. PPh_3 reacts quantitatively with organic hydroperoxides giving rise to the corresponding alcohol plus $Ph_3P{=}O$. The yield of hydroperoxycyclohexene can be quantitatively determined by iodometric titrations or, alternatively, by the amount of $Ph_3P{=}O$ formed. Control experiments showed that the direct reaction of cyclohexene with TP^+ in its excited state does not occur, in agreement with the high cyclohexene oxidation potential (2.14 V *vs.* SCE).

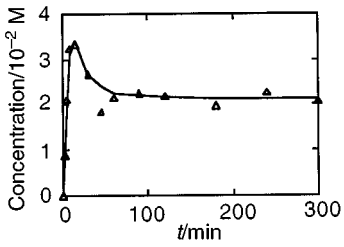


Fig. 2 Hydrogen peroxide concentration profile upon irradiation (visible light, $\lambda > 350$ nm) of TP-NaY (100 mg) in water.

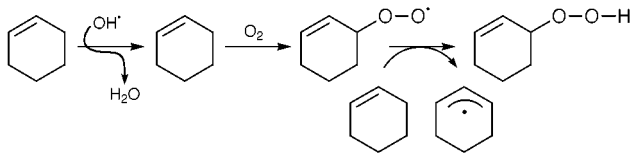


Scheme 2

Large pore Ti molecular sieves are efficient catalysts for the selective epoxidation of alkenes by organic hydroperoxides.[7] We have exploited the ability of TP-NaY to generate a significant concentration of hydroperoxides from light and H_2O–O_2 and coupled it with the subsequent epoxidation converting the whole process in a one-pot reaction.

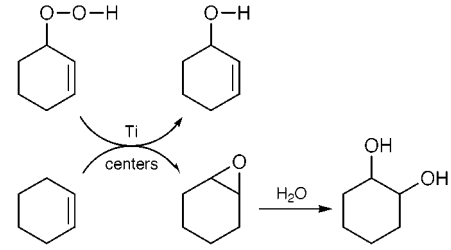
Two different strategies have been explored. The simplest one consists in using a mechanical mixture of two molecular sieves, one containing TP^+ as photocatalyst and the second one having Ti atoms as epoxidation sites. Table 1 summarizes the results that have been achieved using a system containing a mixture of TP-NaY and Ti-β or Ti-MCM-41.[7–10] The major difference between the latter two epoxidation catalysts is the geometry and dimensions of the internal voids, both having in common their relative hydrophocity that favors the preferential adsorption of organic compounds.[7] The structure of β zeolite defines a tridirectional network of oval cages (11 Å major axis) while MCM-41 is formed by an array of hexagonal channels (30 Å diameter).

In agreement with the chemical literature,[7] Al-free Ti-MCM-41 was found more active than Al-free Ti-β. The higher activity of Ti-MCM-41 is easily rationalized based on the larger dimensions of its pores that suit better to the size of the reagents involved in the process. When the TP-NaY/Tiβ mixture was reused in a second and third experiment with fresh feed a notable loss of activity was observed (see Table 1, footnotes *c* and *d*). However, this decay in the efficiency of the photocatalytic mixture is not caused by the bleaching of TP^+ since no changes were observed in the characteristic UV/vis absorption of the solid. Rather, it is more likely that the deactivation is due to blocking of the pores by oligomers or bleaching of Ti atoms out of the Ti-β framework.

Table 1 Results after 4 h irradiation (125 W Hg lamp through Pyrex) at room temperature of cyclohexene (2 ml) in a mixture of MeCN (2 ml)–H_2O (1 ml) in the presence of the corresponding photocatalyst (500 mg, 4% loading of TP^+)

	Products/mg		
Photocatalyst[a]	cyclohexane-1,2-diol	cyclohex-2-enol	cyclohex-2-enone
TP-NaY[b]	1.5	6.8	13.9
TP-NaY/Ti-β	10.9	23.7	16.8
TP-NaY/Ti-β[c]	4.5	13.9	13.8
TP-NaY/Ti-β[d]	2.2	13.6	7.4
TP-NaY/Ti-MCM-41	13.4	17.6	18.7
TP, Ti-β	20.2	39.7	11.5

[a] Blank controls under Ar atmosphere, in the dark or in the absence of TP-Y did not lead to any product. [b] In the absence of Ti-containing co-catalyst. [c] Second run reusing TP-NaY/Ti-β with fresh reagents. [d] Third run reusing TP-NaY/Ti-β with fresh reagents.



Scheme 3

On the other hand, according to Scheme 3, cyclohex-2-enol and cyclohexane-1,3-diol would be concurrently formed in the oxidation step while cyclohex-2-enone would arise from the subsequent overoxidation of cyclohex-2-enol.

Even though the TP-NaY/Ti-zeolite mixtures act as photocatalysts, their activity and selectivity are far from optimal. In order to increase the efficiency of the overall photocatalytic reaction, a fully-integrated approach was explored. It consists of the preparation of a single bifunctional photocatalyst that contains the two centers necessary for the process in the closest possible proximity. For this purpose, we have carried out the ship-in-a-bottle synthesis of TP^+ in a Ti-Beta zeolite following the procedure reported for zeolite Y.[9] As can be seen in Table 1, the efficiency of the overall dihydroxylation process is almost doubled using this novel TP, Ti-β photocatalyst compared to the mechanical mixture of the two separate components. This higher activity of TP,Ti-β for the production of cyclohexane-1,2-diol can be understood as a consequence of the spatial arrangement of the sites that reduces the chances for undesirable decomposition of hydroperoxy cyclohexene.

To establish a valid comparison of the efficiency of the TP, Ti-β photocatalysis, the autooxidation of cyclohexene (2 ml) initiated by azoisobutyronitrile (30 mg) was also carried in MeCN (2 ml) in the presence of Ti-β (200 mg) bubling air through the solution. After 5 h reaction, only 4.5 mg of cyclohexane-1,2-diol was formed. This value is smaller than those achieved with the TP,Ti-β photocatalysis (see Table 1).

Even though further improvements are still needed, herein we have shown that TP,Ti-β acts as a new *positive* photocatalytic system that by using photons promotes the dihydroxylation of cyclohexene using water and oxygen as reagents. The overall process occurs within the pores of zeolites, whose rigid structure embeds and protects the active centers, cooperating in the process in a way reminiscent of the quaternary structure of enzymes around a prostetic group.

Novel hydrogen bonding ring motifs in a model peptide: crystal and molecular conformation

Ashwani K. Thakur, Ashish and Raghuvansh Kishore*

Institute of Microbial Technology, Sector 39-A, Chandigarh - 160 036, India. E-mail: kishore@imtech.ernet.in

Received (in Cambridge, UK) 14th June 1999, Accepted 16th July 1999

The crystal molecular structure of a model peptide, Boc-Ile-Thr-NH_2, unexpectedly revealed two unusual intramolecularly hydrogen bonded ring motifs, *i.e.* an intraresidue main-chain to main-chain interaction (N_i–H···O=C_i) and an interresidue 'newly discovered' side-chain to main-chain interaction (N_i–H···O_i^{γ}Thr), across a polar proteinogenic residue.

The design, synthesis and identification of peptide backbone secondary structural features, stabilised by intramolecularly hydrogen bonding (H-bonding) ring motifs, are of paramount significance since they are targets of *de novo* design, and they also serve as powerful molecular tools for probing the problems of structure–function relationships, protein folding and thermodynamic stabilities.[1] For example, α-bend, β-bend and γ-bend secondary structures, which are frequently observed in proteins and polypeptides and are stabilised by single intramolecular H-bonding interactions, constitute 13-membered (C_{13}-form), 10-membered (C_{10}-form) and 7-membered (C_7-form) ring motifs respectively, and have been the subject of intense conformational investigations over three decades.[2]

The fully extended *intraresidue* H-bonded secondary structure, *i.e.* N_i–H···O=C_i interaction, often referred to as a C_5-structure, constitutes the smallest possible intramolecularly H-bonded conformation across an α-amino acid. Ideally, this five-membered ring is characterised by the backbone torsion angles: $\phi \approx \psi \approx \pm 180$ (±20°) in the Ramachandran map.[3] The conformational characteristics available for this structural motif across proteinogenic residues are extremely rare and poorly understood, presumably due to the non-availability of suitable conformational models. As an attempt to investigate systematically the conformational characteristics of the secondary structure element,[4] we describe here the first unambiguous X-ray diffraction analysis and molecular conformation of this fully extended intramolecularly H-bonded structure, across a chiral proteinogenic residue in a simple model peptide, Boc-Ile-Thr-NH_2 **1**.† In addition to the C_5-interaction, the analysis also revealed the existence of a newly discovered six-membered ring motif stabilised by a main-chain to side-chain H-bond (*i.e.* N_{i+1}–H···O_i^{γ}) interaction, and provided further insight into the folding behaviour of the two ring motifs.[5]

A perspective view of the molecular conformation observed for **1** in the solid state is shown in Fig. 1 and the relevant torsional angles are listed in Table 1. The most surprising feature of the molecular conformation is the observation of an *intramolecular* H-bond between the Thr N2–H and C15=O5 groups. This H-bond results in the formation of a pentagonal ring motif, the 'C_5-structure'. This structure is characterised by the significantly extended backbone torsion angles (ϕ = −163.5°, ψ = +175.6°) and H-bond geometric parameters [bond distance d(N···O) = 2.566 Å, d(H···O) = 2.166 Å, bond angle (N–H···O) = 108.01° and the planarity of the hydrogen bond torsion angle (N_i–H···O=C_i) = 12.4°] (Fig. 2a). The apparent unusual degree of conformational rigidity, imposed by steric effects arising from the exposed amphiphilic C^{β} of the Thr side-chain, appears to be the primary cause of the strong conformational preferences, influencing the location of the Thr side-chain and the secondary-structure-dependent preferred rotation about the C^{α}–C^{β} bond in favour of a C_5-structure.

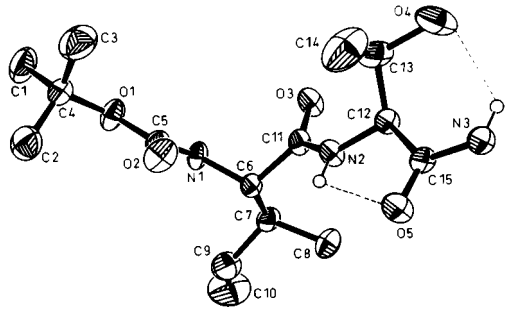

Fig. 1 An ORTEP representation of the molecular structure of Boc-Ile-Thr-NH_2, in the solid state. The thermal ellipsoids are shown at the 40% probability level. Intramolecular H-bonds are indicated by dashed lines.

Table 1 Selected torsion angles (°) for Boc-Ile-Thr-NH_2 **1**

Torsion angle	Ile	Thr
ϕ	−89.7	−163.4
ψ	129.4	175.6
χ_1	170.3,[a] −67.2	−167.8,[b] 69.3
χ_2	163.6	—
ω[c]	179.4	171.3

[a] Torsion angles: N1–C6–C7–C8 = 170.3°; [b] N2–C12–C13–O4 = −167.8°. [c] The C-terminal amide bond, ω_{i+1}, torsion angle C12–C15–N3–H3D = 179.9°.

Another important structural feature of **1** is the influence of the C_5-structural parameters on the unusual energetically unfavourable rotameric distribution of the Thr side-chain.[6] Interestingly, a shift of the Thr C^{α}–C^{β} torsion angle towards a rarely observed *trans* conformation ($\chi_1 \approx -167.8°$) clearly favours the formation of a novel six-membered H-bonded ring motif between the main-chain amide N3–H group and the $O4^{\gamma}$ atom of the Thr side-chain, *i.e.* N_{i+1}–H···O_i^{γ} Thr, interaction. The geometric parameters [d(H···O) = 2.288 Å, d(N···O) = 2.854 Å, bond angle N–H···O = 123.51°, H-bond torsion angle (N_{i+1}–H···O_i^{γ}–C^{β}) = −17.7°] characterise the newly discovered ring motif[5] across a chiral proteinogenic residue (Fig. 2b). In **1**, besides the planarity of the C-terminal amide bond, *i.e.* ω_{i+1}, the set of torsional angles (ψ_i = +175.6° and χ_1 = 167.8°)

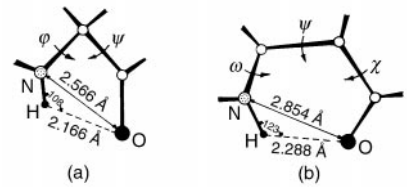

Fig. 2 The geometric characteristics of the two H-bonded ring motifs across the Thr residue: (a) the C_5-structure, N_i–H···O=C_i, main-chain to main-chain interaction; (b) the six-membered ring, N_{i+1}–H···O_i^{γ}Thr, side-chain to main-chain interaction. Relevant torsion angles are marked. Intramolecular H-bonds are indicated by dashed lines. Interacting oxygen and hydrogen atoms are indicated by large and small black circles, respectively.

of the preceding i^{th} residue appear to be the key determinants for the conformational preferences. The topological considerations of the significantly extended torsion angles, $\psi \approx \chi_1 \approx \pm 180$ (±20°), of the Thr residue may not allow the N–H group to approach the O^{γ} atom, precluding the formation of a normal five-membered H-bonding (*i.e.* N_i–H···$O_i{}^{\gamma}$ Thr) interaction. Therefore, an extended backbone ψ torsion angle, in addition to the *trans* χ_1 torsion angle of the i^{th} residue, appears to be the stringent requirement for the juxtaposition of the interacting atoms (N_{i+1}–H···$O_i{}^{\gamma}$) in order to form a six-membered ring across a chiral proteinogenic Thr or Ser residue.[5] In the crystal packing each molecule participates, as a donor or as an acceptor, in the formation of a complex network of intermolecular hydrogen bonding interactions, particularly those involving the Thr and the *trans*-carboxamide NHs. All these interactions probably contribute to the stability of the crystal molecular conformation.

The observation of a rare C_5-interaction across a chiral proteinogenic residue is indeed very interesting since, to date, extensively investigated derivatives and homopeptides incorporating achiral non-proteinogenic $C^{\beta\beta'}$ symmetrically disubstituted Gly residues alone have indicated strong preferences for this structure.[7] Although in these cases the reported average geometric parameters for the C_5-structure are in excellent agreement with those observed for **1**, the conformationally informative τ(N–C^{α}–C′) bond angle of the Thr residue (τ = 106.89°), contrary to our expectation, is not markedly reduced to an average value ≈103°. These results are distinctly inconsistent with the previous results and clearly suggest that the significant narrowing of the τ value may not be mandatory for an effective C_5-interaction, at least across chiral proteinogenic residue(s).

One- and two-dimensional ^{1}H NMR spectroscopic results provided unequivocal evidence, largely consistent with the crystal structure analysis, that in the compact state peptide **1** adopts an intramolecularly H-bonded C_5-structure in solution.[4] However, because of exchange effects (rotation about the C–N bond) the moderately low temperature coefficient ($\Delta\delta/\Delta T \approx -3.66 \times 10^{-3}$ ppm K^{-1}) value obtained for one of the C-terminal primary amide N–H groups was not interpreted as indicative of its involvement in an intramolecular H-bonding interaction stabilising the six-membered ring motif.[4,8] The thermodynamic characteristics of the two stable ring motifs, in a poorly interacting hydrophobic environment, were investigated to gain further insight into their folding–unfolding behaviour. Assuming a two-state process (an equilibrium between intramolecularly H-bonded and non-H-bonded states), the thermodynamic parameters deduced from van't Hoff plots of the variable temperature ^{1}H NMR data indicate that although both the H-bonded ring motifs are enthalpically favoured and entropically disfavoured, among both the ring sizes the more strained five-membered ring is relatively less preferred enthalpically while more favoured entropically (unpublished data).[4,8]

The results of the conformational analysis of **1** indicate that the C_5-structural motif, across an α-amino acid having oxygen atoms(s) in the γ-positions, may facilitate the formation of another six-membered H-bonded ring motif, *i.e.* an N_{i+1}–H···$O_i{}^{\gamma}$ interaction. The variations in the torsional angles ($\phi_i \approx \psi_i$ and $\psi_i \approx \chi_i \approx \omega_{i+1}$) of the five- and six-membered ring motifs, respectively, may characterise the geometric and thermodynamic parameters. It is worth stressing that the combined effect of the two specific ring motifs originating from the chiral moiety, on the molecular conformation appears to be the significant planar arrangement. The marked influence of the main-chain conformational preferences on the side-chain geometry (or *vice versa*) may indicate that χ_1 constrained amino acid derivatives can be exploited as structural tools for *de novo* design of relatively more rigid ring motifs for investigating unexplored structural and functional properties of bioactive molecules. From these observations we are also inclined to suggest that unlike reverse turn structures, the occurrence of such 'flat ring motifs' in proteins and polypeptides may not necessarily be responsible for the chain reversal.

In conclusion, this communication establishes the surprising existence of two fascinating ring motifs, stabilised by intramolecular H-bonding interactions across a chiral proteinogenic residue, and may argue for their intrinsic stabilities. The analysis of conformation-directing effects indicates that unexplored unique local, short range interactions (similar to the Asx-turn motif) might be accessible to small linear peptides incorporating residue(s) bearing a C^{β}-sterogenic centre with short polar side-chain(s). Unambiguous experimental characterisation, in solution as well as in the crystalline state, of the newly described H-bonded topologies are of fundamental importance and may provide an opportunity to examine their occurrence in the highly refined protein data bank; this may further enhance our understanding of polypeptide/protein conformations. Finally, such well defined H-bonded peptide templates/motifs may promise a 'bright future in biochemical and materials science applications.'[9]

This work was supported by a grant from the DBT Government of India. The authors wish to acknowledge the use of the National Diffractometer Facility (DST), New Delhi, for data collection. R. K. is grateful to the Director for his consistent encouragement. This is IMTech communication number 02/99.

Notes and references

† Peptide **1** was synthesised by employing solution phase procedures. A single crystal suitable for an X-ray diffraction study was grown from a methanol solution. The crystal data were collected at 293 K on CAD4 Enraf-Nonius diffractometer with graphite monochromated Cu-Kα radiation (λ = 1.5418 Å) using ω–2θ scan mode. *Crystal data for* **1**: $C_{15}H_{28}N_3O_5$, M = 332.42, orthorhombic, $P2_12_12_1$, colourless needles measuring 1.1 × 0.7 × 0.25 mm^3, a = 8.040(4), b = 12.582(7), c = 18.128(7) Å, $\alpha = \beta = \gamma$ = 90°, V = 1839.7(8) Å^3, Z = 4. The structure was solved by direct methods using SHELXS-97.[10] The structure was refined by full matrix least-squares on F^2 by using SHELXL-97.[11] Final R = 0.0548 [$I > 2\sigma(I)$], R_w = 0.1605. All non hydrogen atoms were refined anisotropically. All hydrogen atoms were placed in idealised positions with assigned isotropic parameters. CCDC 182/1338. A tetranuclear aluminium hydrazide derivative with a ladder-type structure

Joel S. Silverman, Colin D. Abernethy, Richard A. Jones* and Alan H. Cowley*

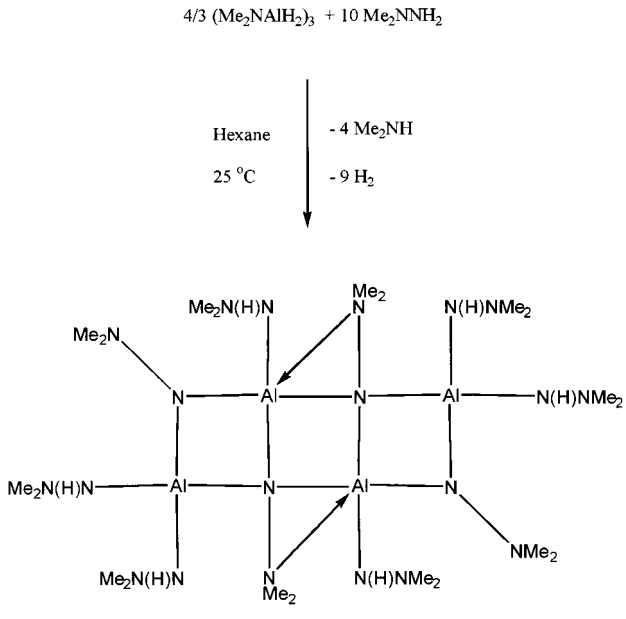
Department of Chemistry and Biochemistry, The University of Texas at Austin, Austin, Texas 78712, USA. E-mail: cowley@mail.utexas.edu

Received (in Columbia, MO, USA) 20th May 1999, Accepted 15th July 1999

The reaction of $(Me_2NAlH_2)_3$ with excess H_2NNMe_2 affords $[Al_4(NHNMe_2)_6(NNMe_2)_4]$; the compound possesses an Al_4N_4 ladder-shaped core.

The renewed interest in group 13 hydrazides can be attributed to two driving forces. Firstly, since hydrazide ligands are potentially multi-functional they can promote the formation of novel rings, cages, and polymers featuring group 13–nitrogen linkages. Secondly, group 13 hydrazides could play an important role as precursors to group 13 nitrides. The most successful current approach to the deposition of such nitrides involves the thermal reaction of the respective metal alkyl with ammonia.[1] Unfortunately, the requisite reaction temperatures are somewhat high (> 900 °C) and lower thermal budgets are desirable to obviate such problems as thermal stresses and stoichiometry losses in the resulting films. Hydrazine[2] and dimethylhydrazine[3] have been suggested as alternative, lower temperature nitrogen delivery sources thus rendering the investigation of group 13 hydrazides an attractive proposition.

Despite being known since 1961,[4] structural information on aluminium hydrazides is confined to that of the dimer, $[Me_2Al\{\mu\text{-}N(H)NMe_2\}]_2$.[5] Moreover, it was only in 1995 that $[Et_2Ga\{\mu\text{-}N(H)NPh_2\}]_2$, the first gallium hydrazide, was prepared.[6] More recent interest has focused on the construction of cage and ring structures from group 13 hydrazides, two important examples of which are $[MeGaN(H)NPh]_4$[7] and an octa-aluminium analogue of a calix[4]pyrrole which features four five-membered AlN_3C rings connected by Me_2Al bridges.[8] Herein, we describe the synthesis and structural assay of a novel tetra-aluminium hydrazide derivative that possesses a ladder-type core.[9] A further distinguishing feature of the present work is that the replacement of a trialkylalane by $(Me_2NAlH_2)_3$[10] as the aluminium source results in lower reaction temperatures.



1

Scheme 1

The reaction of $(Me_2NAlH_2)_3$ with an excess of 1,1-dimethylhydrazine in hexane solution at 25 °C is exothermic and results in the evolution of hydrogen and dimethylamine (Scheme 1). Following filtration of the reaction mixture, cooling of the filtrate to −20 °C resulted in the formation of colourless crystals of **1**.† Mass spectroscopic assay indicated a composition of $C_{20}H_{67}Al_4N_{20}$ for **1** (HRMS: calc. for $(M + H)^+$, 695.512; found, 695.513) and this was in accord with combustion analysis data. Unfortunately, it was not possible to deduce the structure of **1** using ^1H, ^{13}C, and ^{27}Al NMR data† at this stage, hence an X-ray diffraction experiment became necessary.‡

Compound **1** crystallizes in the triclinic space group $P\bar{1}$ with $Z = 2$ (for an asymmetric unit of formula $[Al_2\{NHNMe_2\}_3\{NNMe_2\}_2]$. The crystalline state comprises an array of tetranuclear molecules. $[Al_4\{NHNMe_2\}_6\{NNMe_2\}_4]$ and there are no unusually short intermolecular contacts. As illustrated in Fig. 1, the Al_4N_4 skeleton of **1** adopts a ladder-type arrangement that consists of three fused four-membered Al_2N_2 rings. The

central such ring, which resides on a crystallographic inversion centre, is essentially rectangular with bond angles of 89.43(10) and 90.57(10)° at aluminium and nitrogen, respectively, and a difference of *ca.* 0.2 Å in the Al–N bond distances. In turn, the central Al_2N_2 moiety is flanked on either side by a fused three-membered AlN_2 ring formed by N → Al dative bonding from hydrazide lone pairs. As a consequence, the coordination numbers of Al(1) and Al(1A) are both five. In a formal sense, there are four Al–N σ-bonds (Al(1)–N(5) 2.091(3) Å; Al(1)–N(5A) 1.877(2) Å; Al(1)–N(3) 1.787(2) Å, Al(1)–N(1) 1.959(3) Å and one N → Al dative bond (Al(1)–N(6) 1.957(2) Å) at each aluminium centre. The average Al–N bond distance of 1.934(3) Å is close to that reported for $[Me_2Al\{\mu\text{-}N(H)NMe_2\}]_2$ (1.955(3) Å), the only aluminium hydrazide structurally characterized previously.[5] The bond angles within the AlN_5 coordination sphere range from 42.97(9)° (N(5)–Al(1)–N(6)) to 142.17(10)° (N(1)–Al(1)–N(5)); at best, the geometry can be described as highly distorted trigonal bipyramidal. Not unexpectedly, the geometries at N(5) and N(5A) show a marked departure from the ideal tetrahedral angle and range from 63.72(13)° for Al(1)–N(5)–N(6) to 132.2(2)° for Al(2A)–N(5)–N(6). The outer four-membered Al_2N_2 rings are somewhat rhomboid; however, there is a wide scatter in the Al–N bond distances and intra-ring angles (Fig. 1 caption). The average Al–N bond distance of 1.917(3) Å for the outer Al_2N_2 rings is shorter than that for the inner ring (1.934(3) Å). The geometries at Al(2) and N(1) are distorted tetrahedral and pyramidal, respectively. Overall, the geometry of the Al_4N_4 core of **1** is somewhat similar to that reported[11] for a lithium salt of composition $C_{52}H_{78}Al_4Li_2N_4$.

Ex post facto, the NMR data for **1** can be interpreted satisfactorily and indicate the integrity of the ladder-type structure in solution. Thus, two aluminium environments are evident in the ^{27}Al NMR spectrum and the methyl groups on N(6) and N(6A) are anisochronous. The observation of four, rather than three, $N(H)NMe_2$ environments may be due to the presence of rotational isomers.

We thank the Science and Technology Center Program of the National Science Foundation and the Robert A. Welch Foundation for financial support.

Structures of $[Co(II)(L)(NO_3)(HOCH_3)_n]BPh_4$ (n = 4, 5) complexes (L = *cis,cis*-1,3,5-triaminocyclohexane-based ligand): structural 'snapshots' of anion binding to a metal centre

Clive J. Boxwell and Paul H. Walton*

Received (in Cambridge, UK) 16th June 1999, Accepted 15th July 1999

The crystal structures of $[Co(II)(L)(NO_3)(HOCH_3)_n]BPh_4$ {L = *cis,cis*-1,3,5-tri[(4-*tert*-butylphenyl)propenylideneamino]cyclohexane} complexes demonstrate the role of solvent molecules in the stabilisation of anions within a solvated cavity: the structures can be compared with bicarbonate binding in the active site of carbonic anhydrase.

Small molecule metal complexes have long been used successfully to mimic the immediate metal coordination sphere of metal ions in metalloproteins. Some of the most successful model complexes, especially models of myoglobin,[1] have attempted to model not only the metal and its surrounding ligands but also other active site features. Such models have the potential to provide chemical clues about the mechanistic roles of these features which are remote from the immediate metal coordination sphere. Of late, we have been interested in preparing small molecule complexes which mimic both primary and secondary coordination spheres of the metal ion in the zinc-containing metalloenzyme human carbonic anhydrase II (CA). CA (and its catalytically competent Co(II)-substituted form) is of significant interest since it catalyses the hydration of carbon dioxide at near diffusion-limited rates. The enzyme's active site can be described as a 15 Å deep cleft with a metal ion coordinated by three histidine residues at the 'bottom' of the cleft. There are several amino acid residues remote from the primary coordination sphere of the metal which are critical in maintaining the high catalytic efficiency of the enzyme.[2] Another feature of the active site are chains of hydrogen-bonded water molecules extending from the metal to the 'top' of the cavity; studies show that the active site water molecules have important roles to play in proton transfer and in substrate binding.[3] To model these remote active site features in a synthetic complex requires a ligand design which combines an N_3 face-capping coordination geometry with a rigid 'superstructure', *e.g.* derivatised cyclodextrins[4] and derivatised tris-pyrazolylborate complexes.[5]

We have previously reported the use of propenylidene derivatives of *cis,cis*-triaminocyclohexane ligands (abbreviation: protach) in the modelling of CA.[6] The protach ligand system provides a face-capping N_3 coordination environment on one 'face' of the metal and surrounds the other 'face' with a rigid, hydrophobic superstructure (Fig. 1). We have shown that this superstructure is capable of encapsulating several solvent molecules, modelling the solvated active site cavity seen in CA.[7] In this paper we report two new structures using the protach-based ligand system (4-*tert*-butylphenylprotach). These structures exhibit different degrees of nitrate solvation within the structures' cavities. One structure shows the nitrate coordinated to the metal centre [cobalt(II)], whereas the other structure of the same metal–ligand complex—crystallised under different conditions—shows the nitrate solvated by methanol molecules at the 'top' of the cavity.

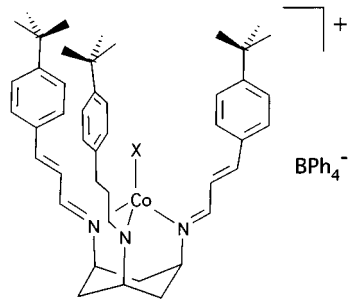

Fig. 1 Metal ligand complex used in this study (X = NO_3).

Condensation of 4-*tert*-butylcinnamaldehyde with *cis*-1,3,5-triaminocyclohexane gave the ligand *cis,cis*-1,3,5-tri[(4-*tert*-butylphenyl)propenylideneamino]cyclohexane (L) in 58% yield. Addition of L to $Co(NO_3)_2{\cdot}6H_2O$ in CH_2Cl_2–CH_3OH (*ca.* 10/90 v/v) solution gave, after slow evaporation of the solvent, crystals of $[Co(L)(HOCH_3)_3](NO_3)(HOCH_3)_2(BPh_4)$ **1** in 65% yield. Repeating the procedure with CH_2Cl_2–CH_3OH (*ca.* 30/70 v/v) solution gave crystals of $[Co(L)(NO_3)(HOCH_3)](HOCH_3)_3(CH_2Cl_2)_2(BPh_4)$ **2** in 74% yield. Satisfactory analyses were obtained for the fully desolvated complexes of **1** and **2**. The crystals of both **1** and **2** rapidly lost all solvent *in vacuo*.

The structures of **1** and **2** were determined by single crystal X-ray diffraction.† The structure of **1** (Fig. 2) shows the cobalt atom in a near octahedral co-ordination geometry, with L co-ordinating in the expected face-capping fashion. The phenylpropenylidene 'arms' of the ligand form a rigid cavity around the metal's remaining co-ordination sites, which are occupied by three methanol molecules. All three co-ordinated methanol molecules are involved in hydrogen bonding with either other methanol molecules or the nitrate anion in the cavity. The OH groups of two coordinated methanol molecules, O(2) and O(3),

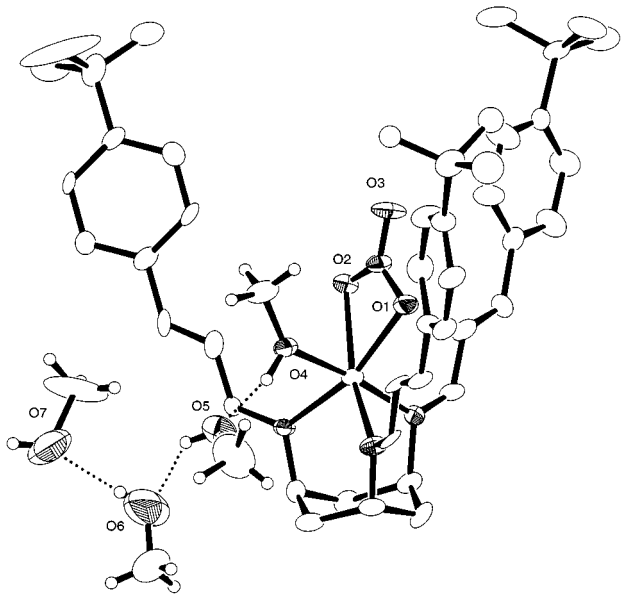

Fig. 3 ORTEP[9] representation of **2** (30% probability elipsoids). Co(1)–O(1) 2.145(11), Co(1)–O(2) 2.244(9), Co(1)–O(4) 2.153(11), O(4)···O(5) 2.602(18) Å, O(4)–H(4)···O(5) 168.3°, O(5)···O(6) 2.73(2) Å, O(5)–H(5)···O(6) 145.1°, O(6)···O(7) 2.54(3) Å, O(6)–H(6)···O(7) 136.2°. Tetraphenylborate anion, dichloromethane molecules and hydrogen atoms on L are not shown for clarity.

are hydrogen-bonded to two oxygen atoms of the nitrate, O(5) and O(4) respectively. The third nitrate oxygen atom, O(6), is hydrogen-bonded to two further methanol molecules, O(7) and O(8)*, at the 'top' of the cavity. The third coordinating methanol molecule, O(1), is hydrogen-bonded to another methanol molecule, O(8); this methanol molecule forms a hydrogen bond to an oxygen of the nitrate anion, O(6)*, of an adjacent asymmetric unit. Accordingly, the two cobalt complex cations form a pseudo-dimer. A tetraphenylborate anion completes the structure.

The structure of **2** (Fig. 3) shows the cobalt atom in a near octahedral co-ordination geometry with L co-ordinating in a face-capping fashion. As before, the phenyl propenylidene 'arms' of the ligand form a rigid cavity around the metal ion's remaining co-ordination sites, which are occupied by the oxygen atom of one methanol molecule and an η^2-nitrate. The oxygen atom of the coordinated methanol molecule, O(4), is hydrogen-bonded to a chain of three further hydrogen bonded methanol molecules, O(5), O(6) and O(7). The nitrate anion is not involved in any hydrogen bonding. A tetraphenylborate anion and two dichloromethane solvent molecules complete the structure. The cobalt coordination geometry matches closely with that of cobalt in the structure of Co-substituted CA (HCO_3^-); in the protein structure the cobalt has a bidentate bicarbonate ligand (analogous to nitrate in the model complex) and a water molecule occupying the sixth coordination site (analogous to methanol).[8]

The structures of **1** and **2** demonstrate the ability of the complexes to encapsulate solvent molecules. These solvent molecules are involved in extensive hydrogen-bonding interactions. It appears that by controlling the concentration of methanol in the crystallising solvent it is possible to control the degree of methanol incorporation in the complexes; this is a powerful tool to study the effects of solvent on the solvation of anions within the cavity of the complex. Comparison of the two structures (see Fig. 4) shows two possible structural 'snapshots' of nitrate binding to cobalt through a shell of solvent molecules. The structure of **1** illustrates one possible stage along the binding pathway in which the nitrate ion forms hydrogen-bond interactions with coordinated solvent molecules. There are

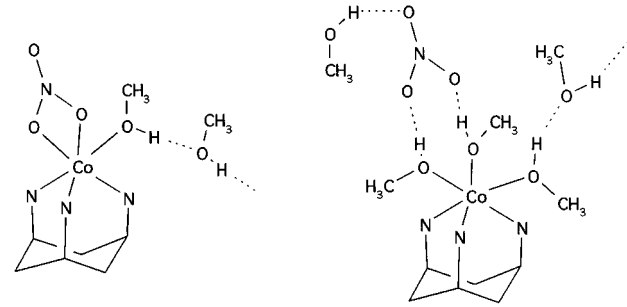

Fig. 4 Schematic comparison of nitrate–metal interactions in **1** (right) and **2** (left). Phenylpropenylidene groups, tetraphenylborate anions and dichloromethane molecules are not shown for clarity.

parallels between our models and the binding of bicarbonate in the Co-substituted form of CA. By analogy it is possible that the transfer of bicarbonate in and out of the active site is stabilised by similar hydrogen-bond interactions between metal-bound water molecules and bicarbonate. Such interactions could be important in facilitating rapid transfer of bicarbonate in and out of the hydrophobic active site. In other words, bicarbonate binding through a hydrophobic active site can be achieved without extensive desolvation of the bicarbonate, and also binding can be achieved with relatively little reorganisation of solvent molecules.

Chemistry Department, Durham University Science Laboratories, South Road, Durham, UK DH1 3LE. E-mail: m.a.fox@durham.ac.uk

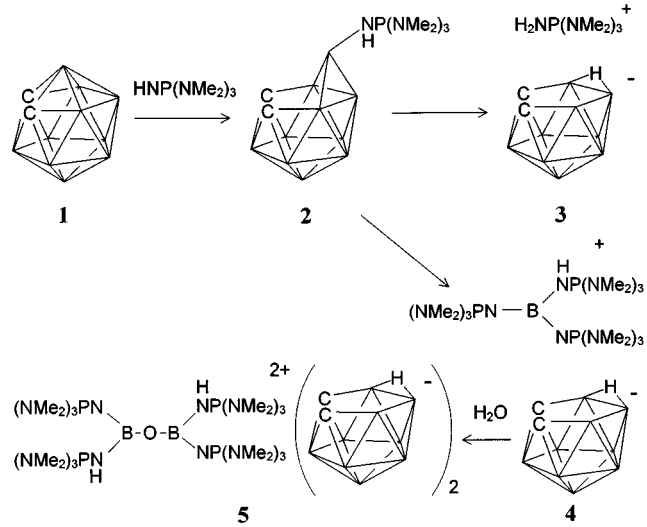
Received (in Cambridge, UK) 16th April 1999, Accepted 20th July 1999

The structures of the adduct *nido*-$C_2B_{10}H_{12}\cdot HNP(NMe_2)_3$ and the borenium salt $[(Me_2N)_3PNHBNP(NMe_2)_3]_2O^{2+}(C_2B_9H_{12}^-)_2$, both obtained from 1,2-$C_2B_{10}H_{12}$ and $HNP(NMe_2)_3$, were determined by X-ray crystallography; the adduct represents the first structurally determined carborane of its type, a possible intermediate in the well known conversion of *closo*-1,2-$C_2B_{10}H_{12}$ into the *nido*-7,8-$C_2B_9H_{12}^-$ anion by bases.

The *closo*-icosahedral carboranes $C_2B_{10}H_{12}$ have an extensive (3-dimensional aromatic) chemistry with implications for neutron scavenging, for materials (thermally stable or conducting or otherwise electroactive oligomers and polymers), for metal extraction, supramolecular chemistry and catalysis.[1] Remarkably resilient to heat and oxidising agents, they are known to have one very important degradation reaction, being susceptible to nucleophilic attack by a select few powerful Lewis bases (*e.g.* alkoxides, fluoride, amines)[2–5] which can remove one of their BH units, formally as BH^{2+}, leaving *nido*-shaped $C_2B_9H_{11}^{2-}$ (or $C_2B_9H_{12}^-$) anionic residues that can strongly bind metal ions to their open C_2B_3 faces,[6] useful for metal-extraction and catalytic applications. However, although such base deboronations have been known for 35 years, details of their mechanisms have remained elusive. Here, we describe work that sheds light on the mechanism, reporting the X-ray structural characterization of an adduct $C_2B_{10}H_{12}\cdot HNP(NMe_2)_3$ **2**, formed in the nucleophilic attack by the new deboronating base $HNP(NMe_2)_3$ on *ortho* carborane, 1,2-$C_2B_{10}H_{12}$ **1**. We also show that the hitherto unknown monoboron cation $(Me_2N)_3PNHB[NP(NMe_2)_3]_2^+$ is a later product of the same reaction, and that the dication $[(Me_2N)_3PNHBNP(NMe_2)_3]_2O^{2+}$ is an unexpected product if traces of water are present.

Iminotris(dimethylamino)phosphorane $HNP(NMe_2)_3$ is very effective in the conversion of *closo*-$C_2B_{10}H_{12}$ **1** into *nido*-7,8-$C_2B_9H_{12}^-$. Several NMR-scale reactions of carborane **1** with dry $HNP(NMe_2)_3$ in anhydrous deuterated toluene at varying temperatures (−20 to 20 °C), ratios (carborane : base 1 : 10 to 10 : 1) and concentrations (0.1 to 0.01 M) were monitored by ^{11}B NMR spectroscopy. We found that boron peaks corresponding to a carborane intermediate were best observed using a 1 : 1 ratio mixture of low concentration (0.01 M) at room temperature after only two minutes reaction time. The peaks observed arising from the intermediate at 34.8 (br), −18.2 (d) and −27.8 (d) ppm accounted for only 2% of the total boron peak intensities (the major carborane is **1** with peaks at −2.0, −8.7, −13.2 and −14.4 ppm at this stage) and disappeared rapidly to peaks corresponding to the carborane anion, $C_2B_9H_{12}^-$.[4] This anion was observed by multinuclear NMR spectroscopy accompanied by a 1 : 1 mixture of the cation $H_2NP(NMe_2)_3^+$ **3** and the novel protonated tris(imino)-borane $(Me_2N)_3PNHB[NP(NMe_2)_3]_2^+$ **4** respectively (Scheme 1).†

A preparative scale reaction was carried out to allow structural characterization of the products. Under nitrogen, slow addition of dry $HNP(NMe_2)_3$ (1.78 g, 10 mmol) in anhydrous toluene (15 ml) to a solution of **1** (1.44 g; 10 mmol) in toluene (15 ml) resulted in the formation of a crystalline product (*ca.* 0.03 g) overnight. Although this product was identified by boron NMR spectroscopy as a mixture of **1** and 7,8-$C_2B_9H_{12}^-$ in solution, an X-ray structural determination on a crystal selected from the material revealed a carborane adduct $C_2B_{10}H_{12}\cdot HNP(NMe_2)_3$ **2** (Fig. 1).‡ The volume of the decanted solution was halved by solvent removal *in vacuo* and, after standing for a week at room temperature, the crystals formed were identified by NMR as the salt $H_2NP(NMe_2)_3^+$ (7,8-$C_2B_9H_{12}^-$) **3** (0.32 g) and confirmed by an X-ray structural determination.‡ The mother liquor was cooled to −20 °C to yield a white solid identified by NMR spectroscopy as the protonated tris(imino)borane salt **4** (0.43 g).



Scheme 1

Calculated (GIAO HF/6-31G*) boron NMR shifts§ generated from the X-ray geometry of the carborane adduct **2** show good agreement with the intermediate observed in the NMR-scale reactions once masking of certain peaks by the starting carborane **1** is taken into account. This suggests that adduct **2** is the first structurally characterized intermediate in the well known conversion of *closo*-1,2-$C_2B_{10}H_{12}$ **1** into *nido*-7,8-$C_2B_9H_{12}^-$. As revealed by the X-ray structure of **2**, the first step of the *closo–nido* conversion is the attachment of the base to the most positively charged boron atom near the two neighbouring carbon atoms which pivots about B(10), cleaving the two B–C bonds and stretching the two B–B bonds to B(9) and B(11). The structure of adduct **2** may be contrasted with the hydrogen-bonded structures of $C_2B_{10}H_{12}\cdot OP(NMe_2)_3$ and $C_2B_{10}Cl_{10}H_2\cdot OSMe_2$ adducts.[7]

As expected from simple skeletal-electron counting rules for a 12-vertex 28 skeletal electron *nido* geometry, the cluster framework of carborane **2** is viewed as a 13-vertex *closo*-deltahedron with a 5-coordinate vertex removed.[8] Positions of

Important interatomic distances (Å) are: P(1)–N(1) 1.651(3), N(1)–H(13) 0.75(4), N(1)–B(12) 1.506(6), B(12)–H(12) 1.18(4), C(7)–C(8) 1.530(6), C(7)–B(11) 1.654(6), C(8)–B(9) 1.651(6), B(12)–B(10) 1.761(6), B(12)–B(9) 2.099(6), B(12)–B(11) 2.091(6), B(10)–B(9) 1.779(6), B(10)–B(11) 1.802(6). Selected angle (°): P–N(1)–B(12) 127.3(3).

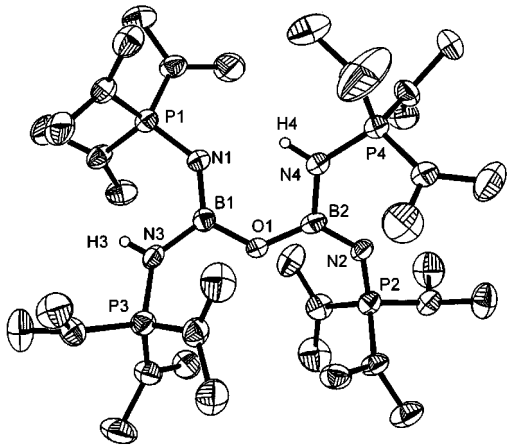


Fig. 2 Molecular structure of cation in **5** (50% ellipsoids; methyl hydrogens omitted for clarity). Important interatomic distances (Å) are: B(1)–N(1) 1.402(6), B(1)–N(3) 1.463(5), B(1)–O(1) 1.373(5), B(2)–N(2) 1.389(5), B(2)–N(4) 1.464(6), B(2)–O(1) 1.416(5), N(1)–P(1) 1.555(3), N(2)–P(2) 1.554(3), N(3)–P(3) 1.630(4), N(4)–P(4) 1.614(3).

the cage carbons in the carborane adduct **2** were conclusively determined by an *ab initio* optimization of a model of $C_2B_{10}H_{12}{\cdot}HNP(NH_2)_3$ at the HF/6-31G* level of theory where both theoretical and experimental geometries are nearly identical. These carbon placements are supported by a similar cage geometry observed in the *nido*-C_2B_{10} moiety of the two-cage anion $[PhCB_{10}H_{10}CB_{10}H_{10}C_2HPh]^-$ structurally characterized by X-ray crystallography.[9]

During attempts to obtain suitable crystals of the salt **4** containing the cation $(Me_2N)_3PNHB[NP(NMe_2)_3]_2^+$ from toluene, a single crystal was characterized by an X-ray study‡ as a salt **5** containing the dication $[(Me_2N)_3PNHBNP(NMe_2)_3]_2O^{2+}$ (Fig. 2). The oxygen atom apparently arose from inadequately dried toluene. According to bond order calculations¶ (AM1) carried out on the structure of the dication $[RN(RNH)BOB(NHR)(NR)]^{2+}$ there is strong BN π bonding within each RN(RNH)B unit to the imino (NR) residue, much less to the imine (RNH) residue, though evidently sufficient to ensure planarity of the $(PN)_2BO$ unit.

Our work suggests that the formation of an adduct $C_2B_{10}H_{12}{\cdot}L$, with an expected *nido*-structure, is the first step in the deboronation of *ortho*-carborane by $HNP(NMe_2)_3$ and presumably other Lewis bases L. Further studies, both experimental and theoretical, will be needed to clarify the later steps.

We are grateful to the EPSRC (M. A. F.), BNFL (T. G. H.) and Durham University (Sir Derman Christopherson Fellowship to J. A. K. H. and studentship to A. M.) for financial support.

Synthesis, X-ray structure, and hydrolytic chemistry of the highly potent antiviral polyniobotungstate A-α-$[Si_2Nb_6W_{18}O_{77}]^{8-}$

Gyu-Shik Kim,† Huadong Zeng, Jeffrey T. Rhule, Ira A. Weinstock† and Craig L. Hill*

Department of Chemistry, Emory University, 1515 Pierce Drive, Atlanta, GA 30322, USA. E-mail: chill@emory.edu

Received (in Bloomington, IN, USA) 14th May 1999, Accepted 5th July 1999

Potently antiviral polyniobotungstates have been structurally characterized; the dimer A-α-$[Si_2Nb_6W_{18}O_{77}]^{8-}$ cleaves cleanly to the monomer A-α-$[SiNb_3W_9O_{40}]^{7-}$ within 1 min in aqueous solution buffered at physiological (neutral) pH establishing that the monomer and not the dimer is pharmacologically relevant.

In recent years, several classes of early transition-metal oxygen-anion clusters or polyoxometalates (POMs) have been documented to exhibit antiviral properties.[1] The size, shape and functional group complementarity of these nanometer-sized inorganic compounds and key enzymatic targets, including the active sites of HIV-1 reverse transcriptase[2] and HIV-1 protease,[3] is substantial. This fact coupled with the growing ability to systematically vary the physical and electronic structures and other properties of POMs,[4] has increased interest in POMs as potential antiviral agents. The double-Keggin POMs of formula A-α- or A-β-$[Si_2Nb_6W_{18}O)_{77}]^{8-}$ (**1**) are as promising as any of the 200+ POMs investigated to date as antiviral agents. The A-β isomer was first prepared by Finke and Droege in 1984,[5] and subsequently shown by our group and others to strongly inhibit a number of viruses including HIV-1, HIV-2, respiratory syncytial virus (RSV) and several strains of influenza and herpes while being essentially non-toxic in mammals.[6] The A-α isomer, A-α-$[Si_2Nb_6W_{18}O_{77}]^{8-}$ (A-α-**1**) has comparable pharmacological profiles (therapeutic indices) to A-β-**1**.[1] Despite the interest in A-α- and A-β-**1**, the structure or hydrolytic form of these dimers in aqueous solution under physiological conditions has never been characterizaed. We report here, that the dimers (A-α- or A-β-**1**) are not present under physiological conditions, because cleavage to the corresponding monomers is thermodynamically and kinetically favorable at serum pH values. We focus here on the A-α system for which X-ray structures of both A-α-**1** and its corresponding monomer A-α-$[SiNb_3W_9O_{40}]^{7-}$ (A-α-**2**) have been obtained. The A-β system exhibits effectively identical aqueous speciation chemistry.

The organic-solvent-soluble tetrabutylammonium (TBA) salt of **1** (A-α-TBA**1**) can be prepared by the peroxide-bisulfite method that Finke and Droege used to make the analogous TBA salt of the A-β isomer.[7] Efforts to use this method[7] to obtain water-soluble forms of either isomer of **1** were hampered by co-precipitation of sulfate-salt byproducts. This problem was overcome in two ways: by selective precipitation using K^+ and Cs^+ salts under carefully controlled conditions and by use of a new sulfate-free synthesis. Selective precipitation was accomplished by adding saturated methanolic solutions of either CsCl (8 equiv.) or of CF_3CO_2K (10 equiv. of neat CF_3CO_2H followed by 24 equiv. of methanolic CF_3CO_2K) to 10 mM acetonitrile solutions of A-α-TBA**1**. Powders of the respective salts obtained were washed with methanol, followed by acetonitrile, to remove excess salts. The Cs^+ salt, (A-α-Cs**1**),‡ was obtained in 90% yield based on A-α-TBA**1**. The K^+ salt (34% yield from A-α-TBA**1**) was partially hydrolyzed by reversible cleavage of one of the three Nb–O–Nb μ-O linkages:‡ subsequent dissolution in 1.0 M HCl and passage of the solution through a Dowex-50 proton exchange resin gave the free-acid form of recondensed **1**, A-α-$H_8[Si_2Nb_6W_{18}O_{77}]$ (A-α-H**1**)‡ in effectively quantitative yield.

The Cs^+ salt of A-α-**1** was also prepared by direct condensation of the monomeric triperoxoniobium precursor A-α-$[Si(NbO_2)_3W_9O_{37}]^{7-}$: a yellow solution of A-α-$Cs_7[Si(NbO_2)_3W_9O_{37}]$ [12 mM in 2.0 M HCl(aq)] was refluxed until it was colorless and CsCl (22 equiv.) was added to give A-α-Cs**1** in 86% yield. Reflux of a yellow acetonitrile solution of A-α-$(TBA)_4H_3[Si(NbO_2)_3W_9O_{37}]$ in the presence of HCl followed by diffusion of diethyl ether into the reaction mixture gave X-ray quality crystals of A-α-TBA**1**§ in 74% yield. The solid state (KBr pellet) IR spectra of all the A-α-**1** salts prepared using these methods exhibit strong Nb–O–Nb bands in the 680–700 cm^{-1} region; the spectra of the monomer, A-α-**2**,‡ does not.

X-Ray crystal structures¶ of A-α-TBA**1** and the A-α-Cs**2** confirm the A-α-isomeric assignments. The structure of A-α-**1** with principal bond distances and angles is given in Fig. 1. Bond valence sum calculations[8] indicate that all the niobium atoms in both A-α-**1** and A-α-**2** are in the +5 oxidation state, a result consistent with the NMR spectra (both POMs are diamagnetic). The 'double Keggin' structure in **1** is known in three other structurally characterized POMs: A-α-$[H_9Si_2Cr^{III}_6W_{18}O_{77}]^{11-}$,[9] a tri-μ-hydroxo compound, and A-β-$[Si_2Ti_6W_{18}O_{77}]^{14-}$,[10] and A-α-$[Ge_2Ti_6W_{18}O_{77}]^{14-}$,[11] both tri-μ-oxo compounds.

With both the dimer, A-α-**1**, and monomer, A-α-**2**, structurally characterized in both the solid state and in solution, the pH-dependent aqueous speciation chemistry of these POMs and the form present at physiological (neutral) pH was readily established. It is well documented that various bases cleave the Nb–O–Nb unit in both metal oxide materials[12] and POMs.[5,13] A combined pH–conductometric titration of A-α-H**1** confirmed that 14 equiv. of hydroxide were required to arrive at the inflection point. This is consistent with eqns. (1) and (2) and the

$$H_8Si_2Nb_6W_{18}O_{77} + 8\ OH^- \rightarrow Si_2Nb_6W_{18}O_{77}^{8-} + 8\ H_2O \quad (1)$$

$$Si_2Nb_6W_{18}O_{77}^{8-} + 6\ OH^- \rightarrow 2\ SiNb_3W_9O_{40}^{7-} + 3\ H_2O \quad (2)$$

fact that **1** is a tri-μ-oxo dimer in acidic aqueous solution. Examination of A-α-**1** and A-α-**2** by both ^{183}W NMR and FTIR in D_2O buffered at pD 7.0 using 3 different systems, *N*-[2-hydroxyethyl]piperazine-*N*′-[2-ethanesulfonic acid] (HEPES), 3-[*N*-morpholino]propanesulfonic acid (MOPS), or phosphate, indicated that only monomer, A-α-**2**, was present in all cases. While these measurements indicated the thermodynamic instability of the dimer relative to the monomer at physiological pH, they did not provide the rate of dimer cleavage, the issue of most relevance to the use of A-α-**1** as an antiviral agent. Unfortunately, overlapping absorbances or instrument-limited acquisition times rendered all the obvious spectroscopic techniques, including FTIR on aqueous buffer solutions, inadequate to assess the rate. However, it was determined that the Nb–O–Nb stretching region of the mid-IR could be used to follow this hydrolytic cleavage process provided D_2O was used as the solvent. Dimer cleavage was assessed by adding 0.156 g (0.0303 mmol) of A-α-**1** to 3.00 mL of 0.609 M MOPS buffer in D_2O to give a clear, colorless solution with a pD of 7.0. An aliquot of this solution was added to an AgBr IR solution cell and the spectrum, obtained in < 1 min showed that no dimer Nb–O–Nb band remained. The same experiments using 0.609 M HEPES or phosphate buffer in place of MOPS yielded the same results. ^{183}W NMR and FTIR established that when the pH of the hydrolyzed neutral solution was decreased to 0, A-α-**1** was re-formed in very high yield (Fig. 2). The corresponding experiments with the A-β system gave analogous results and, in neither system was Baker–Figgis (α–β) isomerisation[14] observed.

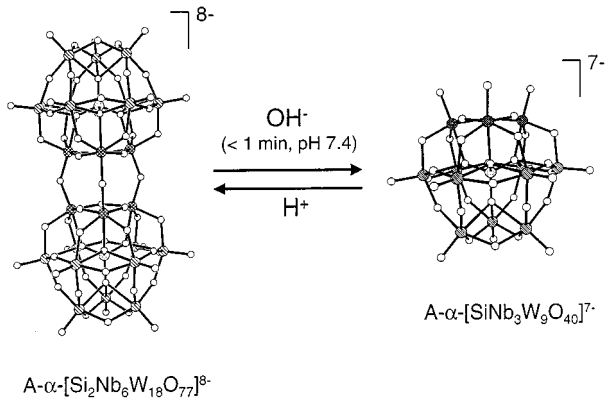

Fig. 2 Summary of dimer–monomer interconversions [eqn, (2) is the balanced reaction].

In summary, the tri-μ-oxo linkages in the double Keggin complexes, A-α-**1** or A-β-**1**, are cleaved quickly and with effectively quantitative selectivity to the corresponding monomers at physiological pH. In consequence, it is highly unlikely that the double Keggin POM structure accounts for any of the extensive biological data reported for these complexes.

Received (in Oxford, UK) 11th June 1999, Accepted 21st July 1999

Ag nanoparticles have been synthesised within a mesoporous template-structured silica film by a chemical route which includes ion-exchange with $Ag(NH_3)_2^+$ followed by reduction.

Thin films of surfactant-templated mesoporous metal oxides have been recently the focus of numerous studies.[1–6] In particular, a sol–gel-based dip-coating method for the rapid synthesis of continuous hexagonal and cubic mesoporous silica films has been developed.[3] The remarkable physico-chemical properties of these advanced materials (mesoporosity, unidimensional channels, preferable orientation with respect to the supporting substrate) are very promising for applications in membrane-based separation, catalysis and sensors. Here, we demonstrate a new potential of such films. Namely, we show that Ag nanoparticles can be chemically synthesised in the pores of mesoporous silica films deposited on glass substrates. To the best of our knowledge this development constitutes a novel application of mesoporous coatings which has, so far, not yet been described in the literature. However different applications of Ag nanoparticles have already initiated the development of numerous approaches for their elaboration, modification and incorporation into the surface layer of various materials *via* sol–gel processing,[7] melt-quenching,[8] electron beam lithography,[9] magnetron cosputtering,[10] ion-exchange,[11] ion-implantation,[12] or covalent linkage to self-assembled monolayers.[13]

Mesoporous silica films were synthesised using a precursor solution prepared in accordance with the published procedure[3] by addition of CTAB cationic surfactant [cetyltrimethylammonium bromide, $Me(CH_2)_{15}N^+Me_3Br^-$] to a silica sol with molar ratio 1 $Si(OC_2H_5)_4$: 22 C_2H_5OH : 5 H_2O : 0.004 HCl. The CTAB concentration in the final solution was 0.06 M, this reagent being essential for the formation of mesoporous silica films consisting of hexagonally packed one-dimensional channels adjacent to the air–film interface and shorter-range structural ordered channels in the core of the film.[3] The transparent and continuous films of *ca.* 100 nm thickness were deposited on Pyrex slides by dip-coating (10 cm min^{-1} withdrawal rate) at room temperature. Calcination in air at 400 °C (heating rate 1 °C min^{-1}) for 10 h resulted in films whose XRD patterns [Fig. 1(a) and (c)] are in accord with the formation of a mesophase with a $d(100)$ value of *ca.* 3.05 nm (assuming a hexagonal phase with a unit cell constant a = 3.52 nm).

For incorporation of silver, Pyrex slides covered with the calcined mesoporous silica films were contacted for 15 s with an aqueous solution of $[Ag(NH_3)_2]NO_3$ (prepared by dropwise addition of 28% NH_3(aq) to 0.05 M aqueous $AgNO_3$ leading to the formation of a clear colourless solution), rinsed thoroughly with deionised water and dried in a stream of nitrogen at room temperature. For the reduction of silver, the as-synthesised samples were treated in an H_2–N_2 (5% H_2) flow at different temperatures (heating rate 5 °C min^{-1}) for 1 h.

† On leave from the Institute of Surface Chemistry, National Academy of Sciences of Ukraine, Pr. Nauki 31, Kiev 252022, Ukraine.

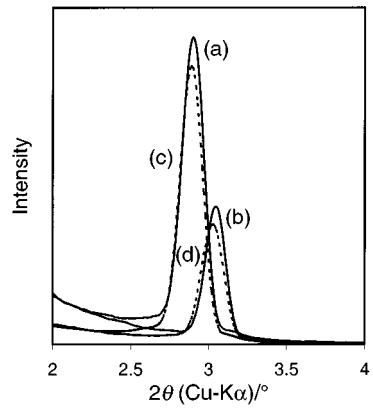

Fig. 1 XRD patterns of two Pyrex substrates with mesoporous silica films after calcination at 400 °C. Before/after [(a)/(b)] contact with an aqueous solution of $[Ag(NH_3)_2]$ NO_3 and subsequent reductive treatment at 400 °C. Before/after [(c)/(d)] contact with an ammoniacal solution and subsequent reductive treatment at 400 °C.

The presence of Ag^+ ions in the mesoporous film after contact with the solution of $[Ag(NH_3)_2]NO_3$ was detected by XPS. X-Ray photoelectron spectra of the as-synthesised samples reveal the presence of intense Ag $3d_{3/2}$ and Ag $3d_{5/2}$ peaks at 374.5 and 368.4 eV, respectively, characteristic for Ag^+.[14] It is reasonable to suggest the following ion-exchange mechanism of silver incorporation into the mesoporous film [eqn. (1)], as a consequence of deprotonation of hydroxy groups

$$Si–OH + Ag(NH_3)_2^+ = Si–OAg(NH_3)_2 + H^+ \quad (1)$$

at the pore surface.[6] Assuming a uniform distribution of Ag^+ ions in the film, their concentration was estimated from the integral intensities of Ag 3d (374.5–368.4 eV) and Si 2p (103.8 eV) envelopes and the atomic sensitivity factors of Ag and Si.[14,15] The experimental I_{Ag}/I_{Si} ratio was close to 3.3 which corresponds to an Ag/Si atomic ratio of 0.17 or to *ca.* 10 wt.% of silver in the mesoporous silica film.

The as-synthesised samples were colourless [Fig. 2(a)] while a yellowish colour appeared after reductive treatment at 100 °C and the intensity of the absorption peak at *ca.* 410–435 nm progressively increased up to 500 °C [Fig. 2(b)–(f)]. The presence of this peak is consistent with the surface plasmon resonance of Ag nanoparticles[8] which are formed upon reduction. The position and the width of the plasmon resonance peak can give information about the average diameter of the nanoparticles. The observed blue shift of the plasmon resonance peak from 435 to 410 nm and the decrease of its width [Fig. 2(b)–(f)] can be related to the increase of the average particle diameter when the reductive treatment continues.[8]

In the X-ray photoelectron spectrum of the sample reduced at 400 °C, the I_{Ag}/I_{Si} ratio was 1.2. This decrease in comparison with the value observed in the as-synthesised sample indicates aggregation of the Ag atoms upon reductive treatment.[16] The formation of the Ag nanoparticles commences with reduction of

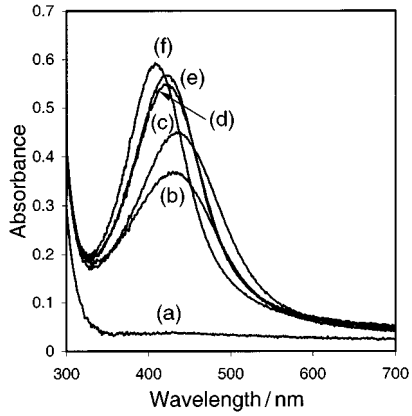

Fig. 2 UV–VIS spectra of a Pyrex slide covered with calcined mesoporous silica film after contacting with an aqueous solution of $[Ag(NH_3)_2]NO_3$ and drying in air (a), and subsequent reductive treatment at 100 °C (b), 200 °C (c), 300 °C (d), 400 °C (e) and 500 °C (f).

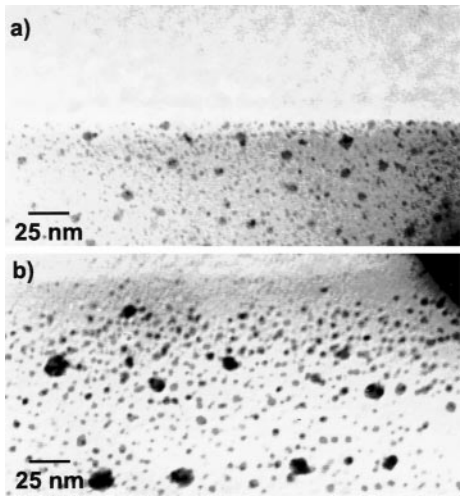

Fig. 3 Transmission electron micrographs of the calcined mesoporous silica film observed in cross-section view after one (a) and three (b) contacts with an aqueous solution of $[Ag(NH_3)_2]NO_3$ and subsequent reductive treatment at 400 °C.

Ag^+ to Ag^0 atoms which migrate within the silica mesoporous matrix.

The sample reduced at 400 °C was also characterised by transmission electron microscopy (TEM) [Fig. 3(a)]. Two types of Ag nanoparticles of different diameter can be distinguished. The first consists in nanoparticles of an almost spherical shape and of 3 nm average diameter while the second type is characterised by an average diameter of 6–7 nm. The existence of two sizes may be ascribed to the presence of defects, such as locally coalesced pores or walls. All particles are well separated from each other and are homogeneously and randomly distributed in the mesoporous silica matrix except in the vicinity of the external surface where ordering of Ag nanoparticles parallel to the surface is clearly seen. This ordering can reasonably be attributed to the preferable parallel orientation of the pore channels in the upper part of the film.[3] This supports the idea that the periodicity of the porous matrix can at least partially control the spatial arrangement of the nanoparticles.

As can be seen from Fig. 1(a) and (b), contact of the calcined sample with the $[Ag(NH_3)_2]NO_3$ solution followed by reductive treatment results in the partial shrinkage of the initial film (decrease of the 1-dH mesophase unit cell constant from *ca.* 3.52 to 3.35 nm). Also, a decrease of the peak intensity at constant width is observed which reveals a decrease of the volumic fraction of the ordered mesoporous domains. In order to ascertain if these effects are connected with the formation of Ag nanoparticles, a sample covered with the calcined film was treated according to the above procedure except that the ammoniacal solution did not contain $AgNO_3$ [Fig. 1(c) and (d)]. Comparing the positions and the relative intensities of the XRD peaks in Fig. 1 it can be concluded that similar modifications occurred for contact with both solutions. This means that both effects are connected with the chemical interaction of the mesoporous silica film with the ammoniacal solution rather than with the formation of Ag nanoparticles. Condensation of the silica framework promoted by ammonia has been reported previously.[4]

Since the organisation of the silica mesoporous film was maintained upon incorporation of Ag nanoparticles, it appeared possible to increase the silver concentration inside the pores. A progressive increase of the intensity of the surface plasmon resonance peak of Ag nanoparticles at 425 nm was indeed observed when the sample was successively contacted with $[Ag(NH_3)_2]NO_3$ solution and subjected to reductive treatment at 400 °C twice and three times.

The sample subjected to three consecutive ion-exchanges and reduction at 400 °C has been characterised by TEM [Fig. 3(b)]. As for the once only treated sample, two types of Ag nanoparticles are observed. Most are of almost spherical shape having an average diameter reaching 5 nm predominate while only a few larger Ag nanoparticles of an average diameter approaching 11 nm are present. The particles are well separated from each other and are homogeneously distributed in the mesoporous silica matrix. It appears that the particles diameter is not limited by the pore size.

In order to clarify whether the possibility of fabrication of Ag nanoparticles in mesoporous silica film relates to its unique structure, a silica film was dip-coated on a Pyrex substrate in the same manner from a precursor solution containing all reactants except CTAB. In this case of a non-mesoporous silica film no evidence of formation of Ag nanoparticles was observed.

Structural variability of the active site of Fe-only hydrogenase and its hydrogenated forms

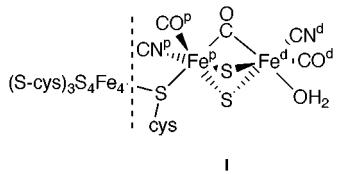
Ian Dance

School of Chemistry, University of New South Wales, Sydney 2052, Australia. E-mail: I.Dance@unsw.edu.au

Received (in Cambridge, UK) 12th May 1999, Accepted 21st July 1999

Density functional calculations show that the (cys-S)-(CO)(CN)FeS_2(μ-CO)Fe(CO)(CN) active site of the Fe-only hydrogenase from *Clostridium pasteurianum* is redox ambivalent and stereochemically flexible at the CO and S bridges, and at the Fe atoms, and with bound hydrogen: the fundamentals of probable mechanisms are revealed.

The hydrogenase enzymes, which catalyse the reaction $H_2 \rightleftharpoons 2H^+ + 2e^-$, occur as the FeNi-enzymes which mainly oxidise H_2,[1–3] and as the Fe-only enzymes which mainly reduce hydrons H^+.[1,4,5] Crystal structures of both types have been reported recently,[6–12] and reveal the presence of biologically unusual CO and CN ligands at the active sites. In particular, the active site of Fe-hydrogenase from *Clostridium pasteurianum* (CpI)[9] contains an Fe_2 site, **I**, in which two Fe atoms are each coordinated by one CO and one CN^- ligand, and bridged by two S atoms and one CO ligand, as shown in Fig. 1: **I** is linked by bridging cysteine to a cubanoid Fe_4S_4(S-cys)$_4$ cluster at the end of an evident electron transfer pathway. Assignment and differentiation of the CO and CN^- ligands in **I** is from the IR data[13] coupled with the occurrence of two hydrogen bonds from surrounding protein.[14]



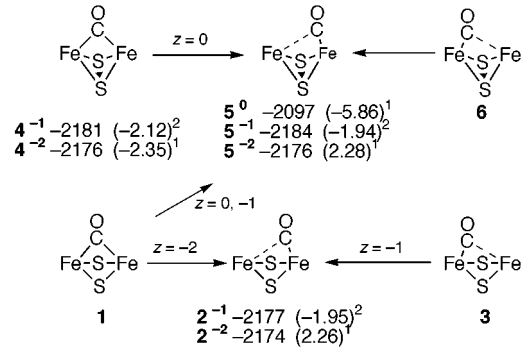
I

Fig. 1 The Fe_2 site **I** as revealed crystallographically for the Fe hydrogenase from *Clostridium pasteurianum*.[9] The Fe atoms and their ligands are labelled as proximal (Fe^p) and distal (Fe^d) to the Fe_4S_4 cluster.

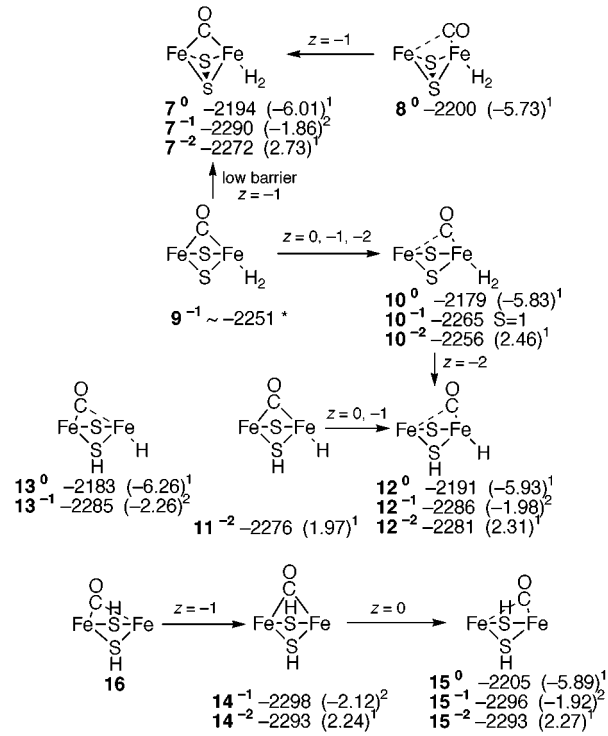
The Fe_2 site **I** is considered to control hydron reduction, the simplest of chemical reactions, but **I** is unprecedented in chemistry. I have investigated the key questions—redox states, stereochemical flexibility, electronic structure, binding of H^+, H and H_2, and mechanism—by density functional calculations† on $[(CH_3S)(CO)(CN)FeS_2(\mu\text{-}CO)Fe(CO)(CN)]^z$, **II**, in which CH_3S^- replaces the cysteine at Fe^p.

Molecule **II** has two low-energy stereochemical variables: (1) the bridging CO ligand can easily swing like a gate between Fe^p and Fe^d; (2) the two bridging S atoms can be separate (at *ca.* 3.3 Å, symbolised S/S), or bonded (S–S, at *ca.* 2.1 Å). Both of these variables are evident in the results shown in Scheme 1, which shows the energies and barrierless transformations of six isomers at three possible redox levels specified by the total charge *z*. The small energy associated with shifts of the CO bridge is evident in the energies of **4** and **5**: $E(\mathbf{4}^{-2}) = E(\mathbf{5}^{-2})$; $E(\mathbf{4}^{-1}) = E(\mathbf{5}^{-1}) + 3$ kcal mol^{-1}; $\mathbf{4}^0$ transforms to $\mathbf{5}^0$ without a barrier. The CO gate shifts left to right for both the S/S (**3** → **2**) and S–S (**6** → **5**) structures, because Fe^d would otherwise be only four-coordinate. Note the small energy differences between isomers with and without S–S bonding: $\mathbf{5}^{-1}$ with an S–S bond is within 7 kcal mol^{-1} of $\mathbf{2}^{-1}$, while for charge –2 the energy difference between **5** and **2** is only 2 kcal mol^{-1}. There are substantial stereochemical changes at Fe^p and Fe^d concomitant with changes in the bridge.

Similar results are found for a model with OH_2 bound to Fe^d. In particular, isomer **1–OH$_2$** as observed in the crystal[9] transforms to isomer **5–OH$_2$** with S–S bonding. There is good agreement between the other bond distances observed and calculated (in parentheses) for **5–OH$_2$**: Fe–Fe 2.62 (2.63); Fe–S



Scheme 1 Relationships between six isomers of $[(CH_3S)(CO)(CN)FeS_2$-(CO)Fe(CO)(CN)]^z, **II**. In these diagrams the CH_3S, terminal CO and CN ligands are omitted; superscripts are the charges *z*. The numbers listed for each minimum are the total energy (kcal mol^{-1}, relative to free atoms) and the (energy/eV)^{population} of the HOMO. Arrows identify barrierless exergonic transformations.



Scheme 2 Isomers of **II** plus two H atoms: diagrams are simplified and information summarised as for Scheme 1. **7**, **8**, **9** and **10** have Fe–H_2 coordination; **11**, **12** and **13** contain SH and Fe–H; **14**, **15** and **16** have $(SH)_2$. * Close-lying electronic states.

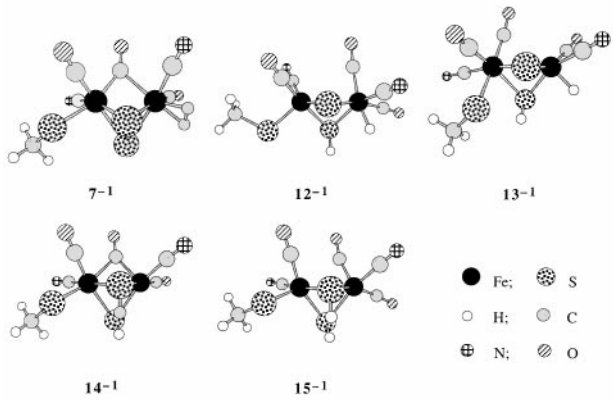


Fig. 2 Optimised structures for five isomers containing 2H, with similar energies but very different bonding patterns, and variations in the coordination stereochemistry at Fe.

2.32–2.34 (2.31–2.39); Fe–SCH_2 2.38 (2.38); Fe-(μ-CO) 2.04–2.10 (1.95–2.03) Å.

What about the redox levels? For $\mathbf{2}^{-1}$ with an $(S^{2-})_2$ bridge the formal oxidation states are $(Fe^{III})_2$ and the doubly occupied HOMO is at −1.95 eV. Reduction to $\mathbf{2}^{-2}$ raises the HOMO to positive energy (Scheme 1). In contrast, $\mathbf{5}^{-1}$ with an $(S_2)^{2-}$ bridge is formally $(Fe^{II})_2$ with the HOMO at −1.95 eV, and $\mathbf{5}^0$ (Fe^{II}, Fe^{III}) has its HOMO at a normal energy of −5.86 eV. In this context it is significant that the Fe_2 hydrogenase from *Desulfovibrio desulfuricans* has a dithiolate bridge $^-SCH_2CH_2CH_2S^-$,[12] and the NiFe hydrogenases have bis-cysteine bridges $(RS^-)_2$,[6–8,10,11] all of which involve redox levels like **5**, not **2**. Extra electron density in the bridging region of CpI[9] could be a dithiolate bridge,[18] or partial occurrence of a S_2^{2-} bridge.

What happens when the active site binds H^+ (at S), H (at S and/or Fe), or H_2 (at Fe)? Scheme 2 displays structures, energies and electronic states of isomers for the model **II** + 2H. Dihydrogen binds to Fe^d, although weakly. The least stable isomer is **9** (*i.e.* the crystal structure with H_2 bound at Fe^d in place of OH_2), which is stabilised by a CO gate shift right (to **10**). In its reduced state $\mathbf{9}^{-2}$ undergoes a mechanistically significant barrierless transfer of one H atom from H_2–Fe to form SH (→ $\mathbf{12}^{-2}$). There is a low barrier for the exergonic S–S bond formation in $\mathbf{9}^{-1}$ (→ $\mathbf{7}^{-1}$). A significant result is that chemically different isomers in Scheme 2 have very similar energies: examples are: $\mathbf{15}^{-1}$ −2296 [$(SH)_2$, CO-right], $\mathbf{14}^{-1}$ −2293 [$(SH)_2$, CO-sym], $\mathbf{7}^{-1}$ −2290 [S–S, Fe–H_2, CO-sym], $\mathbf{12}^{-1}$ −2286 [SH, Fe–H, CO-right], $\mathbf{13}^{-1}$ −2285 [SH, Fe–H, CO-left] kcal mol^{-1}. The calculated geometries of these are presented in Fig. 2, which also emphasises the stereochemical flexibility at Fe^p and Fe^d.

The main conclusion is that the unusual active site of this Fe-only hydrogenase possesses a relatively flat potential energy surface for geometrical change at Fe, CO, S, and bound H. The species in Scheme 2, and others not shown, can be combined in various ways as mechanisms to be calculated in further detail. It is likely that the mechanism involves the following fundamentals:

Received (in Cambridge, UK) 25th May 1999, Accepted 19th July 1999

A highly stable and active Pd–Fe carbon composite catalyst system for hydrodechlorination of chlrohydrocarbons is obtained by a novel modified carbothermal reduction method using ion exchange resins.

Chlorinated hydrocarbons are one of the most widespread and persistent toxic pollutants. The disposal of these organic wastes is a vital environmental issue. Among the several methods proposed for their destruction, catalytic hydrodechlorination (HDC) is of increasing interest because it excludes the formation of more toxic compounds such as dioxins and has a comparatively low reaction temperature.[1–3] Noble metals are the catalysts of choice for this reaction, which is carried out in either the liquid or the gas phase. Chlorobenzene is usually studied as a model compound for the HDC reaction since it represents the halogen species found in many organic wastes. Deactivation of the catalyst by HCl produced during the reaction is a commonly encountered problem.[4] The development of highly stable and active catalysts for this reaction remains as a challenging task. Recently, more attention has been focused on bimetallic catalysts over monometallic catalysts in order to improve longevity and activity.[5] However, it has been reported that the use of bimetallic catalysts instead of monometalic ones can result in a decrease of HDC activity.[6]

In this work we report for first time the preparation of Pd and Pd–Fe carbon composite catalysts by a novel modified carbothermal reduction (CTR) method, and their activity in chlorobenzene HDC. We have been developing a modified carbothermal reduction (CTR) method to prepare highly dispersed and thermally stable metal or metal compound-based carbon composite catalysts.[7] In the CTR process, first an organic ion exchange resin is exchanged with the required metal ions, followed by thermal treatment in the temperature range 500–800 °C. Since the metallic ions adsorbed on the resin are highly dispersed, the catalysts prepared by this method are highly dispersed.

In the preparation of the catalysts, first the required amounts of aqueous solutions of Pd and Fe ($PdCl_2$ and $Fe(NO_3)_3$ precursors used respectively) were added to a commercial chelate type of ion exchange resin (spherical granules) under constant stirring with a magnetic rod. The stirring was continued for about six hours then the solution was filtered and the metal exchanged resin dried at room temperature for about 12 h. The dried samples were then subjected to carbothermal reduction at 800 °C in an N_2 flow (300 ml min^{-1}) for 3 h. After CTR the catalysts retained their spherical shape but were reduced in size.

The catalyst tests were performed in a fixed bed microreactor at atmospheric pressure as described elsewhere.[8]

The physical characteristics of the catalysts along with their compositions are shown in Table 1, which shows that the surface areas and pore volumes are increased in the bimetallic catalysts in comparison with the corresponding monometallic catalysts. In monometallic catalysts pore blocking due to segregation during the CTR process might be the cause of the decrease in these values. The presence of Fe in the bimetallic catalysts may result in a reduction of the Pd segregation.

The XRD pattern of monometallic Pd/C shows peaks arising from metallic Pd. In bimetallic catalysts, the addition of more iron leads to the formation of Fe_3C. In the monometallic Fe/C catalyst, most of the iron exists as Fe_3C.

The HDC of chlorobenzene over mono- (Pd, Fe) and bimetallic (Pd–Fe/C) catalysts resulted in the formation of benzene as the only organic product. Percentage conversion values obtained after the catalysts reached steady state conditions at a reaction temperature of 150 °C are presented in Fig. 1. Note that the monometallic Pd/C catalyst shows very low activity at steady state conditions. The Fe/C catalyst does not show any activity in this reaction. In the bimetallic Pd–Fe/C catalysts the addition of Fe to Pd leads to a substantial increase in the activity, even though Fe is inactive for this reaction. The increased activity of the bimetallic catalysts relative to the monometallic catalysts is in contrast to earlier findings, where a decrease in activity in the cases of bimetallic Pd–Sn, Pd–Rh and Pd–Fe catalysts due to the second metal diluting the catalyst surface was reported.[6,9]

Preparation by the CTR method may result in a different morphology of the catalyst surface. SEM–EDX images of Pd and Fe for a cross-sectional view of a cylindrical granule of the bimetallic 2Pd–2Fe/C catalyst are shown in Fig. 2. It can be seen from Fig. 2(a) that the majority of the Pd is present on the surface whereas most of the iron [Fig. 2(b)] is dispersed inside the catalyst particle. During the CTR the Pd might be

Table 1 Physical characteristics of the mono- and bimetallic Pd–Fe carbon composite catalysts

Catalyst code	Fe content/ g g_{cat}^{-1}	Pd content/ g g_{cat}^{-1}	S_{BET}/m^2 g^{-1}	V_p/ml g_{cat}^{-1}	XRD Peak
2Pd	0	0.069	140	0.071	Fe, Fe_3C
4Pd	0	0.11	209	0.149	Pd
2Pd2Fe	0.036	0.068	331	0.331	Pd
2Pd4Fe	0.079	0.06	333	0.334	Pd
2Pd8Fe	0.111	0.054	370	0.377	Pd, Fe, Fe_3C
2Fe	0.29	0	200	0.327	Pd, Fe, Fe_3C

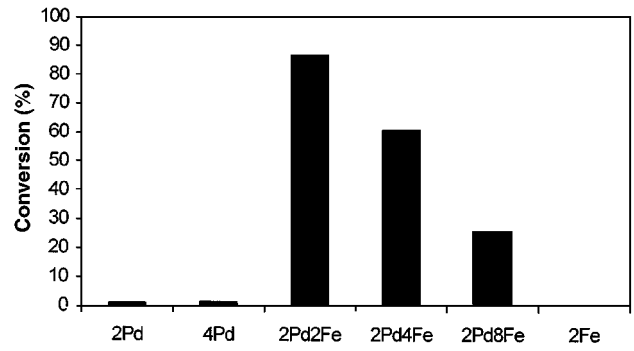

Fig. 1 Hydrodechlorination of chlorobenzene on monometallic Pd and Fe and bimetallic Pd–Fe carbon composite catalysts (reaction temperature: 150 °C; space velocity: 7680 h^{-1}).

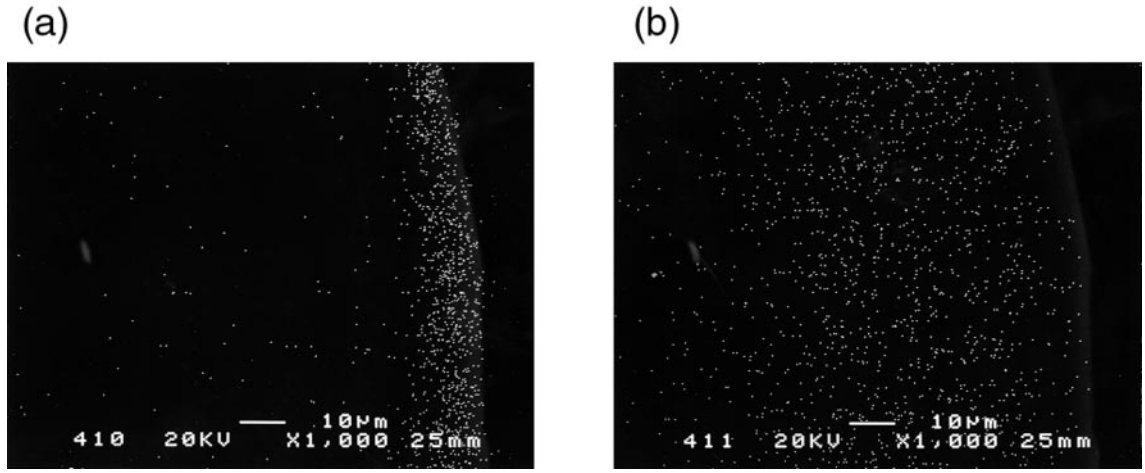

Fig. 2 SEM-EDX images of a cross-sectional view of a spherical granule of the 2Pd–2Fe/C catalyst [(a): EDX of Pd; (b): EDX of Fe].

transported to the surface. Similar behavior has been observed for other bimetallic catalysts.

Wunder and Phillips,[10] in their studies on Pd–Fe supported on graphite, proposed that the iron exists on the surface and the Pd in the bulk. In conventional methods of preparation the iron is present initially as hematite which is later reduced to magnetite and metallic iron during the catalyst runs. During this process most of the iron migrates to the surface.

The TEM data show that in the case of the monometallic Pd/C catalyst the Pd forms large clusters (particle size about 56 nm). The low values of BET surface area and pore volume also suggest the aggregation of Pd. TEM of the bimetallic 2Pd2Fe/C catalyst depicts highly dispersed small particles (about 14 nm) of the bimetallic ensembles. The surface migration of Pd and the formation of small Pd–Fe bimetallic particles may be responsible for the substantial increase in activity in the bimetallic catalysts.

Upon the addition of more Fe to Pd a decrease in activity in the conversion of chlorobenzene was observed. In the high Fe containing catalyst 2Pd–8Fe/C it also observed from SEM–EDX of Pd and Fe that the Pd is present on the surface, similar to other catalysts, but the density of Fe in the catalyst is high, diluting the Pd. Another reason for the low activity reported earlier is that the less active metal Fe, which is present in large amounts, migrates to the surface in the HCl atmosphere generated during the reaction.[6]

Comparisons were made of the highly active 2Pd–2Fe/C catalyst with a catalyst prepared by a conventional impregnation method, with a similar composition, on carbon. The results show that the bimetallic catalyst prepared by modified CTR method possesses higher activity (87% conversion) than the catalyst prepared by the the conventional method (53% conversion).

The advantage of the CTR method over conventional methods of preparation for carbon based catalysts is that the metal ions are well dispersed on the ion exchange resin and this leads to the formation of bimetallic ensembles from a single step, whereas in conventional methods there is a need for separate treatments to obtain the bimetallic ensembles.

This method of preparation can be applied to the preparation of a variety of mono- and bimetallic carbon composite catalysts with varying metal contents.

Time on stream analysis results for 2Pd/C and 2Pd–2Fe/C catalysts, at a reaction temperature of 200 °C, are shown in Fig. 3. It can be seen that the activity of monometallic 2Pd/C steadily decreased with time, whereas the bimetallic 2Pd–2Fe/C catalyst exhibited fairly constant conversion throughout the period of study. The bimetallic catalysts prepared by the modified CTR method revealed high activity with higher stability in the HDC reaction.

Synthesis and crystal structure of $Li[\{Ca_7(\mu_3\text{-}OH)_8I_6(thf)_{12}\}_2(\mu\text{-}I)]\cdot 3THF$, a unique H-bound dimer of a Ca_7-cluster on the way to sol–gels

Received (in Cambridge, UK) 8th June 1999, Accepted 23rd July 1999

In analogy to transition metal clusters, a mixed ligand Ca-cluster, consisting of two Ca_7-units linked *via* H-bonds, has been synthesised and structurally characterised, its thermal decomposition leading to the formation of sol–gels is also described.

In recent years, alkaline earth metal compounds have been increasingly studied owing to their application in different research fields, especially in the search for new precursors for superconductors and complex metal oxides. In this context, inorganic polymers of different dimensionality have been structurally characterised.[1] Furthermore, the synthesis of alkaline earth metal alkoxides has led to higher aggregated cage compounds such as the dimer $[IBa(BHT)(THF)_3]_2\cdot 2THF$,[2] (BHT = $OC_6H_2Bu^t_2$-2,6-Me-4), the cubane like compounds $[Ba(\mu_3\text{-}OBu^t)(OBu^t)(Bu^tOH)_2]_4$,[3] and $[Mg_4(\mu_3\text{-}OMe)_4(OMe)_4(MeOH)_8]$,[4] the large cluster $[Ca_9(OCH_2CH_2OMe)_{18}(HOCH_2CH_2OMe)_2]$[5] or the CO_3^{2-}-insertion product $[Mg_9(\mu_5\text{-}CO_3)(O_2COMe)_8(\mu_3\text{-}OMe)_8(MeOH)_{13}]\cdot MeOH\cdot C_7H_8$.[6] Anionic N-donor ligands also yield clusters such as the THF-solvated hexamer $[(THF)MgNPh]_6$[7] or the solvent free cubane $[BaNP(NMe_2)_2NP(NMe_2)_2NSiMe_3]_4$.[8] The presence of alkoxy- or N-donor-groups and the resulting possibility of oxolation, that is the formation of oxygen bridges by hydrolysis, makes them potential precursors for sol–gel synthesis.

This work reports on the synthesis of a Ca_7-cluster forming dimers by hydrogen bonding [eqn. (1)].

$$CaI_2 + (Bu^nLi)_{1.1}(LiOH) \xrightarrow{THF,\ -(Bu^nLi)_m(LiI)_n} Li[\{Ca_7(\mu_3\text{-}OH)_8I_6(thf)_{12}\}_2(\mu\text{-}I)]\cdot 3THF \quad \mathbf{1} \quad (1)$$

The reaction of CaI_2 in THF with a hexane solution containing Bu^nLi and LiOH yields the ionic cage compound $Li[\{Ca_7(\mu_3\text{-}OH)_8I_6(THF)_{12}\}_2(\mu\text{-}I)]\cdot 3THF$ **1**.† Colorless prismatic crystals suitable for single crystal analysis which crystallise in the trigonal space group $R(\bar{3})$ (No. 148) were obtained by cooling a THF solution to –20 °C.‡ Attempts to synthesise **1** from the reaction of CaI_2 with LiOH failed probably owing to the stability and low solubility of the latter in THF. However, it has been shown that some mixed-anion compounds $(RLi)_m(XLi)_n$ (R = alkyl; X = halide, hydroxide or alkoxide) are synthetically useful reagents owing to their enhanced reactivity compared to the pure components RLi or XLi.[9] In the synthesis of **1**, partial hydrolysis of a Bu^nLi solution obviously leads to a soluble mixed-anion compound which was titrated to be 1.1 M in Bu^nLi and 1 M in LiOH. With this reagent, the synthesis of **1** is reproducible with yields of up to 87%. Addition of further equivalents of $(Bu^nLi)_m(LiOH)_n$, leads to the formation of sol–gels, fewer equivalents lower the yield of **1**.

This cluster compound is synthesised in a similar way as for transition metal clusters. For the latter, a reaction scheme includes, for instance, a metal chloride as metal source, a chalcogenide reagent such as $Se(SiMe_3)_2$ and a ligand compound to protect the outer cluster sphere, the driving force being the formation of a stable, volatile side product $SiMe_3Cl$. For **1**, CaI_2 is used as the metal source with $(Bu^nLi)_m(LiOH)_n$ as the reagent to form LiI and also as bridging ligand source. LiI is partially included in the structure of **1**. The ligands which complete the outer coordination sphere are provided by THF and part of the iodide. Unreacted Bu^nLi and LiI remain in solution, mainly forming the species $(Bu^nLi)_1(LiI)_1$ as determined by titration.

The molecule consists of two neutral Ca_7-clusters of composition $[Ca_7(\mu_3\text{-}OH)_8I_6(THF)_{12}]$ **1a**, linked together by μ-bridging iodide ions which form hydrogen bonds to an OH-group of each cluster unit (Fig. 1). To the best of the author's knowledge, this structural feature is unique for an alkaline earth metal cluster compound with mixed ligands.

The structure of the Ca_7-subunits can be described as two $(Ca–O)_4$ heterocubanes sharing a vertex or as a body-centered Ca-icosahedron with the outer six-membered Ca-ring missing. An alternative description is that of two Ca_4-tetrahedra sharing a vertex, each of the eight triangular faces of the two tetrahedra being μ_3-bridged by a hydroxy anion. The central calcium atom

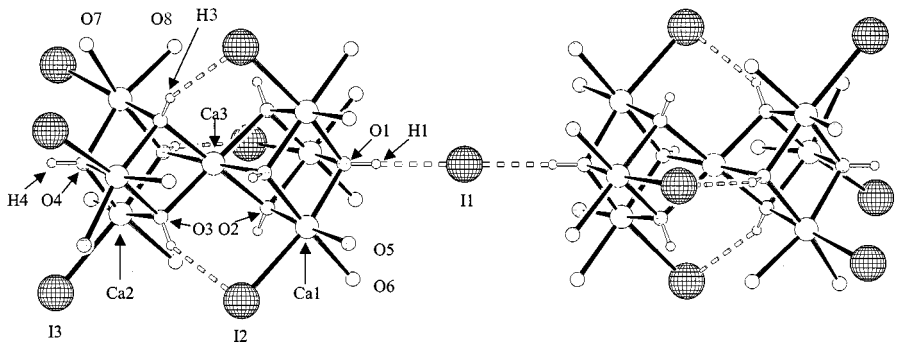

Fig. 1 Crystal structure of **1** along the horizontal C_3 axis passing through Ca3, O1, H1 and I1. Selected bond lengths (Å) and angles (°): Ca1–I2 3.151(1), Ca2–I3 3.147(1), Ca1–O2 2.312(5), Ca1–O1 2.354(4), Ca1–O5 2.413(6), Ca1–O6 2.411(6), Ca1–Ca3 3.557(2), Ca1–Ca1 3.592(3), Ca2–O3 2.322(5), Ca2–O4 2.346(4), Ca2–O8 2.425(7), Ca2–O7 2.438(7), Ca2–Ca3 3.553(3), Ca2–Ca2 3.595(3), Ca3–O3 2.365(5), Ca3–O2 2.388(5), H1–I1 2.68(2), H3–I2 2.87(7); I2–Ca1–Ca3 87.17(5), I2–Ca1–Ca1 131.40(5)–133.93(5), I3–Ca2–Ca3 145.59(6), I3–Ca2–Ca2 100.69(6)–138.28(4), Ca3–Ca1–Ca1 59.68(3), Ca1–Ca1–Ca1 (Ca2–Ca2–Ca2) 60.0, Ca3–Ca2–Ca2 59.61(3), Ca2–Ca3–Ca2 60.77(6), Ca1–Ca3–Ca2 178.87(4), O1–H1–I1 180, O3–H3–I2 149.12.

Ca3 is placed on a three fold axis (0, 0, *z*; *c*) and features an octahedral coordination sphere of six OH-groups as next neighbours. At a longer distance range, it is surrounded by six Ca-atoms, Ca1, Ca2 and their symmetry equivalents, in form of a trigonal antiprism. The Ca–Ca-distances within the tetrahedra lie between 3.553(3) and 3.594(3) Å. Ca1 and Ca2 of the Ca_7-cluster also reach coordination number six, their coordination spheres being completed by three terminal ligands, two THF molecules and one iodide anion per calcium. The Ca–I distances are 3.154(2) Å (Ca1-I2) and 3.147(2) Å (Ca2-I3) and thus only slightly longer than in $CaI_2(THF)_4$ [Ca–I 3.106(2) Å] or ICa(clox)$(THF)_4$ [Ca–I 3.108(3) Å; clox = $OCPh_2CH_2C_6H_4Cl$-4],[2] and correspond to the sum of the Shannon ionic radii [Ca^{2+}(coord. 6) 1.00 Å, I^- 2.20 Å].[10] Ca–O bond lengths to the terminally bound THF-molecules in the range of 2.414(6) to 2.433(7) Å are observed, corresponding to literature data [Ca–O(THF) 2.33–2.454 Å].[2] The Ca–O(OH) distances can be divided into the shorter Ca–O bond lengths Ca1–O and Ca2–O and their symmetry equivalents [2.312(5)–2.354(4) Å] and the longer Ca–O bond lengths of the central Ca3-atom to the hydroxy groups [2.366(5)–2.393(5) Å]. They correspond, on average, to the Shannon ionic radii sum (2.35 Å). The hydroxy groups act as μ_3-ligands.

The threefold axis through Ca3 also passes through O4 and O1 (0, 0, *z*; *c*) and the μ-iodide ligand I1 which, additionally, is placed on an inversion center (0, 0, 0; *a*). Hydrogen bonding occurs along this threefold axis between the two Ca_7-clusters [I1–O1 3.682(6) Å, I1–H1 2.70(7) Å; H–I–H 180° (due to symmetry).] Other H-bonds are formed within the Ca_7-cluster between I2 and H3 [2.89(6) Å], slightly longer than that above as is also the case for the corresponding I2–O3 distance [3.771(6) Å] and the O3–H3–I2 angle is bent to 149.26°. H–I-hydrogen bonds described in the literature are of the same order of magnitude, such as in [*trans*-$(py)_4Mg(OH_2)_2]I_2\cdot$2py with I–O(H) 3.438(7)–3.669(9) Å (2.4–2.7 Å),[11] or in [$Mg(HOMe)_6]I_2\cdot$2tmeda with I–O 3.377(5)-4.209(5) Å and [(tmeda)$SrI_2(HOMe)_3]\cdot$0.5tmeda with I–O(H) 3.516(9)–3.555(7) Å (2.5–3.0 Å).[12] The IR spectrum of **1** in Nujol on CsI plates shows a sharp band for free OH at 3640 cm^{-1} (O4–H4, O2–H2), along with broader bands at 3550, 3300 and 3200 cm^{-1}, indicating hydrogen bonding.

μ_3-Capped Ca_3-triangles as in **1** can be found in the alkoxide aggregate $[Ca_9(OCH_2CH_2OMe)_{18}(HOCH_2CH_2OMe)_2]$[5] in which the coplanar Ca-atoms occupy octahedral holes between two close-packed oxygen layers. A similar tetrahedral feature as in the building units for **1** was found in [Ba(μ$_3$-OBu^t)(OBu^t)(Bu^{t}OH)$_2$]$_4$,[3] where the tetrahedron is formed by Ba-atoms, and the triangle capping OH-groups are formally replaced by OBu^t. The same ligand (OBu^t and Bu^{t}OH) acts as a terminal ligand on the alkaline earth metal, whereas in **1**, different ligands are found on almost every position. Another tetrahedrally built compound is the solvent free [{BaNP(NMe$_2$)$_2$NP(NMe$_2$)$_2$NSiMe$_3$}$_4$] which consists of a RN-capped Ba-tetrahedron and forms, on hydrolysis, a white gel of composition $Ba(OH)_2\cdot xH_2O$. **1** is soluble in THF or other solvents and may also act as a precursor for sol–gels. The capping hydroxy groups can undergo elimination of water with the hydroxy groups of neighbouring cluster molecules, forming oxo bridges between the clusters. This oxolation leads to gels in the classical way. Isolated and washed crystals of **1** decompose in THF after heating to form a white gel. Furthermore, the crystals lose solvent after a short period of time, and thermal treatment (DTA and thermogravimetry) shows the elimination of all the THF at 70 °C followed by water at 110 °C. Other polymerisation mechanisms are envisageable, such as elimination of terminally bound THF and saturation of the thus empty coordination site on calcium by a terminal iodide ligand of a neighbouring molecule to yield a μ-I-bridge, or elimination of iodide by addition of an excess of Bu^{n}Li. Further investigations on the use of **1** as a sol–gel precursor are under way.

This work was financed by the Swiss National Foundation and the University of Geneva. I am grateful to Professor A. F. Williams for his support, Dr H. Goesmann, University of Karlsruhe, Germany and Dr G. Bernardinelli, University of Geneva, for reflection data collection, H. Lartigue for DTA and thermogravimetric measurements, E. Rivara-Minten for ^{7}Li-NMR and M. Martin, University of Geneva, for ICP-MS measurements.

Notes and references

† CaI_2 was dried under vacuum at 200 °C and the reaction carried out under nitrogen atmosphere. The solution of (Bu^{n}Li)$_m$(LiOH)$_n$ in hexane was obtained by partial hydrolysis of a commercially available, upconcentrated 2.1 M solution of Bu^{n}Li in hexane. A Gilman's titration of the solution revealed concentrations of 1.1 M in Bu^{n}Li and 1 M in LiOH.

0.45 g (1.53 mmol) of CaI_2 were dissolved in 20 ml freshly dried and distilled THF to give a light yellow solution. At room temperature, 1.4 ml of a hexane solution containing 1.1 M Bu^{n}Li (1.54 mmol) and 1 M LiOH (1.4 mmol) was added dropwise to the stirred solution. After two days at room temperature, the colorless solution was cooled to −25 °C to give colorless crystals of **1** within 24 h. Yield: 87% (for CaI_2). Satisfactory analysis for Ca, I, C and H. The presence of Li in **1** was determined by ICP-MS and ^{7}Li NMR, giving a signal at δ 1.83 in d_8-THF (LiCl in D_2O as standard). IR (CsI, Nujol) (cm^{-1}): 3640m, 3550s, 3300s, 3200s, 2900vs (Nujol), 1500vs (Nujol), 1370s (Nujol), 1340s (Nujol), 1290s, 1240s, 1180vs, 1050vs, 910vs, 665vs, 575s, 360s, 280m, 240m.

‡ *Single crystal data* for **1**: $C_{112}H_{240}O_{44}LiCa_{14}I_{13}$, M = 4508.90, rhombohedral, space group $R\bar{3}$ (No. 148), a = 21.592(3), c = 36.839(7) Å, V = 14874(4) Å^3, Z = 6, D_c = 1.521 Mg m^{-3}, $F(000)$ = 6723, T = 200 K, λ = 0.71073 Å, μ(Mo-Kα) = 2.450 mm^{-1}, 4.5 < 2θ < 53.86°, 7166 reflections of which 7166 unique and 7161 observed, 296 parameters refined, GOF (on F^2) = 1.026, $R1$ = 0.065, $wR2$ = 0.1677 for $I > 2\sigma(I)$ and $R1$ = 0.1190, $wR2$ = 0.2061 for all data.

Crystals of **1** were measured on an ENRAF-NONIUS four-circle diffractometer at 200 K. The data collection was performed on a crystal of 0.2 × 0.15 × 0.08 mm and an absorption correction was applied by analytical integration. The structure was solved with direct methods and refined by full matrix least squares on F^2 with the SHELX-97 package.[13] Slight disorder was observed for the THF molecules bound to Ca, while severe disorder was observed for the free solvent. All heavy atoms of the cluster could be refined anisotropically. Owing to the presence of heavy atoms such as iodine, the positions of the hydrogen atoms could not be determined and were thus calculated. The Li cation could not be localised in the single crystal structure due to the fact that it is either placed on a special position with a site occupation factor of 1/3 or else disordered, probably coordinated to some free THF. However, the presence of lithium was established by inductively coupled plasma mass spectrometry analysis (ICP-MS Hewlett Packard 4500) of isolated and washed single crystals which were dissolved in dilute HNO_3. CCDC 182/1345. See http://www.rsc.org/suppdata/cc/1999/1659/ for crystallographic files in .cif format.

Received (in Cambridge, UK) 26th May 1999, Accepted 19th July 1999

Novel subphthalocyanines with long thioalkyl chains exhibit hexagonal columnar mesophases at room temperature; their inherent first hyperpolarizability values (β) measured by hyper-Rayleigh scattering (HRS) with fluorescence suppression are (189 ± 30) × 10^{-30} esu at 1300 nm.

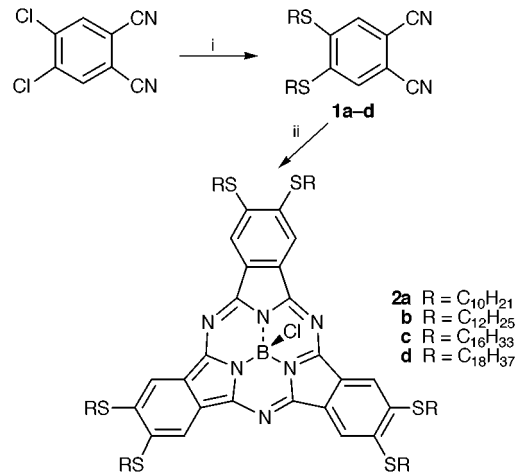
The unique supramolecular architectures of the columnar mesophases[1] have many potential applications in molecular devices.[2] Among columnar liquid crystals, bowl-shaped liquid crystals[3] have attracted considerable attention as potential ferroelectric and/or second-order nonlinear optical (NLO) materials because of their polar organization in the liquid crystalline phases.

Subphthalocyanines (SubPcs) are cone-shaped macrocycles composed of three isoindoline units with a boron inside.[4] They have been used as intermediates for the synthesis of unsymmetrical phthalocyanine (Pc) derivatives.[5] Furthermore, their unique 14 electron π-conjugated system with C_3 symmetry allows them to exhibit large molecular hyperpolarizabilities, mainly due to octupolar contributions.[6]

In our efforts to discover new columnar liquid crystals,[7] we became interested in SubPcs as potential columnar mesogens with NLO properties. Although liquid crystalline Pcs have been studied extensively,[8] there is no report on SubPc derivatives exhibiting liquid crystalline phases. Herein we report syntheses and mesogenic behavior of SubPcs containing long thioalkyl chains. Since molecular hyperpolarizabilities of SubPcs have been overestimated due to their strong fluorescence,[6a] here we also report their hyperpolarizabilities measured by hyper-Rayleigh scattering (HRS) using flurorescence suppression techniques.[9]

Subphthalocyanines containing thioalkyl groups **2a**–**d** were synthesized in two steps as shown in Scheme 1. Reaction of 1,2-dichloro-4,5-dicyanobenzene with alkanethiols ($C_nH_{2n+1}SH$; n = 10, 12, 16 and 18) yields 4,5-bis(alkylthio)phthalonitrile, cyclotrimerization of which in the presence of BCl_3 produces the desired products.‡

SubPcs **2a**–**d** show enantiotropic liquid crystalline behavior as revealed by differential scanning calorimetry (DSC), polarizing optical microscopy, and X-ray diffraction. The phase behavior of these compounds is summarized in Table 1. Compounds **2a** (n = 10) and **2b** (n = 12) exhibit mesomorphic behavior at room temperature. Upon heating, the transition from mesophase to isotropic liquid occurs at 90.9 and 86.1 °C for **2a** and **2b**, respectively. For these compounds, melting or crystallization peaks are not observed in the DSC scan, even down to −40 °C. As usual, the melting temperature increases while the clearing point decreases with increasing side chain length. For example, **2c** (n = 16) shows a phase transition from crystalline to mesophase near room temperature and transforms into an isotropic liquid at 75 °C. Furthermore, **2d** (n = 18) is a solid at room temperature and melts at 43 °C to form a mesophase which turns into an isotropic liquid phase at 70 °C. These compounds have good thermal stability as they decompose above 250 °C.



Scheme 1 *Reagents and conditions*: i, RSH, K_2CO_3, DMSO; ii, BCl_3, 1-chloronaphthalene.

Table 1 Optical and thermal properties of the compounds **2a**–**d**[a]

	T/°C (ΔH/J g^{-1})	
Compound	Heating	Cooling
2a (n = 10)	D_{hd} 90.9 (0.29) I	I 79.6 (0.28) D_{hd}
2b (n = 12)	D_{hd} 86.1 (0.68) I	I 70.5 (1.31) D_{hd}
2c (n = 16)	K 27.2 (13.42) D_{hd} 75.3 (0.35) I	I 67.6 (0.61) D_{hd} 20.9 (10.36) K
2d (n = 18)	K 43.4 (21.80) D_{hd} 70[b] I	I 63[b] D_{hd} 36.6 (0.53) K 33.6 (9.56) K′

[a] Transition temperatures and enthalpies of transition were determined by DSC (scan rate 10 °C min^{-1}). K, K′ = crystalline phase; D_{hd} = hexagonal columnar phase; I = isotropic phase. [b] Transition observed only by microscopy.

† Experimental and spectral data for **2a**–**d** are available from the RSC web site, see http://www.rsc.org/suppdata/cc/1999/1661/

In polarizing optical microscopy, **2a**–**d** in mesophases exhibit pseudo-focal conic textures, which are characteristic of columnar mesophases. Except for **2d**, these textures are maintained at room temperature, demonstrating the stability of the liquid crystalline phases at room temperature. To obtain information on the structures of **2a**–**d** in the mesophases, X-ray diffraction studies were carried out using synchrotron radiation. The X-ray pattern (Fig. 1) of the mesophase of **2c** at room temperature shows an intense peak and two weak peaks in the small-angle region with reciprocal Bragg spacings in a ratio $1:\sqrt{3}:2$. These peaks were assigned to the (100), (110) and (200) reflections of a hexagonal arrangement with a lattice constant a = 33.02 Å. In the wide-angle region a broad halo at 4.43 Å is observed, which is related to the liquid-like correlations between the molten aliphatic chains. Similar X-ray diffraction patterns are observed for other compounds in their mesophases. It is not clear how the cone-shaped molecules are arranged in the mesophase. However, as previously suggested in bowl-shaped mesogens, the cones may be stacked in a head-to-tail fashion to form a polar column which in turn forms a hexagonal array with random polarity.

We measured the molecular first hyperpolarizabilities (β) of **2a**–**c** using HRS techniques.[10] Regardless of the alkyl chain length these compounds have a strong absorption band at ~602 nm and an intense emission at ~612 nm. Since they are highly fluorescent, high-frequency demodulation of multiphoton fluorescence was used to retrieve their fluorescence-free first hyperpolarizability values. A detailed description of the experimental set-up is given elsewhere.[9a] The measurements were performed in $CHCl_3$ solution. Disperse Red 1 was used as the external reference with $\beta = 54 \times 10^{-30}$ esu at 1300 nm.[9c] The inherent fluorescence-free first hyperpolarizability values for **2a**–**c** are the same within the experimental uncertainties: $(189 \pm 30) \times 10^{-30}$ esu at 1300 nm. Using a three-level model,[11] the dispersion-free β value (β_0) was calculated to be $(21 \pm 3) \times 10^{-30}$ esu. These results are in good agreement with the recently reported β value of 40×10^{-30} esu at 1460 nm and β_0 value of 10×10^{-30} esu for a similar SubPc compound.[6b]

In summary, we have synthesized liquid crystalline SubPcs exhibiting hexagonal columnar mesophases at room temperature. Since they are highly fluorescent, their inherent first hyperpolarizability values were measured by HRS using fluorescence suppression techniques. In the mesophases, the cone-shaped molecules appear to be stacked in a head-to-tail fashion to form a polar column which in turn forms a hexagonal array with random polarity. Despite the nonlinearity/transparency trade-off that appears better for dipolar that for octupolar chromophores,[12] the incorporation of dipolar chromophores into stable macroscopic ensembles has been hampered by strong antiparallel dipolar interactions, leading to centrosymmetric arrangements with zero bulk susceptibility. The polar organization of these SubPcs in the liquid crystalline phase will results in a thermodynamically stable non-zero second order susceptibility. The next challenging goal is to align all the columns with the same polarity to achieve large ferroelectricity and second order bulk susceptibility. We are currently working along this line.

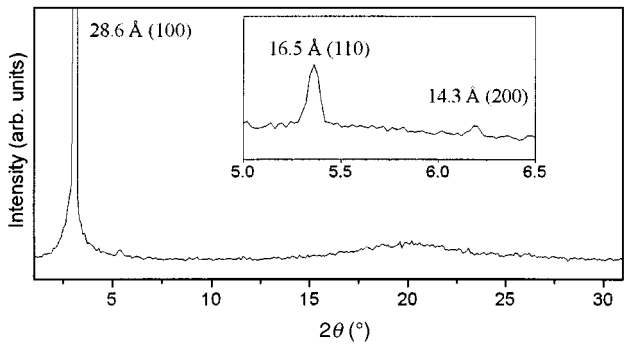


Fig. 1 X-Ray diffraction pattern of **2c** taken at room temperature.

This work was supported by the Creative Research Initiative Program of the Korean Ministry of Science and Technology and by research grants from the Fund for Scientific Research - Flanders (FWO-V) (G.0338.98 and G.0407.98), the Belgian government (IUAP P4/11, 'Supramolecular Chemistry and Supramolecular Catalysis'), the University of Leuven (GOA/95/01). G. O. is a Research Assistant and K. C. is a Senior Research Associate of the FWO-V. The X-ray measurements were performed at the Pohang Accelerator Laboratory (Beamline 3C2).

Notes and references

‡ All the compounds have been fully characterized by ^{1}H NMR, UV-VIS, IR and mass spectrometry and gave satisfactory elemental analyses. *Selected data* for **2a**: Compound **1a** (2.13 g, 4.50 mmol) was dissolved in 1-chloronaphthalene (4 ml) under Ar. After cooling of the solution in an ice bath a solution of BCl_3 (1.5 ml, 1.5 mmol, 1 M solution in *n*-heptane) was added. The mixture was stirred at 0 °C for 10 min and then heated to 100 °C for 4 h. After cooling to room temperature, the mixture was diluted with acetone. The crude product was isolated by filtration and purified by column chromatography on silica gel using CH_2Cl_2 as eluent (0.30 g, 14%); δ_H($CDCl_3$, 300 MHz) 0.88 (t, 18H), 1.59 (m, 84H), 1.89 (m, 12H), 3.31 (m, 12H), 8.51 (s, 6H); δ_C($CDCl_3$, 75 MHz) 14.52, 23.09, 28.86, 29.56, 29.72, 29.74, 29.96, 30.01, 32.31, 34.08, 119.91, 128.69, 141.23, 149.53; ν_{max}(KBr)/cm^{-1} 2955, 2924, 2853, 2360, 2342, 1597, 1462, 1419, 1368, 1080, 979; λ_{max}($CHCl_3$)/nm (log ε) 602 (5.00), 558 (4.50), 415 (4.53), 389 (4.52), 306 (4.85); Fluorescence (excitation was at 360 nm, $CHCl_3$): λ_{max}/nm 613, 504; *m*/*z* (FAB-MS) 1463 $[M+H]^+$ (Calc. for $C_{84}H_{132}BClN_6S_6$: C, 68.88; H, 9.08; N, 5.74. Found: C, 68.48; H, 9.18; N, 5.48%). Compounds **2b**–**d** were synthesized by the same method as **2a**.

Highly regio- and enantio-selective rhodium-catalysed asymmetric hydroformylation without organic solvents

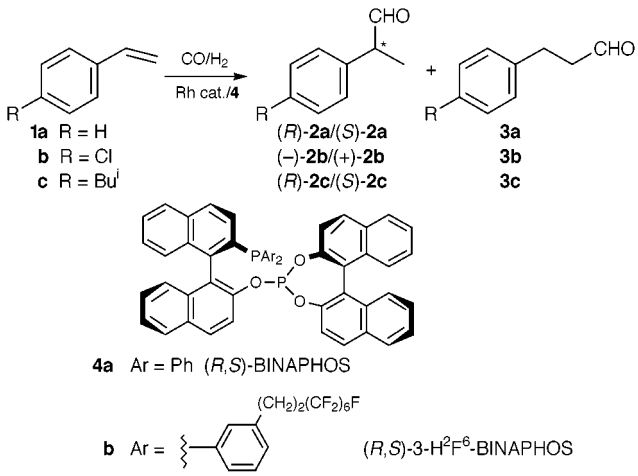
Giancarlo Franciò† and Walter Leitner*

Max-Planck-Institut für Kohlenforschung, Kaiser-Wilhelm-Platz 1, 45470 Mülheim an der Ruhr, Germany. E-mail: leitner@mpi-muelheim.mpg.de

Received (in Liverpool, UK) 25th May 1999, Accepted 15th July 1999

High enantioselectivity and unprecedented high regioselectivity without the need for hazardous organic solvents are achieved in rhodium-catalysed asymmetric hydroformylation with the perfluoroalkyl-substituted ligand (*R,S*)-3-H^{2}F^6-BINAPHOS, whereby the substitution pattern of the ligand is crucial for its successful use in compressed carbon dioxide and for the increased regioselectivity.

Asymmetric hydroformylation using chiral transition metal catalysts is an efficient and well established strategy for the synthesis of functionalised non-racemic organic compounds, providing for example viable routes to important anti-inflammatory drugs starting from simple vinyl arenes.[1] The chiral phosphine/phosphite ligand (*R,S*)-BINAPHOS **4a** allows rhodium-catalysed asymmetric hydroformylation of vinyl arenes **1a**–**c** with outstanding levels of enantiocontrol (Scheme 1).[2] However, the regioselectivity towards the chiral branched aldehydes **2a**–**c** is less satisfactory (88% for **2a**) even under carefully optimised conditions, leading to considerable amounts of linear aldehydes **3a**–**c** as undesired by-products. Furthermore, the established protocols require the use of ecologically and toxicologically hazardous organic solvents, especially benzene, representing another major drawback in light of the potential practical application of the methodology.

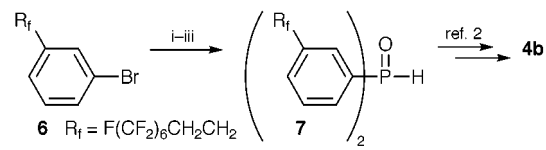


Scheme 1

We now report that the use of the new perfluoroalkyl-substituted derivative (*R,S*)-3-H^{2}F^6-BINAPHOS **4b**[3] allows rhodium-catalysed hydroformylation of vinyl arenes (Scheme 1) to be carried out in compressed (liquid or supercritical) carbon dioxide as a solvent with similar catalytic activity and the same level of enantiocontrol as **4a**, resulting at the same time in unprecedented high regioselectivity for the branched aldehydes. The high regioselectivity originates from the ligand substitution pattern and is retained also during hydroformylations in other solvents or even in the neat substrate.

Supercritical carbon dioxide ($scCO_2$) has gained increasing interest as an environmentally friendly solvent with unique properties for chemical synthesis in general[4] and metal-catalysed reactions in particular.[5] Non-enantioselective hydroformylation has been achieved in $scCO_2$,[6–10] and there are also examples of highly enantioselective catalytic reactions in this medium.[11,12] These promising results encouraged us[9] and others[10c] to apply $scCO_2$ as a reaction medium for asymmetric hydroformylation as well. However, it soon became apparent that **4a** cannot be used efficiently in $scCO_2$, owing to its low solubility in this medium.[9]

We have shown recently that the low solubility of aryl-phosphorous ligands and their metal complexes in $scCO_2$ can be overcome by fixation of perfluoroalkyl substituents $(CH_2)_x(CF_2)_yF$ at the aryl rings.[8a] Following this approach, we set out to synthesise the fluoroalkyl-substituted (*R,S*)-3-H^{2}F^6-BINAPHOS **4b** and its rhodium complex [(**4b**)Rh(acac)] **5b**. The fluoroalkyl substituents were introduced *via* the bisaryl phosphonic acid **7**, which was obtained in a one-pot procedure from the *meta*-substituted aryl bromide **6**[13] (Scheme 2). Crystallisation from pentane provided **7** as a white solid in 63% yield.[14] The remaining route to **4b** was a modified version of the original synthesis of **4a** giving a similar overall yield. The $^{31}P\{^1H\}$ NMR data of the phosphine/phosphite ligand **4b** and its rhodium complex **5b** are almost identical to those reported for the unsubstituted parent compounds **4a** and **5a**.[2,14]



Scheme 2 *Reagents and conditions*: i, BuLi, Et_2O, −30 °C, then 30 min at 0 °C; ii, $(NEt_2)PCl_2$, Et_2O, −30 °C; iii, conc. HCl.

In contrast to **4a**, the perfluoroalkyl-substituted ligand **4b** allows highly efficient asymmetric hydroformylation of styrene **1a** using compressed CO_2 as the reaction medium (Table 1, entries 5–9).‡ The isomer (*R*)-**2a** was formed preferentially with ees between 90 and 94% under various reaction conditions. Quantitative conversion (> 98%) of **1a** could be achieved in less than 16 h at a substrate-to-rhodium ratio of 1000 : 1 and a reaction temperature of 60 °C. Somewhat longer reaction times were required at lower temperatures or lower catalyst loadings. Most remarkably, a very high regioselectivity of 93–96% was achieved consistently for the formation of **2a**.

Similar results were obtained using **4b** in the asymmetric hydroformylation of the substituted vinyl arenes **1b**,**c**. Substrate **1b** bearing an electron-withdrawing chloride substitutent in the *para* position was hydroformylated with a modest enantiomeric excess of 88% ee, but the regioselectivity was again high (92%, entry 12). Substrate **1c**, the precursor for the hydroformylation route to ibuprofen, was hydroformylated with excellent enantioselectivities of up to 93% and an unprecedented high regioselectivity of 96% for **2c** (entries 13, 14).

[a] See note ‡. [b] Density derived from weighed amount of CO_2 and reactor volume for $T > T_c$. [c] Defined as **2**/(**2** + **3**); hydrogenation or other side reactions were insignificant. [d] Data taken from ref. 2(*a*) for comparison.

It is important to note that the positive results achieved with ligand **4a** are *independent* of the phase behaviour of the reaction mixture. At temperatures ≥40 °C and CO_2 densities of $d \geq 0.59$ g cm^{-3}, the reaction mixtures with substrate **1a** were homogeneous by visual inspection and no phase separation was observed throughout the reaction. At T = 36 °C and d = 0.46 g cm^{-3}, *i.e.* in close vicinity to the critical point of pure CO_2 (T_c = 31.1 °C, d_c = 0.466 g cm^{-3}) the formation of small droplets was detected during the latter stages of the reaction. A liquid phase was present throughout the reaction at T = 31 °C. With substrate **1c**, the reaction occurred smoothly and with high selectivity at temperatures above or below T_c of pure CO_2.

The most striking feature of Table 1 is clearly the remarkably increased regioselectivity observed with **4b** as compared to **4a**. In order to distinguish solvent effects[6a,8b] from ligand effects,[15] we carried out control experiments with **4b** in typical organic solvents and in the neat substrate. Excellent regio- and enantioselectivities were observed in all cases (entries 2–4) demonstrating that the higher regioselectivity of the system **4b**/CO_2 compared to **4a**/benzene is mainly due to the ligand substitution pattern rather than the reaction medium.

In summary, we have accomplished the first synthesis of a highly complex ligand containing perfluoroalkyl substituents. The ligand (*R*,*S*)-3-H^{2}F^6-BINAPHOS **4b** allows for the first time efficient and highly regio- and enantio-selective hydroformylation of vinyl arenes using compressed CO_2 as an environmentally and toxicologically benign solvent. Particularly in the case of the practically most important substrate **1c**, the selectivities and reaction rates with ligand **4b** in compressed CO_2 compare favourable to those reported previously using **4a** in benzene under similar conditions. The successful use of CO_2 as a reaction medium raises the attractive possibility of applying our recently developed protocols for catalysis and extraction using supercritical carbon dioxide (CESS process).[8b,12,16] The evaluation of the scope and limitations of this approach and spectroscopic investigations of the rhodium complexes under catalytic conditions are under way.

This work was supported by the Max-Planck-Society, the Deutsche Forschungsgemeinschaft (Gerhard-Hess-Award to W. L.) and the University of Messina (Exchange Fellowship to G. F.). Gifts of chemicals form Celanese GmbH and Degussa AG are gratefully acknowledged. We thank Professor K. Nozaki for fruitful discussions and Professor I. Ojima for a preprint of ref. 10(*c*). Special thanks are due to Professor F. Faraone, University of Messina, for his encouragement in this project.

Notes and references

‡ Hydroformylation experiments were carried out in a window-equipped stainless-steel high-pressure reactor (V = 10 cm^{-3}). Complex **5b** and the ligand **4b** were charged as THF solutions in the reactor under argon. After stirring for 5 min, the solvent was removed *in vacuo* and the substrate was introduced. The reactor was pressurised with a 1:1 mixture of CO and H_2 and then filled with a weighed amount of CO_2 by means of a compressor. The reaction mixture was heated and stirred with a PTFE stirring bar for the desired reaction time. After cooling to 0 °C, the reactor was carefully vented and the products were collected by extraction of the reactor content with toluene for NMR and GC analysis.

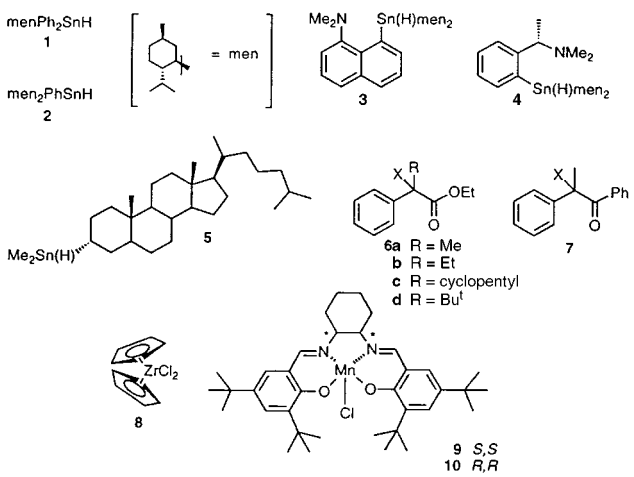
Received (in Cambridge, UK) 14th June 1999, Accepted 16th July 1999

Additions of 1 equiv. of achiral and chiral Lewis acids to free-radical reduction reactions involving (1*S*,2*S*,5*R*)-menthyldiphenyltin hydride 1, bis[(1*S*,2*S*,5*R*)-menthyl]-phenyltin hydride 2, bis[1*S*,2*S*,5*R*)-menthyl][8-(*N*,*N*-dimethylamino)naphthyl]tin hydride 3, bis[(1*R*,2*S*,5*R*-menthyl]{1-(*S*)-*N*,*N*-dimethylaminoethyl]phenyl}tin hydride 4 or 3α-dimethylstannyl-5α-cholestane 5 result in remarkable increases in enantioselectivity.

Despite there being numerous reports of free-radical reactions proceeding with diastereocontrol,[1,2] there are relatively very few examples of free-radical reactions which proceed with genuine enantiocontrol.[2] The majority of examples that demonstrate enantioselective outcomes involve the use of chiral auxiliaries and, as a result, are further examples of diastereoselectivity in free-radical chemistry.[1,2] Of the remaining few reports, the introduction of asymmetry in the substrate through the use of chiral Lewis acid mediation,[3,4] and in the reagent through the use of chiral ligands on the tin atom in suitably constructed stannanes[5–8] have been the methods of choice for achieving enantioselectivity in radical chemistry.

Our approach to the development of synthetically useful chiral stannanes primarily involves the judicious choice of ligand from the multitude of compounds available in the natural chiral pool. Here we report that significant improvements in enantioselectivity during asymmetric reductions involving chiral non-racemic stannanes are achieved by the addition of Lewis acids.

(1*S*,2*S*,5*R*)-Menthyldiphenyltin hydride **1**, bis[(1*S*,2*S*,5*R*)-menthyl)phenyltin hydride **2** and 3α-dimethylstannyl-5α-cholestane **5** were prepared previously within our group.[9] The remaining hydrides **3** and **4** were prepared by reaction of the appropriate aryllithium with bis[(1*S*,2*S*,5*R*)-menthyl]phenyltin chloride followed by $LiAlH_4$ reduction.[9,10] Substrates chosen for this work include bromides **6** (X = Br) employed by Metzger and co-workers in their recent study[8] and the ketone **7** used by Curran and Nanni;[6] in this manner a direct comparison with previous work is possible.



In this study, reductions were carried out at concentrations of approximately 0.1 M of the substrate in to which 1.0 equiv. of the Lewis acid† of choice and 1.1 equiv. of the stannane were added in toluene at −78 °C, initiated using 9-BBN.[11] Reactions were carried out until TLC analysis indicated the absence of starting material (*ca.* 1–2 h) at which time the reaction mixtures were examined by chiral-phase gas chromatography (GC)‡ and the percentage conversion and enantiomeric ratios determined by integration of the signals corresponding to the mixture of reduced compounds **6** and **7** (X = H) against an internal standard (either octane or undecane). Reduced compounds **6** and **7** (X = H) were identified by comparison of their GC retention times with those of the authentic compounds. The absolute configuration of the dominant isomer in each case was assigned by comparison with the GC retention times of the (*S*)-products **6** and **7** prepared and resolved following literature procedures.[12]

Table 1 lists enantioselectivity data for the model substrates **6** and **7** reacting with bis[(1*S*,2*S*,5*R*)-menthyl]phenyltin hydride **2** at −78 °C in toluene in the absence of any additive and in the presence of 1 equiv. of BF_3, zirconocene dichloride **8**, (*S*,*S*)-(−)- and (*R*,*R*)-(+)-*N*,*N*′-bis(3,5-di-*tert*-butylsalycidene)-1,2-diaminocyclohexanemanganese(III) chloride **9** or **10**.[13]

Inspection of Table 1 reveals some interesting features which aid in our understanding of the factors which goven the

stereochemical outcome in the reactions of interest. Firstly, a Lewis acid is crucial in obtaining reasonable enantioselectivities. Experiments carried out in the absence of these Lewis acids give significantly poorer ees. For example, addition of 1 equiv. of BF_3 to the reaction involving **6b** (X = Br) results in an increase in enantioselectivity from 4 to 20%. Increasing Lewis acid bulk results in further increases; 46% ee is observed with the addition of zirconocene dichloride **8**, while addition of **9** results in a remarkable improvement in ee to a value of 86%. It is interesting to note that the (*S*)-isomer of the product dominates in all of the reductions listed in Table 1. It is also important to note, when the reduction of **6b** (X = Br) was repeated with the enantiomer of **2**, bis[(1*R*,2*R*,5*S*)-menthyl]phenyltin hydride, in the presence of **10**, (*R*)-**6b** (X = H) was obtained with an ee of 86% under the same reaction conditions.

Despite the obvious benefit derived by the presence of the Lewis acid, chirality transfer appears to originate with the ligand on tin because the achiral Lewis acid **8** itself has a remarkable effect on the stereochemistry of the reaction in question. In addition, both enantiomeric forms of *N*,*N*′-bis(3,5-di-*tert*-butylsalicylidene)-1,2-diaminocyclohexanemanganese(III) chloride, namely **9** and **10**, result in enantioselectivities within a few percent of each other and with the same enantiomeric form of the reduced substrate dominating.

Table 2 lists the effect that different stannanes have on the observed enantioselectivities at −78 °C for reactions involving Lewis acids **8**, **9** and (for one example) **10**. It should be noted that the achiral stannane, tributyltin hydride, reacts with **6d** (X = Br) in the presence of Lewis acids **8** and **9** to afford **6d** (X = H) with 0 and 8% ee, respectively. The former result is expected; the latter result demonstrates, one again, that chirality in the stannane is more important than that in the Lewis acid.

The reader's attention is drawn to the numerous examples provided in Tables 1 and 2 where the observed enantioselectivity exceeds 80% and the two examples (entries 5 and 14, Table 2) of ees ⩾ 90%. These results are significant as they represent the highest-ever reported enantioselectivities in stannane reduction chemistry,[1,4,14]§ the 96% ee observed for the reaction of **6c** (X = Br) with **4** in the presence of **9** being truly remarkable; indeed, this result exceeds the highest ee achieved in any free-radical reaction.[1,15,16] We believe that, consistent with previous models proposed to account for diastereoselective outcomes in radical reactions,[1–4] the profound increases in enantioselectivity observed upon addition of the Lewis acids in this study are a result of the significant increases in steric bulk[17] associated with the ester group during coordination of the carbonyl moiety of the boron or metal centre in BF_3, **8**–**10**.

In order to explore the synthetic utility of the use of these reagents and catalysts, we repeated the reduction of several substrates in the presence of **9** (entries 9, 14 in Table 1; 5, 14, 22 in Table 2). We were delighted to isolate the reduction products **6** (X = H) in 67–71% yield after workup and chromatography; GC analysis provided ees as listed.¶

We are currently exploring immobilisation of these chiral reagents onto polymer support and the use of catalytic chiral stannane reductions. We thank the Australian Research Council for financial support.

Notes and references

† The use of less than 1.0 equiv. results in noticeably lower ees, while greater amounts provide no increases in ee.

‡ Enantioselectivities were determined by gas chromatographic analyses of the reaction mixtures using a chiral trifluoroacteylated γ-cyclodextrin (Chiraldex™ G-TA, 30 m × 0.25 mm) capillary column purchased from Alltech.

§ To the best of our knowledge, the value of 61% reported by Hoshino and co-workers represents the previous record, see ref. 1, 4, 13. Roberts has reported recently some enantioselective hydrosilation reactions which proceed with ees approaching 95%, see ref. 16.

¶ 96% ee for entry 14 in Table 2 represents a GC-determined lower limit.

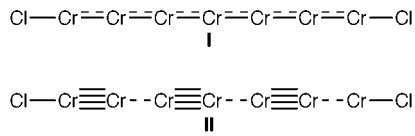
Received (in Cambridge, UK) 22nd June 1999, Accepted 21st July 1999

A heptachromium(II) metal chain helically wrapped by four all-*syn* type teptra^{3-} ligands with delocalized Cr^{II}–Cr^{II}–Cr^{II}–Cr^{II}–Cr^{II}–Cr^{II} multiple bonds is found in the complex $[Cr_7(\mu_7\text{-teptra})_4Cl_2]$. The band structure of a hypothetical one-dimensional chromium string based on this structure is calculated and shows metallic behavior for the string structure.

The bonding interaction of the metal string in oligonuclear linear metal chain complexes, which have the potential as molecular metal-wires is an important and exciting topic.[1–12] Bonding information and the electronic configurations of metal centers on oligonuclear metal complexes from trinuclear metal complexes with *syn–syn* bis(α-pyridyl)amido (dpa) ligand $[M_3(\mu_3\text{-dpa})_4X_2]$, (M = Cu,[1] Ni,[2] Co,[3,6] Cr,[7] Ru,[4] Rh[4]) and from pentanuclear metal complexes with all-*syn* tris(α-pyridyl)diamido (tpda) ligand $[M_5(\mu_5\text{-tpda})_4X_2]$, (M = Ni,[5,8] Co,[5,8] Cr[10,11]) have been described and discussed in detail. Although the Ni–Ni bond order is zero, the Ni–Ni distance altered predictably from 2.379(2) Å for the terminal one to 2.307(1) Å for the intermediate one and to 2.220(2) Å for the innermost one in the heptanickel $[Ni_7(\mu_7\text{-teptra})_4Cl_2]$ complex.[12] The next target of study is the linear oligochromium(II) complexes with a strong Cr–Cr bond (bond order 1.5). In this system, the Cr–Cr distances are found to be 2.36(1) Å in trichromium $[Cr_3(\mu_3\text{-dpa})_4Cl_2]$,[7] and 2.284(1) and 2.2405(8) Å in pentachromium $[Cr_5(\mu_5\text{-tpda})_4Cl_2]$.[11] Here we report the synthesis and structure of the heptachromium(II) metal string complex, $[Cr_7(\mu_7\text{-teptra})_4Cl_2]$, and the band structure of a hypothetical one-dimensional metal string based on the structure of this complex.

The title compound, $[Cr_7(\mu_7\text{-teptra})_4Cl_2]$, was synthesized by using anhydrous $CrCl_2$ and teptraH_3 ligand as the starting materials and naphthalene as the solvent under an argon atmosphere.† Bu^{t}OK was used as a base to deprotonate the amine groups of the teptraH_3 ligand. The teptraH_3 ligand was synthesized in the same manner as previously reported.[13,14] The crystal structure of $[Cr_7(\mu_7\text{-teptra})_4Cl_2]$ is shown in Fig. 1.‡ The space group of the title compound is $P2_1/c$ with a whole molecule and six THF molecules in an asymmetric unit. The structure is essentially identical to those of $[Ni_7(\mu_7\text{-teptra})_4X_2]$, (X = Cl^-, NCS^-)[9,12] with the linear heptachromium chain being wrapped helically by four all-*syn* type teptra^{3-} ligands. The complex exhibits an approximate D_4 symmetry. According to our structural analysis, the Cr–Cr bond lengths are symmetrically distributed in the range 2.211(2)–2.291(2) Å. Logically, the bonding mode in the Cr^{II}_7 unit favors a delocalized arrangement (**I**) over a localized arrangement (**II**).



However, our study shows that the inner chromium ions (Cr(2)–Cr(6)) have anisotropic ellipsoidal structures with a larger thermal parameter in the direction of the metal axis.

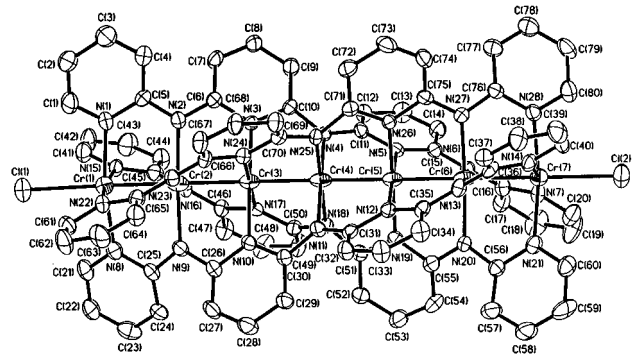


Fig. 1 Crystal structure of $[Cr_7(\mu_7\text{-teptra})_4Cl_2]$ (ORTEP side view). Atoms are shown as 30% vibrational thermal ellipsoids. Pertinent bond lengths (Å) and angles (°): Cr(1)–Cr(2) 2.291(2), Cr(2)–Cr(3) 2.243(2), Cr(3)–Cr(4) 2.211(2), Cr(4)–Cr(5) 2.215(2), Cr(5)–Cr(6) 2.243(2), Cr(6)–Cr(7) 2.280(2), Cr(1)–$N_{av.}$ 2.113(8), Cr(2)–$N_{av.}$ 2.026(7), Cr(3)–$N_{av.}$ 2.051(7), Cr(4)–$N_{av.}$ 2.025(6), Cr(5)–$N_{av.}$ 2.054(7), Cr(6)–$N_{av.}$ 2.024(7), Cr(7)–$N_{av.}$ 2.113(8), Cr(1)–Cl(1) 2.557(3), Cr(7)–Cl(2) 2.544(3), Cl(1)–Cr(1)–Cr(2) 178.6(1), Cr(1)–Cr(2)–Cr(3) 179.35(9), Cr(2)–Cr(3)-Cr(4) 179.74(9), Cr(3)–Cr(4)–Cr(5) 179.58(9), Cr(4)–Cr(5)–Cr(6) 179.79(8), Cr(5)–Cr(6)–Cr(7) 179.7(1), Cr(6)–Cr(7)–Cl(2) 179.6(1).

Although they still have reasonable values (av. U_{11}, U_{22}, U_{33} are 0.078, 0.041, 0.033, respectively), the disordered form of **II** can not be completely excluded. Three types of Cr–Cr bond lengths, with small differences among them, are observed. The averaged values of the bond length are 2.286(2) Å for the terminal Cr–Cr bonds, 2.243(2) Å for the intermediate Cr–Cr bonds and 2.213(2) Å for the innermost Cr–Cr bonds. A comparison of the Cr–Cr distances among the tri-, penta-, and heptachromium(II) complexes are shown in Fig. 2. All of the Cr–Cr distances in $[Cr_7(\mu_7\text{-teptra})_4Cl_2]$ are shorter than those in $[Cr_3(\mu_3\text{-dpa})_4Cl_2]$ (2.36(1) Å),[7] and are comparable with 2.284(1) Å of the terminal Cr–Cr bond, and 2.2405(8) Å of the inner Cr–Cr bond in $[Cr_5(\mu_5\text{-tpda})_4Cl_2]$. In a previous report,[12] the probability of

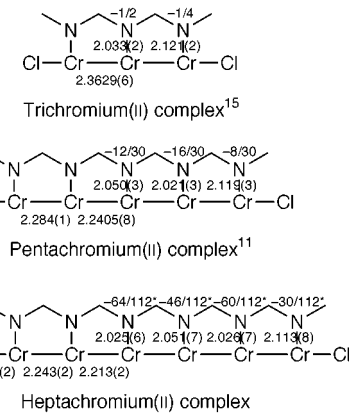

Fig. 2 Comparisons of Cr–Cr and Cr–N distances among tri-, penta- and heptachromium(II) complexes. *: Probability of negative charge distribution on the N atoms according to 112 resonance structures.

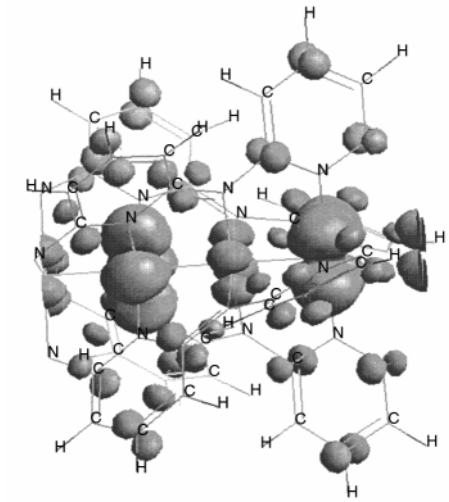

Fig. 3 The HOMO orbital of the $[Cr_4(\mu_4\text{-dpda})_4]_n$ chain.

negative charge distribution on the seven N atoms by 112 resonance structures are shown to be −30/112, −60/112, −46/112, and −64/112 from the terminal N atom to the central N atom, respectively (Fig. 2). This charge distribution is qualitatively similar to the calculated net atomic charges obtained from EHMO and Gaussian/DFT calculations.[12] The results indicate that the bond length of the Cr–N bond should depend on the bonding interaction between the N and Cr atoms. The larger the negative charge is on the N atom, the stronger is the Cr–N bond and the shorter is the Cr–N bond distance. This prediction is proven directly from the Cr–N distances obtained from structural analyse. In Fig. 2, the two terminal Cr–N bond distances are obviously the longest. The Cr–N bond distance neighboring the terminal Cr–N bond and the central Cr–N bond distance are the shortest. This result is in good agreement with the prediction based on the charge distributions.

The electronic band structure of the molecular polynuclear metal-wire is calculated for a hypothetical infinite one-dimensional metal-wire created by extending the length of the linear metal complex. In light of the D_4 symmetry of the metal complex, $[Cr_7(\mu_7\text{-teptra})_4Cl_2]$, a model metal-wire is constructed with $[Cr_4(\mu_4\text{-dpda})_4]_n$ (dpda = dipyridyldiamido moiety) taken from the crystal structure of the $[Cr_7(\mu_7\text{-teptra})_4Cl_2]$, as the repeat unit. The molecular structure of this model is then optimized and the band structure is calculated.§ The results indicate that the linear complex is a metal since the Fermi level is located within the HOMO band and there is thus no band gap. The HOMO orbital (Fig. 3) of this hypothetical metal-wire is delocalized and mainly constitutes of the d_{xy} and the $d_{x^2-y^2}$ orbitals of chromium and the p orbitals of carbon in the $dpda^{2-}$ ligands. The LUMO is localized on the chromium chain, and is composed of the d_{z^2} orbital of chromium. This model shows that the chromium metal-wire can likely serve as a conducting wire in, for example, nanostructure applications.

In summary, we have demonstrated a seven-centered metal multiple bonding scheme for early transition metal ions. The variations of the M–M distances in the Ni_7 system with a weak antiferromagnetic interaction and in the Cr_7 system with a strong M–M bonding have been described and compared. In both cases, the M–M distances converge to *ca.* 2.22 Å. Studies on the application of metal string complexes as molecular metal-wires are in progress.

† *Preparation and characterization of* $[Cr_7(\mu_7\text{-teptra})_4Cl_2]$. Anhydrous $CrCl_2$ (1.40 g, 11.4 mmol) and $teptraH_3$ (1.00 g, 2.8 mmol) were placed in an Erlenmeyer flask, and naphthalene (10 g) was added under nitrogen in a glove box. The mixture was heated (about 160–180 °C) for 20 h under argon. Then a solution of potassium *tert*-butoxide (1.04 g, 9.3 mmol) in *tert*-butyl alcohol (10 mL) was added dropwise. The mixture was refluxed for 18 h continuously. After the mixture had cooled, hexane was added to wash out naphthalene. The remaining solid was extracted with CH_2Cl_2 and recrystallized from DMF–THF. Deep brown crystals were obtained. (Yield: 40%), IR (KBr) ν/cm^{-1} = 1600, 1580, 1546 (C=C). UV/Vis (CH_2Cl_2) λ_{max}/nm (ε/dm^3 mol^{-1} cm^{-1}) = 285 (1.79 × 10^5), 338 (1.28 × 10^5), 409 (1.36 × 10^5), 503 (1.34 × 10^4); 534 (1.14 × 10^4), 745 (1.44 × 10^4). MS(FAB): *m*/*z* (%) 1844 (85) $[M]^+$, 1809 (100) $[M - Cl]^+$, 1721 (21) $[Cr_6(\mu_6\text{-teptra})_4]^+$.

‡ *Crystal data* for $[Cr_7(\mu_7\text{-teptra})_4Cl_2]$•6THF, $Cr_7Cl_2N_{28}C_{104}H_{104}O_6$, M = 2277.05, monoclinic, space group $P2_1/c$, a = 35.2674(2), b = 15.0195(3), c = 19.6563(4) Å, β = 98.615(1)°, V = 10276.9(3) Å^3, D_c = 1.472 g cm^{-3}, Z = 4, μ = 0.834 mm^{-1}. The crystal was sealed in a capillary with the mother liquor since it cracked immediately after leaving the solution. Data were collected on a SMART CCD diffractometer with graphite-monochromated Mo-Kα radiation at 295 K. SADABS absorption correction (T_{min} 0.65 and T_{max} 0.83), a total of 38720 reflections were measured and 13181 unique reflections (2θ < 45°, R_{int} = 0.0514) were used in the refinement. Full-matrix least-square refinement on F^2 (1070 variables) converged to $R(F)$ = 0.103 and $R(wF^2)$ = 0.265 (I > 2σ(I)) and $R(F)$ = 0.145 and $R(wF^2)$ = 0.297 (all data). The THF molecules were refined using 'similarity restraints' in SHELXTL. CCDC 182/1340. See http://www.rsc.org/suppdata/cc/1999/1667/ for crystallographic files in .cif format.

§ *Computational details*. The *ab initio* quantum mechanical calculations were performed with CASTEP 3.9 code.[16,17] Gradient-corrected density functional theory[18,19] (DFT) is used to calculate the electronic ground state of the system. We expand the valence electronic wavefunctions in plane waves up to a 290 eV cut-off and represent the nuclei and core electrons by ultrasoft pseudopotentials. Details of the computational study of the molecular metal-wire for Ni, Co, and Cr complex chains will be published in a separate paper.

Received (in Bloomington, IN, USA) 26th March 1999, Accepted 7th July 1999

The hydrothermal reaction of a mixture of $CuCl_2$, $NaVO_3$, 4,4′-dipyridylamine (dpa) and Et_4NOH in water yields [Cu(dpa)VO_3], a material constructed from one-dimensional $\{VO_2O_{2/2}\}_n^{n-}$ chains and $\{Cu(dpa)\}_n^{n+}$ chains linked into a two-dimensional framework.

The inorganic oxides are characterized by diverse physical properties, resulting in applications to areas as diverse as heavy construction and microelectronics.[1] The widespread interest in inorganic oxide/organic hybrid materials reflects the potential exploitation of these phases for tailoring the structures and properties of oxides. The dramatic influence of organic components on oxide structures has been demonstrated for materials as diverse as biomineralized systems,[2] zeolites,[3] mesoporous compounds of the MCM-41 class,[4] organically templated oxometal phosphates and phosphonates,[5,6] and molybdenum oxides.[7]

Layered inorganic oxides constitute a diverse subclass of the oxides and include clays, layered double hydroxides,[8] and transition metal phosphates and phosphonates.[9, 10] As an extension of our investigations of organically templated metal oxides,[7] we recently described a new class of materials which contain amine-templated transition or post-transition metal cations situated between or decorating the surface of vanadium oxide layers, the VOXI class of materials.[11, 12] In elaborating this chemistry, the role of polymeric cations constructed from geometrically constrained organonitrogen ligands bridging first row transition metal centers on the structures of vanadium oxides has been addressed. The versatility of such polymeric coordination complex cations in providing one-, two-, or three-dimensional substructures suggested that these structural motifs could be exploited as scaffolding for directing the architecture of the vanadium oxide anion component. This expectation has been realized in the preparation of [Cu(dpa)VO_3] (**1**), a two-dimensional material composed of linked $\{Cu(dpa)\}_n^{n+}$ and $\{VO_2O_{2/2}\}_n^{n-}$ one-dimensional chains.

Compound **1** is formed as orange needles in 25% yield‡ in the hydrothermal reaction of $CuCl_2$, $NaVO_3$, 4,4′-dipyridylamine, Et_4NOH, and H_2O in the mole ratio 1:2:2:1:1500 at 160 °C for 72 h. Hydrothermal techniques are now well established for the preparation of materials from relatively insoluble and unreactive precursors. Advantages include enhanced rates of solvent extraction of solids and crystal growth from solution and the ability to overcome differential solubilities of organic and inorganic components. The judicious choice of reaction conditions and precursors 'directs' the self-assembly of metastable phases which are not accessible by other synthetic routes.

The infrared spectrum of **1** exhibits a strong band at 910 cm^{-1} associated with ν(V=O) and a series of bands in the 1050–1450 cm^{-1} range attributed to the ligand. Thermogravimetric analysis exhibits a weight loss of *ca.* 50% in the range 350–420 °C corresponding to loss of the ligand.

As shown in Fig. 1, the structure of **1**§ consists of a two-dimensional covalent network constructed from the linking of $\{Cu(dpe)\}_n^{n+}$ and $\{VO_2O_{2/2}\}_n^{n-}$ chains. The anionic component consists of a buckled chain of corner-sharing $\{VO_4\}$ tetrahedra. Three distinct $\{Cu(dpa)\}_n^{n+}$ chain types provide charge balance and serve to decorate the periphery of the vanadate chains or to bridge the chains into the network structure.

The first polymeric cation chain type (A), shown in Fig. 2, runs parallel to the vanadate chains with the Cu(I) sites bonded to a vanadate oxygen at every fifth vanadium site of the anionic chain, forming a ladderlike double chain motif with the side rails provided by the {V–O–V–} and {Cu–dpe–Cu–} chains and the rungs by the {Cu–O–V} linkages. This architecture also results in an unusual twenty-two membered ring motif of approximate dimensions 11.5 × 3.3 Å. The copper site exhibits $\{CuN_2O\}$ distorted trigonal planar geometry.

These mixed metal double chains are interconnected into a network structure through parallel $\{Cu(dpa)\}_n^{n+}$ chains running at 73° to the axes of the vanadate chains. There are two types of these parallel chains. The first (B) consists of pairs of adjacent $\{Cu(dpa)\}_n^{n+}$ chains which exhibit tetrahedral $\{CuN_2O_2\}$ sites. These cationic chains are orientated with respect to the vanadate

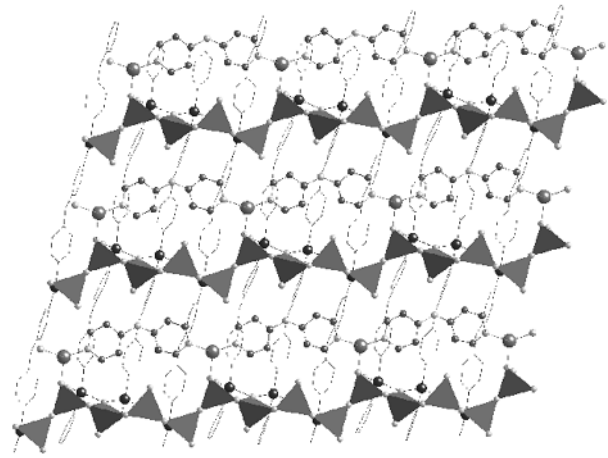

Fig. 1 A view of a single layer of [Cu(dpa)VO_3] (**1**) parallel to the crystallographic *a* axis, showing the crisscross network motif. The vanadium sites are illustrated in polyhedral representation. Copper sites of the (A) chains are grey spheres while the copper atoms of the (B) double chains are black spheres. The copper centers of the (C) chains are masked by the vanadate tetrahedra. Selected bond lengths (Å): chain (A): Cu1–O2, 2.106(4); Cu1–N21, 1.925(5); Cu1–N23, 1.933(5); chain (B): Cu2–N11, 1.931(5); Cu2-N13, 1.936(5); Cu2–O4, 2.122(4); Cu2–O9, 2.357(4); Cu3–N3, 1.975(5); Cu3–N1, 1.988; Cu3–O10, 2.204(4); Cu3-O9, 2.223; chain (C): Cu4–N33, 1.906(5); Cu4–N31, 1.927(5); Cu4–O11, 2.054(4).

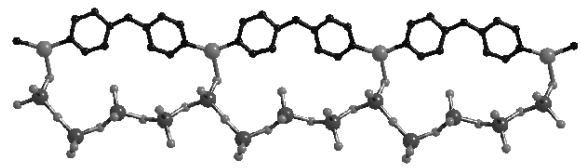

Fig. 2 A view of the double chain formed by fused $\{VO_3\}_n^{n-}$ and parallel $\{Cu(dpa)\}_n^{n+}$ chains.

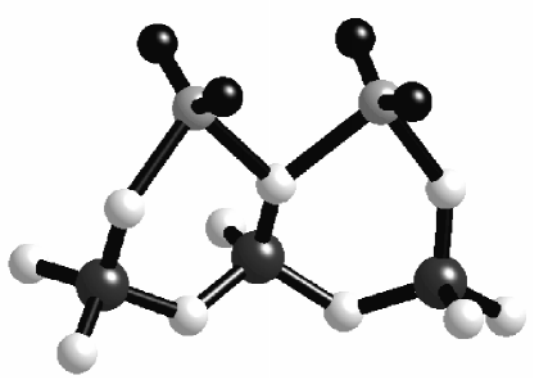

Fig. 3 The $\{V_3Cu_2O_{12}N_4\}$ cluster formed by the interaction of the vanadate chain and the $\{Cu(dpa)\}_n^{n+}$ double chains in the crisscross network.

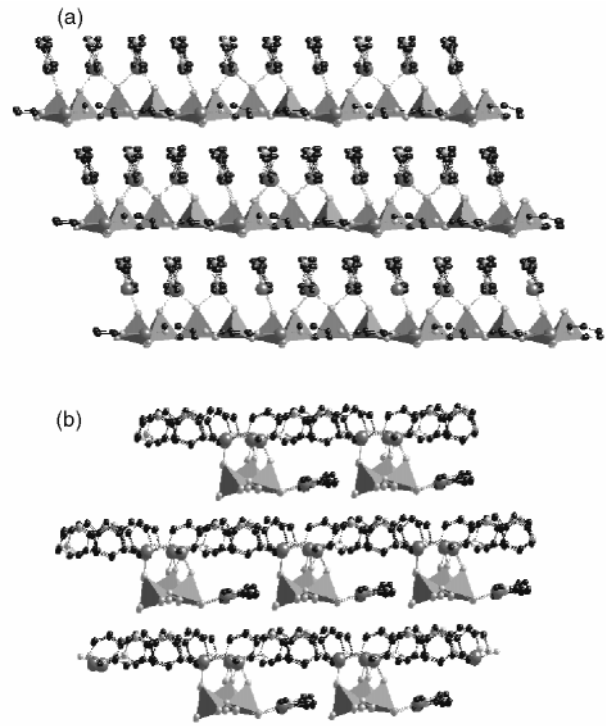

Fig. 4 (a) A view of the structure parallel to the (B) type double chains, showing the alternation of (B) double chains and (C) chains. (b) A view of the stacking of layers parallel to the crystallographic *c* axis, showing the location of (A) chains within the slots formed by vanadate chains and the (B) and (C) chains of neighboring layers. The amine of the (A) chain exhibits hydrogen bonding to an oxo group of the adjacent intralamellar vanadium oxide chain: N32···O7, 2.71 Å. The amines associated with the (B) and (C) chains exhibit interlamellar hydrogen bonding to the adjacent layer: N2···O5, 2.89 Å; N12···O3, 2.85 Å; N22···O1, 2.76 Å.

chains so as to bridge Cu sites on adjacent chains through the oxo group of one vanadate tetrahedron of the anionic chain. The consequence of this arrangement of submotifs is the unusual pentanuclear $\{Cu_2V_3\}$ oxo-bridged cluster shown in Fig. 3.

The buckling of vanadate chain results in a translation by one polyhedral edge length of $\{Cu(dpa)\}_n^{n+}$ chains adjacent to the oxo-bridged pairs, as shown in Figs. 1 and 4. When viewed parallel to this third chain motif (C), the alternation of $\{Cu(dpa)\}_n^{n+}$ paired chains and single chains is apparent. The Cu site of this chain type exhibits distorted $\{CuN_2O\}$ trigonal planar geometry.

The interconnection of these one-dimensional substructures results in the crisscross network pattern shown in Fig. 1. When viewed parallel to the vanadate chain, as in Fig. 4(b), the distinctiveness of the $\{Cu(dpa)\}_n^{n+}$ chain types is highlighted, as well as the unusual architecture of the layer repeat pattern. The $\{Cu(dpa)\}_n^{n+}$ chains designated (A) occupy cavities bordered by adjacent $\{VO_3\}_n^{n-}$ parallel chains, the (B) and (C) type $\{Cu(dpa)\}_n^{n+}$ chains of the same layer and those of an adjacent layer. The folding of the (A) chains into the intralamellar slots results in strong hydrogen bonding between the amine group and the oxo groups of the adjacent vanadate chain.

The preparation of compound **1** emphasizes the power of hydrothermal techniques in the isolation of organic–inorganic oxide materials. Furthermore, the structure of the resulting hybrid solid illustrates the observation that both metal and ligand have significant structure-directing influences on the vanadium oxide substructure which adapts to maximize covalent and noncovalent interactions with the coordination complex cation. In this respect, it is noteworthy that previously described examples of vanadium oxide–inorganic complex hybrid materials which exploited mononuclear coordination complex subunits exhibit two-dimensional vanadate substructures exclusively. In contrast, the coordination complex polymer of **1** directs the vanadate substructure into a one-dimensional type. Thus, while the structure-directing role of the polymeric cation is evident, the chemistry of the organic–inorganic interface is complex and remains largely unmapped, rendering predictability of structures a goal yet to be achieved.

This work was supported by NSF grant CHE 9617232.

Notes and references

‡ The crystals coprecipitate with an amorphous powder. Compound **1** is readily separated from the powder by exploiting its greater density in water. Satisfactory elementary analyses were obtained.

The reaction of difluorodioxirane with caesium trifluoromethoxide

Qun Huang and Darryl D. DesMarteau*

Department of Chemistry, Box 341905, Clemson University, Clemson, S.C. 29634-1905, USA. E-mail: fluorin@clemson.edu

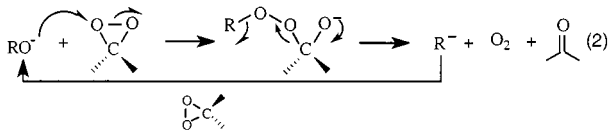
Received (in Corvallis, OR, USA) 17th May 1999, Accepted 19th July 1999

The reaction of difluorodioxirane with caesium trifluoromethoxide in the presence of CsF forms $CF_3OOC(O)F$ and the new compounds $CF_3O(OCF_2O)_nOC(O)F$ (n = 1 ~ 3); ^{13}C labeling shows that the dioxirane undergoes ring opening at the O–O bond.

Dioxiranes are powerful oxygen transfer reagents which have been studied extensively over the last twenty years.[1–3] Epoxidations, heteroatom oxidations and C–H insertion reactions are the most investigated reactions of dioxiranes. The heteroatom oxidations are generally explained by an S_N2 type attack of the heteroatom lone pair (A:) on the dioxirane peroxide bond [eqn. (1)].[4]

(1)

The mechanism is based on the fact that oxygen-type nucleophiles catalytically decompose dioxiranes with evolution of molecular oxygen [eqn. (2)].[5]

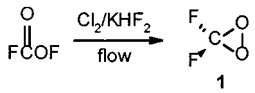


(2)

Until now, no peroxide related product has been detected in these reactions. Our recent investigation of difluorodioxirane **1** chemistry provides direct evidence of this mechanism.

Difluorodioxirane is one of the most stable dioxiranes known. The first successful synthesis of **1** was based on the reaction of its isomer fluorocarbonyl hypofluorite [FC(O)OF] with ClF in the presence of CsF.[6]† As expected, **1** is a powerful oxidant and can undergo reactions that are typical of dioxiranes. It readily transfers oxygen to alkenes, forming epoxides and COF_2 in high yield.[6] Beside this, little is known about the reactivity of **1**. Here we report a very unusual result from the reaction of **1** with COF_2 in the presence of CsF.

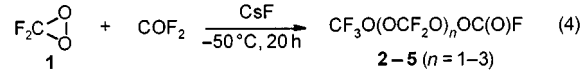
Difluorodioxirane was originally prepared by passing a 1:1 (v/v) mixture of FC(O)OF and ClF over a CsF catalyst.[6] We have improved this method by using Cl_2 and the new catalyst KHF_2.‡ A 1:1 (v/v) mixture of FC(O)OF and Cl_2 passed through a Teflon tube containing the new catalyst KHF_2 provided **1** in moderate but higher yields (30–50%) [eqn. (3)]. Also the dioxirane **1** prepared by this procedure is easily purified by vacuum fractional condensation as a mixture of **1** (70–90%) and COF_2 (10–30%). The mechanism of this reaction is assumed to be the same as previously proposed.[6]



(3)

1

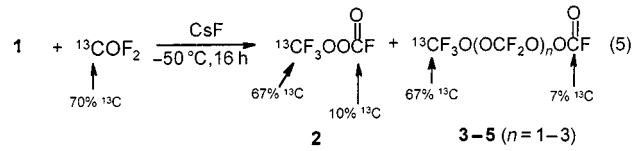
The O–O bond length in **1** is 157.6 pm, and is the longest O–O bond ever calculated and measured.[7] The relatively weak O–O bond should be easily broken but to date no direct evidence was available for this. Recent studies on the reaction of **1** with COF_2 in the presence of CsF show that dioxirane reacts by ring opening at the O–O bond [eqn. (4)].



(4)

2–5 (n = 1–3)

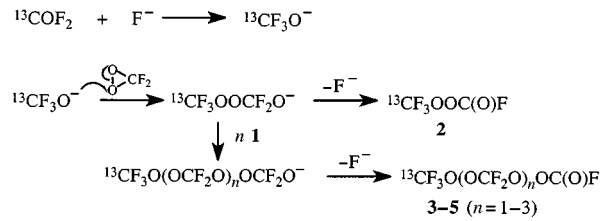
We were able to show that the reaction occurred at the oxygen atom of the difluorodioxirane by using ^{13}C labeled COF_2 [eqn. (5)].§¶



(5)

2 **3–5** (n = 1–3)

A reasonable mechanistic proposal is given in Scheme 1. The well-known trifluoromethoxy anion is first formed by the reaction of carbonyl fluoride with caesium fluoride.[8] Then an S_N2-type attack of this anion on the dioxirane peroxide bond occurs to give $CF_3OOCF_2O^-$, which loses fluoride to form **2**,[9] or reacts further with the dioxirane to form the new oligomeric peroxides **3**–**5**. The ^{13}C distribution in the products makes it clear that the predominate reaction is the attack of CF_3O^- on the dioxirane at oxygen and not at the more electropositive carbon. Previously we had suggested[10] that reaction of **1** with CsF might form CF_3OO^- and **2** could then be formed by reaction with COF_2. However this path would lead to the ^{13}C label in the carbonyl group, contrary to what is observed. The small amount of ^{13}C present in the carbonyl carbon arises from secondary reactions of the products, which have been confirmed by additional ^{13}C labeling experiments. These results will be described in a future publication.



Scheme 1

Remarkably the ^{19}F chemical shifts for **2**–**5** can be assigned from a mixture of the compounds. The NMR data is presented in Fig. 1 for pure **2** and **3** and for **4** and **5** taken from a mixture of **3**–**5**. Compound **2** is unequivocally identified by comparison with known samples prepared by other routes. For **3**–**5** the chemical shifts for the CF_3OO and the $OOCF_2OO$ groups are characteristic and show a large shift relative to CF_3O and OCF_2O functions in fluorocarbon ethers. While the chemical shift differences between **2**–**5** are small, at 188 MHz all the signals except the C(O)F are separated and the expected peak integration for each compound is observed. Finally ^{19}F bound to ^{13}C and ^{12}C exhibits substantial isotopic shifts in the ^{19}F NMR in addition to the large $^1J_{F-^{13}C}$ coupling, making it trivial to discern the presence of ^{13}C.

A variety of other novel fluorocarbon peroxides can be formed by related reactions with other nucleophiles and the

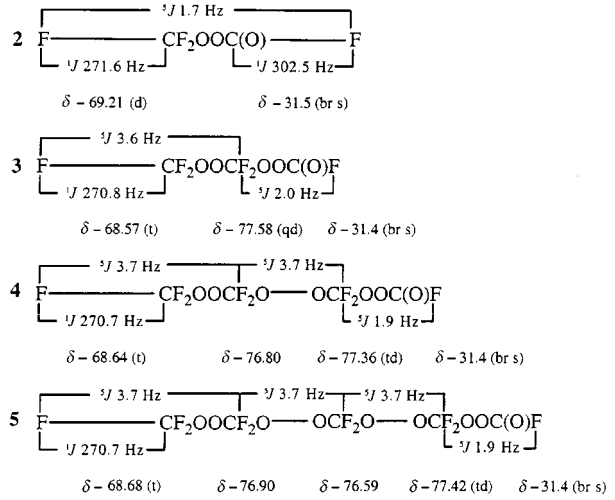


Fig. 1 ^{19}F NMR data for **2**–**5** (CCl_4 solvent, $CFCl_3$ reference, external D_2O lock, 188 MHz). Data for **4** and **5** come from a mixture of **3**–**5**.

chemistry of difluorodioxirane is proving to be quite extraordinary.

We are grateful to Ausimont SPA (Italy) for financial support of this work and to W. Navarrini of Ausimont for technical support.

Notes and references

† **CAUTION!** The chemicals employed in this work are hazardous and should only be used by experienced personnel familiar with the safe handling of toxic strong oxidizers.

‡ In a typical reaction a mixture of equimolar amounts (0.5–3.0 mmol) of FC(O)OF and Cl_2 at 23 °C were passed at reduced pressure through a Teflon FEP tube (35 × 1 cm outer diameter) containing 20 g of pelletized KHF_2 catalyst. The calculated flow rate of the mixture through the tube was 0.37 $cm^3\ s^{-1}$. The effluent exited into a trap cooled to −196 °C and under dynamic vacuum. The gases condensed at −196 °C were vacuum distilled several times through traps at −145 and −196 °C. This procedure gave **1** in the −196 °C trap, contaminated with a small amount of COF_2. *Selected data* for **1**: −92.4 (s), δ_F −20.7 (d, $^1J_{C-F}$ = 283.3) δ_C 119.5 (t). The original report of the ^{19}F NMR data in ref. 6 is in error.

§ Two 500 ml ss cylinders fitted with ss valves were connected to the vacuum line through a PFA tee closed by an ss valve. The cylinders were evacuated and one was filled with 7 mmol of fluorine gas and the other with 7 mmol of ^{13}CO (99%^{13}C). At 22 °C, the cylinders valves were then opened to the closed and evacuated tee in the order fluorine/^{13}CO. After 4 h, the contents of the two cylinders were passed through the tee into a trap cooled to −196 °C under dynamic vacuum. Unreacted F_2 and ^{13}CO passed through the −196 °C trap and through a soda lime scrubber. The contents of the −196 °C trap were then passed through −140 and −196 °C traps under dynamic vacuum to give pure $^{13}COF_2$ (3.5 mmol, 50%) in the −196 °C trap. *Selected data* for $^{13}COF_2$: δ_C 133.8 (t); δ_F −20.7 (d, $^1J_{C-F}$ 311.3); ν_{max}/cm^{-1} 1882.1, 1208.2, 957.9, 749.5, 648.6.

¶ The reactions of **1** with COF_2 and $^{13}COF_2$ were carried out in a 150 ml ss cylinder which contained 2 g of dry powdered CsF. Compound **1** (0.3 mmol) and carbonyl fluoride (0.3 mmol) were then vacuum transferred into the cylinder cooled to −196 °C. The mixture was then allowed to warm to −50 °C over 1 h and remained at −50 °C for 16–20 h. The products were separated by vacuum fractional condensation through traps at −90, −110, −130 and −196 °C. The −90 °C fraction consisted of **3**, **4** and **5** (0.03 mmol), the −110 °C fraction consisted of **3** (0.03 mmol), the −130 °C fraction consisted of **2** (0.07 mmol) and the −196 °C fraction consisted of COF_2 (0.3 mmol). Compounds **2**–**5** were identified by NMR (see Fig. 1) and IR. *Selected data* for **2**: δ_C 122.6 (q, CF_3, $^1J_{C-F}$ 271.6); 141.2 [d, C(O)F, $^1J_{C-F}$ 302.9]; ν_{max}/cm^{-1} 1874, 1254, 1209, 1153, 1005, 930, 750, 614.

New reactions of cyclic sulfoxides under Pummerer conditions

R. Alan Aitken,* Lawrence Hill, Philip Lightfoot† and Neil J. Wilson

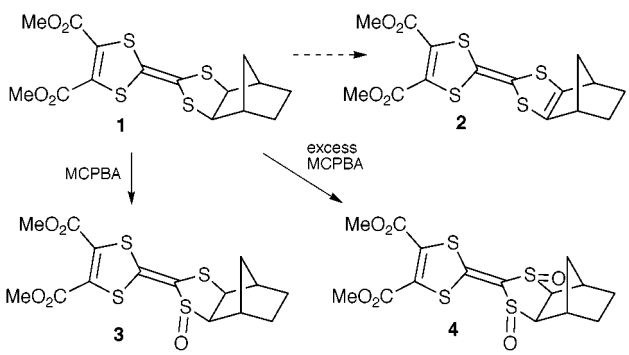
School of Chemistry, University of St. Andrews, North Haugh, St. Andrews, Fife, UK KY16 9ST.
E-mail: raa@st-and.ac.uk

Received (in Cambridge, UK) 18th June 1999, Accepted 20th July 1999

Reaction of the dihydrotetrathiafulvalene monosulfoxide 3 with TFAA results both in deoxygenation to give 1 and rearrangement to give the isomer 8, whose X-ray structure is presented; the corresponding disulfoxide 4 similarly rearranges to give 20.

We recently described the direct construction of norbornane-fused dihydrotetrathiafulvalenes such as **1** by reaction of norbornene with Bu_3P, CS_2 and acetylenic esters such as DMAD.[1] Although such dihydro-TTFs have shown some promise as potential electron donors,[2] the fully unsaturated analogues **2** would clearly be of more interest. We describe here our attempts to convert **1** into **2** which have led to the discovery both of a novel deoxygenation reaction of the sulfoxide **3** under Pummerer conditions and of its unexpected rearrangement to give the isomeric spiro compound **8**.

We decided to adopt a Pummerer approach since this has been successfully applied in the introduction of unsaturation into TTF type systems,[3] although we were aware that the rather strained nature of the expected intermediate **5** might cause some problems. Compound **1** was readily oxidised to its monosulfoxide **3** (55%) using 1 equiv. of MCPBA (Scheme 1), while use of an excess of the reagent gave the disulfoxide **4** (89%).‡ It is interesting to note that no further oxidation occurs in this system and examination of molecular models shows that introduction of oxygen on the face of the dithiolane ring *cis* to the norbornane function is sterically impossible. Both **3** and **4** were obtained as single diastereomers as shown with S=O *trans* to the norbornane function. When the sulfoxide **3** was treated with 1.1 equiv. of TFAA in CH_2Cl_2 either with or without added Hünig's base, evaporation of the reaction mixture followed by chromatography afforded two products. The first of these (38%) was readily identified as the starting dihydro-TTF **1**. Analytical and spectroscopic examination‡ of the second product (42%) revealed that it was an isomer of **3** with most of the original functionality still present, but the ^{13}C NMR signals due to the C=C double bond between the four sulfurs had been replaced by signals at δ_C 189.5 and 82.2. Its structure was finally confirmed by a single-crystal X-ray diffraction study to be the novel spiro tetrathio-orthooxalate **8** (Fig. 1).§



Scheme 1

† To receive correspondence regarding the X-ray structure (e-mail: pl@st-and.ac.uk).

A possible mechanism which accounts for the formation of both **1** and **8** *via* a common intermediate is shown in Scheme 2. In this the key step is participation of the dithiole ring in the initially formed salt **6** leading to a 1,2-shift of the trifluoroacetoxy group to give **7**. Although intramolecular migration of the trifluoroacetoxy group as shown seems quite likely, we cannot exclude the intermediacy of a dication, as shown, in the conversion of **6** into **7**. Attack of the trifluoroacetate at oxygen either in **6** or **7** would then give trifluoroacetyl peroxide and **1**, while the more conventional attack at CO in **7** leads to rearrangement to give **8** and regenerate the TFAA. No evidence was obtained for the formation of trifluoroacetyl peroxide but this is known to be an extremely unstable substance which rapidly decomposes to gaseous products at room temperature.[4] Although this is a completely new reaction in the dihydro-TTF system, there are a few analogous rearrangements which may all be represented as **9** going to **10** where D is an electron donor (Scheme 3). Thus, Ogura and Tsuchihashi found that treatment of the enamines **11** with Ac_2O gave the rearranged products **12**,[5] and the same authors later described the conversion of **13** into **14** with HCl gas in Bu^tOH.[6] The air oxidation of the highly reactive dithiadiazafulvalene **15** to give a low yield of a product formulated as **16**[7] also falls within the same category, as does the recently reported conversion of **17** into **18** by treatment with TFAA followed by hydrolysis.[8]

In view of these results it was of great interest to examine the behaviour of the disulfoxide **4** since the expected intermediate **19**, analogous to **7**, might rearrange with migration of either the sulfoxide sulfur to give **20** or the sulfide sulfur to give the isomer **21** containing the elusive α-keto sulfoxide functionality (Scheme 4). To the best of our knowledge no compound containing the C–C(=O)–S(=O)–C function has ever been isolated, since all attempts at generation in solution by *S*-oxidation of thioesters have resulted in rearrangement to the carboxylic–sulfenic anhydrides C–C(=O)–O–S–C which then react further.[9] In the event, treatment of **4** with 1.1 equiv. of TFAA afforded a rearranged product (42%) whose spectroscopic data‡ were more in keeping with the structure **20**, and

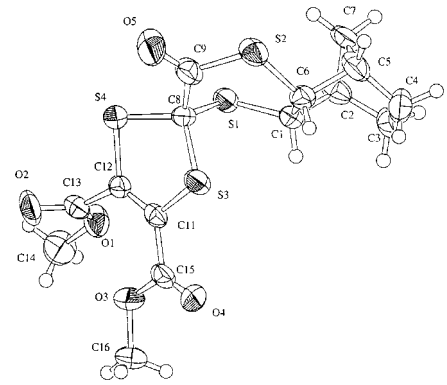


Fig. 1 X-Ray structure of the spiro compound **8**. Selected bond lengths (Å) and angles (°): S(1)–C(1) 1.816(10), S(1)–C(8) 1.834(9), S(2)–C(6) 1.821(10), S(2)–C(9) 1.76(1), C(9)–O(5) 1.21(1), C(9)–C(8) 1.51(1), C(8)–S(3) 1.828(9), C(8)–S(4) 1.825(9), S(3)–C(11) 1.761(9), S(4)–C(12) 1.756(9), C(11)–C(12) 1.31(1); C(1)–S(1)–C(8) 99.8(4), C(6)–S(2)–C(9) 108.6(5), C(8)–S(3)–C(11) 92.7(4), C(8)–S(4)–C(12) 92.4(4).

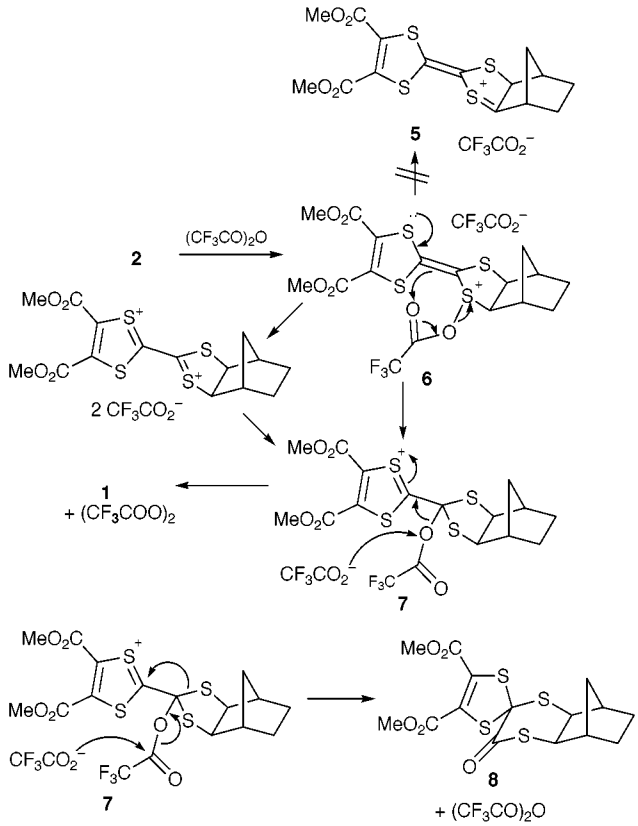
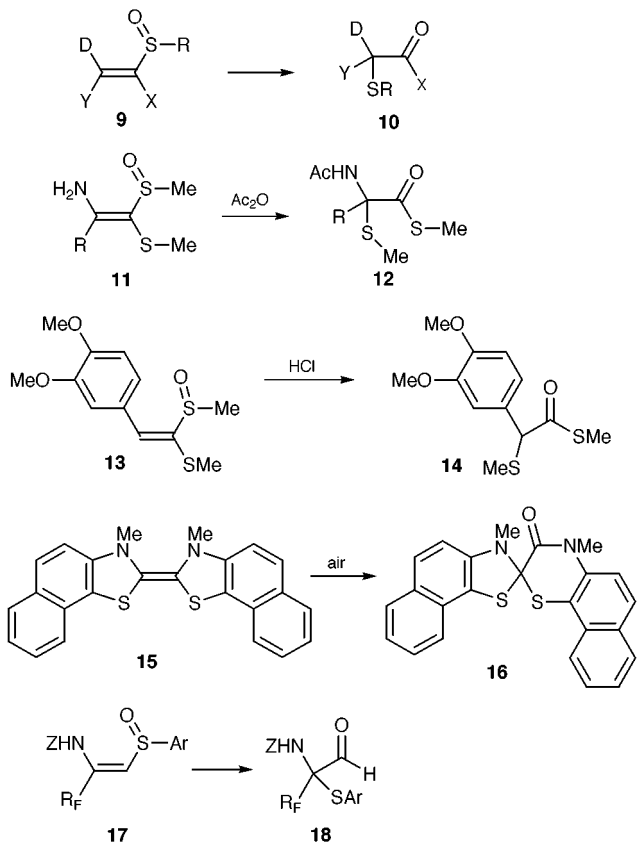


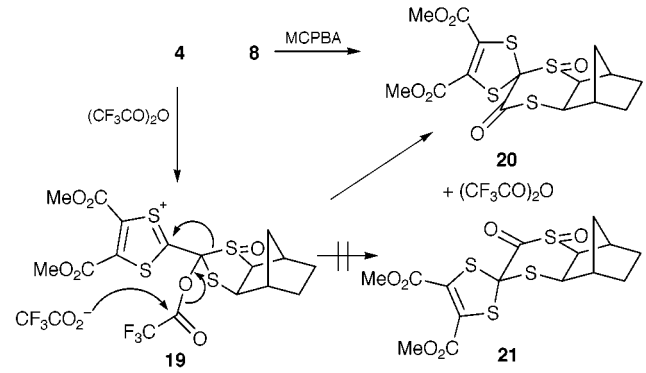
Scheme 2



Scheme 3

this was confirmed by the observation that oxidation of **8** with MCPBA gave an identical product.

Finally, in a further attempt to convert **1** into **2**, it was treated with the well established dehydrogenating agent DDQ, and to our surprise this also afforded **8** (37%). In this case we believe



Scheme 4

the mechanism to involve a series of single electron transfer steps with the oxygen in the product being provided by adventitious water, which also serves to reduce the DDQ.

We thank EPSRC for their generous support of this work (Research Grant J 38895).

When is a polymorph not a polymorph? Helical trimeric O–H···O synthons in *trans*-1,4-diethynylcyclohexane-1,4-diol

Clair Bilton,[a] Judith A. K. Howard,*[a] N. N. Laxmi Madhavi,[b] Ashwini Nangia,[b] Gautam R. Desiraju,*[b] Frank H. Allen[c] and Chick C. Wilson[d]

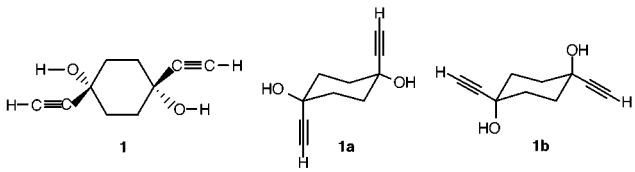
Received (in Oxford, UK) 18th June 1999, Accepted 22nd July 1999

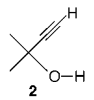
Two polymorphs (A and B) of *trans*-1,4-diethynylcyclohexane-1,4-diol represent a unique example of the simultaneous occurrence of both conformational polymorphism and conformational isomorphism, while a pseudopolymorphic monohydrate is closely related.

Definitions of *polymorphism*, the existence of two or more different crystal structures for the same compound,[1] and *pseudopolymorphism*, the existence of one or more solvated crystalline forms of the same compound,[2] are in common usage. Similarly, the existence of different conformations of the same molecule in crystals have been distinguished[3] by the terms *conformational polymorphism*, the occurrence of different conformers in different polymorphic structural modifications, and *conformational isomorphism*, the occurrence of different conformers in the same crystal structure. Here we describe two structural polymorphs and one pseudopolymorph of *trans*-



1,4-diethynylcyclohexane-1,4-diol **1**, in which the simultaneous occurrence of both conformational polymorphism and conformational isomorphism are the key distinguishing features of the crystal structures, and also provide a unique test of existing definitions.

Our studies of **1** were prompted by recent interest[4] in

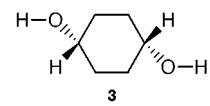


structures containing the *gem*-hydroxyethynyl fragment **2**. As well as the expected O–H···O hydrogen bonds, arrays of C–H···O, O–H·π and C-H··π interactions (π = ethynyl, phenyl), sometimes stabilised by cooperativity, frequently dominate the crystal packing. This variety of interactions leads to considerable structural diversity amongst the > 90 structures containing **2** that are already available in the Cambridge Structural Database (CSD).[5] Simple mono-alcohols exhibit two types of O–H···O aggregates (chains and rings), but even here there is no predominant motif. Thus, the available evidence suggests that structures containing **2** are strongly influenced by the remaining portion of the molecule, prompting us to investigate the crystal structure of compound **1**, in which competitive effects are minimised so that the intrinsic hydrogen-bonding preferences of **2** may be more clearly discerned.

Diol **1** was synthesised by adding TMSC≡C-Li to cyclohexane-1,4-dione and hydrolysis of the TMS groups by KOH. The unwanted *cis*-isomer was separated by repeated recrystallisations from EtOAc. Further recrystallisation of pure *trans*-**1** yielded crystals of two modifications, **A** and **B**, in the same flask. We find that both forms crystallise in space group $P\bar{1}$ with $Z = 3$,† both structures have three symmetry-independent half-molecules occupying distinct inversion centres, and both structures assemble around a spine of helical, cooperatively assisted, trimeric motifs formed *via* O–H···O bonds [**A**: Fig. 1(*a*), **B**: Fig. 1(*b*); *d*(O···H) = 1.70–1.76 Å, θ (O–H···O) = 163–177° over both structures, H-atom positions neutron-normalised). However, Fig. 1(*a*) shows that form **A** contains two molecules of conformer **1a** in which the hydroxy groups are diequatorial, while the third molecule has the diaxial OH conformation (**1b**). Fig. 1(*b*) shows that the reverse is true in form **B**: two molecules have diaxial OH groups (**1b**) and the third has the diequatorial OH conformation (**1a**). Interestingly, form **B** is 3% more efficiently packed than form **A** but this is compensated for by the better O–H···O hydrogen bonds in form A (mean *d* = 1.715 A *vs.* 1.745 in form **B**).

Amazingly, a third crystalline form was isolated from the same flask and characterised by both low-temperature X-ray and neutron diffraction.† Form **C** ($P2_1/c$, $Z = 4$) was shown to be a 1:1 hydrate of the diequatorial OH conformer **1a**, and the crystal structure maintains the helical O–H···O trimer *via* the assembly of two symmetry-independent half-molecules of **1a** and one O–H donor from a water molecule [Fig. 1(*c*), *d* = 1.64–1.80 Å, θ = 164–177°]. The second O–H donor of the water molecule interlinks inversion-related trimers (*d* = 1.91 Å, θ = 174°). In effect, the water molecule replaces the axial OH group in form **A** so that the trimeric O-H···O hydrogen-bonded helical spine is the dominant recurring pattern in all three crystalline forms of **1**.

It would appear that the presence of both conformers is required for the formation of the robust helical trimeric synthon in the unsolvated polymorphs, a supposition that is reinforced by the crystal structure of *trans*-cyclohexane-1,4-diol **3**.[6] The



diol **3** also contains the helical O–H···O trimer and crystallises in space group $P2_1/n$ with 1.5 molecules per asymmetric unit. The molecule in general positions has diequatorial OH groups, while the molecule on an inversion centre has diaxial OH groups. The O–H···O trimer is then formed by two diequatorial and one diaxial conformer, as in form **A** of **1**.

Why is it that both conformers are required for trimer formation in forms **A** and **B** of **1**, and in the diol **3**? It may be that the simultaneous presence of inversion centres (arising from the molecular structures of **1** and **3**), and the 3- or 3_1-axes that could arise if the trimer formed from three *identical* conformers of **1**

or **3**, would impose significant constraints on the packing efficiency. It appears that these constraints are alleviated by the presence of both conformers in forming the trimeric H-bonded synthon. There are no clear or simple ways of supporting or refuting this conjecture. Nevertheless, we note that the CSD contains no examples of single-conformation cyclohexane-1,4-diols that form O–H···O trimers, but that single-conformation alicyclic diols do form such trimers (around 3_1-axes), but only where the molecules do not have additional inversion symmetry. These arguments provide a rationale for the ready incorporation of water in form **C** as a replacement for the 'other' conformer of **1**.

In summary, the structures described above have a number of important implications. (i) This is the first example (to the best of our knowledge) in which the phenomena of conformational polymorphism and conformational isomorphism are observed simultaneously, revealing a new and unforeseen facet of polymorphism. Specifically, **A** or **B** when taken individually exhibit conformational isomorphism while the pair when taken together exhibit conformational polymorphism. (ii) The definition of forms **A** and **B** of **1** as polymorphs and form **C** as a pseudopolymorph can be viewed as somewhat subjective. If **1a** and **1b** are considered as rapidly equilibrating conformers of **1**, then the accepted definitions hold. However, if **1a** and **1b** are viewed as distinct molecular species, then forms **A** and **B** are simply binary crystals of 2:1 and 1:2 stoichiometry, and form **C** is a hydrate of **1a**. (iii) The isolation of three concomitant crystalline modifications of **1** suggest that the energy differences between them are small (1–2 kcal mol^{-1}) and that crystal forces influence the molecular conformation. The polymorph formation is not kinetically controlled and the three forms are stable over time. (iv) The recurrence of the O–H···O helical trimer in structures of **1** and **3** confirms that this is a robust supramolecular synthon which is insensitive to a change in substitution from ethynyl (in **1**) to the much smaller H-atom (in **3**). The extent to which a molecular structure can be perturbed without changing the structure-determining synthons in its crystal structure is a contemporary theme in crystal engineering. (v) The structures of the three forms of **1** resemble the structures of simple diols much more closely that they resemble structures of other *gem*-alkynols, in which there is considerable interference between the stronger O–H···O hydrogen bonds and weaker interactions (C–H···O, O–H·π, C–H··π) that involve the alkyne C–H and π-density. Further structural and computational studies of other *gem*-alkynols are in progress to shed more light on the role of this functional group in crystal packing.

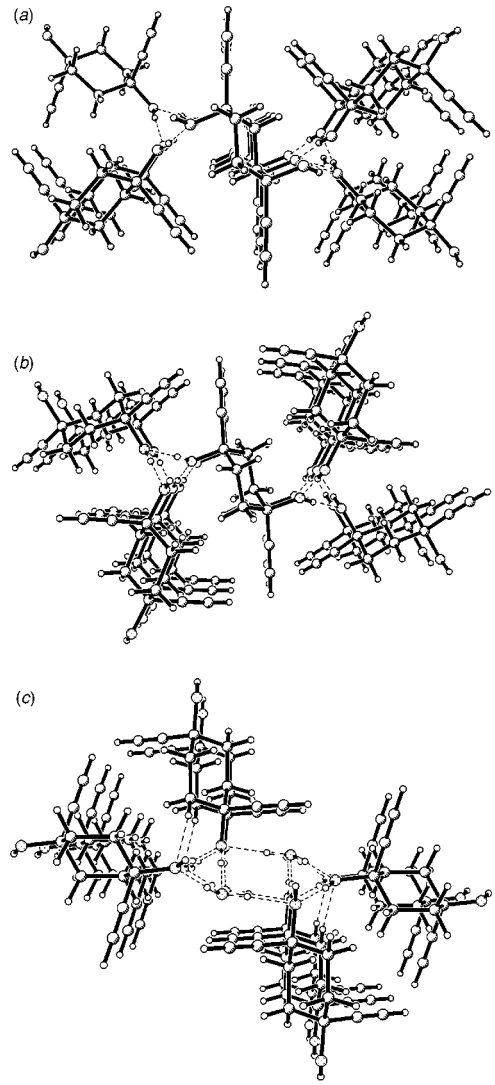


Fig. 1 Perspective views of the crystal structures of (*a*) form **A** of **1**, (*b*) form **B** of **1**, and (*c*) the monohydrated form **C** of **1**, showing the common helical O–H···O trimeric synthon and the conformations adopted by **1**.

Received (in Cambridge, UK) 14th June 1999, Accepted 14th July 1999

We report the determination of the crystal structure of a new polymorph of the pharmaceutical material fluticasone propionate, which is obtained as a microcrystalline powder by a supercritical crystallization procedure; the structure was solved directly from powder diffraction data using our Genetic Algorithm technique (in which a population of trial structures evolves through well-defined procedures for mating, mutation and natural selection) and refined using Rietveld refinement techniques.

Single crystal X-ray diffraction is without question the most powerful tool for elucidating crystal and molecular structures. However, the requirement for single crystal samples imposes a natural limitation on the scope of this technique, as many materials of interest cannot be prepared as single crystals of sufficient size and quality, but are instead available only as microcrystalline powders. Such materials include many industrially important solids, such as pigments, pharmaceuticals and catalysts, as well as many materials of biological importance. Here we report progress in the structure determination of one such material—a new polymorph of the steroid fluticasone propionate, which is important with regard to its pharmaceutical applications—using a Genetic Algorithm technique developed recently for solving crystal structures directly from *powder* diffraction data.

Fluticasone propionate ($C_{25}H_{31}F_3O_5S$; FP) is a potent synthetic anti-inflammatory steroid which suppresses inflammation of the bronchial passages in the lungs. When formulated as an inhaled product (under the trademark‡ Flixotide™ or
