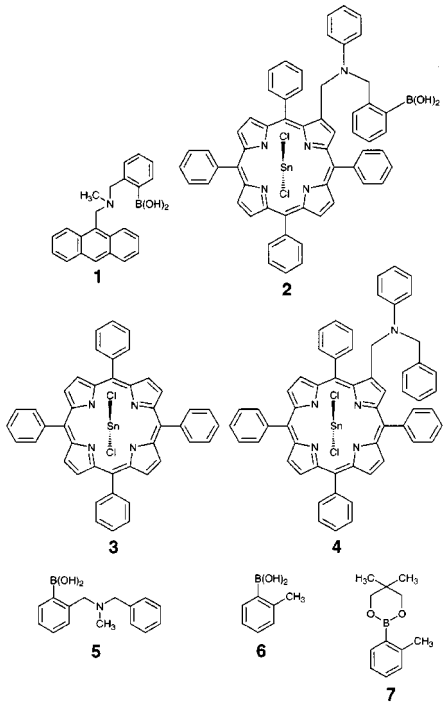
Received (in Cambridge, UK) 23rd August 1999, Accepted 3rd September 1999

A novel PET sensor for sugar sensing which changes its fluorescence intensity in an 'on–off' manner was designed from (tetraphenylporphyrinato)tin(IV)

The concept of photoinduced electron-transfer (PET) sensors has been exploited by de Silva, Czarnik and others for spectroscopic sensing of metal ions and ionic, organic compounds.[1,2] It was later shown that this concept can be successfully applied to spectroscopic sensing of neutral molecules: for example, in a 2-aminomethylphenylboronic acid skeleton the Lewis acidity of the boronic acid group is markedly intensified upon complexation with saccharides, which eventually suppresses the fluorescence quenching efficiency of the amino group.[3–5] A typical example is compound **1** in which the



relative fluorescence intensity increases upon complexation with saccharides.[3] This is a typical '*off–on–type*' PET sensor. It occurred to us that judging from the various requirements for the quantitative analyses of saccharides, a reversed '*on–off–type*' PET sensor would be also useful for spectroscopic sensing. With these objectives in mind we synthesized compound **2** bearing a (tetraphenylporphyrinato)tin(IV) moiety as a fluorescent site[6] and a 2-aminomethylphenylboronic acid group as a saccharide-binding site. Computer simulations[7] suggested that, upon binding to the boronic acid moiety, the ligands are

† Electronic supplementary information (ESI) available: colour version of Fig. 1. See http://www.rsc.org/suppdata/cc/1999/2011/

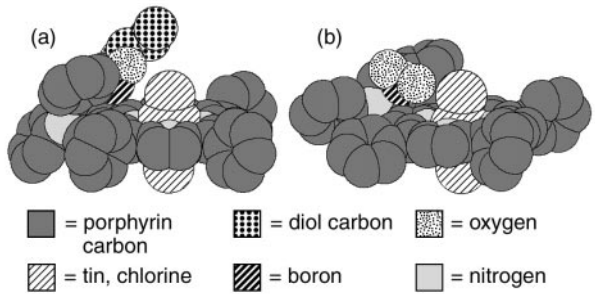


Fig. 1 Minimum energy structures for (a) butane-1,2-diol complexed **2** (b) free **2**: butane-1,2-diol; hydrogens have been omitted for clarity. The B–N distance in (a) is 4.6 Å and in (b) is 3.06 Å. This distance in the free porphyrin can be reduced to allow B–N interaction by thermal motions but steric buffeting between the ligand and the porphyrin prevents this from occurring upon complexation of the diol. Colour version available at http://www.rsc.org/suppdata/cc/1999/2011/

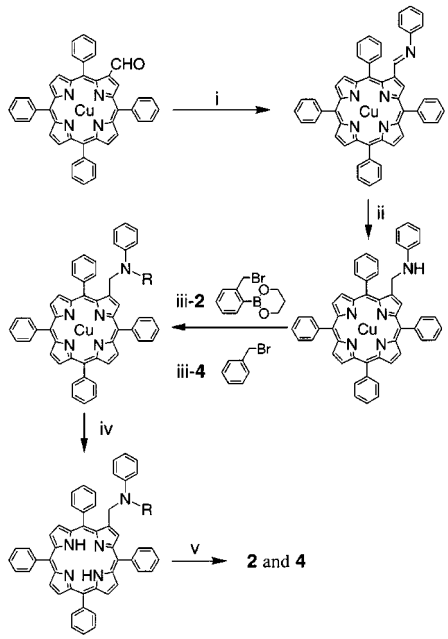
suspended over the plane of the porphyrin where the boron and nitrogen atoms are too far apart to interact (Fig. 1). In the case of the free receptor, however, the boron and tertiary nitrogen can come close enough to interact, including an '*exo*' interaction within the cleft of the adjacent *meso* phenyl rings. Hence, if diol complexation reduces the B–N interaction, **2** should act as a novel 'on–off–type' PET sensor. Compounds **3** and **4**[5] were used as reference compounds related to **2**.

Compounds **2** and **4** were synthesized according to Scheme 1 and identified by ^{1}H NMR and mass (SIMS) spectral evidence and elemental analyses. Initially, we carried out spectroscopic measurements in an aqueous system (25 °C, water : MeOH, 1 : 1 v/v). As expected the fluorescence intensity (I) decreased with increasing saccharide concentrations (pH 10.0 [**2**] = 2.0×10^{-7} mol dm^{-3}, λ_{ex} 417 nm, λ_{em} 605 nm; *e.g.*, I/I_0 = 0.92 and 0.78 at [D-fructose] = 1.0×10^{-3} and 1.0×10^{-2} mol dm^{-3}). We noticed, however, that the fluorescence is sensitive to slight changes in pH and buffer concentration because of axial ligand (Cl^-) substitution.‡ To avoid the complexity arising from axial ligand substitution, the fluorescence measurements were carried out in dichloromethane (but not in aqueous solution) to clarify the mechanism for the fluorescence decrease.

Fig. 2(a) shows the fluorescence spectra of **2**, **3** and **4** in the absence of saccharides: the excitation wavelength is 431 nm near the Soret band. Since the absorbance of these three compounds is similar to each other at this wavelength, one can directly compare their fluorescence intensities. It can be seen from Fig. 2(a) that the fluorescence intensity of **4** (at 605 nm) is only 10.8% of that of **3**, indicating that the intramolecular amino group in **4** efficiently quenches the fluorescence of the (tetraphenylporphinato)tin(IV) moiety. In **2**, on the other hand, the fluorescence intensity was reduced to 31.6% of that of **3**. This implies that the partial B–N interaction does exist but the amino group still retains the fluorescence quenching ability.

Fig. 2(b) shows the fluorescence spectra of **2** in the presence of an excess of a variety of diols; as expected from the original



Scheme 1 *Reagents and conditions* [yields]: i, aniline, benzene, reflux [89%]; ii, $NaBH_3CN$, THF, r.t. [58%]; iii, K_2CO_3, THF, reflux [iii **2**; 29%, iii **4**; 50%]; iv, HCl(g), $CHCl_3$, r.t. [iv **2**; 69%, iv **4**; 80%]; v, $SnCl_2$, DMF, 120 °C [**2**; 68%, **4**; 70%].

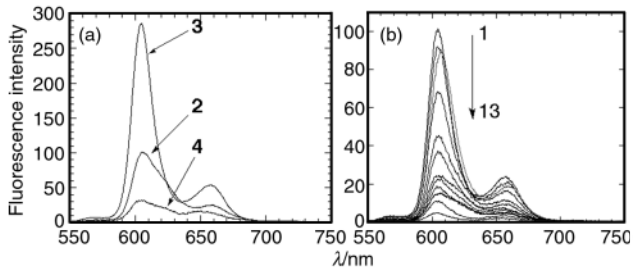


Fig. 2 (a) Fluorescence spectra of **2**, **3** and **4** (2.00×10^{-7} mol dm^{-3}) at 25 °C in CH_2Cl_2: excitation at 431 nm. (b) Fluorescence spectra of **2** (2.00×10^{-7} mol dm^{-3}) in the presence of various diols and saccharides (3.00×10^{-3} mol dm^{-3}) at 25 °C in dichloromethane: excitation 424 nm: 1, none; 2, pinacol; 3, dimethyl L-tartarate; 4, pentane-2,4-diol; 5, *cis*-cyclohexane-1,2-diol; 6, 1,2-diphenylethane-1,2-diol; 7, 2,2-dimethylpropane-1,3-diol; 8, (2*R*,3*R*)-butane-2,3-diol; 9, catechol; 10, butane-1,2-diol; 11, butane-1,3-diol; 12, 1,2,5,6-*O*-bis(isopropylidene)-D-mannitol; 13, (*R*)-1-phenylethane-1,2-diol.

molecular design, complexation with diols decreased the fluorescence intensity of **2**. As a general trend, sterically bulky diols such as (*R*)-1-phenylethane-1,2-diol and 1,2,5,6-*O*-bis(isopropylidene)-D-mannitol and diols with a high affinity for the boronic acid group such as butane-1,2-diol and butane-1,3-diol (frequently used as a protecting group for the boronic acid group) reduced the fluorescent intensity to a large extent. The fluorescence spectra of **3** and **4** were scarcely changed by the addition of these diols, indicating that the spectral change is due to the boronic acid–diol interaction. From plots of the fluorescence intensity *vs.* [diol] for selected diols, the association constants (K_{ass}) were estimated: $K_{ass} = 1.9 \times 10^4$ dm^3 mol^{-1} for 2,2-dimethylpropane-1,3-diol (DMPD), 2.6×10^2 dm^3 mol^{-1} for cyclohexane-1,2-diol, 5.0×10^3 dm^3 mol^{-1} for pentane-2,4-diol and 1.0×10^5 dm^3 mol^{-1} for catechol.

To obtain further insights into the fluorescence decrease induced by the addition of diols we measured ^1H and ^{11}B NMR spectra. In ^1H NMR spectroscopy (600 MHz, $CDCl_3$, 25 °C) DMPD gave a singlet peak at δ 2.16 for the OH protons. When an equimolar amount of **2** (5.0×10^{-3} mol dm^{-3}) was added, this peak nearly disappeared. This change indicates that DMPD forms a six-membered cyclic boronate ester with **2**. It is known that complexation of **5** in aqueous solutions causes an upfield shift of the boron signal of *ca.* 12.0 ppm.[8] In ^{11}B NMR spectroscopy [192 MHz, $CDCl_3$, 25 °C, external standard $B(OMe)_3$] we confirmed that the boron peak for **7** appears at a chemical shift higher by 2.4 ppm than that for **6**. These results indicate that the up-field shift is induced by both the B–N interaction and diol complexation. Compound **2** gave a singlet peak at δ 13.0 but upon addition of an equimolar amount of DMPD (2.5×10^{-2} mol dm^{-2}) a new strong peak appeared at δ 9.0. The shift width is only 4.0 ppm which is sufficiently rationalized by simple complexation with DMPD. We believe, therefore, that even though DMPD is bound to the boronic acid moiety in **2**, the B–N interaction is not specifically intensified as in the case of the previous 'off–on–type' PET sensors. To the best of our knowledge, this is the first example of an 'on–off–type' PET sensor for sugar sensing.[9]

The present study has demonstrated that a novel 'on–off–type' PET sensor can be designed by skilful utilization of steric crowding. Hence, it is now possible to choose either 'on–off–type' or 'off–on–type' PET sensors according to the experimental requirements. This indicates the high potential and versatility of combining the B–N interaction with the PET systems.

6 It is known that the amino group is capable of quenching the fluorescence of the (tetraphenylporphinato)tin(IV) moiety: R. Grigg and W. D. J. A. Norkert, *J. Chem. Soc., Chem. Commun.*, 1992, 1298.

7 Computer simulations were performed using CDiscover as implemented by Insight II ver. 98.0 on a Silicon Graphics Octane workstation. Conformations were explored with molecular dynamics simulations using the ESFF forcefield at 500 K for 40 ps with subsequent minimisation of low energy conformations.

8 C. R. Cooper, N. Spencer and T. D. James, *Chem. Commun.*, 1998, 1365.

9 An alternative mechanism was briefly considered after mass spectrometry consistently demonstrated the loss of one chloride ligand during measurements. Although this phenomenon could result simply from losing chloride to achieve a positive charge, we also considered the possibility of displacement of chloride by a boron-attached oxygen to yield a B–O–Sn self-complexed macrocycle. IR and NMR experiments produced no evidence for this interaction, however, and it was therefore discarded.

Received (in Bloomington, IN, USA) 30th June 1999, Accepted 28th August 1999

IR spectroscopic results, combined with earlier crystallographic and spectroscopic evidence on Fe and Ru nitrosyl complexes, indicate that metastable η^1-O and η^2-NO linkage isomers are formed on low-temperature irradiation of the nitrosyl metalloporphyrins (OEP)Ru(NO)L (L = O-i-C_5H_{11}, SCH_2CF_3); the new compounds are stable at low temperature, but revert to the ground state on warming.

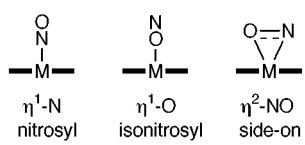
Nitric oxide (NO) plays a crucial role in several biologically important processes such as intercellular signal transduction, blood pressure regulation, and cytotoxic activity of immune systems.[1] NO is synthesized *in vivo* by the enzyme NO synthase, which contains a (por)Fe(SR) heme active site.[2] NO is now known to be produced by several heme-containing denitrifying enzymes.[3] One of the major biological functions of NO is to bind to the metal center of heme-containing soluble guanylyl cyclase, resulting in activation of the enzyme.[4] NO is also known to bind to other heme-containing biomolecules such as cytochrome P450, Hb, Mb, cytochrome *c* oxidase, and heme-containing nitrite reductases.[5]

The photochemistry of nitrosyl metalloporphyrins and -hemes reveal photodenitrosylation (A) and recombination (B) processes [eqn. (1)][6–8] that are probably governed by factors

$$\text{(por)M(NO)} \underset{\text{B}}{\overset{\text{A}}{\rightleftharpoons}} \text{(por)M} + \text{NO} \qquad (1)$$

that include metal oxidation state and the identity and orientation of the *trans* (proximal) ligand. Distal pocket residues also play a role in the geminate recombination of NO in heme proteins.[10] The results of kinetic studies of photochemically induced loss and recombination of NO with hemoproteins[9,10] and metalloporphyrins[11,12] suggest that recombination is a fast and multistage process at room temperature. Clearly, the mechanisms of NO approach, release and subsequent binding to heme and heme models require further investigation.

Until recently, established or proposed descriptions of NO binding to the metal center in heme or heme models have been restricted to N-binding of the NO group to the metal in either linear or bent forms. We have reported novel X-ray crystal structures of coordination and organometallic compounds with photoinduced O-bound (η^1-O) and side-on (η^2-NO) bound nitrosyl groups.[13–15]



These compounds were of the {MNO}^{6} and {MNO}^{10} formulations.[16] We were thus interested in determining if such linkage isomers could exist for group 8 {MNO}^{6} nitrosyl metalloporphyrins of the form (por)M(NO)X with X *trans* to NO. Here, we report the first spectroscopic detection of η^1-O and η^2-NO linkage isomers of nitrosyl metalloporphyrins.

Irradiation of (OEP)Ru(NO)L [L=O-i-C_5H_{11} **1**,† SCH_2CF_3 **2**;†[17] KBr pellets; 330 < λ < 460 nm; Xe lamp][18] at 20 K for 15 min results in IR spectral changes that are attributed to the formation of metastable states possessing η^1-O and η^2-NO linkage isomers (Table 1). For example, irradiation of the alkoxide compound **1** (υ_{NO} 1791 cm^{-1}) results in a reduction of intensity of the original υ_{NO} band, and the appearance of new bands at 1645 and 1497 cm^{-1}. Difference spectra from the samples before and after 15 min of photolysis are shown in Fig. 1(a). Upon ^{15}N labeling, these 1791 and 1645 cm^{-1} bands are downshifted by 36 cm^{-1} (expected shift of 34 cm^{-1} based on simple two-body model), whereas the 1497 cm^{-1} band is downshifted by 17 cm^{-1}. Similar results are observed during photolysis of the thiolate compound **2** [Fig. 1(b) and Table 1].

The following observations support the assignment of the new bands as being due to photoinduced η^1-O and η^2-NO linkage isomers at 20 K, respectively.

(i) Photolysis does not produce free NO which has an absorption band at 1880 cm^{-1}.[19]

(ii) The intensities of the parent nitrosyl bands were restored after the photolysis had ceased and the samples were warmed to room temperature and cooled back to 20 K. Thus, the light-induced reaction is thermally reversible, indicating the formation of a metastable species. For compound **1**, the new band at 1645 cm^{-1} can be seen only below 160 K, while the second new band at 1497 cm^{-1} can be generated only below 80 K. For compound **2**, the new bands are generated simultaneously upon irradiation at temperatures below 60 K. In all cases the photo-induced bands persist for at least several hours if the initial temperature is maintained.

(iii) Both new bands are subject to the ^{15}N-isotope shift, and thus associated with υ_{NO} (Table 1). Thus, the isotope shifts of the η^1-O υ_{NO} bands are 36 and 27 cm^{-1} for photoexcited **1** and **2**, respectively. The isotope shifts of the η^2-NO υ_{NO} bands are 17 and 19 cm^{-1}. Similar υ_{NO} downshifts of 19 and 14 cm^{-1} upon ^{15}N labeling were recently reported for Cr(η^2-NO)[20] and V(η^2-NO),[21] respectively, generated in an Ar matrix .

Table 1 Wavenumbers (cm^{-1}) and shifts of IR absorption bands of nitrosyl and light-induced isomers with iso- and side-on bound nitrosyl of complexes **1** and **2**

	υ(RuN–O)	υ(RuO–N)	υ[Ru(η^2-NO)]
(OEP)Ru(NO)(O-i-C_5H_{11})			
^{14}N	1791	1645 (−146)	1497 (−294)
^{15}N	1755	1609 (−146)	1480 (−275)
$\upsilon(^{14}N) - \upsilon(^{15}N)$	36	36	17
(OEP)Ru(NO)(SCH_2CF_3)			
^{14}N	1788	1660 (−128)	1546 (−242)
^{15}N	1753	1633 (−120)	1527 (−226)
$\upsilon(^{14}N) - \upsilon(^{15}N)$	35	27	19

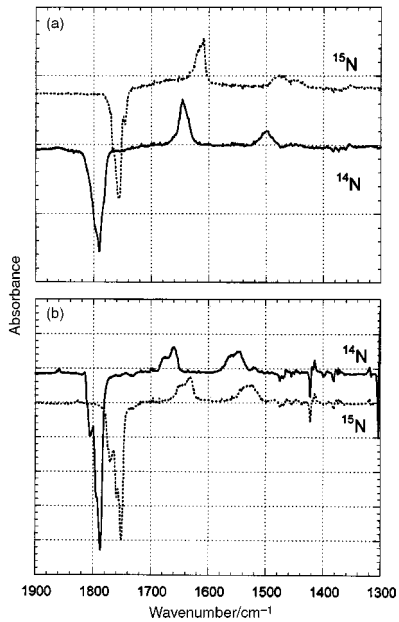


Fig. 1 Difference spectra (spectrum after irradiation minus spectrum prior to irradiation for 15 min) for the ^{14}N and ^{15}N labeled compounds (a) (OEP)Ru(NO)(O-i-C_5H_{11}) and (b) (OEP)Ru(NO)(SCH_2CF_3). The bimodal structure of some of the shifted bands is attributed to crystalline disorder and two possible orientations of the NO group. Conversion percentages are estimated as 1 and 1.5% for (a) and (b), respectively.

(iv) The observed decreases in υ_{NO} upon conversion from nitrosyl to isonitrosyl (η^1-O) and to side-on (η^2-NO) bound nitrosyl (Table 1) are very similar to those recorded for other excited Fe, Ru, Os and Ni nitrosyl complexes.[14,15,22–27] DFT calculations on the nitrosyl linkage isomers in $Na_2[Fe(CN)_5(NO)]\cdot 2H_2O$[28] predict related downshifts of υ_{NO} by 108 and 320 cm^{-1} for the η^1-O and η^2-NO isomers, respectively.

(v) Downshifts in a number of porphyrin skeletal modes (in the region 1600–900 cm^{-1})[31,32] by 3–5 cm^{-1} upon photolysis are also consistent with the data available for six-coordinate Fe(II) porphyrins which indicate that the reduction of π-acid character of the axial ligand causes downshifts of the skeletal absorption bands.[33]

Finally, we report that we have observed similar linkage isomers in two other complexes (OEP)Ru(NO)(Cl) **3** and [(OEP)Ru(NO)(py)]$^+$ **4**, thus expanding the range of compounds to include those having O-, S-, halide- and N-donors *trans* to NO.

In summary, we conclude that the low-temperature IR spectroscopic evidence presented here indicates that η^1-O and η^2-NO linkage isomers are achievable metastable states in nitrosyl metalloporphyrins.

A periodic density functional study of BEDT–TTF salts†

S. A. French,* P. Day and C. R. A. Catlow

The Royal Institution of Great Britain, 21 Albemarle Street, London, UK W1X 4BS. E-mail: sam@ri.ac.uk

Received (in Oxford, UK) 20th August 1999, Accepted 31st August 1999

We report the first *ab initio* computational study of the structural and electronic properties of BEDT–TTF charge transfer salts, which have wide ranging physical properties which are derived primarily from the packing of the donor-radical cations. The calculations accurately reproduce the observed crystal structure of the material and provide new information on the electronic structure of the (BEDT-TTF)[$FeBr_4$] salt.

BEDT–TTF [bis(ethylenedithio)tetrathiafulvalene] or 'ET', first synthesised by Mizuno *et al.*[1] has been extensively studied as it is the organic component of a family of superconducting molecular charge transfer salts. An important structural feature of these systems, based on the donor molecule ET, is the separation of the organic cations and the inorganic anion into alternating layers and stacks. As a consequence, there are many lattice packings of ET, which lead to insulating, semiconducting, metallic and superconducting phases. These physical properties result primarily from the packing of the donor-radical cations in the crystal structure. The orientation and distance between the cations has a critical influence on the electronic behaviour. The sulfur–sulfur interaction is the major influence on the intermolecular interactions owing to the larger size of these heteroatoms. However, the exact mechanistic process by which superconduction occurs below T_c, is unknown.

To investigate the structure and electronic properties of these molecular charge transfer salts we have used density functional theory (DFT); periodic boundary conditions were employed and the calculations were performed using the DMol[3] code,[2] with the local density (LD) exchange and correlation functionals of Perdew and Wang.[3] DMol[3] uses numerical basis sets where the basis functions are given as values on an atomic centred spherical polar mesh. Calculations were performed using the double numeric + polarisation (DNP) basis set. Previously it has only been possible to perform single point calculations but with the increase in computer power we can now perform a full geometry optimisation within the constraint of the observed cell dimensions on (ET)$FeBr_4$.[4] These calculations thus represent a considerable advance in the level of theory applied to these systems, and they include a detailed treatment of steric and crystal field effect; they are, however computationally expensive. We note that previous studies have used much simpler levels of theory such as extended Huckel theory[5–7] or have simply considered the isolated organic cation.[8, 9]

First let us consider the calculated structure. From Fig. 1 and Table 1 it is clear that there is excellent agreement between calculated and experimental structures. There are minor deviations in the hydrogen positions but this is consistent with the crystallographic data[4] which shows hydrogen having the largest thermal ellipsoids. Analyses of the bond lengths in Table 1 show excellent agreement with the experimental values.

Turning now to the electronic structure of the salts, we recall that the mechanism of superconductivity is unknown but clearly charge transfer is vital. The Mulliken population analysis allows examination of the charge distribution on each constituent atom; the combined value for the ET molecule is 0.784 of an electron clearly showing that charge transfer has occurred. By analysing

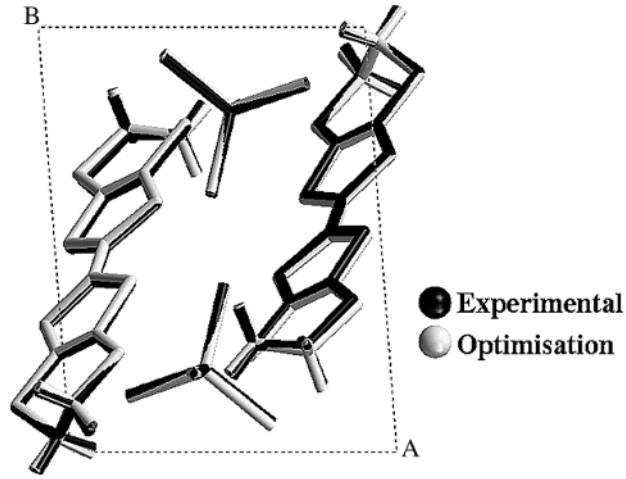

Fig. 1 Superposition of experimental (crystal structure) and calculated structure of (ET)$FeBr_4$.

the spin distribution we find that the calculated spin for the anion, 4.935 electrons is very close to the expected value of 5/2 electron pairs per high spin d^5 Fe^{3+}. As expected, the description of the spin on the anion shows that there is covalent bonding between iron and bromine as the spin density indicates 0.31 electrons donated from iron to each bromine. Of interest is the spin distribution over the ET molecule. The single spin left upon ET after charge transfer implies an unpaired spin on both ET molecules in the unit cell. The Mulliken population analysis shows no spin on the ET cation which suggests that a covalent bond is formed between ET molecules of opposite spin. The bonding interaction is within the combined van der Waals radius of sulfur at *ca.* 3.5 Å.

In the superconducting phases of ET salts, the formation of stacks leads to holes being present at an intermolecular distance of *ca.* 3.6 Å which has led to the hypothesis that the intermolecular sulfur–sulfur interactions are an important component of the interstack transfer integrals and hence the electronic band structure. (ET)$FeBr_4$ has been experimentally categorised as an insulator, owing to the formation of dimers. The calculated band gap of −0.265 eV agrees with the experimental observation. Analysis of the highest occupied

Table 1 Comparison of experimental (crystal structure) and calculated bond lengths (Å) for (ET)$FeBr_4$.

	Exptl.	Calc.		Exptl.	Calc.
Fe–Br	2.337	2.327	$C–S_{6i}$	1.741	1.741
$C=C_i$	1.383	1.383	$C–S_{60}$	1.818	1.810
$C=C_o$	1.371	1.388	C–C	1.497	1.448
$C–S_{5i}$	1.733	1.723	C–H	1.105	0.95
$C–S_{5o}$	1.742	1.730			

molecular orbital (HOMO) of (ET)$FeBr_4$ agrees with previous experimental studies[10–12] and calculations using extended Huckel theory (EHT) and tight binding schemes,[5–7] that the orbital is situated on the ET molecules and in particular on sulfur. For (ET)$FeBr_4$ there are clearly no pathways for the hopping of conduction electrons owing to the barrier of the anions.

Our calculations show that, using DFT methods, it is possible to model accurately the structures and electronic properties of these important materials and it is clear that QM calculations provide a tool for further insight into the electronic properties both of the constituent molecules and their salts.

We are grateful to EPSRC for financial support. We would like to thank MSI for the provision of all the software used and partial support of the project.

Strigol-type germination stimulants: the C-2′ configuration problem

Peter Welzel,* Susanne Röhrig and Zenka Milkova

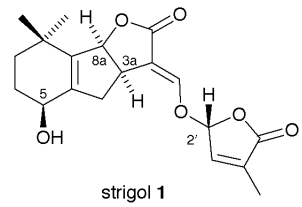
Institut für Organische Chemie der Universität Leipzig, Talstr. 35, D-04103 Leipzig, Germany. E-mail: welzel@organik.orgchem.uni-leipzig.de

Received (in Cambridge, UK) 24th February 1999, Accepted 23rd June 1999

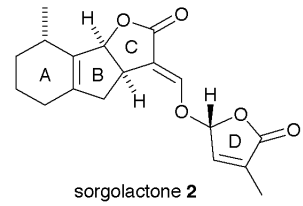
Germination of root parasites of the Scrophulariaceae and the Orobanchaceae is known to be induced by chemicals which are released from the roots of their host plants. An important class of germination stimulants are the strigolactones. Reviewed are (i) the connection of the configuration at C-2′ of the strigolactones and their seed germination potencies, (ii) methods for configurational assignment at C-2′, and (iii) stereocontrol at C-2′ in the synthesis of strigolactones.

Introduction

Root parasitic flowering plants of the genera *Striga*, *Alectra* (Scrophulariaceae) and *Orobanche* (Orobanchaceae) and their respective host plants use a very interesting system of chemical communication. It has long been known that germination of the seeds of the parasites is stimulated by compounds exuded from the roots of their host plant into the soil. Well-known stimulants are strigol (**1**) and its acetate (isolated from *Striga* hosts[1] and from cotton, *Gossypium hirsutum*,[2] a non-host), as well as sorgolactone (**2**, isolated from the root exudates of *Sorghum vulgare*,[3] a host for *Striga*). Recently, orobanchol, an isomer of strigol, has been isolated by Yokota *et al.* from root exudates of the host, *Trifolium pratense*. It is assumed that the secondary hydroxy group in orobanchol is attached to C-4.[4] Finally, from the root exudates of *Vigna unguiculata*[5] (host for *Striga* and *Alectra*) a compound, alectrol, has been isolated. A structure has been proposed for this compound that has recently been rejected.[6]

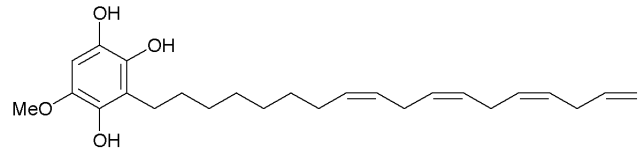


strigol **1**



sorgolactone **2**

It has been claimed that the true stimulants are in fact hydroquinones of type **3** (dihydrosorgoleone).[7] This suggestion will not be further discussed here. The present review will rather restrict itself to the problem of the strigol-type stimulants (also called strigolactones).



dihydrosorgoleone **3**

Structure–activity relationships

The exchange of chemical information indicated above raises basic questions, such as: (i) which structural features of the stimulants are essential to elicit a high seed germination potency; (ii) how is the chemical signal released from the host recognized by the seed; and (iii) how does the primary chemical signal initiate the biochemical processes that are involved in germination?

Whereas over the years an appreciable knowledge on the structure–activity relationships has accumulated (mainly driven by the desire to use this system for a novel approach of parasitic weed control), questions (ii) and (iii) are largely unanswered. Even the results of structure–activity investigations are not clear-cut. They indicate that very specific interactions exist between the stimulants and the binding site(s) at the seeds. However, it has been demonstrated that the interactions are species–dependent and may vary from test to test. Structure–activity relationships obtained from different test systems should, thus, be compared only with great care. The problem has been reviewed and discussed in detail by Zwanenburg and co-workers who also recommended a standard bioassay.[8]

In addition, the configuration at the various stereogenic centres of the stimulants is of great importance with respect to seed germination activity. Much of the older work was performed with mixtures of stereoisomers and is, thus, of

Peter Welzel recieved his PhD from the University of Bonn (with R. Tschesche). After a postdoctoral fellowship with D.H.R. Barton at Imperial College in London he returned to Bonn to work for his habilitation. In 1973 he was appointed Professor at the Ruhr University in Bochum. In 1993 he moved to the University of Leipzig where his is Professor of Organic Chemistry.

Susanne Röhrig received her Diploma from the Ruhr University in Bochum in 1994, and her PhD, entitled 'C-2′-stereoselective synthesis of strigol-type compounds', from the University of Leipzig (with Peter Welzel) in 1997. She is currently a Postdoctoral Fellow in the group of Professor Peter Seeberger at the Massachusetts Institute of Technology.

Zenka Milkova received her MSc from the University of Burgas, Bulgaria, in 1968, and her PhD from the University of Sofia, Bulgaria, in 1976. In 1976 she became a Research Fellow at the Institute of Organic Chemistry, Bulgarian Academy of Sciences (Sofia), where in 1990 she was made an Associate Professor. During this time, she spent two periods (1981–1982 and 1987–1988) as a Research Fellow in the group of Peter Welzel at the Ruhr University in Bochum. Between 1991 and 1992 she worked for Janssen at the Facultes Universitaires Notre-Dame de la Paix (Namur, Belgium). Since 1999 she has been Reader for Organic Chemistry at the University 'Neophit Rilski' (Blagoevgrad, Bulgaria).

limited value. As such, only results from single stereoisomers will be considered.

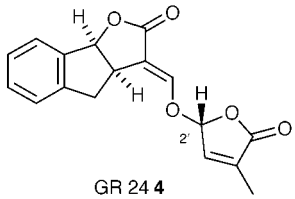
The first study with pure strigol isomers was published by Hauck and Schildknecht who found that strigol (**1**) was active (half-maximum germination) for *Striga asiatica*, *Orobanche aegyptiaca* at concentrations of 6×10^{-11} and 7×10^{-10} mol l^{-1}, respectively. The non-natural *ent*-strigol had to be 500 and 300 times more concentrated to be as active. For *Alectra vogelii*, however, *ent*-strigol was 20 times more active than the natural isomer.[9]

The Hauck study was complemented by work of Bergmann *et al.* showing that, in addition to the absolute configuration, the configuration at C-2′ is of major importance, at least as far as *Orobanche crenata* is involved (see Table 1).[10]

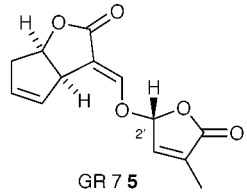
Table 1 Activity of strigol analogues in *O. crenata* seed germination bioassays: $c_{½}$ = concentration of half maximal stimulation of germination (ref. 10)

Compound	Configuration at C-2′	$c_{½}$/mol l^{-1}	$c_{½}$ (relative)
Strigol (**1**)	*R*	$8.5\ 10^{-8}$	1.0
ent-Strigol	*S*	$3.4\ 10^{-6}$	40.0
2′-*epi*-Strigol	*S*	$2.3\ 10^{-6}$	27.1
ent-2′-*epi*-strigol	*R*	$1.0\ 10^{-6}$	11.8
rac-GR24 (**4**)	*RS*	$3.4\ 10^{-7}$	
rac-2′-*epi*-GR24	*SR*	$3.4\ 10^{-6}$	

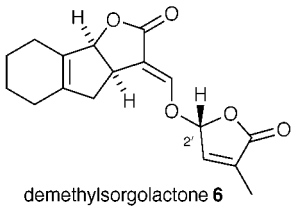
The largest collection of experimental results comes from Binne Zwanenburgś laboratory. Homogeneous stereoisomers in the GR7 (**5**),[11] GR24 (**4**),[12] demethylsorgolactone (**6**),[13] sorgolactone (**2**)[14] and Nijmegen 1 (**7**)[15] series have been



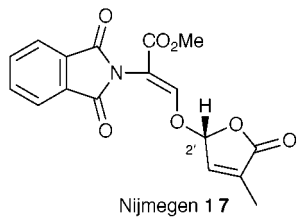
GR 24 **4**



GR 7 **5**



demethylsorgolactone **6**



Nijmegen 1 **7**

prepared. Tables 2 and 3 summarize the structure-activity results for GR7 and GR24. Similar results have been obtained for the other series.

Zwanenburg has stressed that in each experiment a reference compound should be used in order to get reliable results.[8] In most cases a mixture of GR 24 stereoisomers has been employed to serve this purpose. Using a mixture may be tolerated as long as one can be sure that only GR 24 itself (configuration as shown in formula **4**) is biologically active (as was found to be the case for *Striga hermonthica* and *Orobanche crenata*, see Table 3). It was also observed by the Nijmegen group that at higher concentrations differences between various stereoisomers are hidden because all of them are active. Zwanenburg solved this problem by defining a 'sensitive concentration' in each set of experiments in which differences for the stereoisomers are clearly visible (see Tables 2 and 3). Of course, the best solution for this problem is to determine an accurate dosage–activity curve in each case and extract an ED_{50} value (*cf.* the Hauck[9] and Bergmann[10] work described above).

From the results summarized here it follows that single stereoisomers differ greatly in their stimulating activities (under the proper conditions) which appears to permit the conclusion that germination stimulants are highly selectively recognized at the surface of the parasitic seeds. In almost all cases studied so far the correct configuration at C-2′ is of major importance.

Table 2 Germination percentages after exposure to solutions of GR7 (ref. 11)

Species	Compound	Configuration at C-2′	Germination (%) 1 mg l^{-1}	Germination (%) 0.01 mg l^{-1}
S. hermonthica	GR7 (5)	*R*	52.2 + 5.2	30.0 ± 4.1

[a] Mixture of four stereoisomers.

The C-2′ stereochemical problem

Synthesis of strigol-type compounds is interesting for several reasons: (i) to understand the structure–activity relationships of this fascinating chemical communication system; (ii) to set the chemical basis for studying the biochemistry of the recognition and germination processes, respectively and (iii) to develop a novel method for parasitic weed control. Parasitic weeds of the genera *Striga*, *Orobanche* and *Alectra* cause severe damage to gramineous and leguminous crops in the Mediterranean and tropical areas of Africa and the eastern hemisphere. It is known that inducing germination in the absence of the host plant results in starvation of the seedlings after a short time. Thus, introducing a stimulant into the soil to induce germination of the parasitic weeds before planting the desired crop would represent a very selective method for parasitic weed control.[16]

Table 3 Germination percentages after exposure to solutions of GR24 (ref. 12)

Species	Compound	Configuration at C-2′	Germination (%) 1 mg l^{-1}	Germination (%) 0.01 mg l^{-1}
S. hermonthica	GR24 (**4**)	*R*	56.2 ± 4.6	32.5 ± 4.5

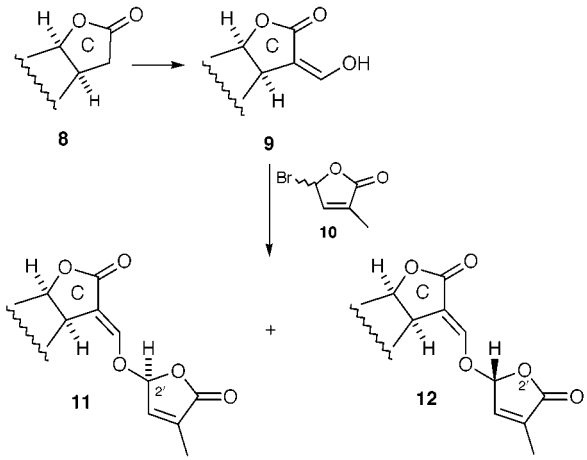
[a] At 0.05 mg l^{-1}

Some of the synthetic analogues have as high a germinating activity as strigol. It is clear now that in each series of compounds only one of the stereoisomers is highly active. For many reasons it is, thus, desirable to use this one active isomer in pure form in the different research and application areas mentioned above.

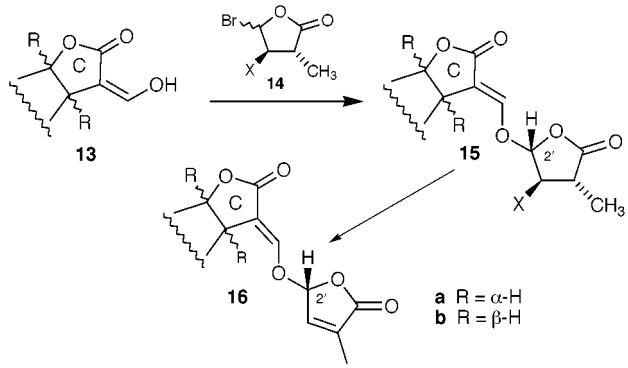
For the synthesis of stereohomogeneous strigol-type compounds four approaches have been employed. (i) Synthesis of a racemic ABC fragment *rac*-**8** (often in truncated form), subsequent formylation (*rac*-**8** → *rac*-**9**) and coupling to the racemic and stereolabile bromo (or chloro) lactone *rac*-**10** to yield the two racemic 2′-epimers *rac*-**11** and *rac*-**12** (Scheme 1). The final products had then to be resolved by a suitable method.[9,17]



Scheme 1

(ii) Synthesis of the enantiomerically pure ABC fragment **8**, formylation and coupling to racemic **10** to yield **11** and **12** as single stereoisomers.[11,12,18–20]

(iii) Synthesis of the ABC fragment in racemic form and coupling after formylation to a homochiral equivalent **14** of the halo butenolide **10** to yield one pair of stereoisomers (if **14** has appropriate stereodirecting properties) from which the desired compound **16a** is released, accompanied by a second stereoisomer **16b** (Scheme 2). In this approach the configuration at C-2′ is known in the final products.[12–15,21,22]



Scheme 2

(iv) Synthesis of the ABC fragment as a single enantiomer, formylation, coupling to **14**, and release of **16a** as a single stereoisomer with known configuration at all stereogenic centres.[22,23]

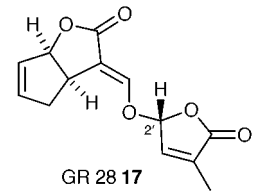
Routes (i) and (ii) may be called classical since all of the older syntheses were performed along these lines.[24] Clearly, after separation of the C-2′ epimers (in most cases easily achieved), the configuration at C-2' had to be determined. Configurational assignment at C-2′ is, however, hampered by the fact that obviously in all known examples the ^{1}H and ^{13}C NMR spectra of strigol-type C-2′ epimers are identical.[25]

In the following paragraphs methods are summarized which can be applied to determine the C-2′configuration. Then synthetic approaches will be reviewed that allow stereocontrol at C-2′. Such methods [routes (iii) and (iv), *vide supra*] have been developed only very recently.

Methods for configurational assignment at C-2′ of strigolactones

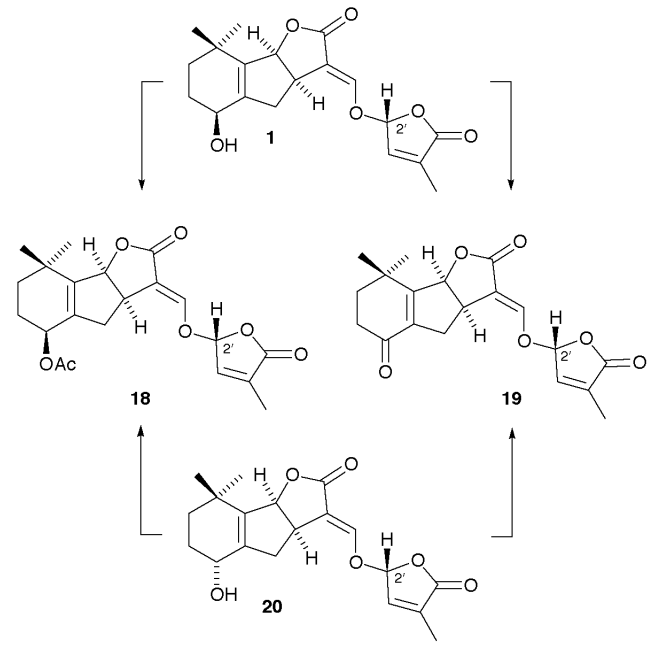
X-Ray analysis

For a long time X-ray analysis was the only means by which the configuration, especially that at C-2′, of strigol-type compounds could be established. X-Ray structures are now available of strigol (**1**),[17,26] its 5-epimer **20**,[25] 5-deoxystrigol,[27] of sorgolactone (**2**),[28] of analogues GR 7 (**5**),[29] GR 24 (**4**),[30] GR 28 (**17**)[25] and of compound Nijmegen 1 (**7**).[15]



Chemical correlation

With many reference compounds of known relative configuration now available (by X-ray analysis), configurational assignment at C-2′ by chemical correlation methods becomes feasable. Yet, this approach has been used very rarely. The C-2′ configuration of the 5-epimer of strigol (**20**) has been assigned by correlation. Thus, *rac*-**20** was converted to *rac*-**18** using the Mitsunobu procedure and the product was shown to be identical with a sample obtained from *rac*-strigol (**1**) by acetylation (Scheme 3). This correlation was secured by dichromate oxidation of both *rac*-**1** and *rac*-**20**, which furnished the same ketone *rac*-**19**. Analogously, the 2′-epimer of *rac*-**20** was correlated with the 2′-epimer of *rac*-strigol.[25]



Scheme 3

Circular dichroism

The relative and absolute configuration of sorgolactone (**2**) has tentatively been assigned on the basis of the similar CD spectra

of **2** and strigol (**1**).[3] The configuration of strigol is known from X-ray studies.[17,26] The configurational assignment of sorgolactone was recently confirmed by synthesis.[28,31] Fig. 1 displays

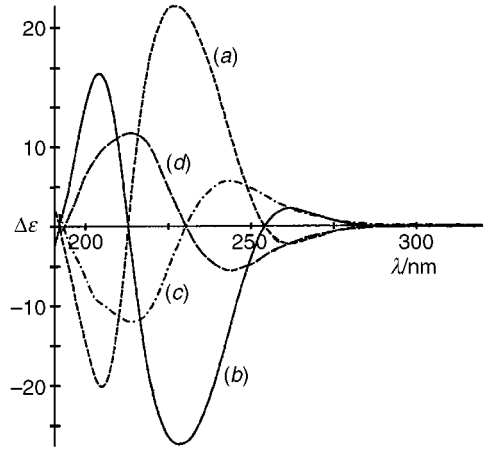


Fig. 1 CD spectra of (*a*) **1**, (*b*) *ent*-**1**, (*c*) 2′-*epi*-**1** and (*d*) *ent*-2′-*epi*-**1**.

the CD spectra of strigol (**1**), its 2′-epimer, and their enantiomers. The CD curves are, of course, sum curves of the different chromophores present in **1** and its stereoisomers. Frischmuth *et al.*[25] studied the CD spectra of **21** and *ent*-**21**, as well as of

22a R = β-H
b R = α-H

Feringa's compounds **22a** and *ent*-**22a**[32] which are reference compounds for the ABC and D parts, respectively, of the strigol isomers. It was found that the CD spectra of the strigol isomers can reasonably well be constructed from the CD spectra of the appropriate ABC and D models, indicating that (to a first approximation) there is no electronic interaction between the two chromophoric systems and, in addition, that the conformations of the 2′-epimers are similar. Thus, the configuration at C-2′ of a pair of C-2′ epimers can be obtained from their CD difference spectrum in which the contribution of the ABC chromophor is cancelled out and twice the CD of the ring D chromophore remains.[33]

A comparison of the CD spectra of **21** and *ent*-**21** with those of **22a** and *ent*-**22a** revealed that the CD band around 250 nm of **22a**/**22b** extends to a longer wavelength than that of **21a** and *ent*-**21**. This means that in the region of about 270 nm of strigolactones only the contribution of the ring D chromophor determines the spectra. Therefore, in strigolactones the configuration at C-2′ can directly be correlated with the sign of the CD around 270 nm. 2′*R* compounds have a negative CD around 270 nm whereas the CD of 2′*S* compounds is positive at this wavelength. This rule has proven its value in several series of strigolactones, in particular in the GR 28,[22] demethylsorgolactone[13] and sorgolactone series.[14]

Stereoselective synthesis

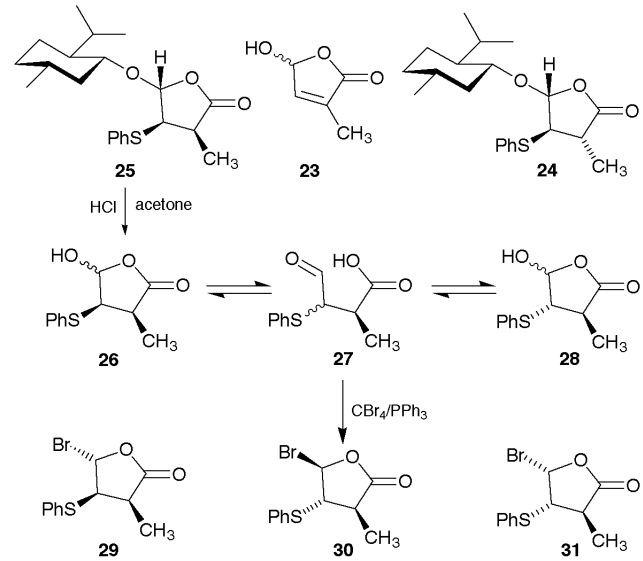
More effective than any of the procedures summarized above are, of course, synthetic methods that allow installation of the correct configuration at C-2′ predictably. This will be the topic of the following paragraph.

Synthetic approaches that allow control of the C-2′ configuration of strigol-type compounds

A general introduction to the problem has been given by Frischmuth *et al.*[34] We shall review here only sequences that lead to stereohomogeneous strigolactones. In addition only sequences will be summarized leading to compounds that contain the methyl group in unit D since it has been found that this methyl group is essential for the bioactivity.[8]

The Michael addition–nucleophilic substitution–elimination approach[22,35]

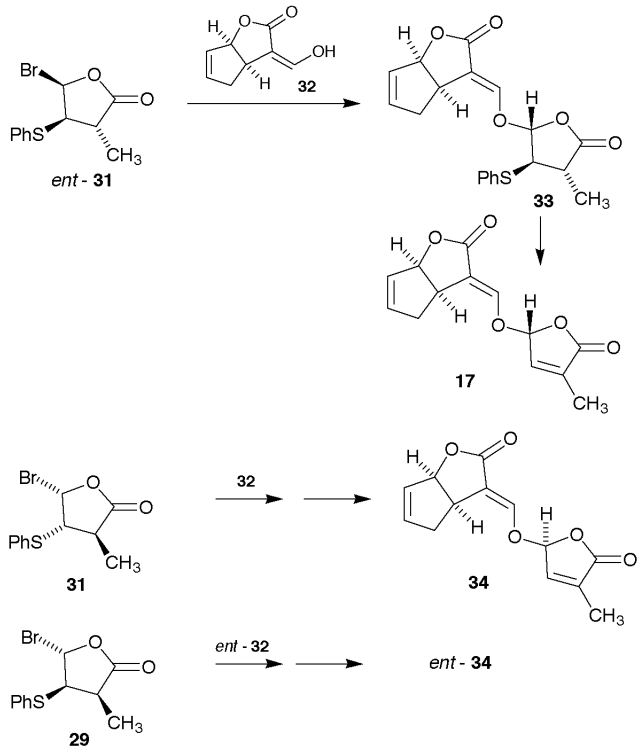
Following Feringa's work, from *rac*-**23** and (−)-menthol the two diastereoisomers **22a** and **22b** were prepared and separated by crystallization at low temperatures.[32] On addition of thiophenol in the presence of triethylamine **22a** formed adducts **24** and **25** with the phenylthio group *trans* to the menthyloxy substituent (Scheme 4). Similar reactions were performed with



Scheme 4

22b. The phenylthio group was introduced with the aim of stereodirecting the coupling of the butenolide moiety to the ABC part of strigolactones. On acid-catalyzed removal of the auxiliary menthyl group from **25** a mixture of compounds was formed which contained more components than expected. When the hydrolysis products of **26** were treated with CBr_4 and PPh_3 three bromo derivatives were obtained which could be separated and shown by careful spectral analysis to have structures **29**–**31**. The formation of **30** and **31** can be explained assuming the hemiacetal hydrolysis products of **25** to be in equilibrium with the ring-opened aldehyde, the α-position of which is, of course, stereolabile.

Coupling of **31**, *ent*-**31** (obtained analogously) and **29** was performed with racemic **32** and with homochiral **32** and its enantiomer (accessible *via* resolution[22,35] and the elegant Pd-mediated enantioselective syntheses of cyclopent-2-en-1-ylacetic acid that have been developed in the laboratories of Trost[36] and Helmchen[37]) using silver carbonate and silver silicate, respectively, as promotors (Scheme 5). The conditions resemble the classical Königs–Knorr glycosylation with the phenylthio substituent as the stereodirecting neighbouring group. Silver silicate turned out to be a more suitable promotor. The results indicate that the phenylthio substituent does indeed force the nucleophilic attack at C-2′ to the opposite face of the ring. The sequence Michael addition–nucleophilic substitution–elimination is, thus, appropriate to control the configuration at C-2′ of strigolactones and to prepare **17**, **34** and *ent*-**34** [on routes (iii) and (iv), *vide supra*]. The problematic point is the stereolability

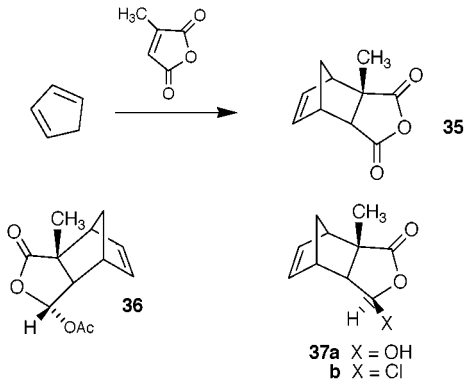


Scheme 5

of **27**, which makes the method unsuitable for practical applications.

The Zwanenburg approach[38]

Stereocontrol at C-2′ has been achieved by Zwanenburg by a sequence involving a Diels–Alder and a retro-Diels–Alder reaction. Compounds **37b** and *ent*-**37b** in which the *endo* face is sterically blocked have been used as synthetic equivalents of **14**. Diels–Alder reaction of cyclopentadiene with citraconic anhydride (Scheme 6), followed by $Li(OBu^t)_3AlH$ reduction of *rac*-

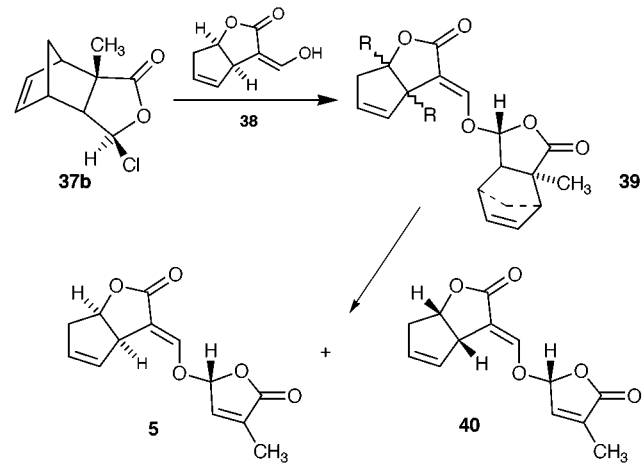


Scheme 6

35 provided *rac*-**37a** which was resolved either classically *via* the (+)- and (−)-menthyl acetals[21] or by making use of an enzymic kinetic resolution yielding *endo*-acetate **36** and the *exo*-alcohol **37a**, both in enantioenriched form.[39] Compounds **37a** and **36** were converted to chlorides **37** and *ent*-**37b**, respectively.

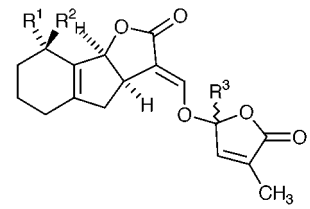
Coupling of **37b** to *rac*-**38** provided a 1 : 1 mixture of **39** (R = β-H) and **39** (R = α-H) (Scheme 7). Cycloreversion then led to diastereoisomers **5** and **40** with known configuration at C-2′. The enantiomers of **5** and **40** were prepared accordingly, making use of *ent*-**37b**.[21]

In a completely analogous fashion the follwing compounds were synthesized GR24 (**4**), its 2′-epimer, and their enantiomers;[12] demethylsorgolactone (**6**), the 2′-epimer and their



Scheme 7

enantiomers;[13] the sorgolactone stereoisomers **41a**–**d** and their enantiomers;[14] Nijmegen 1 and its enantiomer (**7**).[15]



41a R^1 = Me, R^2 = H, R^3 = β-H
b R^1 = Me, R^2 = H, R^3 = α-H
c R^1 = H, R^2 = Me, R^3 = β-H
d R^1 = H, R^2 = Me, R^3 = α-H

The Zwanenburg method, which has proven its merits, involves a resolution step. The advantage of the procedure when excuted as described until now [route (iii) *vide supra*] is that all stereoisomers of a given stimulant are available, a fact that is useful in the context of structure–activity work.

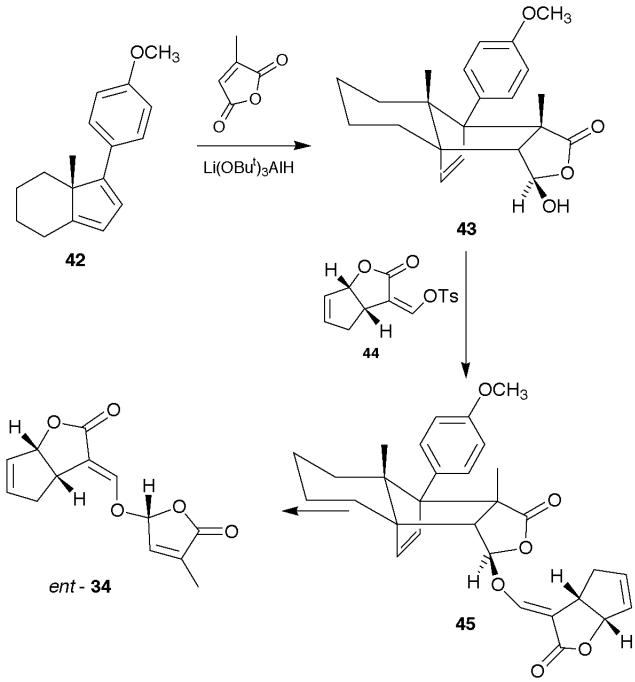
Use of the Winterfeldt template[23,40]

A highly selective route has been developed in Leipzig, which also involves the cycloaddition–cycloreversion strategy but replaces the resolution step, characteristic of the Zwanenburg approach, by an enantioselective synthesis. More specifically, the Winterfeldt diene **42**[41] which is available from the Hajos–Wiechert ketone was employed in the Diels–Alder reaction. Cycloaddition of **42** with citraconic anhydride to yield *endo*-adduct requires high-pressure conditions.[42] Reduction of the adduct with $Li(OBu^t)_3AlH$ furnished **43** as the main product. The coupling of **44** to the other half of the strigolactones posed problems and only the sequence **43** + **44** → **45** was successful (Scheme 8). On flash vacuum pyrolysis (500 °C, 10^{-6} bar), retro-Diels–Alder cleavage occurred and provided strigolactone *ent*-**34** as a single stereoisomer.

The synthesis of *ent*-**34** represents an example of route (iv) (*vide supra*). The important chiral materials used in the synthesis, Winterfeldtś template and **44** (obtained from Helmchenś iodo lactone[37]) are available *via* enantioselective reactions under the control of chiral catalysts.

Epilogue

It appears that many of the problems involved in the chemistry of strigol-type compounds have been solved in the past few years. One may wish to see application of these results in investigations aimed at understanding the mode of action of the strigolactones.



Scheme 8

Acknowledgements

It is a great pleasure to thank all colleagues who contributed to the work of our group. Their names are found in the references. We thank Professor B. Zwanenburg for the data in Table 3. Special thanks go to Professor G. Helmchen (Heidelberg) who generously provided us with the iodolactone of optically active cyclopentenylacetic acid, the precursor of **44**. We also wish to thank the Minister für Wissenschaft und Forschung des Landes Nordrhein Westfalen und the Minister für Wissenschaft und Kunst des Freistaats Sachsen (PhD fellowships), the Deutsche Forschungsgemeinschaft, and the Fonds der Chemischen Industrie for generous financial support.

ChemComm

A metallo-supramolecular double-helix containing a major and a minor groove

Michael J. Hannon,* Claire L. Painting and Nathaniel W. Alcock

Department of Chemistry, University of Warwick, Gibbet Hill Road, Coventry, UK CV4 7AL.
E-mail: m.j.hannon@warwick.ac.uk

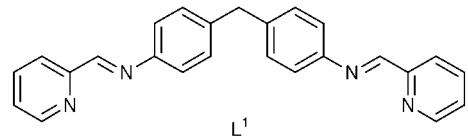
Received (in Basel, Switzerland) 19th July 1999, Accepted 8th September 1999

Control of the microarchitecture in a metallo-supramolecular double-helical array results from inter-strand edge–face π-stacking interactions which pull the ligand strands together thereby creating two distinct helical grooves (major and minor).

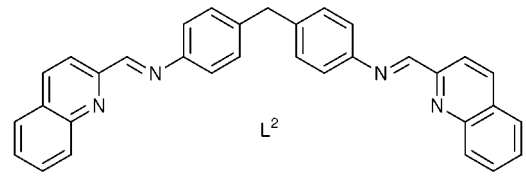
Double-helical molecular architectures retain a unique fascination because life itself is encoded within double-helical DNA arrays. The assembly of synthetic double-helical architectures through metallo-supramolecular design has been an area of intense activity and the construction principles necessary to assemble a double-helix are now fairly well established.[1] However challenges in defining the precise topography or conformation of the helical superstructure remain. To this end, we have recently illustrated how careful selection of the spacer group used to separate the metal-binding domains can be used to control the directionality of ligand strands within a helix.[2] We wish now to report a system, based on our inexpensive and readily-prepared imine ligands,[2,3] in which π-stacking interactions between the spacer groups control the microarchitecture of the helix and give rise to a double-helix containing major and minor grooves reminiscent of B-DNA.

The two distinct grooves in B-DNA arise from the positions through which the sugar–phosphate backbones are connected to the purine and pyrimidine bases; the two strands are not arranged along the vector of the cohesive forces (hydrogen bonds) which hold the helix together but both displaced to one side. This contrasts with the situation found in most synthetic metallo-helicates. The metal binding units usually form an integral part of the ligand backbone.[1] The inherent coordination preferences of the metal ions used in the assembly process (most commonly octahedral or tetrahedral) position these binding units (and hence the ligand strands) symmetrically on opposite sides of the helix. This leads to two equivalent grooves. Achieving distinct grooves within metallo-helicate architectures of this type would therefore appear to require ligand strands that are predisposed to associate on one side of the helical axis.

We have recently described triple-helical complexes formed from the reaction of ligand L[1] with octahedral metal ions.[3] In these triple-helical architectures, inter-strand face–edge π-stacking interactions (aromatic C–H···π)[4] are observed between the phenylene rings of the diarylmethane spacer-groups. Such secondary inter-strand interactions might provide a suitable tool for controlling the spatial orientation of ligand strands in a double-helicate superstructure and we have therefore examined the effect of interacting ligands of this type with tetrahedral metal ions.



L[1]



L[2]

Ligand L[2] is prepared in 93% yield by mixing ethanolic solutions containing 2 equivalents of 2-quinolinecarbaldehyde and 1 equivalent of 4,4′-methylenedianiline. Reaction of L[2] with silver(I) acetate in methanol yields a pale-yellow solution from which a yellow solid is obtained on treatment with $[NH_4][PF_6]$.[5] Mass spectrometry (FAB and ESI) is consistent with the formation of a dimeric species of formula $[Ag_2(L^1)_2][PF_6]_2$. Recrystallisation of the compound from acetonitrile by benzene diffusion afforded X-ray quality crystals and we have determined the X-ray crystal structure to examine the molecular conformation.[6]

The structure reveals a dimeric $[Ag_2(L^2)_2]^{2+}$ cation (Fig. 1). Each silver(I) centre occupies a four-coordinate pseudo-

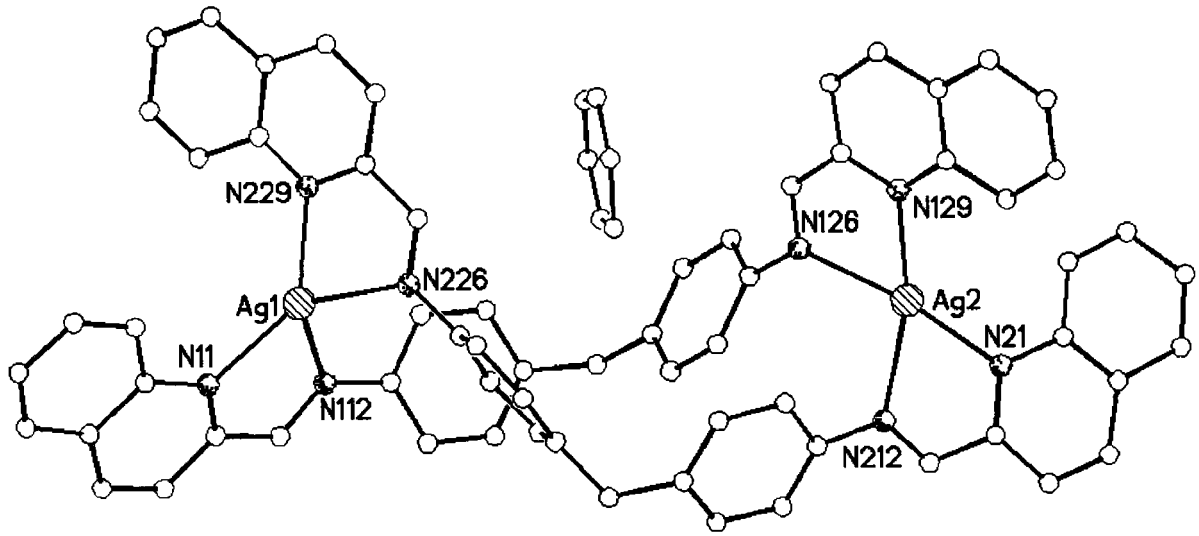


Fig. 1 View of the cation $[Ag_2(L^2)_2]^{2+}$.

tetrahedral environment bound to two pyridylimine units, one from each ligand. The two ligands wrap around the metal–metal axis giving rise to a double-helical structure, both enantiomers of which are observed. The phenyl rings of the diarylmethane spacer, which separates the metal binding units, are face–edge π-stacked[4] with those on the adjacent ligand strand (centroid–centroid: 5.1 and 5.2Å). To achieve this the two ligand strands are pulled together on one side of the helical axis and this leads inevitably to the presence of two distinct grooves (major and minor). The solid state structure reveals a benzene solvent molecule located in the larger (major) groove, however no specific interactions (face–face or face–edge π–π) are identifiable between this benzene and the walls of the groove.

While the solid state structure reveals this sophisticated helical microarchitecture, the solution behaviour is more complicated.[5] Electrospray mass spectrometry reveals the presence only of dinuclear $\{M_2L_2\}$ species. There are two possible basic configurations for such a species. The two ligand strands may either wrap around the metal–metal axis (*rac*-isomer) giving rise to a double-helix or one may pass above the metal–metal axis while the other passes beneath (*meso*-isomer) giving a non-helical metallo-cyclophane.[2,7] The room temperature ^{1}H NMR spectrum of an acetonitrile solution of the silver(I) complex reveals a single set of proton resonances. However on cooling (233 K, 400 MHz) the resonances broaden, indicating some form of fluxional behaviour. The spectrum in dichloromethane solution is broadened at room temperature, and at low temperature (193 K, 400 MHz) reveals two discrete solution species. The (non-diastereotopic) CH_2 protons permit assignment of these species. For the *rac*- (helical) isomer the protons are equivalent and a single resonance is observed while in the *meso*-isomer the structure of the metallo-macrocycle renders them inequivalent and two doublets result. The equilibrium between these species is temperature dependent with the percentage of helical isomer present increasing with decreasing temperature, indicating that this isomer is favoured enthalpically.[8] Two phenyl resonances are observed for the helix; four would be expected in a frozen-out π-stacked configuration. In view of the weak nature of π-stacking interactions it is perhaps unsurprising that this is not observed and it is unclear whether in solution the helical isomer does contain two distinct grooves or whether it has relaxed into a more conventional double-helicate structure with equivalent grooves. The absence of significant upfield shifts for either of the phenyl resonances might support the latter.

We have shown that secondary interactions between the spacer units may be used to control the superstructure of a helical array in the solid state. We are currently extending our studies to examine further routes for controlling the precise microarchitecture of supramolecular arrays.

We are grateful to the Nuffield Foundation (Awards to newly appointed science lecturers, M. J. H.) and the EPSRC (C. L. P.) for support, the EPSRC and Siemens Analytical Instruments for grants in support of the diffractometer and the Swansea National Mass Spectrometry Centre for recording the mass spectra.

7 Such *meso*- and *rac*-systems have also been observed by other workers. See, for example: A. Bilyk, M. M. Harding, P. Turner and T. W. Hambley, *J. Chem. Soc., Dalton Trans.*, 1994, 2783; C. O. Dietrich-Buchecker, J. F. Nierengarten, J. P. Sauvage, N. Armaroli, V. Balzani and L. DeCola, *J. Am. Chem. Soc.*, 1993, **115**, 11 237.

8 The temperature range over which the resonances of the two isomers are distinct is insufficient for accurate determination of thermodynamic parameters. Simple modelling reveals that the box conformation cannot accommodate inter-strand π-stacking interactions. If maintained in solution, the face–edge π-stacking interactions may contribute to the enthalpic preference for the helix and the concomitant restrictions on the free rotation of the phenyl rings in the helix might contribute to the entropic preference for the *meso*-isomer.

Received (in Liverpool, UK) 27th July 1999, Accepted 1st September 1999

For some cationic Gemini surfactants, exchange between the bulk solution and micelles or other aggregates occurs slowly on the NMR timescale; thus NMR spectroscopy provides an efficient tool for studying micelle formation and mixing of various surfactants.

Among the various aggregates amphiphilic molecules form in water, micelles are by far the most common and the most thoroughly studied.[1] The critical micelle (aggregation) concentration (c.m.c.), or the threshold concentration above which monomers co-operatively assemble into micelles (or other aggregates), can be determined by surface tension measurements or conductimetry.[1] Above the c.m.c. rapid exchange occurs between amphiphiles in the bulk and in the micelles (Fig. 1). For single chain surfactants, characteristic times for this exchange are generally of the order of 1 ns to 1 ms and fast techniques such as ultrasonic absorption are required for their measurements.[2,3] Slower techniques such as NMR show averaged signals for the surfactant molecules in their various states.[4] Both c.m.c. values and exchange rates between surfactants in the bulk and in the micelles depend critically on the size of hydrophobic groups in the surfactants. In most cases, simple laws can be expressed between these physical parameters and the number of CH_2 groups in the hydrophobic part of the surfactants.[2,5,6]

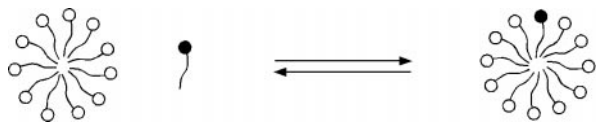

Fig. 1 Schematic representation of surfactant exchange between micelles and bulk phase.

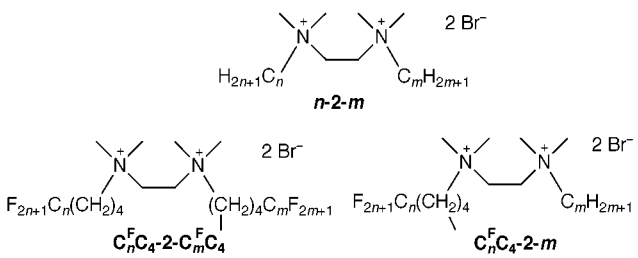
Dimeric (Gemini) or oligomeric surfactants, which consist of two or more conventional surfactant units linked at their polar head groups by a spacer, are attracting a lot of attention in the area of surfactant research because of the many unusual properties that they feature.[7,8] A direct consequence of the presence of two hydrophobic tails in dimeric surfactants is a sharp and uniform decrease in the c.m.c. values, which are 1 to 2 orders of magnitude lower than that of their monomeric counterparts.[7] For the same reason, slower exchange between dimeric surfactants in the bulk and in the aggregates could be anticipated. We now report on such unusually slow exchange and the consequent occurrence of separate ^1H and ^{19}F NMR signals for surfactants in the bulk and in micelles.

The surfactants studied here belong to the series of *n*-2-*m* bis-quaternary ammonium bromides whose structures are shown below.[9] Hydrocarbon, fluorocarbon as well as hybrid hydrocarbon–fluorocarbon[10] surfactants were tested.



Thus, the ^1H NMR spectrum of 14-2-14 in D_2O below its c.m.c. shows one set of sharp signals corresponding to the monomer in the bulk (Fig. 2c). Above the c.m.c. the lines broaden and a second set of signals appears, corresponding to the micelles (Fig. 2a and 2b). The intensity of the micelle signals increases linearly with the surfactant concentration, whilst the intensity of the monomer signals levels off above the c.m.c. The protons belonging to the polar head are deshielded up to 0.2 ppm in the micelles, and are very distinct from the monomer signals. This downfield shift is likely to be the result of the proximity between the cations in the micelles. For the protons belonging to the alkyl chains, chemical shifts are not so different and the various signals partly overlap.

The c.m.c. value can be estimated by integrating the monomer signals and comparing these with an internal standard, or more accurately determined by diluting the sample beyond the disappearance of the micelle signals and plotting the signal intensities as a function of concentration. For 14-2-14, the value measured upon dilution in D_2O (0.12 mM) matches well that obtained using conductimetry in H_2O (0.16 mM). The slight discrepancy may be attributed to expectable differences between H_2O and D_2O.

Line-shape analysis of the broadened signals gives the lifetimes of monomeric and aggregated species at various concentrations, and the characteristic time of exchange τ.[11]† For 14-2-14, τ (0.1 s) is orders of magnitude longer than for single chain surfactants.[3] In a series of *n*-2-*m* surfactants, τ increases with $n + m$. The chain length difference $n - m$ does not considerably affect the exchange, and similar spectra are obtained for 18-2-8 and 16-2-10 ($n + m = 26$), or for 18-2-10, 16-2-12 and 14-2-14 ($n + m = 28$). The borderline between fast and slow exchange on the NMR timescale at 25 °C lies between $n + m = 24$ and $n + m = 26$. As shown in Fig. 2d, two sets of

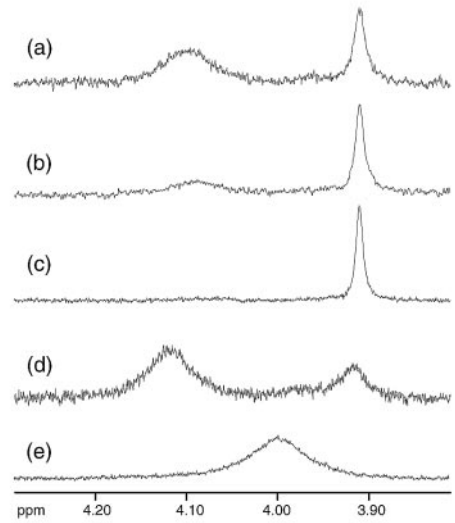


Fig. 2 Part of the 400 MHz ^1H NMR spectra of dimeric surfactants at various concentrations in D_2O (25 °C). The signals observed are those of the $N^+CH_2CH_2N^+$ protons for molecules in the bulk phase (3.92 ppm) and in the micelles (4.03–4.13 ppm). (a) [14-2-14] = 0.25 mM; (b) [14-2-14] = 0.167 mM; (c) [14-2-14] = 0.125 mM; (d) [18-2-8] = 0.5 mM; (e) [12-2-12] = 1.25 mM.

signals are present for 18-2-8 above its c.m.c. (0.3 mM). These signals are broader than those of 14-2-14, indicating faster exchange (τ = 0.04 s). Coalescence occurs for 12-2-12 (c.m.c. = 0.95 mM), and a single broad signal representing a weighted average of monomers and aggregated surfactants is seen (Fig. 2e). For all these dissymetric surfactants, the aggregates formed over a large range of concentration above the c.m.c. have been shown to be micelles.[9] In the case of 14-2-14, slopes of conductivity *versus* concentration suggests that micelles are also formed above the c.m.c., at least over a short concentration range. Bilayers were observed at 5 mM.[9]

Such slow exchange on the NMR timescale between monomeric and aggregated amphiphiles has been reported once for a neutral fluorinated surfactant, forming hydrogen bonds in an aggregated state.[12] These authors recognised the presence of large aggregates (not micelles), and suggested that this may be of importance in the large values of the measured lifetimes.[12] Lipids are much more hydrophobic than usual detergents and also exchange slowly between monomeric and vesicular states.[2,13] However, their critical aggregation concentrations are in the nanomolar range and below,[13] and are too small for NMR investigations. To the best of our knowledge our observations, using micelle-forming hydrocarbon cationic amphiphiles for which no forces other than the hydrophobic effect stabilise the aggregates, are unprecendented.

^{19}F and ^{1}H NMR spectra of the fluorocarbon Gemini surfactant $C_8^FC_4$-2-$C_8^FC_4$ and the hybrid hydrocarbon–fluorocarbon surfactant $C_8^FC_4$-2-12 also show distinct signals for monomers and aggregated surfactants (Fig. 3a).[10] The c.m.c. values deduced from dilution experiments or integration against a CF_3CH_2OH internal standard are 0.03 and 0.2 mM respectively, compared to 0.028 and 0.2 mM measured by conductimetry. For the hybrid surfactant $C_8^FC_4$-2-12, conductimetry and cryo-TEM observations confirm that the aggregates formed are micelles.[10] For the fluorocarbon surfactant $C_8^FC_4$-2-$C_8^FC_4$, vesicles seem to form even at such low concentrations, and the c.m.c. is probably a critical vesicular concentration.[10] The high sensitivity to the environment of fluorine chemical shifts results in large differences between the signals in the bulk and in the aggregates (up to 2.2 ppm for the terminal -CF_3 group). The ^{19}F nuclei located in the hydrophobic part of the molecules are shielded in the micelles and their signals shift upfield, whereas signals of the ^{1}H nuclei close to the polar heads shift downfield.

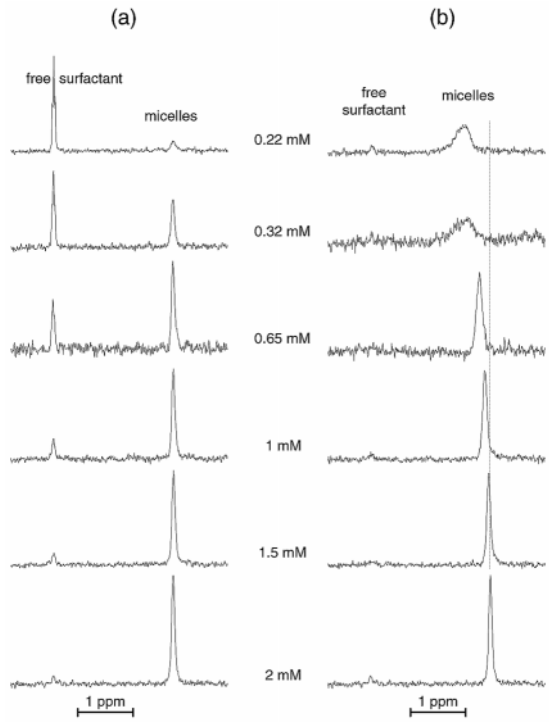

Fig. 3 Part of the 400 MHz ^{19}F NMR spectra of $C_8^FC_4$-2-12 as a function of concentration in 9 : 1 H_2O–D_2O (25 °C). The region covers the signals of the terminal -CF_3 groups in the bulk and in micelles. (a) no additives; (b) in the presence of 12-2-12 at constant total concentration, [$C_8^FC_4$-2-12] + [12-2-12] = 2 mM. The c.m.c. of 12-2-12 is 0.95 mM.

Slow exchange renders NMR studies of co-micellisation of various surfactants very tractable. The example of $C_8^FC_4$-2-12 and 12-12-12 shown in Fig. 3b represents a good illustration. When $C_8^FC_4$-2-12 and 12-2-12 are mixed in different proportions, it can clearly be seen that the hybrid fluorocarbon–hydrocarbon surfactant exists predominantly in the micellar state at concentrations close to, and even below, its c.m.c. At such low concentrations, $C_8^FC_4$-2-12 molecules remain in micelles consisting for the most part of 12-2-12 molecules. The co-micellisation can be traced by following the ^{19}F chemical shifts of $C_8^FC_4$-2-12 (Fig. 3b). As the mixed micelles become richer in 12-2-12, the fluorocarbon chains are less shielded than with pure $C_8^FC_4$-2-12, and the signals assigned to the micelles shift downfield. The concomitant broadening of these signals may result from the distribution of micelle composition, and not from faster exchange with 12-2-12 rich micelles. A ^{1}H NMR spectrum of these mixed micelles presents the original pattern of an aggregate with which one surfactant exchanges slowly, and the other rapidly. A more thorough investigation of the exchange rates for these surfactants is now in progress.

This work was supported by the Centre National de la Recherche Scientifique and the Institut Européen de Chimie et Biologie. We thank E. J. Dufourc for assistance with NMR measurements.

Notes and references

† Determination of the characteristic time of exchange τ may be performed using 1D polarisation transfer or 2D exchange spectroscopy. An estimate can be very simply obtained from lineshape analysis of a sample at a concentration twice the c.m.c. At this concentration the lifetimes of monomeric and aggregated species are both equal to τ, whose value is then given by $1/\tau = \pi\Delta\Delta\nu$, where $\Delta\Delta\nu$ is the linewidth difference between the monomer signal at twice the c.m.c. (broadened by the exchange) and below the c.m.c. (no exchange), as obtained from a least-square analysis of the spectra. The τ values can be measured as long as separate signals are observed, which requires $1/\tau < |\nu_m - \nu_a|$, where ν_m and ν_a are the monomer and the aggregate signal frequencies.

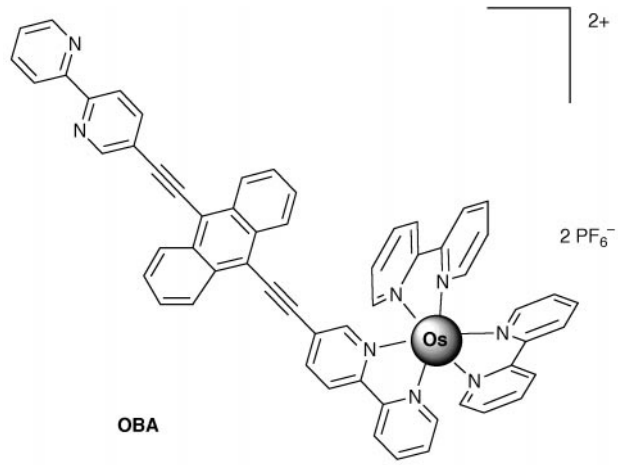
Received (in Cambridge, UK) 23rd July 1999, Accepted 8th September 1999

The combined effects of an ethynylene substituent and reversible energy transfer to an appended anthracene unit provide access to luminophoric osmium(II) tris(2,2′-bipyridyl) derivatives of unusually long triplet lifetime and whose improved optical properties might provide new analytical opportunities.

Derivatives of ruthenium(II) polypyridine complexes are being used for an ever-increasing number of luminogenic assays, especially for biological systems.[1] An attractive feature of these chromophores concerns the relatively long-lived phosphorescence observed for certain complexes at room temperature in deoxygenated solution. Indeed, several strategies are available by which to both prolong the emission lifetime[2,3] and shift the emission maximum to longer wavelength.[4,5] The corresponding osmium(II) polypyridine complexes,[6] which possess attractive absorption and emission spectral profiles, have been largely ignored as regards analytical applications because of their relatively short emission lifetimes. We now describe a simple approach to extend the triplet lifetime of osmium(II) tris(2,2′-bipyridyl) derivatives and, at the same time, push the emission maximum to lower energy.

This strategy requires access to luminescent 'Os(bpy)' (bpy = 2,2′-bipyridine) derivatives functionalized with two key elements. The first requirement involves direct substitution of an alkyne group on the bpy ring. This ensures selective charge injection from the metal centre to the alkyne-bearing bpy ligand under illumination and, because of extended electron delocalization, lowers the triplet energy.[7] The second requirement is to attach a chromophore at the opposite end of the alkyne that can transfer triplet energy reversibly to the 'Os(bpy)' unit.[2,3,8] This demands careful balancing of the triplet energies of the two units and we have found that anthracene is a useful energy shuttle for such systems. In order to obtain the required triplet energy, however, it was necessary to attach ethynylene groups at both the 9- and 10-positions of the anthracene subunit but this has the advantage of providing access to mono- and bi-nuclear 'Os(bpy)'-based systems and to mixed-metal complexes. Several such compounds were synthesized† and their photophysical properties examined in deoxygenated acetonitrile at 20 °C. For brevity, we describe only the properties of **OBA**. We note that, although triplet energy transfer between 'Os(bpy)' derivatives and anthracene has been reported,[9,10] neither reversible energy transfer nor prolongation of the triplet lifetime has been considered before.

The absorption spectrum recorded for **OBA** shows intense transitions between 400 and 520 nm due to the anthracene-based ditopic ligand (Fig. 1). These π,π* transitions overlap the weaker metal-to-ligand, charge-transfer (MLCT) bands associated with the 'Os(bpy)' unit but the corresponding spin-forbidden MLCT transitions can be seen as a tail stretching towards 800 nm. This latter band allows excitation into the 'Os(bpy)' chromophore at wavelengths where few other species absorb and where light scattering from biological materials is less significant. Fluorescence from the ditopic ligand is completely quenched when the terminal 'Os(bpy)' unit is in



place, owing to rapid intramolecular electronic energy transfer. As such, the ditopic ligand acts as a light harvester for the lowest-energy triplet state localized on the 'Os(bpy)' unit.

Luminescence from **OBA** is observed at 20 °C (Fig. 1), the maximum being around 800 nm, that can be assigned to emission from the 'Os(bpy)' terminal. This emission, for which the quantum yield (Φ_L) is 0.0012, decays *via* exponential kinetics corresponding to a triplet lifetime (τ_T) of 415 ± 15 ns. The triplet energy (E_T) calculated by fitting[9] the emission spectrum is 13150 cm^{-1}. These values can be compared with those measured for the parent $[Os(bpy)_3]^{2+}$ complex (Φ_L = 0.0046; τ_T = 60 ns; E_T = 14640 cm^{-1}) showing that, despite its lower triplet energy, **OBA** possesses much the longer-lived triplet state.

The differential triplet absorption spectrum recorded for **OBA** after excitation with a 15 ns laser pulse at 600 nm (Fig. 2)

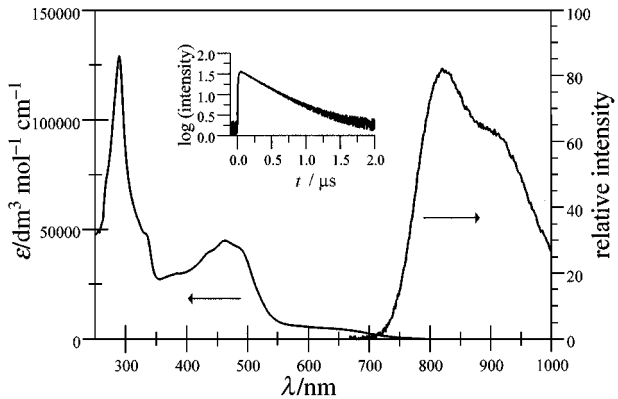


Fig. 1 Absorption and corrected emission spectra recorded for **OBA** in deoxygenated acetonitrile at 20 °C. The emission spectral profile is independent of excitation wavelength while the corrected excitation spectrum matches well with the absorption spectrum. The insert shows the time-resolved emission profile recorded at 850 nm after excitation with a 15 ns laser pulse at 600 nm.

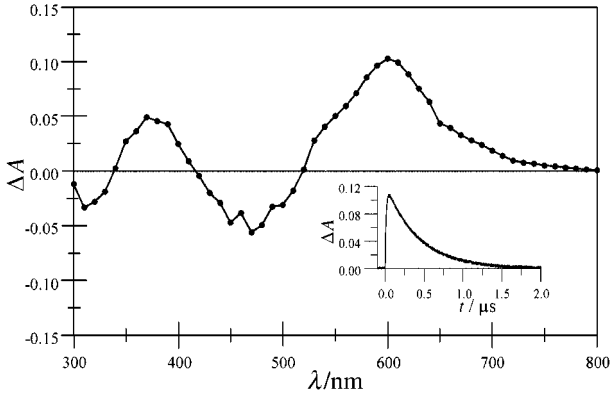

Fig. 2 Differential triplet absorption spectrum recorded for **OBA** in deoxygenated acetonitrile after excitation with a 15 ns laser pulse at 600 nm. The insert shows the decay profile recorded at 600 nm.

is very similar to that measured for the ditopic ligand, although the latter does not phosphoresce in deoxygenated acetonitrile at 20 °C. The absorption signal decays *via* exponential kinetics, at all wavelengths, with an average triplet lifetime of 420 ± 20 ns. Identical spectra and decay kinetics are observed following laser excitation at 355, 450, 600 or 650 nm. The simplest explanation[2,3] for these observations is that the triplet states localised on the 'Os(bpy)' fragment and on the anthracene-based ditopic ligand are in thermal equilibrium at 20 °C. The two triplets decay with a common lifetime of 420 ± 20 ns to restore the ground state. Consistent with this hypothesis is the observation that the triplet energy of the ditopic ligand, established from phosphorescence spectra recorded in micellar media,[11] is 12400 cm^{-1}. Thus, the triplet energy gap is 750 cm^{-1}, with the anthracene-like triplet lying at lower energy, while the equilibrium constant (K) can be estimated as being *ca* 40. This latter value implies that the fraction (α) of 'Os(bpy)' triplets in the equilibrium distribution is only 2.5%. This residual 'Os(bpy)' triplet is highly luminescent, however, since the observed Φ_L is *ca*. 25% that of the parent complex where the triplet yield is quantitative. The 'Os(bpy)' fragment in **OBA**, in fact, is roughly 10-fold more emissive than the parent complex when due allowance is made for the relative concentrations. This increase arises from the longer triplet lifetime (*cf*. 420 *vs*. 60 ns) and longer radiative lifetime (*cf*. 18 *vs*. 13 μs) provided by the improved optical properties.

The rate constant for decay of the equilibrated triplets ($k_D = 1/\tau_T$) can be expressed[2] in terms of the individual rate constants associated with deactivation of triplets localised on the ditopic ligand (k_A) and on the 'Os(bpy)' fragment (k_O).

$$k_D = \alpha k_O + (1 - \alpha)k_A,\ K = (1 - \alpha)/\alpha$$

Since k_A ($= 1.4 \times 10^5\ s^{-1}$) is known from measurements made for the ditopic ligand and $\alpha = 0.025$, it follows that $k_O \approx 9 \times 10^7\ s^{-1}$. This seems a reasonable value for an ethynylated 'Os(bpy)' derivative, where triplet lifetimes tend to range between 10 and 60 ns.[7] As such, reversible triplet energy transfer between the subunits stabilizes the 'Os(bpy)' triplet by a factor ($S = k_O\tau_T$) of *ca*. 38-fold.

Direct excitation into the 'Os(bpy)' chromophore with a sub-ps laser pulse at 600 nm indicates that the equilibrium mixture of triplets is established with a first-order rate constant of $3.0 \times 10^{10}\ s^{-1}$. Allowing for $K = 40$, we can estimate rate constants for triplet energy transfer from 'Os(bpy)' to the anthracene-like triplet ($k_F = 2.9 \times 10^{10}\ s^{-1}$) and for the corresponding reverse process ($k_R = 7.3 \times 10^8\ s^{-1}$). Both reactions are exceptionally fast, especially the reverse step which is strongly endergonic, because of the superb electronic conductivity of the alkyne connector.[12]

Illumination of **OBA** in O_2-saturated acetonitrile generates singlet molecular oxygen, as monitored by its characteristic time-resolved luminescence behaviour. The lifetime of the so generated singlet molecular oxygen ($\tau_D = 75 \pm 5$ μs) remained independent of the concentration of **OBA** while protracted steady-state illumination with an argon ion laser emitting at 514 nm did not damage the chromophore. Clearly, the ethynylene groups stabilize the anthracene unit against oxygenation.[10,13]

In summary, we describe a strategy for designing 'Os(bpy)'-based luminophores possessing improved optical properties and an unusually long-lived triplet state. There are, of course, other ways to prolong the triplet lifetime; *e.g.* freezing the solution or raising the triplet energy.[6] Such approaches do not produce valuable luminogenic reagents. In contrast, combining the special electronic properties[3,7,8,12] (*e.g.* directionality, conductivity, delocalisation) of the alkyne with reversible triplet energy transfer to an anthracene-like subunit provides a useful reagent of exceptional thermal and photostability. It is important to emphasise the complementarity of the system in that each of the three units is essential. Thus, the 'Os(bpy)' fragment provides a long-wavelength absorption profile and the necessary luminescent centre. The alkynylene connector offers structural integrity and an excellent conduit for intramolecular electron exchange whereas the anthracene unit prolongs the triplet lifetime of the emitting species.

We thank Johnson-Mathey PLC for their very generous loan of precious metal salts. Some of the laser spectroscopic studies were made at the Free Radical Research Facility at the Paterson Institute for Cancer Research, Manchester, UK. We thank the EU for providing financial support for the FRRF and to cover travel costs.

Received (in Basel, Switzerland) 17th May 1999, Accepted 1st September 1999

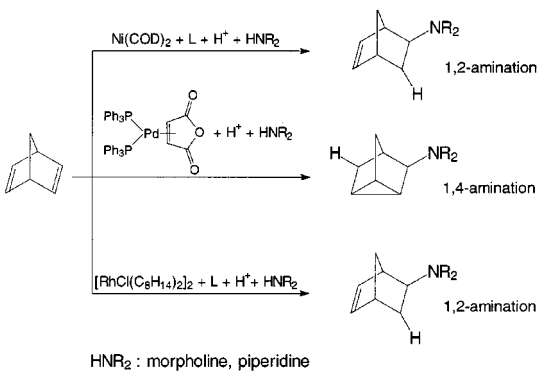
New transition metal-catalyzed reactions of norbornadiene with secondary amines are reported.

The development of efficient protocols for the construction of carbon–nitrogen bonds is of interest owing to the fundamental importance of amines as natural products, pharmacological agents, fine chemicals, and dyes.[1] Regarding the various possibilities to form C–N bonds, the catalytic hydroamination of olefins is the most atom economic process.[1]

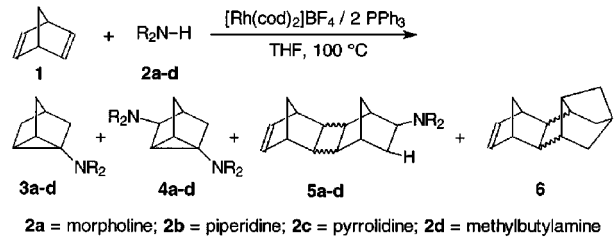
In addition, a wide variety of olefins and amines are both inexpensive and readily available starting materials. Hence, considerable efforts have been undertaken to develop metal-catalyzed hydroamination processes.[2] Among the first transition metal catalysts for hydroamination were Rh salts, *e.g.* $RhCl_3$ introduced by Du Pont.[3] Although a number of Rh complexes catalyze the reaction of ethylene with secondary amines with yields of up to 70%, other olefins do not react. Interestingly, Brunet *et al.*[4] demonstrated later, that $[Rh(PEt_3)_2Cl]_2$ catalyzes both the oxidative amination and the hydroamination of styrene with aniline. Recently, we became interested in catalytic hydroaminations. Our approach to this problem was based on the use of cationic Rh complexes in order to enhance the reactivity of the resulting catalysts. Indeed, a mixture of $[Rh(cod)_2]^+BF_4^-$/2 PPh_3 catalyzes the reaction of aromatic olefins with secondary amines.[5] Surprisingly, no hydroamination takes place, but a rare example of intramolecular oxidative amination is observed to yield *N*-(2-arylethenyl)amines and arylethane in good yields. Here, we describe the first extensions of this methodology to aliphatic olefins, especially norbornadiene (nbd).

The addition of nucleophiles H–X to nbd yields, in general, tricyclic pseudo-1,4-addition products (Scheme 1). This reaction is catalyzed by both acids and Pd complexes.[6]

Adaptation of our previously reported procedure for the oxidative amination of styrene with morpholine to nbd yields, under standard conditions (2.5 mol% $[Rh(cod)_2]^+BF_4^-$, 5 mol% PPh_3, THF reflux), three new amination products **3a**, **4a** and **5a** in 25, 33 and 31% yield, respectively[7] (Scheme 2, Table 1). Furthermore, small amounts (< 3%) of hydrodimerization **6** and hydrooligomerization products were observed. The structure of **3a** and **4a** was unambiguously proved by ^1H and ^{13}C NMR spectroscopy and MS, *e.g.* the ^{13}C NMR spectrum of **3a** exhibit one quaternary, two different secondary and two tertiary carbon centers of the nortricyclene group and two signals of the morpholino ring, while the ^{13}C NMR spectrum of **4a** exhibits one quaternary, four different tertiary and two secondary carbon centers of the nortricyclene group and four signals of the two morpholino rings. **5a** has been identified by GC–MS. Interestingly, **4a** is obtained as a pure diastereomer, where the two morpholino rings point away from each other.



Scheme 1 Known addition of amines to nbd.



Scheme 2 Rh-catalyzed reaction of morpholine with nbd.

Table 1 Reaction of morpholine with norbornadiene

Entry	Catalyst (mol%)	Solvent	Olefin: amine	Yield **3a**[a] (%)	Yield **4a**[a] (%)
1	2.5	THF	4:1	25	33
2	5	THF	4:1	43	14
3	10	THF	4:1	47	5
4	2.5	THF	10:1	7	46
5	2.5	THF	1:2	32	7
6	2.5	Toluene	4:1	3	88

[a] The yield (referred to amine) was determined by GC using an internal standard.

Concerning **3a** and **4a** it is noteworthy that, unlike in previously published amination procedures of nbd, at least one amine is bound directly to one of the C atoms of the cyclopropyl ring. This structural motif can only be explained by a *pseudo*-1,3-addition mode to nbd.[8] To the best of our knowledge *pseudo*-1,3-additions of nucleophiles H–Nu (Nu = NR_2, OR, SR, *etc.*) to nbd have not been reported previously.

Next, we modified the reaction conditions in order to improve the selectivity of the amination reaction. In a series of reactions carried out on 5 mmol scale the amount of catalyst, reaction temperature, solvent and olefin to amine ratio was varied. Reactions employing a larger amount of catalyst (5, 10 mol%) gave significantly higher yields of **3a** (up to 47%) while the yield of the diaminated product **4a** is decreased to only 5%. Use of a ten-fold excess of norbornadiene to morpholine resulted in a drastic decrease of **3a** (7%), but **4a** is obtained in 46%. Consistently at lower amine to olefin ratio the yield of **4a** is

† Dedicated to Professor Dirk Walther on the occasion of his 60th birthday.
‡ Considered as Part 7 of the series Anti-Markovnikov-reactions; for part 6 see M. Beller, H. Trauthwein, M. Eichberger, C. Breindl and T. E. Müller, *Eur. J. Inorg. Chem.*, 1999, 1121.

increased. The use of toluene at higher reaction temperature appeared to be especially suitable for the formation of the diaminated product **4a** (88%).

Analogous to morpholine we reacted other secondary amines and aniline with nbd in the presence of 5 mol% $[Rh(cod)_2]^+BF_4^-$ and 10 mol% PPh_3 in THF in a glass pressure tube at 100 °C (Table 2). While aniline gave only non-aminated dimerization products of nbd, all secondary amines gave a total yield of amination products of 84–99%.

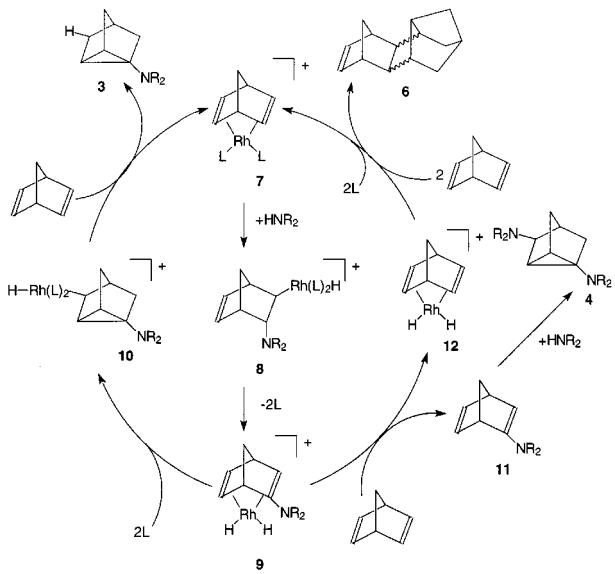
Table 2 Reaction of norbornadiene with amines[a]

Entry	Amine	Yield amines[b] (%)	Yield **3**[c] (%)	Yield **4** (%)
1	Morpholine **2a**	91	43	14[c]
2	Piperidine **2b**	99	52	17[d]
3	Pyrrolidine **2c**	84	52	10[d]
4	*n*-Butylmethylamine **2d**	90	46	13[d]

[a] Ratio of nbd:amine = 4:1, 5 mol% $[Rh(cod)_2]BF_4/2PPh_3$ relative to amine, 20 h reflux in THF. [b] Overall yield of amination products (**3** + **4** + **5**). [c] The yield (referred to amine) was determined by GC using an internal standard. [d] The yield (referred to amine) was determined by GC by percentage area.

The major product under these conditions were the mono-amination products **3b**–**d**. However, in all cases significant amounts of 2,5-bis(*N*-amino)tricyclo[2.2.1.$0^{2,6}$]heptane **4b**–**d** and aminated nbd dimers were formed.

Here, we describe the first example of the catalytic *pseudo*-1,3-addition of nucleophiles (amines) to nbd. In general, amination of nbd with amines proceeds in high yield but with only moderate selectivity. Although the reaction has not been fully optimized, yields of 2-(*N*-morpholino)tricyclo-[2.2.1.$0^{2,6}$]heptane **3a** of *ca.* 50% were obtained in THF at 100 °C. On the other hand a high yield (88%) of 2,5-bis(*N*-morpholino)tricyclo[2.2.1.$0^{2,6}$]heptane **4a** was obtained in toluene at 140 °C. While little mechanistic work has been conducted on the new amination reaction at this time, we propose that the reaction occurs by a catalytic cycle shown in Scheme 3.



Scheme 3 Proposed mechanism for the Rh-catalyzed amination of nbd.

Olefin exchange of cyclooctadiene by nbd will give the corresponding nbd complex **7**. Here, the double bonds are activated for a nucleophilic attack of the amine leading to **8**. Alternatively, **8** may be formed by insertion of the olefin into the Rh–N bond of a hydridoamidorhodium species. Although this mechanism seems unlikely owing to the stereochemistry required for the following β-hydride elimination, it has been shown that cationic Rh complexes are able to activate N–H bonds under similar conditions.

β-Hydride elimination would form the Rh–dihydride complex with a chelating enamine ligand **9**. Stepwise hydrogen transfer with concurrent double bond shift would give the Rh alkyl complex **10**. Subsequently, reductive elimination yields **3**. On the other hand ligand exchange of the enamine with nbd would yield **11** and **12**. It is known in the literature[9] that **11** reacts with amines to give **4**. While it is easy to explain the improved yield of **4** with increased olefin to amine ratio owing to the increased ligand exchange with nbd, we do not understand the influence of the catalyst concentration. In addition it is obvious that higher reaction temperatures (140 °C, toluene) favor the ligand exchange, hence yielding **4** predominantly. The occurrence of the hydrodimerization product **6** confirms the existence of Rh–hydride species.

Regarding the synthetic value of this new method, it is important to note that a number of aliphatic polycyclic amines such as amantadine, memantine, venritidine, carmantadine, oxphaman and amantocillin are interesting pharmacologically active compounds.[10] New analogs may be prepared by our method.

In conclusion, we have developed a new type of Rh-catalyzed amination. Here, nbd is aminated in an unusual *pseudo*-1,3-addition mode. Both mono- as well as di-aminated products are accessible as major products.

7 *General procedure:* 89.3 mg $[Rh(cod)_2]BF_4$ (0.22 mmol) and 115.4 mg PPh_3 (0.44 mmol) were mixed in 10 ml THF. Subsequently, 0.38 ml morpholine (4.40 mmol) and 1.92 ml nbd (17.6 mmol) were added at room temp. The reaction was heated to reflux for 20 h before being cooled to room temp. After removal of the solvent *in vacuo*, the residue was dissolved in 20 ml CH_2Cl_2 and extracted three times with 5% HCl. NaOH was added to the combined aqueous phases until a pH of 9 was reached. The aqueous phase was then extracted three times with CH_2Cl_2. The combined organic layers were dried over $MgSO_4$ and the solvent was distilled off. The products were obtained after column chromatography ($CHCl_3$–MeOH = 30:1). Isolated yields: **3a**: 32% (252 mg); **3b**: 40% (312 mg); **3c**: 37% (266 mg); **3d**: 34% (268 mg); **4c**: 4% (23 mg).

8 We term this reaction of amines with norbornadiene a pseudo-1,3-addition in agreement with literature for 1,4-addition reactions.

Received (in Cambridge, UK) 27th July 1999, Accepted 8th September 1999

Mesoporous silicas have been obtained by the true liquid crystal templating (TLCT) method, using a surfactant Ru^{II} complex as the template; on calcination, ruthenium-containing particles are deposited into the pores; the materials show high catalytic selectivity for the hydrogenation of hex-1-ene.

Since the discovery of the utility of surfactants as templates for mesoporous solids by Mobil,[1] there has been an explosion of interest in these mainly siliceous solids, particularly as pore sizes from, for example, 20–100 Å are now routinely available. For much of the time since these initial developments, the situation has been rather unsatisfactory as there was little pre-emptive control which could be employed to direct the structure of the materials to be synthesised. Thus, while a given set of conditions could reproducibly lead to a given material with given dimensions, some of the structural parameters (pore size, wall thickness, degree of crystallinity) of the solid were largely unpredictable prior to the first experiment. The exact mechanism of the templating attracted much speculation and debate. This was partly due to the fact that the surfactant was present above the critical micelle concentration (cmc), but at concentrations below those necessary for mesophase formation. More recently, this situation changed rather dramatically with the development of the true liquid crystal templating (TLCT) synthesis by Attard *et al.*[2] In this approach, a lyotropic liquid crystal phase was first formed and templating took place around the pre-formed mesophase in a sol–gel hydrolysis of tetramethoxysilane (TMOS). In forming these solids, both neutral and cationic surfactants could be employed. The various approaches to liquid crystal templating have been reviewed recently.[3]

Because of the pore sizes available in mesoporous solids, one of the great attractions is the possibility to carry out reactions therein, using molecules which would not have been able to get inside the pores of microporous materials. This reactivity can take a number of forms. First, it is possible simply to use the acidity of the mesopore surface to facilitate reactions. This is particularly attractive when doping aluminium into the silica, so as to generate Brønsted acid sites. On these sites, ion exchange can take place and the acidity or basicity of the material can be controlled. It is also possible to introduce molecular catalytic species, which may be tethered to the mesopore, to carry out reactions in confined environments. Another avenue for catalytic functionalisation is the deposition of metal particles within the pores and to use the materials as heterogeneous catalysts.[4] In the latter two approaches, it is necessary to pre-form the mesoporous solid and then to introduce the catalyst, or as has recently been shown, to introduce an extra metal-based species during gel formation.[5] What we describe here is the production of a mesoporous solid containing deposited metal particles in one step from the surfactant, exploiting the dual functionality of the surfactant ruthenium complex as, both, structure directing and catalytic site generation agent.

Some of us have been interested in the synthesis and mesomorphism of surfactant metal complexes,[6] and in particular the study of the lyotropic mesomorphism of surfactant derivatives of tris(bipyridine)ruthenium(II) (Fig. 1).[7] As part of this work, we were interested to see whether these complexes could be used to template mesoporous silicates, and in particular whether the TLCT approach could be adopted. To this end, we employed the dinonadecyl-substituted complex **1**, which we know to form a hexagonal H_1 phase in water at elevated temperatures.

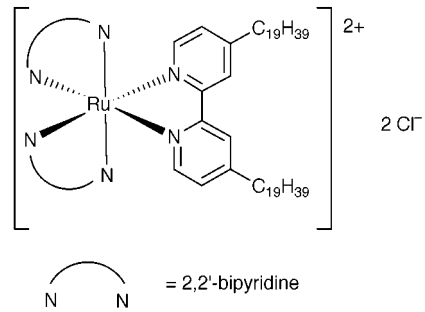

Fig. 1 Structure of the ruthenium complex used for templating.

Thus, a 50 wt% mixture of **1** in water acidified to pH 2 with H_2SO_4 was prepared and maintained at 60 °C, and was shown by polarised optical microscopy to have a non-geometric texture typical of the hexagonal H_1 phase at this temperature. A small amount of methanol was added to the mesophase preparation, in order to aid mixing of the reagents, and was removed under a dynamic vacuum immediately after addition of the TMOS. Hydrolysis of the TMOS starts immediately and the methanol so produced was removed under gentle, dynamic vacuum as it was generated. After 2 h, the gel formation was complete and a strongly red-coloured gel remained, coloured due to the ruthenium complex contained therein. Interestingly, this gel still retains the texture of the hexagonal H_1 phase when viewed in the polarising microscope. The gel was then calcined in air at 600 °C for 6 h leading to a blackened silicate which we calculate to have 6 wt% Ru.

Investigation of this mesoporous silicate by transmission electron microscopy shows a material which retains the hexagonal symmetry of the mesophase on which it was templated and which contains relatively evenly distributed particles of RuO_2 (Fig. 2). Evaluation of the surface area by N_2 adsorption isotherm measurements gave a type IV absorption–desorption isotherm, confirming that the material is mesoporous and led to values in the range 870–980 $m^2\ g^{-1}$ being established

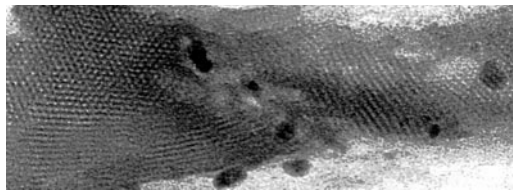

Fig. 2 TEM of the as-obtained silicate (×240 000).

for the BET surface area (depending on the sample). The same measurements also showed a very narrow pore size dispersity (half peak height values of 20–40 Å). In addition, evaluation of the surface-area-to-bulk ratio suggested rather high surface area particles with a CO dispersion of 15%. This compares with a value of 7.5% for MCM-41 impregnated with ruthenium nitrosyl nitrate [$Ru(NO)(NO_3)_3$] which was then converted to RuO_2.[8]

The materials were then tested as catalysts in the hydrogenation of hex-1-ene without prior reduction in hydrogen as a simple model system.[9] Thus, at 373 K and under 22 bar of H_2, hexene was hydrogenated *only* to *n*-hexane[10] at a turnover frequency of 877 mol hexane(mol Ru h)$^{-1}$. This exceeds turnover rates for hydrogenation on AgRu nanoparticles on MCM41 [690 mol hexane(mol metal h)$^{-1}$] under the same conditions,[11] although in its unoptimised state, it falls short of the rates[12] obtained for CuRu nanoparticles on the same support [1560 mol hexane(mol metal h)$^{-1}$].[4]

H. B. J., M. E. R. and T. M. thank the EPSRC and the EU for support. Generous loans of ruthenium salts and access to data from Johnson Matthey are gratefully acknowledged.

8 We thank Johnson Matthey for letting us have sight of these results.
9 The catalytic reactions were performed in a PEEK-lined high pressure reactor (Cambridge Reactor Design) equipped with a stirrer and liquid sampling valve (for withdrawing samples under pressure to evaluate kinetics). In a typical reaction the autoclave was charged with *ca.* 50 g of hex-1-ene and the activated catalyst (*ca.* 20 mg, heated in vacuum at 463 K for 4 h) was directly introduced into the reactor without exposing it to air. The reactor was then pressurised with H_2 to 20 bar and heated to 373 K. Samples were periodically withdrawn without perturbing the pressure in the reactor and analysed by GC using 1,2-dichlorobenzene as the internal standard; a typical mass-balance showed minimal sample loss.
10 Apart from *n*-hexane, isomerised products, namely *cis*-and *trans*-hex-2-ene and small amounts *trans*-hex-3-ene were obtained when Cu_4Ru_{12}, Ag_4Ru_{12} or Pd_6Ru_6 were employed as catalysts for the hydrogenation of hex-1-ene (see ref. 4). There is no detectable thermocracking.

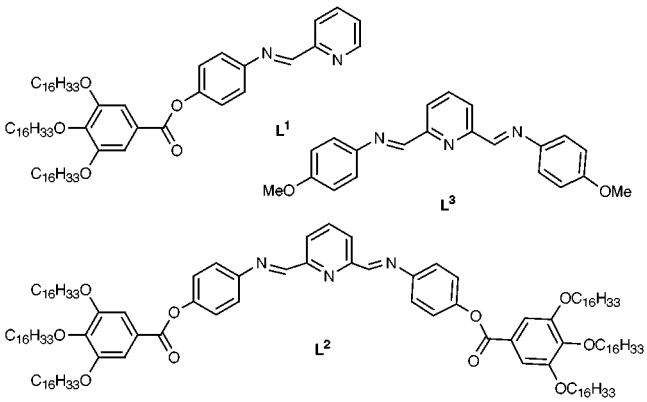
Received (in Basel, Switzerland) 26th May 1999, Accepted 1st September 1999

In the presence of copper(I), certain di- and tri-topic ligands derived from reaction of substituted anilines with 2-pyridinecarbaldehyde or 2,6-pyridinedicarbaldehyde form a new type of polycatenar metallomesogen around the tetrahedral metallic centre.

Metal complexes derived from Schiff-bases are known to form a large variety of molecular architectures, ranging from macrocyclic helicates to infinite coordination polymers.[1,2] In particular, 2-iminopyridines, readily formed *via* reversible reaction between an (achiral or chiral) amine and an appropriate aldehyde, are attractive building blocks for assembling intricate supramolecular species[3] and active polymerization catalysts.[4,5] These ligands can display unusual binding behaviour towards certain cations, leading to the formation of highly stable metallohelicates.[6] The main advantage of such ligands, however, relates to the availability of a free imino site that can be functionalized with a wide variety of appendages. Indeed, the structural attributes provided by 2-iminopyridines look highly promising for the assembly of metallomesogens by attaching flexible paraffinic tails and subsequent rigidification of the head-group by complexation with copper(I) cations. It is worth noting that silver complexes constructed from polycatenar scaffoldings and which exhibit columnar liquid-crystalline mesophases have previously been studied.[7]



Ligands L^1 and L^2 were prepared in 99 and 86% isolated yield, respectively by refluxing 2-formylpyridine or 2,6-diformylpyridine and the corresponding aniline[8] in ethanol containing a trace amount of acetic acid. Each ligand has a well defined melting point at 58 °C (L^1) on 56 °C (L^2). Ligand L^3, which serves as a reference compound, was synthesized by a similar route and has a melting point of 159 °C.

Reaction of either ligand in dichloromethane with 0.5 equiv. of $[Cu(MeCN)_4]BF_4$ leads to immediate formation of a deep-red colouration indicative of complexation of copper(I) to four nitrogen donor ligands[9] {λ_{max} = 505, 500 (sh) and 500 (sh) nm with ε = 5100, 2600 and 3000 dm^3 mol^{-1} cm^{-1}, respectively for $[Cu(L)^n)_2]BF_4$ (n = 1–3) **1**–**3**}. Mass spectrometry is consistent with the isolated products being monomeric without contamination from polynuclear structures. These products, therefore, may be assigned the general formula $[Cu(L^n)_2]BF_4$.† A schematic representation of the complexes and a computer generated CPK model of one of the structures is shown in Fig. 1.

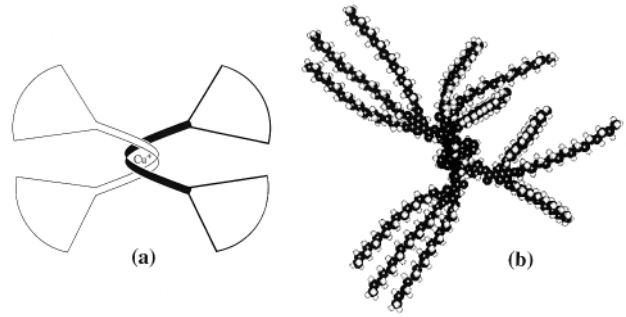


Fig. 1(a) Idealized pictoral representation of complex **2** representing the disk-shape and (b) CPK energy-minimised conformation.

Direct involment of the terminal imino groups in the coordination sphere was confirmed by solid-state and solution-phase FTIR studies and by both ^{1}H and ^{13}C NMR spectroscopy. The NMR studies also indicate that the two ligands bound to Cu(I) are equivalent while the relatively broad signals belonging to the aromatic protons, together with a broad imine signal (for complexes **1** and **2**) are attributed to a fast exchange process between coordinated and free imino N atoms. Similar internal flexibility has been observed previously for related macrocyclic[10] and terpyridine[11] based copper(I) complexes. Solid state FTIR studies of complex **2** reveal the presence of two imino stretching vibrations; one lying close to that of the free ligand ($\nu_{C=N}$ 1626 cm^{-1}) and the second occurring at lower frequency ($\nu_{C=N}$ = 1588 cm^{-1}) owing to coordination to the metal centre. X-Ray crystallography made for a single crystal of complex **3** indicates that two L^3 ligands are wrapped around a single copper cation, each ligand being coordinated *via* a pyridine-imine fragment, while the pendant imino arm is directed away from the metal centre in a *trans* configuration (Fig. 2).‡

It is noteworthy that, despite the *cis* arrangment of the coordinated py-CH=N- fragment and the *trans* conformation of the uncoordinated imino subunit, the overall ligand adopts an almost planar structure. The four-coordinate copper(I) cation shows Cu–N(py) and Cu–N(imine) distances of *ca* 2.085 and 2.021 Å, respectively with chelate bite angles of 81.6 and 81.1°. The uncoordinated imino fragment lies *ca.* 4.706 Å from the cation. There is obvious distortion around the metallic centre that might explain why the molecule stacks into columns, favouring a liquid-crystalline phase (*vide infra*), a situation which is also clearly observed in the CPK energy-minimised conformation [Fig. 1(*b*)].

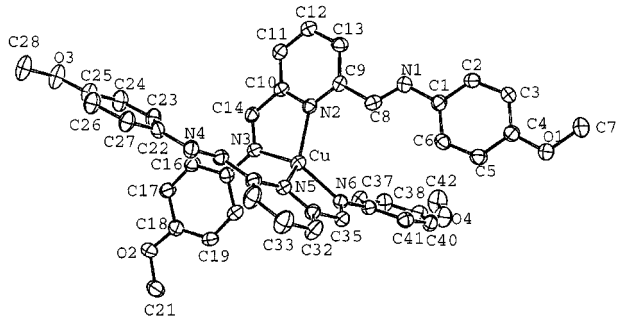

Fig. 2 ORTEP view of complex **3** showing 50% probability thermal ellipsoids. The hydrogen atoms are omitted for clarity.

Although non-mesomorphic themselves, ligands L^1 and L^2 produce thermotropic liquid-crystalline complexes when co-ordinated to copper(I), as demonstrated by differential scanning calorimetry (DSC) and polarizing optical microscopy (POM). The DSC thermograms of **2**, recorded from 20 to 130 °C, contain two sharp peaks, each of which indicates a reversible first-order phase transition. The peak at 49 °C (ΔH = 149.2 kJ mol^{-1}) corresponds to melting of the crystal into a liquid-crystalline phase whereas the peak at 117 °C (ΔH = 3.1 kJ mol^{-1}) can be attributed to clearing of the liquid crystal into an isotropic melt (values are given for the third cycle). The high stability of complex **2** was demonstrated by the absence of significant perturbation of the DSC patterns following several heating–cooling cycles. The optical textures observed for **2** during slow cooling from the isotropic melt are typical of a columnar phase (with pseudo focal-conic textures). This birefringent texture is maintained at room temperature. In contrast, complex **1** melts into the liquid crystal phase at 48 °C (ΔH = 84.6 kJ mol^{-1}) and has a clearing point at 75 °C (ΔH = 10.3 kJ mol^{-1}), but only on the first heating stage. It appears, therefore, that complex **1** is thermally unstable, a feature not entirely unexpected in view of the lack of substituents at the 6-position.

The columnar structure of the liquid crystal phases of **1** and **2** was confirmed by X-ray diffraction studies. It is seen that the rigid aromatic units that comprise the core of the pseudo-tetrahedral copper(I) complexes are superposed on top of one another and embedded in a disordered matrix provided by the molten alkyl chains. These columns are packed laterally into a two-dimensional hexagonal unit cell having parameters of 60 and 47 Å for **1** and **2**, respectively as measured at 60 °C from the small-angle reflection. The larger value found for **1** suggests that a 'phosmidic-type' of columnar mesophase is formed (where several individual molecules aggregate to form a disk), whereas for **2** the individual molecules stack one on top of the other to form columns as in conventional discoid liquid crystalline material.

Liquid crystals obtained from purely organic molecules comprising a tetrahedral carbon atom substituted with four semi-rigid subunits bearing flexible terminal alkyl chains have been reported.[12] However, complexes **1** and **2** are, to the best of our knowledge, the first examples of metallomesogens built around a single tetrahedral metal cation. Many unsuccessful attempts to engineer such metallomesogens have been attempted in the past.[13,14] As such, these materials differ markedly from the liquid-crystalline metallohelicate built around a central binuclear copper(I) helicate.[15] It should be stressed that the 2-iminopyridine moiety is readily amenable for systematic investigation of how the length and number of appended alkyl chains influence the liquid-crystalline properties, especially melting temperature, and to establish the structural and thermodynamic factors that assembles the aromatic cores into columns. Such information, which is critical for a proper theoretical description of metallomesogens, is not yet available for any liquid-crystalline material. We are well aware that the polycatenar ligand L^2 is an attractive substrate for reaction with metal cations that favour octahedral coordination geometries.

We thank Professor Anthony Harriman for his critical review of the manuscript and for the energy-mimimised structure and Dr. Benoît Heinrich (IPCMS) for fruitful and helpful discussions.

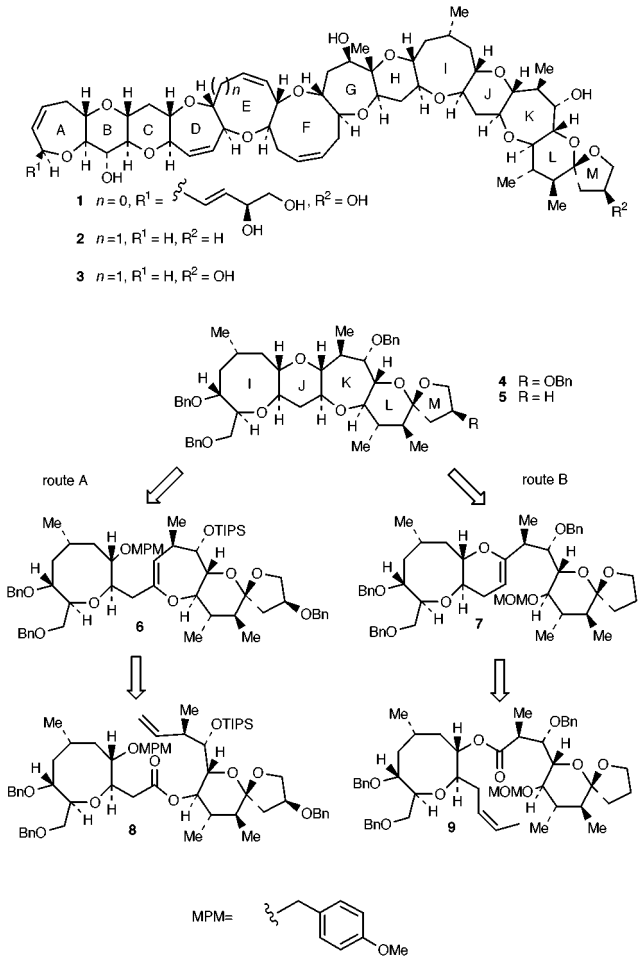
Received (in Cambridge, UK) 23rd August 1999, Accepted 7th September 1999

The IJKLM ring fragment of CTX3C, an important member of the ciguatoxin family, was synthesized *via* ring-closing metathesis using the Tebbe reagent and an improved method of reductive hydroxy ketone cyclization.

Ciguatoxin (CTX1B, **1**) and its congeners, CTX3C (**2**) and **3**, are the causative toxins of ciguatera seafood poisoning prevalent in the tropics and subtropics.[1] Although numerous synthetic studies have been reported because of the striking structure and biological activity of these compounds, efficient synthetic methods are still needed for total synthesis. During the course of our synthetic studies directed toward **1**,[2] we recently succeeded in synthesizing the ABCDE ring framework of **1** based on alkylation and ring-closing metathesis (RCM).[3] We describe herein a convergent synthesis of the IJKLM ring fragment of **2**.

Two synthetic routes were envisaged as outlined in Scheme 1. Tebbe reagent mediated transformation[4] of ester **8** (or **9**) into cyclic enol ethers **6** (or **7**), followed by hydroboration–oxidation and reductive hydroxy ketone cyclization protocol[5] provides the IJKLM ring system.

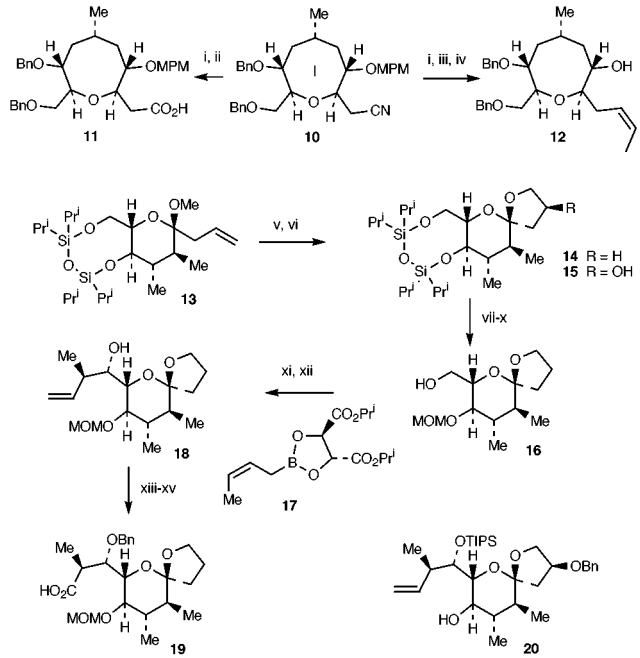


Scheme 1

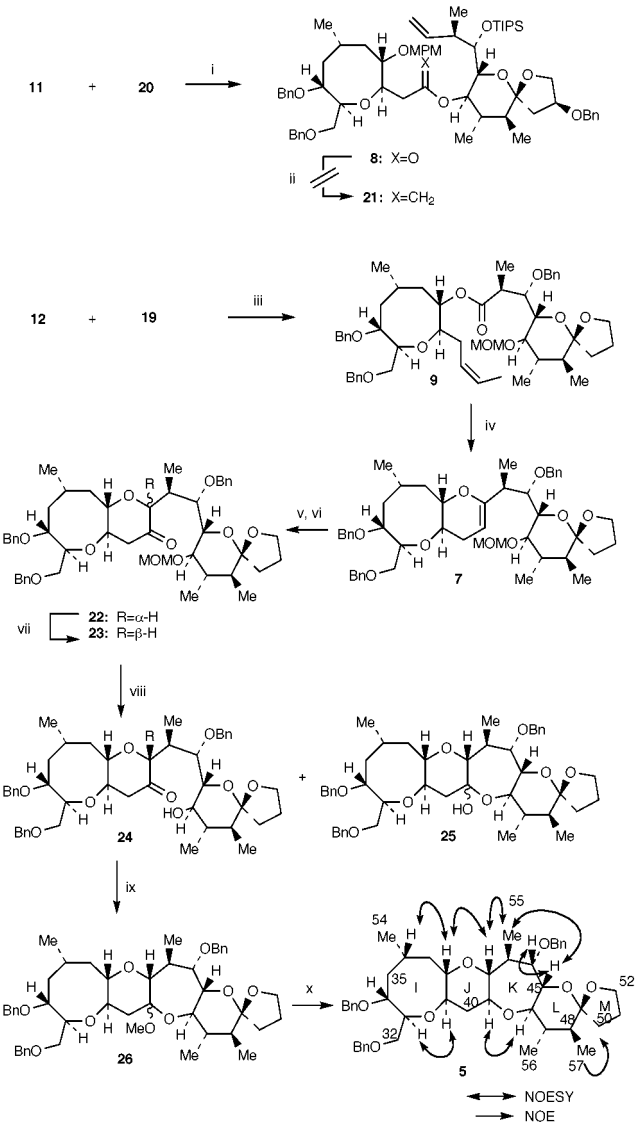
Precursors of the esters **8** and **9** were synthesized as shown in Scheme 2. Carboxylic acid **11** and alcohol **12** were prepared from the I ring moiety **10**[6,7] by the standard procedures. Synthesis of the carboxylic acid **19** corresponding to the LM ring moiety of **2** was initiated with **13**.[8] Hydroboration of **13** using BBN and treatment of the resulting alcohol with CSA gave spiroacetal **14** in 92% yield. Conventional protecting group transformation of **14** yielded alcohol **16**. Dess–Martin periodinane oxidation of **16** followed by asymmetric crotylation using (*R*,*R*,*Z*)-crotylboronate **17**[9] furnished **18** as a single stereoisomer. Protection of the hydroxy group of **18** as a benzyl ether and oxidative cleavage of the double bond gave **19** in 95% yield. Alcohol **20** corresponding to the LM ring moiety of **1** and **3** was synthesized in an analogous manner starting from **15**.[8]

Synthesis of the IJKLM ring fragment was first attempted *via* route A (Scheme 3). Condensation of **11** with **20** using DCC gave **8** in 54% yield, which was treated with the Tebbe reagent in THF at 60 °C. However, olefination of the carbonyl group of **8** did not proceed, and only the initial material **8** was recovered even after 6 h.

The alternative route B was then examined. Coupling of **12** with **19** gave **9** in 74% yield. In contrast to **8**, treatment of **9** with



Scheme 2 *Reagents and conditions*: i, DIBAL-H, CH_2Cl_2, −78 °C; ii, $NaClO_2$, NaH_2PO_4, 2-methylbut-2-ene, Bu^tOH, H_2O, 41% (2 steps); iii, $Ph_3P^+EtBr^-$, BuLi, THF, −78 °C to room temp., 48% (*Z*:*E* = 4:1, 21% recovery of aldehyde); iv, DDQ, CH_2Cl_2, H_2O, 0 °C, 89%; v, BBN, THF then NaOH, H_2O_2, 88%; vi, CSA, CH_2Cl_2, 92%; vii, TBAF, THF; viii, Bu^tCOCl, Et_3N, CH_2Cl_2, 0 °C to room temp.; ix, MOMCl, Pr^i_2EtN, CH_2Cl_2, 0 to 35 °C; x, $LiAlH_4$, Et_2O, 0 °C to room temp., 76% (4 steps); xi, Dess–Martin periodinane, CH_2Cl_2: xii, **17**, toluene, MS4A, −78 to −60 °C, then $NaBH_4$, −60 to 0 °C, 45% (2 steps, 70% based on recovery of **16**); xiii, NaH, BnBr, THF, DMF, 89%; xiv, OsO_4, NMO, Bu^tOH, H_2O, then $NaIO_4$, pH 7 buffer; xv, $NaClO_2$, NaH_2PO_4, 2-methylbut-2-ene, Bu^tOH, H_2O, 95% (2 steps).



Scheme 3 *Reagents and conditions*: i, DCC, DMAP, CSA, CH_2Cl_2, 35 °C, 54% (38% recovery of **20**); ii, Tebbe reagent, THF, 60 °C, 95% recovery of **8**; iii, DCC, DMAP, CSA, CH_2Cl_2, 35 °C, 74%; iv, Tebbe reagent, THF, 60 °C, 63%; v, BH_3, THF, 0 °C then NaOH, H_2O_2, 0 °C, 73%; vi, Dess–Martin periodinane, CH_2Cl_2, 100%; vii DBU, CH_2Cl_2, room temp., 1 h; viii, TMSBr, CH_2Cl_2, −78 to −50 °C, **24**: 30%, **25**: 30%; ix, $CH(OMe)_3$, CSA, benzene, 70 to 80 °C, 50%; x, Et_3SiH, $BF_3{\cdot}OEt_2$, CH_2Cl_2, −73 to 0 °C, 71%.

the Tebbe reagent at 60 °C resulted in the formation of cyclic enol ether **7** in 63% yield *via* methylenation and subsequent RCM.[4] Hydroboration of **7** followed by Dess–Martin periodinane oxidation gave a separable 3:1 mixture of **22** and **23** in 73% yield. The undesired isomer **22** was effectively converted to a 1:1 mixture of **22** and **23** by treatment with DBU in CH_2Cl_2 at room temperature. Removal of the MOM group of **23** with TMSBr gave keto alcohol **24** (30%) and hemiacetal **25** (30%). Direct treatment of the mixture of **24** and **25** with Et_3SiH–TMSOTf[5] gave no products due to reductive hydroxy ketone cyclization. However, reduction of the corresponding methyl acetal[3] **26**, which was prepared from the mixture of **24** and **25**, proceeded stereoselectively using $BF_3{\cdot}OEt_2$ (1.0 equiv.) and Et_3SiH in excess to afford the IJKLM ring fragment **5** in 71% yield without affecting the spiroacetal LM ring moiety.[10] The stereochemistry of **5** was unambiguously determined by ^1H NMR analysis (NOESY and NOE experiments).[11]

In conclusion, we have established a highly convergent route to the IJKLM ring fragment of CTX3C *via* the Tebbe reagent mediated ring-closing metathesis and an improved hydroxy ketone cyclization. Further studies directed toward total synthesis of ciguatoxins are currently in progress in our laboratory.

Fellowships to Y. N. and J.-Y. L. B. from the Japanese Society for the Promotion of Science are gratefully acknowledged.

A novel pyridine-templated open framework gallophosphate

David S. Wragg, Ivor Bull, Gary B. Hix and Russell E. Morris*

E-mail: rem1@st-and.ac.uk

Received (in Oxford, UK) 9th August 1999, Accepted 10th September 1999

A new type of gallium phosphate open framework material has been prepared from solvothermal synthesis and its structure solved using microcrystal X-ray diffraction at a synchrotron source.

The rational design of open framework materials is an established goal of materials science.[1] The potential uses for rationally designed molecular sieves are many, but of particular interest are the applications of such materials as shape selective catalysts for fine chemical synthesis. Within this area the study of gallium phosphates has provided a wide range of interesting new open framework structures, including Cloverite,[2] which has the largest pore size of any microporous material. The work of Férey has illustrated particularly well the structural richness of the gallophosphate system.[3]

The most common methods of preparing open framework materials use templating and the cross-linking of layered materials. Templating involves the use of an organic molecule to organise the inorganic framework into an open structure, while cross-linked materials consist of layers that are joined together so as to produce voids and cavities in the interlayer region. This paper reports the synthesis of a new open framework gallium phosphate material which contains features of both of these types of structures; layers of open zeolite-like structure linked to form a completely novel type of open framework architecture with interconnecting eight membered ring channels. The new material is templated by pyridine.

In the course of a systematic study of the effects of various conditions on the product of a solvothermal gallium phosphate synthesis in which pyridine serves as both solvent and template, a novel type of open framework gallium phosphate structure has been prepared. The new material, pyridine-GaPO-1 [formula: $Ga_6(PO_4)_6F_2{\cdot}2C_5H_6N{\cdot}H_2O$], was prepared by a solvothermal synthesis with pyridine (99%, Fischer) as the solvent and hydrofluoric acid (70% solution in pyridine) as a source of fluoride ions. Phosphoric acid (0.2 g, 85% weight aqueous solution, Aldrich) was diluted with a small amount (2 ml) of distilled water in a plastic beaker and to this pyridine (0.8 ml) was added with vigorous stirring. Ground gallium sulfate (0.5 g, 99.8%, Aldrich) was then added, followed by hydrofluoric acid (*ca.* 0.02 ml) giving an approximate molar oxide ratio of Ga_2O_3: P_2O_5: F: 8 pyridine: 8 H_2O. The mixture (pH 5) was stirred at room temperature for 20 min, transferred to a Teflon-lined stainless steel autoclave and heated at 180 °C for 72 h. The product, a crop of tiny colourless crystals, was recovered by suction filtration, washed with distilled water and acetone and dried at room temperature.

The crystal size (max. 20 × 20 × 8 μm) proved too small for single crystal data collection on a conventional laboratory four circle diffractometer, so data were collected using a Bruker AXS SMART CCD area-detector at the high-flux microcrystal diffraction facility (station 9.8) of the SRS at Daresbury using a wavelength of 0.6849 Å.†

The structure can be thought of as consisting of two parts. The first is a zeolite-related layer made up of $Ga_2P_2O_8$ single four-rings (S4Rs). These S4Rs are linked together to form a layer that contains eight-ring windows. When viewed parallel to the (11$\bar{1}$) direction (Fig. 1), the structure closely resembles that of the zeolite ABW,[4] which is comprised of eight-rings linked by four-rings. This topology has also been observed for a number of other zeolites and zeolite analogues.[5] All of the gallium and phosphorus atoms in layered regions of the structure are tetrahedrally coordinated to four oxygen atoms, and the gallium and phosphorus atoms alternate. These zeolite-like layers are linked into a three-dimensional structure by cross-linking units consisting of a dimeric unit of octahedrally coordinated gallium atoms. The two gallium-centred polyhedra share the two fluorine atoms that make one edge of the octahedra to give a unit with the formula $Ga_2F_2O_8$. The overall structure consists of a three-dimensional framework with interconnecting eight-ring channels (Fig. 2) formed by the linking of the layers, producing pores that run parallel to the plane of the layers, and by the zeolitic nature of the layers themselves, which stack on top of each other to form channels perpendicular to the plane of the layers (Fig. 3). The $Ga_2F_2O_8$ unit causes half of the eight-ring channels to be distorted to an almost circular shape, while the others maintain the oval form normally observed in gallium phosphates. The dimeric $Ga_2F_2O_8$

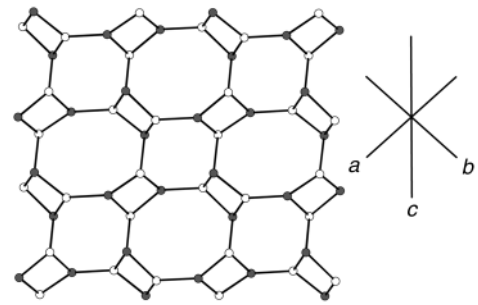

Fig. 1 A view of the zeolite-like layers parallel to the (11$\bar{1}$) direction illustrating the system of eight-rings connected by four-rings. The gallium and phosphorus atoms are shown as open and shaded spheres, respectively. The oxygen atoms would then be placed near the centres of the lines joining the Ga and P atoms.

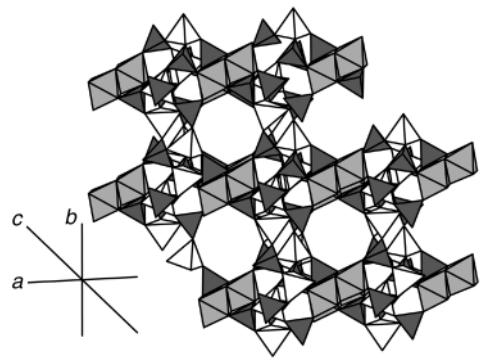

Fig. 2 Polyhedral view of the inorganic framework parallel to the (11$\bar{1}$) direction showing the linking of the layers by the $Ga_2F_2O_8$ dimer and the channels produced that run parallel to this direction. The layers run vertically up the diagram. Template molecules are not shown. The shaded and unshaded tetrahedra are PO_4 and GaO_4, respectively, and the $Ga_2F_2O_8$ unit is shown as lightly shaded edge sharing octahedra.

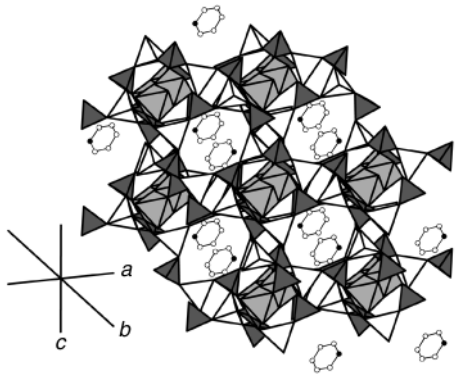

Fig. 3 Polyhedral view parallel to the $(11\bar{1})$ direction showing the eight-ring channels produced by the stacking of the zeolite layers. Also shown is the position of the pyridine template molecules inside these channels. The shaded and unshaded tetrahedra are PO_4 and GaO_4 respectively, and the $Ga_2F_2O_8$ unit is shown as lightly shaded edge sharing octahedra. The nitrogen atoms are shown as shaded spheres and the carbons as unshaded spheres.

unit found linking the layers has not been observed previously in this type of material but the linking of layers into a 3D structure is similar to that observed in the previously reported cyclam-GaPO material,[6] in which an octahedral gallium–cyclam complex joins layers of double four-ring units.

The pyridine template is protonated and hydrogen bonded to a solvent water molecule, which is disordered over two crystallographic sites. The strong binding of this water molecule is illustrated by thermogravimetric analysis, which shows a mass loss corresponding to the loss of water at around 250 °C (observed 1.2%; calculated 1.5%). A second mass loss corresponding to loss of pyridine occurs between 330 and 360 °C (observed 13.0%; calculated 13.3%). The material loses crystallinity at this temperature.

The authors would like to thank Dr David Taylor and Dr Simon Teat of the SRS for their help in the X-ray data collection and the EPSRC for funding. R. E. M. would like to thank the Royal Society for provision of a Personal Research Fellowship.

An unpaired electron incarcerated within an icosahedral borane cage: synthesis and crystal structure of the blue, air-stable {[*closo*-$B_{12}(CH_3)_{12}$]·}$^-$ radical

Toralf Peymann, Carolyn B. Knobler and M. Frederick Hawthorne*

Department of Chemistry and Biochemistry, University of California, Los Angeles, Los Angeles, CA 90095–1569, USA. E-mail: mfh@chem.ucla.edu

Received (in Bloomington, IN, USA) 5th July 1999, Accepted 2nd September 1999

Oxidation of the permethylated icosahedral borane [*closo*-$B_{12}(CH_3)_{12}$]$^{2-}$ 1, by ceric(IV) ammonium nitrate in acetonitrile affords the blue, air-stable paramagnetic anion {[*closo*-$B_{12}(CH_3)_{12}$]·}$^-$ 2, which has been characterized, among other means, by X-ray crystallography.

Radicals differ significantly in reactivity as their persistence largely depends upon the unpaired electron's chemical and physical environment.[1] A major effect that stabilizes paramagnetic species is steric crowding. A radical center surrounded by bulky groups is more persistent than similar species without this protection. Recently, we reported the synthesis of the camouflaged permethylated *closo*-borane [*closo*-$B_{12}(CH_3)_{12}$]$^{2-}$ **1**.[2] Here, we describe paramagnetic {[*closo*-$B_{12}(CH_3)_{12}$]·}$^-$ **2**, obtained from **1** by one-electron oxidation with ceric(IV) ammonium nitrate (CAN) in acetonitrile. In species **2** the unpaired electron is trapped within the hydrocarbon sheath of the permethylated borane cage. Hence, this deep blue radical-anion is surprisingly stable with respect to reaction with oxygen. The anion **2** was characterized by high-resolution fast atom bombardment mass spectrometry (HR-FAB-MS), electron paramagnetic resonance (EPR), UV–VIS spectroscopy, and cyclic voltammetry. Furthermore, the crystal structure of [Ph_3P=N=PPh_3]**2** (PPN**2**), was determined by single crystal X-ray diffraction.

Following CAN oxidation of [NBu^n_4]$_2$**1** (TBA)$_2$**1**, in acetonitrile, the anion **2** was isolated as a PPN salt in 66% yield.† Reduction of **2** with $NaBH_4$ in ethanol regenerated **1** in good yield (Scheme 1).

A solid sample of PPN**2** exhibits an EPR signal with g = 2.0076. The UV–VIS spectrum (Fig. 1) of the blue salt [NEt_4]**2** (TEA**2**) in acetonitrile displays absorption in the visible region.

Cyclic voltammetry (100 mM NEt_4PF_6, Ag/AgCl, MeCN) of **2** reveals a reversible wave with $E_{1/2}$ = 0.44 V for the one-electron process **2** + e$^-$ → **1**. The reduction potential of **2** matches the corresponding oxidation potential previously determined for **1**.[2] The X-ray crystal structure‡ (Fig. 2) confirms that **2** is a permethylated monoanionic *closo*-borane.

In the solid state, the anionic cluster of PPN**2** is less distorted from icosahedral symmetry than the dianionic species **1** studied as a [$(2\text{-}C_5H_4N)_2CH_2$]$^{2+}$ salt [B–B bond lengths: **2** 178.5(8)–180.5(7) pm, **1** 174(1)–181(1) pm, B–C bond lengths: **2** 159.8(9)–161.3(8) pm; **1** 159(1)–170(1) pm].[2] The maximum across-cage methyl carbon separations average 668 pm for the dianionic species **1**,[2] compared to 663 pm for the monoanion **2**. The greater distortion of **1** may be explained by the charge-transfer interaction of the dipositive [$(2\text{-}C_5H_4N)_2CH_2$]$^{2+}$ counter ion and the dianion **1**. This interaction is suggested by the unique color of the blood-red [$(2\text{-}C_5H_4N)CH_2$]**1** salt.[2]

Paramagnetic persubstituted polyhedral *closo*-boranes such as {[*closo*-B_6X_6]·}$^-$ **3**,[3] {[*closo*-B_9X_9]·}$^-$ **4**[4] (X = Cl, Br, I) and [*closo*-$CB_{11}Me_{12}$]· **5**,[5] have been reported previously. As in the synthesis of **2**, these species were obtained *via* metal-ion oxidation of the corresponding reduced borane clusters. In each case, solutions of these paramagnetic species are moderately stable, but decolorize after prolonged contact with air.

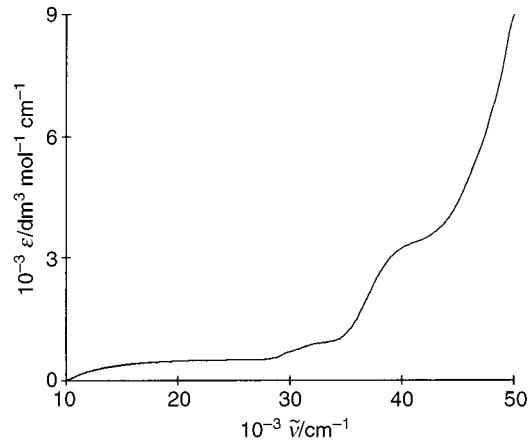

Fig. 1 UV–VIS absorption spectrum of TEA**2** in acetonitrile.

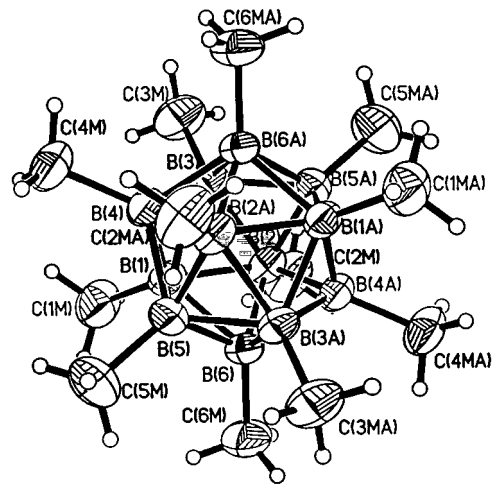

Fig. 2 ORTEP diagram of {[*closo*-$B_{12}(CH_3)_{12}$]·}$^-$ **2**. The ellipsoids represent a 30% probability level. Selected bond lengths (pm): B–B 178.5(8)–180.5(7), B–C 159.8(9)–161.3(8). Atoms X(*n*) and X(*n*A) are symmetry-related by an inversion center.

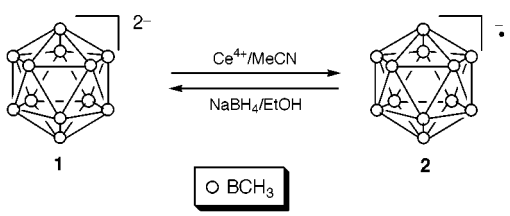

Scheme 1 Chemical interconversion of {[*closo*-$B_{12}(CH_3)_{12}$]·}$^-$ **2** and [*closo*-$B_{12}(CH_3)_{12}$]$^{2-}$ **1**.

The species **2** presents unique possibilities inherent in the concept of camouflaged polyhedral boranes.[7] Here, the persubstitution stabilizes an unusual oxidation state that has not been obtained from the 'naked' parent species [*closo*-$B_{12}H_{12}]^{2-}$ **7**. Upon electrochemical oxidation ($E_{1/2}$ = 1.43 V *vs* SCE), the dianion **7** instead dimerizes [eqn. (1)] by an undetermined mechanism with loss of one *exo* H-atom and dimerization of B_{12}-cages to form the B–H–B bridge of $[B_{24}H_{23}]^{3-}$.[8]

$$2\ [closo\text{-}B_{12}H_{12}]^{2-} \rightarrow [B_{24}H_{23}]^{3-} + H^{+} + 2e^{-} \quad (1)$$

The latter species is structurally related to [a^2-$B_{20}H_{19}]^{3-}$.[9] This reaction pathway is not available for the permethylated radical **1**.

In conclusion, we have presented the synthesis and characterization of {[*closo*-$B_{12}(CH_3)_{12}]^{\bullet}\}^{-}$ **2**, a surprisingly air-stable paramagnetic *closo*-borane. The unique persistence of **2** provided by the steric encumberance of the twelve methyl substituents suggests that **2** might find use in applications requiring a paramagnetic weakly coordinating anion.[10]

We thank Mike Diehl for the EPR measurement. This work was supported by the U.S. Department of Energy (DE-FG02-95ER61975).

ChemComm

A novel single source precursor route to self capping CdS quantum dots

Mike Lazell and Paul O'Brien*†

Department of Chemistry, Imperial College of Science, Technology and Medicine, London, UK SW7 2AY. E-mail: p.obrien@ic.ac.uk

Received (in Cambridge, UK) 29th July 1999, Accepted 8th September 1999

The synthesis of CdS nanocrystals has been carried out from the thermolysis in a dynamic vacuum, between 150 and 300 °C, of the novel asymmetric cadmium dithiocarbamate [Cd{$S_2CNMe(C_{18}H_{37})$}$_2$]; the particles 'self cap' during preparation; different size nanocrystals were synthesised, at different temperatures, and there was a change in phase from cubic to hexagonal CdS at a decomposition temperature of 300 °C.

Nanocrystalline semiconductors have electronic properties intermediate between those of molecular entities and macrocrystalline solids and are at present the subject of intense research.[1–6] Nanometric semiconductor particles exhibit novel properties owing to the large number of surface atoms (and resultant states) and/or the three-dimensional confinement of electrons. Altering the size of the particle alters the degree of confinement of the electrons, and affects the electronic structure of the solid, in particular 'band edges', which are tunable with particle size. Nanoparticles of semiconductors have many potential applications and demonstration devices including light-emitting diodes,[7,8] photocatalysts[9,10] and electrochemical cells[1,6,11] have been reported.

We are interested in developing novel routes to these materials and have previously reported the use of single source precursors to prepare several II–VI chalcogenides.[12–14] These nanocrystals are organically capped with tri-*n*-octylphosphine oxide (TOPO). Other capping groups such as 4-ethylpyridine have also been used to solubilise nanocrystals, for example, InP.[15] We have also recently reported the use of trioctylphosphine sulfide as an air/moisture stable sulfiding precursor[16] for cadmium or zinc sulfide. However, to date there has only been one paper[17] describing the synthesis of nanocrystals in a process in which the particle is capped by a ligand transferred from the precursor; as a single parent molecule is involved, we term this process 'self-capping'. Finely divided silver has been prepared from the salts of fatty acids by a bulk pyrolysis. Here we report the first synthesis of self-capped CdS nanocrystals *via* thermolysis at 150–300 °C, in a dynamic vacuum, of the novel asymmetric cadmium dithiocarbamate, [Cd{$S_2CNMe(C_{18}H_{37})$}$_2$].

The cadmium dithiocarbamate precursor, [Cd{$S_2CNMe(C_{18}H_{37})$}$_2$] was prepared from the amine $HNMe(C_{18}H_{37})$, using a method described elsewhere.[14] The precursor was thermolysed *in vacuo* at temperatures ranging between 150 and 300 °C‡. The resulting solid was readily redispersed in pyridine. The absorption edges of the nanoparticles were calculated using the direct band gap method. The onset of absorption for all the samples showed a clear blue shift: 150 °C, *ca.* 430 nm (2.88 eV), 200 °C, 449 nm (2.76 eV), 250 °C, 465 nm (2.66 eV) as compared to that of bulk CdS, 515 nm (2.41 eV) [Fig. 1(*a*)]. The CdS samples all showed Stokes shifts in their photoluminescence spectra [Fig. 1(*b*)]. However, the observed Stokes shift decreases as the particle size increases: 150 °C, absorption maxima, A_{max}, at 454 nm (2.73 eV) (λ_{exc} = 370 nm) a Stokes shift, (SS), of 0.15 eV; 200 °C, A_{max} = 472 nm (2.63 eV) (λ_{exc} = 400 nm), SS = 0.13 eV; 250 °C, A_{max} = 482 nm (2.57 eV) (λ_{exc} = 390 nm), SS = 0.09 eV. This trend in the shifts of the absorption maxima in the PL spectra is as expected.

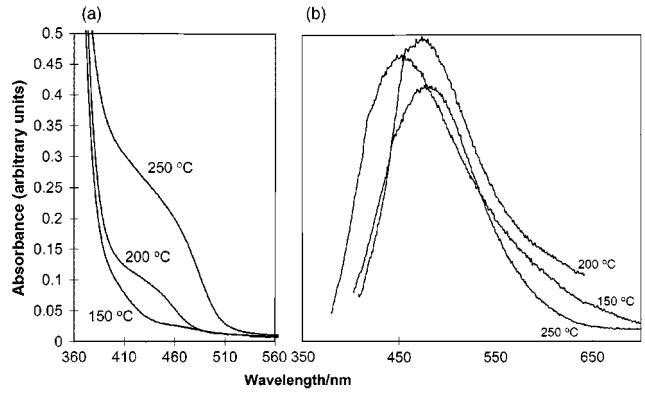

Fig. 1 (a) UV and (b) PL spectra for CdS samples.

XRD of the powdered samples showed an interesting feature in the as-prepared CdS nanoparticles (Fig. 2). The CdS samples prepared at temperatures of 150–250 °C could be indexed to the standard patterns of the cubic phase.§ The largest particles of CdS from the thermolysis at 300 °C, were clearly of the hexagonal phase. There is no evidence that there is a mixing of phases as described by Bawendi *et al.* for CdSe nanocrystals prepared from inverse micelles.[18] The broadening of the peaks in the XRD patterns for all samples is typical of nanoparticles.

The nanoparticles were analysed by IR spectroscopy to establish the nature of the capping group. The capping agent of the nanocrystals could presumably be HNR′R″ or $S_2CNR'R''$. The IR showed no stretches associated with a C–N bond from the CdS nanocrystal samples (a typical C–N bond stretch was seen in the precursor sample). This suggests that the CdS nanocrystals are capped by $HNMe(C_{18}H_{37})$. ^1H and ^{13}C NMR spectroscopy show resonances associated with the amine. This taken with the IR data, is good evidence that the capping group is $HNMe(C_{18}H_{37})$. X-Ray photoelectron spectroscopy was used to analyse the CdS samples prepared at 200 and 300 °C. The analysis shows the presence of Cd, S, N and C. The ratio of C

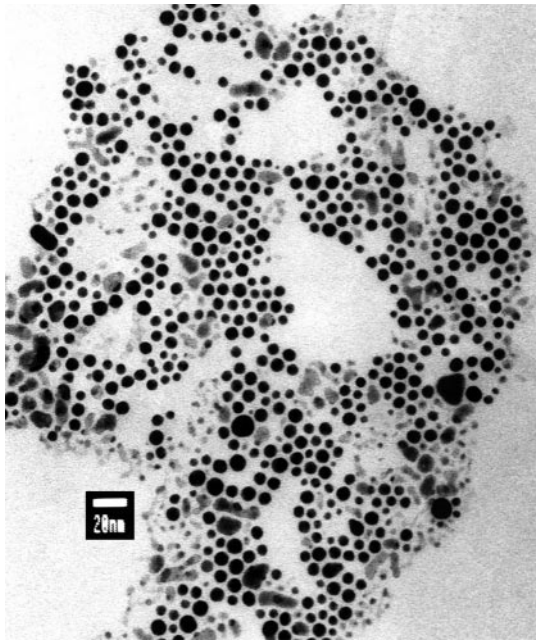

Fig. 3 TEM image of CdS nanoparticles prepared at 150 °C.

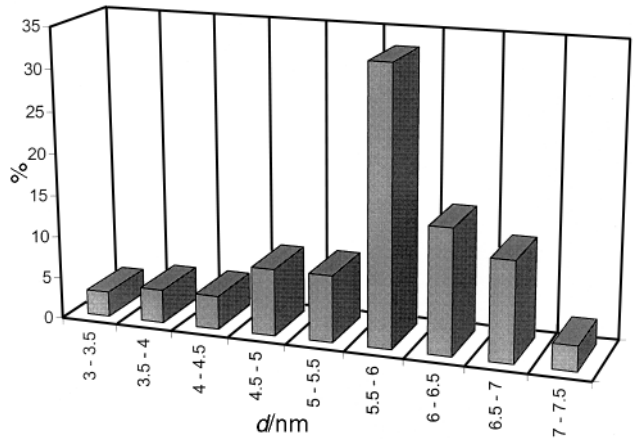

Fig. 4 Size distribution of CdS nanoparticles.

to Cd in the 200 °C sample was significantly higher than in the sample prepared at 300 °C. This observation suggests that there is less capping agent on the sample prepared at 300 °C than that prepared at 200 °C. Hence, the CdS samples prepared at 150–250 °C are very soluble in pyridine while the sample prepared at 300 °C is only partially soluble. TEM images (Fig. 3) show quantum dots of CdS synthesised at 150 °C, which are not agglomerated. The size distribution of the dots is shown in Fig. 4. The dots are predominately of size 5.5–6 nm. The dots synthesised at 250 °C appear to have a halo-like tail structure. This could be the capping group emanating from the CdS nanoparticle. The estimated diameters of the dots are between 5 and 7 nm (Table 1); as calculated using the Scherrer equation and the direct band gap method from the onset of absorption in the UV spectra. These values compare well with those obtained from the TEM images.

Table 1 UV and PL data and calculated diameters of particles using the direct bandgap method (onset of absorption from UV spectra) and the Scherrer equation (XRD data).

Sample[a]	Onset of abs./eV	Abs. max./eV	Av. size/nm (Calc. from UV)	Calc. size/nm (Scherrer eqn.)
150	2.88	2.73	4.5	5
200	2.76	2.63	5	5.5
250	2.66	2.57	6	6

[a] Preparation temperature/°C.

In conclusion, good quality, self capped CdS nanoparticles have been synthesised from the vapour phase thermolysis of the novel cadmium dithiocarbamate, $[Cd\{S_2CNMe(C_{18}H_{37})\}_2]$. The CdS nanoparticles are cubic in nature when prepared at 150–250 °C and hexagonal at 300 °C. The CdS samples were characterised by UV–VIS, IR, PL, XRD, XPS, NMR and TEM. Studies into other metal sulfide precursors are ongoing.

This work has been funded by an EPSRC grant to P. O. B. We would like to thank Mr Keith Pell (QMW) for TEM, Mr Jin-Ho Park (IC) for XRD and Dr Karol Senkiw (IC) for XPS. P. O. B is the Sumitomo/STS Professor of Materials Chemistry at IC and from 1/9/99 Professor of Inorganic Materials at The Manchester Materials Science Centre and The Chemistry Department, Manchester University.

Notes and references

‡ Into a quartz vessel was put *ca.* 0.5 g of $[Cd\{S_2CNMe(C_{18}H_{37})\}_2]$. The decomposition apparatus was then put into a carbolite tube furnace. The apparatus was opened to a dynamic vacuum, *ca.* 0.01 mm Hg, there was also a liquid nitrogen trap to condense any volatiles from the thermolysis. The decomposition apparatus was heated at a range of temperatures, 150–300 °C, for 1 h (timed from temperature stabilisation). The vessel was allowed to cool and the contents, varying from off-white-yellow (150 °C) to dark orange (300 °C), were removed.

§ Optical measurements of the nanoparticles were carried out on a Philips PU 8710 spectrophotometer. The sample solutions were placed in silica cuvettes (path length = 1 cm). The samples were in pyridine solutions and pyridine was used as the reference. IR spectra were carried out using a Matteson Polaris FT-IR spectrometer with Nujol mulls. ^1H and ^{13}C solution NMR spectra were recorded on a Bruker AM 500 or a DRX 400 in $CDCl_3$. XRD patterns were measured using a Siemens D500 series automated powder diffractometer using Cu-Kα radiation at 40 kV/40 mA with a secondary graphite crystal monochromator. Samples were supported on glass slides (5 cm^2). PL measurements were obtained using a Spex FluoroMax instrument with a xenon lamp (150 W) and a 152 P photomultiplier tube as a detector. Silica cuvettes of 1 cm path length were used. Solutions were made using pyridine. A JOEL 2000 FX MK1 electron microscope operating at 200 kV with an Oxford Instruments AN 10000 EDS analyser was used for the conventional TEM micrographs. The samples for TEM were prepared by placing a drop of a dilute solution of sample in toluene on a copper grid (400 mesh, Agar). The excess solvent was wicked away with a paper tip and the sample allowed to dry completely at room temperature. The XPS measurements were performed in the ultra-high vacuum chamber (base pressure 10^{-8} Pa) of a VG ESCALAB-Mk II (VG Scientific) using Al-Kα excitation (analyser pass energy of 50 eV). The energy scale was calibrated using C 1s (at 284.4 eV) as a reference.

Received (in Basel, Switzerland) 19th July 1999, Accepted 29th August 1999

Carboxylato-bridged Ru(I) carbonyl complexes are activated by CO towards both disproportionation and reaction with dihydrogen, through the intermediacy of the unbridged metal–metal bonded valence isomers $(OC)_5RuRu(CO)_3(OCOCR_3)_2$ and $[Ru(CO)_4(OCOCR_3)]_2$.

Catalysis chemistry involving carboxylato-bridged Ru(I) carbonyl complexes of formula $Ru_2(\mu\text{-}\eta^2\text{-}O_2CR)_2(CO)_6$ includes the acid-cocatalyzed water gas shift reaction[1] (WGSR) and the related Reppe olefin carbonylation,[2] CO hydrogenation[3] and syngas homologation of aliphatic carboxylic acids.[4] Furthermore, in the presence of tertiary phosphines, carboxylato-bridged Ru(I) carbonyl complexes are used as catalytic precursors for the addition of carboxylic acids to alkynes,[5] the hydrogenation of carboxylic acids[6] and esters,[7] and the hydroformylation of alkenes.[8] Concerning the nature of the species promoting the activation of simple molecules and organic substrates in these catalytic processes, the present study highlights the unsaturation of $Ru_2(\mu\text{-}\eta^2\text{-}O_2CR)_2(CO)_6$ complexes, vacant coordination sites being generated by the rearrangement of the bridging carboxylato ligands. Thus, $Ru_2(\mu\text{-}\eta^2\text{-}O_2CCF_3)_2(CO)_6$ **1** was found to reversibly add two CO ligands yielding hitherto unknown dinuclear unbridged ruthenium carbonyl carboxylates. The rate of CO uptake is markedly affected by the medium: in toluene, forcing conditions (150 °C, P_{CO} = 120 atm) are required to convert **1** to a nearly equimolar mixture of $(OC)_5RuRu(CO)_3(OCOCF_3)_2$ **2** [ν_{CO} (Nujol mull) 2173m, 2116s, 2102m, 2075s, 2053m and 2023m cm^{-1}] and $[Ru(CO)_4(OCOCF_3)]_2$ **3** [ν_{CO} (Nujol mull) 2133s, 2093vs, 2077s and 2051s cm^{-1}]† [eqn. (1)].

$$\underset{\mathbf{1}}{2\ Ru_2(\mu\text{-}\eta^2\text{-}O_2CCF_3)_2(CO)_6} + 4\ CO \rightleftharpoons \underset{\mathbf{2}}{(OC)_5RuRu(CO)_3(OCOCF_3)_2} + \underset{\mathbf{3}}{[Ru(CO)_4(OCOCF_3)]_2} \quad (1)$$

Remarkably, with trifluoroacetic acid as solvent, reaction (1) is an equilibrium at room temperature. Presumably, hydrogen bonding between bridging carboxylato ligands and solvent molecules assists the conversion of the bridging carboxylato ligand to its monodentate arrangement. Gas volumetric measurements and IR analysis show that **1**, **2** and **3** are present in a 1 : 2.5 : 4 molar ratio in a 0.046 M trifluoroacetic acid solution of **1** under CO at atmospheric pressure.

The molecular structures‡ of **2** and **3** are shown in Fig. 1 and 2, respectively. Binuclear Ru carbonyl complexes without bridging ligands are rare, only anionic $[Ru(CO)_4]_2^{2-}$ [9] and neutral $[Ru(CO)_4(GaCl_2\cdot THF)]_2$[10] and $[Ru(CO)_4(SnMe_3)]_2$[11] being structurally characterized. Compounds **2** and **3** show Ru–Ru distances of 2.836 and 2.853 Å, respectively, indicating a strong metal–metal bond, as compared to the dinuclear compound $[Fe(CO)_4(CO_2CMe_3)_2]_2$,[12] with an Fe–Fe distance of 2.840 Å.

Compound **2**, in which the $Ru(CO)_5$ moiety acts as a donor ligand towards the Ru(II) 16-electron centre, is stable both in the solid state and in diethyl ether solution and constitutes the first structurally characterized adduct of the $Ru(CO)_5$ donor unit. Such an interaction stabilizes $Ru(CO)_5$ towards decarbonylation; however, upon adding an equimolar amount of CF_3CO_2Cs to a 0.02 M THF solution of **2**, free $Ru(CO)_5$ is immediately released into solution where it slowly converts to $Ru_3(CO)_{12}$. According to eqn. (2), the eighteen-electron complex $Ru(CO)_5$ is substituted by the trifluoroacetato ligand yielding the anionic Ru(II) carbonyl complex **4** which was identified spectroscopically [ν_{CO} (THF) 2142m, 2089s, 2072s cm^{-1}].[1]

On these grounds, we conclude that exposure of a solution containing carboxylato-bridged Ru(I) carbonyl complexes to CO can result in equilibrium (1) and then in an irreversible

disproportionation [eqn. (2)], in the presence of the free carboxylato ligand.

We showed that the disproportionation of **1** constitutes the key step of some catalytic processes such as CF_3CO_2H-cocatalyzed WGSR[1] and the related Reppe olefin carbonylations.[2] It now appears that the reaction is a consequence of the carbonylation of **1** giving the reactive adduct **2**. Presumably, this conclusion is general and applies also to carboxylato-bridged Ru(I) carbonyl complexes other than **1**: for instance, $Ru_2(\mu\text{-}\eta^2O_2CMe)_2(CO)_6$, which is indefinitely stable in an acetato-acetic acid solution, was found to absorb CO and to disproportionate at room temperature and atmospheric pressure.

Finally, the present findings can help to elucidate the dihydrogen activation promoted by carboxylato-bridged Ru(I) carbonyl complexes, a step common to several catalytic processes involving ruthenium. Both in toluene and in trifloroacetic acid, **1** fails to react with dihydrogen even under harsh conditions. However, two distinct reaction pathways are encountered under 120 atm of H_2–CO (v/v = 1 : 1), as a function of the solvent: in toluene at 130 °C, $Ru(CO)_5$ and trifluoroacetic acid are quantitatively formed within 1 h while in trifluoroacetic acid catalytic hydrogenation of the solvent to 2,2,2-trifluoroethanol occurs. While the catalytic reaction, which has few precedents in homogeneous catalysis,[13] is under investigation, it is evident that dihydrogen activation by **1** requires CO. An interpretation for this could be given by considering the nature of **2** and **3**, namely the species present under CO. A radical pathway initiated by Ru–Ru bond fission in **3**[14] or, alternatively a H_2 heterolytic splitting promoted by the Ru(II) centre of **2** can then be envisaged. In this connection, the chemistry of these ruthenium(II) containing species is reminiscent of the dihydrogen activation processes promoted by cobalt carbonyl species, which have been reported in earlier studies from these laboratories.[15] It thus appears that the formation of rather weak metal–metal bonds is required.

The authors thank the Ministero dell'Università e della Ricerca Scientifica e Tecnologica (MURST), Programmi di Ricerca Scientifica di Rilevante Interesse Nazionale, Cofinanziamento 1998–9, for financial support, Professor F. Calderazzo for helpful discussions, Mr F. Del Cima for skillful technical assistance and Chimet SpA for a gift of ruthenium.

Notes and references

† Compound **1** (0.8 g, 1.38 mmol) was suspended in 50 ml of toluene in a glass ampoule which was placed in a stainless-steel autoclave, pressurized with CO up to 120 atm and heated to 150 °C in a thermostatted oil bath. After slow cooling and gas venting, the glass ampoule was found to contain pale yellow crystals of two different shapes, while only traces of carbonyl complexes where detected by IR spectroscopy in the liquid phase. The air stable crystals were selected according to their shape. The X-ray single-crystal study showed $(OC)_5RuRu(CO)_3(OCOCF_3)_2$ **2** to constitute the stick-shaped crystals and $[Ru(CO)_4(OCOCF_3)]_2$ **3** to form prismatic shaped crystals. The diffractometric measurements were carried out with a Siemens P4 diffractometer using Mo-Kα radiation, λ = 0.71073 Å. The intensity data were corrected for Lorentz and polarisation effects and for absorption by using a ψ-scan method.[16] Calculations were carried out with the SHELX97[17] program. In both studies, the disordered CF_3 groups were refined as distributed with fixed geometry in two limiting positions. At the end of both refinements residual peaks and holes of *ca.* ±1 e Å^{-3} were present in the CF_3 regions of the difference Fourier maps.

Received (in Cambridge, UK) 5th August 1999, Accepted 10th September 1999

The simple 1:2 adduct $(NBu_4)_2[\{Pt(\mu\text{-}\kappa C^{\alpha}:\eta^2\text{-}C{\equiv}CPh)_4\}(CdCl_2)_2]$ 2 containing unusual η^2-alkyne Cd interactions, as well as the unexpected tetranuclear dimer $(NBu_4)_2[\{Pt(\mu\text{-}\kappa C^{\alpha}C^{\alpha}\text{-}C{\equiv}CPh)_4\}_2(CdCl_2)_2]$ 1 stabilised by alkynyl bridging ligands and platinum–cadmium bonding interactions, have been characterised by X-ray crystallography and their luminescence properties have been also investigated.

Although cadmium organometallics have long been used in organic synthesis,[1] there have been relatively few studies on the species themselves.[2] In particular, alkynyl cadmium complexes are limited to the polymeric derivatives $[Cd(C{\equiv}CR)_2]_n$, (R = H,[3a] Ph,[3a,b] C_6H_{13}[3b]) and to the recently reported mononuclear complex $[Cd(C{\equiv}CPh)_2(tmen)]$,[3c] which is the only example of a structurally characterised cadmium alkynyl complex. Heteropolynuclear organocadmium species with Cd(II) in different environments and with nuclearity ranges from two to seven (or even larger, *i.e.* 9 or 13), have been reported,[1,2] but, up to now, complexes of this type involving alkynyl ligands are unknown.

In the last few years we have shown that anionic homoleptic alkynylplatinate(II) species are suitable precursors for the synthesis of remarkable trinuclear species $[\{Pt(\mu\text{-}\kappa C^{\alpha}:\eta^2\text{-}C{\equiv}CR)_4(ML_n)_2\}]^{x-}$ displaying very unusual η^2-alkyne–M bonding interactions [ML_n = $Pd(\eta^3\text{–}C_3H_5)$,[4a] x = 0; HgX_2,[4b] $CoCl_2$,[4c] x = 2). By using a similar synthetic approach we have now been able to prepare the first examples of organometallic mixed-metal platinum–cadmium compounds.[5] Here, we report the syntheses, X-ray crystal structures and luminescence properties of a trinuclear complex $(NBu_4)_2[\{Pt(\mu\text{-}\kappa C^{\alpha}:\eta^2\text{-}C{\equiv}CPh)_4\}(CdCl_2)_2]$ **2**, stabilised by unusual η^2-alkynyl–Cd interactions, along with the unexpected tetranuclear cluster $(NBu_4)_2[\{Pt(\mu\text{-}\kappa C^{\alpha}C^{\alpha}\text{-}C{\equiv}CPh)_4\}(CdCl)]_2$ **1** containing four Pt(II)–Cd(II) interactions and with alkynyl bridging ligands displaying a rather unusual $\mu\text{-}\kappa C^{\alpha}C^{\alpha}$ bonding mode.

The complex $(NBu_4)_2[Pt(C{\equiv}CPh)_4]$[6] was treated in acetone at room temperature with $CdCl_2{\cdot}2.5H_2O$ (1:2 molar ratio) with the aim of preparing 1:2 adducts analogous to the trinuclear PtM_2 (M = Hg,[4b] Co[4c]) derivatives mentioned above. However, after 50 min of stirring a microcrystalline yellow solid (**1**, 30% yield) was obtained by partial evaporation of the solvent and cooling.† Complex **1** was identified by a single-crystal X-ray diffraction study as the unexpected tetranuclear compound $(NBu_4)_2[\{Pt(\mu\text{-}\kappa C^{\alpha}C^{\alpha}\text{-}C{\equiv}CPh)_4\}_2(CdCl)_2]$ (see below). In addition, evaporation of the filtrate to dryness and treatment with isopropyl alcohol gave the desired trinuclear adduct $(NBu_4)_2[\{Pt(\mu\text{-}\kappa C^{\alpha}:\eta^2\text{-}C{\equiv}CPh)_4\}(CdCl_2)_2]$ **2** as a white solid (45% yield). As might be expected, if the reaction is carried out under similar conditions, but with a 1:1 molar ratio, only the 1:1 Pt/Cd complex **1** is obtained, in high yield (82%).

X-Ray structure analyses of both compounds have been carried out (Fig. 1 and 2). As can be seen, while the anion in **2**‡

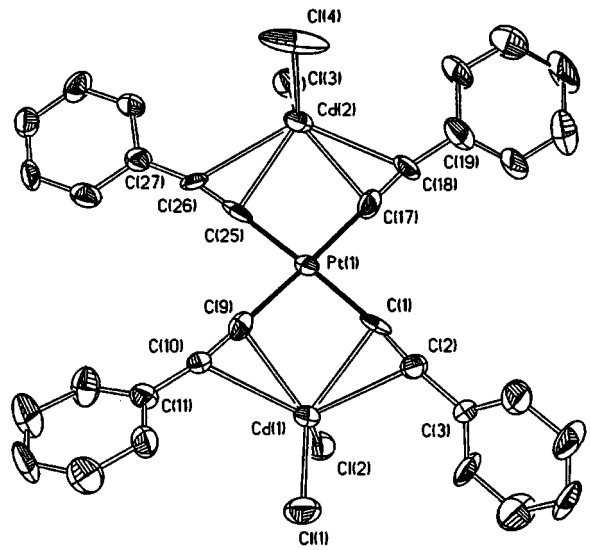

Fig. 2 Structure of the anion $[\{Pt(\mu\text{-}\kappa C^{\alpha}:\eta^2\text{-}C{\equiv}CPh)_4\}(CdCl_2)_2]^{2-}$ in complex **2** (phenyl groups have been omitted for clarity). Selected interatomic distances (Å) and angles (°): Pt(1)–C(1) 1.989(13), Pt(1)–C(9) 2.012(13), Pt(1)–C(17) 2.003(13), Pt(1)–C(25) 1.996(15), Cd(1)–C(1) 2.459(11), Cd(1)–C(9) 2.403(11), Cd(1)–C(2) 2.576(12), Cd(1)–C(10) 2.670(11), Cd(2)–C(17) 2.423(12), Cd(2)–C(25) 2.428(11), Cd(2)–C(18) 2.598(14), Cd(2)–C(26) 2.657(12); C(2)–C(1)–Pt(1) 173.1(10), C(10)–C(9)–Pt(1) 178.3(10), C(18)–C(17)–Pt(1) 176.8(12), C(26)–C(25)–Pt(1) 176.9(10), C(1)–C(2)–C(3) 173.4(13), C(9)–C(10)–C(11) 169.7(12), C(17)–C(18)–C(19) 168.5(14), C(25)–C(26)–C(27) 167.3(13).

is the expected 1 : 2 bis(η^2-alkyne) adduct, the centrosymmetric tetranuclear anion of **1**‡ is formed by two eclipsed 'Pt(C≡PCh)$_4$' units which are connected by two CdCl fragments. In **2**, the two chlorine atoms and the midpoints of the respective *cis* η^2-alkyne fragments form a pseudo-tetrahedral coordination environment about each cadmium, with the $CdCl_2$ fragments almost perpendicular to the coordination plane of the platinum atom (97.4 and 91.1°). On the other hand, in **1** the cadmium atoms are in a rather complicated environment formed by a chlorine atom, four C_α atoms of four alkynyl entities and two Pt–Cd bonds.

The Cd–Cl distances are very similar in the two complexes [2.435(2) **1**, 2.393(4)–2.427(3) Å **2**] and are comparable to other Cd–Cl distances.[2e] It is worth noting that although in both anions the alkynyl ligands remain σ-bonded to the platinum centre their interactions with the cadmium centres are very different in the two complexes. Thus, in **2**, each cadmium is η^2-bonded to two *cis* alkynyl functions, which have the common bonding mode μ-κC$^\alpha$:η^2(σ–π). The Cd atoms are displaced from the Pt(II) coordination plane [1.0878 Å Cd(1) and 0.4405 Å Cd(2)], generating non-planar PtC_4Cd cores. The Pt–Cd distances [Pt(1)–Cd(1) 3.2063(10) Å and Pt(1)–Cd(2) 3.3117(10) Å] are close to the sum of van der Waals radii (3.4 Å)[7] suggesting that only very weak interactions, if any, are present. In contrast, in the tetranuclear anion of **1**, the cadmium atoms are bonded only to the C_α carbon atoms of four alkynyl functions (two associated with each Pt atom), which display the less usual μ-κC$^\alpha$C$^\alpha$(σ-Pt, σ-Cd) bonding mode. The interactions of the C_β atoms with Cd centres can be considered negligible. The very short Pt–Cd distance, close to the sum of the Pauling covalent radii,[8] and the Pt–C_α–Cd bond angles, somewhat smaller than 90° [range 78.59(16)–82.15(16)°], support the possibility of direct bonding interactions between Pt(II) and Cd(II). The donor properties of a d^8 ML$_n$ complex, particularly enhanced in anionic platinate complexes, are now well documented.[9,10] Presumably, in this complex the four Pt···Cd bonding interactions are responsible for the structure and stability of this tetranuclear anionic cluster. However, the particular preference for the final rhombic planar Pt_2Cd_2 metal core [Cd–Pt–Cd 104.49(3)°; Pt–Cd–Pt 75.51(3)°] with the chlorine atoms also contained in the same plane is not clear at the moment. Probably, the driving force in the formation of **1** could be rationalised as an equilibrium between Pt···Cd, Cd···alkynyl and Cd···Cl bonding interactions.

The different bonding mode of the alkynyl ligand in both complexes is particularly reflected in the ν(C≡C) absorption, which in **1** is shifted to slightly higher frequency (2095 cm^{-1}) than in the starting material [$(NBu_4)_2$[Pt(C≡CPh)$_4$][6] 2075 cm^{-1}] and in **2** is shifted to a lower frequency (2066 cm^{-1}).

The presence of metal–metal interactions in **1** is also suggested by preliminary studies of the optical properties of both complexes, which are strongly emissive in frozen solutions ($CHCl_3$) and in the solid state at room temperature. Complex **2** displays a structured emission (maxima at *ca.* 432 and 471 nm; λ_{max}^{exc} = 335 nm, Stokes shift 6703 cm^{-1}) with a vibrational spacing of 2095 cm^{-1} characteristic of ν(C≡C), which is somewhat similar to that of the precursor $(NBu_4)_2$[Pt(C≡CPh)$_4$] (vibronic structural band at *ca.* 447 nm). Thus, the presence of two $CdCl_2$ units η_2 attached to the acetylenic entities does not induce a significant change in this emission, which on the basis of previous spectroscopic work with alkynyl compounds is attributed to a $\pi^*/p_z \rightarrow d_{z^2}$ transition (MLCT).[11] In contrast, complex **1** exhibits an asymmetric emission (with a low energy tail) centred at λ_{max}^{exc} *ca.* 495 nm (20202 cm^{-1}, hwhm of 1873 cm^{-1}). The absence of vibronic progression in the emission profile and the observed red-shift of both the emission and excitation maxima (λ_{max}^{exc} 433 nm) suggest a significant contribution of the Pt–Cd interactions to the orbitals (probably HOMO) involved in the optical transition. On the basis of previous results,[12] we tentatively attribute this emission to the transition π^*(C≡CPh) → CC (Pt_2Cd_2) (cluster centred to ligand charge transfer), mixed with a metal–metal (Pt–Cd) based charge transfer. Further investigation of the reactivity of other alkynyl platinum complexes towards different cadmium substrates and studies (including molecular orbital calculations) of their properties are currently in progress.

We thank the Dirección General de Enseñanza Superior (Spain, Projects PB95-0003C02-01 02 and PB95-0792) and the University of La Rioja (Project API-99/B17 and a grant to J. G.) for financial support.

Laboratoire des Matériaux et Procédés Membranaires, (CNRS UMR 5635) E.N.S.C.M, 8 rue de l'Ecole Normale, F-34280 Montpellier Cedex 5, France. E-mail:prouzet@cit.enscm.fr

Received (in Oxford, UK) 10th August 1999, Accepted 9th September 1999

Spherical particles of mesoporous MSU-X silica in the micrometric size range have been obtained through a new double step process that led to an easy and highly reproducible synthesis pathway giving micelle templated structures with a large surface area and narrow pore size distribution

Micelle templated structures (MTS), like the mesoporous alumino-silicates M41S (MCM-41, MCM-48) are synthesized through an assembly mechanism between long chain quaternary ammonium compounds and inorganic species. They exhibit desirable properties such as high surface area (*ca.* 1000 $m^2\ g^{-1}$) and narrow pore size distribution in the range 20–100 Å.[1,2] Since their discovery, many groups have succeeded in expanding this new field to other ionic surfactants.[3] The possibility of using non-ionic surfactants such as those based on polyethylene oxide and block-copolymers was also demonstrated,[4–9] which led to a whole family of mesoporous silicas such as MSU-V,[10] MSU-G[11] and MSU-*X* (*X* = 1–4), where *X* refers to the non-ionic surfactant molecules that can be either alkyl PEO, alkyl–aryl PEO, polypropylene oxide PEO block copolymers or ethoxylated derivatives of sorbitan fatty esters (Tween™).[4] Although some reactions proceed in acidic or basic media,[12] syntheses of MSU-X materials were generally reported to occur at neutral pH even though syntheses using non-ionic block copolymers under highly acidic conditions (SBA-type materials) were also successfully explored.[8,13]

Whatever the nature of the template, among possible applications such as catalysts, grafting supports, or filtration materials, the use of MTS for chromatography applications has been claimed for years. However, this latter application requires the ability to synthesize homogeneous batches of spherical particles with a mean diameter of at least 5 μm.[14] Even if such particles have been observed once in a pH-dependent synthesis of MCM-41 particles,[15] until now the only specific syntheses have been of sub-μm particles of MCM-41 or MCM-48 materials[16–18] or 2 μm HMS particles.[19] Here, we describe the synthesis of MSU-X silica with perfectly controlled size and shape that would be suitable for liquid phase chromatography applications.

Our synthesis is based on a sodium fluoride aided hydrolysis of tetraethoxysilane dissolved in a dilute solution of non-ionic polyethylene oxide-based surfactants.[6,20] Depending on the initial mixing conditions, a milky mixture is usually obtained that settles to give a colorless microemulsion if conditions are carefully chosen. The final product contains aggregates of small particles (*ca.* 300 nm) with a 3D worm-hole porous structure.[21] We modified this synthesis process by an apparently slight but actually drastic change in the preparation. The main feature of this new approach lies in the capability to discriminate the assembly step from the hydrolysis step. To this purpose we added an intermediate step that utilises a mild acidic medium (pH *ca.* 2–4) in which, prior to the reaction, a stable colorless microemulsion containing all reactants is obtained. Hence, whatever the initial homogeneity of the surfactant–TEOS mixture, the homogeneity at the molecular level is always attained before the reaction starts. Moreover, one can use a TEOS/surfactant molar ratio of up to 25 or a swelling agent such as 1,3,5-trimethylbenzene and still obtain a stable colorless microemulsion, without any reaction. Hence, this approach does not proceed from previously reported systems such as for the synthesis of SBA materials that use block copolymers[8,13] or the synthesis of modified MSU-X materials through an acid $[N^0(N^+)X^-I^-]$ pathway[12] because these syntheses used acid as the hydrolysis catalyst whereas we use it only as an emulsion breaker (actually, a slight hydrolysis is observed but only after several days). As previously reported, the actual catalyst of the hydrolysis still remains sodium fluoride.[6]

In a typical synthesis, TEOS (Aldrich Chemicals) was dispersed in a 0.02 M solution of Tergitol 15S12 ($CH_3(CH_2)_{14}(EO)_{12}$, Union Carbide Chemicals) up to a molar ratio TEOS/surf. = 8. A milky emulsion was obtained, but the addition of 0.25 M hydrochloric acid (final pH between 2.0 and 4.0) destroys this emulsion within minutes, giving a perfectly colorless microemulsion composed of 6–7 nm monodisperse particles containing both surfactant and TEOS, as observed by dynamic light scattering experiments.[22] The solution was left to stand for 18 h and the hydrolysis of TEOS was induced by the addition of a small amount of sodium fluoride [NaF/TEOS = 1–4 (mol%)]. The reaction begins after *ca.* 1 h and although it is almost totally complete after 6 h, the mixture was allowed to stand for 3 days at 35 °C. A white powder was obtained with a yield close to 100% which was filtered off, dried and calcined at 620 °C for 6 h after a 6 h step at 200 °C (heating rate of 3 °C min^{-1}). This new process was successfully applied to the whole family of nonionic surfactants and block-copolymers of MSU-*x* (*x* = 1–4) materials and preparation of large batches was also successful.

The X-ray pattern (Fig. 1) exhibits a single narrow peak assigned to the pore center to center correlation length, characteristic of a worm-hole structure of the porous framework of MSU compounds.[4,6] Transmission electron microscopy (not shown here) reveals that the whole material is made of such a porous framework and that there is no amorphous component. As shown in Fig. 2, the nitrogen adsorption–desorption

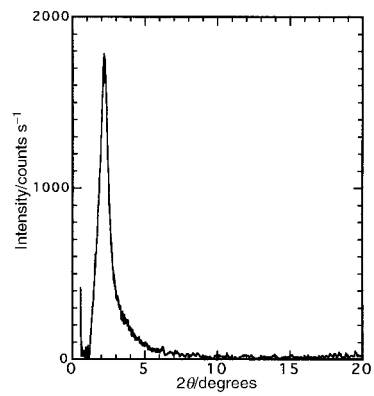

Fig. 1 X-Ray patterns of calcined MSU-1 silica obtained with Tergitol 15S12 and a NaF/TEOS ratio of 4 mol%. The pattern was recorded with a Bruker D5000 diffractometer in Bragg–Brentano reflection geometry. Cu-$L_{3,2}$ radiation was employed that was monochromatized by a graphite single crystal in the diffracted beam.

isotherm is typical of a well defined porous framework without any textural porosity, but the pore size is very dependent on the amount of fluoride. Keeping other parameters constant, the sample synthesized with a 1 mol% NaF/TEOS ratio exhibited a surface area of 910 m^2 g^{-1} and a pore diameter of 24Å (according to the Broekhoff and de Boer model[23]) whereas the sample synthesized with a NaF/TEOS ratio of 4 mol% gave a material with a pore diameter of 35 Å (surface area 1053 m^2 g^{-1}). Along with the higher crystallinity of the calcined material, the ability to increase the pore size by 10 Å by simply changing the amount of fluoride is one of the new features of this synthesis, which makes it different from previous reaction pathways.[4,6,12] This cannot be assigned to a salt effect since adding large amounts of NaCl does not affect the pore size.

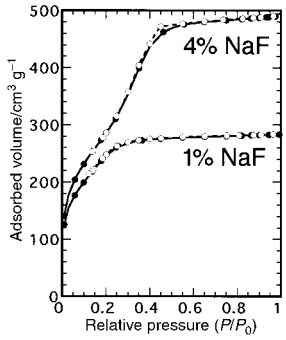

Fig. 2 Nitrogen adsorption (●) and desorption (○) isotherms of MSU-1 silica synthesized with Tergitol 15S12 and different NaF/TEOS molar ratios. Nitrogen adsorption isotherms were measured at 77 K on a micromeretics 2010 Sorptometer using standard continuous procedures and samples degassed at 150 °C for 15 h.

Since the reaction begins in a homogeneous medium, the final shape and size of particles will depend on the respective kinetics of the nucleation and aggregation processes. This competition depends on the quantity of nucleation seeds, and hence upon the NaF/TEOS ratio and on the concentration of the reagents. At low concentrations ([Tergitol 15S12] = 0.02 M), the aggregation process leads to spherical particles as shown by SEM (Fig. 3). The low rate of nucleation (NaF/TEOS = 1–2 mol%) allows the particles to grow up to the micrometer range and the homogeneity of the starting mixture leads to a quite narrow size distribution. Indeed, the mean size of the spherical particles displayed in Fig. 3(A) is 7 μm. A particle size analysis shows that while 98% of the powder volume is comprised of particles < 10 μm, 83% lie in the 3–8 μm size range. However, since the synthesis was not optimized for the preparation of isolated single particles, some of them that grew too closely together are stuck by grain boundaries that appeared during the particle growth.

The key of this reaction is the ability to separate the assembly step from the condensation step. This approach defines not only an improvement of previously reported syntheses of MSU-X materials, but also a different concept, which is particularly illustrated by the different behavior of some synthesis parameters such as sodium fluoride content. Similarly, syntheses using ethoxylated sorbitan molecules (Tween surfactants), which lead to nanometric particles when synthesized by the usual process,[7] also gives micrometric spherical particles when this new process is applied [Fig. 3(B)]. This makes this synthesis a new example of the versatility of the non-ionic route for the synthesis of MTS materials. Both the simple synthetic pathway along with the possibility to control all steps of the reaction, and the well defined morphology and nanostructure of the resulting powders make them suitable for future liquid phase chromatography applications that are currently being investigated.

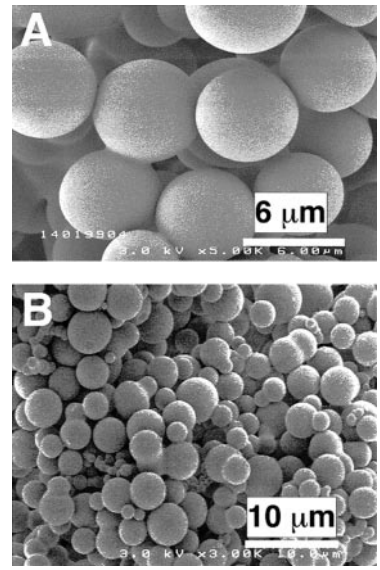

Fig. 3 SEM photograph of (A) calcined MSU-1 silica obtained with Tergitol 15S12, a molar ratio TEOS/surfactant = 8 and NaF/TEOS = 1 mol% and (B) calcined MSU-4 silica obtained with Tween 20, a molar ratio TEOS/surfactant = 4 and NaF/TEOS = 2 mol%. Spherical micrometric particles can be obtained with both surfactants but the mean size depends on various synthesis parameters, especially the TEOS/surfactant and NaF/TEOS ratios. SEM micrographs were obtained on a Hitachi S-5400 FEG microscope.

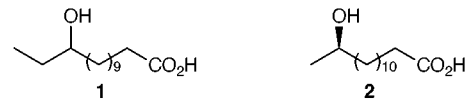
Received (in Liverpool, UK) 20th July 1999, Accepted 6th September 1999

Cytochrome P_{450} from *Bacillus megaterium* catalyses the diastereoselective hydroxylations of 13-hydroxymyristic acid, to predominantly *erythro*-12,13-dihydroxymyristic acid, and of 12-hydroxymyristic acid to give predominantly *threo*-12,13-dihydroxymyristic acid, in reactions that are stereocomplementary and with considerable potential application in biotransformations.

During the past decade, purified enzymes have been widely used to effect transformations of value in synthetic chemistry.[1] In addition to the familiar and widely exploited hydrolases and reductases, there remains a considerable range of potentially interesting and challenging enzyme-catalysed chemical transformations, mostly notably the functionalisation of unactivated positions, to be exploited in this context. We report here the results of our studies on the stereoselectivity and regioselectivity shown by cytochrome P_{450} from *Bacillus megaterium* in the hydroxylation of hydroxy fatty acids, and note a quite remarkable matrix of stereoselective complementarity.

Cytochromes P_{450} form a diverse superfamily of enzymes capable of inserting an atom of oxygen into a dazzling range of substrates, *e.g.* fatty acids, prostaglandins, steroids, polycyclic aromatics.[2] In contrast to the mammalian cytochromes P_{450} which are membrane-bound proteins, cytochromes P_{450} from bacterial sources have proved more tractable for study at the molecular level by virtue of being soluble proteins. The most extensively studied of the bacterial enzyme systems is cytochrome $P_{450\,CAM}$ from *Pseudomonas* which catalyses the hydroxylation of camphor to the 5-*exo*-hydroxycamphor.[3] This system is a typical three component system requiring a cytochrome P_{450} reductase, an iron–sulfur electron transfer protein and the cytochrome P_{450} hydroxylase protein, and exhibits a comparatively tight substrate specificity. Both of these features detract from its use in biotransformations although a number of mutant proteins of broader specificity have recently been reported. In contrast, the class 2 cytochrome P_{450} from *Bacillus megaterium* requires only a single redox component and this forms part of the multifunctional protein that incorporates both the flavoprotein NADPH reductase domain and the heme-containing P_{450} domain.[4] The enzyme has been overexpressed[5] and an X-ray crystal structure of the P_{450} domain has been determined.[6] Cytochrome $P_{450\text{-}BM3}$ catalyses the hydroxylation of a range of fatty acids to give mono- and dihydroxylated fatty acids. Capdevila *et al.* have reported the selective oxidation of arachidonic acid,[7] and our own preliminary observations suggest that the range of potential alternative substrates accepted by the enzyme may be quite large, including steroids, coumarins and sulfides.[8] To determine its potential utility in carrying out useful biotransformations we have explored the regio- and stereo-selectivity in the $P_{450\text{-}BM3}$ catalysed oxidation of hydroxylated fatty acids.

Wild-type cytochrome $P_{450\text{-}BM3}$ is known to catalyse the monohydroxylation of fatty acids such as myristic and palmitic acids at the ω-1, ω-2 and ω-3 positions, and also to give rise to lesser amounts of dihydroxylated products.[4a] The production of these dihydroxylated products clearly arises from a 'second round' of hydroxylation of the first formed monohydroxy fatty acids. The monohydroxy fatty acids are evidently poorer substrates for cytochrome $P_{450\text{-}BM3}$ (Table 1) such that the amount of dihydroxylation product observed will depend on the extent of reaction and the reaction conditions. Although there has been a considerable amount of work reported on the regioselectivity of monohydroxylation of fatty acids by cytochrome $P_{450\text{-}BM3}$,[4a] hitherto there have been no studies on the stereochemical courses of these processes. Furthermore, there has been little reported on the hydroxylation of functionalised fatty acids. In this study we have exploited the enantiomers of 12-hydroxy- **1** and (*R*)-13-hydroxy-myristic acid **2**.



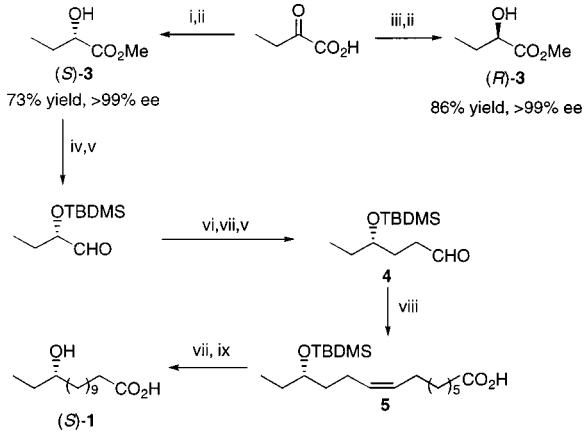
The route for the enantioselective synthesis of 12-hydroxymyristic acid is shown in Scheme 1. The enzyme-catalysed reduction of 2-oxobutanoic acid with either lactate dehydrogenase from *Bacillus stearothermophilus* (*BS*-LDH)[9] or hydroxyisocaproate dehydrogenase from *Lactobacillus bulgaricus* subsp. *delbruckeii* (*LB*-hicDH),[10] gave, after esterification, methyl 2-hydroxybutanoate (*S*)-**3** and (*R*)-**3** respectively. A straightforward series of reactions led to the conversion of the hydroxy ester **3** to the C_6-aldehyde **4** which, on reaction with the C_8-ylide, led to formation of predominantly the *Z*-alkene **5**. Finally deprotection of the alcohol and reduction of the double bond gave either (*S*)- or (*R*)-12-hydroxymyristic acid **1**. (*R*)-13-Hydroxymyristic acid **2** was prepared by a similar route from ethyl (*R*)-3-hydroxybutanoate.

In order to identify the products from the cytochrome P_{450}-catalysed oxidation of **1** and **2**, authentic samples of *erythro*- and *threo*-12,13-dihydroxymyristic acids **6** and **7** were required. Treatment of acetaldehyde with the ylide derived from the C_{12}-salt **8** gave a 9:1 mixture of *Z*:*E* alkenes **9** and **10** (Scheme 2).

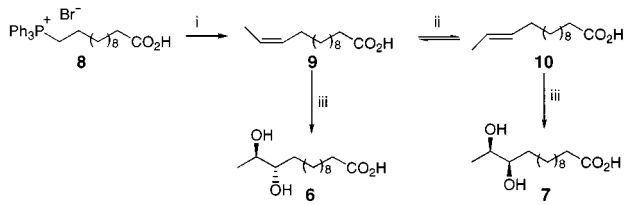
Table 1

Substrate	K_M/μM	k_{cat}[a]/min^{-1}
Myristate	8	3127
(13*R*)-Hydroxymyristate	33	139
(12*R*)-Hydroxymyristate	32	119
(12*S*)-Hydroxymyristate	11	72

[a] k_{cat} values are based upon monitoring of NADPH turnover, and with the exception of myristate, where the coupling efficiency is known to be very high, have not been corrected for uncoupled peroxidase for oxidase activity. The values for hydroxymyristic acid are therefore upper estimates.



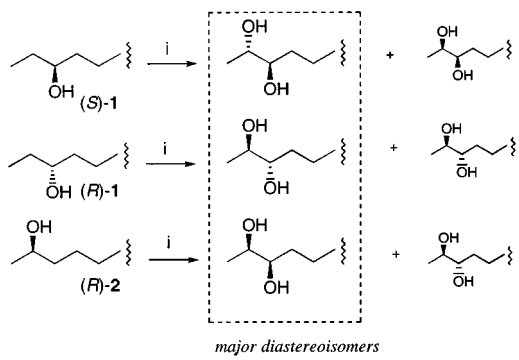
Scheme 1 *Reagents and conditions*: i, *BS*-LDH, NADH, FDH, HCO_2Na; ii, CH_2N_2; iii, *LB*-hicDH, NADH, FDH, HCO_2Na; iv, TBDMSOTf, pyridine; v, DIBAL-H, toluene, −78 °C; vi, Ph_3PCHCO_2Et, CH_3CN; vii, H_2, Pd on $CaCO_3$; vii, $Ph_3P^+CH(CH_2)_6CO_2H$ Br^-, NaH, DMSO; xi, TBAF, THF.



Scheme 2 *Reagents*: i, Bu^tOK, CH_3CHO; ii, I_2; iii, OsO_4 (cat), NMO.

Dihydroxylation of **9** using catalytic osmium tetroxide in the presence of *N*-methylmorpholine *N*-oxide (NMO) gave the *erythro*-diol **6**. Isomerisation of the double bond with iodine followed by dihydroxylation gave predominantly the *threo*-diol **7**.

Incubation of either enantiomer of 12-hydroxymyristic acid **1** or (*R*)-13-hydroxymyristic acid **2** with cytochrome $P_{450\text{-}BM3}$ together with an NADPH-regenerating system[11] (NADP, glucose-6-phosphate, $MgCl_2$ and glucose-6-phosphate dehydrogenase) both gave 12,13-dihydroxymyristic acid as a major product (yields from 13*R*: 85%; 12*R*: 79%; 12*S*: 64% based on total products identified by GC).[12] Using the authentic samples obtained above we have shown that hydroxylation of (*R*)-12-hydroxymyristic acid catalysed by cytochrome $P_{450\text{-}BM3}$ not only occurred regioselectivity but also stereoselectivity at ω-1 giving predominantly the *threo*-12,13-dihydroxymyristic acid [(12*S*,13*S*)-12,13-dihydroxymyristic acid, 80%; (12*S*,13*R*)-12,13-dihydroxymyristic acid 20%] (Scheme 3). Similarly (*S*)-12-hydroxymyristic acid was regioselectivity and stereoselectively hydroxylated at the ω-1 position to give predominantly the enantiomeric *threo*-12,13-dihydroxymyristic acid diastereoisomer [(12*R*,13*R*)-12,13-dihydroxymyristic acid, 80%; (12*R*,13*S*)-12,13-dihydroxymyristic acid 20%]. In contrast to



Scheme 3 *Reagents and conditions*: i, $P_{450\ BM3}$, NADP, glucose-6-phosphate, $MgCl_2$, glucose-6-phosphate dehyrogenase, phosphate buffer (0.1 M, pH 8.0).

this, starting from the (*R*)-13-hydroxymyristic acid, cytochrome $P_{450\text{-}BM3}$ catalyses the second hydroxylation at the ω-2 position stereoselectivity to give predominantly the *erythro*-12,13-dihydroxymyrisitic acid [(12*S*,13*R*)-12,13-dihydroxymyristic acid, 85%; (12*R*,13*R*)-12,13-dihydroxymyristic acid 15%] (Scheme 3). Clearly, in all three cases the preference is for oxygen insertion into the C–H of the methylene group *adjacent* to the hydroxymethylene moiety, rather than into the C–H of the hydroxymethylene goups itself, which would lead to the corresponding ketone. This would be consistent with a mechanism that does not involve a hydrogen abstraction since placement of the radical centre on the carbon atom bearing the hydroxy group would have been expected to be energetically preferred.

The observation of stereoselective hyroxylation of even flexible long chain hydroxy fatty acids catalysed $P_{450\text{-}BM3}$ has demonstrated an interesting, stereocomplementary matrix of biotransformations. The one major drawback that can be envisaged is the requirement for NADPH, however we have already addressed this by developing two systems in which the reducing equivalents are provided directly from an electrode thus allowing the oxidation to be driven electrochemically.[13] We have also demonstrated that $P_{450\text{-}BM3}$ is not restricted to long chain fatty acids and will tolerate a wide range of functionality in the chain. This system holds great potential for further exploitation in synthetic chemistry.

12 Enzymatic oxidation of fatty acids was performed by mixing cytochrome P_{450} (30 μM), substrate (10 mM) and a NADPH-regenerating system (comprising 10 mM NADP, 10 mM glucose-6-phosphate, 10 mM $MgCl_2$ and 1 unit glucose-6-phosphate dehydrogenase) in phosphate buffer (15 ml, 0.1 M, pH 8.0). After incubation for 1 h, the reactions were stopped by addition of 10 mL of 1 M HCl and the products extracted with ethyl acetate (2 × 15 mL). GC-EIMS analysis (70 eV) of the corresponding methyl ester was carried out on a Kratos Concept mass spectrometer (Kratos Instruments. Inc) equipped with a direct capillary interface to a Shimadzu 14A GC with electron impact ionisation using a HP35 capillary GC column (30 m × 0.25 μM HP35, Hewlett Packard). Chromatography of the sample was performed at a linear flow rate of helium gas of 68 cm s^{-1} and, after 2 min at 180 °C, the temperature was raised to 270 °C (at a rate 8 °C min^{-1}) and then held at 270 °C.

Influence of a dimetal ion binding ferrocene ligand on the samarium diiodide promoted pinacol coupling reaction

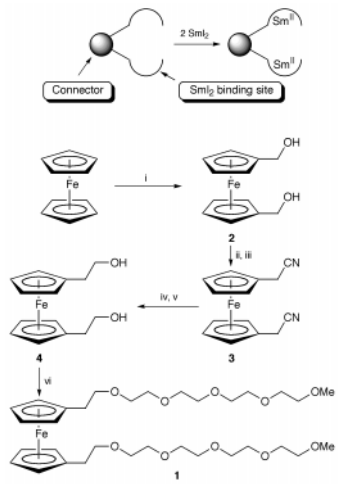
Received (in Liverpool, UK) 25th May 1999, Accepted 1st September 1999

Substantial yield increases have been noted in the use of a di-SmI_2 binding ligand for the pinacol coupling of alkyl aldehydes compared to 1:1 complexes of SmI_2 and tetraglyme. High diastereoselectivities of *ca.* 10:1 are also observed for α-substituted alkyl aldehydes in favour of the (±)-isomers.

Samarium diiodide is an important one-electron reducing agent which has been employed in a multitude of organic synthetic transformations.[1] When pertinent, these reactions are generally associated with high levels of stereochemical control. One exception is the intermolecular pinacol coupling reaction of carbonyl compounds[2] to access vicinal diol systems. With aryl ketones or aldehydes, these reactions have been reported to be high yielding,[3,4] but are also characterised by low diastereoselectivities (±:*meso, ca.* 1.3:1), the exception being when certain metal complexes of aryl aldehydes are used.[5] Only a few examples of alkyl aldehydes have been studied so far where similar ±:*meso* ratios were noted.[3] In our efforts to improve the diastereoselectivities of the SmI_2 promoted pinacol coupling of aryl and alkyl aldehydes, we have recently reported on the beneficial effects the addition of tetraglyme derivatives to the one electron reducing agent may have prior to the coupling step.[6]

We have been interested in synthesising ligands which can bind two divalent samarium ions with the purpose of investigating their influence on the diastereoselectivities and yields in the SmI_2-induced pinacol coupling (Scheme 1). Here we show that the use of one such example may significantly increase yields of the vicinal diols obtained from branched alkyl aldehydes, while still retaining the high ±-selectivity.

As a dimetal ion complexing agent, we prepared the bis-tetraglyme derivative **1** possessing a metallocene unit as the connector (Scheme 1). This ligand was chosen primarily because of the affinity of tetraglyme for divalent samarium ions,[6,7] while rotational freedom of the cyclopentadienyl rings around the iron core[8] allows radical or anionic intermediates of the pinacol coupling to easily find suitable conformations between the two lanthanide metal centers. The ability of ferrocene to absorb in the visible light region also simplifies the isolation of this ligand type upon chromatographic separation of the products.



Scheme 1 *Reagents and conditions:* i, 2.1 equiv. BuLi, 2.1 equiv. TMEDA, then $(CH_2O)_n$, 54%; ii, PCl_3, THF–Pyr; iii, KCN, H_2O–THF, 52% (2 steps); iv, NaOH, EtOH, 89%; v, $LiAlH_4$, THF, 77%; vi, 3.0 equiv. NaH, DMF, then 3.5 equiv. $MeO(CH_2CH_2O)_4Ts$, 86%.

The synthesis of the ferrocene ligand **1** is depicted in Scheme 1, adapting procedures previously developed by Frejd[9] and Moritani.[10] Formation of bis(hydroxymethyl)ferrocene **2** was easily achieved by direct lithiation of ferrocene with 2 equiv. of BuLi followed by addition of paraformaldehyde. The dichloride obtained by treating **2** with PCl_3 was immediately converted to the dicyanide **3**. Basic hydrolysis and reduction then gave the crystalline diol **4** (mp 43–44 °C). Introduction of the complete side chains was achieved by alkylation of **4** with the tosylate of tetraethylene glycol monomethyl ether affording **1** as an orange–brown coloured oil in 86% yield.

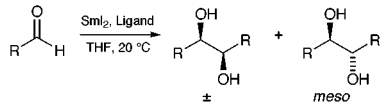
Addition of a 0.1 M THF solution of SmI_2 to 0.5 equiv. of ligand **1** at 20 °C leads to darkening of the solution with eventual precipitation of a black solid. An immediate reaction was noted upon subjecting this mixture to benzaldehyde affording a *ca.* 5:1 diastereoselectivity in favour of the *meso*-isomer (Table 1, entry 1). Augmenting the ligand to divalent samarium ratio to 1:1 had no effect on either the *meso*:± selectivity nor the yields (entry 2). Whereas no notable improvement in the diastereoselectivity of the diol product is noted with ligand **1** compared with a similar reaction using 1 equiv. of tetraglyme (entry 3), these results do suggest that **1** binds two metal ions.†

Noteworthy are the effects observed in the pinacol coupling of alkyl aldehydes. The tetraglyme–SmI_2 complex converts cyclohexanecarbaldehyde to a 10:1 mixture of ±:*meso* isomers albeit in low yield (29%) after 24 h at 20 °C (entry 4). Under similar conditions with **1**–2SmI_2, this yield was remarkably increased to 81% (entry 5) while still maintaining the high diastereoselectivity, making this method competitive with other metal reducing systems.[2] On the other hand, premixing SmI_2 to 1 equiv. of ligand **1** prior to the addition of cyclohexanecarbaldehyde maintains the high diastereoselectivity but lowers the yield of the reaction to 38% (entry 6), a result which resembles that of the tetraglyme–SmI_2 complex. The same trend was noted with tetrahydrobenzaldehyde, where a 24% increase in the pinacol coupling yield was noted with a ±:*meso* selectivity of 11:1 (entries 7 and 8) when ligand **1** was employed instead of tetraglyme.

In the SmI_2 induced dimerisation of isobutyraldehyde, the reaction is less clean affording a modest yield of the diol (entry 9, 44%) with a diastereoselectivity of 1.9:1. Whereas, this yield is even lower with tetraglyme (entry 10), the use of the **1**–2SmI_2 complex retains the 44% yield while increasing the selectivity to 10:1 (entry 11).

The Tischenko-type side reactions are problematic with linear aldehydes such as *n*-octanal, but again an increase in the yield of the coupled product is observed when using ligand **1** (entries 12 and 13). Interestingly, in this case the diastereo-

Table 1 Effect of a dimetal ion binding ligand on the SmI_2 promoted pinacol coupling.[a]



Entry	Aldehyde	Ligand (equiv.)[b]	Yield (%)[c]	Diastereosel (±:*meso*)
1	 **5**	1 (0.5)	89	1:5.0

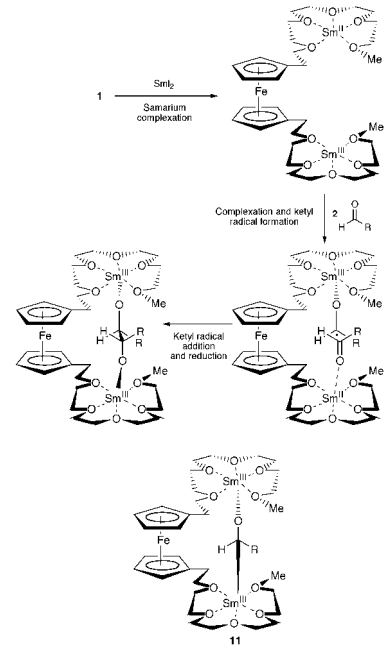
13	**9**	1 (0.5)	68	2.2:1
14	 **10**	None	79	8.5:1
15	**10**	Tetraglyme (1.0)	0	—
16	**10**	1 (0.5)	0	—

[a] Conditions: complexed or uncomplexed SmI_2 (0.1 M, 1.5 equiv.), aldehyde (1 equiv.), THF, 20 °C. [b] Based on the number of equivalents of SmI_2 added. [c] Based on isolated, chromatographically pure material. [d] Taken from ref. 6. [e] Determined after catalytic hydrogenation (Pd/C, H_2) of the diastereomeric mixture of diols.

selectivity is low suggesting that substitution at the α-position of the alkyl aldehyde is necessary for obtaining the high ±:*meso* ratio when using the polyethyleneglycol complexing agents. Increasing the steric bulkiness, as exemplified with pivalaldehyde, surprisingly led to no pinacol coupling with either tetraglyme or **1** (entries 15 and 16). Nevertheless, without these ligands SmI_2 promoted this dimerisation with an 8.5:1 selectivity (entry 14). The steric bulkiness of the aldehyde was sufficient to induce a high diastereoselectivity. These results again support the notion that uncomplexed SmI_2 is not available in solution when the one electron reducing agent is added to 0.5 equiv. of ligand **1**.

The combined findings suggest the formation of a complex between two samarium(II) metal ions and **1** as illustrated in Scheme 2. Coordination of the two aldehyde units to each of the two oxophilic metallic centers may then take place. The slow reactivity of alkyl aldehydes also suggests that there is only a low concentration of a ketyl radical species in solution. The close proximity of the carbon radical center to the other aldehyde, which possesses a low-lying LUMO due to its coordination to SmI_2, could lead to a radical addition step with concomitant reduction of the resulting alkoxyl radical by SmI_2.[6] A two electron reduction of the aldehyde to dianion **11**, which eventually couples to a second aldehyde, is a possible alternative mechanism because ligand **1** improves significantly the yields of these pinacol coupling reactions compared to that of tetraglyme, and although little effect is seen on the diastereoselectivities, these preliminary observations tend to support the radical addition mechanism where the entropy contribution is less important owing to the pseudo-intramolecular nature of this reaction.



Scheme 2

In conclusion, we have shown that dimetal binding ligands can have a substantial effect on the SmI_2 induced pinacol coupling of alkyl aldehydes compared to that of tetraglyme. Efforts are underway to increase the utility of such ligands. The introduction of either planar chirality in the connector or asymmetric carbon centers in the tetraglyme units may also lead to the development of an asymmetric version of the pinacol coupling reaction with alkyl aldehydes.

We thank the University of Aarhus and the Danish National Science Foundation for generous financial support.

Notes and references

† Preliminary investigations of this complex by cyclic voltametry imply that the metallocene center does not influence the oxidation potential of SmI_2 (ref. 6 and 11).

Received (in Basel, Switzerland) 15th June 1999, Accepted 7th September 1999

The *N*,*N*-diisopropylcarbamato complexes of lanthanides(III) from neodymium (*Z* = 60) to ytterbium (*Z* = 70) were found to be isotypical, with Ln–O distances decreasing steadily with increasing *Z*, the lanthanide contraction in this series of molecular complexes being provisionally assigned to an increasing bond strength with increasing atomic number of the central metal atom.

The well known lanthanide contraction was originally recognized[1a] on the basis of X-ray diffractometric data on the ionic oxides and fluorides of the trivalent cations and estimated to correspond to about a 15% decrease of the radii on going from cerium to lutetium,[1] a correction[1b,c] being required for the decreasing coordination numbers (CN) along the series. In fact, no isotypical coordination compounds of lanthanides are known, for halide or oxide ligands, to cover the whole series; normally, changes of both space group and CN are encountered, on going from the first part to the second one[1d,e] of the series.

Coordination chemistry of lanthanides (Ln) is a subject of increasing interest,[2] the focus of the current studies being on uncharged complexes of Ln(III),[3] in view of their role in biochemistry[3a] and in carbon–carbon and carbon–nitrogen bond forming reactions,[3b–r] mainly catalyzed by organometallic derivatives [4] of these elements. A better understanding of these systems should originate from the synthesis of isotypical (*i.e.* with constant CN and geometry) and *neutral* compounds and by the determination of their interatomic parameters through diffraction methods.

We now report the preparation of some isotypical *N*,*N*-dialkylcarbamato complexes of the lanthanides. Although *N*,*N*-dialkylcarbamato complexes of transition d elements are well established,[5] such lanthanide derivatives are still in their infancy, mainly due to synthetic difficulties.[6]

The synthesis of the new *N*,*N*-diisopropylcarbamato derivatives of La, Nd, Eu, Gd and Ho, of the same general formula, has now been achieved by using the ether complexes $LnCl_3(ether)_x$ (ether = THF or Et_2O),[7] as starting materials [eqn. (1)]. Yields

$$4\ LnCl_3(ether)_x + 12\ CO_2 + 24\ NHPr^i_2 \longrightarrow Ln_4(O_2CNPr^i_2)_{12} + 12\ [NH_2Pr^i_2]Cl + 4x\ ether \quad (1)$$

(Ln = La, f^0; Nd, f^3; Eu, f^6; Gd, f^7; Ho, f^{10}; Er, f^{11})

of recrystallized product are generally moderate (20%) to satisfactory (50%).

The new isopropyl derivatives of Nd(III), Eu(III), Gd(III) and Ho(III) were found to be moderately soluble in hydrocarbons; these compounds are isotypical with one another and with the already known Yb(III) analogue.[6]

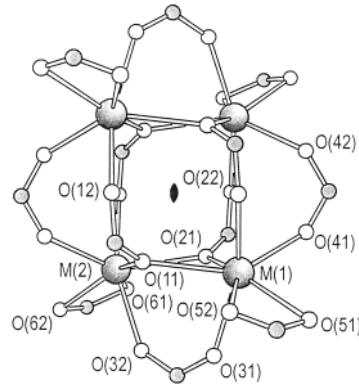

Fig. 1 Molecular structure of the lanthanide derivatives $M_4(O_2CNPr^i_2)_{12}$; M = Nd (*Z* = 60), Gd (*Z* = 64), Ho (*Z* = 67), Yb (*Z* = 70). The heptacoordinated metal atoms are shown with their oxygen donor atoms.

Complete crystal data were collected for the Nd (*Z* = 60), Gd (*Z* = 64), and Ho (*Z* = 67) derivatives,† to be compared with the already available information for the isostructural Yb species (*Z* = 70).[6] In these tetranuclear compounds, the heptacoordinate lanthanide is surrounded by terminal bidentate, bridging bidentate and bridging tridentate diisopropylcarbamato groups. The molecular core of the tetranuclear derivatives is schematically shown in Fig. 1.

The Ln–O average bond distances of the new *N*,*N*-diisopropylcarbamato complexes can be factorized as a function of the type of bonding (Table 1, Fig. 2). The Ln–O bond distance contracts along our series with increasing *Z*; more precisely, by assuming that the lanthanide-coordinated oxygen has the same radius of 1.21 Å as that of bicoordinated oxygen,[1c] the lanthanide contraction, averaged over the four different types of ligands (Table 1) is *ca.* 8% over the eight *Z* values from Nd to

Table 1 Average Ln–O bond distances (Å) in tetranuclear *N*,*N*-diisopropylcarbamato complexes of lanthanides, for different coordination modes. The quadratic dispersion from the average values is given in parentheses.

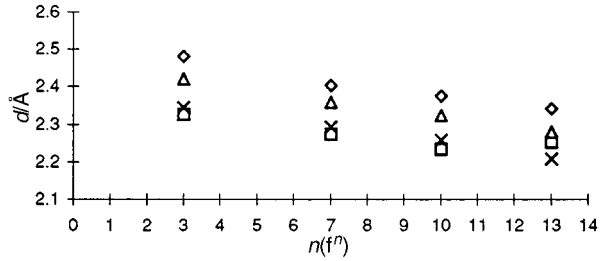

Fig. 2 Lanthanide(III)–oxygen bond distances (Å) *vs.* f^n electronic configuration in the tetranuclear *N,N*-diisopropylcarbamato complexes $M_4(O_2CNPr^i_2)_{12}$; M = Nd (Z = 60), Gd (Z = 64), Ho (Z = 67), and Yb (Z = 70). The ordinate axis shows the average Ln–O bond distances (Å): (◇) type a1, (□) type a2, (△) type b, (×) type c (from top to bottom, see Table 1). The anomalous behavior of the a2 distance for Yb is presumably due to the lower accuracy of the crystal data.[6]

Ho, Yb being excluded because of the lower accuracy of the older structural determination. This result can be linearly extrapolated to the 15 Z series from La to Lu giving a 14% average contraction over the whole series. This is substantially in agreement with the earlier findings for the predominantly ionic oxides.[1c]

An examination of the crystallographic literature[9] has disclosed a few other series of isotypical molecular compounds of lanthanides, namely, (η^6-arene)aryloxides, $Ln(OC_6H_3Pr^i\text{-}2,6)_3(THF)_2$ and THF adducts of tris(cyclopentadienyl), $Ln(\eta^5\text{-}C_5H_5)_3(THF)$, the expected decreasing trend of Ln–O interatomic distances being similarly observed.

A plausible interpretation of the present data is that the bond lanthanides form with oxygen-containing ligands becomes steadily stronger along the series. This suggests that relatively weaker bonds in the oxidation state +III should be found, for lanthanides, at the beginning of the series. This finding may be significant in connection with the catalytic phenomena observed[3e,h,k,n,o–r] with lanthanides.

Work is in progress collecting further accurate crystallographic data on other compounds of this lanthanide series.

The authors wish to thank the Ministero dell'Università e della Ricerca Scientifica e Tecnologica (MURST), Programmi di Ricerca Scientifica di Rilevante Interesse Nazionale, Cofinanziamento MURST 1998-9, the Consiglio Nazionale delle Ricerche (CNR, Roma), the Deutsche Akademischer Austauschdienst (Vigoni Programme) for financial support and Professor Joachim Strähle, Universität Tübingen, for continuous support and interest and for helpful discussions. A generous gift of lanthanide oxides by Rhône-Poulenc Recherches is gratefully acknowledged.

Notes and references

† Complete crystal data were collected for the Nd (Z = 60), Gd (Z = 64), and Ho (Z = 67) derivatives, $Ln_4(O_2CNPr^i_2)_{12}$. The measurements were carried out with a CAD4 and a Siemens P4 diffractometers equipped with Mo-$K\alpha$ radiation (λ = 0.71073 Å). All compounds were monoclinic, space group $C2/c$ (no.15). The intensity data were corrected for Lorentz and polarisation effects by means of the suitable programs.[8] For the Nd and Ho samples, the solvent molecule (octane and heptane, respectively) was found to be slightly disordered; for Gd, the solvent was not localised. Some degree of disorder was occasionally present in the diisopropyl groups. At the end of refinement, residual peaks and holes of *ca.* ± 1 e Å^{-3} were present in the zones of disordered groups or the metal in the difference Fourier maps.

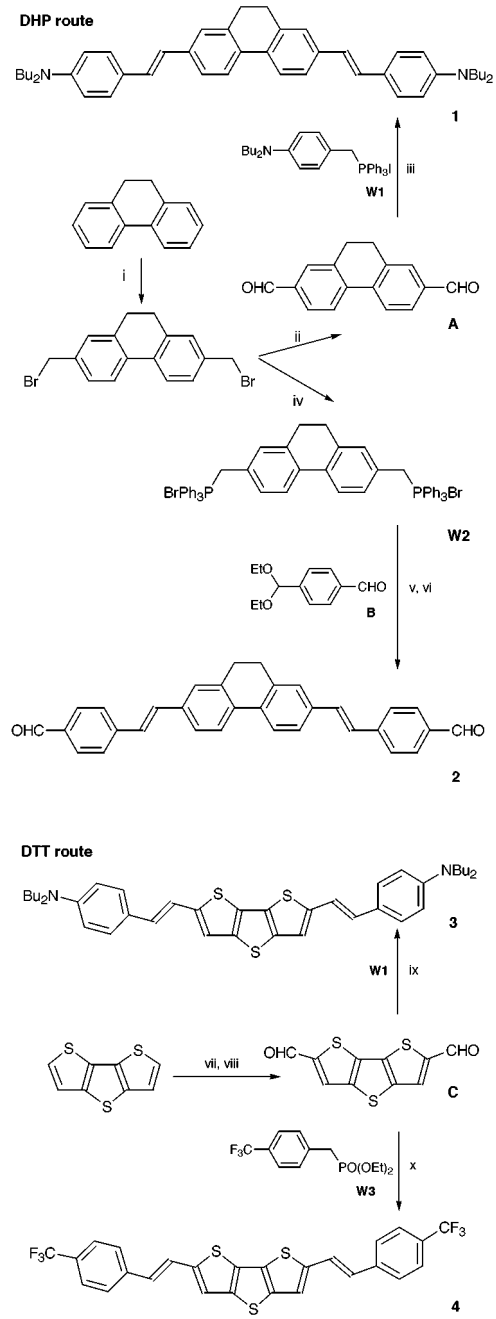
Received (in Cambridge, UK) 30th July 1999, Accepted 8th September 1999

New quadrupolar fluorophores that exhibit enhanced two-photon excited fluorescence were designed according to a molecular engineering approach based on push-push and pull-pull elongated molecules built from a rigid conjugated core (either dihydrophenanthrene or dithienothiophene).

Molecular two-photon absorption (TPA)[1] has found many applications over recent years, including optical power limitation,[2] three-dimensional optical data storage,[3] microfabrication,[4] up-conversion,[5] *etc*. Applications that specifically require excited state fluorescence include two-photon excited fluorescence (TPEF) microscopy,[6] which has gained widespread popularity in the biology community owing to its ability to image at an increased penetration depth in tissue with reduced photodamage. Key ingredients for efficient molecular TPEF are a large two-photon absorption cross section σ_2, and a high fluorescence quantum yield Φ. In most cases, TPEF microscopy applications have relied on molecules originally designed for one-photon fluorescence.[7] It has become increasingly clear, however, that molecules specifically engineered for TPEF may significantly outperform these more conventional molecules.[8] To this end, we have designed, synthesised and characterised new quadrupolar molecules which exhibit enhanced TPEF.

It has been recently observed[8a] that symmetrical phenylene–vinylene oligomers bearing electron-releasing (or electron-withdrawing) groups can display very large σ_2, seemingly correlated to a symmetrical quadrupolar charge redistribution occurring between the edges and the centre of the molecule. Following some of these observations, our goal was to achieve significant two-photon absorption while maintaining high fluorescence quantum yields by the symmetrical grafting of two semi-rigid conjugated rods bearing either donor or acceptor terminal substituents onto a rigid conjugated central building block. The central conjugated block is designed to allow electronic conjugation and high fluorescence yield, and may assist quadrupolar charge redistribution. The dihydrophenanthrene (DHP) and dithienothiophene (DTT) systems, which permit electronic delocalisation and possess decreased rotational degree of freedoms (due to the fused rings in the case of DTT and to the presence of the bis(methylene) bridge in the case of DHP), appeared to be appropriate central moieties. Styrene moieties were selected as conjugated rods.

Based on the above strategy, we have prepared molecules **1**-**4** that possess an extended conjugated system[9] (approximately 22–24 Å long) and either donor (push-push molecules **1**, **3**) or acceptor (pull-pull molecules **2**, **4**) terminal groups (Scheme 1). Molecules derived from DHP can be prepared *via* a double Wittig condensation from symmetrical bisfunctional reagents derived from DHP. Wittig reaction under liquid-liquid[10] or solid-liquid phase transfer conditions[11] of 2.1 equiv. of phosphonium salt **W1**[12] with bisaldehyde **A**[13] afforded push-push molecule **1** in 60% yield after purification by column chromatography on silica gel. Conversely, pull-pull molecule **2** was prepared in 90% yield by reaction of bisphosphonium **W2** with 2 equiv. of commercially available aldehyde **B** , followed by acidic deprotection. The key reagent **W2** was obtained from DHP according to a two step procedure in 50% overall yield.



Scheme 1 *Reagents and conditions :* i, $(CH_2O)_3$, HBr, H_3PO_4, 24 h, 90 °C; ii, $NaHCO_3$, DMSO, 4 h, 115 °C; iii, **W1** (2.1 equiv.), CH_2Cl_2, 50% NaOH, 5 h, room temp.; iv, $P(Ph)_3$ (2 equiv.), CH_2Cl_2, 24 h, room temp.; v, **B** (2 equiv.) CH_2Cl_2, 50% NaOH, 24 h, room temp.; vi, 10% HCl, THF, 1 h, room temp.; vii, BuLi, THF, −78 °C; viii, DMF, −78 °C; ix, **W1** (2.1 equiv.), $KOBu^t$, CH_2Cl_2, 5 h, room temp.; x, **W3** (2.2 equiv.), NaH, THF, 24 h, room temp.

Table 1 One and two-photon absorption and fluorescence properties of fluorophores **1**-**4**. The experimental uncertainty is estimated to be ±15% for TPEF measurements and ±5% for fluorescence quantum yield determinations.

	λ_{max}(abs)/nm	λ_{max}(em)/nm	Φ	λ_{max}(TPA)/nm	$\sigma_2\Phi/10^{-50}$ cm^4 s photon^{-1}	$\sigma_2/10^{-50}$ cm^4 s photon^{-1}
1	421	540	0.77	765	930	1200
2	397	513	0.83	< 730	> 260 [a]	> 320
3	465	582	0.63	795	340	530
4	424	510	0.44	< 730	> 80[a]	> 180

[a] $\sigma_2\Phi$ values measured at 730 nm, the TPA maximum being blue-shifted in the case of fluorophores **2** and **4**.

The same methodology was implemented for the synthesis of molecules **3** and **4** derived from DTT which were prepared in 80–90% yield by reacting bisaldehyde **C**[14] under solid-liquid phase transfer conditions[11] with 2.2 equiv. of either phosphonium salt **W1** or phosphonate **W3**. Molecules **1**–**4** were isolated as pure all-*E* compounds after crystallisation as established by NMR, elemental analyses and/or high resolution mass spectrometry.

The two-photon excitation cross sections were determined by comparing the TPEF of molecules **1**-**4** to that of fluorescein using a mode-locked Ti : sapphire laser operating between 730 and 970 nm and delivering linearly-polarised ~80 fs pulses at 80 MHz. This experimental protocol is described in detail by Xu and Webb[7] and provides the TPEF cross section $\sigma_2\Phi$. The corresponding σ_2 values can then be derived by determining the fluorescence quantum yield Φ from fluorescence measurements.

The experimental data are collected in Table 1. We conclude from these data that fluorophores **1**-**4** indeed combine very large two-photon absorption cross-sections and high fluorescence quantum yields. In particular fluorophores **1** and **3** display σ_2 values more than two orders of magnitude larger than *p*-bis[*o*-methylstyryl]benzene,[7] a shorter generic molecule that lacks donor or acceptor end groups. This demonstrates the importance of the donor (or acceptor) end groups and of the length and electronic function of the central moiety, both of which govern quadrupolar charge redistribution. We note that fluorophores **1** and **3** exhibit very large TPEF cross sections over a wide spectral range (Fig. 1) spanning the visible red to the near IR (700–970 nm). This spectral window is particularly advantageous for imaging in biological tissues.[15] Both fluorophores **1** and **3** have a TPEF cross section about an order of magnitude larger than conventional fluorophores such as fluorescein or rhodamine. Push-push fluorophores **1** and **3** appear to lead to larger TPA cross-sections than corresponding pull-pull derivatives **2** and **4**, concomitant with a red-shift of both one-photon absorption and TPA maxima. Fluorophores **2** and **4** which maintain large TPA cross-sections and display excellent transparency in a wide range of the visible region are promising candidates for optical power limitation applications.

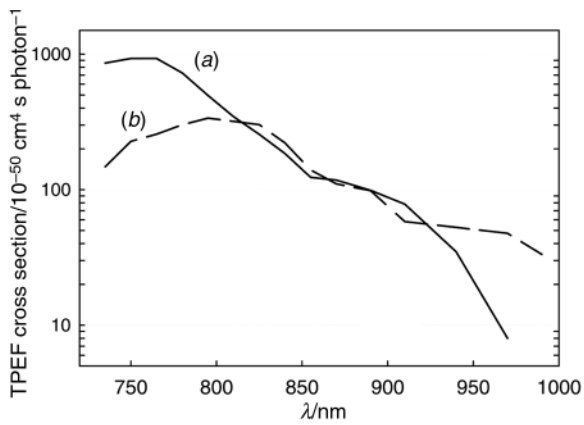


Fig. 1 TPEF excitation spectra of fluorophores (*a*) **1** and (*b*) **3** dissolved in DMSO (10^{-4} M).

In summary, we have demonstrated a successful strategy for the design of fluorophores that combines very large two-photon absorption cross sections and high fluorescence quantum yields. This opens interesting prospects for several applications, particularly in the fields of two-photon microscopy and optical power limitation.

Received (in Cambridge, UK) 10th August 1999, Accepted 7th September 1999

Dendritic poly(L-lysine) combining sixteen free-base porphyrins and sixteen zinc porphyrins hemispherically at the fifth generation was successfully synthesised and showed intramolecular fluorescence energy transfer in DMF.

Before Tomalia proposed the 'dendrimer', a new type of macromolecule,[1] Aharoni *et al*. had described the synthesis and properties of dendritic poly(L-lysine)s up to tenth generation.[2] Unlike the original concept of the dendrimer described Tomalia, the amino groups of L-lysine are not of course symmetrical. However, the chirality of L-lysine is advantageous in the design of functional dendrimers. In addition, the L-lysine residue is useful in combining a special functional group in large numbers at the desired generation. At the fifth generation, there are thirty two side chain amino groups where functional group-carrying L-lysines can be combined. More advantageously, peptide synthetic chemistry can be conveniently applied for design and synthesis of functionalized dendritic poly(L-lysine) by incorporation of photochemically interesting groups such as porphyrin rings.

Porphyrin rings have been formed into clusters using dendritic approaches by several research groups.[3] The most recent clusters involve nine porphyrin rings with designed metallation. However, we hoped to utilise a totally different type of design and synthesis of macromolecules combining a large number of porphyrin rings in any appropriate arrangement. We introduced a number of porphyrin rings (eight, sixteen or thirty-two) into a dendritic poly(L-lysine) in almost the same stratum.[4] The porphyrins showed extremely strong split circular dichroism (CD) ($[\theta]_{428} - [\theta]_{407} = 2.0 \times 10^6$ deg cm^2 dmol^{-1}) under certain conditions (toluene–DMF = 9:1, v/v), while they were silent in DMF. In the present study, we attempted to introduce a crowd of free-base porphyrins and a crowd of zinc porphyrins in separate hemispheres of dendritic poly(L-lysine) (Fig. 1).

The Boc and Fmoc[5] chemistries were alternately applied to build the desired **1** by hemispherical synthesis (Fig. 2). The synthesis was started by the condensation of N^{α},N^{ε}-di-*tert*-butoxycarbonyl-L-lysine [Boc-L-Lys(Boc)-OH] and hexamethylenediamine with benzotriazol-1-yloxytris(dimethylamino)-phosphonium hexafluorophosphate (BOP) and 1-hydroxybenzotriazole (HOBt). The resulting half-amine [Boc-L-Lys(Boc)-NH$(CH_2)_6$NH$_2$] was condensed with N^{α},N^{ε}-difluoren-9-ylmethoxycarbonyl-L-lysine [Fmoc-L-Lys(Fmoc)-OH]. TFA was used to remove the Boc group (0 °C, 1 h), then the Boc hemisphere was expanded by a second condensation with 2 equiv. of Boc-L-Lys(Boc)-OH. The Fmoc protection was removed with 20% piperidine in DMF, then the Fmoc hemisphere was expanded by a second condensation with 2 equiv. of Fmoc-L-Lys(Fmoc)-OH. Thus, Boc and Fmoc chemistries were repeated alternately up to the fourth generation. The condensation reaction proceeded quantitatively (room temperature, 1 h). The completion of the condensation was confirmed at each step by a Kaiser test.[6] At the fifth generation, sixteen Boc-L-Lys(Por(2H))-OH moieties were introduced to the Boc hemisphere of the dendritic poly(L-lysine) intermediate. Expansion of Boc hemisphere to the seventh generation was carried out to bury the free-base porphyrins appropriately in a stratum of the dendritic poly(L-lysine).[4] Subsequently, another half side was condensed with sixteen Fmoc-L-Lys(Por(Zn))-OH moieties with the aid of *O*-(7-azabenzotriazol-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HATU) and 1-hydroxy-7-azabenzotriazole (HOAt). The hemispherical elongation was repeated to give **1**, whose surface is completely covered by seventh generation of Boc-L-Lys(Boc) groups.

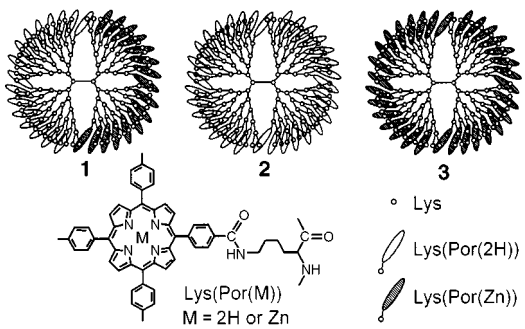

Fig. 1 Dendritic poly(L-lysine)s combining sixteen free-base porphyrins and sixteen zinc porphyrins separately (**1**), thirty-two free-base porphyrins (**2**) and thirty-two zinc porphyrins (**3**) at the fifth generation and covered by an additional two generations. The end-protecting group is *tert*-butoxycarbonyl.

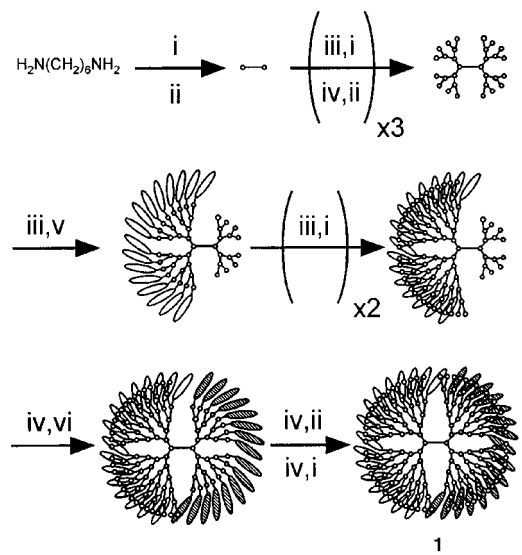

Fig. 2 Synthetic route for dendritic poly(L-lysine) combining hemispherically separated free-base and zinc porphyrins. *Reagents and conditions*: i, Boc-L-Lys(Boc)-OH, BOP, HOBt; ii, Fmoc-L-Lys(Fmoc)-OH, BOP, HOBt; iii, TFA; iv, 20% piperidine in DMF; v, Boc-L-Lys(Por(2H))-OH, BOP, HOBt; vi, Fmoc-L-Lys(Por(Zn))-OH, HATU, HOAt.

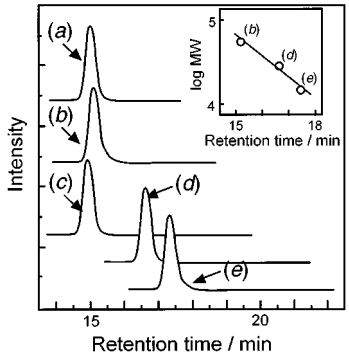

Fig. 3 Analytical size-exclusion chromatograms of dendrimers **1** (*a*), **2** (*b*) and **3** (*c*) and two smaller size homologues (*d*), (*e*) of **2** in DMF. The molecular weights are 56 047, 55 033, 57 061, 27 446 and 13 653 respectively.

Species **1** was purified using a Sephadex LH-60 column (1.8 × 70 cm, DMF) and analyzed by size exclusion chromatography [TSKgel G3000H_{XL} (7.8 × 300 mm) column, with DMF, 2 ng of sample, detected by absorption at 420 nm]. Species **1** was eluted at 14.97 min, the retention time being very close to that (15.16 min) of dendritic poly(L-lysine) combining thirty-two free-base porphyrins (**2**), which was synthesized as previously reported elsewhere.[4] The dendritic poly(L-lysine) with thirty-two zinc porphyrins (**3**) was prepared from **2** and $Zn(OAc)_2$ in CH_2Cl_2–MeOH (3:1, v/v). The formation of **3** was monitored by the disappearance of the Qx(0,0) band of **2** at 650 nm in the absorption spectrum within 3 h. Species **3** showed a single peak at 14.81 min in the size exclusion chromatograph.

The retention times of **1**, **2** and **3** were compared with smaller dendritic poly(L-lysine)s combining eight and sixteen free-base porphyrins[4] at the third and fourth generations, respectively. As shown in the inset of Fig. 3, there is a linear relation between the retention times (17.41, 16.74 and 15.16 min) and the logarithms of the molecular weights (13 653, 27 446 and 55 033) of the dendritic poly(L-lysine)s combining eight, sixteen and thirty-two free-base porphyrins.

Three types of dendritic poly(L-lysine) with thirty-two porphyrins, hemispherically separated free-base and zinc porphyrins (**1**), all free-base porphyrins (**2**) and all zinc porphyrins (**3**), were further characterized by UV-VIS absorption, CD and fluorescence spectra measurements. The absorption spectra in DMF of **2** and **3** were similar to the monomeric free-base and zinc porphyrins respectively. The dendrimer with hemispherically mixed porphyrins (**1**) showed slight deviation (data not shown) from the 1:1 additive spectrum of those of free-base and zinc porphyrins (**2** and **3**). The CD spectra of dendrimers in DMF showed no Cotton effect at the Soret band, whether the porphyrins were free-base or metallated. After addition of toluene (toluene–DMF = 9:1, v/v), **2** with only free-base porphyrins showed an intense split CD ($[\theta]_{428} - [\theta]_{407} = 2.0 \times 10^6$ deg cm^2 dmol^{-1}) for the Soret band as previously observed.[4] However, **1** showed a much weaker CD ($[\theta]_{438} - [\theta]_{421} = 1.8 \times 10^5$ deg cm^2 dmol^{-1}) under the same conditions, while **3** with all zinc porphyrins showed a weak CD ($[\theta]_{440} - [\theta]_{427} = 1.1 \times 10^5$ deg cm^2 dmol^{-1}). The chiral arrangement of free-base porphyrins induced by nonpolar solvent was obviously affected by the crowd of zinc porphyrins.

The fluorescence spectra of the dendrimers are shown in Fig. 4. The dendrimers **2** and **3** in DMF gave typical fluorescence emission upon excitation at 560 nm.[7] A mixed solution of **2** and **3** gave an almost additive spectrum corresponding to both porphyrins. The hemispherical dendrimer **1** gave a fluorescence spectrum in which emission at 610 nm from the zinc porphyrin was significantly quenched. By calculation, about 43% of the

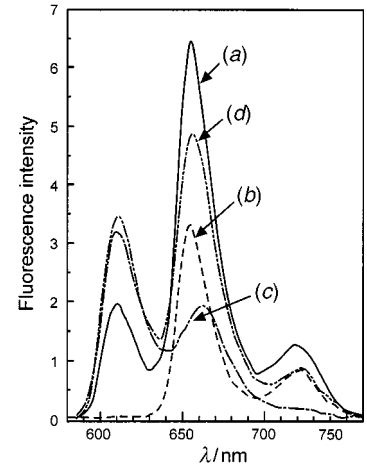

Fig. 4 Fluorescence spectra of dendritic poly(L-lysine)s combining (*a*) hemispherical free-base and zinc porphyrins (**1**, 5.8 μM), (*b*), all free-base porphyrins (**2**, 2.9 μM), (*c*) all zinc porphyrins (**3**, 2.9 μM) and (*d*) a mixture of **2** and **3** (2.9 μM, respectively) in DMF. Excitation at 560 nm.

fluorescence energy of the excited zinc porphyrins was transferred to the free-base porphyrins on the other hemisphere. This fact suggests that about seven of the sixteen porphyrins in each hemisphere might locate on the boundary of said hemisphere, resulting in close contact. The efficiency of the energy migration was slightly increased to 46% by the addition of toluene (toluene–DMF = 9:1, v/v), suggesting that the energy transfer occurs mainly at the hemispherical boundaries and with almost no relation to the mobility of the chromophores.

In conclusion, we have succeeded in the synthesis of dendritic poly(L-lysine) combining separate crowds of free-base and zinc porphyrins, and preliminarily observed fluorescence energy transfer from zinc porphyrins to free-base porphyrins probably due to close contact at the boundaries of the hemispheres. We will further study light harvesting[8] by porphyrin systems arranged in a stratum of the dendrimer. Although they are too primitive to model the antenna chlorophyll membrane proteins revealed recently,[9] it should be possible to mimic the effect of accumulation of porphyrin rings in the compact zone.

Bonded *peri*-interactions govern the rate of racemisation of atropisomeric 8-substituted 1-naphthamides†

Jonathan Clayden,* Catherine McCarthy and Madeleine Helliwell‡

Department of Chemistry, University of Manchester, Oxford Road, Manchester, UK M13 9PL. E-mail: j.p.clayden@man.ac.uk

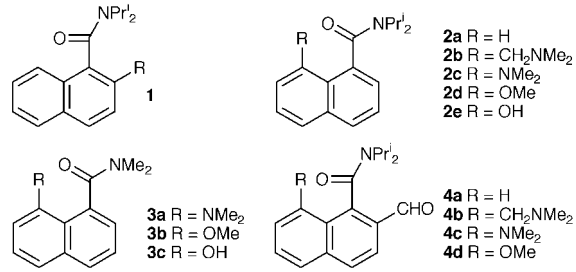
Received (in Liverpool, UK) 3rd August 1999, Accepted 10th September 1999

8-Substituted tertiary 1-naphthamides are chiral, atropisomeric compounds at room temperature, and the rate at which they racemise (by rotation about the Ar–CO bond) depends principally on the extent to which the 8-substituent undergoes incipient nucleophilic addition to the amide carbonyl group, as indicated by X-ray crystallography.

Substituents at the 1- and 8-positions of a *peri*-disubstituted naphthalene lie too close for comfort. Strain is the driving force behind their reactions, and anything that relieves strain is enormously favoured over anything that makes it worse.[1,2] Strain governs the shape of 1,8-disubstituted naphthalenes too: the rings are frequently severely distorted, with the 1- and 8-substituents bending away from one another both in the plane of the ring and perpendicular to it.[3]

Our interest in hindered naphthalenes began with the discovery that 2-substituted tertiary naphthamides **1**, which are axially chiral by virtue of restricted rotation about the Ar–CO axis,[4] undergo highly stereoselective reactions: reagent approach is governed by differentiation of the two faces of the naphthalene ring by the steric and electronic properties of the amide group.[5] Here we show that an 8-substituent can provide a barrier to Ar–CO bond rotation sufficiently large that 8-substituted-1-naphthamides **2** can be configurationally stable chiral compounds even without a bulky 2-substituent. Moreover, we demonstrate that the role of the 8-substituent in hindering rotation is not a steric but an electronic one, depending on the degree of bonded interaction between the 8-substituent and the amide group. [6]

In order to study the rate of racemisation of 8-substituted 1-naphthamides we made four 8-substituted amides **2b**–**e** and, from them, three 2,8-disubstitued amides **4b**–**d**. For crystallographic comparison we also made the *N*,*N*-dimethylamide **3a**.[7] Each of the six compounds **2b**–**d** and **4b**–**d** was resolved by



HPLC on a chiral stationary phase (Whelk-O1 from Regis or Chiralpak-AD from Daicel),[4,8–11] and the separated enantiomers were allowed to racemise in 5–20% EtOH or Pr^{i}OH in hexane at the temperatures shown in Table 1. The change in ee with time was followed by HPLC and in each case showed a simple first order decay—the rate constant for enantiomerisation, *k*, is given in Table 1. $\Delta G^{\ddagger}$ for this process, which represents the barrier to Ar–CO bond rotation, was calculated using the Eyring equation and is also shown in Table 1, along with an estimated half-life for racemisation of each compound at 20 °C, assuming the invariance of $\Delta G^{\ddagger}$ with temperature.[4]

Clearly, 8-substituted 1-naphthamides are atropisomeric: they have a half life at 20 °C greater than 1000 s[12] even in the absence of a 2-substituent, and the most effective 8-substituent, the OMe group, raises the barrier to rotation about the Ar–CO bond by over 30 kJ mol^{-1} (compare entries 1 and 4; 9 and 12)—an OMe group in the 2-position has a similar effect.[4] Despite their greater steric size,[13] the CH_2NMe_2 and NMe_2 substituents have less significant effects in both the 8- and 2,8-disubstituted naphthamides: an 8-CH_2NMe_2 substituent

raises the barrier to rotation about Ar–CO by only about half as much as a comparably sized 2-substituent.[4] There is evidently a non-steric effect at work in the 8-substituted naphthamides,[14] and in order to clarify the nature of that effect we determined the X-ray crystal structures of **2b**–**e** and **3a**. These are shown in Fig. 1.§

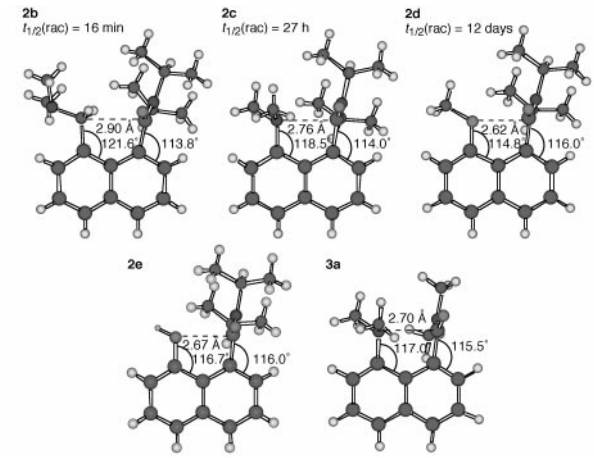

Fig. 1 X-Ray crystal structures. $t_{1/2}$(rac) = half-life for racemisation in solution at 20 °C.

The X-ray structures show that, far from repelling one another, the R and carbonyl groups of **2**, **3** and **4** are drawn together when R = NMe_2 or OMe: only **2b**, with R = CH_2NMe_2, has θ_4 (see Fig. 2) < 120°. Dunitz[3] has shown that pairs of *peri* substituents, one an electrophilic carbonyl group and the other a nucleophilic heteroatom, can exhibit bonding interactions, and we believe this is what we are observing here.

Increasing bonding between R and C=O should lead to several effects, illustrated in Fig. 2. R should bend in towards C=O (θ_4 and δ increase as θ_3 decreases), while the distance *d* between R and the carbonyl carbon atom should decrease as the bond begins to form. The C=O group should adjust its alignment relative to R to let R approach at the 'Burgi–Dunitz angle'[15] of 107° (α should move from 90° towards 107°). The arrangement of atoms around the carbonyl group should move away from trigonal planar towards tetrahedral (δC measures the displacement of the carbonyl carbon atom from the plane of its neighbours), and for the amides the amide nitrogen atom should begin to pyramidalise as it loses conjugation with C=O, the lone pair developing *anti* to the incoming nucleophile (δN measures the displacement of this nitrogen atom from the plane of its neighbours). These values were measured from the crystal structures, and are shown in Table 1. Also included for comparison are the data for the known[3] structures **3b** and **3c**.

The consistent changes in all measured values from entry 2 through entry 3 to entry 4, and from entry 5 to entry 6, makes it clear that the degree of *peri*-bonding increases as R changes from CH_2NMe_2 to NMe_2 to OMe. This is also the order of increasing barrier to Ar–CO bond rotation, and we deduce that this barrier to rotation is controlled not primarily by a repulsive, steric interaction with R but by an attractive bonding interaction. The stereogenic axis of **2** has moved some way towards being a stereogenic centre with a much higher barrier to thermal inversion. The same trend is evident in the barriers to enantiomerisation of **4**.

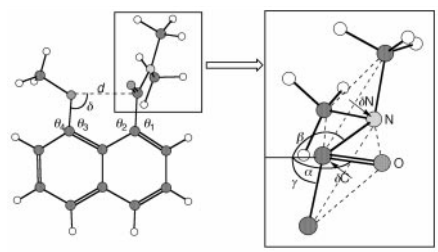

Fig. 2 Geometry of the crystal structures: key measurements. δC and δN are the deviation of each atom from the plane of its neighbours.

The degree of *peri*-bonding also increases to some extent as the amide changes from NPr^i_2 to NMe_2. The last effect is presumably steric in origin, and it is more significant with R = NMe_2 (compare entries 3 and 6) than with R = OMe (compare entries 4 and 7). This may explain why, surprisingly, R = OMe seems to be a acting as a better nucleophile than R = NMe_2: NMe_2 is simply bigger and so cannot get as close to the amide—especially an *N*,*N*-diisopropylamide.

We conclude from these observations that 8-substituted 1-naphthamides can be atropisomeric even in the absence of a 2-substituent, and that the principal factor controlling their rate of racemisation is the electronic nature of the 8-substituent and its ability to form a partial bond to the amide carbonyl group. Given their potential as chiral reagents, ligands or auxiliaries,[16] we expect 8-alkoxy or 8-amino substituents to be an important feature of thermally stable chiral atropisomeric amides.

We are grateful to the EPSRC and Zeneca Pharmaceuticals for an Industrial CASE award (to C. McC.), and to Dr John Cumming and Professor Garry Procter for helpful discussions.

Received (in Liverpool, UK) 20th July 1999, Accepted 6th September 1999

Tricarbonylphthalaldehydechromium complex can be prepared using a 'one pot' procedure starting from tricarbonylbenzenechromium: the protection of one aldehyde function by chiral diamines leads to the formation of two diastereoisomers of the monoaminal of the phthlaldehyde complexes, efficient precursors of enantiopure *ortho*-substituted alkenyl arene complexes.

Tricarbonyl(η^6-arene)chromium complexes have been considered as important intermediates in organic synthesis.[1] Since unsymmetrically 1,2- or 1,3-substituted complexes have planar chirality, recent research in this field has been focused on the development of efficient routes to optically active complexes.[2–6]

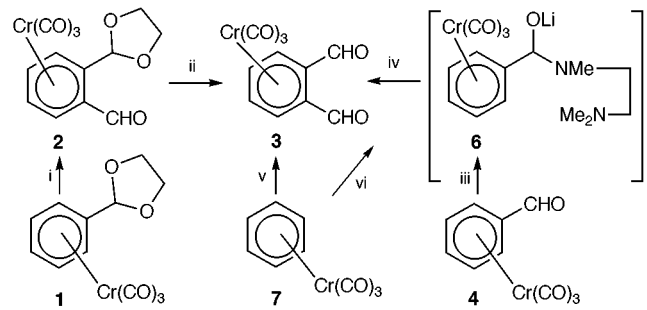
We have shown that chiral diamines having a C_2 axis of symmetry can be considered as an efficient tool for the asymmetric formation of aminals of *o*-substituted tricarbonyl(benzaldehyde)chromium complexes.[3a,7] The ease of handling such aminal complexes prompted us to use them in the preparation of enantiopure monoaminals of tricarbonylphthaldehydechromium complexes, which could be used as precursors of homochiral *o*-substituted styrene complexes for example.[4,8,9]

We now present results which demonstrate that chiral diamines may be used for the preparation of homochiral *o*-substituted styrene complexes from tricarbonylphthaldehydechromium complex **3**. This new synthon has several attractive features, among which the most interesting is the possibility of differentiating the two aldehyde functionalties, thus breaking the plane of symmetry and introducing asymmetry. Compound **3** is easily and efficiently synthesised in a 'one-pot' procedure, by a new methodology, starting from a simple complex: tricarbonylbenzenechromium **7**.

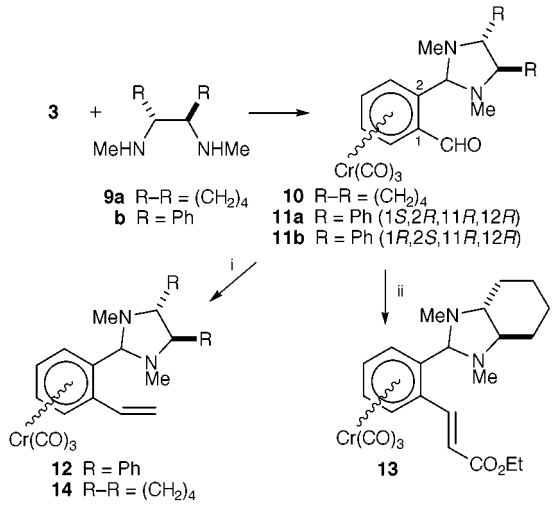
Our first attempts to prepare synthon **3** were as follows: benzaldehyde ethane-1,2-diyl acetal **1** treated with BuLi (4 equiv.) at −78 °C and then with DMF was converted into the monoacetal of phthlaldehyde **2** in 49% yield. Hydrolysis of the acetal did not occur in good yield, as decomplexation of the tricarbonylchromium function became the dominant mode of reaction.[10b] Indeed complex **3** was obtained only in 22 and 19% using either H_2SO_4[3b,c,10] or HCO_2H[11] (Scheme 1). It was also possible to obtain complex **3** by treating tricarbonylbenzaldehydechromium complex **4** with the diamine $MeNHCH_2CH_2NMe_2$ **5** and BuLi.[12] Indeed the amino alcoholate intermediate **6** can be *ortho*-lithiated in order to react with DMF, giving complex **3** in 35% yield only (Scheme 1). Thus, we examined the possibility of obtaining complex **3** directly from tricarbonylbenzenechromium complex **7**, in a one-pot procedure, using the amide $Me_2NCH_2CH_2NMeCHO$ **8**. Complex **7** at −78 °C was treated with BuLi (1.2 equiv.). The formamide **8** (1 equiv.) was added and stirred for 30 min at −30 °C. BuLi (3 equiv.) and DMF (3 equiv.) were then added sequentially. Hydrolysis of the reaction mixture with 0.1 M HCl gave a red solution, which was chromatographed on a silica gel column. Benzaldehyde complex **4** was the first product eluted with a 3:2 mixture of Et_2O–light petroleum (15% after recrystallisation). The second product, the phthaldaldehydechromium complex **3**, eluted with a 7:3 mixture of Et_2O–light petroleum and was obtained in 41% yield after recrystallisation as red crystals (Scheme 1).

Among the various ways to desymmetrise **3**, we focussed on the selective formation of the chiral monoaminal. Condensation of (*R*,*R*)-1,2-bis(*N*-methylamino)cyclohexanediamine **9a**[2] with complex **3** gave two diastereoisomers **10**† in 76% yield which were easily separated by silica gel chromatography (44 and 32% yield) (Scheme 2). After separation, the diastereomeric composition of each stereoisomer was checked by ^{1}H NMR[3a] which showed one singlet for the aminalic proton H7 at δ 4.81 and 4.23. Alternatively, condensation of (*R*,*R*)-1,2-bis(*N*-methylamino)-1,2-diphenylethane[7,8] **9b** with phthalaldehyde **3** at room temperature for 30 min gave two diastereoisomers **11**, inseparable by silica gel chromatography, in the ratio 56:44 in 78% yield. Fortunately, their separation could be achieved by precipitation of one diastereomer **11a** (whose aminalic proton resonated at low field: δ 5.53), which gave suitable crystals for an X-ray analysis, and thus allowed assignment of the aminalic proton chemical shift of this diastereomer by ^{1}H NMR. The ORTEP view, shown in Fig.1, indicated a (1*S*,2*R*) configuration.‡ It is worth noting that the conformation of the $Cr(CO)_3$ tripod is almost staggered with respect to the carbons of the arene ring and that unexpectedly the aldehyde function is not in the plane of the arene ring. Indeed we observed a 12° angle between the carbon–oxygen double bond and the plane of the ring in the direction opposite to the organometallic moiety.

Once synthon **3** was desymmetrised, the free aldehyde functionality of monoaminals **10** and **11** may be reacted with various reagents. As an illustration of this concept, we describe



Scheme 1 *Reagents and conditions:* i, BuLi, DMF, THF, 49%; ii, H_2SO_4, 22% or HCO_2H, 19%; iii, BuLi, $NMe_2CH_2CH_2NHMe$ **5**, THF; iv, BuLi, DMF, THF, 35% from **4**; v, BuLi, $Me_2NCH_2CH_2NMeCHO$ **8**, THF, then BuLi, DMF, then 0.1 M HCl, 41% (and **4**, 15%); vi, BuLi, $Me_2NCH_2CH_2N$-MeCHO **8**, THF.



Scheme 2 *Reagents and conditions:* i, separation of the diastereoisomers, then $MePPh_3Br$, $NaNH_2$, Et_2O, 16% for **12a**, 28% for **12b**; ii, separation of the diastereoisomers, then $[P(O)(OEt)_2]NaCHCO_2Et$, room temp., 87% for **13a**, 85% for **13b**.

here the olefination of the free aldehyde, to obtain optically pure *o*-substituted styrene complexes. Treating the diastereoisomers **10a** or **10b** with $MePPh_3Br$ and $NaNH_2$ in dry Et_2O gave the styrene derivatives **12a** in 16% yield or **12b** in 28% yield. Complexes **11a** and **11b** also reacted with $MePPh_3Br$ and $NaNH_2$ to afford the optically pure styrene derivatives **14a** and **14b** (in 23 and 18% yield) which can be separated by column chromatography. More interestingly, reaction of complex **10a** with the carbanion of the phosphonate $[P(O)(OEt)_2]NaCHCO_2Et$ occured smoothly giving complex **13a**† as orange crystals in 87% yield. The same reaction with diastereoisomer **10b** gave complex **13b**† in 85% yield.

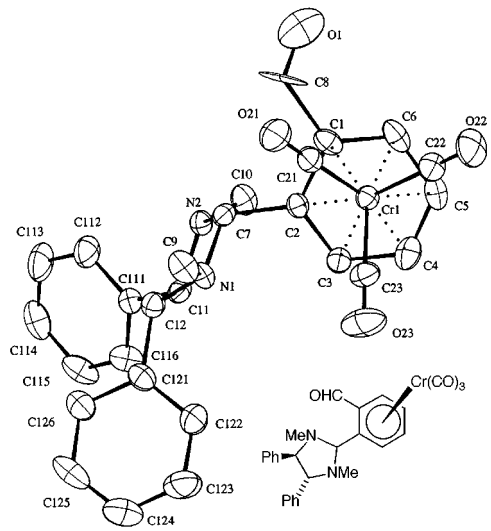


Fig. 1 ORTEP view of the molecular structure of complex **11a**. Selected interatomic distances (Å): Cr(1)–C(1) 2.180(7); Cr(1)–C(2)2.220(6); Cr(1)–C(3) 2.196(6); Cr(1)–C(4) 2.199(7); Cr(1)–C(5) 2.199(7); Cr(1)–C(6) 2.191(7).

In conclusion, these preliminary results open up, *via* a 'one-pot' procedure from benzenechromium complex, a ready access to phthalaldehydechromium complex. It is worth noting that this represents a *facile bifunctionnalisation of benzene* which can lead to chiral *ortho*-disubstituted arenechromium complexes. It can be used for the synthesis of enantiomerically pure styrenechromium complexes substituted at the *ortho* position by potentially versatile aminal groups. The scope of the applications of these new homochiral complexes is currently being investigated in our laboratory.

Notes and references

† *Typical procedure* for **10**: A mixture of complex **3** (0.1 g, 0.37 mmol), diamine **9a** (63 mg, 0.45 mmol) and molecular sieves in dry Et_2O (25 ml) was stirred for 25 min at room temperature under N_2. The solution turned orange. After silica gel chromatography, the first diastereoisomer was eluted with Et_2O–NEt_3–cyclohexane (70 : 0.01 : 30) and obtained in 44% yield (64 mg). The second diastereoisomer was eluted with Et_2O–0.01% NEt_3 and obtained in 32% yield (46 mg). *Selected data* for **10b**: δ_H(400 MHz, $CDCl_3$) 1.13–1.37 (m, 4H), 1.84–2.1 (m, 4H), 2.37 (s, 3H), 2.49 (s, 3H), 2.58 (m, 2H), 4.23 (s, 1H, H7), 5.49 (m, 2H, H4, H5), 5.58 (m, 1H, H6), 5.62 (m, 1H, H3), 10.3 (s, 1H); $[\alpha]_D^{20}$ −98 ($CHCl_3$, *c* 0.08). For **13b**: δ_H 1.23–1.19 (m, 4H), 131 (t, *J* 7, 3H), 1.78–1.82 (m, 4H), 2.27 (s, 3H), 2.28 (m, 2H), 2.56 (s, 3H), 4.30 (q, *J* 7, 2H), 5.21 (d, *J* 6, 1H, H6), 4.39 (s, 1H, H7), 5.30 (d, *J* 6, 1H, H6), 5.36 (m, 1H, H5), 5.47 (m, 1H, H4), 6.03 (d, *J* 6, 1H, H3), 6.22 (d, *J* 15, 1H), 7.87 (d, *J* 15, 1H); $[\alpha]_D^{20}$ +340 ($CHCl_3$, *c* 0.01). All novel complexes (**10**–**14**) were characterised by microanalyses, NMR and IR spectra and low resolution MS.

‡ *Crystal data* for **11a**: $C_{27}H_{24}N_2O_4Cr$, M = 492.5, orthorhombic, space group $P2_12_12_1$, a = 7.333(2), b = 14.455(3), c = 22.976(4) Å, D_C = 1.34 g cm^{-3} , Z = 4, 0.20 × 0.20 × 0.64 mm, μ = 4.91 cm^{-1}, 1466 data collected at room temperature on a Nonius CAD4 diffractometer. Absorption correction using DIFABS was applied (T_{min} = 0.92, T_{max} = 1). Anomalous dispersion terms and correction of secondary extinction were applied. The structure was solved by standard Patterson–Fourier techniques and refined by least-squares analysis using anisotropic thermal parameters for all non-hydrogen atoms. H atoms were located on a difference Fourier map and introduced in the refinement as fixed contributors with an overall isotropic thermal parameter. 1771 reflections, with $I > 3\sigma(I)$, were used to solve and refine the structure to R = 0.042 and R_w = 0.048 (unit weights), 309 least-squares parameters. The programs used were CRYSTALS and CAMERON. The shape of the anisotropic displacement ellipsoid for C8 suggests some disorder. Unfortunately, attempts to deal with this disorder failed. Acid/base-catalyzed ester hydrolysis in near-critical water

Heather P. Lesutis, Roger Gläser, Charles L. Liotta and Charles A. Eckert*

Schools of Chemical Engineering and Chemistry and Biochemistry and Specialty Separations Center, Georgia Institute of Technology, Atlanta, GA 30332-0100, USA. E-mail: cae@che.gatech.edu

Received (in Corvallis, OR, USA) 2nd August 1999, Accepted 1st September 1999

Hydrolyses of substituted benzoic acid esters in near-critical water (250–300 ºC) show autocatalytic kinetic behavior and surprisingly give the same rate constant regardless of substituent, suggesting that an acid-catalyzed mechanism predominates under our reaction conditions.

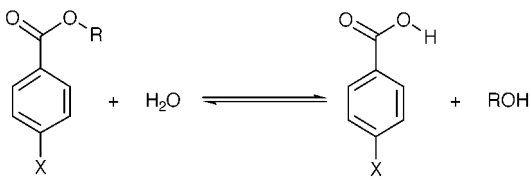
Liquid water in the near-critical region (250–300 °C) is a unique, environmentally benign solvent which affords opportunities for pollution minimization in a wide variety of commercially important chemical processes.[1–3] As the temperature is raised, the hydrogen bonding in water diminishes.[4,5] Both the relative permittivity and the density decrease,[6] giving near-critical water properties similar to those of typical polar organic solvents. While near-critical water can still solubilize salts, it can also dissolve organic compounds.[7]

In addition, the ionization constant of water increases by three orders of magnitude in going from ambient to near-critical conditions,[8] making it a strong source of both hydronium and hydroxide ions. These ions can act as catalysts in acid- or base-catalyzed conversions, respectively.[1,9] Because the protons and hydroxide ions derived from the auto-ionization of hot water do not require neutralization, formation of unwanted salt by-products can be reduced or eliminated in many processes. Further, the ease of separation of products from water by cooling to ambient conditions makes it an economically viable replacement for less environmentally benign solvents.

Because near-critical water is such a promising solvent for a wide variety of processes, we sought a more thorough understanding of chemical reactions and mechanisms in this medium. We chose to study the hydrolysis of several simple benzoic acid esters as a model system (Scheme 1) to elucidate mechanistic pathways followed in near-critical water. It has previously been shown that the main products formed from the hydrolyses of di-*n*-butyl phthalate[10] and ethyl acetate[11] in near-critical water are the corresponding acids and alcohols. The formation of thermolysis products, such as alkenes and carbon oxides, is considerably slower in near-critical water than when performed neat.

Several 3.0 ml titanium reactors were loaded with benzoate ester and an excess of water (Aldrich, HPLC grade), where the excess of water makes the back reaction negligible. Reactors were placed in a heating block at 250 °C, and pairs of reactors were removed and quenched at various reaction times. Reactor contents were diluted in acetone and analyzed using GC-FID and GC-MS.

Data measuring conversion *vs.* time yielded S-shaped curves (Fig. 1), suggesting an autocatalytic mechanism. Because benzoic acid is one of the products, autocatalysis suggests the



Scheme 1

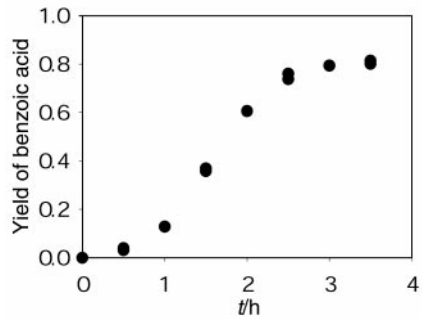


Fig. 1 Fractional conversion of *n*-propyl benzoate *vs.* time.

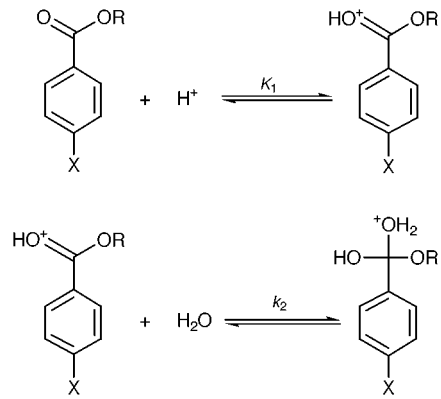
reaction is acid-catalyzed. The $A_{AC}2$ mechanism for acid-catalyzed hydrolysis of esters yields a rate equation of the form shown in eqn. (1),

$$\frac{dx}{dt} = k[\text{ester}][H_2O][H^+] \quad (1)$$

where $k = k_2 K_1$;[12] k_2 is the rate constant for the addition of water to the protonated ester, and K_1 is the equilibrium constant for the protonation of the ester (Scheme 2). The second step is rate-determining, and its product equilibrates rapidly to benzoic acid and the alcohol. The concentration of protons is determined from the dissociation constant of water and that of benzoic acid at 250 °C. The dissociation constant of benzoic acid under our conditions is 3.7×10^{-6} M,[13,14] and the Hammett reaction constant ρ for this dissociation increases by only 2% from 25 to 250 °C.[15] We calculated values for the dissociation constants of *p*-chlorobenzoic acid and *p*-trifluoromethylbenzoic acid at 250 °C and integrated numerically to ascertain k for each reaction. Table 1 reports these rate constants as products of k_2 and K_1*, where K_1* is the equilibrium constant for protonation of the nonsubstituted ester. For the acidity of the substituted benzoic acids, we assumed that the effect of substituents on the equilibrium constant for acid dissociation is the same as that for protonation of the ester.

Rates of hydrolysis of isobutyl benzoate were also measured at 260 and 300 °C. Utilizing dissociation constants of benzoic acid at these temperatures,[13,15] the activation energy was



Scheme 2

Table 1 Rate constants at 250 °C for the hydrolysis of benzoate esters, where K_1* is the equilibrium constant for the protonation of nonsubstituted ester

R	X	k_2K_1*/l² mol^{-2} h^{-1}
Me	H	26.9 ± 2.5
Et	H	25.7 ± 0.9
Pr	H	10.4 ± 0.5
Bu	H	17.1 ± 0.6
Bu^i	H	6.7 ± 0.3
Bu^i	Cl	7.4 ± 0.6
Bu^i	CF_3	7.0 ± 0.5

calculated to be 101 ± 13 kJ mol^{-1}, indicating that mass transfer limitations were negligible. Similar activation energies were obtained for the acid-catalyzed hydrolysis of substituted benzoic acid esters in low temperature aqueous solvents with a stoichiometric addition of acid.[16]

As expected, longer alkyl chains on the esters yield slower hydrolyses, and the branched butyl benzoate hydrolyzes more slowly than the linear butyl benzoate. As the carbonyl carbon becomes more sterically hindered, nucleophilic attack by water becomes more difficult, resulting in a slower hydrolysis.

Hydrolyses of substituted isobutyl benzoates provide further evidence that an acid-catalyzed mechanism predominates under near-critical conditions. It is clear from Table 1 that substituents have very little effect on rates of hydrolysis of benzoic acid esters under these conditions. Because of competing effects in the first two steps of the $A_{AC}2$ mechanism (Scheme 2), substituents exhibit a negligible effect on the rate constants. This negligible substituent effect is a well-documented characteristic of ester hydrolysis *via* an acid-catalyzed mechanism in aqueous solvents at lower temperature.[17] Hammett plots of acid-catalyzed ester hydrolyses have ρ = 0, compared to ρ = 2.4 for base-catalyzed hydrolyses of esters.[17] In addition to the reactions reported in Table 1, the hydrolysis of isobutyl *p*-hydroxybenzoate was also attempted, but the hydroxy group is strongly electron donating (σ = −0.38), and the ester decarboxylated.

In summary, benzoate esters can be cleaved to benzoic acid and the corresponding alcohol in near-critical water without the addition of any acid or base catalyst. Preliminary investigations indicate that the pathway for acid-catalyzed hydrolysis according to an $A_{AC}2$ mechanism is dominant. First, the S-shaped conversion *vs*. time curve is consistent with autocatalysis. The acidity of near-critical water seems sufficient to initiate hydrolysis of the benzoate and formation of the autocatalytic species benzoic acid. Also, the addition of electron-withdrawing substituents does not affect reaction rate, as predicted by the proposed acid-catalyzed mechanism and demonstrated for many acid-catalyzed hydrolyses in the literature. Thus, despite the fact that near-critical water is quite different from water under ambient conditions, hydrolyses in it follow the mechanistic pathway commonly observed at lower temperatures.

We would like to thank Kris Griffith for synthesizing the substituted benzoic acid esters and Greg Ladzinske for help collecting data.

Glycosidase-catalysed synthesis of α-galactosyl epitopes important in xenotransplantation and toxin binding using the α-galactosidase from *Penicillium multicolor*

Suddham Singh, Michaela Scigelova and David H. G. Crout*

Department of Chemistry, University of Warwick, Coventry, UK CV4 7AL. E-mail: msrky@csv.warwick.ac.uk

Received (in Cambridge, UK) 26th July 1999, Accepted 2nd September 1999

The α-galactosidase from *Penicillium multicolor* catalyses highly regioselective galactosyl transfer on to mono- and disaccharide acceptors that have a non-reducing terminal galactose unit to give products containing the α-D-Gal*p*-(1→3)-D-Gal*p* epitope found on pig tissue and which is responsible for the hyperacute rejection response in xenotransplantation of pig organs into man.

The α-D-Gal*p*-(1→3)-β-α-Gal*p* moiety of glycoconjugates has been found to be of considerable biological importance. It has attracted attention mainly because of its significance in the development of the xenotransplantation of animal organs into human patients,[1] a development driven on the one hand by the success of organ transplantation in the latter part of the twentieth century and on the other by an acute shortage of donor organs. Current research is directed towards the use of pig organs in humans (discordant xenotransplantation), as the pig is considered the best organ donor given the constraints imposed by the popular opposition to the use of organs from primates. The major problem with pig-to-man xenotransplantation is the extremely rapid human antibody-mediated hyperacute rejection that occurs following transplantation into human patients. The antigenic epitopes responsible for this hyperacute rejection response contain the α-D-Gal*p*-(1→3)-β-D-Gal*p* terminus and have been identified as α-D-Gal*p*-(1→3)-β-D-Gal*p*-R, α-D-Gal*p*-(1→3)-β-D-Gal*p*-(1→4)-β-D-Glc*p*-R, α-D-Gal*p*-(1→3)-β-D-Gal*p*-(1→4)-β-D-GlcNAc*p*-R and α-D-Gal*p*-(1→3)-β-D-Gal*p*-(1→4)-β-D-GlcNAc*p*-(1→3)-β-D-Gal*p*-(1→4)-β-D-Glc*p*-R, known collectively as 'α-Gal' epitopes.[2] These epitopes specifically bind to human anti-α-Gal antibodies during xenotransplantation.[3] They are found on tissues of almost all mammals except man and old world primates. Antibodies against the α-Gal epitope expressed in man comprise approximately 1% of circulating immunoglobulin G.[4] Recent investigations have shown that human anti-Gal antibodies can bind to, and be neutralised by, α-Gal-related oligosaccharides.[5] An α-D-Gal*p*-(1→3)-β-D-Gal*p*-(1→4)-β-D-GlcNAc*p* trisaccharide, representing the natural α-Gal epitope, is capable of neutralising anti-Gal antibodies at low concentrations.[6] A further reason for interest in the α-Gal epitope is that it has been identified as a receptor for the toxin from *Clostridium difficile*, a micro-organism that is a major cause of antibiotic-associated diarrhoea and the causative agent of a serious condition, pseudomembranous colitis, in the elderly following antibiotic therapy.[7]

The possibility of utilising the adhesion of bacteria and viruses to specific carbohydrates has become an attractive goal in attempts to find alternatives to antibiotic therapy. Developments in this area have taken place against a background of increasing concern about the development of antibiotic resistance in important species of pathogenic bacteria.[8] An immobilised version of the *C. difficile* toxin receptor is in development for the treatment of *C. difficile*-associated diarrhoea.[9]

The use of α-Gal oligosaccharides for clinical applications would require large amounts of α-Gal oligosaccharides. Conventional synthesis of carbohydrates, although well developed over the last decade, requires multiple protection and deprotection steps.[10] Consequently, enzymatic synthesis is an attractive alternative for the synthesis of oligosaccharides.[11] Enzymatic syntheses of α-Gal oligosaccharides have been reported.[12] However, the α-galactosyl transferase method requires the use of a complex donor and is limited by the availability of the appropriate enzymes.[12*a*] The use of glycosidases has been reported but these have been limited by rather low yields and by the production of mixtures.[12*b–d*]

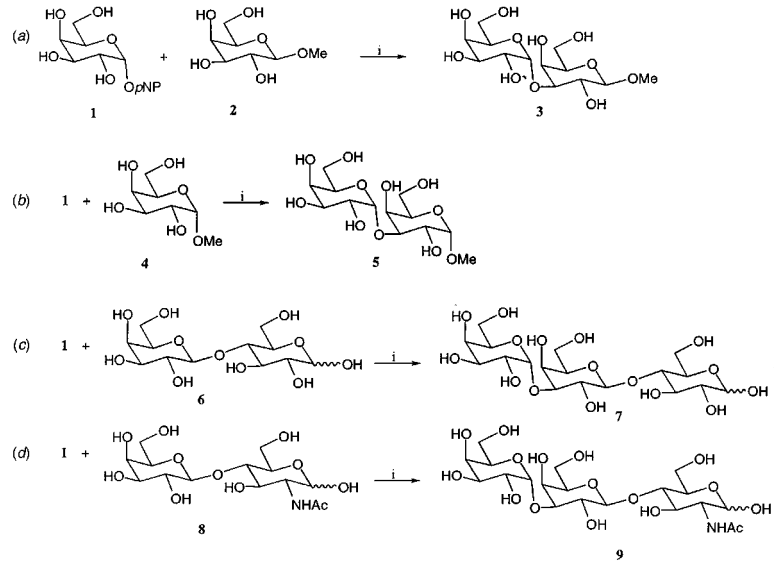
Here we report simple, regiospecific, glycosidase-catalysed syntheses of α-D-Gal*p*-(1→3)-β-D-Gal*p*-OMe and α-D-Gal*p*-(1→3)-α-D-Gal*p*-OMe disaccharides and α-D-Gal*p*-(1→3)-β-D-Gal*p*-(1→4)-D-Glc*p* and α-D-Gal*p*-(1→3)-β-D-Gal*p*-(1→4)-D-GlcNA*cp* trisaccharides catalysed by an α-galactosidase from *Penicillium multicolor* discovered during a major screening programme for synthetically useful glycosidases.[13] The great advantage of this enzyme is that it is highly specific for α-(1→3) transfer and thus represents a considerable improvement over existing methods for the synthesis of α-Gal oligosaccharides.

Transfer of an α-galactosyl unit from *p*-nitrophenyl α-D-galactopyranoside **1** on to methyl β-D-galactopyranoside **2** using an α-galactosidase from *Penicillium multicolor* gave only one disaccharide α-D-Gal*p*-(1→3)-β-D-Gal*p*-OMe **3** in 43% yield [Scheme 1(*a*)]. Similarly, transfer of an α-galactosyl unit from donor **1** on to methyl α-D-galactopyranoside **4** gave the disaccharide α-D-Gal*p*-(1→3)-α-D-Gal*p*-OMe **5** in 46% yield [Scheme 1(*b*)]. These results suggest that by changing the conformation at the anomeric position in the acceptors **2** and **4** the regioselectivity of the transfer was not affected. This indicates that 'anomeric control', in which regioselectivity is influenced by the anomeric configuration in the glycosyl acceptor, does not operate in this system.[14] In both cases the product obtained was a (1→3)-linked disaccharide.

Transfer of the α-galactosyl unit from donor **1** on to lactose **6** gave again the (1→3)-linked product α-D-Gal*p*-(1→3)-β-D-Gal*p*-(1→4)-D-Glc*p* **7** in 25% yield [Scheme 1(*c*)]. Similarly transfer of α-galactosyl unit from the donor **1** on to lactosamine **8** gave the trisaccharide α-D-Gal*p*-(1→3)-β-D-Gal*p*-(1→4)-D-GlcNA*cp* **9** in 32% yield [Scheme 1(*d*)].

In all these reactions the conversion (donor) was 40–50%. This was not taken into account in calculating yields. The incomplete consumption of donor indicated product inhibition. If this could be overcome, even higher yields should be obtainable. We found that the released *p*-nitrophenol inhibited the enzyme and showed that this inhibition could be largely overcome by operating in less concentrated solutions. Thus by decreasing the overall concentration of donor **1** (from 0.34 to 0.17 M) and the acceptor **8** (from 1.3 to 0.65 M), 90% conversion was achieved and the isolated yield of the trisaccharide **9** increased from 32% to 48%.

The α-galactosidase used in these experiments was isolated from Lactase P from *Penicillium multicolor* (KI Chemicals, Japan). The proteins from a crude extract were precipitated by EtOH (50% v/v) and separated by DEAE-Sepharose [equilibrated with potassium phosphate buffer (10 mM, pH 6.5) and eluted with a linear gradient of NaCl (0–0.8 M)] followed by



Scheme 1 *Conditions*: i, α-Galactosidase from *Penicillium multicolor; p*NP = *p*-nitrophenyl.

chromatography on ceramic hydroxyapatite [equilibrated with potassium phosphate buffer (5 mM, pH 6.5) and eluted with a linear gradient (5–400 mM) of potassium phosphate buffer (pH 6.5)]. Active fractions were concentrated using a Centriprep (Amicon) membrane with a 30 kDa cut-off to give a preparation [6.4 U cm^{-3}, 150 U (mg protein)$^{-1}$] free of β-galactosidase activity.

The method described here provides a remarkably simple one-step enzymatic synthesis of α-galactosyl epitopes and can be scaled up for clinical applications. Given the potential demand for α-Gal di- and tri-saccharides, the method described here offers an inexpensive and economical route to these compounds.

In a typical experiment *p*-nitrophenyl α-D-galactopyranoside **1** (0.1 g, 0.332 mmol) and *N*-acetyllactosamine **8** (0.5 g, 1.305 mmol) in citrate–phosphate buffer (0.05 M, 2 ml, pH 4.0) were incubated with the α-galactosidase from *Penicillium multicolor* (0.15 cm^3, 0.96 U) at 30 °C for 6 h. The reaction was stopped by heating in a boiling water bath for 5 min. Examination of the crude product by HPLC indicated that a single trisaccharide was formed. The product mixture was purified by carbon–Celite chromatography[15] to give trisaccharide **9** in 48% yield. The product was confirmed to be a single isomer by ^{1}H and ^{13}C NMR.

We thank the Biotechnology and Biological Sciences Research Council (UK) for financial support and Dr K. Ajisaka for providing the Lactase P.

Fine-tuning of pore size of MCM-41 by adjusting the initial pH of the synthesis mixture

Anjie Wang*[a] and Toshiaki Kabe[b]

[a] *Laboratory of Comprehensive Utilization of Carbonaceous Resources, Dalian University of Technology, 158 Zhongshan Road, Dalian 116012, P.R. China. E-mail: hykyb@mail.dlptt.ln.cn*

Received (in Cambridge, UK) 3rd August 1999, Accepted 8th September 1999

The pore size of MCM-41 can be finely tuned from 38.3 to 52.7 Å with a narrow distribution by carefully adjusting the initial pH of the synthesis mixture from 11.5 to 10.0.

MCM-41, with well-defined mesopores and extremely high surface area, has been the focus of much research interest since its discovery by the researchers at the Mobil Research and Development Corporation in 1992.[1] The precise tuning of its pore size is among the many favorable properties of MCM-41. Recently, many synthesis techniques, aiming at enlarging the pore size with narrow distribution, have been developed.[2] Some approaches use surfactants with different chain lengths or binary templating agents to expand the pore size.[1–3] Other routes use high temperatures in synthesis or postsynthesis treatment.[4–6]

It is well known that MCM-41 is typically characterized by an X-ray reflection in the vicinity of $2\theta = 2°$. However, the mesoporous materials synthesized by different researchers were not exactly the same under similar synthesis conditions (temperature, mixture composition, *etc.*),[1,7] unlike the case of microporous zeolite synthesis in which the characteristic X-ray reflections are well known. In our recent study, it was shown that the difference in the d_{100} spacing stems from the initial pH of the synthesis mixture, and we found that the pore sizes of the synthesized materials can be adjusted in a relatively wide range (> 14 Å) with a narrow pore distribution by varying the initial pH of the synthesis mixture.

The general procedure for synthesizing MCM-41 is as follows: 5.2 g of sodium silicate hydrate from Kigida Chemical Co. Ltd. (Japan) was dissolved in 25 ml of deionized water. The pH of the solution was adjusted to the desired value by adding 4 M H_2SO_4 to obtain a silica gel. A precision pH paper (Macherey-Nagel, Germay) was used to determine the pH of the gel. After vigorously stirring for 30 min at ambient temperature, an aqueous solution of CTAB (cetyltrimethylammonium bromide) was added into the gel to produce the synthesis mixture (typical composition: SiO_2•0.5Na_2O• 0.24CTAB•60H_2O). The mixture was allowed to stir at ambient temperature for 1 h, then placed in a static stainless steel autoclave kept at different temperatures for various time periods. After cooling to ambient temperature, the resulting solid material was recovered by filtration, washed with water and dried at 353 K for 4 h. The as-synthesized materials were calcined at 823 K for 6 h.

The X-ray diffraction patterns were recorded on a Rigaku RAD-2X diffractometer using nickel-filtered Cu-Kα radiation at 35 kV and 20 mA. Nitrogen adsorption measurements were performed using a Coulter SA 3100 adsorption analyzer which reports adsorption isotherm and BET specific surface area and pore volume automatically. Before the adsorption analysis the samples were outgased for 4 h at 573 K. The primary mesopore size w_d is determined by using eqn. (1), the distance between pore centers a_0 is calculated using eqn. (2), and the pore wall thickness b_d is given by eqn. (3).[8]

$$w_d = 1.213 d_{100} \sqrt{\frac{2.2V_p}{1 + 2.2V_p}} \quad (1)$$

$$a_0 = 2d_{100}/\sqrt{3} \quad (2)$$

$$b_d = a_0 - w_d \quad (3)$$

The X-ray diffraction patterns of samples synthesized at different pH are shown in Fig. 1. It can be seen that all the samples prepared at pH 10.0–12.0 show strong reflections at *ca.* $2\theta = 2°$, indicating that the mesostructures are well developed. Moreover, the interplanar spacing d_{100} changes between 38.4 and 53.8 Å when the initial pH of the synthesis mixture varies from 11.5 to 10.0. The material prepared at pH 12.0 seems to be a lamellar mesophase, showing no distinct X-ray diffraction peaks after calcination. And no X-ray reflections were determined for the samples prepared at pH < 10.0 and pH > 12.0.

The synthesis conditions and characteristic parameters of the obtained mesoporous materials are summarized in Table 1. It is indicated that the mesostructures prepared at pH 10.0–11.5 are well developed with high surface area and large pore volume. When the initial pH of the synthesis mixture changes from 11.5 to 10.0, the pore size of the product varies from 38.3 to 52.7 Å and the pore wall thickness increases from 6.0 to 9.4 Å. The mesophase obtained at pH 12.0 has relatively low surface area and small pore volume, indicating that the structure may collapse after calcination.

The effects of CTAB/silica ratio and synthesis temperature on the pore size were also investigated. As shown in Table 2, the

[a] The as-synthesized sample, which showed no X-ray diffraction reflection after calcination at 823 K for 6 h.

Table 2 Preparation of MCM-41 at different CTAB/SiO_2 molar ratios and temperatures

T/ K	t/h	pH	CTAB/SiO_2 ratio	d_{100} spacing/Å
403	12	11.0	0.24	44.1
403	12	11.0	0.18	43.7
403	12	11.0	0.12	43.3
373	72	11.0	0.24	42.0

mesostructure characterized by the d_{100} spacing undergoes little change when varying the CTAB/silica ratio from 0.12 to 0.24 at pH 11.0. The synthesis temperature greatly affects the polymerization rate of the silica wall, but has little influence on the pore size of MCM-41, when elevated from 373 to 403 K.

Since the variation of pH only changes the OH^- concentration in the mixture, we propose that the pH of the synthesis mixture may affect the mesopore size by altering the charge matching pattern in the mixture. According to the model proposed by Huo and co-workers,[9] there are two basic pathways, one *via* direct self-assembly of a cationic inorganic species (I^+) and an anionic surfactant (S^-), and the other mediated by counterions of opposite charge. Our results seem to suggest that the synthesis of MCM-41 by our approach may take the mediated pathway, with OH^- working as the counterion. Because the mesopores are hexagon-shaped due to the Si–O bond conformation, while the micelles of the surfactant are theoretically spherical to minimize surface tension, the pores and the micelles do not match geometrically. We propose that the I^- anions and S^+ cations may be mediated by a layer of aqueous solution of inorganic ions (*i.e.* OH^-) which balance the charges. At lower pH, the thickness of the counterion layer may increase to keep the total OH^- constant in order to balance the charge, resulting in the enlargement of the pore size of the product. pH variation may also change the electrostatic charge distribution in the mixture, affecting the interactions of head groups in the micelle and resulting in the expansion of the micelle.[10]

The results reported here provide a convenient way of finely tuning the pore size of mesoporous MCM-41, which is promising in pore engineering and 'molecular sieving' with adjustable pore size, and may find wide application in shape-selective catalysis in fine chemicals, bio-separation and adsorption.

The authors thank Associate Professor A. Ishihara, Dr W. Qian, Mr J. Lee and Mr H. Shirai for their kind help, and thank the Chinese and Japanese governments for financial support in carrying out the Cultural Exchange Program.

A large enhancement in the binding affinity of artificial hosts by Os^{VI} chelation

Kyu-Sung Jeong,* Jung Wha Lee, Tae-Yoon Park and Sung-Youn Chang

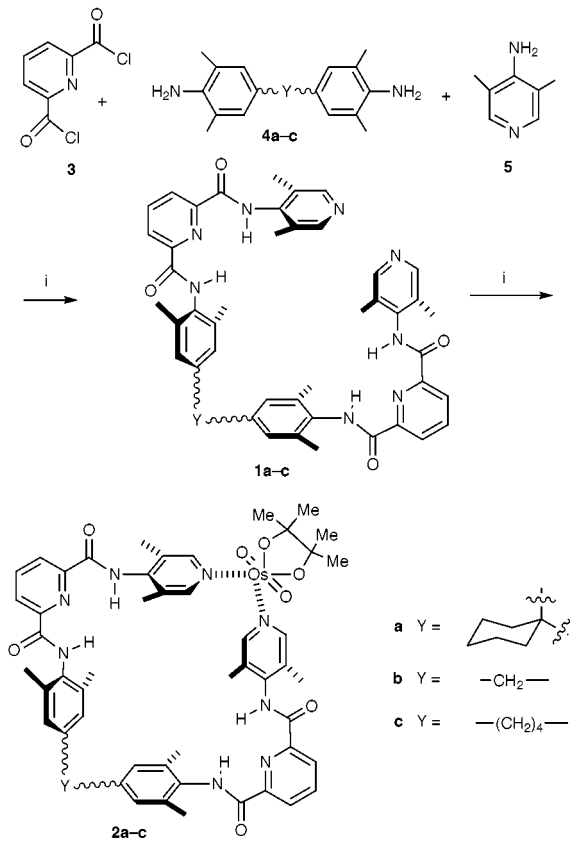
Department of Chemistry, Yonsei University, Seoul 120-749, Korea. E-mail: ksjeong@alchemy.yonsei.ac.kr

Received (in Cambridge, UK) 2nd August 1999, Accepted 8th Septmber 1999

Mononuclear Os^{VI}-chelated macrocycles, self-assembled from OsO_4, 2,3-dimethylbut-2-ene and bispyridyl ligands, bind diamides much more strongly than the Os^{VI}-free ligands ($\Delta\Delta G$ = −14.6 kJ mol^{-1}).

Self-assembly by weak noncovalent interactions has recently attracted a great deal of attention in the area of host–guest and supramolecular chemistry. The strategy has been effectively used to synthesise artificial receptors in which two or more subunits are spontaneously coordinated to a metal ion to generate a binding cavity complementary to the targeted substrates.[1] On the other hand, metal ion chelation to one part of a flexible host may result in the structural reorganisation of another binding site, leading to allosteric behaviour in the binding events.[2–5] Here, we have prepared three bispyridyl ligands **1a**–**c** that spontaneously self-assemble into the corresponding macrocyclic complexes **2a**–**c** in the presence of alkene and OsO_4,[6,7] and compared the binding affinities of **1a**–**c** and **2a**–**c** toward diamide guests.

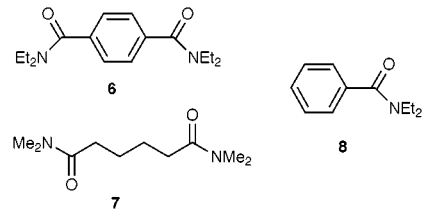
As shown in Scheme 1, the bispyridyl ligands **1a**–**c** were prepared by dropwise addition of diamines **4a**–**c** followed by aminolutidine **5** to a solution of pyridine-2,6-dicarbonyl dichloride **5** in CH_2Cl_2. The yields were 10–18% after repeated chromatography. The neutral macrocyclic complexes **2a**–**c** were spontaneously assembled within a few minutes by addition of OsO_4 (~1 equiv., 0.1 M in toluene) to a 1:1 molar mixture of the ligands **1a**–**c** and 2,3-dimethylbut-2-ene in a $CHCl_3$ at room temperature. After concentration, the residues were thoroughly washed with Et_2O to afford the Os^{VI}-complexes **2a**–**c** as brown solids (66–88% yield).



Scheme 1 *Reagents and conditions*: i, $EtNPr^i_2$, 0 °C to room temp.; ii, 2,3-dimethylbut-2-ene, OsO_4.

Elemental analysis of the products agreed well with 1:1:1 molar composition of OsO_4, 2,3-dimethylbut-2-ene and the ligand. Their IR spectra show a strong, characteristic band near 830 cm^{-1} diagnostic of the *trans* O=Os=O moiety of the octahedral dioxoosmium^{VI} complexes.[8] In the ^{1}H NMR spectra, the lutidyl C–H resonances of **2a**–**c** were shifted downfield (~0.28 ppm) relative to those for ligands **1a**–**c**, as expected upon coordination of the nitrogen to the Os^{VI} ester. The ^{1}H NMR spectra remain constant over a wide range of concentrations (0.25–10 mM) and temperatures (−40 to 40 °C) in $CDCl_3$, indicating that no aggregation or dissociation occurs under these conditions. ^{1}H NMR integration also confirmed a 1:1 molar ratio of the ligand and 2,3-dimethylbut-2-ene. The FAB-MS analyses strongly support the formation of mononuclear complexes **2a**–**c**. For example, the mass spectrum of **2a** shows the molecular ion [MH$^+$] peak at 1169.4 (intensity 1.8%, 1168.4 calc. for $C_{56}H_{64}N_8O_8{}^{192}Os$), [M − O]$^+$ at 1152.4 (intensity 3.3%), and [M − $(O_2C_2(CH_3)_4)$]$^+$ at 1052.4 (intensity 2.4%). The observed isotopic distribution patterns of all these peaks are consistent with those calculated for the mononuclear macrocycle **2a**. The complexes **2b** and **2c** also show the same FAB-MS spectral behaviour as seen for complex **2a**.

The binding properties of hosts **1a**–**c** and **2a**–**c** with diamide guests **6** and **7** were revealed in $CDCl_3$ by ^{1}H NMR titration



experiments, performed by adding the guest solution (5–10 mM) to the host stock solution (1–2 mM, 500 μl) in small potions. The time-averaged signals for the free and bound species were observed due to a fast exchange on the NMR time–scale. The association constants (K_a/M^{-1}) were calculated by non-linear least-squares fitting[9] of the titration data, which corresponded well to the expression for a 1:1 binding isotherm. All the hosts contain two different NH protons, and both N–H signals of the hosts were significantly downfield shifted ($\Delta\delta \geq$ 1 ppm) when guests **6** and **7** were added, indicating significant hydrogen bond formation. As a representative example, the two NH signals in the Os^{VI} complex **2a** were shifted downfield from δ 8.83 and 9.22 to δ 9.80 and 10.62, respectively, upon complexation with terephthalamide **6**. The titration curves, plotting either NH chemical shift change *vs.* equivalents of guest, gave essentially identical association constants within experimental error (<5%), indicating that both NHs are involved in a single binding mode.

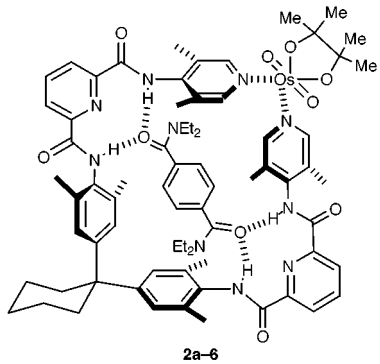
As seen in Table 1, the association constants between Os-free ligands **1a**–**c** and guests **6** and **7** decrease in the order **1a** > **1b** > **1c**. This is expected because **1a** contains conformationally the most rigid linker, while **1c** possesses the most flexible

Table 1 Association constants (K_a/M^{-1}) of ligands **1a–c** and Os complexes **2a–c** with diamide guests **6** and **7** in $CDCl_3$ at 25 ± 1 °C

Guest	Ligand	K_a/M^{-1} [a]	Os complex	K_a/M^{-1} [a]	$\Delta\Delta G°$/ kJ mol^{-1} [b]
6	**1a**	2800	**2a**	1.7×10^4	−4.5
6	**1b**	580	**2b**	1.9×10^4	−8.6
6	**1c**	80	**2c**	2.9×10^4	−14.6
7	**1a**	210	**2a**	1.6×10^4	−10.7
7	**1b**	95	**2b**	2.9×10^4	−14.2
7	**1c**	30	**2c**	6.1×10^3	−13.2

[a] Titrations were duplicated and errors in K_a are within 10% for $K_a < 1 \times 10^4$ M^{-1} and within 30% for $K_a > 1 \times 10^4$ M^{-1}. [b] $\Delta\Delta G° = \Delta G°$(Os complex) − $\Delta G°$(ligand).

linker. More important a trend in the association constants is that Os complexes **2a–c** bind the guests **6** and **7** much more strongly than the corresponding Os-free ligands **1a–c**. The difference in the binding energy is up to $\Delta\Delta G° = -14.6$ kJ mol^{-1}, depending on the linker group; the more flexible the linker is, the greater the difference observed. The large enhancements of the association constants in the Os^{VI} complexes are possibly attributed to the following two factors. One is the conformational preorganization of the hosts **2a–c** as a consequence of Os^{VI} chelation, which greatly reduces the conformational entropy loss upon association of the host and guest. Another contributing factor may be the increased hydrogen-bonding donor ability of the lutidyl N–H protons as a result of Os^{VI} chelation to the terminal nitrogens.



2a–6

The ligand **1a** and its Os^{VI} complex **2a** strongly bind diamide guest **6**, while they bind only slightly the monoamide analogue, *N*,*N*-diethylbenzamide **8** ($K_a \leq 15$ M^{-1} in $CDCl_3$, observed $\Delta\delta_{max} \leq 0.15$ ppm). The Job plots[10] showed a 1:1 stoichiometry between the host **1a** or **2a** and the diamide guest **6**. These observations clearly indicate that two hydrogen-bonding sites in the hosts must simultaneously participate in the complexation, as shown in the proposed structure of the complex **2a**·**6**. Additional evidence for the complex structure was obtained from ^{1}H NMR spectroscopy (Fig. 1). When **2a** and **6** are mixed in a 1:1 molar ratio, the NH signals of the host **2a** are largely downfield shifted ($\Delta\delta \geq 1$ ppm), and more importantly, the aryl C–H signal of the guest **6** is significantly upfield shifted ($\Delta\delta \sim 1.5$ ppm). The latter strongly suggests that the guest **6** is located inside the cavity surrounded by the host aryl walls,

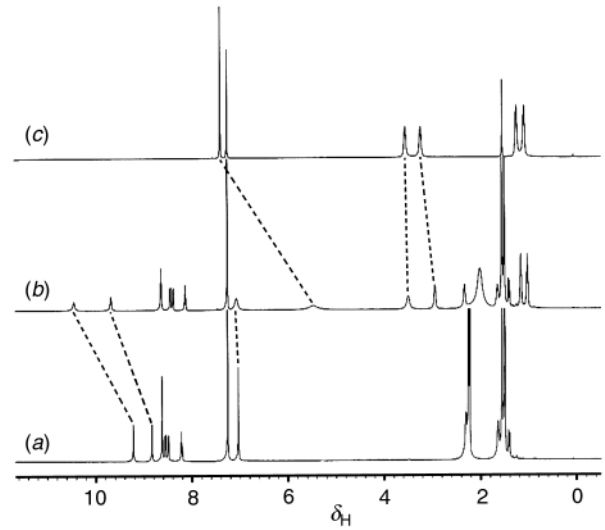


Fig. 1 ^{1}H NMR spectra of (*a*) host **2a** (3 mM), (*b*) host **2a** (3 mM) + guest **6** (3 mM), and (*c*) guest **6** (3 mM) in $CDCl_3$ at 25 °C.

which induce an anisotropic shielding environment in the ^{1}H NMR spectrum.

In conclusion, we have shown the self-assembly of cleft-like bispyridyl hosts into the corresponding macrocycles by Os^{VI} ester chelation, which significantly increases the binding affinity toward guests. Further studies are underway to develop optically active hosts for the chiral recognition of peptide derivatives.

Received (in Corvallis, OR, USA) 3rd June 1999, Accepted 7th September 1999

The new perhalogenated porphyrin 2,3,7,8,12,13,17,18-octabromo-5,10,15,20-tetrakis(trifluoromethyl)porphinato-nickel(II) exhibits several striking features, including an extremely ruffled macrocycle with a very short Ni–N distance, an unusually red-shifted optical spectrum, and, surprisingly, hindered rotation of the *meso*-trifluoromethyl substituents ($\Delta G^{\ddagger}_{278}$ = 47 kJ mol^{-1}).

During the last decade a number of highly nonplanar dodeca-substituted porphyrins have been synthesized, including dodecaarylporphyrins (*e.g.* **1**), dodecaalkylporphyrins (*e.g.* **2**), octaalkyltetraphenylporphyrins (*e.g.* **3**), tetraaryloctahaloporphyrins (*e.g.* **4**), octaethyltetranitroporphyrin (**5**), and systems with substituents fused to the pyrrole rings (*e.g.* **6**).[1] Detailed studies of these compounds have provided a much greater understanding of the effects of nonplanar distortions on the properties of porphyrins, and have also led to speculation about possible functional roles for the nonplanar deformations seen for some tetrapyrroles in biological systems.[1] Two classes of dodecasubstituted porphyrin which have so far proved elusive are the tetraalkyloctahaloporphyrins (**7**) and octaalkyltetrahaloporphyrins (**8**); the non-availability of these compounds can be related to undesirable side-reactions (*e.g.* benzylic substitution and bromodealkyation) which occur during the bromination of tetraalkyl- and octaalkyl-porphyrins.[2] Here we report the first synthesis of a tetraalkyloctahaloporphyrin, **9** (M = Ni), and describe some of the unusual features of this compound.

In an attempt to avoid the side-reactions seen during the bromination reactions of tetraalkyl- and octaalkyl-porphyrins, we investigated bromination of the tetra(perfluoroalkyl)porphyrin **10** (M = Ni). The precursor porphyrin **10** (M = 2H) was prepared using a literature procedure.[3] Refluxing **10** (M = 2H) with $Ni(acac)_2$ in toluene gave **10** (M = Ni) which was more suitable for use in the bromination reactions. Bromination of **10** (M = Ni) proved difficult but was eventually achieved by refluxing a solution of the porphyrin in $CHCl_3$ containing a large excess of Br_2 for 10 days under argon. The perhalogenated porphyrin **9** (M = Ni) was then isolated in 88% yield after column chromatography (silica gel/cyclohexane) and recrystallization (from CH_2Cl_2 with slow diffusion of MeOH). Porphyrin **9** (M = Ni) gave satisfactory mass spectral analysis (M^+ 1269.27; calc. for $C_{24}N_4Br_8F_{12}Ni$ 1269.27) and microanalysis (found C, 23.54; H, 0.00; N, 4.43; calc. C, 23.79; H, 0.00; N, 4.62%), and was further characterized by X-ray crystallography and visible and NMR spectroscopy as described below.

The crystal structure of **9** (M = Ni)† (Fig. 1) revealed a very ruffled macrocycle in which the *meso* positions were displaced alternately up or down by an average of 1.06 Å with respect to the least-squares plane of the porphyrin ring. The average out-of-plane displacement for all of the porphyrin atoms with respect to the least-squares plane of the porphyrin macrocycle was 0.50 Å. By these measures **9** (M = Ni) is the most ruffled porphyrin ever reported; the largest ruffling distortion previously observed was for **11** (M = Zn), where the corresponding displacements were only 0.90 and 0.44 Å.[4] The conformation seen for **9** (M = Ni) can be contrasted with the saddle conformation seen for the perhalogenated tetraarylporphyrin **12** (M = Ni),[5] where the *meso* carbons are in the least-squares plane of the porphyrin macrocycle and the pyrrole rings are tilted alternately up or down. The strongly ruffled structure of **9** (M = Ni) is accompanied by an extremely short Ni–N distance of only 1.88 Å. This can be compared to Ni–N distances of 1.90 Å in the very saddle-distorted porphyrin **12** (M = Ni)[5] and 1.96 Å in planar (triclinic A) NiOEP.[6] The significant shortening of the Ni–N distance seen for **9** (M = Ni) is consistent with the

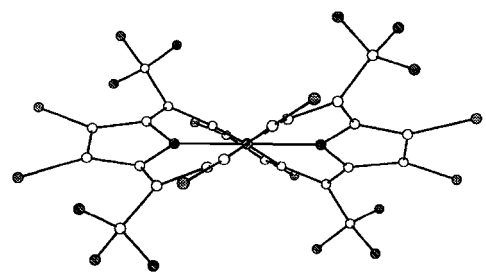

Fig. 1 Crystal structure of porphyrin **9** (M = Ni).

larger degree of core contraction expected for ruffling *versus* other types of nonplanar distortion.[7] Molecular modelling studies using a previously published force-field[7–9] demonstrated that the conformations seen in the crystal structures of **9** (M = Ni) and **12** (M = Ni) were the minimum energy structures for these porphyrins, and that the different Ni–N distances in the two compounds could be accurately reproduced.

Porphyrin **9** (M = Ni) possesses some unusual spectroscopic characteristics. Nonplanarity is known to cause a red-shift in the optical spectra of porphyrins due to a greater destabilization of the HOMO compared with the LUMO,[1] and the optical spectrum of **9** (M = Ni) [λ/nm (ε/dm^3 mol^{-1} cm^{-1}) 444 (77 000), 636 (8100) and 690 (24 000)] is indeed red-shifted compared to the spectrum of **10** (M = Ni) [408 (120 000), 550 (7700) and 590 (25 000)]. However, the red-shift of the $Q_{(0,0)}$ band upon addition of eight β bromo substituents to **10** (M = Ni) (2450 cm^{-1}) is substantially larger than that seen upon addition of eight β bromo substituents to **13** (M = Ni) (1050 cm^{-1}) or **14** (M = Ni) (1250 cm^{-1}) which yields saddle-distorted macrocycles. This suggests that the porphyrin π-system may be more sensitive to ruffle *versus* saddle distortions of the macrocycle. Additional support for this idea comes from the fact that other properties related to the porphyrin π-system (*e.g.* the frequencies of Raman marker lines[10] and the magnitude of the porphyrin ring current effect[11]) are also affected more by ruffle than by saddle distortions.

The 283 MHz ^{19}F NMR spectrum of **9** (M = Ni) in CD_2Cl_2 at ambient temperature displayed an unusually broad signal at δ −39 (referenced to internal CF_2Cl_2 at δ −8.0)[12] for the *meso* trifluoromethyl substituents. Heating the complex resulted in a sharp singlet at δ −39.0, whereas cooling produced two signals at δ −34.7 (d, 2F, $J_{F\text{-}F}$ = 114 Hz) and −47.8 (t, 1F, $J_{F\text{-}F}$ = 114 Hz). The activation energy ($\Delta G^{\ddagger}$) for the observed dynamic process was calculated to be 47 kJ mol^{-1} at the coalescence temperature of 278 K. In contrast, the unbrominated precursor **10** (M = Ni) gave a single sharp CF_3 signal at all of the temperatures studied. The non-equivalence of the trifluoromethyl fluorines in **9** (M = Ni) indicates that rotation of the CF_3 groups is slow on the NMR timescale at low temperatures. Hindered CF_3 rotation is a rare phenomenon but has been observed in some very sterically crowded compounds. For example, the activation energy for CF_3 rotation in CF_3CCl_2I is 36 kJ mol^{-1} at 201 K,[13] with the coupling constant between the fluorines being 101 Hz in the slow exchange spectrum. The unusually slow rotation of the CF_3 groups in **9** (M = Ni) provides evidence of a very high degree of steric crowding in this compound.

In earlier NMR studies of nonplanar porphyrins, dynamic processes in **1** (M = 4H),[14] **2** (M = Ni)[14] and **15** (M = 2H or Zn)[15] were initially attributed to macrocyclic inversion but subsequently reassigned as substituent rotation.[16–18] In an attempt to avoid any confusion about the nature of the dynamic process in **9** (M = Ni), we used molecular mechanics calculations[8,9] to estimate the energies of the two possible CF_3 rotation pathways (CF_3 rotation about a ruffled porphyrin core *versus* CF_3 rotation during inversion of the porphyrin macrocycle). The barrier for rotation of the CF_3 groups in the ruffled structure was calculated to be 34 kJ mol^{-1}. The lowest energy inversion–rotation barrier (103 kJ mol^{-1}) was found between the ruffled structure (designated αβαβ) and a structure which had three CF_3 groups on the same side of the porphyrin plane (designated αααβ). On the basis of these calculated energies it seems probable that the process being observed for **9** (M = Ni) is rotation of the CF_3 groups in the ruffled structure.

Porphyrin **9**, with a novel combination of a strongly ruffled macrocycle and very electron-withdrawing substituents, clearly has many unusual features even when compared with other very nonplanar dodecasubstituted porphyrins. It will be interesting to investigate this porphyrin further and perhaps to examine how **9** compares with tetraaryloctahaloporphyrins in terms of catalyzing the oxygenation reactions of unactivated alkanes.[19]

† Crystals were grown by the slow diffusion of cyclohexane into a CH_2Cl_2 solution of **9** (M = Ni) ($C_{24}N_4Br_8F_{12}Ni$). The selected crystal (0.06 × 0.06 × 0.04 mm) had an orthorhombic unit cell, space group *Pnma*, cell dimensions a = 8.1106(7), b = 23.587(2), c = 15.5831(14) Å, V = 2981.2(5) Å^3, Z = 4 (FW = 1270.27). Data were collected in ω scan mode to 2θmax = 63° (29685 total reflections measured) on a Bruker SMART 1000 diffractometer with graphite monochromated radiation from a ceramic sealed tube source [λ(Mo-Kα) = 0.71073 Å]. The crystal was cooled to 93(2) K during data collection with an anhydrous N_2 stream supplied from a CryoIndustries low temperature apparatus. The structure was solved by direct methods (SHELXS-97) and refined (based on F^2 using all data) by full matrix least-squares methods with 232 parameters (SHELXL-97). Of 3511 unique reflections used in the refinement ($2\theta_{max}$ = 55°), 1937 were observed [$I > 2\sigma(I)$]. An empirical absorption correction (SADABS) (ref. 20) was applied [T_{min} = 0.546, T_{max} = 0.657, ρ_{calc} = 2.83 g cm^{-3}, μ = 11.47 mm^{-1}]. Final R factors were $R1$ = 0.042 (observed data) and $wR2$ = 0.077 (all data). CCDC 182/1413.

High-affinity nucleic acid recognition using 'LNA' (locked nucleic acid, β-D-*ribo* configured LNA), '*xylo*-LNA' (β-D-*xylo* configured LNA) or 'α-L-LNA' (α-L-*ribo* configured LNA)

Vivek K. Rajwanshi, Anders E. Håkansson, Ravindra Kumar and Jesper Wengel*

Center for Synthetic Bioorganic Chemistry, Department of Chemistry, University of Copenhagen, Universitetsparken 5, DK-2100 Copenhagen, Denmark. E-mail:wengel@kiku.dk

Received (in Cambridge, UK) 18th August 1999, Accepted 8th September 1999

Remarkably strong binding affinities towards complementary single stranded DNA and RNA were obtained for 10- and 14-mer LNAs (locked nucleic acids) containing diastereoisomeric β-D-*ribo*, β-D-*xylo* or α-L-ribo configured LNA thymine monomers; a possible relevance of these results in relation to nucleic acid evolution is discussed.

As recently summarized, Eschenmoser and co-workers have intensively studied the basic chemical properties of a number of potential natural nucleic acid alternatives containing various hexopyranosyl or pentopyranosyl monomeric units.[1] Many of these alternatives have displayed efficient and strong Watson–Crick base-paring, indicating that this property has not been a decisive driving force during the evolution of RNA (ribofuranosyl nucleic acids),[1b] at least not with respect to the carbohydrate part of RNA. The possibilities exist that RNA was selected for synthetic reasons favouring the formation of RNA, or for functional reasons inherent in the β-D-ribofuranosyl structure of RNA. In the latter scenario it is conceivable that the RNA structure resulted from selection and optimization among irregular nucleic acids consisting of mixtures of, *e.g.* different pentofuranosyl and/or pentopyranosyl monomeric nucleotide units. Although several pentofuranosyl configurational isomers of RNA have been synthesized, *e.g.* the β-L-ribofuranosyl[2] and β-D-arabinofuranosyl[3] isomers, their binding affinities, especially in stereoirregular oligonucletides, have not been much studied.

We and others have recently reported unprecedented thermal affinities of duplexes involving the oligonucleotide analogue 'LNA'[4] (locked nucleic acid, $\mathbf{T^L}$, β-D-*ribo* isomer, Fig. 1).† The furanose ring of LNA, being part of a dioxabicyclo[2.2.1]heptane skeleton, is efficiently locked in a C3'-*endo* (N-type) conformation. We have initiated a program focusing on the synthesis and properties of conformationally locked configurational isomers of LNA. Very recently, we have published the syntheses of the first two diastereoisomeric forms of LNA, namely '*xylo*-LNA' ($\mathbf{xT^L}$, β-D-*xylo* isomer,† Fig. 1) containing one or more 2'-*O*,4'-*C*-methylene-β-D-xylofuranosyl nucleotide monomer(s), and 'α-L-LNA' ($^{\alpha L}\mathbf{T^L}$, α-L-*ribo* isomer,† Fig. 1) containing one or more 2'-*O*,4'-*C*-methylene-α-L-ribofuranosyl nucleotide monomer(s).[5]

The LNA oligomers **5** and **7**–**9** (Table 1) were synthesized on an automated DNA synthesizer by use of the phosphoramidite approach[6] using conditions (pyridine hydrochloride; 10 min coupling time; > 98% step-wise coupling yields) optimized earlier for synthesis of *xylo*-LNA and α-L-LNA.[5] Importantly, the use of polystyrene supports, loaded with the 3'-end penultimate thymidine monomer, allowed synthesis of the (almost)‡ fully modified *xylo*-LNA **7** and α-L-LNA **8**. The oligomers **5** and **7**–**9** were synthesized in the DMT-*ON* mode and, after cleavage from the solid support, purified using disposable reversed phase chromatography cartridges (Cruachem) yielding products with > 80% purity as judged from capillary gel electrophoresis. The compositions of LNAs **5**, **7** and **9** were verified by MALDI-MS analysis.§

In Table 1, hybridization data for 10- and 14-mer thymine LNA derivatives are shown. Sharp and monophasic transitions were obtained in all experiments (except with *xylo*-LNA **5**) towards complementary DNA (dA_{14}) or complementary RNA (rA_{14}). Control experiments without complementary strands showed no indication of the formation of well-defined and stable homocomplexes (no cooperative self-melting). The results obtained for references **1** and **2** and for the different LNA derivatives **3**, **4** and **6** have been reported earlier.[4a,5] Especially noteworthy is the unprecedented binding affinity of the fully modified parent LNA **6**[4a] and the apparent and significant

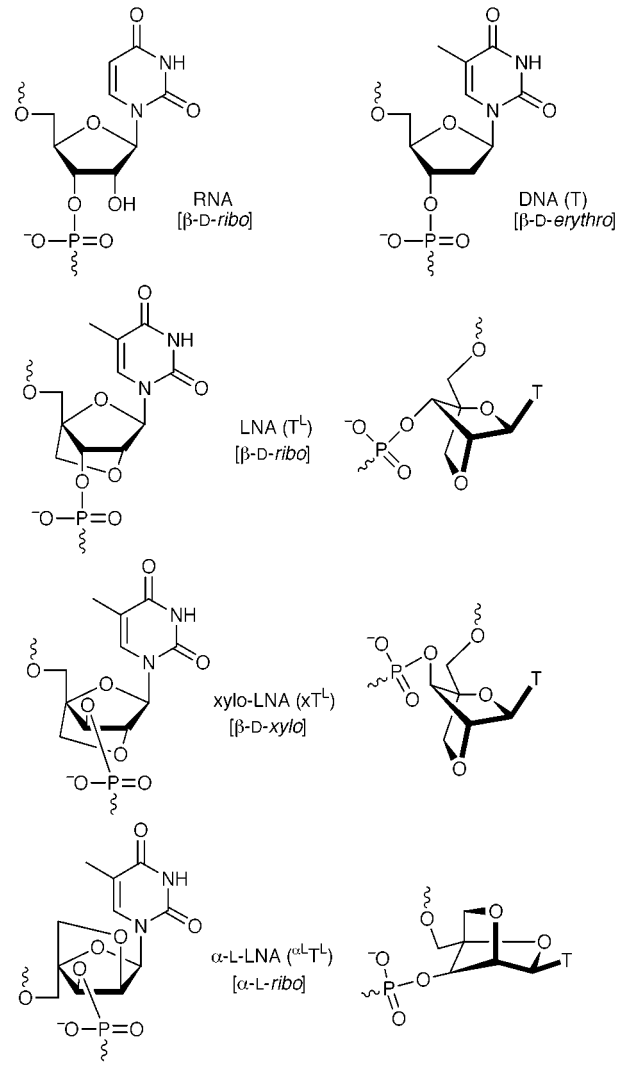

Fig. 1 Structure of the monomeric nucleotide units of RNA, DNA (T), LNA ($\mathbf{T^L}$), *xylo*-LNA ($\mathbf{xT^L}$) and α-L-LNA ($^{\alpha L}\mathbf{T^L}$); the configurations are shown in the square brackets; thymine derivatives are shown except in the case of RNA (uracil derivative shown). Also indicated are the locked furanose conformations of the three differently configured LNA monomers as obtained from molecular modelling ($\mathbf{T^L}$: C3'-*endo* conformation; $\mathbf{xT^L}$: C3'-*endo* conformation: $^{\alpha L}\mathbf{T^L}$: C3'-*exo* conformation).

affinity enhancing properties of LNA monomers as well as α-L-LNA monomers when incorporated into otherwise unmodified DNA strands (LNA **3**[4a] and α-L-LNA **4**;[5] ΔT_m = +5.0 and +4.5 °C towards complementary RNA, respectively; ΔT_m = increase in T_m value per modification; T_m = melting temperature, see text below Table 1).

A detrimental effect caused by the introduction of *xylo*-LNA monomers (*xylo*-LNA **5**) on the thermal stability can be seen from Table 1, confirming earlier obtained results for a singly substituted *xylo*-LNA.[5] In contrast, the fully-modified *xylo*-LNA **7** displayed very strong binding affinity towards DNA and RNA (ΔT_m = +3.1 and +4.3 °C, respectively). Likewise, remarkable thermal affinities were obtained for the fully-modified α-L-LNA **8** (ΔT_m = +4.8 °C towards DNA and +5.3 °C towards RNA). Modeling studies on α-L-LNA monomer $^{\alpha L}\mathbf{T}^{L}$ and LNA monomer $\mathbf{T}^{L}$ indicate a three-dimensional proximity of the thymine moieties and of the 5'- and 3'-oxygen atoms. This apparent structural similarity, despite the inverted configurations at the 2'-, 3'- and 4'-carbon atoms, offers an explanation of the observed very strong binding of the 14-mer 'stereoirregular LNA' **9** (containing four consecutive $\mathbf{T}^{L}$ monomers and four consecutive $^{\alpha L}\mathbf{T}^{L}$ monomers) towards both DNA and RNA (ΔT_m = +4.0 and +4.4 °C, respectively).

The results presented herein demonstrate that conformational restriction of fully modified diastereoisomeric LNA derivatives with β-D-*xylo* and α-L-*ribo* configurations (*xylo*-LNA **7** and α-L-LNA **8**) leads to high-affinity recognition of complementary DNA and RNA.¶ Thus, whereas LNA[4] is the nucleic acid analogue synthesized so far displaying the strongest binding affinity towards complementary DNA and RNA, the T_m values obtained herein likewise rank *xylo*-LNA and α-L-LNA, together with *e.g.* 2'-fluoro N3'-P5' phosphoramidates[7] and hexitol nucleic acids,[8] among the strongest DNA and RNA binders known. This is an important point with respect to the possibility of using LNA derivatives as antisense oligonucleotides or diagnostic probes.

Interestingly, whereas Eschenmoser and co-workers have found efficient cross-pairing between the diastereoisomeric conformationally restricted *pentopyranosyl* family of nucleic acid analogues but no pairing of these towards RNA,[1] the three differently configured *pentofuranosyl* LNAs discussed herein are able to very efficiently bind to RNA (itself a pentofuranosyl system). These results, in combination with the RNA-binding reported for β-D-arabinofuranosyl nucleic acids,[3f] suggest that constitution (rather than configuration) could have been a decisive factor in an early-stage combinatorial chemical evolution of the nucleic acid structure. It can be imagined that eventual optimization based on functional aspects, *e.g.* base-pairing strength or potential for stereoregular non-enzymatic replication, caused by differences in configuration and thus conformational equilibria between the various pentofuranosyl (or pentopyranosyl) diastereoisomers, could have favoured the current β-D-ribofuranosyl structure of the nucleic acids.

We are continuing our examination of the LNA family of molecules. A fourth LNA diastereoisomer ('α-L-*xylo*-LNA') is currently being synthesized which, together with the three diastereoisomers discussed herein and an enantiomeric RNA target, will allow us to study the properties of all eight possible LNA stereoisomers (in stereoregular or stereoirregular oligomers).‖

The Danish Natural Science Research Council, The Danish Technical Research Council and Exiqon A/S are thanked for financial support. Dr Carl Erik Olsen is thanked for recording MALDI-MS spectra, and Ms Britta M. Dahl is thanked for synthesis of the LNAs.

[a] Melting temperatures (T_m values) obtained from the maxima of the first derivatives of the melting curves (A_{260} *vs.* temperature) recorded in medium salt buffer (10 mM $NaHPO_4$, 100 mM NaCl, 0.1 mM EDTA, pH 7.0) using 1.5 mM concentrations of the two complementary strands assuming identical extinction coefficients for all thymine nucleotides [ref. 4(*b*)]. [b] The change in T_m value per modification (ΔT_m) compared with the T_m value for the reference of similar length. [c] Ref. 4(*a*). [d] The T_m values obtained for the reference strands varied from one experimental series to another [ref. 4(*a*), 5]. [e] Reference duplex. [f] Ref. 5. [g] No transition was observed above 20 °C. [h] In the original publication [ref. 4(*a*)], these ΔT_m values were erroneously calculated as +4.9 and +4.3 °C. [i] These ΔT_m values are calculated average values for the different LNA monomers incorporated.

Notes and references

† We have defined LNA as an oligonucleotide containing one or more 2'-*O*,4'-*C*-methylene-β-D-ribofuranosyl nucleotide monomer(s). The natural β-D-ribo configuration is generally assigned to LNA (and LNA monomers) as the positioning of the 1-nitrogen and 2'-, 3'- and 5'-oxygen atoms are equivalent to the one found in RNA. Strictly following carbohydrate nomenclature, however, the configuration of LNA nucleosides depends on the priorities between the two 4'-*C*-substituents (β-D-*ribo* or α-L-*lyxo* configuration in the case of parent LNA). Analogously, all *xylo*-LNA derivatives and all α-L-LNA derivatives are considered as having β-D-*xylo* and α-L-*ribo* configuration, respectively.

‡ For synthetic ease, the LNAs **6**-**8** were synthesized on commercially available T-supports. However, these LNAs are described herein as 'fully modified'.

§ MALDI-MS ($[M-H]^-$; found/calc.): **5** (4305.4/4307.8); **7** (3229.8/3231.1); **9** (4421.4/4419.8).

¶ The generality (base-pairing selectivity, mixed sequence contexts, strand orientations *etc*.) of the hybridization of diastereoisomeric forms of LNA has yet to be proven as has already been done for the parent LNA (ref. 4).

‖ The indirect evaluation of the RNA binding affinity of the remaining four LNA stereoisomers will be undertaken in a collaborative project with Dr Stefan Pitsch (Institute of Organic Chemistry, ETH, Zürich), involving the use of enantiomeric RNA. It should be noted that the formation of LNA derivatives of *arabino* and *lyxo* configuration† is precluded because of the inherent *syn*-positioning of the 2'-oxygen and 4'-carbon atoms.

Polymer supported cobalt carbonyl complexes as novel traceless alkyne linkers for solid-phase synthesis

Alex C. Comely,*[a] Susan E. Gibson (née Thomas)[a] and Neil J. Hales[b]

[b] *AstraZeneca, Mereside, Alderley Park, Macclesfield, UK SK10 4TG*

Received (in Liverpool, UK) 22nd July 1999, Accepted 1st September 1999

The immobilisation of functionalised alkynes onto 'polymer-bound triphenylphosphine', their chemical manipulation and subsequent release has been demonstrated for the first time, thus illustrating that cobalt carbonyl complexes can be used as 'traceless' π-alkyne linkers.

Solid-phase synthesis continues to excite ever-greater interest,[1] particularly as a means to facilitate the elaboration of compound libraries *via* combinatorial chemistry.[2] Of especial importance to this technology is the linker, the structural motif which joins the substrate under chemical manipulation to the polymeric support. A legacy of solid-phase peptide synthesis is the release of compounds bearing carboxylic acid or amide functionality derived from an ester linkage. While appropriate for some target molecules, this has rather limited appeal in a more general synthetic sequence. Efforts to address this problem have stimulated the evolution of 'traceless' linkers,[3] those which leave minimal vestige of the solid support upon release of the product. A good example is the tethering of compounds containing an aromatic ring by means of an aryl–silicon bond.[4] The linker is cleaved to reveal only a hydrogen atom at the former aromatic linkage site.

In this respect, transition metals offer a very alluring solution: the temporary and reversible immobilisation of an unsaturated substrate *via* π-interactions to the molecular scaffold dispenses with the functional group transformation necessarily required by a covalent system. In recent months this concept was illustrated for the first time with the immobilisation of arenes through a chromium carbonyl linker.[5] Liberation of the product by oxidative decomplexation returns the aromatic ring unchanged.

Surprisingly, there currently exists no method for the release of an alkyne from a polymeric support.[6] A system which allows the addition and later release of this functionality, without a compromise to its integrity, would thus represent a valuable extension to linker technology. The chemistry of cobalt carbonyl alkyne complexes is well established in the solution phase and has been applied to great effect in organic synthesis:[7] alkyne protection,[7a] the Nicholas reaction[7b] and Pauson–Khand cyclisations,[7c] for example, are amply documented. Given the ease of formation and tolerance to diverse reaction conditions of these complexes, it appeared to us that cobalt carbonyl species offered considerable potential as alkyne linkers for solid-phase synthesis.

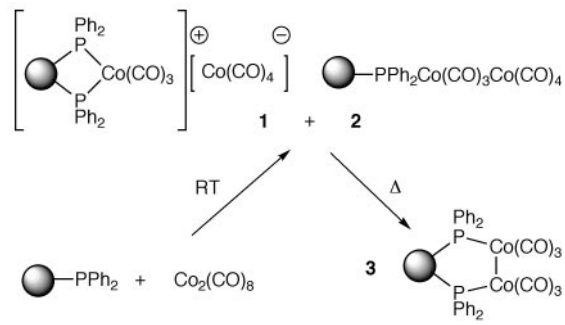
Our initial investigations involved the reaction of 'polymer-bound triphenylphosphine'† with $Co_2(CO)_8$ in THF at room temperature to generate a cobalt carbonyl resin, a support to which alkynes could be added directly (Scheme 1). The purple, stable resin was characterised on the basis of its IR and ^{31}P NMR spectra: strong absorptions ascribed to ionic **1** were accompanied by weaker peaks indicating a minor presence of the monophosphine-substituted complex **2**.[8] Heating of this resin at 60 °C in 1,4-dioxane cleanly converted it into a second form, assigned the structure of the neutral bisphosphine **3** on the basis of its IR and ^{31}P NMR spectra.[9]

The alkyne complexation of a phosphine-substituted cobalt carbonyl complex, $[(Bu_3P)Co(CO)_3]_2$, has been reported.[10] In view of the elevated temperature required, the simultaneous conversion of (**1** + **2**) into **3** *and* complexation of an alkyne becomes a feasible transformation (Scheme 2). Treatment of the resin bearing complexes **1** and **2** with hex-5-yn-1-ol in 1,4-dioxane at 70 °C generated the purple resin-bound alkyne complexes **4**, presumably *via* the intermediary carbonyl complex **3**. Comparison of overlapping sets of IR absorptions with literature data,[11] and data from samples of $Ph_3P(OC)_2CoCo(CO)_3$(hex-5-yn-1-ol) and $[Ph_3P(OC)_2Co]_2$(hex-5-yn-1-ol) prepared ourselves, indicates the presence of both mono- and bisphosphine substituted alkyne complexes, **4a** and **4b**, and that the latter is the major component.‡ The ^{31}P NMR spectrum of **4a**/**4b** supports alkyne complexation (with a 20% phosphorus site occupancy).

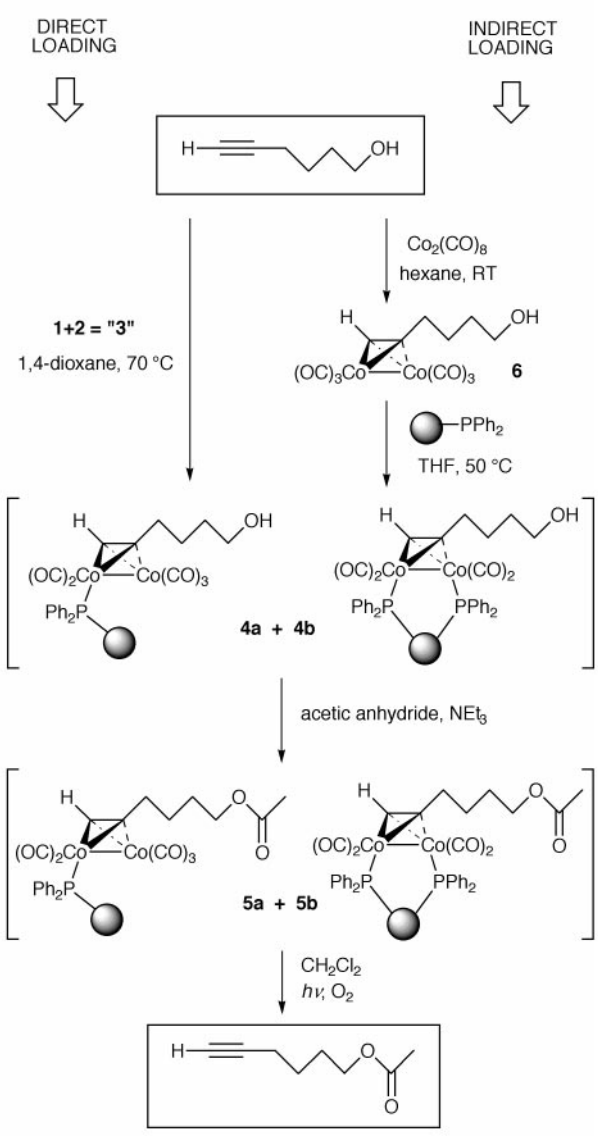
Acetylation of resin **4** to afford **5** using acetic anhydride–NEt_3 is supported by an additional acetate absorption at 1734 cm^{-1}. Decomplexation was achieved by aerial oxidation in CH_2Cl_2 under white light for 72 h. Filtration and washing of the brown polymeric residue delivered hex-5-yn-1-yl acetate as the sole product in 70 ± 20% yield from **4**.

A second approach with the same overall objective involved the reaction of 'polymer-bound triphenylphosphine' with a preformed alkyne complex (indirect loading) (Scheme 2). Designed to permit comparison between the two routes, hex-5-yn-1-ol was complexed with $Co_2(CO)_8$ to give **6**, a deep red oil (85%). Loading onto the polymer was effected in THF at 50 °C to afford **4**§ possessing similar IR characteristics to the resin prepared by the direct method. A comparison of the strengths of bands attributed to the mono- and bisphosphine derivatives[11] identifies the former as the major component *via* this route.‡ ^{31}P NMR spectroscopy is extremely valuable here.¶ A well-resolved resonance integrates to an 80% complexation of phosphorus sites (the benign phosphine oxide, polymer-$P(O)Ph_2$, occupying the remaining 20%) and a loading of 0.94 ± 0.02 mmol[hexynol] g^{-1}. Acetylation proceeded as before: that the metal carbonyl stretches and the ^{31}P NMR spectrum undergo no change demonstrates the stability of this linker to these conditions. Hex-5-yn-1-yl acetate (12 mg, 60 ± 10% from **4**) was recovered from the resin following acetylation of resin **4** (150 mg) and decomplexation over 72 h.

Each loading technique has its own advantage: overall yields *via* indirect loading are significantly higher than those obtained from direct loading. The latter, however, obviates pre-formation of a cobalt alkyne complex and thus offers convenience: once



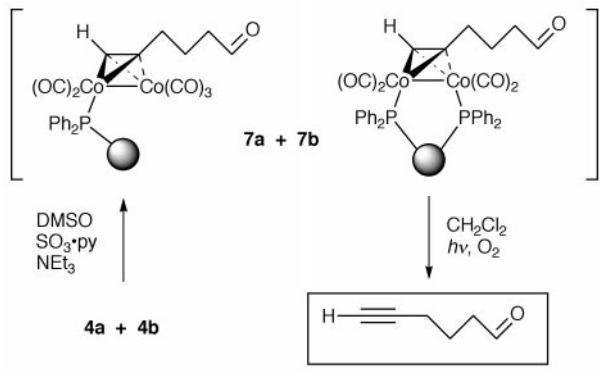
Scheme 1



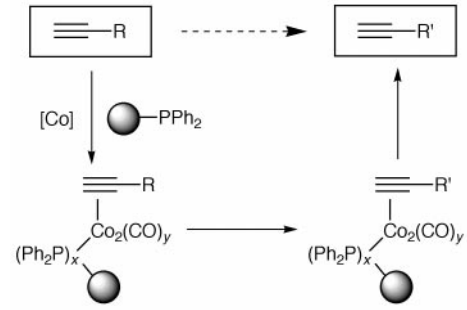
Scheme 2

prepared, the resin-linker complex (**1** + **2**) can be stored and used as required.

Finally, in preliminary experiments to explore the versatility of this linker, alcohol **4** (prepared by direct loading) was oxidised in the presence of SO_3·py-activated DMSO and NEt_3[12] to afford the aldehyde complex **7** (Scheme 3), displaying a diagnostic aldehyde stretch at 1723 cm^{-1}. Significantly, all other data (IR and ^{31}P NMR) of resin **7** are unchanged from those of **4**, thus demonstrating the linker's stability to these oxidising conditions. Hex-5-yn-1-al was isolated in 17 ± 5% yield after decomplexation as before (the low yield here is attributed to the volatility of the aldehyde).



Scheme 3



Scheme 4

In conclusion, we have demonstrated for the first time the utility of cobalt carbonyl complexes as linkers for the 'traceless' immobilisation and subsequent release of alkyne substrates (Scheme 4). The linker is stable to certain widely-used reaction conditions and the work described herein is applicable to various combinatorial methods.

The authors thank Jon Cobb for invaluable NMR assistance and AstraZeneca for a studentship (ACC).

Footnotes and references

† 'Polymer-bound triphenylphosphine' (commercially available from Fluka, ~1.6 mmol P g^{-1}) describes a diphenylphosphino polystyrene polymer crosslinked with 2% divinylbenzene.

‡ Details of estimates used in this study are as follows: **4a**:**4b** ratios were estimated from IR intensities (3:7 and 6:4 for direct and indirect routes respectively). Solution calibration studies verify this estimate. Solid phase ^{31}P NMR spectra can be accurately integrated but show no resolution of mono- and bisphosphine derivatives. The error margins for yield and loading calculations are estimated as follows: IR spectra, 5%; ^{31}P NMR spectra, direct method, 10%; ^{31}P NMR spectra, indirect method 5%.

§ The experimental procedure for indirect formation of **4** is as follows: polymer-bound triphenylphosphine (1 g, ~1.6 mmol P) was suspended in oxygen-free anhydrous THF (10 cm^3) and allowed to swell for 30 min under nitrogen agitation. A solution of hexacarbonyl(hex-5-yn-1-ol)dicobalt(0) complex (1.2 g, 3.2 mmol) in anhydrous THF (5 cm^3) was added and the black suspension was heated to 50 °C for 4 h. After cooling, the resin beads were filtered, washed with alternate aliquots of THF and Et_2O until the filtrate became colourless, and dried *in vacuo* to afford deep purple beads of **4** (1.46 g, 80% P site occupancy, 0.94 ± 0.02 mmol[hexynol] g^{-1}).

¶ Polymer samples for ^{31}P NMR were swollen in THF and scanned with a D_2O capillary lock at 145.7 MHz for 2 h. Different phosphine species are readily distinguished: polymer-PPh_2-[Co], δ_P = 50–80; polymer-P(O)Ph_2, δ_P = 28.8; polymer-PPh_2, δ_P = −6.3.

Ditopic ligands for the simultaneous solvent extraction of cations and anions

David J. White,*[a] Norman Laing,[a] Hamish Miller,[a] Simon Parsons,[a] Simon Coles[b] and Peter A. Tasker*[a]

[a] *Department of Chemistry, The University of Edinburgh, Joseph Black Building, Kings Buildings, West Mains Rd., Edinburgh, UK EH9 3JJ. E-mail: P.A.Tasker@ed.ac.uk*

[b] *EPSRC National Crystallography Service, Department of Chemistry, University of Southampton, Southampton, UK SO17 1BJ*

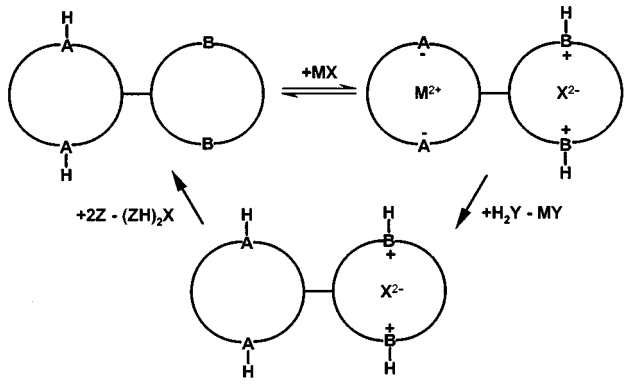
Received (in Basel, Switzerland) 9th August 1999, Accepted 13th September 1999

Incorporation of a dianionic binding site for transition metal cations and a dicationic binding site for anions into a lipophilic molecule has produced a ligand with a high efficacy for the solvent extraction of a transition metal salt [$M^{2+}X^{2-}$].

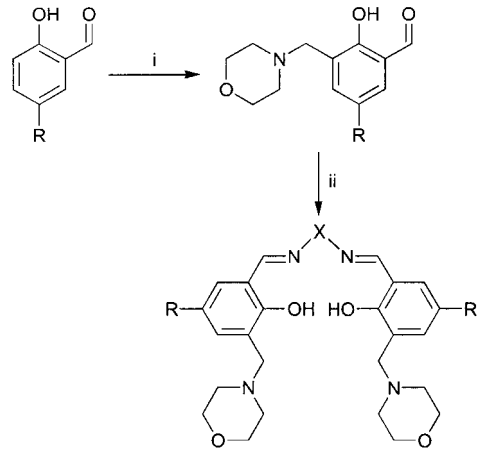
Most man-made processes to separate transition metal ions from aqueous solutions depend on ion exchange processes, in which the desired metal cation M^{n+} replaces a different metal cation (often Na^+) or protons from an anionic group in a complexing agent.[1] Such complexing agents are deployed on solid supports in processes using ion exchange resins, or in a water immiscible liquid in solvent extraction. Although toxic or detrimental metal ions may be sequestered in this way, true purification of the aqueous stream is not achieved because (i) the number of ions present in solution is, at best, unchanged and is often increased; (ii) in the case of proton exchange the pH of the stream may be significantly lowered; and (iii) the anions remain in solution. The harmful effects of anionic species such as phosphate and sulfate have led to control of environmental discharge levels for these species.

These considerations, combined with the need for novel separation technologies to process leach solutions in primary metal recovery, have led us to investigate a new class of extractant which simultaneously sequesters both a transition metal cation and its attendant anion in a ditopic system with the features illustated in Scheme 1.

There are few examples of ligands which simultaneously bind cations and anions and the majority of these address alkali or alkali earth metal or ammonium salts.[2] A recent example invovles the extraction of technetium as the $[NH_4][TcO_4]$ ion pair.[3] Our prototype for a new class of ditopic ligand (Scheme 2) has a ligand framework similar to the uranyl salen anion receptors of Reinhoudt and coworkers,[4] but is designed to provide separate dianionic and dicationic binding sites which are derived from the zwitterionic form of the ligand created by transferring the phenolic protons to the nitrogen atoms of the pendant morpholine groups (Schemes 1 and 3). These features provide for efficient stripping to recycle the extractant and for



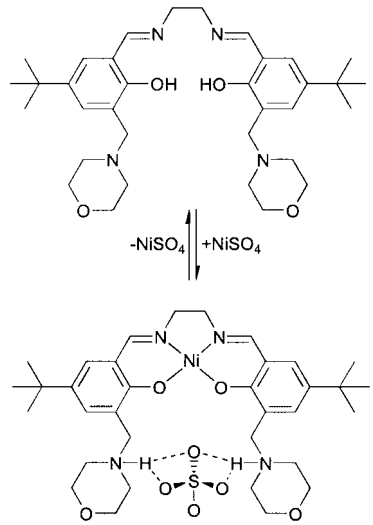
Scheme 1 Schematic representation of ditopic ligands for metal salts with diacid/dibasic sites to enable the hydrometallurgical unit operations of concentration and separation.



Scheme 2 i, 4-Ethoxyethylmorpholine, MeCN, N_2, reflux 66 h; ii, diamine, Et_2O–EtOH (1 : 1), room temp. 12 h. R = Me, Bu^t or nonyl (mixed isomer); X = CH_2CH_2 or $CH_2CH_2CH_2$, H_2NXNH_2 = (±)-*trans*-cyclohexane-1,2-diamine or benzene-1,2-diamine. Ligands referred to here are **1**: R = Bu^t, X = CH_2CH_2, **2**: R = nonyl, H_2NXNH_2 = (±)-*trans*-cyclohexane-1,2-diamine.

the possibility of separately recovering the metal and anion components in articles of commerce. These new ligands, exemplified by **1** and **2** (Scheme 2), can be readily prepared in a four-step convergent synthesis from a substituted salicylaldehyde, paraformaldehyde, morpholine and a diamine of choice.†

When a chloroform solution of the lipophilic ligand **2** (0.01 M) is contacted with aqueous $CuSO_4$ (1 M) at pH 3.8 a dark brown colour develops rapidly. Analysis of the organic phase by ICP-AES for copper and sulfur indicates close to 100% loading of $CuSO_4$. Some of the possible modes of binding of divalent transition metals and their attendant anions have been defined



Scheme 3 Sequestration of $NiSO_4$.

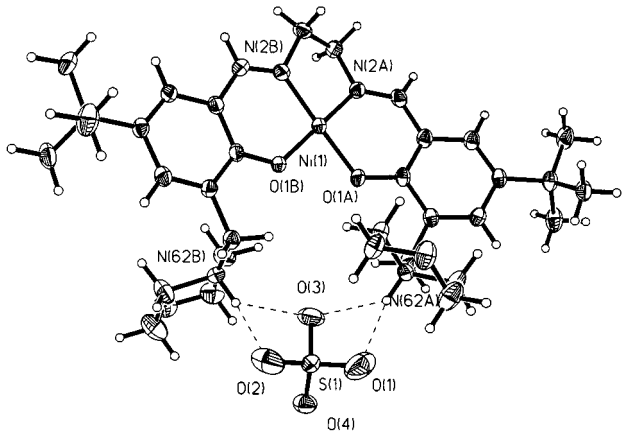


Fig. 1 Molecular structure of [Ni(**1**)SO_4]. Selected bond lengths (Å) and angles (°): Ni(1)–N(2A) 1.846(2), Ni(1)–N(2B) 1.858(2), Ni(1)–O(1A) 1.848(2), Ni(1)–O(1B) 1.854(2); O(1A)–Ni(1)–N(2A) 93.67(8), O(1B)–Ni(1)–N(2B) 94.51(8).

by X-ray structure determinations of nickel(II) complexes of ligand **1** which were readily crystallised from methanol. Reaction of **1** with $NiSO_4·7H_2O$ in methanol (Scheme 3) yields an orange precipitate with a FAB mass spectrum and microanalysis data consistent with the formulaion of the product as [Ni(**1**)SO_4]·$6H_2O$.[5]

An X-ray crystal structure‡ shows (Fig. 1) that the Ni^{2+} cation is coordinated in the planar $N_2O_2^{2-}$ cavity of the salen moiety with bond distances and angles typical of such coordination environments.[6] The coordination of the Ni^{2+} ion has two important effects on the structure of the ligand. The two protons liberated from the phenols of the metal binding site have been transferred to the nitrogen atoms of the pendant morpholine groups and the ligand has been organised to bring the two morpholine groups into close proximity[7] to produce a dicationic binding site for the sulfate anion. This represents an example of cooperativity[8] in which binding of the metal cation directly enhances binding of the anion. The sulfate dianion is bound by both electrostatic interactions and two separate bifurcated hydrogen bonds, one to each quaternary amine (Table 1).

Table 1 Hydrogen bonded distances (Å) and angles (°) around the sulfate anion in [Ni(**1**)SO_4]

	N···O	N–H···O	H···O
O1···H62A–N62A	2.870(4)	166.2	1.958
O2···H62B–N62B	2.923(3)	154.1	2.322
O3···H62A–N62A	2.993(4)	128.8	2.058
O3···H62B–N62B	2.915(4)	132.1	2.209

Note: the N–H distances were fixed at 0.91 Å. H-bonds were assigned using the Platon program[15] to interactions of the oxygen and nitrogen atoms that were < 3.12 Å.

The prototype extractants exemplified by **1** have useful features for developing working systems[9] for the recovery of metal salts from process streams, acid mine drainage streams or effluents. The disposition of both the salicylaldimine units and the pendant amine functions can be separately varied in attempts to 'tune' selectivity for particular combinations of metal cation and attendant anions. The aldimine functionality is resistant to hydrolysis[10] when used in solvent extraction processes, even when contacted with relatively strong acidic media providing the options for efficient stripping protocols as otulined in Scheme 1. These and the possibility of immobilising the extractants on solid supports are the subject of current work.

We thank Mr J. Millar and Mr W. Kerr for obtaining NMR spectra, Mr A. Taylor and Mr H. MacKenzie for mass spectra and Ms L. Eades for elemental analysis. We gratefully acknowledge the EPSRC for a ROPA award (GRM/33303) and Avecia plc for funding.

Notes and references

† *Experimental procedures:* the starting 2-hydroxy-5-alkylbenzaldehydes were prepared by the method of Levin and coworkers[11] and 4-ethoxymethyl morpholine and hydroxy-3-(morpholin-4-ylmethyl)benzaldehydes by the methods described by Fenton and coworkers.[12]

Example syntheses: **1**: 2-hydroxy-3-(morpholin-4-ylmethyl)-5-*tert*-butylbenzaldehyde (6 g, 21.7 mmol) was dissolved in diethyl ether (60 ml) and added to a solution of ethane-1,2-diamine (0.636 g, 10.6 mmol) in ethanol (60 ml). The resulting yellow solution was stirred overnight then concentrated *in vacuo* to give a yellow oil which on trituration in hexane at −78 °C gave a waxy yellow solid. This was washed with hexane (15 ml) and diethyl ether (15 ml) and dried *in vacuo* (5.8 g, 95%); mp 155–158 °C (Found: C, 70.60; H, 9.06; N, 9.67. Calc. for $C_{34}H_{50}N_4O_4$: C, 70.56; H, 8.71; N, 9.68%). MS (FAB, thioglycerol) *m/z*, 579 (MH^+ 62%).

[Ni(**1**)SO_4]: **1** (0.50 g, 86 mmol) was dissolved in hot methanol (30 ml) and added to a hot solution of $NiSO_4·7H_2O$ (0.245 g, 0.86 mmol) in methanol (20 ml), instantly producing a dark orange colour. On standing the product precipitated as a deep red solid (0.59 g, 93.6%). Recrystallisation from MeOH–H_2O (3 : 1) gave a red microcrystalline material formulated as [Ni(**1**)SO_4]·$6H_2O$; mp 235–240 °C (Found: C, 48.86; H, 7.37; N, 6.53. Calc. for $C_{34}H_{62}N_4NiO_{14}S$: C, 48.53; H, 7.43; N, 6.66%). MS (FAB, thioglycerol) *m/z* 733 [(LNiSO_4)H^+ 10.1%]. Crystals suitable for X-ray diffraction were obtained by evaporation of a saturated methanol solution of the complex.

‡ *Crystal data*: [Ni(**1**)SO_4]·3.75MeOH: The structure was solved by Patterson methods (DIRDIF)[13] and refined against F^2 (SHELXL-97).[14] $C_{37.75}H_{65}N_4NiO_{11.75}S$, M = 518.14, monoclinic, space group $P2/c$, a = 18.9754(4), b = 12.8666(3), c = 19.7197(4) Å, β = 118.571(1)°, U = 4228.2(2), Z = 4, D_c = 1.332 g cm^{-3}, T = 150(2) K, μ(Mo-Kα) = 0.571 mm^{-1}, wR_2 = 0.1457 (8643 independent reflections), R = 0.0502 [$F > 4\sigma(F)$]. The MeOH solvate (2.701 e/cell) was treated in the manner described by van der Sluis and Spek.[15] CCDC 182/1414. See http://www.rsc.org/suppdata/cc/1999/2077/ for crystallographic files in .cif format.

5 When **1** was treated with nickel(II) acetate in methanol the neutral complex [Ni(**1** − 2H)] was formed which has been characterised crystallographically. The ability to isolate neutral complexes containing *either* a metal salt, *e.g.* [Ni(**1**)SO_4] *or* the metal cation alone *e.g.* [Ni(**1** − 2H)] is a special feature of these ditopic ligands and depends on the pH of solution or the basicity of the conjugate anion. Complete details will be reported in a full paper.
6 A survey of the CCDC reveals 66 square planar Ni(II) salen complexes. Ni–N and Ni–O distances average 1.86 and 1.85 Å, repectively: D. A. Fletcher, R. F. McMeeking and D. J. Parkin, *J. Chem. Inf. Comput. Sci.*, 1996, **36**, 746.
7 A preliminary X-ray structure of the free ligand shows that in the solid state the torsion around the ethylene linker group places the chelating units in a *trans* configuration and it is therefore not predisposed for complexation. During the course of this work the structure of a related ligand was published and also shows the *trans* configuration. S. Shanmura Sundara Raj, R. Thirumugan, G. Shanmugan, Hoong-Kun Fung, J. Received (in Liverpool, UK) 20th July 1999, Accepted 15th September 1999

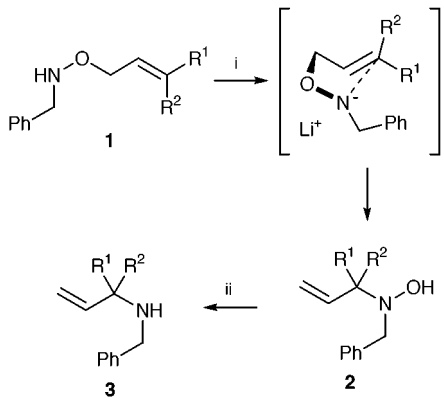
Lithium (*E*)-*N*-benzyl-*O*-(4-methoxy-4-phenylbut-2-enyl)-hydroxylamide undergoes a highly diastereoselective rearrangement *via* a chelated transition state, to afford after reduction, *syn*-3-benzylamino-4-methoxy-4-phenylbut-1-ene as a single diastereoisomer.

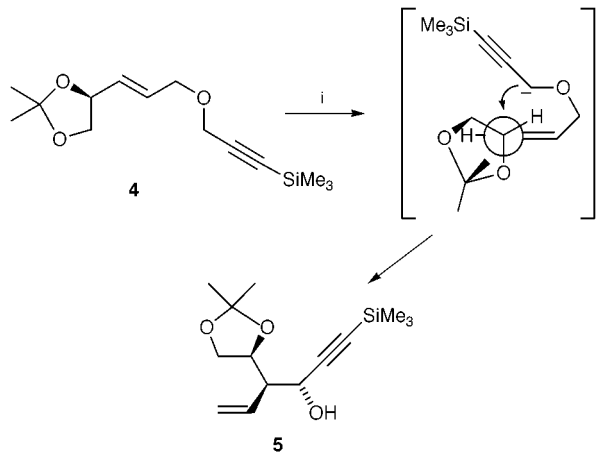
Intramolecular sigmatropic rearrangements have found widespread use in synthetic organic chemistry, primarily due to the high selectivities observed in these transformations.[1] We have recently reported on a novel intramolecular [2,3]-rearrangement of *N*-benzyl-*O*-allylic hydroxylamines **1** to afford *N*-benzyl-*N*-hydroxyallylamines **2**, which may be reduced to the corresponding *N*-benzyl-*N*-allylamines **3** in good yield (Scheme 1).[2] The transition state of this N,O rearrangement may be compared with that of the [2,3]-Wittig rearrangement;[3] deprotonation of **1** affords a lithium amide which rearranges through an envelope like transition state.



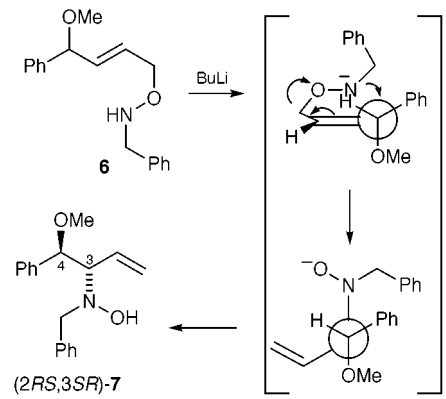
Scheme 1 *Reagents and conditions*: i BuLi, THF; ii, Zn, aq. HCl.

Previous investigations into the synthetic utility of the [2,3]-Wittig rearrangement[4] have revealed that allylic ethers with stereogenic centres bearing a heteroatom substituent adjacent to the migration terminus have the capacity to undergo diastereoselective rearrangement.[5] For example, deprotonation of allylic ether **4** with BuLi in THF at −78 °C affords the rearranged product **5**, containing two new stereogenic centres, in 66% de (Scheme 2)[6]. Facial selectivity in this case is controlled *via* a transition state where the carbanion attacks antiperiplanar to the heteroatom *via* a conformation which directs the allylic hydrogen on the original stereogenic centre to the 'inside' site.

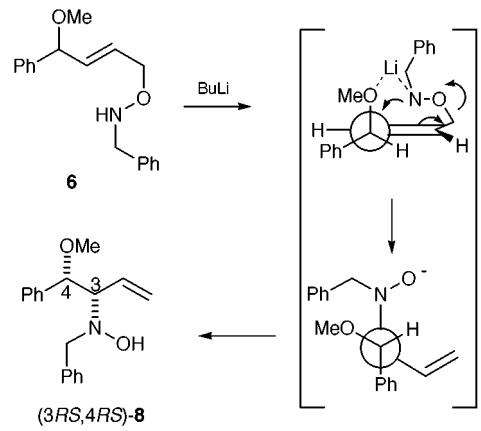
This type of stereoelectronic effect might also operate to control facial selectivity during the [2,3]-N,O rearrangement of the lithium anion of (*E*)-*N*-benzyl-*O*-(4-methoxy-4-phenylbut-2-enyl)hydroxylamine **6**, however in contrast to the Wittig rearrangement, in this case the possibility of chelation control is also present. If N,O rearrangement of the lithium anion of **6** proceeds *via* a transition state where facial selectivity is determined by stereoelectronic effects, then the *anti*-diastereoisomer **7** will be formed (Scheme 3), while a rearrangement pathway which proceeds *via* a chelated transition state would result in the *syn*-diastereoisomer **8** (Scheme 4).



Scheme 2 *Reagents and conditions*: i, BuLi, THF, −78 °C.

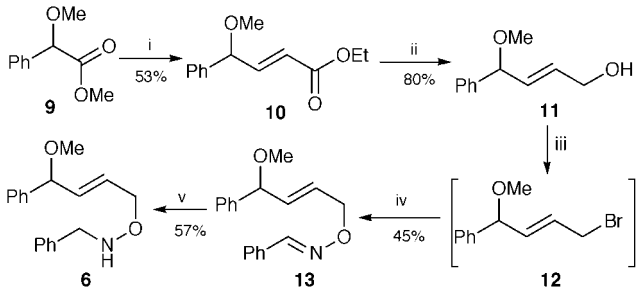


Scheme 3



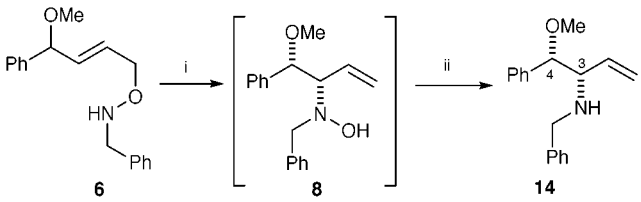
Scheme 4

Thus (*E*)-*N*-benzyl-*O*-(4-methoxy-4-phenylbut-2-enyl)hydroxylamine **6** was prepared from racemic methyl *O*-methylmandelate **9** *via* our previously described synthetic protocol for this class of hydroxylamine.[2] Methyl *O*-methylmandelate **9** was reduced with DIBAL-H in toluene at −78 °C and the resulting aldehyde treated *in situ* with ethoxycarbonylmethylene(triphenyl)phosphorane to afford the α,β-unsaturated ester **10** in an unoptimised 53% yield. Reduction of ester **10** with DIBAL-H in toluene gave allylic alcohol **11** in 80% yield, which was treated with NBS in the presence of PPh_3 to afford an unstable allylic bromide **12**. Subsequently, the crude reaction product of the bromination reaction was treated with the potassium anion of *syn*-benzaldehyde oxime to afford oxime **13** in an overall 45% yield from allylic alcohol **11**. Reduction of oxime **13** with pyridine·borane/HCl gave the desired rearrangement substrate (±)-(*E*)-*N*-benzyl-*O*-(4-methoxy-4-phenylbut-2-enyl)hydroxylamine **6** in 57% yield (Scheme 5).



Scheme 5 *Reagents and conditions*: i, DIBAL-H, toluene, −78 °C, then $Ph_3P{=}CHCO_2Et$; ii, DIBAL-H, toluene, −78 °C; iii, NBS, PPh_3, CH_2Cl_2; iv, PhCH=NOK, THF; v, pyridine·BH_3, EtOH, HCl.

Treatment of hydroxylamine **6** with 1.1 equiv. of BuLi in THF at −78 °C, followed by warming to room temperature over 1 h resulted in complete [2,3]-rearrangement to afford a single diastereoisomer of 3-benzyl(hydroxy)amino-4-methoxy-4-phenylbut-1-ene **8** in 94% conversion as determined by ^{1}H NMR spectroscopic analysis of the crude reaction mixture. Subsequent reduction of the unstable *N*-hydroxy compound **8** to *syn*-3-benzylamino-4-methoxy-4-phenylbut-1-ene **14** with zinc in aqueous hydrochloric acid was achieved in 63% isolated yield (Scheme 6).†



Scheme 6 *Reagents and conditions*: i BuLi, THF, −78 to 25 °C; ii, Zn, aq. HCl.

X-Ray crystallographic analysis of the crystalline HCl salt of *syn*-3-benzylamino-4-phenylbut-1-ene **14** clearly revealed that [2,3]-rearrangement of **6** had occurred to afford *syn*-**8** where the relative stereochemistry of the two newly formed stereogenic centres was (3*RS*,4*RS*) (*vide infra*) (Fig. 1).‡

The *syn*-selectivity of diastereoisomer **14** found during rearrangement of **6** is clearly in accord with the chelation control transition state model described in Scheme 4, rather than the stereoelectronic model described in Scheme 3.

In conclusion, (*E*)-*N*-benzyl-*O*-(4-methoxy-4-phenylbut-2-enyl)hydroxylamine **6** undergoes a highly diastereoselective rearrangement to afford, after reduction, *syn*-3-benzylamino-4-methoxy-4-phenylbut-1-ene **14** containing two new stereogenic centres with complete diastereoselectivity *via* a chelated transition state.

‡ *Crystal data* for **14**·HCl·H_2O: $C_{18}H_{24}ClNO_2$, *M* = 321.84, monoclinic, space group *P*1 2_1/n 1, *a* = 6.403(1), *b* = 27.046(1), *c* = 10.252(1) Å, β = 97.85(2)°, *V* = 1758.8 Å^3, *T* = 180 K, *Z* = 4, D_c = 1.21 g cm^{-3}, *T* = 180 K, μ(Mo-*K*α) = 0.22 mm^{-1}, 3109 independent reflections were measured, of which 2050 were used, *R* = 0.11, R_W = 0.16. Rint = 0.08. The sample was one of many pieces cut from clear plate-like crystals. Although the cut samples remained clear, the diffraction patterns showed that they were always severely damaged by shearing parallel to the large face during the cutting. The final sample was obtained by repeatedly shaving very thin slices away from the edges of the original large crystal. The best obtainable diffraction pattern did not represent a simple single crystalline sample. Data extraction from the 90 images (180 degrees) collected on a Nonius DIP2000 diffractometer were complicated by the presence of more than one reciprocal lattice. Reflections from the strongest lattice were used as the basis for the structure analysis, but were inevitably contaminated by data from the weaker lattice. We could not determine a valid twin law relating the two lattices—the sample was probably polycrystalline. The weakest data showed the greatest discrepancy between F_o and F_c, presumably because the accidental overlap of a strong component of the minor lattice on a weak component of the strong lattice had a more damaging effect than the inverse. Data with $I < 6\,\sigma(I)$ were therefore excluded from the refinement. The value of '6' is subjective, but was chosen by looking at the residual distribution so as to preserve as many 'fair' reflections as possible, and at the same time reject as many 'suspect' reflections as possible. Only one of the water hydrogen atoms could be located. CCDC 182/1415. See http://www.rsc.org/suppdata/cc/1999/2079/ for crystallographic data in .cif format.

Sol–gel process: temperature effect on textural properties of a monophasic hybrid material

Geneviève Cerveau, Robert J. P. Corriu* and Eric Framery

Laboratoire de Chimie Moléculaire et Organisation du solide, UMR 5637, Université Montpellier II, cc 007, Place E. Bataillon, 34095 Montpellier Cedex 5, France. E-mail: cmos@crit.univ-montp2.fr

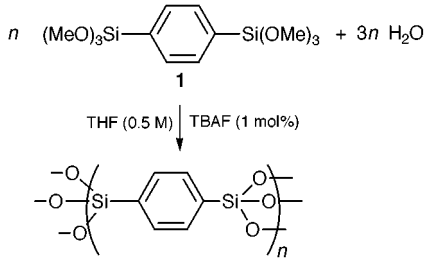
Received (in Cambridge, UK) 26th July 1999, Accepted 21st September 1999

Monophasic hybrid materials with controlled porosity are obtained by varying the temperature, without change of the polycondensation at silicon atoms, confirming the kinetic control of formation of the solids.

The sol–gel processes which correspond to an inorganic polycondensation offer very wide possibilities since they allow the synthesis of materials from the molecular scale as illustrated in Scheme 1.[1] Hybrid organic–inorganic materials are one of the most attractive targets achievable by this chemistry.[2–8] Using the sol–gel route, it is possible to introduce a large variety of organic moieties into inorganic matrices, so leading to the possibility to tailor physico-chemical properties.[2] However, textural control of the solids obtained by the sol–gel route is difficult. For instance, it is known that the aging and drying of gels influence the textural properties for both silica and hybrid solids.[1,3] Furthermore, it has been observed that textural parameters (specific surface area, porosity, *etc*.) drastically change with the experimental conditions,[9–12] and some correlation with kinetic measurements in the first steps of the process have been performed.[1,13] These solids are considered as unstable[1] and reproducibility is often difficult to obtain from literature data since all the experimental details are of importance and are not always precisely reported. However, while *all* experiments are reproducible when a precise analytical procedure is *strictly* followed[9–12] predictability of the obtained product is not yet possible. We have shown previously that organic-inorganic materials are kinetically controlled solids with the properties of the solids being highly dependent on the chemical parameters such as nature and concentration of the catalyst,[9,10] nature of the solvent,[11] concentration of the precursor,[9] nature of the leaving group[11] and nature of the organic unit.[9,12] Here, we report the drastic influence of temperature which is a very important physical parameter for kinetic studies.

Adequate predictability will be attained when the parameters which control all the different steps of the sol–gel type synthesis are known (precursor → oligomers → polymers → colloids → sol → gel). The results presented here suggest that the polycondensation at silicon does not control the textural properties of the resulting solids.

The hydrolytic polycondensation of the molecular precursor 1,4-$C_6H_4[Si(OMe)_3]_2$ **1** (Scheme 1) has been studied in THF using tetrabutylammonium fluoride (TBAF) as catalyst at the −20, 3, 20 and 55 °C.† The entire experiment (addition of the reagents, gelation, aging) was performed at the given temperature. NMR and BET measurements were from the same sample.



Scheme 1

Considering the identification of the solids at the 'molecular level', ^{13}C and ^{29}Si CP MAS NMR spectra showed that no SiC bonds had been cleaved during reaction.[14,15] The ^{13}C CP MAS spectra showed the presence of the unmodified organic fragment along with some residual methoxy groups. For all solids the ^{29}Si CP MAS NMR spectra exhibited only T^1 [C–Si(OR)$_2$(OSi)], T^2 [C–Si(OR)(OSi)$_2$] and T^3 [C–Si(OSi)$_3$] substructures with no signal in the ranges δ −90 to −110 being observed. While CP MAS spectroscopy is not quantitative, it has been shown[12,16] that single pulse experiments (SPE) do not reveal any significant variation in relative peak intensities from CP MAS spectra if hydrogen atoms are absent in the direct vicinity of the studied nucleus. For the hybrid materials studied here, quantitative reliable ^{29}Si SPE MAS NMR spectra of gels obtained from **1** have been collected and compared to the ^{29}Si CP MAS NMR spectra.[12] The SPE MAS and CP MAS percentages found for the different T^x units were found to be similar. The percentages of the different substructures determined by deconvolution of CP MAS spectra (Table 1) gives a good estimation of the degree of polycondensation of the silsesquioxane network. We observe that the temperature of the hydrolysis–polycondensation reaction has no influence on the polycondensation around silicon, the relative contributions of the T^x units being very similar whatever the temperature.

Table 1 ^{29}Si CP MAS NMR data for xerogels obtained from **1**

Xerogel	*T*/°C	Site population[a] (%)			Level of condensation (%)
		T^1	T^2	T^3	
1a	−20	18	49	33	71
1b	+3	19	53	28	69
1c	+20	16	64	20	67
1d	+55	18	42	40	74

[a] Obtained by deconvolution of ^{29}Si CP MAS NMR spectra.

By contrast, specific surface areas and porosities of the xerogels appeared to be very sensitive to temperature. They were determined by 35-point adsorption–desorption isotherm plot measurements[17] and evaluated using the BET equation.[18] The determination of the porous volume by the BJH method[19,20] and evaluation of the microporous volume by the analysis of the *t*-plot diagram were performed in each case. The values of specific surface areas were very high whatever the temperature being in the range 900–1300 m^2 g^{-1}. The main influence of the temperature was observed in the porosity of the gels. The shape of the curves of the adsorption–desorption isotherms depended strongly on the temperature (Fig. 1). At low temperature [−20 °C (**1a**) and 3 °C(**1b**)], the isotherms were of type I [Fig. 1(a) and (b)] indicating a largely microporous solid with a low mesoporous contribution, though vestiges of hysteresis loops characteristic of capillary filling of mesopores were evident. The microporous volume represented 40–55% of total porous volume. The mesopores did not exhibit a narrow pore size

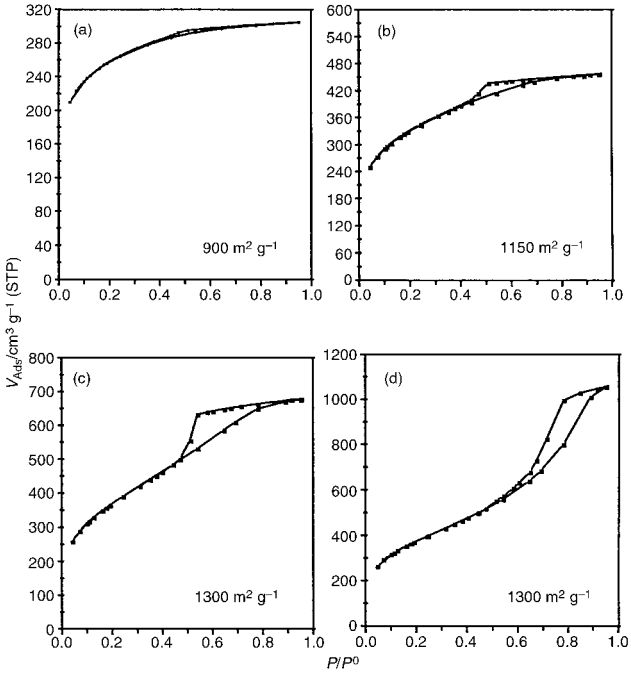


Fig. 1 N_2 adsorption–desorption isotherms of xerogels at −20 (a), 3 (b), 20 (c) and 55 °C (d).

distribution (20–120 Å). When the temperature was raised to +20 °C (**1c**), the isotherm became characteristic of type IV [Fig. 1(c)]. The microporous volume was 10% and the mesopore size lay in the range 20–120 Å. At +55 °C (**1d**), only 5% of micropores were present and mesopores showed a narrow pore size distribution (55–70 Å) characteristic of isotherms of type IV [Fig. 1(d)]. The results presented here thus show the drastic influence of temperature on the texture of the xerogels variation of which allows control of the porosity of the materials. At low temperatures, solids were mainly microporous whereas at higher temperature mesoporous solids with narrow pore size distribution were obtained.

In summary, this work confirms that hybrid materials obtained by hydrolytic polycondensation are under kinetic control. The temperature appears to be a fundamental parameter which allows the control of the textural properties of the solids. However, the drastic change observed in the porosity is not correlated with any change in the degree of polycondensation at silicon which remains insensitive to the temperature. This fact suggests that textural properties such as porosity are not controlled by the process of polycondensation at silicon.

Notes and references

† *Experimental procedure*: the preparation of gels was carried out according to the following general procedure. The precursor **1** was analytically pure (Anal. Calc. for $C_{12}H_{22}O_6Si_2$: C, 45.26; H, 6.96; Si, 17.64. Found: C, 44.88; H, 6.91; Si, 17.41%). The preparation of xerogel **1a** is given as an example. To 2.86 g (9 mmol) of **1** in 9 ml of dry (distilled over Na) THF (3 μmol H_2O/ml measured by the Karl Fisher method) was added at −20 °C a solution in 8.40 ml of dry THF of 90 μl (90 μmol) of TBAF (in THF, $[F^-]$ = 1 mol l^{-1} as measured by electrochemistry[21]) and 486 μl (27 mmol) of H_2O. The mixture was kept at −20 °C and after 90 min a monolithic gel had formed. After further aging for 6 days at −20 °C, the solid was collected, ground and washed twice with ethanol, acetone and diethyl ether. The resulting solid was dried at 120 °C *in vacuo* for 3 h yielding 1.70 g of a white powder **1a**. CP MAS NMR: ^{13}C, δ 133.6 (aromatic C), 50.7 (residual OMe); ^{29}Si, δ −62.0 (T^1), −69.5 (T^2), −78.0 (T^3).

Received (in Cambridge, UK) 21st July 1999, Accepted 10th September 1999

The first synthesis and Z-scan measurements of an octupolar polymer with off-resonant third order nonlinear optical properties are discussed; two other new molecular thiophene-based octupoles with similar nonlinearities are also reported.

In the quest for materials suitable for electro-optical and all-optical devices,[1] the last decade has witnessed considerable interest in the quadratic nonlinear optical (NLO) properties of organic or organometallic octupolar molecules.[2] Such octupolar compounds with multi-directional charge-transfer transitions enlarge the scope of molecular engineering for nonlinear optics,[3] previously restricted to dipolar compounds with single-directional charge-transfer transitions. Improving the NLO efficiency/transparency (or figure-of-merit) trade-off stands out among the important goals of this approach. Indeed, the particular symmetry of octupoles may lead to a better transparency and improved stability compared with classical dipoles,[2] although the question has not been completely elucidated as yet.[4] Besides, all-optical poling, which does not require a permanent dipole, has been shown to allow for noncentrosymmetric statistical macroscopic orientation.[2]

In all-optical applications based on the optical Kerr effect, it is also of paramount importance to improve the figures-of-merit[5] (recalled below) of cubic NLO materials because high nonlinear refractive indices in dipolar organics are generally obtained *via* resonant enhancement, at the expense of large linear or nonlinear absorption losses. However, only a small number of studies have reported cubic NLO properties of octupolar compounds. Large nonlinear refractive indices have been effectively measured in only two recent works, one dealing with organic octupolar molecules[6] and the second with organometallic octupolar complexes.[7] But in both cases, resonant enhancement of the nonlinear refractive index occurred, resulting from, respectively, three- or two-photon dispersion effects associated with absorption losses.

Moreover, to the best of our knowledge, no synthesis of octupolar polymers having NLO properties has so far been reported in the literature in spite of their potential interest towards further material and device investigations.

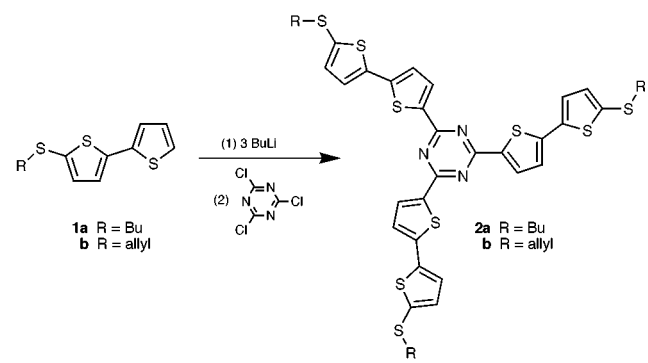
We report here the first efficient synthesis of an octupolar polymer {poly[2,4,6-tris(5′-(5-allylthio-2,2′-bithienyl-5-yl)-1,3,5-triazine]} as well as two new molecular octupoles [2,4,6-tris(5′-alkylthio-2,2′-bithienyl-5-yl)-1,3,5-triazine] which exhibit large non-resonant nonlinear refractive indices. The synthesis, UV-visible spectroscopy and Z-scan measurements of these three compounds are presented and their figures-of-merit are also discussed.

† Present Address: PPSM-Département de Chimie, Unité Mixte de Recherche CNRS n°8531, Ecole Normale Supérieure, 61 Avenue du Président Wilson, F-94235 CACHAN cedex, France.

We chose 5-*n*-butylthio-2,2′-bithiophene **1a** and 5-allylthio-2,2′-bithiophene **1b** as precursors in view of the two following assets: (i) the *n*-butyl chain of **1a** helps to increase the solubility of final molecule **2a**, and (ii) the allylthio function of **1b** can be easily homopolymerised using AIBN as a radical initiator.[8]

These two precursors **1a**,**b** were synthesised following Hill *et al.*[9] All products were purified by column chromatography with light petroleum–CH_2Cl_2 (1 : 1) as eluent. According to our earlier method,[10] octupoles **2a**,**b** were synthesised *via* a triple aromatic nucleophilic substitution of 3 equiv. of 5′-alkylthio-2,2′-bithienyl-5-yllithium salt on cyanuric chloride (see Scheme 1). Such reactions are efficient, with yields as high as 90%. The trisubstituted products **2a**,**b**‡ were only isolated because such reactions are activated by the mesomer attractive power of the three nitrogen atoms of cyanuric chloride. This electronic property stabilises the intermediate species of the aromatic nucleophile substitution. Octupoles **2** display D_{3h} symmetry. These molecules are completely planar in the absence of steric hindrance around the 1,3,5-triazine centre. Such symmetry has been confirmed by *ab initio* and semi-empirical computations as well as by electrochemical characterisation in the case of similar octupolar molecules.[11]

The new polymer **3** was synthesised in quantitative yield by radical homopolymerisation of octupolar monomer **2b** with AIBN as radical precursor (see Scheme 2). In order to obtain the pure polymer only, the reaction was continued until monomer **2b** was no longer detectable by thin layer chromatography. The crude polymer was then precipitated in Et_2O to obtain pure polymer **3**‡ as an orange–yellow powder. The octupolar character of monomer **2b** is retained during its homopolymerisation because the monomer is based on a very rigid sp^2 skeleton. All products **2** and **3** are very soluble in toluene at concentrations close to 0.1 mol l^{-1}. Also, THF is a good solvent. The polymer was analysed by SEC (THF solution, evaluation by comparison with a polystyrene standard) giving M_n = 1970 g mol^{-1}, M_w = 4800 g mol^{-1} and polydispersity =



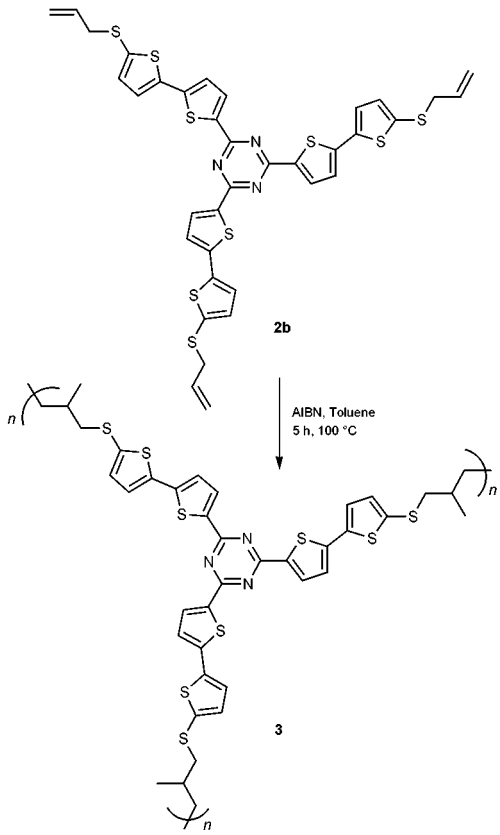
Scheme 1

2.43. Therefore, from SEC analysis, polymer **3** can be considered as an oligomer (3–6 monomers).

UV-visible spectra in toluene exhibit a single narrow linear absorption band of 30 nm width, centred at 380 and 376 nm for octupoles **2** and polymer **3**, respectively.

Z-scan measurements were performed in the picosecond range using a sensitive single-shot multi-channel method.[12] With this method, it was possible to perform closed- and open-aperture Z-scans for the same incident pulse to allow simultaneous measurements of the nonlinear refractive index and the nonlinear absorption.[13] Linearly polarised 50 ps TEM_{00} pulses at 1064 nm were delivered by a mode-locked Nd:YAG laser at a repetition rate of 10 Hz. The confocal parameter in our experimental setup was $Z = 23.5$ mm. All compounds were tested in solution (concentration 0.12 mol l^{-1}) in toluene with a 2 mm thick quartz cell. Under our experimental conditions, the nonlinear refraction of the solvent alone was beneath the baseline noise of our apparatus. The nonlinear samples were measured with an incident energy of $E = 37$ μJ and a linear transmittance[14] $S = 0.62$ for n_2 measurements (closed-aperture Z-scan) and $S = 1$ for β measurements (open-aperture Z-scan). The nonlinear refractive indices n_2 and the two-photon absorption coefficients β for all compounds were measured according to the procedure described by Sheik-Bahae *et al.*[14] The experimental data were calibrated using the standard CS_2 reference ($n_{2(CS2)} = 3.5 \times 10^{-18}$ m^2 W^{-1}).

For all three compounds, the measured relative nonlinear index $n_2/n_{2(CS2)}$ was 0.6. None of the octupoles **2** and polymer **3** exhibited detectable two-photon absorption at 1064 nm. This is in accordance with the position of the linear absorption peak wavelengths, giving a two-photon absorption band around 760 nm, far from the exciting wavelength. Hence, octupoles **2** and polymer **3** in solution have an off-resonant nonlinear refractive index close to that of pure CS_2. The expected extrapolated values n_2 for the solutes are close to the best off-resonance nonlinear refractive index data reported for single crystal polydiacetylene toluene-*p*-sulfonate (PTS)[15] ($n_2 = 2.2 \times 10^{-16}$ m^2 W^{-1} @ $\lambda = 1600$ nm). However, one should keep in mind that the extrapolation from solution to the solid state is not straightforward. Nonlinear refraction and absorption measurements on thin solid films of the new polymer **3** are currently being performed so as to investigate this critical issue.



Scheme 2

Stegeman *et al.*[5] defined two figures-of-merit, $W = n_2 I/\alpha\lambda$ and $T = \lambda\beta/n_2$, to assess the suitability of a cubic NLO material for realistic all-optical applications based on the optical Kerr effect. The two criteria, $W >> 1$ or $T << 1$, must be satisfied whether the nonlinearity and the losses in the material are dominated by linear or two-photon absorption, respectively. As no linear (α) or two-photon (β) absorption has been detected in our measurements, we have introduced the limit sensitivities ($\alpha_{min} < 0.05$ m^{-1} and $\beta_{min} < 2 \times 10^{-12}$ m W^{-1}) of our experimental setup. For compounds **2** and **3**, this yields $W > 2200$ and $T < 1$ as an estimation of the lower and upper limits of the figures-of-merit *W* and *T*, respectively. All three materials in solution exhibit very good figures-of-merit. Moreover, the photostability of the polymer in solution has been found to be very satisfactory up to energies per pulse of 120 μJ, *i.e.* intensities up to 18 GW cm^{-2}, corresponding to the damage threshold of the quartz cell.

In conclusion, we have reported the synthesis of the first octupolar polymer and two new octupolar thiophene-based molecules, which exhibit off-resonant third order NLO properties. Due to the absence of detectable linear and nonlinear absorption at 1064 nm, the figures-of-merit are good. Moreover, no modification with respect to the nature of the substituant has been detected on the nonlinear refractive index and on the linear and two-photon absorption properties.

The authors thank Dr A. J. Attias (DMSC, ONERA, France) for his help with the polymer characterisation by SEC.

'Sticky' gold colloids through protection–deprotection and their use in complex metal–organic–inorganic architectures†

Marcus Bartz, Nicole Weber, Jörg Küther, Ram Seshadri‡ and Wolfgang Tremel*

Institut für Anorganische und Analytische Chemie, Johannes Gutenberg-Universität Mainz, Duesbergweg 10-14, D-55099 Mainz, Germany. E-mail: tremel.wolfgang@t-online.de

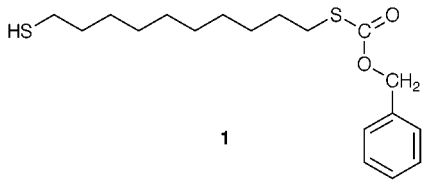
Received (in Oxford, UK) 17th August 1999, Accepted 1st September 1999

Exposing bare gold colloids to long-chain dithiols results in their precipitation owing to cross-linking of the thiol groups with gold surfaces; here, we demonstrate that through the use of a dithiol that has one of the thiol groups protected, we can, through attachment followed by deprotection, prepare gold colloids with exposed thiol; the uses of such 'sticky' colloids in creating complex architectures is demonstrated by using them to template the growth of PbS particles.

The notion that gold colloids in the nanometre range provide surfaces on which thiol self-assembly can be achieved has been employed by us for a variety of new functionalizations. Using suitable thiols, we have, for example, attached polymerization catalysts on colloid surfaces.[1] The use of thiol monolayer surfaces on gold in templating the crystallization of inorganic minerals such as calcium carbonate[2,3] has been extended by us to the use of thiol-coated colloids as crystallization nuclei.[4,5] This has opened a new dimension of surface-templated crystallizations since a dispersed, spherical colloid offers a very different geometry from a large, planar surface.

In coating gold colloids with thiols in solution, there are a few points that need to be examined. The first is that the thiol should protect the colloid and keep it in solution. The second is that the surface functionality of the thiol (the ω group on the long chain) should be compatible with the use to which the colloids are put. For example, in a previous work, we used long chain glycol-based thiols to take colloids into aqueous solution but the surfaces so formed on the colloids inhibit the crystallization of calcium carbonate.[5] We have been interested in coating dithiols on gold colloids since particles so coated would offer an SH functionality on the surface (the ω group) that would be compatible with inorganic sulfides. However, if dithiols are added to a gold colloid sol, immediate precipitation results owing to the cross-linking of the thiols with the colloid surfaces.[6]

The strategy that we present here borrows from peptide chemistry and uses a protection group for the thiol functionality.[7] We have prepared half-protected dithiols **1** with $n = 6$,



1

10 and 12.§ The self-assembly of these thiols on flat gold surfaces and the possibility to deprotect the ω thiol functionality with aq. NH_3 has been established using surface plasmon resonance spectroscopy (SPS), as has the propensity of the deprotected surface to stick gold colloids. The thiols have been assembled on gold colloids¶ in a toluene solution. The colloids are precipitated by and washed with methanol followed by redissolving them in CH_2Cl_2 where the protecting group is removed with aq. NH_3. These 'sticky' colloids are then dissolved in THF and PbS‖ is deposited around them. The templated growth of PbS particles on SAM surfaces has been studied extensively by Meldrum *et al.*[8]

Fig. 1 displays the SP spectra** of a clean gold surface and the surface after various steps of thiol self-assembly, deprotection, exposure to colloids, *etc.* as explained in the figure caption and associated scheme. These establish the possibility to deprotect the surface as well as to subsequently stick gold colloids on it. Fig. 2 displays SE micrographs of PbS particles grown from THF solutions in the absence (a) and in the presence of dithiol-coated gold colloids (b,c). The thiol group in Fig. 2(b) is still protected so the significant modification in the morphology of the particles and their spherical shape, suggests that the particles are grown around the colloids with unprotected thiol groups in (c). At the present time, we are unable to establish whether it is a single colloidal particle that nucleates the growth of a PbS shell or a cluster of particles. We have determined that it is not the thiol alone that results in the morphologies displayed in (c) (through the inhibition of certain surfaces for example) so the colloid does play a critical role. Attempts to understand the nature of the architecture through the preparation of smaller shells and the use of TE microscopy are under way.

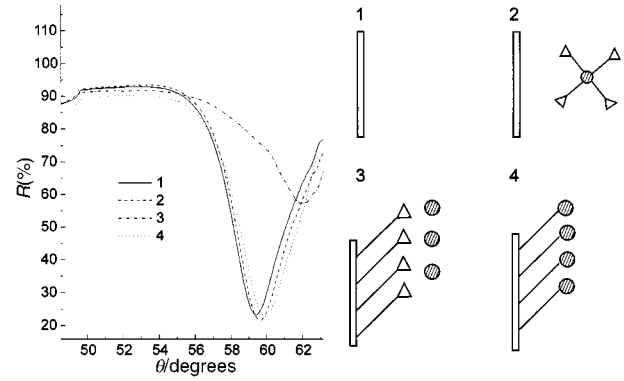


Fig. 1 Surface plasmon spectra of a clean gold surface (1), a clean gold surface exposed to protected gold colloids (2), a gold surface modified with the half protected decanedithiol and exposed to bare gold colloids (3) and a gold surface after deprotection of the dithiol and exposure to bare gold colloids (4). The schemes on the right correspond to the different SP spectra with rods indicating the thiol, spheres the gold colloids, and triangles the protecting groups.

PbS is a semiconductor and the thiol layer is insulating. We recognize links between the structures of MOSFETs (Metal oxide semiconductor based field effect transistors) and of the metal colloid, thiol, PbS architectures presented here. The materials that are the subject of the present work could perhaps be referred to as 'MOSFETs in a test tube'.

We thank Professor W. Knoll (Max-Planck-Institut für Polymerforschung Mainz) for help and encouragement and Dr F. C. Meldrum for preliminary TEM studies. Degussa AG is thanked for a generous gift of chemicals. R. S. would like to acknowledge the RSC for a Journals Grant.

† Dedicated to Professor Felsche on the occasion of his 60th birthday.

‡ Present address: Solid State & Chemistry Unit, Institute of Science, Bangalore 560 012, India.

The crystals so formed correspond to the cubic system of lead sulfide; (b) image of products crystallizing in the presence of protected gold colloids; (c) round particles found after crystallization of PbS in the presence of unprotected gold colloids.

Notes and references

§ The dithols were prepared from 1,*n*-dibromo alkanes using the Bunte Salt method.[1,9] The protection of one of the thiol groups using the benzoyloxocarbonyl group was achieved using a procedure of Scott and Harrison after modification.[10] Briefly, to the dithiol (5 g) in acetone (50 ml) with 2 M NaOH in water (60 ml), benzoyloxycarbonyl chloride (2.8 g) in acetone (20 ml) and 2 M NaOH (40 ml) in water were added simultaneously dropwise, over 30 min while cooling with ice. After stirring overnight at room temp. the acetone was removed and the residue was worked up with diethyl ether. The organic layer was separated and chromatographed on silica to separate **1** from the unprotected and diprotected compounds.

¶ Gold colloids were prepared in toluene following the method of Brust *et al.*[11] Deprotection could be carried out with aq. NH_3 (40 ml) in CH_2Cl_2 (40 ml), stirring overnight. The deprotected colloids in the organic layer were collected after removing the solvent and dissolved in THF for the crystallization experiments.

‖ Crystallization of PbS was carried out using an aqueous solution (3 mmol) of $PbNO_3$ (3 ml) in THF (100 ml) and deprotected gold colloids (0.1 g) were added. After glass slides were placed at the bottom of the vessel it was exposed to an H_2S-atmosphere in a desiccator for 24 h. The solvent was removed and the glass slides were dried at room temperature. The material collected on the slides were studied by X-ray diffraction (Siemens D5000, transmission, Cu-Kα_1 radiation) to confirm the NaCl structure of PbS and by SE microscopy (Zeiss DSM 962).

** SPS measurements were performed in the Kretschmann configuration.[12] Optical coupling was achieved with a LASFN9 prism (n = 1.85 at λ = 632.8 nm) and index matching fluid (n = 1.70) between the prism and the BK270 glass slides. The plasmon was excited with p-polarized radiation using a He–Ne laser (632.8 nm, 5 mW). The glass slides were cleaned with aq. NH_3–H_2O_2–water (1:1:7) for 10 min at 80 °C and coated with gold using a Balzers BAE250 vacuum coating unit under a pressure of $< 5 \times 10^{-6}$ hPa, typically depositing 48 nm of gold after first depositing 2 nm of Cr. The slides were exposed to the organic thiol solution (10 mmol) for 24 h.

Hyperbranched chiral catalysts for the asymmetric reduction of ketones with borane

Carsten Bolm,* Nadine Derrien and Andreas Seger

Institut für Organische Chemie, RWTH Aachen, Professor-Pirlet-Strasse 1, D-52074 Aachen, Germany. E-mail: carsten.bolm@oc.rwth-aachen.de

Received (in Liverpool, UK) 28th July 1999, Accepted 6th September 1999

Optically active dendritic amino alcohols catalyse the enantioselective borane reduction of ketones with good yields and high enantiomeric excesses.

Dendrimers represent a new class of polymeric compounds which are distinguished from traditional polymers by their unusual fractal-like architecture.[1] Due to their unique characteristic features they appear attractive for applications in the fields of biology and materials sciences as well as for use in homogeneous catalysis.[2,3] For enantioselective catalysis chiral dendrimers[4] are required; as yet, however, very few dendritic chiral catalysts have been described.[5–11] In a recent study we reported on the synthesis of chiral dendrimer-bound pyridyl alcohols and their application in the asymmetric addition of diethylzinc to benzaldehyde.[11] Various generations of these hyperbranched chiral catalysts (hccs) were tested, and gratifyingly, no significant loss of catalyst activity and enantioselectivity was observed, when compared to catalysis with the parent pyridyl alcohol. Thus, even in reactions with higher hcc generations the resulting secondary alcohols were obtained in satisfying yields, having ees of up to 86%. Considering possible applications of dendritic chiral catalysts in continuously operated membrane reactors,[3e,12] we also envisioned other strategies for the synthesis of optically active alcohols. Here, we report the first use of dendritic catalysts for the enantioselective borane reduction of prochiral ketones leading to the desired products with up to 96% ee.

Readily available building block (*S*)-**1** was chosen as a chiral unit, since high catalytic efficiency and convenient applicability of various compounds containing **1** had been elegantly demonstrated by Itsuno *et al.*[13,14] In addition, results of catalyses with polymer-supported **1** under homogeneous[12a] and heterogeneous[14] conditions could serve as reference points. Chiral dendrimers (*S*)-**2** to (*S*)-**5** were synthesised in good yields by the convergent-growth approach introduced by Hawker and Fréchet[15] using (*S*)-2-amino-3-(*p*-hydroxyphenyl)-1,1-diphenylpropan-1-ol (**1b**) and appropriate polyether wedges derived from 3,5-dihydroxybenzyl alcohol or 4,4-bis(4′-hydroxyphenyl)pentanol, respectively.[16]

The asymmetric borane reductions[17] were studied under the following conditions: 10 mol% of dendritic amino alcohol (*S*)-**2** to (*S*)-**5**, BH_3•SMe_2 as reductant, THF as solvent, at room temperature. Various prochiral substrates were used, and the results are summarised in Table 1.

In general, excellent ketone conversion was achieved, and the corresponding optically active alcohols were obtained in good yields (> 75%). The enantioselectivities were high (81–96% ee), and reductions of alkyl aryl ketones led to the predominant formation of the (*R*)-configured products. Compared to the parent systems containing **1**, all hccs performed well. For example, even with stoichiometric amounts of **1a** only 87% ee had been achieved in the reduction of acetophenone.[13] Here, with 10 mol% of catalyst (*S*)-**4**, (*R*)-1-phenylethanol was obtained with 91% ee. Among all hccs evaluated in this reaction (Table 1, entries 1–4), (*S*)-**4** was the best catalyst in terms of yield and ee. Presumably, the higher rigidity of the dendritic backbone in **2** and **3** and the increased steric crowding in the

higher-generation catalyst **5** led to product formation with slightly reduced enantioselectivity.

The highest ee values were found in reductions of α-chloroacetophenone giving the corresponding alcohol with up to 96% ee (Table 1, entries 11 and 12). These results are particularly important because α-(chloromethyl)benzyl alcohol is a valuable precursor for the synthesis of phenyloxirane.[18]

The potential of these new dendritic catalysts which operate homogeneously is also highlighted by the fact that under heterogeneous conditions with polymeric **1c** significantly lower enantioselectivities were achieved (*cf.* acetophenone: 76% ee; propiophenone: 79% ee; α-chloroacetophenone: 84% ee).[14,19]

In summary, we have demonstrated the feasibility of performing highly enantioselective borane reductions of prochiral ketones using dendritic catalysts (hccs), and we are currently investigating their possible applications in continuously operating reactor systems.[20,21]

We are grateful to the Bundesministerium für Forschung und Technologie (BMFT) and the Fonds der Chemischen Industrie for financial support of this work. We thank the Degussa-Hüls for the generous donation of chemicals.

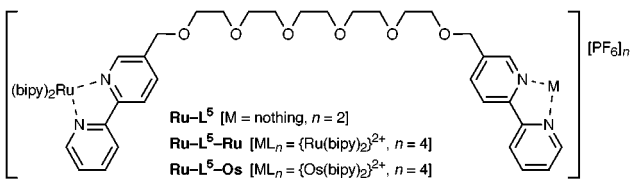
Received (in Basel, Switzerland) 18th August 1999, Accepted 13th September 1999

Solvent-dependent conformational changes of a poly(oxoethylene) bridge linking $[Ru(bipy)_3]^{2+}$ and $[Os(bipy)_3]^{2+}$ units can be probed by measuring the extent of Ru→Os photoinduced energy transfer.

Photoinduced energy-transfer between Ru(II) and Os(II) polypyridine units across nanometric bridging ligands has been extensively studied recently,[1–5] largely because of the relevance of such complexes to potential applications such as light energy collection and conversion[5] and luminescence-based sensors and switches.[6–8] In such complexes the bridging ligand is of fundamental importance. It can be either geometrically rigid or flexible, so that the distance between the photoactive partners may be fixed or may vary; and it may contain electronically conducting or insulating units. In some cases, some units of the bridge can also interact with the environment, so that modulation or switching of the Ru→EOs energy transfer process can be observed.[2]

We describe here a Ru(II)/Os(II) dyad in which the two metal components are separated by a flexible poly(oxoethylene) chain derived from penta(ethylene glycol).† In these complexes the



conformation of the poly(oxoethylene) chain is expected to be solvent dependent, based on the known properties of poly(ethylene glycol)[9] and various simple model compounds,[10] and this in turn is expected to lead to controllable variation of the metal–metal separation, d_{MM}. In this study, by using steady-state and time-resolved luminescence measurements, we show that for **Ru-L^5-Os** the Ru→Os energy transfer can indeed be influenced by the solvent and we ascribe this effect to differences in the conformation of the poly(oxoethylene) chain.[11]‡

Table 1 lists some spectroscopic and photophysical properties for the mononuclear model complex **Ru-L^5**, and the heterodinuclear complex **Ru-L^5-Os**, as obtained in neat MeOH (protic) and CH_2Cl_2 (aprotic) solvents. Fig. 1 compares the luminescence spectra obtained by exciting samples of **Ru-L^5-Os** in mixed MeOH–CH_2Cl_2 solvent of varying proportions. The excitation wavelength was 450 nm so that both the Ru and Os-based chromophores were excited, approximately in a 1:0.8 ratio, (Table 1). The luminescence spectra of **Ru-L^5-Os** (Fig. 1) feature two band maxima, occurring in the ranges 600–606 and 710–715 nm. The relative intensities of these are consistent with the occurrence of partial quenching (*ca.* 90%) of the Ru unit, owing to Ru→Os energy transfer (ΔG *ca.* −0.3 eV). Thus, the band at *ca.* 600 nm is due to a residual Ru-based emission, and the band at *ca.* 710 nm is Os-based, with a luminescence intensity which includes contributions from both direct excitation and Ru→Os sensitisation. It will be seen that as the solvent polarity decreases (from MeOH to CH_2Cl_2), the Ru-based emission relatively decreases in intensity with respect to the Os-based emission, consistent with improved Ru→Os energy transfer arising from a shorter metal–metal separation.

This was confirmed by analysis of the time-resolved luminescence decay of **Ru-L^5-Os**, which was measured in the same mixed-solvent system at the wavelengths of the two emission band maxima. At 600 nm a single (Ru-based) exponential decay was found; at 710 nm the Os-based decay took place according to a dual exponential law, with a rise time and a decay time. We found that in each case the Ru-based decay time (obtained at 600 nm) corresponds to the Os-based rise time (observed at 710 nm), consistent with the occurrence of Ru→Os energy transfer. Also, on the basis of $k_{en} = 1/\tau_q - 1/\tau$ we can obtain the Ru→Os energy transfer rate constant as a function of solvent composition (τ is the lifetime of the reference complex, **Ru-L^5**). The results are shown graphically

Table 1 Spectroscopic and photophysical data[a]

	Absorption		Emission[b]		
	λ_{max}/nm (10^{-3} ε/dm^3 mol^{-1} cm^{-1})		λ_{max}/nm	10^2 Φ	τ/ns
MeOH					
Ru-L^5	287 (90.0)	450 (13.4)	604	1.6	240
Ru-L^5-Ru	287 (147)	450 (27.6)	606	1.5	210
Ru-L^5-Os	289 (145)	450 (24.6)	606,[c] 715[d]		18.8,[c] 32[d]
CH_2Cl_2					
Ru-L^5	287 (97.0)	453 (14.4)	598	3.3	410
Ru-L^5-Ru	288 (145)	452 (27.6)	600	3.5	405
Ru-L^5-Os	289 (150)	452 (26.6)	600,[c] 710[d]		5.8,[c] 65[d]

[a] Room temperature, in the indicated air-equilibrated solvents. Sample concentrations were 2×10^{-5} M. [b] Excitation wavelength 450 nm. The emission maxima (±2 nm) are from uncorrected spectra. Quantum yield values (±20%) are from corrected spectra. Lifetimes are accurate to ±8%. [c] Ru-based luminescence. [d] Os-based luminescence.

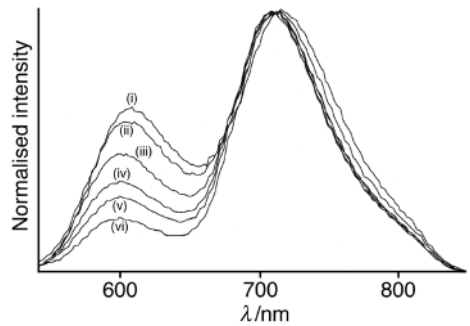


Fig. 1 Normalised luminescence spectra of **Ru-L^5-Os** in mixed MeOH–CH_2Cl_2 solvents (spectroscopic grade) of proportions (MeOH–CH_2Cl_2): (i) 100:0; (ii) 80:20; (iii) 60:40, (iv) 40:60; (v) 20:80; (vi) 0:100. The solutions were isoabsorptive at the excitation wavelength (450 nm) and the spectra are normalised to the Os-based emission.

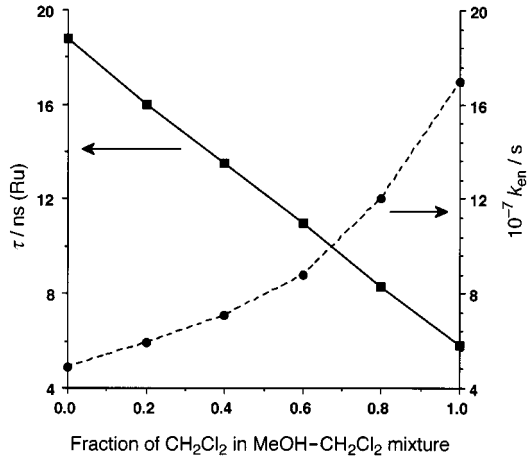

Fig. 2 Photophysical behaviour of **Ru-L^5-Os** in mixed MeOH–CH_2Cl_2 solvents, showing the steady decrease of Ru-based emission lifetime (squares, solid line) and the concomitant increase in Ru→EOs energy-transfer rate constant (circles, dashed line) as solvent polarity decreases.

in Fig. 2. It is clear that improved quenching of the Ru emission as the solvent polarity decreases is accompanied by improved Ru→Os energy transfer. The extent of quenching for the Ru-based emission in **Ru-L^5-Os** is therefore solvent dependent, being maximised in neat CH_2Cl_2. As a control experiment, a 1:1 mixture of **Ru-L^5** and $[Os(bipy)_3]^{2+}$ (each 2×10^{-5} M) resulted in no detectable quenching of the Ru-based luminescence, confirming that intermolecular effects are not significant, as would be expected at these low concentrations.

Two possible mechanisms, exchange and dipole–dipole, can be invoked to account for Ru→EOs energy transfer.[12] It is well documented that through-bond, two-electron exchange is likely to be involved for cases where the bridging ligand is highly unsaturated,[1,2,4] because the energetically accessible HOMO and LUMO orbitals of the bridge provide a pathway linking the appropriate metal orbitals.[13] In contrast, saturated units behave like insulators towards electronic communication because the HOMO–LUMO energy separation is large. EHMO calculations on the poly(oxoethylene) chain [taken as $Me(OCH_2CH_2)_5OMe$] indicate that its HOMO–LUMO energy gap (32 eV) is comparable to that of the corresponding hydrocarbon chain [taken as $Me(CH_2)_{16}Me$] (41 eV),[14] so the amount of the intermetal electronic communication mediated by the bridging ligand L^5 is expected to be negligible. On this basis, we ascribe the occurrence of energy transfer in **Ru-L^5-Os** to the dipole–dipole (Förster) mechanism, [eqn. (1)].[12]

$$k_{en}^{F} = \frac{8.8\times10^{-25}K^2\Phi}{d_{MM}{}^6 n^4 \tau} J^F \qquad (1)$$

where Φ and τ are the luminescence quantum yield and lifetime, respectively, of the energy donor (**Ru-L^5**); J^F is the integral overlap between the luminescence spectrum of the donor (Ru chromophore) and the absorption spectrum of the acceptor (Os chromophore), K^2 is a geometric factor (taken as 2/3), and n is the refractive index of the solvent. From eqn. (1) and by using the pertinent spectroscopic (Table 1) and calculated parameters ($J^F = 4.7 \times 10^{-14}$ cm^6 mol^{-1} in both solvents), we conclude that $d_{MM} = 15$ and 12 Å in neat MeOH and CH_2Cl_2, respectively. These values may be compared with the calculated[14] end-to-end distance of 22 Å for the fully extended ligand L^5.

This solvent-dependence of the bridging ligand conformation is exactly consistent with the known behaviour of both poly(ethylene glycol)[9] and simple model compounds such as dimethoxyethane.[10] In these molecules the conformation about the central C–C bond of the OCH_2CH_2O unit is predominantly *trans* in a low-polarity medium, but predominantly *gauche* in a high-polarity medium. The *gauche* conformation, which results in a higher dipole moment for the poly(oxoethylene)chain, is also associated with a more expanded structure for the chain—in exact agreement with our observations.

In conclusion, with **Ru-L^5-Os** we have used Ru→EOs energy transfer as a diagnostic tool for probing solvent-specific conformational properties of a flexible bridging ligand. This is an appealing way of providing quantitative information on the conformations of soluble polymers, an area of considerable importance.[9] Work is also in progress to probe the use of metal cations to control the conformation of the bridging ligand and hence the metal–metal interaction.[15]

We thank the European Community for a post-doctoral fellowship (S.E., contract no. 980226) and for a COST award (COST-D11-0004/98), and the EPSRC (UK) for a post-doctoral fellowship (N.C.F.).

Notes and references

† *Preparations*: L^5: penta(ethylene glycol) (0.310 g, 1.26 mmol) in dry THF (100 ml) was treated with NaH (60% dispersion in mineral oil; 0.40 g, 10.0 mmol) and stirred at room temp. for 40 min. When effervescence ceased, 5-bromomethyl-2,2′-bipyridine (1.30 g, 5.20 mmol) was added, and the mixture was refluxed for 24 h. After removal of the solvent the brown residue was chromatographed on silica, eluting with 10% methanol in CH_2Cl_2, to give the product (the second major fraction off the column) as a clear oil after removal of the solvent. Yield 0.704 g, 97%.

$[Ru(bipy)_2(L^5)][PF_6]_2$ **Ru-L^5**: reaction of L^5 (327 mg, 57 μmol) and $[Ru(bpy)_2Cl_2]\cdot 2H_2O$ (240 mg, 0.46 mmol) in EtOH at reflux for 3 h afforded an orange–red solution. Chromatography on Sephadex-SP25, eluting with 0.3 M aqueous NaCl, afforded a red band from which **Ru-L^5** precipitated on addition of NH_4PF_6: yield, 0.262 g (35%). Also isolated was the dinuclear complex $[\{Ru(bipy)_2\}_2(L^5)][PF_6]_4$ **Ru-L^5-Ru** (eluted with 0.5 M aqueous NaCl); yield, 0.088 g (9%).

$[(bipy)_2Ru(L^5)Os(bipy)_2][PF_6]_4$ **Ru-L^5-Os**: A mixture of **Ru-L^5** (74.6 mg, 0.58 mmol) and $[Os(bpy)_2Cl_2]$ (60 mg, 98 μmol) were heated together at 120 °C for 24 h in ethylene glycol (10 ml). The reaction mixture was cooled, added to water (100 ml) and introduced onto Sephadex SP25, and the primary green band eluted with 0.55 M aqueous sodium chloride solution. The product was precipitated with NH_4PF_6 and collected on Celite. The nearly pure compound was further purified by chromatography on Sephadex-LH20 eluting with acetone–methanol (1:1) to give pure **Ru-L^5-Os**: yield; 84.3 mg (70%). Satisfactory ^{1}H NMR and mass spectroscopic data, and elemental analyses, have been obtained for all new compounds.

‡ The solvent-dependent conformation of a polypeptide chain has been exploited to modulate photoinduced electron-transfer between covalently linked $[Ru(bipy)_3]^{2+}$ (donor) and fullerene (acceptor) units: see ref. 11.

Synthesis and structure of η^5-bonded pyrrolyl complexes of calcium and strontium

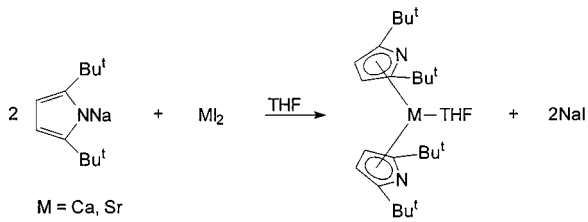
Herbert Schumann,* Jochen Gottfriedsen and Jörg Demtschuk

Institut für Anorganische und Analytische Chemie der Technischen Universität Berlin, Straße des 17. Juni 135, D-10623 Berlin, Germany. E-mail: schumann@chem.tu-berlin.de

Calcium and strontium diiodide react with 2,5-di-*tert*-butylpyrrolylsodium in THF yielding [M(pyr*)$_2$(THF)] (M = Ca, Sr; pyr* = NC$_4$H$_2$Bu$^t_2$-2,5) for which NMR spectra and the X-ray structures confirm the η^5-bonding character of the ligands.

2,5-Di-*tert*-butylpyrrolyl (pyr*) complexes of some main group elements (Pb, Sn), transition metals (Ti, Fe, Co), and lanthanides (Nd, Sm, Tm, Yb, Lu) are already known.[1,2] In all these complexes, the pyr* ligand coordinates to the metal atom in an η^5-π-bonding fashion. The two bulky *tert*-butyl substituents at the 2,5-carbon atoms of the pyr* ring prevent a σ-donor coordination of the pyrrolyl nitrogen atom to the corresponding metal. Another coordination mode of the pyr* ligand was established for a binuclear zinc complex in which a pyr* ligand is bridging the two metal centers by forming a σ-N donor bond to one zinc atom and coordinating the other zinc atom by the 3,4-carbon atoms of the pyr* ring in an η^2-fashion.[3] Whereas a series of homoleptic alkyl-substituted cyclopentadienyl complexes of alkaline earth metals have been synthesized in recent years,[4] corresponding pyrrolyl (synonymous with azacyclopentadienyl) complexes of these metals have not been described until now. For this reason, we started to examine the coordination behaviour of pyr* towards alkaline earth metals and report here, the results we obtained for calcium and strontium.

The reaction of 2,5-di-*tert*-butylpyrrolylsodium with calcium diiodide or strontium diiodide (2:1 mole ratio, Scheme 1) in THF at room temperature afforded the mono-THF adducts of bis(2,5-di-*tert*-butylpyrrolyl)calcium and bis(2,5-di-*tert*-butylpyrrolyl)strontium [M(pyr*)$_2$(THF)] [M = Ca (**1**), Sr (**2**)], which were isolated in yields of 50% by crystallization from *n*-hexane at −20 °C. The colorless crystals of **1** melt at 113 °C, whereas those of **2** decompose at 200 °C, but sublime at 179 °C/0.5 mbar without decomposition. Both compounds are soluble in polar and non-polar solvents such as THF, diethyl ether, toluene, benzene, or *n*-hexane.



Scheme 1 Synthesis of the pyrrolyl complexes

In the NMR spectra of **1** and **2**, recorded in benzene-d$_6$, the ^{1}H/^{13}C resonances of the 3,4-CH groups of the pyr* ring show shifts of δ 6.34/105.2 for **1** and δ 6.30/104.5 for **2**. Since in the solution spectra of [Li(pyr*)(THF)$_2$][3] (the solid state structure establishes Li–N$_{pyr*}$ σ-bonds) and [Na(pyr*)][2b] (no solid state structure determined) the corresponding signals appear at δ 5.61/96.8 and δ 5.59/100.13, respectively, the low field shifts of the CH resonances of **1** and **2** are indicative of π-bonded pyr* ligands.

The single crystal X-ray structure analyses of **1** and **2** show monomers with a bent sandwich structure, thus unequivocally confirming the π-bonding nature of the pyr* ligands. Except for the different ionic radii of calcium and strontium, the two complexes are isostructural. Each structure shows two independent molecules, A and B, and each unit cell contains four molecules A, eight molecules B, and four disordered hexane (solvent) molecules. A and B differ only slightly in bond distances and angles. Molecules A possess a twofold rotation axis. In each of the four molecules **1**A,B (Fig. 1) and **2**A,B, the metal atom is seven-coordinated by two η^5-π-bonded pyr*

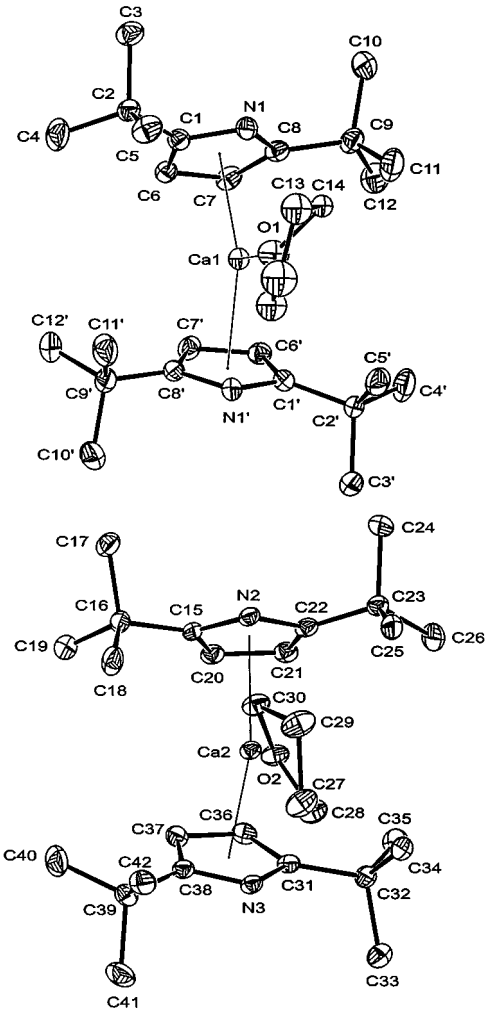


Fig. 1 ORTEP plot of the structure and numbering scheme of **1**, with 30% probability thermal ellipsoids. For clarity, all hydrogens are omitted. Selected bond lengths (Å) and angles (°) with estimated standard deviations of **1** and {**2**}: M–Cg 2.376(16)(A)/2.381(2)(B)/2.381(2)(B) {2.520(1)(A)/2.530(5)(B)/2.530(10)(B)}, M–O 2.373(4)(A)/2.389(3)(B) {2.538(6)(A)/2.533(4)(B)}; Cg–M–Cg 127.4(3)(A)/127.74(7)(B) {122.0(2)(A)/124.0(3)(B)}.

ligands and one THF molecule in a pseudo-trigonal planar arrangement. The pyr* rings are planar within limits of error with the 2,5-*tert*-butyl substituents placed above these planes away from the metal center. The pyr* ring planes form interplanar angles of 47.67 and 45.55° in **1**A and **1**B or 51.11 and 47.77° in **2**A and **2**B, with the ring nitrogen atoms situated at the 'open' side. The Cg–M–Cg angles (Cg defines the centroid of the pyr* ring) of 127° for **1**A,B or 122 and 124° for **2**A and **2**B are smaller than the $Cp_{centroid}$–M–$Cp_{centroid}$ angles in comparable cyclopentadienyl complexes, *e.g.* in $\{M[C_5H_3(SiMe_3)_2\text{-}1,3]_2(THF)\}$[5] [135° (M = Ca), 134° (M = Sr)], whereas the average M–Cg distances of 2.38 Å (**1**A,B) and 2.525 Å (*2*A,B) are in good agreement with the M–$Cp_{centroid}$ distances estimated for the above mentioned cyclopentadienyl complex [2.397 Å (M = Ca), 2.551 Å (M = Sr)]. The ring slippage towards the nitrogen atom of 0.126 Å (**1**A), 0.172 and 0.178 Å (**1**B), 0.178 Å (**2**A), and 0.214 and 0.207 Å (**2**B) indicates a certain tendency of the pyr* ligand towards an η^3-bonding mode. The third ligand, the O-coordinated THF is disordered in molecules A. The hexane solvent molecules do not have any contacts to the molecules of **1** and **2**.

Unusual desulfurization of a nickel dithiolene by bis(2-diphenylphosphinophenyl)phenylphosphine (tp) to produce Ni(tp)(R_4btimdt) [R_4btimdt = 5,5′-bis(1,3-dialkyl-4-imidazolidine-2-thione-4-thiolate], the first complex of this class of ligands

Received (in Cambridge, UK) 5th August 1999, Accepted 7th September 1999

A novel desulfurization reaction induced on the title nickel dithiolenes by a tripodal phosphine producing the first complex of the S,S-dianionic title ligand, which belongs to a novel family of redox active heterocycles, and the fully oxidised trimeric form of this ligand are described.

The interest in the [Ni(R_2timdt)$_2$] complexes **1** (R_2timdt is the −1 charged 1,3-dialkyl-imidazolidine-2,4,5-trithione)[1,2] and related derivatives,[3] is related both to their possible application as near-IR dyes,[4] and for their chemistry. In fact they are promising candidates in neodymium lasers (which operate at 1064 nm) technology, since they show low-energy electronic absorption,[4] typical of this class of complexes, at *ca.* 1000 nm with remarkably high absorption coefficients coupled with a high thermal and photochemical stability. Moreover these complexes show a rich and peculiar chemistry, being the source of a variety of unusual products including mixed-valence complexes[2] and new sulfur-rich donors which have not been obtained, as yet, by other routes.[3]

As a further example of a peculiar behaviour of this class of nickel dithiolenes, we report here, the results obtained by reacting **1** with mono- and poly-functional phosphines. While with mono- (PPh_3) or bi-functional [dppe = 1,2-bis(diphenylphosphino)ethane] phosphines the reagents are recovered unchanged, the reaction of **1** with a tri-functional phosphine [tp = bis(2-diphenylphosphinophenyl)phenylphosphine] unexpectedly produces [Ni(tp)(R_4btimdt)] (R = Bu, **2**) [R_4btimdt = 5,5′-bis(1,3-dialkyl-4-imidazolidine-2-thione-4-thiolate] according to Scheme 1.[5]

The molecular structure of [Ni(tp)(Bu_4btimdt)] **2**,[6] is shown in Fig. 1 with the corresponding atom-labelling scheme. The nickel ion is coordinated in a trigonal bipyramidal geometry with the three P atoms of the tp ligand lying on a face of the bipyramid. The chelation of tp produces the formation of two pentaatomic rings showing an 'envelope' conformation. The newly formed ligand Bu_4btimdt acts as a bidentate ligand being coordinated to the metal through the two thiolato sulfur atoms, in such a way that a heptaatomic ring including the metal is formed.

Complex **2** contains the first example of the S,S dinegative chelating ligand Bu_4btimdt, generated *in situ* by elimination of one of the two vicinal sulfur atoms on each ligand coordinated

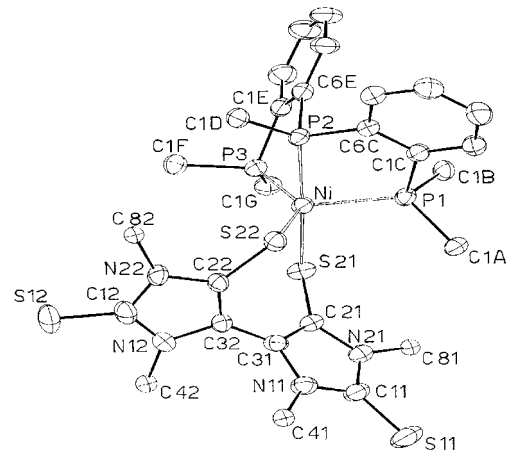

Fig. 1 Molecular structure of [Ni(tp)(Bu_4btimdt)] **2** (Bu and Ph groups omitted for clarity). Selected bond distances (Å) and angles(°): Ni–S(21) 2.270(3), Ni–S(22) 2.342(3), Ni–P(1) 2.296(3), Ni–P(2) 2.171(3), Ni–P(3) 2.203(3), S(11)–C(11) 1.686(8), S(21)–C(21) 1.710(7), S(12)–C(12) 1.698(9), S(22)–C(22) 1.745(10); S(21)–Ni–S(22) 100.5(1), S(21)–Ni–P(1) 97.6(1), S(21)–Ni–P(2) 170.0(1), S(21)–Ni–P(3) 85.9(1), S(22)–Ni–P(1) 103.5(1), S(22)–Ni–P(2) 88.4(1), S(22)–Ni–P(3) 136.5(1), P(1)–Ni–P(2) 84.7(1), P(1)–Ni–P(3) 118.4 (1), P(2)–Ni–P(3) 84.4(1).

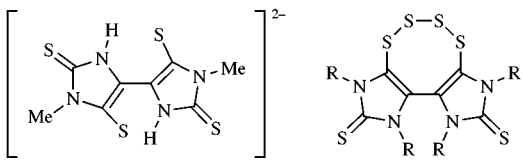
to the metal in the nickel dithiolene with concomitant C–C coupling between the two imidazole rings.

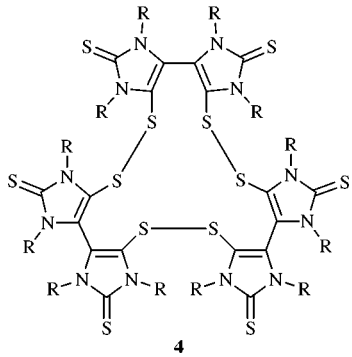
A dianion, H_2X^{2-}, belonging to the same class of Bu_4btimdt^{2-} has been obtained *via* an unusual method by reacting elemental sulfur with 1-methylimidazole.[7] This anion was isolated in the solid state as the salt $(PPh_4)_2H_2X$ structurally characterized, and proposed as a new ligand of special interest owing to its multi-electron redox properties. However, to the best of our knowledge, its coordination chemistry is still unexplored. Also a neutral compound obtained from oxidation of this ligand has been isolated but not characterized.

These ligands are related to the class of 4,5,6,7-tetrathiocino[1,2-*b*:3,4-*b*′]diimidazolyl-1,3,8,10-tetraalkane-2,9-dithiones **3**[8] which exhibit promising anticancer properties now under testing *in vivo* by National Cancer Institute of Bethesda (USA).

By reacting **3** with an alcoholate, the R_4btimdt anion is formed in solution and can be isolated in the complex [Ni(dppe)(R_4btimdt)], when [Ni(dppe)Cl_2] is added to the reaction mixture, buffered with ammonium acetate. When non-coordinated, the anion is oxygen sensitive and attempts to isolate it as a salt gave a mixture from which the new macrocycle **4** was isolated in low yield. Macrocycle **4** is prepared more conveniently (40% yield) by buffering with ammonium acetate and oxidizing the reaction mixture with O_2 or H_2O_2.[9] **4** can be considered as a trimer of R_4btimdt where the monomeric units are linked together through disulfide bridges.



H_2X^{2-} **3**



4

Crystals suitable for structural characterization were obtained for **4**·2EtOH (R = Et). Its molecular structure,[6] is shown in Fig. 2 with the corresponding atom-labelling scheme. The molecule has a twofold axis. The structural data are similar to those previously observed by us in thione derivatives with similar moieties.[2,8] Interactions of the type S···C and C···C[3.46(1)–3.79(3) Å] determine the packing so that the eighteen-membered rings of the molecules give rise to channels, parallel to *c*, which contain the guest solvent molecules.

In conclusion a novel desulfurization reaction with concomitant C–C coupling between two imidazoline rings, not reported previously, has been described. This reaction represents a promising template synthesis to prepare, starting from nickel dithiolenes, new chelating S,S-dianionic ligands, which are not easily attained by other routes.

Novel concise synthesis of 2-substituted 3,4-dihydro-2*H*-1,4-benzoxazines by ring opening of glycidols under solid-liquid phase transfer catalysis conditions†

Domenico Albanese,* Dario Landini and Michele Penso

Dipartimento di Chimica Organica e Industriale dell'Università e Centro CNR, via Golgi 19, I-20133 Milano, Italia. E-mail: domenico@iumchz.chimorg.unimi.it

Received (in Liverpool, UK) 2nd August 1999, Accepted 17th September 1999

The ring opening of glycidols with *N*-(2-fluorophenyl)toluene-*p*-sulfonamide under SL-PTC conditions, followed by ring closure with Bu^{t}OK, provides a novel high yielding synthesis of 2-substituted 3,4-dihydro-2*H*-1,4-benzoxazines.

3,4-Dihydro-2*H*-1,4-benzoxazine derivatives have received considerable attention due to their wide range of biological and therapeutic properties.[1] The 1,4-benzoxazine skeleton is usually built up by cyclocondensation of *o*-aminophenols with various dibromo derivatives[2] or α-halogeno acyl bromides.[3] Recently 2-vinyl-1,4-benzoxazines have also been prepared with ees up to 79% by reaction of (*Z*)-1,4-diacetoxybut-2-ene with *N*-protected *o*-aminophenols in the presence of a palladium catalyst associated with phospine ligands.[4,5]

Following an alternative approach we devised a novel synthesis of 2-substituted 3,4-dihydro-2*H*-1,4-benzoxazines through formation of the C–N bond by ring opening of glycidols with a suitable nitrogen nucleophile. The benzoxazine synthesis could be completed through nucleophilic aromatic substitution of a good leaving group incorporated in the incoming nucleophile. We report herein our preliminary results in this area which reveals that the new approach enables the efficient synthesis of non-racemic chiral 2-substituted benzoxazines.

In previous papers we reported on the ring opening of epoxides with nitrogen nucleophiles under solid/liquid phase transfer catalysis (SL-PTC) conditions affording corresponding β-hydroxyamides in good to excellent yields.[6,7] On the basis of these results and due to the good nucleofugality of fluoride anion in aromatic nucleophilic substitution, *N*-(2-fluorophenyl)toluene-*p*-sulfonamide **1** was chosen as the nitrogen nucleophile incorporating the aromatic moiety of benzoxazine and the leaving group.

Thus, the ring opening was performed by stirring at 90 °C a heterogeneous mixture of 1,2-epoxy-3-phenoxypropane **2a**, sulfonamide **1** (1.1 equiv.), anhydrous K_2CO_3 (0.1 equiv.), $BnEt_3NCl$ (0.1 equiv.) and dioxane, affording *N*-(2-fluorophenyl)-*N*-(2-hydroxy-3-phenoxypropyl)toluene-*p*-sulfonamide **3a** in 95% yield after 17 h (Scheme 1). The optimisation of reaction conditions (Table 1) led us to discover that the best results were obtained without solvent, giving 94% of **3a** after 1 h. The PTC agent is essential in order to give high yields in short reaction times since 56 h were necessary to generate 86% of **3a** in the absence of $BnEt_3NCl$.

Table 1 Synthesis of β-hydroxysulfonamide **3**[a]

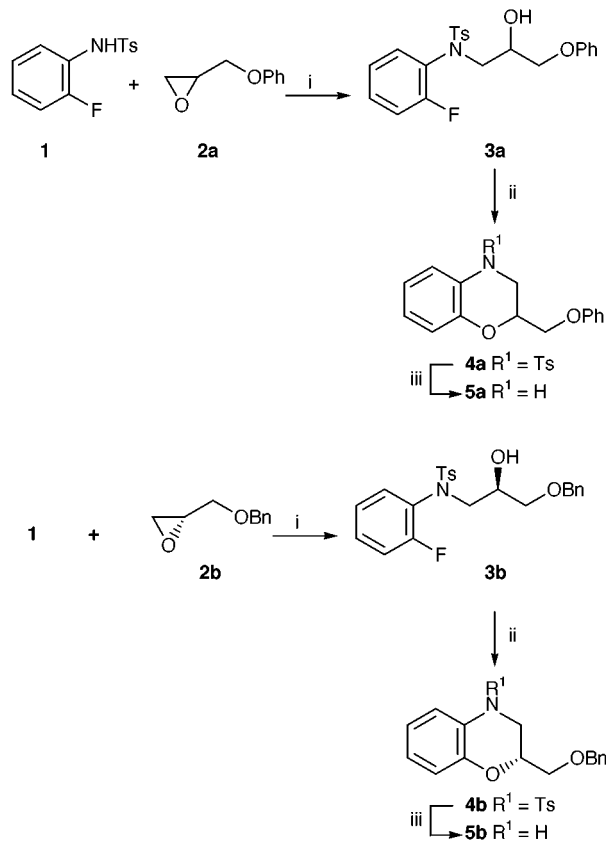
Entry	Epoxide	Dioxane/M	*t*/h	Yield (%)[b]
1	**2a**	2.5	17	95
2	**2a**	10	3	85
3	**2a**	—	1	94
4	**2a**	—	56	86[c]
5	(*S*)-**2b**	—	2	90

[a] All reactions carried out using 1.1 equiv. of sulfonamide **1**, 0.1 equiv. of $BnEt_3NCl$ and 0.1 equiv. of anhydrous K_2CO_3. [b] Isolated yield. [c] Without $BnEt_3NCl$.

† Experimental and spectral data for **3a**,**b**, **4a**,**b** and **5a**,**b** are available from the RSC web site, see http://www.rsc.org/suppdata/cc/1999/2095/

The ring opening takes place in a completely regioselective fashion, affording β-hydroxysulfonamides derived from the nucleophilic attack on the less substituted carbon atom of the oxirane ring. In accordance with the observed regiochemistry, non-racemic chiral glycidols generate enantiopure β-hydroxysulfonamides, as revealed in the case of (2*S*)-[(benzyloxy)methyl]oxirane (*S*)-**2b** which generates (2*R*)-*N*-(2-fluorophenyl)-*N*-(2-hydroxy-3-benzyloxypropyl)toluene-*p*-sulfonamide-(*R*)-**3b** in 90% yield after 2 h.‡

With a viable route to β-hydroxysulfonamides **3** in hand, it remained to perform the ring closing step to demonstrate the utility of this strategy. The 1,4-benzoxazine ring can be formed by intramolecular nucleophilic substitution (S_Ni Ar) of fluoride anion promoted by a suitable base. In particular the base should selectively generate the alkoxide anion without direct substitution of fluoride. Only isolated examples of S_Ni Ar of fluoride anion by thiolate[8] or phenolate anion[9] have been reported along with a single example of bromide substitution by phenolate.[10] The task was achieved with a cheap non-nucleophilic strong base such as Bu^{t}OK. In fact *N*-tosyl-2-phenoxymethyl-



Scheme 1 *Reagents and conditions*: i, K_2CO_3–$BnEt_3NCl$, 90 °C; ii, Bu^{t}OK, THF, reflux; iii, Na, naphthalene, DME, −78 °C.

1,4-benzoxazine **4a** was isolated in 85% yield when reacted with Bu^{t}OK in THF for 30 min at reflux. Moreover the yield could be increased up to 92% by portionwise addition of Bu^{t}OK. Similarly (*R*)-**3b** was converted into the corresponding 1,4-benzoxazine (*R*)-**4b** in 86% yield after 1 h.

It is likely that the ring closure proceeds through a pure S_Ni Ar mechanism due to the activation exerted by the *p*-tolylsulfonyl group even though an $S_{RN}1$ or benzyne pathway cannot at the moment be ruled out.

In order to probe the scope and limitations of the process, *N*-(2-chlorophenyl)-*N*-(2-hydroxy-3-phenoxypropyl)toluene-*p*-sulfonamide **7** was prepared in 94% yield by ring opening of **2a** with *N*-(2-chlorophenyl)toluene-*p*-sulfonamide **6** as previously described. However **7** did not generate the corresponding benzoxazine when treated with Bu^{t}OK.

Removal of the *N*-tosyl group with Na/naphthalene[11] gave the unprotected 1,4-benzoxazines **5a,** (*R*)-**5b** in 77–84% yield. Conversion of (*R*)-**5b** into the corresponding Mosher amide confirmed that the ring closure occurs without racemisation.§

In view of the availability of a wide variety of enantiopure epoxides[12] this method provides a straightforward and new approach towards the synthesis of chiral 2-substituted 3,4-dihydro-2*H*-1,4-benzoxazines since the stereocenter of the epoxide is not affected during the ring opening and the next cyclisation occurs without racemisation.

Financial support from CNR and MURST (National Project 'Stereoselezione in Sintesi Organica, Metodologie e Applicazioni') is acknowledged.

Photophysical studies on the photochromism of *trans*-10b,10c-dimethyldihydropyrene

R. Scott Murphy, Yongsheng Chen, Timothy R. Ward, Reginald H. Mitchell* and Cornelia Bohne*

Received (in Corvallis, OR, USA) 8th July 1999, Accepted 7th September 1999

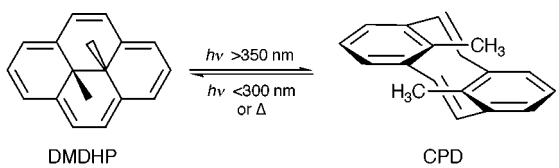
Photophysical studies on the photochromism of *trans*-10b,10c-dimethyldihydropyrene showed that several transients, including the triplet excited state of the cyclophanediene, were observed.

Dimethyldihydropyrene derivatives and their isomeric cyclophanes can be interconverted photochemically. Once the less stable isomer is formed photochemically it reverts back to the more stable form in a thermal reaction.[1] In the case of *trans*-10b,10c-dimethyldihydropyrene (DMDHP, Scheme 1), the cyclophanediene (CPD) is the less stable isomer by 3 kcal mol^{-1}.[2]

Photochromic molecules have considerable potential as optical switches.[3–5] Dimethyldihydropyrene derivatives are photochromic and have been synthetized with sophisticated multiple switching sites.[6,7] However, photophysical studies have mostly been limited to irradiation with broadband light sources. Although theoretical studies have discussed the possible intermediates involved in the isomerization reaction,[2,8] experimentally no studies have been reported on the detection of reactive intermediates. The latter is the subject of this report.

DMDHP was synthesized as previously described.[9] Its absorption spectrum extends up to 650 nm,[10] and when excited (PTI QM-2 fluorimeter) at 470 nm its fluorescence centered at 640 nm was observed. The energy for the S_1 state is 44 kcal mol^{-1},[11] and its geometry is similar to that of the ground state since no wavelength shift was observed between the emission maximum and the absorption maximum at the longest wavelength. The CPD absorption is shifted to the blue because this molecule is less conjugated than DMDHP and the S_1 energy is higher than 80 kcal mol^{-1}.

Laser flash photolysis[12] was employed to obtain the transient spectra for DMDHP. A flow cell was used to ensure that a fresh solution was irradiated for each laser pulse. Irradiation of DMDHP at 355 nm led to a bleaching at wavelengths longer than 300 nm and the detection of transients in the 250–320 nm region (Fig. 1). No transient signals were detected between 550 and 650 nm. Upon excitation, DMDHP is transformed into transients with higher molar absorptivities in the UV region of the spectrum and loss of absorption in the visible region. For delays longer than 70 ns the transient spectrum had a maximum at 280 nm (transient **I**) and an isosbestic point was observed at 310 nm (inset Fig. 1). The latter suggests that at long delays only DMDHP and **I** were present. At very short delays (< 50 ns) a transient at 310 nm was detected (transient **II**). The transient kinetics showed a short- and a long-lived component (Fig. 2). The lifetimes for these components were the same for the decay at 280–290 nm and the growth at 340 nm, indicating that **I** and



Scheme 1

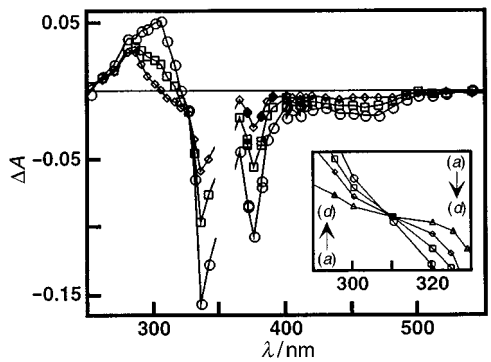


Fig. 1 Transient absorption spectra of DMDHP in cyclohexane at short delays after the laser pulse: (○) 10, (□) 50 and (◇) 70 ns. The inset shows the absorption region close to the isosbestic point at long delays: (*a*) 1, (*b*) 5, (*c*) 10 and (*d*) 15 μs.

II reformed DMDHP. Transient **I** did not decay back to the baseline [inset (*a*) in Fig. 2] and the bleaching at 340 nm did not completely recover (≤ 2 ms). This 'permanent' absorption change was assigned to the formation of CPD. The lifetime of **I** was longer than 5 μs and was very dependent on the presence of trace amounts of oxygen. The lifetime for **II** was shorter than the time-resolution of our system (< 12 ns) and the time-profile observed was that of the laser pulse (Fig. 2).

CPD, obtained by irradiating DMDHP in MeCN at −40 °C above 550 nm, was excited at 266 nm and −35 °C.[13] At 280 nm bleaching was observed indicating that some CPD reacted. In contrast, at 340 and 470 nm a positive absorption appears suggesting that CPD was isomerized into DMDHP. These results show that the transient phenomena being observed are due to the photochromism of DMDHP.

Quenching studies were performed to obtain information about the chemical nature of **I**. Oxygen readily reacts with **I** [(3.3 ± 0.6) 10^9 M^{-1} s^{-1}]. Quenchers with different triplet energies (E_T) were employed to check if **I** is a triplet excited

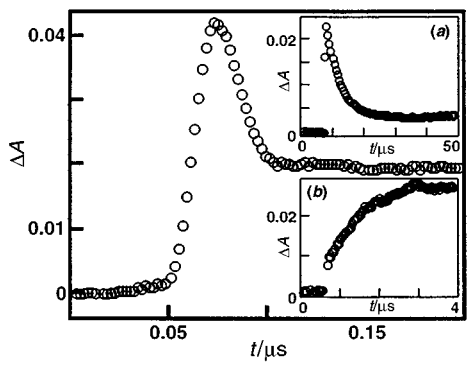

Fig. 2 Kinetic traces for the decay of transient **II** monitored at 290 nm (short time scale). Inset (*a*) shows the decay of transient **I** at 280 nm on a long time scale. Inset (*b*) shows the growth for triplet β-carotene (20 μM) when DMDHP is irradiated.

state. Cyclohexa-1,3-diene (E_T = 52 kcal mol^{-1})[14] or ferrocene (E_T = 38 kcal mol^{-1})[15] did not shorten the lifetime of **I**. However, β-carotene (E_T = 21 kcal mol^{-1})[14] quenched **I**. The triplet β-carotene was observed as a growth at 520 nm [Fig. 2, inset *(b)*] and the quenching rate constant was estimated to be *ca.* 10^{10} M^{-1} s^{-1}. These results show that **I** is a triplet state with an energy between 21 and 38 kcal mol^{-1}.

The quantum yield for the DMDHP to CPD photoisomerization ($\phi_{DMDHP\rightarrow CPD}$) was estimated from the magnitude of the'permanent' bleaching ($\tau \geq 2$ ms) at 470 nm using benzophenone [(ϕ_{isc} = 1, $\varepsilon(BP)_{530}$ = 7220 M^{-1} cm^{-1}][14] as a standard. Samples in cyclohexane containing benzophenone or DMDHP with matched absorptions at the laser excitation wavelength were excited at different laser energies and the values of ΔA at 530 nm for benzophenone and the bleaching at 470 nm for DMDHP were measured. These values are related by eqn. (1) [$\varepsilon(DMDHP)_{470}$ = 8200 ± 600 M^{-1} cm^{-1}, from *A vs.* [DMDHP] plots].

$$|\Delta A(\text{DMDHP})| = \frac{\varepsilon(\text{DMDHP})_{470}\,\phi_{\text{DMDHP}\rightarrow\text{CPD}}}{\varepsilon(\text{BP})_{530}\,\phi_{isc}}\Delta A(\text{BP}) \quad (1)$$

The recovered value for $\phi_{DMDHP\rightarrow CPD}$ (0.03 ± 0.01, three determinations) agrees well with the reported value (0.02).[1]

Based on the quenching by β-carotene and the absorption maximum at 280 nm, we assign **I** to the excited triplet state of CPD. The absorption at 280 nm indicates that, compared to DMDHP, a considerable amount of conjugation was lost, suggesting that the transannular bond was broken. Twisting of the bonds without breaking the transannular bond will not lead to a significant loss of conjugation. For this reason transient **I** cannot be the triplet excited state of DMDHP. The triplet CPD has a biradical character. In this respect, **I** is similar to the triplets of photoenols and xylylenes where these excited states are the biradicals of the corresponding ground state molecules.[16–18] The decay of **I** is probably determined by the rate of intersystem crossing to the singlet biradical which will rapidly form DMDHP or CPD.

The energy for **I** has been bracketed between 22 and 38 kcal mol^{-1} which overlaps with the energy for the transition state for the thermal reversion of CPD to DMDHP (Fig. 3). The triplet and singlet biradical reaction surfaces are likely to be close to the ground state surface and the reaction can proceed diabatically to the ground state surface once intersystem crossing to the singlet biradical occurs. In contrast, the reactivity from the excited singlet DMDHP could occur through a concerted or biradical mechanism. Although the formation of CPD was previously attributed to the reaction of the excited singlet DMDHP[1] it cannot be excluded that some CPD is formed from an excited triplet state with a low quantum yield.

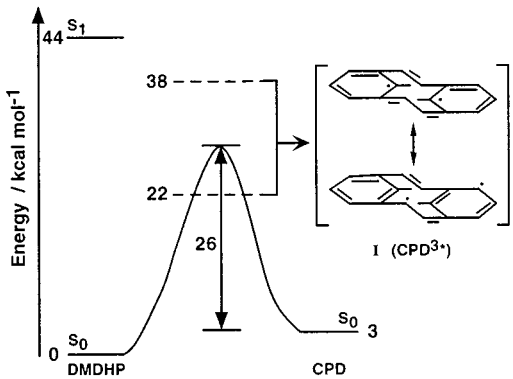

Fig. 3 Diagram representing the thermal conversion between DMDHP and CPD and some of the excited states of these isomers (only two resonance structures for **I** are shown).

Transient **II** cannot be definitely assigned because of its short lifetime. Its spectrum shows a maximum at 310 nm indicating that the DMDHP conjugation has been lost and **II** cannot be the excited singlet or triplet state of DMDHP. In addition, **II** is not the excited singlet state of CPD, since this state is not accessible on energetic grounds from the S_1 of DMDHP. One possibility, which is still speculative, is that **II** corresponds to the singlet biradical of CPD. Since the lifetime for **II** is shorter than the lifetime for triplet CPD, **II** can only be detected at short delays when formed from the excited singlet of DMDHP.

In conclusion, we report for the first time the transients formed in the irradiation of DMDHP. Detailed future studies on the photophysics of DMDHP derivatives will establish the importance of these transients when designing switches with high photoisomerization quantum yields.

Construction of tetracyclic ring systems by $Co_2(CO)_8$-catalyzed tandem [2 + 2 + 1]/[2 + 2 + 2] cycloaddition reaction of diynes: a simple one-pot reaction†

Soon Hyeok Hong,[a] Jong Wook Kim,[a] Dai Seung Choi,[a] Young Keun Chung*[a] and Sueg-Geun Lee[b]

[b] *Korea Research Institute of Chemical Technology, PO Box 9, Daedeogdanji, Daejeon, Korea*

Received (in Cambridge, UK) 21st July 1999, Accepted 10th September 1999

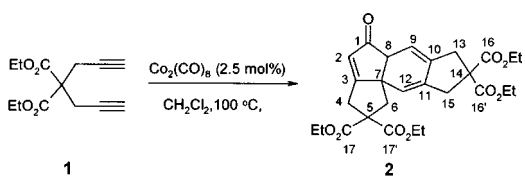
The $Co_2(CO)_8$-catalyzed tandem [2 + 2 + 1]/[2 + 2 + 2] cycloaddition reaction of terminal diynes under CO produces an unnatural novel tetracyclic compound.

Transition metal-catalyzed cycloaddition reactions of unsaturated substrates have provided many prominent methods for the construction of complex cyclic compounds.[1] Among them, the [2 + 2 + 1] cycloaddition provides a powerful tool for the assembly of five-membered ring containing polycyclic natural products. In particular, the Pauson–Khand [2 + 2 + 1] cycloaddition has attracted much attention for the preparation of a variety of cyclopentenone systems.[2] However, cyclopentadienones[3] have played no role in five-membered ring construction due to their high reactivity in Diels–Alder reactions, even though some cyclopentadienone derivatives are known. Transition metal-mediated [2 + 2 + 1] cycloaddition of two alkynes with CO can be a good way to generate and stabilize cyclopentadienones. However, the application of this method to organic synthesis has been hampered[4] by low yields, and the requirement for the presence of specific substituents, and the necessity of a demetalation step, even though $Fe(CO)_5$ or $CpCo(CO)_2$ have successfully been employed in some intramolecular carbonylative cycloaddition reactions.[5,6] All the reported reactions are stoichiometric. In the studying the Pauson–Khand reaction,[7] we became interested in the cycloaddition reaction of hepta-1,6-diynes employing $Co_2(CO)_8$ as catalyst because no successful examples of catalytic [2 + 2 + 1] cycloaddition reactions of α,ω-diynes had been reported.

Here we report a facile construction of unnatural novel tetracyclic compounds by the $Co_2(CO)_8$-catalyzed tandem [2 + 2 + 1]/[2 + 2 + 2] cycloaddition reactions of diynes under CO.

Reaction of diethyl dipropargylmalonate **1** in CH_2Cl_2 in the presence of 2.5 mol% $Co_2(CO)_8$ at 100 °C for 2 days under 20 atm of CO gave a tandem [2 + 2 + 1]/[2 + 2 + 2] cycloaddition reaction to produce the tetracyclic enone derivative **2** in 85% yield as the sole product (Scheme 1 and Table 1).†

The structure of **2** was established by ^1H and ^{13}C NMR spectroscopic investigations (COSY, long range COSY, DEPT, HETCOR, long range HETCOR, phase sensitive NOESY, and 2D-INADEQUATE),‡ mass spectrometry and elemental analysis. No isomerized products were observed. The reaction involves the formation of four carbon–carbon bonds. Although this multibond formation reaction seems to be complex, it is simple and provides a unique pathway to a tetracyclic framework. The reaction of a 4,4-*gem*-disubstituted 1,6-diyne **3**, under the same reaction conditions, gave a tetracyclic enone derivative **4** in 78% yield. The present reaction can be extended to the use of an oxygen-containing ether. Subjecting the oxygen-containing substrate **5** to the same reaction conditions provided the oxatetracyclic enone derivative **6** in 35% yield. The nitrogen containing substrate **7** produced azatetracyclic enone derivative **8** in 89% yield. All the terminal diynes except dipropargyl ether gave high yields. For the mono-substituted



Scheme 1

† Synthetic and spectroscopic details for **2**, **4**, **6**, **8**, **10** and **13** are available from the RSC web site, see http://www.rsc.org/suppdata/cc/1999/2099/

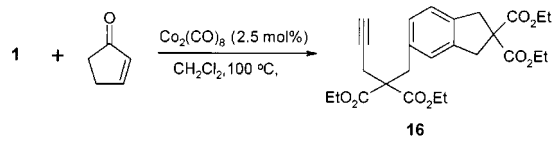
Table 1 Cycloaddition reactions of diynes [a]

Diyne	Cycloadduct	Yield (%)[b]
		85%
		78%
		35%
		89%
		80%
		19%
	—	NR
	—	NR

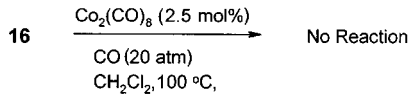
[a] $Co_2(CO)_8$ (2.5 mol%) CO (20 atm), 100 °C, CH_2Cl_2. [b] Isolated yields.

1,6-diyne **9**, a 10 : 2.4 mixture of two regioisomers (**10** and **11**) was obtained in 80% yield. For the disubstituted 1,6-diyne **12**, a [4 + 2] cycloaddition between [2 + 2 + 1] cycloadducts gave **13** in 19% yield with concomitant formation of unidentified polymeric materials. The steric effect of substituents at the external terminus of the diyne substrates is an important factor for the second [2 + 2 + 2] cycloaddition to proceed. Substrates (**14** and **15**) bearing substituents at the external termini of the alkyne and substrates having tethers lengthened or shortened by one carbon did not afford the corresponding tetracyclic compounds.

The following observations may provide some clues to help understand the catalytic reaction. Treatment of **1** with $Co_2(CO)_8$ in the presence of cyclopentenone afforded **16**[8] (Scheme 2). Cyclopentenone was not involved in the cycloaddition reaction. Resubjecting **16** to the original cyclization conditions ($Co_2(CO)_8$, CH_2Cl_2, 20 atm CO, 100 °C, 2 days) gave no corresponding cycloaddition product (Scheme 3).



Scheme 2



Scheme 3

Thus, the [2 + 2 + 2] cycloaddition reaction between diyne substrates does not occur before the [2 + 2 + 1] cycloaddition between CO and a substrate. We presume that initially a [2 + 2 + 1] cycloaddition between diyne and carbon monoxide catalyzed by $Co_2(CO)_8$ gives the corresponding bicyclic cyclopentadienone, and a subsequent [2 + 2 + 2] cycloaddition reaction between the bicyclic cyclopentadienone and diyne catalyzed by $Co_2(CO)_8$ leads to the tetracyclic cyclopentenone. We cannot rule out the possibility of alkene insertion to give a cobaltacycloheptadiene intermediate and reductive elimination of the tetracyclic cyclopentenone.

In summary, the reaction described herein demonstrates a novel one-step entry to unprecedented tetracyclic enone systems from acyclic starting substrates. The starting materials are readily prepared, and the resulting fused tetracycles have an unnatural framework which is difficult to prepare using conventional methods.

Zinc-mediated domino elimination–alkylation of methyl 5-iodopentofuranosides: an easy route to unsaturated carbohydrates for transition metal-catalyzed carbocyclizations

Lene Hyldtoft, Carina Storm Poulsen and Robert Madsen*

Received (in Cambridge, UK) 27th August 1999, Accepted 16th September 1999

5-Iodopentofuranosides are converted with zinc and allyl/propargyl bromide into dienes/enynes which are further used in carbohydrate annulation reactions.

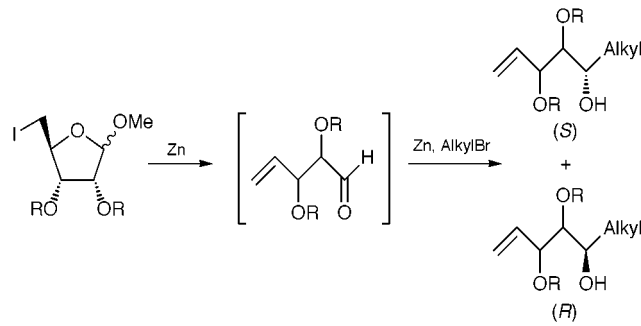
Domino reactions are becoming a very attractive tool for enhancing synthetic efficiency by allowing several bond-forming transformations to be carried out in a single synthetic operation.[1] Such a strategy could be particularly important in the area of carbohydrate chemistry: because carbohydrates are densely functionalized, synthetic applications are often hampered by the need for many reaction steps, usually for manipulation of different protecting groups. In particular, the conversion of carbohydrates into carbocycles is a major task and has been the subject of intense study due to the biological significance of the products.[2] Herein, we report a zinc-mediated domino elimination–alkylation of methyl 5-deoxy-5-iodopentofuranosides to prepare carbohydrate-derived dienes and enynes. These are important substrates for transition metal-catalyzed carbocyclizations,[3] and we demonstrate the use of the obtained dienes in the ring-closing metathesis reaction.[4,5]

Zinc-mediated reductive elimination of ω-iodoglycosides is a valuable reaction for introducing a terminal double bond in carbohydrates,[6] but the instability of the liberated aldehyde can be a problem leading to side reactions and decomposition. We reasoned that the aldehyde could be trapped *in situ* by a Barbier-type alkylation[7] (Table 1). Zinc would then serve a dual purpose by promoting both the reductive elimination and reacting with an alkyl halide to perform the Barbier reaction. Hereby, a C–C double bond, a C–C single bond and a new stereocenter would be generated in the same pot.

Allyl and propargyl bromide were selected as the alkyl halides. Initial experiments were carried out on isopropylidene ribofuranoside **1**.[8] When **1** was reacted with allyl bromide and zinc, the desired diene was obtained in quantitative yield as a 4:1 diastereomeric mixture (entry 1, Table 1). Switching to propargyl bromide gave rise to the corresponding enyne, but now in an improved 9:1 diastereomeric ratio (entry 2). Notably, no isomerization from alkyne to allene was observed under these conditions. In general, for these sequential transformations to go to completion, 3 equiv. of allyl bromide was needed while the reaction with propargyl bromide required 5 equiv. Allyl bromide was added at the beginning of the reaction while propargyl bromide was added during the course of the reaction to minimize the formation of Wurtz coupling products. The reactions were carried out under sonication in aq. THF.[7] The THF:H_2O ratio influenced the rate, but had little effect on the diastereoselectivity. Addition of more H_2O generally enhanced the rate of the overall transformation.

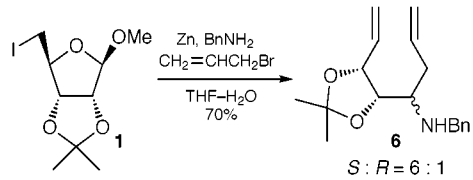
These conditions were then applied to substrates **2**–**5** (Table 1). Interestingly, the reaction of unprotected ribofuranoside **2** with allyl bromide now gave the opposite diastereomer as the major product as compared to isopropylidene-protected **1** (entries 1 and 3). However, the reaction of **2** with propargyl bromide failed to give any of the desired enyne. The reason for this is not clear, but is probably associated with the unprotected hydroxy groups. As a result, the remaining furanosides were

Table 1 Domino elimination–alkylation of methyl 5-iodofuranosides[a]



Entry	Furanoside	Alkyl Br	Yield (%) (*S*:*R*)[b]
1	 **1**		quant. (4 :1)[c]
2			73 (9 : 1)
3	 **2**		quant. (3 : 7)
4			0
5	 **3**		82 (3 : 7)[c]
6			56 (3 : 7)
7	 **4**		89 (3 : 1)
8			61 (7 : 3)
9	 **5**		94 (5 : 6)[c]
10			64 (2 : 3)

[a] General procedure: To a solution of the iodofuranoside (1.6 mmol) and allyl bromide (0.4 ml) in THF–H_2O (4:1, 10 ml) was added zinc (1 g, pre-activated with aq. HCl). The mixture was sonicated at 40 °C for 4 h under Ar atmosphere, filtered through Celite, and worked up by extraction with CH_2Cl_2 or stirring with ion-exchange resin followed by flash chromatography. [b] The stereochemistry of the enynes from the propargylations was assigned after hydrogenation to the corresponding dienes with Lindlar catalyst. In entry 10 the stereochemistry of the major enyne isomer was determined after conversion into its known MEM-protected derivative (ref. 9). Hydrogenation with Lindlar catalyst subsequently showed that the major diene isomer in entry 9 had the same absolute stereochemistry. [c] Protecting group removed in the work-up by acidic ion-exchange resin.



Scheme 1

protected as triethylsilyl (TES) ethers **3**–**5**. The reaction of these in the presence of allyl/propargyl bromide proceeded smoothly to give the dienes/enynes in good to excellent yields (entries 5–10). Unfortunately, the 2-deoxyribose substrate **5** gave a poor diastereoselectivity in the alkylation. For the protected furanosides **1**, **3** and **4**, on the other hand, the selectivity for addition to the intermediate aldehyde generally followed the Felkin–Anh model.[10]

The intermediate aldehyde can potentially be intercepted with an amine prior to the alkylation (Scheme 1). The alkylation would then take place on the formed imine resulting in the introduction of an amino group. In fact, treatment of **1** with zinc, benzylamine and allyl bromide succeeded in giving the amino diene product **6** in both good yield and diastereoselectivity. To prevent significant allylation of the intermediate aldehyde, it was important to add allyl bromide slowly during the course of the reaction.

Dienes and enynes are useful in transition metal-catalyzed carbocyclizations.[3] Hydroxylated enynes have previously been used in palladium-catalyzed coupling of the A-ring in vitamin D derivatives[9,11] and in cobalt-mediated Pauson–Khand reactions.[12] Hydroxylated dienes are useful for carbocyclization by ring-closing olefin metathesis. We have carried out the metathesis reaction on the major dienes from the allylations by the use of 5–10% Grubbs catalyst $[RuCl_2(CHPh)\{PCy_3\}_2]$[13] in CH_2Cl_2 (Table 2). These reactions also allow the stereochemical outcome of the allylations to be determined. The unprotected dienes in entries 1–4 all gave the desired cyclohexenes **7**–**10** in near quantitative yields. When the ammonium salt of diene **6** (Scheme 1) was subjected to Grubbs catalyst, significant decomposition took place and only a moderate yield of the cyclohexene could be obtained. However, when **6** was N-acetylated the ring-closing metathesis reaction went smoothly to give **11** in very high yield (entry 5, Table 2).

Table 2 Ring-closing olefin metathesis of the major diene products from the allylations

Entry	Diene	Cyclohexene	Yield (%)
1		 **7**[a]	96
2		 **8**[b]	95
3		 **9**[c]	97
4		 **10**[c]	95
5		 **11**[d]	94

[a] Ref. 14, [b] Ref. 15. [c] Ref. 16. [d] Ref. 17.

In conclusion, we have developed a zinc-mediated elimination–alkylation of 5-iodopentofuranosides which permits 'one-pot' formation of several bonds and a stereocenter in a controlled manner. The obtained dienes and enynes are valuable in carbohydrate annulation by transition metal catalysis, and we have processed the dienes in the ring-closing metathesis reaction. Hereby, a range of complex carbocyclic structures are easily available as chiral building blocks from cheap sugar starting materials by two consecutive organometallic transformations.

Received (in Oxford, UK) 24th June 1999, Accepted 16th August 1999

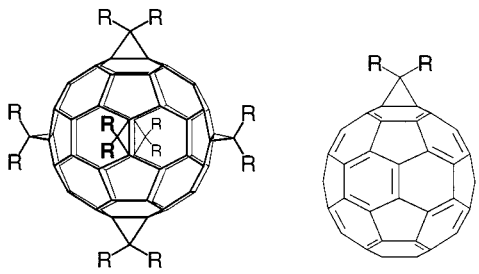
A hexa-adduct of [60]fullerene was synthesized by addition of a mesomorphic twin cyanobiphenyl malonate derivative to C_{60}; whereas the malonate derivative gave a monotropic nematic phase, the fullerene hexa-adduct showed an enantiotropic smectic A phase.

The recent discovery of [60]fullerene-containing thermotropic liquid crystals[1] is of interest considering the current activity devoted to the search of fullerene-based new materials.[2] The unique magnetic, optical and redox properties of [60]fullerene (C_{60}) and its derivatives motivated these studies.[3]

The above liquid-crystalline mono-adduct C_{60} derivatives[1] were prepared by functionalizing the C_{60} core with a mesomorphic malonate framework containing cholesterol as a mesomorphic promoter. These materials showed smectic A phases.

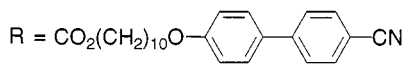
[60]Fullerene offers multiple possibilities for the design of functionalized derivatives.[4] To further explore the capability of C_{60} to give rise to mesomorphic structures, we focussed on hexa-adducts. Observation of liquid-crystalline properties from such an addition pattern would be of interest to rationalize and better understand the *structure–liquid-crystalline properties* relationship for this new family of liquid crystals.

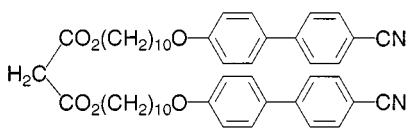
We describe herein the synthesis, characterization and thermal behavior of the fullerene hexa-adduct **1**, which represents a novel example of a mesomorphic C_{60} derivative, and of the fullerene mono-adduct **2**. Compounds **1**† and **2**† were



1

2





3

prepared by addition of the malonate derivative **3**† to C_{60} in 9 and 43% yield, respectively. The thermal properties of **3** are also reported. The liquid-crystalline phases‡ and thermal properties§ of **1**–**3** were investigated by differential scanning calorimetry (DSC, rate: 10 °C min^{-1} under N_2) and polarized optical microscopy (POM).

Malonate derivative **3** gave a monotropic nematic phase (I → N: 87 °C, ΔH = 2.7 kJ mol^{-1}; N → Cr: 57 °C, ΔH = 50 kJ mol^{-1}; peak transitions)¶ which was identified by POM from the observation of typical *schlieren* and homeotropic textures.

Mono-adduct **2** was found to be non-mesomorphic. The only event which was observed was melting of the sample into the isotropic fluid (Cr → I: 114 °C, ΔH = 31 kJ mol^{-1}; peak transition; first heating run).

Hexa-adduct **1** gave interesting results. By DSC, an endotherm was detected at 133 °C (ΔH = 42 kJ mol^{-1}, *i.e.* 3.5 kJ mol^{-1} per cyanobiphenyl group; onset transition) during the first heating run. Reversibility of this transition was observed during the cooling scan. The formation of a liquid-crystalline phase was observed by POM between about 80 and 133 °C. Slow cooling of the sample from the isotropic fluid revealed the formation of focal-conic and homeotropic textures typical of the smectic A phase (Fig. 1). The transition recorded by DSC at 133 °C corresponded to the clearing point. The fact that no melting point was detected by DSC is, most likely, a consequence of the amorphous character of **1** in the solid state (**1** was recovered by evaporation of the solvents after preparative HPLC†); no glass transition was observed by DSC.

The bulky C_{60} unit acts as a spacer separating the molecules from each other: for mono-adduct **2**, the intermolecular interactions are too weak to generate mesomorphism. The influence of C_{60} can be thwarted by using malonate derivatives possessing a higher liquid-crystalline character than that of **3**, as we have already demonstrated.[1]

The liquid-crystalline behavior of **1** emphasizes the role played by C_{60} in the case of hexa-addition: assembling twelve cyanobiphenyl units around a focal point generates the required structural anisotropy and intermolecular interactions for mesomorphism to occur. It is noteworthy that polyaddition can be used for the preparation of fullerene-containing thermotropic liquid crystals from addends with low liquid-crystalline tendencies. Observation of a smectic A phase for **1** indicates that the cyanobiphenyl units are not oriented radially around the C_{60} but

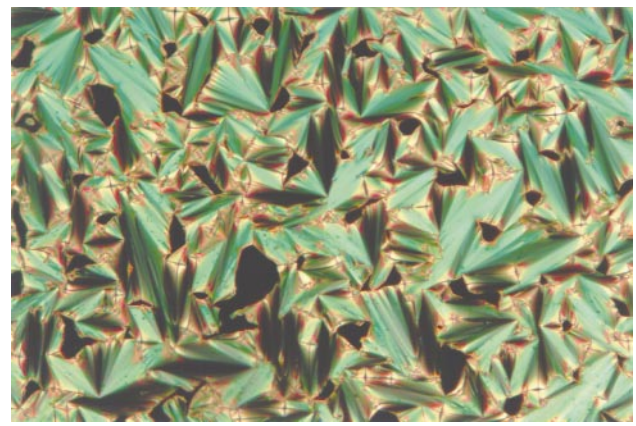


Fig. 1 Thermal optical micrograph of the focal-conic fan texture displayed by **1** in the smectic A phase upon cooling the sample (0.01 °C min^{-1}) from the isotropic liquid to 129 °C.

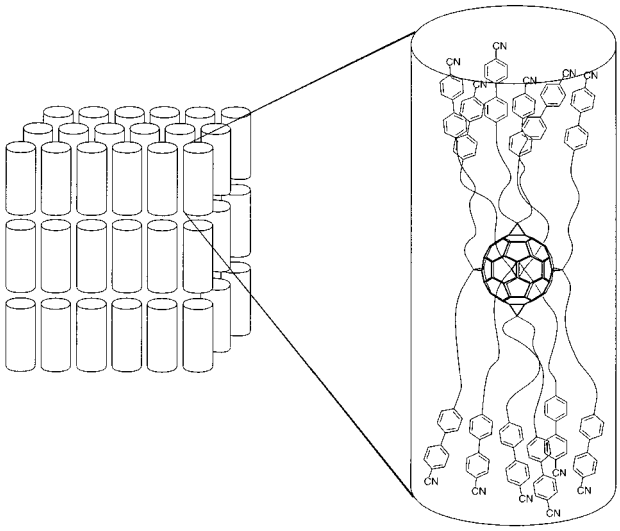

Fig. 2 Proposed model for the organization of **1** within the smectic A phase.

form a cylinder-like structure with the mesogenic fragments oriented upward and downward. Such a structure favors the formation of layers (Fig. 2) as reported for liquid-crystalline dendrimers[5] and siloxysilane derivatives[6] which are analogous to **1**, *i.e.* a central core is functionalized by a large number of mesogenic groups.

The liquid-crystalline properties obtained from the hexa-adduct described above and mono-adducts we recently reported[1] prove that C_{60} can be employed in designing a great variety of mesomorphic materials.

† Experimental procedure for **3**: prepared from 4′-cyano-4-hydroxybiphenyl, 10-bromodecan-1-ol and malonyl chloride analogously to the synthesis of bis{10-{4-[(cholest-5-en-3β-yloxy)carbonyl]phenoxy}decyl} propanedioate [ref. 1(*a*)]; δ_H(400 MHz, $CDCl_3$) 7.68 (d, 4H, arom.), 7.63 (d, 4H, arom.), 7.52 (d, 4H, arom.), 6.98 (d, 4H, arom.), 4.14 (t, 4H, CO_2CH_2), 4.00 (t, 4H, OCH_2), 3.37 (s, 2H, $O_2CCH_2CO_2$), 1.84–1.77 (m, 4H, aliph.), 1.68–1.61 (m, 4 H, aliph.), 1.51–1.43 (m, 4H, aliph.), 1.37–1.25 (m, 20H, aliph.); δ_C(100 MHz, $CDCl_3$) 166.68, 159.76, 145.22, 132.52, 131.21, 128.28, 127.02, 119.07, 115.04, 110.01, 68.11, 65.61, 41.66, 29.44, 29.39, 29.32, 29.18, 29.15, 28.43, 26.00, 25.74. (Anal. calc. for $C_{49}H_{58}N_2O_6$ (771.01): C, 76.33; H, 7.58; N, 3.63. Found: C, 76.17; H, 7.79; N, 3.61%.

For **1**: Under nitrogen, 9,10-dimethylanthracene (116 mg, 0.562 mmol) was added to a solution of C_{60} (40.5 mg, 0.0562 mmol) in PhMe (60 ml, HPLC grade). The solution was stirred for 2 h. Then **3** (433.6 mg, 0.562 mmol), CBr_4 (186.1 mg, 0.562 mmol) and DBU (171 mg, 1.125 mmol) were added. The mixture was stirred for 3 weeks protected from light and evaporated to dryness. The crude mixture was purified by flash-chromatography on silica gel 60 (0.04–0.063 nm, Merck); elution with hexane (to remove 9,10-dimethylanthracene) and then with PhMe–EtOAc 96 : 4 gave **1** ($R_f \cong 0.25$, PhMe–EtOAc 96 : 4, Riedel-de Haen TLC-Sheets 60 F254) which was detected by mass spectrometry (see below). Further purification of the recovered sample by preparative HPLC (diameter of the column: 2 cm, elution rate: 15 ml min^{-1}) on Nucleosil (5μ) (first: PhMe–EtOAc 95.5 : 4.5, 9.1 min; second: PhMe–EtOAc 97 : 3, 26.3 min) gave pure **1** (26.8 mg, 9%) as a pale yellow solid. δ_H(400 MHz, $CDCl_3$) 7.66 (d, 24 H, arom.), 7.60 (d, 24H, arom.), 7.49 (d, 24H, arom.), 6.95 (d, 24H, arom.), 4.23 (t, 24H, CO_2CH_2), 3.96 (t, 24H, OCH_2), 1.80–1.73 (m, 24H, aliph.), 1.71–1.64 (m, 24H, aliph.), 1.45–1.37 (m, 24H, aliph.), 1.36–1.23 (m, 120H, aliph.); δ_C(100 MHz, $CDCl_3$) 163.84, 159.74, 145.79, 145.13, 141.13, 132.52, 131.24, 128.77, 126.99, 119.00, 115.02, 110.09, 69.13, 68.10, 66.95, 45.45, 29.52, 29.48, 29.41, 29.24, 28.42, 26.06, 25.83; *m/z* (FAB-MS, NBA), 5334 (M^+).

For **2**: To a solution of C_{60} (193 mg, 0.268 mmol) and **3** (201 mg, 0.261 mmol) in dry PhMe (100 ml), were added CBr_4 (93 mg, 0.280 mmol) and then, dropwise, DBU (78 mg, 0.512 mmol). The reaction mixture was stirred at room temperature for 18 h under light protection and concentrated. Purification of the residue by column chromatography (silica gel, 0.070–0.200 mm, SDS; eluent: PhMe) and crystallization (PhMe–EtOAc, overnight at room temperature and then for one day at 8 °C) gave pure **2** (163 mg, 43%). δ_H(400 MHz, $CDCl_3$) 7.68 (d, 4H, arom.), 7.63 (d, 4 H, arom.), 7.51 (d, 4 H, arom.), 6.97 (d, 4 H, arom.), 4.50 (t, 4H, CO_2CH_2), 3.99 (t, 4H, OCH_2), 1.88–1.76 (m, 8H, aliph.), 1.48–1.29 (m, 24H, aliph.) Anal. calc. for $C_{109}H_{56}N_2O_6$ (1489.65): C, 87.89; H, 3.79; N, 1.88. Found: C, 87.89; H, 3.99; N, 1.84%.

Communication 9/05058B

A chemiluminescent catalytic antibody†

James D. Stevenson, Anja Dietel and Neil R. Thomas*

School of Chemistry, University of Nottingham, University Park, Nottingham, UK NG7 2RD. E-mail: neil.thomas@nottingham.ac.uk

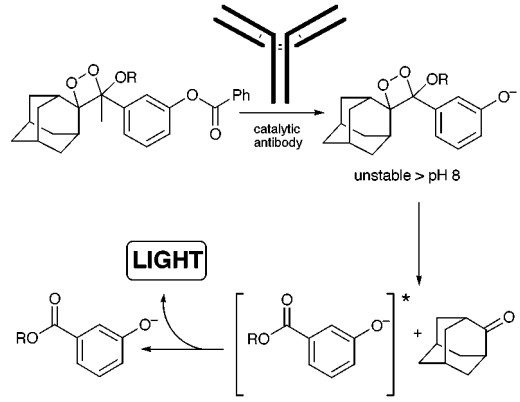
Received (in Cambridge, UK) 12th August 1999, Accepted 9th September 1999

A monoclonal antibody elicited against a phosphonate transition state analogue was shown to initiate chemiluminescence from luminogenic spiro[adamantane-2,3′-(1,2-dioxetane)] substrates by selectively cleaving a benzoate ester triggering group.

Serendipity has played a large part in the identification of many of the catalytic antibodies reported in the literature to date.[1] Typically, 5–50 monoclonal antibodies selected on the basis of their affinity for a transition-state analogue as judged by Enzyme-Linked ImmunoSorbent Assay (ELISA)[2] have been produced in sufficient quantity to screen for catalytic activity. Such an approach has led to the identification of, at best, a handful of catalysts. Given that the humoral response generates at least 10^8 unique antibody binding sites, only a tiny fraction are examined for their catalytic activity. The probability of identifying the most efficient antibody catalyst for any given reaction from the library available using this approach is therefore very low, as screening for catalysis only occurs at a late stage. As a result it is currently difficult to optimise either the design of the antigen to elicit antibodies for a specific reaction, or the immunisation and immortalisation protocol (*in vivo* or *in vitro*, hybridoma or bacteriophage display) used in their creation. In order to overcome this limitation we present here an example of the use of a chemiluminescent reporter assay in the identification of an antibody catalyst.[3] Chemiluminescent assays benefit from low background interference and are finding increasing use in the analytical laboratory. The assay system described here offers the opportunity for catalytic activity to be detected at an early stage in antibody production when only small quantities of antibody are available, and hence should allow large libraries of antibodies or other materials to be screened for hydrolytic activities.

Recently, a number of papers have appeared which use either *screening* or *selection* methods for the identification of new catalysts: the complementation of auxotrophic bacteria,[4] the use of fluorogenic substrates,[5] immobilised mechanism based inhibitors,[6] catELISA,[7] proximity coupling,[8] or pH indicators.[9] Compared to many of these approaches the highly sensitive chemiluminescent assay system based around a spiroadamantyl-substituted dioxetane substrate offers a simple one-step approach for which automated equipment is already commercially available.

Thermally stable spiroadamantyl-substituted dioxetanes, which undergo enzyme triggered chemiluminescence, have been developed for use in chemiluminescent reporter assays.[10] These luminogenic substrates undergo Chemically Initiated Electron-Exchange Luminescence (CIEEL) following cleavage of a triggering group which can be tailored to the desired enzyme activity. The dioxetanes offer the advantages of an efficient chemiluminescent reaction (ϕ_{CL} = 10^{-3}–10^{-6} in aqueous solution) which has both a long half-life and low background interference. To determine the utility of CIEEL for identifying new catalytic activities we chose the simple example



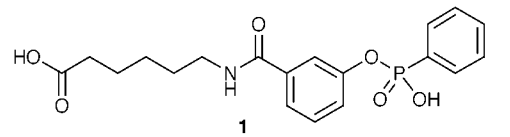
Scheme 1

of ester hydrolysis (Scheme 1), and designed a transition-state analogue (hapten **1**)† based around a phosphonate core accordingly. In order to direct most of the antibody–antigen recognition towards the phosphonate portion of the transition-state analogue, the reactive and potentially immunogenic adamantyl dioxetane moiety was omitted from hapten **1**. The position of the linker arm in the hapten for attachment to an appropriate carrier protein was chosen to orientate the dioxetane group away from the antigen binding site. This ensures that the excited ester generated following dioxetane decomposition will be released quickly from the antigen binding site, minimising the possibility of quenching of the excited state through molecular collision with the antibody, rather than through light emission.

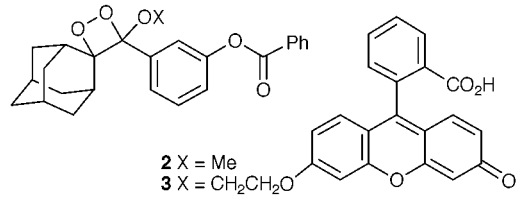
Hapten **1** was conjugated to both Bovine Serum Albumin (BSA) and Keyhole Limpet Hemocyanin (KLH) *via* its *N*-hydroxysuccinimide ester, using standard carbodiimide chemistry.[11] The degree of conjugation to the relevant carrier protein was established using the trinitrobenzenesulfonic acid (TNBS) assay.[12]

Three Balb/c mice were hyperimmunised with the KLH conjugate (4 × 100 μg per mouse) over a period of 15 weeks, and hybridomas were generated from the spleens of these mice by fusion with P3X63Ag8 myeloma cells using standard protocols.[13] Twenty-six hybridomas producing antibodies specific for hapten **1** were identified by ELISA, and 10 of these were selected for cloning.

Substrate **2** was synthesised by modifying a route previously described.[14] Introduction of the benzoate triggering group could



1



† Experimental details for the preparation and characterisation of hapten **1** and substrates **2** and **3,** and the monoclonal antibodies together with kinetic data are provided as electronic supplementary information. See http://www.rsc.org/suppdata/cc/1999/2105/

only be accomplished on the methyl enol ether intermediate, and not on the 3-hydroxyaryl spiroadamantyl dioxetane itself. The conditions for the chemiluminescent assay were as follows: the antibody (2 μM final concentration) was taken up in 190 μl of Tris HCl (50 mM, pH 9.0) in individual microtitre plate wells and was preincubated at 30 °C. The dioxetane **2** in MeCN (10 μl) (at the appropriate stock concentration to give a final substrate concentration of 1–100 μM in the incubation) was then added, and the light generated over a period of 2 h was measured using a Dynex MLX Microtitre® plate luminometer. The chemiluminescent decomposition of **2** occurs in a reasonable quantum yield ($\phi_{CL} = 1.4 \times 10^{-5}$), however, this was significantly improved by addition of fluorescein (2 mM) to the incubation medium ($\phi_{CL} = 1.0 \times 10^{-4}$). A further improvement in signal was obtained by covalently tethering the fluorescein to the dioxetane substrate **3** ($\phi_{CL} = 1.1 \times 10^{-3}$).[10] This increases the quantum yield from 0.0012% for the phenolate generated from **2** to 0.39% for the phenolate from **3** due to the efficient intramolecular energy transfer to the fluorescer. In turn this extends the lower detection limit for dioxetane decomposition from 10^{-13} moles for **2** to 10^{-16} moles for **3**. The synthetic route for the preparation of substrate **3** is described in the supporting material.† The increase in sensitivity it provides is clearly seen in Fig. 1, which also demonstrates that the antibodies are capable of at least five substrate turnovers per antigen-binding site.

Of the eight monoclonal antibodies which survived to this stage, antibody 7F11 was identified as an active catalyst and produced a chemiluminescent signal which was well above background levels with both dioxetane substrates. Larger quantities of this antibody were produced for detailed kinetic studies. The antibody-catalysed hydrolysis obeyed saturation kinetics with $k_{cat} = 0.020\ s^{-1}$, $K_m = 2.5$ μM for substrate **2** and $k_{cat} = 0.0028\ s^{-1}$, $K_m = 3.1$ μM for substrate **3** respectively. The lower k_{cat} value for substrate **3** can be explained by an increased amount of non-productive binding of this substrate (the reaction is inhibited by fluorescein which bears some structural resemblance to the hapten). No light was detected in the absence of the antibody, or in the presence of non-catalytic mAb's with either substrate. Therefore, assuming an upper limit for k_{uncat} of $1 \times 10^{-8}\ s^{-1}$ based on the detection limit of the chemiluminescent assay, the rate enhancement (k_{cat}/k_{uncat}) observed is 2.0×10^6 for substrate **2**, and 2.8×10^5 for substrate **3**, respectively. This suggests that 7F11 is one of the most efficient antibodies at catalysing benzoate hydrolysis that has yet been obtained,[1] although it is still several orders of magnitude slower than comparable esterases. The antibody is inhibited competitively by hapten **1** with Dixon analysis of the kinetic data affording a K_i value of 97 nM.† This result demonstrates that the catalysis is due to an antibody, rather than a contaminating enzyme. We are currently producing a single-chain antigen-binding fragment of 7F11 to further confirm this fact.

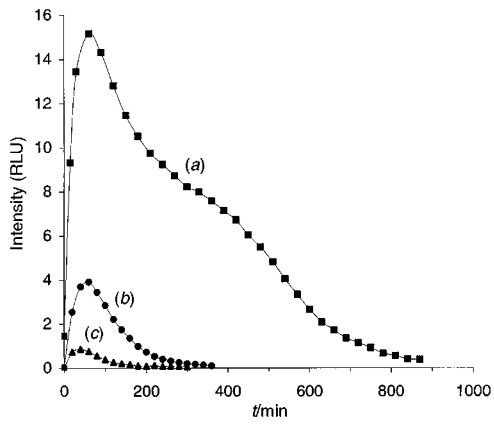


Fig. 1 Total light emission for 20 μM dioxetane (**2** or **3**) in 200 μl of 50 mM Tris buffer at pH 9.0, 37 °C in the presence of antibody 7F11 (2 μM): (*a*) **3**, (*b*) **2** + fluorescein (2 mM) and (*c*) **2**.

In conclusion we have shown that it is possible to identify antibody catalysts using a chemiluminescent substrate system. The absolute sensitivity of the assay using substrate **3** is sufficient for detection of catalysts in hybridoma supernatants or phage-displayed antibody libraries[5] and these are currently being screened. Modification of the spiroadamantyl dioxetane to allow screening of other hydrolytic activities, and for 'remote' release is currently underway. The use of the chemiluminescent catalytic antibody in a chemiluminescent imaging system is being investigated as a possible replacement for enzyme–secondary antibody conjugates, or for enzyme–antibody/protein A fusion proteins as required by ELISA.[15] These self-marking antibodies could be useful in a wide range of immunochemical assays including microtitre plate immunoassays, immunoblotting and immunohistochemistry.

This research was supported by a Royal Society Fellowship to N. R. T., an EPSRC studentship to J. D. S. and funding from the University of Nottingham. Drs Michael Price, Graeme Denton and Barbara Gunn are acknowledged for their assistance in the creation of monoclonal antibodies, and Dr Nigel Kenward for useful discussions.

ChemComm

A novel and highly regioselective Cr-mediated route to functionalised quinone boronic ester derivatives

Mark W. Davies,[a] Christopher N. Johnson[b] and Joseph P. A. Harrity*[a]

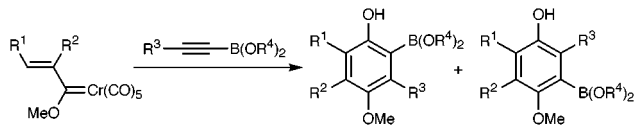
Received (in Liverpool, UK) 10th August 1999, Accepted 13th September 1999

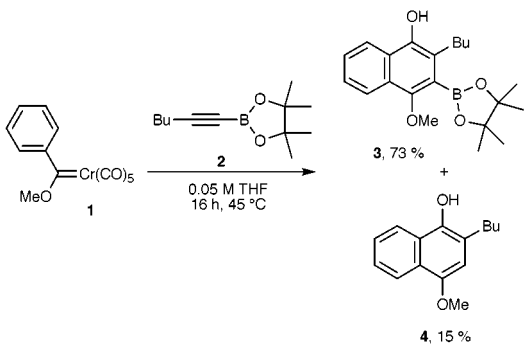
A novel and highly regioselective route to quinone boronic ester derivatives has been developed using a Fischer carbene mediated benzannulation process.

Arylboronic acids and esters represent one of the most heavily utilised classes of synthetic intermediates of recent times.[1] These compounds are typically prepared using alkyllithium or Grignard reagents and a suitable boronic ester or halide. More recently, palladium catalysed coupling of aryl halides with alkoxydiboron[2] or alkoxyborane[3] reagents has provided a mild alternative for conducting this transformation. In an effort to develop an efficient method for the preparation of complex aryl boronic esters, we envisaged a conceptually novel approach to these compounds by the employment of a Dötz annulation reaction[4] of Fischer carbene complexes[5] with alkynylboronates.[6] As illustrated in Scheme 1, this approach would provide a direct technique for the assembly of highly functionalised boronic ester derivatives from simple starting materials. We were mindful that disubstituted alkynes generally undergo insertion with low levels of regioselectivity[7] and therefore our initial goal was to investigate whether arylboronic esters could be prepared in this manner with useful levels of regiocontrol.

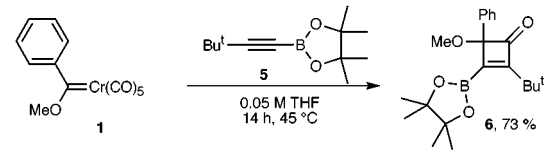


Scheme 1

As shown in Scheme 2, we were pleased to find that complex **1** reacted smoothly with pinacol ester **2** to provide arylboronate **3** in excellent yield, and remarkably, as a single regioisomer. Notably, a minor quantity of deboronated cyclisation product **4** was also produced but was easily separated from **3** by chromatography. The origin of the generation of **4** has not been unambiguously established although it likely arises from protodeboronation of **2** followed by annulation of the terminal alkyne.[8] The regiochemistry of boronate ester **3** was elucidated by X-ray crystallography and shows that the boronate unit is inserted adjacent to the methoxy unit.[9] We also examined the



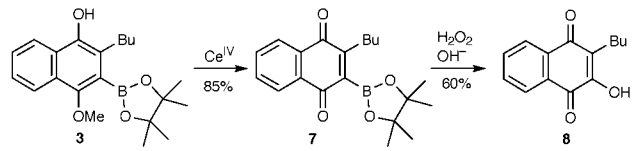
Scheme 2



Scheme 3

scope of the cyclisation process with respect to sterically hindered alkynylboronates (Scheme 3). The employment of *tert*-butyl substituted boronate **5** led only to the formation of cyclobutenone **6**. This result is in accord with Yamashita's observations that bulky electron deficient alkynes provide cyclobutenone products at the expense of benzannulated compounds.[10] Nonetheless, again a single regioisomer was observed and the product displayed an analogous insertion pattern to that outlined in Scheme 2.[9]

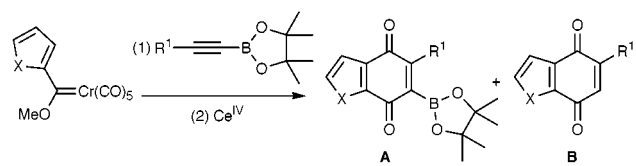
Having developed the technique to access hydroquinone boronic esters we turned our attention to conversion of these compounds to the corresponding quinones. As outlined in Scheme 4, hydroquinone **3** was oxidised smoothly to **7** in good yield with cerium ammonium nitrate in only 30 min at room temperature. *Significantly, these quinones represent a novel class of boronic esters and are a potentially valuable source of a range of quinone containing medicinally important agents.*[11] Whilst a thorough investigation of the functionalisation of the carbon–boron bond must await future studies, we have found that **7** is readily further oxidised to hydroxyquinone **8** through treatment with basic H_2O_2 for 20–30 min.



Scheme 4

In general, direct oxidation of the crude reaction mixture after benzannulation provided a simple and routine method for the isolation of quinone boronic ester compounds (Scheme 5). We briefly investigated the scope of this technique with respect to alkynylboronates and Fischer carbene complexes, as shown in Table 1.

Initial screening showed the reaction to be efficient in both polar and non-polar solvents. However, THF gave consistently higher yields of boronate esters. We attempted to promote the reaction by the employment of dry state conditions (Table 1, entry 3).[12] Unfortunately, adsorption onto silica gel served only



Scheme 5

Table 1 Benzannulation reaction of alkynylboronates and Fischer carbene complexes (see Scheme 5)

Entry	X	R^1	Conditions[a]	Product **A**	Yield (%)	Product **B**	Yield (%)

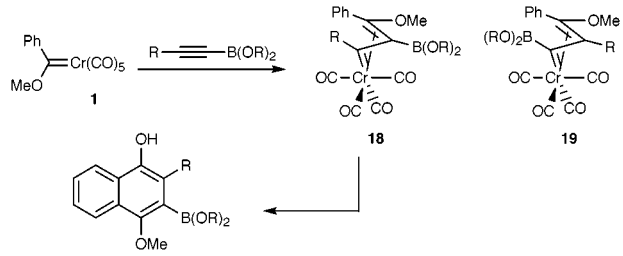
[a] Reaction conditions: (1) 0.05 M solution of complex and 3 equiv. of alkyne heated for 14–16 h under inert atmosphere. (2) Crude reaction mixture dissolved in Et_2O and stirred for 0.5 h with 0.5 M Ce^{IV} in 0.1 M aq. HNO_3.



Scheme 6

to provide quinone **9**, albeit in high yield. The reaction was found to be readily extended to furan complex **10**, although higher temperatures and longer reaction times were generally required for complete conversion and resulted in the recovery of larger quantities of deboronated products (entries 4 and 6, Table 1). Nonetheless, these quinones were again isolated as single regioisomers.[13]

The origin of the high preference of insertion of the boronate group in the more hindered position adjacent to the MeO group is not clear at this time, however we are currently investigating three possible rationales. The insertion may simply be sterically controlled and therefore follows traditional insertion patterns where the boronate unit acts as the sterically less demanding group.[14] Alternatively, Hofmann has proposed that η^3-vinylcarbene complex intermediates are responsible for controlling regiochemical insertion patterns.[15] Therefore, **19** may be energetically disfavoured due to the positioning of the electron withdrawing boronate unit adjacent to the electrophilic carbene carbon atom (Scheme 6). Finally, a model proposed by Wulff to explain the contrasteric insertion of alkynylstannanes in the benzannulation process may be invoked whereby the regiochemistry is controlled by a Lewis acid/base interaction [CO→B(OR)$_2$] in the metallohexatriene intermediate **18**, thus directing regiochemical insertion.[16]

In conclusion, this study provides a rapid and efficient approach to a novel class of hydroquinone and quinone boronate esters.[17] Additionally, the boron unit is incorporated into these structures in a reliable and predictable fashion, and with excellent selectivity. Studies on the origin of regioselectivity are currently underway as are the employment of these intermediates in transition metal catalysed C–C coupling reactions.

The authors are grateful to the EPSRC for a studentship (M. W. D.) and to SmithKline Beecham for generous financial support. We also wish to thank Dr S.L. Heath and Mr H. Adams for assistance with X-ray data.

8 Alkynylboronates are readily hydrolysed to the parent alkyne in the presence of protic reagents, (ref. 6), it is therefore plausible that the phenolic benzannulated product mediates alkyne protodeboronation. Indeed, hex-1-yne was recovered in the volatile material isolated from the reaction mixture in Table1, entry 1.

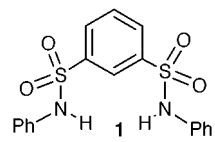
Received (in Columbia, MO, USA) 9th July 1999, Accepted 15th September 1999

The disulfonamide receptor 1 catalyzes imine formation from aldehyde and amine, apparently by binding the transition state for the rate-determining nucleophilic attack of amine on the aldehyde.

Catalysis by abiotic receptors[1] is a rapidly developing field in supramolecular chemistry, and systems have been developed that mimic enzyme properties by binding preferentially the transition state over the ground (reactant) state.[2] Most compounds developed for that purpose are macrocycles.[3] Molecular clefts with appropriately convergent recognition sites can give unexpectedly strong binding for anionic substrates[4] and some elegant examples of open clefts catalyzing reactions involving anionic transition states *via* hydrogen bonding have been reported.[5] The increased skeleton flexibility in open clefts *vs.* macrocycles can be favorable for catalysis if the open-chain receptor accommodates better the changes along the reaction coordinate.[1b] In other examples, interaction of the anionic intermediate with a metal center[6] rather than with a hydrogen bond donor group is responsible for catalysis. Some of the reported cases[6b–f] involve imine formation catalysis.

Receptor **1** seemed a good choice as an imine formation



1

catalyst because it is known[4b] to bind strongly to halide ions as well as acetate [*e.g.* $K_a(M^{-1}) = 2.1 \times 10^4$ for the 1:1 complex with OAc^-]. The reaction of an aldehyde with an amine to give an imine was chosen as the catalytic reaction because the rate determining[7] nucleophilic attack of amine has a R(Nu)HC–O^- transition state that should be bound more tightly than the starting aldehyde. The imine product, having only one lone pair, is not expected to be optimally bound by the receptor, so catalyst poisoning by the imine product should be avoided. We now find that the easily available[4b] disulfonamide **1** catalyzes the reaction of eqn. (1) at −20 °C in CD_2Cl_2 with anhydrous $MgSO_4$ present to remove water (Bn = benzyl).

$$p\text{-}MeC_6H_4CHO + BnNH_2 \rightarrow p\text{-}MeC_6H_4CH{=}NBn + H_2O \quad (1)$$

Initial rate experiments, carried out under pseudo-first order conditions[8] show that **1** (8 mol% *vs.* RCHO) is an effective catalyst for the reaction, causing a 6.1-fold acceleration of imine formation (Figs. 1 and 2) as measured by ^{1}H NMR resonance integrations. The initial rate of imine formation was increased by a factor of 6.1 in the presence of catalyst as compared to the control which did not contain **1**. Eqn. (1) is subject to general acid catalysis, and the most appropriate control is *o*-chlorophenol because it has a pK_a (8.49) most comparable with the disulfonamide **1** (p$K_a \approx 8.05$).[9] As shown in Fig. 1(*c*), even 100 mol% of *o*-chlorophenol only shows a small rate acceleration *versus* 8 mol% of **1** [Fig. 1(*a*)]. 100 mol% of phenol [pK_a = 9.89, Fig. 1(*e*)] gave almost no acceleration. Only much stronger acids, such as *p*-nitrophenol [pK_a = 7.15, Fig. 1(*b*)], gave substantial acceleration.

By analogy with the known[4] mode of association of anions with the receptor, a favorable two point hydrogen bonding interaction of the two convergent sulfonamide groups with the anionic oxygen of the transition state for eqn. (1) (see **2**) may be responsible for catalysis.

The known[4b] binding properties of **1** with oxyanions allow an estimate of the association constant (K_a) for the transition state **2**. For acetate, the observed K_a of 2.1×10^{-4} M^{-1} corresponds to a ΔG of binding of −24.2 kJ mol^{-1}. By transition state theory, often used to predict rate enhancements,[10] the rate acceleration is related to the ratio of the binding constant of the receptor with the transition state *versus* the binding constant with the substrate. We were not able to accurately determine the binding constant with the substrate owing to exchange of the

2

N–H sulfonamide resonance with trace protic impurity and the chemical shift change for the C–H aromatic resonance being too small to allow accurate titration monitoring. From literature data,[5a] association constants in CH_2Cl_2 for hydrogen bond receptors having two convergent hydrogen bond donor groups with neutral carbonyl substrates are in the range of 1 to 2×10^3 M^{-1}. Assuming that the transition state is bound to the receptor approximately as well as acetate (2×10^4 M^{-1}) an acceleration factor of 10–20 is predicted, a value comparable with the experimental value of 6.1.

Molecular cleft receptors, even very simple ones like **1**, can be catalytically active for reactions such as eqn. (1), where the transition state for the slow step is thought to be bound more strongly than starting materials or products. As a cleft rather than a macrocycle, this receptor is expected to bind the substrate carbonyl group without significantly blocking access of the nucleophile to the carbonyl.

We thank the US National Science Foundation for funding, and Professor David J. Austin for valuable suggestions.

Water and hydrogen atom elimination from ionised *n*-propanol: extraordinarily large kinetic isotope effects

Richard D. Bowen,*[a] Simon J Mandeville,[a] Moschoula A. Trikoupis[b] and Johan K Terlouw[b]

[a] *Chemical and Forensic Sciences, University of Bradford, Bradford, West Yorkshire, UK, BD7 1DP. E-mail: r.d.bowen@bradford.ac.uk*

[b] *Department of Chemistry, McMaster University, Hamilton, Ontario L8S 4M1, Canada*

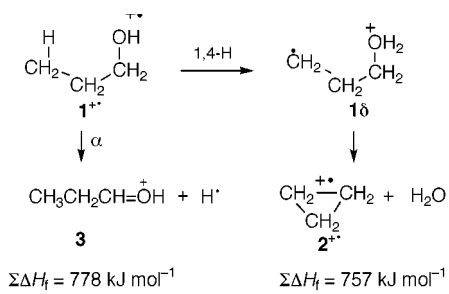
Received (in Cambridge, UK) 24th August 1999, Accepted 16th September 1999

Hydrogen atom loss from ionised *n*-propanol occurs specifically from the α-carbon atom and is subject to a kinetic isotope effect of approximately 500 : 1; somewhat smaller, though still very large, isotope effects are manifested in water loss, which is initiated by an essentially site-specific 1,4-hydrogen transfer.

The properties and reactions of ions in the absence of solvent may be conveniently studied by mass spectrometry. Low-energy (metastable) ions almost always dissociate from the ground electronic state with internal energies in the transition states that are comparable to those found in classical solution experiments.[1,2] Perhaps the most compelling evidence indicating the importance of relative critical energies[3] in influencing the relative rates of competing reactions of metastable ions is the frequent intervention of kinetic isotope effects, some of which are large, especially for small species.[4,5]

Direct bond cleavages, which are probably the simplest of all elementary chemical reactions, are ubiquitous in the dissociation of radical cations.[6] Isotope effects often contain information on bond cleavages and several detailed studies have shown that alkyl radical elimination by seemingly simple cleavages may be more complicated than expected.[7–11] The related process of hydrogen atom loss occurs less frequently,[6] and may involve some unique features.

Metastable ionised *n*-propanol **1**$^{+\cdot}$, dissociates by two routes, each of which has been shown to proceed with extremely high site selectivity.[12] The dominant reaction, loss of water, takes place after a unidirectional 1,4-hydrogen transfer from the γ-carbon atom to the oxygen atom to give the distonic[13] ion,[14] ·$CH_2CH_2CH_2OH_2^+$, **1δ**, which then expels water to form ionised cyclopropane, **2**$^{+\cdot}$. About 2% of **1**$^{+\cdot}$ dissociates by eliminating a hydrogen atom to give protonated propionaldehyde **3** (Scheme 1). Labelling evidence[12] provides indirect evidence that one of the α-hydrogen atoms is specifically lost, but expulsion of deuterium (D·) rather than protium (H·) has not yet been detected. Thus, it has been shown that both $CH_3CH_2CH_2OH^{+\cdot}$ and $CH_3CD_2CH_2OH^{+\cdot}$ eliminate predominantly H_2O and a minor proportion of H·. On the other hand, $CD_3CH_2CH_2OH^{+\cdot}$ loses HOD and H· in comparable quantities. Moreover, $CH_3CH_2CD_2OH^{+\cdot}$ expels essentially only H_2O (but no H· or D·), whereas $CH_3CH_2CHDOH^{+\cdot}$ loses mainly H_2O, a little H·, but no D·.



Scheme 1

These data indicate that both the 1,4-hydrogen transfer which initiates water loss and cleavage of the carbon–hydrogen bond resulting in hydrogen atom elimination are influenced by very large isotope effects. Although a lower limit of 30 : 1 for the isotope effect for hydrogen atom loss was set,[12] an accurate value could not be determined because $CH_3CH_2CHDOH^{+\cdot}$ does not lose D· at a measurable rate. However, the overall isotope effect on water loss was estimated to be *ca.* 44 : 1 from the difference in the ratios of hydrogen atom and water lost from $CH_3CH_2CH_2OH^{+\cdot}$ and $CD_3CH_2CH_2OH^{+\cdot}$. The total enthalpy of formation (778 kJ mol^{-1}) of the products of hydrogen atom loss, which appears to involve little or no reverse critical energy[15] even though it entails a large isotope effect, is only slightly higher than that (757 kJ mol^{-1}) of the products of water expulsion.[12] Moreover, the energy of the transition state for the 1,4-hydrogen transfer must lie above 757 kJ mol^{-1} because this step is rate-limiting and subject to an isotope effect. Consequently, the competition between water and hydrogen atom loss is strongly influenced by relatively small differences in the energetics of these reactions.

In order to obtain a better estimate of the ^{2}H isotope effect on hydrogen atom loss and to determine whether this process also shows a ^{13}C isotope effect, a wider range of labelled analogues of **1**$^{+\cdot}$ has been investigated (Table 1). In general, where these data overlap with those previously reported,[12] the agreement is good, although there are some minor variations that may be attributed to instrumental parameters. Hydrogen atom loss competes slightly more effectively with water loss and the kinetic energy releases are marginally larger in the new data. Three significant deductions may be made from the new data.

Table 1 Reactions of metastable ionised *n*-propanol and labelled analogues

	Neutral species lost							
	H_2O		HOD[a]		H·		D·	
Initial structure	*R*[b]	*T*[c]	*R*[b]	*T*[c]	*R*[b]	*T*[c]	*R*[a]	*T*[c]
$CH_3CH_2CH_2OH^{+\cdot}$	97.4	1.4			2.6	8.3		
$CH_3CH_2CHDOH^{+\cdot}$	93.6	1.6			6.4	10.0	< 0.05	
$CH_3CH_2CD_2OH^{+\cdot}$	100	1.7					< 0.01	
$CH_3CD_2CH_2OH^{+\cdot}$	89.9	1.2	[d]		10.1	10.3		
$CD_3CH_2CH_2OH^{+\cdot}$	[d]		41.0	1.9	59.0	12.4		
$CH_2DCH_2CH_2OH^{+\cdot}$	77.8	2.0	7.5	2.2	2.8	12.3		
$CD_3CH_2CHDOH^{+\cdot}$	[d]		49.4	1.7	30.5	8.8	0.1	[e]
$CH_3CH_2{}^{13}CH_2OH^{+\cdot}$	92.4	1.5			7.6	4.3		
$CD_3CH_2{}^{13}CH_2OH^{+\cdot}$			42.4	1.6	57.6	7.7		

[a] None of these metastable ionised labelled propanols loses D_2O. [b] *R* = Relative abundances normalised to a total of 100 units and measured by metastable peak heights on the VG Analytical ZAB-R mass spectrometer (ref. 20). [c] *T* = Kinetic energy release (in kJ mol^{-1}), estimated from the width at half-height of the appropriate metastable peak with no correction for the width of the main beam. Values are quoted to one decimal place to aviod introducing rounding errors. [d] Extremely weak peaks were detected, but these signals are attributable to water loss from the ^{13}C satellite signal of the $[M–H]^+$ peak. [e] Peak too weak to permit accurate measurements.

First, the value of *ca*. 54:1 obtained for the overall isotope effect on water loss is quite similar to that (*ca*. 44:1) reported previously[12] from considering the suppression of HOD loss relative to H· elimination from $CD_3CH_2CH_2OH^{+\cdot}$ compared to the behaviour of $CH_3CH_2CH_2OH^{+\cdot}$. However, the loss of H_2O and HOD in the ratio of *ca*. 10:1 from $CH_2DCH_2CH_2OH^{+\cdot}$ corresponds to a much smaller primary isotope effect of only *ca*. 5:1 for the initial hydrogen transfer step. This value is a lower limit and would be approximately doubled if account were taken of the overlapping loss of H_2O and HOD in similar quantities from the ^{13}C satellite signal of the oxonium ion, $CH_2DCH_2CH{=}OH^+$, formed by hydrogen atom loss from $CH_2DCH_2CH_2OH^{+\cdot}$. The discrepancy between the extremely large overall isotope effect and the much less pronounced, although still substantial, primary isotope effect probably indicates that a significant secondary isotope effect operates in this system. Thus, the rate of D transfer from the CD_3 group of $CD_3CH_2CH_2OH^{+\cdot}$ is reduced by both a primary isotope effect (because a C–D bond is being broken) and a secondary isotope effect (because a CD_2 group in which the hybridisation at carbon changes from sp^3 to sp^2 is left at the migration origin). In contrast, the rate of D transfer from the CH_2D group of $CH_2DCH_2CH_2OH^{+\cdot}$ is reduced by the same primary isotope effect (because a C–D bond is being broken), but the secondary isotope effect does not operate (because a CH_2 group is at the migration origin). Although secondary isotope effects usually are smaller than primary isotope effects, there are clear examples of systems in which secondary effects are comparable in magnitude to primary effects.[16] Water loss from $\mathbf{1}^{+\cdot}$ appears to be another example of this behaviour.

Secondly, a better estimate for the isotope effect on hydrogen atom loss may be obtained by considering the behaviour of $CD_3CH_2CHDOH^{+\cdot}$ because the dominant water loss reaction is slowed by the isotope effects influencing the initial D transfer, thus permitting H· (and, to a very limited extent, D·) loss to compete. Even so, the signal for D· loss is barely detectable and is only *ca*. 0.2% of that for H· elimination. This enormous isotope effect of *ca*. 500:1 is probably the largest so far detected in the dissociation of any ion containing four heavy atoms. This estimate is a lower limit for the primary isotope effect since any secondary isotope effect would favour D· loss.

Thirdly, the small but reproducible increase in the ratio of HOD to H· loss from $CD_3CH_2CH_2OH^{+\cdot}$ (0.70:1) and $CD_3CH_2{}^{13}CH_2OH^{+\cdot}$ (0.74:1) gives a value of *ca*. 1.06:1 for the overall ^{13}C isotope effect on hydrogen atom loss. This value is increased to *ca*. 1.2 if peak areas rather than heights are used to estimate the relative abundances of the competing processes. Although ^{13}C isotope effects are by their nature much smaller than ^2H isotope effects and this particular ^{13}C isotope effect is quite large, it is surprisingly small in view of the enormous ^2H isotope effect of *ca*. 500:1. Furthermore, the behaviour of $CH_3CH_2{}^{13}CH_2OH^{+\cdot}$, for which the ratio of H_2O loss relative to H· elimination (12:1) is reduced compared to that (37:1) for $CH_3CH_2CH_2OH^{+\cdot}$, seems to suggest that water loss is somehow affected by a ^{13}C isotope effect (*ca*. 3.1:1 from peak heights or *ca*. 2.1:1 from peak areas). Any such ^{13}C isotope effect on water loss would offset that on hydrogen atom elimination and give values of *ca*. 3.2:1 (peak heights) or 2.6:1 (peak areas) for the true ^{13}C isotope effect on hydrogen atom loss. This value is exceptionally large and is in keeping with the enormous ^2H isotope effect of *ca*. 500:1.

The unanticipated conclusion that water loss is affected by a ^{13}C isotope effect is supported by a similar reduction in the ratio of H· loss relative to H_2O elimination (15:1) for $CH_3CH_2CHDOH^{+\cdot}$, compared to that found for $CH_3CH_2CH_2OH^{+\cdot}$, thus suggesting that a secondary ^2H isotope effect of *ca*. 2.6:(peak heights) or *ca*. 2.5:1 (peak areas) also discriminates against water loss. Recent high-level molecular orbital calculations on ionised ethanol reveal that the C–C bond is unusually long.[17] Geometry optimisations at the MP2(FC)6-311G** level[18] of theory using the GAUSSIAN 94 suite of programs[19] indicate that the C(1)–C(2) bond is similarly elongated (to 1.738 Å) in the lowest energy structure of $\mathbf{1}^{+\cdot}$. In contrast, the corresponding bond in $\mathbf{1\delta}$ is not appreciably elongated (1.515 Å) and is very similar in length to the C(2)–C(3) bond (1.501 Å). The peculiar geometry of the minimum energy form of $\mathbf{1}^{+\cdot}$ may provide a key to explain the unusual features of water and hydrogen atom loss. This structure is inappropriate for water elimination (the methyl and hydroxy groups are held well apart, thus preventing the initial hydrogen transfer) and hydrogen atom elimination (the wrong bond is stretched and further elongation would lead to ethyl radical loss by α-cleavage). In order to facilitate either water or hydrogen atom elimination, quite considerable changes to the C(1)–C(2) bond length would be necessary, thus accounting for the large isotope effects on both reactions.

Regardless of their precise origin, the sheer magnitude of these isotope effects, particularly that for hydrogen atom loss, reveals that α-cleavage and hydrogen transfers are sometimes complex processes worthy of further investigation.

Financial support from the British Mass Spectrometry Society, the Fred Elison Travel Fund and the Natural Sciences and Engineering Research Council of Canada (NSERC) is gratefully acknowledged.

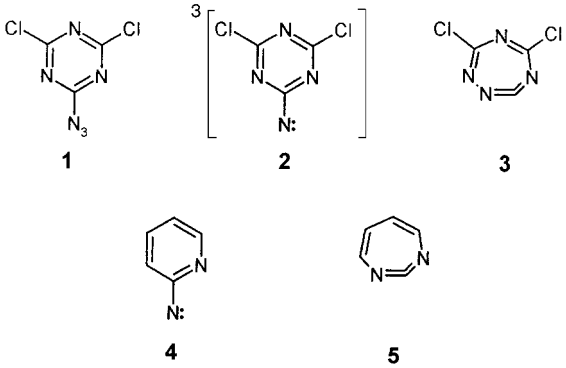
Received (in Cambridge, UK) 23rd July 1999, Accepted 17th September 1999

2-Azido-4,6-dichloro-*s*-triazine 1, matrix-isolated in Ar at 10 K, yields triplet nitrene 2 and the strained cyclic carbodiimide 3 upon photolysis.

The photochemistry of phenyl azides has been a controversial topic for a long time.[1,2] The generally accepted pathway includes primary formation of an open-shell singlet nitrene[3,4] followed by intersystem crossing (ISC) to the ground-state triplet nitrene and/or cycloaddition to a neighbouring C=C double bond in the arene system. The efficiency of the latter reaction depends on factors such as temperature and substitution. It yields didehydroazepines *via* intermediary azirines.[5] Heteroaromatic aryl azides have also been studied in some detail.[6] For instance, 2-pyridylnitrene **4**, generated from 2-azidopyridine or the isomeric tetrazolopyridine, yields didehydro-1,3-diazepine **5** (a cyclic carbodiimide) upon photolysis

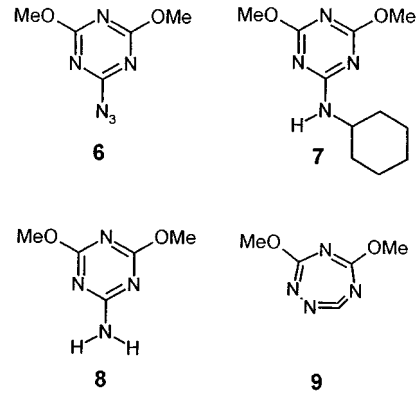


1 **2** **3** **4** **5**

in an Ar matrix.[7] A variety of heteroaromatic aryl nitrenes could be characterized by EPR,[8] and in some instances also by IR spectroscopy.[6]

The products isolated following thermolysis[9] or photolysis[10] of azido-*s*-triazines in solution exclusively arise from reactions of the triplet or singlet nitrenes. Thus, thermolysis of 2-azido-4,6-dimethoxy-1,3,5-triazine **6** in cyclohexane yielded the C–H insertion product **7** and the aminotriazine **8**.[9] The formation of **8** is likely due to a reaction of the ground-state triplet nitrene, while **7** is probably formed through the S_1 state of the nitrene. Surprisingly, no products ascribable to reactions of a didehydrotetrazepine (*e.g.* **9**) have been reported. Their absence could be due to a lack of stability, or it could reflect an increased barrier for cycloaddition towards a nitrogen atom. Here we present our recent results on the photolysis of matrix-isolated 2-azido-4,6-dichloro-*s*-triazine **1** which are different from the ones described for **6**.

The matrix isolation set-up used in these experiments has been described elsewhere.[11] Argon was chosen as the matrix material. During deposition, the cold window (KBr or sapphire) was kept at 30 K, otherwise the temperature of the matrix was held at 10 K. Azide **1**[12] was sublimed at 10 °C/10^{-6} mbar. In experiments using UV–VIS detection, it was photolysed by the



6 **7** **8** **9**

output of a 75 W Xe arc lamp coupled to a monochromator. The irradiation wavelength selected was 320 nm. In the case of IR detection, the output of a mercury low-pressure lamp (λ = 254 nm) was used. Brief irradiation (8 min) under these conditions led to the disappearance of the IR bands of **1** and to the formation of new bands at $\tilde{\nu}$ = 1951.2, 1550.0, 1467.6, 1446.4, 1254.5, 1246.8, 1110.2 and 1050.0 cm^{-1} along with some weaker bands below 900 cm^{-1} and around 2100 cm^{-1}. Upon extended irradiation with λ = 254 nm, these bands disappeared again, while the new absorptions at $\tilde{\nu}$ = 2271.2, 2214.2, 2112.9 and 2094.4 cm^{-1} were indicative of nitrile and possibly isonitrile and/or cumulene functionalities in the final product mixture.[13] Long-wavelength irradiation (λ > 420 nm) of the primary photoproducts led to a decrease in intensity of some bands ($\tilde{\nu}$ = 1467.6, 1446.4, 1254.5, 1246.8, 848.7, 787.9 and 580 0 cm^{-1}), while the intensity of other bands ($\tilde{\nu}$ = 1951.2, 1550.0, 1110.2, 1050.0 and 814.4 cm^{-1}) increased. Thus, the experimental findings are consistent with two compounds (these can be interconverted by long-wavelength photolysis) being predominantly formed during the initial stages of photolysis, which yield other, presumably ring-opened products, upon extension of 254 nm photolysis. In the UV–VIS, the product primarily formed showed absorption maxima at λ = 330 and 356 nm and a broad band between 380 and 490 nm with vibrational fine structure. Irradiation into this band (λ > 420 nm, Hg high pressure lamp with cut-off filter) led to the disappearance of the primary photoproduct and to the formation of a secondary photoproduct with λ_{max} = 328 and 352 nm (Fig. 1). Consistent with the results obtained using IR spectroscopy, this secondary photochemistry proved to be at least partially reversible. Photolysis of the product mixture thus obtained using λ = 320 nm again led to the formation of the spectrum with λ_{max} = 330, 356 and 380–490 nm, albeit with slightly reduced intensity. A likely explanation for this behaviour is formation of secondary (ring-opened) photoproducts, which do not show pronounced long-wavelength absorptions.

The vibrational spectra of triplet nitrene **2** and dehydrotetrazepine **3** were calculated using density functional theory (B3LYP with a 6-31G* basis, unscaled).[14] The comparison with

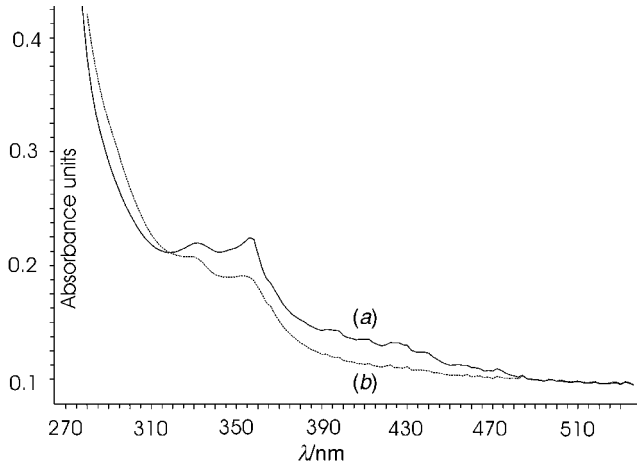


Fig. 1 (*a*) UV–VIS spectrum obtained after photolysis (3 h, λ = 320 nm) of **1** in Ar, 10 K. (*b*) UV–VIS spectrum obtained by photolyzing the same sample subsequently with λ = 475–620 nm, 2 h.

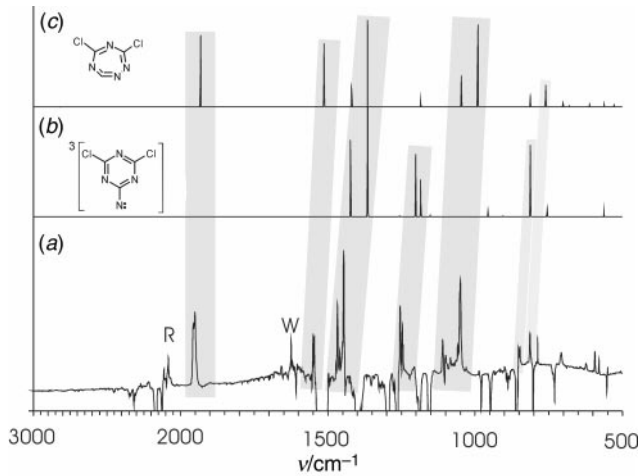

Fig. 2 (*a*) Difference IR spectrum obtained by subtracting the spectrum of **1** (Ar, 10 K) from the spectrum obtained after 8 min photolysis (λ = 254 nm). The bands pointing downward belong to **1**. Bands pointing upward are assigned to **2** and **3**, with the exception of the bands labelled W (water) and R (ring-opened secondary photoproduct). (*b*) Calculated IR spectrum (UB3LYP 6-31G*) of triplet nitrene **2**. (*c*) Calculated IR spectrum of **3** (B3LYP 6-31G*). The correlation with the experimental spectrum is highlighted by grey shading. The intensity of the band at $\tilde{\nu}$ = 1446.4 cm^{-1} is *ca.* 0.2 absorbance units.

the experimental data shows **2** and **3** to be indeed formed as primary products (Fig. 2).[15] This assignment is also consistent with the UV–VIS data, as the characteristics of the product initially formed upon photolysis at 320 nm (λ_{max} = 330 and 356 nm, broad band between 380 and 490 nm) are in line with the expected behavior of a triplet nitrene.[2]

The UV–VIS-spectrum attributed to **3** (λ_{max} = 328 and 352 nm) is very similar to a spectrum obtained by Yamada *et al.*[16] in a glassy EPA matrix at 77 K that was assigned to arise from triplet 4,6-dimethoxy-*s*-triazinyl nitrene. It thus appears likely that the product observed by them has to be reassigned to didehydrotetrazepine **9** or to its trapping products.[17]

The observation of didehydrotetrazepine **3** upon photolysis of azide **1** in an argon matrix could indicate that tetrazepines may actually be formed in the solution photochemistry of triazinyl azides. Experiments directed towards the isolation of derivatives of these heterocycles therefore may prove useful and are in progress.

12 *Synthesis* of **1**: The preparation given before (C. V. Hart, *J. Am. Chem. Soc*., 1928, **50**, 1928) gave only mixtures of products that could not be separated by crystallization, and the melting point stated to be 85 °C is most likely incorrect. The following method was successful: To a solution of cyanuric chloride (3.000 g, 16.27 mmol) in acetone (20 ml) in a small separation funnel, a solution of NaN_3 (1.000 g, 15.38 mmol) in water (10 ml) was added and the mixture shaken for 5 min. The organic phase was then separated and allowed to evaporate at room temperature. The crystals were chromatographed (silica gel, CH_2Cl_2–light petroleum = 1:1) to give pure **1** (1.13 g, 5.92 mmol, 36%) as a colorless powder, mp 59.5–61 °C; δ_H(300 MHz, $CDCl_3$) no signal; δ_C(75.5 MHz, $CDCl_3$) 171.39, 172.60; *m/z* (FAB) 190.99 (100, M + H$^+$); $\tilde{\nu}_{max}$/cm^{-1} (Ar, 10 K) 2168.9 (s), 1531.0 (vs), 1512.0 (vs), 1396.8 (s), 1295.8 (s), 1268.0 (s), 1187.6 (m), 1159.9 (m), 947.9 (w), 857.2 (m), 803.8 (w), 730.5 (vw).
13 The characterization of these final products is in progress; results will be published at a later time.
14 GAUSSIAN 98 software was used in the calculations.
15 *Selected data* for **2**: $\tilde{\nu}_{max}$/cm^{-1} (Ar, 10 K) 1467.6 (s), 1446.4 (vs), 1254.5 (s), 1246.8 (m), 852.9 (w), 848.7 (w), 787.9 (m), 580.0 (w). For **3**: $\tilde{\nu}_{max}$/cm^{-1} (Ar, 10 K) 1957.0 (vs), 1951.2 (vs), 1550.0 (m), 1546.2 (m), 1110.2 (m), 1050.0 (vs), 814.4. An N=C=N stretching band at $\tilde{\nu}$ = 1957.0 cm^{-1} for **3** is in the range expected for such a compound. For comparison, simple open-chain *N*-dialkylamino substituted carbodiimides absorb at ν = 2090 cm^{-1} (ref. 18). The decrease in frequency in **3** reflects the decrease in bond energy induced by strain. A similar trend has been observed in the case of other cyclic carbodiimides (ref. 6).
16 H. Yamada, H. Shizuka and K. Matsui, *J. Org. Chem.*, 1975, **40**, 1351.
17 There is a complete lack of absorption beyond λ = 420 nm in the spectra given by Yamada *et al.* However, a broad band would be expected for a triplet nitrene. In an EPA matrix, trapping of the didehydrotetrazepine by EtOH has to be considered.

Received (in Liverpool, UK) 13th August 1999, Accepted 8th September 1999

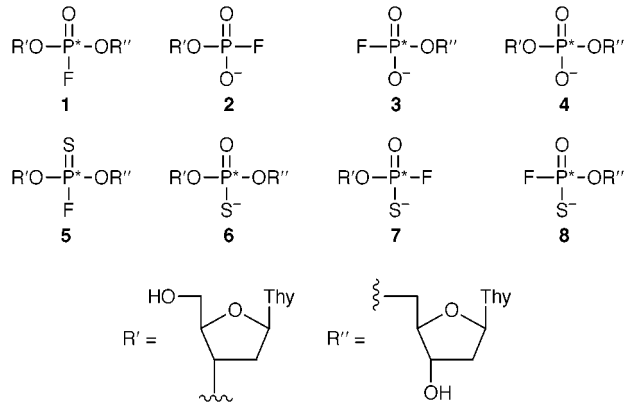
***Spleen* or *snake venom* nuclease-assisted cleavage of P–F bonds in nucleotides bearing a phosphorofluoridate moiety occurs at negatively charged phosphates only.**

Catalytic promiscuity of enzymes has attracted the attention of researchers studying the problem of a common binding site and common mechanistic features in catalysis involving substrates bearing functional groups different from those naturally cleaved by these enzymes.[1] Since such studies may shed light on the evolutionary diversification of enzymes, each example of 'unusual' activity of enzymes requires meticulous scrutiny.

In this respect, the cleavage of the P–O bond in dinucleoside 3′,5′-phosphorofluoridates ($N_{PF}N'$) by *spleen* phosphodiesterase (*spleen* PDE) and *snake venom* phosphodiesterase (*sv* PDE), as reported recently in several papers by Dabkowski *et al.*,[2] attracted our attention. Both enzymes are known as phosphodiester hydrolases that cleave oligonucleotides with natural 3′-5′-phosphodiester linkages to produce the corresponding nucleoside 3′- or 5′-phosphates.[3] These enzymes are known to require the presence of a negative charge at the cleavable phosphate moiety[4] and can also accept as substrate various charged oligonucleoside phosphate analogues. For example, dinucleoside 3′,5′-phosphorothioates ($N_{PS}N'$)[5] are recognised by *snake venom* phosphodiesterase albeit the rate of cleavage of the diastereomers differs significantly. This observed stereodifferentiation has been used for determination of absolute configuration of $N_{PS}N'$[6] and related compounds, *e.g.* ATPαS[7] and thymidine 5′-phosphorothiofluoridate,[8] and also as a practical method of preparing single diastereomers of $N_{PS}N'$ by selective degradation of a pool of chemically synthesised oligonucleoside phosphorothioates[9] In contrast to these, uncharged dinucleotide analogues, *e.g.* dinucleoside alkyl phosphates and dinucleoside methylphosphonates, are not substrates for *sv* and *spleen* PDE, most likely due to the lack of a negative charge at the cleavage site.[10]

In light of the above, the results of Dabkowski *et al.*[2] have to be viewed with caution, although a speculation that the strongly polarised P–F bond could mimic the P–O$^-$ bond cannot be rejected *a priori*. However, the reported data[2] (*viz.* presence of thymidine, thymidine 5′-phosphorofluoridate and unreacted $T_{PF}T$, after 3 h exposure to *sv* PDE in enzymatic buffer solution) seemed to be at odds with the hydrolytic instability of $N_{PF}N'$ in buffered media[11] and the fact that nucleoside 5′-phosphorofluoridate monoesters are known to be good substrates for *sv* PDE yielding nucleoside 5′-phosphates as products.[12] These factors prompted us to reinvestigate the problem of the susceptibility of uncharged nucleotide analogues containing the P–F bond towards *snake venom* and *spleen* phosphodiesterases, and as model compounds for our studies we chose a dinucleoside 3′,5′-phosphorofluoridate and the corresponding phosphorothiofluoridate.

Dithymidine 3′,5′-phosphorofluoridate **1** (mixture of two diastereomers, *ca.* 1:1 ratio) was obtained by two independent methods[11,13] and isolated by means of silica gel chromatography.† The reference compounds, thymidine 3′-phosphorofluoridate **2** and thymidine 5′-phosphorofluoridate **3** were obtained either in DBU-assisted reactions of protected thymidine 3′- or 5′-(2-oxo-3-oxa-1-thia-2-phosphaspiro[4.5]decane)s[14] with triethylamine trishydrofluoride,‡ or independently, in reactions of pyridine solutions of suitably protected thymidine hydrogen 3′- or 5′-phosphonate with trimethylsilyl chloride, followed by treatment with iodine and triethylamine trishydrofluoride.[15]



The hydrolytic stability of phosphorofluoridate **1** was checked in various buffer solutions using an RP-HPLC assay.§ It was found that compound **1** (0.1 mM) dissolved in 0.05 M acetate buffer (pH 5.0) (*spleen* PDE buffer) at 37 °C was quantitatively hydrolysed within 5 min providing dithymidine 3′,5′-phosphate **4**. The same results were obtained using 0.1 M Tris-HCl (pH 8.0) containing 20 mM $MgCl_2$ (*sv* PDE buffer) as medium. Incubations performed in a presence of *spleen* PDE¶ (0.15 U ml^{-1}) and *sv* PDE¶ (0.005 U ml^{-1}), using the same buffer systems as for the blank experiments, in both instances resulted in formation of phosphodiester **4** only (5 min, no starting material present) without detectable amounts of phosphorofluoridate **2** and **3**, respectively (RP-HPLC analysis using genuine samples of **2**, **3** and **4**). Prolonged incubation times (20, 40 and 60 min) led to a gradual hydrolysis of the initially formed phosphodiester **4** to produce thymidine and thymidine 3′- or 5′-phosphate, respectively. In separate experiments we found that rates of enzymatic hydrolysis (*sv* and *spleen* PDE) of pure phosphodiester **4** and that produced *in situ* from phosphorofluoridate **1** were identical, indicating that fluoride anion neither accelerated nor inhibited the activity of these phosphodiesterases.

We also confirmed earlier observations by Wittmann[12] and others[12] that products of a putative enzymatic hydrolysis of phosphorofluoridate **1** claimed by Dabkowski *et al.*,[2] *viz.* compounds **2** or **3**, are substrates for phosphodiesterases. We found that phosphorofluoridate **2** was hydrolysed by *spleen* PDE slower than phosphodiester **4**, and thus if **1** were a substrate for this enzyme (cleavage of the P–O bond), transient formation of **2** would be anticipated. In the instance of *sv* PDE, we could not exclude a remote possibility that phosphorofluoridate diester **1** underwent slow enzymatic hydrolysis with

P–O bond cleavage to produce thymidine 5′-phosphorofluoridate **3**, since the latter was found to be a better substrate for the enzyme than phosphodiester **4**.

A diastereomeric mixture of dithymidine 3′,5′-phosphorothiofluoridate **5** (ratio *ca.* 1:1)[8,13] was also examined as a potential substrate for *spleen* and *snake venom* phosphodiesterases. Compound **5**‖ was found to be significantly more hydrolytically stable than its oxo congener **1** in the buffer solutions used (*vide supra*) and required *ca.* 1 h at 37 °C for complete hydrolysis to produce dithymidine 3′,5′-phosphorothioate **6**. Attempted enzymatic hydrolysis of **5** was performed using a 10× higher concentration of *spleen* and *sv* PDE than those used in experiments with phosphorofluoridate **1**. It was found that during incubations of **5** with *spleen* and *sv* PDE no trace of products resulting from P–O bond cleavage, *i.e.* thymidine 3′-*O*-phosphorothiofluoridate **7**[8,15] or 5′-phosphorothiofluoridate **8**,[8,15] respectively, could be detected (RP-HPLC assay). After 1 h, the only product present was phosphorothioate diester **6** (diastereomeric ratio *ca.* 1:1) that upon prolonged enzymatic incubation (samples analysed after 2, 4 and 8 h) yielded gradually thymidine and thymidine 3′- or 5′-phosphorothioate, respectively, as the sole products. For the reactions performed in the presence of *sv* PDE, as expected, a stereoselective digestion of (R_P)-**6** was observed.[6] Since in our earlier studies[8] we demonstrated that (R_P)-phosphorothiofluoridate **8** is a good substrate for *sv* PDE one should expect the accumulation of (S_P)-phosphorothiofluoridate **8** in the reaction mixture, if an enzymatic cleavage of the P–O bond in **5** produced both diastereomers of **8**.

In conclusion, the presented results on enzymatic hydrolysis of dithymidine 3′,5′-phosphorofluoridate **1** and dithymidine 3′,5′-phosphorothiofluoridate **5** by *spleen* and *snake venom* phosphodiesterases indicate that these compounds first undergo chemical hydrolysis to dinucleotides **4** and **5**, respectively, which are subsequently hydrolysed enzymatically to the corresponding nucleoside and nucleotide derivatives. The released fluoride anion under the reaction conditions did not inhibit the nucleolytic activity of the investigated enzymes.

These studies support the earlier findings that *sv* and *spleen* PDE accept as substrates negatively ionised phosphate derivatives and thus the enzymatic hydrolysis of phosphorofluoridate diesters by these enzymes reported by Dabkowski *et al.*[2] could not be confirmed.

Work presented here was financially assisted by the State Committee for Scientific Research (KBN), grant no. 4 PO5F 006 17 (to W. J. S), the Swedish Natural Science Research Council, and the Swedish Foundation for Strategic Research.

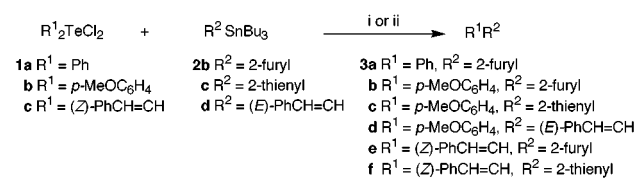
The palladium- and copper-catalyzed cross-coupling of diaryl- or divinyl tellurium dichlorides with organostannanes has been achieved in the presence of $PdCl_2$ (10 mol%) or CuI (10 mol%) with Cs_2CO_3 (2 equiv.) in MeCN in good to moderate yields; alternatively, the palladium- and copper-catalyzed carbonylative cross-coupling of organotellurium dichlorides with organostannanes was readily accomplished under atmospheric pressure of CO in good to moderate yields.

The palladium-catalyzed cross-coupling of organostannanes with an organic electrophile (*i.e.* halides and triflates), known as the Stille reaction,[1] has become an extremely powerful tool for the construction of carbon–carbon bonds. As alternatives to organic electrophiles, hypervalent iodonium salts[2] and the main group metal lead[3] have been employed in the cross-coupling with organostannaes. Recently Uemura *et al.* reported[4] the palladium-catalyzed carbonylation[4a] and homocoupling[4b] of vinyltellurides as well as the Heck type reaction[4c] of vinyltellurides. However the cross-coupling of aryl- or vinyltellurium dichlorides with organostannanes is not known. We assumed that the use of tellurium as one of the 6A group metals would expand the scope of the cross-coupling reaction. Here we report the palladium- and copper-catalyzed cross-coupling and carbonylative cross-coupling of diaryl- and divinyl-tellurium dichlorides[5] with organostannanes.

The results of Pd- and Cu-catalyzed cross-coupling and carbonylative cross-coupling of diaryl- or divinyl-tellurium dichlorides in MeCN at room temperature are summarized in Scheme 1 and Table 1. The palladium-catalyzed coupling of diphenyltellurium dichloride **1a** with 2-furyltributylstannane **2b** was carried out to find the optimum conditions. Of the catalysts tested [$PdCl_2$, $Pd(PPh_3)_4$, $Pd_2(dba)_3{\cdot}CHCl_3$, $PdCl_2(PPh_3)_2$], $PdCl_2$ was the best choice. Among the bases used, Cs_2CO_3 was more suitable than K_2CO_3, Na_2CO_3 and NaOMe. As solvent MeCN was the most preferable. In our hands, the cross-coupling of $PhTeCl_3$, *p*-$MeOC_6H_4TeCl_3$ and (*E*)-$PhCH{=}CHTeCl_3$ with 2-furylstannane gave the cross-coupling products in rather low yields. Diphenyltellurium dichloride **1a** reacted with 2-furyltributylstannane **2b** in the presence of $PdCl_2$ (10 mol%) and Cs_2CO_3 (2 equiv.) in MeCN at room temperature for 3 h to afford 2-phenylfuran (**3a**)[6] in 89% isolated yield. Under the same conditions but with CuI (10 mol%) as catalyst at 70 °C the reaction gave **3a** in 72% yield (method B in entry 1, Table 1). We tested various copper catalysts to discover a palladium-free Stille protocol, and the cross-coupling of the organostannane **2b** with **1a** was achieved at 70 °C. Of the catalysts used, CuI (10 mol%) was the most preferable among CuI, CuBr, and $Cu(OAc)_2$. As base, Cs_2CO_3 was more suitable than K_2CO_3, Na_2CO_3 and NaOMe. The solvent MeCN was the best choice, presumably because of the solubility of organotellurium compounds. The reaction of di(*p*-methoxyphenyl)tellurium dichloride **1b** with **2b** in the presence of $PdCl_2$ at room temperature and CuI at 70 °C proceeded to give 2-(*p*-methoxyphenyl)furan **3b**[7] in 89 and 68% yields, respectively (methods A and B in entry 2). This coupling method was also applied to alkenyl-substituted stannane **2d**. The reaction of **1b** with β-(*E*)-styrylstannane **2d** gave the substituted stilbene **3d**[8] (entry 4). When di[β-(*Z*)-styryl]tellurium dichloride **1c** was treated with 2-furylstannane **2b**, 2-β-(*Z*)-styryl substituted furan **3e** was readily obtained in 70 and 56% yields, respectively (methods A and B in entry 5). The (*Z*)-stereochemistry of **3e** was confirmed by the coupling constant J = 12.1 Hz for the vinylic protons.

We then extended this reaction to carbonylative cross-coupling with organostannanes (Scheme 2). The diphenyltellurium dichloride **1a** was successfully coupled with 2-furyltributylstannane **2b** under atmospheric pressure of CO under palladium or copper catalysis to furnish 2-benzoylfuran **4a**[9] in 84 and 63% isolated yields (methods A and B in entry 7).



Scheme 1 *Reagents and conditions:* i (method A), $PdCl_2$ (10 mol%), MeCN, Cs_2CO_3 (2 equiv.), room temp., 3 h; ii (method B), CuI (10 mol%), MeCN, Cs_2CO_3 (2 equiv.), 70 °C, 7 h.

Table 1 Pd- and Cu-catalyzed cross-coupling and carbonylative cross-coupling of organotellurium dichloride with organostannanes

Entry	Organotellurium compounds	Organostannanes	Reaction conditions[a]	Products	Isolated yields (%)
Cross-coupling					
1	**1a**	**2b**	A	**3a**	89

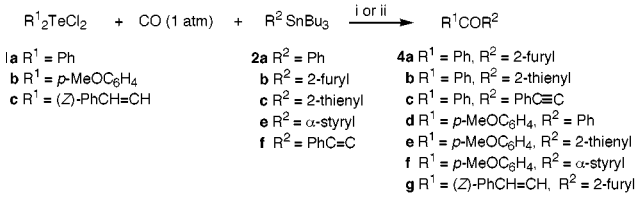
13	**1c**	**2b**	A	**4g**	70
			B		52

[a] A: $PdCl_2$ (10 mol%), Cs_2CO_3 (2 equiv.), room temp. B: CuI (10 mol%), Cs_2CO_3 (2 equiv.), 70 °C. Carbonylative cross-coupling carried out under atmospheric pressure of CO.



Scheme 2 *Reagents and conditions:* i (method A), $PdCl_2$ (10 mol%), MeCN, Cs_2CO_3 (2 equiv.), room temp., 3 h; ii (method B), CuI (10 mol%), MeCN, Cs_2CO_3 (2 equiv.), 70 °C, 7 h.

Treatment of **1a** with 2-thienyltributylstannane **2c** under the same conditions afforded 2-benzoylthiophene **4b**[10] in 85% yield (entry 8). This carbonylative coupling was also applied to alkynyltributylstannane **2f** to provide alkynyl-substituted ketone **4c** (entry 9).[11] For the di(*p*-methoxyphenyl)tellurium dichloride **1b**, phenyltributylstannane **2a** and 2-thienyltributylstannane **2c** were smoothly coupled to give ketones **4d**[11] and **4e**,[11] respectively, in 83% yield (entries 10 and 11). When the tellurium dichloride **1b** was treated with α-styryltributylstannane **2e**, unexpectedly the carbonylative cross-coupled product **4f**[12] was obtained as the sole product in 90% yield without any *cine*-substitution[13] product (entry 12). Finally, di[β-(*Z*)-styryl]tellurium dichloride **1c** was successfully coupled with **2b** under CO to afford β-(*Z*)-styryl-substituted ketone **4g**[14] in 70 and 52% yields, respectively (methods A and B in entry 13).

In considering a plausible mechanism for the cross-coupling it is presumed that oxidative addition of organotellurium compounds with Pd^0 or Cu^I gives $R^1PdTeR^2Cl_2$ or $R^1CuTeR^2Cl_2$, which is subjected to transmetallation with stannanes followed by reductive elimination to afford the cross-coupled products.

In summary, the palladium- and copper-catalyzed cross-coupling and carbonylative cross-coupling of diorganotellurium dichlorides with organostannanes were achieved under mild conditions in good to moderate yields.

5 N. Petragnani, in *Tellurium in Organic Synthesis*, Academic Press, 1994 and references therein. General procedure as follows. Diphenyltellurium dichloride (**1a**): $TeCl_4$ (40 mmol) and PhHgCl (80 mmol) were heated under reflux in anhydrous dioxane (100 ml) for 2 h. The solution is cooled to 10 °C and the $HgCl_2$ dioxane precipitate filtered off and washed with cold dioxane (15 ml). The filtrate was poured with stirring into 1% ice-cold HCl (400 ml). The dichlorides precipitate as crystalline solids and were recrystallized from benzene–light petroleum (bp 30–60 °C. Di[β-(*Z*)-styryl]tellurium dichloride (**1c)**: $NaBH_4$ (9 mmol) was added in small portions to a stirred suspension of Te (3 mmol) in EtOH (15 ml), and THF (5 ml) was added to the hot mixture, which was then refluxed. After 15 min the mixture turned dark violet and the reflux was continued until all the Te had disappeared. The heat source was removed and the phenylacetylene (7.8 mmol) added. When the color changed to yellow, the mixture was cooled at room temperature, diluted with EtOAc (50 ml) and washed first with saturated aqueous NH_4Cl (3 × 30 ml) and then with brine (3 × 30 ml). The organic phase was separated, dried ($MgSO_4$) and evaporated in a rotary evaporator. The residue dissolved in a small amount of $CHCl_3$ was treated dropwise, while cooling (ice bath) and stirring, with a solution of an equimolar amount of SO_2Cl_2 in the same solvent. By addition of a large excess of light petroleum (bp 30–60 °C) the dihalide precipitates as a crystalline solid.

Received (in Cambridge, UK) 28th July 1999, Accepted 10th September 1999

Chiral recognition of 19 common amino acids is achieved by investigating the collision-induced dissociation spectra of protonated trimers formed by electrospray ionisation of amino acids in the presence of one of the following chiral selectors: L- and D-*N*-*tert*-butoxycarbonylphenylalanine (BPhe), L- and D-*N*-*tert*-butoxycarbonylproline (BPro) and L- and D-*N*-*tert*-butoxycarbonyl-*O*-benzylserine (BBSer).

Chiral recognition is an important topic in chemistry and biochemistry. A number of approaches[1] have been used for the chiral recognition of organic compounds, including polarimetry, circular dichroism, nuclear magnetic resonance, chromatography and capillary electrophoresis. Attentions has also been paid to the use of mass spectrometry[2,3]due to the many advantages of the technique, *e.g.* high sensitivity, short analysis time, ability to analyse mixtures by tandem mass spectrometry (MS/MS) or in combination with chromatography, and the ability to study the intrinsic properties of the chiral effect by isolating the interacting molecules in the gaseous phase.

Since the first observation of chiral effects in mass spectrometry by Fales and Wright,[4] about 50 papers have been published in this field.[3] In most of the studies, enantiomers were allowed to ionise in the presence of chiral selectors, and chiral recognition was observed by comparing the relative extent of the formation (MS) or fragmentation (MS/MS) of the diastereomeric complex ions. While chemical ionisation (CI)[5–8] was the main ionisation mode used in the early development of chiral mass spectrometry, significant results have been reported by applying the fast atom bombardment (FAB) mode.[9–14] A number of data evaluation methods are also available for the analysis, such as the relative peak intensity method (*i.e.* the internal standard method),[9] the deuterium-labelled method,[10] the stability constant method,[11] and the two-internal-standards method.[12] In spite of these efforts, only limited success has been achieved; so far, not even a single class of chiral compounds can be systematically recognised by mass spectrometry. In general, problems encountered in the systematic recognition of a class of chiral compounds include the limited recognition ability of chiral selectors and the poor reproducibility of mass spectra, as well as the requirement of high concentration or high volatility for the association between enantiomers and chiral selectors.

We now report the first systematic study of chiral recognition of 19 amino acids by comparing the relative extent of fragmentation (MS/MS signal intensities) of the diastereomeric protonated trimers formed by the amino acids and chiral selectors. Three new chiral selectors, namely, L- and D-*N*-*tert*-butoxycarbonylphenylalanine (BPhe), L- and D-*N*-*tert*-butoxycarbonylproline (BPro) and L- and D-*N*-*tert*-butoxycarbonyl-*O*-benzylserine (BBSer), were used in the present study. Electrospray ionisation (ESI)[15] was applied to provide complex ions of the amino acids and chiral selectors; a typical mass spectrum of the amino acid/chiral selector mixture is depicted in Fig. 1. Thus, the amino acid (X) combines with chiral selector (Y) to form protonated dimer XYH^+, protonated trimer XY_2H^+, protonated tetramer XY_3H^+ *etc*. The protonated trimers (XY_2H^+) were subsequently chosen for investigation because of their high intensities and large chiral discrimination toward most amino acids. The XY_2H^+ complex ion was fragmented by collision-induced dissociation (MS/MS) to form protonated dimers XYH^+ (Fig. 2). All amino acids were studied in four combinations with the chiral selectors, *i.e.* LD and DL (heterochiral) and LL and DD (homochiral), and the chiral recognition ratio *R* was defined according to eqn. (1).[14]

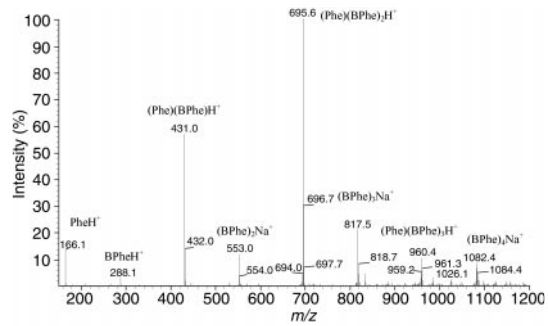

Fig. 1 ESI spectrum of a mixture of Phe (1 mM) and BPhe (1 mM). Major cluster ions are indicated. Conditions for ESI: heated capillary 50 °C, sheath gas 60 psi, spray voltage 4 kV, syringe pump 10 μL min^{-1}. Samples were run on a Finnigan LCQ mass spectrometer.

$$R = \frac{([XYH^+]/[XY_2H^+\})_{\text{hetero}}}{([XYH^+]/[XY_2H^+])_{\text{homo}}} = \frac{([XYH^+]/[XY_2H^+])_{\text{LD}} + ([XYH^+]/[XY_2H^+])_{\text{DL}}}{([XYH^+]/[XY_2H^+])_{\text{LL}} + ([XYH^+]/[XY_2H^+])_{\text{DD}}} \quad (1)$$

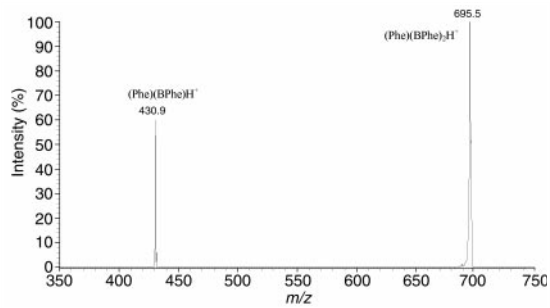

Fig. 2 MS/MS spectrum of protonated trimer from Phe and BPhe. Collision energy was 8%, isolation width 18 u, mass range 350–750 u.

[a] All enantiomerically pure L- and D-BPhe, BPro, BBSer and amino acids were purchased from Sigma and used without further purification. [b] Standard deviation for *R*. [c] $R > 1.1$ or $R < 0.9$. [d] Protonated trimers in low intensities, thus the MS/MS spectra of protonated dimers were measured instead. [e] Should also be suitable.

The results (Table 1) indicated that the maximum relative standard deviation for the chiral recognition ratio *R* is 1.42%. Therefore at the 99% (or better) probability level, any chiral recognition ratio falling outside the range of 1.000 ± 0.081 *(i.e.* $1.000 \pm 9.92 \times 1.42\%/3^{0.5}$) would indicate a significant discrimination of chirality. In other words, chiral discrimination could be recognised by an *R* value larger than 1.1 or smaller than 0.9. On this basis, our data clearly show that each amino acid could be discriminated by at least one chiral selector, suggesting a successful chiral recognition of all 19 amino acids by mass spectrometry using BPhe, BPro and/or BBSer as chiral selectors.

In summary, we have developed a mass spectrometric method to recognise the chirality of common amino acids. The results indicate that ESI-MS/MS is a promising approach for chiral recognition. This method can provide abundant complex ions even when the samples are at low concentrations or bear large/labile groups. The continuous introduction of sample mixtures *via* a syringe pump and the averaging of MS/MS spectra ensure a high precision of the results. ESI-MS/MS can be used to study the chirality of compounds in a mixture, and it only requires minimal sample preparation.

This work was financially supported by an RGC Competitive Earmarked Research Grant (HKUST 598/95P) and a Royal Society of Chemistry Research Fund Grant. The LCQ instrument used in this study was provided by the Biotechnology Research Institute of HKUST.

15 Solutions of D- and L-amino acids and D- and L-BPro (2 mM) were prepared in 50% MeOH containing 1% AcOH. Solutions of D- and L-BPhe and D- and L-BBSer (2 mM) were prepared in MeOH. The solutions of amino acid and chiral selector were mixed in a 1:1 ratio prior to mass spectrometric analysis. Mass spectrometry was carried out in a Finnigan LCQ instrument (San Jose, CA, USA) fitted with an ESI ion source. Conditions for ESI were: heated capillary 50 °C, sheath gas 60 psi, spray voltage 4 kV, syringe pump 10 μL min^{-1}. The LCQ was operated with the Automatic Gain Control (AGC) mode. The AGC target values were: Full MS—5e + 007, MS^n—2e + 007. The default maximum injection time was 500 ms with 5 micro scans. Helium was introduced and maintained a pressure of 1 mtorr for improving the trapping efficiency of the ion trap and for use as the collision gas during the MS/MS process. Typical MS/MS conditions were: relative collision energy 8%, isolation width 18 u and mass range 300–850 u when BBSer was used as the chiral selector; relative collision energy 6.5%, isolation width 15 u and mass range 250–700 u for BPro; and relative collision energy 8%, isolation width 18 u and mass range 300–800 u for BPhe.

Dual p- and n-type doping in an acid sensitive alternating bi(ethylenedioxythiophene) and pyridine polymer

David J. Irvin, C. J. DuBois, Jr. and John R. Reynolds*

Department of Chemistry, Center for Macromolecular Science and Engineering, University of Florida, Gainesville, FL 32611, USA. E-mail: reynolds@chem.ufl.edu

Received (in Columbia, MO, USA) 7th June 1999, Accepted 9th August 1999

Poly[2,5-bis(3,4-ethylenedioxy-2-thienyl)pyridine] exhibits multi-color electrochromism *via* easily accesible p- and n-type doping, and can be switched between a pale blue reduced state, a red neutral state, and a blue–purple oxidized state.

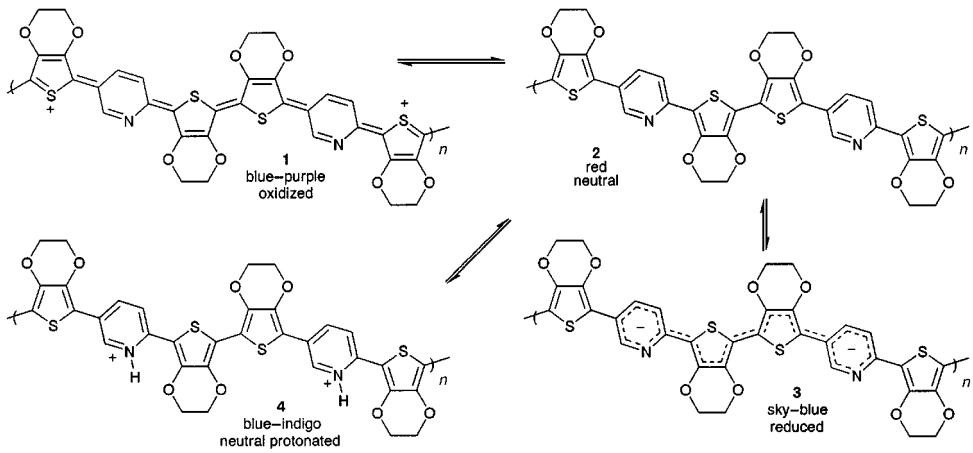
The ability to easily access both p- and n-type redox states in conducting and electroactive polymers may lead to useful materials.[1] While it is well-known that conjugated hydrocarbon polymers can be both p- and n-type doped, only recently has this been made possible in an electrochemically deposited film.[2] It has been shown by de Leeuw[3] that nitrogen-containing poly(heterocycles) induce stability in n-doped systems. One such example is poly(pyridine), which has a reduction potential of −2.1 V.† Other examples include poly(quinoline-2,6-diyl) which reversibly n-dopes at −1.8 V, along with poly(1,5-naphthyridine)[3] and poly(4,4′-dialkyl-2,2′-bithiazole-5,5′-diyl)s.[4] Relatively electron rich polyheterocycles are typically used in oxidative electropolymerization due to their propensity to form highly electroactive materials. While their p-doping characteristics are well-documented and can be outstanding, few systems show useful n-doping.[5–9] In many instances where a reduction is observed, the process is either irreversible and leads to rapid degradation of electroactivity, or leads to pinned anions and not true n-doping.[6]

We have undertaken a study of polyheterocycles containing alternating electron donor (D) and acceptor (A) units prepared *via* efficiently oxidatively polymerizable D–A–D monomers. Judicious choice of D and A units allows control of the energies of the π-system's effective HOMO and LUMO levels, which determine the polymer's oxidative (p-doping) and reductive (n-doping) properties, respectively. Thus, it has been shown that the electronic band gap of the polymer can be reduced significantly.[10] In addition, by using repeat units that are sensitive to the chemical environment, polymers that can provide an optical or electrical response upon exposure to species in electrolyte solutions can be used as sensor materials.

In designing an electroactive polymer that has three accessible charge states (oxidized, neutral, and reduced), while simultaneously being responsive to the pH of the bathing electrolyte solution, we prepared poly[2,5-bis(3,4-ethylenedioxy-2-thienyl)pyridine] [poly(BEDOT-Py)], which is efficiently synthesized *via* the corresponding D–A–D monomer. We have previously shown that 3,4-ethylenedioxythiophene is extremely effective as the oxidatively polymerizable moiety for the synthesis of poly(BEDOT-arylene)s that are highly electroactive and provide structurally controlled electrochromic properties.[11,12] It has been shown that while separate films of poly[2,5-bis(2-thienyl)pyridine] (PBTh-Py) can be p- or n-type doped, an electrochemical memory effect precludes both states from being accessed in a single film.[13] In addition to its propensity to stabilize reduced systems, the pyridine central unit is sufficiently basic to yield distinct spectroscopic shifts in an acidic medium and may be useful as a pH sensitive switching material.

BEDOT-Py was synthesized using a Negishi-type aryl cross coupling reaction (93% yield). Electropolymerization/film formation of poly(BEDOT-Py) was carried out using either repeated scan or constant potential methods from 10 mM BEDOT-Py and 0.1 M Bu_4NClO_4 in MeCN–CH_2Cl_2 (1:1) or 7.5 mM BEDOT-Py and 0.1 M Bu_4NClO_4 in MeCN. The monomer oxidizes at a bare Pt electrode with a peak ($E_{p,m}$) at 0.65 V. The redox processes for poly(BEDOT-Py) include broad oxidation and reduction (to the neutral form) peaks centered at 0.55 and 0.37 V, respectively, resulting in an $E_{1/2}$ of 0.49 V. While the monomer's $E_{p,m}$ is comparable to BEDOT-benzene (0.61 V), the resultant poly(BEDOT-Py) exhibits a higher $E_{1/2}$ by >250 mV when compared to poly(BEDOT-benzene).[11] This confirms the dominance of the terminal EDOT during polymerization, while the electron-accepting pyridine has a strong effect on the polymer's redox properties.

To study the optical properties and combined p- and n-doping electrochemistry, poly(BEDOT-Py) was deposited potentiostatically from a 7.5 mM MeCN solution since CH_2Cl_2 is not stable to the reduction potentials used during the experiment. Fig. 1 shows a combination of the separate and stable oxidative and reductive cyclic voltammetric scans for a film deposited onto a Pt button electrode. This method allowed isolation of the two processes while experiments conducted by repeatedly cycling



Scheme 1

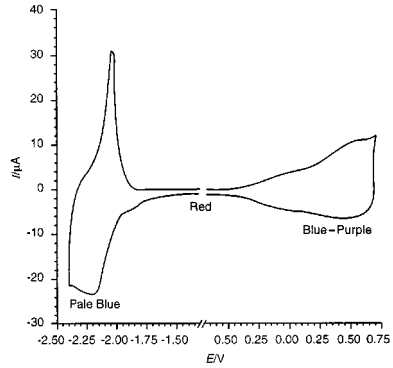


Fig. 1 Oxidative and reductive cyclic voltammetric scan of poly(BEDOT-Py) on a Pt button in 0.1 M TBAP in MeCN; scan rate = 100 mV s^{-1}.

between p- and n-doped states led to the formation of pre-peaks that increased in intensity with each subsequent scan. These pre-peaks, which may be due to trapped charge carriers,[6] can be misinterpreted as redox doping peaks if separate oxidation and reduction experiments are not performed.

The band gap of neutral poly(BEDOT-Py) is estimated to be 1.9 eV from the onset of the π–π* transition, with λ_{max} = 478 nm. It was observed that, with increasing film thickness, the absorbance does not change significantly at energies below 1.9 eV, indicating a well-reduced polymer with little or no trapped charges.

The observance of reduction peaks in the cyclic voltammogram is not proof on n-doping. It has been shown that reduction of polybithiophene does not lead to n-doping, and this process has been attributed to the formation of pinned anionic states.[6] Our group has observed similar results in cyanovinylene-linked poly(biheterocycles).[14] To establish the definitive formation of charge carriers and the ability to access both the p- and n-type states in a single film, spectroelectrochemistry was carried out on poly(BEDOT-Py) through both the oxidative and reductive processes. It should be noted that the latter experiment requires rigorous exclusion of oxygen and water due to the reactivity of the reductively doped state. Fig. 2(*a*) shows the spectroelectrochemical series for p-doping from 0.0 to +1.0 V, while Fig. 2(*b*) shows the series for n-doping from 0.0 to −1.8 V. When the polymer is held between −1.5 and +0.2 V the neutral film is a deep red in color. This optical state is quite similar to polythiophene and its alkyl substituted analogs, and, as expected, the band gap lies between the values observed for poly(3,4-ethylenedioxythiophene) (PEDOT) and polypyridine. Stepwise oxidation [Fig. 2(*a*)] leads to the typical evolution of the spectra for p-doping with peaks at *ca.* 1 and 1.75 eV as bipolaronic charge carriers are formed. The oxidized form is a deep blue–purple in color, again analogous to the polythiophene parent.

Comparison of the results shown in Fig. 2(*a*) and 2(*b*) bring out the unique spectroscopic nature of this polymer upon reduction. The similarity of the results, loss of intensity of the interband transition with concurrent evolution of peaks at 1 and 1.75 eV, are proof of the facile n-doping of this polymer and the fact that both the p- and n-doped states can be attained in the same film. Interestingly, the relative intensity of these two

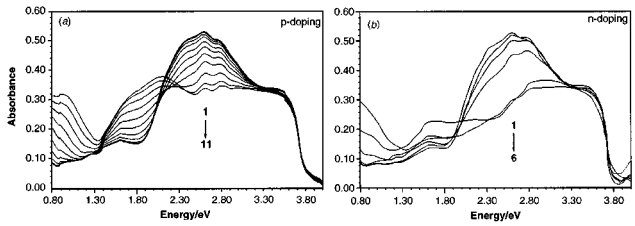

Fig. 2 Spectroelectrochemical series for p- and n-type doping of poly(BEDOT-Py): (*a*) p-doping at (1) 0.0, (2) 0.1, (3) 0.2, (4) 0.3, (5) 0.4, (6) 0.5, (7) 0.6, (8) 0.7, (9) 0.8, (10) 0.9 and (11) 1.0 V; (*b*) n-doping at (1) 0.0, (2) −1.4, (3) −1.5, (4) −1.6, (5) −1.7 and (6) −1.8 V.

peaks is different in the two forms. While they are similar in intensity in the p-doped form, the NIR peak is dominant in the n-doped form. This has a profound effect on the electrochromic properties as the n-doped form is sky-blue in color and more highly transmissive to visible light. Note the high degree of light transmission between 1.5 (825 nm) and 2.5 eV (500 nm) corresponding to a major fraction of the visible spectrum. This is similar to the optical properties observed for the p-doped PEDOT family of polymers.

A unique property of poly(BEDOT-Py) is that it contains sites that can be quaternized. A series of UV–VIS–NIR spectra were obtained for the neutral film as a function of pH upon exposure to an aqueous citric acid buffer and 0.1 M HCl. There is little change in λ_{max} as the pH is reduced to 2, upon which there is a sharp 70 nm red-shift through pH 1 as the band gap is lowered to 1.5 eV. The neutral film changes from red to indigo–blue with exposure to acid, and the resulting band gap is close to that observed for the PEDOT family of polymers. It is interesting to note that protonation of the film occurs at a much higher acidity than for pyridine. This observation is supported in the literature in which a set of thiophene- and furan-substituted pyridines show a marked decrease in basicity relative to pyridine and can be attributed to an electron-withdrawing inductive effect of the 2-EDOT rings.[15] The films can be reversibly switched between the protonated and neutral state by exposure to 1 M HCl followed by rinsing with deionized water.

The unique chemical and electrochemical properties of poly(BEDOT-Py) are outlined in Scheme 1. The as-made blue–purple p-doped state **1** can be converted to the red neutral form **2** upon reduction. The neutral form can be reversibly reoxidized back to **1**, reduced to the sky-blue n-doped state **3**, or protonated to yield blue–indigo polycationic, electrochemically neutral state **4**. Studies are underway to further elucidate the redox properties of polycationic polymer **4** (both protonated and alkylated), and gain a deeper understanding of the n-doped form **3**.

This work was supported by grants from the AFOSR (F49620-96-1-0067), the NSF (CHE 96-29854), and the NAWC, China Lake CA. We appreciate the donation of EDOT from the AG Bayer corporation.

Reduction of *N*-arylporphyrins to *N*-arylphlorins: opposite stereochemical courses as a function of the reducing agent

Romain Ruppert, Christophe Jeandon, Anna Sgambati and Henry J. Callot*

Faculté de Chimie, 1 rue Blaise Pascal, 67008 Strasbourg Cedex, France. E-mail: callot@chimie.u-strasbg.fr

Received (in Cambridge, UK) 13th July 1999, Accepted 17th September 1999

Electrochemical or $Na_2S_2O_4$ reduction of *N*-arylporphyrins gives stable phlorins epimeric to those obtained by tosylhydrazine or $NaBH_4$ reduction.

Phlorins are non-aromatic tetrapyrrolic macrocyclic isomers of chlorins. In these dihydroporphyrins the two additional hydrogens are located at the *meso* and N positions. The first stable phlorin was isolated by R. B. Woodward[1] during the synthesis of chlorophyll *a*. Factors favouring the formation of phlorins by chemical or electrochemical reduction or by nucleophilic addition to porphyrins are steric strain,[1,2] complexation with high valent metal ions,[3] and electrophilicity of the macrocycle.[4]

We found[5–7] that the reduction of *N*-arylporphyrins **1** with tosylhydrazine or $NaBH_4$ gave *N*-arylphlorins **2** (*N*,*meso*-dihydroporphyrins; *anti* isomer) instead of the expected *N*-arylchlorins (β,β-dihydroporphyrins). It was proposed that in this case the driving force of the reaction, as well as the explanation for the stability of the products, was the rotation experienced by the *N*-substituted pyrrole resulting in a significant decrease of the steric strain.

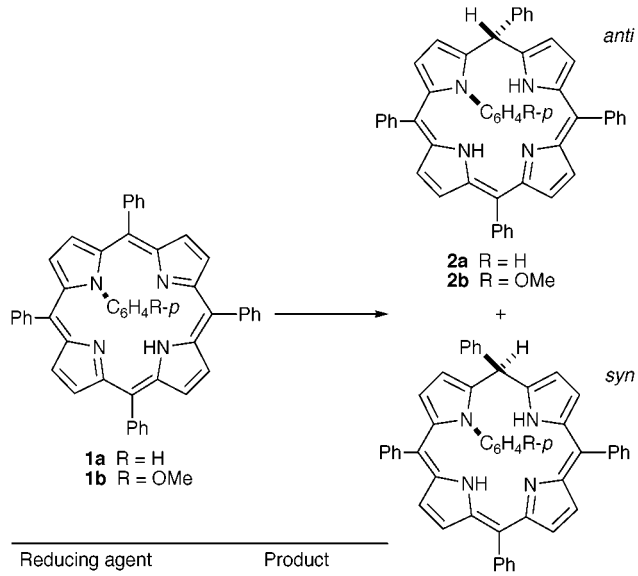
Recently,[8] a phlorin derived from heme *c* was proposed as an intermediate in the catalytic cycle of hydroxylamine oxidoreductase (HAO). This phlorin is a heme *c* group arylated at C-5 by a tyrosine moiety. The position of the aryl group above the plane in the intermediate strongly suggested an C-5 sp^3 carbon and thus a phlorin. Here we describe the preparation and structural characterization of new phlorins whose out-of-plane *meso*-aryl groups bear a resemblance to such intermediates.

We found that reduction of *N*-arylprophyrins **1** with aged $NaBH_4$ gave a mixture of the expected phlorin and a very similar product, at least where the UV-visible data were concerned. This product proved to be rather unstable under chromatographic conditions, but NMR data suggested an epimeric structure. In order to assign a structure to this new phlorin and to find conditions suitable for its preparation in acceptable yields, we tested a new set of reducing agents. Borane·THF was not satisfactory, giving mixtures of phlorins and dihydrophlorins *etc.*, but cathodic reduction, sodium dithionite and dihydropyridine **4** (Hantzsch ester) all gave quantitatively phlorins (Scheme 1).

Electrochemical reduction of *N*-aryl-*meso*-tetraphenylporphyrin **1** was performed in an electrolysis cell fitted with three compartments separated by glass frits (Hg cathode, Pt counter electrode, SCE reference electrode). The experiments were conducted on a 25 to 50 μmol scale in a protic electrolyte (THF–MeOH, 2:1; 0.25 M LiCl). The reduction of the porphyrin and the concomitant reduction of the protons led to an increase of the electrolyte basicity during electrolysis. Therefore, the working potential (−0.8 to −1.2 V *vs.* SCE) was continuously adjusted during the electrolysis in order to keep the current density approximatively constant (5 mA cm^{-2}). The progress of the reaction was followed by TLC and showed that only one reduction product was formed. A very simple work-up procedure (addition of CH_2Cl_2, washing with water and crystallisation of the crude product from CH_2Cl_2–MeOH) afforded the pure phlorins **3a** or **3b** as green crystals (60% isolated yield.) Phlorins **3a** and **3b** were found to be stable as solids and stable enough in solution to grow crystals (see below), but reverted to the starting *N*-arylporphyrins **1a** and **1b** rapidly when chromatographed.

Compounds **3a** and **3b** showed phlorin UV-visible spectra [**3a**: λ_{max} 422 nm (ε = 34000) and 685 (29700)]. The NMR spectra of **3a** and **3b** revealed the loss of aromaticity suffered by the porphyrin ring: the pyrrolic protons are located between *ca.* δ 6.5 and 7, the *meso* proton of **3b** was found at δ 6.87, a value 2.53 ppm downfield from that of the *meso* proton of **2b** (δ 4.34). Of particular interest are the signals of the *N*-anisyl group protons of **3b**: the aromatic protons appear at δ 5.78, 5.96, 6.13 and 6.29, strongly suggesting a face-to-face (*syn*) arrangement of this group and the *meso*-phenyl attached to the reduced bridge (the *N*-phenyl analog **3a** showed a broadening of the *N*-phenyl signals, possibly due to restricted rotation). In the epimeric phlorin **2b** (*anti*), the anisyl protons are located between δ 6.4 and 6.8.

Single crystals of *syn*-phlorin **3a** could be obtained by slow diffusion of MeOH in a solution of **3a** in $CHCl_3$. The structure could be solved† and is shown in Fig. 1. The close face-to-face arrangement of the phenyl rings was confirmed, and is illustrated by the very short distance (3.14 Å) between the closest C atoms. The rotation of the *N*-phenyl pyrrole is shown by its angles with the remaining pyrrole units: AC = 106°; AB



Reducing agent	Product
$TsNHNH_2$	**2**
$NaBH_4$	**2**
cathodic reduction (Hg)	**3**
$Na_2S_2O_4$	**3**
4	**2** + **3** (1:2)

Scheme 1

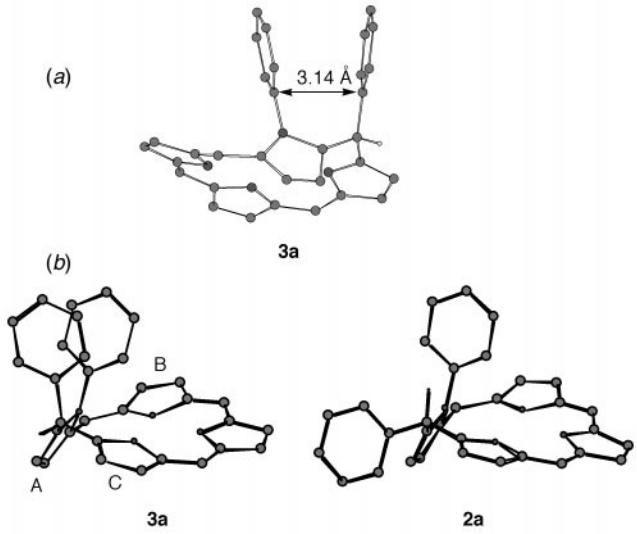


Fig. 1 (*a*) Side-view of phlorin **3a**, showing the face-to-face arrangement of the *meso*-and *N*-phenyl groups, and (*b*) comparison of phlorin **3a** with the epimeric **2a** (for the sake of clarity, three *meso*-phenyl groups and all of the hydrogen atoms except the *meso*-H are omitted).

= 130°. This last value is very similar to that found in *N*-*o*-tolyl-*meso*-tetraphenylporphyrin,[9] showing that all the deformation of the macrocycle occurred across the reduced bridge.

The use of an excess of sodium dithionite as a reducing agent in a biphasic system (water–CH_2Cl_2, 1:1) containing NMe_4Cl gave phlorins **3** from porphyrins **1** in 70% isolated yield. However, reduction of **1b** by Hantzsch ester **4** (6 equiv. in refluxing PhCl; microwave oven, 0.5 h), although quantitative, gave a mixture of both *syn* and *anti* phlorins **2b** and **3b** (1:2 ratio), Approximately 2.5 equiv. of **4** were consumed.

These results suggest two mechanistically different routes from *N*-arylporphyrins **1** to the corresponding phlorins.[10] Under electron transfer conditions (cathodic reduction, sodium dithionite) a radical anion was formed and the *meso*-bridge specifically protonated on the face opposite to the *N*-substituent. Further reduction of the radical and protonation gave **3**. Reducing agents like $NaBH_4$ or Hantzsch ester **4** are hydride donors and transferred this hydride irreversibly to the porphyrin. Tosylhydrazine reduction, although involving intermediates, might similarly begin with a nucleophilic attack of the *meso*-bridge. In these cases, steric hindrance to the approach of the reagent may govern the isomeric ratio, with the most hindered hydride donor, **4**, having difficulty approaching from the same side of the *N*-aryl group as $NaBH_4$ or tosylhydrazine, and giving *syn* **3** as the major component.

We thank the 'Service Commun de Rayons X' (A. Decian and N. Kyritsakas) for solving the structure, and A. Roth for help.

Unprecedented and novel hetero [6+3] cycloadditions of fulvene: a facile synthesis of the 11-oxasteroid framework

Bor-Cherng Hong,* Hsu-I Sun and Zhong-Yi Chen

Department of Chemistry, National Chung Cheng University, Chia-Yi, 621, Taiwan, R. O. C.
E-mail: chebch@ccunix.ccu.edu.tw

Received (in Cambridge, UK) 24th August 1999, Accepted 9th September 1999

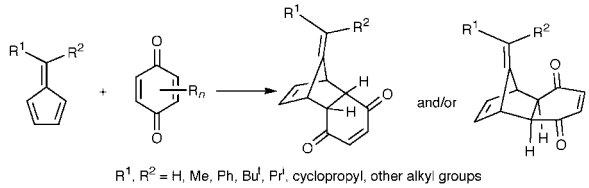
In contrast to the Diels–Alder reaction of fulvenes and benzoquinone, 6-dimethylaminofulvene reacts with benzoquinones to give the hetero [6+3] cycloaddition adduct, constituting an efficient and novel route to cyclopenta[*c*]-chromenes including 11-oxasteroids.

Fulvene and its derivatives have received a great deal of attention over the years.[1] Cycloadditions of fulvenes (*e.g.* [4+3],[2] [2+2],[3] [4+2],[4] [2+4],[5] [6+4],[6] [6+2][7]) provide general and powerful approaches to various polycyclic systems and natural products. We recently reported a new type of reaction: the [6+3] cycloaddition of fulvenes[8] for the facile synthesis of indane derivatives.[9] In conjunction with our continuing efforts in fulvene chemistry,[10] we have developed a novel hetero [6+3] cycloaddition of 6-dimethylaminofulvene[11] to benzoquinone that provides a series of cyclopenta[*c*]chromene derivatives. The latter constitute the basic skelton of biologically active 11-oxasteroids.

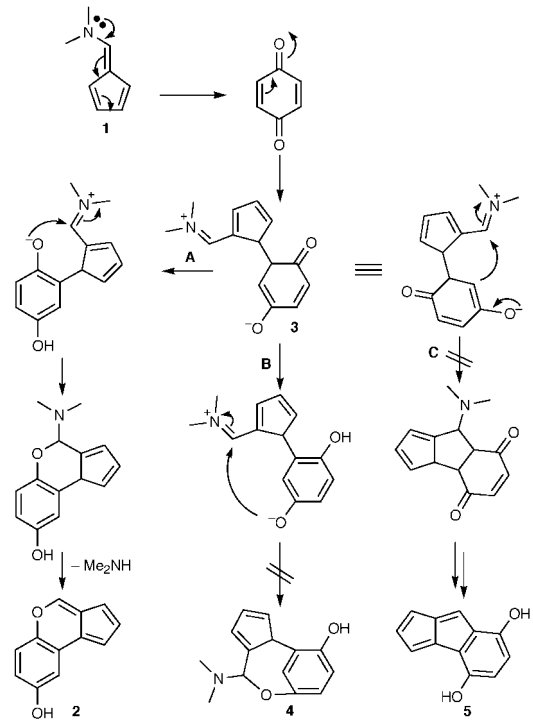
Fulvenes usually react with benzoquinones to give the [4+2] cycloaddition adducts (Scheme 1).[12] In contrast, we have found that reaction of the 6-dimethylaminofulvene **1** and benzoquinone results in the formation of the oxatricyclic product **2** (Scheme 2).[13] Syntheses of the cyclopenta[*c*]pyrans and cyclopenta[*c*]chromene have received a lot of attention.[14] To the best of our knowledge, this is the first example of the synthesis of the 3-oxa-bicyclo[4.3.0]nonane system *via* the [6+3] approach. Reaction of 6-dimethylaminofulvene and benzoquinone in benzene at 25 °C for 20 min provided the cyclopenta[*c*]chromene **2** in 65% yield as the only isolable adduct (entry 1, Table 1). The structure of **2** was assigned based on IR, ^{1}H and ^{13}C NMR, COSY, DEPT, HMQC, HMBC, MS and HRMS analyses.† This striking difference in the chemoselectivity of fulvene **1** *vs*. regular fulvenes may be attributed to an increase in the electron density of the 6-dimethylaminofulvene π-system. The formation of **2** may be rationalized *via* the following stepwise mechanism, shown in Scheme 2. Initial addition of **1** to benzoquinone generates the zwitterionic intermediate **3**, and tautomerization followed by loss of dimethylamine (path **A**) gives the hetero [6+3] product **2**. On the other hand, the direct cyclization of the hydroquinone intermediate (path **B**) is prohibited since it would lead to a highly strained and unstable product **4**. The reason why the pentalene product **5** does not form is not clear. This may be due to the HSAB principle, namely that *O*-alkylation (hard base) of the iminium salt (hard acid) is favored over the *C*-alkylation (soft base).

A series of homologous benzoquinones were also reacted with **1** to give the corresponding cyclic products **6**–**14** (entries 2–10, Table 1). Reaction of **1** with 1,4-naphthoquinone affords the adduct **13** (Table 1, entry 9), which constitutes the basic skeleton of the 11-oxasteroids. The synthesis and physiological activity of heterosteroids have received a lot of attention over the years.[15] In light of the physiological significance of the 11-oxoadrenocortical hormones, heterosteroids in which the methylene group at position 11 is replaced by a heteroatom are of special interest (Scheme 3).[16] For example, 11-oxaprogesterone **15** shows little progestational activity, but had significantly enhenced ovulation inhibitory activity. In addition, 11-oxaestradiol **16** shows extremely low estrogenic (uterotropic) activity but possesses antifertility activity.[17] The ratio of antifertility activity to estrogenic activity is *ca.* 10 times larger than estradiol. Many other 11-oxasteroids with antiandrogenic, corticoid and antiinflammatory activities have been reported.[18] However, the syntheses of oxasteroids reported so far are based on tedious transformation of available steroids (10–22 steps),[19] a serious bottleneck for the biological testing of 11-oxasteroids. Hydrogenation of **13** for 1 and 6 h affords **17** and **18**, respectively. As illustrated by the entries of Table 1, the combination of [6+3] cycloaddition followed by hydrogenation allows a rapid and efficient entry into the terahydropyran ring systems as well.

In summary, the hetero [6+3] cycloaddition provides a remarkably efficient route to the 3-oxabicyclo[4.3.0]nonane system. This method also establishes the experimental framework for a conceptually new approach to 11-oxasteroids. Further investigation of the scope of this hetero [6+3] cycloaddition as well as the application of this methodology to

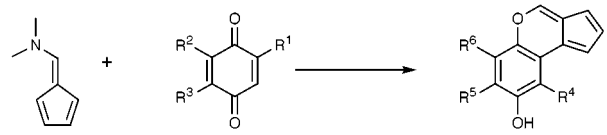


Scheme 1



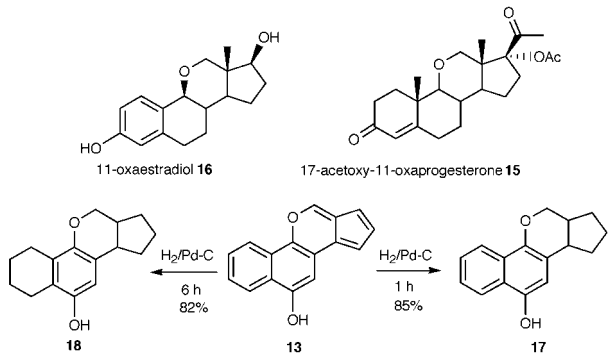
Scheme 2

Table 1 Hetero [6+3] cycladdition of benzoquinones to fulvene



Entry	Benzoquinone R¹	R²	R³	Product	R⁴	R⁵	R⁶	Yield (%)[a]
1	H	H	H	**2**	H	H	H	65[b]
2	Me	H	H	**6a**	H	H	Me	82
				6b	H	Me	H	(2.1 : 1)
3	Me	H	Me	**7**	Me	H	Me	77
4	Me	Me	H	**8**	Me	Me	H	77
5	Cl	H	H	**9a**	H	Cl	H	86
				9b	H	H	Cl	(2.2 : 1 : 3.8)
				9c	Cl	H	H	
6	Cl	H	Cl	**10**	Cl	H	Cl	85
7	Cl	Cl	H	**11**	Cl	Cl	H	80
8	Br	H	Br	**12**	Br	H	Br	79
9	H	–CH=CHCH=CH–		**13**	H	–CH=CHCH=CH–		75
10	H	–CH=CHC(OH)=CH–		**14**	H	–CH=C(OH)CH=CH–		82

[a] Isolated yield based on starting fulvene. [b] Some of the products decomposed during the purification or after few hours at ambient temperature. However, protection of the alcohol as a benzoate (Et_3N, cat. DMAP, BzCl) in one pot before work up gave the stable benzoate of **2** in better yield (75%).



Scheme 3

the synthesis of various oxasteroids for biological studies are currently underway in our laboratories.

Notes and references

† All new compounds gave satisfactory spectral and analytical data. Typical experimental procedure: To a solution of 6-dimethylaminofulvene **1** (ref. 20) (242.2 mg, 2 mmol) in dry benzene (3 ml) was added a solution of benzoquinone (259.2 mg, 2.4 mmol) in dry benzene (3 ml). The suspension was vigorously stirred for 20 min at 25 °C. The solution was concentrated *in vacuo* and the residue was purified by flash column chromatography with 8% EtOAc–hexane (R_f = 0.30 in 10% EtOAc–hexane) to give **2** as a yellow solid (239.2 mg, 65% yield). ν_{max}(neat)/cm^{-1} 3300–3000, 2930, 1627, 1470, 1359, 1194, 1092, 816, 738; δ_H(DMSO-d_6, 400 MHz) 6.77–6.78 (dd, *J* 4.5, 0.8, 1 H), 6.85–6.88 (m, 2 H), 7.00–7.02 (dd, *J* 4.6, 2.5, 1 H), 7.32–7.33 (d, *J* 2.8, 1 H), 7.50-7.52 (d, *J* 9, 1 H), 8.64 (s, 1 H); δ_C(DMSO-d_6, 100 MHz) 106.85 (CH), 110.81 (CH), 113.11 (CH), 115.43 (CH), 119.22 (CH), 121.25 (C), 123.29 (C), 123.64 (C), 131.96 (CH), 141.37 (C), 147.54 (CH), 154.91 (C); *m/z* 184 (M^+, 100), 155 (13), 128 (17), 127 (14), 92 (17), 77 (10), 63 (15), 51 (21) [calc. for $C_{12}H_8O_2$ (M^+): 184.0524; found 184.0521].

Photochemically generated nitrilium phosphane-ylid tungsten complexes and their reactivity towards alkyne and nitrile derivatives

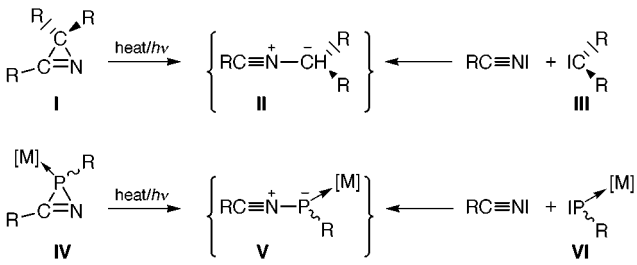
Rainer Streubel,* Hendrik Wilkens and Peter G. Jones

Institut für Anorganische und Analytische Chemie der Technischen Universität Braunschweig, Postfach 3329, D-38106 Braunschweig, Germany. E-mail: r.streubel@tu-bs.de

Received (in Basel, Switzerland) 14th July 1999, Accepted 6th September 1999

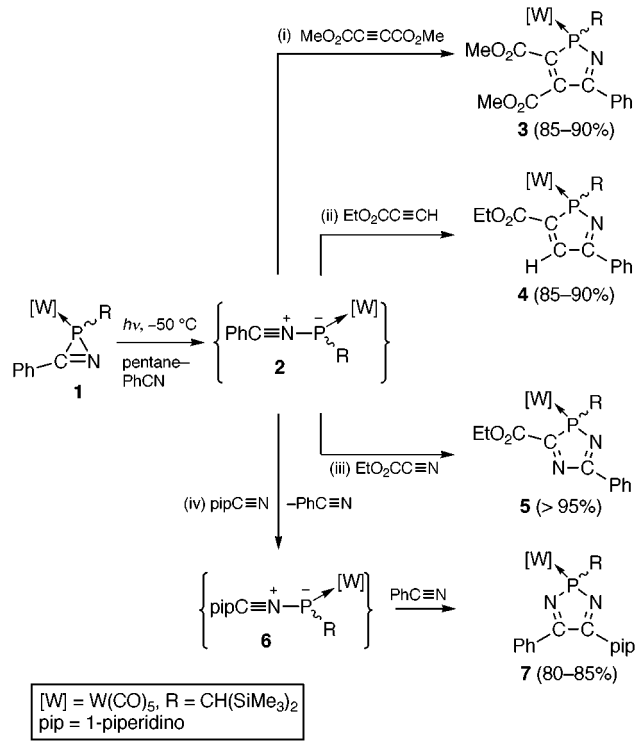
The photochemically generated nitrilium phosphane-ylid tungsten complex 2 reacts with different activated alkynes, dimethyl acetylenedicarboxylate (DMAD) (i) and ethyl acetylenecarboxylate (ii), and nitriles, ethyl cyanoformate (ECF) (iii) and 1-piperidinonitrile (iv), giving [3+2] cycloaddition products such as the 2*H*-1,2-azaphosphole complexes 3 (i) and 4 (ii), the 2*H*-1,4,2-diazaphosphole complex 5 (iii) and the 2*H*-1,3,2-diazaphosphole complex 7 in good to excellent yields, the latter complexes, 4–7, being formed regioselectively; the structure of the first ester-functionalized 2*H*-1,4,2-diazaphosphole complex 5 was established by X-ray analysis.

Nitrile ylides **II**, which are useful reactive intermediates in synthetic chemistry, can be generated by thermally[1] or photochemically[2] induced ring opening of 2*H*-azirenes **I** or by *N*-terminal 1,1-addition of singlet carbenes **III** to nitriles[3] (Scheme 1). So far, nitrilium phosphane-ylid complexes **V** have been transiently formed only by thermal ring opening of 2*H*-azaphosphirene complexes **IV**[4] or by *N*-terminal 1,1-addition of singlet type terminal phosphanediyl complexes **VI** to nitriles:[5] we have termed the latter process C,N,P-1,3-dipole transylidation. Although the yields are sometimes unsatisfactory, thermally induced ring opening of 2*H*-azaphosphirene complexes provides access to, *e.g.*, 2*H*-1,2-azaphosphole,[4] 2*H*-1,4,2-diazaphosphole[6] and 2*H*-1,3,2-diazaphosphole complexes.[6] In order to broaden the synthetic applicability of 2*H*-azaphosphirene complexes in synthetic chemistry, we have now started to investigate their photochemistry in the presence of activated alkynes and nitriles as trapping reagents; the first results are reported here.



Scheme 1 Synthetic routes to nitrile ylides and nitrilium phosphane-ylid complexes ([M] = metal complex fragment, R denotes ubiquitous organic substituents).

Photochemical ring opening of the 2*H*-azaphosphirene complex **1**[7] in pentane–benzonitrile (50–100 : 1) at −50 °C in the presence of 2 equiv. of dimethyl acetylenedicarboxylate (DMAD) (i), ethyl acetylenecarboxylate (ii), ethyl cyanoformate (ECF) (iii) and 1-piperidinonitrile (iv) furnished the [3+2] cycloaddition products in good to excellent yields (80–95 %), which are significantly higher than those obtained by thermal reactions. Reactions (i) and (ii) yielded 2*H*-1,2-azaphosphole complexes **3**[4] and **4**, and (iii) and (iv) the 2*H*-1,4,2-diazaphosphole complex **5** and the 2*H*-1,3,2-diazaphosphole complex **7**.[6] Of note is the very high regioselectivity of reactions (ii) and (iii) and also that of (iv); in the latter case the regioisomer **7** provides support for the assumption of a transylidation process, giving complex **6** and a subsequent [3+2] cycloaddition of this reactive intermediate to benzonitrile. It is also remarkable that satisfying results were obtained only if pentane–benzonitrile mixtures were employed as solvent for these low-temperature photochemical reactions (Scheme 2).



Scheme 2 *Reagents and conditions*: (i), (ii) a solution of 0.14 mmol of **1,** 80 mL *n*-pentane, 0.5 mL benzonitrile and 0.5 mmol alkyne was irradiated at −50 °C for 1.5 h (low-pressure Hg-lamp, Heraeus TQ150); evaporation of the solvent yielded complexes **3** and **4** as orange to red oils, which, in the case of complex **4**, yielded **4** as an orange solid (mp 61 °C, decomp.) after work-up by column chromatography at low temperature and crystallization from pentane; (iii) a solution of 0.28 mmol of **1**, 80 mL *n*-pentane, 0.5 mL benzonitrile and 16 mmol ethyl cyanoformate was irradiated at −50 °C for 2 h, work-up by column chromatography at low temperature and crystallization from pentane afforded **5** as red crystals (mp 67 °C, decomp.); (iv) a solution of 0.14 mmol of **1**, 80 mL *n*-pentane, 0.5 mL benzonitrile and 0.5 mmol 1-piperidinonitrile was irradiated at −50 °C for 1 h; evaporation of the solvent yielded **7** as a yellow oil.

Apart from the known complexes **3** and **7**, the composition of complex **4** and the ester-functionalized 2*H*-1,4,2-diazaphosphole complex **5** were confirmed by elemental analyses and mass spectrometry† and the structural formulation is based on the characteristic NMR spectral data† in solution. Furthermore, the ring constitution of complex **5** was confirmed by X-ray structure analysis‡ (Fig. 1).

The phosphorus nuclei of **4** and **5** display resonances at δ 94.4 and 122.4, which are in the expected range of such heterocycle complexes, with phosphorus–tungsten coupling constants

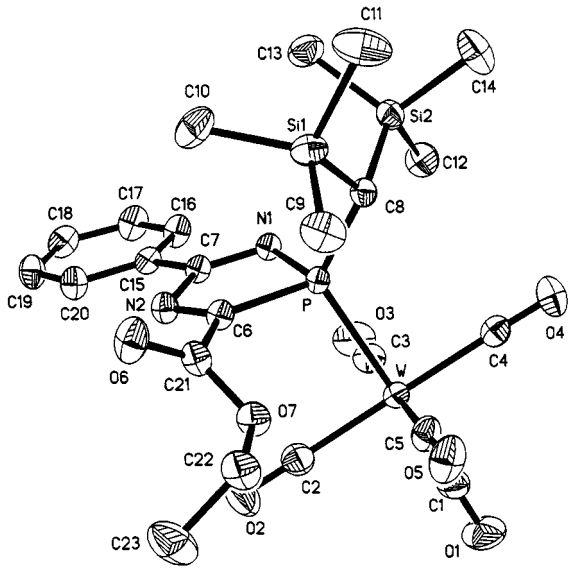


Fig. 1 Molecular structure of complex **5** in the crystal. Radii are arbitrary. Selected bond lengths (Å) and angles (°): P–W 2.5039(5), N1–P 1.7007(16), P–C6 1.8678(19), C6–N2 1.284(2), N2–C7 1.438(2), C7–N1 1.287(2), P–C8 1.8221(19); N1–P–C6 89.05(8), P–C6–N2 110.61(13), N2–C7–N1 119.60(16), C7–N1–P 110.08(13), W–P–C8 121.98(6).

|*J*(W,P)| of 227.2 and 233.6 Hz, respectively. The assignment of the resonances to the carbon atoms of the heterocyclic system in complexes **4** and **5** is unambiguous, if the carbon atoms are bonded either to phosphorus or to hydrogen leading in the first case to significantly greater magnitudes of |*J*(P,C)| (in general) and/or to characteristic spectra if DEPT experiments were performed. The carbon atom resonances of the heterocycle in complex **4** appear at δ 138.0 (C^3), 162.4 (C^4) and 170.5 (C^5) with phosphorus–carbon coupling constants |*J*(P,C)| of 23.5, 9.0 and 9.6 Hz, respectively. The ^{1}H resonance at δ 8.41 with a 32.7 Hz coupling to phosphorus is also structurally important; it is significantly low-field shifted compared to 4-substituted constitutional isomers, which have resonances at δ *ca*. 7.5.[8] As in the 3,5-diphenyl-substituted 2*H*-1,4,2-diazaphosphole tungsten complex **8**,[6] the ester-functionalized complex **5** displays a typical phosphorus resonance (**5**: δ 122.4, |*J*(W,P)| 233.6 Hz; **8**: δ 110.6, |*J*(W,P)| 227.8 Hz[6]). The ester group effectively increases not only the coupling constant |*J*(W,P)|, but also |*J*(P,C)|, which was observed in the ^{13}C NMR spectra of complex **5** for the C^3- and C^5-resonances (**5**: δ 195.6, |*J*(P,C)| 29.8 Hz and 167.2, |*J*(P,C)| 7.0 Hz; **8**: δ 198.5, |*J*(P,C)| 22.3 Hz and 169.5, |*J*(P,C)| 5.1 Hz[6]).

The five-membered ring system of the 2*H*-1,4,2-diazaphosphole complex **5** is almost planar and the phenyl group subtends an interplanar angle to the five-membered ring of 4.2°, thus enabling an efficient π–π electron interaction of the two rings. The N–C distances, N1–C7 1.287(2) and N2–C6 1.284(2) Å, are in the typical range of nitrogen–carbon double bonds;[9] the latter is somewhat shorter than the value of 1.302(9) Å in complex **8**.[6] The coordination spheres of the phosphorus atoms in **5** and **8** are both distorted tetrahedral, displaying identical $\Sigma°P_{PR_3}$ values [310.9° (**5**) and 311° (**8**)], identical N1–P–C6 angles [89.05(8)° (**5**) and 90.2(3)° (**8**)[6]] and only slightly different W–P–C8 angles [121.98(6)° (**5**) and 119.6(3)° (**8**)[6]], but different phosphorus–tungsten distances of 2.5039(5) Å (**5**) and 2.532(2) Å (**8**).[6] Together with the other distances and angles, this shows a predominant electronic effect of the ester group on these structural parameters.

We are currently investigating the reactivity of photochemically generated nitrilium phosphane-ylid complexes towards other π-systems.

This work was supported by the Fonds der Chemischen Industrie and by the Deutsche Forschungsgemeinschaft; the Figure was prepared by Mr F. Ruthe.

Membrane transport of neurotransmitter acetylcholine and related compounds across a phospholipid bilayer by a calix[6]arene ester

Takashi Jin

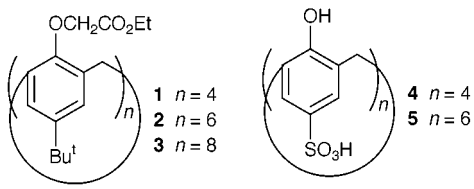
Section of Intelligent Materials and Device, Research Institute for Electronic Science, Hokkaido University, Sapporo, 060-0812, Japan. E-mail: jin@imd.es.hokudai.ac.jp

Received (in Cambridge, UK) 24th August 1999, Accepted 20th September 1999

A calix[6]arene ester 2 acts as a carrier for neurotransmitters such as acetylcholine, carbachol and choline in a phospholipid bilayer membrane.

Artificial acetylcholine receptors have been of great interest for the development of acetylcholine detection techniques[1,2] and for the understanding of biological recognition[3] of acetylcholine (ACh). Several macrocyclic compounds[1–6] have been reported as artificial acetylcholine receptors which recognize the quaternary ammonium moiety of acetylcholine. Recently, it was reported that sulfonated calix[4]- and calix[6]-arenes have binding abilities toward acetylcholine and related choline derivatives in water.[2,6] To the best of our knowledge, however, there has been no report of membrane transport of acetylcholine mediated by synthetic ionophores for the detection and separation of acetylcholine. We now report that a calix[6]arene ester **2** can act as a selective acetylcholine carrier in a phospholipid bilayer membrane.

Calixarene esters are known to have selective ion complexing abilities, and also have ion transporting abilities toward alkali-metal ions.[7–10] For example, calix[4]-, calix[5]- and calix[6]-arene esters act as selective Na^+ ,[7–10] K^+ [10] and Cs^+ carriers[7,10] in bilayer membranes as well as in bulky liquid membranes. Although much information has been accumulated on the metal ion transport properties of calixarene esters, molecular ion transport properties of the calixarenes are known to a lesser extent.[11] Here we have focused our attention on the use of calixarene esters as quaternary ammonium ion carriers, and examined their membrane transport abilities for neurotransmitters such as acetylcholine, carbachol (carbamylcholine) and choline in a phospholipid bilayer system.



Five calixarene derivatives **1**–**5** were tested for their neurotransmitter transport abilities. Compounds **1**–**3** were prepared according to the literature method.[7] The sulfonated calixarenes **4** and **5** were purchased from Acros Organics. Membrane transport of neurotransmitters by calixarene derivatives across planar phospholipid bilayers was investigated by a voltage clamp method.[10,12] Planar phospholipid bilayers[12,13] (soybean phospholipids) were prepared at an aperture (diameter, 0.2 mm) in a Teflon film (thickness, 12.5 μm) which separated two Teflon chambers† (*cis* and *trans* chamber; volume, 1.7 ml). Calixarenes were added as 100 μM DMSO solutions to the *cis* chamber after the formation of the bilayers.

Fig. 1(*a*) shows the generation of membrane currents upon the addition of calix[6]arene ester **2** to the *cis* chamber, where both chambers were filled with 100 mM acetylcholine chloride solutions (pH 7.2, 25 mM HEPES-TRIS buffer). Membrane currents resulting from the transport of acetylcholine cations (ACh^+) were measured at an external voltage at 100 mV. In the absence of **2**, membrane conductance was *ca*. 200 GΩ: the control level of the membrane current was 0.5 pA at 100 mV. When a microliter aliquot (20 μl) of the DMSO solution of **2** was added to the chamber, the membrane conductance immediately increased. A control experiment was performed where only neat DMSO was added to the *cis* chamber. The addition of 200 μl of DMSO did not change the membrane conductance. To confirm the transport of ACh^+ across the phospholipid bilayer, the membrane conductance was measured under LiCl (100 mM)/LiCl (100 mM) ionic conditions. The addition of **2** (20 μl) to the chamber filled with the LiCl solution did not lead to the generation of membrane current, suggesting that the membrane current observed in Fig. 1(*a*) is due to the transport of ACh^+ cations, not the transport of Cl^- anions. Fig. 1(*b*) shows the concentration dependence of calix[*n*]arene esters *versus* the membrane currents. With increasing concentration of **2**, the membrane currents significantly increased. In contrast, the addition of **1** and **3** did not increase the membrane conductance for concentrations of calixarenes up to 10 μM. Furthermore, we tested water-soluble sulfonated calix[4]- and calix[6]-arene, which are known to form 1:1 acetylcholine complexes[6] in water. The addition (100 μl) of these calixarenes, however, did not increase the membrane conductance. Except for **2**, we could not detect ion transport for acetylcholine in the bilayer membrane.

The evidence for the complexation of acetylcholine with **2** was confirmed by the ^1H NMR measurements in $CDCl_3$. Fig. 2 shows the changes in ^1H NMR spectrum of acetylcholine in the

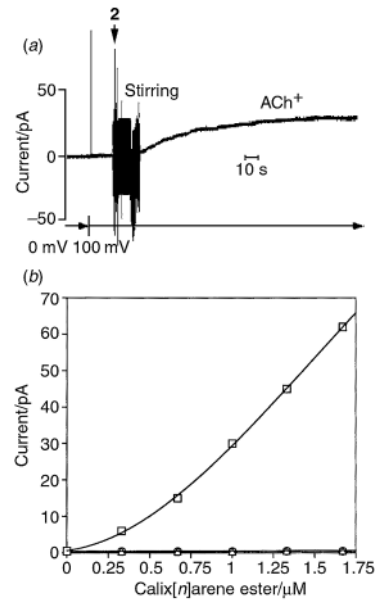


Fig. 1 (*a*) Generation of membrane currents (ACh^+) at 100 mV upon the addition of 20 μl of **2** (100 μM DMSO solution); (*b*) the membrane currents (ACh^+) *versus* the concentration of calix[*n*]arene ester in the *cis* chamber: (○) **1**, (□) **2** and (△) **3**.

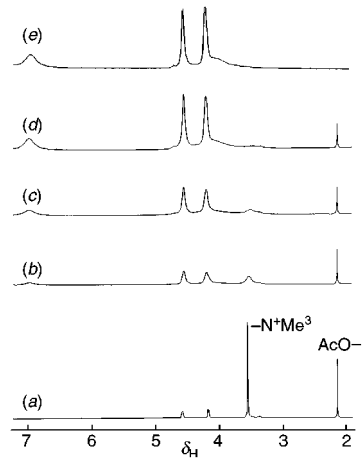

Fig. 2 Changes in ^{1}H NMR spectra ($CDCl_3$) of acetylcholine in the presence of **2**: [**2**]/[ACh] = (*a*) 0, (*b*) 0.5, (*c*) 1 and (*d*) 2, [ACh] = 14 mM. For comparison, the ^{1}H NMR spectrum of **2** is shown in (*e*).

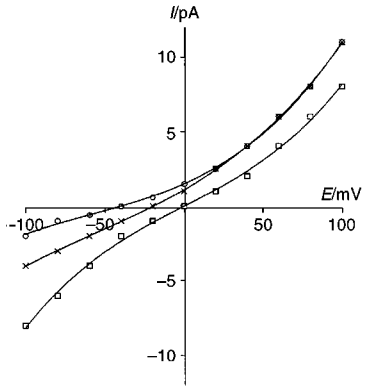

Fig. 3 The current–voltage (*I-E*) curves for different ionic conditions (pH = 7.2, 25 mM HEPES–TRIS buffer). All measurements were carried out at 25 °C. (□) ACh^+(*cis*)/ACh^+(*trans*), (×) $Carbachol^+/ACh^+$ and (○) $Choline^+/ACh^+$.

presence of **2**. Upon addition of **2**, the N^+Me_3 protons (δ 3.54) in acetylcholine moved to lower field ($\Delta\delta$ −0.06 ppm at [**2**]/[ACh] = 2) and the signal became very broad upon increasing the ratio of [**2**]/[ACh]. On the other hand, the chemical shift of the CH_3CO protons in acetylcholine was not affected by the addition of **2**: the line broadening of the CH_3CO singnal was much less than that of the N^+ Me_3 signal. The shift of the N^+ Me_3 protons to lower magnetic field suggests that the binding site of acetylcholine toward **2** is the quaternary ammonium moiety, not the acetyl moiety.[2] The line broadening of both the N^+Me_3 and CH_3CO protons in the presence of **2** may be explained by a fast exchange between the complexed and free acetylcholines on the NMR time scale: the resolved signals resulting from the two acetylcholine species were not observed at [**2**]/[ACh] < 1.

To evaluate the transport selectivity of **2** for acetylcholine and related compounds (carbachol and choline), we examined current–voltage (*I-E*) relations. Fig. 3 shows the *I-E* curves for three sets of ionic conditions (100 mM Cl^- salts). In the case of ACh^+/ACh^+ ionic conditions, a non-linear *I-E* curve which did not obey Ohm's law was obtained. This voltage-dependent *I-E* curve suggests that the transport of acetylcholine proceeds *via* a carrier mechanism.[14,15] In fact, a similar voltage-dependent *I-E* curve for a ACh^+/ACh^+ system has also been observed in the case of calix[*n*]arene ester-mediated carrier transport of alkali-metal ions across phospholipid bilayer membranes.[8,10] To determine ion permeability ratios, we exchanged the acetylcholine solution in the *cis* chamber with other neurotransmitter solutions and then measured *I-E* curves. It should be noted that in the X^+ (*cis*)/ACh^+ (*trans*) ionic conditions, positive currents of *ca*. 2 pA were generated at 0 V. This implies that acetylcholine cations are transported by **2** from the *trans* to the *cis* chamber in the absence of external voltages. From the *I-E* curves in the X^+/ACh^+ ionic conditions, the reversal potentials were determined as follows: −18 mV for $Carbachol^+/ACh^+$ and −42 mV for $Choline^+/ACh^+$. According to the Goldman–Hodgkin–Katz equation,[15] the reversal potentials ($\Delta\phi$) in XCl (*cis*)/YCl (*trans*) systems is related to the ion permeability (*P*), as shown in eqn. (1), where *R* and *F* express the gas constant and

$$\Delta\phi = \frac{RT}{F}\ln\frac{P_X[X]_{cis} + P_{Cl}[Cl]_{trans}}{P_Y[X]_{trans} + P_{Cl}[Cl]_{cis}} \quad (1)$$

the Faraday constant, respectively. Since **2** does not transport choline anions across the bilayer membranes (P_{Cl} = 0), the cation permeability ratio (P_X/P_Y) can be easily calculated as follows: 0.48 for $P_{Carbachol^+}/P_{ACh^+}$ and 0.18 for $P_{Choline^+}/P_{ACh^+}$. The permeability of acetylcholine across the planar bilayer membrane is larger than that of carbachol and choline by a factor of 2.1 and 5.6, respectively. This result shows that the calix[6]arene ester **2** acts as a selective acetylcholine carrier in a phospholipid bilayer membrane. The lower transport selectivity of choline and carbachol toward **2** may be due to the higher hydrophilicities of those compounds, which depress the stability of the complex in the water–lipid interface.

In conclusion, we have demonstrated that a calix[6]arene ester **2** can transport neurotransmitters, especially acetylcholine, across a phospholipid bilayer. For the other calix[4]- and calix[8]-arene esters (**1** and **3**) and sulfonated calixarenes (**4** and **5**), we could not determine the neurotransmitter transport activity in the bilayer membrane. To the best of our knowledge, this is the first report of an artificial acetylcholine carrier which is active in a phospholipid bilayer membrane. We believe that the calix[6]arene ester **2** has potential for use as an acetylcholine carrier in biological membrane systems.

We thank Mr E. Yamada for the measurement of ^{1}H NMR spectra.

Notes and references

† The side to which the compounds were added was defined as the '*cis*' chamber and the opposite side was the '*trans*' chamber. The external voltage was fed to the *trans* chamber *via* an Ag/AgCl electrode and the *cis* chamber was grounded *via* an Ag/AgCl electrode.

Thiazolylketoses: a new class of versatile intermediates for glycoside synthesis

Alessandro Dondoni* and Alberto Marra

Dipartimento di Chimica, Laboratorio di Chimica Organica, Università di Ferrara, Via Borsari 46, 44100 Ferrara, Italy. E-mail: adn@dns.unife.it

Received (in Cambridge, UK) 11th May 1999, Accepted 13th July 1999

An account is provided on the very recent work carried out in the authors' laboratory dealing with the preparation of thiazolylketose acetates and their use as effective glycosyl donors in reactions with oxygen, carbon, nitrogen and phosphorus nucleophiles. These reagents are formed by addition of 2-lithiothiazole to sugar lactones followed by acetylation of the resulting thiazolylketoses. Coupling reactions, promoted by TMSOTf in CH_2Cl_2, are described with primary and secondary sugar alcohols, trimethylsilyl azide, triethyl phosphite and various *C*-nucleophiles. Suitable transformations of the resulting glycosides are carried out owing to the ready conversion of the thiazole ring into the formyl group followed by reduction to alcohol and/or oxidation to carboxylic acid. Thus, anomeric glycosyl amino acids, ketosyl and ulosonyl disaccharides and phosphonates have been prepared. Special applications include the synthesis of *O*-glycosyl calix[4]arene derivatives (calixsugars) and a cyclic ketotrisaccharide. The triethylsilane reduction of thiazolylketose acetates leads to thiazolyl *C*-glycosides that once subjected to the thiazole-to-formyl conversion afford formyl *C*-glycosides. These anomeric sugar aldehydes are convenient starting reagents for the synthesis of various *C*-glycosides and *C*-glycoconjugates, such as (1→6)-disaccharides and oligosaccharides, glycosyl aminoacids (glycine, serine, asparagine), and a galactocerebroside. Formyl *C*-glycosides participate in the azomethine ylide 1,3-dipolar cycloaddition reaction to C_{60} fullerene to give sugar fullerenes. The cover illustration shows some products of these reactions and a view of Palazzo dei Diamanti (Palace of Diamonds), a beautiful and unique building in the architectural context of Ferrara, constructed in the first half of 1500. The façade of the Palace is decorated with more than eight thousand five-hundred diamond shaped small blocks of marble.

Alessandro Dondoni has been Professor of Organic Chemistry at the University of Ferrara since 1975. His research interests include the design of new reagents and the development of stereoselective synthetic methods. Recent work has been focussed on the preparation of natural product-like compounds, particularly small peptide and glycoconjugate analogues. He started a new program on glycosylated calixarenes and calixarene-containing polymers. In 1999 he obtained the Avogadro–Minakata Lectureship Award of the Chemical Society of Japan and the Ziegler–Natta Lectureship Award of the German Chemical Society. In the same year he was awarded the Lincei National Academy prize in Chemistry sponsored by the Italian Minister of Cultural Heritage and Activities.

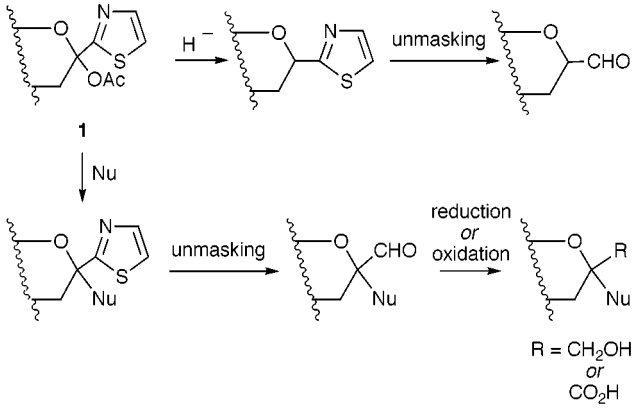
Alberto Marra graduated in Pharmaceutical Sciences from the University of Pisa in 1985 and obtained his PhD in Organic Chemistry from the University Paris VI in 1989 under the supervision of Professor P. Sinaÿ. He spent one more year in Paris at the Ecole Normale Supérieure as Associated Researcher of the French National Research Council. He was postdoctoral Research Associate at the University of Zurich with Professor A. Vasella (1991) and then moved to the University of Ferrara where he joined the group of Professor A. Dondoni. He was appointed to a lectureship in Organic Chemistry at the Faculty of Engineering from 1992 to 1998 and was promoted to the position of Associate Professor in 1998 at the same University. As in his early activities, his present research interest centres on carbohydrate chemistry. Recent work also deals with the synthesis and properties of calixarene derivatives.

Introduction

Carbohydrates, mainly in the form of oligosaccharides and glycoconjugates (glycoproteins and glycolipids), have been recognized in relatively recent years to play a vital role in fundamental biological functions such as cell-to-cell recognition and cell-to-external agents interactions.[1] These processes are manifested in living organisms by various phenomena, some of which are beneficial, such as fertilization and immune defence, some others are detrimental such as inflammation, viral and bacterial infections, cancer metastasis.[2] Problems still exist in determining the exact function at the molecular level of carbohydrate moieties in a given glycoconjugate. To explore these properties, glycobiology, the science dealing with the nature and role of carbohydrates in biological events,[1] is posing a pressing need for access to usable quantities of natural oligosaccharides and glycoconjugates in homogeneous and pure form. However the isolation and purification of these materials from natural sources are quite difficult and when possible provide the products in very low yields. The same need exists for unnatural analogues of oligosaccharides and glycoconjugates that may be used in structure–activity relationship (SAR) and drug development studies. Thus, organic synthesis constantly reinforced and rejuvenated by the design of new reagents and the invention of new methods[3] is providing a great contribution to the solution of these problems. Remarkable progress has been made in recent years in the field of natural oligosaccharide synthesis[4] both in solution and the solid phase as well as glycopeptide[5] and glycolipid synthesis.[6] To this end some monosaccharide building blocks have been conveniently exploited, among which glycals[7] and 1,6-anhydro sugars[8] have proved their importance. Nevertheless, innovations are still required in this area. On the other hand, the synthesis of carbon-linked sugars, *e.g.* disaccharide[9] and a few oligosaccharide[10] isosteres, has been reported in relatively recent years while the methods employed lack generality. The same situation exists for the synthesis of carbon-linked glycosyl amino acids[11] that may serve as building blocks for the preparation of modified glycopeptides. Hence substantial development of existing methods and invention of new approaches are needed in this area as well.

We report in this account on the preparation and use of a new class of sugar building blocks, namely thiazolylketoses, which

activated as *O*-acetyl derivatives **1** serve as efficient glycosyl donors toward various oxygen, carbon, nitrogen and phosphorous nucleophiles (Scheme 1). The thiazole ring of the resulting



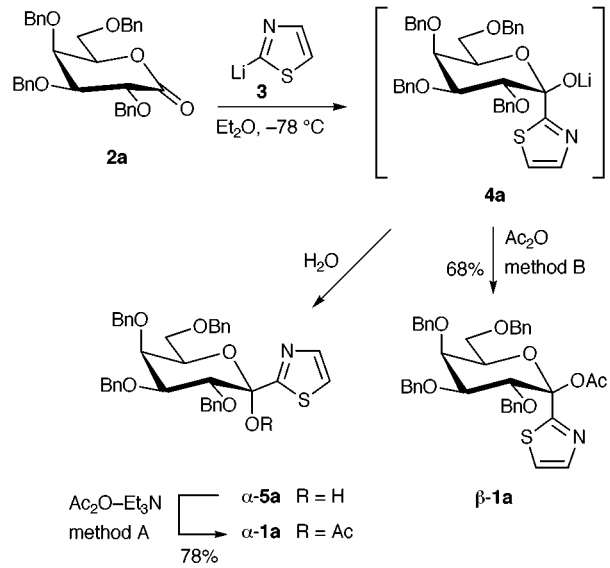
Scheme 1

coupling products is readily transformed into the formyl group that in turn is oxidized to carboxylic acid or reduced to alcohol. A special transformation of acetates **1** consists in their reduction and thiazole-to-formyl conversion, so called *unmasking*, to give formyl *C*-glycosides, a class of valuable intermediates for the synthesis of various and more complex *C*-glycosides.

Preparation of thiazolylketose acetates

Given the well documented service of thiazole as a formyl group equivalent in numerous synthetic methods,[12] the idea that was behind this programme was to install the thiazole ring at the anomeric carbon of sugars and take advantage of the above synthetic equivalence to reach synthetic targets otherwise difficult or impossible to access. While other manipulatable groups, such as cyano,[13] 2-furyl,[14] 1,3-dithianyl,[15] and alkynyl,[16] have been installed at the anomeric carbon of sugars and in some cases transformed into the formyl or carboxylate group, they can hardly compete with thiazole for combining high stability and ready conversion into the corresponding masked functionality under conditions which are tolerated by other protective groups and do not affect the configuration of stereocenters of the molecule. The thiazole-to-formyl protocol consists of a three-reaction sequence (*N*-methylation, reduction, metal-assisted hydrolysis), each step taking place under almost neutral and non-oxidative conditions.[12]

After several unsuccessful approaches of direct glycosylation of thiazole at C-2, the addition of 2-metallated thiazoles to sugar lactones turned out to be the method of choice in our programme.[17] It was not of secondary importance that both reagents can be easily prepared starting from inexpensive, commercially available materials and therefore the reactions can be carried out on a multigram scale. Typically, the reaction of 2,3,4,6-tetra-*O*-benzyl-D-galactonolactone **2a** with 2-lithiothiazole **3**, generated *in situ* from 2-bromothiazole and BuLi at −78 °C in Et_2O, followed by quenching with an aqueous pH 7 buffer produced the thiazolylketose α-**5a** that was isolated in 78% yield by chromatography (Scheme 2). Treatment of this ketose with Ac_2O–Et_3N at room temperature afforded the corresponding *O*-acetate α-**1a** in essentially quantitative yield (method A). On the other hand, quenching the crude reaction mixture at low temperature with Ac_2O, the ketose acetate anomer β-**1a** was obtained in 68% yield (method B). Thus, it appeared that the acetylation at low temperature allows the efficient trapping of the β-ketose **4a**, the product of kinetic selectivity arising from the addition of **3** to the less hindered face of the lactone **2a**. Evidently, the conversion of the β-ketose **4a** into the more stable α-anomer **5a** must occur quite rapidly at room temperature, being very likely controlled by the electronic effect of the ring oxygen (anomeric effect).



Scheme 2

The above reaction scheme was expanded to various pyrano- as well as furano-lactones. In all cases the addition of **3** to the chosen lactone proceeded smoothly to give the thiazolylketose **5** in the hemiketalic form with only occasionally the presence of the open-chain isomer. The corresponding thiazolylketose acetates **1b**–**g** were prepared as either α- or β-anomers depending on the quenching method A or B (Fig. 1). The yields

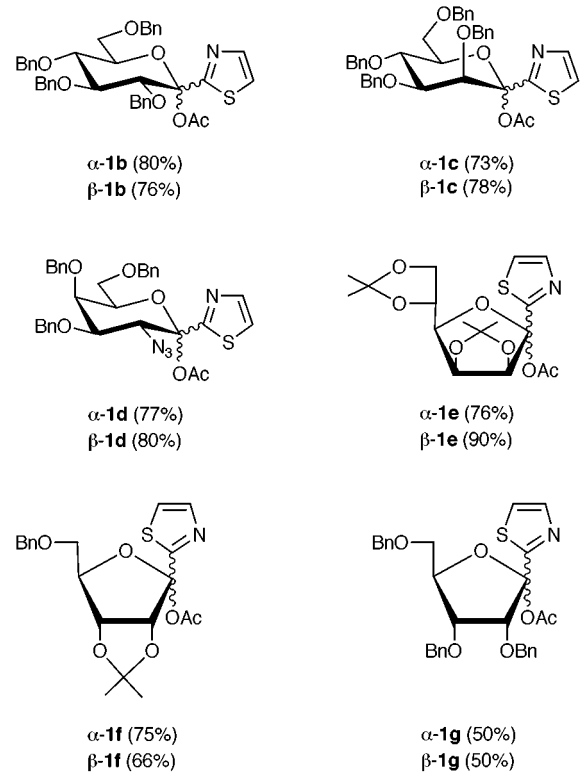


Fig. 1

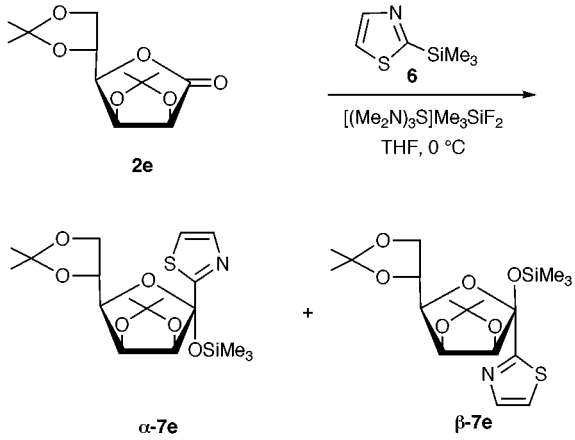
of isolated products were consistently close to those quoted in Scheme 2. Noteworthy among the compounds prepared is the 2-azidogalactose derivative **1d** since this compound can be the precursor of galactosamine derivatives of biological relevance.[18]

Instead of 2-lithiothiazole **3** generated *in situ* at low temperature, 2-trimethylsilylthiazole (2-TST) **6** can be employed as a stable thiazol-2-yl carbanion equivalent in addition reactions to sugar lactones (Scheme 3). We observed that **6** in the presence of equimolar tris(dimethylamino)sulfonium di-



Scheme 3

fluorotrimethylsilicate (TASF) reacts readily with the D-mannonofuranolactone diacetonide **2e** to give the trimethylsilyl thiazolylketoside **7e** as a mixture of α- and β-anomers in 4.5 : 1 ratio and 92% overall yield.[19] Thus, unlike the spontaneous reactions of 2-TST **6** with other carbon electrophiles (aldehydes, ketones, acyl chlorides),[12] this reaction requires the activation of **6** by a fluoride ion releasing promoter. Although the silylated thiazolylketose **7e** can eventually be converted into the acetate **1e** by desilylation and acetylation, the method does not appear to offer substantial advantages over that employing 2-lithiothiazole **3** since it requires more steps and the use of TASF, an expensive and difficult to handle reagent. In fact, other fluoride ion releasing promoters (Bu_4NF, CsF) proved to be much less efficient in this reaction since the thiazolylketose **5e** was recovered in *ca*. 10% yield together with unreacted **2e**.

Why activation of thiazolylketoses as *O*-acetates?

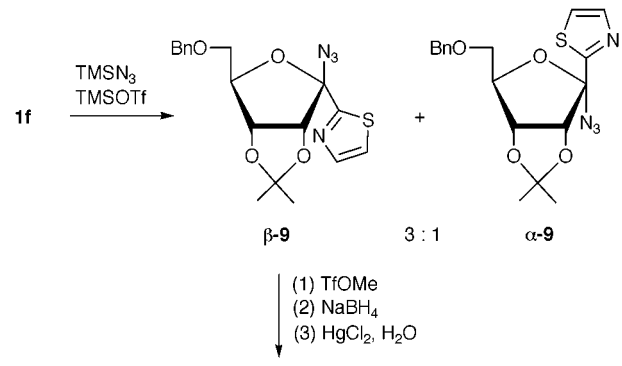
Rather soon at the outset of this research we realized that the thiazolylketose **5a** and the other analogues could hardly be used as glycosyl donors. Efficient ketosyl donors, such as those bearing an electron-rich substituent at the anomeric centre, are known to be very reactive under Lewis acid catalysis at low temperature. For example glycosidation[20] and anomeric deoxygenation[14f,h] of furylketoses occur rapidly under these conditions. On the other hand we failed to reduce various pyrano- and furano-ketoses **5** either under radical or polar conditions.[17] Very likely the electron-poor character of the thiazole ring and interaction with the catalyst through the basic nitrogen atom cause the unsuccessful reactions. Thus, the activation of thiazolylketoses **5** by conversion of the hydroxy group into a better leaving group appeared to be a prerequisite for the use of these compounds as glycosyl donors. The conversion into *O*-acetates **1** turned out to be a winning move since these compounds are easy and inexpensive to prepare, are stable to storage, and nevertheless sufficiently reactive under polar glycosylation conditions. Finally, although their reactions occur at room temperature, the stereoselectivity ranged from good to excellent levels based on high yield of isolated products. Some reactions are illustrated below in support to these anticipated results.

N-Glycosidation and formal synthesis of (+)-hydantocidin

The first test on the ability of thiazolylketose acetates **1** to serve as glycosyl donors (Scheme 1) was carried out with trimethylsilyl azide ($TMSN_3$) as nitrogen nucleophile.[21] Equally important for synthetic purposes, was proving the compatibility of various functional group manipulations, particularly the cleavage of the thiazole ring adjacent to the quite reactive azido group. The synthesis of the peculiar α-azido aldehyde **8** sharing its central carbon atom with the D-ribofuranose ring constituted an interesting target in the above context. The importance of **8** relies on its being an advanced intermediate[22] for the synthesis of the herbicide and plant growth regulator (+)-hydantocidin, a natural product produced by fermentation processes[23] (Scheme 4).

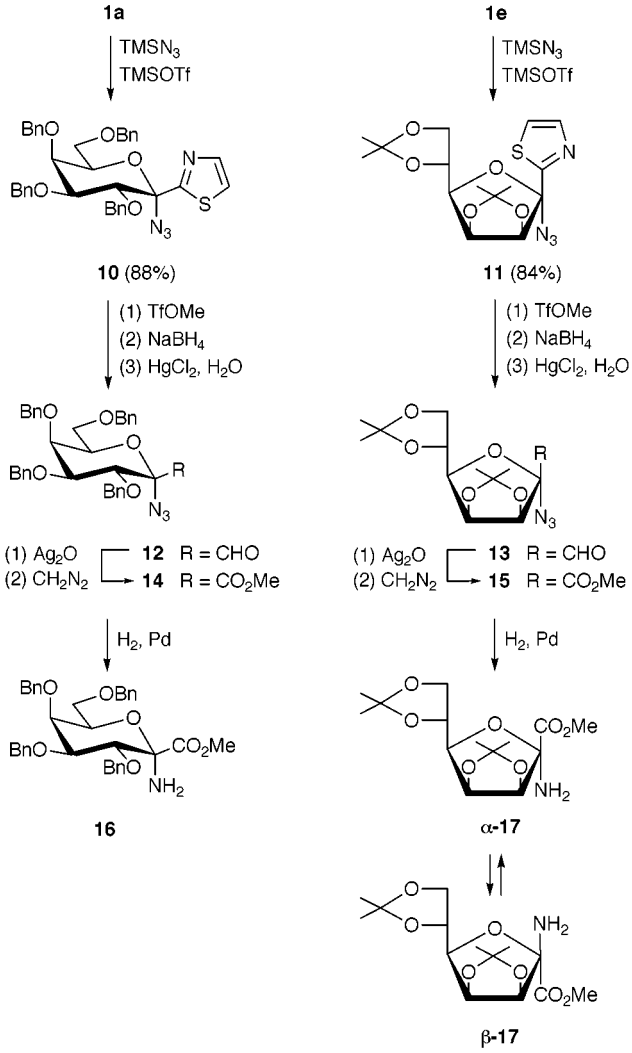
Scheme 4

Either α- or β-anomer of thiazolyl-D-ribofuranose acetate **1f** proved to be an excellent glycosyl donor toward $TMSN_3$ upon activation by trimethylsilyl triflate (TMSOTf) in CH_2Cl_2 at room temperature.[21] In both cases, the reaction afforded the same mixture of α- and β-azido glycosides **9** in 1 : 3 ratio and 84% overall yield (Scheme 5). After separation and identification of the major stereoisomer β-**9**, the conversion to the azido aldehyde **8** was carried out with satisfactory yield (57%) by suitable adjustments of the standard thiazole-to-aldehyde procedure to avoid cycloaddition side-reactions between the *N*-methylthiazolium ring, an intermediate of the unmasking protocol, and the adjacent azido group acting as a 1,3-dipolar partner. The conversion of **8** into the anomeric spirohydantoin of D-ribose featured by (+)-hydantocidin was reported earlier by Mio and co-workers.[22]



Scheme 5

A better evaluation of the scope of the *N*-glycosidation reaction was obtained starting from the D-galactoketopyranose acetate **1a** and the D-mannoketofuranose acetate **1e**. The *N*-glycosidation of these compounds with $TMSN_3$ under the above conditions occurred with high α-selectivity to give exclusively the anomeric azido sugars **10** and **11** in gratifying 88 and 84% isolated yields (Scheme 6). This stereochemical outcome is that expected on the basis of a glycosidation reaction scheme proceeding through a sugar oxycarbenium ion intermediate undergoing a sterically controlled nucleophilic addition (Fig. 2). Evidently, this stereochemical control was much weaker in the case of the D-riboketofuranose **1f** due to the intrinsic configuration of this sugar and consequently the azide **9** was formed as a mixture of α- and β-anomers (Scheme 5). Taking advantage of the modified conditions of the thiazole-to-formyl protocol developed for the conversion of **9** to **8**, compounds **10** and **11** were transformed into the azido aldehydes **12** and **13** without any problem. At this stage, a further elaboration was carried out as a confirmation of the synthetic value of the thiazole sugars **1**. Crude aldehydes **12** and **13** were oxidized to the azido esters **14** and **15** that in turn were transformed into the sugar aminoesters



Scheme 6

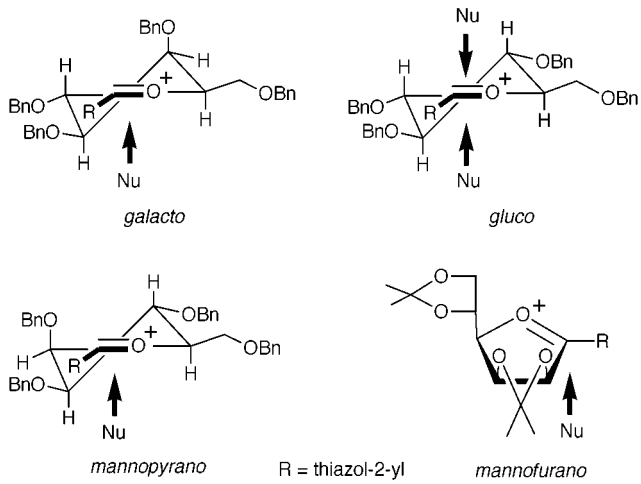


Fig. 2

16 and **17** by selective reduction of the azido group by Pd-catalyzed hydrogenation. Compounds **16** and **17** are representative of a new class of unnatural glycosyl amino acids which can be considered as anomeric sugar glycines wherein the central carbon atom of the amino acid coincides with C-1 of the sugar moiety.

P-Glycosidation by Arbuzov-type reaction

Triethyl phosphite was the model phosphorus nucleophile employed in this study. It underwent α-selective glycosylation reaction by various thiazolylketose acetates **1** in an Arbuzov-type coupling reaction carried out in CH_2Cl_2 at room temperature[24] to give exclusively glycosyl phosphonates **18** as α-D-anomers in high isolated yields (Table 1). As an exception, the

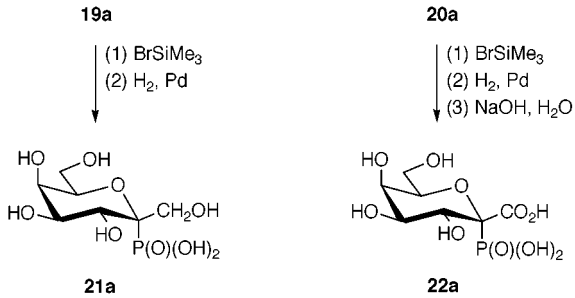
Table 1 *P*-Glycosidation of thiazolyketose acetates **1** with $P(OEt)_3$ (TMSOTf, CH_2Cl_2, room temperature)

Acetate **1**	Phosphonate **18**	Phosphonates **19** and **20**
1a	 **18a** (84%)	 **19a** R = CH_2OH (61%) **20a** R = CO_2Me (62%)
1b	 **α-18b** (52%)	 **α-19b** R = CH_2OH (58%) **α-20b** R = CO_2Me (62%)
1b	 **β-18b** (35%)	 **β-19b** R = CH_2OH (56%) **β-20b** R = CO_2Me (59%)
1c	 **18c** (88%)	 **19c** R = CH_2OH (50%) **20c** R = CO_2Me (51%)
1d	 **18d** (78%)	 **19d** R = CH_2OH (57%) **20d** R = CO_2Me (59%)
1e	 **18e** (93%)	 **19e** R = CH_2OH (56%) **20e** R = CO_2Me (54%)

gluco derivative **18b** although isolated in excellent yield was composed of a mixture of α- and β-anomers in 3:2 ratio. Thus, also in this case the stereochemistry of the glycosidation reaction appears to be controlled by steric factors emerging in the sugar oxycarbenium ion intermediate. The lack of selectivity of the D-glucoketopyranose acetate **1b** is not surprising in view of the small steric difference around the two diastereotopic faces of the corresponding oxycarbenium ion (Fig. 2).

There is current interest in the synthesis of glycosylphosphonate analogues[25] of aldose 1-phosphates, the biological glycosyl donors,[26] because the unnatural *P*-glycosides can act as

inhibitors of carbohydrate processing enzymes and therefore can serve as lead structures in drug discovery against carbohydrate-based metabolic disorders.[2b] Having easy access to thiazolylglycosylphosphonates **18** we were in a position to prepare isopolar glycosylphosphonate analogues of ketose and ulosonic acid 2-phosphates. Accordingly, phosphonates **18a**–**e** were converted into the corresponding aldehydes by the standard thiazole-to-formyl protocol[27] and each product was both reduced to the alcohol **19** (ketosylphosphonate) and oxidized to carboxylic acid **20** (ulosonylphosphonate) (Table 1). Finally, in order to demonstrate a viable route to fully deprotected phosphonic acids, the alcohol and acid protective groups of phosphonates **19a** and **20a** were removed to give the free ketosyl and ulosonyl phosphonic acids **21a** and **22a**, respectively (Scheme 7). It is worth mentioning that the assignment of the anomeric configuration of phosphonates of the *mannopyrano* and *mannofurano* series was carried out by hitherto unreported heteronuclear NOE experiments consisting of the irradiation of the phosphorus nucleus instead of the adjacent protons.[24] In closing this section, it has to be pointed out that phosphonates **19** and **20** represent two new classes of *P*-glycosides. A single example of a ketosylphosphonate was previously reported, *i.e.* the isopolar monophosphonate analogue of β-D-fructose 2,6-bisphosphate prepared in the Vasella laboratory some years ago.[28]

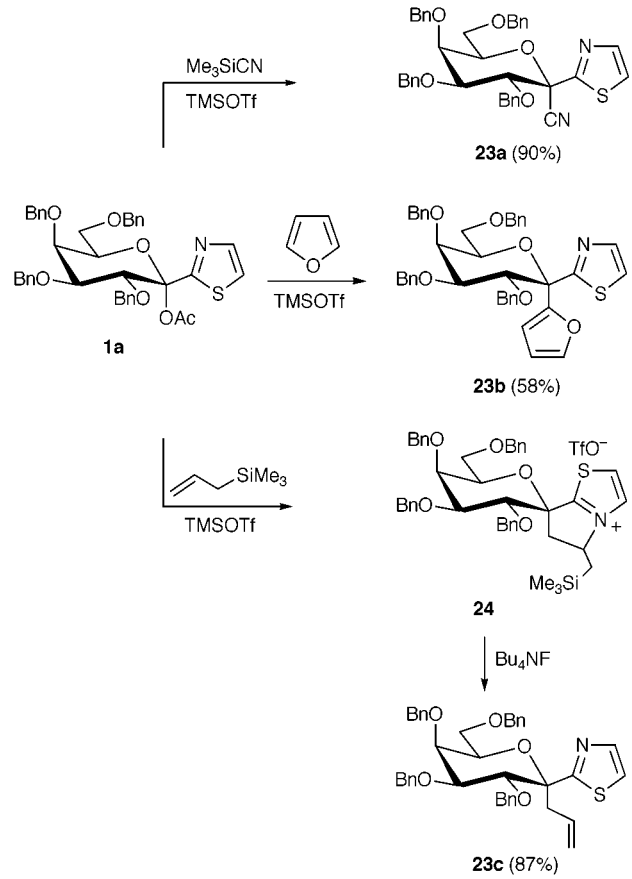


Scheme 7

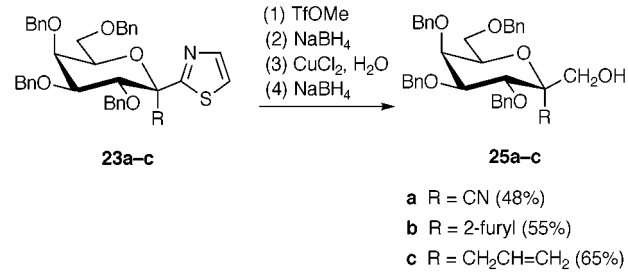
C-Glycosidation and synthesis of a *C*-ketodisaccharide

A positive response on the synthetic utility of thiazolylketose acetates **1** as glycosyl donors came also from their reactions with carbon nucleophiles. The multigram scale coupling of **1a** with trimethylsilyl cyanide (TMSCN), furan and allyltrimethylsilane under the usual mild conditions (TMSOTf, CH_2Cl_2, room temperature) afforded exclusively the corresponding α-D-linked *C*-glycosides **23a**–**c** in good yields (Scheme 8).[29] The allyl derivative **23c** was obtained upon desilylation (Bu_4NF) of the initially formed thiazolium salt **24**. Intuitively, this compound should be formed *via* intramolecular alkylation of the thiazole ring by the anomeric propyl cation intermediate generated in the first step of the *C*-glycosylation reaction. As a further demonstration of the key service of thiazole, the heterocycle of compounds **23a**–**c** was transformed into the formyl group and the resulting crude aldehydes were reduced to give the *C*-ketosides **25a**–**c** (Scheme 9).

Unlike alkyl and aryl *C*-aldosides,[30] *C*-ketosides have been described in only a few instances.[16g,31] The problem of the control of the stereochemistry at the anomeric centre becomes even more difficult in these cases. With the allyl *C*-thiazolylgalactoside **23c** in hand, we sought a rapid entry to the β-D-(1→6)-*C*-ketodisaccharide **30** (Scheme 10), *i.e.* the galactose counterpart of the *C*-Glu-β-D-(1→6)-Glu recently prepared in the Schmidt laboratory starting from the protected D-gluconolactone.[32] Thus, in three successive steps the double bond of the allyl chain of **23c** was hydroxylated, the diol protected as an acetonide, and the thiazole ring transformed into the formyl



Scheme 8

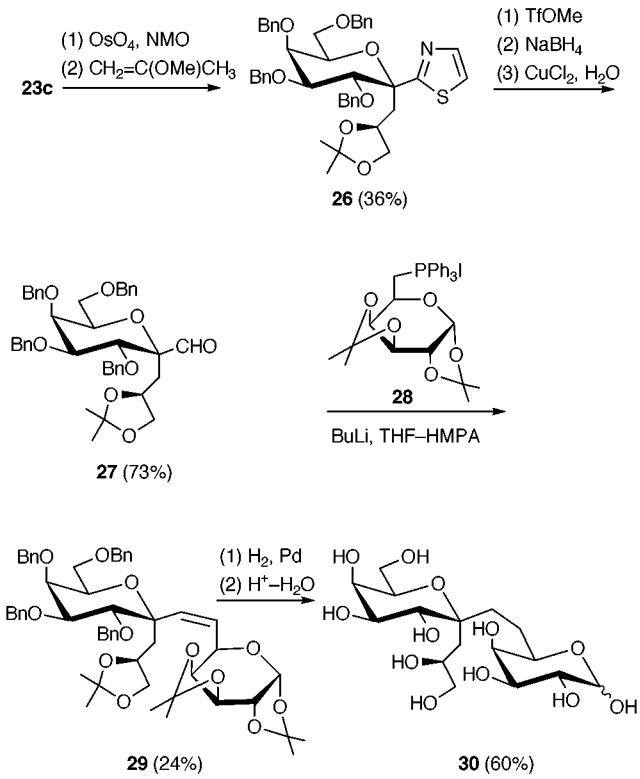


Scheme 9

group. Then the olefination of the aldosulose **27** with the ylide generated from the phosphonium salt **28** gave the olefin **29** as a single *Z*-isomer although in rather low yield (24%). Nevertheless this compound was transformed into the deprotected target product **30** by reduction of the double bond and removal of all hydroxy protective groups.[29] It has been suggested[32] that *C*-ketodisaccharides like **30** can be employed for the synthesis of inhibitors of carbohydrate processing enzymes.

O-Glycosidation with sugar alcohols

At this stage the challenge lay in demonstrating that ketose acetates **1** were suitable glycosyl donors toward more complex nucleophiles such as primary and secondary sugar alcohols. While the *O*-glycosidation of aldoses is routine owing to the numerous efficient methods developed in the last two decades or so,[4] the same reaction with ketoses has been much less exploited. Recent methods have been described involving the use of a phosphite activated fructofuranose[33] and variously activated ketopyranoses.[34] Danishefsky in early syntheses of ulosonic acids[20a] employed furylketoses as glycosyl donors since the furan ring is an electron-rich heterocycle that favours



Scheme 10

the glycosidation reaction and at the same time serves as a masked carboxylate group. Thus it was quite rewarding to find that despite the electron-poor character of thiazole, either α- or β-anomers of the *galactopyrano*, *glucopyrano* and *mannofuranno* thiazolylketose acetates **1a**, **1b**, and **1e** reacted under the usual conditions (TMSOTf, CH_2Cl_2, room temperature) with methyl 2,3,4-tri-*O*-benzyl- and 2,3,6-tri-*O*-benzyl-α-D-glucopyranoside acceptors **31** and **32** to give the corresponding thiazolylketodisaccharides **33a**-**37e** in fairly good isolated yields[20b] (Table 2). The α-D selectivity was the rule for the reactions of **1a** and **1e**, whereas the gluco derivative **1b** gave α- and β-D-linked disaccharides **35b** in nearly equal amounts. It was proved that the use of the participating solvent acetonitrile does not affect the above stereochemical outcome. These results are in agreement with the transition state models outlined in Fig. 2. The glycosidation of **1e** with the primary sugar alcohol **31** was compared with the reaction of other mannoketofuranosyl donors with the same alcohol (Scheme 11). As expected, the inactivated furylketose **38** reacted more readily than **1e** to give at low temperature the ketodisaccharide **39** in satisfactory yield. On the other hand the glycosidations of the methylketose acetate **40** and methylulosonate acetate **41** were less efficient as judged from the lower yield of isolated ketosyl disaccharide **42** and the almost complete lack of formation of the ulosonyl disaccharide **43.** The role of thiazole on the reactivity of thiazolylketose acetates **1** as glycosyl donors is open to conjecture. It was suggested[20b] that the heterocyclic ring exerts an anchimeric effect as shown in **A** that assists the acetoxy group removal induced by the Lewis acid E and therefore favours the formation of the oxycarbenium ion intermediate **B** (Scheme 12).

It appeared important in the above context to demonstrate the convenient use of thiazolylketoses for the preparation of disaccharides that are otherwise difficult to access. Compound **43** as well as ulosonyl disaccharides in general represent one of those categories of compounds. Thus, the thiazolyl ketodisaccharide **37e** was subjected to the usual thiazole-to-formyl deblocking protocol and the resulting crude aldosulose **44** was both reduced to the ketose **45** and oxidized to the ulosonate **43** in good overall yields (Scheme 13). The same procedure was applied to the other disaccharides of Table 2 to afford similar results.

Table 2 *O*-Glycosidation of thiazolyketose acetates **1** with sugar alcohols **31** and **32** (TMSOTf, CH_2Cl_2, room temperature)

Acetate **1**	Alcohol **31** or **32**	Ketodisaccharides **33**–**37**
1a	 **31**	 **33a** (73%)
1a	 **32**	 **34a** (60%)
1b	**31**	 **α-35b** (38%) **β-35b** (25%)
1e	**31**	 **36e** (70%)
1e	**32**	 **37e** (62%)

In closing this section a short comment is worth notice with regard to the use of the furyl instead of the thiazolyl group in this synthetic methodology. For example the readily available furylketodisaccharide **39** shown in Scheme 11 is in principle a precursor of the ulosonyl disaccharide **43** *via* the oxidative cleavage of the furan ring to carboxylic acid.[35] In a similar way other ulosonyl disaccharides should be accessible starting from the furyl analogues of compounds **33a**–**37e** of Table 2. However, the strong oxidizing reagents, such as RuO_4 or O_3, that are employed for the unmasking of the carboxylate function from the furan ring impose some caution on the use of this approach since harsh oxidative conditions are likely to be incompatible with various functional and protective groups such as the benzyl group.[36]

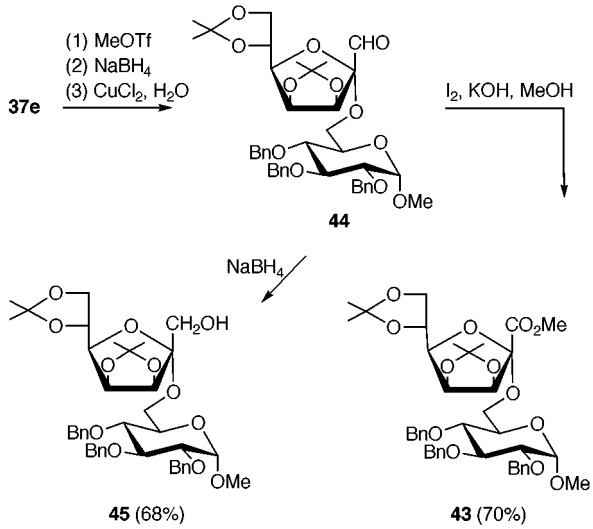
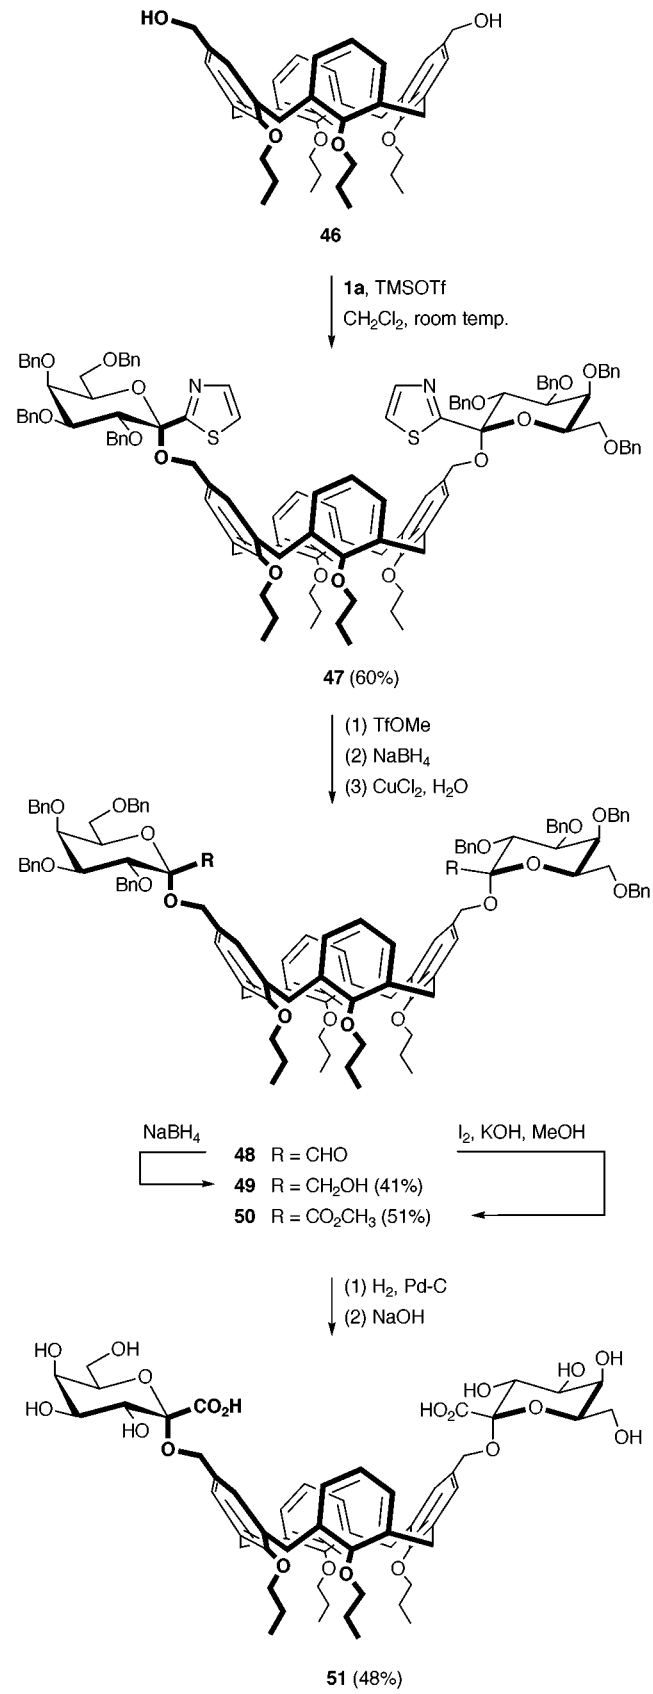


Scheme 13

O-Glycosidation with calix[4]arene alcohols

The rather special glycosylation of primary alcohols attached to one rim of the quite popular macrocyclic phenol-formaldehyde oligomers called calixarenes,[37] belongs to a research programme in our laboratory aiming at the construction of well organized chiral polar domains anchored to a rigid scaffold.[38] The idea behind this project is to use these potentially water soluble systems, named calixsugars, as selective receptors of chiral highly polar organic molecules. Applications in biological systems can also be foreseen as multivalent ligands and inhibitors.[39] Initial work was centred on the *O*-glycosylation of calix[4]arene derived diols and tetrols with aldoses.[38a,b] Then, the coupling of these polyols with thiazolylketose acetates **1** provided the opportunity of a multiple installation of ketosyl and ulosonyl groups.[40] A complete reaction sequence is illustrated in Scheme 14. The reaction of the D-*galacto*



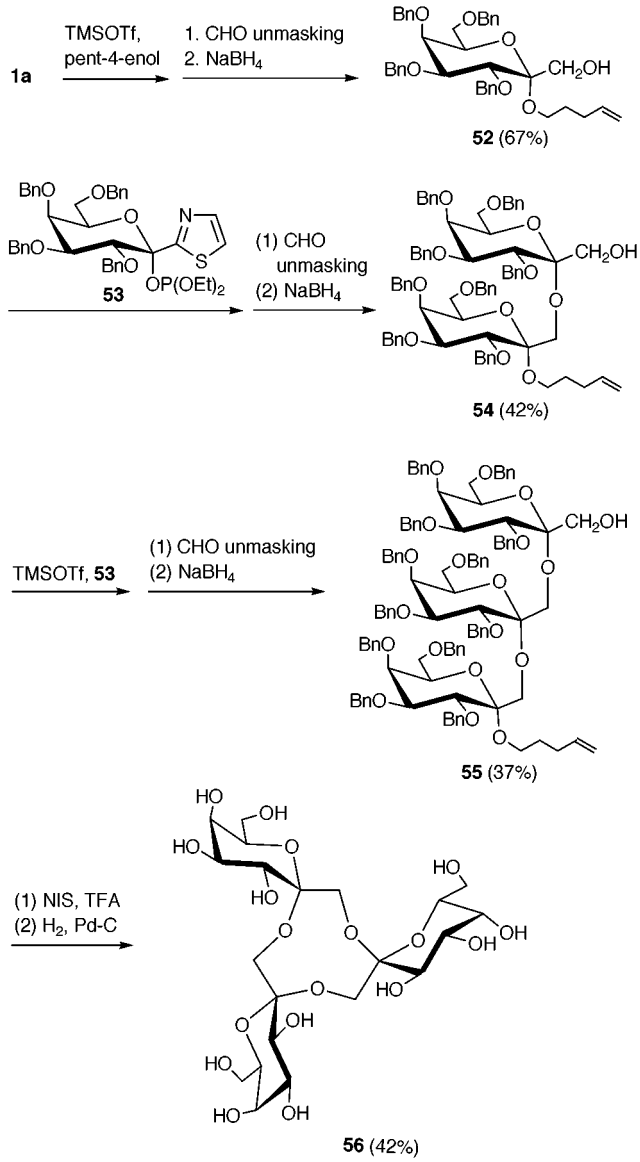
Scheme 14

derivative **1a** with the symmetrical calixarene diol **46** under the usual TMSOTf promoted conditions (CH_2Cl_2, room temperature) afforded the bis-*O*-ketosyl calixarene derivative **47** in good isolated yield. It was firmly established by NMR analysis

that both ketosyl moieties were linked with an α-D (axial) orientation and that the calixarene system retained the cone conformation as in the initial compound **46**. Application of the reaction conditions illustrated in Scheme 13 for the elaboration of **37e** transformed the product **47** into the dialdehyde **48**, which in turn was either reduced to the diol **49** or oxidized to the diester **50**. Finally debenzylation and saponification of **50** afforded the protective group free calixsugar **51** featuring two heptulosonic acid moieties at the upper rim. Compound **51** represents the first member of a class of calixsugars bearing charged functional groups at C-1 of the sugar moieties.

Iterative *O*-glycosidation and synthesis of a cyclic ketotrisaccharide

Having demonstrated the feasibility of the ketodisaccharide synthesis under the thiazolylketose paradigm, we wondered whether the method could be extended to the synthesis of higher oligomers by iterative glycosylation and thiazole cleavage. The orthogonally activated thiazolylketose phosphite **53**, obtained from the thiazolylketose **5a**, and the pentenyl hydroxymethylketoside **52** were used in the stepwise assembly of 2→1-ketoside units to give linear and cyclic D-*galacto*-2-heptulopyranose oligomers[41] (Scheme 15). The first chain-elongation cycle

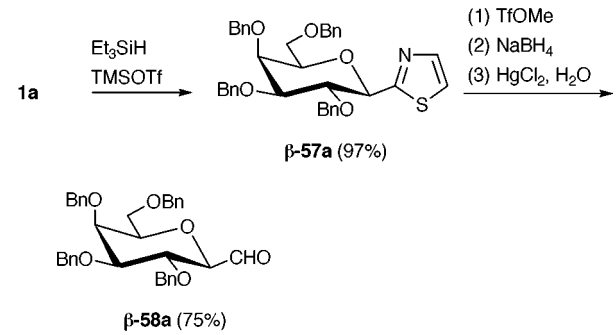


Scheme 15

consisted of the TMSOTf promoted coupling between **53** acting as the glycosyl donor and **52** acting as the acceptor followed by the aldehyde liberation from thiazole and reduction to alcohol. This reaction sequence afforded the ketodisaccharide **54** that in turn was used as the acceptor in a second cycle to give the ketotrisaccharide **55** in satisfactory overall yields. Although there were no apparent indications that we reached the limit of the application of the linear iterative process, the intramolecular cyclization in **55** was demonstrated to occur readily under the Fraser-Reid glycosylation conditions using *N*-iodosuccinimide and trifluoromethanesulfonic acid as promoters.[42] Exhaustive debenzylation of the resulting product afforded the hydroxy group free and water soluble cyclic (α,α,α)-D-ketotrisaccharide **56**. There are no precedents for natural or synthetic cyclic oligosaccharides[4c] similar to compound **56** featuring pyranose units arranged in a spiro fashion around a crown ether skeleton. Related products are the so-called cyclofructins, namely cyclic oligosaccharides constituted by (2→1)-linked fructofuranose units, which are obtained by enzymatic degradation of inulin.[43] Compound **56** can be considered a special type of carbohydrate-based crown ether, *i.e.* a 1,4,7-trioxacyclononane carrying three pyranose rings whose anomeric carbon atoms are part of the methylene bridges. Also from this perspective, no examples can be found in the literature.[44] As a crown-ether, perbenzylated **56** exhibited a remarkable complexing ability in organic solvents toward various ions including calcium and magnesium.

Reduction of thiazolylketose acetates

While the removal of the hydroxy group of the ketose α-**5a** was unsuccessful under various conditions,[17] the corresponding acetates α-**1a** and β-**1a** were readily reduced upon treatment with excess triethylsilane in the presence of TMSOTf as described in the above glycosidation reactions (Scheme 16).



Scheme 16

Under optimized conditions the reaction afforded the β-linked thiazolyl *C*-glycoside β-**57a** in very good isolated yield (97%). This compound was transformed into the corresponding aldehyde β-**58a** that constituted the final target of the whole procedure. The same reaction sequence was employed for the preparation of various α- and β-D-linked formyl *C*-glycosides **58** (Fig. 3) starting from the ketose acetates **1** shown in Fig. 1. Most acetates **1** (*galactopyrano*, *mannopyrano*, *mannofurano*) were reduced with very high levels of diastereoselectivity to give essentially the β-anomer *C*-glycoside **57** according to the transition state models shown in Fig. 2. Thus, in all these cases only the β-linked aldehydes **58c**–**e** were obtained. As expected, the reduction of glucopyranosylketose acetate α-**1b** or β-**1b** was unselective as it afforded a mixture of α- and β-linked *C*-thiazolyl glycosides in a 1:1 ratio. In this case, both α- and β-formyl *C*-glucopyranosides **58b** were prepared. However in a more recent work[45] we observed that the SmI_2 promoted deoxygenation of ketose acetates **1** occurs with opposite diastereoselectivity to that obtained by the use of Et_3SiH–TMSOTf. A remarkable example is the reduction of the *mannofurano* derivative α-**1e** in which the inversion of selectivity is almost complete[9a] (Scheme 17). Therefore both α- and β-linked aldehydes **58e** were prepared with good efficiency

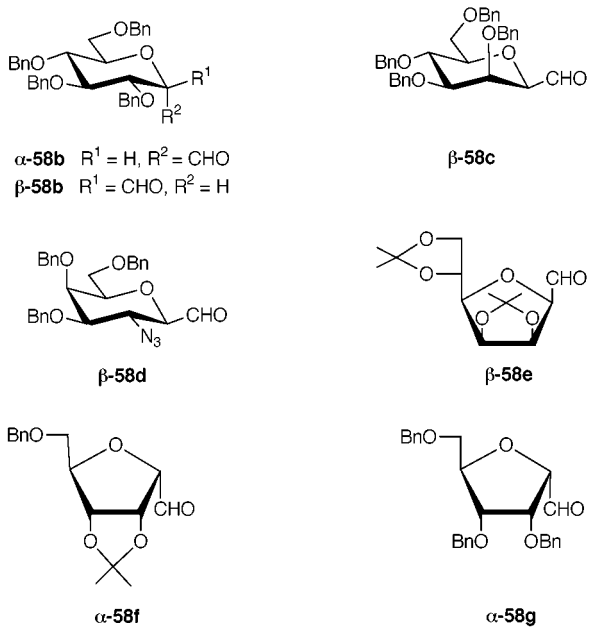


Fig. 3

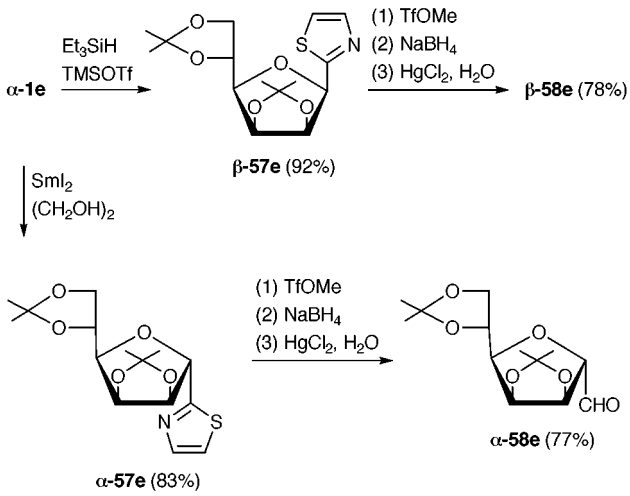


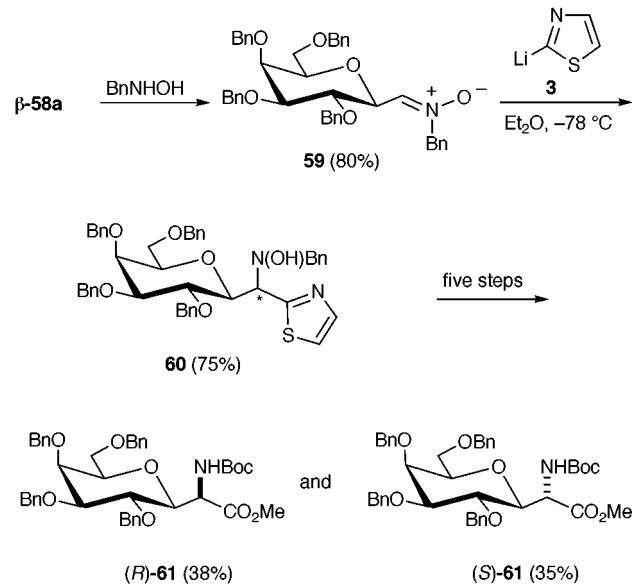
Scheme 17

starting from the same thiazolylketose acetate α-**1e**. Unfortunately the tunable stereoselective reduction was much less efficient with other acetates **1**.

Since the installation of the formyl group at the anomeric carbon of carbohydrates is far from being a trivial problem, other synthetic methods have been reported which use various formyl group equivalents.[10a,15,16e,16j,46] However the application of these methods has often been limited to the synthesis of one or two compounds. On the other hand the efficiency and wide scope of the above thiazole-based method is substantiated by the preparation of a variety of glycopyranosyl and glycofuranosyl aldehydes **58**. The service of the thiazole ring as a formyl group equivalent appeared to have been especially highlighted in this synthetic methodology!

Synthetic applications of formyl *C*-glycosides

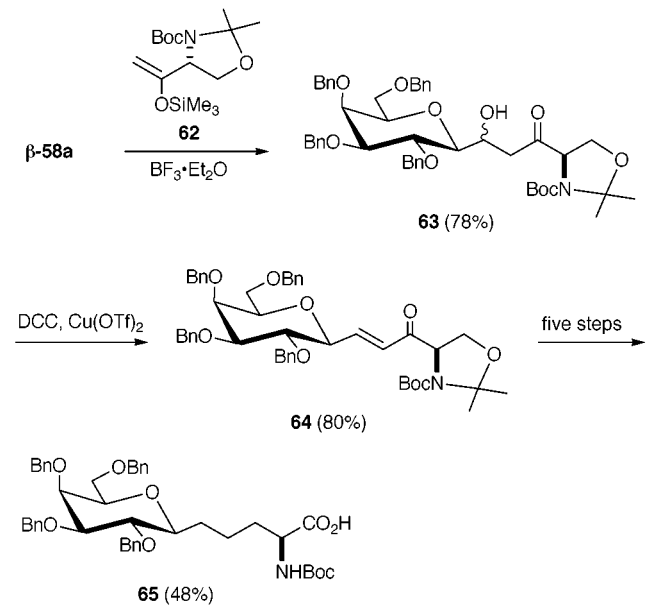
The highly reactive formyl group of sugar aldehydes **58** makes these compounds attractive building blocks in synthetic endeavours to more complex *C*-glycosides. The axial (α-D) or equatorial (β-D) orientation of this substituent already *in situ* on the sugar moiety overcomes the problem associated with the control of the stereochemistry of the *C*-glycosidation reaction. The programme was inaugurated with the synthesis of *C*-glycosyl α-amino acids[20c] by application of a nitrone based aminohomologation technique of aldehydes developed in our group.[12,47] The method is succinctly illustrated in Scheme 18 wherein the key step is the addition of 2-lithiothiazole **3** to the



Scheme 18

nitrone **59** generated from the aldehyde β-**58a**. This reaction afforded the *N*-benzyl hydroxylamine **60** in satisfactory yield (75%) but as a mixture of epimers in *ca*. 3:1 ratio. Suitable elaboration of **60** including reductive *N*-dehydroxylation by $TiCl_3$ and transformation of the thiazole ring into the carboxylate group, afforded the (*R*)- and (*S*)-epimer α-amino ester **61** (*C*-glycosyl glycines) that were individually isolated and characterized (38 and 35%, respectively).[20c]

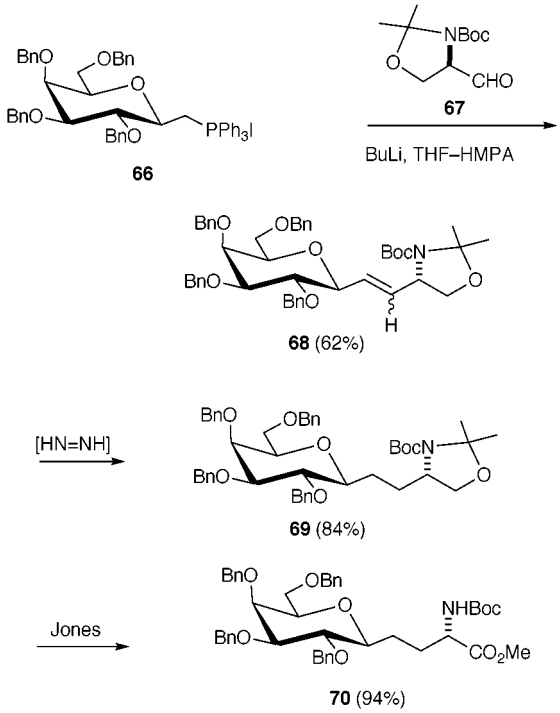
The above synthesis of *C*-glycosyl α-amino acids suffered from poor stereochemical control in the construction of the glycinyl group. The same problem did not exist in a more recent approach to a class of *C*-glycosyl amino acids featuring a three-carbon atom tether.[11] In this method the masked α-amino acid moiety is already present in the form of an oxazolidine ring in the silyl enol ether **62** employed as a reagent in the coupling reaction with the aldehyde β-**58a** (Scheme 19). The resulting



Scheme 19

aldol **63** was isolated as a mixture of diastereomers in good overall yield and transformed into the sugar amino acid **65**

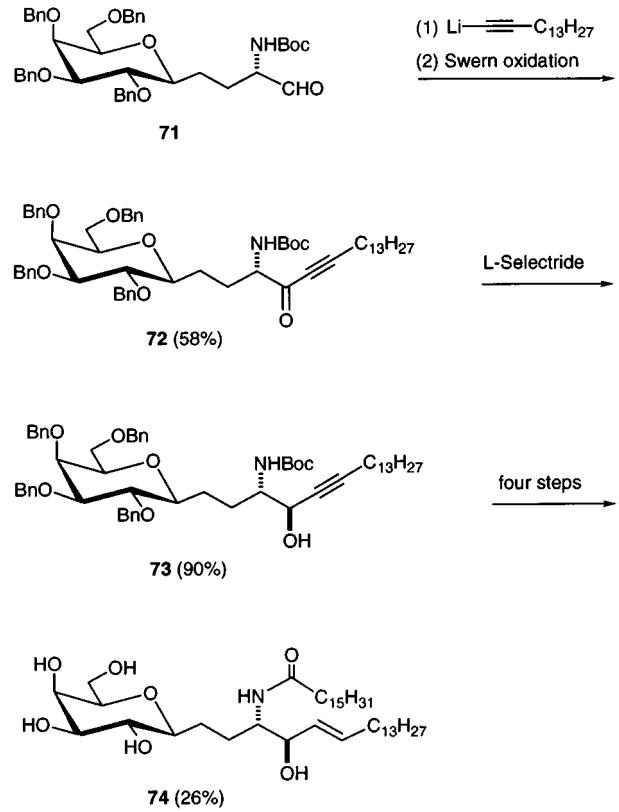
through a series of reactions involving the stepwise removal of the two oxygen atoms from the carbon chain and the oxidative cleavage of the oxazolidine ring. The same reaction sequence was employed for the preparation of the *gluco* and *manno* analogues of **65**. These amino acids represent a class of hitherto unreported carbon-linked isosteres of *N*-glycosyl asparagines wherein the amidic group has been replaced by an ethylene group. In a related programme were also prepared α- and β-linked galactose and glucose serine methylene isosteres by coupling of silyl enol ether **62** with the corresponding glycosyl trichloroacetimidates.[11] Despite considerable efforts, the yield of this glycosidation reaction could not be increased to values higher than 22–32% of isolated product. A complementary approach to this class of *C*-glycosyl amino acid was demonstrated[48] by the synthesis of the galactose derivative **70** (Scheme 20) whose relevance as a precursor to biologically active



Scheme 20

compounds was earlier demonstrated by Bednarski.[49] In our synthesis the aldehyde β-**58a** was transformed into the phosphonium iodide **66** and the ylide generated from the latter was coupled with the quite popular amino aldehyde **67**.[50] From the resulting alkene the conversion to the amino acid **70** was straightforward by reduction of the double bond with *in situ* generated diimide and one-step cleavage of the oxazolidine ring with Jones' reagent.

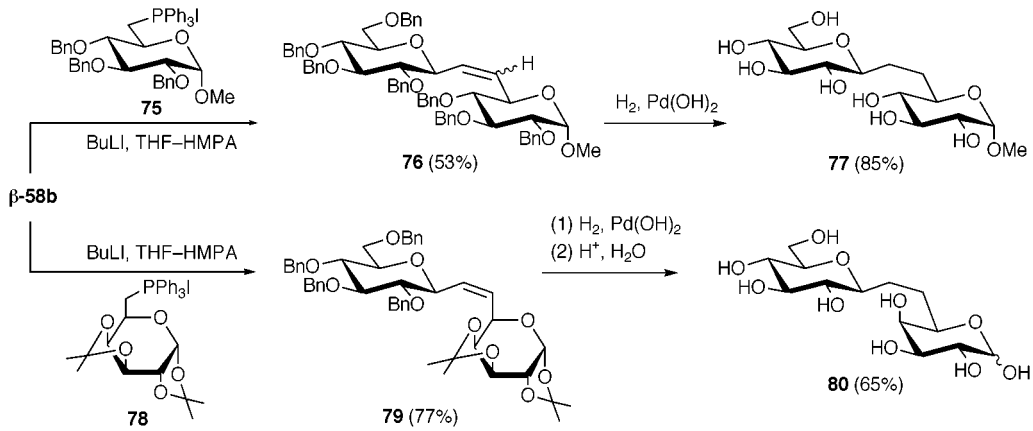
As an extension of the chemistry described above we have considered[51] the synthesis of the carbon-linked galactose cerebroside **74** featuring a carbon–carbon bond between the carbohydrate and the ceramide moieties (Scheme 21). In natural



Scheme 21

compounds these molecular fragments are connected by an oxygen atom. Taking advantage of the satisfactory entry to compound **69** shown in Scheme 20, a rapid assembly of the remaining parts directed to the synthesis of **74** was easily envisaged. By a suitable elaboration of the oxazolidine ring, compound **69** was transformed into the α-amino aldehyde **71** to which pentadec-1-ynyllithium was added and the resulting crude mixture of diastereomeric amino alcohols was oxidized to the ketone **72**. Highly stereoselective reduction of this compound with L-selectride (dr 95%) afforded the amino alcohol **73** showing the correct *anti* relationship between the amino and hydroxy groups as in natural sphingosines. The synthesis of **74** was completed by reduction of the triple bond and replacement of the *N*-Boc with the long chain stearoyl group.

As a further development of this programme, we envisaged the reaction of formyl *C*-glycosides **58** with carbohydrate



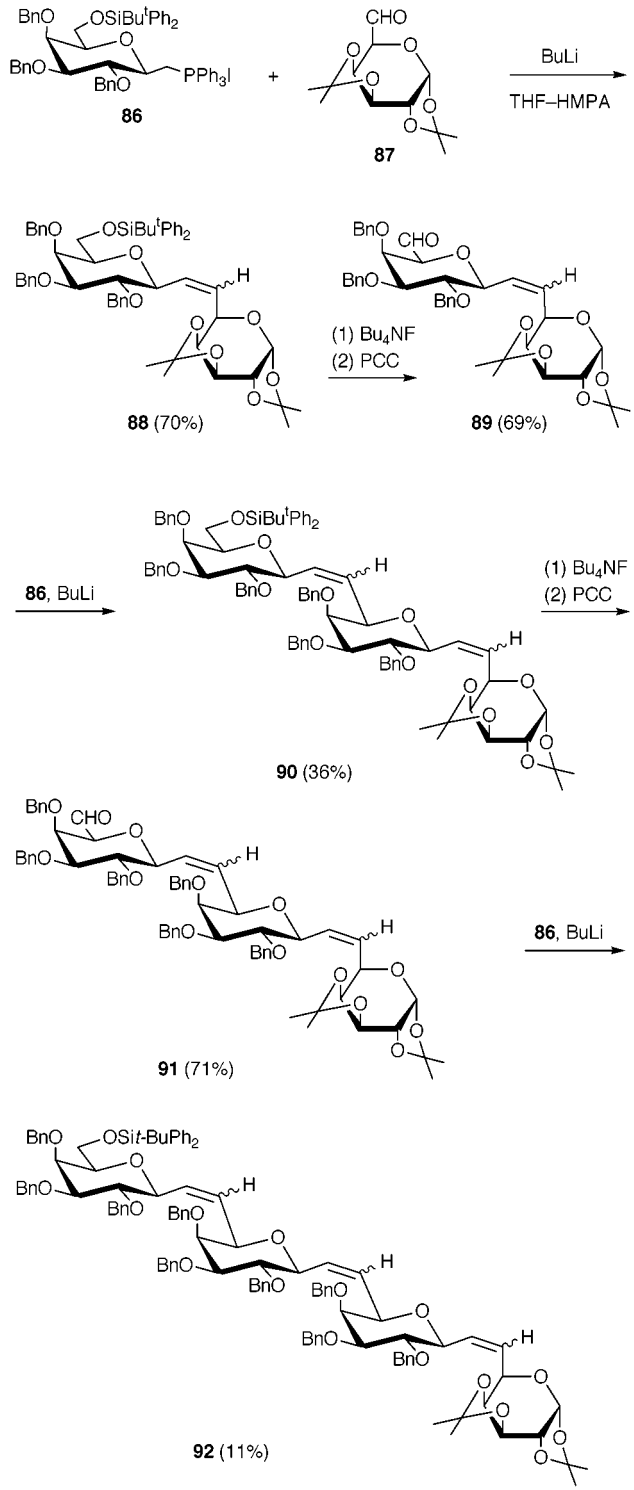
Scheme 22

derivatives bearing a suitable functional group to give carbon-linked disaccharides.[9a] We selected the coupling of **58** with glycopyranose 6-phosphoranes directed to the synthesis of (1→6)-*C*-disaccharides, genuine isosteres of natural products as pointed out by Sinaÿ in the early eighties.[52] The method is illustrated in Scheme 22 showing as an example the synthesis of methyl β-D-*C*-gentiobioside **77** (*C*-Glcβ1,6Glc). A two step reaction sequence constituted by the Wittig olefination of β-**58b** with the ylide generated from the glucopyranose phosphonium salt **75** and the concomitant reduction and debenzylation of the alkene **76** leads to the *C*-disaccharide **77** in a simple and efficient manner.[9a] In a similar way was carried out the synthesis of the *gluco*-to-*galacto*-linked isomer **80** (*C*-Glcβ1,6Gal) with only a minor change that was required for the removal of the isopropylidene protective group. The versatility of this approach was demonstrated in the synthesis of various (1→6)-*C*-disaccharides with both α- and β-linkages (Table 3).

Table 3 Selected (1,6)-*C*-disaccharides prepared form formyl *C*-glycosides **58** by the olefination-reduction sequence

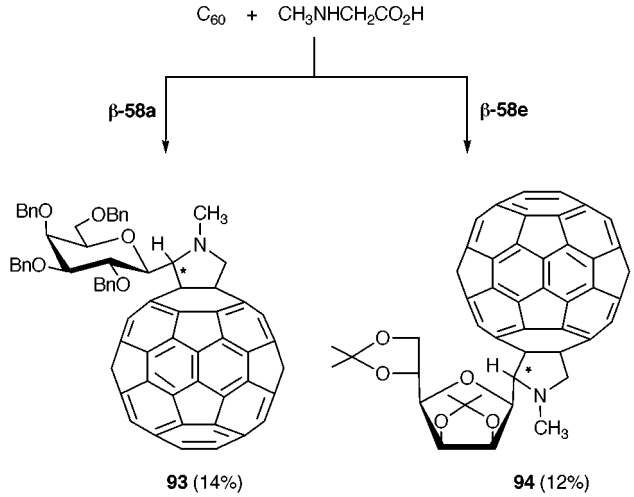
Aldehyde **58**	Phosphonium salt **75** or **78**	*C*-Disaccharides **81**–**85**
β-**58a**	**75**	 **81**
β-**58a**	**78**	 **82**
β-**58c**	**78**	 **83**
β-**58d**	**75**	 **84**
β-**58g**	**78**	 **85**

It was in dealing with this issue that we sought the application of iterative olefination for the assembly of more extensive carbon-linked (1→6)-oligosaccharide chains. In a first approach[10e] the chain growing was initiated by coupling the readily available dialdose **87** with the ylide generated from the phosphonium salt **86** (Scheme 23). The orthogonal protection of the hydroxy groups in the resulting sugar alkene **88** allowed a rapid generation of the aldehyde **89** by desilylation and oxidation of the primary alcohol. This olefination cycle was reiterated twice. Unfortunately the yield of isolated alkene that was rather good in the first cycle (**88**, 70%) dropped substantially in the second (**90**, 36%) and third cycle (**92**, 11%) due to the partial consumption of aldehydes **89** and **91** by 1,2-elimination of BnOH. Nevertheless compounds **88**, **90** and **92** were transformed in the corresponding carbon-linked di-, tri- and tetra-saccharides by desilylation, debenzylation and reduction of the double bonds.



Scheme 23

In closing this section, the use of formyl *C*-glycosides in sugar-fullerene synthesis deserves a short description. Among the multitude of fullerene derivatives that have been prepared in recent years,[53] fullerenes bearing one or more carbohydrate moieties have been reported only in two instances.[54] The interest for glycosylated fullerene derivatives stems from the hope of changing the physicochemical properties of fullerene and improve solubility and biocompatibility. We have installed sugar moieties derived from aldehydes **58** on C_{60} by the Prato azomethine ylide method.[55] In particular, heating a mixture of C_{60} fullerene, *N*-methylglycine (sarcosine), and the aldehyde β-**58a** in refluxing toluene resulted in the formation of a rather



Scheme 24

complex mixture of 1,3-dipolar cycloadducts (Scheme 24). The monoadduct **93** was formed as a 2:1 mixture of diastereomers which were separated and characterized. Similar results were obtained by the use of the aldehyde β-**58e**.

Conclusion

The results that have been presented in this account demonstrate that thiazolylketoses constitute an emerging class of valuable intermediates for carbohydrate synthesis. Once suitably activated by conversion of the anomeric hydroxy group into a good leaving group, they become excellent ketosyl donors. This role appears quite wide in scope as proved by the different types of glycosyl acceptors employed as well as their structural variations. To complete the picture, there is the remarkable contribution of the thiazole ring, which serves as a precursor to various very important functionalities (CHO, CH_2OH, CO_2H), and allows the preparation of various classes of ketosides, some of which are very difficult to access, such as ulosonyl ketosides. The conversion of thiazolylketoses into formyl *C*-glycosides represents a special evolution channel of this chemistry into new synthetic methods for *C*-glycoside synthesis. The synthesis of some important targets (*C*-glycosyl amino acids, *C*-cerebrosides, *C*-oligosaccharides) has been illustrated in this report but further improvements and developments of the methods employed are still required. The extension of these methods to solid-phase techniques should have priority in future research programmes. Other objectives can be also delineated. For example, a formyl *C*-glycoside and compounds derived from it have recently been employed in the Ugi and Passerini multicomponent reactions as an access to glycoconjugate libraries.[56] Thus the combinatorial synthesis in other multicomponent systems, for instance the Biginelli reaction,[57] offers another wide field of application of formyl *C*-glycosides.

Acknowledgement

It is a pleasure to address special thanks to Marie-Christine Scherrmann (Université Paris XI, Orsay), who initiated and developed a great deal of this research during her time in our laboratory as a post-doctoral research associate. We are also grateful to all who contributed to this programme and whose names appear in the references. This work has been supported by various agencies, including the Ministero dell' Università e della Ricerca Scientifica e Tecnologica (MURST COFIN 98), Ministero degli Affari Esteri, Consiglio Nazionale delle Ricerche, Ministère des Affaires Etrangères-Programme Lavoisier (France), the European Community (Erasmus and TMR programmes), Association pour la Recherche contre le Cancer (France), CAPV (Spain) and the United States Research Office.

Paper 9/03758F

Facile, metal promoted, oxidation of η^4-1,3-diphosphacyclobutadiene by water or methanol: synthesis of [MoCl(CO)(η^4-1,3-$P_2C_2Bu^t_2$)(η^5-L)] (L = C_5H_5, C_5Me_5) and [MoCl(CO){η^3,λ^3,λ^5-$PC_2Bu^t_2PH(OR)$}(η^5-L)] (L = C_5H_5, R = H, Me)

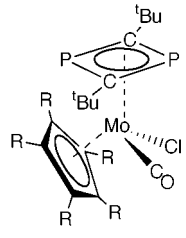
Received (in Basel, Switzerland) 29th June 1999, Accepted 13th September 1999

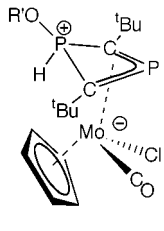
The new complexes [MoCl(CO)(η^4-1,3-$P_2C_2Bu^t_2$)(η^5-L)] (L = C_5H_5 1, C_5Me_5 2) are reported; facile oxidation of 1 with water or methanol affords a rare example of a mixed valence phosphaphosphonietinyl in [MoCl(CO){η^3,λ^3,λ^5-$PC_2Bu^t_2$-PH(OR)}(η^5-C_5H_5)] (R = H, Me), which has also been structurally characterised for R = H.

We have previously reported on studies directed towards the development of the transition metal chemistry of η^2(4e)-bonded phosphaalkynes.[1,2] Mindful of the relationship between phosphaalkynes and their isoelectronic alkyne counterparts we have examined the reactivity of P≡CBu^t towards the molybdenum complexes [MoCl(CO)$_3$L] (L = η^5-C_5H_5 or η^5-C_5Me_5). It has been shown[3,4] that [MoCl(CO)$_3$(η^5-C_5H_5)] reacts thermally with PhC_2Ph to form the four-electron donor diphenylacetylene complex [MoCl(η^2-PhC_2Ph)(CO)(η^5-C_5H_5)]. In the event, however, this study has revealed for the first time that a coordinated 1,3-diphosphacyclobutadiene ligand can undergo a facile and selective reaction with water or methanol to give a mixed valence η^3,λ^3,λ^5-phosphaphosphonietinyl ligand.

Addition of 2.1 equiv. of P≡CBu^t to pentane solutions of [MoCl(CO)$_3$L] (L = η^5-C_5H_5 or η^5-C_5Me_5) and gentle heating (40 °C) for 78 and 24 h respectively, results in the isolation of orange [MoCl(CO)(η^4-1,3-$P_2C_2Bu^t_2$)L] (L = η^5-C_5H_5 **1**, η^5-C_5Me_5 **2**) in moderate and good yield, respectively.



1 R = H
2 R = Me



3 R' = H
4 R' = Me

A single crystal X-ray diffraction study performed on **2** confirmed the structure, and this will be reported in full at a later date.[5] The NMR spectra of **1** and **2** are also fully consistent with this description.† Two different environments are observed for each of the phosphorus and carbon atoms in the 1,3-diphosphacyclobutadiene ring and the appended Bu^t groups, as a consequence of the asymmetry introduced by the carbonyl and chloride ligands. This demonstrates that the 1,3-$P_2C_2Bu^t_2$ ligand does not rotate on the NMR timescale at room temperature, an observation that has been precluded previously by the relatively high symmetry of associated metal fragments in other 1,3-diphosphacyclobutadiene complexes.[6,7] However, the 1,3-diphosphacyclobutadiene ligand in **1** does begin to rotate on the NMR timescale at higher temperatures, the onset of coalescence of the Bu^t signals being observed in the ^{1}H NMR spectrum at +60 °C at 400 MHz.

Complex **2** is remarkably stable to the ambient environment, C_6D_6 solutions remaining unchanged (by ^{1}H and ^{31}P{^{1}H} NMR spectroscopy) on exposure to air or water for 2 weeks. In sharp contrast, **1** undergoes reaction with water (slowly with atmospheric, *ca.* 2 days on addition of 10 equiv.) or methanol (7 days) to afford complexes in which one of the coordinated phosphorus atoms has undergone formal oxidative addition of HOR (R = H, Me). The resulting complexes [MoCl(CO){η^3,λ^3,λ^5-PC_2-Bu^t_2PH(OR)}L] (L = η^5-C_5H_5, R = H **3**, or Me **4**), are formed in essentially quantitative yield for **3** and in *ca.* 90% yield for **4** (impurities present are compound **3** and at least two other unidentified compounds). The solid state structure of **3** is shown in Fig. 1.‡

It is apparent that one of the phosphorus atoms is no longer coordinated to the metal [Mo(1)···P(1) 2.8745(13) Å]. Moreover, P(1) is bent away from the plane of the η^3-phosphaallyl group [C(12)–P(2)–C(7)] by 25.12° and also bears a hydroxy group [P(1)–O(1) 1.581(3) Å] and a direct P–H bond. Both the hydroxy and phosphorus bound hydrogens were located in the difference map and refined without constraints. The remaining bond lengths and angles are consistent with the description of **3** as a η^3,λ^3,λ^5-phosphaphosphonietinyl complex, and as such are unremarkable.

From a bonding perspective, **3** can be viewed in terms of the two canonical forms **A** and **B**; one in which there is a formal bond between Mo and P(1) (**A**) or a zwitterionic alternative in which there is no bond between these two atoms (**B**). On the basis of the long Mo–P(1) distance coupled with the fact that in the IR spectrum the carbonyl group stretch is observed at > 60 cm^{-1} to lower frequency compared with **1,** which is consistent with a negative charge on Mo, we suggest that **B** represents the

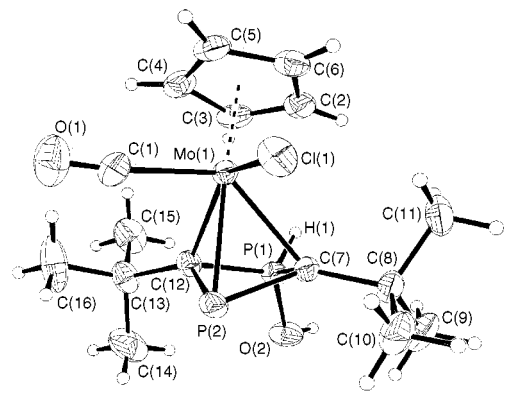


Fig. 1 Crystal structure of one molecule within the asymmetric unit of compound **3** showing the labelling scheme used. Thermal ellipsoids are represented at the 30% probability level. Selected bonds distances (Å): Mo(1)–Cl(1) 2.5468(11), Mo(1)–C(1) 2.036(4), Mo(1)–P(1) 2.8745(13), Mo(1)–P(2) 2.4179(10), P(2)–C(12) 1.848(3), P(2)–C(7) 1.839(3), P(1)–C(12) 1.742(3), P(1)–C(7) 1.742(3), P(1)–O(2) 1.581(3).

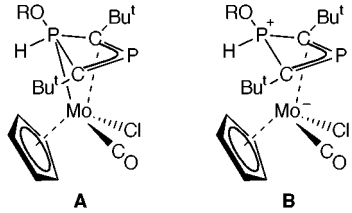
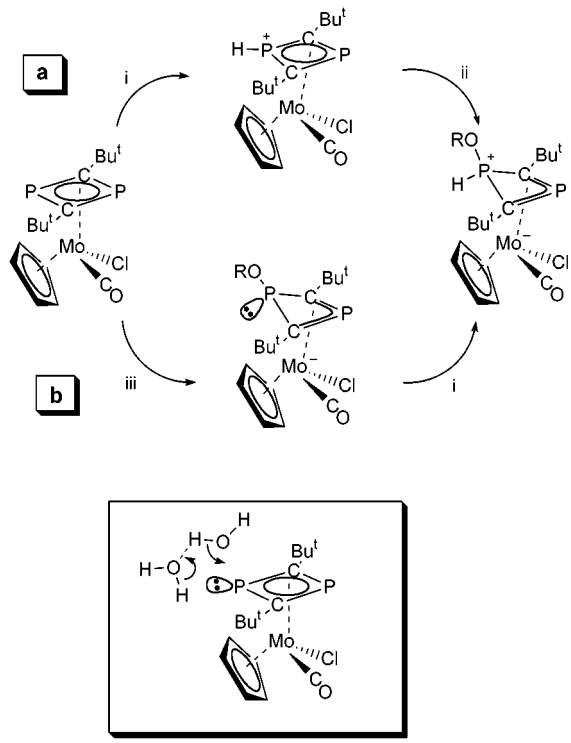


mode of bonding in **3**. In either canonical form P(1) may be considered formally as being phosphorus(V).

The NMR data for **3** and **4** are very similar; for both compounds H(1) is observed as a doublet of doublets in the ^{1}H NMR spectrum, the very large value of one of the couples [J(PH) ≈ 500 Hz] confirming the presence of a direct P–H bond. Although the hydroxy proton in **3** is not observed in the ^{1}H NMR spectrum, presumably owing to fast exchange in solution, in **4** the methoxy group is clearly seen as an integral 3H doublet. In the ^{31}P{^{1}H} NMR spectra of **3** and **4** two different phosphorus environments are observed [**3**: δ(^{31}P) 8.9, −15.8, **4**: δ(^{31}P) 10.6, −16.7], shifted significantly to higher field from those in **1**, with the broader, low field resonance, split on retention of coupling to ^{1}H.

As previously stated, the formulation of compounds **3** and **4** corresponds to the unprecedented selective oxidative [P(III)→P(V)] addition of water or methanol respectively to one of the phosphorus centres present in the 1,3-diphosphacyclobutadiene complex, **1**. Although it has been previously shown that one of the phosphorus lone pairs of a coordinated 1,3-diphosphacyclobutadiene can coordinate onto transition metal Lewis acid fragments,[8] it seems unlikely that the formation of **3** or **4** involves an initial deprotonation of H_2O or MeOH (Scheme 1, pathway **a**,) followed by nucleophilic attack by HO^- or MeO^- on the resulting [1,3-PP(H)C_2]$^+$ ring. More likely is pathway **b** of Scheme 1 since it has been previously reported [9] that in the solid state structure of [Mo(η^5-C_9H_7)(CO)$_2$(η^4-1,3-$P_2C_2Bu^t_2$)][BF_4] the [BF_4]$^-$ anion is bonded to one of the phosphorus centres resulting in the formation of the zwitterionic species [Mo(η^5-C_9H_7)(CO)$_2$(η^3-1,3-$PC_2Bu^t_2PFBF_3$)] **5**. Whereas, in solution, [BF_4]$^-$ rapidly dissociates from **5**, in the case of the formation of **3** and **4**, *trans*-nucleophilic attack by H_2O or MeOH is consummated by addition of H^+ to the phosphorus centre. Additional support for this mechanism comes from the zwitterionic complex [Ru(η^5-C_5H_5)(η^3-1,3-$PC_2Bu^t_2PFCBu^tP$)] **6**, generated from a putative intermediate resulting from [PF_6]$^-$ attack at a coordinated 1,3-diphosphacyclobutadiene ring.[10] There is, of course, a more subtle variation on these two pathways, which depends on hydrogen bonding (Scheme 1) and involves simultaneous protonation and nucleophilic attack. In agreement with these suggestions, involving rate determining breaking of an OH bond, is the observation of a large positive kinetic isotope effect $k_D/k_H \approx 3.6$ [$t_{1/2}$(H_2O) 5.5 h, $t_{1/2}$ (D_2O) 20 h].



Scheme 1 *i* + [H]$^+$; *ii* + [OR]$^-$ (R = H or Me); *iii* + HOR (R = H or Me), −[H]$^+$.

We have reported here the synthesis of two new readily accessible 1,3-diphosphacyclobutadiene complexes, and for one, facile oxidative addition of water or methanol, a reaction without precedent. The robust nature of **2** combined with the reactivity of **1** presages a wealth of chemistry associated with this system which is currently under investigation.

We thank the EPSRC (J. M. L.) and the University of Bath (C. D. A.) for support.

Mono-amidinate complexes stabilized by a new sterically-hindered amidine†

Joseph A. R. Schmidt and John Arnold*

Department of Chemistry, University of California at Berkeley and Chemical Sciences Division, Lawrence Berkeley National Laboratory, Berkeley, California 94720-1460, USA. E-mail: arnold@socs.berkeley.edu

Received (in Bloomington, IN, USA) 12th July 1999, Accepted 16th September 1999

A novel amidinate ligand incorporating a bulky terphenyl group is used to prepare unusual, low-coordinate lithium and yttrium mono-amidinate complexes.

The search for ancillary ligands capable of facilitating a wide variety of catalytic processes is a challenging problem in inorganic chemistry. Metal complexes incorporating amidinate ligands have been actively studied over the past few years; a broad range of chemistry has appeared and important applications, for example, olefin polymerization, have been described.[1–7] A major goal of work in this area is to prepare ligands that can be easily tuned, sterically and electronically, in order to promote the formation of complexes displaying unusual structures and reactivities.

We now report the synthesis of a novel amidinate ligand incorporating a bulky terphenyl group that exerts steric control in its metal derivatives. The synthesis of an unusual Li salt and examples of Ln mono-amidinates are described. These are noteworthy since bis-amidinates are generally formed in Ln systems,[8,9] a situation that parallels, to some extent, the related cyclopentadienyl chemistry to which amidinates are frequently compared.[1,10]

Previous efforts to prepare bulky amidinates relied on adamantyl or $C_6H_3Pr^i_2$-2,6 substitutions at the N atoms,[11–13] giving rise to ligands that are essentially bulky only in the amidine plane [Fig. 1(a)]. In contrast, we envisaged use of a terphenyl substituent on the amidine carbon atom to provide steric hindrance not only in the plane of the ligand, but also above and below this plane, resulting in a more 'bowl'-shaped environment [Fig. 1(b)]. Terphenyl groups are now well known to support unusual coordination environments,[14–17] the closest analogy to our work being the formation of hindered carboxylate complexes reported recently.[18,19]

The sterically demanding amidine *N*,*N*′-diisopropyl(2,6-dimesityl)benzamidine (Hdimb)[20] was isolated in 94% yield by addition of *N*,*N*′-diisopropylcarbodiimide to 2,6-dimesityl-(lithiobenzene)[21] followed by an aqueous work-up (Scheme 1).

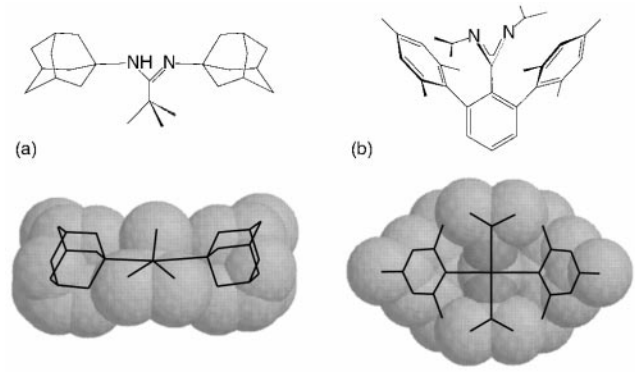

Fig. 1 Side (wire) and top (space-filling) views of (*a*) *N*,*N*′-bis(adamantyl)neopentamidine (ref. 12) and (*b*) *N*,*N*′-diisopropyl(2,6-bismesityl)benzamidine.

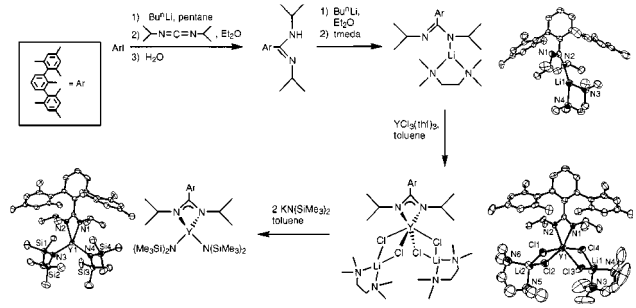
† Electronic supplementary information (ESI) available: characterization data.



Scheme 1

In contrast to simple non-bulky amidines examined previously, the ^{1}H NMR spectrum of Hdimb is complex at room temp., showing two independent sets of amidine resonances. TOCSY data allowed deconvolution of the ^{1}H NMR resonances into two independent sets of peaks. As shown in Fig. 2, the four Pr^i resonances are differentiated into two pairs: one pair from the imine N and one pair from the amine N. A NOESY spectrum showed chemical exchange between the two Pr^i groups in each pair.[22] We attribute this exchange to interconversion between the *Z*- and *E*-*syn* isomers on the NMR timescale. Recently, Boeré *et al*. reported similar structural effects in bulky *N*,*N*′-bis(2,6-diisopropylphenyl)benzamidines.[13]

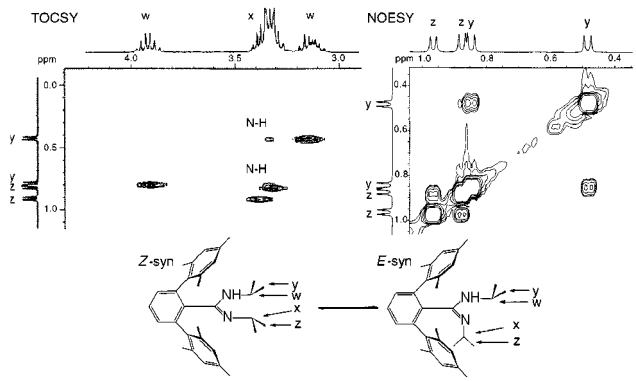


Fig. 2 2D ^{1}H NMR spectra and the indicated equilibrium.

Lithiation of the amidine with Bu^nLi in hexanes, followed by addition of *N*,*N*,*N*′,*N*′-tetramethylethylenediamine (tmeda) gave the Li derivative [(dimb)Li(tmeda)] [20] shown in Scheme 1, which was isolated in 64% yield as colorless crystals from Et_2O. The ^{1}H NMR spectrum shows two different Pr^i resonances, three inequivalent mesityl methyls, and two different mesityl aromatic signals, indicating an unsymmetrical product with C_s symmetry. For comparison, Li salts of simple amidines such as $[PhC(PhN)_2]$Li(tmeda) show spectra consistent with C_{2v} symmetry in solution.[23] The solid-state structure of [(dimb)Li-(tmeda)][24] (Scheme 1) shows that the amidinate is coordinated in a monodentate fashion to the Li which resides in a distorted trigonal planar environment [sum of angles around Li = 358.4(3)°] made up of one amidinate N atom and both tmeda N atoms. Some localization is evident in the N–C–N core, with C(1)–N(1) 1.316(4) Å and C(1)–N(2) 1.337(4) Å. The amidi-

nate N–Li bond [1.942(6) Å] is the shortest observed in a Li amidinate complex and the N–C–N angle is substantially more obtuse [126.5(3)°] than in related species.[25] In contrast, the N(tmeda)–Li bonds [2.115(6) and 2.126(6) Å] are typical.[26] To our knowledge, all reported complexes of the type (amidinate)-Li(tmeda) display four-coordinate Li in solution and in the solid state.[23] We attribute the unusual Li coordination in our compound to steric effects arising from the sterically bulky amidinate ligand.

The Li salt is a useful reagent for the synthesis of metal amidinates. For example, reaction of 1 equiv. of the Li amidinate with $YCl_3(thf)_3$ proceeds as shown in Scheme 1, with the colorless, crystalline product being isolated in moderate yield from Et_2O. The empirical formula, [(dimb)YCl_4Li_2-(tmeda)$_2$],[20] follows straightforwardly from ^{1}H NMR spectroscopy and elemental analysis, and confirmation of the solid-state structure is provided by X-ray diffraction.[27,28] The six-coordinate Y ion resides in a distorted octahedral coordination environment with a single amidinate ligand coordinated in the usual bidentate fashion. Examination of Y–Cl and Y–N bond lengths (av. 2.66 and 2.32 Å, respectively) show no anomalous values, although the N–C–N bond angle in the amidinate (*ca.* 111°) is nearly 5° less obtuse than in related Y compounds.[8,9,29–31] Although mixed amidinate/cyclopentadienyl and amidinate/cyclooctatetraenyl compounds have been previously characterized,[31,32] studies involving Y compounds having exclusively amidinate ligands as ancillary ligands have only resulted in the formation of bis-amidinate compounds,[8,9] making this the first example of a mono-amidinate yttrium halide species.

To test the robustness of the mono-amidinate moiety, (dimb)Y, towards substitution chemistry, [(dimb)YCl_4Li_2-(tmeda)$_2$] was treated with $KN(SiMe_3)_2$ as shown in Scheme 1. The metathesis proceeded smoothly to form [(dimb)Y{N-$(SiMe_3)_2$}$_2$][20] in excellent yield as colorless crystals from pentane. The compound shows a simple ^{1}H NMR spectrum and the solid state structure again features a mono-amidinate complex with the Y now four-coordinate in a distorted tetrahedron.[33] The Y–N(amidinate) bond lengths (av. 2.34 Å) are nearly the same as those observed in the parent compound and the N–C–N bond angle has opened slightly (113°), yet it remains narrower than previously reported related complexes.[8,9,31] The Y–N(amide) bond lengths (av. 2.24 Å) are well within the expected range.[34]

The authors gratefully acknowledge the Department of Defense Science and Engineering Graduate (NDSEG) Fellowship Program for fellowship support (JARS), as well as Dr Corey Liu for insightful discussions regarding the 2D NMR data.

Promotion by sulfur of gold catalysts for crotyl alcohol formation from crotonaldehyde hydrogenation

Jillian E. Bailie and Graham J. Hutchings*

Department of Chemistry, Cardiff University, PO Box 912, Cardiff, UK CF10 3TB. E-mail: hutch@cardiff.ac.uk

Received (in Cambridge, UK) 11th August 1999, Accepted 22nd September 1999

Thiophene doping of supported gold catalysts increases the rate of formation of the unsaturated alcohol for the hydrogenation of the α,β-unsaturated aldehyde, crotonaldehyde, providing the first example of the promotion of gold by sulfur.

During the last decade the use of gold as a heterogeneous catalyst has been the subject of renewed interest, with most research being directed at oxidation reactions, particularly the room temperature oxidation of carbon monoxide.[1,2] The activity of such catalysts has been associated with the existence of sites at the gold–support interface where an intimate contact between the small hemispherical gold particles (< 6 nm) and the support exists.[1] Relatively little attention has been given to the development of Au-based hydrogenation catalysts and in addition there have been no studies concerning the role of promoters or additives with gold catalysts. Most previous studies of Au as hydrogenation catalysts involve relatively simple molecules such as CO and CO_2[3–5] and alkadienes,[6] whereas there are only a very limited number of reports of selective hydrogenation of multifunctional organic molecules.[7,8] Molecules such as α,β-unsaturated aldehydes, ketones and esters are difficult to hydrogenate with high selectivity to the corresponding unsaturated alcohols. However, these reactions are of considerable importance in many areas of the chemical industry, often being employed in the manufacture of fine chemicals, pharmaceuticals and fragrances. For example, crotyl alcohol is currently produced using stoichiometric hydrogen donors and an improved catalytic process would be advantageous. Many studies[9–14] of the hydrogenation of α,β-unsaturated aldehydes and ketones have tried to gain fundamental information on selectivity control in these reactions by using different approaches in attempts to design and develop suitable catalysts.

The present work shows that supported Au catalysts, when appropriately prepared, can be highly selective for the formation of unsaturated alcohols, and furthermore, pre-treatment of supported Au catalysts with thiophene can improve the selectivity to crotyl alcohol in the hydrogenation of crotonaldehyde, whilst also maintaining catalytic activity.

ZnO and ZrO_2 supported Au (5 wt% Au^0) were prepared by a co-precipitation technique and Au/SiO_2 was prepared by impregnation.† Reactions were carried out in a continuous flow, fixed-bed, micro-reactor at atmospheric pressure (weight hourly space velocity = 0.7 h^{-1}, H_2 : crotonaldehyde = 14:1) using on-line GC analysis. The catalysts (200 mg) were reduced *in situ* in a flow of hydrogen at 250 °C for 1 h. Crotonaldehyde was fed into the system by means of a calibrated syringe pump into a flow of hydrogen. Modification of the catalyst was achieved *via* direct injection of 0.5 μl thiophene into a flow of hydrogen with the catalyst at 250 °C after reduction.

The results obtained for the hydrogenation of crotonaldehyde at 250 °C over unmodified and thiophene-treated samples are given in Table 1. After an initial stabilisation period, both Au/ZnO and Au/ZrO_2 catalysts display similar activities while the Au/ZnO is more selective for C=O bond hydrogenation to give crotyl alcohol. Both Au/ZnO and Au/ZrO_2 when modified by sulfur, after initial stabilisation, give much higher rates of synthesis of crotyl alcohol when compared to the undoped catalyst (Fig. 1). It is also observed that the rate of butanal formation is maintained when Au/ZnO is modified by sulfur and is slightly decreased for the reaction over sulfur modified Au/ZrO_2. However, when sulfur modification of silica supported Au is examined, it is observed that sulfur effectively decreases the rate of hydrogenation as would usually be expected. This indicates that the nature of the oxide support is of importance to observe this rate enhancement. It is suggested from these observations that sites present on the surface of ZnO and ZrO_2 supported catalysts are very different in nature to those available at the surface of Au/SiO_2. Examination of the Au particle size for the catalysts has been carried out using both X-ray line broadening and transmission electron microscopy. For catalysts prepared by co-precipitation, the Au particles are typically 2–4 nm in size. However, the catalysts prepared by impregnation exhibit much larger particle sizes (typically > 150 nm). It is this difference in particle size which we consider to be important and the high catalytic activity and selectivity of Au catalysts is associated with small Au particles.

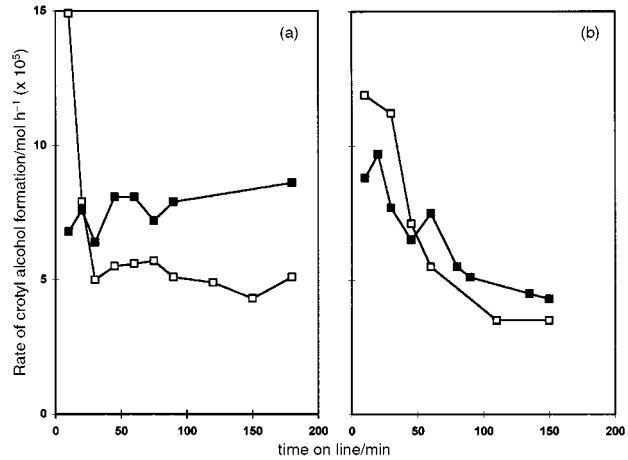

Fig. 1 Effect of thiophene addition on the rate of crotyl alcohol formation (mol $h^{-1} \times 10^5$) over (a) Au/ZnO and (b) Au/ZrO_2: (□) Unmodified, (■) Thiophene treated.

An Au/ZnO catalyst was also prepared by impregnation and subjected to the same reduction and reaction treatments as the Au/ZnO catalysts prepared by co-precipitation. The catalyst prepared by impregnation was found to be inactive in the hydrogenation of crotonaldehyde, emphasising that the method of preparation of Au/ZnO is crucial for this reaction system.

For Au/ZnO it was observed that increasing the temperature of reduction from 250 to 400 °C resulted in a progressive increase in selectivity to crotyl alcohol (reaching a maximum of 82% for Au/ZnO reduced at 400 °C) without major loss of activity. This selectivity is much higher than previous literature data for this reaction.[11–14]

Initial characterisation of these systems by *in situ* FTIR studies of CO adsorption have been performed.‡ CO adsorption on reduced, unmodified, Au/ZnO prepared by co-precipitation produced a band at 2035 cm^{-1} at low CO coverages which shifted to 2045 cm^{-1} as the amount of CO adsorbed was increased. This band has been tentatively assigned to CO

Table 1 Crotonaldehyde hydrogenation at 250 °C over unmodified and thiophene-treated 5 wt% Au catalysts

[a] B-AL = butanal, C-OL = crotyl alcohol, B-OL = butan-1-ol, 2EH = 2-ethylhexanal, 2E2H = 2-ethylhex-2-enal, Others = butane and trace C_3 molecules. S-prefix indicates thiophene modified sample.

adsorbed on Au defect sites or isolated Au atoms in the support matrix. Preadsorption of thiophene at 250 °C caused this band to shift to higher wavenumbers by 15 cm^{-1} and a shift of similar magnitude to higher wavenumbers was again observed as the CO coverage increased. This shift, which we consider to be electronic in nature, provides evidence for the direct modification of the Au surface by thiophene or products of thiophene adsorption.

One possible explanation of the superior catalytic performance of the Au/ZnO and Au/ZrO_2 catalysts, compared to the Au/SiO_2 system, can be based on the work of Haruta,[1,2] concerning CO oxidation, that when Au catalysts are prepared by co-precipitation the support can provide interfacial sites adjacent to hemispherical Au particles that are involved in the activation of reactants, either alone or in association with nearby Au sites. In this case, the presence of sites at the Au-support interface on Au/ZnO and Au/ZrO_2 surfaces could be responsible for the preferential activation of the carbonyl function to hydrogenation. Obviously, such interfacial sites would not then be present on the Au/SiO_2 since no crotyl alcohol was detected. This could be due to the presence of larger, less strongly bonded particles which are more spherical in shape as is often observed with Au catalysts prepared by impregnation. The effect of thiophene may therefore be to electronically modify these interface sites in such a way as to improve activation of the carbonyl group or alternatively to create new active sites by the modification of non-interfacial sites.

We consider these results are the first observation of a promotional effect of sulfur for a Au catalyst. It is clear that the observed promotion is dependent on the nature of the preparation method and the oxide support. We have made no attempt to optimise the rate enhancement and it can be expected that further improvements can be observed by appropriate modification of the experimental conditions and catalyst design. We thank the EPSRC and Synetix for financial support. We also acknowledge C. H. Rochester, J. A. Anderson and H. A. Abdullah of Dundee University for *in situ* FTIR studies.

Notes and references

† Au/ZnO and Au/ZrO_2 were prepared by mixing solutions of $Zn(NO_3)_2{\cdot}H_2O$ or $Zr(O)(NO_3)_2{\cdot}xH_2O$ with $HAuCl_4$ solution, which all contained calculated amounts of Zn, Zr and Au salts required to give a 5 wt% loading of Au^0 on ZnO or ZrO_2. The mixed solutions were heated to 80 °C and 1 M Na_2CO_3 solution was added with continual stirring until a pH of *ca.* 9 was reached. The precipitate was then aged for 20 min prior to vacuum filtration, washing with approximately 1 l of hot deionised H_2O and drying overnight at 110 °C. The samples were then calcined at 400 °C for 4 h in static air. The Au/SiO_2 catalyst was prepared by adding the required amount of silica (Cab-O-sil M5) to a solution containing a calculated amount of $HAuCl_4$ to give a 5 wt% loading of Au^0. The mixture was allowed to evaporate to dryness at 80 °C (approximately 5 hours) with continual stirring after which the residual cake was dried overnight at 110 °C and calcined at 300 °C for 4 h in static air.

‡ A catalyst disc was mounted in a glass IR cell linked to a vacuum line and reduced *in situ* in a flow of hydrogen at 250 °C for 1 h. The sample was then cooled to room temperature and exposed to increasing pressures of CO and FTIR spectra were recorded after each addition of CO. For modified samples, a low level (< 1 mm Hg) of thiophene was admitted to the sample at 250 °C immediately after reduction. The sample was then cooled to room temperature and CO adsorption was performed and monitored by FTIR spectroscopy as before.

Base-catalyzed cleavage and homologation of polyhedral oligosilsesquioxanes

Frank J. Feher,* Raquel Terroba and Joseph W. Ziller

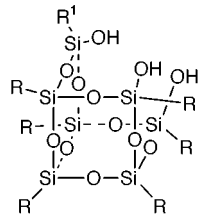
Department of Chemistry, University of California, Irvine, CA 92697-2025, USA. E-mail: fjfeher@uci.edu

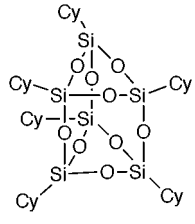
Received (in Bloomington, IN, USA) 5th August 1999, Accepted 9th September 1999

Readily available $Cy_6Si_6O_9$ 2 (Cy = c-C_6H_{11}) reacts with aqueous NEt_4OH in THF to afford *endo*-C_{2h}-$Cy_6Si_6O_7(OH)_4$ 3a, which upon further hydrolysis produces $CySi(OH)_3$ fragments capable of reacting with 3a to produce *endo*-C_3-$Cy_7Si_7O_9(OH)_3$ 1b; the reaction of 2 with aqueous NEt_4OH in the presence of (vinyl)$Si(OMe)_3$ affords *endo*-C_s-Cy_6(vinyl)$Si_7O_9(OH)_3$ 1c *via* trapping of 3a with monosilanes derived from (vinyl)$Si(OMe)_3$.

Polyhedral oligosilsesquioxanes (POSS) are an interesting class of three-dimensional Si/O clusters derived from the hydrolytic condensation of trifunctional organosilicon monomers (*i.e.* $RSiX_3$).[1–3] Since their discovery in 1946,[4] many stoichiometrically well defined POSS frameworks have been reported, including a wide variety of fully condensed $[RSiO_{3/2}]_n$ frameworks with synthetically useful functional groups.[5–14] Until very recently, the reaction chemistry of fully condensed POSS frameworks was limited mainly to organic transformations of the group attached to silicon. Clean reactions involving the selective cleavage of framework Si–O bonds were virtually unknown.[15] This situation has changed dramatically over the past three years,[16–20] and it is now possible to effect the selective cleavage of one or more Si–O–Si linkages by reacting $R_6Si_6O_9$ and $R_8Si_8O_{12}$ frameworks with strong acids (*e.g.* $HBF_4{\cdot}OEt_2$–BF_3 or triflic acid). Still, there are enormous incentives for developing practical methods for synthesizing incompletely condensed POSS frameworks, particularly trisilanols such as **1a**.

Here we report a number of unprecedented reactions involving $R_6Si_6O_9$ frameworks, including the base-catalyzed homologation of $Cy_6Si_6O_9$ **2** to $Cy_6(R)Si_7O_9(OH)_3$, where R = Cy **1b** or vinyl **1c**. The implications of these results for both the continued development of POSS-based hybrid inorganic–organic polymers and the use of silsesquioxanes as ligands for transition-metal catalysts are discussed.

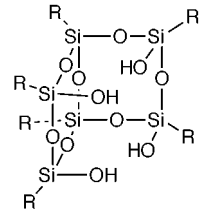




2

1a R = alkyl R^1 = functionalized organic
b R = R^1 = Cy = c-C_6H_{11}
c R = Cy R^1 = vinyl

The reaction of **2**[21–23] with aqueous NEt_4OH in THF occurs rapidly over a period of several hours at room temperature. The first product to appear is a C_{2h}-symmetric tetrasilanol derived from cleavage of both Si_3O_3 rings. This product was assigned as **3a** on the basis of multinuclear NMR spectroscopy and electrospray mass spectrometry data.† Of particular spectroscopic relevance was the ^{29}Si NMR spectrum ($CDCl_3$), which exhibited two resonances at δ −59.4 and −68.8 with relative integrated intensities of 4:2. These resonances, as well as the resonances observed in both the ^{1}H and ^{13}C NMR spectra for this compound, were strikingly similar to those observed for known tetrasilanol **3b**,[24] suggesting that hydrolysis of both Si_3O_3 rings occurred with complete retention of stereochemistry at Si.

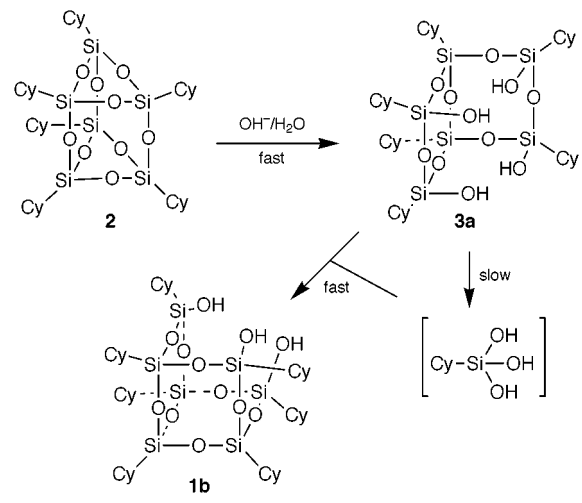


3a R = Cy
b c-C_7H_{13}

Tetrasilanol **3a** can be isolated as a white microcrystalline solid in 63% yield after 1 h at 25 °C. If the reaction is allowed to continue for several hours, ^{29}Si NMR resonances for **3a** are gradually replaced by the characteristic resonances for trisilanol **1b**,[22] which can be isolated in 30–40% yield after the resonances for **3a** disappear.

The base-catalyzed decomposition of **3a** by NEt_4OH in wet THF is not surprising. However, the formation of trisilanol **1b** in good yield is quite remarkable considering that the only Si-containing species present at the start of the reaction contains six Si atoms. This observation suggested the mechanism illustrated in Scheme 1, and it prompted us to examine the reaction of **2** with NEt_4OH in the presence of silane monomers capable of producing reactive $RSi(OH)_3$ fragments faster than the decomposition of **3a**. The results from these experiments confirm our mechanistic hypothesis, and they provide a potentially general route to trisilanols with six cyclohexyl groups and one unique pendant group. For example, the reaction of **2** with aqueous NEt_4OH in the presence of (vinyl)$Si(OMe)_3$ affords trisilanol **1c** in excellent isolated yield.‡ Similar results are observed when aqueous NEt_4OH is added to a solution of **2** and either $[H_2C{=}CH(CH_2)_6Si(OMe)_3$ or *p*-$ClCH_2C_6H_4Si(OMe)_3$.

The structure of **1c** can be unambiguously assigned on the basis of multinuclear NMR spectroscopy data: (i) both the ^{13}C and ^{29}Si NMR data are consistent with a C_s-symmetric



Scheme 1

$Si_7O_9(OH)_3$ framework; (ii) the ^{29}Si NMR spectrum exhibits one downfield resonance characteristic of two CySi(OH) groups in Si_4O_4 rings (δ −60.0 *cf.* δ −68.7 for $Cy_8Si_8O_{12}$) and one upfield resonance assignable to a single (vinyl)Si(OH) group in a Si_4O_4 ring [δ −71.9 *cf.* δ −80.1 for $(vinyl)_8Si_8O_{12}$]; (iii) the ^1H NMR spectrum exhibits resonances for six Cy groups and one vinyl group, as well as a single time-averaged OH resonance at δ 7.01 for the three mutually hydrogen-bonded SiOH groups. ^1H resonances at δ 6–7 for SiOH groups are characteristic of incompletely-condensed silsesquioxanes with three or more mutually hydrogen-bonded Si–OH groups.[22,24–27] It would be difficult to rationalize this feature without structure **1c**. Our assignment of **1c** is also supported by electrospray mass spectrometry data and a preliminary single crystal X-ray diffraction study, which is good enough to establish that **1c** adopts the same hydrogen-bonded dimeric structure observed for other crystallographically characterized $R_7Si_7O_9(OH)_3$ compounds,[20,22] but not good enough to locate all of the carbon atoms on the disordered organic groups.§

We have only begun to explore the scope and generality of these reactions, but it is already clear that base-catalyzed homologation of $R_6Si_6O_9$ will find many applications. From the standpoint of developing new routes to POSS-based hybrid inorganic–organic polymers,[8,28,29] our results with Cy-substituted frameworks provide access to many new synthons for preparing well defined POSS monomers. In fact, our homologation methodology represents an important advance in silsesquioxane chemistry, if it can be generalized to synthesize heteroleptic trisilanols from other $R_6Si_6O_9$ frameworks[30]—especially silylated spherosilicates.[9,31–34] [*e.g.* $(TMSO)_6Si_6O_9$][9,35] For applications such as catalytic epoxidation of olefins by $Cy_7Si_7O_9TiX$ (X = NR_2, OR, Cp),[36,37] the ability to produce trisilanol ligands with reactive pendant groups provides an attractive method for immobilizing the catalyst.[38] We are currently exploring these possibilities and will provide a full account of our work in due course.

These studies were supported by Hybrid Plastics (Fountain Valley, CA) under an Advanced Technologies Program grant from the National Institute of Standards and Technology and the National Science Foundation.

Notes and references

† *Preparation of* **3a**: a solution of $Cy_6Si_6O_9$ (200 mg, 0.24 mmol) and 35% aqueous NEt_4OH (0.1 mL, 0.25 mmol) in THF (2.5 mL) was stirred at 25 °C for 1 h then neutralized with dilute aqueous HCl. Evaporation of the volatiles, dissolution in Et_2O, drying over $MgSO_4$, and concentration afforded **3a** as a white microcrystalline solid in 63% yield (135 mg). $^{29}Si\{^1H\}$ NMR (99.3 MHz, $CDCl_3$, 25 °C) δ −59.4, −68.8 (s, 4:2). ^1H NMR (500 MHz, $CDCl_3$, 25 °C) δ 7.02 (br s, 4 H, OH), 1.78 (vbr m, 30H), 1.28 (vbr m, 30H), 0.81 (vbr m, 6H). $^{13}C\{^1H\}$ NMR (125.8 MHz, $CDCl_3$, 25 °C) δ 27.55, 27.47, 26.86, 26.62 (CH_2); 23.68, 23.16 (4:2, SiCH). MS (ESI, 100% MeOH): *m/z* 846 ($[M + H]^+$, 48%), 869 ($[M + Na]^+$, 95%), 885 ($[M + K]^+$, 100%). Anal. Calc. (found) for $C_{36}H_{70}O_{11}Si_6$: C, 51.02 (51.00); H, 8.33 (8.23)%.

‡ *Preparation of* **1c**: a solution of 35% aqueous NEt_4OH (0.2 mL, 0.50 mmol) was added to a solution of $Cy_6Si_6O_9$ (409 mg, 0.49 mmol) and $(vinyl)Si(OMe)_3$ (0.08 mL, 0.48 mmol) in THF (5 mL). The solution was stirred for 75 min then worked up as described above to afford **1c** as a white microcrystalline solid. The crude product, which is obtained in practically quantitative yield, is > 90% pure by NMR spectroscopy. Colorless crystals were obtained in 23% yield after one recrystallization from toluene–acetonitrile. $^{29}Si\{^1H\}$ NMR (99.3 MHz, $CDCl_3$, 25 °C) δ −60.0 (s, 2 Si, Cy–Si–OH), −68.1 (s, 1 Si), −69.0 (s, 2 Si), −69.6 (s, 1 Si), −71.9 [s, 1 Si, (vinyl)Si–OH]. ^1H NMR (500 MHz, $CDCl_3$, 25 °C) δ 7.01 (br s, 3 H, OH), 5.90 (m, 3 H, –CH=CH_2), 1.75, 1.26, 0.78 (m, 66 H, C_6H_{11}). $^{13}C\{^1H\}$ NMR (125.8 MHz, C_6D_6, 25 °C) δ 135.36 (s, =CH_2), 130.80 (s, –CH=), 27.51, 27.45, 26.81, 26.66, 26.58, 26.54, 26.48 (s, CH_2); 23.81, 23.53, 23.35, 23.09 (s, CH). MS (ESI, 100% MeOH): *m/z* 917 ($[M + H]^+$, 75%), 939 ($[M + Na]^+$, 100%). Anal. Calc. (found) for $C_{38}H_{72}O_{12}Si_7$ C, 49.74 (49.44); H, 7.91 (7.70)%.

§ Trisilanol **1c** crystallizes as well formed but very poorly diffracting crystals from toluene–acetonitrile. *Crystal data* for **1c**: $C_{38}H_{72}O_{12}Si_7$, M = 917.59, orthorhombic, space group *Cmca*, a = 19.179(2), b = 23.530(2), c = 22.519(2) Å, V = 10162.5(18) Å^3, T = 158 K, Z = 8, D_c = 1.199 M g m^{-3}, μ = 0.239 mm^{-1}, $F(000)$ = 3952, λ = 0.71073 Å, crystal dimensions: 0.47 × 0.43 × 0.40 mm, 3.28 ⩽ 2θ ⩽ 56.6°; of the 32677 collected reflections, 6378 are independent and only 1392 (22%) had $I > 2.0\sigma(I)$.

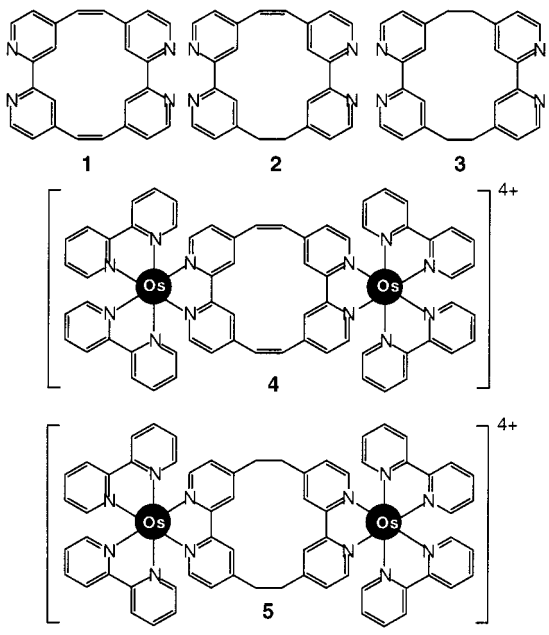
The synthesis of a new macrocyclic exo-ditopic ligand bearing two, 2,2′-bipyridine units interconnected at the 4 and 4′ positions by two –CH=CH– spacers was achieved, and its Os(II) homobinuclear diastereomeric complexes were prepared, separated and characterised in the solid state by X-ray diffraction on single crystals; the two stereoisomers showed almost identical electrochemical and UV–VIS characteristics and rather weak metal–metal interactions.

Inter-metallic electronic communication in di- or poly-nuclear transition metal complexes is currently under active investigation.[1] Often, this challenging problem is further complicated by stereoisomerism which occurs when metals with octahedral coordination geometry and chelating ligands are used.[2] The role of diastereoisomerism on the physical properties of metal complexes has recently been elegantly discussed.[3] The combination of Ru(II) and/or Os(II) and bipyridine containing ligands has been shown to exhibit interesting photochemical and electrochemical properties. In order to study intramolecular short- and long-range electron or energy transfer, a variety of homo- and hetero-bincuclear complexes bearing oligopyridine ligands have been prepared.[3,4]

We believed that compound **1** might be of interest for studying both inter-metallic communication between metal centers through conjugation and the effect of diastereoisomerism on such a process. The design of **1** was based on two 2,2′-bipyridine units doubly interconnected at the 4 and 4′ positions by two π systems (CH=CH). The choice of 4 and 4′ positions for interconnecting the two chelate moieties was based on electronic and geometric reasons. For some time now, we have been involved in the design and synthesis of exo-bis-bidentate ligands based on two 2,2′-bipyridine units interconnected at the 4 and 4′ positions by two alkyl[5] as well as two silyl[6] spacers.



Here, we report the first synthesis and solid state structural analysis of compound **1** and of its binuclear Os(II) diastereoisomeric complexes **4** as well as the redox behavior of separated and structurally characterised *rac*-**4** (Δ,Δ;Λ,Λ) and *meso*-**4** (Δ,Λ) diastereoisomers.

The synthesis of ligand **1** was based on the dehydrogenation of the previously reported compound **3**.[5a] Thus, treatment of **3** with 2.5 equiv. of DDQ[7] in bromobenzene at 132 °C for 20 h, afforded a mixture of the starting material **3** (20%), the partially oxidized compound **2** (10–15%) and the desired compound **1** (30% isolated yield). Attempts to increase the yield by changing the reaction conditions such as the DDQ/**3** ratio, temperature or reaction time failed. Owing to the rather close R_f values for compounds **1**–**3**, the separation had to be performed carefully and was achieved by column chromatography (Al_2O_3, AcOEt–$CHCl_3$–EtOH = 60:39:1). The pure compound **1** was further recrystallised from CH_2Cl_2–hexane. In addition to NMR spectroscopy, compound **1** was also characterised by X-ray diffraction on single crystals.

Using the ligand **1**, the synthesis of binuclear Os(II) diastereomeric complexes **4** with PF_6^- as the counter anion was achieved in 62% yield upon refluxing a mixture of **1** and $Os(2,2'\text{-bipy})_2Cl_2$ in butanol–water (2:1) for 24 h under an argon atmosphere. The dark green solid thus obtained after evaporation was then dissolved in water, and upon addition of KPF_6 and heating at 40 °C for 3 min, the binuclear Os(II) complexes **4** were recovered by filtration as a 4:6 mixture of *meso*- and *rac*-**4** stereoisomers. Diastereoisomeric separation of *rac*- and *meso*-**4** was achieved by column chromatography (Sephadex SP C25, 0.1 M sodium *O*,*O*′-dibenzoyl-L-tartrate in H_2O) following reported procedures.[8] Single crystals of both stereoisomers were obtained after two weeks by the slow diffusion of benzene into a nitromethane solution containing the complex at 6–8 °C. For comparison purposes, homobinuclear Os(II) diastereomeric complexes **5** using the ligand **3** were also prepared and separated.

In the solid state, the structure of *meso*-**4** was studied by X-ray diffraction on a single crystal† (Fig. 1). In addition to *meso*-**4**, $4PF_6^-$, $2C_6H_6$, $2MeNO_2$ and $2H_2O$ molecules were present in the solid state. In marked contrast with the free ligand **3**, both bipy units in the complex adopt a *cisoid* conformation with NCCN dihedral angles of −2 and 4° allowing, as expected, the chelation of Os(II) cations. The macrocycle is not planar but rather adopts a bent conformation with CCCC dihedral angles around the ethylene spacers of 3.9 and 7.6°. For both Os(II) centers, the coordination sphere is composed of six nitrogen atoms amongst which four are belonging to the two auxiliary bipy units, and the remaining two are part of the macrocyclic ligand **1**. The coordination geometry around each Os(II) was

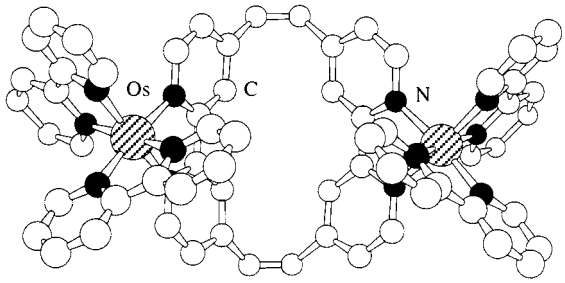


Fig. 1 X-Ray crystal structure of the *meso*-**4** Os(II) binuclear complex obtained with ligand **1**. For the sake of clarity, anions, solvent molecules and H atoms are not represented (for distances and angles see text).

almost octahedral with an average Os–N distance of *ca.* 2.05 Å. The two Os(II) centres are separated by a distance of 9.368 Å.

The structure of *rac*-**4** was also studied by X-ray diffraction on a single crystal† (Fig. 2). In this case, in addition to *rac*-**4**, $4PF_6^-$, C_6H_6 and $2MeNO_2$ molecules were found to be present in the crystal. As before, both bipy units in the complex adopt a *cisoid* conformation with NCCN dihedral angles of −9.4 allowing the coordination of Os(II) cations in the chelate mode. The macrocycle is again not planar but adopts a bent shape with a CCCC dihedral angle around the ethylene spacers of 4.7°. Again, both Os(II) centers are coordinated to six nitrogen atoms with an average Os–N distance of *ca.* 2.05 Å and in almost octahedral geometry. Interestingly, the two Os(II) centers are separated by a distance of 8.177 Å.

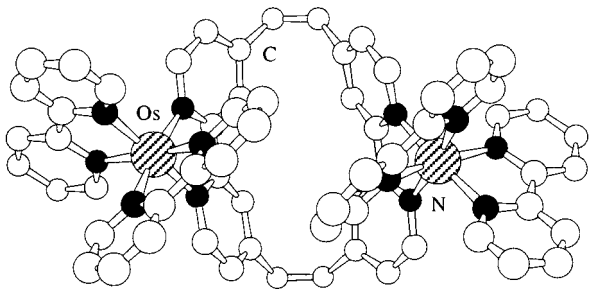

Fig. 2 X-Ray structure of the *rac*-**4** Os(II) binuclear complex obtained with ligand **1**. For the sake of clarity, anions, solvent molecules and H atoms are not represented (for distances and angles see text).

The electrochemical behaviour of *meso*-**4**, *rac*-**4** and **5** as a mixture of stereoisomers was studied by cyclic voltametry (CV) at 1 mM concentration under argon (MeCN, 25 °C, 0.1 M NBu_4PF_6, Pt disk, ferrocene as internal reference, potential values are given with respect to SCE). Although the Os–Os distances for the *meso*-**4** (9.368 Å) and the *rac*-**4** (8.177 Å) stereoisomers are substantially different, for both complexes, only one reversible di-electronic oxidative wave at 0.84 and 0.87 V were observed, respectively. For **5** also a single wave was observed at 0.83 V. Attempts to separate the observed waves into two mono-electronic components using differential pulsed voltametry were unsuccessful. Interestingly, the ΔE_p values of 90 and 88 mV observed for *meso*- and *rac*-**4**, respectively, were significantly higher than the ΔE_p of 70 mV obtained for **5** or the expected value of 59 mV for a reversible process. This observation indicates a weak but nevertheless existing electronic communication between the two Os(II) centers. The rather weak nature of the communication may be rationalised on the basis of structural information obtained in the solid state. Indeed, because of the strength imposed by the rather short spacers that leads to the bent conformation of the macrocyclic portion of ligand **1** in the complexes **4**, the conjugation between the two bipyridine units through the ethylene bridges may be significantly weakened.

In conclusion, using the conjugated macrocyclic exo-ligand **1** based on the interconnection of two 2,2′-bipyridine units by two ethylene spacers at the 4 and 4′ positions, two diastereoisomeric binuclear Os(II) complexes **4** were synthesised, separated and structurally characterised in the crystalline phase. Both *meso*- and *rac*-**4** isomers showed identical electrochemical characteristics and rather weak metal–metal interactions. The photochemical behaviour of both **4** and **5** as well as their heterobinuclear Ru(II)Os(II) complexes are under current investigation. The formation of coordination networks using compound **1** is also currently under study.

The first observation of a muonium–carbonyl adduct with a negative muon coupling constant

Christopher J. Rhodes,*[a] Ivan D. Reid[b] and Roderick M. Macrae[c]

Received (in Cambridge, UK) 12th July 1999, Accepted 16th September 1999

Muonium atom addition to cyclopent-4-ene-1,3-dione I leads to the adduct radical II; in contrast with all other muonium adducts of carbonyl (C=O) compounds so far studied, in which the isotropic muon coupling is of positive sign, the temperature dependence of the muon coupling in II reveals that its sign is negative; this may be explained as a consequence of the electronic 'push–pull' interaction within the MuO–C–C=C–C=O system, which reduces the out-of-plane vibrational amplitude of the muon by increasing the MuO–C/MuO=C partial π-bond character.

There have been a number of studies[1–12] made of free radicals formed by addition of the light hydrogen isotope, muonium (a hydrogen atom with a positive muon as its nucleus) to compounds containing a single carbonyl (C=O) group, which include aldehydes, ketones, esters and amides. All these radicals possess the common structural feature of a muonium atom which is bound close to the radical plane (C$^{\bullet}$–O–Mu), but which can make vibronic (out-of-plane) excursions from it: the observed coupling is now a compromise between two contributions; one providing negative spin density in the muonium 1s orbital, arising from spin polarisation of the O–Mu bond by spin density at the oxygen atom, and the second, which is a positive transfer of spin density to the muon, as the out-of-plane vibration permits a degree of overlap with the spin bearing formal carbon $2p_z$ orbital. This may be expressed by, $A(\mathrm{Mu}) = B_0 + B_1 \cdot f(T)$, with B_0 being of negative sign.

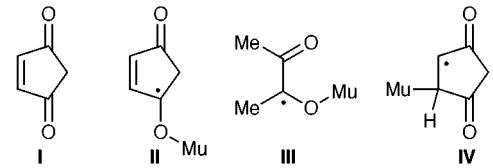
In consequence, the muon couplings measured in carbonyl adducts are all small (which contrasts the large, positive, values normally found in carbon centred radicals[13,14]), and in all examples so far investigated are of positive sign, as deduced from the fact that the couplings all increase with increasing temperature,[1,2] and so the positive term $B_1 \cdot f(T)$ is dominant.

Recently,[1] we reported a theoretical study of the muonium adduct of a 1,2-dicarbonyl compound (biacetyl, MeCOCOMe), which aimed to explain its extremely small experimental coupling of 1.9 MHz (at 294 K), but were unable to decide entirely between the possible effects (i) and (ii) mentioned below, and now appeal to experimental evidence. To this end, we have measured the temperature dependence of the isotropic muon coupling (Table 1) which is positive, and therefore shows[1,2] that the sign of the coupling is also positive; so although the two contributions are now almost equal, the transfer of positive spin density still wins, but the very low value of the coupling means that the muon is more closely confined to the radical plane than in all cases of radicals derived from a *single* carbonyl group. The presence of the second C=O group, therefore, has a profound effect on the electronic structure of the radical. There are two possible reasons for this: (i) the adduct has adopted an s-*cis* geometry, with an intramolecular hydrogen (Mu) bond between the two oxygen atoms (**III**); (ii) the s-*trans* conformation of the parent biacetyl molecule is preserved, but the electronic 'push–pull' character of the Mu–O–C–C=O system confines the muon by increasing the O–C/O=C π-bond character of the Mu–O–C unit (it is this which determines the potential barrier to the out-of-plane excursion of the bound muon[1,2]).

Table 1 Temperature dependences of the muon coupling in the adduct radicals formed from cyclopent-4-ene-1,3-dione **I**[a] and biacetyl[b]

Coupling[a]/ MHz	*T*/K	Coupling[b]/ MHz	*T*/K
5.42	242	1.64	284
4.68	255	1.90	294
4.16	265	2.06	297
3.40	275	2.29	303
2.83	285	4.45	323
2.26	299	5.65	335
1.81	303		
1.58	308		

In order to examine the influence of a potential 'through-bond', π-electronic effect, in the absence of intramolecular hydrogen bonding, we chose a dicarbonyl substrate, cyclopent-4-ene-1,3-dione **I**, in which the carbonyl groups are in communication *via* a C=C bond, but are fixed mutually *trans* by the bridging methylene group, so that intramolecular H(Mu)-bonding is impossible.



Two radicals were detected using the transverse-field muon spin rotation (TF-MuSR) method[13,15] (Fig. 1): the desired carbonyl adduct **II**, for which the coupling measured as a function of temperature is shown in Table 1, and the C=C adduct **IV** with a coupling of 384 MHz measured at 299 K; the relative yields are 0.35 (C=O) and 0.65 (C=C).

It is quite clear that the coupling decreases in absolute magnitude as the temperature increases—the first example of such behaviour for a muonium/carbonyl adduct. Since the out-of-plane vibrational amplitude of the muon increases on heating, and so the interaction with positive spin density must also increase, the overall muon hyperfine coupling constant must be of *negative* sign (the term B_0 being dominant), becoming more positive at the higher temperature. This means that the O=C π-bond character of the Mu–O–C group can be significantly enhanced by the electronic effect alone, and so an intramolecular hydrogen bond is not required to explain the unexpectedly small coupling either in this or in the biacetyl/muonium adduct; indeed, the effect is greatest in the present example, probably owing to its more extensive conjugation.

This electronic system, which is unusual for a free radical, is now the subject of calculations at various levels of theory in an effort to probe their relative application in the elucidation of

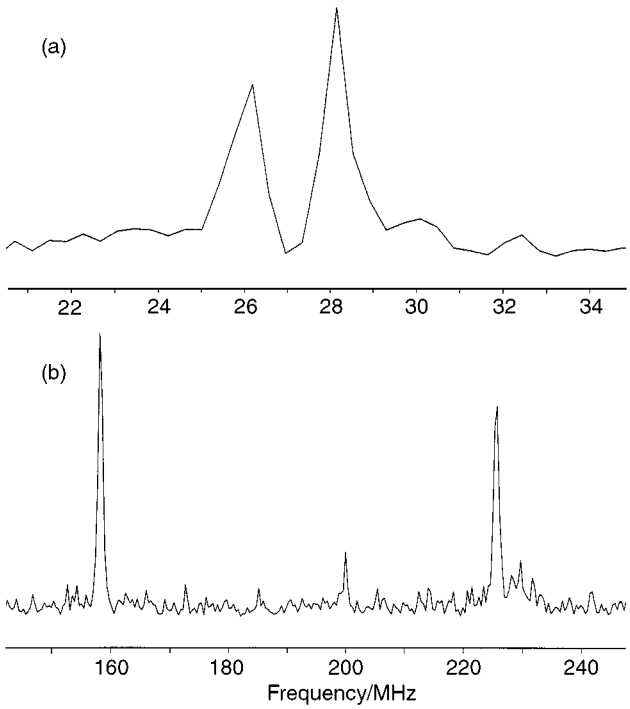


Fig. 1 Transverse-field MuSR spectrum of radicals formed by muonium atom addition to **I** at 299 K, the low-frequency region (a) corresponding to **II** while that (b) at much higher frequencies corresponds to **IV**.

detailed electronic and vibrational effects in organic free radicals.

The structural characterisation of $Ph_3PSe(Ph)I$. The first charge transfer (CT) complex of a tertiary phosphine containing a pseudohalogen

Philip D. Boyle, Stephen M. Godfrey,* Charles A. McAuliffe, Robin G. Pritchard and Joanne M. Sheffield

Department of Chemistry, University of Manchester Institute of Science and Technology, Manchester M60 1QD. E-mail: stephen.m.godfrey@umist.ac.uk

Received (in Basel, Switzerland) 26th July 1999, Accepted 6th September 1999

The reaction of 2 mol equivalents of triphenylphosphine with diphenyldiselenyldiiodine ($Ph_2Se_2I_2$) produces the charge transfer (CT) complex $Ph_3PSe(Ph)I$ in quantitative yield; this compound represents the first report of a CT complex of a tertiary phosphine that contains a pseudohalogen.

The ability of organic molecules that contain a group 15 or 16 donor atom to form charge transfer (CT) complexes with dihalogens or interhalogens has long been recognised,[1] however, it is only relatively recently that such complexes have been crystallographically characterised. The structural identification of these materials has now proved to be a topical area with several research groups currently involved in investigating a variety of these materials that have shown remarkable diversity in their solid-state structure. Thus, the dihalogen adducts of tertiary phosphines,[2–6] arsines,[7] stibines,[8] tertiary phosphine sulfides,[9–11] selenides,[12,13] diorgano sulfides[14] and selenides[15,16] and selenoamides[17,18] have all received considerable study. In addition, very recently the CT complexes of cyclic thioethers with I_2 and IBr have been extensively studied by Schröder and coworkers.[19–21] Generally speaking, adducts of diiodine or IX (X = Br, Cl) are CT compounds which contain an approximately linear E–I–X arrangement (E = P, As, S, Se) whereas adducts of the lighter dihalogens usually produce an X–E–X arrangement with the E atom in trigonal bipyramidal, disphenoidal see-saw or T-shaped geometry depending on the E atom and the organic substituents, although some exceptions to this rule have been identified. Despite the ongoing interest in these dihalogen adducts, very little is known regarding the pseudohalogen adducts of these donor molecules, despite the fact that the solid-state structures of such systems are likely to be quite different to the dihalogen analogues owing to electronic and especially steric factors. We have recently reported[22] that reaction of R_3P with XCN results in the formation of ionic compounds $[R_3PCN]X$ [R = 2,4,6-$(MeO)_3C_6H_2$, 2,6-$(MeO)_2C_6H_3$, $NCCH_2CH_2$, C_6H_{11} or $PhCH_2$; X = Br or I] which display no cation–anion interaction regardless of the nature of R or X. In order to establish the identity of a CT complex of a tertiary phosphine adduct containing both halide and pseudohalide moieties, we have turned our attention to the reaction of 2 mol equivalents of triphenylphosphine with diphenyldiselenyl diiodide. The very interesting structure of $Ph_2Se_2I_2$, itself a CT adduct, has been described by du Mont and coworkers[23] and consists of a dimeric centrosymmetric moiety containing short [2.775(1) Å] and long [3.588(1) Å] iodine–iodine distances. $Ph_2Se_2I_2$ was reacted with 2 mol equivalents of Ph_3P in dichloromethane according to eqn. (1).

$$2\,Ph_3P + Ph_2Se_2I_2 \xrightarrow[N_2(g),\ \text{room temp.}]{ca.\ 1\ d,\ CH_2Cl_2} Ph_3PSe(Ph)I \qquad (1)$$

Triphenylphosphine reacts very rapidly with $Ph_2Se_2I_2$, this being evident from the dramatic colour change in the reaction vessel (from the deep burgundy of $Ph_2Se_2I_2$ to bright yellow upon addition of Ph_3P). Nevertheless, the reaction mixture was allowed to stir for *ca.* 1 d to ensure reaction completion. The resultant compound, $Ph_3PSe(Ph)I$, was isolated in quantitative yield. Recrystallisation of this bright yellow powder from dichloromethane–diethyl ether solution (*ca.* 1:1) produced a large quantity of well formed crystals, one of which was selected for analysis by single crystal X-ray diffraction. The crystal structure of $Ph_3PSe(Ph)I{\cdot}CH_2Cl_2$ is illustrated in Fig. 1 (the dichloromethane solvate molecule is omitted for clarity). This compound is clearly shown to adopt a CT structure analogous to triphenylphosphine diiodine, $Ph_3P–I–I$. The *d*(Se–I) in $Ph_3PSe(Ph)I$, 3.2564(5) Å, lies well within the van der Waals' radius for the iodine and selenium atoms (4.1 Å) and is similar to *d*(I–I) in Ph_3PI_2, 3.142(2) Å,[2] and significantly shorter than *d*(I–I) in $PhMe_2PI_2$, 3.408(2) Å.[24] There are no non-bonded long-range contacts between $Ph_3PSe(Ph)I$ and the dichloromethane solvate molecule (which shows no sign of disorder) or between $Ph_3PSe(Ph)I$ and an adjacent molecule.

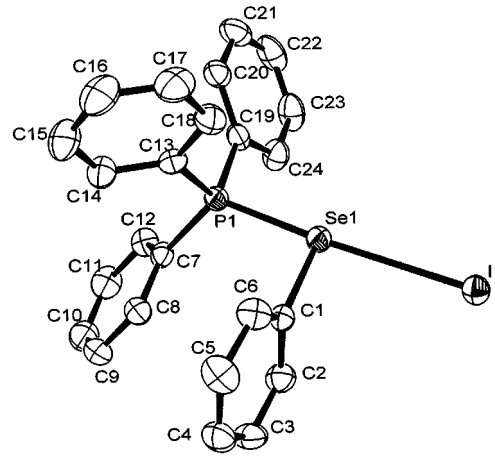

Fig. 1 Perspective view of the molecular structure of $Ph_3PSe(Ph)I$. Selected bond lengths (Å) and angles (°): Se(1)–I(1) 3.2564(5), Se(1)–P(1) 2.2585(9), Se(1)–C(1) 1.921(3), C(1)–Se(1)–P(1) 93.59(9), P(1)–Se(1)–I(1) 176.09(5), C(1)–Se(1)–I(1), 88.84(5).

There is great similarity between Ph_3PI_2 and $Ph_3PSe(Ph)I$ in the $^{31}P\{^1H\}$ NMR spectra of the two materials. We have previously reported that $Ph_3PI–I$ ionises in $CDCl_3$ to produce the ionic $[Ph_3PI]I$ (δ 44). Remarkably, the $^{31}P\{^1H\}$ NMR spectrum of $Ph_3PSe(Ph)I$ in CD_2Cl_2 shows a single peak at δ 44 *i.e.* identical to that observed for $[Ph_3PI]I$. No phosphorus–selenium coupling constant was obtained from this spectrum; however, $^1J(^{13}C–^{31}P)$ = 111 Hz. This preliminary NMR data would seem to suggest, therefore, that either (a) $[Ph_3PI]^+$ and $Ph_3PSe(Ph)I$ are electronically very similar, or (b) in solution $Ph_3PSe(Ph)I$ exists as $[Ph_3PI][SePh]$. The absence of P–Se coupling seems to suggest that the latter option is correct; our investigations into the structure of $Ph_3PSe(Ph)I$ in solution are continuing and will be discussed in detail in a full report of this work. The solid-state CT nature of $Ph_3PSe(Ph)I$ is confirmed by the geometry at the selenium centre which is T-shaped [P(1)–Se(1)–C(1) 93.59(5)°, P(1)–Se(1)–I(1) 176.09(5)°, C(1)–Se(1)–I(1) 88.84(5)°] and not bent, as would be expected for an ionic compound. The *d*(P–Se) of 2.2585(9) Å lies within the range

expected for a P–Se single bond and is very similar to the *d*(P–Se) we have previously observed for T-shaped dibromine adducts of tertiary phosphine selenides [*e.g.* *d*(P–Se) for $(Me_2N)_3PSeBr_2$ = 2.262(2) Å].[13] No compound of formula $R_3PSe(R)X$ has previously been reported. However, the related ionic compound $[Ph_3PSeMe][ClO_4]$ has been described by Jones and Thöne[25] and exhibits a P–Se–C bond angle of 97°, closer to that expected for bent geometry at the selenium centre. As previously stated, $Ph_3PSe(Ph)I$ represents the first reported CT complex of a tertiary phosphine which contains a pseudohalogen and we are currently investigating whether this compound is able to oxidise crude metal powders analogous to our previous studies concerning R_3PI_2. Our results will form the basis of a forthcoming paper.

We would like to thank the EPSRC for a research studentship to P. D. B.

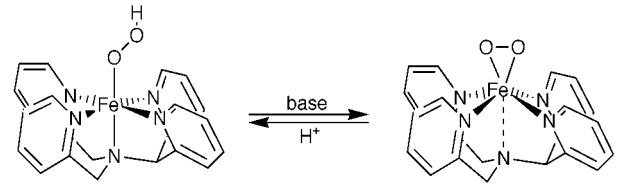
Received (in Bloomington, IN, USA) 8th July 1999, Accepted 21st September 1999

The deprotonation of $[Fe^{III}(N4Py)(\eta^1\text{-}OOH)]^{2+}$ 1 gives $[Fe^{III}(N4Py)(\eta^2\text{-}OO)]^+$ 2, as unequivocally demonstrated by resonance Raman spectroscopy, and leads to the loss of alkane hydroxylation activity by 1.

Iron–peroxo species have been established or postulated in the chemistry of dioxygen activation at mononuclear iron centres in biology.[1,2] For example, activated BLM,† the form of the antitumor drug bleomycin responsible for its DNA cleavage activity,[3,4] is formulated as a low spin $Fe^{III}–\eta^1$-OOH species.[5] Similarly, an $Fe^{III}–\eta^1$-OOH moiety is strongly implicated in the mechanism of cytochrome P450 and considered the key intermediate immediately prior to the cleavage of the O–O bond to generate the high valent iron–oxo oxidant.[6] Both $Fe^{III}–\eta^1$-OOH species are proposed to derive from the one-electron reduction of oxy adducts ($[Fe–O_2]^{2+}$) and subsequent protonation, possibly *via* an $[Fe^{III}–\eta^2\text{-}O_2]^+$ species. Such $[Fe^{III}–\eta^2\text{-}O_2]^+$ species are also postulated to be the source of nucleophilic peroxides that are implicated in substrate oxidations by heme enzymes such as aromatase[7] and heme oxygenase.[8] A related $[Fe^{III}–\eta^2\text{-}O_2]^+$ species has been suggested to account for the *cis*-dihydroxylation chemistry of the Rieske dioxygenases.[9] Significant effort has been devoted in the characterisation of small molecule analogues of such peroxo intermediates. Two high spin $[Fe^{III}–\eta^2\text{-}O_2]^+$ species, namely $[Fe^{III}(EDTA)(O_2{}^{2-})]$[10,11] and $[Fe(porphyrin)O_2]^-$,[12] have been identified, while the first examples of synthetic $Fe^{III}–\eta^1$-OOH species have just appeared in the last few years.[13–15] We have sought to establish a precedent for the interconversion between an $[Fe^{III}OOH]^{2+}$ species and its deprotonated form $[Fe^{III}O_2]^+$, implicit in the mechanisms of bleomycin and cytochrome P450. Such an equilibrium was recently reported for Fe^{III}(N-R-trispicen) complexes (R = Me, Et, Bn),[16] but no Raman data was provided to establish the binding mode of the $[Fe^{III}O_2]^+$ species. Here, we provide unequivocal Raman evidence for the η^2-peroxo binding in the $[Fe^{III}(N4Py)O_2]^+$ species, obtained from the deprotonation of the $[Fe^{III}(N4Py)(\eta^1\text{-}OOH)]^{2+}$ species. In addition we show for the first time that protonation of the $[Fe^{III}O_2]^+$ species is essential for alkane oxidation.

The purple $[Fe^{III}(N4Py)(OOH)]^{2+}$ complex **1** (λ_{max} 547 nm, ε_M 1300 dm^3 mol^{-1} cm^{-1}) is generated at −20 °C by addition of 5 equiv. H_2O_2 to a methanolic solution of $[Fe^{III}$(N-4Py)(OMe)$]^{2+}$, obtained by pretreating $[Fe^{II}(N4Py)(MeCN)]^{2+}$ with 5 equiv. H_2O_2 at room temperature.[15] Upon addition of 5 equiv. NH_3 (aq) at −45 °C, the purple chromophore converts to a blue species **2** (Scheme 1) with an absorption maximum at 685 nm (ε_M 520 dm^3 mol^{-1} cm^{-1}). Addition of perchloric acid reverses this colour change and quantitatively regenerates the original purple solution. The conversion of **1** to **2** can also be monitored by EPR spectroscopy. Addition of base converts the characteristic low-spin Fe^{III} EPR spectrum of **1** with *g* values at 2.3, 2.1 and 1.9 to one with an intense isotropic signal at g = 4.3, which is typical of a mononuclear rhombic high-spin Fe^{III} center (E/D = 1/3). In the case of the Fe^{III}(N-R-trispicen) complexes, the addition of base to the Fe^{III}–OOH species converts them to high-spin Fe^{III} complexes with more axial EPR spectra ($E/D \approx 0.08$).[16]



1 2

Scheme 1 Proposed structures for **1** and **2**.

Electrospray ionisation mass spectrometry provides the elemental composition of **2**. As reported earlier, the ESMS of **1** shows a prominent feature at *m*/*z* 555, whose mass and isotope distribution pattern unequivocally assigns this ion as {[Fe(N-4Py)(OOH)]ClO_4}$^+$.[13a] The ESMS of **2**, on the other hand, exhibits a prominent feature at *m*/*z* 455, a value which corresponds to the loss of $HClO_4$, relative to that of **1**. The isotope distribution pattern associated with this feature matches well with that calculated for, $[Fe(N4Py)(OO)]^+$, thus supporting the notion that **2** is the conjugate base of **1**.

Resonance Raman spectroscopy provides further insight into this transformation. Excitation into the peroxo-to-iron(III) charge transfer band of **1** generates a Raman spectrum with features at 632 and 790 cm^{-1} [Fig. 1(*a*)].‡ The latter is unequivocally assigned to ν(O–O) by its ^{18}O shift of −46 cm^{-1}, while the former is associated with a coupled Fe–OOH mode.[14] These features are considered the Raman signature for a low spin Fe(III)–OOH species. Conversion to **2** results in a significantly different Raman spectrum with prominent peaks at 495 and 827 cm^{-1} [Fig. 1(b)].§ The use of $H_2{}^{18}O_2$ shifts the two features to 478 ($\Delta\nu$ = −17) and 781 ($\Delta\nu$ = −46) cm^{-1}, respectively [Fig. 1(c)], which are fully consistent with their assignments as ν(Fe–O_2) ($\Delta\nu_{calc}$ −18 cm^{-1}, based on Hooke's Law for diatomic harmonic oscillators) and ν(O–O) ($\Delta\nu_{calc}$ −47 cm^{-1}), respectively. Consistent with these assignments, the introduction of ^{54}Fe in **2** does not affect the 827 cm^{-1} vibration but upshifts the 495 cm^{-1} feature by 3 cm^{-1} ($\Delta\nu_{calc}$ +3 cm^{-1}) [Fig. 1(d)]. Furthermore, unlike for **1**,[14] the use of $^2H_2O_2$ does not affect the Raman spectrum of **2**. Thus the Raman spectra support the notion that **2** is an $[Fe^{III}–O_2]^+$ complex.

Strong evidence for the η^2-peroxo binding mode has been obtained from the Raman spectrum of **2** with H_2O_2 containing 61% ^{18}O (Fig. 2).¶ Although the various isotopic components of

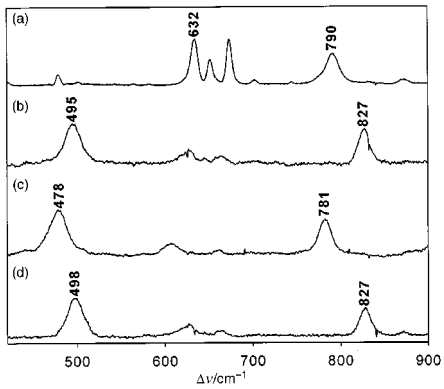


Fig. 1 Resonance Raman spectra of **1** and **2**. (a) **1** generated by the addition of 5 equiv. H_2O_2 to a methanolic solution of $[Fe^{III}(N4Py)(OMe)]^{2+}$ (10 mM) at −35 °C. (b) **2** generated by the addition of 5 equiv. NH_3(aq) to the solution of **1** at −35 °C. (c) Same as (b), except $H_2{}^{18}O_2$ was used. (d) Same as (b) except that the ^{54}Fe complex was used. All spectra were obtained with a backscattering geometry on liquid-N_2 frozen samples using 568.2 nm laser excitation at 20 mW power at the sample. The Raman frequencies were referenced to indene.

the ν(Fe-O_2) feature centred at 486 cm^{-1} are unresolved, three peaks associated with the ν(O–O) feature are readily discerned at 781, 802 and 826 cm^{-1} and can be fitted with peaks having approximately equal linewidths. The fact that the peak arising from the $^{16}O^{18}O$ isotopomer has a linewidth equal to those of $^{16}O^{16}O$ and $^{18}O^{18}O$ isotopomers strongly implies an η^2-peroxo binding mode, as found for $[Fe^{III}(EDTA)(\eta^2\text{-}O_2)]$[10,11] and suggested for $[Fe^{III}(N\text{-}R\text{-}trispicen)(O_2)]^+$.[16] At this point, we do not have enough information to determine whether the iron centre in **2** becomes seven-coordinate, as illustrated in Scheme 1, or remains six-co-ordinate by a decrease in the denticity of the N4Py ligand. The latter may come about by detachment of one of the pendant pyridines or, by breaking the already weak tertiary amine bond as the η^2-peroxo ligand pulls the iron centre further out of the plane defined by the four pyridine ligands to achieve a coordination geometry similar to that found in the structure of $[Mn(TPP)(\eta^2\text{-}O_2)]^-$.[17]

With the peroxo binding mode of **2** established, we now compare the relative abilities of **1** and **2** to oxidise substrates. We have previously found that $[Fe^{II}(N4Py)(MeCN)]^{2+}$ can catalyse the hydroxylation of cyclohexane with H_2O_2 in acetone *via* intermediate **1**.[13a] With 5 equiv. H_2O_2, we observe 1.6 and 0.4 turnovers of cyclohexanol and cyclohexanone, respectively. In CD_3OD the number of turnovers is lower, 0.8 and 0.4 turnovers, respectively, owing to a competing oxidation of the solvent to $D_2C{=}O$ (1.4 turnovers). When 5 equiv. NH_3 (aq) is added prior to or after the formation of **1** in CD_3OD, no oxidation of cyclohexane is observed. These results suggest that, whereas **1** is capable of activating the O–O bond to oxidise alkanes, **2** is unreactive towards such substrates, resembling the inertness of other $[Fe^{III}(\eta^2\text{-}O_2)]$ species.[11,18] Our demonstration of an $[Fe^{III}(\eta^1\text{-}OOH)]$/$[Fe^{III}(\eta^2\text{-}OO^-)]$ interconversion allows us to support unequivocally the hypothesis that protonation of the peroxo species activates it for participation in the oxygen activation mechanisms by iron enzymes.[6,11]

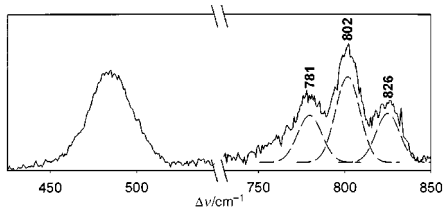

Fig. 2 Raman spectrum of **2** generated with a statistical mixture of H_2O_2 isotopomers (61% ^{18}O). The dashed lines represent the curve fit of the features associated with the ν(O–O) peaks. The curve was fitted with three peaks with the $^{18}O^{18}O$ feature constrained to a frequency of 781 cm^{-1} and a linewidth of 16 cm^{-1} as found for $[Fe(N4Py)(^{18}O_2)]^+$. The fitted data gave the other two peaks at 802 and 826 cm^{-1} with linewidths of 16.3 and 15.9 cm^{-1}, respectively. The latter matched well the properties of the ν(O–O) feature in $[Fe(N4Py)(^{16}O_2)]^+$.

We acknowledge C. M. Jeronimus-Stratingh and A. P. Bruins for advice and assistance with mass spectrometric measurements and financial support from Unilever (Vlaardingen, The Netherlands) and the National Institutes of Health (Grant GM-33162).

Notes and references

† Abbreviations used: BLM = bleomycin; N4Py = *N*-[bis(2-pyridyl)methyl]-*N*,*N*-bis(2-pyridylmethyl)amine; N-R-trispicen = *N*-alkyl-*N*,*N*′,*N*′-tris(2-pyridylmethyl)ethane-1,2-diamine.

‡ Resonance Raman spectra were collected on an Acton AM-506 spectrometer (2400-groove grating) using Kaiser Optical holographic super-notch filters with a Princeton Instruments liquid N_2-cooled (LN-1100PB) CCD detector with 4 or 2 cm^{-1} spectral resolution. Spectra were obtained by back-scattering geometry on liquid N_2 frozen samples using 568.2 nm laser excitation from a Spectra Physics 2030-15 argon ion laser and a 375B CW dye (Rhodamine 6G). Raman frequencies were referenced to indene.

§ Aside from the features at 495 and 827 cm^{-1}, weaker features at 625 , 645, 664 cm^{-1} are also observed and are sensitive to ^{18}O labeling. However the intensities of these features vary relative to the intensities of the 495 and 827 cm^{-1} features with different samples, suggesting that these minor features are not associated with **2**. We have ruled out the possibility that these minor features are associated with **1** since the features at 626, 648, and 668 cm^{-1} are slightly shifted from those of **1** and a corresponding 790 cm^{-1} feature is not observed. The assignment of these features is currently under investigation.

¶ $H_2{}^{18}O_2$ (90% ^{18}O-enriched, 2% solution in $H_2{}^{16}O$) was obtained from ICON Services Inc. Communication 9/05535E

Influence of short- and long-range factors in the Brønsted acidity of MCM-22 zeolite

German Sastre, Vicente Fornes, and Avelino Corma*

Instituto de Tecnologia Quimica U.P.V.-C.S.I.C. Universidad Politecnica de Valencia. Av. Los Naranjos s/n, 46022 Valencia, Spain. E-mail: acorma@itq.upv.es

Received (in Cambridge, UK) 27th July 1999, Accepted 24th September 1999

The acidity of the Brønsted sites of MCM-22 zeolite is calculated by atomistic simulation techniques and the effects of long- and short-range contributions in acidity are analysed; the two IR bands detected experimentally are reproduced in the calculations.

Since their introduction in fluid catalytic cracking, zeolites have been widely used as solid acid catalysts in a growing number of industrial chemical processes such as reforming, isomerisation, hydrocracking, oligomerisation, and others. Much attention has been devoted to the acid function in zeolites, and in particular Brønsted acidity has been characterised mainly by IR and NMR spectroscopies, as well as by computational chemistry methods.

The first simulations of Brønsted acidity in zeolites, employed the cluster model and the quantum chemistry methodology. Clusters of the size of the disiloxane molecule with a Si atom substituted by a trivalent atom T^{III}, mainly Al, and a proton bound to the oxygen atom in the $SiOT^{III}$ bridge are able to give reasonable OH stretching frequencies compared to IR experiments.[1] Among other results from quantum chemistry studies, a linear correlation was found between OH stretching frequency and SiO(H)Al angle,[2] and this has been used to explain acidity differences between different zeolites or between different acid centres in a given zeolite. The question whether the long range factors—not accounted by the cluster model—do influence the acidity and to what extent, has led to calculations both with larger clusters and with periodic boundary conditions. The latter, require a considerable amount of computational resources, and thus less demanding methodologies to treat periodic solids such as those based on force fields are a reasonable alternative.

In spite of their lower accuracy, owing to the interactions neglected or averaged, force field methods have been successfully used to characterise different properties of zeolites such as cell parameters, geometry, framework stability, Al distribution, and Brønsted acidity.[3] This methodology allows us to assess the short- and long-range contributions to acidity, and this makes it possible to span the number of calculations necessary to explore the different locations of the acid centres in a zeolite. It is the aim of this work to carry out a characterisation of the Brønsted acidity of the MCM-22 zeolite, and compare the results with IR data.

The calculations have been performed using the GULP code,[4] employing the Ewald method for summation of the long-range Coulombic interactions, and direct summation of the short-range interactions with a cutoff distance of 12 Å. The RFO technique was used as the cell minimisation scheme with a convergence criterion of a gradient norm below 0.001 eV $Å^{-1}$. An empirical shell model forcefield[5] (denoted empirical ff), and an *ab initio* shell model forcefield d[6] (denoted *ab initio ff*), have been used throughout. Electric fields, and OH stretching frequencies have been calculated with the GULP code. OH frequencies have been corrected for the empirical forcefield by substracting an anharmonicity constant of 150 cm^{-1},[7], and for the *ab initio* forcefield by multiplying by a factor of 0.90.[8].

The hexagonal *P*6/*mmm* structure of pure silica MCM-22[9] has been used as a starting point and then has been minimised without symmetry constraints. Then, a single Al atom has been introduced in the unit cell to create a Brønsted site and the resulting cell has been again minimised. The Al atom has been introduced in all the eight different T positions of the MCM-22 structure (Fig. 1), and the proton has been placed in all the four non-equivalent oxygen atoms linked to the corresponding Al in each case. Only the protons located on SiOSi angles of 180º have been excluded, which correspond to the Si(1)–O–Si(1), and the Si(4)–O–Si(5) sites (Fig. 1). 29 different possibilities were considered, and this comes from the possible locations of a proton on each of the four oxygens linked to eight different T sites (32 possibilities), from which the T(1)–O–T(1), T(4)–O–T(5) and T(5)–O–T(4) linkages have been subtracted. We distinguish between T(x)–T(y) and T(y) – T(x) ($1 \leqslant x,y \leqslant 8$) because in the first case the Al is on T(x), whereas in the second case the Al is on T(y).

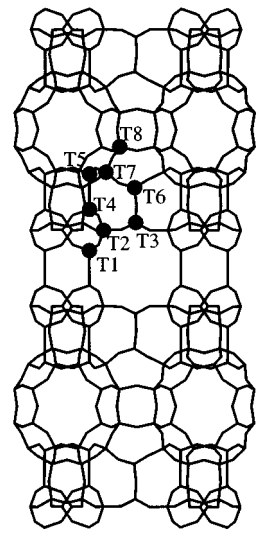

Fig. 1 Structure of MCM-22 showing the eight different T sites. Two independent void systems are present: a sinusoidal 10 MR, and a system of large (12 MR in size) cavities interconnected by short 10 MR conduits.

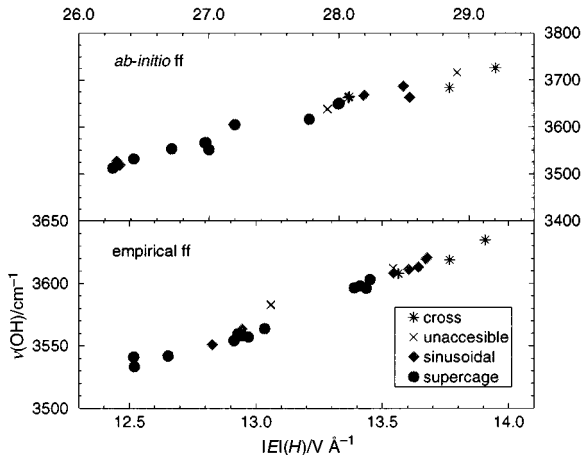
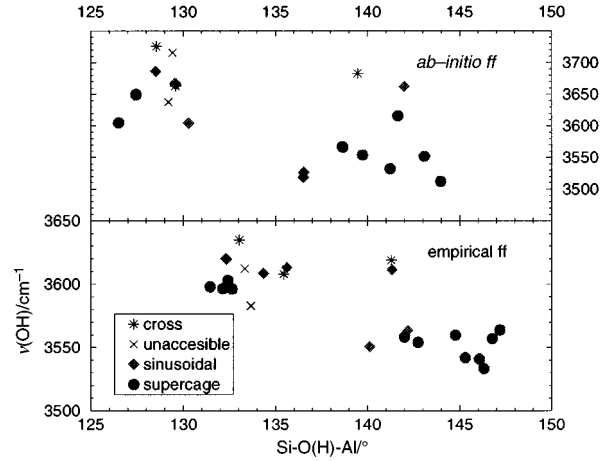
We have calculated the stretching OH frequency, ν(OH), for all the cases and the results are shown in Fig. 2, where they are plotted against the modulus of the electric field at the proton site, $|E_H|$. Two conclusions are drawn from this plot. First, the calculated values of ν(OH) (with the empirical ff) cover a wide range of 3530–3640 cm^{-1} (Fig. 2), and they can be grouped in two bands: one around 3550 cm^{-1}, and the other around 3610 cm^{-1}. This result can be compared with experimental measurements of ν(OH) by IR spectroscopy performed on calcined MCM-22 of Si/Al ≈ 15, where two bands appear at 3575 and 3620 cm^{-1}.[10] Similarly, bands at 3550 and 3650 cm^{-1}appear when using the *ab initio* forcefield (Fig. 2). The agreement with experiment is very reasonable, with the advantage that the simulations give a more detailed information about the origin of each OH frequency. The protons of MCM-22 can vibrate into four different environments: 'unaccessible' (for those which can not be reached by sorbate molecules), 'cross' (in the



Fig, 2 Correlation between the modulus of the electric field at the proton ($|E_H|$) and the calculated OH stretching frequency, ν(O–H) in the Brønsted sites of MCM-22. The location of the protons is indicated in the figure, showing no relation between environment and OH frequency. Two forcefields have been used as described in the text.



Fig, 3 Relation between the Si–O(H)–Al angle and the calculated OH stretching frequency, ν(OH) in the Brønsted sites of MCM-22. The location of the protons is indicated in the figure, showing no relation between environment and Si–O(H)–Al angle. The lack of correlation between Si–O(H)–Al angle and ν(OH) shows that the long-range factors (as well as the short-range) are important to determine the acidity. Two forcefields have been used as described in the text.

intersection between supercages), 'sinusoidal' (in the 10 MR sinusoidal system), and 'supercage' (inside the 12 MR supercage). Fig. 2 shows that some Brønsted sites located in the supercage belong to the low frequency band whereas others in the supercage belong to the high frequency band, and the same can be said about sites located in the sinusoidal system. A relation between cavity size and OH stretching frequency has not been found, in agreement with previous results.[11] The second conclusion we draw refers to the relationship between ν(OH) and the modulus of the electric field at the proton site, $|E_H|$, which is a straight line regardless of the forcefield employed (Fig. 2), thus showing the direct correlation between the two properties. This shows the influence of the long range factors on acidity, as the electric field is caused by all the atoms of the zeolite framework.

In order to further explore the role of the short- and long-range factors in the Brønsted acidity we have plotted the OH stretching frequency against the Si–O(H)–Al angle, the latter being a geometric property that has been related to acidity as noted above. The results in Fig. 3 show a much poorer correlation than in the previous case. We find cases for which increasing angles give increasing frequencies and also cases with the opposite behaviour. Although the points are scattered (Fig. 3), a somewhat loose correlation shows decreasing OH frequencies as the Si–O(H)–Al angles increase, as noted in the literature.[2] The present calculations show that short range factors such as Si–O(H)–Al angles are not sufficient to fully explain the Brønsted acidity, and that a better correlation is found with a long range property, the modulus of the electric field at the proton site.

We thank the Spanish CICYT (project MAT-97-1016-C02-01) for financial support.

Chemistry in interphases. The solid-phase synthesis of well defined rhodium and iridium phosphine complexes†

Joachim Büchele and Hermann A. Mayer*

Institut für Anorganische Chemie der Universität Tübingen, Auf der Morgenstelle 18, 72076 Tübingen, Germany. E-mail: hermann.mayer@uni-tuebingen.de

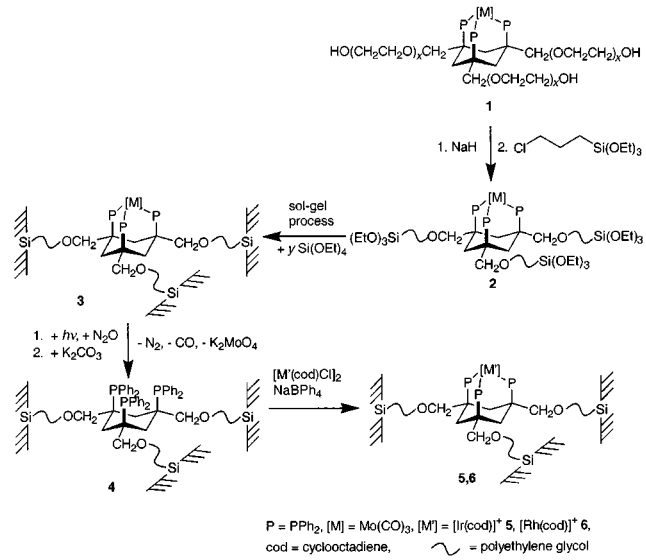
Received (in Cambridge, UK) 5th August 1999, Accepted 27th September 1999

After polyethylene glycol functionalized metal complexes were supported by the sol–gel technique the organometallic protection group was eliminated in a combined photochemical/oxidative procedure and the immobilized non-coordinated ligand was treated with organometallic fragments to give new supported well defined rhodium and iridium complexes.

Transition metal catalysts anchored onto insoluble supports are of great interest since they are useful in industrial scale processes.[1–3] They allow easy purification as well as catalyst recycling and therefore play an important role with respect to ecological and economic aspects.[4,5] The main draw backs of catalysts which are bound to the surface of pre-formed supports are leaching of the active metal centre and reduced reactivity and selectivity compared to their homogeneous counterparts.[6] The simultaneous co-condensation of various types of alkoxysilanes with functionalized metal complexes under sol–gel process conditions lead to highly cross-linked polymers as stationary phases. If these stationary phases are penetrated by a mobile phase (solvent, reactant) particular regions exist in which the reactive centres become highly mobile.[6,7] Such interphases display reduced leaching and high reactivity and selectivity.[6] The synthesis of stationary phases is challenging as hydrolysable functional groups have to be attached to transition metal complex fragments. In addition the precursor complexes of the catalytically active species also have to withstand the sol–gel conditions which are considered as mild in terms of temperature but the chemical conditions (solvent, pH) are often not in favour of the reactive centre. Here, we present our preliminary findings on the support of well defined transition metal complexes using the $Mo(CO)_3$ fragment as the protecting group.[8]

The synthesis of the polyethylene glycol functionalized molybdenum complex **1** was carried out as described earlier.[9] The average chain length *x* was adjusted to 5–10, 50, 145 and 285, respectively. The properties of the PEG-functionalized molybdenum complexes **1** vary from amorphous powders with high decomposition points (x = 5–10) to waxy materials with low melting points (x = 145, 285). The solubility changes from CH_2Cl_2, acetone to THF and water with increasing chain length and the swelling abilities increase in the same order. The hydroxylic end groups of the homologous polymers of **1** react with $Cl(CH_2)_3Si(OEt)_3$ under Williamson ether synthesis conditions to the corresponding tris[(triethoxy)silyl] functionalized complexes **2**.‡ Simultaneous co-condensation of **2** with various amounts (y = 0, 6, 30 equivalents) of tetraethoxysilane (TEOS) allows generation of organic–inorganic hybrid polymers with different properties. When y is small (y = 0, 6) the PEG-functions dominate the character of the material (*vide supra*). Increasing the amount of TEOS (y = 30) leads to materials which are more like silica.§ As the polyethylene glycol spacers already offer a high flexibility, TEOS was used as co-condensing agent to achieve a high cross-linking of the polymer. To remove the $Mo(CO)_3$ protecting group from **3**, a suspension of the polymer in THF was irradiated with UV light in the presence of N_2O. After activation of the metal carbonyl bond with UV light the oxygen transferring agent N_2O is able to selectively oxidise the $Mo(CO)_3$ fragment to MoO_3 and generate **4** quantitatively.[8]¶ This was shown by a shift of the ^{31}P resonance to higher field (δ 29) in the ^{31}P CP MAS spectrum of **4** and confirmed by the absence of the ν(CO) absorptions due to the $Mo(CO)_3$ fragment in the IR spectrum. After conversion of MoO_3 into MoO_4^- with K_2CO_3 the molybdate was extracted by washing procedures. While a number of functionalized phosphine monomers were accessible in this manner in homogeneous solution[8] a partial oxidation of the supported phosphine ligand **4** is observed in the interphase. This was attributed to the high oxophilicity of the polyethylene glycol groups and is prevented by adding reducing agents like PBu^n_3 to the suspension. The quantitative replacement of the carbonyl fragment demonstrates the easy accessibility of the metal complex in the polymer material by small molecules like N_2O. When the supported tripodal phosphine ligand **4** is treated with Vaska's complex no reaction is observed. Obviously the $Ir(PPh_3)_2(CO)Cl$ complex is too large to enter the interphase and react with the tripodal phosphine. The dimers $[M(cod)Cl]_2$ (M = Rh, Ir) are readily split by **4** in the presence of $NaBPh_4$ to form the new anchored rhodium and iridium complexes **5,6**.‖ The characteristic ^{31}P NMR signals are shifted to δ 38.4 and −7, respectively.

All materials were characterised by multinuclear solid-state NMR spectroscopy. The ^{29}Si CP MAS NMR spectra confirm the presence of a polysiloxane network built up with different T (δ −56.0 to −66.3, T^1–T^3) and Q (δ −91.0 to −109.9, Q^2–Q^4) species. The ^{31}P CP MAS NMR spectra of the polymers **3**–**6** display single unique resonances characteristic for the complexes and ligand, respectively. The spectra are comparable



Scheme 1

† Dedicated to Professor Reinhard Schmutzler on the occasion of his 65th birthday.

with the corresponding monomer complexes in solution. This confirms the integrity of the reactive centres in the polymers and establishes that the method described above allows the support of well defined transition metal complexes. Interestingly the linewidth of the ^{31}P resonances strongly depend on the spacer lengths as well as the amount of co-condensate used and shows large differences between the ligand **4** and the complexes **3**, **5** and **6**, respectively. It was found that the flexibility of the supported complexes increases when the degree of polymerisation of the PEG spacer is expanded from 50 to 145. If the degree of polymerisation is enlarged to 285 the mobility is reduced which is caused by a stronger interaction among the polyethylene glycol chains. The strong increase of the linewidth from the ligand **4** to the complexes **5** and **6** is interpreted in terms of the larger chemical shift dispersion in metal complexes. This is caused by the hindered rotation of the phenyl groups of the sterically crowded transition metal complexes in the solid state.

The Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie are greatly acknowledged for financial support.

‡ *Standard procedure for* **2**: after a suspension of **1** (258 mg, 0.249 mmol) and NaH (54 mg, 2.241 mmol) in 70 ml of THF was stirred for 2 h at 80 °C, 357 μl (1.494 mmol) of $Cl(CH_2)_3Si(OEt)_3$ were added dropwise at room temp. and stirred for 20 h at 60 °C. The reaction mixture was allowed to cool to room temp. and was neutralised and separated from precipitated salts by passing the suspension over a column of dry NH_4Cl (3 cm). The solvent was removed *in vacuo* and the oily residue treated with 30 ml of *n*-pentane. The yellow precipitate was separated and washed with *n*-pentane three times and dried *in vacuo*, Yield: 288 mg (70.0%). IR (KBr, cm^{-1}): 1938, 1849 ν(CO). $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ 46.7. ^1H NMR (acetone-d_6): δ 0.54–0.60 (m, $SiCH_2$), 1.17 (t, $^3J_{HH}$ 7.2 Hz, OCH_2CH_3), 1.55–1.75 (m, $SiCH_2CH_2$), 1.77–1.93 (m, $CH H_e$), 2.44–2.79 (m, $CH H_a$), 3.30–3.62 (m, OCH_2-$CH_2OCH_2CH_2$), 3.75 (q, $^3J_{HH}$ 7.2 Hz, OCH_2CH_3), 7.05–7.39 (m, C_6H_5). $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ 7.1 (s, $SiCH_2$), 17.5 (s, OCH_2CH_3), 23.3 (s, $SiCH_2CH_2$), 30.3 (m, CH_2), 39.3 (br s, CP), 57.3 (s, OCH_2CH_3), 67.4–76.7 (m, $OCH_2CH_2OCH_2CH_2$), 127.5 (s, *m*-C_6H_5), 128.9 (s, *p*-C_6H_5), 136.3 (m, *ipso*-, *o*-C_6H_5).

§ *Standard procedure for* **3**: compound **2** (182 mg, 0.11 mmol), TEOS and H_2O were homogenised for 30 min at room temp. with a minimum amount of ethanol (0.5 ml). After one drop of $SnBu^n_2(OAc)_2$ was added, the reaction mixture was warmed to 60 °C for 4 h and dried for another 4 h at 60 °C. The inhomogeneous gel particles were stirred in *n*-hexane (3 times for 3 h in 50 ml) and after drying *in vacuo* (1 h) washed with ethanol, acetone and *n*-hexane (each 3 × 10 ml) and again dried *in vacuo*. IR (KBr, cm^{-1}): 1936, 1846 ν(CO). ^{31}P CP MAS NMR: δ 45.0 (s). ^{29}Si CP MAS NMR (Si-substructure): δ −59.7 (T^2), −67.2 (T^3), −92.1 (Q^2), −100.8 (Q^3), −109.2 (Q^4).

¶ *Standard procedure for* **4**: a suspension of **3** in 50 ml acetone placed in a double-walled Duran Schlenk tube was degassed and 5 ml of PBu^n_3 added under N_2O atmosphere. The vigorously stirred suspension was cooled to 10 °C and N_2O was added (1.3–1.5 bar). The reaction mixture was irradiated for 30 min with the UV-light of a TQ 150W (Original Hanau) high-pressure mercury lamp, which was located 5 cm from the Schlenk tube. After complete conversion of the educt (monitored by ^{31}P CP MAS NMR spectroscopy) the red solution was filtered off and the yellow powder was washed twice with 5 ml of an aqueous solution of K_2CO_3 (0.05 M) and three times each with 10 ml of acetone and *n*-pentane. The material was dried *in vacuo*. ^{31}P CP MAS NMR: δ 29.8 (s).

‖ *Standard procedure for* **5** *and* **6**: to 227 mg (0.035 mmol) of **4** suspended in 35 ml of CH_2Cl_2 were added 21.9 mg (0.035 mmol) of $[Ir(cod)Cl]_2$. The yellow suspension was stirred for 30 min and 24 mg (0.07 mmol) of $NaBPh_4$ in 4 ml of CH_2Cl_2 was added to the reaction mixture. After stirring for 20 h the product was separated from the solution, washed with acetone and *n*-hexane (each 3 × 5 ml) and dried *in vacuo*. IR (KBr, cm^{-1}): 1415 ν(C=C). ^{31}P CP MAS NMR: δ 7.3 (br s). Material **6** was prepared according to the same procedure except that the suspension of **4** was added to the solution of $[Rh(cod)Cl]_2$ in CH_2Cl_2. IR (KBr, cm^{-1}): 1462 ν(C=C). ^{31}P CP MAS NMR: δ 38.4 (br s).

Pt^{II} coordination to guanine-N7: enhancement of the stability of the Watson–Crick base pair with cytosine

Roland K. O. Sigel and Bernhard Lippert*

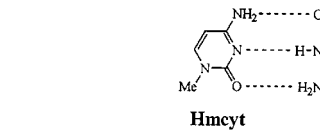
Fachbereich Chemie, Universität Dortmund, D-44221 Dortmund, Germany. E-mail: Lippert@pop.uni-dortmund.de

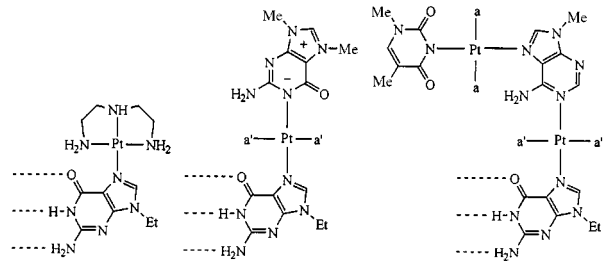
Received (in Cambridge, UK) 1st April 1999, Revised manuscript received 19th August 1999, Accepted 27th September 1999

Concentration-dependent ^{1}H NMR shift experiments in $(CD_3)_2SO$ reveal that Pt^{II}-coordination to N7 of guanine enhances the stability of the Watson–Crick pair with cytosine.

Metal ions are indispensable for charge compensation of negatively charged nucleic acid strands, thereby relieving mutual repulsion.[1] On the other hand, in cases of high affinity to donor atoms of the heterocyclic nucleobases, metal ions can lead to a concentration-dependent destabilisation of double-stranded DNA.[2] Different reasons can be responsible for these findings, *e.g.* blocking of hydrogen bonding sites, loss of electronic complementarity, or steric distortion. In recent years theoretical calculations have addressed the question how metal ion coordination to the periphery of a base pair or a base triple influences the strength of the nucleobase associate.[3–6] In some cases, polarisation effects of the metal ion have been proposed to lead to an enforcement of hydrogen bridges (*e.g.* GC-pair, GGC-triplet), whereas in other cases the hydrogen bonds apparently are not affected (*e.g.* AAT-triplet).[3a] To the best of our knowledge, it has not been examined until now, if such an influence also occurs in solution, and definitely no relevant studies have been conducted with respect to N7-platination of guanine. Predictions are difficult to make: on the one hand, N7-metalation acidifies the N1 proton[7]—a feature expected to lead to a strengthening of the hydrogen bond to cytosine-N3—on the other hand the simultaneous reduction of the basicity of O6 should reduce the acceptor property of this atom towards the amino proton of cytosine, thereby weakening the base pair with cytosine. As demonstrated by X-ray crystallography, Watson–Crick base pairing is, in principle, also possible with N7-platinated guanine,[8,9] as further confirmed by solution studies with DNA fragments containing intrastrand-G,G adducts.[10,11] However, no conclusions concerning the thermodynamic strength of such base pairs can be drawn from these observations. Our own solution studies in $(CD_3)_2SO$ with the model nucleobase 9-ethylguanine (Hegua) and 1-methylcytosine (Hmcyt), as well as with the three Pt^{II} complexes **1**–**3**[12–14] (Scheme 1) now definitely prove that N7 platination of Hegua enhances the stability of the Watson–Crick base pair with Hmcyt.

We have determined the association constant of the Watson–Crick base pair Hegua–Hmcyt by evaluating the concentration-dependent change of the chemical shift of the NH protons which are involved in base pair formation through hydrogen bonding.† The obtained value of $K = 6.9 \pm 1.3$ dm^3 mol^{-1} is in good agreement with data from the literature for guanosine/cytidine in the same solvent.[15] The corresponding values for the Watson–Crick base pairs of Hmcyt with the Pt^{II} complexes **1**, **2** and **3** are $K = 13.2 \pm 2.0$, $K = 22 \pm 10$ and $K = 16.3 \pm 4.0$ dm^3 mol^{-1} (all errors correspond to twice the standard deviation). As an example, the chemical shift of the NH protons is shown as a function of the concentration of the two partners Hmcyt and **2** (Fig. 1) together with a stackplot of the aromatic part of the ^{1}H NMR spectra at four different concentrations of the same components. All the other ^{1}H NMR resonances are practically concentration-independent in the presence of the corresponding partner, showing that no other interactions between the nucleobases (*e.g.* stacking) are present in $(CD_3)_2SO$ solution and that also the change in ionic strengths during the dilution experiment has no effect on the chemical shifts. It should be





Scheme 1

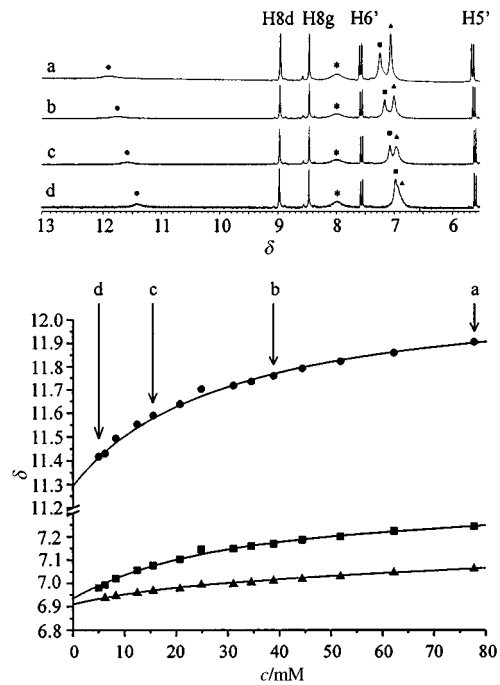


Fig. 1 Stackplot of the aromatic ^{1}H NMR spectra of a 1 : 1 mixture of **2** and Hmcyt in $(CD_3)_2SO$ at various concentrations (77.72, 38.86, 15.54, 4.97 mM, from top); the NH protons of the Hegua and Hmcyt moieties show a dependence in concentration whereas all other resonances [including NH_2 of the 7,9-dimethylguanine (*)] are unaffected (top part). In the bottom part the concentration dependency of the chemical shifts of the NH protons of 9-ethylguanine (N1H, ●; NH_2, ■) and 1-methylcytosine (NH_2, ▲) of the same system are shown. The arrows indicate those concentrations of the mixture of which the spectra are shown at the top.

noted that diluting a solution of the single compounds does not result in a change in chemical shift. The distinctly stronger influence on the N1H resonance of Hegua as compared to the two NH_2 resonances ($\Delta\delta \approx 2:1$), is in accord with the view that only one of the two amino protons takes part in base pairing, yet that there is signal averaging owing to fast rotation of the exocyclic amino group. Similar arguments apply to the NH_2 resonance of Hmcyt.

The ^{1}H NMR data for **1**–**3** prove that Pt^{II} coordination at the N7 position of 9-ethylguanine significantly enhances the stability of the Watson–Crick base pair with 1-methylcytosine in $(CD_3)_2SO$. Considering the proven similarity of nucleotides and their corresponding model nucleobases with respect to platinum binding properties, we propose that our observations are true for nucleotides as well. We note that although stability constants for Watson–Crick pairs have been determined, without exception, in non-physiological solvents such as Me_2SO or $CHCl_3$, they still reflect the different stabilities of G, C and A, T pairs in double stranded DNA. This fact further corroborates our claim.

The question whether an enhancement in base pair stability translates into a thermal stabilisation of DNA depends, however, on additional factors, such as conformational changes upon Pt^{II} coordination, DNA sequence, or ionic strength of the medium,[16] in which the melting behaviour of platinated DNA is measured. Thus the observed lowering of the melting point T_m of DNA containing bifunctional *cis*-$(NH_3)_2Pt(G,G)$ adducts is probably largely due to DNA distortion and loss of stacking, which overrules any gain in base pair stability between platinated G and C in the complementary strand brought about by the heavy metal. The accessibility of solvent (H_2O) to bases in a kinked DNA structure and the resulting competition with H_2O for H bonding sites at the bases might also contribute to this situation. The reported[17] increase in T_m of DNA at low levels of monofunctional (dien)Pt^{II} binding (base : Pt < 0.01) and at low ionic strength (10 mM $NaClO_4$) is in line with a stabilisation of GC pairs as described now, though it should also be noted that at higher platination levels conformational distortion of DNA leads again to a drop in T_m.[16,17]

The authors wish to thank the following institutions for support of this work: Deutsche Forschungsgemeinschaft (DFG), Fonds der Chemischen Industrie (FCI), and the Swiss National Science Foundation and the Swiss Federal Office for Education and Science (TMR fellowship to R. K. O. S.; No. 83EU-046320).

Notes and references

† An equimolar mixture of Hegua, **1**, **2** or **3** and Hmcyt in $(CD_3)_2SO$ was stepwise diluted in the concentration range of *ca.* 80–10 mM and at each concentration a ^{1}H NMR spectrum was recorded. The concentration-dependent chemical shifts of the NH protons involved in Watson–Crick base pairing were fitted with a non-linear least-squares program after Newton–Gauss, similar to a procedure described in ref. 18. Three independent dilution experiments were measured and evaluated; fitting the chemical shifts of each of the three NH protons, three association constants were obtained for each experiment, from which the weighted mean K^* was calculated. From these three values of K^*, the final association constant K was calculated, corresponding to the weighted mean of these three values. All errors correspond to twice the standard deviation. For the system **1**–Hmcyt, the resonances of the NH_2 groups of the guanine ligand and 1-mcyt coincide, so that only two data sets could be evaluated.

$(CD_3)_2SO$ was dried over 4 Å molecular sieves for at least one week before use. The residual water concentration was *ca.* 10 mM. It should be noted that there is an inverse relationship between the water content and K: the higher the concentration of the residual water, the lower the K value. The same is true for non-platinated guanine, but here the influence of the water concentration is less pronounced.

^{1}H NMR spectra were recorded on a Bruker AC200 (200.13 MHz) instrument at 20 °C. The quintet of $(CD_3)(CHD_2)SO$ was used as internal reference (δ 2.5025 relative to TMS).

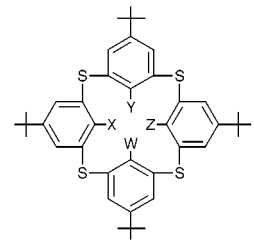
Received (in Basel, Switzerland) 27th July 1999, Accepted 13th September 1999

The synthesis of *p-tert*-butyltetramercaptotetrathiacalix[4]arene 1 bearing eight sulfur atoms was achieved in high overall yield (80%); the synthetic strategy used was based on the synthesis of *p-tert*-butyltetrathiacalix[4]arene 2, treatment of the latter with *N,N*-dimethylthiacarbamoyl chloride under mild conditions, thermal transposition of the *O*-thiacarbamoyl into the *S*-thiacarbamoyl derivatives in quantitative yield and deprotection of the sulfur centres by treatment with hydrazine hydrate; the conformation of compound 1 was investigated in the solid state by X-ray diffraction on a single crystal, which revealed that compound 1 adopts the 1,3-alternate conformation.

Calixarenes, and in particular, calix[4]arene derivatives are among the most used macrocyclic frameworks.[1] The increasing interest in calixarenes is due to the almost endless structural as well as functional possibilities that such backbones allow to explore. Indeed, one may not only elaborate new compounds by modifying the upper and/or the lower rim of the calix unit, but one may also replace the methylene junction between the aromatic moieties by other elements or groups. Recently, the synthesis[2] and the structural analysis[3] of thiacalix[4]arenes, which are a new class of calix[4]arene derivatives, based on the substitution of the CH_2 groups linking the aromatic rings by sulfur atoms was reported.[4] Furthermore, the partial as well as complete oxidation of the thioether junctions into sulfoxide[5] and sulfone[6] respectively was achieved. For the parent calix[4]arene derivatives, the binding of metal cations[1] and main group elements such as silicon[7] takes place at the lower rim through the OH groups. For the thiacalixarene derivatives, it has been demonstrated that upon replacement of the methylene groups by sulfur atoms, the number of coordination sites increases leading thus to a large diversity in the coordination properties.[8] For sulfur containing calixarenes, the synthesis of di[9]- and tetra[10,11]-mercapto calix[4]arenes, in which two and four OH groups were replaced by two and four SH groups, respectively, as well as their ability to bind mercury cation was reported. More recently, other examples of dimercapto calix[4]arene derivatives bearing two long alkyl chains was achieved and their ability to extract selectively Hg^{2+} cations from water into $CHCl_3$ was demonstrated.[12] We believe that ligand **1**, which is based on the thiacalixarene framework and bears four SH groups, may be of great interest for both its coordination features and as a backbone for the elaboration of other ligands.

Here we report the first synthesis and the solid state X-ray structure of tetramercaptotetrathiacalix[4]arene **1**.

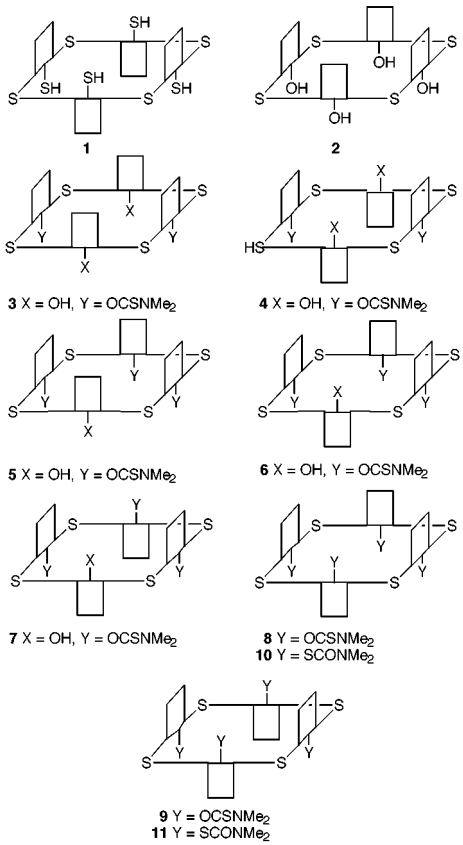
The synthesis of **1** was first attempted by treatment of *p-tert*-butylthiophenol by S_8 under the same conditions as those used for the preparation of thiacalixarene **2**.[2] Unfortunately, no condensation reaction could be detected using these conditions. The synthesis of **1** was then based on the preparation of the tetrathiacalixarene **2**[2] and subsequent transformation of all four OH groups into SH functionalities. The key step in the strategy used was the thermal Newman–Kwart rearrangement of the $OCSNMe_2$ groups into $SCONMe_2$,[9–11,13,14] followed by the generation of the SH groups. In a first attempt, compound **2** was treated with *N,N*-dimethylthiacarbamoyl chloride ($ClCSNMe_2$) in diglyme at 180 °C[10] and in the presence of NaH as base. Unfortunately, the condensation generated a variety of di- and tri-substituted derivatives. No tetra substituted conformer could be isolated from the ensuing complicated mixture. However, dithiacarbamate compounds **3** (10%) and **4** (10%) and trithiacarbamate compounds **5** (10%), **6** (10%) and **7** (8%) were isolated and structurally characterised either by 2-D NMR or by X-ray diffraction on single crystals in the case of **4**–**6**. In order to generate the tetra-substituted derivatives, one could, as previously reported for tetramercaptocalix[4]arene,[10] treat further the di- or tri-substituted compounds above by $ClCSNMe_2$; instead, the formation of the tetra-substituted compounds was investigated under other basic and solvent conditions. It was found that the treatment of **2** with $ClCSNMe_2$ in refluxing acetone in the presence of K_2CO_3 afforded two tetra-substituted compounds **8** (12%) and **9** (80%). Whereas the structure of **8** was elucidated in the solid state by X-ray diffraction on a single crystal, the conformation of compound **9** was studied by 2-D NMR methods.



1 X = Y = Z = W = SH
2 X = Y = Z = W = OH
3 or **4** X = Z = OH, Y = W = $OCSNMe_2$
5, **6** or **7** X = OH, Y = Z = W = $OCSNMe_2$
8 or **9** X = Y = Z = W = $OCSNMe_2$
10 or **11** X = Y = Z = W = $SCONMe_2$

Based on the observation mentioned above, in order to study the role of alkali metal cations M^+ present in M_2CO_3 (M = Li, Na, K and Cs) on the yield of formation of the tetra-substituted compounds, a systematic investigation was undertaken. Whereas for Li^+ cation, 30% of the disubstituted compound **4** and 5% of the trisubstituted conformer **6** were obtained, in the presence of Na^+, 30% of **4** and 3% of **7** were isolated. For Cs^+ as for K^+, 12% of **8** and 80% of **9** were obtained. The effect of alkali metal cations on the alkylation of **2** has been previously investigated.[15] In marked contrast with *p-tert*-butylcalix[4]arene for which under the same conditions no tetra substituted derivative could be obtained, for tetrathiacalixarene **2**, the tetra-substituted conformers were formed in 92% yield under rather mild conditions.

Since for the final compound **1**, the SH groups may freely pass though the annulus of the calix, we believed that it was not necessary to separate the 1,2-alternate **8** and the 1,3-alternate **9** conformers. Thermal rearrangement was thus performed in quantitative yield on the purified mixture of the two conformers **8** and **9** at 300 °C *in vacuo*. As expected, two transposed



conformers **10** and **11** were obtained. The final deprotection of the sulfur groups leading to the desired compound **1** was first attempted under reductive conditions using $LiAlH_4$ in either refluxing THF for 2 h, and at room temperature for 3 h. In both cases, 50 and 75% of an undesired compound in which three out of four $SCONMe_2$ units were transformed into SH groups was obtained. Refluxing the mixture in THF for a longer period of time resulted in the decomposition of the mixture of conformers. Finally, the desired compound **1** could be obtained in 90% yield upon treatment of the mixture of **10** and **11** by hydrazine hydrate at 100 °C for 18 h. It is worth noting that starting from **2**, the overall yield for the synthesis of **1** was 80%.

In $CDCl_3$ solution at 25 °C, the ^1H NMR spectrum of **1** was extremely simple and comprised a singlet (δ 7.84) corresponding to the aromatic protons and two other singlets at δ 1.25 and 4.72 corresponding to the *tert*-butyl and SH groups, respectively. Owing to the absence of the methylene groups, using only NMR observations, the differentiation between the cone and 1,3-alternate conformers is not feasible. However, the solid state conformation of **1** could be studied by X-ray diffraction on a single crystal (Fig. 1).† In marked contrast with the parent compound **2** which adopts the cone conformation in the crystalline phase,[3] compound **1** adopts the 1,3-alternate conformation in the crystalline phase. The aromatic rings located on the same face of the ligand are almost parallel. The average C–S and C–SH distances are 1.78 and 1.76 Å, respectively.

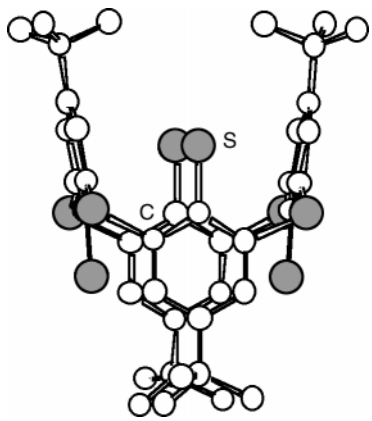


Fig. 1 : X-Ray analysis of *p-tert*-butyltetramercaptotetrathiacalix[4]arene **1**. For the sake of clarity, H atoms and solvent molecules are not represented (for distances see text).

In conclusion, a fast and efficient synthesis of compound **1** was achieved. In the solid state, it was shown that **1** adopts the 1,3-alternate conformation. The complexation ability of **1** towards transition metal cations is currently under investigation.

Vinyl esters as ethylene equivalents in the Khand annulation reaction

William J. Kerr,* Mark McLaughlin, Peter L. Pauson and Sarah M. Robertson

Department of Pure and Applied Chemistry, University of Strathclyde, 295 Cathedral Street, Glasgow, Scotland, UK G1 1XL. E-mail: cbas69@strath.ac.uk

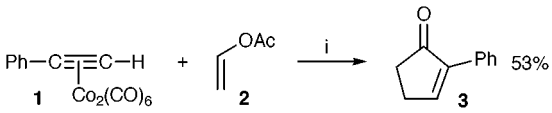
Received (in Liverpool, UK) 13th August 1999, Accepted 6th September 1999

A preparatively convenient and mild method for modified Khand cycloadditions is described; vinyl esters are employed as the olefinic reaction partner to provide cyclopentenone products more normally obtained with ethylene.

The simple one step cobalt carbonyl mediated annulation of an alkyne, an alkene, and carbon monoxide to form substituted cyclopentenones (the Khand reaction)[1] has emerged as one of the most widely used organometal-based transformations in organic synthesis. Indeed, in recent years the development of modified techniques for promoting this reaction has led to its increased utilisation in a wide variety of synthetic endeavours.[1,2] In particular, the application of amine *N*-oxide promoters has allowed the annulations to be performed under mild reaction conditions to deliver highly improved product yields.[3] More specifically, studies in our own laboratory have led to *N*-oxide techniques which allow the application to both asymmetric cyclisation strategies[4] and to the establishment of markedly improved procedures for use with gaseous alkenes such as ethylene.[2h,5] Here we report the discovery of a novel use of non-gaseous ethylene equivalents in the Khand cyclisation.

With a view to gaining access to (poly)oxygenated cyclopentenones and, more especially, with the advent of the mild amine *N*-oxide strategies, we envisaged that it would be possible to employ relatively sensitive vinyl esters as olefinic substrates. Since the phenylethyne–cobalt complex **1** was known[6,7] to give mixtures of 4- and 5-ethoxy-1-phenylcyclopent-2-en-1-one in poor yield when treated with ethyl vinyl ether under the generally less effective traditional reaction conditions, this complex was utilised in our initial experiments with vinyl acetate **2**. To our surprise, under the *N*-oxide conditions shown in Scheme 1 the only organic product isolated was the monosubstituted 2-phenylcyclopent-2-en-1-one **3**, lacking the anticipated acetate functional unit. Despite the moderate 53% yield, we recognised that this result had considerable potential as the basis for the development of a procedure which would employ what could be considered as a non-gaseous ethylene equivalent in Khand cycloadditions. To this end, we sought to optimise this modified Khand process by varying the reaction promoter, the vinyl ester, and the general reaction conditions.

In the reaction shown in Scheme 1, the ketone **3** had been obtained using trimethylamine *N*-oxide dihydrate at 45 °C. On the other hand, by employing the alternative mild oxidant, *N*-methylmorpholine *N*-oxide monohydrate (NMO·H_2O),[3a] we found that the same class of transformation could be promoted at room temperature. In turn, this *N*-oxide was adopted for use in comparative experiments. As can be seen from Table 1, in reactions with complex **1**, a range of vinyl esters (**2**, **4**–**6**) all successfully afforded the cyclopentenone **3**. Additionally, use of vinyl bromide **7** also led to the formation of the same enone product.†



Scheme 1 *Reagents and conditions*: i, Me_3N^+–O^-·$2H_2O$ (9 equiv.), toluene–MeOH (10:1), 45 °C.

Table 1 Modified Khand reactions of vinyl substrates with phenylethyne complex **1**[a]

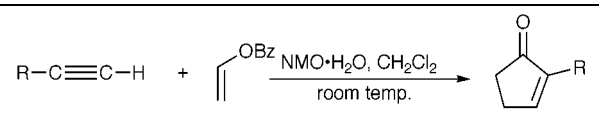
	X	Yield of **3** (%)
2	AcO	52
4	CF_3CO_2	50
5	BzO	58
6	Bu^tCO_2	31
7	Br	54

[a] 9–10 equiv. of NMO·H_2O employed.

Based on the results shown in Table 1, vinyl benzoate **5** was selected for further optimisation. Subsequently, it was established that slow (syringe pump) addition of the *N*-oxide promoter (NMO·H_2O) over a 3 h period led to an excellent 80% yield of **3** at room temperature.‡ Indeed, the enhanced efficiency of this modified Khand process now compares favourably with the optimum yields achieved when using ethylene gas with Me_3N^+–O^-·$2H_2O$ and complex **1**; ethylene reaction at 40 °C and 25–30 atm provides a 71% yield of **3** whilst reaction at room temperature and 1 atm proceeds in 55% yield.[2h,5b]

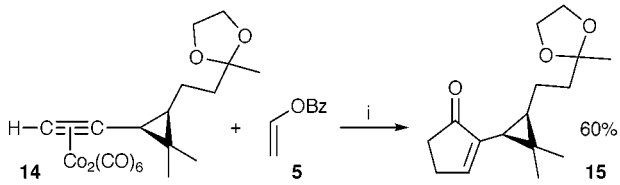
Having developed the slow addition procedure, these conditions were applied to a range of alkyne complexes (Table 2).§ Overall, we have found that the efficiency of the new vinyl benzoate technique is at least comparable with the optimum ethylene methods and, in most instances (where a comparison can be made), significant enhancement in the yield of cyclopentenone can be realised. A particularly vivid example of the improved efficacy of the ethylene equivalent method is provided when THP-protected propargyl alcohol is utilised as the alkyne substrate; using vinyl benzoate with NMO·H_2O at

Table 2 Modified Khand reactions of vinyl benzoate **5** with alkynes[a]



R	Product	Yield (%)
Ph	**3**	80
n-C_5H_{11}	**8**	77
Me_3SiCH_2	**9**	45
$THPOCH_2$	**10**	87
$THPO(CH_2)_2$	**11**	80
$HO(CH_2)_2$	**12**	61
$HOCH_2$	**13**	33

[a] Typically the alkyne $Co_2(CO)_6$ complex and excess vinyl benzoate (as co-solvent)¶ are stirred as NMO·H_2O (8–10 equiv.) is added over 0.5–3 h as a solution in CH_2Cl_2 before stirring is continued at room temp.



Scheme 2 *Reagents and conditions*: i, NMO·$2H_2O$ (10 equiv.), CH_2Cl_2, 2 h addition, room temp.

room temperature an excellent 87% yield of cyclopentenone **10** is achieved, whereas the maximum yield obtained under the optimum ethylene conditions was only 33%.[2h,5b]‖

As a final example, and to show the utility of the modified methods in natural product synthesis, we chose to employ alkyne complex **14**. In our previously reported total synthesis of (+)-taylorione,[2h,5a] the key step in our sequence towards this target had been the Khand reaction of **14** with ethylene. When reacted with vinyl benzoate under the conditions described here (Scheme 2), complex **14** gave cyclopentenone **15** in a 60% yield.** This result constitutes an improvement in the carefully optimised yield of 41% obtained for the same transformation with ethylene under ambient conditions. On the other hand, it is not equal to the best autoclave yield of 81% achieved with $Me_3N^+–O^-·2H_2O$ at 40 °C and 25 atm. Nonetheless, it is worth noting that, in the instances where higher yields are achievable using gaseous alkenes, autoclave facilities and conditions of elevated temperature and pressure are required. In contrast, the ethylene equivalent procedures disclosed here show how cheap, readily available and easily handled vinyl esters can be employed under ambient conditions to provide cyclopentenone products in yields which are at least competitive with and, more usually, improved over those of the equivalent optimised ethylene process.

In the developed modified Khand process it is clear that the isolated cyclopentenones are the products of reduction. In this respect, the C–O cleavage and subsequent replacement of the ester oxygen with H must involve a low oxidation state cobalt species, as this would be expected, under the reaction conditions, to be the only available reducing agent. Additionally, the reaction only proceeds to give the reduced products under inert (N_2) atmospheres. However, when using vinyl acetate **2** with complex **1** in air only a very low yield (7%) of the 5-acetoxycyclopentenone is obtained. We believe that the required hydrogen atom to complete the reduction process is supplied from water (*e.g.* from the hydrated *N*-oxide). This theory was supported when the reaction of **1** and **2**, promoted by anhydrous NMO, was performed in the presence of excess D_2O and exclusively yielded 5-deuterio-2-phenylcyclopent-2-en-1-one. Such regioselective incorporation of deuterium also implies that the reductive cleavage occurs after the coupling of the alkyne and alkene.

In summary, we have developed a novel method by which vinyl esters can be utilised as non-gaseous ethylene equivalents in the Khand annulation. The mild conditions and simple techniques employed provide significant advantages, both in terms of practical convenience and, in the majority of cases explored, reaction yield, over the corresponding gaseous alkene procedures.

We gratefully acknowledge financial support from the Carnegie Trust for a postgraduate scholarship (M. M.) and Pfizer Central Research, Sandwich, for generous funding of our research endeavours. We also thank the EPSRC Mass Spectrometry Service, University of Wales, Swansea, for analyses.

Notes and references

† Under more traditional conditions of elevated temperature with no *N*-oxide promoters, in reaction with complex **1**, vinyl bromide had been shown to give the product of reductive debromination, cyclopentenone **3**, in the low yield of 19% (ref. 8).

‡ Performing the NMO slow addition experiments for the reaction of complex **1** with vinyl benzoate **5** at a range of higher or lower temperatures (from −70 to 40 °C) led to less efficient cyclisations and lower yields of **3**.

§ All compounds exhibited satisfactory analytical and spectral data.

¶ Excess vinyl benzoate is readily recoverable on completion of the reaction.

‖ Using thermal conditions with no promoter, THP-protected propargyl alcohol completely failed to yield any cyclopentenone products when reacted with ethylene (ref. 9).

** This result provides the ketal protected form of the recently reported (+)-nortaylorione (ref. 10) and constitutes a formal total synthesis of this natural product, which has been prepared from **15** by our novel PPh_3/CBr_4 ketal deprotection method [ref. 2(*h*), 5(*a*), 11].

Received (in Cambridge, UK) 22nd July 1999, Accepted 23rd September 1999

2,4,6-Triphenylpyrylium ions entrapped inside the supercages of Y zeolite exert a remarkable catalytic effect toward the electrochemical oxidation of dopamine and norepinephrine (neurotrasmitter catecholamines) in neutral aqueous media.

Encapsulation of organic species inside the rigid matrix of microporous zeolites has proved to be a general methodology to control the molecular properties of the incorporated guest.[1] Zeolites are a large family of crystalline aluminosilicates whose structure defines strictly uniform channels and cavities of molecular dimensions (micropores). It is in these internal voids where a guest can be accommodated provided that its molecular size is smaller than the void dimensions. In particular, the structure of zeolite Y is formed by an array of spherical cavities (1.4 nm diameter) that are tetrahedrally interconnected through four smaller apertures (0.74 nm diameter).

We have already reported that the bulky 2,4,6-triphenylpyrylium ion (TP^+, ≈ 1.3 nm) can be prepared inside the zeolite Y supercages through a 'ship-in-a-bottle' synthesis that relies on the diffusion of much smaller synthetic precursors.[2] After the encapsulation, TP^+ remains mechanically immobilized inside the zeolite Y supercages, but it still can interact with smaller molecules through the cavity windows.

Recently one of us has shown that while the BF_4^- salt of TP^+ in water undergoes a rapid hydrolytic ring opening, when TP^+ is encapsulated within the restricted space provided by the supercages of zeolite, the host framework protects it from the nucleophilic attack of water.[3] As a result, TP^+ within Y zeolite (TPY) is completely persistent in water. This opens the opportunity for new applications of TP^+ in aqueous media, as reported herein on the catalytic effect of TPY on the electrochemical oxidation of catecholamines in aqueous solution.

The electrochemistry of pyrylium ions in solution is well understood. TP^+ undergoes one-electron reduction in protic solvents.[4] Controlled potential electrolysis produces the corresponding dipyran which in turn can be reoxidized back to TP^+. In aprotic solvents, reduction of pyrylium ions leads to the corresponding bipyranylidene together with pyrane.[5] In this case, the transient reduction wave is controlled kinetically by the irreversible dimerization of the radicals formed after the initial electron transfer.[6] Bipyranylidene and pyrane are produced by the reversible reduction of the dimer.[7] We have found that upon encapsulation in the internal voids of zeolites, owing to the impossibility to form dimers, pyrylium ions display an apparently more simple electrochemistry consisting on the quasi-reversible reduction to TP. Compartmentalization of TP^+ inside the zeolite Y impedes its diffusion and eventually that of the corresponding TP pyranyl radicals, and therefore radical coupling is inhibited.

Preliminary experiments on the electrochemistry of TP^+ incorporated within zeolite Y confirmed the inhibition of dimerization processes. Paraloid B72† and Elvacite 2044,‡ were used to obtain polymer film electrodes containing TPY as modifiers. As can be seen in Fig. 1, polymer film electrodes (PFEs) modified by zeolite Y containing TP^+, TPY-MEs, exhibit a well defined reduction process. As can be seen in Fig. 2, cyclic voltammograms show a one-electron couple at an equilibrium potential of −0.28 V *vs.* SCE in acetonitrile. The peak potential separation is about 150 mV suggesting that the electrochemical process is kinetically reversible. The morphology of voltammograms is practically identical upon immersion of the modified electrode in neutral aqueous solutions, denoting that hydrolytic ring opening is inhibited by encapsulation. The voltammetric response is enhanced on increasing the contact time of the electrode into the solution and remains stable upon repetitive cycling of the potential scan. The absence of additional peaks in repetitive cyclic voltammetry denotes that no parallel chemical reactions occur. Identical results were obtained at working electrodes with self-supported finely ground zeolite pressed onto the surface of the bare electrode. Although the internal *versus* external nature of the electrochemical response involved in zeolite-modified electrodes remains controversial,[8,9] it appears that the observed electrochemistry is essentially attributable to the population of TP^+ located at the boundary region of zeolite grains.[10,11]

The reduction process involves the incorporation of charge-balancing positive ions from the supporting electrolyte to the zeolite boundary sites and can be represented by eqn. (1).

$$TP^+_{(zeolite)} + M^+_{(sol)} + e^- = TP^\bullet_{(zeolite)} + M^+_{(zeolite)} \quad (1)$$

Encapsulation of pyrylium ions inside zeolite Y and the resulting stability in aqueous solutions has enabled us to test this material as an electrocatalyst for the oxidation of the neuro-

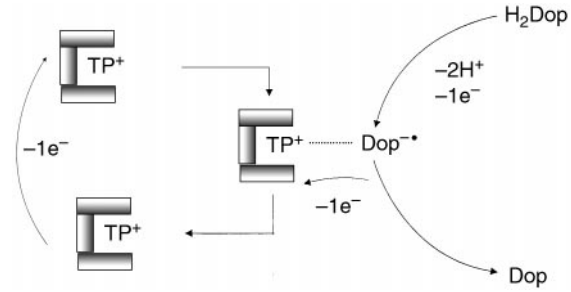
transmitter catecholamines, dopamine and norepinephrine. These compounds play an essential role in neurochemistry. Since the loss of neurotransmitter-containing neurons may result in some serious diseases such as Parkinsonism,[12] the determination of such compounds in real biological systems is an obvious target in neurochemical studies.[13]

Dopamine and norepinephrine have a common dihydroxyphenethylamine moiety that is responsible for their observed electrochemistry. These species exhibit a well defined electrochemical oxidation at *ca.* +0.2 V *vs.* SCE in neutral aqueous media. The electrochemical oxidation process leads to the corresponding *o*-quinone which can be intracycled and again oxidized.[14] This electrode process has been previously used for analytical purposes by using unmodified[15] and modified electrodes.[16]

At zeolite-modified electrodes lacking encapsulated TP^+, Y-MEs, the oxidation peak of dopamine or norepinephrine is almost identical to that recorded at the basal glassy carbon electrode. In contrast, using TPY-MEs, the peak current is about 10–20 times enhanced with respect the peak obtained at the basal glassy carbon electrode. As an example, the catalytic effect of TPY on the electrochemical oxidation of dopamine is shown in Fig. 3. On scanning the potential in the anodic direction, an oxidation peak appears at −0.25 V, that corresponds to the oxidation of TP to TP^+ in the electrochemically accessible sites of the zeolite. A second prominent anodic peak is observed at *ca.* +0.20 V corresponding to the enhanced dopamine oxidation. Similar results were obtained for norepinephrine solutions. In both cases, the electrocatalytic effect was not observed at modified electrodes containing pristine Y zeolite lacking encapsulated pyrylium groups, indicating that the electrocatalytic effect must be attributed to the fraction of pyrylium ions located at the boundary sites of the zeolite particles. The electrocatalytic current increases on lowering the potential scan rate and increasing the contact time of the modified electrode with the solution prior to the electrochemical runs. All these data indicate that the net electrocatalytic effect depends on the net amount of diffusive transfer into the zeolite particles.



Scheme 1

The measured peak currents for dopamine and norepinephrine oxidations produced linear calibration graphs for 1×10^{-6} to 1×10^{-4} M concentrations of catecholamine. The sensitivity for dopamine oxidation using differential pulse voltammetry (12 A cm^{-2} M^{-1}) is similar to that for norepinephrine oxidation (10 A cm^{-2} M^{-1}), enabling the use of TPY-MEs as electrochemical sensors.

The oxidation process of dopamine and norepinephrine involves two consecutive one-electron transfer processes coupled with deprotonation reactions. The electrocatalytic effect is likely to be caused by the stabilization of the catecholamine anion radical intermediates resulting from the first electron transfer process upon adduct formation with surface-confined pyrylium, with a subsequent electron-transfer that yields the *o*-quinone and surface-confined TP, as depicted in Scheme 1.

The observation of this novel electrocatalytic effect using pyrylium ion incorporated stabilized into zeolites realizes the new opportunities that the stabilization of organic species by encapsulation inside the rigid framework of microporous materials can offer, such as for the development of new electrochemical sensors with light selectivity and increased sensitivity.

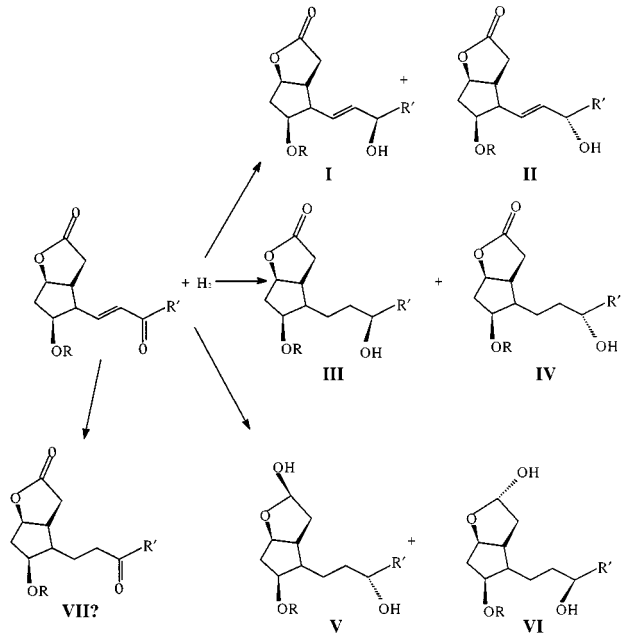
Received (in Oxford, UK) 31st August 1999, Accepted 23rd September 1999

Low metal loading Ru-MCM-41 (0.134 and 0.667 wt% Ru) have been prepared by adsorption of ruthenocene from a diethyl ether solution, calcination and reduction under flowing hydrogen at 350 °C; the physical characteristion by a combination of several techniques has shown that Ru is homogeneously distributed inside the MCM pores, and that it is only partially reduced; these catalysts exhibit a very high diastereoselectivity in hydrogenation of an F prostaglandin intermediate leading only to the 11*S*,15*R* diastereomer.

Diastereoselective hydrogenation is generally considered to occur on high loading noble metal catalysts (min. 5 wt%) in the absence of any chiral modifiers.[1,2] Some beneficial effects of the latter[3] or of some chiral auxiliaries have even been reported.[4,5] In all these cases the diastereoselectivity is related to some specific features of the metallic species or to the choice of an adequate reaction solvent. Otherwise the reaction product is a racemic blend. In most cases the diastereomeric excess (de) is low. Diastereoselective hydrogenation of α,β-unsaturated carbonyl compounds such as prostaglandin intermediates (Scheme 1) raises some additional problems because the interesting compounds are the allylic alcohols and from the thermodynamic point of view it is easier to hydrogenate the C=C double bound than the carbonylic one. Some shape selectivity effects have already been reported in the case of cinnamaldehyde hydrogenation[6] but it is still not clear if, for high metal loading and microporous supports, the effect of some adjacent Lewis sites, which are well known to exert a positive influence in this reaction, is not responsible for the observed results.



Scheme 1 Possible routes in hydrogenation of the F prostaglandin intermediate.

Here, we report a first example of the positive influence exerted by the mesoporous texture in the diastereoselective hydrogenation of a F prostaglandin intermediate on Ru-MCM-41 catalysts with very low Ru content using hydrogen as the reducing agent. Hydrogenation of the 15-carbonylic bond with generation of the chiral allylic structure is of special interest for these molecules because of its pharmaceutical applications.

The MCM-41 silica catalyst support was synthesised using sodium silicate (Aldrich) as the source of silicon and hexadecyltrimethylammonium bromide as the template. The synthesis was conducted at 70 °C and pH 11 for 7 days. The MCM-41 material was then filtered off, washed, dried and calcined at 550 °C for 12 h. The calcined material had a BET surface area of 1127 $m^2\ g^{-1}$ and a BJH pore diameter of 27 Å.

The catalysts used in the present study were prepared by adsorption of ruthenocene from a diethyl ether solution. After Ru deposition the catalysts were dried and calcined for 6 h at 550 °C, after raising the temperature at 1 °C min^{-1}. The reduction of these catalysts was performed under flowing hydrogen for 3 h at 350 °C with a heating rate of 1 °C min^{-1}. The Ru loading was determined using ICP-AES. Catalysts containing 0.134 and 0.667 wt% Ru were respectively obtained. The catalysts were characterised using surface area measurements by standard N_2 adsorption at 77 K, H_2-TPR, Mossbauer spectroscopy, H_2-chemisorption and XRD. The parameters determined using the above measurements are reported in Table 1.

Hydrogenation of the substrate was carried out in a stainless steel stirred autoclave under 2–8 atm hydrogen pressure at 20 °C using a solution of prostaglandine intermediate in anhydrous

Table 1 Characteristics of the Ru-MCM-41 catalysts

	MCM-41 Catalyst	
Property	0.13 wt% Ru	0.67 wt% Ru
BET surface area/$m^2\ g^{-1}$	807	739
BJH pore diameter/nm	2.6	2.6
Ru $3p_{3/2}$/eV	462.7	462.2
Ru/Si (XPS)	3.4×10^{-3}	5.3×10^{-3}

[a] Determined from Mossbauer spectroscopy. [b] Determined from H_2 chemisorption.

methanol, ethanol or isopropyl alcohol. Analysis of the reaction products was carried out by HPLC using a Nucleosil 5C18 column as well as by ^{13}C and ^{1}H NMR. The diastereoselective excess (de) was defined using eqn. (1):

$$de = \{[(15R) - (15S)]/[(15R) + (15S)]\} \times 100 \quad (1)$$

We defined 15*R* and 15*S* as the allylic chiral products from the reaction scheme.

Data presented in Table 1 show that at such low loadings, Ru is only partially reduced. The same conclusion was reached from the H_2-TPR measurements. In addition these determinations indicated only one reduction peak thus suggesting the presence of only one reducible Ru species. The good concordance beween the XPS and the analytical Ru/Si ratios suggests that Ru is homogeneously distributed inside the mesopores. However, H_2-chemisorption results indicate that even at such a low concentration Ru has a tendency to agglomeration. XRD indicates however (no diffraction peak of Ru or of a Ru compound), that these particles are rather small which is again in good concordance with chemisorption data.

The activity of the Ru-MCM-41 catalysts was found to increase with Ru content (Fig. 1). For each catalyst, increasing the pressure resulted in an increase of both the conversion and the selectivity to allylic alcohol. For the catalyst containing 0.13 wt% Ru the conversion increases by 15 times, and for that with 0.67 wt% Ru by 5 times, when the pressure is increased from 2 to 8 atm. At an Ru loading of 0.67 wt% a conversion of near 100% was reached. In all cases the formation of the allylic alcohol occurs with a total de in the 11*S*,15*R* form (product **II** in Scheme 1). Other studies using high Ru loading on zeolite Y,[6] showed that when the reaction occurs on the external surface of the catalysts, and in the absence of any chiral modifiers, only the racemic blend was obtained. Under these conditions an increase of the pressure led to a decrease of the selectivity to allylic alcohol.

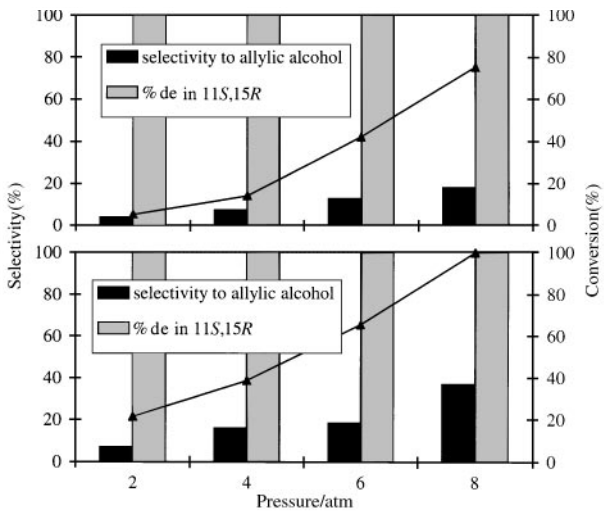

Fig. 1 Variation of the conversion, selectivity to allylic alcohol and de *vs.* pressure (a) 0.13 wt% Ru-MCM-41, (b) 0.67 wt% Ru-MCM-41; solvent methanol, room temp., 2h).

The variation of the same parameters as a function of the solvent (Fig. 2) shows that the solvent affects the total conversion and the selectivity to allylic alcohol. The best conversions were obtained using methanol and the best selectivities to allylic alcohol with isopropyl alcohol. The de was 100% in the 11*S*,15*R* form irrespective of the solvent nature.

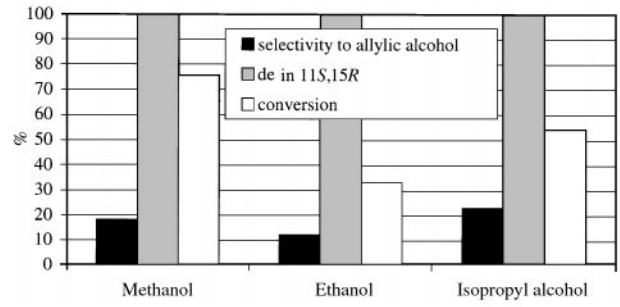

Fig. 2 Variation of the conversion, selectivity to allylic alcohol and de with solvent (0.67 wt% Ru-MCM-41, room temp. 2 h).

To explain these data one should accept that all the reaction parameters, namely the conversion, the selectivity to allylic alcohol and the diastereoselectivity are determined by the access of the prostaglandin intermediate to the MCM pores. The kinetic diameter of this molecule is rather high, and its penetration in the pores is diffusionally controlled. Ru is well distributed inside of these and even if it exhibits a tendency to agglomeration, the metal patches are smaller than those generally reported to have activity in such reactions. A deeper penetration of the reactant molecule leads to an increased number of molecules involved in a direct CO···Ru interaction. Under these conditions, because of the relatively small Ru size, the hydrogenation of the C=C double bond becomes less favoured and the selectivity to allylic alcohol increases. Other effects such as pore hindrance could be expected. The MCM-41 support is a pure silica, and therefore no Lewis acid sites are expected. The complete diastereoselective hydrogenation is very probably the consequence of the steric hindrance described below. As mentioned above the 11-OH group is in the *S* conformation. Owing to this conformation, an extended hydrogen bond interaction *via* the hydrogen of the alcohol group is possible. Because of this, hydrogen will attack the CO bond on the other side of the F prostaglandin intermediate molecule leading to the 15*R* isomer (compound **II** in Scheme 1). A cooperative contribution between the solvent and the pore hindrance is also sustained by the observed differences in conversion and selectivity in various solvents.

In conclusion, this data shows that the diastereoselective hydrogenation of large enones such as the F prostaglandin intermediate can be improved by using pore size controlled mesoporous materials as support for the ruthenium. It is also shown that in such a surrounding these reactions could also be carried out at very low metal loading, namely < 1 wt%, which is rather unusual for such large molecules.

Received (in Cambridge, UK) 24th August 1999, Accepted 1st October 1999

A mesoporous carbon with regular three-dimensionally interconnected 2 nm pore arrays using AlMCM-48 as a template has been synthesised; the mesoporous carbon exhibited excellent performance as an electrochemical double layer capacitor.

The development of mesoporous silica materials by Mobil Oil researchers in 1992 stimulated explosive research on the preparation of porous materials through template approaches.[1] Various types of organic templates including surfactant self-assemblies, block copolymers and polymer lattices have been utilized to synthesize such mesoporous inorganic materials.[2] Recently many types of nanostructured carbons have been produced through templating approaches.[3] Electrochemical double-layer capacitors (EDLCs) find new promising applications as pulse power sources for digital communication devices and electric vehicles.[4] The popularity of these devices is derived from their higher energy density relative to conventional capacitors and their longer cycle life and higher power density relative to batteries. Here, we report the first synthesis of a mesoporous carbon material with regular three-dimensionally interconnected pore channels. We also present preliminary results on the EDLC performance of the mesoporous carbon. In our approach, a mesoporous MCM-48 aluminosilicate with three-dimensional channel structure has been utilized as a template. Mesoporous silica MCM-48 was prepared by the reported method.[1] Aluminium was implanted onto MCM-48 to generate strong acid catalytic sites for the polymerization of phenol and formaldehyde. Phenol and formaldehyde were incorporated into the pores of aluminium-implanted MCM-48 (AlMCM-48) by heating for 12 h at 90 °C under reduced pressure. The polymerization of phenol and formaldehyde to obtain the phenol resin inside AlMCM-48 was carried out by heating the mixture under a nitrogen atmosphere at 125 °C for 5 h.[5] The resulting AlMCM-48–phenol resin composite was heated under an N_2 flow at a heating rate of 5 °C min^{-1} to 700 °C and held there for 7 h to carbonize phenol resin inside the MCM-48 channels. The dissolution of MCM-48 frameworks using 48% aqueous hydrofluoric acid (HF) generated mesoporous carbon, designated SNU-1 (Seoul National University).

The ordered mesoporous structure of SNU-1 was investigated by X-ray diffraction (XRD), transmission electron microscopy (TEM) and gas adsorption measurements. XRD patterns were obtained at various times during the course of the synthesis. Fig. 1(a) shows the characteristic pattern of the AlMCM-48 template with a *d* spacing value of 3.37 nm.[6] To our surprise, intense peaks at $2\theta = 1.6$ and 2.7° from the long-range ordering of mesopores is clearly shown in the XRD pattern of SNU-1 carbon [Fig. 1(b)]. This result revealed that the carbon networks formed inside the mesopores of AlMCM-48 are strong enough to survive even after the removal of the aluminosilicate framework by HF etching. Elemental analysis (EA) revealed a high C/H molar ratio of 9.3 and < 1 mol% aluminosilicate residue in the SNU-1 carbon material (EA result: 93.24% C, 0.84% H, 0.09% N, 2.56% O). TEM studies of mesoporous SNU-1 carbon showed a regular array of 2 nm diameter holes separated by 2 nm thick carbon walls (Fig. 2). The specific surface area of SNU-1 was found to be 1257 m^2 g^{-1} from

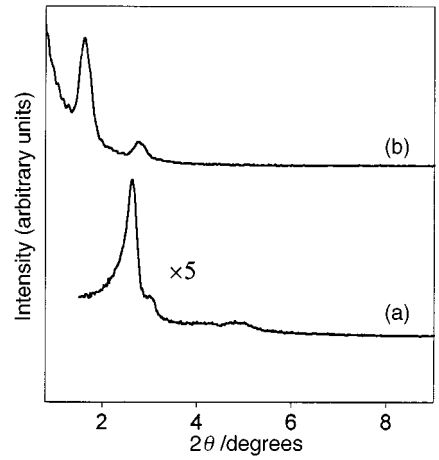

Fig. 1 X-Ray diffraction (XRD) patterns of AlMCM-48 template (a) and mesoporous SNU-1 carbon (b). Trace (a) was obtained with a Rigaku D/Max-3C diffractometer equipped with a rotating anode and Cu-Kα radiation ($\lambda = 0.15418$ nm) and trace (b) was acquired on a Bruker GADDS small-angle X-ray scattering diffractometer with a general area detector.

nitrogen BET adsorption measurements. This is comparable to values reported for other mesoporous inorganic materials. Nitrogen adsorption–desorption curves showed hysteresis at high relative pressure characteristic of mesopores. The pore size distribution data calculated from the adsorption branch of the nitrogen isotherm by the BJH (Barrett–Joyner–Halenda) method showed that pores are uniform with an average pore size of 2.3 nm (Fig. 3).

The EDLC performance of SNU-1 was compared to the most popularly applied activated carbon, MSC-25. Fig. 4 shows the cyclic voltammograms of two carbon electrodes that were obtained in organic electrolyte (1 M NEt_4BF_4 in propylene carbonate). An immediately apparent feature is that SNU-1 shows a more ideal capacitor behavior than MSC-25 with a steeper current change at the switching potentials (0.0 and 3.0 V), resulting in a more rectangular-shaped (mirror-imaged) *i*–*V* curve. An important characteristic of electrical energy storage in a capacitor is that energy is retrievable in discharge over the same potential range as that required to store the energy on charging, otherwise the energy storage is limited. The slow changes at the switching potentials in the cyclic voltammogram (CV) of MSC-25 electrode stem from the slow re-organization

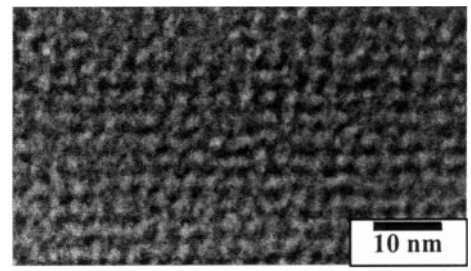

Fig. 2 Transmission electron micrograph (TEM) of mesoporous SNU-1 carbon. The image was obtained with a Phillips CM-20 instrument.

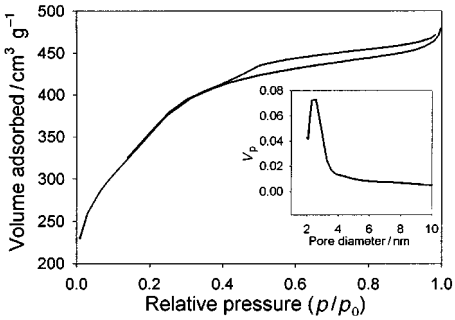

Fig. 3 N_2 adsorption and desorption isotherms of mesoporous SNU-1 carbon. (Inset) The corresponding pore size distribution curve calculated from the adsorption branch of the nitrogen isotherm by the BJH method. V_p is the incremental pore volume. The isotherms were collected at 77 K on a Micrometrics ASAP2010 Gas Adsorption Analyzer after the carbon material was degassed at 250 °C at 30 μTorr for 5 h.

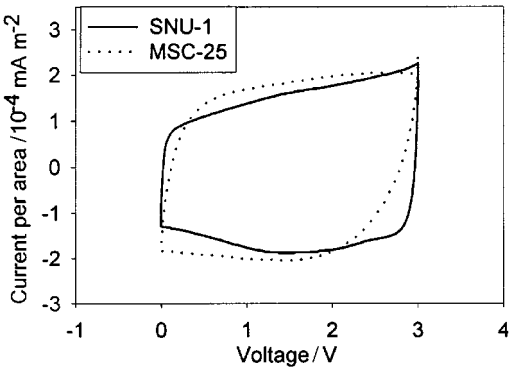

Fig. 4 Cyclic voltammograms of SNU-1 and MSC-25 activated carbon in organic electrolyte (1 M NEt_4BF_4 in propylene carbonate). A two-electrode system consisting of working and counter electrodes was used. These two electrodes were fabricated with equal amounts of the carbon materials. CV measurements were made in the potential range 0–3 V with a scan rate of 5 mV s^{-1}.

of the double layer owing to slow ionic motions in micropores. The steep changes in the CV of the SNU-1 electrode in turn reflect the dominance of regular interconnected mesopores among electrochemically usable pores.

When cyclic voltammetry of SNU-1 carbon was performed in an aqueous electrolyte solution (2 M H_2SO_4), a similar rectangular-shaped pattern was obtained. Rectangular-shaped cyclic voltammograms over a wide range of scan rates is the ultimate goal in EDLC. This behavior is very important for practical applications. First, a higher energy density is expected, because the usable potential range is wide. Second, a higher power density is expected as the critical scan rate is increased. SNU-1 carbon is much closer to this behavior than MSC-25. When cyclic voltammograms were recorded for these two carbons in an aqueous electrolyte solution by varying the scan rate from 5 to 50 mV s^{-1}, SNU-1 carbon retained a rectangular shape up to a scan rate of 20 mV s^{-1}. By contrast, MSC-25 carbon showed a deformed cyclic voltammogram at a scan rate of 10 mV s^{-1} and a completely collapsed one at a scan rate of 20 mV s^{-1}.

Received (in Columbia, MO, USA) 7th July 1999, Accepted 27th September 1999

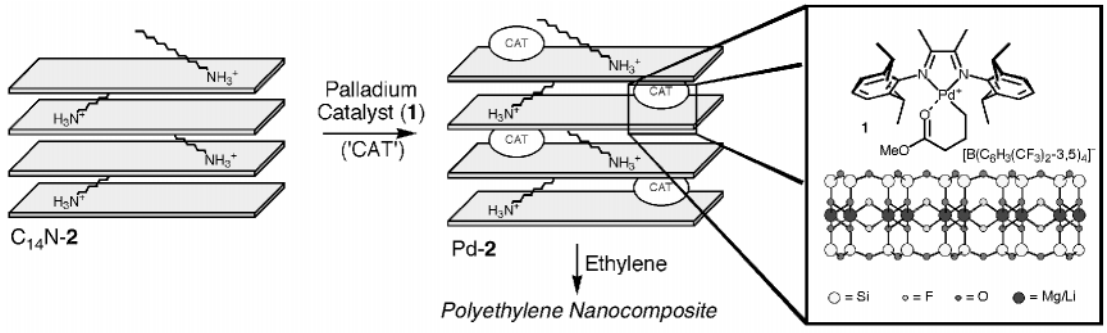
An organically modified fluorohectorite intercalated by a well-defined cationic palladium complex forms an exfoliated polyolefin–silicate nanocomposite material when exposed to olefinic monomer.

Polymer nanocomposites are a class of hybrid materials composed of an organic polymer matrix that is imbedded with inorganic particles which have at least one dimension in the nanometer size range.[1] At this scale, they can strongly impact the macroscopic properties of the polymer even though the materials typically contain only a few weight percent of the inorganic modifier. Dramatically improved properties such as higher heat distortion temperatures, enhanced flame resistance, increased modulus, better barrier properties, decreased thermal expansion coefficient, and altered electronic and optical properties have been discovered.[1–3] Due to the synergistic effects that result from adding a small amount of an inexpensive silicate, the synthesis and characterization of polymer nanocomposites has been intensely investigated in the last decade.[4] The majority of these studies have employed layered, anionic phyllosilicates as the inorganic component due to their high aspect ratio and ease of ionic modification. However, a simple physical mixture of the polymer and an intact, multilayered silicate does not typically yield improved properties. It is imperative that the polymer separates the individual silicate sheets, either in an intercalated morphology (silicate registry is retained) or preferably in a delaminated (or exfoliated) structure that is microscopically isotropic.

Despite the prime importance of polyethylene and polypropylene in a diverse array of applications, the synthesis of polyolefin–silicate nanocomposites remains a scientific challenge. Polymer nanocomposites can be synthesized by three primary strategies. The first is the melt intercalation of a polymer into an organically modified silicate.[5] Although this strategy works well with polar polymers such as polysiloxanes, polyethers and polystyrene,[1] polypropylene nanocomposites have only been formed using maleic anhydride modified polypropylene oligomers,[6] and ammonium-modified silicates are only partially intercalated by polyethylene.[7] The second strategy is the *in situ* formation of a layered silicate in an aqueous polymer solution.[8] Even though the development of this promising technique is just in its infancy, it will likely be limited to polymers that are soluble in water. A third strategy that is receiving increasing attention involves a silicate that is intercalated by an initiator or catalyst,[9] and, upon introduction of a monomer an intercalated or exfoliated polymer nanocomposite is formed (Scheme 1). This approach can eliminate both entropic and enthalpic barriers associated with intercalating polar silicates with nonpolar polymers, and has been used to synthesize a range of polymer nanocomposites. Concerning polyolefins, O'Hare and coworkers have reported the intercalation of synthetic layered silicates with a cationic Ziegler–Natta catalyst after protecting the internal surfaces with methylaluminoxane.[10,11] Addition of propylene produced polypropylene oligomers, however the post-polymerization structure of the silicate–polymer mixture was not reported.[10] It must be noted that the silicate galleries often contain protic impurities and polar functional groups; therefore only a select group of initiators and catalysts can be employed in unprotected silicate galleries. Although the vast majority of olefin polymerization catalysts are highly sensitive to Lewis bases and water, Brookhart and coworkers have reported a remarkable class of late-transition metal olefin polymerization catalysts that are particularly stable under these conditions.[12,13] In this paper we report the synthesis of polyolefin nanocomposites by employing these robust catalysts using an *in situ*, 'ship-in-the-bottle' polymerization approach.

We chose to investigate Brookhart's single component palladium-based complex {**1**; [{2,6-$Pr^i_2C_6H_3N$=C(Me)C(Me)=$NC_6H_3Pr^i_2$-2.6}$Pd(CH_2)_3CO_2Me$][$B(C_6H_3(CF_3)_2$-3,5)$_4$]}[13] and the well-studied synthetic silicate fluorohectorite (**2**)[14] as the polymerization catalyst and inorganic component of our composite, respectively. Lithium cations occupy the galleries of synthetic fluorohectorite; initial attempts to intercalate **2** with **1** failed, as evidenced by an immutable powder X-ray diffraction (XRD) pattern. Therefore we turned to an organically modified fluorohectorite (C_{14}N-**2**) that had 1-tetradecylammonium cations in the place of the interlayer lithium cations.[14] Suspension of C_{14}N-**2** in a toluene solution of **1**† yielded an orange–brown powder (Pd-**2**) that was visually

† Electronic supplementary information (ESI) available: Scanning transmission microscope (STEM) bright-field image of Pd-2. See http://www.rsc.org/suppdata/cc/1999/2179/



Scheme 1

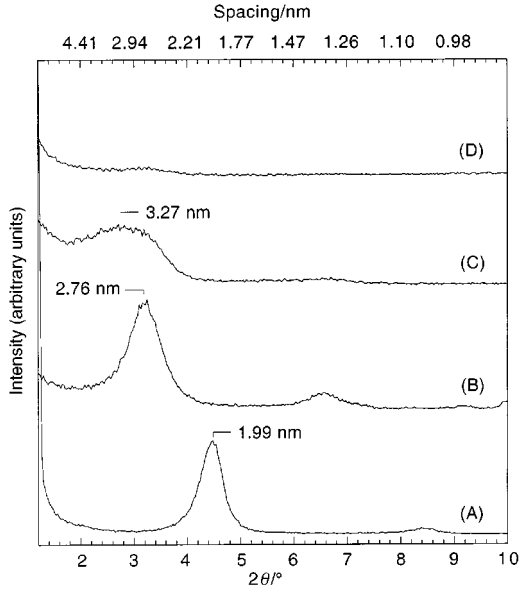


Fig. 1 Plot of powder X-ray diffraction intensity *versus* scattering angle: (A) 1-tetradecylammonium modified fluorohectorite (C_{14}N-**2**); (B) C_{14}N-**2** after intercalation by **1** (Pd-**2**); (C) Pd-**2** after exposure to ethylene for 135 min; (D) Pd-**2** after exposure to ethylene for 24 h.

different from the white, pristine C_{14}N-**2**. This reaction is irreversible, as **1** cannot be extracted from Pd-**2** with excess toluene. Powder XRD of Pd-**2** revealed a structural change of the silicate, as an increase in the basal spacing of C_{14}N-**2** from 1.99 to 2.76 nm was measured. Molecular modeling shows that an interlayer spacing of at least 2.1 nm is necessary for **1** to exist in the interlayer galleries; therefore the new spacing of 2.76 nm can easily accommodate the palladium complex. However, on the basis on these results, it was not clear whether this reaction was a cation exchange process, in which ammonium ions were exchanged for the cation of **1**, or whether the entire ionic palladium complex entered the silicate without ammonium discharge. Analysis of the material remaining in solution after intercalation using ^{1}H NMR spectroscopy revealed the absence of shifts due to the aliphatic ammonium cation, and the ratio of signal intensities assigned to the cation and anion of unintercalated **1** remained unchanged. These results clearly demonstrate that both the cation and anion of **1** enter the ammonium-modified silicate, and the ammonium cation remains in the silicate as well. The driving force for this reaction is not currently known.

To investigate the polymerization activity of Pd-**2**, the dry solid was exposed to ethylene gas.‡ Over a two hour period, we observed monomer consumption and a dramatic increase in the size of the silicate–catalyst composite. After 12 h, the Pd-**2** material was unrecognizable; in the place of a small amount of orange, Pd-**2** powder was a large mass of colorless, rubbery polymer. Based on the elemental analysis of Pd-**2** and the assumption that all intercalated palladium species produced polyethylene, the turnover frequency [TOF = mol ethylene/(mol Pd h)] of the catalyst in Pd-**2** is 162 h^{-1}. Consistent with the results of Brookhart, the polymer produced is highly branched. Analysis of the toluene-extracted polyethylene by gel-permeation chromatography revealed high molecular weight polymer (M_n = 159 000; M_w = 262 000 *versus* polystyrene standards).[13] To establish the arrangement of the silicate sheets in the polymer matrix, the polyethylene composite formed after 24 h was examined by powder XRD. The complete absence of diffraction peaks strongly suggests the formation of an exfoliated polymer nanocomposite. Under the same conditions addition of propylene gas to Pd-**2** also produces a polypropylene–silicate nanocomposite, however at a much slower rate (TOF = 5.6 h^{-1}).

To further confirm that silicate delamintion occurs during ethylene polymerization, we monitored the progress of the reaction using XRD. Shown in Fig. 1 are the XRD data as a function of reaction time. At t = 0, the mean repeat distance of the silicate sheets is 2.76 nm. After exposure of Pd-**2** for 135 minutes the interlayer spacing increases to 3.27 nm. The significant increase in peak width is due to the loss of crystallinity of the silicate. Finally, at 24 h the XRD revealed the absence of significant diffraction, consistent with dispersion. Since XRD only provides informative data at spacings less than 5 nm, we employed scanning transmission electron microscopy (STEM) to provide structural information at larger layer spacings (longer reaction times). By terminating the reaction at 12 h, we were able to identify layer spacings in the 5–8 nm range, well outside the range that we could achieve by XRD. A bright-field STEM image of the nanocomposite is available as supplementary data (http://www.rsc/org/suppdata/cc/1999/2179). It shows overlaid stacks of the silicate layers (dark area), where the polymer-intercalated layers remain predominantly coplanar at this stage of the reaction.

In conclusion, we report the first synthesis and characterization of polyolefin nanocomposite materials using an *in situ* polymerization approach. In the initial stages of the reaction polymer-intercalated silicates are formed; at later stages of the reaction the XRD data are consistent with silicate exfoliation. Efforts to extend this strategy for the synthesis of nanocomposite materials using isotactic polypropylene and linear polyethylene as the continuous phase are currently underway.

Brookhart for helpful discussions. G.W.C. gratefully acknowledges a Camille and Henry Dreyfus New Faculty Award, an Alfred P. Sloan Research Fellowship, an NSF Career Award, as well as Dupont and 3M for support of this research.

Notes and references

† Fluorohectorite (**2**) employed in these experiments had a cation exchange capacity of 1.5 mmol Li^+ g^{-1} ($Li_{1.12}[Mg_{4.88}Li_{1.12}]Si_8O_{20}F_4$). The initial interlayer spacing is 1.20 nm. The catalyst-intercalated fluorohectorite was synthesized by adding 50 ml of dry toluene to 95 mg of C_{14}N-**2**[14] and 155 mg of **1**, and stirring for 12 h at 22 °C. The suspension was filtered off, washed with toluene, and dried *in vacuo* to give 174 mg of Pd-**2**. Based on the increase in weight of C_{14}N-**2**, the composition of Pd-**2** is calculated to be $(\mathbf{1})_{0.55}\{H(CH_2)_{14}NH_3\}_{1.12}[Mg_{4.88}Li_{1.12}]Si_8O_{20}F_4$. Based on the interplanar spacing of Pd-**2** (27.6 Å) and an estimated volume of **1** (1750 Å^3), the composition of Pd-**2** is calculated (neglecting the contribution of surface-bound **1**) to be $(\mathbf{1})_{0.4}\{H(CH_2)_{14}NH_3\}_{1.12}[Mg_{4.88}Li_{1.12}]Si_8O_{20}F_4$. Elemental analysis of Pd-**2** corresponds to $(\mathbf{1})_{0.7}\{H(CH_2)_{14}NH_3\}_{1.12}[Mg_{4.88}Li_{1.12}]Si_8O_{20}F_4$: calc. (found): C, 36.38 (36.47); H, 3.92 (4.15); N, 1.75 (1.58%). Therefore, the composition of Pd-**2** can only be estimated at the current time.

‡ Ethylene gas (80 psi) was reacted with solid Pd-**2** (129 mg) at 22 °C for 12 h, yielding 3.50 g of a rubbery, white solid.

Change of electron-transfer path-selectivity in a triad by F^--coordination at a boronate-ester bridge

Hideo Shiratori,[a] Takeshi Ohno,[b] Koichi Nozaki[b] and Atsuhiro Osuka*[a]

[a] *Department of Chemistry, Graduate School of Science, Kyoto University, Kyoto 606-8502, Japan. E-mail: osuka@kuchem.kyoto-u.ac.jp*

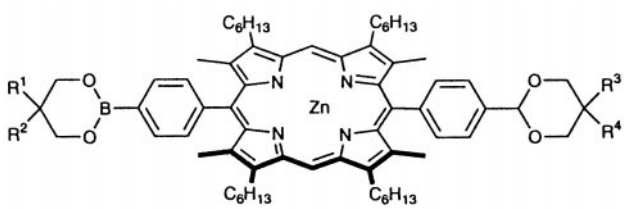
[b] *Department of Chemistry, Graduate School of Science, Osaka University, Toyonaka, 560-8531, Japan*

Received (in Cambridge, UK) 10th August 1999, Accepted 28th September 1999

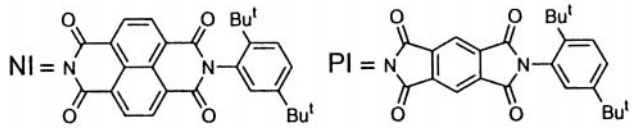
In a triad comprising of a zinc porphyrin donor (ZP) appended to a naphthalene-1,8:4,5-tetracarboxylic diimide (NI) and a pyromellitic diimide (PI) through a boronate ester and an acetal bridge, respectively, F^--coordination at the boronate bridge induced clear switching of the electron-transfer path from ^{1}ZP* → NI to ^{1}ZP* → PI.

Electron-transfer (ET) path-selectivity is one of the key issues in understanding the mechanism of primary charge separation in photosynthetic reaction centers (RCs).[1] In spite of the highly C_2 symmetric structure, only the L-branch is ET active in RC. This ET path-selectivity is strongly guided by the surrounding proteins in which electron carriers of the RC are embedded and it seems difficult to realize ET flow along the M-branch even in RCs of a variety of site-directed mutants.[2] Control of ET path-selectivity such that an unfavorable ET path can be made preferential over a favorable one without a drop in rate by external input will be quite useful not only for construction of artificial ET molecular devices but also in understanding the factors which govern biological ET reactions. In order to realize this control, the external input must trigger two effects, *i.e.* to *block* a *favorable* ET path and simultaneously to *accelerate* an *unfavorable* ET path. Here, we demonstrate that this ET path control is indeed possible in triad **1** comprising of a zinc porphyrin donor (ZP) appended to a naphthalene-1,8:4,5-tetracarboxylic diimide (NI) and a pyromellitic diimide (PI), through a boronate ester and an acetal bridge, respectively (Scheme 1). Important structural features are as follows; (1) the two bridges are similar in length,[3] (2) NI is a stronger electron acceptor than PI by 0.3 V,[4] and (3) intramolecular ET from ^{1}ZP* to NI across a boronate bridge can be suppressed upon F^--coordination.[5]

In benzene, the fluorescence intensities of **1**, **2** and **3** relative to that of **4** were 0.45, 0.44 and 0.89, respectively. This fluorescence quenching suggests intramolecular charge separation (CS) between ^{1}ZP* and NI or PI which has been confirmed by picosecond-time resolved transient absorption spectra (Fig. 1).[6] Absorption peaks due to the radical anion were observed at 475, 610 and 790 nm (NI^-) for **2**, and at 721 nm (PI^-) for **3**, providing clear evidence for formation of NI^-–ZP^+ and ZP^+–PI^-,[4] respectively. The transient absorption studies revealed that excitation of ZP with 532 nm laser pulses in **2** and **3** yielded NI^-–ZP^+ with τ_{CSN} = 0.52 ns and ZP^+–PI^- with τ_{CSP} = 1.1 ns, respectively.[7] Lifetimes of these ion pairs were both longer than 6 ns. Upon similar laser excitation of ZP in **1**, the absorbance due to ^{1}ZP* around 460 nm decayed with τ = 0.46 ns, and the transient absorption spectrum at 3 ns delay time is practically the same as that of **2** except for a small band at 721 nm due to PI^-, indicating that CS between ^{1}ZP* and NI is dominant in **1**. Comparison of decay time constants of ^{1}ZP* in **1**–**3** led to the conclusion that excitation of ZP in **1** leads to formation of NI^-–ZP^+ and ZP^+–PI^- in a ratio of 11:1 (Scheme 2).



1 ; R^1=NI, R^3=PI, R^2=R^4=H
2 ; R^1=NI, R^2=H, R^3=R^4=Me
3 ; R^1=R^2=Me, R^3=PI, R^4=H
4 ; R^1=R^2=R^3=R^4=Me



Scheme 1 Structures model **1** and reference molecules **2**–**4**.

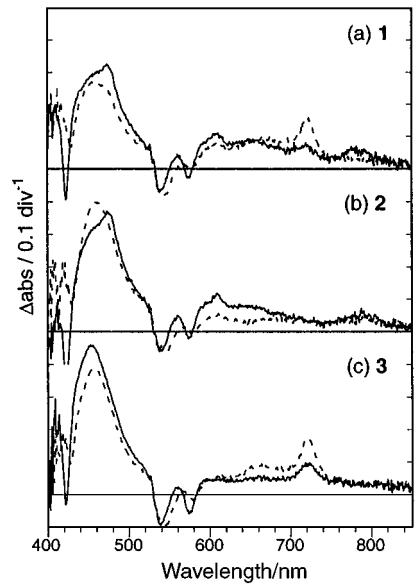


Fig. 1 Transient absorption spectra of (a) **1**, (b) **2** and (c) **3** in benzene at 3 ns; (——) no TBAF; (·····) in the presence of 1.2 equiv. TBAF.

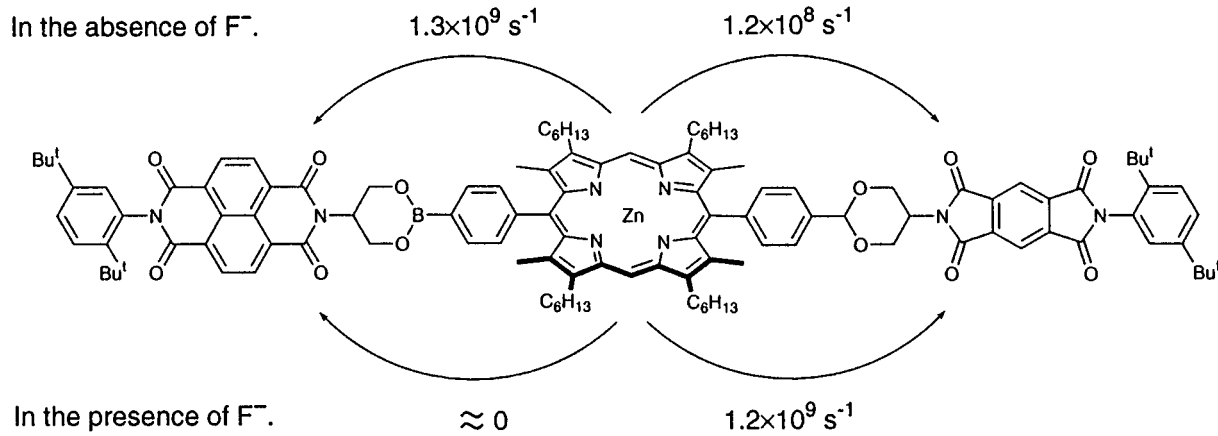
In the presence of 1.2 equiv. of tetra-*n*-butylammonium fluoride (TBAF), relative fluorescence intensities of **1**, **2** and **3** to **4** were 0.65, 0.98 and 0.72, respectively. The transient absorption spectra of **2** [Fig. 1(b), dotted line] are practically the same as those of **4** (not shown) from 20 ps to 6 ns delay times, featuring no CS but simple intersystem crossing of ^{1}ZP* → ^{3}ZP* with τ = 1.5 ns. Thus CS between ^{1}ZP* and NI in **2** is completely suppressed in a F^--coordinated form as reported previously.[5] This CS suppression may be explained in terms of decreased electronic coupling between ^{1}ZP* and NI across a F^--coordinated boronate bridge possibly due to the high energy LUMO of the bridge in comparison to that in a neutral bridge.[8] Considering the similar CS suppression in **1**, its fluorescence quenching should be ascribed to CS between ^{1}ZP* and PI. This



Scheme 2 ET-path selectivity of **1** in the absence and presence of F^-.

has been confirmed by the transient absorption spectrum [Fig. 1(a), dotted line], which shows the appearance of a 721 nm absorption peak, thus indicating CS between ^{1}ZP* and PI instead of NI. Here it is interesting to note that the F^--coordination not only blocks ET to NI but also accelerates ET to PI significantly. On the basis of the analysis of the time profile of the rise at 721 nm, the CS rate constant in F^--coordinated **1** has been determined to be 1.2×10^9 s^{-1}, which is *ca.* 10 times larger compared to that occurring in neutral **1**. Similar acceleration of CS between ^{1}ZP* and PI was also observed in F^--coordinated **3** ($k_{CS} = 6.5 \times 10^8$ s^{-1}). The acceleration of CS between ^{1}ZP* and PI upon F^--coordination on the boronate bridge can be explained on the basis of Coulomb interaction between the negative charge on the F^--coordinated boron atom and the ion-pair ZP^+–PI^-. In nonpolar solvents like benzene, the tetracoordinated boronate exists as a tight ion pair. However, it is reasonable to consider that electrostatic attraction between the negative charge at the tetracoordinated boronate and the positive charge at the ZP^+ must be most influential among other electrostatic interactions in the system and thus the F^--coordination eventually leads to a decrease in the energy level of ZP^+–PI^-, thereby enhancing CS reaction between ^{1}ZP* and PI.

Switching of ET path-selectivity of **1** upon F^--coordination is summarized in Scheme 2, where the ET to NI is suppressed mainly by the electronic factor and the ET to PI is accelerated mainly by the nuclear factor. The boronate-bridged acceptor–donor–acceptor architectures will be useful, since they provide a convenient and efficient way to control the ET path selectivity in a predictable manner as such that ET over the boronate-bridge will be suppressed and ET in the opposite direction from the boronate bridge will be accelerated.

Rapid syntheses of difluorinated polyols using a cleavable carbamate

Andrew S. Balnaves,[a] Michael J. Palmer[b] and Jonathan M. Percy*[a]

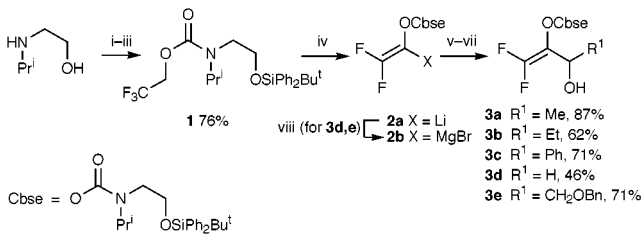
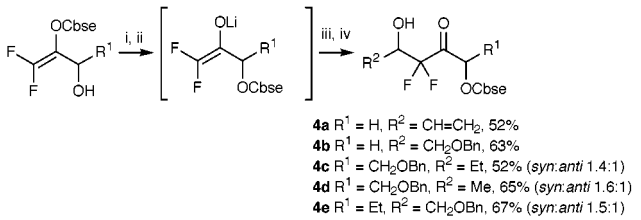
Received (in Cambridge, UK) 6th September 1999, Accepted 28th September 1999

Trifluoroethyl *N*-[2-(*tert*-butyldiphenylsilyloxy)ethyl]-*N*-isopropylcarbamate undergoes smooth dehydrofluorination–metallation followed by $BF_3{\cdot}OEt_2$ mediated addition to aldehydes to afford a range of allylic alcohols; aldol reaction with a second aldehyde, then reduction, affords products which can be deprotected to afford difluorinated polyols.

We have been developing metallated difluoro-enol carbamates[1] derived from trifluoroethanol as versatile building blocks[2] for the synthesis of selectively fluorinated polyfunctional molecules. To date, we have concentrated on *N*,*N*-diethylcarbamates which, while synthetically versatile[3,4] and inexpensive to synthesise, are chemically robust. The latter property represents an apparent impediment to carbamate cleavage and hydroxy group unmasking so recently, we made use of the cleavable carbamate described by Derwing and Hoppe,[5] synthesising **1** by a standard route (Scheme 1). Dehydrofluorination–metallation to **2a** proceeded smoothly under our published conditions[6] and allylic alcohols **3a**–**c** were synthesised in moderate to good yield using $BF_3{\cdot}OEt_2$ to attenuate the transacylation reaction.[7] Acceptable yields of **3d** and **3e** (46 and 71% respectively) could only be secured by transmetallating **2a** to **2b** using $MgBr{\cdot}OEt_2$ prepared freshly according to the method of Harwood *et al*.,[8] and raising the reaction temperature to −30 °C before the addition of the Lewis acid and electrophile. Next, we explored the aldol chemistry and confirmed that our published conditions transferred smoothly; adducts **4a**–**e** were duly prepared (Scheme 2) in moderate to good yields by treatment of the allylic alcohols with BuLi at low temperature and allowing the enolate solution to warm to −10 °C before the addition of the aldehyde electrophile. Stereoselectivities were low as expected but the *syn* and *anti* diastereoisomers could be separated by careful column chromatography.†

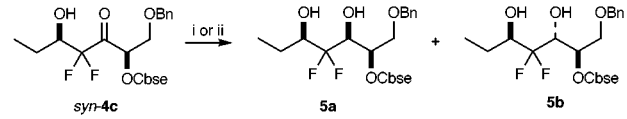


Scheme 1 *Reagents and conditions*: i, Bu^tPh_2SiCl (1.1 equiv.), DMAP (0.5 equiv.), CH_2Cl_2, reflux, 12 h; ii, diphosgene (0.5 equiv.), Et_3N (1.5 equiv.), CH_2Cl_2, 0 °C, then room temp., 16 h; iii, CF_3CH_2ONa, THF, reflux, 16 h; iv, LDA, THF (2.0 equiv.), –78 °C; v, R^1CHO; vi, $BF_3{\bullet}OEt_2$, then warm to 0 °C; vii, NH_4Cl (aq.); viii, $MgBr_2{\bullet}OEt_2$.

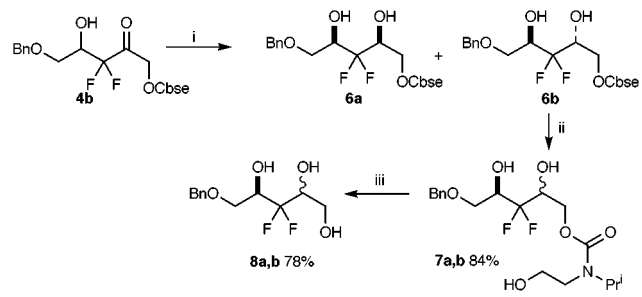


Scheme 2 *Reagents and conditions*: i, BuLi, THF, –78 °C; ii, warm to –10 °C; iii, R^2CHO; iv, NH_4Cl (aq.).

To make further progress in the direction of polyol targets, reduction of **4c** was attempted under the stereoselective conditions described by Kuroboshi and Ishihara,[9] but very sluggish reactions ensued (Scheme 3). We had hoped that the reductions would proceed smoothly, and that the β-hydroxy group would provide control over the stereochemical course of the reduction, overriding any asymmetric induction exerted by the adjacent (α) stereogenic centre. Under the *syn*-selective conditions (DIBAL-H, $ZnCl_2$, TMEDA), both the yield of **5a** and **5b** (31% combined) and stereoselectivity (1.8:1 *syn*:*anti*)‡ were low from *syn*-**4c** and the conversion was poor (37% recovered **4c** after 6 h), a consequence presumably of the bulk of the carbamoyloxy group. The *anti*-selective Meerwein–Pondorf–Verley reduction [$Al(OPr^i)_3$, PhH] conditions were more successful affording a higher (66% combined) yield of **5a** and **5b**. However, whereas the published procedure achieves the reduction smoothly overnight at room temperature, we failed to observe any reaction until the mixture had stirred for 4 days. We then turned our attention to the less stereochemically complex **4b**; both stereoselective reductions failed completely, so to take compound through to the diol stage, we performed a simple $NaBH_4$ reduction and isolated a 2:1 mixture of *syn*- and *anti*-diols **6a** and **6b** in 78% yield (Scheme 4).§ Attempts to cleave the carbamate protection then ensued. We modified the published conditions and found that dilute HF in aqueous MeCN effected a satisfactory desilylation, allowing triols **7a** and **7b** to be isolated in 84% yield. Exposure to KOH (1 equiv.) in MeOH at room temperature allowed the isolation of **8a** and **8b** in a disappointing 20% yield. However, removing the MeOH *in vacuo* then taking the residue up in EtOAc followed by an extractive work up yielded separable triols **8a** and **8b** (78%),



Scheme 3 *Reagents and conditions*: i, DIBAL-H, $ZnCl_2{\bullet}$TMEDA, THF, –78 °C; ii, $Al(OPr^i)_3$, PhH, room temp., 4 days.



Scheme 4 *Reagents and conditions*: i, $NaBH_4$, MeOH, 0 °C; ii, 48% HF (aq.)–MeCN (1:9), room temp.; iii, KOH (1.0 equiv.), MeOH, room temp.

proving that the Hoppe carbamate can be deployed successfully in our dehydrofluorination–metallation and aldol chemistry *and* that protecting group removal can be achieved under mild conditions. Clearly, there exists considerable scope for the improvement of functional group manipulation chemistry: studies describing our efforts to develop stereoselective reduction chemistry and optimise deprotection will be described elsewhere.

The authors wish to thank the Engineering and Physical Sciences Research Council of Great Britain and Pfizer Central Research for a CASE Award (to A. S. B.).

Notes and references

† Diastereoisomer ratios were assigned on the basis of ^{19}F NMR chemical shifts as described in ref. 6.

‡ This assignment assumes the same sense of stereoselection as that described in ref. 9.

§ The two diastereoisomers have radically different ^{19}F NMR spectra; one isomer appears as a well-separated AB system split further by $^{3}J_{H\text{-}F}$ couplings whereas the other appears as a broad unresolved signal. We have tentatively assigned these spectra to the 1,3-*syn* and 1,3-*anti* diastereoisomers **6a** and **6b** respectively on the basis that the fluorine atoms in the former are decidedly heterotopic. In the latter, the *pseudo*-C_2 symmetry confers a degree of homotopicity upon the fluorine atoms, hence the appearance of the signal observed. Obviously, definitive proof of this assignment is being sought currently.

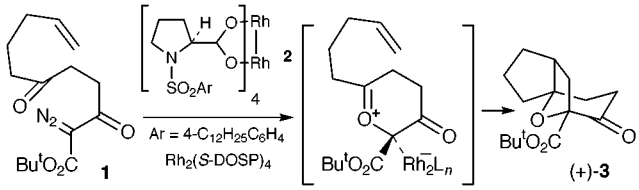
Received (in Liverpool, UK) 19th August 1999, Accepted 17th September 1999

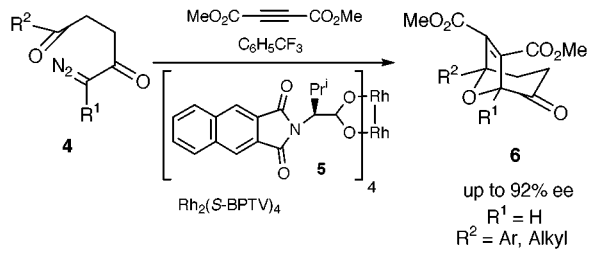
Catalytic enantioselective tandem carbonyl ylide formation–cycloadditions of α-diazo-β-keto ester 1 using 0.5 mol% dirhodium tetrakis(1,1′-binaphthyl-2,2′-diyl phosphate) catalysts 7–9 and 14 to give the cycloadduct 3 in good yields and up to 90% ee are described.

There are currently few methods to achieve catalytic enantioselective 1,3-dipolar cycloadditions, despite the potential utility of such asymmetric transformations.[1] In 1997 we reported the first observations of catalytic enantioselective tandem carbonyl ylide formation–cycloaddition (up to 53% ee) using unsaturated α-diazo-β-keto esters.[2] For example, reaction of α-diazo-β-keto ester **1** using 1 mol% Rh_2(*S*-DOSP)$_4$ **2** in hexane at room temperature gave cycloadduct (+)-**3**† in 93% yield and 52% ee (Scheme 1).[3]



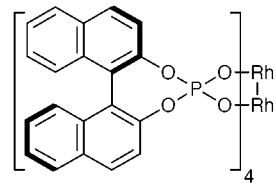
Scheme 1

More recently, research groups led by Doyle,[4] Ibata[5] and Hashimoto[6] have reported conceptually related (but intermolecular) asymmetric carbonyl ylide cycloadditions. The asymmetric induction in these cycloadditions was low (< 30% ee), aside from the work by Hashimoto using α-diazo ketones with DMAD as the dipolarophile, where ees up to 92% were reported (Scheme 2, R^1 = H, R^2 = Ph, absolute sense of asymmetric induction not determined).

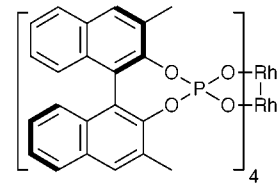


Scheme 2

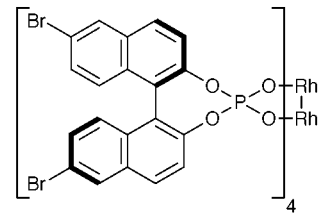
Although we have screened a number of chiral rhodium carboxylate catalysts with α-diazo-β-keto ester **1**,[7] none have delivered asymmetric induction levels close to those observed with Rh_2(*S*-DOSP)$_4$ **2**. Also, applying the optimised catalyst–solvent combination for intermolecular cycloaddition of α-diazo ketones with DMAD reported by Hashimoto[6] [Rh_2(*S*-BPTV)$_4$ **5**, $PhCF_3$, *cf*. Scheme 2] to α-diazo-β-keto ester **1** at 25 °C resulted in only essentially racemic cycloadduct **3** (90% yield, 1% ee). Furthermore, cycloadduct **6** (R^1 = CO_2Et, R^2 = Me) was obtained in only 33% ee under the same conditions in the reaction of α-diazo-β-keto ester **4** (R^1 = CO_2Et, R^2 = Me) with DMAD [α-diazo ketone **4** (R^1 = H, R^2 = Me) gave cycloadduct in 80% ee].[6] These latter results indicate that ee is rather sensitive to variation in the electronic structure of the dipole. A variety of chiral, non-racemic dirhodium carboxylates and carboxamidates have been extensively examined as asymmetric catalysts in a number of diazocarbonyl transformations.[4] However, in seeking to develop more efficient catalysts for asymmetric carbonyl ylide formation–cycloaddition, we were attracted to the isolated reports in 1992 by Pirrung[8] and McKervey[9] concerning 1,1′-binaphthyl-2,2′-diyl phosphate (BNP) catalysts Rh_2(*S*-BNP)$_4$ (*ent*-**7**) and Rh_2(*R*-BNP)$_2$(O_3CH)$_2$·5H_2O respectively for diazocarbonyl decomposition. C–H insertion and cyclopropanation were among the asymmetric processes investigated (up to 60% ee). Here we communicate our preliminary studies on such catalysts which lead to improved enantioselectivities in tandem carbonyl ylide formation–cycloaddition of α-diazo-β-keto esters.



Rh_2(*R*-BNP)$_4$ **7**



Rh_2(*R*-DMBNP)$_4$ **8**



Rh_2(*R*-DBBNP)$_4$ **9**

Initial investigation of Pirrung's structurally well-defined catalyst Rh_2(*R*-BNP)$_4$ **7** with α-diazo-β-keto ester **1** in hexane at 25 °C gave an immediate improvement in ee of the cycloadduct (+)-**3** (64% ee, Table 1, entry 1) compared with Rh_2(*S*-DOSP)$_4$ **2** (52% ee), even though Rh_2(*R*-BNP)$_4$ **7** was only partially soluble in hexane at 25 °C. Interestingly, asymmetric induction was maintained in CH_2Cl_2 at 25 °C (65% ee, entry 2); this compares with 8% ee previously obtained using Rh_2(*S*-DOSP)$_4$ **2** in CH_2Cl_2.[2] Whilst Rh_2(*R*-BNP)$_4$ **7** remained soluble in CH_2Cl_2 at 0 °C, no improvement in ee was observed (64%, entry 3). The results with Rh_2(*R*-BNP)$_4$ **7** prompted a study of the effects of structural variation of the binaphthyl core on enantioselectivity.

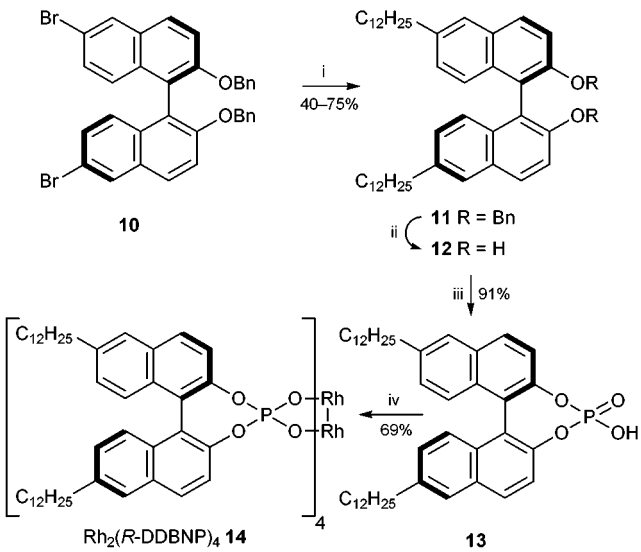
Substitution at the 3,3′-positions was first examined using Rh_2(*R*-DMBNP)$_4$ **8**, which was prepared (79%) by an analo-

Table 1 Effect of catalyst on the yields and enantioselectivities of formation of cycloadduct **3** from α-diazo-β-keto ester **1**

Entry	Catalyst	Solvent	*T*/°C	Yield of **3** (%)	Ee of **3** (%)[a]
1	**7**	hexane	25	65	64
2	**7**	CH_2Cl_2	25	83	65
3	**7**	CH_2Cl_2	0	55	64
4	**8**	CH_2Cl_2	25	50	7
5	**9**	hexane	25	34	66
6	**9**	CH_2Cl_2	25	67	58
7	**9**	CH_2Cl_2	0	36	61
8	**14**	CH_2Cl_2	25	80	68
9	**14**	hexane	25	76	81
10	**14**	hexane	0	81	88 (89)
11	**14**	hexane	−15	66	90 (90)

[a] Ees were determined on the methyl ester [obtained from **3** by hydrolysis–esterification (TFA, CH_2Cl_2, then MeOH, TsOH)] by ^{1}H NMR analysis of the split methoxy signal using Pr(hfc)$_3$. Ees in parentheses were determined on the benzyl oxime ether (*O*-benzylhydroxylamine hydrochloride, NaOAc, MeOH) of the methyl ester by HPLC analysis (Daicel Chiralpak AD, 10% EtOH–hexane) of the major geometric isomer.

gous procedure[8] to Rh_2(*R*-BNP)$_4$ from $Rh_2(OAc)_4$ by ligand exchange using the known 3,3′-dimethyl-1,1′-binaphthyl-2,2′-diyl hydrogen phosphate.[10] However, reaction of Rh_2(*R*-DMBNP)$_4$ **8** with α-diazo-β-keto ester **1** led to no cycloadduct in hexane and a low ee (7%) of (+)-**3** in CH_2Cl_2 (Table 1, entry 4), possibly due to steric congestion at the axial binding sites on the dirhodium core, which (in CH_2Cl_2) might also facilitate catalyst release to give the free ylide for cycloaddition. Substitution at the 6,6′-positions has been a successful tactic to alter asymmetric induction with binaphthyl-based catalysts.[11] Rh_2(*R*-DBBNP)$_4$ **9**, available from 6,6′-dibromo-1,1′-binaphthyl-2,2′-diyl hydrogen phosphate,[12] induced similar ees to Rh_2(*R*-BNP)$_4$ **7** (entries 5–7). With the primary aim of investigating a more hydrocarbon-soluble catalyst, Rh_2(*R*-DDBNP)$_4$ was synthesised according to Scheme 3.



Scheme 3 *Reagents and conditions*: i, $C_{12}H_{25}MgBr$, $Ph_2P(CH_2)_3PPh_2$–$NiCl_2$ (1 mol%), Et_2O, reflux, 48 h; ii, TMSCl, NaI, MeCN, $PhCH_3$, 40 °C, 2 h (89%); iii, $POCl_3$, Py, 25 °C, 1 h, then H_2O, $NaHCO_3$; iv, $Rh_2(OAc)_4$, PhCl, reflux, 5 h.

The known bisether **10**[13] was cross-coupled[14] with commercially available dodecylmagnesium bromide (40–75%, Scheme 3). Deprotection of the resultant didodecyl bisether **11** using TMSI[15] gave diol **12** (89%). Formation of the acid **13** (91%) from the diol **12** under standard conditions followed by ligand exchange[16] gave Rh_2(*R*-DDBNP)$_4$ **14** (69%).‡ Although only a slight rise in the ee of (+)-**3** was noted with Rh_2(*R*-DDBNP)$_4$ **14** in CH_2Cl_2 (Table 1, entry 8) compared with Rh_2(*R*-BNP)$_4$ **7** at 25 °C, the new catalyst was significantly more effective in hexane (81% ee, entry 9). Moreover, catalyst solubility and activity were maintained in hexane at 0 °C and asymmetic induction rose to give the cycloadduct (+)-**3** in 81% yield and 89% ee (entry 10). A similar ee (90%) was observed on conducting the reaction at −15 °C (entry 11) whereas reaction at −30 °C was very slow and gave a complex product mixture from which no cycloadduct was isolable.

Our results indicate that dirhodium tetrakis(1,1′-binaphthyl-2,2′-diyl phosphate) catalysts can be superior to the more commonly utilised carboxylates and carboxamidates in asymmetric transformations of diazocarbonyl compounds and deserve to be more fully investigated.

We thank Zeneca (now AstraZeneca) for support of this work, St. Hugh's College for a Jubilee Scholarship (to P. A. S.), the EPSRC National Mass Spectrometry Service Centre for mass spectra and Dr D. J. Watkin (Chemical Crystallography Laboratory, University of Oxford) and J. Ouzman for assistance with the X-ray structure analysis. We are also grateful to Professor M. C. Pirrung (Duke University) for an initial test sample of Rh_2(*S*-BNP)$_4$ and Dr I. Nash (AstraZeneca) for useful discussions.

Abatement of N_2O in the selective catalytic reduction of NO_x on platinum zeolite catalysts upon promotion with vanadium

Yvonne Traa, Beate Burger and Jens Weitkamp*

Institute of Chemical Technology I, University of Stuttgart, 70550 Stuttgart, Germany. E-mail: jens.weitkamp@po.uni-stuttgart.de

Received (in Cambridge, UK) 27th August 1999, Accepted 29th September 1999

The selectivity to N_2O during the selective catalytic reduction of NO_x on platinum-containing zeolite catalysts is reduced by incorporation of vanadium into the catalyst.

The selective catalytic reduction of nitrogen oxides by hydrocarbons is a promising process for the purification of exhaust gases from diesel-powered engines. Since the average temperature of diesel exhaust gases is well below 300 °C,[1] platinum-containing catalysts have proven to be efficient for this process owing to their low lightoff temperature. Another important advantage of platinum-containing catalysts is that they are comparatively insensitive to water in the exhaust gas.[2] However, a major drawback of these catalysts is that large portions of the nitrogen oxides are converted to nitrous oxide rather than to nitrogen. Nitrous oxide is highly undesirable, since it is a strong greenhouse gas and contributes to stratospheric ozone destruction.

In the past, several attempts were undertaken to overcome the N_2O problem with platinum-containing catalysts: Doumeki *et al.* reported that the selectivity to N_2 can be enhanced by using organoplatinum complexes such as $PtMe(OSiPh_3)(cod)$ instead of inorganic complexes as precursors for the preparation of Pt/SiO_2 or Pt/Al_2O_3 catalysts.[3] However, the N_2O selectivity remained as high as 65%. Wunsch *et al.* found that, upon adding CeO_2 to a Pt/ZSM-5 catalyst ($m_{CeO_2}/m_{Pt} \approx 4$), the maximum NO_x conversion increased from 48 to 59% without a change in temperature, whereas the selectivity to N_2O decreased from 62 to 54%.[4] More favourable results were reported by Seker and Gulari who observed an N_2O selectivity of only 17% on a Pt/alumina catalyst not prepared by the usual impregnation procedure but by a sol–gel process.[5] These results seem to be very promising, but further tests on the long-term and hydrothermal stability of the catalyst have yet to come. A totally different approach was followed by Burch and Ottery by changing the reductant: On a Pt/Al_2O_3 catalyst, no detectable amount of N_2O was formed with toluene as reducing agent at any temperature.[6] However, with this method one would be bound to toluene as reductant which is not a constituent of the exhaust gas stream.

We followed still another approach: in order to tune the activity and selectivity of platinum-containing catalysts we used a second metal as promoter. As depicted in Fig. 1, the selectivity to N_2O (S_{N_2O}) on platinum- and/or vanadium-containing H-ZSM-35 zeolites decreases considerably with increasing vanadium content of the catalyst. By contrast, the maximal NO_x conversion ($X_{NO_x,max}$) at T_{max} on Pt-V/H-ZSM-35 samples is similar to that on catalysts containing platinum only (Table 1). However, with increasing vanadium content of the samples, the temperature at the maximal NO_x conversion shifts to higher values. An explanation for this effect could be that the platinum is diluted by vanadium and, thus, the platinum clusters are smaller, facilitating effective NO_x reduction only at higher temperatures.

On catalysts containing platinum *and* vanadium, oscillations of the NO_x concentration with large amplitudes ($\Delta X_{NO_x,max}$[8]) tend to occur [Fig. 2(a), *cf.* ref. 9]. Owing to these oscillations, a precise determination of the selectivity to N_2O (*cf.* Fig. 1)

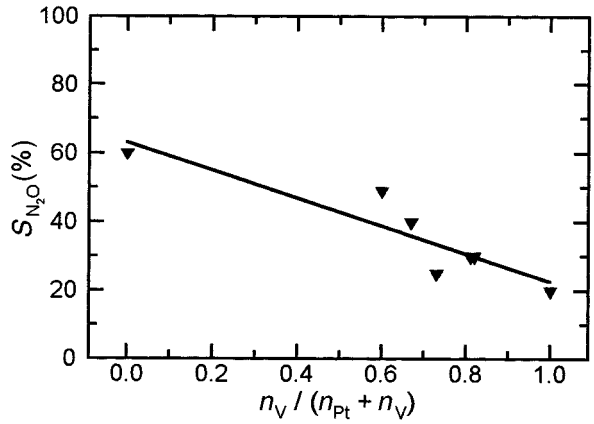

Fig. 1 Average selectivity to N_2O in the selective catalytic reduction of NO_x with propene as a function of the molar ratio $n_V/(n_{Pt} + n_V)$ of platinum- and/or vanadium-containing H-ZSM-35 zeolites.[7]

Table 1 Catalytic results on platinum- and/or vanadium-containing H-ZSM-35 samples

Catalyst	$X_{NO_x,max}$ (%)	$\Delta X_{NO_x,max}$ (%)	T_{max}/°C
1.0V/H-ZSM-35[a]	41	—	303
2.6Pt–3.1V/H-ZSM-35	81	19	215
0.9Pt–1.0V/H-ZSM-35	89	32	205
3.0Pt–2.2V/H-ZSM-35	82	21	212
1.9Pt–1.0V/H-ZSM-35	90	26	196
2.6Pt–1.0V/H-ZSM-35	97	40	177
2.7Pt/H–ZSM-35	85	—	165

[a] The numbers before the metals indicate the metal content in wt% in the dry catalyst.

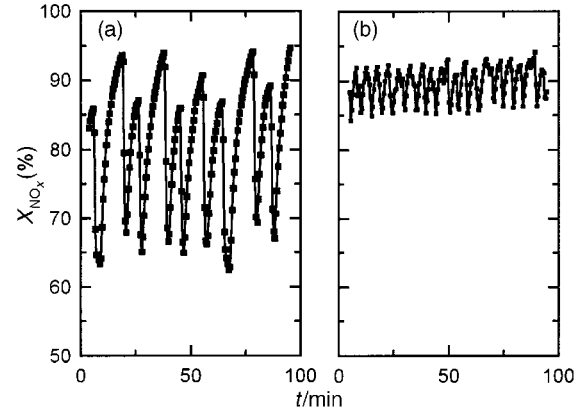

Fig. 2 NO_x conversion on (a) 0.2 g 2.6Pt–1.0V/H-ZSM-35, T_{cat} = 183 °C and (b) 0.2 g 2.6Pt–1.0V/H-ZSM-35 diluted with 0.7 g quartz, $T_{cat.}$ = 190 °C.

turns out to be difficult, because the N_2 concentration fluctuates considerably. Obviously, reaction, adsorption and desorption take place simultaneously and cannot be separated more properly, since the N_2O and N_2 concentrations change independently. First attempts to reduce the amplitude of the oscillations by diluting the catalyst with quartz sand are promising: for a mechanical mixture of the catalyst with quartz, the amplitude of the oscillations is strongly decreased, whereas the average NO_x conversion is even increased from 81 to 90% [Fig. 2(b)].

These observations prompted us to look in some detail into previously proposed reaction mechanisms. Burch *et al.* proposed that, on platinum, NO molecules are adsorbed in addition to N and O atoms resulting from NO dissociation.[10] The formation of N_2 can then be accounted for by recombination of two adsorbed N atoms, while the formation of N_2O is best interpreted in terms of the reaction of an adsorbed NO molecule with an N atom. We speculate that, in our system, most platinum atoms have vanadium atoms as next nearest neighbours. Owing to the higher affinity of vanadium for oxygen, the dissociation of NO could then be promoted resulting in a lower NO concentration on the surface and, hence, a lower selectivity to N_2O.

In conclusion, vanadium as a promoter is able to reduce considerably the selectivity to N_2O during the selective catalytic reduction of nitrogen oxides on platinum-containing zeolite catalysts. If the oscillations occurring on Pt–V/H-zeolites do not affect activity in real car exhausts or if the amplitudes can be strongly reduced by coating the catalyst onto monoliths in much the same way as this can be achieved by dilution with quartz, a major obstacle for the use of platinum catalysts in diesel exhaust gases could be overcome.

7 The catalytic experiments were performed in a flow-type apparatus with a fixed-bed reactor at atmospheric pressure. The gaseous components of the model exhaust gas were premixed and afterwards saturated with water vapour at 45 °C. Typically, the feed contained *ca.* 0.02 vol% NO_x, 0.06 vol% C_3H_6, 0.03 vol% CO, 4 vol% CO_2, 9 vol% O_2 and 10 vol% H_2O in He at a flow rate of 150 cm^3 min^{-1}. Tests with water concentrations of 6.6 and 3.3 vol% revealed that the influence of water on the average NO_x conversion is small. The mass of the hydrated catalyst amounted to 200 mg. The product stream was analysed for NO_x with a chemiluminescence detector; all other components were analysed by capillary gas chromatography.

Received (in Cambridge, UK) 27th August 1999, Accepted 14th September 1999

In the radical anion ($\mathbf{1}^{\bullet-}$) of acepentalene, generated by photooxidation of the corresponding dianion ($\mathbf{1}^{2-}$), the spin population appears to be evenly distributed over the nine-membered perimeter due to a rapid interconversion between two bowl-shaped C_s forms and a relatively low lying planar C_{2v} transition structure (TS).

Although the acepentalene dianion moiety $\mathbf{1}^{2-}$ in the recently isolated acepentalenediide **1**–Li_2[1,2] is non-planar, it must be considered as aromatic undergoing a rapid bowl-to-bowl inversion, according to NMR data. While the parent compound, neutral acepentalene **1**, which thus far was experimentally characterized only by mass spectrometry, is antiaromatic, based on computed data,[3,4] the corresponding radical anion, $\mathbf{1}^{\bullet-}$, should lie 'in between'. The aromatic nature of open-shell species, in general, is an experimentally unanswered question which was addressed in a computational investigation just recently.[5] In this context, we report on the generation and combined experimental as well as computational characterization of $\mathbf{1}^{\bullet-}$.

The title species was generated by photooxidation of $\mathbf{1}^{2-}$ to $\mathbf{1}^{\bullet-}$.[6,7] Following this procedure, a 10^{-3} M solution of **1**–Li_2 in anhydrous THF was sealed under argon in an EPR cell and UV-irradiated *in situ* at 250 K. The resulting spectrum (Fig. 1; g = 2.0022 ± 0.0002) exhibits a septet arising from six equivalent protons spaced by $|a_H|$ = 0.215±0.005 mT. The spectrum did not markedly change in the 200–270 K temperature range. The hyperfine components were very broad, having a peak-to-peak distance of 0.1 mT. The half-life of the observed paramagnetic species was about 10 min at 250 K, as deduced from the decay of the EPR signals.

Undoubtedly, the six-proton septet originates from the radical anion $\mathbf{1}^{\bullet-}$ formed by loss of an electron from $\mathbf{1}^{2-}$. The equivalence of the protons and the lack of a marked temperature dependence indicate that any dynamic process must be rapid on the hyperfine time-scale (10^7 s^{-1}). In addition to the bowl-to-bowl inversion, $\mathbf{1}^{\bullet-}$ should be subject to an interconversion between two Jahn–Teller structures. The large width of the hyperfine components is in line with such an effect,[8,9] although some broadening may also be caused by an unresolved hyperfine splitting from the ^7Li nucleus of the Li^+ counterions present abundantly in the solution. In contrast to the closed-shell diamagnetic dianion $\mathbf{1}^{2-}$, the radical anion $\mathbf{1}^{\bullet-}$ should have a degenerate singly occupied orbital (*e* or *e*") if it pertains C_{3v} or D_{3h} symmetry. Simple Hückel molecular orbital (HMO) models for structures with these symmetries would lead to a description in which the unpaired electron density is distributed evenly over the nine-membered π-perimeter, so that the spin distribution in $\mathbf{1}^{\bullet-}$ should be similar to that of the hitherto unknown nonatetraenyl radical. Each of the nine peripheral π-centers in $\mathbf{1}^{\bullet-}$ is thus expected to bear 1/9th of the total spin population which, using the proportionality factor Q = −2.2 to −2.6 mT for cyclic radical anions, yields the coupling constant a_H = −0.24 to −0.29 mT. The finding that the observed value $|a_H|$ is smaller may be due to the bowl-shaped geometry of $\mathbf{1}^{\bullet-}$. Deviations of the π-system from planarity are known to decrease the $|a_H|$ value of the proton attached to a π-center because they provide positive contributions to the negative coupling constant of such a proton.[10,11] On the other hand, the symmetry of $\mathbf{1}^{\bullet-}$ may be lower owing to Jahn–Teller distortion, modifying the coupling constant.

To elucidate this point further, we utilized computational methods to characterize the structure of $\mathbf{1}^{\bullet-}$ and to determine the barrier for ring inversion. As done before,[3] gradient-corrected density functional theory (Becke–3–Lee–Yang–Parr, B3LYP),[12–14] in conjunction with the 6-31G* basis set[15] as implemented in the GAUSSIAN 94 program suite,[16] was used for geometry optimizations (B3LYP/6-31G*); stationary points were characterized by analytical vibrational frequency computations which were also used to correct for zero-point vibrational energies (ZPVE) and thermal effects. As spin contamination (expressed in the spin operator expectation value of Slater determinants, $< S^2 >$) may pose a problem for open-shell species, single-point energies on these geometries were evaluated at two higher levels of theory, namely at B3LYP/6-311+G**[17,18] and MP4SDQ/cc-pVDZ.[19]

Computations in C_{3v} or D_{3h} symmetry result in electronically unstable (symmetry breaking) or higher-order stationary structures, *i.e.* $\mathbf{1}^{\bullet-}$ undergoes Jahn–Teller distortion to a lower, non-degenerate symmetry (C_s, Fig. 2). The bowl–inversion transi-

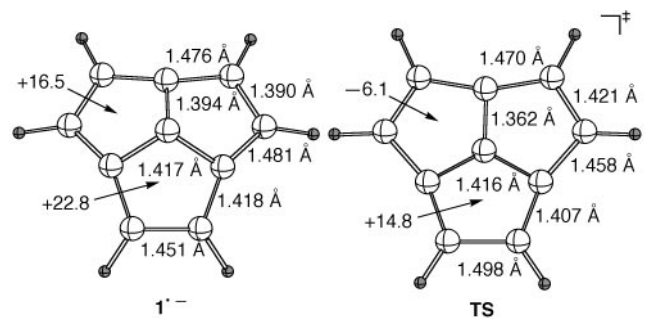

Fig. 2 B3LYP/6-31G* optimized structures of $\mathbf{1}^{\bullet-}$ (C_s) and the **TS** (C_{2v}) for the bowl-to-bowl inversion. Ring centers: NICS values (see text).

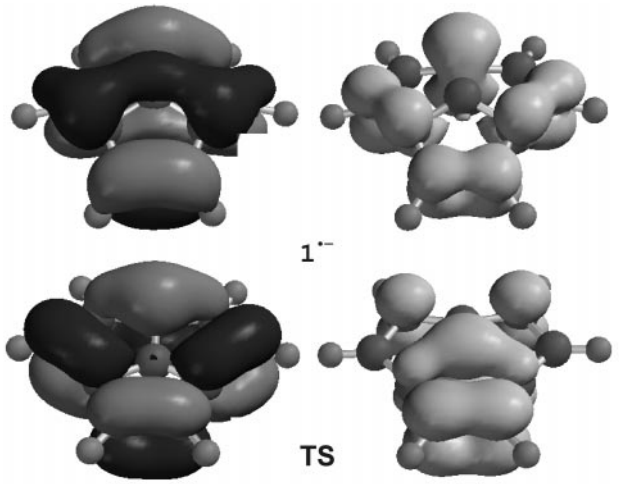

Fig. 3 SOMO (left) and spin populations (right) of the acepentalene radical anion (top) and its transition structure for bowl-to-bowl inversion (bottom).

tion structure, **TS**, is, as expected, planar (C_{2v}) and is associated with a relatively low barrier: $\Delta G^{\ddagger}_{298}$ = 6.9 and 6.1 kcal mol^{-1} at B3LYP/6-311+G** ($< S^2 >$ = 0.76) and MP4SDQ/cc-pVDZ ($< S^2 >$ = 1.13), respectively. This is in accord with a rapid exchange of the two bowl-shaped **1**$^{\bullet-}$ minima on the EPR time scale so that the corresponding spectrum shows only a time-averaged structure. Hence, the hyperfine coupling constants reflect the electron spin distribution of **1**$^{\bullet-}$ *and* the **TS**, which are complementary due to symmetry (Fig. 3, right). By analogy, the highest singly occupied molecular orbitals (SOMOs) for these two structures are similarly shaped (Fig. 3, left), so that the overall spin and electron distribution averaged over both structures indeed appears to be rather symmetrical, in agreement with the observed EPR spectrum.

The inversion barrier for **1**$^{\bullet-}$ is low and comparable to that of **1** and **1**$^{2-}$: $\Delta H^{\ddagger}$ = 5.4 and 7.1 kcal mol^{-1} at B3LYP/6-311+G*//B3LYP/6-31G* + ZPVE, respectively.[3] The inherent strain energy in the **TS** apparently is overcome by a significant aromatic character of the five-membered rings in the **TS** as assessed by computing the nucleus-independent chemical shifts (NICS computed in the geometric ring centers; NICS is a probe for aromaticity: negative values correspond to aromatic, positive to antiaromatic character) [20] which are much smaller in the **TS** than in **1**$^{\bullet-}$ (Fig. 2). While **1**$^{\bullet-}$ clearly has antiaromatic cyclopentadienyl moieties, the **TS** consists of two aromatic and one antiaromatic ring. The same arguments hold true for **1** which is, at least in its bowl-shaped singlet state, highly antiaromatic (the ground state is a triplet).

Chemoselective allylation of aldimine with allyltriethylgermane by the combined use of BF_3•OEt_2 and AcOH

Takahiko Akiyama,* Junko Iwai, Yuji Onuma and Hirotaka Kagoshima

Department of Chemistry, Faculty of Science, Gakushuin University, 1-5-1, Mejiro, Toshima-ku, Tokyo 171, Japan. E-mail: takahiko.akiyama@gakushuin.ac.jp

Received (in Cambridge, UK) 17th September 1999, Accepted 28th September 1999

Allyltriethylgermane reacts with aldimines in preference to aldehydes by means of BF_3•OEt_2 and AcOH to afford homoallylic amines in high yields; three component syntheses of homoallytic amines starting from aldehyde, aniline and allylgermane were successfully achieved.

Lewis acid promoted nucleophilic addition of allylic organometallics to imines constitutes an important reaction for the preparation of homoallylic amines.[1] Although numerous kinds of activator of aldimines have been reported, the addition toward aldimines has been less extensively explored due to its inherent lower reactivity in comparison with that toward aldehydes.[2] Recently, several groups have developed imine selective activators.[3] For instance, Yamamoto and co-workers reported Pd^{II} catalyzed chemoselective allylation of aldimines with allylstannanes.[4] Kobayashi and co-workers found that lanthanide or scandium triflate[5] mediated allylation reactions proceeded smoothly toward aldimines in preference to aldehydes.[6] BF_3•OEt_2 catalyzed chemoselective allylation of aldimines, generated from aldehydes and carbamates[7] or sulfonamides,[8] with allylsilane has been realized. We have also reported that $Sc(OTf)_3$ catalyzed allylation with allylgermane took place highly chemoselectively toward aldimines in preference to aldehydes.[9]

We have recently shown that Brønsted acids activate imines chemoselectively in the presence of aldehydes in aqueous media.[10] Thus, upon reaction of aldimines and silyl enolates in the presence of a catalytic amount of HBF_4, Mannich-type reactions proceeded smoothly in aqueous media to afford β-amino carbonyl compounds in high yields. Three component syntheses of β-amino carbonyl compounds starting from aldehydes and anilines have been also successfully achieved. Furthermore, the Brønsted acid catalyzed Mannich-type reaction proceeded smoothly in water without organic solvent in the presence of surfactants such as SDS.[11]

We report herein that aldimines underwent allylation with allylgermane highly chemoselectively in preference to aldehydes by the combined use of BF_3•OEt_2 and AcOH and that three-component syntheses utilizing aldehydes, amines and allylgermanes furnished homoallylic amines in high yields.

In the first place, the chemoselectivity of the allylation with allylgermane was studied and the results are shown in Table 1. On reaction of an equimolar amount of benzaldehyde and *N*-benzylideneaniline in the presence of allyltriethylgermane (1.5 equiv.) and BF_3•OEt_2 (1.0 equiv.) in MeCN at room temperature, allylation proceeded towards aldehyde to afford a homoallylic alcohol **1a** in a good yield accompanied by a homoallylic amine **2a**. Interestingly, addition of a proton source changed the reaction course dramatically and the aldimine underwent allylation exclusively. As an additive, AcOH gave the best result. It is noted that the present allylation did not proceed at all with the aldimine derived from benzaldehyde and benzylamine. The presence of the *N*-aryl group is mandatory.

After screening the reaction conditions, use of 1.0 equiv. of BF_3•OEt_2 and 0.5 equiv. of AcOH gave the best results.[12,13] It is noted that allylation did not proceed at all with AcOH alone without BF_3•OEt_2. Results for the chemoselective allylation with several aromatic aldimines are shown in Table 2. Allylation of the aldimines proceeded smoothly and showed high chemoselectively in preference to the aldehyde.

Since aldimines are not always stable, it would be synthetically quite useful if the allylation of imines could be achieved *via* reaction with aldimines generated *in situ* from aldehydes and amines. The three component synthesis of homoallylic amines starting from aldehyde, amine and allylgermane took place smoothly in the presence of BF_3•OEt_2 (0.5 equiv.), AcOH (1.0 equiv.) and MS 3A in MeCN to afford homoallylic amines in high yields; the results are shown in Table 3. Not only aldimines derived from aromatic aldehydes but also those derived from aliphatic and α-keto aldehydes worked reasonably well to afford the corresponding homoallylic amines in high yields.

Finally, the chemoselectivity of Si, Ge and Sn reagents was studied. In the presence of equimolar amounts of aldimine and aldehyde, allylic metals were treated with BF_3•OEt_2 (0.5 equiv.) and AcOH (1.0 equiv.) and the results are shown in Table 4. The reaction with allylsilane was sluggish and the corresponding adduct was obtained in a low yield. Although the reactivity of

allylstannane turned out to be higher than that of allylgermane, allylgermane showed the highest chemoselectivity toward aldimines.

In summary, we have found a simple method for the selective allylation of aldimines. Salient features are (i) environmentally benign organogermanium reagents are employed, (ii) the combination of a conventional Lewis acid and a Brønsted acid is found to be an effective activator of aldimines, and (iii) addition of a small amount of protic acid to BF_3•OEt_2 alters the reactivity dramatically.

Communication 9/07538K

Synthetic studies directed towards the potent cytotoxic natural product ottelione A: stereoselective construction of the complete framework

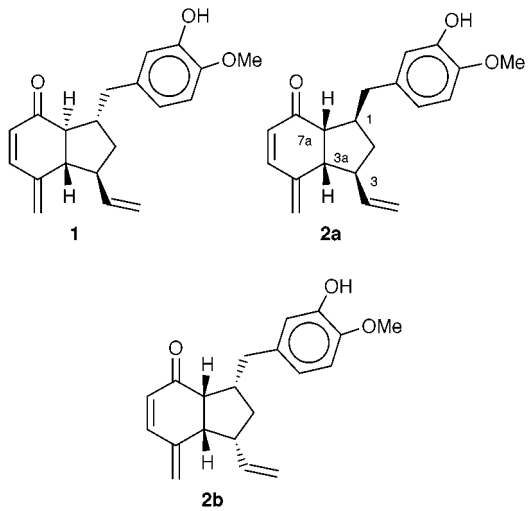
Goverdhan Mehta* and D. Srinivasa Reddy

Department of Organic Chemistry, Indian Institute of Science, Bangalore, 560 012, India.
E-mail: diroff@admin.iisc.ernet.in

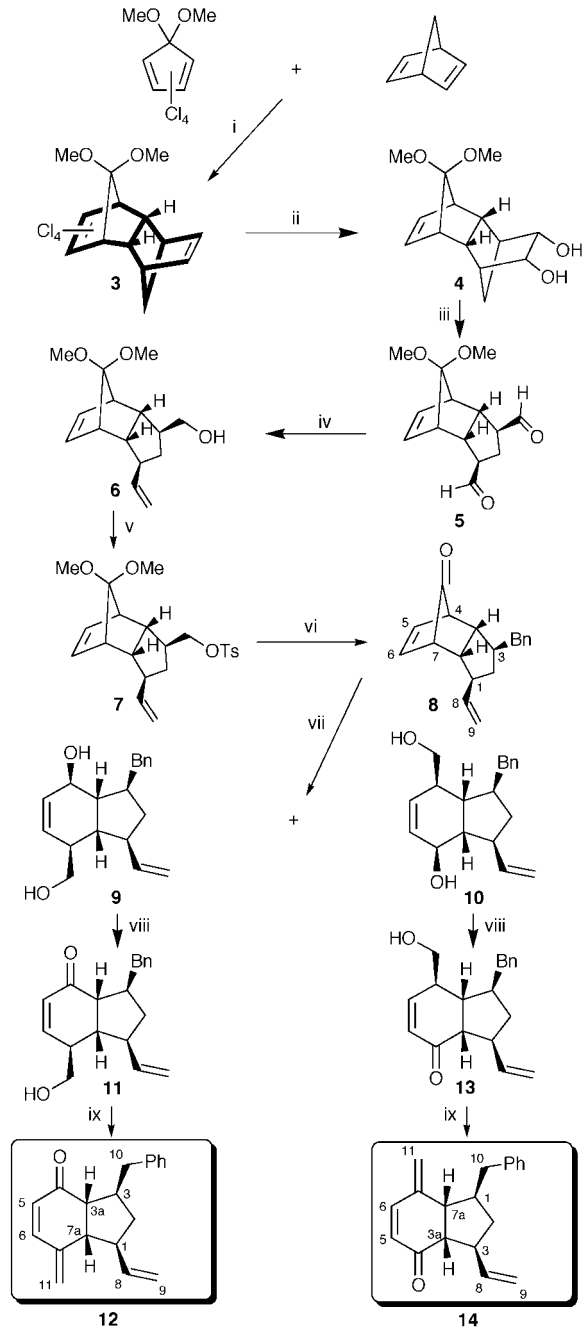
Received (in Cambridge, UK) 8th August 1999, Accepted 29th September 1999

A stereoselective strategy for the rapid acquisition of the complete framework (dideoxyottelione A) of the promising cytotoxic agent ottelione A, with four contiguous stereogenic centres on a hydrindane skeleton and a sensitive 4-methylenecyclohex-2-enone functionality, from the readily available Diels–Alder adduct of 1,2,3,4-tetrachloro-5,5-dimethoxycyclopentadiene and norbornadiene, is delineated.

Towards the end of 1998, the isolation and structure determination of two novel, diastereomeric 4-methylenecyclohex-2-enone moiety-bearing natural products, otteliones A and B, from the fresh water plant *Ottelia alismoides* that grows partially under water, was reported.[1] While ottelione B was assigned structure **1**, even the most incisive analyses of the



NMR data and modelling did not permit unambiguous assignment to ottelione A. For ottelione A, structures **2a** and **2b** were considered and on the basis of available data **2a** was very much favoured without fully ruling out **2b**.[1] Ottelione A was also found to be identical with the compound reported earlier in the patent literature by Leboul and Provost at Rhone-Poulenc Rorer.[2] Our interest in otteliones A and B was aroused by the observation of remarkable antitumor and antileukemia activity exhibited by them.[1–3] It was shown that **1** and **2** inhibit tubulin polymerisation into microtubules in a manner reminiscent of colchicine, vincristine and vinblastine. When subjected to *in vitro* screening against a panel of *ca*. 60 human tumor cell lines at NCI, both **1** and **2** showed remarkable cytotoxicity against most of the cell lines at nM–pM concentrations.[1] Such a promising biological activity profile, the unusual bicyclic structure with four stereogenic centres, the presence of a sensitive 4-methylenecyclohex-2-enone moiety[4] and the uncertainty associated with the structure assigned to ottelione A **2** prompted us to explore synthetic approaches towards this novel molecule. Herein, we describe a stereoselective and flexible approach, targeted towards the favoured formulation **2a** for



Scheme 1 *Reagents and conditions*: i, reflux, 14 h, 93%; ii, OsO_4, NMO, 24 h, 90%, then Na/NH_3, THF, EtOH, 15 min, 65%; iii, $NaIO_4$, aq. THF, 30 min, 85%; iv, $MePPh_3Br$, Bu^tOK, THF, 10 min, then $NaBH_4$, MeOH, 15 min, 42% for two steps; v, TsCl, Py, 4 h, 95%; vi, PhMgBr, CuBr, 30 min, 62%, then Amberlyst-15, acetone, 2 h, 95%; vii, 30% H_2O_2–NaOH, MeOH, 12 h, then $LiAlH_4$, THF, 2 h, 50–60% for two steps; viii, PDC, EtOAc, cat. AcOH, 2 h, 75%; ix, MsCl, DMAP, CH_2Cl_2, 4 h, then DBU, CH_2Cl_2, 45 min, 90% for two steps.

ottelione A, which has resulted in the acquisition of the complete framework of ottelione A and set the stage for the synthesis of the natural product.

The key element of our projected synthesis of ottelione A **2a** was the identification of the stereochemically well-defined tricyclic compound **3**,[5] readily available through inverse electron demand Diels–Alder reaction between 1,2,3,4-tetrachloro-5,5-dimethoxycyclopentadiene and norbornadiene, as a propitious starting point (Scheme 1). In **3**, the bicyclic hydrindane framework as well as all the four stereogenic centres present in ottelione A are firmly imbedded (see bold lines in **3**) and the main task was to disengage the requisite framework from **3**, preserving the stereochemical features, and sequentially generate the complex and extensive functionalization pattern present in the target molecule **2a**.

Regioselective OsO_4-mediated dihydroxylation of the unsubstituted norbornene double bond in **3**[5] and reductive dehalogenation furnished the *cis*-diol **4**.[6] Periodate cleavage led to the dialdehyde **5** which was directly subjected to controlled mono-Wittig olefination and the remaining aldehyde functionality was reduced to furnish **6**. Tosylation of the hydroxy group in **6** to **7** and Cu^{I} mediated cross-coupling reaction with PhMgBr and acetal deprotection readily led to **8**[6] with the correct stereochemical disposition at all the four stereogenic centres (*cf*. 1, 3, 3a and 7a positions in **2a**)[1] and the desired two substituents on the five-membered ring. The hydrindane framework from the key compound **8** was extracted through Baeyer–Villiger oxidation to two regioisomeric lactones (55:45) and LAH reduction to furnish the diols **9** and **10**, respectively. PDC oxidation of **9** and **10** led to the enones **11**[6] and **13**,[6] respectively, and extensive high field 2D NMR studies on these enones established their structural identity.[6] The sensitive 4-methylenecyclohex-2-enone moiety from **11** was generated quite uneventfully through conversion of the primary hydroxy group to the mesylate and DBU mediated elimination to yield dideoxyottelione A **12**[6] (Scheme 1). The ^{1}H and ^{13}C NMR data for **12** exhibited remarkable similarity to that of the natural product **2a**, as the only difference between them is the presence of the aromatic substitution in the latter. In a similar manner, enone **13** was transformed to **14**,[6] a regioisomer of the natural series in which the benzyl and vinyl moieties are interchanged.

In short, we have outlined a simple and flexible strategy, emanating from abundantly available starting materials, towards a promising cytotoxic natural product ottelione A **2a**. Our approach can be readily adapted to the synthesis of **2a** itself through minor tactical modifications and is inherently well-suited to delivering a variety of analogues for biological evaluation. Efforts along these lines are underway and will be reported shortly.

We thank JNCASR for financial support and the SIF facility at I.I.Sc. for the high field NMR data. One of us (D. S. R.) thanks UGC for a research fellowship.

Synthesis and identification of two halogenated bipyrroles present in seabird eggs

Gordon W. Gribble,*[a] and David H. Blank[a] and Jerry P. Jasinski[b]

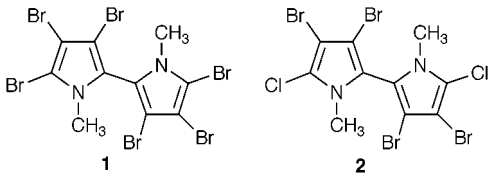
Received (in Corvallis, OR, USA) 13th August 1999, Accepted 22nd September 1999

Two of the four halogenated bipyrroles recently discovered in seabird eggs and eagle liver samples have been identified by synthesis as 1,1′-dimethyl-3,3′,4,4′,5,5′-hexabromo-2,2′-bipyrrole 1 and 5,5′-dichloro-1,1′-dimethyl-3,3′,4,4′-tetrabromo-2,2′-bipyrrole 2, and the structure of the latter compound, which is the major component in the mixture, is further confirmed by X-ray crystallography.

Although more than 3200 naturally occurring organohalogen compounds are now known to exist,[1] most of these are produced by marine organisms, bacteria, fungi and terrestrial plants. Very few have been found in higher animals. The recent report[2] of the presence of several novel halogenated bipyrroles in the eggs of Pacific and Atlantic Ocean seabirds (albatross, puffin, gull, petrel, auklet) and in bald eagle liver samples dramatically reveals that natural organohalogen compounds are more pervasive in the environment than previously believed.

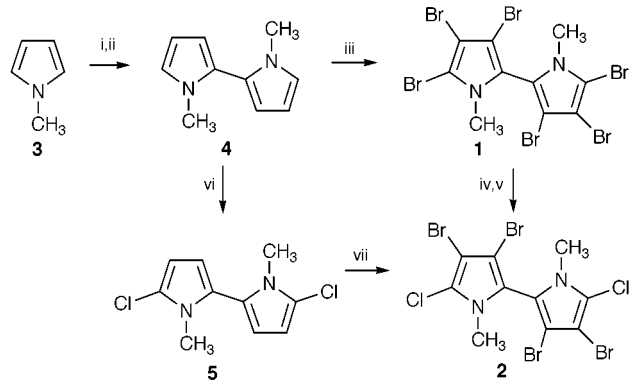
Although sufficient material was not available for full characterization of these compounds, low- and high-resolution mass spectrometry tentatively identified the four major groups of compounds, $C_{10}H_6N_2Br_4Cl_2$, $C_{10}H_6N_2Br_6$, $C_{10}H_6N_2Br_5Cl$ and $C_{10}H_6N_2Br_3Cl_3$, as hexahalogenated 1,1′-dimethyl-2,2′-bipyrroles.[2] We now describe the synthesis and identification of two congeners in this mixture as 1,1′-dimethyl-3,3′,4,4′,5,5′-hexabromo-2,2′-bipyrrole **1** and 5,5′-dichloro-1,1′-dimethyl-3,3′,4,4′-tetrabromo-2,2′-bipyrrole **2**, and establish their probable identity with the two major compounds found in seabird eggs. Bipyrrole **2** appears to be the major seabird compound and is present, for example, in bald eagle liver at a concentration up to 140 ppb.



We began with the premise that the compound with molecular formula $C_{10}H_6N_2Br_6$ would have structure **1** and that, given the propensity of pyrroles to undergo electrophilic substitution at C-2, compound $C_{10}H_6N_2Br_4Cl_2$ most likely would have structure **2**. This proved to be correct. Our syntheses of **1** and **2** are shown in Scheme 1.

The known[3] 1,1′-dimethyl-2,2′-bipyrrole **4**, which is readily available from 1-methylpyrrole **3**, was treated with excess NBS to give **1**† in 79% yield. Regioselective halogen–lithium exchange to give the presumed more stable 5,5′-dilithio intermediate followed by chlorination with 2 equiv. of hexachloroethane[4] gave **2**† in 80% yield. The structures of **1** and **2** are fully established by spectral and analytical data, and the X-ray crystallographic molecular structure of **2**‡ is shown in Fig. 1. Compound **2** was also prepared by treating **4** with NCS to give **5**‡ (97% yield). Reaction of **5** with excess NBS afforded **2** in 76% yield, identical with the material prepared from **1**. A one pot reaction of **4** first with NCS and then NBS was less successful and led to a mixture.[5] Interestingly, this mixture closely matched by GC-MS the natural product mixture from the seabirds that contains several other halogenated bipyrroles of formulas $C_{10}H_6N_2Br_4Cl_2$, $C_{10}H_6N_2Br_5Cl$ and $C_{10}H_6N_2Br_3Cl_3$, perhaps implicating a somewhat random biological halogenation sequence involving first chlorination with chloroperoxidase and then bromination with bromoperoxidase.[1] In any event, based on a data set of retention times derived from a series of chromatograms, compounds **1** and **2** are the probable compounds found in the seabirds.[6]

The presumed dietary origin of these halogenated bipyrroles is unknown, although it is relevant that 3,3',4,4',5,5'-hexabromo-2,2'-bipyrrole has been isolated from the marine bacterium *Chromobacterium* sp. along with 2,3,4,5-tetrabromopyrrole.[7] Furthermore, several polybrominated 1-methylpyrroles and polychlorinated pyrroles are produced naturally.[1] Compound **2** and the other as yet unidentified mixed



Scheme 1 *Reagents and conditions*: i, BuLi; ii, $NiCl_2$ (55% for 2 steps); iii, NBS (7 equiv.), −78 °C to room temp. (79%); iv, BuLi; v, Cl_3CCCl_3, −78 °C to room temp. (80% for 2 steps); vi, NCS (2 equiv.), −78 °C to room temp. (97%); vii, NBS (5 equiv.), −78 °C to room temp. (76%).

4 6

Scheme 2 *Reagents and conditions*: i, NCS (7 equiv.), −78 °C to room temp. (91%).

bromochlorobipyrroles represent the first examples of naturally occurring pyrroles containing both chlorine and bromine.[8]

We have also synthesized the hexachloro analogue **6**† by treating **4** with excess NCS (Scheme 2). The use of sulfuryl chloride in chlorinations of **4** to give either **5** or **6** was less successful.

The obvious relationship of these polyhalogenated bipyrroles to polychlorinated biphenyls (PCBs) leads one to wonder if the former natural compounds will have similar toxicity profiles to the anthropogenic PCBs. One further wonders if some of the earlier reports of anthropogenic chlorinated compounds in seabirds, fish, and marine mammals were in reality describing, at least in part, naturally occurring organohalogen compounds.

We thank the donors of the Petroleum Research Fund administered by the American Chemical Society for partial support of this project, Dr Ross Norstrom and Sheryl Tittlemier for their assistance and interest on this project, Jennifer Taylor and Sarah Lievens for technical assistance, and Drs Jonathan Sessler and Philip Gale for some unpublished carbon-13 NMR spectral data on bromopyrroles for comparison purposes.

The first enantiocontrolled synthesis of naturally occurring polyoxygenated cyclohexenylmethanol dibenzoates (–)-zeylenol, (–)-uvarigranol G, (–)-tonkinenin A and (+)-pipoxide

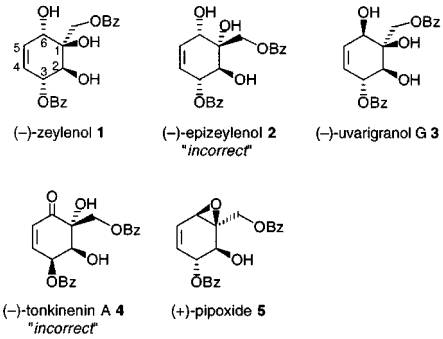
Kou Hiroya and Kunio Ogasawara*

Pharmaceutical Institute, Tohoku University, Aobayama, Sendai 980-8578, Japan.
E-mail: konol@mail.cc.tohoku.ac.jp

Received (in Cambridge, UK) 12th July 1999, Accepted 22nd September 1999

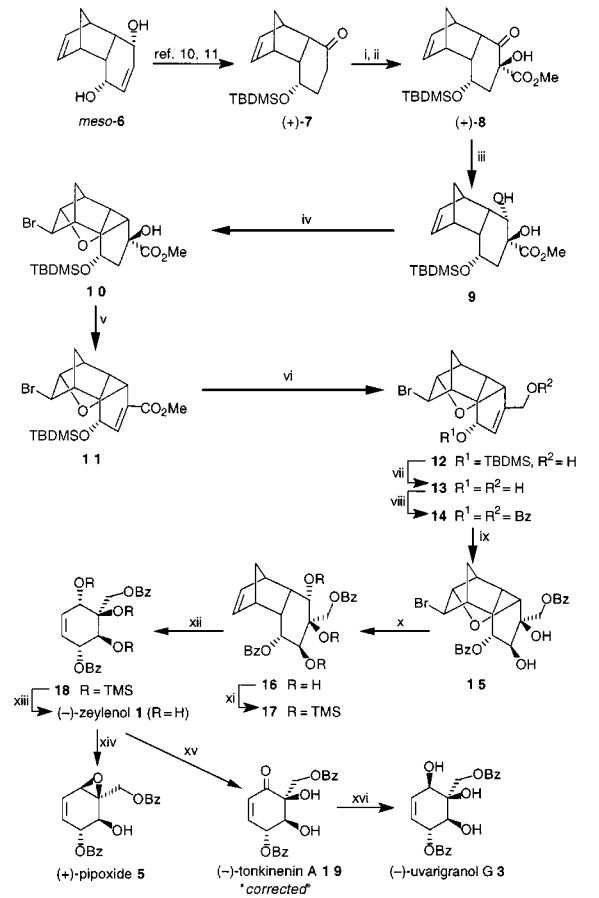
The first enanticontrolled synthesis of five naturally occurring polyoxygenated cyclohexenylmethanol dibenzoates has been achieved to confirm three [(–)-zeylenol, (–)-uvarigranol G, (+)-pipoxide], revise one [(–)-tonkinenin A] and disprove one [(–)-epizeylenol] of the proposed structures.

The isolation has been reported[1] of five polyoxygenated cyclohexenylmethanol dibenzoates, (–)-zeylenol[2,3] **1**, (–)-epizeylenol[2,4] **2**, (–)-uvarigranol G[5] **3**, (–)-tonkinenin A[6] **4** and (+)-pipoxide[2,7] **5**, from plants of the genus *Uvaria* which are



widely distributed across Asia, Africa, and Australia and are used in Chinese traditional medicine to treat digestive disorders. Although the structures of two, **1** and **5**, have been determined unambiguously on the basis of chemical correlation[8] and the racemic synthesis of the latter as well as X-ray analysis[7] of the racemate, the structures of the other three were proposed only on the basis of spectroscopic measurements. Since the diastereo- and enantio-controlled synthesis of these natural products has so far not been reported, we were interested in the construction of these natural products utilizing the chiral cyclohexanoid building block[9] **7** prepared from the *meso*-enediol **6** by either a catalytic[10] or an enzymatic[11] asymmetric desymmetrization procedure. We report here our study leading to the first diastereo- and enantio-controlled synthesis of all of these five compounds which concluded the validity of the proposed structures of three, (–)-zeylenol **1**, (–)-uvarigranol G **3** and (+)-pipoxide **5**, and the invalidity of two, (–)-epizeylenol **2** and (–)-tonkinenin A **4**. The present work has determined the structure of (–)-tonkinenin A not as **4** but as **19**, unambiguously, although the structure of (–)-epizeylenol still remains to be ascertained.

Besides diastereo- and enantio-controlled introduction of their oxygen functionalities, one difficulty which had to be resolved in the construction of these polyoxygenated molecules was regioselective introduction of two benzoyl groups on appropriate oxygen functionalities. To this end, we first transformed the (+)-siloxy ketone[10,11] **7** into the β-hydroxyketo ester† **8**, mp 110 °C, $[\alpha]_D^{29}$ +60.1 (*c* 0.95, $CHCl_3$), by sequential α-methoxycarbonylation and convex-face selective α-hydroxylation as we have carried out in the synthesis of its enantiomer (Scheme 1).[12] Reduction of **8** with $NaBH_4$ occurred diastereoselectively from the convex-face to give the single *trans*-1,2-diol **9**. To block the cyclopentene olefin, **9** was exposed to NBS to give the bromo ether **10**, $[\alpha]_D^{29}$ −22.6 (*c* 2.65, $CHCl_3$). Dehydration of **10**, followed by reduction of the resulting α,β-unsaturated ester **11**, mp 155–156 °C, $[\alpha]_D^{29}$ −8.4 (*c* 1.45, $CHCl_3$), gave the primary alcohol **12** which, on desilylation, afforded the diol **13** having an appropriate structure for dibenzoylation and diastereoselective dihydroxylation. Thus, **13** was benzoylated to give the dibenzoate **14**, mp 134–135 °C, $[\alpha]_D^{28}$ −36.1 (*c* 1.31, $CHCl_3$), whose dihydroxylation using a catalytic amount of OsO_4 and NMO occurred stereoselectively from the convex-face to give the single diol **15**. At this stage, the cyclopentene olefin was regenerated by treating the bromo ether



Scheme 1 *Reagents and conditions*: i, NaH, $(MeO)_2CO$, THF, room temp. (89%); ii, O_2, KF, $(EtO)_3P$, DMSO, ~30 °C (82%); iii, $NaBH_4$, MeOH–THF, −15 °C; iv, NBS, CH_2Cl_2, −15 °C (96%, 2 steps); v, $POCl_3$, pyridine, 50 °C (84%); vi, DIBAL-H, toluene, −78 °C; vii, Bu_4NF, THF, room temp. viii, BzCl, pyridine, DMAP (cat.) (97%, 3 steps); ix, OsO_4 (cat.), NMO, aq. THF, room temp. x, Zn, NH_4Cl, aq. Scheme 2 *Reagents and conditions*: i, BzCl, pyridine, DMAP (cat.) (90%); ii, *M*CPBA, CH_2Cl_2, room temp. (91%); iii, $BF_3{\cdot}OEt_2$, toluene, –20 °C; iv, TsOH, $CHCl_3$, ~30 °C; v, HF, MeCN, THF, ~30 °C (83%, 3 steps); vi, BzCl (1 equiv.), pyridine, DMAP (cat.) (52%); vii, Zn, NH_4Cl, aq. THF, reflux (77%); viii, TMSCN, DMF, 80 °C; ix, Ph_2O, reflux, 25 min; x, HF, MeCN, ~30 °C (76%, 3 steps).

15 with zinc in aqueous THF containing NH_4Cl to give the triol **16**, mp 166–168 °C, $[\alpha]_D^{29}$ −55.4 (*c* 0.66, $CHCl_3$), having four contiguous oxygen functionalities on the cyclohexane moiety.

Having introduced the requisite functionalities, the triol **16** was pertrimethylsilylated using TMSCl[13] in DMF to give the silyl ether **17** which was heated in refluxing Ph_2O for 15 min to give (–)-zeylenol **1**, mp 129–130 °C, $[\alpha]_D^{23}$ −140.5 (*c* 1.02, $CHCl_3$) [lit.,[3] mp 144–145 °C, $[\alpha]_D^{25}$ −116.3 (*c* 0.915, $CHCl_3$)], after desilylation of the crude product.

(+)-Pipoxide **5** was obtained from (–)-zeylenol **1** under Mitsunobu conditions.[14] Thus, on treatment with DEAD and PPh_3 in THF, **1** afforded (+)-pipoxide **5**, mp 129 °C, $[\alpha]_D^{28}$ +55.2 (*c* 0.78, $CHCl_3$) [lit.,[7] mp 152 °C, $[\alpha]_D^{23}$ +53 (*c* 0.02, $CHCl_3$)], stereoselectively.

In order to obtain (–)-uvarigranol G **3**, which was proposed as the C-6 epimer of (–)-zeylenol **1**, we attempted its synthesis from **1** by sequential allylic oxidation and stereoselective reduction. Thus, we first treated **1** with MnO_2 in a mixture of CH_2Cl_2 and EtOAc to give the enone **19**. To our surprise, the physical and spectroscopic data of the enone **19**, mp 158–160 °C, $[\alpha]_D^{27}$ −26.0 (*c* 0.89, MeOH), obtained quantitatively, were found to be identical with those of (–)-tonkinenin A, mp 158–159 °C,[6] $[\alpha]_D^{24}$ −21.6 (*c* 1.71, MeOH),[6] which was proposed as **4**.[6] Thus, we were able to accomplish the first synthesis of this natural product unexpectedly and have revised its structure as **19**. As expected, reduction of **19** with $NaBH_4$/$CeCl_3$[15] allowed diastereoselective reduction of the enone carbonyl to give (–)-uvarigranol G **3**, mp 62–64 °C, $[\alpha]_D^{29}$ −45.8 (*c* 0.73, $CHCl_3$) [lit.,[5]: mp 67–69 °C, $[\alpha]_D^{16}$ −44 (*c* 0.08, $CHCl_3$)].

To obtain (–)-epizeylenol **2**, which was proposed as the C-1 epimer of (–)-zeylenol **1**, the primary alcohol **12** was benzoylated to give **20**, which was converted into the epoxide **21**, diastereoselectively, from the convex-face (Scheme 2). On exposure to $BF_3{\cdot}OEt_2$[16] in toluene, **21** afforded a mixture of the secondary and the primary monobenzoates **23** and **24** after hydrolytic work-up, presumably through the 1,3-dioxolenium intermediate **22**. The mixture without separation was then stirred in $CHCl_3$ containing TsOH to converge to the single primary monobenzoate **24**, which was desilylated to give the triol **25**, mp 208–209, $[\alpha]_D^{30}$ –70.3 (*c* 0.92, THF). Benzoylation of **25** using 1 equiv. of BzCl allowed regioselective monoacylation at the desired position to give the single dibenzoate **26**, mp 254–256 °C, $[\alpha]_D^{31}$ −94.4 (*c* 0.59, THF), along with a minor amount of the separable regioisomer. The observed preferential generation of **26** may be due to the steric hindrance of the primary benzoate functionality, which shields the *exo*-hydroxy functionality considerably. The bromo ether linkage of **26** was then cleaved reductively to yield the triol **27**, mp 169–170 °C, $[\alpha]_D^{28}$ –64.5 (*c* 0.54, $CHCl_3$). As above, on sequential per-*O*-silylation, thermolysis and desilylation, **27** afforded the cyclohexene dibenzoate having the structure **2** which was proposed as (–)-epizeylenol, mp 154–155 °C, $[\alpha]_D^{27}$ −139.1 (*c* 0.22, $CHCl_3$), but its physical and spectroscopic data were not identical with those reported for the natural product, mp 206–207 °C.[4] It was also confirmed that the secondary benzoyl functionality of **2** was not rearranged during these transformation reactions as it afforded the corresponding 6-keto derivative, mp 230–232 °C, $[\alpha]_D^{29}$ −220.5 (*c* 0.12, $CHCl_3$). Thus, the proposed structures of (−)-epizeylenol **2** and (−)-tonkinenin A **4** were both found to be erroneous.

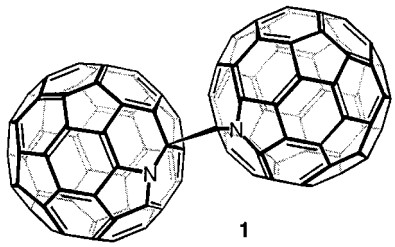
Received (in Liverpool, UK) 17th August 1999, Accepted 13th September 1999

The thermal treatment of the heterofullerene dimer $(C_{59}N)_2$ with ketones and aldehydes in the presence of TsOH and air leads to Mannich-type functionalized heterofullerenes $RC_{59}N$.

We have shown recently[1] that arylated heterofullerenes $ArC_{59}N$ are easily accessible in yields up to 90% by the treatment of $(C_{59}N)_2$ **1**[2–5] with an electron-rich aromatic in the presence of TsOH and air. The proposed mechanism of this reaction involves an electrophilic aromatic substitution by $C_{59}N^+$, which is presumed to be formed *via* homolysis of the dimer, followed by oxidation of the $C_{59}N$ radical. The oxidation is a critical step, since running the reaction under an argon atmosphere did not yield arylated products. Here we report on the facile formation of the Mannich bases $RC_{59}N$ [R = CH(R′)COR″], obtained by the analogous treatment of **1** using enolizable aldehydes, ketones and 1,3-diketones as nucleophiles.



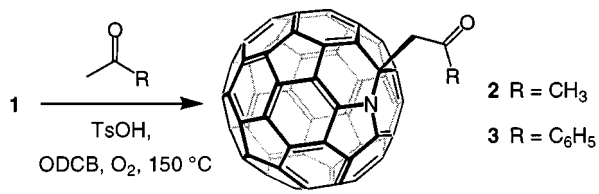
1

Mannich bases **2** and **3** were obtained in almost quantitative yield by the treatment of **1** in 1,2-dichlorobenzene with 20 equiv. of acetone or acetophenone and 40 equiv. of TsOH at 150 °C in a constant stream of air (Scheme 1). After 15 min the conversion was completed. The isolation of the products was achieved by flash chromatography on silica gel using toluene as mobile phase, where **2** and **3** elute as the least polar olive green coloured fraction.

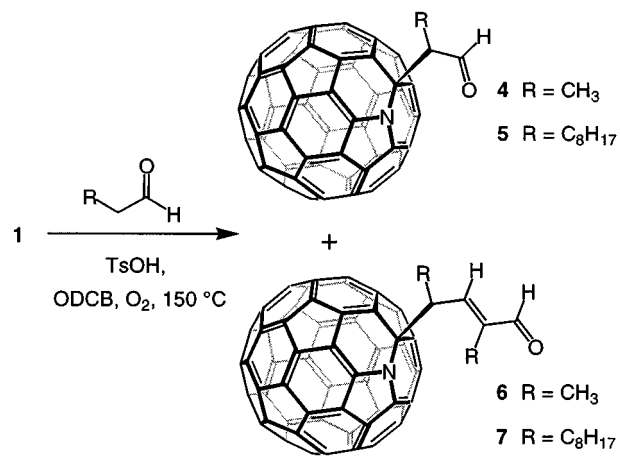
The complete structural characterization of **2** and **3** was carried out by ^{1}H NMR, ^{13}C NMR, UV–VIS and FT-IR spectroscopy as well as by mass spectrometry.† The ^{1}H NMR spectrum of **2**, for example, shows singlets for the methylene and the methyl groups at δ 4.91 and 2.79. The ^{13}C NMR spectrum clearly proves C_s symmetry, showing the 30 expected fullerene resonances in the sp^2 region between δ 155 and 123. The methylene group and the methyl group resonate at δ 53.84 and 30.90, respectively. The signal at δ 78.37 is due to the resonance of the sp^3 C-atom of the fullerene skeleton. The carbonyl C-atom resonates at δ 201.80. Except for the resonances of the addends the ^{13}C NMR spectrum of **3** is qualitatively the same. The UV–VIS spectra of the olive green solutions of **2** and **3**, with the most intensive absorptions located at 257, 320, 445, 589 and 724 nm, display the typical fingerprint for this type of heterofullerene derivatives.[1–5] The FT-IR spectra of **2** and **3** show the typical characteristics of fullerene derivatives (monoadducts), especially the absorptions in the fingerprint region between 480 and 590 cm^{-1}, with the strongest peak at about 524 cm^{-1}. The absorptions at 1729 (**2**) and 1692 cm^{-1} (**3**) are due to the C=O vibrations. EI mass spectrometry shows the M^+ peak of each compound together with a strong fragmentation peak at *m/z* 722 for $C_{59}N^+$.

The treatment of **1** with aldehydes like propanal and decanal under the same experimental conditions led also to complete conversion and the formation of the Mannich bases **4** and **5** respectively (Scheme 2). However, in these cases the aldol condensation products **6** and **7** are formed simultaneously. The amount of condensation products **6** and **7** increases with increasing reaction time, indicating that the condensation step proceeds with the initially formed heterofullerene derivatives **4** and **5**. Aldehydes **4**–**6** were completely characterized by ^{1}H NMR, ^{13}C NMR, UV–VIS and FT-IR spectroscopy as well as by mass spectrometry and exhibit very similar properties to ketones **2** and **3**. The *trans* configuration at the C=C double bonds in **6** and **7** was determined by NOE NMR spectroscopy.

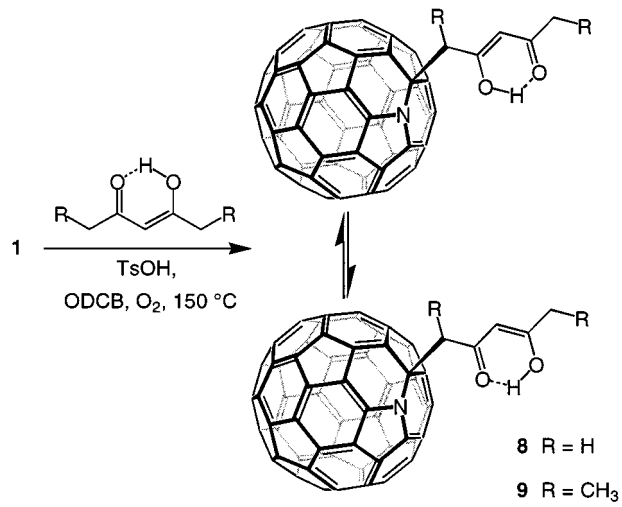
The corresponding reactions of **1** with 1,3-diketones afforded the functionalized azafullerene derivatives **8** and **9** (Scheme 3) which were completely characterized. The fact that the addition proceeded exclusively at the terminal instead of the central C-atoms of the 1,3-diketones is presumably due to steric hindrance. The tautomerization within **8** is comparatively fast on the NMR timescale because only one set of signals for the protons of the addend are found. In the ^{1}H NMR spectrum of **9**, however, two sets of signals for the two corresponding tautomers are found, indicating a much slower process. This is also demonstrated by the fact that the two individual signals for the protons of the hydrogen bridges at δ 15.91 and 15.82 are much sharper than those of **8**. In the reaction mixture obtained from the treatment of **1** with heptane-3,5-dione, in addition to **9** another component **10**, with a simpler ^{1}H NMR spectrum showing one set of signals for magnetically equivalent methyl,



Scheme 1

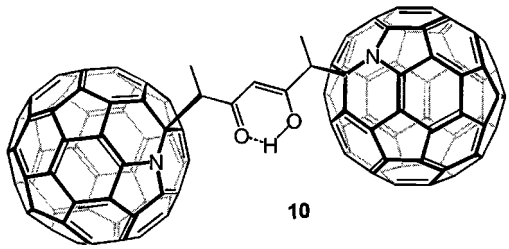


Scheme 2



Scheme 3

methine, enol and olefinic protons, could be detected. The spectroscopic data of **10** are consistent with a bisadduct formed as a side product.



The findings of this contribution support the formation of $C_{59}N^+$ from the dimer **1** after thermolysis and oxidation of the radical $C_{59}N$ (Scheme 4). In the arylations reported previously[1] $C_{59}N^+$ serves as electrophile for the attack of electron-rich aromatics. In the present cases it reacts here with enolizable ketones and aldehydes to afford Mannich bases involving a heterofullerene sphere (Scheme 4). This new derivatization method of $C_{59}N$ opens up a facile access to a broad variety of new functionalized heterofullerenes.

We thank the DFG for financial support.

Encapsulation of polysilane into shell cross-linked micelles

Takanobu Sanji, Yuriko Nakatsuka, Fuminobu Kitayama and Hideki Sakurai*

Department of lndustrial Chemistry, Faculty of Science and Technology, Science University of Tokyo, 2641 Yamazaki Noda, Chiba 278-8510, Japan. E-mail: sakurai@ci.noda.sut.ac.jp

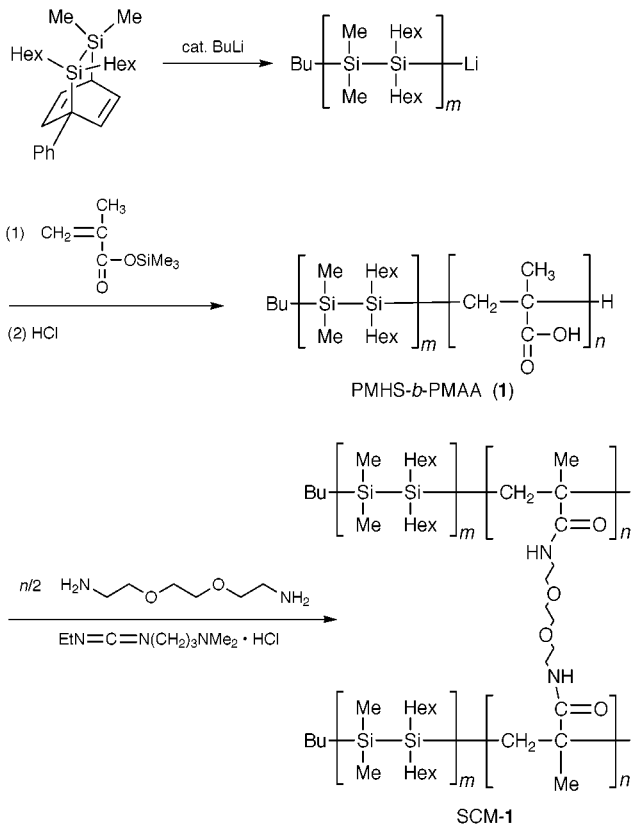
Received (in Oxford, UK) 9th August 1999, Accepted 29th September 1999

The cross-linking reaction of the poly(methacrylic acid) block of poly(1,1-dimethyl-2,2-dihexyldisilene)-*b*-poly(methacrylic acid) with 1,10-diaza-4,7-dioxadecane and 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride afforded the first shell cross-linked micelles of polysilane.

Very recently, a vesicle of an amphiphilic multi-block copolymer with poly(phenylmethylsilane) has been reported.[1] We also reported preparation and formation of micelles of an amphiphilic diblock copolymer, poly(1,1 -dimethyl-2,2-dihexyldisilene)-*b*-poly(2-hydroxyethyl methacrylate).[2]

In this area of the chemistry, the formation and properties of shell cross-linked micelles (SCMs) have been investigated actively in recent years.[3,4] The macromolecular architectures of SCMs are nanometer-sized, with amphiphilic core-shell spheres that are prepared by the self-assembly of amphiphilic block copolymers into polymer micelles, followed by cross-linking of the side chains along the block composing the shell of the polymer micelles. Here, polysilane-based shell cross-linked micelles are reported for the first time.

Poly(1,1-dimethyl-2,2-dihexyldisilene)-*b*-poly(methacrylic acid) **1** (PMHS-*b*-PMAA) was prepared by the sequential anionic polymerization of masked disilenes[5] and trimethylsilyl methacrylate, followed by hydrolysis of the trimethylsilyl protecting group (Scheme 1).† The copolymer, insoluble in $CHCl_3$, was converted to methyl-esterified copolymer by the reaction with CH_2N_2 and the molecular weight was estimated by size exclusion chromatography with $CHCl_3$ as eluent (M_n = 2.8 × 10^4, M_w/M_n = 1.07, calibrated with polystyrene standards). Then the molecular weight of **1** was estimated to be $M_n = 2.4 \times 10^4$. The ^{1}H NMR data of **1** in D_2O gave the relative proportion of PMHS to PMAA and the chemical formula of the copolymer was estimated as $(PMHS)_{12}(PMAA)_{240}$. NMR analysis might underestimate the proportion of polymerization of the polysilane block, because the region of the polysilane blocks on the block polymer has a colloidal nature.



Scheme 1

PMHS-*b*-PMAA **1**, which is soluble in water, is expected to self-assemble in water to form polymer aggregates. In fact, dynamic light scattering (DLS) studies indicated the formation of near-monodisperse micelle, with an intensity-averaged micelle diameter of 170 nm in water (0.2 g l^{-1}, 25 °C). Since the calculated length of the stretched copolymer is about 60 nm with an assumption of all *trans* conformation, the micelle may be swollen to some extent. At this stage, the possibility that **1** forms vesicles instead of micelles cannot be excluded, but the formation of spherical SCMs (*vide infra*) supports the formation of micelles. The critical micelle concentration (CMC) was found for **1** to be 8.1 × 10^{-9} mol l^{-1} as studied by the fluorescence probe method with 8-anilinonaphthalene-l-sulfonic acid (ANS) in water. The hydrophobic PMHS block should exist as the core with the hydrophilic PMAA block as the shell, since the PMHS shows UV absorption at λ_{max} 330 nm, similar to the case of PMHS-*b*-poly(2-hydroxyethyl methacrylate).[2]

Since **1** has a reactive methacrylic acid block, the shell cross-linking reaction of the polymer micelles was examined. A solution of the polymer micelles was prepared in water at a concentration high enough to allow the formation of micelles. The shell cross-linking of the carboxylic acid on the poly(methacrylic acid) block of **1** was achieved by the reaction with 1,10-diaza-4,7-dioxadecane and 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride to the solution.[6]‡ After the cross-linking reaction, ^{1}H NMR signals of the cross linked block copolymer could not be detected in D_2O solution because of very long relaxation times due to its colloidal nature, despite the apparent solubility. Although an amount of cross-linking reagent equivalent to the methacrylic acid units was used, the proportion of the cross-linked methacrylic acid units on the block copolymer to the uncross-linked was *ca.* 50% as estimated by ^{1}H NMR in D_2O–THF-d_8. However, it is difficult to estimate the ratio of the cross-linking accurately. Upon addition of an excess of THF-d_8 to the solution, however, signals of the PMHS core part became observable, indicating that the PMHS block was solvated under these conditions. Interestingly, DLS studies indicated that SCM-**1** in THF was monodispersed, the intensity-averaged diameter of the particles being 230 nm. The (uncross-linked) block copolymer **1** in THF does not form particles. This fact indicates clearly the formation of SCM-**1**. These significant changes in particle size must result from the solvation of the PMHS blocks under these conditions.

Further studies supported the formation of SCMs. In the solid state CP-MAS ^{29}Si NMR of SCM-**1**, two signals were observed at δ_{Si} −27.6 and −35.7, assignable to dihexylsilylene and

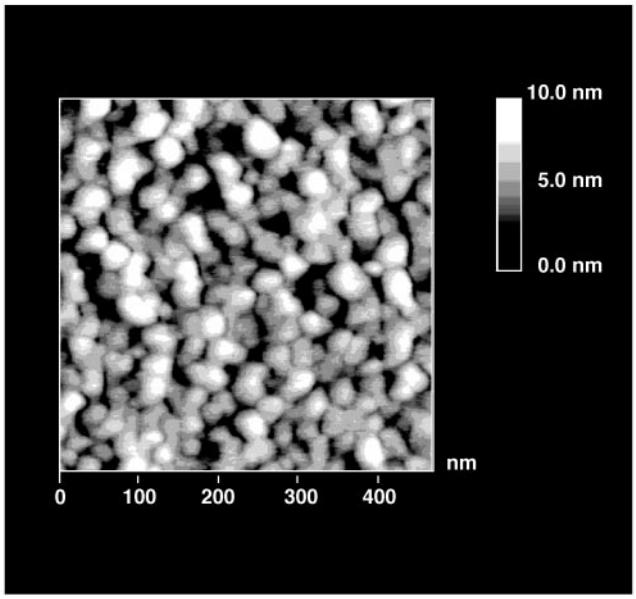


Fig. 1 AFM image of SCM-**1** film of Pyrex glass plate.

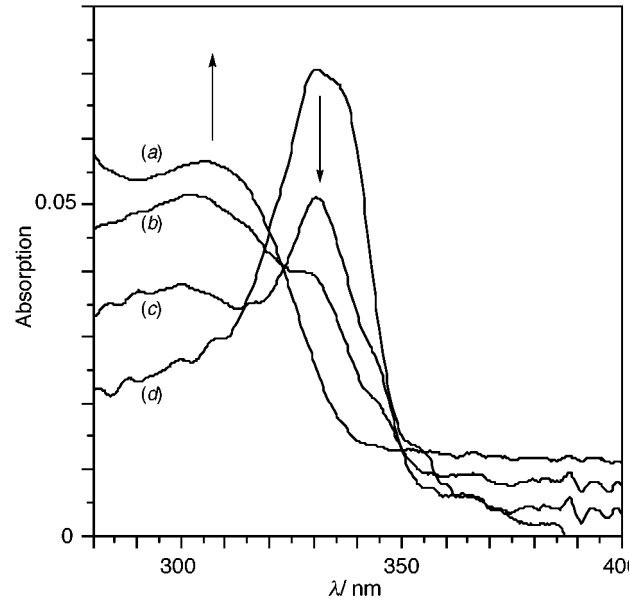

Fig. 2 UV absorption of SCM-**1** in H_2O: (*a*) 0, (*b*) 10, (*c*) 20 and (*d*) 100% H_2O.

dimethylsilylene units, respectively. The IR spectrum of SCM-**1** shows absorption bands for both the carboxylic acid and the amide groups at 1710, 1631 and 1569 cm^{-1}, although that of **1** shows only the absorption band for the carboxylic acid at 1702 cm^{-1}. The DLS studies indicated the intensity-averaged diameter of the particles to be 160 nm with monodispersed spheres, which agreed very closely with the size of the original micelles composed of the block copolymer **1**.

An atomic force microscopy (AFM) image of SCM-**1** provided information on the size and shape of the shell cross-linked spheres.[7] Samples for AFM measurement were prepared by placing a drop of SCM-**1** solution in water (0.045 mg ml^{-1}) on the surface of a Pyrex glass plate and allowing it to dry in air. Fig. 1 shows the AFM image of SCM-**1** film on a Pyrex glass plate operating in the contact mode. Spherical particles of *ca.* 25 nm diameter in the dry state are clearly observed. Under the conditions, the cross-linked corona will eventually shrink onto the glassy PMHS core as the film dries. The measured radius of the dry sphere may fit the molecular length of **1**.

It is worthwhile to examine the electronic properties of the polysilanes encapsulated as the core and protected by the cross-linked hydrophilic corona, since polysilanes exhibit unique electronic spectra depending upon their conformation, which is sensitive to the environment around the chain.[8] SCM-**1** shows an absorption maximum at 333 nm, which is almost identical to those observed both in the solid state and in micelle **1**, where the PMHS block takes the *trans* conformation.[9] This indicates that the PMHS blocks form the unsolvated micelle core, with the cross-linked PMMA forming the solvated corona. In a water–THF mixed solvent, however, the absorption maximum of SCM-**1** undergoes an abrupt shift from 333 to 305 nm (Fig. 2). In THF, SCM-**1** shows an absorption maximum at 305 nm, indicating that the PMHS block takes a random-coil conformation. The (uncross-linked) block copolymer **1** in THF also shows absorption maximum at 305 nm.

We thank Dr Satomi Ohnishi of the National Institute of Materials and Chemical Research for AFM measurements. This work was supported by a Grant-in-Aid from the Ministry of Education (New Polymers and Nano-Organized Systems) and the Japan Society for the Promotion of Science (Research for the Future Program).

Notes and references

† A hexane solution of BuLi (0.72 mmol) was added to 1-phenyl-7,7-dihexyl-8,8-dimethyl-7,8-disilabicyclo[2.2.2]octa-2,5-diene (masked disilene, 2.0 g, 4.9 mmol) and THF (20 ml) at −78 °C. The mixture was stirred for 20 min after removal of the cooling bath. After complete polymerization of the masked disilenes, trimethylsilyl methacrylate (0.77 g, 4.9 mmol) was added to the reaction mixture at −78 °C. The mixture was stirring for 2 h at −78 °C and then a few drops of 1.5 M HCl solution were added to the mixture. After removal of the solvent, fractional precipitation followed by drying *in vacuo* gave water-soluble polymer **1** as a white powder (270 mg, 15.2%). *Spectral data* for **1**: δ_H(D_2O, 300 MHz) 0.08 (br s), 0.87–1.26 (br), 1.78 (br s); δ_C(D_2O, 75.5 MHz) 17.2, 45.4, 49.2, 184.5; ν_{max}(KBr)/cm^{-1} 1702 (COOH).

‡ Synthesis of SCM-**1**: to an aqueous solution of PMHS-*b*-PMAA (100 mg in 22 ml H_2O, 4.5 mg ml^{-1}), 1,10-diaza-4,7-dioxadecane (0.18 mg, 0.21 mmol) and 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride (0.23 mg, 1.20 mmol) were added at room temperature. The amount of the cross-linking reagents corresponds to 100% of the total amount of methacrylic acid units. The mixture was stirred for 1 h at room temperature and then transferred to a dialysis bag followed by dialysis against distilled water for 2 days. After drying *in vacuo*, a solid sample of SCM-**1** was obtained (90 mg, 90%). *Selected data* for SCM-**1**: δ_H(D_2O–THF-d_8, 300 MHz) 0.4–0.5 (br s, $SiMe_2$), 1.15–1.68 (br, $SiHex_2$, CH_3), 2.08 (br s, CH_2C); δ_C(D_2O–THF-d_8, 75.5 MHz) 18.6, 44.8, 54.3, 166, 177; δ_{Si}(Solid-state CP-MAS) −35.7, −27.6; ν_{max}(KBr)/cm^{-1} 3600–2500 (OH), 1710 (COOH), 1631, 1569 (NHC=O).

[b] *Otto-von-Guericke-Universität Magdeburg, Universitätsplatz 2, D-39106 Magdeburg, Germany*

Received (in Basel, Switzerland) 18th August 1999, Accepted 3rd October 1999

The synthesis and crystal structure of the Yb(II) half-sandwich complex $[\{(\eta^5\text{-}C_5Me_4)SiMe_2OSiMe_2(\eta^1\text{-}O)\}Yb(thf)]_2$ containing the new linked tetramethylcyclopentadienyl-silanolate ligand $C_5Me_4SiMe_2OSiMe_2O^{2-}$ are reported.

Lanthanide compounds coordinated by bidentate cyclopentadienyl ligands with different coordination mode capacities are of essential fundamental interest from the point of view of their structure, stability and chemical properties. Various cyclopentadienyl ligands bearing in the side chain a Lewis base group such as an ether,[1,2c] amine,[1c,2] or phosphine[3] have been successfully employed in organolanthanide chemistry and derived complexes have attracted considerable interest in recent years. Examples of substituted cyclopentadienyl ligands with a pendant functional group able to form σ Ln–X (X = oxygen,[4] nitrogen[5]) bonds and to realize constrained geometry complexes are not numerous and are limited mainly to the trivalent Sc, Y and Lu derivatives of the linked cyclopentadienyl-amido class.[5a–e] To the best of our knowledge, half-sandwich *divalent* lanthanide analogues have not yet been reported.

Complexes with heterobifunctional cyclopentadienyl ligands are very intriguing and promising because of their use as effective and stereoselective catalysts in various reactions. The complex $[\{(\eta^5\text{-}C_5Me_4)SiMe_2(\eta^1\text{-}NCMe_3)\}(PMe_3)Sc(\mu_2\text{-}H)]_2$ has been shown to exhibit catalytic activity in α-olefin polymerization[5b] while the 'ate'-complexes $Li[Ln\{(\eta^5\text{-}C_5R_4)SiMe_2(\eta^1\text{-}NCH_2CH_2X)\}_2]$ (Ln = Y, Lu; $C_5R_4 = C_5Me_4$, $C_5H_3Bu^t$; X = OMe, NMe_2) readily initiate ring-opening polymerization of ε-caprolactones.[5d]

The present research was aimed towards the preparation of a new functionalized cyclopentadienyl ligand with a pendant hydroxy group suitable for coordination to a divalent lanthanide ion and to the synthesis of the corresponding Yb(II) derivative. Related ligands with pendant O or N functional groups are of great importance in organotransition metal chemistry.[6] Up to now, linked cyclopentadienyl-silanol ligands have not been described. 1,1,3,3-Tetramethyl-3-tetramethylcyclopentadienyl-disiloxane-1-ol was synthesized in two steps (Scheme 1).

$$C_5Me_4HLi \xrightarrow{i} \underset{\mathbf{1}}{C_5Me_4HMe_2SiOSiMe_2Cl} \xrightarrow{ii} \underset{\mathbf{2}}{C_5Me_4HMe_2SiOSiMe_2OH}$$

Scheme 1 *Reagents and conditions*: i, $ClMe_2SiOSiMe_2Cl$, molar ratio $C_5Me_4HLi:ClMe_2SiOSiMe_2Cl$ = 1:5, thf, 18 h room temp.; ii, H_2O, py, thf, 4 h, room temp.

In the first step (Scheme 1, step i)† a five-fold excess of $ClMe_2SiOSiMe_2Cl$ was used to avoid possible formation of $C_5Me_4HMe_2SiOSiMe_2C_5Me_4H$. Hydrolysis of **1** was carried out in thf in the presence of pyridine and afforded **2** in 68% yield, which was purified by flash chromatography on silica gel. Compound **2**‡ gave a satisfactory microanalysis and ^1H NMR spectrum. An HPLC analysis confirmed its purity.

For the synthesis of the targeted ytterbium(II) complex the reaction of protolytic substitution of naphthalene in highly reactive $(C_{10}H_8)Yb(thf)_2$ **3**[7] by the new ligand was used. Similar reactions have been previously shown to be a convenient synthetic route to various Yb(II) and Yb(III) derivatives.[8] Interaction of $(C_{10}H_8)Yb(thf)_2$ with $C_5Me_4HSiMe_2OSiMe_2OH$ readily occurs in thf at room temperature, affording H_2, $C_{10}H_8$ and $[\{(\eta^5\text{-}C_5Me_4)SiMe_2OSiMe_2(\eta^1\text{-}O)\}Yb(thf)]_2$ **4** (Scheme 2) which was obtained as ruby red crystals after recrystallization from thf–hexane in 57% yield.§ Surprisingly no oxidation with formation of Yb^{3+} species takes place during the course of the reaction despite the presence of siloxide functional groups.

$$(C_{10}H_8)Yb(thf)_2 + C_5Me_4HMe_2SiOSiMe_2OH \xrightarrow{-H_2,\ -C_{10}H_8} \underset{\mathbf{4}}{[\{(\eta^5\text{-}C_5Me_4)SiMe_2OSiMe_2(\eta^1\text{-}O)\}Yb(thf)]_2}$$

Scheme 2

Compound **4** is highly sensitive to oxygen and moisture, soluble in thf and DME, sparingly soluble in toluene and diethyl ether and insoluble in aliphatic hydrocarbons. Magnetic measurement and NMR studies have shown **4** to be diamagnetic, corresponding to the Yb^{2+} oxidation state. Compound **4** has been characterized by microanalysis, IR and ^1H NMR spectroscopy as well as by an X-ray diffraction study (Fig. 1).¶ The dimeric complex possesses inversion symmetry imposing the central four membered ring Yb–O2–Yba–O2a to be planar. The endocyclic ytterbium oxygen distances are slightly different [Yb–O2 227.4(2), Yb–O2a 231.9(2) pm] and somewhat shorter than the exocyclic one [Yb–O3 238.1(1) pm). The tetra-

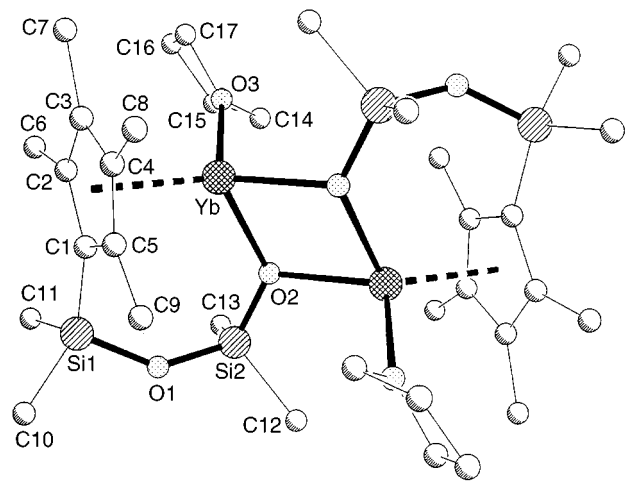

Fig. 1

methylcyclopentadienyl ligand is essentially planar with an ytterbium–centroid distance of 241 pm. The thf molecule displays an envelope conformation with O3 52.5 pm out of the plane defined by C14, C15, C16 and C17. The mean deviation from this best plane is 5.2 pm. The silicon oxygen bond lengths vary from 161.2(2) pm (Si2–O2, the ytterbium briding oxygen) to 164.7(2) pm (Si1–O1).

In an initial reactivity study it was found that **4** does not catalyze propylene polymerization at 20 °C and atmospheric pressure.

We thank the Russian Fund of Basic Research for financial support of this work (RFBR Grants No. 99-03-32905 and 93-03-04131).

Notes and references

† *Synthesis* of **1**: to the solution of 5.04 g (24.85 mmol) of $ClSiMe_2OSiMe_2Cl$ in 20 ml of thf solid C_5Me_4HLi (0.637 g, 4.97 mmol) was added under stirring at −30 °C. The reaction mixture was stirred for 2 h, warmed to room temp. and left overnight. The volatiles were removed under reduced pressure (20 mm Hg), the residue was washed with hexane and the extract was filtered to separate the product from LiCl. Hexane was evaporated under reduced pressure and the resulting yellow oil was distilled under vacuum (106–108 °C/4 mm Hg) yielding 1.26 g (88%) of **1**. Anal. Calc. for $C_{13}H_{25}ClOSi_2$: C, 54.07; H, 8.65; Cl, 12.27. Found: C, 54.36; H, 8.18; Cl, 12.73%. ^{1}H NMR ($CDCl_3$): δ 0.04–0.08 (m, 12H, $SiMe_2$), 1.94 (s, 6H, C_5Me_4H), 2.00 (s, 6H, C_5Me_4H), 2.98 (m, 1H, C_5Me_4H).

‡ *Synthesis* of **2**: to a solution of **1** (1.26 g, 4.36 mmol) and 0.35 ml (0.345 g, 4.36 mmol) of pyridine(py) in 15 ml of thf, 0.078 ml (4.36 mmol) of H_2O were added dropwise at 0 °C and the reaction mixture warmed to room temp. and stirred for 4 h. A white precipitate was separated by filtration; thf was evaporated in vacuum and the resulting pale-yellow oil purified by flash chromatography on silica gel 60 (cyclohexane–ethylacetate, 20 : 1) yielding 0.79 g (68%) of **2**. Anal. Calc. for $C_{13}H_{26}O_2Si_2$: C, 57.76; H, 9.61; Si, 20.78. Found: C, 57.30; H, 9.57; Si, 20.34%. ^{1}H NMR ($CDCl_3$): δ 0.04–0.08 (m, 12H, $SiMe_2$), 1.90 (br s, 1H, OH), 1.92 (s, 6H, $C_5\mathit{Me}_4H$), 2.00 (s, 6H, $C_5\mathit{Me}_4H$), 2.98 (m, 1H, $C_5Me_4\mathit{H}$).

§ *Synthesis* of **4**: to a suspension of 0.62 g (1.39 mmol) of **3** in 25 ml of thf a solution of 0.38 g (1.40 mmol) of **2** in 10 ml of thf was added slowly under vigorous stirring. The reaction mixture turned reddish-brown, the residue of **3** slowly dissolved and H_2 evolved. After 16 h the solution was filtered, thf was evaporated under vacuum and the resulting brown residue was heated (1 h, 50 °C) to separate by sublimation the naphthalene by-product (0.16 g, 93%). The resulting brown solid was recrystallized from thf–hexane to afford 0.41 g (57%) of **4** as ruby red crystals. Anal. Calc. for $C_{17}H_{32}O_3Si_2Yb$: C, 39.77; H, 6.23; Yb, 33.69. Found: C, 39.55; H, 6.11; Yb, 33.98%. IR (Nujol, KBr, cm^{-1}): 460, 610, 680, 740, 800, 830, 890, 950, 1025, 1035, 1050, 1075, 1150, 1260, 1325. ^{1}H NMR (d^8-thf): δ 0.04 (s, 6H, $SiMe_2$), 0.21 (s, 6H, $SiMe_2$), 1.84 (s, 6H, C_5Me_4), 1.93 (s, 6H, C_5Me_4).

¶ *Crystal data*: the measurement on **4** was performed at −100 °C using a Siemens SMART CCD system with Mo-Kα X-radiation (λ = 0.71073 Å) and a graphite monochromator. A selected crystal of **4** was coated with mineral oil, mounted on a glass fibre and transferred to the cold nitrogen stream (Siemens LT-2 attachment). A full hemisphere of the reciprocal space was scanned by ω in three sets of frames of 0.3°. As an absorption correction the SADABS routine was applied.

4: $C_{34}H_{64}O_6Si_4Yb_2$, M = 1027.29, orthorhombic, space group *Pbca*, a = 14.6684(10), b = 16.4898(2), c = 17.3574(2) Å, U = 4198.39(8) Å^3, Z = 4, D_c = 1.625 Mg m^{-3}, F(000) = 2048, μ(Mo-Kα) = 4.579 mm^{-1}, max/min transmission 1.00/0.69, ruby red prism 0.56 × 0.52 × 0.32 mm. A total of 26491 reflections were collected, over a range $2.2 < \theta < 28.3°$, of which 5197 were independent (R_{int} = 0.023). The structure was solved by direct methods.[9] Refinement was by full-matrix least squares on F^2 and converged to $R1$ = 0.0194 (conventional) and $wR2$ = 0.0461 (all data), with goodness of fit = 1.091, 216 parameters, weighting scheme $[\sigma^2(F_o^2) + 0.0181P)^2 + 4.3441P]$, where $P = (F_o^2 + 2F_c^2)/3$. Intracluster transmetalation of cuprates with stannanes

Cristina Mateo, Diego J. Cárdenas, Belén Martín-Matute and Antonio M. Echavarren*

Departamento de Química Orgánica, Universidad Autónoma de Madrid, Cantoblanco, 28049 Madrid, Spain. E-mail: anton.echavarren@uam.es

Received (in Liverpool, UK) 5th August 1999, Accepted 13th September 1999

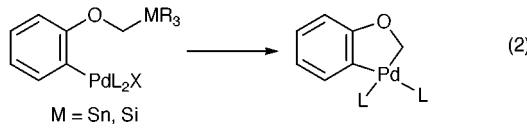
Alkylarylcuprates with intramolecularly tethered stannanes undergo an intracluster Cu^{I}/Sn^{IV} transmetalation to yield arylstannanes.

Transmetalation of diorganocuprates with alkenyltrialkylstannanes allows for the selective synthesis of mixed organocuprates with concomitant formation of stable tetraalkylstannanes [eqn. (1)].[1] This method has been successfully extended to the

$$R^1SnR^2_3 + R^3{}_2CuLi \longrightarrow R^1R^3CuLi + R^3SnR^2_3 \qquad (1)$$

preparation of allyl cuprates.[2] However, despite the synthetic importance of this reaction[1–3] little is known about its mechanism.

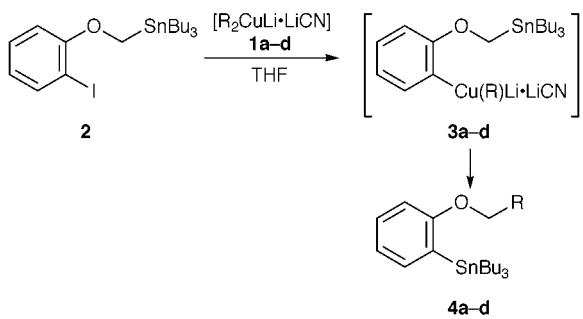
We have been able to isolate the Pd/Sn and Pd/Si transmetalation steps of the Stille and Hiyama coupling reactions, respectively, by performing the reaction intramolecularly in a system which was unable to reductively eliminate because of the instability of the resulting organic product [eqn. (2)].[4] We



(2)

decided to use a similar approach to study the Cu/Sn transmetalation.

Recently, Sakamoto demonstrated that mixed arylmethylcuprates can be obtained from iodobenzenes by iodine–copper exchange reaction with [$LiCuMe_2$·LiCN] (**1a**).[5,6] Therefore, we chose to study the reactivity of arylcuprates **3**, synthesised by reaction of aryl iodide **2** with **1** (Scheme 1 and Table 1). Upon warming of the solution of **3a**[7] from −78 to 23 °C, arylstannane **4a** was cleanly formed in high yield by an apparent intramolecular Cu/Sn transmetalation.[8,9]† A similar reaction was observed with cuprates **3b**–**d** formed *in situ* from aryl iodide **2** by reaction with the corresponding homocuprates **1b**–**d**, although yields were lower due to the slower iodine/copper exchange reaction as compared with that of **1a**. Stannane **4a** was also obtained by reaction of **2** with [$LiCuMe_2$·LiI], although the reaction was not so clean. Reaction of **2** with either MeLi or BuLi (2 equiv. each) failed to give any of the rearranged products **4a** or **4b**, instead yielding **5** after hydrolysis.

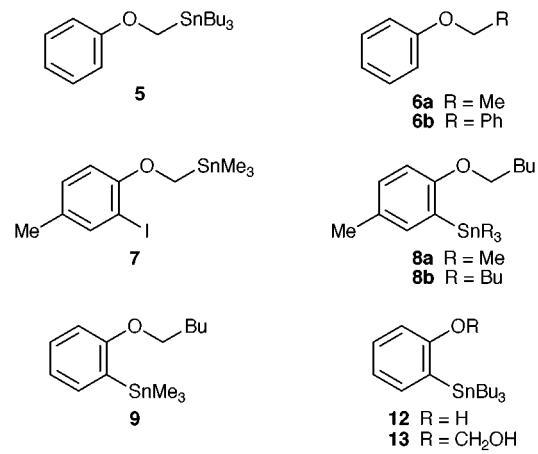


Scheme 1

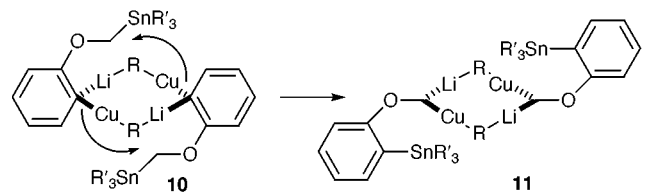
Table 1 Reaction of stannane **2** with cuprates **1a**–**d**

1 (equiv.)	R	Product	Isolated yield (%)
1a (1.1)	Me	**4a**	96
1a (2.0)	Me	**4a**	38
1b (1.6)	Bu	**4b**	40
1b (2.0)	Bu	**4b**	50
1c (1.5)	Bu^t	**4c**	37
1c (2.0)	Bu^t	**4c**	26
1d (1.2)	Ph	**4d**	43

Arylstannanes **4** presumably arise by Cu/Sn transmetalation, followed by reaction of the resulting cuprate with RI formed in the first iodine/copper exchange process. Although a direct intramolecular process on **3** appears to be forbidden due to endocyclic restriction,[10] the following experiment also excludes a simple intermolecular pathway. Thus, treatment of a mixture of stannane **5** and iodobenzene with **1a** failed to give any of ethers **6a**,**b** and phenyltributylstannane.[11] Similarly, no Cu^{I}/Sn^{IV} exchange was observed between **5** and [$LiCuPh_2$·LiCN] (**1d**).



On the other hand, treatment of a 1:1 mixture of **2** and **7** with [Bu_2CuLi·LiCN] led to a mixture of the four possible products **4b**, **8a**, **8b** and **9**.[12] Although apparently puzzling, this crossover experiment can be readily explained if the usual dimeric structure of the cuprates is taken into account (Scheme 2).[13] Thus, reaction of cuprates **1** with the aryl iodides would furnish



Scheme 2

dimer alkylarylcuprates **10**,[14] which could suffer a selective intracluster transmetalation to afford mixed cuprate **11**. Evidence for the formation of species **11** was obtained by the isolation of stannane **12**[15] in the reactions of **1b** with **2**, presumably as a result of the hydrolysis of hemiketal **13** resulting from the oxidation of cuprate **11** (R = R′ = Bu) by oxygen. Final coupling of cuprates **11** with RI (R = Me, Bu, Bu^t, Ph) formed in the first iodine/copper exchange reaction accounts for the formation of products **4a–d** (Scheme 1).

Thus the present study demonstrates that transmetalation of stannanes with cuprates can proceed in an intracluster manner. This is also the first example of transmetalation of alkylstannanes with organocuprates. Similar transformations could be conceived with organostannanes bonded to the lithium atoms of cuprate dimers through the appropriate directing groups.

We are grateful to the DGES (Project PB97-0002-C2-02) for support of this research and to the MEC for a predoctoral fellowship to B. M.-M.

6 For the structure of organocuprates generated from CuCN: N. Krause, *Angew. Chem., Int. Ed.*, 1999, **38**, 79.

7 Formation of an arylcuprate intermediate was demonstrated by the formation of *o*-allylphenol by treatment *o*-iodophenol allyl ether with **1a** (73% yield). For a similar rearrangement: J. Barluenga, R. Sanz and F. J. Fañanás, *Tetrahedron Lett.*, 1997, **38**, 6103.

8 Best results were obtained with 1.1–1.5 equiv. of cuprate **1a**. The use of larger amounts led to lower yields of **4a**, presumably as a result of the early quenching of MeI by the excess **1a** (ref. 5).

9 The mixed cuprates could not be prepared by the direct Sn/Cu exchange from the *o*-substituted arylstannanes, probably due to steric hindrance. Thus, no reaction was observed in the reaction of **1a** or **1b** with 2-(tri-*n*-butylstannylmethoxy)phenyltri-*n*-butylstannane, while the reaction between phenyltri-*n*-butylstannane and **1b** yields tetra-*n*-butylstanne (74% isolated yield).

A new approach towards the synthesis of sp³ 1,1-diiodoalkanes

Lionel Aufauvre,[a] Paul Knochel[b] and Ilan Marek[a]*

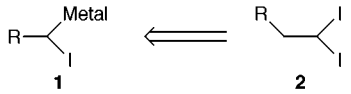
[a] *Department of Chemistry and Institute of Catalysis Science and Technology, Technion-Israel Institute of Technology, Technion City, Haifa 32 000, Israel. E-mail: chilanm@tx.technion.ac.il*

[b] *Institute fur Organische Chemie der Ludwig-Maximilians-Universitat Munchen Butenandstr.5-13, D-81377 Munchen, Germany*

Received (in Cambridge, UK) 10th September 1999, Accepted 24th September 1999

An easy and straightforward method for the synthesis of *gem*-diiodo derivatives is reported.

Carbenoids **1**, in which a single carbon atom carries both a metal atom and a leaving group, are valuable reactive molecules and have been used extensively in organic synthesis.[1] They are generally prepared from *gem*-dihaloalkanes by metal–halogen exchange and more specifically from 1,1-diiodoalkanes **2** since they are far more reactive than the corresponding other halogens; in some cases iodides are the only reactive halides[2] [eqn. (1)].

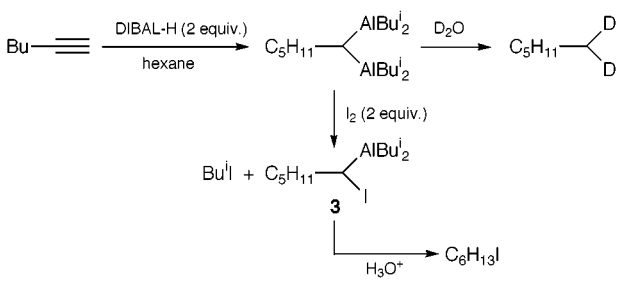


(1)

Unfortunately, they are also more difficult to prepare because of this high C–I bond reactivity. Indeed, few methods have been reported for their preparation[3] and to date, the more versatile approach is based on the alkylation of the diiodomethyllithium or diiodomethylsodium with reactive electrophiles.[4] The major drawback of this strategy is that these reactants are unstable at temperatures above −95 °C, which preclude their preparation on a large scale. So, in the course of our studies on the synthesis and reactivity of carbenoids,[5] we needed a more general approach for the preparation of 1,1-diiodoalkanes allowing access to a large variety of carbon skeletons on multigram scales. For this purpose, we have investigated the iodolysis of 1,1-bis(diisobutylalumino)alkanes,[6] which are readily accessible *via* double hydroalumination of alk-1-ynes.[7] As expected the deuterolysis of 1,1-bis(diisobutylalumino)hexane gave us 1,1-dideuterohexane in good chemical yield (which proved the presence of the 1,1-bisanion) but the addition of 2 equiv. of I_2 gave only the 1-iodohexane, as described in Scheme 1.

In order to obtain *gem*-diiodohexane, it was necessary to add more than 6 equiv. of I_2 since each isobutyl group on the aluminium atom reacts faster than the carbenoid **3**. To overcome this large excess of iodine, we thought to use a hydroaluminating reagent with nontransferable alkyl groups, such as dichloroaluminium hydride[8] ($HAlCl_2$). This is easily obtained by mixing $AlCl_3$ with $LiAlH_4$[9] as described in eqn. (2).

The LiCl formed during the preparation of $HAlCl_2$ is not troublesome for the following step and no separation was required. The double hydroalumination of various alkynes with



Scheme 1

$$3\ AlCl_3 + LiAlH_4 \xrightarrow{Et_2O} 4\ AlCl_2H + LiCl \qquad (2)$$

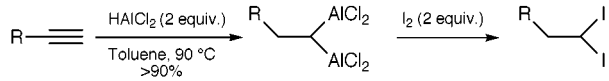
$HAlCl_2$ occurs in very high yields (> 95%) even on a large scale (except entry 3, Table 1). Moreover, the addition of 2 equiv. of I_2 at 0 °C leads now to the formation of 1,1-diiodoalkane derivatives as described in Scheme 2 and in Table 1.

The results reported in Table 1 fulfil our expectations. In the experiments described in the entries 1, 2 and 6 the yields in 1,1-diiodoalkanes are good.

Table 1 Synthesis of 1,1-diiodoalkanes

Entries	R	Compounds	Yield (%)[a]
1	Hexyl	**4**	81
2	Octyl	**5**	75
3	Bu^t	**6**	52
4	Ph	**7**	50
5	$PhCH_2$	**8**	46
6	$PhCH_2CH_2$	**9**	75

[a] Isolated yields after hydrolysis.



Scheme 2

For the double hydroalumination of *tert*-butylacetylene (entry 3) the yield is lower since it was difficult to obtain in good yield the corresponding 1,1-bis(dichloroalumino)-3,3-dimethylbutane (the starting material is very volatile). The presence of an electon-withdrawing substituent on the triple bond, as in phenylacetylene (entry 4), increases the acidity of the acetylenic hydrogen and hence leads to increased metalation during the double hydroalumination. Thus, the reaction of phenylacetylene with 2 equiv. of $HAlCl_2$ in toluene gives the expected product but a possible metalation of the triple bond could impair the yield of the bis-alane (entry 4). In a similar way, when the reaction is performed on 3-phenylprop-1-yne (entry 5), the presence of acidic benzylic and propargylic hydrogens decrease the yield. Moreover, the hydrolysis of the reaction mixture is also a crucial step and needs to be done at 0 °C. Indeed, after iodinolysis, 2 equiv. of the strong Lewis acid $IAlCl_2$ are present in the reaction and can affect the chemical yield (see experimental procedure[10]).

In conclusion, we have elaborated a new and straightforward approach for the one-pot synthesis of sp³ 1,1-diiodoalkanes in good yield *via* the synthesis of 1,1-bis(dichloroalumino)alkanes. Low temperature is not required (90 °C for the bismetallic synthesis and 0 °C for the reaction with I_2) and the method has been applied to large scale preparations.

9 The $LiAlH_4$ was used as an ethereal solution which was titrated either by the iodometric method (H. Felkin, *Bull. Soc. Chim. Fr.*, 1951, **18**, 347) or with salicylaldehyde phenylhydrazone as indicator (B. E. Love and E. G. Jones, *J. Org. Chem.*, 1999, **64**, 3755).
10 *Experimental procedure*: To a suspension of $AlCl_3$ (0.66 g, 4.95 mmol, 1.65 equiv.) in 3 ml of pentane and 7.5 ml of Et_2O was added an ethereal solution of $LiAlH_4$ (1.09 M, 1.51 ml, 1.65 mmol, 0.55 equiv.) at room temperature. After stirring for 5 min, the solvents were removed at room temperature under vacuum (20 mmHg) through $CaCl_2$ to give a white suspension of LiCl and $HAlCl_2$ (6.6 mmol, 2.2 equiv.). 6 ml of toluene was then added, followed by dec-1-yne (0.415 g, 3 mmol, 1 equiv.). The reaction mixture was heated at 90 °C for 3 h to give the 1,1-bis(di-chloroalumino)decane. After cooling to 0 °C, 20 ml of THF was added and a solution of I_2 (1.675 g, 6.6 mmol, 2.2 equiv.) in 20 ml of cold THF was then added. The reaction mixture was allowed to warm to room temperature and stirred for 15 min. The reaction mixture was then transferred into a cold solution (0 °C) of aqueous HCl (1 M, 100 ml). After stirring for 5 min, the aqueous layer was extracted with Et_2O, the collected organic phases were washed with aq.$Na_2S_2O_3$ and saturated brine, and then dried over $MgSO_4$. After filtration and evaporation of the solvents, the residue was chromatographed on silica gel.

Ferromagnetic ordering in the perovskite $La_{1.5}Sr_{0.5}RhMnO_6$

B. Bakowski,[a] P. D. Battle,*[a] E. J. Cussen,[a] L. D. Noailles,[a] M. J. Rosseinsky,*[a] A. I. Coldea[b] and J. Singleton[b]

[a] *Inorganic Chemistry Laboratory, Department of Chemistry, University of Oxford, South Parks Road, Oxford, UK OX1 3QR. E-mail: peter.battle@chem.ox.ac.uk; matthew.rosseinsky@chem.ox.ac.uk*

[b] *Clarendon Laboratory, Department of Physics, University of Oxford, Parks Road, Oxford, UK OX1 3PU*

Received (in Oxford, UK) 10th September 1999, Accepted 5th October 1999

The non-metallic, magnetically-dilute, cation-disordered perovskite $La_{1.5}Sr_{0.5}RhMnO_6$ is shown to be a soft ferromagnet with T_C = 105 K with an ordered magnetic moment of 3.56(8) μ_B per Mn.

There has been a resurgence of interest in ferromagnetic oxides due to the strong coupling between spin ordering and charge transport found in the $La_{1-x}Sr_xMnO_3$ perovskites, which display colossal magnetoresistance (MR).[1] The Mn(III) perovskite $LaMnO_3$ is an antiferromagnetic insulator below 143 K, but the partial oxidation to Mn(IV) which occurs when Sr^{2+} is substituted for La^{3+} changes the electronic properties markedly. At low temperatures, $La_{1-x}Sr_xMnO_3$ is a ferromagnetic insulator for $0.1 \leqslant x \leqslant 0.15$ and a ferromagnetic metal for $0.15 \leqslant x \leqslant 0.6$.[2] The temperature of the transition to the magnetically ordered phase is a function of x, but for $x \geqslant 0.15$ it is coincident with the metal–insulator transition, and the highest MR effects are seen around this point. The suppression of the zero-field resistance in an applied field can be as large as 100 $\Delta\rho/\rho(H = 0)$ = 99.9% in fields of over 50 kG, but achieving significant MR in the low fields required for information storage applications has proved a difficult barrier for the current generation of materials. The present lack of understanding of the MR effect in perovskites has hindered attempts to overcome this barrier; although it is agreed that double exchange is an important factor, it is also recognised that it is not the only factor.[3] A number of strategies have been adopted in order to enhance our understanding of the electronic properties relevant to MR in oxides, with particular emphasis on the magnetic behaviour of mixed-valence manganates. We demonstrate here that ferromagnetism is retained in $La_{1.5}Sr_{0.5}RhMnO_6$, a non-metallic perovskite with a 50% diluted Mn sublattice where the mean oxidation state is $Mn^{3.5+}$.

Preliminary investigation of the $La_{2-x}Sr_xRhMnO_6$ system in air showed that a sample with the nominal composition La_2MnRhO_6 was polyphasic, with La_2O_3/$La(OH)_3$ impurities being apparent in diffraction patterns. However, we were able to prepare monophasic perovskite samples in the system $La_{2-x}Sr_xRhMnO_6$ for x = 0.2, 0.5 and 0.6, that is by increasing the mean oxidation state of the transition metal; the composition $La_{1.5}Sr_{0.5}RhMnO_6$ will be the focus of this communication. Samples were prepared by the reaction of pre-dried La_2O_3, $SrCO_3$, MnO_2 and Rh_2O_3 for 24 h at 800 °C, followed by 48 h at 1000 and 1200 °C and ending with 96 h at 1400 °C. The products were quenched in liquid nitrogen after the final heating to ensure the formation of a highly crystalline, homogeneous product. The X-ray diffraction patterns of samples prepared in this way showed only the peaks expected from a $GdFeO_3$ - like pseudo-cubic perovskite.[4]

Magnetisation *versus* temperature measurements† made in an applied field of 100 G suggested that all three compositions order ferromagnetically, with T_C = 95, 105 and 105 K for x = 0.2, 0.5 and 0.6 respectively. The data collected on the composition x = 0.5 are shown in Fig. 1; Curie–Weiss behaviour is not observed within the measured temperature range, and hysteresis is apparent between the ZFC and FC data below T_C. The $M(H)$ magnetisation isotherm at 5 K is characteristic of a soft ferromagnet, with a saturation magnetisation of 3.9(1) μ_B per Mn being achieved in 10 kG at 5 K. Neutron powder diffraction data† (D2B, ILL) collected on the x = 0.5 composition prove that this sample exhibits long range ferromagnetic ordering at low temperature. Rietveld[5] refinement of data collected at 290 K proceeded smoothly (R_{wpr} = 4.97%, χ^2 = 1.96) within a model which considered only nuclear scattering; there was no evidence of Mn/Rh cation ordering over the six-coordinate sites. Successful analysis (R_{wpr} = 5.30 %, χ^2 = 2.0) of the data collected at 1.7 K required the inclusion of an ordered magnetic moment of 3.56(8) μ_B on the Mn cations; the atomic moments align along the [010] axis. Four-probe dc conductivity measurements showed (Fig. 2) that the compound is non-metallic, albeit with a varying activation energy, both above and below the Curie temperature.

The oxidation states of the different cations which occupy the electronically active B site are not directly defined by our measurements, but consideration of the established oxide chemistries of Mn and Rh leads to the assumption that Rh is present solely as Rh^{III} (low spin t_{2g}^6), resulting in a mean Mn

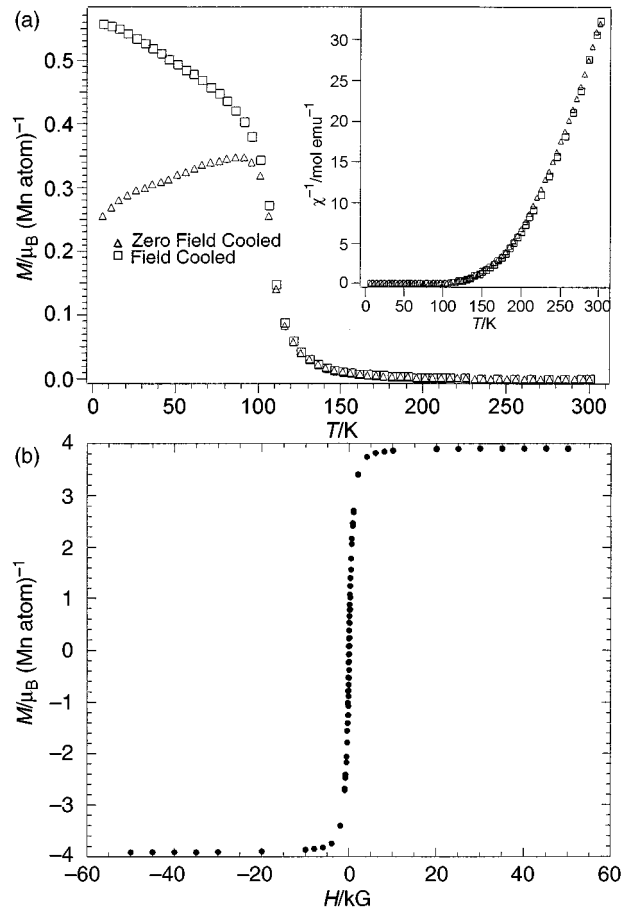

Fig. 1 (a) Temperature dependence of magnetisation and (inset) inverse molar susceptibility of $La_{1.5}Sr_{0.5}RhMnO_6$, measured in a field of 100 G. (b) Magnetisation as a function of field at 5 K for $La_{1.5}Sr_{0.5}RhMnO_6$.

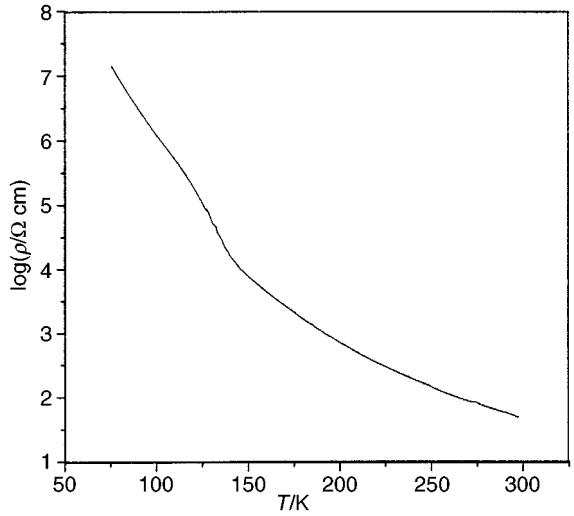

Fig. 2 Temperature dependence of the electrical resistivity of $La_{1.5}Sr_{0.5}RhMnO_6$.

oxidation state of +3.5 in $La_{1.5}Sr_{0.5}RhMnO_6$. This is the same oxidation state that occurs in $La_{0.5}Sr_{0.5}MnO_3$, a ferromagnetic, metallic composition with $T_C \approx 350$ K. Although the ferromagnetism of the Rh-free sample has been ascribed to double exchange, the non-metallic nature of the $x = 0.5$ composition rules out the conventional form of that mechanism in $La_{1.5}Sr_{0.5}RhMnO_6$. Our results suggest that ferromagnetic superexchange interactions dominate the magnetic coupling in the 1:1 random array of localised-electron Mn^{3+} and Mn^{4+} cations, and that they are strong enough to produce long-range magnetic order at 105 K, even with 50% dilution by a diamagnetic cation. The magnitude of the ordered magnetic moment determined by neutron diffraction is as large as can be expected for a mean oxidation state of $Mn^{3.5+}$. The Goodenough–Kanomori rules[6] would then suggest that ferromagnetic σ superexchange between Mn^{3+} and Mn^{4+} cations is a very strong effect in this compound, and that it outweighs the antiferromagnetic interactions between pairs of like ions. However, this argument ignores the effect that local atomic displacements will have on the sign of the magnetic exchange constants. Although our neutron diffraction data indicate that the six-coordinate environment of the disordered transition metal species is an essentially regular octahedron, this is a description of the average site, and the temperature-dependence of the anisotropic thermal parameters indicates that static disorder is present, most noticably on the O(1) sublattice. We must therefore guard against over-simplification of the problem.

The behaviour of $La_{1.5}Sr_{0.5}RhMnO_6$ contrasts sharply with that of another magnetically-dilute, mixed-valence perovskite, $Sr_2FeTiO_{5.81}$, which shows spin-glass behaviour at low temperatures.[7] In this and other related materials, the absence of ordering in the cation distribution has been held responsible for the lack of long-range magnetic order. It is therefore reasonable to postulate that in the present case, Mn^{3+}/Mn^{4+} ordering does occur, but over a distance scale too short to be detected in a neutron diffraction experiment. This should be investigated using the appropriate experimental techniques. An alternative explanation to that based on superexchange could lie in the relatively extensive nature of the Rh 4d orbitals, which might allow significant Mn–Rh–Mn coupling, leading to the partial delocalisation of an e_g electron and hence ferromagnetic coupling. This model effectively removes the distinction between Mn^{3+} and Mn^{4+} oxidation states and invokes double exchange over a limited volume. Although we are not yet able to elucidate in detail the cause of ferromagnetism in $La_{1.5}Sr_{0.5}RhMnO_6$, it is a significant observation to be considered when discussing the relative importance of double exchange and superexchange in oxides which show colossal MR.

We acknowledge funding from the UK EPSRC.

Palladium catalysed cross-coupling of (fluoroarene)tricarbonylchromium(0) complexes

David A. Widdowson* and René Wilhelm

Department of Chemistry, Imperial College of Science Technology and Medicine, London, UK SW7 2AY. E-mail: d.widdowson@ic.ac.uk

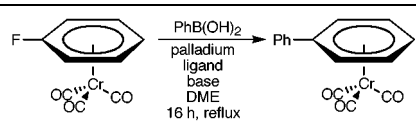
Received (in Liverpool, UK) 2nd August 1999, Accepted 29th September 1999

Fluoroarenetricarbonylchromium(0) complexes were found to undergo Suzuki reactions with arylboronic acids to form biaryltricarbonylchromium(0) complexes in the presence of trimethylphosphine/palladium dibenzylideneacetone and caesium carbonate or caesium fluoride.

The Suzuki reaction is one of the most widely used and successful processes for the synthesis of biaryls and styrenes.[1] Although aryl iodides and bromides are the most commonly used halide partners in the reaction, in some remarkable recent developments, aryl chlorides, hitherto regarded as inert to palladium coupling, have been shown to be effective participants provided that an electron-withdrawing group on the aryl ring[2] (including an η^6-tricarbonylchromium group[3]) or a basic phosphine ligand for palladium[4–9] is present. In the latter case, it has been shown that tricyclohexylphosphine and tri-*tert*-butylphosphine ligands on the palladium catalyst are particularly effective, even with electron rich aryl chlorides.[4] We have previously demonstrated the unique synthetic potential of monofluoroarene complexes in the synthesis of polyfunctionalised aromatics[10,11] and given the ease and efficiency with which chloroarenetricarbonylchromium complexes undergo cross-coupling reactions,[3] we were prompted to attempt the Suzuki reaction of the fluoro complexes as a route to highly functionalised biaryls. We now report the first step towards that objective, the palladium catalysed cross-coupling of aryl fluorides.

Using standard conditions for Suzuki coupling,[1] tetrakis(triphenylphosphine)palladium catalyst, fluorobenzenetricarbonylchromium(0) and phenylboronic acid gave the coupled complex but only in trace amounts (Table 1, run 1). When the reaction was repeated with tris(dibenzylidenacetone)dipalladium/tricyclohexylphosphine and caesium fluoride as the base (Fu conditions[4]), no coupled product was detectable (run 2) but tris(dibenzylidenacetone)dipalladium/trimethylphosphine (run 3) did produce the biphenyltricarbonylchromium(0) complex in 52% yield.

Table 1 Suzuki coupling reactions of fluorobenzenetricarbonylchromium(0) and phenylboronic acid



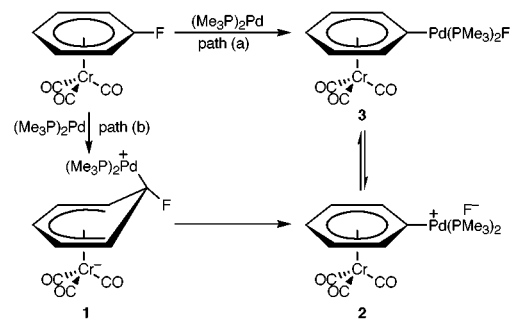
Run	Ligand	Palladium	Base (equiv.)	Yield (%)
1[a]	—	$Pd(PPh_3)_4$	Na_2CO_3 (2.2)	Trace
2	PCy_3	$Pd_2(dba)_3$	CsF (4)	0
3	PMe_3	$Pd_2(dba)_3$	CsF (4)	52
4	—	$Pd_2(dba)_3$	CsF (4)	0
5[b]	PMe_3	$Pd_2(dba)_3$	—	0
6	PMe_3	$Pd_2(dba)_3$	Cs_2CO_3 (2.2)	61
7	PMe_3	—	Cs_2CO_3 (2.2)	0

[a] Toluene as solvent. [b] 4-Methoxyphenylboronic acid replaced phenylboronic acid.

The participation of a fluoroarene, albeit as its tricarbonylchromium complex, in a palladium catalysed cross coupling is unprecedented[12] and required careful evaluation. Control experiments covering the more obvious factors were carried out and the results are summarised in Table 1. Firstly, the ready displacement of fluoride in these complexes by other nucleophiles,[13–16] particularly higher halides, which could then undergo cross-coupling, required that the system be free of any source of such nucleophiles. Thus no solvent/additive which might release higher halide was used and initially, high purity (99.9%) caesium fluoride was used as the base. In principle fluoride should be catalytic but attempts to demonstrate this failed.

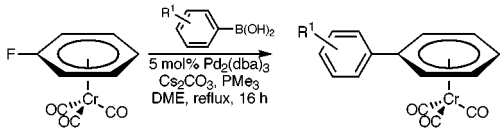
The ineffectiveness of tricyclohexylphosphine as ligand (run 3) could be a consequence of steric hindrance between the bulky tricarbonylchromium unit and the bulky phosphine, and the smaller trimethylphosphine was used in all subsequent experiments. In the absence of any phosphine, the coupling failed (run 4). Reaction without a base (run 5) also failed but the use of caesium carbonate (run 6) increased the yield to 61%. A reaction in the presence of base and phosphine but without palladium (run 7) gave no coupling. The presence of unchanged starting material from this reaction removed the possibility that a borate anion was displacing the fluoride group from the complex and that the resultant arylborate was the active cross coupling partner. This result also demonstrated the unreactivity of neutral phosphine to the fluoro complex, but to reinforce this conclusion a reaction between trimethylphosphine and fluorobenzene complex under cross-coupling conditions was attempted. The complex was recovered unchanged in 98% yield. This precludes a process of phosphonium salt formation and participation of this in cross-coupling[17,18] as the reaction sequence.

These experiments provide strong evidence for direct participation of the fluorobenzene complex in the coupling process with the implication of an unprecedented oxidative addition of the C–F bond to the palladium(0) intermediate.[19] Whether this is a concerted insertion [Scheme 1, path (a)] or an addition–elimination sequence [Scheme 1, path (b)] *via* an *exo*-addition[20] of palladium to form **1** followed by fluoride loss to produce **2** cannot be determined at this point. The insertion product could be active in the catalytic cycle in either neutral (**3**) or cationic (**2**) form.[12]



Scheme 1

Table 2 Suzuki coupling reactions of η^6-(fluorobenzene)tricarbonylchromium(0)



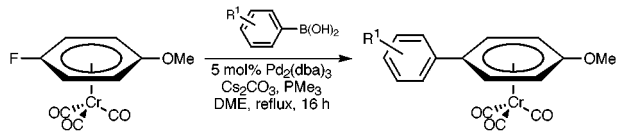
Run	R^1	Yields (%)
1	H	61
2	4-MeO	87
3	2-MeO	78
4	4-Me	81
5	2-Me	79
6	4-Br	0[a]

[a] An intractable oligomeric/polymeric material containing no chromium(0) was produced.

With suitable conditions established, the fluorobenzenechromium complex was coupled with a series of electron-rich arylboronic acids (Table 2).[21] Both moderately hindered (runs 3, 5) and unhindered boronic acids (runs 1, 2, 4) gave good yields. The polymerisation of 4-bromophenylboronic acid under the reaction conditions can be attributed to the greater reactivity of the C–Br bond over the C–F bond.

To further investigate the scope of this process, the more electron-rich 4-methoxyfluorobenzenetricarbonylchromium complex was studied.[21] The yields (Table 3), with both the moderately hindered and the unhindered boronic acids, were comparable to those of the parent complex despite the expected reduction in reactivity of the alkoxy analogue.

Table 3 Suzuki coupling reactions of η^6-(4-fluoromethoxybenzene)-tricarbonylchromium(0)



Run	R^1	Yield (%)
1	H	76
2	2-Me	77
3	4-Me	74

These results clearly raise intriguing mechanistic questions, which we continue to address. The couplings demonstrate the versatility of the arenetricarbonylchromium(0) complexes and add further possibilities to the exploitation of their already widely established role in synthesis.

A highly enantioselective addition reaction of a chiral allylsilane to an activated *N*-acylisoquinolinium ion

Ryohei Yamaguchi,* Masato Tanaka, Tomohiko Matsuda and Ken-ichi Fujita

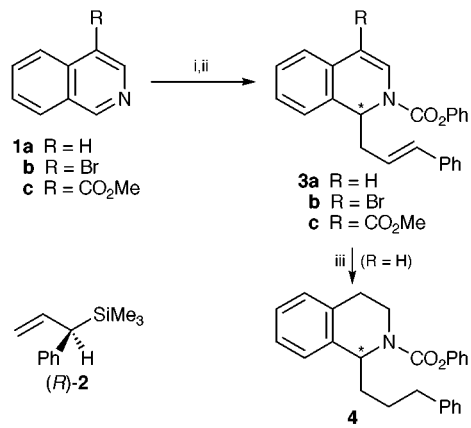
Faculty of Integrated Human Studies and Graduate School of Human and Environmental Studies, Kyoto University, Yoshida Kyoto 606-8501, Japan. E-mail: yama@kagaku.h.kyoto-u.ac.jp

Received (in Cambridge, UK) 31st August 1999, Accepted 16th September 1999

The addition reactions of a chiral allylsilane to activated *N*-acylisoquinolinium ions proceeded in a highly enantioselective manner (more than 90%) to afford homochiral 1-allyl-1,2-dihydroisoquinolines in good yields.

Considerable efforts have been made for the stereoselective introduction of carbon substituents into isoquinoline systems.[1] Although many diastereo- and enantio-selective methods have been available for the stereoselective addition of carbon nucleophiles to 3,4-dihydroquinolines systems (cyclic imines and imine *N*-oxides),[2,3] few reactions have been reported for stereoselective additions to isoquinoline itself and all of them have exploited the diastereoselective additions of achiral organometallic reagents to isoquinolines with chiral auxiliaries in the activating groups.[4] The enantioselective addition reaction of a chiral organometallic reagent to achiral isoquinoline has not been reported. We have recently reported that quinolines and isoquinolines are activated by $ClCO_2Ph$ and AgOTf such that these *N*-acylated aza-aromatic ions can readily react with allylsilanes and alkynylsilanes to afford allylated and alkynylated products chemo- and regio-selectively in good yields.[5] We disclose here the fact that the addition reaction of a chiral allylsilane to the activated *N*-acylisoquinolinium ion proceeded in a highly enantioselective manner to give homochiral 1-allyl-1,2-dihydroisoquinoline. To the best of our knowledge, this is the first example of the addition reaction of a chiral organometallic reagent to an achiral nitrogen heteroaromatic ion with high enantioselectivity.

Isoquinoline **1a** was activated by treatment with $ClCO_2Ph$ (1.2 equiv.) and a catalytic amount of AgOTf (0.1 equiv.) in MeCN, and then a chiral allylsilane, (*R*)-3-phenyl-3-trimethylsilylpropene **2**[6] (81% ee determined by a chiral GLC analysis), was added to the mixture under ice-cooling. The reaction mixture was stirred at room temperature for 24 h to yield a single 1-allylated 1,2-dihydroisoquinoline adduct **3a** in 54% yield (Scheme 1).† The ^{1}H NMR coupling constant (J = 16 Hz) of the olefinic protons indicates that the stereochemistry of the allylic double bond was *E*. These results suggest that the present allylic silicon substitution reactions proceed in an *anti* S_E2' manner (*vide infra*). Since **3a** could not be separated by chiral HPLC. **3a** was hydrogenated to give tetrahydroisoquinoline derivative **4**, the ee of which was determined to be 77% by chiral HPLC analysis. Thus, it is apparent that the chirality transfer of the present reaction is as high as 95%. Similarly, the reactions of functionalized isoquinolines with (*R*)-**2** proceeded in good yields with a high degree of enantioselectivity (more than 90%) as well. The results are summarized in Table 1.



Scheme 1 *Reagents and conditions*: i, $ClCO_2Ph$ (1.2 equiv.), AgOTf (0.1 equiv.), MeCN; ii, (*R*)-**2** (1.0 equiv.), room temp., 24 h; iii, H_2, Pd-C, MeOH. Spectral data for **3b**,**c**, **4**, **6** and **7** are available from the RSC web site, see http://www.rsc.org/suppdata/cc/1999/2213/

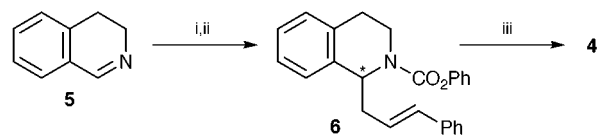
Table 1 Enantioselective additions of (*R*)-**2** to activated *N*-acylisoquinolinium ions

Entry	**1**	R	Yield of **3** (%)[a]	Ee of **2** (%)[b]	Ee of **3** (%)	Enantioselectivity (%)
1	**a**	H	54	81	77[c]	95
2	**b**	Br	86	83	78[d]	94
3	**c**	CO_2Me	78	83	77[d]	93

[a] Isolated yield. [b] Determined by a chiral GLC (Chiral-DEX CB) analysis. [c] Determined by a chiral HPLC (SUMICHIRAL OA-2000) analysis of the hydrogenated product **4**. [d] Determined by a chiral HPLC (CHIROSE C1) analysis.

In contrast with the above results, the similar reaction of 3,4-dihydroisoquinoline **5** with (*R*)-**2** showed a moderate degree of enantioselectivity (Scheme 2). The results are summarized in Table 2. Thus, 76% enantioselectivity was obtained in the reaction even at −15 °C. These results could indicate that the planarity of *N*-acyliminium salts is critical to obtain a high degree of the enantioselectivity (*vide infra*).

The absolute configuration of **4** was determined as follows (Scheme 3): **4** (55% ee) was deprotected[7] to give 1-(3-phenylpropyl)-1,2,3,4-tetrahydroisoquinoline **7**, the optical rotation of

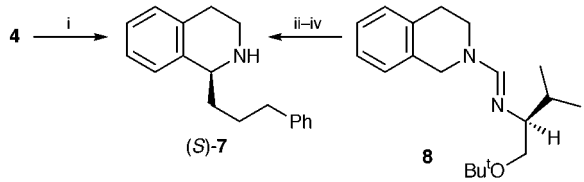


Scheme 2 *Reagents and conditions*: i, $ClCO_2Ph$ (1.2 equiv.), additive (0.1 equiv.), MeCN; ii, (*R*)-**2** (1.0 equiv.), 24 h; iii, H_2, Pd-C, MeOH.

Table 2 Enantioselective additions of (*R*)-**2** (81% ee) to *N*-acyl-3,4-dihydroisoquinolinium ion

Entry	Additive	*T*/°C	Yield of **6** (%)[a]	Ee of **4** (%)[b]	Enantioselectivity (%)
1	AgOTf	0	83	59	73
2	$AgClO_4$	0	67	61	75
3	AgOTf	−15	53	62	76

[a] Isolated yield. [b] Determined by a chiral HPLC (SUMICHIRAL OA-2000) analysis.



Scheme 3 *Reagents and conditions*: i, KOH, Pr^iOH–H_2O, reflux, 3 d; ii, LDA, THF, −78 °C; iii, $PhCH_2CH_2CH_2Br$, −90 °C; iv, NH_2NH_2, AcOH, EtOH.

which was determined to be levorotatory ($[\alpha]_D^{20}$ −28). Since authentic (*S*)-**7** was prepared from **8** according to Meyers' procedures[8] and the optical rotation of (*S*)-**7** is levorotatory ($[\alpha]_D^{20}$ −43), the absolute configuration of **4** should be *S*. Thus, it is apparent that the reactions of isoquinolines with (*R*)-**2** afford (*S*)-1-[(*E*)-3-phenylprop-2-enyl]-1,2-dihydroisoquinolines in a highly enantioselective manner.

It has been generally proposed[9] that the electophilic addition reactions of chiral, acyclic allylsilanes take place in an *anti*-S_E2' manner to form the allylic *E* double bond. Thus, it is highly probable that the present addition reactions proceed through a highly selective *anti*-S_E2' mode. It has also been suggested that two transition models, *i.e.* antiperiplanar and synclinal, are possible in non-chelation transition states. In the present reactions of isoquinolinium ions with (*R*)-**2**, the antiperiplanar *anti*-S_E2' transition state **A** is expected to produce the (*S*)-adduct, while the synclinal *anti*-S_E2' transition state **B** would produce the (*R*)-adduct. Since the (*S*)-adduct is obtained as mentioned above, it is evident that the reactions proceed through the antiperiplanar *anti*-S_E2' transition state **A** (Fig. 1).

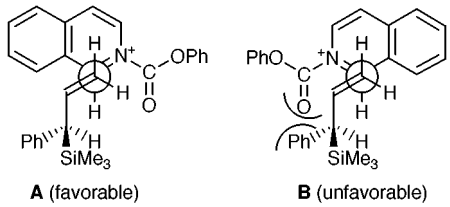


Fig. 1 Possible transition states of the enantioselective *anti*-S_E2' addition reactions of (*R*)-**2** to *N*-acylisoquinolinium ions.

The recent X-ray crystal analysis of an *N*-acylisoquinolinium ion proves that the aromatic rings are coplanar with the carbonyl groups.[10] This conformation is also preferred for maximum overlap of the C=N and C=O bonds, which could make the isoquinolinium ions more electrophilic. Thus, the synclinal *anti*-S_E2' transition state **B** should be unfavorable because of steric repulsion between the carbonyl and the phenyl groups.

In summary, we have demonstrated the highly enantioselective addition reactions of a chiral allylsilane to achiral isoquinolinium ions. A high degree of enantioselectivity (more than 90%) can be obtained in these reactions even at room temperature. Further studies on the reactions of other nitrogen aromatics as well as applications to alkaloids synthesis are underway.

This work was supported by the Ministry of Education, Sciences, Sports and Culture of Japan (No. 10650832).

Notes and references

† *Typical procedure*: To a solution of **1** (1.0 mmol) in MeCN (3.0 ml) was added $ClCO_2Ph$ (0.15 ml, 1.2 mmol, 1.2 equiv.) and AgOTf (0.10 mmol, 0.10 equiv.) at 0 °C. The reaction mixture was stirred for 30 min at 0 °C. Then, to the reaction mixture was added **2** (1.0 mmol, 1.0 equiv.) at 0 °C. The reaction mixture was warmed to room temperature and stirred for 24 h. Et_2O (5.0 ml), aqueous $NaHCO_3$ (3.0 ml) and aqueous Na_2CO_3 (3.0 ml) were added, and the organic layer was separated. The aqueous layer was extracted with Et_2O (5 × 5.0 ml). The combined organic layer was washed with brine and dried over Na_2SO_4. After evaporation of the solvent, the residue was purified by flash column chromatography (eluent: hexane–EtOAc) to give the product. The yields and ees are shown in Table 1. All new compounds gave satisfactory analytical and spectral data. *Selected data* for (*S*)-**3a**: mp 117–119 °C; $[\alpha]_D^{25}$ +266 (*c* 0.075, $CHCl_3$) (77% ee); ν_{max}(KBr)/cm^{-1} 1722, 1633, 1215, 756; δ_H(500 MHz, $CDCl_3$, 55 °C, TMS, a mixture of rotamers) 7.12–7.37 (m, 13H), 7.07 (d, *J* 7, 1H), 7.00 (d, *J* 8.0, 1H), 6.39 (d, *J* 16, 1H), 6.24 (dt, *J* 16, 8, 1H), 6.08, 5.99 (d, *J* 7, 1H), 5.57–5.65 (br m, 1H), 2.58–2.82 (m, 2H); δ_C(125.7 MHz, $CDCl_3$, 55 °C, TMS, a mixture of rotamers) 151.1, 150.9 (C), 137.6, 137.3 (C), 133.5 133.0 (CH), 132.4 (C), 130.4, 130.0 (C), 129.2 (CH), 128.5 (CH), 127.9, 127.8 (CH), 127.3, 127.1 (CH), 127.1, 127.0 (CH), 126.4, 126.3 (CH), 126.3 (CH), 125.8, 125.5 (CH), 125.3, 125.1 (CH), 124.9 (CH), 124.2 (CH), 121.5 (CH), 110.1, 109.5 (CH), 56.9, 55.9 (CH), 39.5, 39.4 (CH_2) (calc. for $C_{25}H_{21}NO_2$: C, 81.72; H, 5.76. Synthesis of glycosyl boranes and glycosyl borinates†

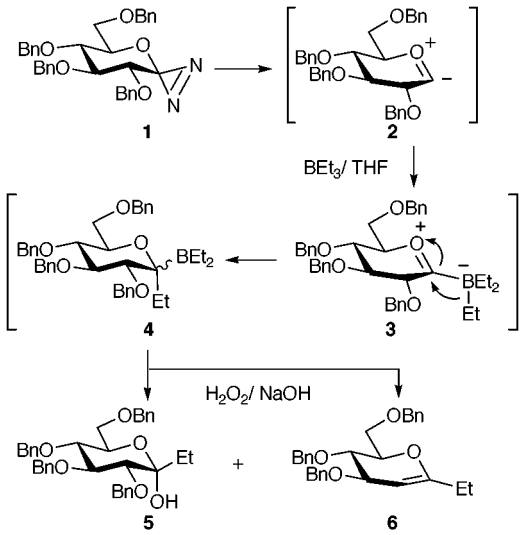
Andrea Vasella,* Wolfgang Wenger and Thennati Rajamannar

Laboratorium für Organische Chemie, ETH-Zentrum, Universitätstrasse 16, CH–8092 Zürich, Switzerland. E-mail: vasella@sugar.org.chem.ethz.ch

Received (in Liverpool, UK) 5th August 1999, Accepted 17th September 1999

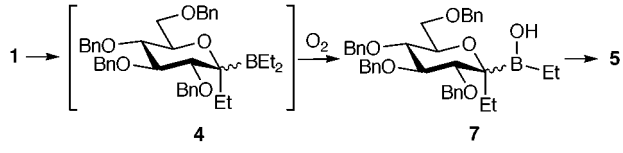
Insertion of glycosylidene carbenes into a B–C bond of BEt_3 leads to unstable glycosyl boranes, while insertion into a B–C bond of borinic esters yields stable anomeric glycosyl borinates.

Insertion of glycosylidene carbenes, generated by thermolysis or photolysis of glycosylidene diazirines, into HX bonds leads to *O*-, *C*- and *N*-glycosides,[1] glycosyl phosphines[2] and glycosyl stannanes.[3] We speculated that reaction of a borane with the carbene **2** would lead to a zwitterion such as **3**; migration of a B-substituent—as proposed for the reaction of methoxycarbene with trialkylboranes[4]—should lead to the as yet unknown glycosyl boranes (Scheme 1).



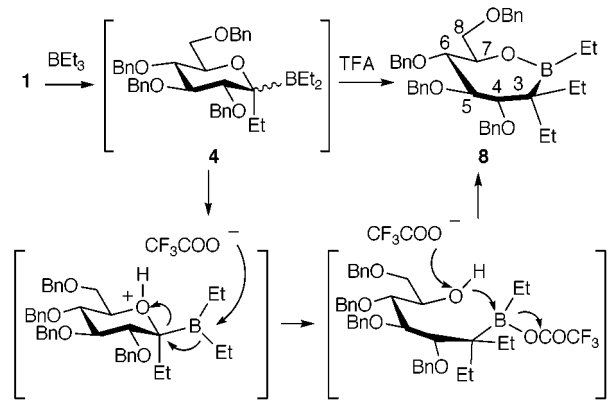
Scheme 1

Thermolysis of the diazirine **1**[5] in degassed THF in the presence of 1.5 equiv. of BEt_3 at 25 °C, followed by treatment with excess 30% alkaline H_2O_2 and aqueous work-up, yielded 55% of hemiacetal **5** and 13% of the *C*-ethylglucal **6**. These products suggest the intermediate formation of anomeric glycosyl boranes **4**. Treatment with alkaline H_2O_2 leads either (depending on the borane configuration?) to oxidation[6] and (after anomerisation?) to the hemiacetal **5**, or to elimination of the C(1) boron substituent and the vicinal benzyloxy group.[7] *trans*-Elimination is suggested by the observation (^{13}C NMR) that **6** is only formed after additon of alkaline H_2O_2. Thermolysis of the diazirine **1** in the presence of 1.5 equiv. of BEt_3 in oxygen-containing THF yielded 25% of the borinic acid **7** after rapid chromatography (Scheme 2). The borinic acid **7** was rapidly converted into the hemiacetal **5** (isolated in *ca.* 75%) by exposure to air, storage in oxygen–containing $CDCl_3$, or treatment with alkaline H_2O_2. The ^{11}B NMR of air-stable mixtures of **7** and 2 equiv. of PPh_3 shows a broad signal at δ 56.5, typical for dialkyl borinic acids.[8] The ^1H NMR shows a broad singlet of an exchangeable H at δ 8.16, corresponding to B–OH, two doublets of quintets at δ 1.8 and 1.6 (2 H), a triplet at δ 0.9 (3 H) for the *C*-ethyl and a multiplet at δ 1.0–0.9 (5 H) of the *B*–Et group. The ^{13}C NMR signal for the boron substituted anomeric carbon is missing, as expected.[9]



Scheme 2

The intermediate formation of a glycosyl borane was further evidenced by treating the product of thermolysis of **1** and BEt_3 in degassed THF with excess TFA, followed by aqueous work-up (Scheme 3). The resulting cyclic borinic ester **8**, isolated in 45%, showed a ^{11}B signal at δ 51, typical for *O*-alkyl borinates.[10]

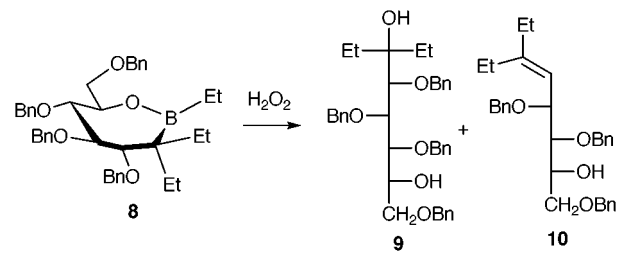


Scheme 3

The ^1H NMR spectrum of **8** shows signals for a $BC(Et)_2$ moiety and a multiplet at δ 0.9–0.7 for a BEt group. H–C(7) is strongly shifted downfield due to the R_2BO substituent [H–C(5) in **6** at δ 4.02, H–C(7) in **8** at δ 4.77].

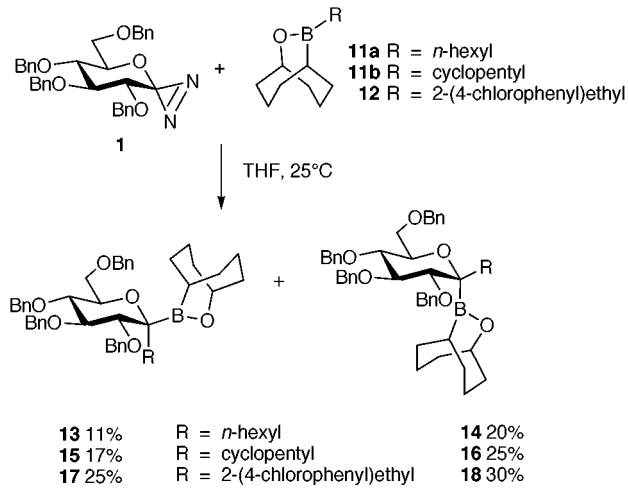
The formation of **8** is rationalised by protonation of the ring oxygen of **4**, nucleophilic attack of trifluoroacetate at boron, 1,2-migration of an ethyl substituent with concomitant ring-opening, and nucleophilic attack of HO–C(7) at boron. Treatment of **8** with alkaline H_2O_2 in THF leads to the diol **9** (37%) and the alkene **10** (39%) (Scheme 4).

To prepare glycosyl borinates, we exposed the diazirine **1** to the exceptionally stable borinates **11**–**12**[11] derived from 10-bora-9-oxabicyclo[3.3.2]decane (Scheme 5). This led to



Scheme 4

† Glycosylidene Carbenes Part 28. For Part 27, see ref. 1(*b*).



Scheme 5

diastereoisomeric mixtures **13**/**14** (31%; 35:65), **15**/**16** (42%; 40:60) and **17**/**18** (55%; 45:55) that were isolated by flash chromatography. The isomers **15**/**16** and **17**/**18** were separated by HPLC. The glycosyl borinates **13**–**18** were characterized by FAB-MS, ^{11}B NMR, ^{1}H NMR, ^{13}C NMR and IR spectroscopy. They were stable at −10 °C for several weeks and not affected by air.

The configuration of **17** and **18** was deduced from NOE experiments (Fig. 1), with **17** showing NOEs between H–C(2) and H–C(5), H–C(2) and H–C(7), and H–C(1′) and H–C(4), indicating an axial orientation of the anomeric alkyl group. In contradistinction, a small NOE between H–C(1′) and H–C(5) and the lack of other NOEs > 1% for **18** indicate an equatorial orientation of the anomeric alkyl group.

Received (in Cambridge, UK) 25th June 1999, Accepted 30th September 1999

Reacting hexacyanochromate(III) with a mononuclear Mn(II) complex chelated by a tetradentate ligand that leaves two coordination sites available in *cis* position leads to a new molecular ferromagnet (T_C = 17 K) with an unusual architecture.

Cyanide-bridged systems are generally obtained by reacting a hexacyanometalate with a mononuclear assembler complex where some of the coordination sites may be blocked by a chelating ligand. In the absence of such ligands or when the ligand is bidentate, three-dimensional cubic networks are obtained.[1,2] On the other hand, when the chelating ligands block more than two coordination sites around the assembler complex, different structures become accessible.[3–5] For example, when $Ni(tren)^{2+}$ [tren = tris(2-aminoethyl)amine is a tetradendate ligand that leaves two available coordination sites on Ni^{II} in *cis* position] is reacted with $[Fe(CN)_6]^{3-}$, a non-cubic three-dimensional compound that orders ferrimagnetically (T_C = 8 K) is obtained.[4] Using $Ni(bpm)_2^{2+}$ [bpm = bis(1-pyrazolyl)methane] instead of $Ni(tren)^{2+}$ affords a discrete pentanuclear complex $[Fe(CN)_6]_2[Ni(bpm)_2]_3\cdot H_2O$.[5] Magnetic ordering at T_C = 23 K is observed owing to intermolecular ferromagnetic interaction. The formation of a discrete μ-cyanide species in the latter and not in the former compound is probably due to the steric hindrance of the bidentate ligand bpm. We have shown as well that such a pentanuclear species is obtained with $Ni(IM2\text{-}py)_2^{2+}$ (IM2-py = 2-(2-pyridyl)-4,4,5,5-tetramethyl-4,5-dihydro-1*H*-imidazolyl-1-oxy] where IM2-py is a bidentate ligand as bulky as bpm or bipy.[6]

Here we report on the structure and the preliminary magnetic properties of a new μ-cyano Cr^{III}–Mn^{II} polymeric compound obtained from the reaction of $Mn^{II}(bispicen)Cl_2$ and hexacyanochromate(III). $Mn^{II}(bispicen)Cl_2$ [bispicen = *N*,*N*′-bis(2-pyridylmethyl)-1,2-ethanediamine] was chosen because bispicen chelates the metal ion leaving the two chloride atoms in *cis*-position.[7] We reasoned that (i) this *cis* arrangement should be retained in the final compound where the two chloride atoms may be substituted by two nitrogen atoms of two $Cr(CN)_6$ units. and (ii) because the size of the manganese complex which is intermediate between that of $Ni(tren)^{2+}$ and $Ni(bpm)_2^{2+}$ [or $Ni(bipy)_2^{2+}$], a compound with a different dimension† should be obtained.

Yellow plates were obtained using the gel technique.[8], X-ray crystallography‡ reveals the formation of a one-dimensional neutral 3/2 : Mn/Cr polymer of formula $[Cr(CN)_6]_2[Mn(bispicen)]_3\cdot 6H_2O\cdot 0.5EtOH$ **1**. The asymmetric unit contains three crystallographically independent manganese and two crystallographically independent chromium ions [Fig. 1(a)]. The body of the one-dimensional assembly (along the *b* crystallographic axis) is made of Cr_2Mn_2 units sharing Cr(1) vertices; each chromium vertex is linked through one apical cyanide to a Mn(bispicen) complex which is itself connected to a terminal molecule of $Cr(CN)_6$. The pendant Mn(3)Cr(2) units are placed alternately below and above the body of the polymer. All the Mn^{II} complexes are surrounded by two $Cr(CN)_6$ entities in *cis* position as expected from the nature of the chelating ligand. The surroundings of the Mn^{II} metal ions is that of a distorted octahedron (see Fig.1 caption). The Mn–N–C angles, where NC is a bridging cyanide, vary from 161.5° to 177.7° for Mn(1) and Mn(2). The highest deviation from 180° is found for the Mn(3)–N(13)–C(13) angle (147.1°). Fig. 1(b) shows a H-bond network along the *a* axis involving four water molecules linking amine nitrogen atoms belonging to a pendant and to an in-body Mn

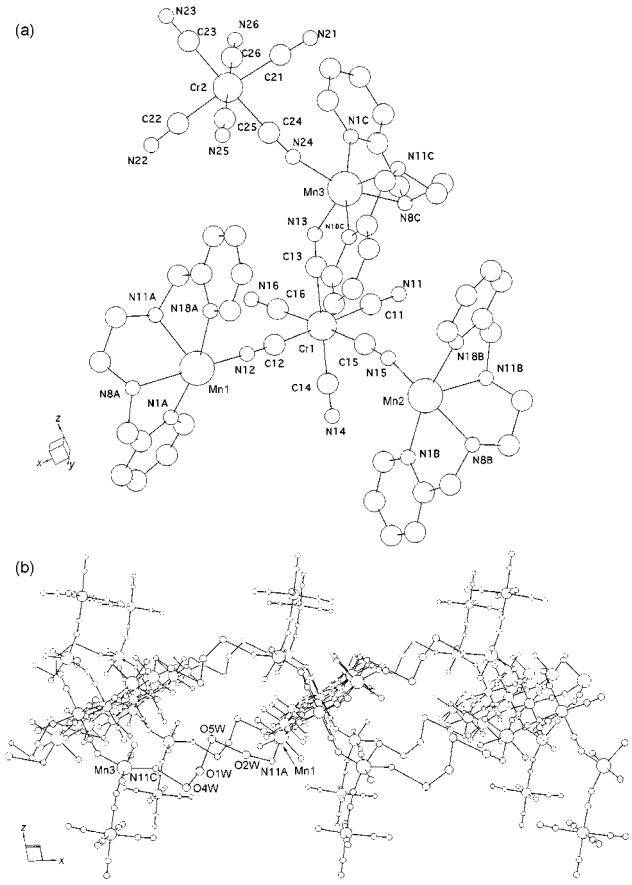

Fig. 1 (a) View of the asymmetric unit with atoms numbering. Selected bond distances and angles: Mn(1)–N(12) 2.162(6), Mn(1)–N(11) 2.173(6), Mn(1)–N(8A) 2.273(5), Mn(1)–N(1A) 2.282(5), Mn(1)–N(11A) 2.291(5), Mn(1)–N(18A) 2.315(5), Mn(2)–N(15) 2.180(6), Mn(2)–N(16) 2.182(6), Mn(2)–N(8B) 2.270(6), Mn(2)–N(1B) 2.276(6), Mn(2)–N(11B) 2.286(5), Mn(2)–N(18B) 2.288(6), Mn(3)–N(24) 2.137(6), Mn(3)–N(13) 2.174(6), Mn(3)–N(11C) 2.249(7), Mn(3)–N(18C) 2.268(6), Mn(3)–N(1C) 2.298(7), Mn(3)–N(8C) 2.330(7), Cr(1)–C(14) 2.045(7), Cr(1)–C(11) 2.055(7), Cr(1)–C(12) 2.055(7), Cr(1)–C(13) 2.056(7), Cr(1)–C(16) 2.068(7), Cr(1)–C(15) 2.078(7), Mn(1)–N(12)–C(12) 177.7(6); Mn(1)–N(11)–C(11) 163.6(5), Mn(2)–N(15)–C(15) 167.3(5), Mn(2)–N(16)–C(16) 161.5(5), Mn(3)–N(13)–C(13) 147.1(6), Mn(3)–N(24)–C(24) = 168.1(6). (b) View along the *b* axis showing the H-bond connections along the *a* axis between the amine nitrogen atoms of pendant and in-body Mn(bispicen) complexes belonging to two different polymers.

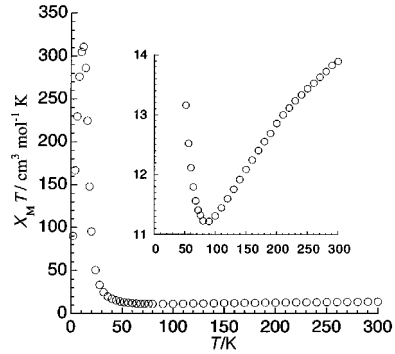

Fig. 2 $\chi_M T$ = f(T) plot performed at H = 1 kOe, the inset shows the decrease of $\chi_M T$ on cooling to T = 84 K.

complex of two different polymers. The other two water and the ethanol molecules do not participate in the extended two-dimensional network. No connection is observed along the *c* direction where the shortest metal–metal distance (11.08 Å) is between two pendant chromium ions of two neighbouring polymers.

Mixing two aqueous solutions of $[NBu^n_4]_3[Cr(CN)_6]$ and Mn(bispicen)Cl_2 in a 2:3 stoichiometric ratio leads to the immediate precipitation of a yellow powder. The IR spectrum of the powder was found to be identical to that of a collection of single crystals obtained by the gel technique. In the 2000–2200 cm^{-1} region, two bands centred at 2151 and 2130 cm^{-1} are present corresponding to bridging and non-bridging cyanides, respectively. TG analysis reveals a mass loss corresponding to six water molecules per unit formula.§

Magnetic studies were carried out on a powdered sample using a SQUID magnetometer. Fig. 2 shows the $\chi_M T$ = f(T) plot performed in an applied field of 1 kOe. On cooling from room temp., $\chi_M T$ (13.9 cm^3 mol^{-1} K) decreases, reaches a minimum at T = 84 K (insert of Fig. 2) then increases abruptly below T = 30 K and reaches a maximum value of 311 cm^3 mol^{-1} K at 11 K. The decrease of $\chi_M T$ on cooling indicates that the exchange interaction between Cr^{III} and Mn^{II} through the cyanide bridge is antiferromagnetic as has already been observed.[11] The abrupt increase of $\chi_M T$ at low temperature and the high value measured at 11 K may be due to a three-dimensional ordering leading to a molecular ferromagnet; the decrease below T = 12 K would in this case be due to the saturation of the susceptibility. In order to confirm this, magnetisation *vs.* field studies were performed at T = 2 K ; the curve shows that saturation is attained (Fig. 3) when a very small field of 400 Oe is applied. This is the signature of the occurrence of a magnetic ordering within the compound. The magnetisation value at H = 55 (8.9 μ_B) confirms the antiferromagnetic interaction between adjacent metal ions. Field cooled magnetisation curve obtained with an applied field of 30 Oe are in line with the presence of a magnetic ordering below a critical tempertaure T_C = 17 K (Fig. 3 insert).¶ The

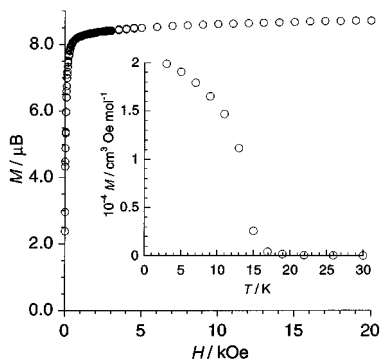

Fig. 3 M = f(H) magnetisation curve at T = 2 K, inset: M = f(T) at H = 30 Oe.

origin of the behaviour is not clear yet. The H-bond network may be responsible of a ferromagnetic interaction between the polymers along the *a* axis. However, since no connections are present in the third direction, only dipolar interactions along the *c* axis can account for the three-dimensional magnetic order.

Magnetic studies on dehydrated samples and on oriented single crystals should bring insights on the origin of three-dimensional order and on the absence of coercive field and remnant magnetisation (curves not presented here) for powders below T_C.

This work was supported by the Franco–British joint program Alliance No. 96175 from the French Foreign Ministry and the British Council.

Notes and references

† We restrict the word dimension here to μ-cyanide bridges, *i.e.* a three-dimensional compound structurally is one where μ-cyanide bridges spread in the three directions of space while a compound containing discrete cyanide-bridged species is zero-dimensional.

‡ *Crystal data* for **1**: $C_{55}H_{63}Cr_2Mn_3N_{24}O_{6.5}$, M = 1433.11, monoclinic, space group $P2_1/n$ a = 17.5085(10), b = 15.5670(10), c = 26.4406(17) Å, U = 7128.6(8) Å^3, β = 94.4330(10), T = 150 K, Z = 4, 31415 reflections measured, of which 10185 were unique (R_{int} = 0.1055). The structure was solved by direct methods (SIR92)[9] and refined with SHELXL-97.[10] The final conventional R-factor [based on F and 10185 data with $F > 4\sigma(F)$] was 0.0793. CCDC 182/1428.

§ Elemental analysis of a powder sample fits well with the proposed formula $Cr(CN)_6]_2[Mn(bispicen)]_3 \cdot 6H_2O$ which does not contain ethanol. Found (calc.) for $C_{54}H_{60}N_{24}O_6Mn_3Cr_2$: C, 45.98 (46.02); H, 4.30 (4.26); N, 23.83 (23.84); Mn, 11.39 (11.69); Cr, 7.25 (7.38)%. Only water is used as solvent when preparing the powder while the crystals are obtained using a gel containing a small amount of ethanol. Since, the crystallographic studies reveal that ethanol does not participate to an extended H-bond network, its absence should not have an influence on the magnetic properties (see below).

¶ Field-cooled magnetisation measurements (H = 30 Oe) were performed on a few single crystals embedded in the gel; below 17 K an abrupt increase confirms that the crystals order magnetically at the same temperature as the powder.

Synthesis and structures of two new 12-member ring crown-shaped oxovanadium borophosphates

Yongnan Zhao,† Guangshan Zhu, Wang Liu, Yongcun Zou and Wenqin Pang*

Key Laboratory of Inorganic Synthesis and Preparative Chemistry, Department of Chemistry, Jilin University, Changchun, 130023, China. E-mail: zhaoyn@263.net

Received (in Cambridge, UK) 17th August 1999, Accepted 5th October 1999

Two new oxovanadium borophosphates have been hydrothermally synthesized; they are structural analogues and are both constructed by $[(VO)_{12}\{O_3POB(O)_2OPO_3\}_6]^{18-}$ 12-member ring clusters with NH_4^+ and K^+ cations encapsulated in the rings, respectively; an extended network of hydrogen bonds between anions, cations and crystal water molecules link the structures in three dimensions.

Template synthesis of novel compounds utilizing intrinsic host–guest relationships has opened up a new field for chemists to create microporous, host or cluster structures and has resulted in numerous novel metal phosphates with open frameworks.[1–5] The current interest in vanadium phosphates derives from their notable catalytic properties and structural diversity. Vanadium can bind to oxygen in a variety of valences to form tetrahedra, square pyramids, octahedra or large aggregates by condensation of polyhedra through shared oxygen atoms. Template controlled linking of these units has led to a large number of oxovanadium phosphates with open framework structures.[6] Notably the successful synthesis of $[NH_2Me_2]K_4[V_{10}O_{10}(H_2O)_2(OH)_4(PO_4)]\cdot 4H_2O$ demonstrates that inorganic species can also mimic biologically relevant structures.[7] The three-dimensional frameworks $[HN(CH_2CH_2)_3NH]K_{1.35}[V_5O_9(PO_4)_2]\cdot xH_2O$ and $Cs_3[V_5O_9(PO_4)_2]\cdot xH_2O$ provide the largest cavities of open-framework structures known up to now.[8]

While metal phosphates have been expansively exploited, few reports on the synthesis of metal borophosphates have appeared. The introduction of boron into the framework has been proved to generate novel motifs and unique structures and several microporous aluminoborates have been prepared.[9] Recently the synthesis and structures of several new vanadium borate clusters were reported[10] stimulating chemists to incorporate boron into further inorganic systems. $CoB_2P_3O_{12}(OH)\cdot C_2H_{10}N_2$ was reported as the first microporous metal phosphate.[11] The synthetic $M^IM^{II}(H_2O)_2(BP_2O_8)$ (M^I = Na, K; M^{II} = Mg, Fe, Co, Ni, Zn),[12] $M^{II}[BPO_5]$ (M^{II} = Ca, Sr), $Ba[BP_3O_{12}]$,[13] $Zn[BO_3PO_4]$,[14] $CoBP_3O_{14}$,[15] $Ln_7O_6(BO_3)(PO_4)_2$ (Ln = La, Nd, Gd, Dy)[16] and two mineral phases $Mg_3B_2P_2O_8$,[17] $MnBPO_4(OH)_6$[18] are also examples of borophosphates. Recently Zubieta *et al.* reported the synthesis and structures of VOBOPO-1, a three-dimensional oxovanadium borophosphate $[H_3NCH_2CH_2NH_3]_2(VO)_5(H_2O)\{O_3POB(O)_2OPO_3\}_2]\cdot 1.5H_2O$[19] and VOBOPO-2, the first oxometalate borophosphate molecular cluster, $(H_3NCH_2CH_2NH_3)_2[Na(VO)_{10}\{HO_3POB(O)_2OPO_3H\}_5]\cdot 22.5H_2O$.[20] More recently, a borophosphate anion $[N_2C_6H_{14}]_2VO(PO_3OH)_4(B_3O_3OH)\cdot H_2O$ containing a single vanadium atom was reported.[21] Nevertheless metal borophosphates are still relatively undeveloped. Herein we report the synthesis and structures of two 12-member ring oxovanadium borophosphates, denoted VBP-J1 and VBP-J2 (J = Jilin University), templated by triethylenetetraamine.

Compounds VBP-J1 and VBP-J2 were hydrothermally synthesized using H_3BO_3 (99.5%), H_3PO_4 (85 wt%), NH_4VO_3 (99%), V_2O_5 (99%), KCl (99.5%) and triethylenetetraamine (> 95%) as the starting materials. Typical synthesis of VBP-J1 was performed as follows: 1.0 g H_3BO_3, 3.4 g H_3PO_4 and 1.9 g NH_4VO_3 were first dispersed into 20 ml water under vigorous stirring. Then 1.6 g of triethylenetetraamine were added. The final mixture was sealed in a 40 ml Teflon-lined stainless steel autoclave and heated at 180 °C for two days under autogenous pressure. In the synthesis of VBP-J2, NH_4VO_3 was replaced by 0.75 g V_2O_5 and 2 g KCl. The blue rhombic crystals obtained in both cases were filtered off, washed with water and dried at room temperature. The products were characterized by powder X-ray diffraction, IR, TG, chemical analysis (elemental ratio 2V : 2P : B) and single crystal determinations. Single crystals of VBP-JI (0.15 × 0.10 × 0.05 mm) and VBP-J2 (0.18 × 0.15 × 0.06 mm) were selected for structure analysis.‡

VBP-J1 and VBP-J2 are both constructed by 12-member ring $[(VO)_{12}\{O_3POB(O)_2OPO_3\}_6]^{18-}$ clusters which are charge compensated by protonated triethylenetetraamine. An extended network of hydrogen bonds between anions, cations and crystal water molecules link the structures in three dimensions.

The asymmetric unit of VBP-J1 and VBP-J2 both contain six vanadium atoms, six phosphorus atoms and three boron atoms (Fig. 1). The vanadium atoms are all coordinated by five oxygen atoms to form square pyramids with one short vanadyl (V=O) bond [1.593(5)–1.615(5) Å]. The neighboring two vanadium atoms form an edge-sharing binuclear unit, which shows an *anti*-configuration of the vanadyl groups with respect to the $\{V_2O_2\}$ bridging group. Each binuclear unit is linked to four PO_4 groups by four oxygen atoms. Bond valence calculations give a bond valence for vanadium atoms of 4.[22]

The six phosphorus atoms are each coordinated by four oxygen atoms. The P–O distances range from 1.486(6) to 1.576(6) Å and the O–P–O angles lie between 106.4(3) and 113.0(3)°. In each PO_4 tetrahedron, two oxygen atoms are shared with the VO_5 square pyramid and one oxygen atom is shared with the BO_4 tetrahedron. The remaining oxygen atom is unshared and pendant. Each of the boron atoms is coordinated by four oxygen atoms with B–O distances in the range 1.430(9)–1.505(9) Å. The BO_4 group shares two oxygen atoms with the neighboring two PO_4 tetrahedra and forms a dense $\{O_3POB(O)_2OPO_3\}^{7-}$ borophosphate unit. Similar $\{O_3POB(O)_2OPO_3\}^{7-}$ trimers have been found in VOBOPO-1, VOBPO-2 and $[N_2C_6H_{14}]_2VO(PO_3OH)_4(B_3O_3OH)\cdot H_2O$.[19–21] The $\{BO_4\}$ group contributes a μ_3-bridging oxygen to each of two neighboring binuclear $\{V_2O_{10}\}$ moieties. In this fashion each $\{O_3POB(O)_2OPO_3\}^{7-}$ exhibits three-point attachment to each of two binuclear $\{V_2O_5\}$ sites. The linking of six $\{V_2O_{10}\}$ moieties and six borophosphate ligands produces the 12-member ring structure with NH_4^+ or K^+ cations encapsulated in the rings (Fig. 2). In VBP-J1, the NH_4^+ cation is linked to the six *endo* oxygen atoms of the vanadyl by hydrogen bonds. In VBP-J2, the K^+ cation is six-coordinated by the six *endo* oxygen atoms of the vanadyl groups.

The ring diameters are 5.856(O8A–O8B) × 5.411(O35A–O35B) × 5.560(O22A–O22B) Å and 5.415(O24–O24A) × 5.415(O10–O10A) × 5.235(O36–O36A) Å for VBP-J1 and VBP-J2, respectively. Differences may be accounted for by the difference of the ion diameter between NH_4^+ (1.66 Å) and K^+ (1.44 Å).

In conclusion, two new oxovanadium borophosphates have been hydrothermally synthesized. They are structural analogues and have a similar motif to VOBOPO-1 and VOBOPO-2.[19,20]

† Present address Institute of Physics & Center for Condensed Matter Physics, Chinese Academy of Science, Beijing 100080, China.

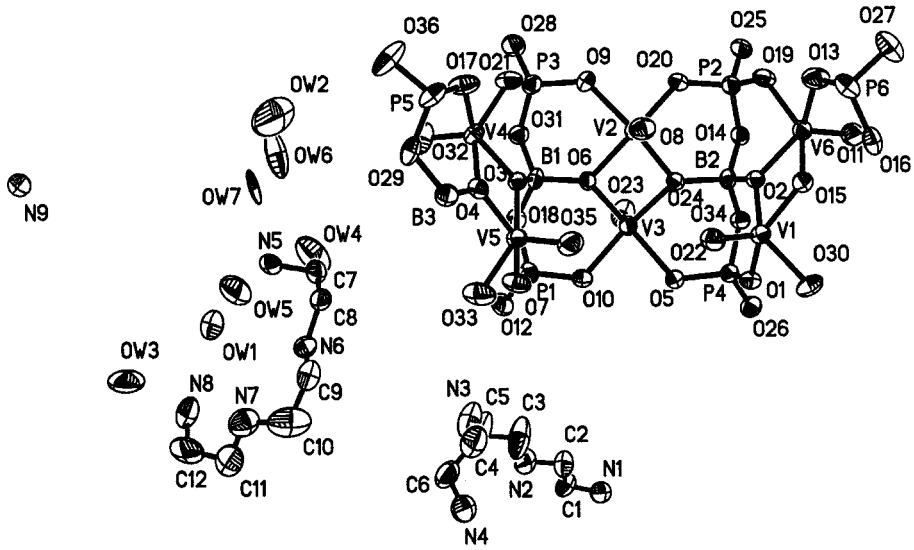

Fig. 1 The asymmetric unit of VBP-J1.

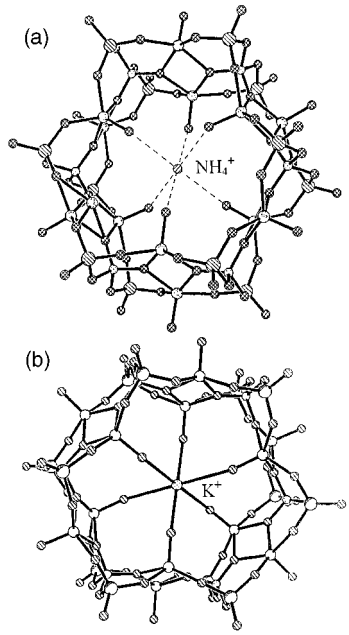

Fig. 2 The 12-member ring clusters of (a) VBP-J1 with NH_4^+ encapsulated in the center and (b) VBP-J2 with K^+ encapsulated in the center.

This successful synthesis leads to the possibility to synthesize larger rings using larger cations than NH_4^+ and K^+. Furthermore the various vanadium oxygen polyhedra with numerous linkage forms of the vanadium oxygen polyhedra, boron oxygen polyhedra and PO_4 tetrahedra are expected to lead to a variety of oxovanadium borophosphates.

Chemically functionalised exfoliated graphite: a new bulk modified, renewable surface electrode

P. Ramesh and S. Sampath*

Department of Inorganic and Physical Chemistry, Indian Institute of Science, Bangalore 560 012, India. E-mail: sampath@ipc.iisc.ernet.in

Received (in Cambridge, UK) 2nd July 1999, Accepted 20th September 1999

Graphite particles are exfoliated and chemically functionalised to covalently attach electroactive molecules and subsequently pressed in the form of a pellet, without the use of a binder, to yield a bulk modified, renewable surface electrode material.

Research on the development and chemical modification of new electrode materials leading to improved catalytic and electroanalytical properties has received considerable attention in the last two decades.[1–14] Murray[1] has pioneered the area of chemically modified electrodes that includes modification of a variety of surfaces such as metals, metal oxides and to some extent carbon. Bulk modification of the material would lead to re-useable electrodes. Presently, the most popular bulk modified electrode is based on carbon paste. However, fouling and contamination of the surface and leaching of the modifier during operation pose significant hurdles in the long-term use of this material. Additionally, use of silicon oil as a binder leads to the deterioration of the material with time. Hence, it is pertinent to have covalently modified, renewable surface electrode materials based on inert binders that do not deteriorate with time. There have been a few attempts based on graphite–epoxy[12] and sol–gel silicate[9–11,13] matrices in this direction. It is very desirable to have the electrodes fabricated without any binder to have an unlimited storage and cycle life. Herein, we report, for the first time, the chemical functionalisation of exfoliated graphite particles and its use as a bulk modified, surface renewable electrode material. The electrodes are in the form of pressed pellets prepared without any binder.

Exfoliated graphite (EG) is an expanded graphite with low density and high temperature resistance.[14] The exfoliation of graphite is a process in which graphite expands by up to hundreds of times along the *c*-axis resulting in a puffed-up material. The compression of the EG results in a material of high lubricity and flexibility. The advantage of compression is that a high density porous substrate is formed with a surface area that is relatively high compared with other graphitic adsorbents.[15] Some of the demonstrated applications of this material include high temperature gaskets, seals, packings, thermal insulators, conductive resin composites, lubricant, catalyst supports and adsorption substrates.[14,16–18] Very few reports deal with the use of this material in electrochemical studies.[19–21]

Natural graphite of particle size 300–400 μm (Stratmin Graphite, USA) were soaked in a mixture of conc. H_2SO_4–HNO_3 (3:1, v/v) for 24 h. The material was then exfoliated by giving a thermal shock at 800 °C in air. The EG particles were treated with a mixture of conc. H_2SO_4–HNO_3 at *ca.* 100 °C for 4 h and the acid was later filtered off. The excess acid present on the material was neutralised with an alkali and the powder was subsequently washed with dilute HCl and excess distilled water. This oxidative pretreatment introduces and increases the number of oxygen containing functional groups on the EG surface. These functional groups thus introduced on to the graphite particles were reduced using $NaBH_4$ in methanol. The resulting –CH_2OH and –OH groups were attached to AQ or Fc using anthraquinone carboxylic acid or ferrocene acetic acid and *N*,*N*′-dicyclohexylcarbodiimide as a coupling agent. Soxhlet extraction with methanol for a prolonged period was carried out to make certain that the material does not contain any physisorbed reactants.

The graphite particles were chemically characterized at every stage by XRD, IR, XPS, elemental analysis and the morphology was followed by SEM. Electrochemistry was carried out using pellets pressed without the use of any binder. Fig. 1 shows the cyclic voltammograms obtained with anthraquinone modified EG electrode. The peak potentials are well defined and the value of ΔE_p ($E_p^c - E_p^a$) varies with the scan rate. The control voltammogram using EG electrode without the electroactive component does not show any redox activity as expected (Fig. 1, inset). The redox peak currents vary linearly with the scan rate showing that the redox species is bound to the surface of the electrode (Fig. 2). However, there is a tendency for the peak currents to saturate at higher scan rates (above 120 mV s^{-1}) which may be due to the proton transport limitation to the bound electroactive species. Additional experiments in buffers of different pH also confirm this. The formal redox potential varies with the solution pH and the slope of the linear plot corresponds to 59 mV $decade^{-1}$ thus confirming that the process involves $2e^-$ and $2H^+$ as expected. The surface coverage was measured by integrating the area under the peak and was found to be 1.2 $\times 10^{-9}$ mol cm^{-2}. This value, however, is only a representative figure since the real surface area is different (owing to roughness created by the emery sheet) from the geometric area used for the calculation. The surface roughness is found to play a major role in the functionalisation and in turn the electroactivity of the modified material. Modified electrodes with smooth surfaces do not give rise to any peaks while an increase in surface roughness leads to better definition of the peaks. The cyclic voltammograms in Fig. 1 has roughness created using a 400 grit SiC paper. The SEM image (Fig. 3) shows the rough surface used in the present study. It is clear that roughening the surface results in an increase in the ratio of edge to basal planes. This points to the fact that the edge planes of the graphite are

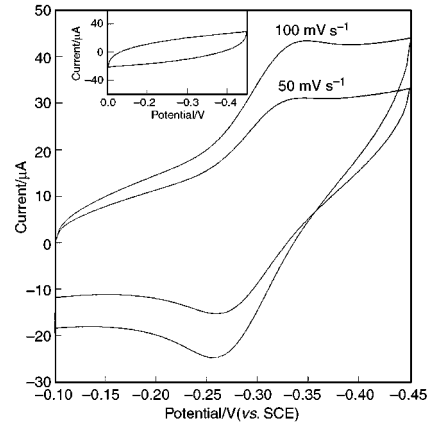

Fig. 1 Cyclic voltammograms of AQ modified EG electrode in acetate buffer, pH 3.5, at two different scan rates. The geometric area of the electrode is 0.08 cm^2. Inset: control cyclic voltammogram of the EG electrode prepared without AQ at a scan rate of 50 mV s^{-1}. Other conditions are as above.

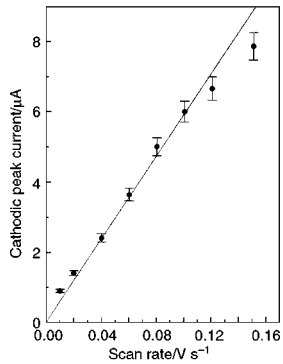

Fig. 2 Plot of reduction peak current *vs.* scan rate for AQ modified electrode in phosphate buffer, pH 7.

those that are functionalised with the redox moiety and are hence electrochemically active.

The bulk modification of the EG leads to reproducible electrochemical data. Mechanical polishing of the electrode exposes a new surface and different surfaces give rise to cyclic voltammograms that are very similar. The standard deviation in the peak currents for four successive polishings was < 5%. The fact that the quinone is chemically attached to the matrix and not physically adsorbed was confirmed by the following: non-modified EG particles were intentionally adsorbed with anthraquinone carboxylic acid and the resulting modified material was subjected to electrochemical measurements. Cyclic voltammograms show that the reduction of the adsorbed quinone occurs at −0.385 V while the chemically bonded quinone is reduced at −0.325 V at a scan rate of 10 mV s^{-1}. The difference in reduction peak potentials is expected to be due to combined effects of physical adsorption and the presence of $–CO_2H$ group for the physisorbed material compared to the chemically functionalised EG. Second, the change in the reduction peak potentials with scan rate is much larger for the physisorbed quinone (120 mV for a change from 10 to 100 mV s^{-1}) than the chemically bound (30 mV for the same range) moiety. This reveals that the electrochemical reduction kinetics and the reversibility of the physisorbed quinone is sluggish compared to the chemically bound AQ. Third, quinones are known to get physically adsorbed on to the basal as well as edge planes and hence the voltammograms on the smooth surfaces (basal planes) are expected to show electrochemical activity.[22] Indeed, this is observed with the physisorbed quinone modified electrode. The chemically functionalised EG material did not show any activity on smooth surfaces and this again confirms the modification on the edge plane surfaces as revealed by the cyclic voltammograms.

The chemical modification is also confirmed by IR measurements. The IR spectrum of the unmodified graphite particles show the presence of phenolic and alcoholic –OH groups on the surface as confirmed by the XPS C 1s spectrum. Treatment with a conc. H_2SO_4–HNO_3 mixture is expected to result in the formation of graphite oxide in addition to other oxygen containing functional groups.[23] Experiments using various techniques have established that graphite oxide contains different amounts of tertiary C–OH groups, ether C–O–C groups, > C=O < double bonds as well as enol and ketone

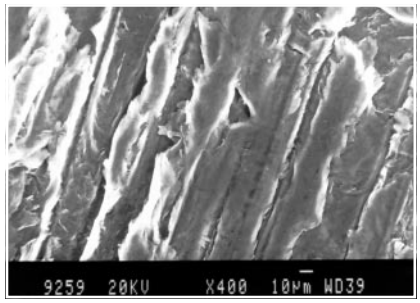

Fig. 3 SEM image of a rough EG electrode. Roughness created using 400 grit SiC paper.

groups.[24] On $NaBH_4$ treatment, the functional groups that are formed on the EG particles, are reduced to –OH and $–CH_2OH$ groups. Subsequent attachment of AQ or Fc through the –OH and $–CH_2OH$ groups on the graphite would result in linkages of the type –COC(=O)AQ/Fc. Hence, the IR of the modified surface is expected to contain carbonyl functionalities from the quinone and the other ester type functionalities as described above. Indeed, the IR spectrum of the modified surface reveals the presence of these functional groups at *ca.* 1700 cm^{-1} for carbonyl and at *ca.* 1200 cm^{-1} for the CC(=O)–O stretch; the reduction in frequency for the latter is due to the conjugation of the phenyl ring. The modification is also confirmed by X-ray photoelectron spectroscopic studies. The deconvoluted C 1s spectrum of EG indicates the presence of graphitic, phenolic and carboxylic functional groups in the ratio of 77 : 4.4 : 18.7 while the AQ modified EG is found to contain graphitic, phenolic, carboxylic and, in addition, carbonyl functional groups in the ratio of 70.7 : 7.5 : 11.1 : 11.8. The presence of *ca.* 12% of carbonyl groups is a clear indication of the modification of EG by AQ. The ferrocene modified EG electrode shows a similar behaviour.

The exfoliated material is easy to prepare and is amenable to chemical modification. As demonstrated here, the electrode can be fabricated without the use of any binder, which is very advantageous. The electron transfer rate, however, increases with increasing number of edge sites. Detailed comparative studies on exfoliated graphite, modified exfoliated graphite, carbon paste and glassy carbon will be reported in due course.

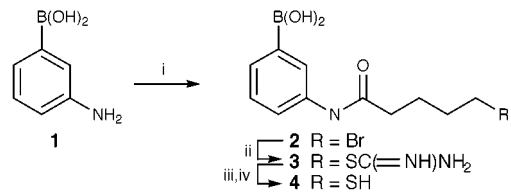
Received (in Oxford, UK) 9th August 1999, Accepted 27th September 1999

A novel self-assembling vicinal diol receptor, *N*-(3-dihydroxyborylphenyl)-5-mercaptopentanamide, has been synthesised *via* a three step procedure, characterised by NMR, mass spectoscopy and FTIR spectroscopy and shown to be functionally active by contact angle analysis, surface plasmon resonance and QCM.

The recent explosion in biosensor technology has led to the need for a greater variety of surface bound receptor systems. Thiol monolayer self-assembly is a technique of growing importance in many fields, particularly for the protection[1] or modification[2] of surfaces and the production of functionalised layers in sensor systems.[3–5]. The chemistry is versatile and robust, with a variety of headgroups attached to long-chain, thiol-terminated backbones. It has been suggested that the development of this technology may be hampered by a lack of new receptor systems.[6] Introduction of novel headgroup chemistry would continue to expand the uses of this technology. Here we report the synthesis of a new self-assembling vicinal diol receptor, based upon a thiol-modified boronic acid.

The interactions of sugars has been of interest to many with an increase in the use of boronic acids as receptors, however much of the work has taken place in free solution[7] or at air–water interfaces.[8] Boronic acids have long been known to interact with heavily hydroxylated species such as glycerol.[9] The semi-specific attachment point for vicinal diol groups, based upon the orientation of two adjacent hydroxy groups within a molecule, is covered in an excellent review by James *et al.*[10] Many saccharides contain hydroxy groups in the correct orientation and form stable cyclic esters when brought into contact with boronic acids.[11] Phenylboronic acids are known to form five-membered rings with *cis*-1,2-diol groups and less stable six-membered rings with the *trans*-isomer.[7] The synthesis of a self-assembling molecular layer capable of binding a wide variety of diol-containing moieties may open a route to producing a range of more specific multi-layer sensors.

Reaction of 3-aminophenylboronic acid **1** with 6-bromopentanoyl chloride in ethanolic solution (Scheme 1) yielded 3-(5-bromopentanoylamino)phenylboronic acid **2**. Further reaction with thiourea in methanolic solution over four days gave thioamidine **3**, which when treated with base prior to acidification was reduced to *N*-(3-dihydroxyborylphenyl)-5-mercaptopentanamide **4**.



Scheme 1 *Reagents and conditions*: i, 6-bromopentanoyl chloride, $NaHCO_3$, H_2O–EtOH, 25 °C, 2 h, stirred; ii, thiourea, MeOH, 25 °C, 4 days, stirred under N_2; iii, NaOH, MeOH, 25 °C, 4 days, stirred under N_2; iv, HCl.

Analysis of **4** by ^{1}H NMR† spectroscopy showed that > 85% of the sample was the desired thiol boronic acid. A small amount of the 3-aminophenylboronic acid starting material was also present. Further characterisation by LC-MS‡ and FTIR§ analysis gave molecular weight and structural information supporting the NMR data (Table 1).

Table 1 FTIR data for **4**

Position/cm^{-1}	Transmittance (%)	Assignment
3322	4.20	B–OH
2934	41.7	CH_2
2361	79.0	CH_3 (Possible S–H)
1663	3.20	*meta* substituted aromatic
1538	5.70	CH_2–NH
1344	5.80	C–N

The self-assembly characteristics of **4** were investigated by several techniques. Time resolved, sessile drop contact angle measurements of 2 μl water droplets were recorded on 38 nm gold films evaporated onto polished microscope slides. Initial contact angles for water droplets of 64 ± 3° (N = 6) were noted. Upon exposure to a 1 mM ethanolic solution of **4** in a clean environment, the contact angle was observed to decrease with time to 37 ± 2° (N = 6) after 2.5 h (Fig. 1). This is indicative of the rapid self-assembly mechanisms observed in simple long chain thiols on gold surfaces[12] and strongly suggested that surface modification had taken place *via* the widely accepted thiol–gold self-adsorption route,[13] the boronic acid headgroups rendering the surface more hydrophilic.

Characterisation of the self-assembly in real time using a Kretschmann configuration surface plasmon resonance (SPR) instrument, also employing 38 nm gold films as the SPR substrate, gave a 0.31º dual rate increase in SPR angle upon a 2.5 h exposure, at a concentration of the compound in ethanolic solution equal to that used for the contact angle measurements.

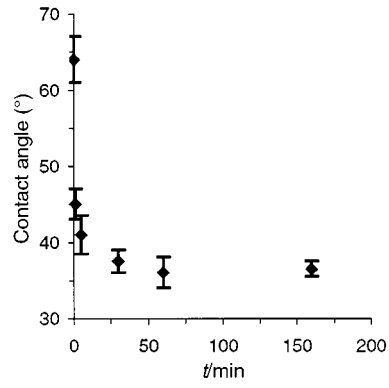


Fig. 1 Plot of sessile drop, water contact angle *vs.* time of immersion for a 38 nm gold coated microscope slide treated with a 1 mM ethanolic solution of **4** (droplet size 2 μl, T = 25 °C, N = 6 ± standard deviation).

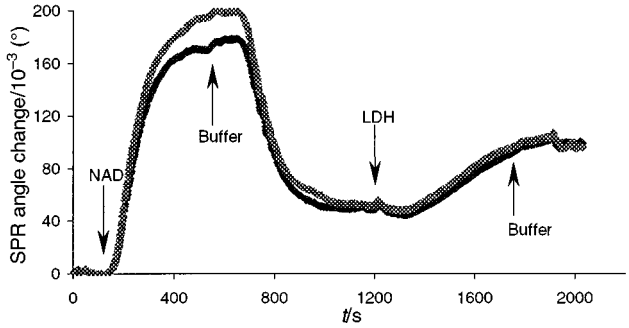

Fig. 2 SPR angle change for the binding of NAD (1 mg m^{-1}) to a gold substrate previously treated with **4** followed by lactate dehydrogenase (1×10^{-6} M) (flow rate = 4 μl min^{-1}, T = 30 °C, pH 7.2 Sorensons PBS).

Increases in SPR angle equate to material attachment to the substrate surface. Non-linear regression using a four parameter, double exponential rise relationship to the SPR data gave R = 0.99 and rate constants, $K1 = 1.1 \times 10^{-3}$ s^{-1} and $K2 = 6.91 \times 10^{-3}$ s^{-1}.The value of the measured $K1$ is of the order found by Debono *et al.*,[14] (4.3×10^{-3} s^{-1}) with SPR for the adsorption of dodecanethiol from ethanolic solution at an equal concentration. These results follow the distinct two step adsorption process found by DeBono *et al.*[14] and Bain *et al.*[12] The results show a very fast initial step lasting a few minutes giving rise to an 80–90% monolayer coverage, followed by a slower step lasting between minutes and hours depending upon the structure of the thiol, in which time the monolayer reorganises and completes its formation.

A similar two stage adsorption profile was observed upon the exposure of a 10 MHz lapped quartz crystal, thickness shear mode sensor with gold electrodes to a 1 mM ethanolic solution of the compound. A total frequency decrease of 126 Hz was recorded over an 8 h period for a single electrode in contact with the solution. The increased time required for the adsorption process to reach equilibrium is thought to be due to surface roughness; 2–3 μm troughs are found in the lapped crystal surface compared to the sub-micron polished surface used for SPR analysis.

Surface functionality of the adsorbed boronic acid SAM was further confirmed by contact angle and SPR experiments. Gold coated slides, previously exposed to the monolayer forming solution, with contact angles measuring 37 ± 2° (N = 6), were placed in a 1 mg ml^{-1} solution of nicotinamide adenine dinucleotide (NAD) in Sorenson's buffer, pH 7.2. Following a 15 min incubation at 30 °C the slides were removed, washed with further buffer, dried and the water contact angle measured as described previously. A further decrease in angle was recorded [27 ± 1.0° (N = 6)], suggesting that binding of the NAD to the surface may have occurred.

Real time analysis of NAD binding (Fig. 2) was carried out using SPR. NAD (1 mg ml^{-1}) in a buffer stream was passed over a boronic acid treated gold slide (4 μl s^{-1}). A residual SPR angle increase of 40 ± 2 millidegrees, (N = 3) verified that NAD had bound to the boronic acid layer. A similar profile was observed for lactose and maltose with SPR angle increases of 32 ± 3 (N = 3) and 24 ± 2° (N = 3) respectively. No residual change in SPR angle was observed when untreated gold surfaces were similarly challenged.

After treatment of the SPR slides with NAD, injections of lactate dehydrogenase (1×10^{-6}M, LDH), followed by a buffer wash were made. Fig. 2 shows strong binding to the NAD treated slides, with a residual SPR angle increase of 47 ± 3° (N = 3) and very little evidence of desorption. No overall change in SPR angle was observed for injection of LDH if the NAD was not present. This would support the binding of NAD *via* its diol groups to the surface, leaving the binding regions, at the adenine and nicotinamide units, available for LDH and a range of other dehydrogenases.[15]

In summary, this report describes a novel self-assembling boronic acid derivative with the potential to specifically interact with vicinal diol groups found within a range of nucleotides, saccharides, antibiotics and other systems. It has been shown that with a clean environment, formation of a correctly orientated layer on the surface is achieved and that vicinal diol containing species attach strongly only to the modified surface. Further, enzyme–cofactor binding has been demonstrated as part of a multilayer system, potentially opening new avenues for enzyme studies, *via* a relatively simple attachment route, applicable to a range of novel analysis tools such as SPR and QCM.

The authors wish to dedicate this paper to the memory of Dr Jim Baker who passed away prior to submission. We thank the EPSRC and SmithKline Beecham for financial support under the CASE award scheme, Award #G77.

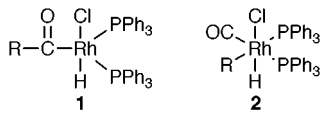
Received (in Cambridge, UK) 25th August 1999, Accepted 5th October 1999

A novel Wilkinson's catalyst-mediated carbon–carbon bond forming reaction is described which is exemplified by the synthesis of the polycyclic compounds 14 and 18 from the keto aldehydes 13 and 17.

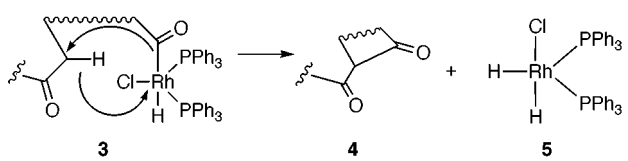
Transition metal mediated reactions leading to the formation or rupture of the C–H and C–C bonds of organic substrates constitute an area of research of wide importance.[1] In particular those involving C–H activation and decarbonylation of the CO(H) moiety of aldehydes are of considerable interest.[2] Chlorotris(triphenylphosphine)rhodium (I) (Wilkinson's catalyst) is a versatile catalyst for reactions such as hydrogenations,[3] hydrosilylations,[4] hydroformylations,[5] hydroborations,[6] isomerisations,[7] oxidations[8] and cross coupling reactions.[9] The stoichiometric homogeneous decarbonylation of aldehydes using Wilkinson's catalyst is a very useful synthetic transformation. It has been proved beyond doubt that decarbonylation of aldehydes by Wilkinson's catalyst proceeds *via* a stepwise mechanism[10] through an acyl rhodium hydride intermediate **1** and the alkyl rhodium hydride intermediate **2**.



1 **2**

The potential utility of the acyl rhodium hydride intermediate **1** in a variety of reactions, such as hydroacylations (addition to olefins) and the synthesis of organocarbonyl complexes,[11] is currently being intensely studied. We anticipated that the acyl-rhodium hydride intermediate **3** might undergo an intramolecular C–C bond formation (Scheme 1) with suitable substrates having weakly acidic C–H bonds (*e.g.* $CO–CH_2$ or similar systems) *via* an intramolecular hydride migration from the substrate to the Rh metal and the migration of the CO–Rh bond to generate the corresponding 1,3-diketone **4**. We report herein for the first time Wilkinson's catalyst mediated intramolecular carbon–carbon bond formation in the synthesis of polycyclic ring systems.

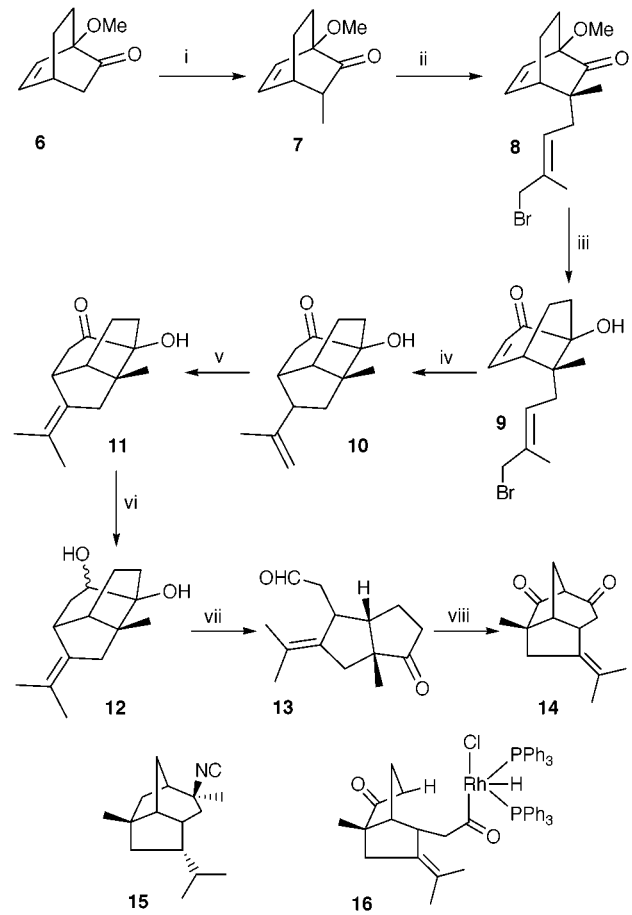
The synthesis of the requisite substrate, the keto aldehyde **13**, is shown in Scheme 2. Alkylation of the known[12] ketone **6** with LDA/MeI afforded exclusively the ketone **7**, which upon treatment with LDA and 1,4-dibromo-2-methylbut-2-ene afforded the product **8** in good yield. Treatment of **8** with a catalytic amount of perchloric acid (70%) in CH_2Cl_2 furnished the hydroxy enone **9**, which was converted into the tricyclic hydroxy olefin **10** through 5-*exo-trig* allyl radical cyclization[13] *via* treatment with Bu_3SnH. Isomerisation of the olefin **10** was carried out with TsOH in refluxing benzene to afford the hydroxy ketone **11**. $NaBH_4$ borohydride reduction of **11** furnished the 1,2-diol **12**, which was cleaved with periodic acid to the keto aldehyde **13** in quantitative yield.†



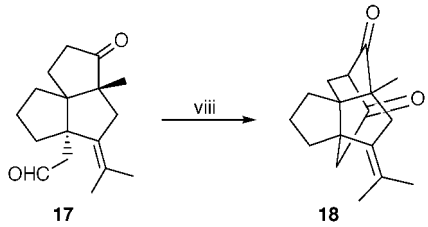
3 **4** **5**

Scheme 1

Treatment of the keto aldehyde **13** with a stoichiometric amount of chlorotris(triphenylphosphine)rhodium(I) in PhCN at 160 °C for 1.5 h afforded the expected 1,3-diketone **14** in 75% yield, whose structure was deduced from its spectral characteristics.† The formation of **14** can be only explained through the acyl rhodium hydride complex **16** of the keto aldehyde **13** (Scheme 3) through the intramolecular hydride transfer mechanism (Scheme 1). An alternative mechanism‡ involving a rhodium(I) catalyzed reversible aldol condensation, followed by the dehydrogenation of the resulting ketol leading to the formation of the product **14**, cannot be ruled out at this stage. This methodology constitutes, the first synthesis of a novel



Scheme 2 *Reagents and conditions*: i, LDA, THF, MeI, −78 °C (89%); ii, LDA, THF, HMPA, 1,4-dibromo-2-methylbut-2-ene, −78 °C (76%); iii, $HClO_4$ (cat), CH_2Cl_2, 0.5 h, (76%); iv, Bu_3SnH, AIBN, C_6H_6, reflux, 6 h (80%); v, TsOH, C_6H_6, reflux, 45 min (89%); vi, $NaBH_4$, MeOH, 0 °C (94%); vii, HIO_4, EtOH–H_2O (4:1) (100%); viii, Wilkinson's Catalyst (1 equiv.), PhCN, reflux, 1.5 h (75%).



Scheme 3

tricyclo[5.2.1.0^{4,8}]decane derivative, the norallopupukeanane-2,10-dione **14**, and can be used for the synthesis of the natural product 2-isocyanoallopupukeanane[14] **15**. Thus Wilkinson's catalyst can be used in catalytic amounts since the rhodium dihydride species **5** easily eliminates one molecule of hydrogen under the reaction conditions leading to the active catalyst species, the chlorobis(triphenylphosphine)rhodium(I) complex, which is recycled.

Similarly the angular triquinic keto aldehyde[15] **17** is transformed into the tetracyclic 1,3-diketone **18** by treatment with Wilkinson's catalyst under the same conditions in 72% yield.† This reaction is a novel and elegant methodology for the construction of complex polycyclic 1,3-diketones from the corresponding keto aldehydes. In both the examples the anticipated decarbonylation of the aldehyde group did not occur. The scope and limitations of this reaction in the synthesis of cyclic systems is currently under investigation.

The electrophilic reactivity of the porphodimethene skeleton towards nucleophiles led the establishment of a synthetic methodology to unprecedented forms of porphyrinogen containing the vinylidene substituents as well as other functionalities in the *meso*-positions

The intermediacy of porphodimethenes[1,2] in the oxidation of porphyrinogen to porphyrin is well accepted. Work on the chemistry of the porphodimethene skeleton[3] has suffered, however, for a long time from the absence of a real synthetic methodology, which is now available[4] for exploring its reactivity. Porphodimethenes are the target molecules of this report, since they allow one to enter the field of unprecedented forms of porphyrinogen. The latter compounds have been obtained studying the reactivity of lithium and nickel hexaethylporphodimethenes (5,15-diethyl-*meso*-tetraethylporphyrin) towards nucleophiles. The synthetic sequences are displayed in Schemes 1 and 2.

Complex **1**[4] underwent a stepwise deprotonation by $LiNMe_2$ to the monovinylidene porphomethene complex **2**,[5] containing a trianionic tetrapyrrolic derivative, which undergoes further deprotonation to the bisvinylidene porphyrinogen Ni derivative **3**. Both complexes **2** and **3** can be protonated back to the starting material by employing PyHCl.

The stepwise deprotonation of **1** to **3** requires the preliminary attack of a nucleophile, *i.e.* $[NMe_2]^-$, at the mono-substituted *meso*-position of **1**. Such a pathway is supported by the reactivity of **1** with nucleophiles other than $[NMe_2]^-$, namely LiBu, $LiHBEt_3$ and $LiCH_2CN$, and by the reactions in Scheme 2, leading to *meso*-functionalized octaalkylporphyrinogens.[6] Compounds **2** and **3** have been fully characterized including the X-ray analysis of **3**. The ^1H NMR of **3** revealed the presence of an equimolar mixture of the two possible isomers with two quartets and two doublets of equal intensity for the vinylidene groups and eight doublets for the β-protons to the pyrroles. This spectroscopic analysis has been confirmed with an X-ray structure revealing a statistical distribution of the Me and H groups around the vinylidene carbon, although not in the same ratio observed in solution. We should draw attention to the structural similarity of **3** with the 5,15-dioxoporphyrinogen.[7]

The structure of the anionic moiety of **3** is displayed in Fig. 1, with a selection of the structural parameters which support the proposed bonding scheme.‡ The presence of two *meso*-sp^3 carbons gives rise to a saddle shape conformation of the porphyrinogen with nickel 0.011(3) Å above the N_4 plane. A relevant structural feature is the two short Ni–H contacts [Ni1···H15A and Ni1···H15A′ 2.92 Å (prime denotes a symmetry operation $-x, y, -z + 1/2$)] with two *meso*-ethyl groups from the same face of the N_4 coordination plane.

Complex **3** contains a novel form of porphyrinogen, which may have considerable synthetic potential and may be available either from the demetalation or the transmetalation of **3**. We

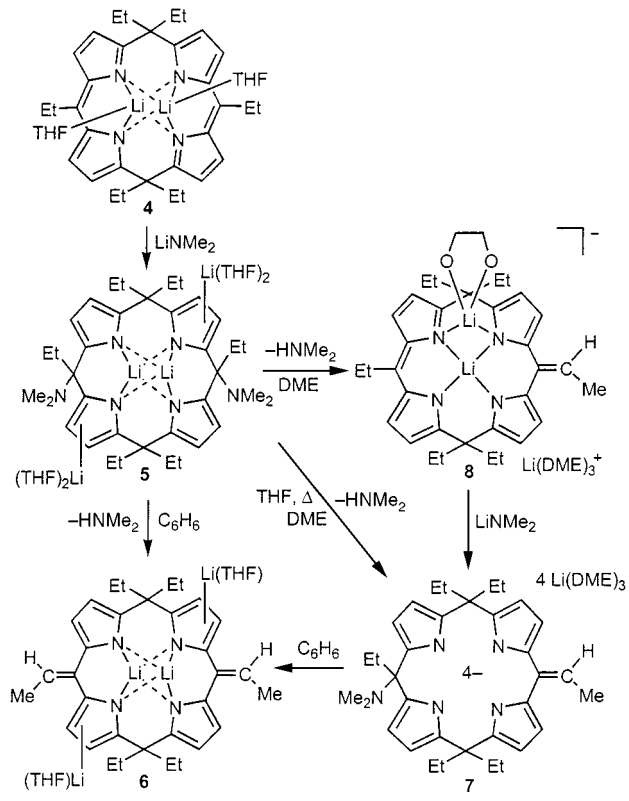

Scheme 2

† Syntheses of complexes **2**, **3**, **5**, **6**, **7** and **8**, and complete ORTEP drawings of **3** and **7**, are available from the RSC web site, see http://www.rsc.org/suppdata/cc/1999/2227/

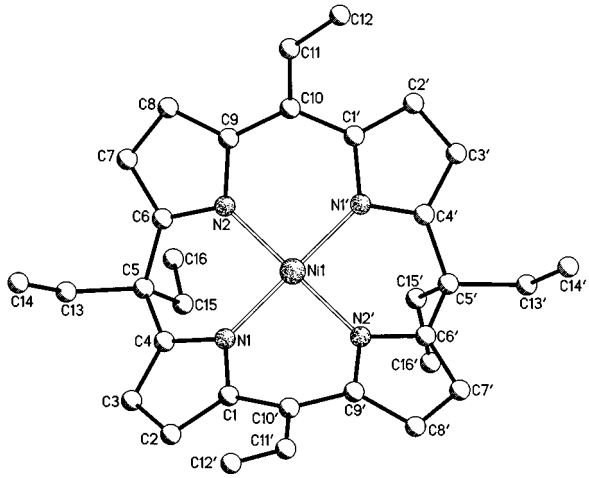

Fig. 1 A plot of the dianion of **3** [hydrogen atoms, $Li(DME)_3^+$ cations and disorder have been omitted for clairty]. Selected bond distances (Å): Nil–N_{av} 1.887(4) C10–C11 1.32(1). Prime indicates the following symmetry operation: $-x, y, \frac{1}{2}-z$.

found, however, a better access to the bisvinylidene porphyrinogen tetraanion bonded to Ni^{II} in **3** from the direct deprotonation of the *meso*-hexaethylporphodimethene dilithium derivative **4**[4] (see Scheme 2).

In addition, such a reaction shed light on the deprotonation mechanism of the porphodimethene skeleton as a function of the metal and the reaction solvent. The addition of $LiNMe_2$ to **4**, regardless of the solvent (THF, DME or benzene), led to the formation of the bisdimethylamino porphyrinogen **5**, which upon heating underwent $HNMe_2$ elimination to give different porphyrinogen derivatives according to the solvent, namely to **6** in benzene, **7** in THF, and **8** in DME. Scheme 2 displays also the relationship between **6**, **7** and (preliminarily) **8**.[5] Compounds in Scheme 2 have all been isolated and characterized. The X-ray structure is reported only for **7**. Those two structures, along with that of **3**, give the complete picture of the vinylidene porphyrinogen derivatives. The structure of the ion pair form of **7** is shown in Fig. 2 with some structural parameters which support the proposed bonding scheme.‡ In the absence of a transition metal ion, the porphyrinogen skeleton does not display any well-defined conformation and **7** occurs either in the ion-separated or in the ion-pair form[8] (Fig. 2). Lithium cations show different geometry: Li1 has a quasi-square planar

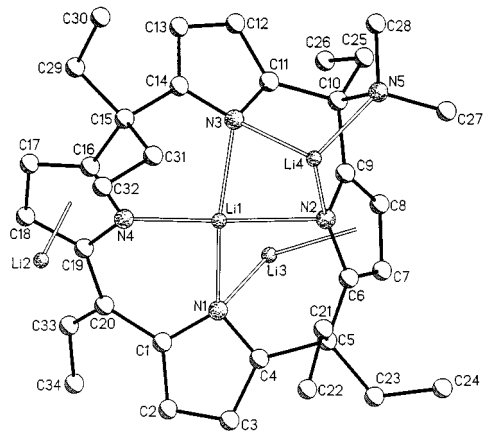

Fig. 2 A view of compound **7** (hydrogen atoms, DME and disorder have been omitted for clarity). Selected bond distances (Å): Li1–N1 2.050(6), Li1–N2 2.206(6), Li1–N3 2.136(6), Li1–N4 1.984(6), Li2–η^5(Pyr) 1.904(6), Li3–η^5(Pyr) 2.183(6), Li3–N1 2.110(7), Li4–N2 2.057(6), Li4–N3 2.070(6), Li4–N5 2.123(6), C30–C33 1.347(5), C10–N5 1.543(4). η^5(Pyr) indicates the centroid.

arrangement [out-of-plane of 0.160(5) Å from the N_4 core], Li2 is η^5-linked to one pyrrolyl moiety, Li3 links one nitrogen atom (N1) and is also η^5-bonded to one pyrrole, while Li4 lies in between two pyrroles and is bonded to the nitrogen of the NMe_2 group. Each lithium cation (except Li1) competes its coordination sphere with DME.

The procedures reported here should be applicable to the synthesis of novel forms of porphyrinogen and functionalization of the *meso*-positions using the reactivity of the porphodimethene skeleton towards nucleophiles, in the case of both the transition metal and the lithium derivatives. Furthermore, the lithiated forms are of direct use for the synthesis of a variety of transition metal derivatives.

A self-assembled monolayer of a fluorescent guest for the screening of host molecules

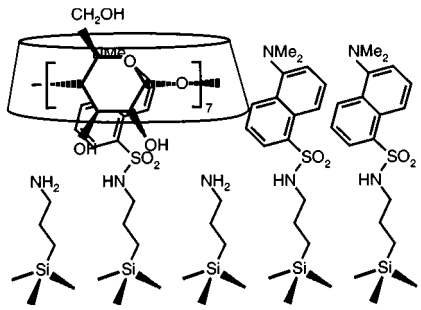
Simon Flink, Frank C. J. M. van Veggel* and David N. Reinhoudt*

Department of Supramolecular Chemistry and Technology, and MESA+ Research Institute, University of Twente, PO Box 217, 7500 AE Enschede, The Netherlands. E-mail: d.n.reinhoudt@ct.utwente.nl

Received (in Cambridge, UK) 12th August 1999, Accepted 29th September 1999

The polarity-dependent fluorescence of self-assembled monolayers of dansyl adsorbates on glass enables monitoring of its specific interactions with β-cyclodextrin.

Host–guest interactions are intensively studied phenomena in supramolecular chemistry.[1] The synthesis and functionalization of host molecules has led to a large variety of compounds with high affinities and selectivities for guests, varying from metal ions to (bio)organic molecules. Recent developments in combinatorial chemistry allow the preparation of synthetic receptor libraries.[2] The large number of host molecules that is generated in this way requires analytical techniques which enable the fast selection of suitable hosts for a specific guest. Self-assembled monolayers (SAMs) offer the possibility to immobilize guest derivatives on a variety of substrates, and monitor their interactions with compounds in the contacting solution. So far, several groups have used electrochemically active SAMs of ferrocene for the binding of macrocyclic hosts from aqueous solutions.[3] The complexation of the ferrocene headgroup resulted in a shift of its redox potential, which can be detected by cyclic voltammetry. Fluorescent self-assembled monolayers have rarely been used to monitor host–guest interactions. Hieftje *et al.* used a monolayer of fluorescently labeled single-stranded DNA to monitor interactions with proteins by fluorescence anisotropy.[4] Myles *et al.* reported the detection of barbituric acid derivatives by a self-assembled monolayer of fluorescent receptors on gold.[5] Here we describe the selective binding of β-cyclodextrin to self-assembled dansyl monolayers on quartz and oxidized silicon wafers, detected by fluorescence spectroscopy.



Self-assembled monolayers of dansyl adsorbates were prepared in a two-step procedure. First, a monolayer of 3-aminopropyltriethoxysilane was attached to the substrate.[6] This layer was converted into the desired dansyl SAM by reaction with dansyl chloride.[7] Ellipsometric measurements showed that the initially formed propylamine layer had a thickness of 6.7 ± 0.4 Å, which is close to the estimated length of the molecule (7.5 Å based on CPK models).[8] After reaction with dansyl chloride the layer thickness increased by 5.3 Å to a value of 12.0 ± 0.4 Å. Since the length of a dansyl group is 8.4 Å, the observed increase of only 5.3 Å was attributed to a relatively loose packing of the fluorescent groups. From these numbers a surface coverage of approximately 60% of the most densely packed monolayer was calculated. Wettability studies showed advancing contact angles with water of 67 ± 1 and 58 ± 1° for the 3-aminopropyltriethoxysilane SAM and the dansyl monolayer, respectively.[9] The hysteresis between advancing and receding contact angle for both surfaces was 30 to 35°, which indicates that monolayers were formed with a high degree of disorder. UV-VIS absorbance of the monolayer showed a strong absorption at 220 nm with a shoulder at 250 nm, and a third weak absorption at 330 nm (see Fig. 1).[10] Both position and relative intensity of these peaks are in good agreement with a spectrum of dansylamide taken in MeCN. The absorption at 220 nm was used to estimate the surface density of dansyl groups (ρ) from the Beer–Lambert law ($\rho = A\varepsilon^{-1}$), using the experimentally determined absorption coefficient of dansylamide in MeCN (ε_{220} = 38900 M^{-1} cm^{-1}). The resulting density of 0.93 dansyl groups per 100 Å^2 indicates that only 25% of the amino groups had reacted with dansyl chloride.[11] Based on a CPK model, the adsorbate would cover an area of approximately 52 Å^2. This results in a surface coverage of 50%, which is in reasonable agreement with the 60% surface coverage calculated from the ellipsometric thickness.

Fluorescence measurements of the dansyl SAM in air showed the characteristic broad emission centered at 480 nm.[12] Exposure of the monolayer to water resulted in a shift of the emission maximum to 510 nm. Hence, the well-known polarity dependence of the emission maximum of 1-(dimethylamino)-naphthalene-5-sulfonate[13] was maintained upon its immobilization in a monolayer. Apparently, the packing density was not enough to prevent water from solvating the dansyl groups.

Titration of the layer with aliquots of a concentrated aqueous solution of β-cyclodextrin resulted in an increase of the monolayer fluorescence, accompanied by a shift of the fluorescence maximum from 510 nm (pure water) to 480 nm (11.3 mM of β-cyclodextrin), as shown in Fig. 2. This indicates that the host molecules are bound to the layer, which results in an effective shielding of the dansyl groups from the aqueous environment.[14] The dansyl SAM showed no significant changes of the position or the intensity of the emission maximum in

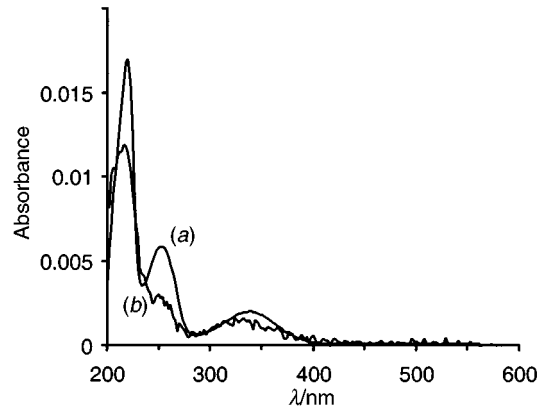


Fig. 1 UV–VIS absorption spectra of (*a*) 44 μM dansylamide in MeCN (shown absorbance was divided by a factor of 100) and (*b*) two dansyl monolayers (one on each side of the quartz slide).

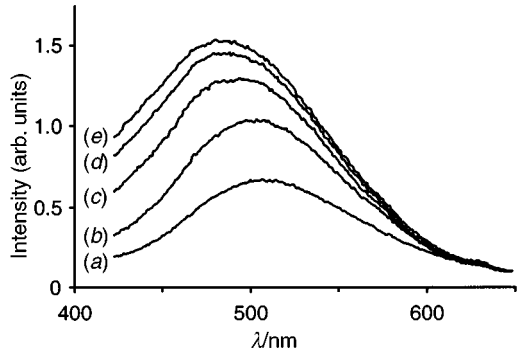

Fig. 2 Emission spectra of a dansyl monolayer (excitation at 350 nm) at different concentrations of β-cyclodextrin in the contacting aqueous solution: (*a*) 0, (*b*) 2.4, (*c*) 5.3, (*d*) 8.8 and (*e*) 11.3 mM.

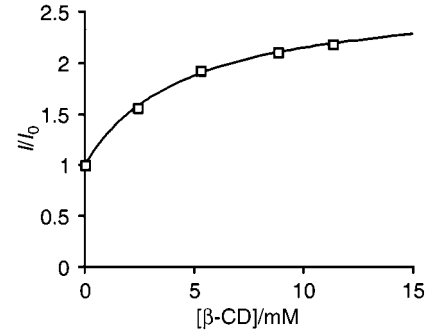

Fig. 3 Relative fluorescence intensity at 505 nm in dependence of the β-cyclodextrin concentration. The solid line shows eqn. (2) with an association constant of K = 221 M^{-1} and k_{compl}/k_{dans} = 2.67.

titration experiments with solutions of α- and γ-cyclodextrin. Hence, the observed changes of the emission spectra were the result of molecular recognition rather than aspecific binding of cyclic oligosaccharides to the dansyl monolayer. Moreover, the addition of aliquots of a competitive guest (50 mM cyclohexanol) to the 10 mM β-cyclodextrin solution resulted in decomplexation from the dansyl layer and changed the wavelength of the emission maximum and its intensity to the values observed in pure water. Due to the covalent binding of the dansyl group to the propylamine monolayer, we exclude the possibility of the complexation of one dansyl group by two β-cyclodextrin molecules as was reported by Dunbar *et al.* for solution experiments.[15] Consequently, the observed phenomena are attributed to the 1 to 1 complexation of the immobilized dansyl guests by β-cyclodextrin hosts.

To provide enough space for every dansyl group to bind a β-cyclodextrin molecule, the average area per dansyl group should be 180 Å^2, which would result in a layer thickness well below the determined 12 Å. This means that not every dansyl is capable of forming an inclusion complex. The determined surface density of fluorophores would allow 60% of the dansyl groups to be complexed by a cyclodextrin molecule. Consequently, the observed emission spectrum is the sum of the two fluorescent species present at the surface (free dansyl, and the complex of β-cyclodextrin and dansyl). The fluorescence intensity (I) at a given wavelength is therefore given by eqn (1),

$$I = k_{dans}[dans] + k_{compl}[comp] \quad (1)$$

where k_{dans} and k_{compl} represent the proportionality constants that connect the intensities and the surface concentration of the species.[16] Combined with the equation for the association constant (K = [compl]/[dans][β-CD]) this results in eqn. (2),

$$\frac{I}{I_0} = \frac{1 + (k_{compl}/k_{dans})K[\beta - CD]}{1 + K[\beta - CD]} \quad (2)$$

where I_0 is the emission intensity in the absence of β-cyclodextrin. From the fit of eqn. (2) to the experimental values, an association constant of 221 ± 19 M^{-1} was obtained (see Fig. 3), which is of the same order of magnitude as the reported values of 100–200 M^{-1} for complexes in aqueous solutions.[14]

In summary, self-assembled monolayers of 3-aminopropyltriethoxysilane can be effectively modified by reaction with sulfonyl chlorides. In this way, different functions like dyes can be introduced. Efficient solvation of the surface-bound dansyl groups maintains their polarity dependent emission, which has been used to study the interactions with several hosts in aqueous solutions.

Isothiocyanatoporphyrins, useful intermediates for the conjugation of porphyrins with biomolecules and solid supports

Oliver J. Clarke and Ross W. Boyle*

Department of Biological Sciences, University of Essex, Wivenhoe Park, Colchester, Essex, UK CO4 3SQ. E-mail: rossb@essex.ac.uk

Received (in Liverpool, UK) 3rd August 1999, Accepted 23rd September 1999

***meso*-Phenylporphyrins bearing a single isothiocyanate group react efficiently under ambient conditions with primary amino groups on proteins and polystyrene resins.**

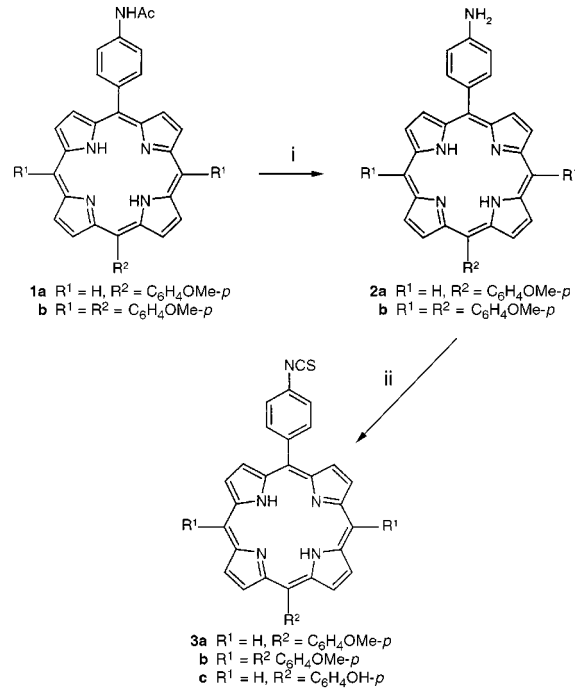
Porphyrins are molecules of great interest due to the wide range of potential applications associated with them, these include photochemotherapy,[1] oxidation catalysis,[2] optoelectronics[3] and fluorescence imaging.[4] In order to customise porphyrins for uses such as these it is often necessary to attach the core macrocycle to either biological targeting agents, such as proteins, or solid supports. The conjugation of porphyrins with these species is often complicated by solvent incompatibilities and/or the forcing conditions commonly required to react substituents on the porphyrin periphery. We have recently become interested in developing mild methods for the conjugation of porphyrins and report here a facile method for generating a single isothiocyanate group on a porphyrin and the reaction of these species with amines in solution, on polypeptides and on polystyrene resins.

Previous attempts have been made to conjugate porphyrinoid structures with a variety of biologically active macromolecules including lipoproteins,[5] monoclonal antibodies[6] and serum albumin.[7] Many of these complexes rely on non-covalent linkages which, while more easily formed, are inherently less stable than covalent conjugates. Immunoconjugates[8] have been produced *via* non-covalent interaction of a porphyrin hapten at specific binding sites present on the surface of antibodies. Such porphyrin immunoconjugates have been used to confer specificity to photochemotheraputic techniques but the preparation and stability of the conjugate is heavily dependent on conditions such as solvent, pH and temperature. Clearly a covalently bound porphyrin antibody conjugate would be more flexible in terms of the physical and chemical conditions it could be exposed to. The majority of attempts to covalently conjugate porphyrin molecules with polypeptides have relied on carbodiimide mediated coupling to protein amino residues, *via* carboxy functionality on the macrocycle. These reactions are however slow and require the *in situ* generation of a reactive intermediate, which can lead to extensive loss of porphyrin as the *N*-acyl urea derivative.

Isothiocyanates are commonly used for the attachment of fluorescent probes to sensitive biological substrates under very mild conditions with no by-products,[9] however the use of this type of functionality in porphyrin chemistry has, strangely, not been developed. Collman[10] recently reported the use of porphyrin isocyanates as molecular building blocks for the construction of capped and strapped porphyrins. The high reactivity of isocyanates makes them useful synthetic tools, but their use is complicated by rapid hydrolysis of the NCO group upon exposure to moisture. Currently this synthesis involves reaction of amino porphyrins with highly toxic phosgene or triphosgene under inert atmosphere conditions. Isothiocyanates in contrast are slightly less reactive, but considerably more stable, their hydrolysis being much slower under aqueous conditions. Here we present a convenient method for synthesising porphyrin isothiocyanates and demonstrate their use in porphyrin conjugation with amino bearing substrates.

Acid hydrolysis of mono acetamido porphyrins, synthesised according to Adler *et al.*[11] and Boyle *et al.*,[12] yielded the corresponding mono amino derivatives. Subsequent treatment with 1,1′-thiocarbonyldi-2,2′-pyridone (TDP)[13] in CH_2Cl_2 at room temperature (Scheme 1) gave, quantitatively, the respective monoisothiocyanato porphyrins after 30 to 40 min. The by-product, 2-hydroxypyridine, was easily removed during an aqueous work up. The resulting monoisothiocyanato porphyrins are relatively stable to air and can be handled without the need for inert atmosphere conditions. In order to test the reactivity of these compounds a number of reactions were performed under standard conditions, in solution, using a variety of amines; these results are summarised in Table 1.

It can be seen from these results that the isothiocyanate functionality reacts cleanly and in good to excellent yield with most amines. Primary aliphatic amines were found to react fastest with times typically in the region of 30 min. Aromatic and secondary amines react more slowly and the combination of these structural features in the same molecule (*e.g.* diphenylamine) resulted in no detectable product being formed, even after 10 days. *N*-Terminal amino residues of phenylalanine, leucine and valine were also found to react cleanly. All the resulting thioureidyl porphyrin derivatives showed good stability, including those formed from amino acids. We believed that this was important with regard to the use of monoisothiocyanato porphyrins for bioconjugation with polypeptides.



Scheme 1 *Reagents and conditions*: i, 6 M HCl, 100 °C, 3 h, 10% Et_3N–CH_2Cl_2, aqueous workup; ii, 1,1′-thiocarbonyldi-2,2′-pyridone (2 equiv.), CH_2Cl_2, 25 °C, 0.5–1 h, aqueous workup. Porphyrins **1a** to **3c** characterised by ^1H and ^{13}C NMR, MS and UV-VIS spectroscopy.

Encouraged by these results we set out to explore the potential of monoisothiocyanato porphyrins for bioconjugation and attachment to polystyrene resins.[14] Bovine and human serum albumin (BSA and HSA) are well-characterised proteins which have been used in drug delivery[15] and for raising antibodies by haptenisation of small molecules. We therefore selected BSA as a model protein to study the potential of monoisothiocyanato porphyrins for bioconjugation. Model reactions on amines with monoisothiocyanato porphyrins had previously been performed in organic solvents; in order to facilitate conjugation with proteins under aqueous conditions, a 5,15-diphenylporphyrin was synthesised bearing a more hydrophilic hydroxy group on one phenyl ring and an isothiocyanate group on the opposing phenyl ring[12] (Scheme 1, **3c**).

In a typical experiment a stock solution of 5-(4-hydroxyphenyl)-15-(4-isothiocyanatophenyl)porphyrin **3c** in anhydrous DMSO (10 mg ml^{-1}) was prepared. 100 μl of the stock solution was added to a gently stirred solution of BSA (10 mg) in carbonate buffer (1 ml, pH 9.2). The reaction was protected from light, and agitated at room temperature for 17 h. Purification of the conjugate was achieved using gel filtration (Sephadex G-25) eluting with carbonate buffer at pH 8.9. The porphyrin–BSA conjugate was contained in the first fluorescent band eluted from the column, and was characterised by SDS-PAGE. Once the gel had been run to completion (200 mA, 45 min) the unstained gel plates were illuminated with a UV lamp revealing a red fluorescent band which, on subsequent staining with silver nitrate, corresponded with BSA at 66 kD in the protein reference ladder.

The UV–VIS spectrum of the red fluorescent material at 66 kD exhibited both the characteristic Soret and Q bands of the porphyrin and an absorption peak at 284 nm corresponding to BSA. The same material showed strong porphyrin fluorescence at 620 nm. Standard spectroscopic methods[16] were used to determine the labelling ratio of the porphyrin–BSA conjugate, which was found to be 1 : 1.

Finally, monoisothiocyanato porphyrin was reacted with Rink amide resin (Novabiochem). Pre-swelling of the resin in CH_2Cl_2 followed by Fmoc deprotection of the amino group in 20% piperidine–DMF, then washing with MeOH, CH_2Cl_2, DMF and water yielded the free amino Rink resin. Monoisothiocyanato porphyrin (3 equiv.) was then mixed with the resin (1 equiv.) in CH_2Cl_2 and agitated for 17 h at 25 °C in the dark. The loading value for monoisothiocyanato porphyrin on the Rink resin was calculated at 0.718 mmol g^{-1}, representing a loading efficiency of 94.1%. Treatment with 1% TFA–CH_2Cl_2 solution for 17 h resulted in quantitative cleavage of porphyrin from the resin as the thiourea derivative. Interestingly, cleavage conditions for Rink amide resin usually require at least 50% TFA solutions.[17]

O. J. C. thanks the University of Essex for a studentship. The authors thank the Wellcome Trust (052724) for financial support and the EPSRC mass spectrometry service, Swansea for analyses.

An enantioselective synthesis of heteroaromatic *N*-tosyl α-amino acids

Mogens Johannsen*

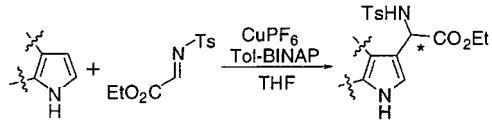
Department of Organic Chemistry, Technical University of Denmark, Building 201, DK-2800 Lyngby, Denmark. E-mail: okmj@pop.dtu.dk

Received (in Liverpool, UK) 18th August 1999, Accepted 22nd September 1999

A new synthesis of optically active β-indolyl and pyrrolyl *N*-tosyl α-amino acids has been developed which uses readily available starting materials and proceeds with a high degree of enantioselection, giving the α-amino acids with up to 96% enantiomeric purity in 89% yield using 1–5 mol% of a chiral copper(I)–Tol-BINAP catalyst.

Within the last few years new catalysts have emerged for the classical and industrially very important Friedel–Crafts acylation of aromatics.[1] However, the addition of unsaturated compounds such as aldehydes and imines, which would lead to new and interesting compounds with stereogenic centers, has received only scant attention. Moreover, as far as the author is aware, the catalytic asymmetric version of such an addition has only one precedent the addition of ethyl pyruvate to 1-naphthol promoted by a chiral zirconium complex gave the addition product in 56% yield and with 84% ee.[2]

Recently considerable progress has been achieved with the long-standing problem of catalytic enantioselective addition of nucleophiles to imines.[3] This prompted us to investigate the enantioselective addition of a variety of aromatic compounds to imines. We now report our findings using a complex of copper(I) salts and Tol-BINAP[4] (the Lectka system)[3a] to catalyse the enantioselective addition of *N*-tosylimino esters of ethyl glyoxylate to electron-rich aromatics such as indole and pyrrole (Scheme 1).[5]

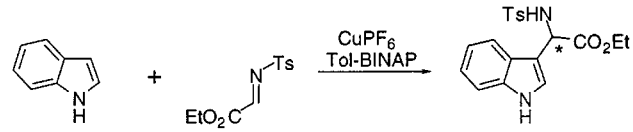


Scheme 1

Using as substrate furan we were able to isolate 15% of the desired aromatic addition product with 38% ee after 2 days at room temperature. This made us focus on the pyrrole and indole systems as these are known to be more active than furan in aromatic electrophilic substitution.[6] To our delight the reaction between indole **1a** and the imine **2** in THF was complete within a few hours, giving the 3-substitution product **3a** in almost quantitative yield and with 87% ee (Table 1, entry 1).[7] Running the reactions at lower temperatures (−20 and −78 °C) increased the enantioselectivity to 91 and 96% ee, respectively (entry 2, 3).[8] A simple recrystallisation gave the enantiopure *N*-protected α-amino acid **3a**.[9,10] Running the same reaction in CH_2Cl_2 gave a more sluggish conversion with more by-products and a lower enantioselection than in THF (entry 4). Finally, the amount of catalyst was reduced to 1 mol% almost without any change in yield or enantioselectivity [> 99% ee, 71% yield (recryst.)] (entry 5).

To test the scope of the reaction a variety of 5-substituted indole derivatives were screened.[11] As evident from Table 2 all the addition reactions give the 3-substituted indole derived amino acids.[12] The addition to the electron-rich methoxy-substituted substrate works particularly well, giving the product in 89% yield and more than 97% ee [> 99% ee, 73% yield (recryst)] (entry 2). The indole substrates with the electron-withdrawing substituents **1c,d** also react in a very enantioselective fashion, but a slightly higher reaction temperature was required in order to complete the reactions (entry 3,4). The 5-brominated indole reacts as the other indoles exclusively at the 3-position giving the addition product in 75% yield and with 88% ee [> 98 % ee, 55% yield (recryst.)] (entry 5).[13] The bromo product offers an interesting opportunity to test a variety C–C coupling reactions to give other enantiomerically pure 5-substituted indole alkaloids.[14]

Table 1 Enantioselective addition of imino ester **2** to indole **1a**



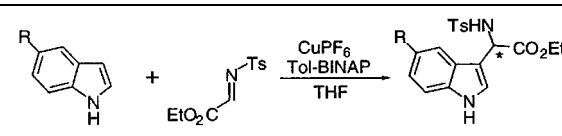
1a **2** **3a**

Entry	Catalyst/ mol%	Solvent	*T*/°C	Yield[a] (%)	Ee[bc] (%)
1	5	THF	room temp.	98	87
2	5	THF	−20	90	91
3	5	THF	−78	89	96
4	5	CH_2Cl_2	−78 to −10	57	78
5	1	THF	−78	89 (71)	94 (> 99)

[a] Yield after recrystallisation in parentheses. [b] Ee after recrystallisation in parentheses. [c] Ee determined by HPLC on a DAICEL OD-H or OJ column.

After having established the generality of the indole additions, focus was turned to the pyrrole systems. Two representative derivatives were chosen as model substrates, *viz.* *N*-methylpyrrole and 2-acetylpyrrole. The catalysed (5 mol% cat.) addition to *N*-methylpyrrole gives according to ^{1}H NMR approxiamtely a 1:1 mixture of the 2- and 3-substituted products **5** and **6**. After flash chromatographic separation, the two regioisomers were obtained in a total yield of 89%, the enantioselectivity being 84 and 56%, respectively. One recrystallisation of the 2-substituted product gave the enantiopure amino acid **6** [27% yield (recryst.)] (Scheme 2).

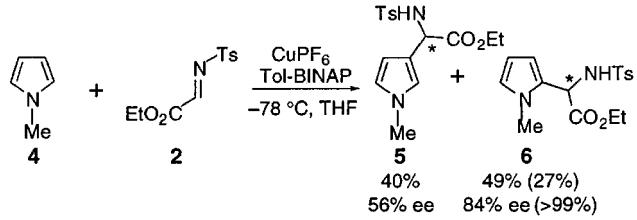
Table 2 Enantioselective addition of imino ester **2** to 5-substituted indoles **1a–e**



1a–e **2** **3a–e**

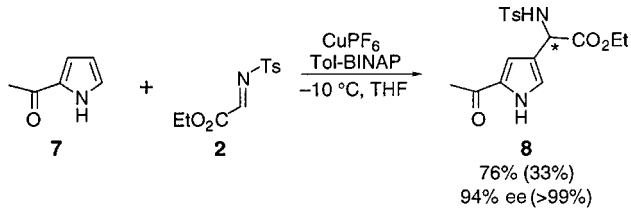
Entry	Catalyst/ mol%	R	*T*/°C	Yield[a] (%)	Ee[b] (%)
1	1	**1a** H	−78	89 (71)	96 (> 99)[c]
2	5	**1b** OMe	−78	89 (73)	97 (> 99)[c]
3	5	**1c** NO_2	−78 to −10	71	78
4	5	**1d** CO_2Me	−40	67 (52)	94 (> 98)[d]
5	5	**1e** Br	−10	75 (55)	88 (> 98)[d]

[a] Yield after recrystallisation in parentheses. [b] Ee after recrystallisation in parentheses. [c] Ee determined by HPLC on a DAICEL OD-H or OJ column. [d] Ee determined by ^{1}H NMR using a lanthanide shift reagent (ref. 13).



Scheme 2

In contrast to the *N*-methylated pyrrole **4**, the deactivated 2-acetylpyrrole **7** reacts primarily at the 4-position. The addition product was isolated in 76% yield, with a surprisingly high ee of 94% [> 99% ee, 33% yield (recryst.)] when compared to **5** (Scheme 3).



Scheme 3

Finally, it should be mentioned that the catalysed addition of **2** to pyrrole gives the *N*-addition product as the main product. It is the only case where we have observed this kind of amino acetal product during our investigation.

At present not much is known about the mechanism of the reaction. Earlier studies by Lectka *et al.* have shown the capability of the system to effect highly enantioselective imino aldol reactions.[3a,b] On the other hand we have found that the Mannich reaction of 1-morpholinocyclohex-1-ene with the tosyl imine **2** was very fast (< 1 min, −78 °C) giving the anticipated imino aldol product after hydrolysis. However, the enantiomeric excess was very low (< 10% ee). The fact that the enamine moiety of the substrates is a part of a heteroaromatic system is therefore crucial for the effectiveness of this new addition reaction. The present reaction should therefore most adequately be considered as an aromatic electrophilic substitution rather than a Mannich reaction.

In summary a novel synthesis of useful optically pure heteroaromatic α-amino acids has been developed. The procedure allows for the simple preparation of an array of electronically different indole α-amino acids. These might be used in the synthesis of natural products and pharmacologically interesting compounds as well as new chiral ligands for asymmetric catalysis. The presence of the different 5-substituents permits the systematic testing of the influence of electronics on the activity of the new indole derivatives. Simple pyrrole systems also worked well as substrates, giving access to new optically pure heteroaromatic α-amino acids.

Recent advances in the preparation of semiconductors as isolated nanometric particles: new routes to quantum dots

Mark Green and Paul O'Brien*†

Department of Chemistry, Imperial College of Science Technology and Medicine, South Kensington, London, UK SW7 2AY. E-mail: p.obrien@ic.ac.uk

Received (in Cambridge, UK) 25th May 1999, Accepted 16th September 1999

Nanoparticles of semiconductor materials have been the subject of intense research in the last five years owing to the novel electronic, catalytical and optical properties observed in such materials. The unusual properties of these so called quantum dots can be attributed to two main factors: the large surface to volume ratio of atoms and the confinement of charge carriers in a 'quantum mechanical box'. Small particles of semiconductors have been prepared by a number of routes, often using colloidal chemistry methods but more recently using organometallic routes. The recent advances have resulted in high quality nanoparticles which have been incorporated into simple devices. In this article we cover some of the key advances in the preparation of nanometric particles of semiconductors. The cover illustration depicts three sizes of TOPO capped CdSe.

Introduction

Isolated quantum dots are a novel form of semiconductor of theoretical interest and with potential to develop as an important class of materials for the electronics industry of the 21st century. The electronic properties of a bulk semiconductor are determined principally by the band gap of the material and its type. Typically, bulk samples of CdS, irrespective of their size once > *ca.* 20 nm, will absorb all electromagnetic radiation with an energy greater than the band gap ($h\nu$ > 2.42 eV); which is classified, in this case, as direct.[1] However, as particles become smaller, their electronic structure changes, eventually the description of the material as containing continuous bands breaks down and there are discrete bonding and antibonding levels in the material.[2] The electronic properties of such small particles are hence more like those of a molecule than an extended solid. The electronic, optical and catalytical properties of such small particles will depend on their size and the material of which they are composed.[3]

For a semiconductor such as CdS, these effects were predicted some years ago to become important in the size range from *ca.* 2 to 10 nm and Brus and coworkers published a number of keynote papers.[4–6] The preparation of stable particles in this size range has presented a considerable challenge to the chemist and such materials have been synthesised from aqueous solutions, adapting the approaches of colloid chemistry, or by the controlled decomposition of organometallic or metal organic compounds. Such small particles have relatively large surface areas and control of their surface chemistry has been important in developing stable forms of these materials and in controlling their properties.

Electronic properties

The 'band gap' of a quantum confined semiconductor is greater than that of the parent bulk material from which it is derived. This is an effect which is a consequence of the confinement of the electron in a three-dimensional 'box' with discrete energy levels rather than in the quasi-continuous band of a bulk material (Fig. 1).[4] The absorption of electromagnetic radiation by quantum dots, of materials such as CdS, is hence relatively easy to appreciate. However, explaining the luminescent

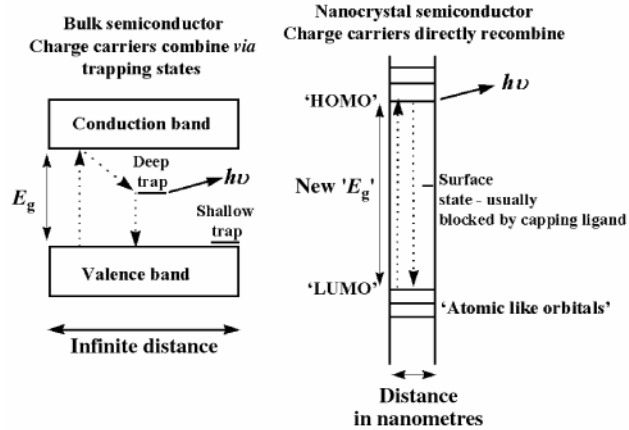

Fig. 1 Spatial electronic state diagram for bulk semiconductor and nanoparticles, after Brus and coworkers.[4]

Dr Mark Green obtained his BSc in chemistry from the Manchester Metropolitan University in 1995. He carried out research for his PhD at Imperial College for Professor Paul O'Brien between 1995 and 1998, studying new routes to nanoparticulate semiconductors. He is currently a post doctoral associate in the O'Brien group looking at nanoparticulate metals and semiconductors.

Professor Paul O'Brien graduated from Liverpool University in 1975, obtained a PhD from the University of Wales, Cardiff in 1978 and was immediately appointed as a lecturer at Chelsea College of Science and Technology. Following the University of London re-structuring, he moved to Queen Mary and Westfield College in 1984 and was promoted to a chair in 1994. In 1995 he moved to Imperial College where he was appointed as a Professor of Inorganic Chemistry and Sumitomo STS Professor of Materials Chemistry (1997–1999) and was Royal Society Amersham fellow (1997–1998). He holds a visiting Professorship at the Georgia Institute of Technology and is also a distinguished scholar at the Molecular Design Institute. In October 1999, he will take up a new position as Professor of Inorganic Materials, a joint appointment between the University of Manchester Chemistry Department and the Manchester Materials Science Centre.

† Current address: Department of Chemistry and the Manchester Materials Science Centre, The University of Manchester, Oxford Road, Manchester, UK M13 9PL.

behaviour of such materials is much more complicated but crucially important in identifying materials of sufficient quality for potential practical application. The ideas that have emerged for explaining such phenomena illustrate an interesting interplay between experiment and theory. Brus explained, on the basis of theoretical considerations and studies of excited state lifetimes, the main features expected in the luminescence spectra of quantum confined semiconductors and successfully anticipated the results of subsequent experiments.[4] Emission from passivated semiconductor quantum dots is often found to be 'band-edge' referring to the direct recombination of charge carriers from the atomic like orbitals (Fig. 1). Charge carriers in bulk semiconductors recombine from deep and shallow traps (crystal and surface defects) giving emission at different wavelengths from the band edge.

An alternative view of such structures, which has some conceptual appeal, is that they may be viewed as 'super atoms'. Electrons within the solids are confined within an approximately spherical particle (the diameter of the quantum dot). The solutions of the Schroedinger equation for this three-dimensional confinement can be viewed for a single electron as resembling a super atom with electronic states which resemble the orbitals of atoms (s, p, d. . .). The transitions observed are analogous to those observed in atomic spectroscopy.[7] Consequently one way to view the current excitement, and interest, in this area of science is that we are put into a position in which we can produce a material which has the electronic properties of a 'tailor-made atom'.

Methods of preparation

Many synthetic methods for nanoparticles have been reported in the literature. Many use methods based on colloid chemistry, decomposition of organometallic compounds or growth in a restricted reaction space. An ideal route should result in pure, monodispersed, crystalline particles which are stable, *i.e.* they have robust surface passivation. Nanoparticles of metals, metal oxides, carbides, borides and nitrides have also been produced and have been reviewed elsewhere.[8–10]

Elemental semiconductors have also been studied. For instance, germanium nanoparticles have been produced by the reaction of $GeCl_4$ and lithium naphthalide in tetrahydrofuran.[11] The quantum dots formed were between 60 and 200 Å in diameter. Laser illumination of a hexane solution resulted in further growth and increased crystallinity. Similarly oxide coated silicon nanoparticles have been produced by the combustion of silane.[12]

Problems with nanoparticles grown by colloidal or restricted growth routes, centre around their air sensitivity and poor crystallinity. Nanoparticles prepared in structured media also have their dimensions dictated by the restricting material. The removal of the matrix or the effect of its removal also needs to be considered when developing strategies for materials of practical importance.

Colloidal routes

The first reported routes to such small particles involved the controlled precipitation of dilute colloidal solutions and the cessation of growth soon after nucleation. The synthesis of highly monodispersed colloids was explained in the 1940's by La Mer *et al.*[13–15] who suggested that if seeds (nuclei) could be made to grow in concert into larger particles, monodispersed sols could be formed. In this early work the particles were typically micrometric. However, if nucleation and growth are properly controlled, particles with dimensions of the order of nanometres can be reproducibly synthesized. Small crystals, which are less stable, dissolve and then re-crystallise on larger more stable crystals; a process known as Ostwald ripening. For such methods to be effective, the quantum dots in question must have low solubility, which can be achieved by the correct choice of solvent, pH, temperature and passivating agent. Highly monodispersed samples are obtained if the processes of nucleation and growth are distinctly separated, *i.e.* fast nucleation and slow growth. The colloidal stability of these crystals has been improved by using solvents with low dielectric constants or by using stabilisers such as a styrene/maleic acid copolymer. Henglein,[16] Brus and coworkers[17,18] and Weller[19] have made significant contributions to this field, especially in studies of CdS.

A typical example involved the reaction between aqueous solutions of $CdSO_4$ and $(NH_4)_2S$. Control of the size of nanocrystalline CdS was achieved by altering nucleation kinetics using pH.[17] Although these methods can be efficient, some important semiconductors cannot easily be synthesised, *e.g.* CdSe, GaAs, InP and InAs. Annealing of amorphous colloidal particles is also a problem as these tend to be low temperature processes producing poorly crystalline material. Such aqueously prepared nanoparticles are not sufficiently stable at higher temperatures for annealing without agglomeration. CdS and ZnS have also been produced from methanolic media without the use of an organic ligand for stabilisation, using the repulsion of the electrostatic double layer to stop agglomeration.[18]

Zn_3P_2 and Cd_3P_2 have both been produced by aqueous methods, by the injection of phosphine gas into a solution of the relevant metal perchlorate.[20,21] The quantum dots obtained were coloured, from white for small Cd_3P_2, to brown for the larger particles. The white particles were reported to have band gaps of up to 4.0 eV. Luminescence was reported to be strong at short wavelength, but little attention was paid to crystal morphology. Murphy and coworkers have produced manganese activated (Mn occupying surface sites) and manganese doped (Mn occupying lattice sites) ZnS dots by aqueous routes, displaying increased quantum yields and orange emissions respectively.[22]

Synthesis in confined matrices

Materials which provide distinct defined cavities have been used to synthesise quantum dots. These well defined zones have been used as nanometre sized reaction chambers. Zeolites,[23] micelles,[24] molecular sieves[25] and polymers[26] have all been used to restrict growth. The matrix may also play a role in determining the final properties of the particle, for example, micelles are labile. CdSe and ZnS nanoparticles have been produced in inverse micelle solutions.[27,28] A microemulsion containing the metal ion was reacted with a silylchalcogenide, resulting in nanoparticles. The surface was then capped by phenyl groups or another semiconductor. The surface composition of the crystals were interesting owing to their ability to react further with other silyl groups owing to the excess Cd^{2+} sites, effectively growing larger and developing a different surface capping.

Growing particles in the internal cavities of zeolites also limits the particle size of materials, usually no larger than 20 nm. CdS has been synthesised in two different zeolites by ion exchange from the sodium cationic form to the cadmium cationic form, followed by exposure to H_2S gas. Depending upon the amount of cadmium utilised, different sized particles were obtained.[23] Cadmium telluride nanoparticles have also been prepared in a sodium or potassium zeolite. Exchange of the metal with cadmium nitrate followed by reduction by hydrogen at 450 °C prepared the zeolite for vapour phase deposition of tellurium, resulting in CdTe clusters. The size of the clusters could be controlled by using either the potassium or sodium resin, which altered pore diameters.[29]

Q-GaP has also been synthesised in the pores of zeolite Y.[30] The vapour transfer of Me_3Ga into a dry Na^+/H^+ exchange zeolite resulted in methane evolution and the formation of

$Me_{3-x}Ga$ sites. Exposure of this to an excess of PH_3 at various temperatures (200–400 °C) resulted in the growth of particles with a size range of 10–12 Å. The nanocrystals formed were analysed by EXAFS and solid state NMR spectroscopy.

Q-PbS was obtained by exchanging Pb^{2+} into ethylene/methacrylic acid copolymer, followed by exposure to H_2S.[26] The size of the particles was again controlled by Pb^{2+} concentration, with sizes ranging from 13 to 125 Å. A similar technique was used to grow in the interlamellar regions of a layered host, $Zr(O_3PCH_2CH_2CO_2H)_2$. Conversion of the host to $M^{II}[Zr(O_3PCH_2CH_2CO_2)_2]$ (M = Pb, Cd, Zn) followed by treatment with H_2E (E = S, Se) resulted in growth of ME nanoparticles.[31]

An organometallic route to polymeric composites of CdSe and ZnSe has been developed by Cole-Hamilton and coworkers.[32–34] The polymer 2-pyridyl-polybutadiene was reacted with a group IIb metal alkyl, to give an adduct. A toluene solution of the polypyridine bound metal alkyl was exposed to H_2Se gas to give a coloured precipitate. The size of the nanoparticles was determined by both the solvent and the reaction temperature (−76 to 60 °C); quantum dots synthesised at lower temperatures were smaller. Hexagonal CdSe was obtained in the size regime 1–6 nm, with the use of light petroleum instead of toluene giving larger particles. The particles were characterised by HRTEM, powder XRD, UV and photo-acoustic spectroscopy (PAS).

Metal–organic routes

A popular method for the preparation of high quality, crystalline, monodispersed nanoparticles was first described by Murray *et al.* in 1993.[35] In this method, a volatile metal alkyl (dimethylcadmium) and a chalcogen source TOPSe (tri-*n*-octylphosphine selenide) were mixed in tri-*n*-octylphosphine (TOP) and injected into hot TOPO (tri-*n*-octylphosphine oxide), a polar coordinating Lewis base solvent. Nucleation of nanoparticulate CdSe was achieved by the sudden introduction of the concentrated reagents resulting in abrupt supersaturation and the formation of nuclei, followed by slower growth and annealing, consistent with an Ostwald ripening process. The nanoparticles were passivated by a monolayer of the solvent ligands and hence could be isolated by solvent/non-solvent interactions. The particles produced by this method were highly monodispersed (±5%, Fig. 2) and crystalline. By varying the

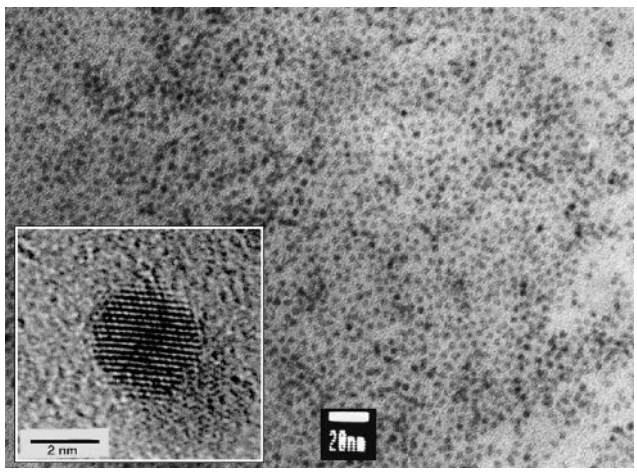

Fig. 2 TEM image of TOPO capped CdSe nanoparticles prepared as described in ref. 38 (scale bar = 20 nm); inset, HRTEM image, scale bar = 2 nm.

temperature of synthesis the diameter can be controlled in the size range 24–230 Å. The organic surface cap can be replaced by other organic groups such as pyridine, 4-picoline, tris(2-ethylhexyl)phosphate, and 4-(trifluoromethyl)thiophenol.[36] Computer modelling of XRD patterns suggests that Q-CdSe prepared at temperatures of up to 300 °C have around one defect per nanocrystal.[35]

Alivisatos and coworkers produced similar quantum dots with fewer crystal defects by using a higher temperature synthesis (350 °C) and tributylphosphine instead of tri-*n*-octylphosphine.[37] Replacing the metal alkyl with an adduct of the metal alkyl produces similar quality quantum dots whilst reducing the risks of using pyrophoric precursors.[38] The physical chemistry of TOPO capped nanoparticles has been thoroughly investigated.[39–41] Emission from TOPO capped II–VI materials is found to be near band edge with quantum yields of *ca.* 10% (Fig. 3).[35]

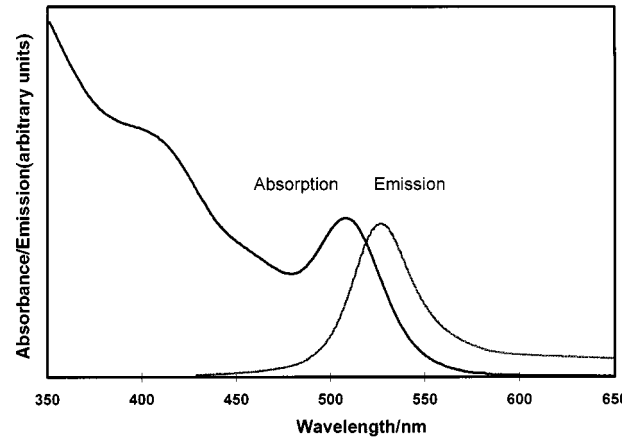

Fig. 3 Electronic and photoluminescence spectra of TOPO capped CdSe nanoparticles prepared as described in ref. 38.

The nanoparticles prepared by this method are of high quality, but the reaction requires harsh/difficult conditions, such as the injection of hazardous metal alkyls at elevated temperatures (*ca.* 350 °C) which is clearly undesirable. One way to avoid such potential problems is the use of a single-molecular precursor in which the metal–chalcogen bond is already in place. Trindade and O'Brien investigated cadmium dithio- and diseleno-carbamate complexes as precursors for the preparation of TOPO capped II–VI materials.[42,43] Thermolysis of the air stable complex $[Cd(S_2CNEt_2)]_2$, in TOPO resulted in high quality nanoparticles of CdS. The thermolysis of the analogous diselenocarbamate complex in TOPO resulted in micrometric particles of selenium. However, compounds of the formula $RCd(E_2CNEt_2)$, (R = neopentyl, Me; E = S, Se) were efficient precursors to CdE nanoparticles on thermolysis in TOPO (reaction scheme shown in Fig. 4). Such compounds eliminate the need for volatile metal alkyls, but are however air-sensitive; air-stable precursors would be preferred. Simple diselenocarbamate complexes of cadmium with unsymmetrical R groups, such as hexyl and methyl $(CdSe_2CNMeHex)_2$, are air stable and are found to be excellent precursors for CdSe.[44] GC–MS studies have suggested the decomposition mechanisms of symmetrical diselenocarbamates, which produce selenium clusters.[45] However, unsymmetrical diselenocarbamates (with alkyl groups longer than hexyl) produce only the metal selenide and organic by-products. Revaprasadu *et al.* have also recently doped nanoparticulate ZnS with Mn, giving emission in the orange region of the visible spectrum rather than the blue.[46]

Hines and Guyot-Sionnest[47] and Revaprasadu *et al.*[48] reported simultaneously the preparation of TOPO capped ZnSe. Hines and Guyot-Sionnest[47] used the same methodology adopted by Bawendi *et al.*,[35] *i.e.* dimethylzinc and tri-*n*-octylphosphine selenide as precursors. However, the use of TOPO/TOP as capping agents failed and a mixture of hexadecylamine and TOPO was used instead. Revaprasadu *et al.*[48] used the single source complex $[EtZn(E_2CNEt_2)]_2$ (E = S, Se) in TOPO to prepare crystalline capped nanoparticles of ZnE. Comparison of Hines' metal alkyl route and the single source route suggests there may be surface differences in the as-

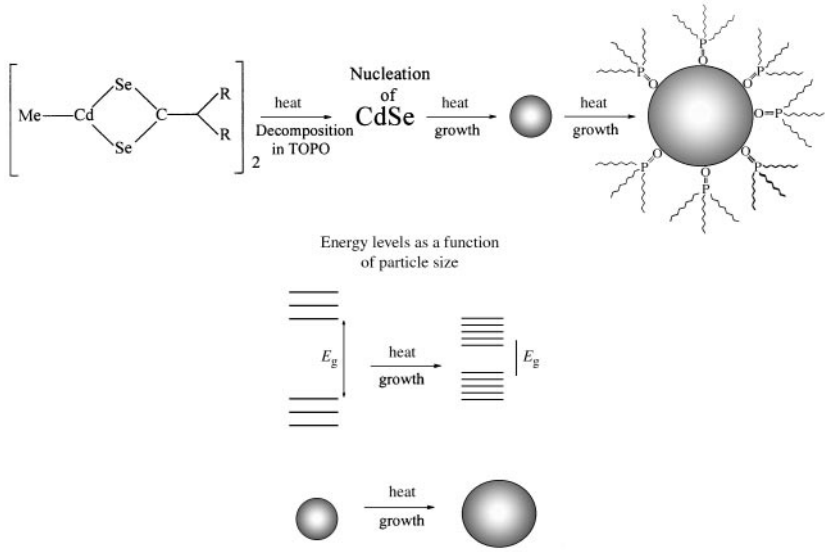

Fig. 4 Theoretical decomposition schematic for the preparation of TOPO capped CdSe using a single source precursor.

prepared materials. Comparisons of CdSe nanoparticles prepared by single source precursors and the metal alkyl by IR spectroscopy again suggest different surface environments which are currently under investigation by our group.

The preparation of lead chalcogenide nanocrystals has also been achieved using various lead dithio- and diseleno-carbamates.[49] Group IV–VI semiconductors are a prime example of materials where precursors such as highly toxic lead alkyls are undesirable. The nanoparticles of lead chalcogenides have a cubic shape inherent in PbS materials (Fig. 5). Nanoparticles of PbE and CdE (E = Se, S) have been linked using bridging ligands such as 2,2′-bipyrimidine.[43]

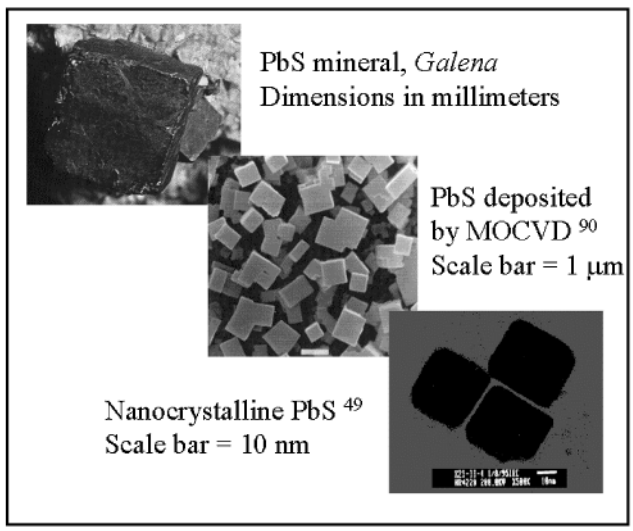

Fig. 5 Photo, SEM and TEM of PbS of various sizes.

Nanoparticles of TOPO capped II–VI materials are found to degrade in the presence of light and oxygen, forming unstable chalcogen oxide species which leave surface defects.[50] One significant recent advance is the preparation of quantum dot–quantum wells, where one nanoparticle is capped by a layer of another semiconductor.[51,52] The surface is then protected and photoluminescence of the core semiconductor is enhanced, with quantum yields of up to 50%. Experiments have also indicated that upon excitation, the hole is confined to the core whilst the electron is delocalised through the entire structure. Precursors for such core–shell structures are generally metal alkyls and bis(trimethylsilyl)sulfide, but core–shell structures of CdSe–CdS have also been grown using single molecular precursors.[53] Thin films of CdSe nanoparticles in a ZnSe matrix, grown by electrospray-organometallic chemical vapour deposition, have also been reported.[54]

The preparation of III–V materials is significantly more difficult to achieve. The increased covalent character results in the routes to crystal formation being hampered by large energetic barriers. There is, therefore, no discrete nucleation step and separation of nucleation and growth is difficult. Precursors for III–V materials, such as $InCl_3$ coordinate to the reaction solvent inhibiting direct reaction between the reagents, which is often suggested as a key step in the nucleation and growth steps.[55] Nozik and coworkers[56] and Alivisatos and coworkers[57] have developed the dehalosilylation reaction as first reported by Wells *et al.*,[58] and Barron and coworkers,[59] to prepare III–V quantum dots capped with TOPO or TOP. In these reactions, $InCl_3$ is complexed to either TOPO or TOP, followed by the injection of $E(SiMe_3)_3$ (E = As, P). Growth and annealing take up to 7 days at *ca.* 265 °C. The size distribution is large (*ca.* 20%) and the final product is contaminated by oxide side products. Photoluminescence from the final material is near to band edge and dependent upon surface oxidation. InP dots are reported not to luminesce until the surface is oxidised, highlighting the importance of the surface state whilst emission from InAs dots is insensitive to oxidation.[57,60] The formation of stable surface species is reported to hinder size fractionation procedures, but is reversible using hydrogen fluoride etching processes.[61]

We have recently developed a single molecular precursor route to InP and GaP using metal diorganophosphides as precursors.[62,63] The compounds $M(PBu^t_2)_3$, (M = Ga, In) are dissolved in 4-ethylpyridine and heated at reflux for up to 7 days. Nanoparticles of *ca.* 8 nm diameter (±20%) could be isolated by solvent/non-solvent interaction and a glass formed upon prolonged evacuation. These single source routes avoid the need for volatile precursors such as silylated pnictides. The use of diorganophosphides has been extended to the preparation of high quality TOPO and 4-ethylpyridine capped Cd_3P_2 using the precursor $[MeCdP(Bu^t)_2]_3$.[64,65] Cadmium phosphide is reported to have a large excitonic diameter (*ca.* 36 nm, *cf.* CdS *ca.* 3 nm) which means the band edge can be shifted over a wide spectral range upon quantum confinement of the charge carriers. Nanometer sized Cd_3P_2 prepared by conventional colloidal chemistry can have band gaps between 0.5 and 4.0 eV. Colloidally prepared Cd_3P_2 is air-sensitive and decomposes upon illumination, whilst TOPO capped Cd_3P_2 appears more resistant to photodegradation. The organic substituent on the diorganophosphide appears to control reactions, changing the

tert-butyl group for a phenyl or cyclohexyl group results in bulk cadmium with an extremely small amount of nanometric material. GC–MS and TGA analysis were used to deduce two competing mechanisms; reductive elimination, which leads to elemental cadmium and β-hydrogen elimination (for $[MeCdP(Bu^t)_2]_3$) resulting in nanoparticles of Cd_3P_2. The mechanisms were found to be temperature dependent, with β-hydrogen elimination predominating at lower (< 150 °C) temperatures giving purer Cd_3P_2.

Zinc phosphide quantum dots have also been prepared by using dimethylzinc and di-*tert*-butylphosphine in either TOPO or 4-ethylpyridine. The nanocrystals are *ca.* 4 nm in diameter, with band gaps shifted up to 3.5 eV depending upon the capping agent and reaction conditions.[66]

TOPO is not the only Lewis base to be utilised in nanocrystal preparation. Nanoparticles of GaP and GaAs have been synthesised by refluxing $GaCl_3$ with either $P(Na/K)_3$ or $As(Na/K)_3$ in toluene/glyme to give crystalline glyme capped quantum dots.[67] The same reaction in aromatic solvents alone again yields nanoparticles which are capped with methanol upon extraction. Nanoparticulate GaP has also been produced through the thermolysis of a single source precursor $[X_2GaP(SiMe_3)_2]_2$ (X = Br, I) and $(Cl_3Ga_2P)_n$ with both decomposing at relatively low temperatures whilst under vacuum to yield crystalline Q-GaP.[68] Q-GaP and Q-GaAs have also been produced by thermolysis of $[H_2GaE(SiMe_3)_2]_3$ (E = P, As) at 450 °C in xylenes, giving nanoparticles *ca.* 5 nm in diameter. The capping agent was not discussed.[69]

The groups of Alivisatos[70] and Nozik[71] used a similar method to Bawendi's[35] to produce GaAs nanoparticles, by refluxing $GaCl_3$ and tris(trimethylsilyl)arsine in quinolene at 240 °C for 3 days. Flame annealing at 450 °C was used to improve crystallinity, but resulted in a slight loss of solubility. Crystalline InAs nanoparticles of size 1–8 nm have been synthesised by the reaction of $In(acac)_3$ with tris(trimethylsilyl)arsine in triglyme at 216 °C for 70 h. Investigations were also carried out into the non-linear optical properties of the resulting materials.[72] The same method was applied successfully to GaAs using $Ga(acac)_3$.[73] These methods are attractive because they present routes that do not use hazardous precursors, *e.g.*, phosphine or arsine.

Nanoparticles of CdSe has been also been synthesised by pyrolysis of the single source precursors $Cd(SePh)_2$ and $[Cd(SePh)_2]_2[Et_2PCH_2CH_2PEt_2]$ in 4-ethylpyridine.[74] Cd_3P_2 has been produced by the methanolysis of $Cd[P(SiPh_3)_2]_2$.[75]

Manipulation of quantum dots

The organisation of quantum dots into ordered structures presents a significant challenge and lends itself to potential industrial applications. Superlattices of TOPO capped CdSe have been prepared by controlled crystallisation in an octane–octanol mixture under reduced pressure.[76] Alivisatos and coworkers have also prepared dimers of TOPO capped CdSe by linking the nanoparticles with *N*-methyl-4-sulfanylbenzamide followed by size selective precipitation.[77] Alivisatos and coworkers have also investigated the effects of mixing organically capped CdSe with the conjugated polymer poly[2-methoxy,5-(2′-ethyl)hexyloxy-*p*-phenylenevinylene] (MEH-PPV).[78] TOPO capped nanoparticles had the surface ligand exchanged for pyridine. The pyridine capped dots were mixed with a solution of polymer and spin coated onto indium tin oxide (ITO) coated glass. Excitation of the polymer resulted in an electron being transferred onto the nanoparticle. This resulted in quenching of polymer luminescence, consistent with charge separation at the polymer/quantum dot interface. The resulting Q-CdSe/MEH-PPV composite luminescence efficiency was found to be 12% when loaded with high concentrations of quantum dots. TEM demonstrated a distinct interconnected network forming at concentrations of *ca.* 90% CdSe. The incorporation of quantum dots into a conducting medium is an essential step towards device fabrication.

The idea of incorporation was further advanced by the removal of surface TOPO and replacement with a polymer back-bone rather than a simple dispersion.[79,80] In this method, nanoparticles of either CdSe or CdSe coated with ZnSe, were prefabricated by the normal method, and added to a solution of copolymer containing phosphine/phosphine oxide norbornene blocks. The addition of $[MTD]_{300}$ and $[NBE\text{-}CH_2O(CH_2)_5P(Oct)_2]_{26}$ (MTD = methyltetracyclododecene, NBE = 5-norbornen-2-yl) resulted in excellent take up of the quantum dots, and led to increased fluorescence, whilst the addition of $[MTD]_{300}$ alone had negligible results. Further addition of the polymer resulted in an increase of 2% in the quantum yield, indicating passivation of the quantum dots by the polymer bound phosphine. TEM experiments showed networks of nanoparticles segregated by phosphine rich domains. An investigation was also undertaken into the potential competition between TOPO and TOP to passivate the surface of the crystals. Further addition of TOPO resulted in a small increase in luminescence, whilst addition of TOP doubled the emission. This suggests TOP binds to the unpassivated selenium sites, whilst TOPO specifically binds to cadmium.

Thin films have also been prepared by spin-coating TOPO capped nanoparticles onto various substrates such as nano-polished monocrystalline semiconductor wafers.[81] Further layers can be added by various methods such as chemical bath (electroless) deposition or MOCVD. Fig. 6 shows a nano-composite prepared by spin coating TOPO capped CdSe onto a GaAs substrate, followed by deposition of a layer of CdS by chemical bath.

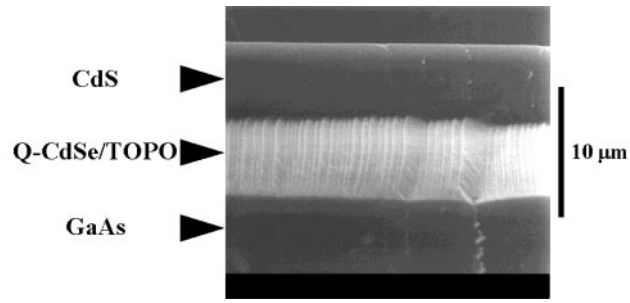

Fig. 6 SEM side profile of a nanocomposite heterostructure. The substrate is nanopolished GaAs. A layer of nanocrystalline CdSe is spin coated on top, followed by a layer of CdS deposited by chemical bath deposition.[81]

Other recent advances of note are the uses of DNA in nanocrystal processing, with possible applications in developing chemical biosensors. Mirkin *et al.* have used thiol capped, non complementary DNA oligonucleotides to assemble 13 nm Au quantum dots into a macroscopic material.[82] In similar work, Alivisatos *et al.* synthesised *ca.* 3 nm Au nanocrystals which were then attached to single strand oligonucleotides, which organised into spatially defined structures on addition of a single complementary DNA strand, due to Watson–Crick interactions.[83]

Applications

Alivisatos and coworkers have produced an electroluminescence device using TOPO capped CdSe nanocrystals with sizes between 3 and 5 nm, and a semiconducting polymer, poly(*p*-phenylene–vinylene) (PPV).[84] The device was fabricated by multiple exposures of a indium tin oxide (ITO) plate or ITO/PPV plate, pre-treated with hexane thiol, to a toluene solution of nanocrystals. For stability, the layer is built up to 1000 Å. Electrical contact is made by silver coated magnesium. The colour of the emission can be controlled by the particle sizes giving red to yellow emissions. At increased voltage, green luminescence from the polymer layer is predominant. This was

then improved upon by fabrication of a LED using CdSe nanocrystals capped with CdS instead of the organic ligand.[85] The device was produced by using the same basic techniques but using a pre-PPV polymer precursor deposited on ITO coated glass. This film was then annealed at 300 °C for 3 h before having CdSe/CdS spin deposited onto the PPV. The use of CdSe/CdS instead of CdSe/TOPO results in an increase in efficiency by a factor of eight and a factor of ten increase in lifetime. This is attributed to the inorganically capped particles being resistant to photo-oxidation.

Electroluminescence has been reported from TOPO capped CdSe when incorporated into thin films of poly(vinylcarbazole) (PVK) and an oxadiazole derivative.[86] The film was then sandwiched between ITO and Al electrodes. The device was tuneable from *ca.* 530 to 650 nm by varying the size of the dots. Low temperature studies (77 K) also indicated that only the nanocrystals luminesced at low voltage, whilst at higher voltages both the dots and the PVK matrix electroluminesce. Electroluminescence efficiency was also found to increase at 77 K.

The anaerobic conditions employed to manufacture TOPO capped quantum dots used in device fabrication have the advantage of avoiding potential doping with oxygen. For this reason, aqueous routes to nanocrystals were often assumed to be unfavourable. However, Gao *et al.* fabricated a device using CdSe nanocrystals synthesised using a Cd salt and H_2Se in aqueous solution with thiolactic acid, at pH 11.[87] The thiolactic acid acted as a capping agent, effectively giving the particle a negatively charged surface, which facilitates adsorption onto the substrate. The size of the particles was controlled by altering the molar ratios between Cd^{2+} and H_2Se, with intense fluorescence obtained by adding an excess of Cd^{2+} shortly after synthesis. Optical glass and ITO coated glass which had been coated with PEI [poly-(ethyleneimine)] to give a positively charged surface, were used as substrates. The next step involved the exposure of the substrate to a solution of the nanoparticles for a defined time giving a monolayer of quantum dots. Positively charged PAH [poly(allylamine hydrochloride)] or a precursor for poly(*p*-phenylene–vinylene) (pre-PPV) were then adsorbed on top. The application of a number of inorganic and organic layers was repeated until 20 double layers had been applied. The CdSe/PPV multilayer film was then obtained by heating the CdSe/pre-PPV at 130 °C *in vacuo* for 11 h. The device was finished by the evaporation of an aluminium electrode on the top layer. The device produced almost white light electroluminescence (500–850 nm) under a forward bias of 3.5–5 V with the positive pole on the ITO electrode. Such a broad emission, similar to that of the CdSe solution, was attributed to deep traps, surface defects and a large size distribution. It is interesting to note that a device incorporating aqueous derived nanocrystals has a broad emission, which may be attributable to doping with oxygen. The device is reported to have a longer lifetime than similar simple organic devices.

Single electron transistors have also been reported in devices in which a single nanoparticle is trapped between two gold electrodes by dithiols.[88] Biological applications are now being explored such as water soluble semiconductor nanoparticle fluorophores used to examine mouse fibroplasts.[89] Other potential uses include amplification of electromagnetic radiation in fibre optic communication systems and non-linear optical effects in the region of absorption edges.

Advances in the preparation of highly luminescent, nearly monodispersed nanocrystals have led to materials which now have the potential for use in optoelectronic applications. The use of oxide nanoparticles in photovoltaic devices is well documented, however, a wide range of other applications are now being investigated. The reproducible preparation and easy manipulation of organically passivated quantum dots offers simple routes to practical devices. The widening of the 'band gap' in a semiconductor quantum dot can be controlled by careful alteration of the particle's dimensions (often referred to as band gap engineering) and has opened up possible new areas of electronic research with a wide range of applications such as tunable diodes and lasers. The degree of control over small particles is exhibited in the preparation of single electron transistors, where the particle can be specifically placed between two electrodes. The preparation and manipulation of semiconductor nanoparticles is an interesting and exciting area of current research.

Received (in Basel, Switzerland) 6th September 1999, Accepted 6th October 1999

Gallium or indium atoms are shown to react with methane in solid Ar matrices upon UV photolysis (λ = 200–400 nm) to give initially the methylmetal hydride which undergoes photodissociation on broad-band irradiation (λ = 200–800 nm) to yield the methylmetal(I) compound, CH_3M (M = Ga or In); the products are characterised by their IR spectra afforced by the results of DFT calculations.

Volatile organo or hydrido derivatives of the group 13 metals excite attention particularly by virtue of their use or potential as precursors to the metal or a compound semiconductor.[1,2] Yet the number of such compounds, and especially those with the requisite properties of volatility, thermal stability, *etc*. decreases sharply when aluminium gives way to gallium, and again when gallium gives way to indium.[2,3] The only monomethyl compound of the group 13 metals to be detected previously in the laboratory is CH_3Al, which has been identified in the gas phase by its pure rotational spectrum,[4] by neutralization–reionization mass spectrometry (NRMS),[5] and also in a cooled jet by high-resolution resonance-enhanced multiphoton ionization (REMPI) spectroscopy.[6] Otherwise we are largely dependent on quantum chemical methods[7–10] for whatever knowledge of CH_3Al and CH_3Ga we possess. The incentive for characterising these molecules comes partly from their potential intermediacy in chemical vapour deposition processes starting from trivalent methylmetal compounds[1,2] and partly from the desire to gain a better understanding of the bonding in organometallic compounds of the univalent group 13 metals.

Irradiation of a CH_4-doped Ar matrix containing thermally generated gallium atoms with UV light with λ = 200–400 nm over a period of 10 min resulted in the appearance of new IR absorptions at 1719.7, 752.9, 528.7 and 475.5 cm^{-1}, apparently belonging to a single product **1a** [Fig. 1(b)]. The most intense and distinctive features were those at 1719.7 and 752.9 cm^{-1}. Similar results have been reported earlier,[11,12] the new bands being attributed to the divalent gallium species CH_3GaH formed by insertion of a Ga atom into a C–H bond of methane. Continued irradiation under these conditions produced little further change in the spectrum. By contrast, after photolysis for a further 10 min, with broad-band UV–VIS light (λ = 200–800 nm), the matrix exhibited the IR spectrum depicted in Fig. 1(c). Hence it was apparent that the bands due to **1a** had been totally extinguished, to be replaced by a new family of bands having a common origin in a second product **2a**. These occurred at 2986.9, 1403.9, 1147.9 and 476.2 cm^{-1}, the feature at lowest frequency being the most intense. Extending the period of photolysis gave little further change in the spectrum. The reaction was also followed by monitoring the UV–VIS spectrum of the matrix. Our results are in line with those of Lafleur and Parnis[11] and show that the formation of **1a** occurs at the expense of Ga atoms. The experiments were repeated using either CD_4 or $^{13}CH_4$ as the reagent; the corresponding frequencies for the normal and isotopically enriched versions of **1a** and **2a** are given in Table 1. Experiments carried out for various metal and methane concentrations show that strong signals of **2a** are obtained for conditions that have favoured the generation of **1a** (the greatest yield was achieved using a furnace temperature of 950 ºC and an argon matrix containing 2% CH_4). The obvious inference to be drawn from the IR spectra is that **2a** is the simple methylgallium(I) molecule, CH_3Ga.[13] Previous experiments with GaH_2 and InH_2 have shown that under similar photolysis conditions, cleavage of a Ga–H or In–H bond leads to the formation of the monohydrides, GaH and InH, respectively.[14] DFT calculations[15,16] lead to an

[a] Calculation for singlet $CH_3{}^{115}In$. Symmetry C_{3v}: C–H = 1.103 Å, In–C = 2.226 Å, H–C–In = 111.5°. Intensities (km mol^{-1}) are given in parentheses; r.m.s. deviation of observed from calculated frequencies 5.7%. [b] Too weak to be observed or hidden by methane absorptions.

equilibrium geometry with C_{3v} symmetry for the CH_3Ga molecule. There are therefore six distinct IR-active vibrational fundamentals spanning the representation $3a_1 + 3e$. Our experiments located IR absorptions with relative intensities, frequencies and isotopic shifts in close accord with those predicted here and elsewhere[7,8] by quantum chemical calculations for four of the fundamentals (Table 1). Of the two missing features that due to ν_4 (*e*) was most probably masked by the strong methane absorption, whereas that due to ν_6 (*e*) lacked the intensity to be detected. Quantum mechanical calculations indicate that the excited electron originates in an orbital with a high electron density along the Ga–H axis,[17] so that photodissociation of the Ga–H bond may result. Other possible explanations include the formation of methylgallium from the metal atoms and methyl radicals following decomposition of methylgallium hydride to CH_3· and Ga and H atoms.

Analogous experiments were carried out to follow the reaction of methane with thermally evaporated In. A similar pattern was observed. Thus, irradiation of the matrix at wavelengths between 200 and 400 nm for 10 min led to the appearance of new IR absorptions at 1545.9 and 696 cm^{-1} (Fig. 2). These showed obvious affinities to the IR bands belonging to **1a** and are most plausibly ascribed to the indium analogue **1b**. Subsequent exposure of the matrix to broad-band UV-VIS radiation (λ = 200-800 nm) for 10 min brought about the disappearance of the absorptions due to **1b** with the simultaneous growth of a new set of absorptions at 2976.2, 2905.2, 1424.0, 1115.3 and 422.1 cm^{-1}. The circumstances of the experiment, allied to the spectroscopic resemblance of this second product to **2a**, suggest that it is to be identified with the indium analogue **2b**, CH_3In. The experiments giving rise to the products **1b** and **2b** were repeated using either CD_4 or $^{13}CH_4$ as the reagent, with the results included in Table 2. DFT calculations[15,16] give an optimized geometry resembling closely that of the gallium compound and having the vibrational properties listed in Table 2. In this case our experiments identify five of the six fundamentals, the only absentee being the CH_3 rocking mode, $\rho(CH_3)$, which is anticipated in any case to be unusually weak in IR absorption. Information about the isotopomers CD_3In and $^{13}CH_3In$ is unfortunately rather sparse, partly because we were unable to secure such high concentrations and partly because of the masking effects of other absorptions. Nevertheless, the experimental results approximate closely to the properties computed by DFT methods.

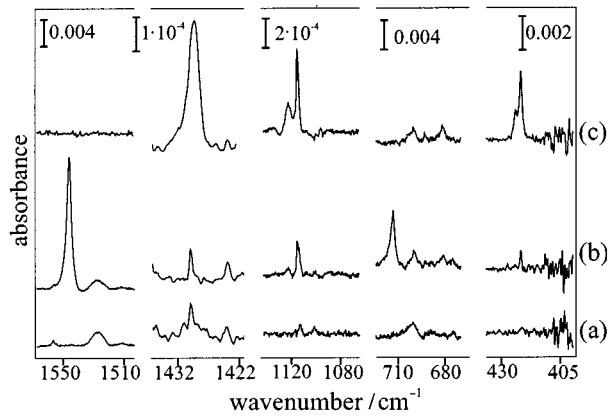

Fig. 2 IR spectra of an Ar matrix containing In atoms and CH_4: (a) after deposition; (b) after photolysis with UV light (λ = 200–400 nm); and (c) after broad-band UV–VIS photolysis (λ = 200–800 nm).

Experiments were also carried out to explore the effects of co-condensing laser-ablated indium atoms with methane and an excess of argon. In this case, IR bands due to both the products **1b** and **2b** were observed upon deposition, presumably as a result of the UV-VIS radiation emanating from the metal target. The subsequent response of the products to further photolysis was as detailed above. These experiments also support our assignments to monometallic species, as it is known[18,19] that laser ablation of solid elements generates predominantly atoms rather than aggregates.

The authors thank (i) the EPSRC for support of this research and for the award of an Advanced Fellowship to T. M. G., and (ii) the Deutsche Forschungsgemeinschaft for the award of a postdoctoral grant to H.-J. H.

A solid-state phase transition at 41 K involving the cooperative ordering of a fluxional pseudo-Jahn–Teller Cu^{II} system

Michael A. Leech,*[a] Nayan K. Solanki,[b] Malcolm A. Halcrow,[c] Judith A. K. Howard[a] and Slimane Dahaoui[a]

[a] *Department of Chemistry, University of Durham, South Road, Durham, UK DH1 3LE. E-mail: m.a.leech@dur.ac.uk*

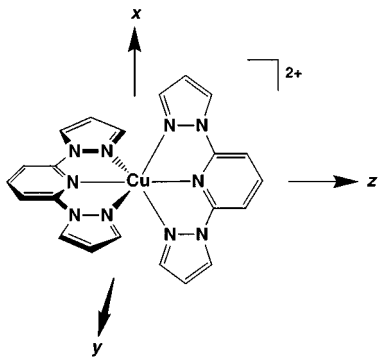
Received (in Cambridge, UK) 24th August 1999, Accepted 7th October 1999

The complex $[Cu\{2,6\text{-di(pyrazol-1-yl)pyridine}\}_2](BF_4)_2$ undergoes a solid-state phase transition at 41 K, involving the cooperative ordering of its planar dynamic pseudo-Jahn–Teller system; this unique phase transition is characterised by single-crystal X-ray diffraction techniques, employing an open-flow helium cryostat.

The structural and electronic consequences of the Jahn–Teller effect in transition metal chemistry continue to be well studied.[1] For Cu^{II} complexes of meridional tris-N-donor ligands, the Jahn–Teller distortion takes the form of an elongated axis, which in the solid state is often dynamically disordered in the molecular *xy* plane (Scheme 1).[2–4]



Scheme 1 Molecular axes of $[CuL_2]^{2+}$.

We have recently described one compound that undergoes this behaviour, namely $[CuL_2](BF_4)_2$ [L = 2,6-di(pyrazol-1-yl)pyridine], whose powder EPR spectrum at room temperature exhibits the 'inverse' $g_\perp > g_\parallel > g_e$ pattern typical of a planar dynamic $\{d_{x^2-y^2}\}^1$ Jahn–Teller system.[4] At lower temperatures, this spectrum becomes rhombic as the Jahn–Teller fluxionality is frozen out and the static $g_\parallel > g_\perp > g_e$ spectrum is reached only below 20 K.[4,5] In order to quantify the solid state fluxionality in $[CuL_2](BF_4)_2$,[6] we have undertaken a variable temperature X-ray diffraction study of this compound. We describe herein that it undergoes a unique[1] reversible phase transition at 41 K, involving a complex ordering of the Jahn–Teller axis of elongation in the molecular *xy* plane.

The structure was determined both above (**1**: 50 K) and below (**2**: 31 K) the phase transition. The structure at 50 K reveals one $[CuL_2]^{2+}$ and two $[BF_4]^-$ ions in the asymmetric unit (Fig. 1). One $[BF_4]^-$ ion is disordered over two positions [0.69(3) and 0.31(3) occupied] equivalent to a rotation of approximately 23° about one B–F bond vector. The Cu coordination is distorted slightly from octahedral geometry owing to the conformational requirements of the tridentate ligands. The bond distances within the Cu coordination sphere (Table 1), show short bonds along the molecular *z*-axis, long bonds along the molecular *x*-axis and intermediate length bonds along the molecular *y*-axis. This range reflects the disorder of the Jahn–Teller axis of elongation about the molecular *x*- and *y*-vectors, with the longer

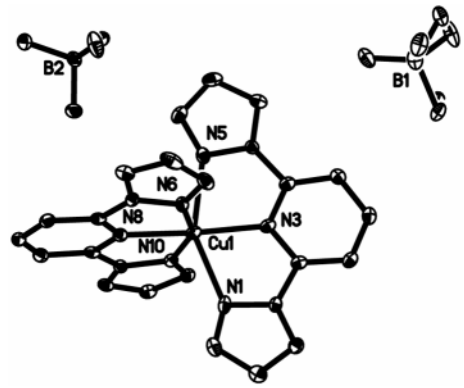


Fig. 1 Crystallographic asymmetric unit at 50 K.

Table 1 Cu–N distances (Å) at 50 and 31 K

		Cu–N distance (Å)		
	50 K	31 K **A**	**B**	**C**
Cu–N6 (*y*-axis)	2.1080(17)	2.058(2)	2.261(2)	2.056(2)
Cu–N10 (*y*-axis)	2.1210(17)	2.076(2)	2.286(2)	2.077(2)
Cu–N5 (*x*-axis)	2.2259(18)	2.282(2)	2.072(2)	2.266(2)
Cu–N1 (*x*-axis)	2.2527(18)	2.290(2)	2.088(2)	2.306(2)
Cu–N3 (*z*-axis)	2.0175(15)	2.028(2)	1.963(2)	2.026(2)
Cu–N8 (*z*-axis)	1.9763(14)	1.967(2)	2.037(2)	1.958(2)

Cu–N bonds along the molecular *x*-axis indicating a larger statistical population in this direction.

On cooling, the crystal undergoes a sharp, reversible phase transition at 41 K accompanied by a tripling of the crystallographic *b* axis. The transition was followed successfully using a CCD diffractometer, by taking a series *hk*0 zone images intermediate to cooling the crystal in −1 K steps. Two such images are shown in Fig. 2, taken at 42 and 40 K. The additional

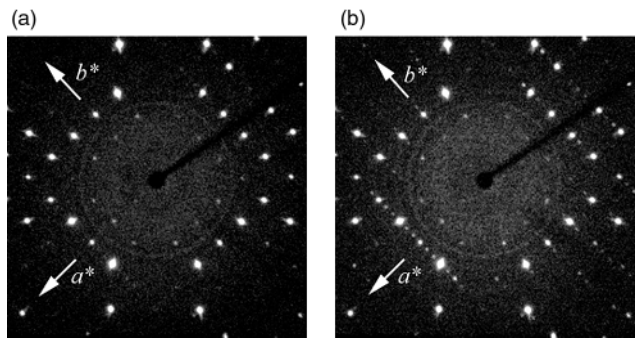

Fig. 2 *hk*0 zone images with the two reciprocal-lattice axes labelled: (a) above the phase change at 42 K and (b) below the phase change at 40 K. The additional reflections in the 40 K image correspond to the tripling of crystallographic *b* axis.

reflections in the 40 K image correspond to the tripling of *b* axis.

The structure at 31 K reveals three $[CuL_2]^{2+}$ and six $[BF_4]^-$ ions in the asymmetric unit (Fig. 3). The Jahn–Teller elongated axis, which is disordered in the molecular *xy* plane above 41 K, is now ordered. The elongated axis of two of the three independent cations (**A** and **C**) are aligned along the molecular *x*-axis, while in the third cation (**B**), it is aligned along the molecular *y*-axis; see Cu–N distances in Table 1. It is interesting to note that the mean Cu–N distances for all three molecules correspond closely to those found in the disordered 50 K structure. This indicates that the population distribution of the elongated axis along the *x* and *y* vectors is similar, both above, and below the phase change. Furthermore, the $[BF_4]^-$ ion, which is disordered above 41 K, is now ordered into three non-equivalent sites, two in one orientation and the third in another. Again, this corresponds to the populations of the two orientations in the disordered structure (0.69 : 0.31). Thus, the ordering of the Jahn–Teller elongated axis in the cation and of the $[BF_4]^-$ ion are intimately linked, suggesting cooperative van der Waals interactions between the two moieties. Cooperative ordering of the Jahn–Teller elongated axis has been seen previously in Tutton salts[7] and copper methoxyacetate.[8] However, these materials possess H-bonded networks, which may act as the mechanism for mediating the cooperative interactions.

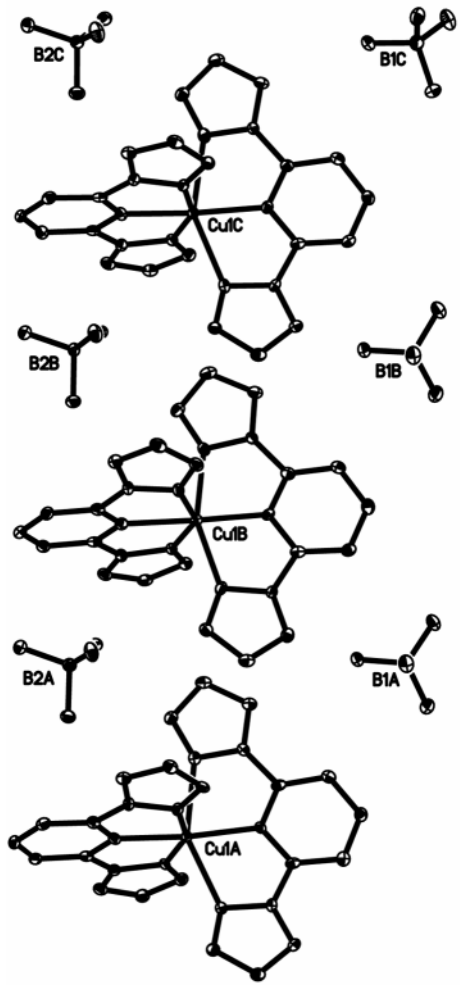

Fig. 3 Crystallographic asymmetric unit at 31 K.

In conclusion, this is the first example of a structurally characterised phase transition, involving the low-temperature ordering of a dynamically disordered Jahn–Teller system. That the mechanism for co-operation between the molecules relies on weak van der Waals interactions alone makes this system unique. Additionally, the reversible phase transition is extremely sharp and shows no hysteresis effects, making this material highly suitable as a temperature standard in the sub-liquid nitrogen temperature range, which has recently become more accessible with the introduction of the open-flow helium cryostat.[9]

The authors would like to thank Dr J. E. Davies (Cambridge) for preliminary studies and the Royal Society (M. A. H.), EPSRC (M. A. L., N. K. S., S. D. and J. A. K. H., Senior Research Fellowship) and ICI R&T Division (N. K. S.) for financial support.

Mechanistic aspects of the steam reforming of methanol over a $CuO/ZnO/ZrO_2/Al_2O_3$ catalyst

John P. Breen,* Frederic C. Meunier and Julian R. H. Ross

Centre for Environmental Research, University of Limerick, Limerick, Ireland. E-mail: john.paul.breen@ul.ie

Received (in Cambridge, UK) 5th August 1999, Accepted 11th October 1999

CO is not a primary but is a secondary product of the steam reforming of methanol over a $CuO/ZnO/ZrO_2/Al_2O_3$ catalyst, CO is formed as a secondary product by the reverse WGS reaction only when the methanol has reacted.

The steam reforming of methanol is attracting growing interest as a means of producing hydrogen for use in fuel cells. CO produced in the steam reforming reaction is currently a poison to the promising proton-exchange membrane (PEM) fuel cells and as a result much attention has been focused on the mechanism of CO formation during the reaction. The formation of carbon monoxide as a product and the fact that copper is a good catalyst for the water–gas shift (WGS) reaction[1] has led some workers[2–5] to speculate that a decomposition/WGS reaction sequence is involved [eqn. (1) and (2)]:

$$CH_3OH \rightarrow CO + 2H_2 \quad (1)$$

$$CO + H_2O \rightleftharpoons H_2 + CO_2 \quad (2)$$

$$CH_3OH + H_2O \rightarrow CO_2 + 3H_2 \quad (3)$$

However, Amphlett *et al.*[6,7] have more recently noted that carbon monoxide production is less than that predicted from equilibrium. As a result, they have revised their reaction scheme to one containing parallel reactions, the steam reforming of methanol [eqn. (3)] occurring in parallel to the decomposition of methanol to CO and H_2 [eqn. (1)]; they suggest that adjustment of the CO/CO_2 ratio also occurs as a result of the WGS reaction [eqn. (2)]. Peppley *et al.*[8,9] found that the methanol decomposition reaction is much slower than the steam reforming reaction but argued that it must be included in the overall reaction scheme. Takahashi *et al.*[10] found that methyl formate was formed at low water/methanol ratios and so they incorporated methyl formate into their reaction scheme [eqn. (4)–(6)]:

$$2CH_3OH \rightarrow CH_3OCHO + 2H_2 \quad (4)$$

$$CH_3OCHO + H_2O \rightarrow HCOOH + CH_3OH \quad (5)$$

$$HCOOH \rightarrow CO_2 + H_2 \quad (6)$$

Jiang *et al.*[11,12] carried out a detailed kinetic analysis of the steam reforming reaction and found that the reaction over a $Cu/ZnO/Al_2O_3$ catalyst could also be explained by eqn. (4)–(6), they suggested that the carbon monoxide observed in the product stream is produced *via* the decomposition of methyl formate. Studies of the surface mechanism of the steam reforming reaction have been limited[9] and authors have instead tended to use the large quantity of data published on the methanol synthesis reaction to support their mechanistic surface reaction models.[9,12]

We have previously reported[13] that copper–zirconia containing catalysts are very active for the steam reforming of methanol and that they give good selectivities towards CO_2 production. We have now obtained clear evidence from both kinetic measurements and *in situ* DRIFTS experiments for the formation of CO as a secondary product during the reforming reaction over a $CuO/ZnO/ZrO_2/Al_2O_3$ catalyst and details of the surface species involved in the reaction are given here.

The $CuO/ZnO/ZrO_2/Al_2O_3$ catalyst was prepared by sequential precipitation, the order and method of precipitation having been described elsewhere.[13] The reactants and products of the reaction were analysed by GC equipped with a Porapak Q column. This column gave satisfactory separation of CO and N_2 at a column temperature of 25 °C, the limit of detection for CO was *ca.* 1000 ppm with an accuracy of ±2%. The reaction was carried out in a quartz plug-flow microreactor, the composition of the reactant gases being 28.5% H_2O, 21.5% CH_3OH, with a balance of N_2. Prior to introduction of the reaction mixture, the catalyst was reduced *in situ* in a 5% H_2–N_2 mixture at a temperature of 240 °C for 4 h, ramping to this temperature at a rate of 5 °C min^{-1}. IR measurements were carried out using a Nicolet Magna 550 FTIR fitted with a diffuse reflectance cell and incorporating a high-pressure, high-temperature catalytic chamber.

The effect of contact time on the distribution of reaction products was studied by varying the *W*/*F* ratio while using a constant feed composition at two different temperatures (200 and 300 °C). Fig. 1 shows the methanol conversions and the percentages of hydrogen, carbon dioxide and carbon monoxide in the product stream as a function of the (pseudo-)contact time, *W*/*F* (g min cm^{-3}), at 300 °C. Two equilibrium lines for the carbon dioxide and hydrogen production are also shown as dotted lines; the top line (line '*m*') in each case represents the equilibrium values obtained by excluding carbon monoxide from the calculations whereas the bottom line (line '*n*') shows calculated equilibrium values with the inclusion of carbon monoxide as a product. It must be noted that the equilibrium lines '*m*' and '*n*' correspond to the situation when complete conversion of methanol is assumed; the equilibrium values shown in Fig. 1 are the results of thermodynamic calculations carried out using the HSC Chemistry for Windows software package (Outokumpu Research Oy). This software uses the Gibbs Free Minimisation Method to calculate equilibrium compositions.[14]

At 200 °C, 100% conversion of methanol was not attained and carbon monoxide was not detected in the product stream at any of the pseudo-contact times.

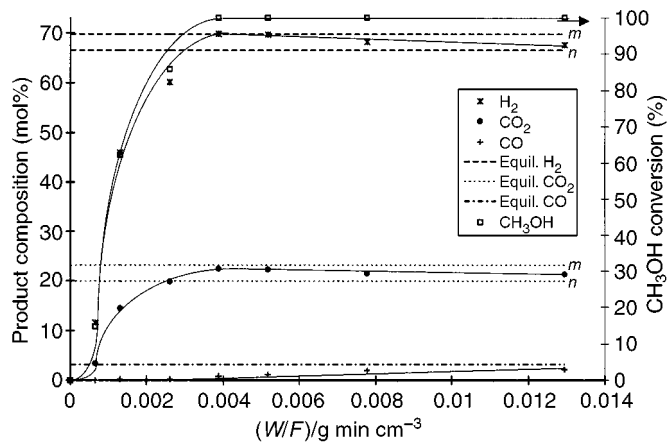

Fig. 1 The influence of *W*/*F* on the product compositions at T = 300 °C over a $CuO/ZnO/ZrO_2/Al_2O_3$ catalyst, m = equilibrium excluding CO from calculations, n = equilibrium including CO in calculations (H_2O/CH_3OH = 1.3, P = 101 kPa).

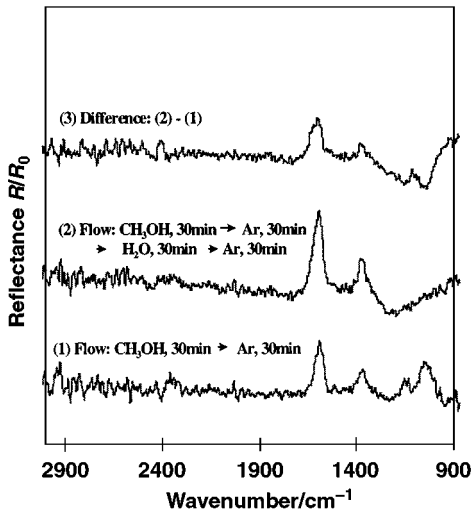

Fig. 2 FTIR spectra of surface species generated by methanol adsorption followed by water adsorption on a $CuO/ZnO/ZrO_2/Al_2O_3$ catalyst at 240 °C.

At 300 °C, the percentages of hydrogen and carbon dioxide produced were higher than those at 200 °C for all values of contact time. Carbon monoxide was not detected at the shorter contact times; however, as the value of *W*/*F* was increased, carbon monoxide was detected and its molar percentage increased steadily with increasing contact time, approaching, but not attaining, the predicted equilibrium value at higher values of *W*/*F*. It is evident from Fig. 1 that carbon monoxide was a secondary product; this effectively rules out the possibility of the occurrence of a mechanism involving methanol decomposition followed by the water–gas shift reaction as proposed by several authors over their catalysts.[2–5].

When 100% methanol conversion was achieved at 300 °C (Fig. 1), the hydrogen and carbon dioxide molar compositions exceeded the equilibrium line '*n*'; at a value of $W/F = 0.00389$ g min cm^{-3}, there was very little carbon monoxide production and the hydrogen and carbon dioxide compositions were very close to the equilibrium values calculated for the steam reforming reaction when carbon monoxide was excluded from the product stream (line '*m*'). At values of $W/F > 0.00389$ g min cm^{-3}, the proportions of hydrogen and carbon dioxide decreased and that of carbon monoxide increased with increasing contact time, approaching equilibrium '*n*' values (a sequence including CO formation) with high contact times. At 100% methanol conversion and a reaction temperature of 300 °C, the carbon dioxide and hydrogen percentages were greater than those predicted by equilibrium (*n*) whereas the carbon monoxide percentages were less than equilibrium predictions by a similar amount at the different values of *W*/*F*.

These results provide evidence of a consecutive reaction scheme in which methanol and water react first to produce carbon dioxide and hydrogen [eqn. (3)] and the carbon dioxide and hydrogen then react *via* the reverse WGS reaction [eqn. (2)] to produce CO. There was no evidence of the occurrence of the methanol decomposition reaction [eqn. (1)].

In order to investigate the nature of the surface species involved in the steam reforming reaction over the $CuO/ZnO/ZrO_2/Al_2O_3$ catalyst, *in situ* IR measurements were carried out. Fig. 2 [spectrum (1)] shows the surface species generated on the surface of the catalyst at 240 °C after passing methanol over the catalyst and then flushing through with Ar. The peaks at 1590 and 1380 cm^{-1} can be attributed to a formate species, the peak at 1150 cm^{-1} to π bonded formaldehyde and the peak centred around 1050 cm^{-1} to a methoxy species.[15] Water was then introduced and the spectrum [Fig. 2, spectrum (2)] taken after the introduction of the water showed that neither the methoxy nor the formaldehyde peaks were evident but that the intensity of the formate peaks had increased. This is illustrated in spectrum (3) of Fig. 2 which shows the difference between spectra (2) and (1). This indicates that the methoxy and/or the formaldehyde species were readily converted to formates by reaction either with gas phase water or more probably with OH groups generated by the dissociative adsorption of water. *In situ* DRIFTS analysis of species during the steam reforming reaction showed that in addition to surface formates, there was an absorption centred at 1033 cm^{-1} which can probably be attributed to gas phase methanol in addition to some adsorbed methoxy species. Gas phase CO_2 (2364 cm^{-1}), was also detected but there was no evidence of either gas phase CO or adsorbed CO species. Formates are known to decompose on $CuO/ZnO/ZrO_2$ aerogels[16] according to eqn. (7) to give either CO and surface OH groups or CO_2 and H_2:

$$OH_{(s)} + CO_{(g)} \leftarrow HCOO^-_{(s)} \rightarrow CO_{2(g)} + 1/2H_{2(g)} \quad (7)$$

The results of the kinetic study, however, showed that CO did not form when methanol was present and that CO_2 and H_2 were the primary products, but that when methanol was fully converted, CO was evident in the gas stream. This points to a mechanism whereby the decomposition of formates to CO is either inhibited in the presence of methanol, or more probably, by the methoxy and/or formaldehyde species formed from the adsorption of methanol on the catalyst. The mechanism of the inhibition of the formation of CO by methanol is the subject of further research.

Stepwise assembly of a polyoxovanadate from mononuclear units in an organic solvent: carboxylate-stabilised fragments in the conversion of $[VOCl_4]^{2-}$ to $[V_{15}O_{36}]^{5-}$

Received (in Bloomington, IN, USA) 6th August 1999, Accepted 30th September 1999

The $[VOCl_4]^{2-}$/AgOAc reaction system in MeCN gives $[V_5O_9Cl(OAc)_4]^{2-}$, $[V_9O_{19}(OAc)_5]^{3-}$ and $[V_{15}O_{36}]^{5-}$ for reagent ratios of 1:2, 1:3 and 1:4, respectively: the V_5 and V_9 cores are fragments of the V_{15} core, suggesting the V_5 and V_9 units are carboxylate-stabilised intermediates in the assembly of the V_{15} polyoxovanadate.

Polyoxometalates represent a venerable and greatly explored area of early transition metal chemistry.[1–4] They are of interest from a variety of viewpoints, including structural aesthetics,[1–4] routes to new materials,[5–7] catalysis[8] and medical applications,[9] to name but a few. These molecular species often possess cage-like structures and in many cases encapsulate a small neutral or charged group.[3,4,10] One such example (amongst many) is the encapsulation of Cl^-, Br^- or CO_3^{2-} 'guests' within the approximately spherical $[V_{15}O_{36}]^{5-}$ polyoxovanadate 'host' cage.[11]

The steps by which a polyoxometallate such as $[V_{15}O_{36}]^{5-}$ assembles and the precise importance of the encapsulated guest to the identity and stability of the host are important to know. Bowl-like polyoxovanadates that can be considered structural fragments of (and putative intermediates to) cage-like structures are rarely encountered but one such example is approximately hemispherical $[V_{12}O_{32}(MeCN)]^{4-}$ containing an MeCN molecule in the concave cavity.[12] In the somewhat related field of fullerene chemistry, the preparation of structural fragments of the fullerene cage, so-called buckybowls, is a very topical area.[13] In this report, we describe the development of methodology that allows possible intermediates in the assembly of the $[V_{15}O_{36}]^{5-}$ cage to be stabilized by carboxylate ligands and identified. This approach has also provided access to the empty $[V_{15}O_{36}]^{5-}$ cage, a host without a guest.

The reaction of $[NEt_4]_2[VOCl_4]$ **1** with 2 equiv. of NaOAc in MeCN under nitrogen, followed by brief exposure to air gives a deep green solution from which can be obtained $[NEt_4]_2[V_5O_9Cl(OAc)_4]\cdot$MeCN **2** ($4V^{IV},V^{V}$) in 20–25% yield: this procedure is analogous to that previously reported for $[NEt_4]_2[V_5O_9Cl(O_2CPh)_4]$.[14] A related reaction using AgOAc in place of NaOAc and omitting the aerial oxidation step also gives **2** in comparable yield. Increase of the $[VOCl_4]^{2-}$:AgOAc reaction ratio to 1:3 gave instead a blue solution which, after *ca.* 50% volume reduction *in vacuo* and filtration, slowly produced dark blue–black crystals of $[NEt_4]_3[V_9O_{19}(OAc)_5]\cdot 2$MeCN **3** ($5V^{IV}$, $4V^{V}$) in 20–30% yield.† Further increase of the reaction ratio to 1:4 gave a purple solution which, after *ca.* 50% volume reduction and filtration, produced dark purple–black crystals of $[NEt_4]_5[V_{15}O_{36}]\cdot 1.28$MeCN **4** ($8V^{IV}$, $7V^{V}$) in 45–50% yield.† The anion of **2** (Fig. 1)‡ has the same $[V_5O_9Cl]^{2+}$ core reported previously[14] for $[V_5O_9Cl(O_2CPh)_4]^{2-}$, with a V_5 square-pyramid (V^{V} at the apex) and O^{2-} and Cl^- ions triply and quadruply bridging the vertical and basal faces, respectively. The novel $[V_9O_{19}]$ core of **3** (Fig. 2) may be considered an extension of the core of **2**, giving an approximately hemispherical bowl that contains an *anti,anti*-bridging AcO^- group. This is reminiscent of $[V_{12}O_{32}(MeCN)]^{4-}$ where a MeCN molecule is held inside a bowl.[12] The other AcO^- groups are like those in **2**, *i.e.* bridging V···V edges of the $[V_xO_y]$ unit and blocking further aggregation. The $[V_{15}O_{36}]^{5-}$ anion of **4** (Fig. 3) is a known polyoxovanadate, but in this case it is empty, previous examples containing an anionic guest ion inside the cage.[11]

Given the similar synthetic procedures to **2**–**4**, it is reasonable to suggest that the $[V_5O_9]$ and $[V_9O_{19}]$ cores of **2** and **3** may be

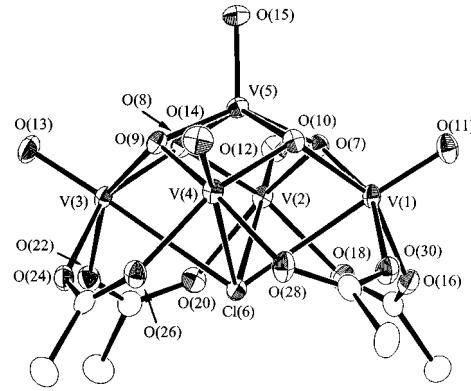

Fig. 1 ORTEP representation with 50% probability ellipsoids of the $[V_5O_9Cl(OAc)_4]^{2-}$ anion of **2**.

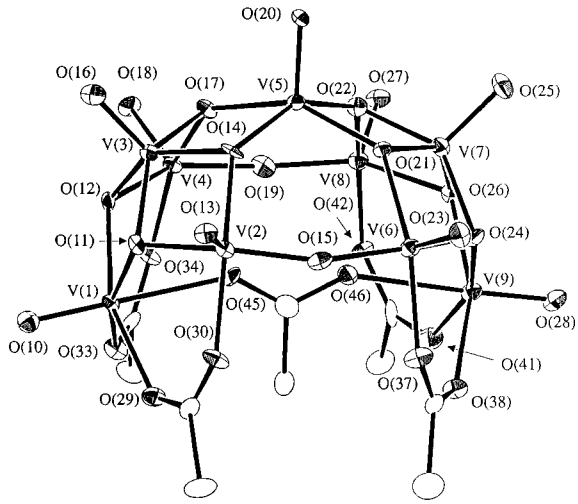

Fig. 2 ORTEP representation with 50% probability ellipsoids of the $[V_9O_{19}(OAc)_5]^{3-}$ anion of **3**.

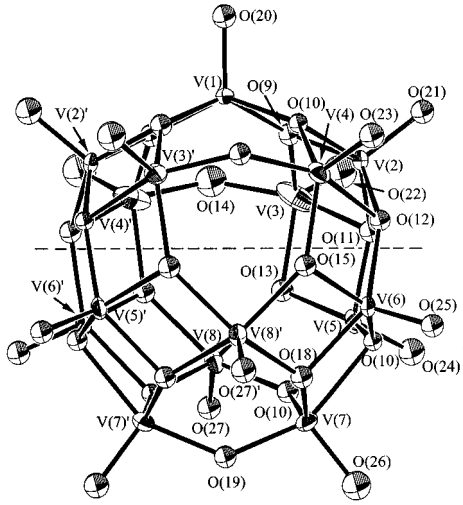

Fig. 3 ORTEP representation with 50% probability ellipsoids of the $[V_{15}O_{36}]^{5-}$ anion of **4**. The $[V_7O_{17}]$ portion of the structure above the dashed line is the same as in the anion of **3** (Fig. 2).

considered carboxylate-stabilised intermediates in the assembly of the $[V_{15}O_{36}]^{5-}$ ion of **4** in MeCN, and that the minimal sequence in its formation is that in eqn. (1). This is supported by

$$[VO]^{2+} \rightarrow [V_5O_9]^{3+} \rightarrow [V_9O_{19}]^{2+} \rightarrow [V_{15}O_{36}]^{5-} \quad (1)$$

the structural relationship between the $[V_9O_{19}]$ core and $[V_{15}O_{36}]^{5-}$ (Fig. 3). A common $[V_7O_{17}]$ unit is seen: in **3**, the O atoms at left and right of this [O(11)/O(12) and O(24)/O(26) of Fig. 2] bind to only two V atoms [V(1) and V(9)], whereas in **4** they bind to four V atoms [V(5), V(5)′, V(6), V(6)′ of Fig. 3] allowing the $[V_{15}O_{36}]$ shell to form. Interestingly, the complete $[V_9O_{19}]$ core of **3** is a fragment of the $[V_{18}O_{42}]$ cage-like polyoxovanadate with T_d symmetry.[4] Note that the acetate O atoms of **2** and **3** occupy sites that would otherwise be occupied by O^{2-} ions giving higher nuclearity products. The AgOAc reagent that causes formation of **2**–**4** from **1** clearly has multiple functions: (i) as a source of AcO^- groups both to stabilise the fragments in **2** and **3** *and* to act as Brønsted bases to facilitate formation of O^{2-} ions from H_2O molecules [O : V ratios are 1 : 1 (**1**), 1.8 : 1 (**2**), 2.1 : 1 (**3**) and 2.4 : 1 (**4**)]; (ii) as a Cl^- abstracting reagent; and (iii) as an oxidizing agent [average V oxidation states are 4+ (**1**), 4.2+ (**2**), 4.44+ (**3**) and 4.47+ (**4**)]. It is thus reasonable that the AgOAc : **1** ratio is so important. Indeed, treatment of redissolved **3** in MeCN with additional AgOAc gives a colour change from blue to purple and subsequent crystallisation of **4**.

The solid-state effective magnetic moment (μ_{eff}) of **3** gradually decreases from 3.62 μ_B at 300 K to 3.15 μ_B at 2.00 K. For **4**, μ_{eff} gradually decreases from 2.86 μ_B at 300 K to 2.67 μ_B at 30.0 K, and then increases slightly to 2.83 μ_B at 3.00 K. Fitting of magnetization data collected in the 0.05–5 T and 2.00–4.00 K ranges gave $S = 3/2$, $g = 1.70$ and $D = 0.00$ cm^{-1} for **3** and $S = 3/2$, $g = 1.62$ and $D = 0.00$ cm^{-1} for **4**. The magnetic properties of $[V_5O_9Cl(O_2CR)_4]^{2-}$ species such as **2** have been previously described.[14] More detailed analysis of the exchange interactions in **3** and **4** will be provided elsewhere.[15]

The formation of **2**–**4** from **1** suggests that stepwise control of the assembly of polyoxometallates may indeed be feasible by suitable choice of solvent and reagents (and their ratios) allowing access to a variety of bowl-like species. Further experimentation along these lines is in progress.

This work was supported by the U.S. Department of Energy.

† Further volume reduction or addition of *e.g.* Et_2O gives significantly greater yields of **3** and **4** but the coloured products are contaminated with white solids. The described procedures avoid this but at the expense of large yields. Dried solids are hygroscopic and analysed satisfactorily (C, H, N).

Synthesis of racemic brevioxime

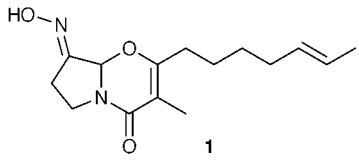
Derrick L. J. Clive* and Soleiman Hisaindee

Chemistry Department, University of Alberta, Edmonton, Alberta, Canada T6G 2G2. E-mail: derrick.clive@ualberta.ca

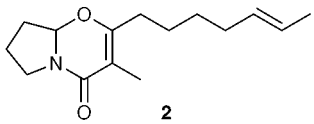
Received (in Corvallis, OR, USA) 10th August 1999, Accepted 24th September 1999

Amine hydrochloride 12 and β-keto thioester 16 were coupled and treated with TFA; the resulting alcohols 18 were oxidized and converted into a mixture of oximes 20, from which the major product, racemic brevioxime 1, was isolated.

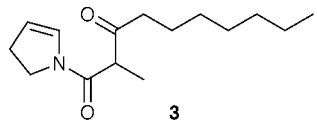
We report the synthesis of brevioxime **1** in racemic form. Natural brevioxime, which is optically active, was isolated[1] from the fungus *Penicillium brevicompactum* Dierckx, and is of



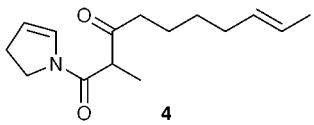
1



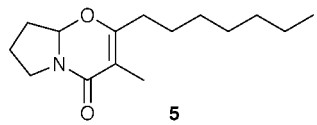
2



3



4



5

potential value as a lead compound in pesticide research because it is an inhibitor of juvenile hormone biosynthesis.[1] The related compounds **2**,[2] **3**[3] and **4**[2] have been obtained from the same fungus. The last two are also inhibitors of juvenile hormone and, while **2** shows insecticidal activity, its primary mode of action does not appear to have been established.

The structure of brevioxime is of an unusual type, and the natural products **1** and **2**, together with the totally synthetic **5**,[3] appear to be the only representatives.†

Our synthetic plan, which was developed after a number of exploratory experiments,‡ was based on the idea that an amide aldehyde of type **6** (Scheme 1) should cyclize[5,7] in the presence of acid, so as to generate the required heterocyclic system directly (**6** → **7** → **8**).

On the basis of the above considerations, we first made the amine hydrochloride **12**. Preparation of this compound was initially troublesome, but we eventually found that it is accessible by the route summarized in Scheme 2. Epoxy acetal **9**, readily available by epoxidation (HOCl, water, < 5 °C; 72%) of acrolein dimethyl acetal,[8] was treated with potassium cyanide (KCN, EtOH–water, room temperature, 24 h; 62%),[9] so as to afford the cyano alcohol **10**, which was protected by silylation (Bu^tMe_2SiCl, Et_3N, CH_2Cl_2, reflux, overnight; 81%). The nitrile function of **10** was then reduced by catalytic hydrogenation in the presence of 6 equiv. of $CHCl_3$ (PtO_2, dry EtOH, $CHCl_3$, 50 psi, 24 h, room temperature; 64–75%);[10] other conditions§ were unsuccessful.

With the amine hydrochloride in hand, the next task was to convert it into a β-keto amide (*cf.* **6**). The preparation of such amides is often best done by treating a β-keto thioester with an amine;[11] in the present case the appropriate β-keto thioester was **16**. We initially made this compound by alkylation of the simple thioester **13**[12] with (*E*)-6-iodohex-2-ene, using the technique of double deprotonation,[13] but the yield was poor (33%). A better route involved acylation[14] of thioester **15**[15] with the imidazolide derived from the known (*E*)oct-6-enoic acid.[16] Under optimum conditions,¶ the required β-keto thioester **16** can be obtained in 64% from acid **14** (Scheme 3).

The amino component and the thioester were coupled by condensation in the presence of silver triflate[11]‖ [**12** + **16** → **17**; Et_3N (2 equiv.), AgOTf (2 equiv.), THF, room temperature, 30 min; 92%]. At this point, exposure to aqueous TFA [50% aq. TFA, $CHCl_3$ (1:2)] brought about the intended series of cyclizations (see Scheme 1), and gave an almost quantitative yield of the desired alcohols **18**, as a 1:1 mixture of diastereoisomers. The chromatographically less polar isomer was easily oxidized by the Dess–Martin reagent (CH_2Cl_2, 2 h, *ca.* 100%), taking the route as far as ketone **19**. The isomeric alcohol was more difficult to oxidize, but it did react with tetrapropylammonium perruthenate (TPAP)[18] [TPAP, NMO, CH_2Cl_2, 4 Å molecular sieves, 2 h; 23%, after correction for recovered starting material (19%)]. Treatment of ketone **19** with hydroxylamine hydrochloride under classical conditions[19] [hydroxylamine hydrochloride (5 equiv.), NaOAc (5.2 equiv.), water, EtOH, 2 h; *ca.* 100%] gave the oximes **20**, with the desired *E*-isomer predominating (4.3:1). This isomer was readily separated by chromatography, so as to afford racemic brevioxime, whose spectroscopic properties (^1H NMR, ^{13}C NMR) were the same as those reported for material isolated from the natural source.

The above route illustrates the utility of the cyclization of an amide nitrogen onto an aldehyde carbonyl for generating certain nitrogen heterocycles. The route is short, if one ignores the simple steps needed to prepare acid **14**, and the approach is convergent, and it should be amenable to the synthesis of analogues.

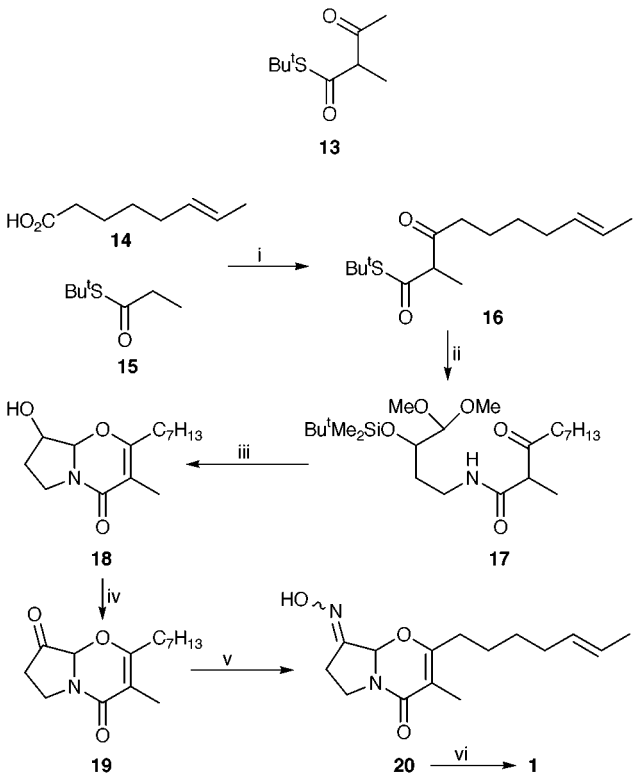
Scheme 2 *Reagents and conditions*: i, KCN, EtOH–water, room temp., 24 h, 62%; ii, Bu^tMe_2SiCl, Et_3N, CH_2Cl_2, reflux, overnight, 81%; iii, PtO_2, dry EtOH, $CHCl_3$ (6 equiv.), 50 psi, 24 h, room temp., 64–75%.



Scheme 3 *Reagents and conditions*: i, see note ¶; ii, amine hydrochloride **12**, Et_3N (2 equiv.), AgOTf (2 equiv.), THF, room temp., 30 min, 92%; iii, 50% aq. TFA, $CHCl_3$ (1 : 2), *ca.* 100%; iv, Dess–Martin reagent, CH_2Cl_2, 2 h, *ca.* 100%; for more polar alcohol, TPAP, NMO, CH_2Cl_2, 4 Å molecular sieves, 2 h, 23%, after correction for recovered alcohol (19%); v, hydroxylamine hydrochloride (5 equiv.), NaOAc (5.2 equiv.), water, EtOH, 2 h, *ca.* 100%; vi, flash chromatography over silica gel.

Notes and references

† However, benzo-fused analogues, such as 1,2,3,3a-tetrahydro-9*H*-pyrrolo[2,1-*b*][1,3]benzoxazin-9-one, are known (see *e.g.* ref. 4), as are substances lacking the 2,3-double bond (see *e.g.* ref. 5).

‡ These were based on *N*-acyl-2-pyrrolines (*cf.* ref. 6).

§ We also tried reduction with $LiAlH_4$ or Pd-C/H_2.

¶ The acid was first converted into its imidazolide (1,1′-carbonyldiimidazole, THF, 0 °C to room temperature, 30 min). The thioester **15** was deprotonated (LDA, THF, −78 °C, 10 min), and the resulting enolate (3 equiv.) was added by cannula to the imidazolide (−78 °C). After 30 min, the cold bath was removed and, after a further 5 min, the mixture was quenched with saturated aqueous ammonium chloride. Instead of the imidazolide, the corresponding derivative of 2,2′-carbonylbis(3,5-dioxo-4-methyl-1,2,4-oxadiazolidine) can be used (*cf.* ref. 17), in which case only 1 equiv. of **15** is required.

‖ We used AgOTf instead of $AgOCOCF_3$ (ref. 11). The AgOTf was added in one portion to a stirred solution of the other components.

Received (in Cambridge, UK) 30th July 1999, Accepted 4th October 1999

***p*-Nitroaniline molecules were intercalated between the layers of kaolinite, and an acentric arrangement of *p*-nitroaniline induced by the asymmteric environment of the interlayer region was accomplished.**

Layered materials have been utilized for immobilizing and organizing functional substances in their interlayer spaces to form supramolecular inorganic–organic hybrid systems.[1–3] The advantage of the use of layered materials is its confinement of guest species in their two-dimensional regions to induce selective orientation. A typical field demanding preferred orientation is nonlinear optics, using organic molecules with hyperpolarizabilities (β) like *p*-nitroaniline (*p*NA), which needs to be oriented noncentrosymmetrically.[4] To achieve an acentric arrangement of *p*NA, various hosts such as cyclodextrins,[5] and microporous and mesoporous molecular sieve hosts[6,7] have been utilized. Layered materials like layered double hydroxides,[8] saponite[9] and $MnPS_3$[10] have also been applied for the arrangement of molecules with hyperpolarizabilities such as *p*NA and stilbazolium ions. However, an outer electrical field[9] or guest-guest interactions[8,10] are needed for alignment of the molecules because the interlayer spaces of the layered materials are sandwiched between identical surfaces of adjacent layers.

Kaolinite has a unique layered structure because the interlayer region is sandwiched between the hydroxy groups of the $AlO_2(OH)_4$ sheets on one side and the oxide arrangements of the silicate sheets on the other[11] [Fig. 1(*a*)], affording an asymmetric nanoenvironment. Guest molecules like DMSO are easily intercalated and aligned in one direction between the layers of kaolinite.[12] Thus, kaolinite is an excellent host material for organizing supramolecular hybrid systems. Here we report the successful formation of a kaolinite–*p*NA intercalation compound and its nonlinear optical properties.

The kaolinite [ideal chemical formula, $Al_2Si_2O_5(OH)_4$] used was KGa1, a highly crystalline Georgia kaolinite obtained from the Source Clays Repository of the Clay Minerals Society (USA).[13] The reactivity of kaolinite for intercalation is very low due to the inherent hydrogen bonding between the layers. Although small polar molecules such as DMSO can be intercalated directly,[14] *p*NA has been reported not to be intercalated into kaolinite.[15] In order to overcome this obstacle, a fine guest displacement method using a kaolinite–methanol intercalation compound as the intermediate was applied (Fig. 1).[16–18] To synthesize a kaolinite-methanol intercalation compound, a kaolinite–*N*-methylformamide (NMF) intercalation compound was prepared and treated repeatedly with methanol eight times to displace NMF completely.[15] The wet kaolinite–methanol intercalation compound (1 g) was stirred in a CH_2Cl_2 solution of *p*NA (0.60 g *p*NA per 20.0 ml CH_2Cl_2) at room temperature for 3 days to form the kaolinite–*p*NA intercalation compound.

The intercalation of *p*NA molecules between the layers of kaolinite was proved by powder X-ray diffraction (Fig. 2). The basal spacing of kaolinite is 0.72 nm and it increased to 1.50 nm in the kaolinite–*p*NA intercalation compound, the value of which was larger than that of the kaolinite–methanol intercalation compound (1.11 nm). The increase of 0.78 nm after intercalation is smaller than the length of the *p*NA molecules (0.90 nm). Considering the amount of *p*NA (24 mass%), which corresponds to $pNA/Al_2Si_2O_5(OH)_4 = 0.6$, the *p*NA molecules are thought to take a monomolecular arrangement, with their molecular axis inclined to the aluminosilicate layers by *ca*. 60° [Fig. 1(*b*)].

In the ^{13}C CP/MAS NMR spectrum of the product, typically four signals due to the aromatic ring carbons of *p*NA were observed at δ 112, 128, 135 and 155,† indicating that the *p*NA molecules were incorporated into the kaolinite. On the other hand, a signal at δ 49 was observed which was assigned to CH_3O, suggesting that a small amount of methanol or methoxy groups attached to the octahedral sheets were present.

The main driving force for the intercalation of *p*NA into kaolinite is thought to be hydrogen bonding between the

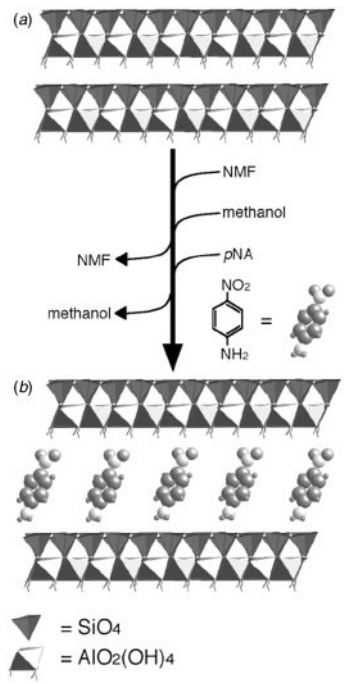

Fig. 1 (*a*) Structure of kaolinite (ref. 11) and (*b*) ideal structure of kaolinite–*p*NA intercalation compound.

† ^{13}C and ^{29}Si CP/MAS NMR and IR spectral data for the kaolinite–*p*NA intercalation compound are available from the RSC web site, see http://www.rsc.org/suppdata/cc/1999/2253/

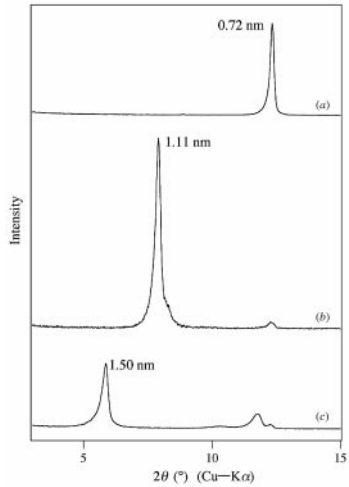

Fig. 2 X-Ray diffraction patterns of (*a*) kaolinite, *(b*) kaolinite–methanol intercalation compound and (*c*) kaolinite–*p*NA intercalation compound.

Table 1 SHG efficiency (referenced to urea) of the samples

Sample	SHG intensity
*p*NA	same level as background
Kaolinite	same level as background
Kaolinite–*p*NA intercalation compound	0.93
Mixture of kaolinite and *p*NA[a]	same level as background
Mixture of kaolinite and *p*NA[b]	0.03–0.05

[a] A physically ground mixture of kaolinite and *p*NA powders. [b] A mixture prepared by dispersing kaolinite with a THF solution of *p*NA.

electrophilic NO_2 groups of *p*NA and the hydroxy groups of kaolinite, which is supported by the intercalation behavior of nitrobenzene and aniline. It was found that nitrobenzene molecules were intercalated between the layers of kaolinite (the basal spacing increased to 1.46 nm) whereas aniline molecules were not.[19] However, the interactions between the NH_2 groups of *p*NA and the silicate sheets of kaolinite presumably contribute to the formation of the kaolinite–*p*NA intercalation compound, because no intercalation reaction took place with *N*,*N*-dimethyl-*p*-nitroaniline.[20]

The interactions between the silicate sheets and the *p*NA molecules were investigated by solid state ^{29}Si NMR spectroscopy.† The Q^3 environments of Si in the tetrahedral silicate sheets of kaolinite showed a signal at around $\delta -91$ with a slight splitting,[21] whereas that of the kaolinite-*p*NA intercalation compound showed the signal shifted to δ −91.5 without splitting. The chemical shift is the same as those observed for kaolinite–alkylamine intercalation compounds (for example, δ −91.5 for an octylamine–kaolinite intercalate) where NH_2 groups interact with the silicate sheets, suggesting that similar interactions are occurring with *p*NA. The IR spectrum of the kaolinite–*p*NA intercalation compound showed that the bands due to $\nu(NH_2)$ at 3494 and 3402 cm^{-1} are shifted to higher wavenumbers than those for *p*NA crystals (3482 and 3361 cm^{-1}).† These findings indicate the presence of weaker hydrogen bondings between NH_2 groups and silicate sheets as compared with those in *p*NA crystals.

The second harmonic generation (SHG) intensities of the materials treated here are shown in Table 1.[22] The kaolinite–*p*NA intercalation compound is SHG active and its intensity is similar to that of urea. No SHG signals were observed for *p*NA crystals, because their second order nonlinear susceptibility is cancelled by their centrosymmetric structure ($P2_1/n$).[23] Almost no signals were observed for kaolinite and a physical mixture of kaolinite with crystalline *p*NA powder where the *p*NA powder was adsorbed only on the outer surface of the kaolinite particles. When *p*NA was dissolved in THF and the solution was mixed with kaolinite to form a mixture where the *p*NA molecules were spread over the outer surface of the mineral, the SHG intensity of the mixture was less than 0.05. Consequently, the observed SHG intensity of the intercalation compound is almost entirely ascribable to *p*NA molecules in the interlayer space of kaolinite; the interactions between the unique interlayer structure of kaolinite and the *p*NA molecules induce the noncentrosymmetric orientation of *p*NA molecules exclusively. Although there are no definitive data on the degree of noncentrosymmetric orientation of the *p*NA molecules, the present results show that kaolinite is an excellent host for immobilizing photofunctional materials in its unique interlayer region. The effect of *p*NA loading on the properties and the preparation of thin films are now under investigation.

The spontaneous arrangement of guest molecules by the interlayer surface structure is a further step towards highly selective catalytic reactions, stereoselective organic synthesis, and the formation of specific molecular assemblies with unusual chemical, photochemical and electrical properties, which will be increasingly important for nanomaterials design for advanced technological applications.

This work was financially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science, Sports and Culture of the Japanese Government. The authors thank Mr Ryoji Takenawa for experimental assistance.

Biosynthesis of longianone from *Xylaria longiana*: a metabolite with a biosynthetic relationship to patulin

Rebecca J. M. Goss, Jens Fuchser and David O'Hagan*

Department of Chemistry, Science Laboratories, South Road, Durham, UK DH1 3LE.

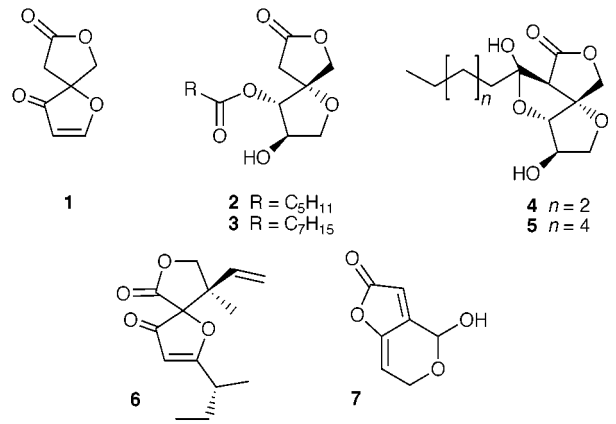
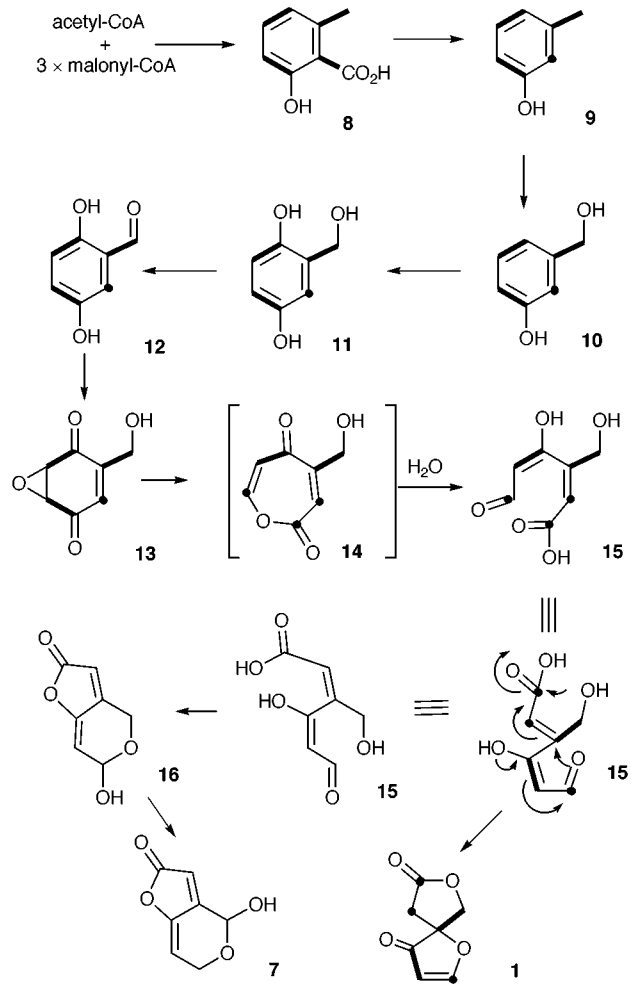
Received (in Cambridge, UK) 9th September 1999, Accepted 1st October 1999

Longianone, a metabolite of *Xylaria longiana*, is an isomer of the well known fungal toxin, patulin; it is demonstrated that longianone is biosynthesised from 6-methylsalicylic acid in a pathway closely related to that found in patulin biosynthesis.

The isolation and structure of the metabolite longianone **1** was recently reported from *Xylaria longiana*.[1] Longianone **1** posesses an intriguing spiro-bicyclic ring structure (1,7-dioxaspiro[4,4]non-2-ene-4,8-dione). It is optically active, however the absolute configuration of the natural product is unknown at present. Structurally, longianone **1** represents a rare parent ring system. The only related bicyclic ring systems are the secosyrins **2** and **3** and their more elaborated co-metabolites, the syringolides **4** and **5**, metabolites of the bacterium *Pseudomonas syringia* pv. *tomato*.[2,3] A biosynthesis has been proposed[3] for the secoserins **4** and **5** which involves the combination of a polyketide chain with a pentose sugar moiety, however this is not based on experimental evidence. Another related ring system is found in the hyperlactones A–C **6** isolated from *Hypericum chinensis*.[4] However, in that case the ester functionality occupies a different site in the ring system and the hyperlactones are clearly terpenoid in origin and have no biosynthetic relationship to longianone **1** or the secosyrins. It is noteworthy that longianone **1** has a structural formula ($C_7H_6O_4$) which is isomeric with the fungal mycotoxin, patulin **7**. Patulin **7** has an intriguing biosynthetic origin derived from oxidative ring opening of the aromatic polyketide metabolite, 6-methylsalicylic acid (6-MSA) **8**[5–8] and the pathway to patulin biosynthesis is illustrated in Scheme 1. The interesting structure of longianone **1** and its constitutional relationship to patulin **7** stimulated us to initiate a biosynthetic investigation of **1** from *X. longiana*.



An initial experiment involved feeding [1,2-$^{13}C_2$]acetate to static cultures of *X. longiana*.[1] This resulted in a low (0.4%) but detectable incorporation of isotope into the resultant longianone **1**. ^{13}C NMR analysis revealed reciprocal couplings between C-3/C-4 ($J_{13C\text{-}13C}$ = 55 Hz) and C-5/C-6 ($J_{13C\text{-}13C}$ = 34 Hz) of **1**, indicating the incorporation of two intact acetate units. This was the first indication of a polyketide origin, and the labelling pattern was consistent with the intermediacy of 6-MSA **8** and a similarity to patulin biosynthesis, as illustrated in Scheme 1. In order to reinforce this hypothesis an experiment with [3,5-$^2H_2$]-6-MSA **8a** was conducted. A sample of ethyl 2-hydroxy-6-methylbenzoate was synthesised following an established route,[9] then deuterium was exchanged into the aromatic nucleus by refluxing with DCl, D_2O and MeOD for 24 h and the ester was hydrolysed to [3,5-$^2H_2$]-6-MSA **8a** by refluxing with NaOH. The subsequent feeding experiment resulted in a sample of longianone which was enriched with deuterium (^2H NMR analysis) at C-2 [Fig. 1(*b*)]. There was a minor enrichment at C-3 arising from some exchange into the aromatic precursor **8a** at C-4 during isotope exchange [Fig. 1(*b*)]. *m*-Cresol **9** and *m*-hydroxybenzyl alcohol **10** are established intermediates in patulin biosynthesis[7] and in order to assess if they have a role in longianone biosynthesis they were each prepared enriched with deuterium, and fed in separate experiments to *X. longiana* cultures. An experiment with [2,4,6-$^2H_3$]-*m*-cresol **9a**, prepared



Scheme 1

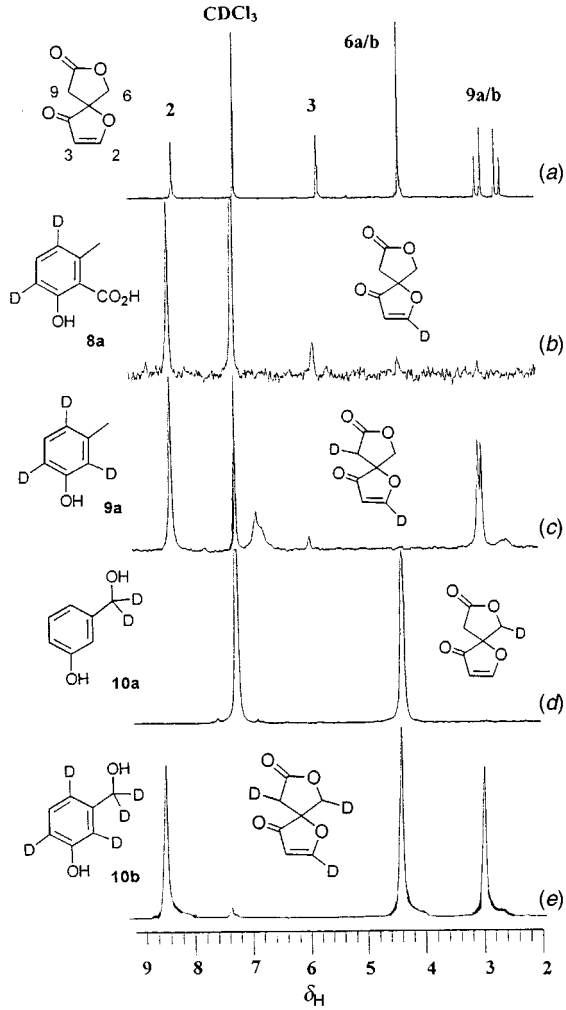


Fig. 1 (*a*) ^{1}H NMR ($CDCl_3$) spectrum and assignment of longianone **1**; (*b*) ^{2}H NMR ($CHCl_3$) spectrum of **1** after feeding **8a**; (*c*) ^{2}H NMR ($CHCl_3$) spectrum of **1** after feeding **9a**; (*d*) ^{2}H NMR ($CHCl_3$) spectrum of **1** after feeding **10a**; (*e*) ^{2}H NMR ($CHCl_3$) spectrum of **1** after feeding **10b**.

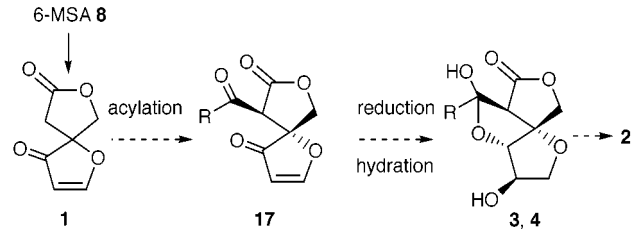
by reaction with PBr_3 and D_2O,[10] resulted in deuterium incorporation into **1** at C-2 and C-9 as determined by ^{2}H NMR [Fig. 1(*c*)]. The methylene hydrogens at C-9 are diastereotopic and well resolved by NMR, and the resulting ^{2}H NMR spectrum after feeding **9a** indicated a stereospecific enrichment into C-9, however upon storage (3 months) a slow racemisation was witnessed. Incorporation of 3-hydroxy[α,α-$^2H_2$]benzyl alcohol **10a**, prepared by reducing methyl 3-hydroxybenzoate with $LiAlD_4$, resulted in labelling at C-6 in **1** [Fig. 1(*d*)]. It was not clear from this latter experiment whether both deuterium atoms were processed through to the C-6 methylene group of longianone **1** as these deuterium atoms, which are formally diastereotopic, have nonetheless similar chemical shifts in the resultant ^{2}H and ^{1}H NMR spectra. In order to gain information on this issue a second experiment was carried out using **10b**, which was prepared with deuterium atoms located both at the hydroxymethyl group and at C-2, C-4 and C-6 of the aromatic ring. The resultant ^{2}H NMR spectrum [Fig. 1(*e*)] of longianone **1** showed three clear enrichments at C-2, C-6 and C-9, with *similar intensities*. We have drawn the conclusion therefore that only one deuterium atom from the methylene group of 3-hydroxybenzyl alcohol **10b** became incorporated into the C-6 methylene group of longianone and therefore the hydroxymethyl group is oxidised up to the aldehyde level during the biosynthesis.

The isotopic labelling experiments reveal a common biosynthetic pathway to both longianone **1** and patulin **2** which



Scheme 2

diverges at a late stage. Both metabolites are derived from 6-MSA **8** and have **9** and **10** as common biosynthetic intermediates. Also oxidation of the hydroxymethyl group to the aldehyde level is revealed as common to both cases and the aromatic ring is cleaved across the same bond. The conversion of gentisaldehyde **12** to phyllostine **13** is a biochemically characterised step[11] in patulin biosynthesis and the intermediacy of neopatulin (also termed isopatulin) has been established from mutant studies,[8] so reasonably the pathway progresses through **14**[12] with hydrolysis to **15**. Different *E/Z* isomers of **15** emerge as the likely branchpoint of the two pathways, with straightforward ester and intramolecular Michael-type cyclisations to generate both rings of longianone. An alternative cyclisation of **15** (ester and hemiacetal formations) generates neopatulin **16** which is a precursor to patulin **7** requiring an oxidation and a reduction. Perhaps longianone **1** is a shunt metabolite of an organism which has lost the capacity to complete patulin **7** biosynthesis.

In view of the above experimental evidence an alternative hypothesis to that recently proposed[2,3] emerges for the biosynthesis of the secosyrins **2** and **3** and the syringolides **4** and **5**. This would involve an origin from a longianone skeleton derived from 6-MSA, followed by acylation α to the lactone to generate intermediate **17**, as illustrated in Scheme 2. Elaborations such as reduction and hydration would generate **4** and **5** and a retro-aldol reaction would generate **2** and **3**. It remains to be determined whether this or the previous proposal[3] is the more valid for the biosynthesis of those metabolites.

We thank Dr Raymond L. Edwards of the University of Bradford for providing a strain of *Xylaria longiana* and Ian McKeag of the University of Durham for ^{2}H NMR analysis. The EU and Isle of Man Education Authority is gratefully acknowledged for a Studentship (R. J. M. G.).

First total synthesis of (±)-longianone

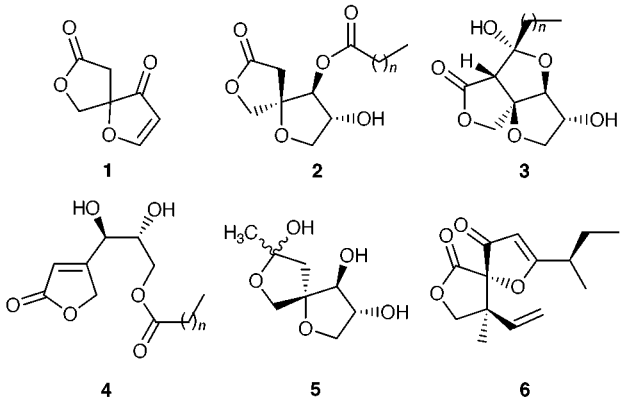
Patrick G. Steel*

Department of Chemistry, University of Durham, Science Laboratories, South Road, Durham, UK DH1 3LE. E-mail: p.g.steel@durham.ac.uk

Received (in Cambridge, UK) 9th September 1999, Accepted 1st October 1999

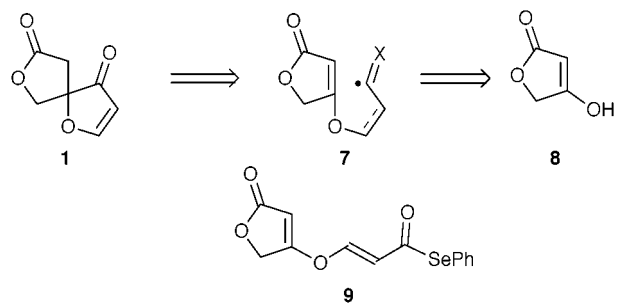
The first total synthesis of (±)-longianone, isolated from *Xyloria longiana*, is reported starting from tetronic acid.

Longianone **1**, recently isolated from the fungal strain *Xyloria longiana* found in various tropical and temperate locations



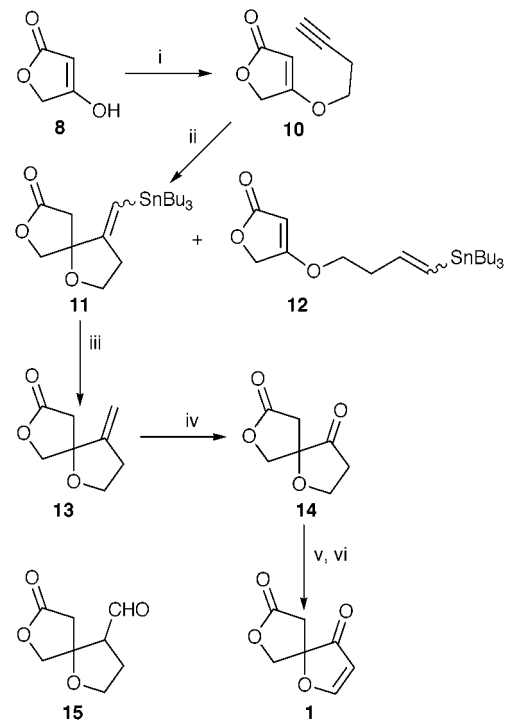
throughout the world, possesses an unusual 1,7-dioxaspiro-[4,4]non-2-ene-4,8-dione skeleton.[1] As such it is the simplest member of a family of structurally related but biosynthetically different natural products containing this spirobicyclic core.[2] These include the bacterial metabolites Secosyrins **2** and the related syringolides **3** and syributins **4** isolated from *Pseudomonas syringae*[3,4] as well as sphydrofuran **5** obtained, much earlier, from a strain of Actinomycetes. Reflecting this unusual skeleton there has been considerable interest in the synthesis of these natural products, resulting in a number of total syntheses.[5–9] A synthesis of a structurally similar natural product, hyperolactone A **6**, which possess an alternative 1,7-dioxaspiro-[4.4]non-2-enedione skeleton, has also been recently communicated.[10] Here we report a highly concise synthesis of (±)-longianone which, in addition to being the first synthesis of this natural product, has potential to provide advanced intermediates for the synthesis of these other natural products.

We envisaged a synthetic route in which the crucial spirocentre could be established by means of an intramolecular radical cyclisation of a suitably functionalised tetronate derivative (Scheme 1).[11] In the ideal situation, the use of an α,β-unsaturated acyl radical precursor **7** (X = O), as pioneered by Pattenden, would generate Longianone in a single operation.[12] Unfortunately, generation of the required acyl selenide was complicated by the instability of several of the proposed intermediates and we turned to a more stepwise route involving cyclisation of a vinyl radical species **7** (X = CHR).



Scheme 1

Condensation of but-3-ynol with tetronic acid **8** was achieved by heating under reflux in a Dean–Stark apparatus using a catalytic amount of TsOH as catalyst (Scheme 2).[13]† Slow addition of Bu_3SnH to a refluxing solution of this vinylogous ester **10** in benzene containing AIBN (10 mol%) afforded a separable 5 : 1 mixture of the desired spirocycle **11** accompanied by the vinyl stannane **12** generated by simple alkyl hydrostannylation.[14] Initial attempts to convert the vinyl stannane to the desired ketone by ozonolysis in CH_2Cl_2 were complicated by preferential formation of the rather unstable aldehyde **15**. This reaction presumably proceeds *via* oxidative cleavage of the carbon–tin bond to give the enol and subsequent tautomerisation. Related conversions of alkyl–tin bonds have been previously reported.[15] This minor difficulty could simply be circumvented by protiodestannylation after separation of the isomeric vinyl stannanes.[16] Subsequent ozonolysis of the resulting alkene **13**, with a reductive work up using dimethyl sulfide, proceeded smoothly to afford the desired bicyclic ketone **14** in good overall yield.



Scheme 2 *Reagents and conditions*: i, but-3-ynol, TsOH, PhH, 18 h, 76%; ii, Bu_3SnH, AlBN (10 mol%), PhH, reflux, 5 h, 71% (**11**:**12** = 5:1); iii, 1 M HCl, CH_2Cl_2, room temp. 1 h, 100%; iv, O_3, CH_2Cl_2, −78 °C, then DMS, −78 °C to room temp., 2 h, 79%; v, PhSeCl, THF, H_2O (cat), 5 days, 38% (+15% **14**); vi, O_3, CH_2Cl_2, −78 °C, then purge N_2 and warm to room temp. 12 h, 44%.

To complete the synthesis we sought a method for the introduction of the α,β-unsaturation which requires selective reaction at the ketone carbonyl group. Initial attempts to generate the silyl enol ether using standard combinations such as LDA/TMSCl or TMSOTf/Et_3N proved unsuccessful. Attempts to directly introduce an α-seleno group through direct reaction of the enolate with PhSeX (X = Cl, SePh) led principally to decomposition of the starting material, presumably *via* β-elimination of the β-alkoxy ketone unit. This conversion was ultimately achieved following an earlier precedent reported by Sharpless involving stirring the ketone and phenylselenenyl chloride in THF containing a trace amount of water.[17] The yellow selenoketone was obtained in moderate yield as a 1 : 1 mixture of diastereoisomers. Attempted oxidation and selenoxide elimination using aqueous oxidants failed to yield any isolable products, presumably due to Michael addition and subsequent ring opening of the lactol ring under the reaction conditions. In the course of his isolation studies Edwards has noted the propensity for the natural product to form the corresponding methanol adduct.[1] These problems could be circumvented by carrying out the oxidation, using ozone as the oxidant, in anhydrous CH_2Cl_2 at −78 °C, followed by warming to room temperature overnight to achieve the elimination. Following simple chromatography, racemic longianone **1**, identical in all respects (TLC, mp, NMR, IR and *m/z*) with an authentic sample,[2] was isolated in 44% yield. All attempts to enhance this process and avoid isolation of the selenide through the use of the corresponding benzeneseleninic anhydride afforded only a trace amount of the desired enone accompanied by significant decomposition.[18]

In conclusion, we report a concise synthesis of (±)-longianone that can also provide access to the structurally related secosyrins and syringolides. Studies in this direction and those towards an enantioselective synthesis are in progress and will be reported in due course.

We thank Professor David O'Hagan for bring this structure to our attention and for providing an authentic sample of longianone, the EPSRC Mass Spectrometry Service at Swansea for accurate mass determinations, Dr A. M. Kenwright and Mr I. H. McKeag for assistance with NMR experiments, and Dr M. Jones for mass spectra.

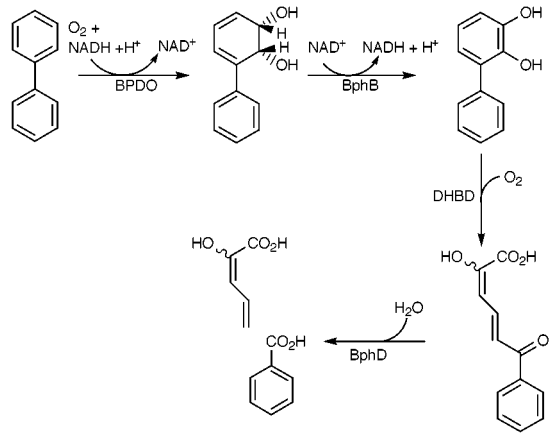
Received (in Corvallis, OR, USA) 7th September 1999, Accepted 28th September 1999

Monochloro DHBs 1a–d and 2a–c have been regioselectively synthesised in good overall yields by a combination of directed *ortho* metalation and Suzuki–Miyaura cross-coupling.

The aerobic microbial degradation of aromatic compounds such as toluene, naphthalene and biphenyl is an essential link in the global carbon cycle and generally proceeds *via* catechol intermediates involving cleavage by either intradiol or extradiol dioxygenases.[1] For biphenyl, fundamental interest in understanding the respective proposed mechanisms of the extradiol cleavage of catechol by 2,3-dihydroxybiphenyl-1,2-dioxygenases (DHBDs)[2,3] and the subsequent hydrolysis of the ring cleaved product catalysed by 2-hydroxy-6-oxo-6-phenylhexa-2,4-dienoate hydrolase (BphD)[3] (Scheme 1) is intensified by the prospect of exploiting these enzymes in the degradation of environmental pollutants such as polychlorinated biphenyls (PCBs).[4,5] In connection with ongoing studies in this area,[6] we describe the regiospecific synthesis of all six isomeric monochloro-2,3-dihydroxybiphenyls (DHBs) **1b–d** and **2a–c**. The synthetic route takes advantage of combined Directed *ortho* Metalation (D*o*M)[7] and Pd-catalyzed Suzuki–Miyaura cross-coupling[8] reactions, a methodological theme currently evolving in our laboratories.[9] The key conceptual features, depicted for **3–5** (Scheme 2), include new strategies of oxygen-directed metalation group (DMG) use in walk-around-the-ring functionalization (**2a**, **2c**).

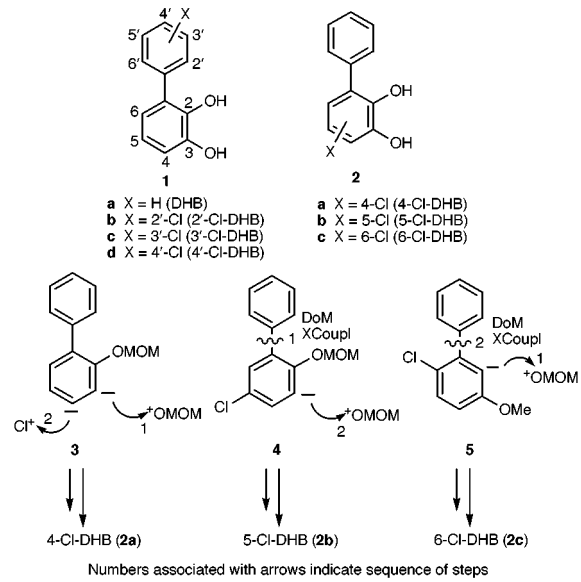


Scheme 1 Enzymes involved in the aerobic microbial degradation of biphenyl and PCBs: BPDO = biphenyl dioxygenase; BphB = 2,3-dihydro-2,3-dihydroxybiphenyl dehydrogenase; DHBD = 2,3-dihyroxybiphenyl dioxygenase; BphD = 2-hydroxy-6-oxo-6-phenylhexa-2,4-dienoate hydrolase.

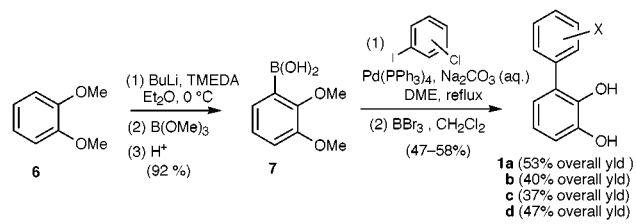
† Current address: Department of Microbiology and Immunology, University of British Columbia, Vancouver, B.C., Canada V6T 1Z3.

Metalation[7] and a trimethyl borate quench of **6** (Scheme 3) afforded the boronic acid **7** which, in crude form, was subjected to Suzuki–Miyaura cross-coupling with bromobenzene or commercially available isomeric chloroiodobenzenes followed by standard BBr_3 deprotection to furnish biaryls **1a–d** in modest overall yields on a gram scale. A comparable yielding (58%) alternate synthesis (Scheme 4) of parent compound **1a** from 2-MOM biphenyl **8**, prepared (NaH, MOMCl, THF, room temperature) from inexpensive 2-hydroxybiphenyl, proceeded by metalation–boronation–oxidation[10] to introduce an OH^+ synthon to afford **9** followed by hydrolysis.

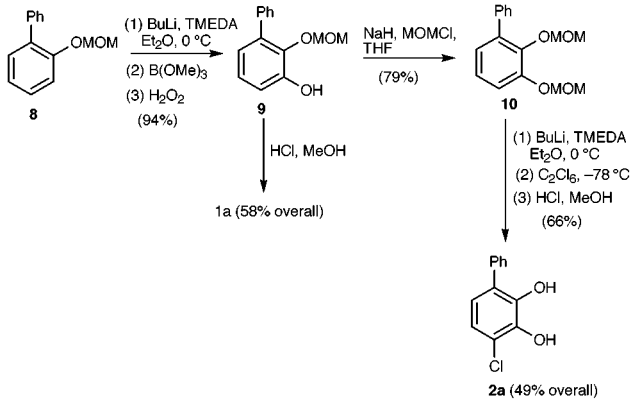
Intermediate **9** also served for a concise synthesis of 4-chloro-DHB **2a** (Scheme 4). Thus, conversion to the MOM derivative **10** as before followed by a second D*o*M reaction,



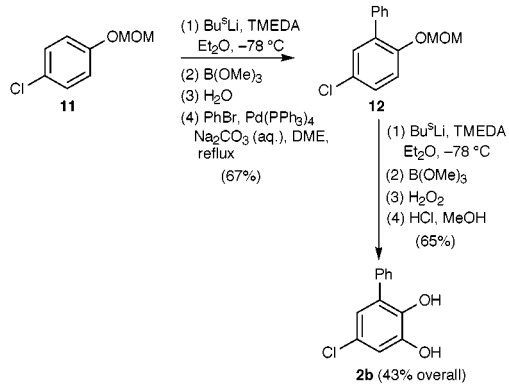
Scheme 2



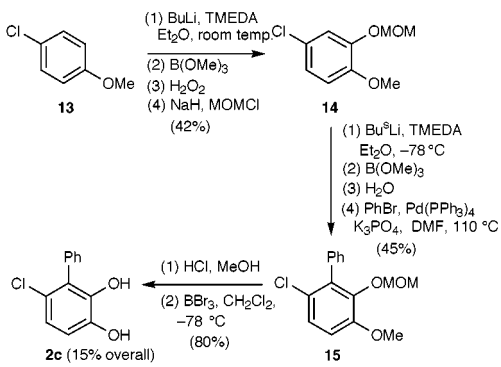
Scheme 3



Scheme 4



Scheme 5



Scheme 6

chlorination with C_2Cl_6, and HCl-mediated deprotection completed the walk-around-the-ring sequence to afford **2a** in good overall yield (49%). The regiospecific construction of 5-chloro-DHB **2b** (Scheme 5) began from the 4-chlorophenol-derived **11** which, upon metalation–boronation-cross-coupling, gave the biphenyl **12**. Adapting the OH^+ synthon introduction as for **8**, followed by hydrolysis, led to **2b** in an acceptable overall yield (43%). The synthesis of 6-chloro-DHB[11] **2c** (Scheme 6) was achieved in a similar fashion, again exploiting the walk-around-the ring sequence. Thus, metalation of **13** followed by boronation–oxidation afforded the intermediate phenol which was converted to the MOM derivative **14**. Subsequent metalation–trimethyl borate quench afforded the 2-boronic acid, which, in crude form, was subjected to Suzuki–Miyaura cross-coupling with bromobenzene to give **15**, followed by hydrolysis and BBr_3 deprotection to afford **2c** (15%). The regiospecificity of all DoM reactions was established by 1D- and 2D-NMR. Final products were obtained in purities > 99% as required for the substrate specificity and inhibition studies of DHBD and BphD.[6]

This work demonstrates the expedient synthesis of all monochloro 2,3-DHBs by the directed *ortho* metalation–Suzuki–Miyaura cross-coupling sequence.[7] The key attribute of DoM, its regioselectivity, is imparted singularly and in an iterative manner (**3**), and leads to single isomer chloro-DHBs in high purity and in gram quantities. The method is being used for the provision of other diverse chloro-DHBs as well as catechols[12] to gain further understanding of the respective catalytic mechanisms of DHBD and BphD.[2,3]‡

We are grateful to NSERC (Strategic grant STP0193182) for generous support of this interdisciplinary study.

Spontaneous oxidation of a sulfide in zeolite CaY: the unprecedented reaction of a sulfide radical cation with oxygen

Wenhui Zhou and Edward L. Clennan*

Department of Chemistry, University of Wyoming, Laramie, WY 82071, USA. E-mail: clennane@uwyo.edu

Received (in Corvallis, OR, USA) 23rd July 1999, Accepted 24th September 1999

Addition of 1,5-dithiacyclooctane (1,5-DTCO) to CaY resulted in electron transfer formation of the corresponding radical cation, which was characterized by EPR and diffuse reflectance UV–VIS spectrometry and which undergoes an unprecedented reaction with molecular oxygen to give mono- and bis-sulfoxide products.

The spontaneous formation of radical cations in zeolites has been extensively investigated with the realization that electron transfer is pivotal to many processes promoted by these important catalysts.[1] The lifetimes of radical cations are often dramatically extended in the interior of the zeolite allowing spectroscopic characterization, however, these species are not inert[2] and dimerizations,[3] rearrangements,[4] ring contractions,[5] and loss of protons[6,7] have all been observed. We report here the first example of the formation of a 2σ–1σ* radical cation[8] in the interior of CaY and the ability of the zeolite to promote a reaction of this radical cation that is not observed in homogeneous solution.

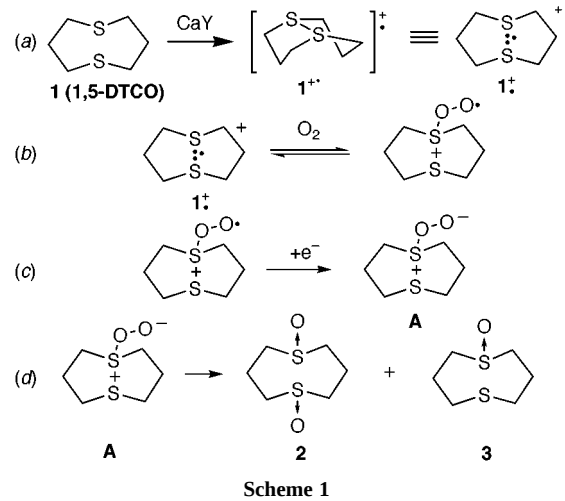
The substrate chosen for examination was 1,5-dithiacyclooctane (1,5-DTCO). 1,5-DTCO adopts a boat chair conformation in which lone pairs on the two sulfur atoms point in towards one another.[9] Its molecular volume is 193 Å^3 and it can conveniently fit in a 6 × 6 × 6 Å box.[10] Consequently, it can diffuse readily though the 7.4 Å windows into the 13 Å diameter supercages of CaY.

The oxidation of 1,5-DTCO has been extensively examined, and both its radical cation $\mathbf{1}^{+\cdot}$ and dication $\mathbf{1}^{2+}$ have been characterized.[8] The radical cation is conveniently synthesized by one-electron oxidation of 1,5-DTCO or by treatment of the corresponding 1-oxide with acid. The unique stability of $\mathbf{1}^{+\cdot}$ has been attributed to a transannular interaction between the two sulfur atoms to form a three electron bond species. Asmus[11] has described this unique bonding situation as an overlap of the p-orbitals on each sulfur to form a bond consisting of a filled σ and a half-filled σ* orbital. The suggestion, from electrochemical data, that the second oxidation of 1,5-DTCO is 20 mV easier that the first provides a dramatic confirmation of this bonding picture.[12]

Addition of 5 ml of a 0.04 M 1,5-dithiacyclooctane (1,5-DTCO) hexane solution to 0.3 g of a freshly prepared sample of CaY[13] under an argon atmosphere followed by GC monitoring of the hexane revealed a rapid and nearly quantitative (> 96% in all cases) adsorption of the sulfide by the zeolite. Immediate evidence for successful formation of $\mathbf{1}^{+\cdot}$ was provided by the fact that the hexane remained colorless during the absorption process while the zeolite immediately changed color from white to bright yellow.[14] An EPR spectrum of the yellow solid/hexane slurry confirmed this suggestion by exhibiting five lines (g = 2.0123; a_H = 14.50 G) indicative of an unpaired electron on sulfur interacting with four equivalent hydrogens. This EPR and the three line spectra generated by introducing 2,2,8,8-tetradeutero-1,5-dithiacyclooctane into the zeolite (g = 2.0121; a_H = 14.43 G) are nearly identical to those assigned to $\mathbf{1}^{+\cdot}$ by Hirschon and Musker for the solution oxidation of 1,5-DTCO.[15] In addition, the diffuse reflectance UV–VIS spectrum of the yellow zeolite exhibited a λ_{max} at 420 nm identical to that reported for $\mathbf{1}^{+\cdot}$ in MeCN.

The zeolite encapsulated radical cation has a lifetime in excess of 8 h in an argon atmosphere, but the diagnostic yellow color and the EPR signal disappear after approximately 2 h when air is introduced into the reaction mixture. Samples which had been purged with oxygen until the yellow color faded were extracted with THF and the products analyzed by GC or GC/MS. The products were identified by comparison to authentic samples as 1,5-dithiacyclooctane 1,5-dioxide **2** and 1,5-dithiacyclooctane 1-oxide **3**, and were formed in > 90 and < 7% yields, respectively (Scheme 1). This extractive workup procedure resulted in material balances in excess of 80% in all cases, consisting primarily of the products accompanied by only traces of 1,5-DTCO and an unidentified material.

Monitoring of the reaction in air by diffuse reflectance UV-VIS spectrometry (Fig. 1) for more than three half-lives demonstrated that the yellow color (λ_{max} = 420 nm band)



Scheme 1

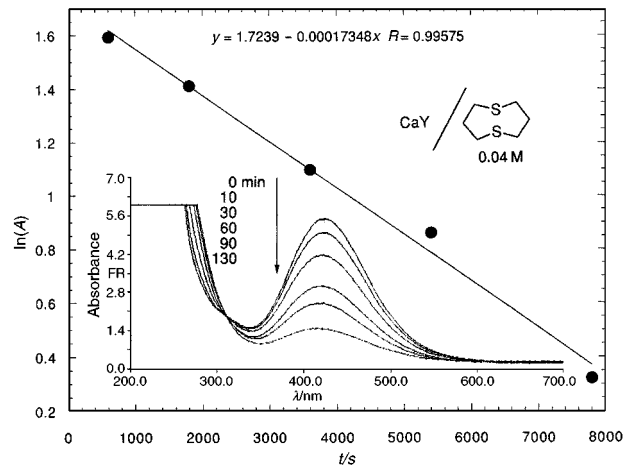


Fig. 1 Plot of the first order decay of the 420 nm band generated by encapsulation of 1,5-DTCO in CaY. Insert: diffuse reflectance UV–VIS spectra of the 1,5-DTCO/CaY sample in the presence of air showing the decrease in the 420 nm band and the isobestic point at 310 nm.

disappears in a strictly first order process. The presence of an isobestic point at 310 nm suggests a simple process, as shown in Scheme 1.

The overall process is initiated by a spontaneous formation of the 2σ–1σ* radical cation. Reported examples of spontaneous formation of sulfur-centered radical cations in the interior of zeolites are rare. Nevertheless, Roth and co-workers[4,5] have reported formation of both diphenyl disulfide and 2-phenyl-1,3-dithiane radical cations in ZSM-5. Electron transfer oxidations of encapsulate substrates [Scheme 1(*a*)] have often been discussed in terms of electron transfer to a Lewis acid or defect site formed during zeolite pretreatment or as an oxidation by absorbed oxygen.[1] The formation of $\mathbf{1}^{+\cdot}$ in CaY is clearly a function of its ease of oxidation. Radical cations were not formed in CaY calcined at 100 or 500 °C upon adsorption of 1,5-dithiacyclononane **4**, 1,4-dithiacycloheptane **5**, 1,3-dithiacyclohexane **6** or 1,4-dithiacyclohexane **7**. All of these bis(sulfides) are more difficult to oxidize than 1,5-DTCO as demonstrated by their oxidation potentials *vs.* Ag/0.01 M $AgNO_3$ in MeCN, shown in Fig. 2.

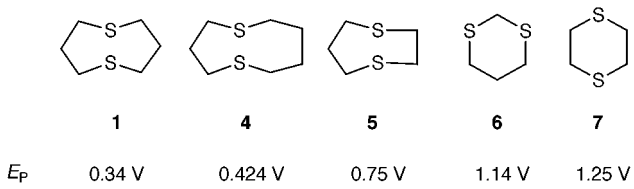

Fig. 2 Oxidation potentials of **1** and **4**–**7**.

The addition of O_2 to $\mathbf{1}^{+\cdot}$ [Scheme 1(*b*)] is unprecedented and is not observed in solution.[16] Asmus has attributed the lack of reactivity of oxygen with 2σ–1σ* sulfur centered radicals to an orbital mismatch between the LUMO on oxygen and the highly energetic antibonding electron in the σ* orbital on sulfur.[11] Consequently, oxidations of sulfur centered radical cations with molecular oxygen have only been accomplished at high O_2 pressures.[17,18] We suggest that the successful oxidation in the interior of the zeolite can be attributed to the proximity of the reducing agent, which traps the oxygen adduct [Scheme 1(*c*)] prior to its reversion to $\mathbf{1}^{+\cdot}$ and O_2. This reduction produces a persulfoxide which is a well established intermediate in the reactions of singlet oxygen with sulfides. The persulfoxide **A** (Scheme 1) has been independently produced by addition of singlet oxygen to 1,5-DTCO in acetone and is known to give predominately the bis(sulfoxide) **2**, identical to the result observed in the interior of the zeolite.[19]

In conclusion, we have demonstrated that CaY is limited in its ability to spontaneously produce sulfur-centered radical cations to easily oxidized sulfides. We further conclude that the reduction potential of the acceptor in CaY is approximately 0.4 V or less *vs.* Ag/0.01 M $AgNO_3$. In addition the minor amount of monosulfoxide **3**, which would be the expected product from reaction of the 1,5-DTCO dication with the residual water in CaY, reveals that the zeolite overwhelmingly functions as a one- rather than as a two-electron oxidizing agent. It is likely that 1,5-DTCO, once oxidized to the radical cation, is restricted in its ability to diffuse to a second oxidizing site to be converted to the dication.

The unprecedented discovery that CaY can promote oxidation at sulfur with only molecular oxygen as an oxidant has far reaching environmental and economic implications. A great need exists for an economical means of selectively oxidizing waste thioethers.[17,18] Further work with other zeolites to extend the generality of this important discovery will be reported in due course.

We thank the National Science Foundation and the donors of the Petroleum Research Fund, administered by the American Chemical Society, for their generous support of this research.

Wittig rearrangement of allyl and propargyl furfuryl ethers leading to 2-furylmethanol derivatives

Masayoshi Tsubuki,* Teruyoshi Kamata, Hiroyuki Okita, Mayumi Arai, Atsushi Shigihara and Toshio Honda*

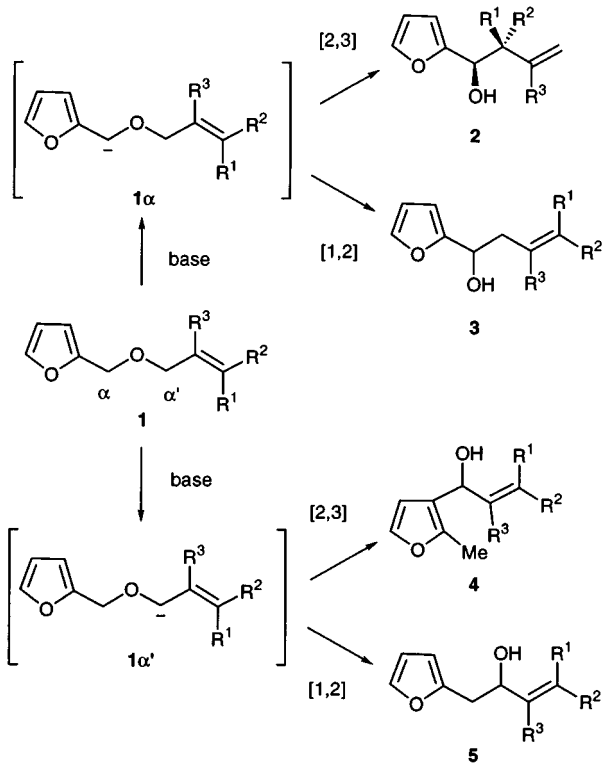
Faculty of Pharmaceutical Sciences, Hoshi University, Ebara 2-4-41, Shinagawa, Tokyo 142-8501, Japan. E-mail: tsubuki@hoshi.ac.jp; honda@hoshi.ac.jp

Received (in Cambridge, UK) 9th September 1999, Accepted 5th October 1999

The first example of the Wittig rearrangement of furfuryl ethers is presented and its application to the preparation of 3-(2-furyl)-3-hydroxy-2-methylpropionates is described.

We have recently shown that the Wittig rearrangement of 3-furylmethyl ethers could proceed to give 2,3- and 1,2-rearrangement products.[1] An advantage of this Wittig rearrangement is that the deprotonation occurred selectively at the allylic position, and either 2,3- or 1,2-rearrangement occurred preferentially depending on the base used. Our interest in defining the scope, limitations and utility of this rearrangement in furylmethyl ethers has directed our attention to Wittig rearrangement of furfuryl ethers. Although the Wittig rearrangement of arylmethyl ethers has been widely studied,[2] there has been no successful report on the rearrangement of a furfuryl ether.[3] Herein, we report the first example of the Wittig rearrangement of allyl and propargyl furfuryl ethers to provide a variety of furyl alcohols, especially 2-furylmethanol derivatives.

The Wittig rearrangement of allyl furfuryl ethers **1a**–**e**†‡ was initially investigated under the conditions[1] described before. Allyl furfuryl ether **1** can theoretically produce both 2,3-rearrangement products **2** and **4** and 1,2-rearrangement products **3** and **5** depending on the position, α and α′, of deprotonation[4] (Scheme 1). The results are summarised in Table 1. Selective deprotonation at the α position was generally effected by Bu^{t}Li in THF at −78 °C, thus providing 2,3-rearrangement products **2a**–**e** as major isomers. In contrast, weaker bases, such as BuLi and Bu^{s}Li, favoured α′ over α deprotonation in the reactions of **1a**–**d**, giving 2,3-rearranged products **5a**–**d** together with 1,2-rearranged products **4a**,**b**. (*Z*)-Crotyl furfuryl ether **1d** afforded *syn* product[5] **2d** with high diastereoselectivity, whereas (*E*)-crotyl ether **1c** yielded *anti* isomer[5] **2c**, albeit in moderate selectivity. It is noteworthy that the (*E*)-crotyl ether **1c** underwent [2,3] Wittig rearrangement furnishing the *anti* isomer **2c** as a major compound, while the corresponding (*E*)-crotyl benzyl ether afforded a mixture in which the *syn* isomer was favoured.[2]



Scheme 1

In order to gain an understanding of the relative thermodynamic stabilities of **1α** and **1α′** anions, we undertook *ab initio* calculations involving full optimisations using the GAUSSIAN 92 quantum mechanical package.§ As one might expect, the calculations suggest that the energy minimums of the **1a**–**e** α anions were favoured by 12.0-28.5 kJ mol^{-1} over the energy minimums of the **1a**–**e** α′ anions at the RHF/6-31+G* level. It became apparent that the energy minimum of the prenyl ether **1e** α anion was predicted to be 9.7 kJ mol^{-1} lower than that of the allyl ether **1a** α anion. These results support the idea that the Wittig rearrangement of allyl furfuryl ethers **1a**–**e** proceeded through deprotonation mainly at the α position, giving 2,3-rearrangement products **2a**–**e**.

Table 2 shows that the diastereoselectivity in the Wittig rearrangement of crotyl ethers **1c**,**d** was influenced by the solvent used. Surprisingly, changing the solvent from THF to Et_2O caused the opposite diastereoselectivity in the reaction of

Table 1 Wittig rearrangement of furfryl ethers **1a**–**e**

Substrate	Base[a]	Yield (%)	Product Distribution[b] (%) 2	3	4	5
1a R^1 = R^2 = R^3 = H	BuLi	53	31[c]		19	50

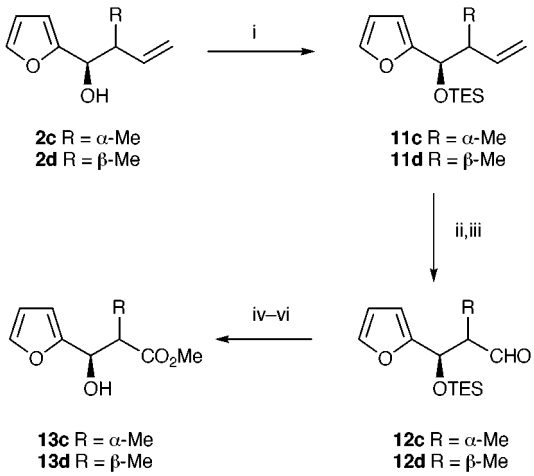
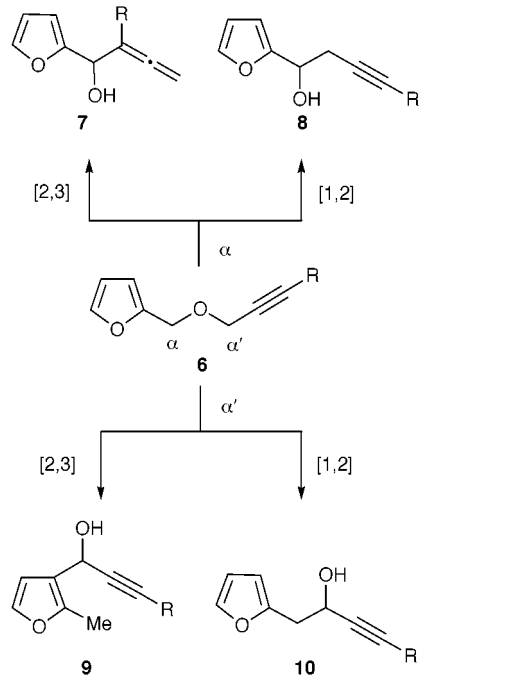
1d	toluene	92:8	51
1d	hexane	>99:<1	60[b]

[a] The results from Table 1. [b] Based on the recovery of the starting material.



Scheme 2 *Reagents and conditions*: i, TESCl, Pr^i_2EtN, CH_2Cl_2 (87% for **11c**, 89% for **11d**); ii, OsO_4, NMO, acetone–H_2O; iii, $NaIO_4$, CH_2Cl_2–H_2O (2 steps: 54% for **12c**, 47% for **12d**); iv, $NaClO_2$, 2-methylbut-2-ene, NaH_2PO_4, Bu^{t}OH, H_2O; v, MeI, $NaHCO_3$, DMF; vi, TsOH, MeOH (3 steps: 65% for **13c**, 59% for **13d**).

Table 3 Wittig rearrangement of furfuryl propargyl ethers **6a**,**b**



Substrate	Base[a]	Yield (%)	Product Distribution[b] (%) 7	8	9	10
6a R = H	BuLi	73	—	45	6	49
6a R = H	Bu^{s}Li	62	—	65	14	21
6a R = H	Bu^{t}Li	61	—	89	—	11
6b R = Me	BuLi	67	9	—	70	21
6b R = Me	Bu^{s}Li	64	12	—	85	3
6b R = Me	Bu^{t}Li	52	9	—	82	9

[a] Reactions were carried out with base in THF at −78 °C. BuLi (10 equiv.) was employed and the reaction was allowed to warm to −20 °C. Bu^{s}Li (3 equiv.) was employed. Bu^{t}Li (5 equiv.) was employed. [b] Determined by 270 MHz NMR analysis of the crude products.

(*E*)-crotyl ether **1c**. The same trend was observed even in a non-polar solvent. On the other hand, better results were found in Et_2O, toluene and hexane, where 84–98% de was obtained in the reactions of (*Z*)-crotyl ether **1d**. A trace amount of **5c,d** was formed in all cases.

The promising results for the Wittig rearrangement of allyl furfuryl ethers prompted us to examine the rearrangement of propargyl ethers **6a**,**b** (Table 3). For propargyl ether **6a** deprotonation with Bu^{s}Li or Bu^{t}Li proceeded through the dianion at the α and terminal alkyne positions to give 1,2-rearrangement product **8a** preferentially. In contrast, propargyl ether **6b** was deprotonated at the α′ position to produce mainly 2,3-rearrangement product **9b**.

Employing *anti* and *syn* alcohols **2c**,**d** we prepared 3-(2-furyl)-3-hydroxy-2-methylpropionates **13c**,**d**, key intermediates for the synthesis of several natural products.[6] Protection of the hydroxy group in **2c**,**d** as a TES ether afforded **11c**,**d**, which were oxidised to aldehydes **12c**,**d** by dihydroxylation of the alkene followed by glycol cleavage in 47 and 42% yield, respectively. Oxidation of **12c**,**d** with sodium chlorite gave the carboxylic acids, which were esterified and then deprotected with TsOH to furnish propionates **13c**,**d** in 65 and 59% yield, respectively.

In summary, Wittig rearrangement of furfuryl ethers offers a new route for the synthesis of furyl alcohols, especially 2-furylmethanol derivatives.

This work was supported by a Grant-in-Aid for Scientific Reseach (C) from the Ministry of Education, Science, Sports and Culture, Japan.

Notes and references

† Furfuryl ethers **1a**–**e** and **6a**,**b** were prepared by reaction of furfuryl alcohol with the corresponding halides in DMF using 2 equiv. of sodium hydride (ref. 7).

‡ All new compounds exhibited satisfactory elemental analyses and/or HRMS and ^{1}H and ^{13}C NMR and IR spectral data. In general furans with low molecular weight are volatile.

§ MO calculations were performed using the IBM RS/6000 version of the GAUSSIAN 92 suite of programs.

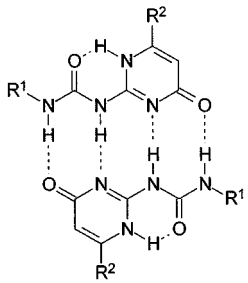
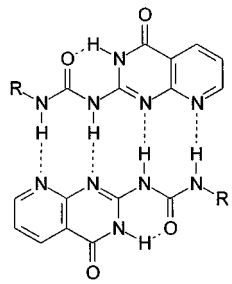
Received (in Cambridge, UK) 6th September 1999, Accepted 1st October 1999

_N_-Carbamoyl squaramides 3, readily available from dialkyl squarate 5, form hydrogen-bonded dimers in solution and in non-polar organic solvents; in $CDCl_3$ they show no significant dissociation down to concentrations of ~0.5 mM.

The continuing development of supramolecular self-assembly requires accessible subunits which can be relied upon to associate strongly and predictably through non-covalent interactions. Particular attention has recently been paid to systems capable of forming four intermolecular hydrogen bonds,[1–4] such as the self-complementary 'DDAA' units **1** and **2** studied



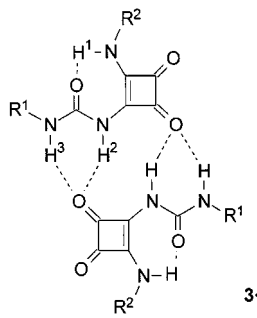
1



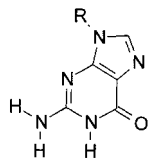
2

by the groups of Meijer[1] and Zimmerman,[2] respectively. These units self-associate essentially completely in solvents such as $CDCl_3$, and are only disrupted by significant quantities of polar solvents such as DMSO.

Herein we report a new homodimer which is related to **1** and **2** but with significant geometric differences. It is nearly as strongly bound, while being exceptionally compact and easy to construct. The new system **3·3** is based on the squaramide unit,



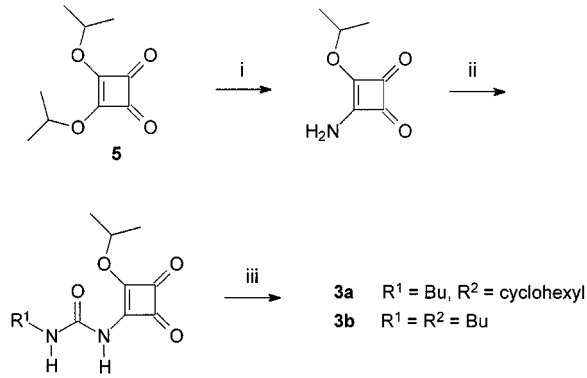
3·3



4

previously shown by Ballester, Costa and co-workers to provide a distinctive array of H-bonding sites for molecular recognition.[5,6] Unlike the earlier squaramides, monomer **3** possesses a ureidyl substituent capable in principle of intramolecular hydrogen bonding to the neighbouring NH. The result should be a well-defined, roughly planar structure with an intriguing resemblance to guanine derivatives **4**.

Planning to investigate the interaction of **3** with nucleobases, we synthesized examples **3a** and **3b** from diisopropyl squarate **5** as shown in Scheme 1. Preliminary ^1H NMR binding experiments in $CDCl_3$ gave unexpected results, leading us to suspect that the squaramides self-associated to some degree.



Scheme 1 *Reagents and conditions*: i, NH_3, MeOH–CH_2Cl_2, room temp.; ii, R^1NCO, Et_3N, MeCN, room temp.; iii, R^2NH_2, CH_2Cl_2, room temp.

However, dilution studies in this solvent showed no substantial changes in the spectra of **3a** or **3b** ($\Delta\delta < 0.1$ ppm) over a wide range of concentrations (~25–0.5 mM), suggesting either that association was not taking place or that it was very strong indeed.

Suspecting the latter, we obtained crystals of **3a** from CH_2Cl_2–light petroleum and subjected them to X-ray crystallography.† As shown in Fig. 1, **3a** exists as a centrosymmetric dimer in the crystal, apparently maintained by four NH···O=C hydrogen bonds. The carbamoylsquaramide units are essentially planar, and exhibit the expected intramolecular hydrogen bond.

The hypothesis that **3** dimerises strongly in $CDCl_3$ was tested by NMR studies in the presence of 'competitive' co-solvents. Addition of CD_3CN (up to 40% v/v) to $CDCl_3$ solutions of **3a** resulted in *upfield* movements of all three N*H* signals. For H(1) and H(3) the motions were moderate ($\Delta\delta \sim -0.7$ ppm), while

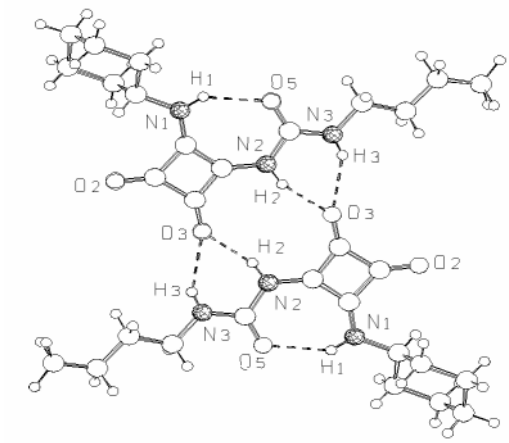


Fig. 1 Crystal structure of **3a** showing the relationship between adjacent H-bonded molecules. Selected distances (Å) and angles (°) are H(1)···O(5) 2.120(2), H(2)···O(3) 1.936(1), H(3)···O(3) 2.204(6), H(1)–N(1) 0.869(6), H(2)–N(2) 0.900(3), H(3)–N(3) 0.832(2); N(1)–H(1)···O(5) 136.65(6), N(2)–H(2)···O(3) 160.96(8), N(3)–H(3)···O(3) 149.03(9), H(2)···O(3)···H(3) 60.81(9).

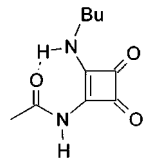
Table 1 ^{1}H NMR dilution studies for compounds **3** in $CDCl_3$–CD_3CN (95 : 5)[a]

Compound	R^1, R^2	K_d/M^{-1}[b]	$\delta_{dimer} - \delta_{monomer}$ (ppm) H(2)	H(3)
3a	Bu, cyclohexyl	5800 ± 1100	2.32	0.59
3b	Bu, Bu	6100 ± 1300	2.42	[c]
3c	2,6-difluorophenyl, Bu	9800 ± 900	2.99	0.62

[a] Experiments performed at 303 K. Concentrations of **3** were varied between ~25 and ~0.2 mM. [b] Dimerisation constants K_d and error limits (standard deviations) were estimated from the movements of the signal due to H(2) using HOSTEST version 5.0 (ref. 7). [c] Not calculated, due to signal broadening.

for H(2) a substantial $\Delta\delta$ of −2.2 ppm was recorded. In the absence of self-association, downfield motions would have been expected due to the formation of NH···N≡C hydrogen bonds.‡ The observed upfield movements presumably result from the break-up of the aggregate, with the loss or weakening of the stronger NH···O=C hydrogen bonding.

The solvent system $CDCl_3$–CD_3CN (95:5) proved suitable for quantitative ^{1}H NMR dilution studies. Results are summarised in Table 1. In addition to **3a** and **3b**, the difluorophenyl-substituted example **3c** was synthesized (*cf.* Scheme 1) and studied under these conditions.§ In each case the signal due to H(2), which appeared between δ 10.3 and 10.9 at high concentrations, moved upfield upon dilution. The data were consistent with simple 1 : 1 dimerisations, yielding dimerisation constants (K_d) in the range 5×10^3 to 10^4 M^{-1}, and limiting chemical shift differences ($\delta_{dimer} - \delta_{monomer}$) in the range 2.3–3 ppm. The signals due to H(3), starting at δ ~6.5 for **3a**/**b** and δ ~8.1 for **3c**, also moved upfield during the experiments. Their motions were smaller and difficult to follow accurately due to broadening, but generally supported the analyses of H(2). A study of **3a** in $CDCl_3$–$(CD_3)_2SO$ (99 : 1) also suggested dimerisation, but with the lower K_d of ~180 M^{-1}. A re-examination of **3a** in $CDCl_3$ gave data consistent with $K_d \sim 10^6$ M^{-1}, on the assumption that (δ_{dimer}–$\delta_{monomer}$) is likely to be between 3 and 4 ppm in this solvent. The rôle of H(3) in maintaining the dimer was confirmed by a study of *N*-acetylsquaramide **6**, for which a K_d of just 120 M^{-1} was measured in $CDCl_3$–CD_3CN (95 : 5).



6

The tendency of **3** to dimerise was also revealed in the FAB$^+$ mass spectrum of **3b**. In addition to the monomer at *m/z* 268 (MH^+), there was a significant (~30%) signal for the dimer at *m/z* 535 (M_2H^+). Signals for higher aggregates M_nH^+ (n = 3-5) appeared at <1.5%. Interestingly the addition of AcONa promoted not only the M_nNa^+ signals as expected, but also a series of general formula $[M_n - mH + (m + 1)Na]^+$ ($1 < m < n$). These ions presumably arise from substitution of the relatively acidic H(2) by Na, followed by clustering in various combinations with **3b** itself.

When compared with **1** and **2**, the present system **3**·**3** would seem to be somewhat less strongly associated. For example, K_d values of *ca.* 10^3 M^{-1} are reported for both **1** and **2** in $CDCl_3$–$(CD_3)_2SO$ (95 : 5).[1,2] However, **3**·**3** is more tightly bound than other systems joined by four hydrogen bonds,[3,4] being maintained down to very low concentrations in $CDCl_3$. Given the accessibility, variability and compact size of **3**, this moiety should be capable of playing a distinctive rôle in the design of self-assembling systems.

Financial support for this work was provided by Enterprise Ireland, the Irish Health Research Board and the Wellcome Trust. We are grateful to Professor C. S. Wilcox for access to the HOSTEST binding analysis programme.

Synthesis of 3-substituted and 2,3-disubstituted 4-chlorofurans

Ram N. Ram* and I. Charles

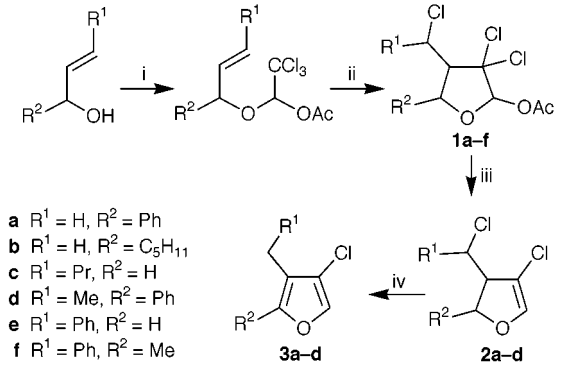
Received (in Cambridge, UK) 8th September 1999, Accepted 1st October 1999

A simple method for the synthesis of 3-substituted and 2,3-disubstituted 4-chlorofurans is described which involves CuCl/bipy-catalysed regioselective cyclisation of 1-acetoxy-2,2,2-trichloroethyl allyl ethers followed successively by dechloroacetoxylation with Zn dust and tandem dehydrohalogenation–aromatisation with Bu^{t}OK/18-crown-6.

The synthesis of variously substituted furans continues to be of considerable interest[1] due to the presence of the furan nucleus in commercially important pharmaceuticals,[2] flavors[3] and a variety of naturally occurring biologically active compounds.[4] Furans also serve as useful synthetic intermediates for the synthesis of aromatic, alicyclic and acyclic molecules.[5] Since furans undergo electrophilic substitution and lithiation at the 2- and 5-positions, bypassing any of these positions to substitute the 3- and/or 4-positions is not straightforward. Therefore, β-mono-, di- and tri-substituted furans having either or both of the 2- and 5-positions unsubstituted are generally synthesised *via* acyclic routes. If the substituent happens to be a functional group, particularly at the 3- and/or 4-position(s), a variety of furans can be prepared by simple functional group transformations, thus widening the scope of the synthesis. In this respect, bromo and iodo groups have served particularly well by undergoing replacement with alkyl, alkenyl, alkynyl, aryl, heteroaryl, formyl and acyl groups.[5a,6] Since the chloro compounds, in general, are less expensive and more stable, there is considerable current interest in the replacement of the chloro group of aryl and vinyl chlorides with carbon groups.[7] However, there are very few reported methods for the preparation of 3- and/or 4-chlorofurans.[8] Furthermore, these methods have their own limitations with regard to yields,[8a] the nature of the other substituents[8b,e] and the substitution pattern.[8b–e,9] Therefore, herein we disclose a simple, new and broader route to prepare 3-substituted and 2,3-disubstituted 4-chlorofurans, which also complements the few reported methods for 3- and/or 4-chlorofuran synthesis.

Our interest in the chemistry of reactive aldehydes and metal-ion-promoted reactions[10] led us to use a reaction analogous to the reported[11] Cu^I-catalysed cyclisation of β-chloroethyl allyl ethers as the key step for the present synthesis. Thus, chloral hemiacetals, prepared by simply mixing chloral with readily accessible allylic alcohols, after protection as acetates, underwent regioselective cyclisation with CuCl/bipy, as expected, to afford the tetrahydrofurans **1a**–**f**. Dechloroacetoxylation of **1a**–**d** with Zn dust gave the 2,3-dihydrofurans **2a**–**d** as stereoisomeric mixtures in 61–81% overall yields. Dehydrochlorination of **2a**–**d** with KOH/EtOH followed by isomerisation of the crude isofurans with catalytic amounts of conc. H_2SO_4 and purification thereafter by column chromatography (silica gel, *n*-hexane) furnished the 4-chlorofurans **3a**–**d** in 31–65% overall yields (starting from the allyl alcohols). When the dehydrochlorination was performed with Bu^{t}OK/18-crown-6/THF, tandem isomerisation of isofurans was observed, giving the 4-chlorofurans **3a**–**d** in better overall yields (51–74%) (Scheme 1).

During dechloroacetoxylation, reduction of the benzylic chloro group was observed in the case of **1e**–**f**. The 4-chlorofuran **3e** was, however, prepared in 81% overall yield by a simple modification involving preparation of trichloroethyl cinnamyl ether by the reaction of trichloroethanol with cinnamyl bromide, followed by CuCl/bipy cyclisation and dehydrochlorination with DBU (Scheme 2).[12]

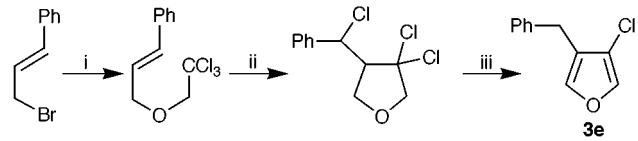


Scheme 1 *Reagents and conditions*: i, CCl_3CHO, 2 h, then Ac_2O, pyridine, DMAP, room temp., overnight; ii, 30 mol% of CuCl/bipy (1:1 mixture), 1,2-dichloroethane, reflux, 2 h; iii, Zn, THF, reflux, 4 h; iv, Bu^{t}OK, 18-crown-6, THF, reflux, 10 h.

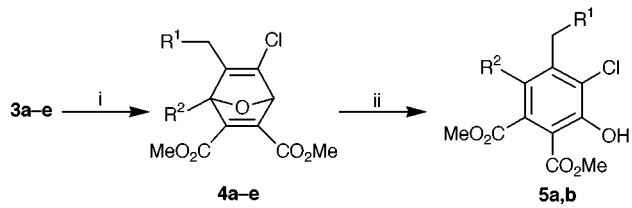
These chlorofurans are fairly stable in hydrocarbon solvents but tend to deteriorate in chlorinated or oxygenated solvents. The decomposition is faster when they are stored as neat liquids.

All the compounds have been characterised by IR, NMR and mass spectral studies. The chlorofurans **3** were also characterised by their transformation into the Diels–Alder adducts **4** on reaction with dimethyl acetylenedicarboxylate. In the case of **3a**, the reaction proceeded further to give the phenol **5a** under the reaction conditions used (neat, 100 °C, 10 h). The furan **3b** gave a mixture of the cycloadduct **4b** and the phenol **5b**, which was completely converted into the phenol **5b** on slight warming with $BF_3{\cdot}OEt_2$ (Scheme 3).

An additional advantage of the present method of furan synthesis is that it can be used to prepare 2,3-dihydrofurans as well, which, like furans, are also widely distributed in Nature[13] and are useful synthetic intermediates.[5c,14] This advantage is not



Scheme 2 *Reagents and conditions*: i, CCl_3CH_2OH, K_2CO_3, acetone, reflux, 6 h; ii, 30 mol% of CuCl/bipy (1:1 mixture), 1,2-dichloroethane, reflux, 2.5 h; iii, DBU, benzene, reflux, 3 h.



Scheme 3 *Reagents and conditions*: i, DMAD, 100 °C, 10 h; ii, $BF_3{\cdot}OEt_2$, 40–50 °C.

available with the existing methods of β-chlorofuran synthesis. We expect that in the present method of furan synthesis the chloro group might provide a branching point in the synthetic tree at the 2,3-dihydrofuran or furan stage or later during synthetic applications, to give access to a variety of di-, tri- and tetra-substituted furans and other interesting molecules.

Financial assistance by the DST, New Delhi, is gratefully acknowledged.

A bimodal dithiadiazolyl diradical: crystal structure and magnetic properties of the 2,2′-dimethylbiphenylene bridged derivative

T. M. Barclay,[a] A. W. Cordes,[a] N. A. George,[b] R. C. Haddon,[c] M. E. Itkis[c] and R. T. Oakley*[b]

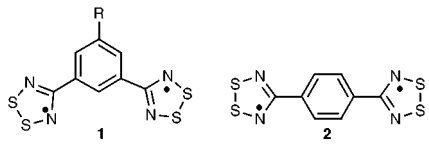
Received (in Cambridge, UK) 7th September 1999, Accepted 5th October 1999

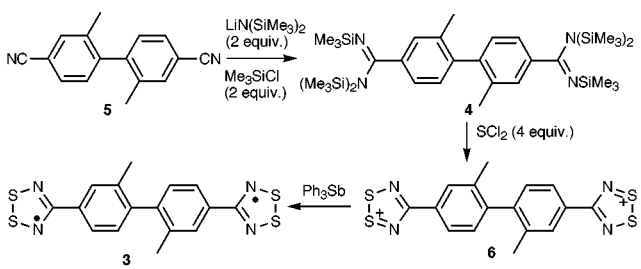
The two termini of the torsionally strained dithiadiazolyl diradical S_2N_2C–C_6H_3Me–MeC_6H_3–CN_2S_2 3 possess different solid state structural environments; the bulk magnetic susceptibility of 3 is interpreted in terms of the distinct properties of the two radical centres.

The potential applications of 1,2,3,5-dithiadiazolyl (DTDA) radicals in molecular magnets,[1] conductors[2] and thin film devices[3] has led to increasing interest in both the diversity and control of the structural features of these systems.[4] Most monofunctional derivatives associate in the solid state to afford diamagnetic dimers, and suppression of this dimerization hence represents a major experimental challenge. Recently, Rawson and co-workers have reported several radicals that are unassociated[1,5] or only very weakly spin paired.[6] Most significantly, the β-phase of *p*-cyanoperfluorophenyl-DTDA is weakly ferromagnetic below 36 K.[1]

Bifunctional radicals, *e.g.* **1** (R = H, CN, Bu^t)[7,8] and **2**,[3,9] have also been examined, but in the systems studied to date the



two termini have been crystallographically equivalent, as a result of which the bulk magnetic properties are a function of a single spin centre. In order to explore the relationship between structure and magnetic behavior in DTDA diradicals we have prepared and characterized the 2,2′-dimethylbiphenylene (DMBP) bridged derivative **3** (Scheme 1). We selected this bridge in the hope that torsion about the central C–C bond of DMBP would inhibit both the π-stacked structures found for **1** and the herringbone arrangement exemplified by **2**. Colourless crystals (mp 142–145 °C) of the necessary bis-amidine **4** [$\delta_H(CDCl_3)$ 0.065 (s, *Me*$_3$Si, 54 H), 7.34–7.56 (AA′BB′, 8 H)] were prepared in 65% yield from the dinitrile **5**[10] using standard methodology.[11] Reaction of **4** (3.00 g, 4.3 mmol) with SCl_2 (2.00 g, 19.3 mmol) in 100 ml of MeCN at reflux gave the crude bis(dithiadiazolylium chloride) **6**, which was reduced with Ph_3Sb (2.0 g, 5.7 mmol) to yield **3** (1.36 g, 82%), which was



Scheme 1

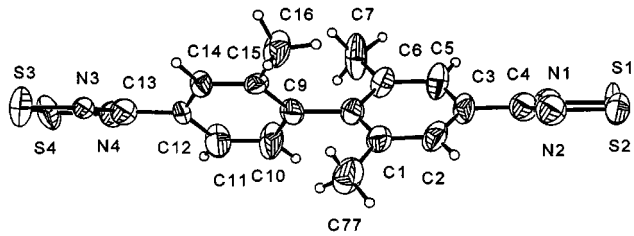


Fig. 1 ORTEP drawing of **3**, illustrating the torsion within the molecule. The C7 (C77) methyl group is disordered.

purified by fractional sublimation at 160–100 °C/10^{-3} torr, affording black reflective nodules, mp 242 °C.†

The molecular structure‡ (Fig. 1) of **3** exhibits a minor disorder in both CN_2S_2 rings, which were refined as rigid groups, and also in one of the methyl groups, which was refined with 50% occupancy of the two (C7/C77) positions. These imperfections aside, the molecule displays the anticipated torsion (74.0°) about the central C–C bond of the DMBP bridge; in biphenyl itself, for example, the two rings are coplanar,[12] but in 2,2′-dimethyl-4,4′-diaminobiphenyl the torsion angle opens to 86°.[13] The crystal packing of **3** (Fig. 2) represents a significant departure from the two classes of solid state motifs represented by **1** and **2**. Moreover the two DTDA radicals within each molecule are located in very different solid state environments. One end (S3/S4) is essentially undimerized, and the arrangement of these DTDA rings resembles an array of footprints running parallel to the *y* direction. At the other end of the molecule the DTDA ring (S1/S2) is dimerized in a *trans*-

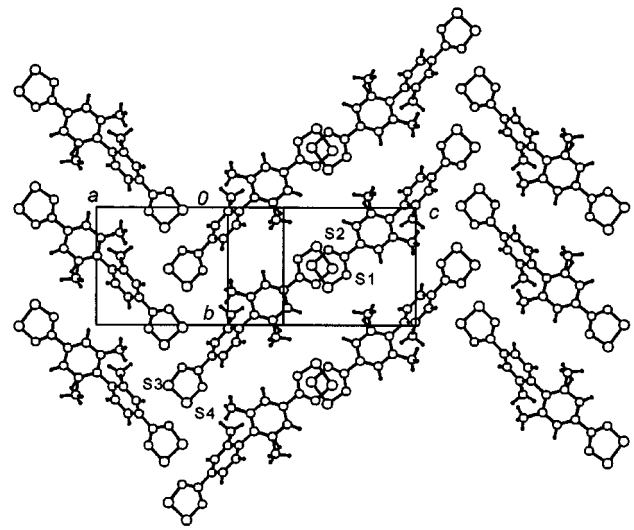

Fig. 2 PLUTO drawing of the layer-like packing in **3**, illustrating the *trans*-cofacial (S1/S2) and undimerized (S3/S4) radical rings. The C7 (C77) methyl group is disordered.

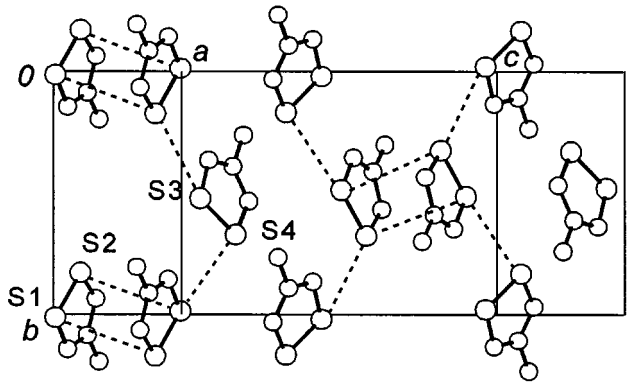

Fig. 3 A single layer of DTDA rings in **3** (DMBP bridges removed), showing close intermolecular contacts.

cofacial manner across an inversion centre to an equivalent radical on a neighbouring molecule. This hitherto unobserved orientation for radical association produces rather long S···S contacts [d(S1···S2′) = 3.68(2) Å], but the separation of the DTDA planes of the dimer is a tight 3.24 Å, easily short enough to effect spin pairing (*vide infra*). We note *en passant* that this mode of dimerization lies near to the proposed transition state for the photochemical isomerization of 1,3,2,4- to 1,2,3,5-DTDAs.[14] Although Fig. 2 suggests the two ends of the molecule are well separated, closer inspection of the packing of the DTDA rings (Fig. 3) reveals two short contacts [d(S1···S4′) = 3.38(2) Å and d(S2···S3′) = 3.38(2) Å]. These dimer/radical bridging interactions may facilitate magnetic exchange between the spins on the S3/S4 rings.

The extent of spin coupling in these two radical environments in **3** has been assessed by magnetic susceptibility measurements over the temperature range 4–400 K. The magnetic behavior (Fig. 4) of the compound can be divided into high (> 200 K), and low (< 200 K) temperature regions, both of which are interpreted in terms of Curie paramagnetism. We associate the low temperature paramagnetism primarily with the undimerized (S3/S4) end of the molecule. On the first scan through this region we find an unpaired spin count of n = 1.11 per molecule. The slight excess paramagnetism over n = 1 may be associated with the high temperature magnetic regime or experimental error. At low temperatures there is a hysteretic phase transition (75–150 K) that quenches some of the molecular spins. The Weiss constant for the ordering transition in all of these states is about −100 K and therefore strongly antiferromagnetic. Thus, at low temperatures, thermal cycling apparently leads to a coupling of some of the radical electrons at this end of the molecule. This may reduce the structural disorder noted above.

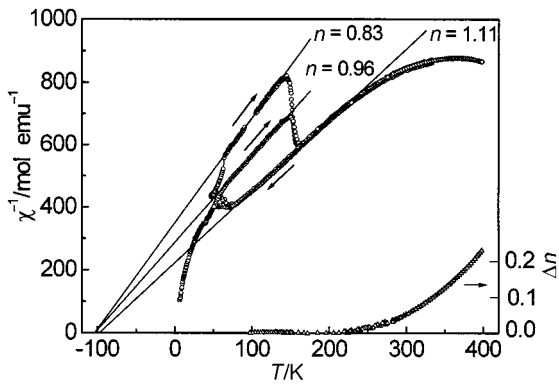

Fig. 4 Plots of $1/\chi$ (χ = magnetic susceptibility) and excess Curie Spins (Δn) of **3** as a function of temperature.

In the high temperature regime the departure from simple n = 1.11 Curie behavior probably arises from the thermal dissociation of the coupled spins at the dimerized (S1/S2) end of the molecule. The excess spins created (Δn) are shown on the right. Similar paramagnetic enhancements at elevated temperatures have been observed in the π-stacked structures of **1**.[7,8]

New insights into the mechanism of methane formation in the protonation of methyl complexes†

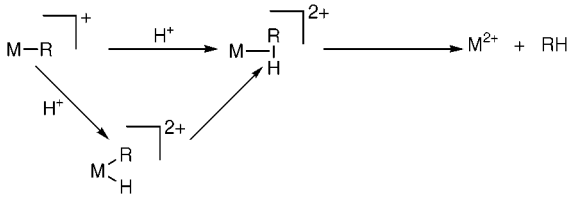
Richard A. Henderson* and Kay E. Oglieve

Nitrogen Fixation Laboratory, John Innes Centre, Norwich Research Park, Colney, Norwich, UK NR4 7UH. E-mail: r.a.henderson@ncl.ac.uk

Received (in Cambridge, UK) 1st September 1999, Accepted 7th October 1999

The reaction between $[NiMe\{(Ph_2PCH_2CH_2)_2PPh\}]^+$ and anhydrous HCl (in MeCN) involves initial protonation of nickel to form $[Ni(H)Me\{(Ph_2PCH_2CH_2)_2PPh\}]^{2+}$, but methane is not produced until after additional, direct protonation of the methyl group.

There have been many investigations into the formation of alkanes in the reaction of acid with metal–alkyl complexes,[1–3] and the consensus view is that the mechanism involves either direct protonation of the metal–carbon bond or initial protonation of the metal followed by intramolecular coupling of the hydrido and methyl ligands (Scheme 1).



Scheme 1

The kinetics of these reactions are frequently too simple to be diagnostic of one particular mechanism and consequently the detection or isolation of a hydrido species has often been invoked as evidence of the coupling pathway. Here, we describe unprecedented complex kinetics for protonation of an alkyl complex which demonstrates, for the first time, that detection of a hydrido species is an insufficient criteria to define the intimate mechanism of alkane formation. Specifically, we show that initial protonation of $[NiMe(triphos)]^+$ [triphos = $(Ph_2PCH_2CH_2)_2PPh$; eqn. (1)] occurs at nickel to form a hydrido complex, but the formation of methane has to await further direct protonation of the methyl group.

$$[NiMe(triphos)]^+ + HCl \rightarrow [NiCl(triphos)]^+ + MeH \quad (1)$$

The reaction between $[NiMe(triphos)]^+$ and an excess of anhydrous HCl in MeCN occurs in two stages: a rapid, acid-dependent reaction which was studied by stopped-flow spectrophotometry, and the subsequent release of methane which was followed by GLC.

In the reaction between $[NiMe(triphos)]^+$ and HCl alone, the kinetics of the first stage exhibit a first order dependence on the concentration of complex and an apparent first order dependence on the concentration of HCl as described by eqn. (2), and illustrated in Fig. 1.

$$\frac{-d[NiMe(triphos)^+]}{dt} = (3.4 \pm 0.3) \times 10^2 [NiMe(triphos)^+][HCl] \quad (2)$$

The simplicity of these kinetics are consistent with either of the two pathways shown in Scheme 1. However, addition of Cl^-

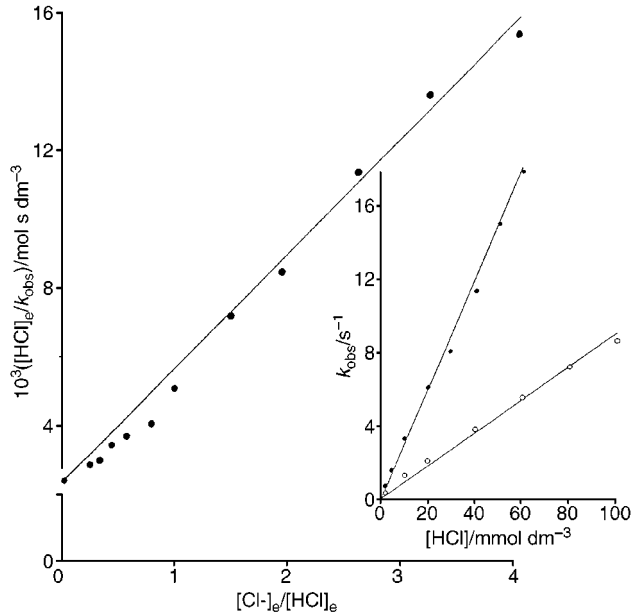


Fig. 1 Dependence of $[HCl]_e/k_{obs}$ on $[Cl^-]_e/[HCl]_e$ for the reaction of $[NiMe(triphos)]^+$ with HCl in the presence of $[NEt_4]Cl$, in MeCN at 25.0 °C. Line drawn is that defined by eqn. (3). [Insert: Dependence of k_{obs} on the concentration of HCl (●) and DCl (○) in the absence of $[NEt_4]Cl$].

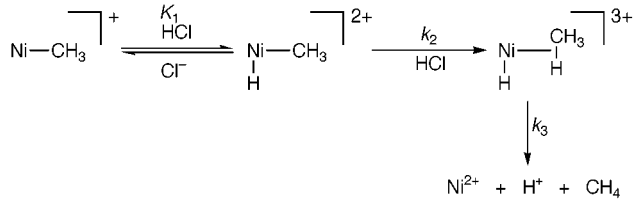
reveals a more complicated behaviour (Fig. 1).‡ The *true* rate law is that shown in eqn. (3).

$$\frac{-d[NiMe(triphos)^+]}{dt} = \frac{(3.0 \pm 0.4) \times 10^2 [NiMe(triphos)^+][HCl]_e{}^2/[Cl^-]_e}{1 + (0.78 \pm 0.05)[HCl]_e/[Cl^-]_e} \quad (3)$$

Eqn. (3) demonstrates that two protons bind to the complex prior to methane release. Such kinetics have not been observed before but are in line with the general protonation characteristics of metal sites containing hydrocarbon residues, in which both metal and carbon can be protonated.[4,5]

The mechanism shown in Scheme 2 involves initial, rapid protonation at nickel to form the hydrido species. However, the kinetics dictate that this protonation is insufficient to produce methane. Rather formation of methane has to await additional protonation of the methyl group. Clearly, diprotonation of the



Scheme 2 Mechanism of the formation of methane in the reaction of $[NiMe(triphos)]^+$ with HCl in MeCN.

† Present address: Department of Chemistry, Bedson Building, University of Newcastle, Newcastle upon Tyne, UK NE1 7RU.

nickel is untenable since this would form a formal Ni^{VI} species.

The rate law associated with this mechanism is shown in eqn. (4) and is derived assuming that protonation at nickel is a rapidly established equilibrium, whilst protonation of the carbon is slow and irreversible.

$$\frac{-\mathrm{d}[\mathrm{NiMe(triphos)}^+]}{\mathrm{d}t} = \frac{K_1 k_2 [\mathrm{NiMe(triphos)}^+][\mathrm{HCl}]_e^{\,2}/[\mathrm{Cl}^-]_e}{1 + K_1[\mathrm{HCl}]_e/[\mathrm{Cl}^-]_e} \quad (4)$$

Comparison of eqns. (3) and (4) gives $k_2 = (3.8 \pm 0.4) \times 10^2$ $dm^3\ mol^{-1}\ s^{-1}$ and $K_1 = 0.78 \pm 0.05$. When $[Cl^-]$ is low, eqn. (4) simplifies to eqn. (5), consistent with the experimental observations. Comparison of eqns. (2) and (5) gives $k_2 = (3.4 \pm 0.3) \times 10^2$ $dm^3\ mol^{-1}\ s^{-1}$, in excellent agreement with that derived from eqn. (4).

$$\frac{-\mathrm{d}[\mathrm{NiMe(triphos)}^+]}{\mathrm{d}t} = k_2[\mathrm{NiMe(triphos)}^+][\mathrm{HCl}]_e \quad (5)$$

Consistent with the k_2 step involving rate-limiting protonation of the methyl group, studies with DCl show a primary isotope effect, $(k_2)^H/(k_2)^D = 3.5$ (Fig. 1).

Further evidence that nickel is the most rapidly protonated site comes from ^1H NMR spectroscopy. Our mechanism indicates that the addition of 1 mol equivalent of HCl to a MeCN solution of $[NiMe(triphos)]^+$ will produce an approximately equimolar mixture of the parent complex and $[Ni(H)Me(triphos)]^{2+}$. The ^1H NMR spectrum of such a mixture (Fig. 2)§ shows a multiplet at δ 9.9 (J_{HP} 50 Hz, J_{HP} 430 Hz). We tentatively attribute this low field signal to the hydride ligand in the five-coordinate, formally Ni^{IV} species, $[Ni(H)Me(triphos)]^{2+}$. This multiplet is not present in the ^1H NMR spectra of either $[NiMe(triphos)]^+$ or $[NiCl(triphos)]^+$.

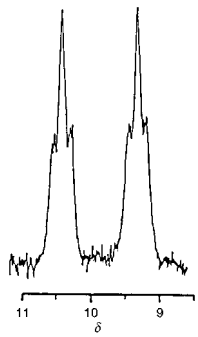


Fig. 2 The multiplet observed in the ^1H NMR spectrum on addition of 1 mol equivalent of HCl to $[NiMe(triphos)]^+$.

Mass spectrometry of the gas formed from the reaction of $[NiMe(triphos)]^+$ and an excess of DCl showed essentially exclusive formation of CH_3D, with little or no other isotopomers. This is also consistent with our mechanism since, once formed, the methane ligand does not undergo proton exchange before it dissociates.

Why does the complex bind two protons when only one is needed for the stoichiometric reaction? Clearly it does not need to. Diprotonation occurs because the nickel is protonated *faster* than the methyl group, and consequently the reaction is *enforced* to operate through the hydrido species. However, intramolecular coupling of the hydride and methyl ligands is *slow* and so methane formation can only occur *after* additional, protonation of the methyl group.

The release of methane (measured by GLC) occurs at a rate which shows a first order dependence on the concentration of complex, but is independent of the concentration of HCl [$k_3 = (4.5 \pm 0.5) \times 10^{-2}$ s^{-1}]. This indicates that, at high concentrations of acid, the putative σ-methane complex is long-lived¶ having a half-life of *ca*. 15 s. Relatively long-lived alkane complexes have been detected previously[6,7] but this kinetic approach has not been adopted before, and potentially is a general method of understanding the factors stabilising such σ-alkane complexes.

The mechanism of methane formation described herein is unexpected, but sufficiently simple that it seems likely that it is not unique to $[NiMe(triphos)]^+$. It is a salutary thought that this pathway has remained unidentified in analogous systems until now because: (i) the detection of hydrido complexes were consistent with the intramolecular coupling pathway (Scheme 1) and (ii) the kinetics of these reactions were not (or could not) be studied in the detailed manner described herein. Just because a hydrido complex is detected in solutions containing acid and a metal alkyl complex does not mean that the hydride is kinetically competent to produce alkane.

We thank BBSRC for supporting this research.

Notes and references

‡ Anhydrous HCl was prepared *in situ* by mixing equimolar amounts of $SiMe_3Cl$ and MeOH in MeCN. The reactions were deliberately performed in MeCN (dried over CaH_2 and distilled immediately prior to use) since solution equilibria (such as pK_a and homoconjugation constants) are known in this solvent.[8] The concentrations of $[HCl^-]_e$ and $[Cl^-]_e$ are those calculated having allowed for the homoconjugation equilibrium, $HCl + Cl^- \rightleftharpoons HCl_2^-$, $K_H = 158.5$ $dm^3\ mol^{-1}$.

§ In these experiments the resonances attributable to the Me groups in $[NiMe(triphos)]^+$ (δ 0.9, unresolved multiplet) and the putative $[Ni(H)Me(triphos)]^{2+}$ are obscured by the peak due to $SiMe_3$ (from the mixture of $SiMe_3Cl$ and CD_3OH used to generate anhydrous HCl). Further evidence that the multiplet at δ 9.9 is attributable to the hydride comes from analogous experiments with DCl where this resonance is missing.

¶ We believe that this is a true measure of the stability of the putative σ-methane complex, rather than an artefact associated with measuring the kinetics of methane transfer from solvent to gas phase, since the rate of the reaction is independent of the concentration of complex used and the speed with which the reaction mixture is agitated.

First synthesis of bis[1,2,3]triazolo[1,5-*b*;5′,1′-*f*][1,3,6]thiadiazepine derivatives by [2+1] condensation of 1,2,3-thiadiazoles with vicinal diamines

Natalya N. Volkova,[a] Evgeniy V. Tarasov,[a] Wim Dehaen*[b] and Vasiliy A. Bakulev*[a]

Received (in Cambridge, UK) 16th September 1999, Accepted 8th October 1999

Novel bistriazolo[1,3,6]thiadiazepine derivatives have been prepared by the base-catalyzed condensation of aromatic and aliphatic 1,2-diamines with 5-chloro-1,2,3-thiadiazoles, *via* a multistep process which is thought to involve two Dimroth rearrangements and subsequent loss of hydrogen sulfide by intramolecular nucleophilic substitution.

Seven-membered rings fused with azoles are of special interest as biologically active compounds due to their structural similarity to benzodiazepine tranquilizers and to the aglycon of coformycin nucleoside antibiotics.[1] Despite a large number of papers devoted to various seven-membered heterocycles containing oxygen and nitrogen there are only a few dealing with sulfur containing compounds of this type.[2] We report here a very efficient synthesis of a novel ring system, ditriazolothiadiazepine.

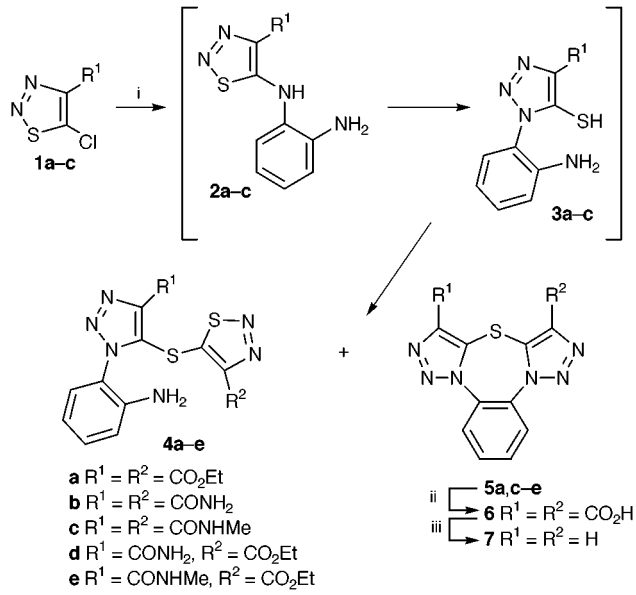
5-Halo-1,2,3-thiadiazoles, when substituted in the 4-position by an electron-withdrawing group, will on reaction with amines undergo a Dimroth rearrangement,[3] and the resulting 5-mercaptotriazoles can react with a second equivalent of thiadiazole to afford 5-(1,2,3-triazol-5-ylsulfanyl)-1,2,3-thiadiazoles.[4] We decided to apply this reaction to 5-chlorothiadiazole ester **1a** and 1,2-phenylenediamine (Scheme 1). We found the outcome of the reaction to be dependant on both reaction time and the presence of Et_3N catalyst. Without catalyst, the only product from the reaction of phenylenediamine and 2 equiv. of **1a** (EtOH, reflux) is the expected [2+1] adduct **4a**. In the presence of 1 equiv. of phenylenediamine, 2 equiv. of **1a** and 3 equiv. of Et_3N, a 2:1 mixture of **4a** and the unexpected bistriazolo[1,5-*b*;5′,1′-*f*][1,3,6]thiadiazepine derivative **5a** was isolated after 3 h reflux in EtOH. Prolonged heating of the reaction mixture gave **5a** as the sole product in 70% yield. Therefore it seemed logical to assume that sulfide **4a** was an intermediate in the formation of **5a**. This fact was confirmed by heating of isolated **4a** with Et_3N in EtOH, which also gave **5a**. The highly symmetrical structure of **5a** was immediately apparent from its ^1H and ^{13}C NMR spectroscopic data.[5]

On the other hand, the 5-chloro-1,2,3-thiadiazole amides **1b**,**c** gave only the sulfides **4b**,**c**, which did not transform to the corresponding fused thiadiazepines **5b**,**c**, even on prolonged heating in the presence of Et_3N. This behaviour is probably the result of the lower reactivity of the thiadiazole 5-carbon of **4b**,**c** towards intramolecular nucleophilic attack. The sulfides **4d**,**e** could be prepared from **2b**,**c** and **1a** in the presence of Et_3N, and cyclized to the unsymmetrically substituted thiadiazepines **5d**,**e**. The compounds **2b**,**c** were prepared from a 2:1 mixture of phenylenediamine and **1b**,**c** in DMF without the addition of Et_3N.

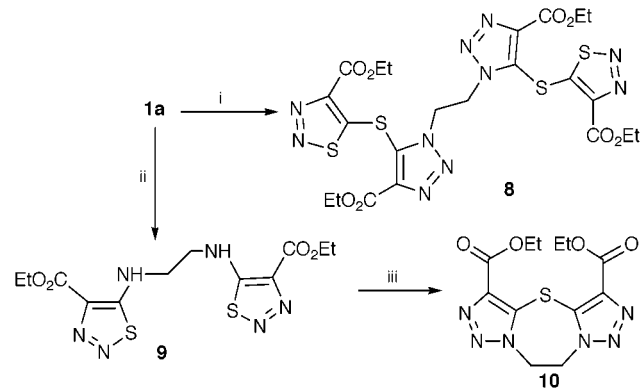
The parent ring system **7** could be prepared by saponification of diester **5a**, followed by the smooth decarboxylation of the diacid **6** by heating the melt at 180 °C. Again, the highly symmetrical structure is apparent from the ^1H and ^{13}C NMR spectroscopic data.[5] The bisamide **5c**, which is not accessible directly from phenylenediamine and **1c**, has been prepared in good yield from **5a** by condensation with excess $MeNH_2$.

The aliphatic 1,2-diaminoethane was reacted with chloroester **1a** (Scheme 2). Again, the outcome of the reaction was dependant on the reaction circumstances. Using the same conditions as above (Et_3N, EtOH, reflux) gave the [4+1] adduct **8** in 60% yield. On the other hand, the reaction of **1a** and ethylenediamine at reflux temperature in $CHCl_3$ gave the bisadduct **9**. Interestingly, **9** rearranged in EtOH with the formation of thiadiazepine **10** when refluxed in the presence of 3 equiv. of Et_3N.

From these results we can conclude that aliphatic amines are more reactive towards the chloroester **1a**. Moreover, the subsequent Dimroth rearrangement of **9** goes faster because the



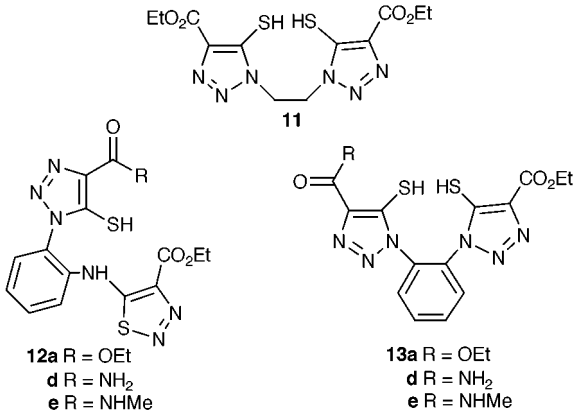
Scheme 1 *Reagents and conditions*: i, Et_3N, EtOH, reflux; ii, NaOH, then HCl; iii, 180 °C.



Scheme 2 *Reagents and conditions*: i, EtOH, $H_2NCH_2CH_2NH_2$, reflux; ii, $CHCl_3$, $H_2NCH_2CH_2NH_2$; iii, Et_3N, EtOH, reflux.

resulting *N*-alkyltriazole **11** is more stable than the corresponding *N*-aryltriazole **13**.[6]

We can argue that in both cases, either with aliphatic or aromatic amines, bisthiols of types **11** and **13** are formed, which



can react *via* an intra- or inter-molecular nucleophilic substitution. For ethylenediamine the bisthiol **11** is formed from **9** by two Dimroth reactions. For aryldiamines the Dimroth reaction of monoadducts **2a**–**c** takes place before the second substitution reaction, with the formation of thiols **3a**–**c**, which are not isolated but immediately react with a second equivalent of 5-chlorothiadiazoles **1a**–**c** to afford **4a**–**c**. Compounds **4d**,**e** are formed in a similar way from **1a** and **2b**,**c**. The 1,2,3-thiadiazole rings of **4a**,**d**,**e** are electron-poor enough to activate for intramolecular amine substitution, and thiols **12a**,**d**,**e** are formed, which undergo fast Dimroth rearrangement to dithiols **13a**,**d**,**e**. Finally, hydrogen sulfide is lost from dithiols **11** or **13a**,**d**,**e** by another intramolecular nucleophilic substitution, yielding thiadiazepines **10** or **5a**,**d**,**e**.

The intramolecular nucleophilic substitution of dithiol **11** is slower because of the more electron-rich and hence less reactive *N*-alkyltriazole, and will only occur if no intermolecular reactions with 5-chlorothiadiazole are possible, *e.g.* on isolated **9**. Otherwise, the [4+1] adduct **8** is obtained. Another, perhaps even more important reason why the intramolecular nucleophilic substitution of **11** is slow can be found in the larger degree of freedom of the flexible ethylene as compared to the rigid 1,2-phenylene group. Indeed, **11** is likely to exist mainly in a conformation with the two heterocyclic thiol groups widely separated.

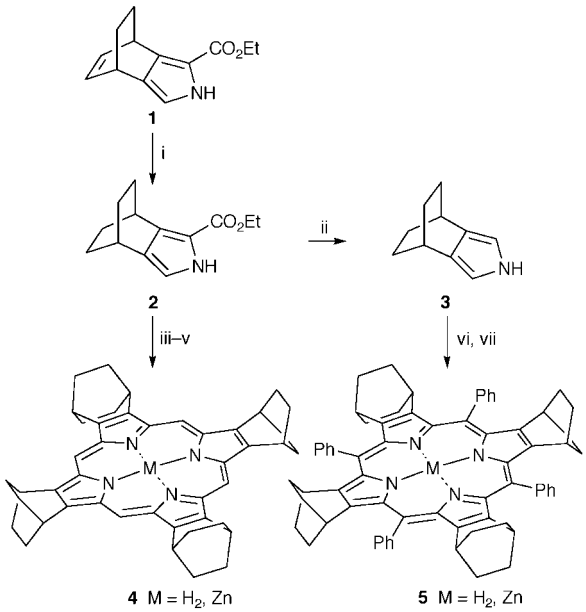
Received (in Cambridge, UK) 14th September 1999, Accepted 5th October 1999

Porphyrins fused with bicyclo[2.2.2]octene frameworks are prepared; the bicyclo[2.2.2] units rigidify the porphyrin ring to maintain planar conformations in solution.

In order to develop new functions and properties of porphyrins, variously substituted porphyrins have been extensively studied. For example, electron withdrawing groups,[1] electron donating groups[2] and sterically hindered groups[3] have been introduced into the porphyrin periphery to control the redox, spectroscopic and catalytic properties of metalloporphyrins. However, porphyrin rings are flexible enough to adopt various distorted conformations such as saddle, wave, ruffle and dome conformations depending the size of periphery substituents and the central metal.[3,4] Furthermore, π–π stacking of porphyrin rings also affects their conformations and electronic properties.[4] Here we report a new type of porphyrin which has a more rigid core than octaethylporphyrin (OEP) and *meso*-tetraphenylporphyrins (TPPS). Our new strategy to control the structure and properties of porphyrins is based on the annelation of porphyrins with bicyclo[2.2.2]octene frameworks, such as **4** and **5** in Scheme 1.† Bicycloannelation of annulenes has been extensively used to control the structure and electronic properties of various aromatic and non-aromatic compounds.[5] Thus, various annulenes fused with bicyclo[5.4.0]octene frameworks give stable oxidized products such as cation radicals and dications.[5] In a similar way, porphyrins fused with bicyclo[2.2.2]octene units are expected to have raised HOMO energies and conformationally rigid structures due to the presence of the fused frameworks.



Scheme 1 *Reagents and conditions*: i, H_2, Pd/C, EtOH, room temp., 8 h, 95%; ii,KOH,$HOCH_2CH_2OH$, 160 °C, 2 h, 79%; iii, $LiAlH_4$, THF, 0 °C, 2 h; iv, TsOH, $CHCl_3$, room temp., 12 h; v, *p*-chloranil, room temp., 12 h, 34% (3 steps); vi, PhCHO, $BF_3{\cdot}OEt_2$, $Zn(OAc)_2$, $CHCl_3$, room temp., 12 h; vii, *p*-chloranil, room temp., 3 h, 32% (2 steps).

The key pyrroles **2** and **3** were prepared from **1**[6] by hydrogenation and deethoxycarbonylation. Pyrrole **2** was converted into porphyrin **4** in about 30% yield by reduction with $LiAlH_4$ and the subsequent treatment with acid and oxidation. Porphyrin **5** was prepared by the reaction of **3** with benzaldehyde in the presence of $BF_3{\cdot}OEt_2$ and $Zn(OAc)_2$ and subsequent oxidation.

Theoretical calculations and experimental data on the effects of non-planarity indicate that the HOMO energy should be destabilized with respect to the LUMO energy, resulting in a red shift of the first visible absorption band.[1c] The chemical shifts of NH and the red-shifts of the electronic absorption correlate with deviation from planarity of the porphyrin ring.[3b] So the spectroscopic data of porphyrins **4**, **5** and their Zn complexes were compared with those of other related porphyrins, 2,3,7,8,12,13,17,18-octaethylporphyrin (OEP), 2,3,7,8,12,13,17,18-octamethoxyporphyrin (OMP), 5,10,15,20-tetraphenylporphyrin (TPP) and 2,3,7,8,12,13,17,18-octaethyl-5,10,15,20-tetraphenylporphyrin (OETPP). The electronic absorptions of **4** and Zn-**4** are blue shifted compared to the corresponding OEP and Zn-OEP, and such blue shifts are more enhanced in the Q (0,0) bands. The Q bands of **4** and Zn-**4** are at 610 and 558 nm, respectively, which are considerable blue-shifted compared to those of OEP (622 nm), Zn-OEP (569 nm), OMP (618 nm) and Zn-OMP (573 nm). The Q band of Ni-**4** is at 543 nm, which is also blue shifted compared to Ni-OEP (551 nm). Several factors are operative in the absorption spectra of porphyrins.[1–3] Recent studies show that the shifts of spectra originate from ring conformations and substituent effects.[1a,b] As the substituents of **4** and OEP consist of alkyl groups and have similar electronic properties, ring conformations should be the main factors controlling the blue shifts of **4**. The porphyrin cores are flexible and can adopt various conformations in solution. In fact, NiOEP, NiTPP, CuTPP and other related porphyrins are present as a mixture of both planar and nonplanar conformations in solution.[7] In particular, large deviations from planarity are observed in TTP derivatives.[7] Thus, the blue shifts of **4** and Zn-**4** shows quite clearly that they exist in planar conformations in solution. The ^{1}H NMR chemical shifts also support the planar conformation of **4**. The difference of the chemical shifts between the N-H and *meso*-H resonances of **4**, $\Delta\delta$ = 14.84 ppm, is larger than that of other porphyrins ($\Delta\delta$ of OEP is 13.92 and that of OMP is 14.47 ppm). The planar structure of **4** in solution leads to the large $\Delta\delta$ of **4**.[8]

Conformational distortions of porphyrin rings are enhanced by the introduction of substituents at the *meso* position. The introduction of alkyl, perfluoroalkyl, aryl and nitro groups at the *meso*-positions induces the distortion of porphyrin cores.[1,3] So, **5** and Zn-**5** were prepared, and their properties were compared with those of OETPP and Zn-OETPP. It is well-established that the red shift of absorptions observed for OETPP (686 nm) and Zn-OETPP (637 nm) is due to the non-planar distortions of their rings. On the other hand, the absorption λ_{max} values of **5** (665 nm) and Zn-**5** (551 nm) are not as red-shifted as OETPP and Zn-OETPP, when compared to those of TPP (645 nm) and Zn-TPP (552, 596 nm). The ^{1}H NMR chemical shift of NH in **5** appears

at $\delta -3.10$, whereas those of TPP and OETPP appear at $\delta -2.78$ and -2.0, respectively. These results indicate that **5** and Zn-**5** have planar conformations, while OETPP derivatives adopt nonplanar conformations in solution.

The stereochemistry of the porphyrin macrocycles has been studied extensively by X-ray diffraction. Porphyrin cores are very flexible and most porphyrins adopt nonplanar shapes in the solid state. The shapes are readily changed by periphery substituents, central metals and their axial ligands.[4] For example, Zn-OETPP adopts a saddle conformation,[3a] where a maximum displacement of 1.18 Å (for C_β) from the porphyrin mean plane is observed. The dihedral angles of the phenyl rings with the nitrogen plane are about 45–47°. The structure of Zn-**5**, as shown in Fig. 1,‡ is different from that of Zn-OETPP. The porphyrin ring is fairly planar, exhibiting a mean plane deviation of only 0.06 Å for from the 24 core atoms. The reported mean plane deviation of distorted porphyrins is about 0.3–0.5 Å depending on steric crowding and the size of the central metal.[4] The angles between the phenyl rings and the porphyrin plane of Zn-**5** are 89 and 78°. The structure of Zn-**5** is very close to that of nickel(II) *meso*-tetrakis(2,6-dichlorophenyl)-β-tetranitroporphyrin,[1d] where steric crowding between the phenyl and nitro groups is minmized by adopting a near planar conformation. Nonplanar distortions of OEP and TPP derivatives are derived from ring contraction about the central metal ion or from steric crowding about the porphyrin periphery. On the other hand, steric interactions in porphyrins **4** and **5** shoud be at a minimum in planar or near-planar conformatons, as steric interactions between the bicyclo[2.2.2]octene units are increased by adopting nonplanar conformations. Simple calculations also suggest the planar structure as the most stable conformer for **4** and **5**.

The oxidation potentials were determined by cyclic voltammetry (CV) for Zn-**4** and Zn-**5** in 0.1 M Bu_4NClO_4 in CH_2Cl_2. The CVs of other related porphyrins were also measured under the same conditions. Although the CVs of Zn-**4**, Zn-OEP and Zn-**5** showed two reversible peaks, the highly distorted Zn-OETPP gave only one peak. The first oxidation potentials of Zn-**4** and Zn-**5** were +0.38 and +0.26 V (*vs.* Ag/Ag^+, Fc/Fc^+ = +0.19 V), respectively. They are a little higher than those of Zn-OEP (+0.35 V) and Zn-OETPP (+0.22 V). The second oxidation potential of Zn-**4** (0.74 V) is also a little higher than that of Zn-OEP (+0.68 V). The second oxidation potential of Zn-**5** is 0.43 V, but the CV of Zn-OETPP gives one peak at $E_{1/2}$ = +0.22 V. It is reasonable to assume that the first and second oxidation of Zn-OETPP takes place at this potential. However, further studies are necessary to confirm this conclusion. Although the difference is very small, the HOMO energy levels of Zn-OEP and Zn-OETPP are a little higher than those of Zn-**4** and Zn-**5,** respectively. It is well-established that the distortion of nonplanarity on Zn-OETPP raises the HOMO enegy level.[3,4] The CV data suggest that the HOMO energy of Zn-OEP is also slightly raised by a contribution from nonplanar conformations of Zn-OEP in solution. As the LUMO energy levels are less sensitive to nonplanar distortion compared to the HOMO energy levels,[1] the energy difference between the HOMO and LUMO levels of **4** or Zn-**4** is larger than that of OEP or Zn-OEP. Thus, the absorption spectra of **4** and its metal complexes are blue shifted compared to OEP derivatives. It is noteworthy that the HOMO energy levels of porphyrin derivatives are sensitive to such small deviations from planarity of the porphyrin rings in cases such as OEP in solution. Considering the destabilization effect on the HOMO level of annulenes of the σ–π conjugation of fused bicyclo[2.2.2]octene units, which is general in the other macrocycles,[5] conformational distortions may be major factors in controlling the electronic properties of alkyl substituted porphyrins like **4** and OEP.

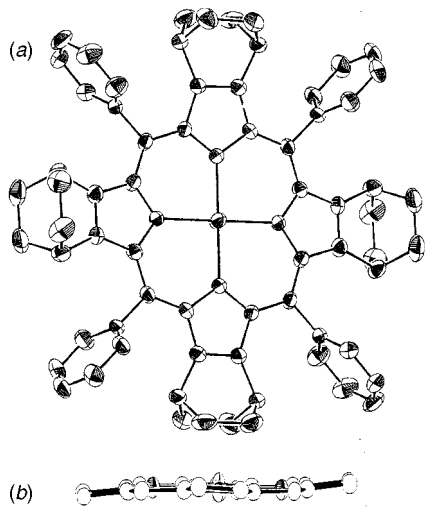


Fig. 1 (*a*) X-Ray crystal structure of Zn-**5**. Hydrogens and solvents are omitted for clarity. Average of bond distance (Å) and angles (°): N–C_α 1.383, Zn–N 2.067, C_α–C_β 1.454, C_β–C_β 1.351, C_α–C_m 1.403, C_m–C_ϕ 1.498; NZnN 90.0, $C_\alpha NC_\alpha$ 107.3, $ZnNC_\alpha$ 126.1, $NC_\alpha C_m$ 125.3, $NC_\alpha C_\beta$ 108.9, $C_\beta C_\alpha C_m$ 125.9, $C_\alpha C_m C_\alpha$ 121.9, $C_\alpha C_\beta C_\beta$ 107.5. (*b*) Edge-on view of Zn-**5** (substituent groups are omitted for clarity).

In conclusion bicyclo[2.2.2]octene frameworks are useful to rigidify porphyrin rings in order to maintain planar conformations in solution. Although planar porphyrins have problems of solubility due to π–π stacking, porphyrins fused with bicyclo[2.2.2]octene units have good solubility in various organic solvents such as CH_2Cl_2, benzene and THF. Thus, porphyrin **4** and its derivatives may be useful as standards for planar porphyrins in solution.

Department of Advanced Materials Science and Engineering, Faculty of Engineering, Yamaguchi University, 2-16-1 Tokiwadai, Ube 755-8611 Japan. E-mail: hi-khm@po.cc.yamaguchi-u.ac.jp

Received (in Cambridge, UK) 9th August 1999, Accepted 12th October 1999

Novel hydrogen storage Mg/G composites prepared by mechanical grinding of magnesium (Mg) and graphite carbon (G) with benzene have been found to incorporate new hydrogen-storing sites, other than those due to the magnesium component, and can take up hydrogen reversibly.

Much research effort has been concentrated on the storage of hydrogen in metals, for which magnesium metal and magnesium-containing alloys are considered promising candidate materials.[1] Recently, new carbon materials, *e.g.* carbon nanotubes [2] and graphite nanofibers,[3] have become of interest for possible use in hydrogen storage.

We have proposed the application of composites, prepared by mechanical grinding of magnesium (Mg) and graphite carbon (G) in the presence of organic additives (tetrahydrofuran, cyclohexane or benzene) using a planetary-type ball mill, as novel hydrogen storage materials.[4–7] In the mechanical grinding of magnesium and graphite for Mg/G composite formation, the presence of the organic additives is important in determining the characteristics of the resulting composites. Such organic compounds regulate the solid-phase reaction between magnesium and graphite carbon during grinding, leading to a strong influence on the composite structures and the hydriding–dehydriding properties of the magnesium component. The hydriding activity of these composites is much better than reported previously.[8] In this communication, we report experimental findings that new hydrogen-storing sites, other than those due to the magnesium component in the composites, are formed during grinding in the presence of benzene and that these sites reversibly take up hydrogen.

X-Ray diffraction (XRD) patterns revealed decomposition of the graphite component in the composites with grinding.[4–7] However, there was a great difference in the modes of degradation of the graphite structure between the Mg/G composites ground with and without the organic additives. Raman spectroscopy has proved that upon mechanical grinding, the structural degradation of graphite in the $(Mg/G)_{BN}$† composite predominantly occurs by cleavage along the graphite layers, while the graphite in $(Mg/G)_{none}$† is broken irregularly with no discernible order, leading to rapid amorphization.[7] In marked contrast to the graphite in $(Mg/G)_{none}$, only the cleavage-degraded graphite intimately interacted with finely divided magnesium with charge-transfer as evidenced by XPS, developing a synergism which leads to the enhanced hydrogen-storing properties.[7] These facts reflect differences in hydrogenation behaviour between $(Mg/G)_{BN}$ and $(Mg/G)_{none}$.

For various $(Mg/G)_{BN}$ samples previously exposed to hydrogen at 3 MPa, differential scanning calorimetry (DSC),‡ which was measured at a scanning rate of 5.0 K min^{-1} under a 0.1 MPa hydrogen atmosphere, showed characteristic endothermic peaks (Fig. 1). When pure magnesium powder was used for comparison, DSC indicated that the peak temperature of MgH_2 decomposition was 707 K, close to the results reported by Huot *et al.*[9] The DSC trace of $(Mg/G)_{none}$, ground without any additives, exhibited a broad endothermic peak at 668 K which was similarly assigned to the decomposition of MgH_2. It seems that magnesium particles with cracked irregular surfaces produced by the ball milling technique show improved hydriding–dehydriding kinetics.[10]

The mechanical grinding with benzene led to significant changes in DSC behaviour. A very important characteristic of the DSC traces for $(Mg/G)_{BN}$, prepared at varying grinding times (4–40 h), is that they indicate a series of transformations leading to the formation of composites during grinding. Mechanical grinding of $(Mg/G)_{BN}$ for 4 h led to a DSC peak at about 664 K [Fig. 1(a)]. As only magnesium hydride was identified in the XRD pattern of the sample, this endothermic peak was assigned to decomposition of the hydride. Upon grinding for 10 h or longer, new endothermic peaks, other than that due to the decomposition of MgH_2 appeared. The DSC traces, notably the numbers and temperatures of peaks, changed significantly with grinding. Grinding for 40 h resulted in the loss of all but one peak [Fig. 1(e)]. This was also found to be due to decomposition of MgH_2 by reference to the XRD pattern of the sample. For $(Mg/G)_{BN}$, the endothermic DSC peaks corresponding to decomposition of the magnesium hydride were obviously shifted to lower temperatures as the grinding times were prolonged. To clarify what causes the changes in the DSC traces, temperature programmed desorption (TPD) measurements for the same $(Mg/G)_{BN}$ samples were made *in vacuo* by continuously monitoring desorbed hydrogen *via* quadrupolar

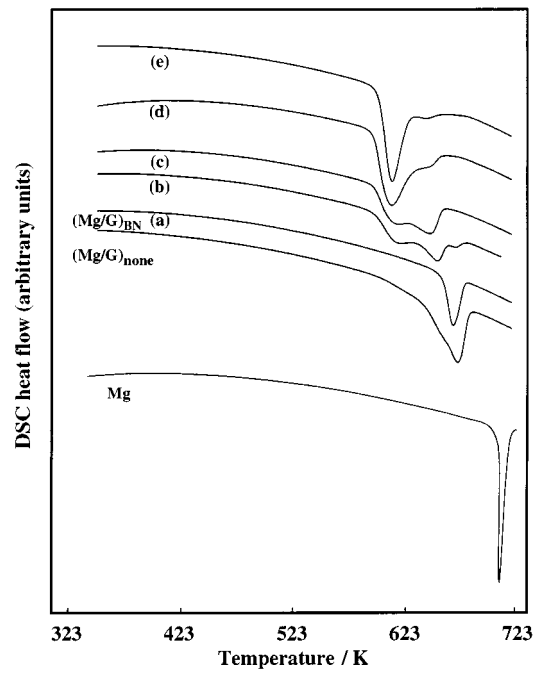

Fig. 1 DSC traces for various $(Mg/G)_{BN}$, $(Mg/G)_{none}$ and Mg samples. The $(Mg/G)_{BN}$ composites were prepared by grinding with benzene (8.0 cm^3) for (a) 4 h, (b) 10 h, (c) 20 h, (d) 30 h and (e) 40 h. $(Mg/G)_{none}$ was prepared by grinding without benzene for 15 h.

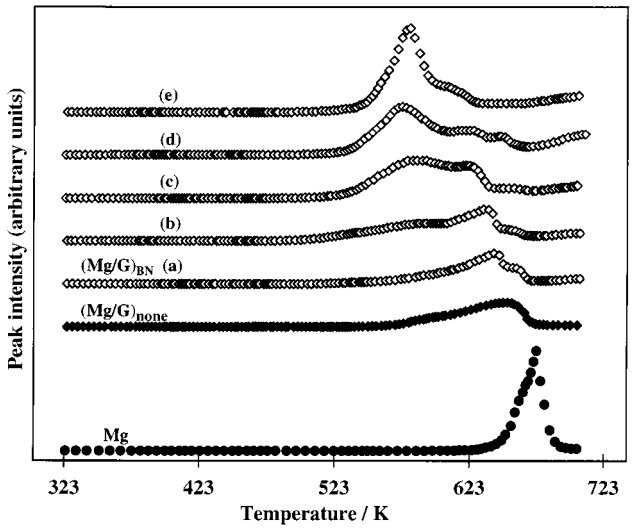

Fig. 2 TPD of various $(Mg/G)_{BN}$, $(Mg/G)_{none}$ and Mg samples. The $(Mg/G)_{BN}$ composites were prepared by grinding with benzene (8.0 cm^3) for (a) 4 h, (b) 10 h, (c) 20 h, (d) 30 h and (e) 40 h. $(Mg/G)_{none}$ was prepared by grinding without benzene for 15 h.

mass spectrometry. As shown in Fig. 2, the TPD results gave a good correspondence with the DSC measurements for each sample; both displayed similar peak shapes and approximately the same number of peaks. This proves that the newly emerged DSC peaks were derived from endothermically desorbed hydrogen. Further confirmation is provided by the fact that the DSC peaks of $(Mg/G)_{BN}$ prepared by grinding for 20 h are essentially reproducible in repeated scans of the same sample when pressurized under 3 MPa of hydrogen, followed by continuous heating from 350 to 700 K under a hydrogen pressure of 0.1 MPa, (Fig. 3).

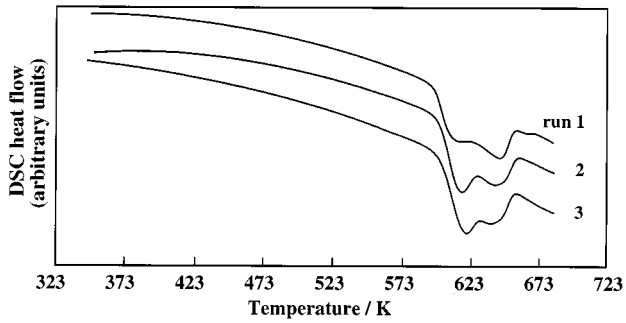

Fig. 3 Repeated DSC measurements (run 1–3) on $(Mg/G)_{BN}$, prepared by grinding with benzene (8.0 cm^3) for 20 h.

Another interesting feature of the hydrogen uptake by $(Mg/G)_{BN}$ is that the DSC traces were significantly dependent upon the pressure of hydrogen to which the sample had been exposed. For $(Mg/G)_{BN}$ ground for 20 h, exposure to hydrogen at pressures up to 0.5 MPa gave a single DSC peak only (Fig. 4), which was assigned to the decomposition of MgH_2. Upon exposure to hydrogen pressure of more than 0.7 MPa, new endothermic peaks other than that due to the decomposition of MgH_2 began to appear and increased with hydrogen pressure applied. These results give evidence that hydrogen storage by sites or phases other than those from the magnesium component simultaneously occurred, in which the pressure dependence of hydrogen uptake was observed. The proportion of additionally stored hydrogen can be roughly estimated from the DSC or TPD peak area; an approximate measurement corresponded to about 50% of the total hydrogen stored by $(Mg/G)_{BN}$ exposed to hydrogen at 3 MPa. The H_2 uptake discovered here is characterized by excellent reversibility and marked pressure dependence. However, there were no changes in the XRD patterns for variations in hydrogen pressure applied; only magnesium hydride was identified in the $(Mg/G)_{BN}$ composite.

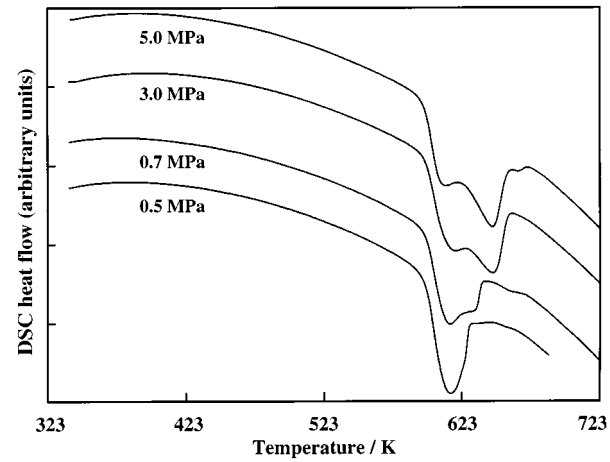

Fig. 4 Influence of hydrogen pressure applied to the sample on the DSC traces of $(Mg/G)_{BN}$, prepared by grinding with benzene (8.0 cm^3) for 20 h.

Exactly which sites in the composites store the additional hydrogen, or the method by which this occurs, is as yet unknown.

Pure graphite itself and graphite subjected to grinding did not take up hydrogen; neither showed any DSC response. $(Mg/G)_{none}$ did not show similar behaviour to that observed for $(Mg/G)_{BN}$. The most effective $(Mg/G)_{BN}$ composites are those in which there are synergic interactions between magnesium and graphite carbon as a result of mechanical grinding with benzene. The formation of Mg/G composites upon such grinding led to not only a drop in the onset temperature of MgH_2 decomposition, but the formation of additional hydrogen-storing sites in $(Mg/G)_{BN}$. However, as shown in Fig. 1(e) and 2(e), prolonged grinding led to detrimental effects on additional hydrogen uptake; the hydrogen-storing sites formed were decomposed. This is probably related to the extent of amorphization of the graphite component by excessive grinding.[7]

Notes and references

† Magnesium (99.95%; 100 mesh) and graphite (grade: SP-1) were used as obtained from Rare Metallic Co. Ltd. and Union Carbide Co., respectively. Benzene (BN) was purified by distillation in the presence of sodium wire. The preparation of Mg/G composites was carried out by mechanical grinding using a planetary-type ball mill (High G: BX 254; Kurimoto Ltd.), capable of operating under conditions of 150 G. Magnesium powder (4.2 g) and graphite (1.8 g) were placed in a stainless steel container (160 cm^3; lined with zirconia) with zirconia balls (3 mm in diameter; 238 g) under a dry nitrogen atmosphere. The mixtures were subjected to mechanical grinding with and without benzene (8.0 cm^3) for 4–40 h to yield the Mg/G composites, referred to here as $(Mg/G)_{BN}$ and $(Mg/G)_{none}$, respectively.
‡ DSC measurements were made on a TA Instruments 910S machine with a Thermal Analyst 2200 system.

Covalent self-assembly of a dimeric borazaaromatic macrocycle†

Paul J. Comina, Douglas Philp,* Benson M. Kariuki and Kenneth D. M. Harris

School of Chemistry, University of Birmingham, Edgbaston, Birmingham UK B15 2TT. E-mail: dphilp@bham.ac.uk

Received (in Liverpool, UK) 2nd August 1999, Accepted 4th October 1999

Bis(10-hydroxy-10,9-boraza-2-phenanthryl) ether is capable of covalent self-assembly upon dehydration in solution to form the corresponding cyclic dimer.

Self-assembly processes,[1] which allow the construction of large, highly ordered molecular or supramolecular arrays, directly and spontaneously, from simple constituents, are an important and developing[2] area of synthetic chemistry. Strict self-assembly[3] processes require that the pathways leading to the desired product must be completely reversible and that the target assembly should be stable at thermodynamic equilibrium. In addition, all of the information necessary to fabricate the target structure must be encoded within the constituent components of the assembly. Traditionally, these requirements have led to assembly pathways that rely upon non-covalent interactions, such as hydrogen bonding or metal–ligand coordination, to achieve the necessary molecular recognition and organisation. This approach, however, has one major disadvantage—the entropic cost of arranging the required constituents is only compensated for by the enthalpic contributions from relatively weak non-covalent interactions and, therefore, a significant number of these interactions are usually required for self-assembly to be successful. This problem can be overcome by exploiting systems in which the pathway leading to the formation of the target assembly makes use of covalent bonds.[4] The higher enthalpic gain as a result of covalent bond formation more than overcomes the entropic cost of organising[5] the components of the assembling structure and, hence, fewer covalent bonds are required to produce a stable assembly.

Here, we describe the use of a bis(borazaaromatic) in the covalent self-assembly of a dimeric macrocycle and the characterisation of this assembly process by ^{1}H NMR spectroscopy, X-ray diffraction and MALDI-TOF mass spectrometry. In order for covalent self-assembly to be successful, we reasoned that the information required to encode the target assembly must be described by the conformational space[4] accessible to the starting monomer. Hence, we identified the competition between the formation of discrete, cyclic structures and the formation of linear polymers from the same bifunctional monomer as an appropriate starting point for these studies. Accordingly, we designed and prepared the bis(borazaphenanthrene) **1** in five steps from Ph_2O. Compound **1** contains two boraza aromatic units connected by a phenyl ether oxygen atom which allows the two borazaphenanthrene rings to pivot with respect to each other. We have demonstrated[6] that hydroxyborazaaromatics can undergo reversible dehydration in solution to the corresponding anhydrides readily under appropriate conditions. Therefore, several dehydration reactions of **1** can be envisaged (Fig. 1). For example, dehydration may occur to afford a series of linear oligomers of varying chain lengths. In addition, ring closure of the linear oligomers could give rise to cyclic oligomers. In the simplest case, this would give rise to the dimeric anhydride **2** which can potentially exist in two isomeric forms—either face-to-face or helical (Fig. 1).

Compound **1** can be converted readily to the dimeric anhydride **2** in acetone solution, at room temperature, through dehydration by the addition of 4 Å molecular sieves. Conversely, **2** can be readily hydrolysed to give **1** in acetone solution by the addition of an excess (> 10 equiv.) of water. In order to assess the progress of the self-assembly process, a sample of **1** was dissolved in acetone and the evolution of the species present in solution, as a function of time, was monitored by MALDI-TOF mass spectrometry [Fig. 2(*a*)]. Initially, the cyclic dimer **2** and acyclic dimer $\mathbf{A}_2$ [Fig. 2(*a*), t = 0.5 h] are observed in solution. As the dehydration progresses, however, higher molecular weight species, such as the acyclic trimer $\mathbf{A}_3$ and tetramer $\mathbf{A}_4$ can be observed [Fig. 2(*a*), t = 7.5 h], in addition to the desired cyclic dimer **2**. After 4 days, the higher molecular weight species have diminished in concentration and after 12 days, the only oligomeric species present in solution is the cyclic dimer **2**. This behaviour can be rationalised in terms of the kinetic scheme shown in Fig. 2(*b*). The first species formed in the oligomerisation process must be the acyclic dimer $\mathbf{A}_2$. Cyclisation of this species to form the cyclic dimer **2** would be expected to be favourable[7] as it is intramolecular. However, if the effective molarity for this cyclisation[8] is not particularly high then the chain extension pathways, leading from $\mathbf{A}_2$ to $\mathbf{A}_3$ and beyond, will be able to compete to some extent with this cyclisation. This behaviour would explain the emergence of higher oligomers at intermediate time periods. Since the pathways leading to the acyclic oligomers $\mathbf{A}_n$ are reversible, all of the material in the reaction manifold will ultimately be recycled back through $\mathbf{A}_2$ and into the cyclic dimer **2**, which is clearly the thermodynamic product of this process. Hence, once the assembly process is complete, the only oligomeric species present in solution is the cyclic dimer **2**.

Single crystals‡ of **2**, suitable for X-ray diffraction, were grown by slow evaporation of a solution of **2** in acetone and hexane. In this structure, each molecule of **2** is present (Fig. 3) as the helical form§ shown schematically in Fig. 1 and the unit cell contains four pairs of enantiomers. The solid state structure contains channels, aligned parallel to the crystallographic *c* axis, which contain a number of disordered solvent molecules which

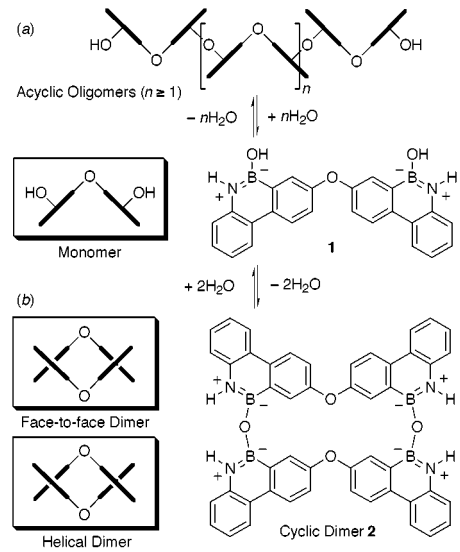

Fig. 1 Compound **1** can be dehydrated to give, for example: (*a*) linear oligomers with a distribution of chain lengths, and (*b*) a discrete cyclic dimer **2** which can adopt either a helical or a face-to-face conformation.

† These compounds have also been referred to as borazaroaromatic species in earlier papers.

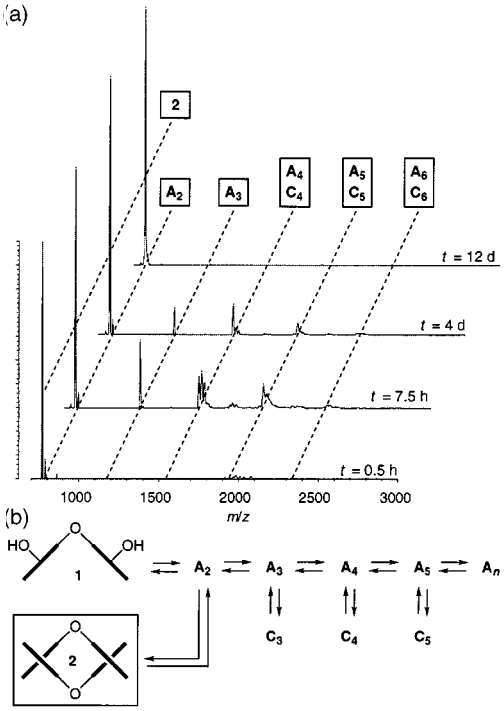

Fig. 2 (*a*) The evolution of the MALDI-TOF mass spectrum of a sample of **1** dissolved in acetone in the presence of 4 Å molecular sieves as a function of time. The elapsed time in this experiment is indicated to the right of each spectrum. (*b*) Proposed kinetic scheme for the equilibration of oligomers of **1**. The acronym $\mathbf{A}_n$ represents acyclic oligomers of **1** containing *n* repeat units and the acronym $\mathbf{C}_n$ represents cyclic oligomers of **1** containing *n* repeat units. Note that, for clarity, all spectra are scaled such that the *m/z* 772 peak, arising from **2**, is the base peak in all spectra. This scaling does not represent the true distribution of species after 0.5 h since the sample contains mostly monomer **1** at this time.

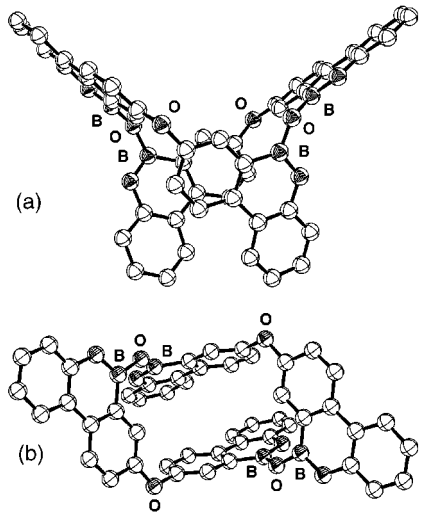

Fig. 3 ORTEP diagrams of the solid state structure of **2** as determined by X-ray diffraction. The molecule is shown in two orientations: (*a*) side view and (*b*) top view. Hydrogen atoms have been omitted for clarity.

are lost rapidly when the crystals are removed from the mother liquor. Examination¶ of these desolvated crystals by MALDI-TOF mass spectroscopy demonstrated that the crystals contained only the cyclic dimer **2**. The desolvated crystals were then heated at 150 °C for 3 h. Further analysis by MALDI-TOF mass spectroscopy demonstrated that, in addition to **1** and **2**, significant quantities of higher molecular weight materials were present. Surprisingly, only oligomers containing an even number of monomer units were observed. Whilst the origin of this selectivity and the mechanism of this process are, as yet, not understood, there are, however, suggestions that this behaviour may be intrinsic to monomer **1** and dimer **2**, and is simply an expression of the natural predispositions[4] of these compounds.

Closer examination of the assembly process in solution [Fig. 2(*a*)] reveals that in the case of the trimer ($\mathbf{A}_3/\mathbf{C}_3$) and pentamer ($\mathbf{A}_5/\mathbf{C}_5$), the acyclic species ($\mathbf{A}_3$ and $\mathbf{A}_5$) are strongly favoured. However, in the case of the tetramer ($\mathbf{A}_4/\mathbf{C}_4$) both the cyclic and acyclic species are formed, with $\mathbf{C}_4$ persisting in solution for a much longer period of time than $\mathbf{A}_4$.

In conclusion, we have demonstrated the utility of bis(boraza aromatic)s as building blocks for strict self-assembly mediated by covalent bond formation. The conformational space accessible to compound **1** successfully encodes for the exclusive formation of the cyclic dimer **2** upon dehydration. Logical extensions of this strategy, which allow the synthesis of more complex self-assembled systems, are currently under investigation in our laboratory.

We thank the Leverhulme Trust (Postdoctoral fellowship for P. J. C.), the EPSRC (Postdoctoral fellowship for B. M. K.) and the BBSRC (Grants 6/B03840 and 6/B04100) for financial support of this work.

Soc.*, 1999, **121**, 874.

3 Large, complex architectures can be constructed using strict self-assembly. The classical example is the Tobacco Mosaic Virus, see A. Klug, *Angew. Chem., Int. Ed. Engl.*, 1983, **22**, 565.

4 For other elegant examples of covalent self-assembly, see S. J. Rowan, P. A. Brady and J. K. M. Sanders, *Angew. Chem., Int. Ed. Engl.*, 1996, **35**, 2143; P. A. Brady and J. K. M. Sanders, *Chem. Soc. Rev.*, 1997, **26**, 327; S. J. Rowan, D. G. Hamilton, P. A. Brady and J. K. M. Sanders, *J. Am. Chem. Soc.*, 1997, **119**, 2578; S. J. Rowan and J. K. M. Sanders, *J. Org. Chem.*, 1998, **63**, 1536; S. J. Rowan, D. J. Reynolds and J. K. M. Sanders, *J. Org. Chem.*, 1999, **64**, 5804; J. Ipaktschi, R. Hosseinzadeh, P. Schlaf and E. Dreiseidler, *Helv. Chim. Acta*, 1998, **81**, 1821; J. Ipaktschi, R. Hosseinzadeh and P. Schlaf, *Angew. Chem., Int. Ed.*, 1999, **38**, 1658. Sanders uses the term predisposition to describe the encoding of a thermodynamically-favourable oligomeric structure through the conformational properties of the monomer once incorporated into this larger structure. In this language, the conformational space which is open to monomer **1** should predispose, or encode, the formation of a particular oligomer of **1**.

5 An example of this phenomenon, known as nucleation, can be seen in the assembly of oligonucleotides to form double helical structures which is essentially an all-or nothing process once a critical chain length is reached. Total synthesis of (±)-quinolizidine 207I, an alkaloid from *Mantella baroni*, a Madagascan mantelline frog

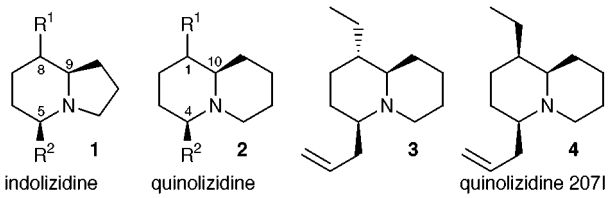
Patrick Michel and André Rassat

Département de Chimie, Ecole Normale Supérieure, 75231 Paris Cedex 05, France. E-mail: andre.rassat@ens.fr

Received (in Cambridge, UK) 8th September 1999, Accepted 4th October 1999

The first synthesis of quinolizidine 207I was achieved by a totally stereocontrolled approach starting from a 9-azabicyclo[3.3.1]nonane derivative, thus establishing the exceptional axial stereochemistry of the ethyl group at position 1.

Several alkaloids of the indolizidine **1** and quinolizidine **2** series have been isolated from the skin of certain poisonous frogs and



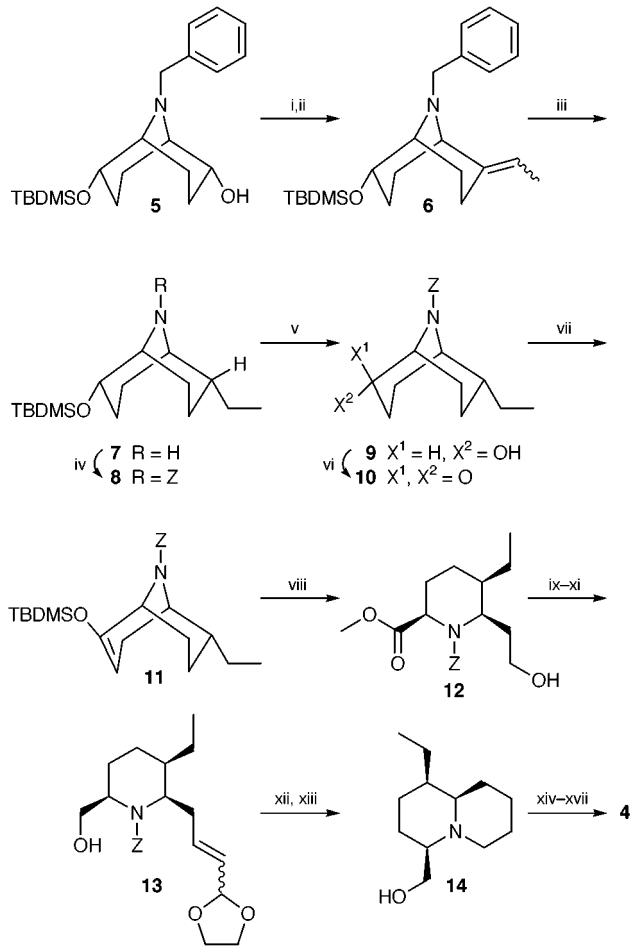
toads.[1] While the structures of the 5,8-disubstituted indolizidines are well-known and have in some cases been confirmed by synthesis,[2] the 1,4-disubstituted quinolizidine are a relatively new class of alkaloids. They have been isolated in minute quantities, and their structure determined mainly on the basis of GC-FTIR and GC-MS: the presence of significant Bohlmann bands[3] in the FTIR spectra shows that the hydrogens at position 4 and 10 are *cis*, but does not provide any information on the relative configuration at position 1, which is only tentative and must be confirmed by synthesis.

One of these alkaloids, quinolizidine 207I, was assigned structure **3** for which a total synthesis was reported in 1997 by Momose and co-workers.[4] However the synthetic material was found to be different from the natural one. Quinolizidine 207I was then reassigned the epimeric structure **4**, the first example of a 1,4-disubstituted quinolizidine with an axial 1-substituent.

We report herein the first synthesis of (±)-**4** (Scheme 1). In this totally stereocontrolled approach, the three asymmetric centres were introduced at an early stage by the use of a *pseudo*-pelletierine derivative **5**. Furthermore, this synthesis is formally enantioselective: because of the C_2 symmetry of the diol precursor of this synthon, it may safely be expected that the enantiomers of this diol as well as all the intermediates obtained in this synthesis will not undergo racemization at any point.

We have recently developed a facile access[5] to this new molecule from cycloocta-1,5-diene by modification of Ganter's approach to related systems.[6] Swern oxidation of **5** followed by a Wittig reaction afforded **6** in 90% yield, as a 1/9 mixture of *Z* and *E* isomers. Although easily separated by column chromatography, this mixture was directly hydrogenated in MeOH with 10% palladium on (wet) charcoal to give the debenzylated amine **7** as a single epimer, of *endo* stereochemistry, as will be proved at the quinolizidine stage. The amine was then protected with BnO_2CCl and the alcohol function liberated with HF to give **9** (82% yield from **6**). In order to open the bicyclic skeleton, this alcohol was oxidised (Swern) and converted to the silyl enol ether **11**. Treatment with O_3 gave the piperidine **12** after reduction and esterification (52% from **9**). Two carbons were added to the alcoholic chain by classical methods, and **13** was obtained (72% from **12**) as a mixture of isomers, after reduction of the methyl ester with Super-Hydride®. After hydrolysis of the dioxolane, hydrogenation with Pd/C removed the carbamate function and at the same time reduced both the double bond and the intermediate imine to yield **14** (69% from **13**). At this stage, the axial stereochemistry of the ethyl side-chain was determined from the coupling constant of the protons at positions 1 and 10, thus establishing the *endo* stereochemistry of this substituent in **7**. Target molecule **4**[7] was then obtained in 25% yield from **14** through two Wittig reactions. The total yield from **5** for this 17-step synthesis is 6.8%.

A sample of this molecule has been analysed at NIH-NIDDK: it had an FTIR spectrum identical in all respects with the natural product and it co-chromatographed with it on the achiral GC column that had produced the best separations in this series.



Scheme 1 *Reagents and conditions*: i, Swern oxidation (93%); ii, Ph_3EtPBr, Bu^tOK, THF (98%); iii, H_2, Pd/C 10% (wet), MeOH; iv, ZCl, K_2CO_3, acetone; v, HF 40%, MeCN (82% in 3 septs); vi, Swern oxidation (81%); vii, KH, THF, TBDMSCl (88%); viii, O_3, MeOH–CH_2Cl_2, then $NaBH_4$, then CH_2N_2 (71%); ix, Swern oxidation (81%); x, [$Ph_3PCH_2CH(OCH_2CH_2O)$] Br, Bu^tOK, THF (95%); xi, Super-Hydride®, THF, 0 °C (94%); xii, THF, HCl (1.2 M) (89%); xiii, H_2, Pd/C 10%, MeOH–H_2O (78%); xiv Swern oxidation (75%); xv, ($Ph_3PCH_2OCH_3$)Cl, Bu^tOK, THF (83%); xvi, THF, HCl (4 M); xvii, Ph_3MePBr, Bu^tOK, THF (41% in 2 steps).

Furthermore, the synthetic racemate can be separated on a chiral column, and the natural compound co-chromatographed with one of the synthetic enantiomers.

Because this synthesis is totally stereocontrolled, it establishes the relative configuration of the three epimeric centres: structure **4** can thus definitely be assigned to natural quinolizidine 207I. Since, as said before, this synthesis is formally enantioselective, resolution of an intermediate at an early stage should determine the absolute configuration of the natural product. Work along these lines is in progress.

The strategy used here is general and may provide an easy access not only to other natural (R^1 = Me or Pr) or unnatural quinolizidines **2**, but also to similar natural (R^1 = Me, Et or Pr) or unnatural indolizidines **1**. Syntheses following this approach should make possible a systematic exploration of the unknown pharmacological properties of these two series.

We thank Drs Thomas Spande and John Daly (National Institutes of Health) for providing us with the results of comparisons of our synthetic quinolizidine 207I with the natural alkaloid by GC-FTIR and chiral GC.

Received (in Oxford, UK) 6th September 1999, Accepted 4th October 1999

The sol-gel process has been used to prepare new organic–inorganic hybrid materials with various textures from cyclam derivatives bearing four hydrolysable SiX_3 groups (X = OEt, H) as well as from the corresponding Cu^{II} and Co^{II} complexes of the cyclam derivative (X = OEt).

It is a challenge to prepare materials able to incorporate strongly chelated metal cations which remain chemically accessible. In order to do that, it is necessary to include a good chelating ligand within the solid and to control the texture as well as the structure of the material. Since saturated polyazamacrocycles and especially 1,4,8,11-tetraazacyclotetradecane (cyclam) have long been known for their remarkable binding ability towards transition metal cations,[1,2] we set out to incorporate cyclam units within silica matrices by using the sol-gel process. Indeed the hydrolysis and polycondensation of molecular precursors substituted by more than one hydrolysable groups such as $Si(OR)_3$ allow the preparation of nanostructured hybrid materials.[3–6] This new class of monophasic materials constitutes an expanding area of research in materials science. In this way, the silica matrix is built around the organic moiety during the hydrolytic polycondensation. Silica gel was recently used for the immobilization of polyazacycloalkanes including cyclam, by using a grafting process.[7] However, though this method of attachment of organic groups at the silica surface produced highly effective adsorbents[8,9] and catalysts,[10,11] it presents some drawbacks especially as the loading of the macrocycles is often low (< 0.4 mmol g^{-1}) and is uncontrolled.

Nanocomposite materials incorporating tetraazamacrocycles within silica matrices have been made[12] by the sol-gel process. Here we report the first preparation of monophasic hybrid materials with various textures obtained from isolated cyclam derivatives bearing four hydrolysable SiX_3 groups (X = OEt, H). The hydrolysis of the Cu^{II} and Co^{II} complexes of the cyclam derivative (X = OEt) is also described.

Tetrasilylated cyclam derivative **1** was prepared by reaction of 4 equiv. of 3-iodopropyltriethoxysilane with cyclam under basic conditions;† the corresponding hydrosilylated derivative **2** was obtained by $LiAlH_4$ reduction of **1**.[13] Complexation of Cu^{2+} and Co^{2+} by the tetrasilylated macrocycle **1** was performed in the presence of 1 equiv. of $CuCl_2$ or $CoCl_2$ in THF heated under reflux to afford respectively the complexes **3a** and **3b** in high yield [eqn. (1)]. Sol-gel polycondensation of **1**, **2**, **3a** and **3b** was achieved in the presence of a stoichiometric amount of water (6 equiv.) and under different experimental conditions to yield respectively xerogels **X1a–e**, **X2** and **X3a–b** (Table 1). All the gels were allowed to age for five days at room temperature before being powdered, washed twice with EtOH followed by Et_2O, and finally dried (120 °C at 20 mm Hg for 12 h). It is important to note that after this processing, metal cations were quantitatively retained within the xerogels (measured by elemental analysis and X-ray fluorescence). We had previously observed that 95% of Na^+ and 96% of K^+ was retained within the xerogels obtained by hydrolysis and polycondensation of Na^+ or K^+ complexes of bisilylated dibenzo-18-crown-6.[14] The solid state ^{13}C NMR spectra of the xerogels displayed the

signals which characterise the cyclam moieties. Solid state ^{29}Si NMR spectroscopy showed that there was no Si–C bond cleavage during the sol-gel process (absence of any signal corresponding to SiO_4 substructures). All the ^{29}Si NMR spectra display one major resonance centred at δ −65 (substructure T^3 [C–Si(OSi)$_3$]) except for **X1a** and **X1c** which were not well condensed (major substructure T^0 [C-Si(OR)$_3$]). The BET surface areas of the xerogels were determined by N_2 adsorption–desorption measurements and the average pore diameter by the BJH method.[15]

Overall the results reported in Table 1 show that it is possible to obtain materials with various textures by changing the experimental conditions of gelification. The following parameters appear to be of importance.

(1) *Nature of the hydrolysable SiX_3 group* (entries 1 and 6): in the absence of catalyst, the hydrosilane **2** was much more readily hydrolyzed than the corresponding alkoxysilane **1**. Thus, gel formation of **2** took less than 1 min at 0 °C giving rise to the mesoporous xerogel **X2** while that of **1** occurred within 36 h affording the non-porous xerogel **X1a**.

(2) *Nature of the catalyst* (entries 1, 2 and 4): hydrolysis and polycondensation of **1** without catalyst, or in presence of base, yielded respectively the non-porous xerogels **X1a** and **X1b** while hydrolysis of **1** in the presence of 1% TBAF afforded the essentially microporous xerogel **X1d** with a rather large surface area.

(3) *Effect of solvent and of the concentration of the precursor*: all the results reported in Table 1 have been obtained using molar solutions of precursor. We observed that increasing the concentration of the precursor up to 3 M affected neither the specific area nor the pore diameter. In contrast, the nature of the solvent is of importance. Thus, running the hydrolysis in EtOH, THF or CH_2Cl_2 did not change significantly the material, while using formamide as the solvent yielded a material without specific surface area (compare entries 3 and 4).

(4) *Effect of the temperature*: if we compare the results of entries 4 and 5, it is clear that both the surface area and the porosity are strongly dependent on the temperature. The higher the temperature, the larger the surface area and the average pore diameters. The difference between the textures of the xerogels X**1d** and X**1e** appears clearly in Figs. 1 and 2. The adsorption isotherm of **X1d** is typical of a microporous solid [type I of BDDT classification,[15] Fig. 1(*a*)] while that of **X1e** shows a type IV isotherm, characteristic for mesoporous materials [Fig. 1(*b*)]. It is also to be noted that the pore distribution in **X1e** is rather narrow [Fig.2(*b*)], which is not the case for the microporous solid **X1d** [Fig. 2(*a*)]. Another interesting feature of these materials is that they contain up to 1.4 mmol of cyclam per gram of solid (based on nitrogen elemental analyses), which is notably more than the silica gel-supported cyclam.[7]

We have described the preparation of monophasic hybrid materials with various textures from well defined cyclam precursors bearing four hydrolysable SiX_3 groups (X = OEt, H). These materials are fundamentally different from those previously described including cyclam units[7,12] due to the mode of their preparation. We have also shown that the complexation of metal cations by **1** survives the sol-gel process which indicates that, in spite of the high degree of condensation of the network observed in most of the cases, the tetraazamacrocycle is flexible enough to maintain the complexation during the polycondensation. The study of the binding properties of this new class of materials is currently in progress.

A di-iron dithiolate possessing structural elements of the carbonyl/cyanide sub-site of the H-centre of Fe-only hydrogenase

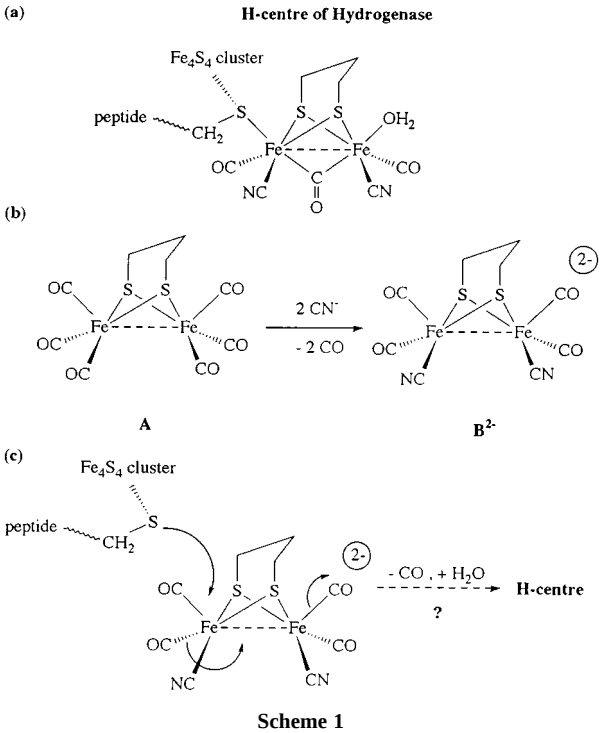
Received (in Cambridge, UK) 5th August 1999, Accepted 1st October 1999

The synthesis and characterisation of the first {2Fe2S}-cluster bearing both CO and CN ligands is described; the iron atoms are linked by the bridging 1,3-propanedithiolate unit that has been identified in the crystallographic structure of the {2Fe2S} sub-unit of the H-centre of the all-iron hydrogenase from *Desulfovibrio desulfuricans*.

Two recent X-ray crystallographic structures of Fe-only hydrogenases isolated from *Desulfovibrio desulfuricans*[1] and *Clostridium pasteurianum*[2] show that the H-centre, the active site at which protons are reduced to dihydrogen, is comprised of a conventional {4Fe4S}-cluster linked by a bridging cysteinyl ligand to an extraordinary 'organometallic' di-iron sub-site. The combined structural data, taken together with FTIR data obtained for the Fe-only hydrogenase from *Desulfovibrio vulgaris*,[3] strongly suggest that the sub-site is ligated by terminal CO and CN molecules with the two iron atoms linked by a 1,3-propanedithiolate ligand and bridged by a carbonyl group; the *exo* Fe atom is either coordinatively unsaturated[1] or is ligated with a water molecule[2] [Scheme 1(a)].

We now report the synthesis and characterisation of the first dinuclear iron–sulfur complex with both CO and CN ligation at the iron atoms. Importantly, this dianion also possesses the bridging propanedithiolate structural motif identified in the higher resolution protein X-ray structure.[1]

The known di-iron complex $[(CO)_3FeSCH_2CH_2CH_2S\text{-}Fe(CO)_3]$ **A**[4] reacts with 2 equivalents of NEt_4CN in MeCN at room temperature to give the dianionic salt $[NEt_4]_2[(CO)_2(NC)FeSCH_2CH_2CH_2SFe(CN)(CO)_2]$, $\{[NEt_4]_2\mathbf{B}\}$, essentially quantitatively. $[NEt_4]_2\mathbf{B}$ was isolated as an orange, air-sensitive, crystalline material [Scheme 1(b)].



Scheme 1

^1H, $^{13}C\{^1H\}$ NMR and Mössbauer spectroscopy are consistent with the formulation of $[NEt_4]_2\mathbf{B}$ and indicate an arrangement in the dianion with two CO ligands and one CN ligand at each Fe centre. The Mössbauer spectrum displays a well defined doublet with isomer shift and quadrupole splitting parameters similar to those of the parent hexacarbonyl and related molecules with sulfur bridging two metal–metal bonded Fe^I atoms.† FTIR spectra (NEt_4^+ salt, MeCN solution) show ν(CO) 1964s 1922s 1885s and 1871sh cm^{-1} with ν(CN) at 2075m cm^{-1}. The ^{13}CN-labelled salt [18-crown-6·K]$_2$**B** shows $\nu(^{13}CN)$ at 2031 cm^{-1}; the shift in frequency of 44 cm^{-1} from that of the ^{12}CN complex is close to that theoretically expected (43 cm^{-1}). The ν(CO) stretches are not shifted in the labelled complex, this shows that the CN oscillator(s) is not coupled with CO. In addition, the solution FTIR spectrum of the mixed labelled complex shows no additional absorptions which would be indicative of coupling between the two CN ligands.

X-Ray crystallographic analysis of an incomplete, low-angle diffraction data-set confirms the skeletal arrangement of the dianion $\mathbf{B}^{2-}$, *viz.* two iron atoms bridged by the 1,3-propanedithiolate ligand, with dimensions very close to those observed for the sub-unit in the enzyme,[1] and three further ligands (CO/CN) attached to each Fe atom.‡

Normal coordinate analysis, using a Cotton–Kraihanzel force field,[6,7] of the CO IR data shows that the pattern of ν(CO) bands is consistent with the dianion possessing pseudo-C_s symmetry with eclipsed CN ligands as represented in Scheme 1(b).

Given the general robustness of $\{Fe_2S_2(CO)_6\}$ units, it is somewhat surprising that substitution occurs under such mild conditions.[5] The reaction is not confined to **A** but occurs with other dithiolate-bridged di-iron hexacarbonyl clusters, for example, we have synthesised and characterised the bridge-functionalised complex $[NEt_4]_2[(CO)_2(NC)FeSCH_2CH(CH_2OH)SFe(CN)(CO)_2]$, $\{[NEt_4]_2\mathbf{C}\}$ from the corresponding hexacarbonyl precursor.†

Primary (irreversible) reduction of the dianion $\mathbf{B}^{2-}$ occurs at $E_p^{red} = -2.33$ V *vs.* SCE and primary (irreversible) oxidation occurs at $E_p^{ox} = -0.11$ V *vs.* SCE {recorded in MeCN–0.1 M NBu_4BF_4 at vitreous carbon, 100 mV s^{-1}, room temp.}. $\mathbf{B}^{2-}$ is both stable and *very* soluble in water as the $[NEt_4]^+$ salt, although it neither reacts with nor electrocatalyses the reduction of protons in aqueous solution over the pH range 8.4–4.0. Why $\mathbf{B}^{2-}$ does not effect the reduction of protons, whereas the sub-unit of the H-centre does so, is probably linked to the relative electron-richness of the 2Fe2S units. With respect to the synthetic cluster, the enzyme sub-unit has a bridging cysteinyl group formally displacing an electron-withdrawing terminal CO ligand into a bridging mode and also a CO ligand formally replaced by a donor water molecule [Scheme 1(c)]. We thus predict that the enzymic sub-unit would be oxidised at a potential substantially negative of that of $\mathbf{B}^{2-}$ and sufficient to

drive proton reduction at modest pH. That $\mathbf{B}^{2-}$ is both highly water soluble and stable over a wide range of pH suggests that it could be involved in the cellular biosynthesis of the H-centre [Scheme 1(c)].

We thank Elaine Barclay for recording Mössbauer spectra. This work was supported by the BBSRC, the France–UK Alliance Programme, and the Ministère de l'Enseignement Supérieur et de la Recherche.

Note added in proof: We thank Professor J. W. Peters for a pre-print of an X-ray crystallographic study of the CO inhibited form of the Fe hydrogenase from *C. pasteurianum*. This shows CO replaces coordinated H_2O at the distal iron atom of the H-centre 2Fe2S sub-unit *cf.* the inability of $\mathbf{B}^{2-}$ to catalyse proton reduction.

‡ The overall geometry of the anion is well established. The Fe_2(dithiolate) core is well resolved and shows reasonable molecular dimensions, *e.g.* the four Fe–S bonds lie in the range 2.251(17)–2.318(17) Å, mean 2.276(14) Å, and the Fe–Fe distance is 2.528(11) Å. The two S–C bond lengths are 1.87(5) and 1.84(5) Å and the bridging C–C lengths are each 1.60(6) Å. Each iron is five coordinate with a square pyramidal geometry (octahedral coordination completed by a bent Fe–Fe bond[5]).

Cation-controlled formation of $[\{MCl_4\}_n]^{2n-}$ chains in [4,4′-H_2bipy][MCl_4] (M = Mn, Cd): an alternative to the A_2MCl_4 <100> layer perovskite structure†

Amy L. Gillon,[a] A. Guy Orpen,*[a] Jonathan Starbuck,[a] Xi-Meng Wang,[a] Yolanda Rodríguez-Martín[b] and Catalina Ruiz-Pérez[b]

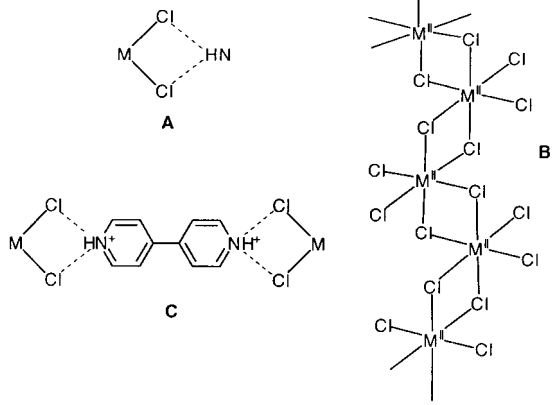
Received (in Oxford, UK) 20th September 1999, Accepted 6th October 1999

The *cis*-$MCl_2\cdots HN^+$ chelated hydrogen bond synthon has been exploited in preparation of crystalline [4,4′-H_2bipy][MCl_4] (M = Mn 2 and Cd 3), which shows a one-dimensional substructure of the form $[\{MCl_4\}_n]^{2n-}$ consisting of a kinked chain of doubly edge sharing MCl_6 octahedra. These chains are cross-linked by hydrogen bonding to the [4,4′-H_2bipy]$^{2+}$ ions.

The <100> layer perovskites A_2MX_4 (A = ammonium cation NH_3R^+ or A_2 = $NH_3(CH_2)_nNH_3^{2+}$, *etc.*; M = Cr^{II}, Mn^{II}, Cu^{II}, Cd^{II}, Pb^{II}, *etc.*; X = Cl or other halide) have attracted sustained interest because of their magnetic, electronic and other physical properties and the possibility of tuning both geometry and properties by variation of the organic cation.[1] The hydrogen bond donor properties of the ammonium ions serve to promote the formation of two-dimensional $[\{MCl_4\}_n]^{2n-}$ sheets, whose structure may be formally derived from that of cubic perovskite. We have previously shown that the *cis*-$MCl_2\cdots HN^+$ supramolecular synthon **A** may be used to construct a hydrogen bonded



polymeric ribbon structure $\{[4,4'\text{-}H_2bipy][MCl_4]\}_n$ for M = Pt[2] while an hydrogen bonded dimeric ring motif is formed for M = Co.[3] Here, we show that a third family of structures exists of stoichiometry [4,4′-H_2bipy][MCl_4] in which the tetrachlorometallate anions polymerise to form a one-dimensional chain. This form contrasts both with the two other structure types and with the layer perovskite structures seen for primary ammonium salts of the same dianions.

In exploring the range of metals for which [4,4′-H_2bipy]$^{2+}$ salts of $[MCl_4]^{2-}$ ions form the dimeric ring structure we obtained crystals of [4,4′-H_2bipy][MCl_4] (M = Zn **1** and Mn **2**) by routes in which the metal halides were crystallised from aqueous solution in the presence of 4,4′-bipyridinium and chloride ions.‡ The zinc species§ is isostructural (Fig. 1) with its cobalt analogue and shows NH···Cl hydrogen bonds of length 2.30 and 2.63 Å.[3] The manganese species has a quite different structure (Fig. 2) in which the metals are octahedrally coordinated and the $MnCl_6$ octahedra are linked into kinked chains (as in the $ZrCl_4$ structure **B**[4]) which extend along the crystallographic *c* axis. The $[\{MCl_4\}_n]^{2n-}$ chains are linked by NH···Cl hydrogen bonding to [4,4′-H_2bipy]$^{2+}$ into neutral sheets lying parallel to the *ac* plane. In these sheets synthon **A** is used at both ends of the dication (see **C** and Fig. 2). The neutral layers then pack along the *b* axis to form the overall

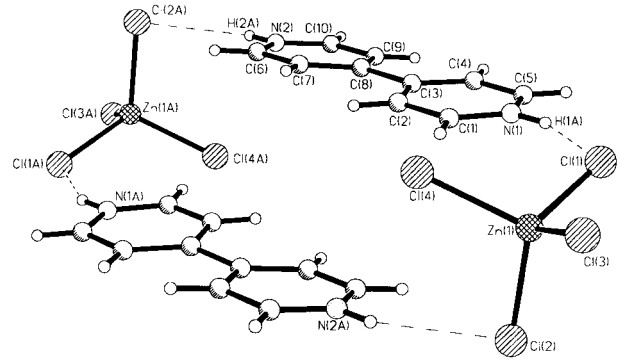


Fig. 1 Structure of the hydrogen bonded dimeric ring in [4,4′-H_2bipy]-[$ZnCl_4$] **1**. The NH···Cl hydrogen bonds are indicated. Important bond lengths (Å): Zn(1)–Cl(1) 2.2934(7), Zn(1)–Cl(2) 2.2977(8), Zn(1)–Cl(3) 2.2526(7), Zn(1)–Cl(4) 2.2546(7).

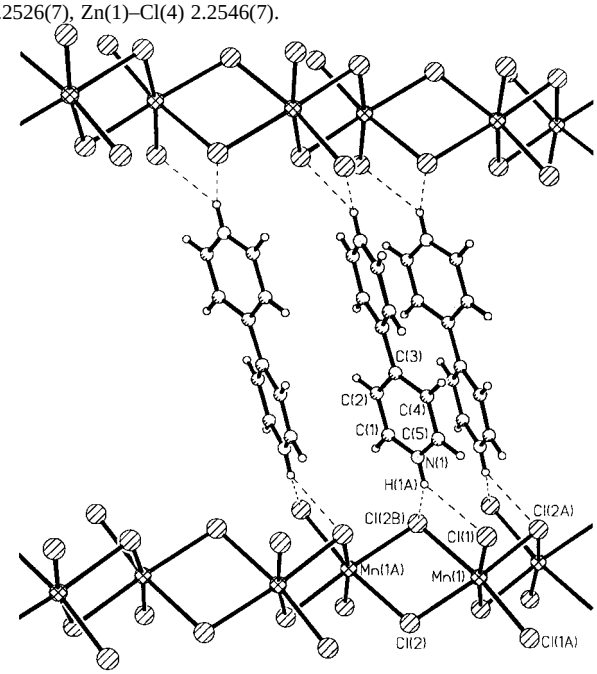

Fig. 2 Structure of a layer of [$MnCl_4$] chains cross-linked by [4,4′-H_2bipy] in crystalline [4,4′-H_2bipy][$MnCl_4$] **2**. The NH···Cl hydrogen bonds are indicated. Important bond lengths (Å): Mn(1)–Cl(1) 2.4904(6) [2.5733(8)], Mn(1)–Cl(2) 2.6294(6) [2.7031(7)], Mn(1)–Cl(2A) 2.5946(7) [2.6672(8)]. Values in square brackets are for the isostructural [4,4′-H_2bipy][$CdCl_4$] **3**.

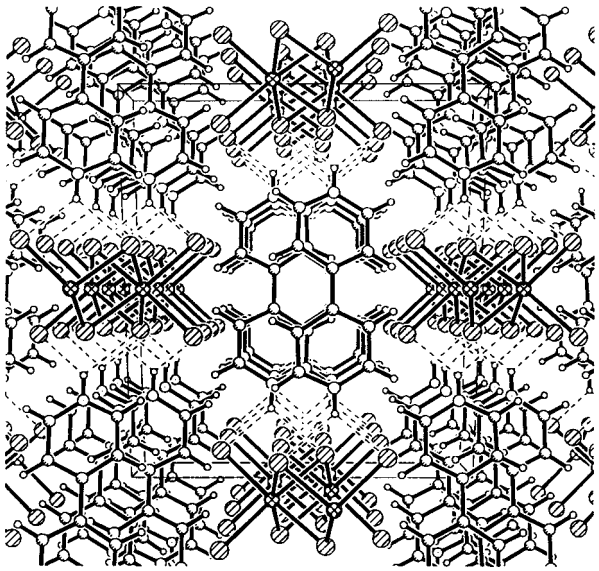

Fig. 3 The crystal structure of [4,4′-H_2bipy][$MnCl_4$] **2** viewed along the *c* axis, parallel to the metal chains. The NH···Cl hydrogen bonds are indicated.

structure (Fig. 3). There is very weak intrachain antiferromagnetic coupling of the paramagnetic Mn^{II} centres with negligible interchain coupling (Mn···Mn distances along the chain are 4.011 Å).¶

Despite the wide variety of cations for which $[MnCl_4]^{2-}$ salts have been structurally characterised, only two structure types have been observed: tetrahedral $[MnCl_4]^{2-}$ units or sheets of corner sharing $\{MnCl_6\}$ octahedra in a <100> layer perovskite structure. As such these $[MnCl_4]^{2-}$ salts are representative of a much larger set of salts of tetrahalometallate dianions of the transition and post-transition metals.[1] For example, of 24 $[CdCl_4]^{2-}$ salts in the Cambridge Structural Database[5] all bar one[6] (which has a chain structure of corner linked trigonal bipyramidal $CdCl_5$ units) also show only isolated tetrahedral (10 examples) or <100> layer perovskite structures (13 examples). In organic–inorganic layer perovskites it is generally thought that the hydrogen bonding capability of the organic (primary ammonium) cations promotes the observed structures. Indeed in general, in these structures each NH_3 makes three strong NH···Cl hydrogen bonds. We reasoned that the different hydrogen bonding capabilities of the [4,4′-H_2bipy]$^{2+}$ cation might provide a general route to the new chain structure type for those metals which are readily able to form octahedral $\{MCl_6\}$ moieties in their +II oxidation state. Given the behaviour of the $[CdCl_4]^{2-}$ salts noted above, cadmium was chosen as a representative example. Treatment of aqueous cadmium chloride with [4,4′-H_2bipy]$^{2+}$ does indeed lead to formation of a salt [4,4′-H_2bipy][$CdCl_4$] **3** in which the new structure type is adopted.‡ Compound **3** is isostructural with its manganese analogue.§ As in **2** synthon **A** is present [NH···Cl 2.54 and 2.60 Å in **3** for Cl(1) and Cl(2), respectively; *cf.* 2.51, 2.58 in **2**] as well as two CH···Cl bonds per chlorine (2.71–2.85 Å in **3**, 2.70–2.85 Å in **2**).

It is noteworthy that the same polymeric $\{MCl_4\}_n$ substructure has been observed in neutral MCl_4 species (*e.g.* $ZrCl_4$)[4] and in monoanionic form (*e.g.* in [Hpy][$SbCl_4$])[7] but not previously in dianionic species. Such chains are a substructure of the familiar $CdCl_2$ structure.[8] Presumably the [4,4′-H_2bipy]$^{2+}$ cation plays a vital role in stabilising the chain structure. As noted above, despite the wide variety of cations employed in salts of $[MCl_4]^{2-}$ (M = Mn or Cd) the new structure type has not previously been observed. The chain structure has as many bridging (four per metal) and terminal (two per metal) chlorines as does the layer perovskite form of the $[\{MCl_4\}_n]^{2n-}$ polymer. However the perovskite structure has nearly linear M–Cl–M bridges (angles typically 160–165°) compared with the much more normal M–Cl–M angles in **2** and **3** [100.29(2) and 99.38(2)°, respectively]. The more open perovskite structure apparently requires greater strain at the μ-Cl site. This strain is presumably compensated by formation of stronger NH···Cl hydrogen bonds (usually six per metal, as in A_2MX_4 structures with A = primary ammonium) than for the chain structure in **2** and **3** where there are just two NH groups per metal. Notably $[Hpy]_2[MnCl_4]$[9] contains tetrahedral manganese centres implying that it is not merely the number of NH hydrogen bond donors that influences the polymerisation of the $MnCl_4$ moieties. The willingness of the metal to be octahedrally coordinated must also be important. Thus the [4,4′-H_2bipy][MCl_4] (M = Co or Zn) salts contain $[MCl_4]$ tetrahedra rather than polymeric anions. Notably the same is true of $[NH_3(CH_2)_nNH_3]^{2+}$ (n = 2, 3) salts of tetrachlorometallate anions: only those cases where M = Zn or Co have tetrahedral dianions. In other cases, *e.g.* M = Cr, Mn, Fe, Ni, Cd or Cu the <100> layer perovskite structure, with octahedral (or distorted octahedral) coordination of the metal, is adopted.

The ability of [4,4′-H_2bipy]$^{2+}$ to control the aggregation of other metal anions, such as metal–oxo species has been noted.[10] In the present case it seems that the hydrogen bonding capability of [4,4′-H_2bipy]$^{2+}$ may provide access to a new faimily of chain polymers of perhalometallate anions which may offer intriguing and potentially useful properties.

Enantioselective allylic substitution catalyzed by an iridium complex: remarkable effects of the counter cation

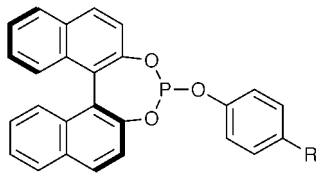
Kaoru Fuji,*[a] Naosumi Kinoshita,[a]† Kiyoshi Tanaka[b] and Takeo Kawabata[a]

[a] *Institute for Chemical Research, Kyoto University, Uji, Kyoto 611-0011, Japan. E-mail: fuji@scl.kyoto-v.ac.jp*
[b] *School of Pharmaceutical Sciences, University of Shizuoka, 52-1 Yada, Shizuoka 422-8526, Japan*

Received (in Cambridge, UK) 22nd September 1999, Accepted 4th October 1999

Allylic substitution of a methyl carbonate of cinnamyl alcohol with the anion of dimethyl malonate gave the branched olefin with high enantioselectivity in the presence of (*S*)-1,1′-binaphthyl-2,2′-diyl phenyl phosphite when a combination of lithium and zinc was used as counter cation.

Unlike palladium-catalyzed allylic alkylations, iridium-catalyzed alkylations take place at the more substituted allylic terminus.[1] Recently, asymmetric versions of this reaction have been reported, where chiral phosphinooxazolines[2] or phosphorous amidites[3] were used as ligands. We report here enantioselective allylic substitutions catalyzed by an iridium complex of chiral aryl phosphite (*S*)-**1**.



1 R = H
2 R = OMe
3 R = CF_3

We chose **4a** as a standard substrate to avoid ambiguities arising from a chiral centre (Scheme 1), although the ester of an isomeric secondary alcohol, 1-phenylprop-2-en-1-ol, can also be a substrate for the same reaction. It has been reported that the iridium-catalyzed allylic substitution of acetates of secondary alcohols proceeds with 70–80% retention of configuration.[3] Aryl phosphites are known to be efficient ligands for allylic alkylation with soft carbon nucleophiles catalyzed by an iridium complex.[1] Chiral phosphites **1**,[4] **2**[5] and **3**[6] have been used as ligands. Diethylzinc was used as a base because it is known to give a greater ee than other bases in allylic alkylations catalyzed by a palladium–(*R*)-BINAP complex.[7] The results are shown in Table 1. Both electron-releasing and -withdrawing groups on the phenyl rings of the ligands gave lower ees (entries 2 and 3) than the parent phosphite (*S*)-**1** (entry 1). CH_2Cl_2 is the solvent of choice (compare entry 1 with entries 4–6). Allylic methyl carbonate **4b** gave a better yield than the corresponding acetate **4a** in a shorter reaction time (entries 1 and 7).

The effect of the counter cation was investigated using **4b**, and the results are shown in Table 2. A conspicuous feature of these results is that the proportion of (*R*)-**5** to (*S*)-**5** increases as the ionic character of the malonate anion increases (entries 1–3). Thus, (*R*)-**5** was obtained in 36% ee by using Bu^tP_4 base, which is known to generate naked anions.[8,9] Metals, such as lithium and zinc, that strongly coordinate with anion gave (*S*)-**5** as the major enantiomer. The intermediacy of a π-allyl–iridium complex has been suggested for iridium complex-catalyzed allylic alkylation with triphenyl phosphite as ligand.[1] On the other hand, the involvement of a σ-allyl–iridium complex is indicated for the alkylation of secondary allylic acetates.[3] Although there is an apparent divergence of mechanistic considerations, the π-allyl–iridium complex is more likely than the σ-complex when aryl phosphites are used as ligands. The predominant formation of (*S*)-**5** with lithium and/or zinc as the

[a] General procedure (entry 1): A solution of (*S*)-**1** (81.7 mg, 0.2 mmol), $[Ir(COD)Cl]_2$ (33.6 mg, 0.05 mmol) and cinnamyl acetate (83.1 μl, 0.5 mmol) in dry CH_2Cl_2 (1 ml) was stirred for 45 min under argon. To this solution was added a solution prepared by stirring dimethyl malonate (133 mg, 1.0 mmol) and Et_2Zn (1.0 M in hexane, 1.0 ml) in CH_2Cl_2 (3 ml) under argon for 1 h at room temperature. After stirring for the indicated time, usual extractive work-up with EtOAc followed by preparative TLC (EtOAc–hexane 1 : 6) gave 58 mg of a mixture of **5** and **6**. [b] All reactions were performed at room temperature. [c] Determined by GLC on a Chirasil-DEX CB column at 150 °C. [d] Determined by HPLC on CHIRALCEL OJ-R (MeOH–H_2O = 75 : 25). [e] The number in parenthesis indicates the yield based on the consumed starting material.

counter cation may be explained by the transition state, shown in Fig. 1. The bulky phosphite ligand should be located *trans* to the more-substituted allylic terminus to avoid steric repulsion. Nucleophilic attack *anti* to the phosphite ligand gives (*S*)-**5**. As the anion becomes harder, it favours initial attack at iridium metal, which is harder than the allylic carbon. Intramolecular migration of malonate from iridium to the allylic carbon proceeds to give (*R*)-**5**.

Another feature is that the ee of (*S*)-**5** is remarkably increased to 96% when lithium and zinc are present in the reaction medium (entry 7). It is premature to give a detailed rationalization for this extraordinary increase in ee. However, it is possible that lithium chloride formed *in situ* may play a role.[3] Work is currently underway along these lines.

Stereoselective radical-tandem reaction of aniline derivatives with (5*R*)-5-menthyloxy-2,5-dihydrofuran-2-one initiated by photochemical induced electron transfer

Samuel Bertrand,[a] Norbert Hoffmann,*[a] Jean-Pierre Pete[a] and Véronique Bulach[b]

[a] *Laboratoire de Réactions Sélectives et Applications, UMR CNRS et Université de Reims Champagne-Ardenne, UFR Sciences, B.P. 1039, F-51687 Reims, Cedex 02, France. E-mail: norbert.hoffmann@univ-reims.fr*

[b] *UMR CNRS No. 7513, Université Louis Pasteur, Laboratoire de Cristallochimie et de Chimie Structurale, Institut Le Bel, 4 rue Blaise Pascal F-67070 Strasbourg, Cedex, France*

Received (in Liverpool, UK) 23rd July 1999, Accepted 5th October 1999

The radical tandem reaction of simple alkyl derivatives of aniline to a chiral furanone can be carried out stereoselectively in high yields; the furanone is also involved as oxidant in a rearomatisation process (formation of by-products) where it can be replaced efficiently by acetone.

Radical reactions have become a valuable tool in preparative organic chemistry,[1] even if control of the stereochemistry involved in these processes is still a challenge in organic synthesis.[2] Radical induced cyclisations and radical-tandem processes are particularly interesting due to the large variety of complex organic molecules available using these methods.[3]

Among radicals having a nucleophilic character which can be considered for addition reactions with electron deficient alkenes, α-aminoalkyl radicals[4] seem very attractive. When prepared directly from tertiary amines, these radicals were reported to add with moderate yields.[5] Similar results were described on the tandem addition of $PhNMe_2$.[6] These reactions become efficient only with functionalised amines especially with α-silylated tertiary amines.[4,7] However, we recently described a very efficient addition of tertiary amines to electron deficient alkenes, using 4,4′-dimethoxybenzophenone or Michler's ketone as sensitizers to produce α-aminoalkyl radicals *via* a photoinduced electron transfer process (PET).[8,9]

We envisaged that an easy and general access to 1,2,3,4-tetrahydroquinoline derivatives might include a multistep process induced by PET. We now report an efficient and stereoselective tandem reaction of *N*,*N*-dialkylanilines with (5*R*)-5-menthyloxy-2,5-dihydrofuran-2-one **1**[10] and the origin of the rearomatisation step involved during the reaction. Owing to their biological activity, these compounds are of great interest.[11]

When a solution of **1** and *N*,*N*-dimethylaniline **2a** in MeCN was irradiated in the presence of 4,4′-bis(*N*,*N*-dimethylamino)-benzophenone **3**, four products were isolated from the reaction mixture (Scheme 1, Table 1, entry 1).† The diastereomers **4a** and **5a** were the expected products from a radical tandem addition of the tertiary aromatic amine to **1**. The configuration of the main product **4a** was also determined by X-ray analysis (Fig. 1).‡ From the structure of **4a**, it could be deduced that the attack of the α-aminoalkyl radical **A** on **1** proceeded mainly *anti* with respect to the menthyloxy substituent.

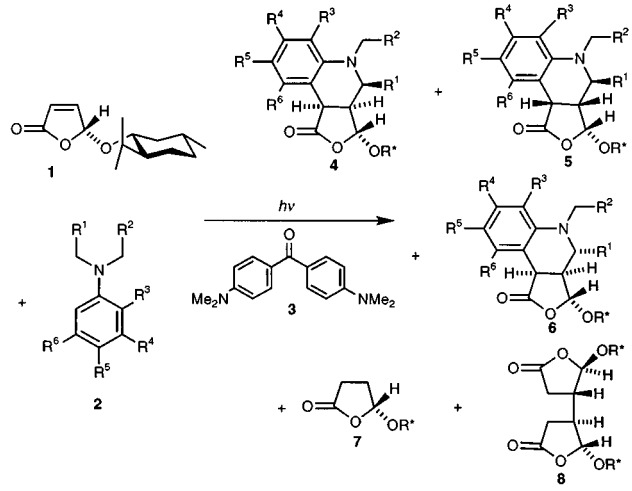
9	**h**	$-(CH_2)_2-$		H	H	H	H	39	—	32	—	—
10	**i**	$-(CH_2)_3-$		H	H	H	H	48	—	26	—	—

[a] The reaction was been carried out in the absence of acetone. [b] **5** was isolated in the same fraction as **4**. [c] Two regioisomers were formed.

The large amount of byproducts **7** and **8** limited the transformation of **1** into the tricyclic adducts **4a** and **5a**. When the concentration of **1** was diminished (5×10^{-3} mol l^{-1}), the reduction product **7** could be isolated in higher yield (23%), while the formation of **8** could be suppressed. The observation that the reduction products **7** and **8** and products **4a** and **5a** were isolated with similar yields might indicate a coupling of the processes responsible of their formation. Further, formation of **4a** and **5a** needs an oxidation step for rearomatisation. Little information is available on this oxidising step in the absence of oxygen for similar reactions.[12] In order to decrease the amount of reduction products of **1** and to get more information on the formation of the byproducts **7** and **8**, we carried out the reaction with **2a** labeled by deuterium either at the 2, 4 or 6 position of the aromatic ring (**2a′**) or on the methyl groups (**2a″**). From **2a′**, we found that **7′** had incorporated deuterium exclusively in the α-position (degree of deuterium incorporation: 45%). From **2a″**, the deuterium was transferred to the β-position of **7″** (degree of deuterium incorporation: 55%). In both cases deuterium was found in one of the α-positions of **8**. Therefore, the mechanism of the reaction of **1** can be summarised as in Scheme 2. Formation of the α-aminoalkyl radical **A** involves a PET process induced by excited Michler's ketone **3**.[9,13] Addition of **A** to **1** leads to the oxoallyl radical **B** which yields **C** after an intramolecular addition process on the electron rich aromatic ring. The rearomatisation occurs by transfer of a hydrogen atom to **1**. This transfer proceeds in two steps



Scheme 1

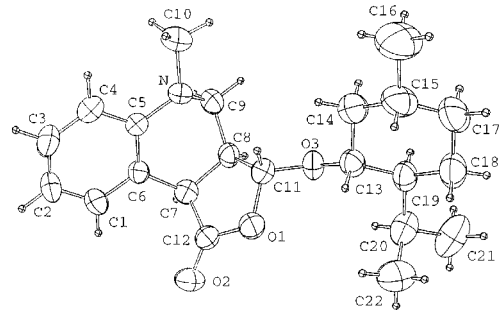


Fig. 1 ORTEP plot of **4a**. Ellipsoids are scaled to enclose 50% of the electronic density. Hydrogen atoms have arbitrary radii.

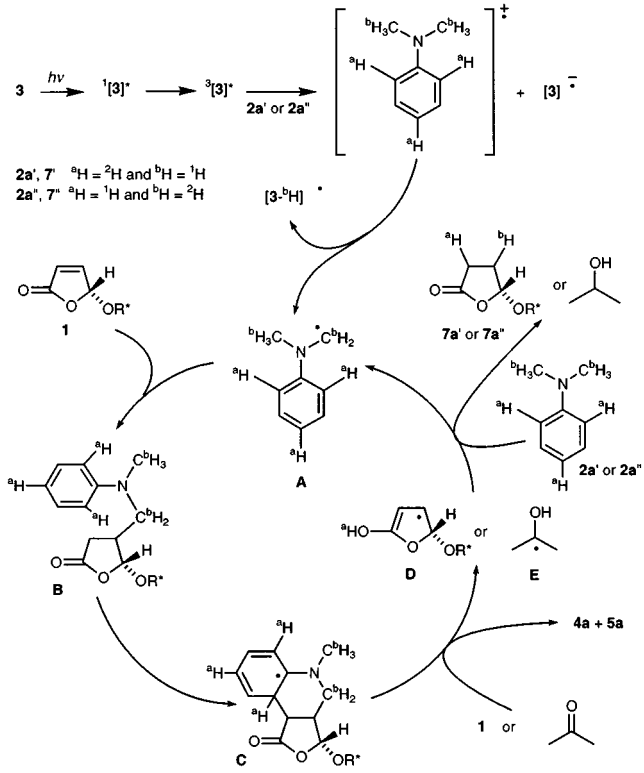
(Scheme 3). First an electron transfer from **C** to **1** takes place to yield the cationic species **F**. In the second step, a proton is transferred to the radical anion.

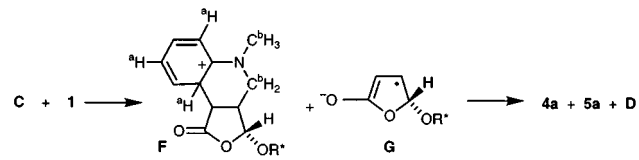
When starting from **2a′** deuterated on the aromatic ring, deuterium was transferred to the carbonyl function of **1**. The resulting radical **D** can produce **7′** deuterated at the α-position by tautomerisation and preferred abstraction of hydrogen from an *N*-methyl group of **2a′**.[4] Alternatively, **D** can add to **1** which leads to **8** after hydrogen abstraction from **2a′**. This mechanism also explains the deuteration in the β-position of **7″** and the α-position of **8** when started with **2a″**.

In order to avoid the hydrogen transfer to the substrate **1**, we added a mild oxidant to the reaction mixture (Scheme 2). By addition of acetone in excess, the formation of byproducts **5** and **6** could be completely suppressed and the yield of **4a** and **5a** was doubled (Table 1, entry 2).

Under these optimised reaction conditions, a variety of *N*,*N*-dialkylamino benzenes **2** similarly yielded the corresponding 1,2,3,4-tetrahydroquinolines **4**, **5** and **6** (Scheme 1, Table 1). In the case of the *N*,*N*-dimethylaminobenzenes **2a**–**f**, the facial diastereoselectivity was about 90% (Table 1, entries 1–7). In the reaction of **1** with **2g**–**i**, a total facial selectivity with *anti* approach *vs.* the menthyloxy substituent was observed. However, the configuration of the second chiral center, in the position α to the nitrogen atom, was not efficiently controlled and the products **6g**–**i** were isolated in similar yields (Table 1, entries 8–10).



Scheme 2



Scheme 3

In conclusion, we have described an efficient and stereoselective addition of tertiary aromatic amines to (5*R*)-(−)-5-menthyloxy-2,5-dihydrofuran-2-one **1** through a radical-tandem process. The reaction, leading to 1,2,3,4-tetrahydroquinoline derivatives **4** involves an oxidative addition on the aromatic ring. When carried out in the presence of acetone, the competitive reduction of **1** was suppressed.

Notes and references

† A Rayonet Photochemical Chamber Reactor equipped with lamps emitting at λ = 350 nm was used as light source. Solutions were degassed with argon prior to the irradiation.

Irradiation of derivatives **2** under optimised conditions (Table 1): A solution of **1** (240 mg, 1 mmol), **2** (20 mmol), **3** (30 mg, 0.1 mmol) and 1 ml acetone in 15 ml MeCN was irradiated for 6 to 7 h. The solvent was evaporated and the residue was subjected to flash chromatography.

‡ *Crystal data* for **4a**: $C_{22}H_{31}NO_3$, M = 357.50, orthorhombic, space group $P2_12_12_1$, a = 8.4839(3), b = 13.709(1), c = 17.887(1) Å, V = 2080.5(4) Å3, Z = 4, ρ_{calc} = 1.14 g cm^{-3}, μ(Mo-Kα) = 0.075 mm^{-1}. Data were collected on a Nonius CAD4-MACH3 diffractometer using Mo-Kα graphite monochromated radiation (λ = 0.71073 Å) at room temperature. Colorless crystal, 0.30 × 0.30 × 0.20 mm^3, 2428 reflections collected, 2.5 < θ < 26.3°. 1459 reflections having $I > 3\sigma(I)$ were used for structure determination and refinement. The structure was solved using direct methods and refined against |*F*|. Hydrogen atoms were introduced as fixed contributors. Absorption corrections from the psi curves of 7 reflections, transmission factors: 0.92/1.00. For all computations the Nonius Open-MoleN package (OpenMoleN, Interactive Structure Solution, Nonius B.V., Delft, The Netherlands 1997) was used. The known configuration of the menthol fragment was therefore used to assign the correct configuration. Final results: $R(F)$ = 0.039, $Rw(F)$ = 0.051, GOF = 1.046, maximum residual electronic density = 0.15 e Å^{-3}. CCDC 182/1432. Polyphenylene dendrimers *via* Diels–Alder reactions: the convergent approach

Uwe-Martin Wiesler and Klaus Müllen*

Received (in Cambridge, UK) 10th September 1999, Accepted 4th October 1999

Polyphenylene dendrimers and dendrons can be obtained using [2 + 4]cycloaddition and Knoevenagel cyclocondensation in a convergent approach.

Due to their outstanding properties, such as molecular shape- and size-persistence and narrow molecular weight distribution, dendrimers are the object of increasing interest.[1] In this context we developed a divergent method to synthesize polyphenylene dendrimers based on the selective Diels–Alder cycloaddition between tetraphenylcyclopentadienones and ethynyls.[2] We are thus able to synthesize dendrimers up to the fourth generation, which exist as shape-persistent nanoparticles.[3]

While the divergent approach builds dendrimers layer-by-layer from a central core to the periphery, the convergent strategy builds the dendrimer in the opposite manner, from the periphery toward the central core. Thus, the dendrimer branches, also called dendrons, are synthesized first and then added to a central core. This approach not only allows the symmetric functionalization of the dendrimer surface as in the divergent approach, but also the controlled functionalization of the dendrimer by adding differently functionalized dendrons to selectively protected cores.[4]

Here, we present a convergent approach for the synthesis of polyphenylene dendrons and dendrimers based on two alternating orthogonal reactions: (i) the Diels–Alder cycloaddition of tetraphenylcyclopentadienones to phenylene-substituted ethynyls, and (ii) the Knoevenagel condensation of benzils with 1,3-diphenylacetones to give cyclopentadienones.

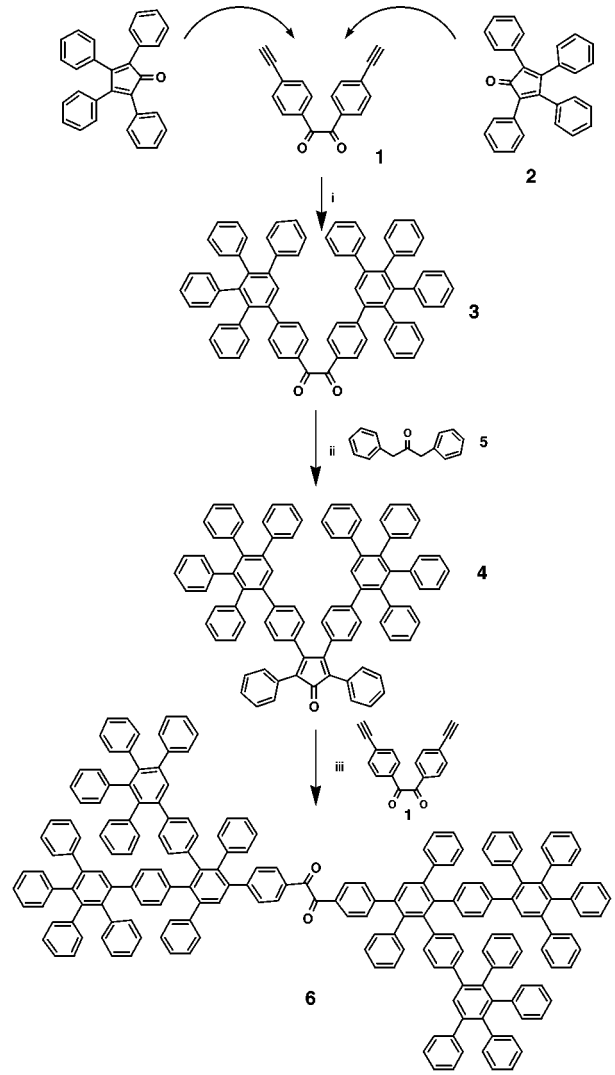
The starting point of the synthesis is 4,4′-diethynylbenzil **1** which contains two ethynylic dienophile units and one ethanedione function which can react in a Knoevenagel condensation (Scheme 1). The starting material **1** is prepared *via* the Sonogashira[5] coupling of triisopropylsilylacetylene and 4,4′-dibromobenzil and subsequent cleavage of the TIPS groups with KF in DMF (70%, yellow crystals).

The two-fold Diels–Alder cycloaddition of an excess of tetraphenylcyclopentadienone **2**, which has to be regarded as a first-generation dendron, to **1** in refluxing xylene leads to the second generation **3** in the form of a benzilic dendron (91%, pale yellow amorphous powder). The Knoevenagel condensation of **3** to the corresponding cyclopentadienone dendron **4** with 1,3-diphenylacetone **5** is achieved in dioxane and in the presence of Bu_4NOH as base. Like **3**, the cyclopentadienone dendron **4** can be easily precipitated in EtOH as a pale red solid in 85% isolated yield.

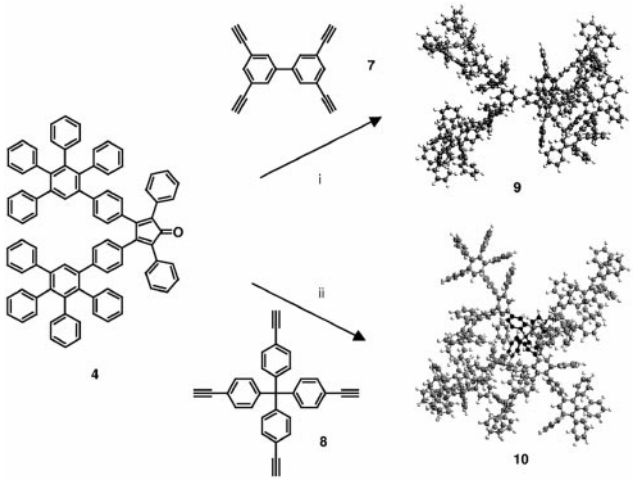
The next generation benzil **6** is obtained, similar to the second generation, by addition of an excess of dendron **4** to **1** in refluxing xylene. Isolation after precipitation in EtOH affords the benzil **6** as an amorphous yellow powder in 89% yield. Further base-catalyzed condensation of **6** with 1,3-diphenylacetone **5** provides a complex mixture of products, determined by mass spectrometry, consisting of small amounts of third generation cyclopentadienone dendron and further side-products of the polycondensation of **5** with **6**. This can be explained by the high steric hindrance of the polyphenylenic branches of the benzil **6**, which will prefer a conformation where the dendrons (and thus the vicinal carbonyls) are oriented in opposite directions. This arrangement prevents the favourable orientation of the benzilic carbonyls required for the nucleophilic attack of **5** and subsequent formation of the cyclopentadienone ring (see Scheme 1).

The four-fold cycloaddition of an excess of cyclopentadienone dendron **4** to the tetraethynylbiphenyl **7** and the tetrakis(ethynylphenyl)methane **8** in Ph_2O at 200 °C leads to dendrimers **9** and **10**, respectively (see Scheme 2). The products are isolated by precipitation from the reaction mixture using EtOH (89 and 85% isolated yield, respectively). Molecules **9** and **10** correspond to the second generation polyphenylene dendrimer previously made by the divergent method.[6]

Whereas in the synthesis of dendrimer **9** the reactants have to be heated for two days, the reaction time in the case of dendrimer **10** is about one week. The MALDI-TOF mass spectra taken at various stages during the reaction reveal that three ethynyl groups of both cores react rapidly with dendron **4**,



Scheme 1 *Reagents and conditions*: i, xylene, 14 h, 91%; ii, **5**, 1,4-dioxane, Bu_4NOH, 100 °C, 1 h, 85%; iii, **1**, xylene, reflux, 14 h, 89%.



Scheme 2 *Reagents and conditions*: i, **7**, Ph_2O, 200 °C, 2 days, 89%; ii, **8**, Ph_2O, 200 °C, 7 days, 85%.

while the reactivity of the last group depends on the flexibility of the core. In this view the tetraethynylbiphenyl core **7** allows rotation about the phenyl–phenyl bond of the core, so that the fourth ethynyl group can be brought into a favorable position for the sterically demanding cycloaddition of dendron **6**. In contrast the fourth ethynyl groups of the tetrakis(ethynylphenyl)methane core **8** does not have such mobility.

The disparity in reaction times required for obtaining **9** and dendrimer **10** can also be understood examining ball-and-stick models, which are generated using the MM2 (85) force field with the CERIUS 2 program package and applying the Conjugate Gradient 200 algorithm (compare Scheme 2).[7] Whereas dendrimer **9** possesses a dumb-bell like structure, with easily accessible holes close to the phenyl–phenyl bond of the core, the methane center of dendrimer **10** is densely surrounded by phenylene groups which increase the stiffness of the whole molecule and render the core difficult to access.

Neverthless, both the dendrons and the dendrimers are very soluble in organic solvents such as toluene and CH_2Cl_2. Characterization was carried out by field-desorption mass spectrometry for the dendrons with molecular masses up to 2000 g mol^{-1} and matrix-assisted laser desorption ionization time of flight mass spectrometry (MALDI-TOF MS) for the higher molecular mass dendrons and the dendrimers. The purity and monodispersity of the analyzed molecules was confirmed by the perfect agreement between calculated and experimentally determined *m/z* ratios.† A characteristic feature of the synthesized dendrimers **9** and **10** is their high thermal and chemical stability. They decompose under air only at temperatures higher than 550 °C according to thermogravimetric analysis. Their chemical stability is also noteworthy. For example boiling in concentrated HCl or in 30% KOH for seven days fails to produce any decomposition. The dendrimers react only with strong electrophiles, like H_2SO_4, *via* aromatic electrophilic substitution, but without change in the polyphenylene framework. This opens a way to chemically functionalize dendrimers at their surface.

Compared to the divergent approach, the convergent method at first glance yields the same monodisperse products with similarly high yields. However, though the convergent method can be used to synthesize dendrimers only up to the second generation, this method opens the way to dendritic polymers carrying substituents of more than just one kind. In contrast, the divergent approach may be successfully used up to the fourth generation, but it only allows the ordered attachment of one kind of functional group. Both methods have in common the fact that they yield monodiperse polyphenylene dendrimers in high yield.

In conclusion, we can say that: (i) using a convergent approach, polyphenylene dendrons and dendrimers with more than 60 benzene rings can be obtained *via* [2 + 4] cycloadditions and Knoevenagel condensations; (ii) by attachment of the polyphenylene dendrons to different cores, dendrimers with different shapes are obtained; (iii) the dendrimers show high thermal and chemical stability.

Our current investigations involve the convergent synthesis of dendrimers with various substitution patterns as possible carriers in catalysis.

We thank the Foundation of the Chemical Industries (Fonds der Chemischen Industrie) and the Bundesministerium für Bildung und Forschung for financial support.

Dioxygen–copper reactivity at trinuclear centers: formation of hexanuclear and mixed-valent adducts

Kenneth D. Karlin,* Qin-fen Gan and Zoltan Tyeklár

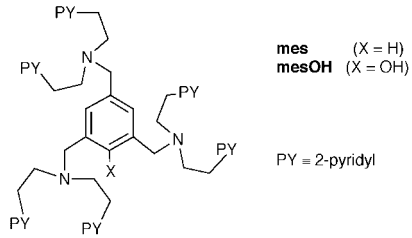
Department of Chemistry, The Johns Hopkins University, Charles & 34th Streets, Baltimore, MD 21218 USA. E-mail: karlin@jhu.edu

Received (in Cambridge, UK) 18th August 1999, Accepted 15th October 1999

New copper(I) complexes $[Cu^{I}_3(mesO^-)]^{2+}$ (3) and $[Cu^{I}_3(mesOH)]^{3+}$ (4) have been generated from a phenol-containing trinucleating ligand, mesOH; reactions with O_2 reflect the unsymmetrical ligand environment, and lead to peroxo and/or hydroperoxo cluster complexes, including those with mixed-valent copper ion centers.

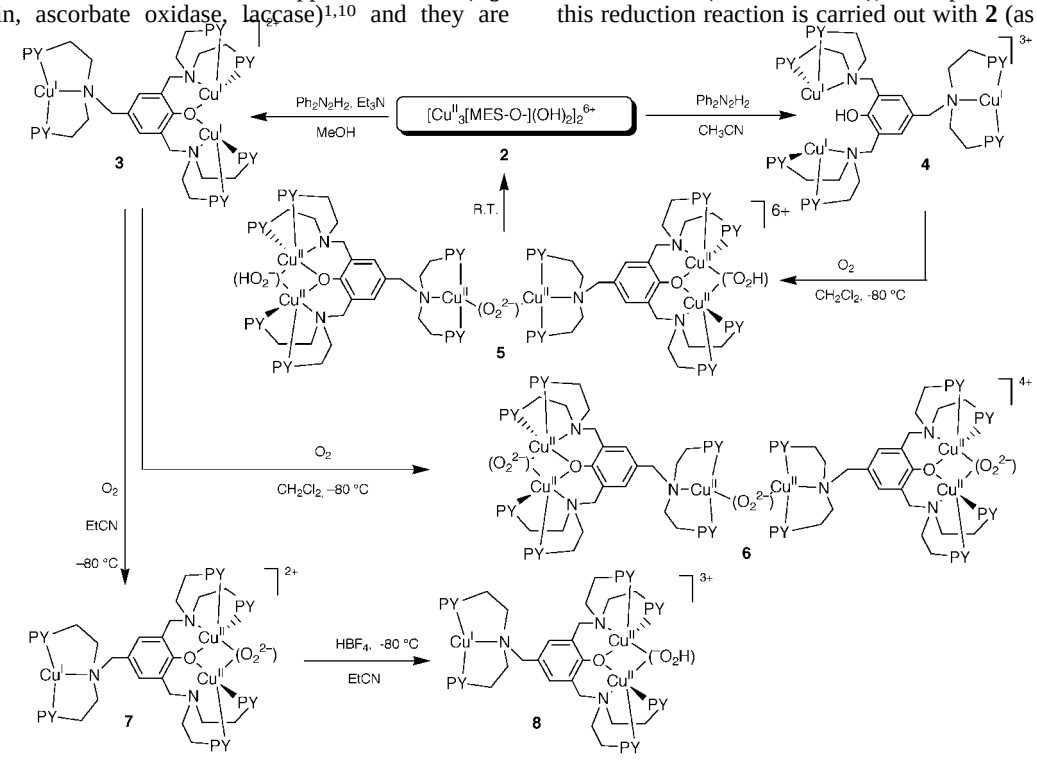
Continuing interest in studies of the reactivity of O_2 with discrete copper(I) complexes is for the most part driven by bioinorganic interests, *i.e.* the occurrence of copper-dioxygen carrier proteins, oxygenases which insert O-atoms into substrates, and oxidases which couple substrate oxidations to copper-mediated O_2-reduction to water or H_2O_2.[1,2] Our own efforts in elucidating fundamental aspects of (ligand)Cu^{I}/O_2 reactivity, and those of others, have focused on mono- or binuclear copper(I) compounds, their kinetics/thermodynamics of reaction,[3] the structures and spectroscopy of O_2-adducts, and substrate reactivity.[2–5] The products most often form *via* a $Cu:O_2$ 2:1 reaction stoichiometry, leading to bridged peroxo [μ-1,2- or μ-$\eta^2:\eta^2$-peroxodicopper(II)], hydroperoxo- or bis-μ-oxo[dicopper(III)] species.[2–5] An exception was described by Stack and co-workers,[6] where a $(L')Cu^{I}:O_2$ 3:1 reaction occurs, producing a mixed-valent cluster, $[Cu_3(\mu\text{-}O)_2(L')_3]^{3+}$ (L′ = *N*,*N*,*N*′,*N*′-tetramethyl-(1*R*,2*R*)-cyclohexanediamine).

Few discrete trinuclear copper(I) complexes exist,[7–9] and still fewer have associated O_2-chemistry.[7,8] Yet, (ligand)-Cu^{I}_3/O_2 chemistry is of considerable interest, since trinuclear copper cores occur in 'blue' multicopper oxidases (*e.g.* ceruloplasmin, ascorbate oxidase, laccase)[1,10] and they are

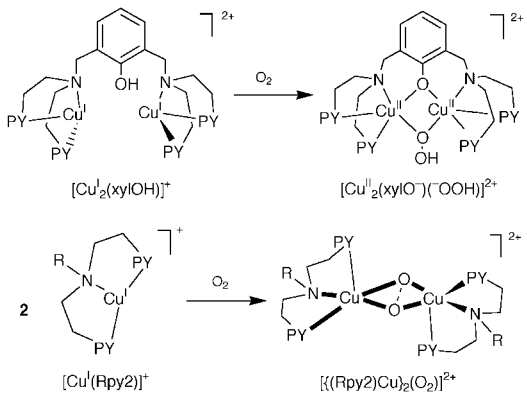


implicated at active sites in the copper-dependent methane monooxygenase.[1,11] It also has been shown in certain systems[12] that three-electron reduction of O_2 (*i.e.* from three Cu(I) ions) is essential for O–O bond reductive cleavage, of relevance in O_2-activation processes. In this report, we describe novel results in (ligand)Cu^{I}_3/O_2 reactivity studies, employing mesOH as an unsymmetrical trinucleating ligand.

Ligand mesOH was obtained following oxygenation of the tricopper(I) complex $[Cu^{I}_3(mes)]^{3+}$ (**1**); the hydroxylation reaction affords a hexanuclear cluster complex $[\{Cu^{II}_3(mesO^-)(OH^-)_2\}_2]^{6+}$ (**2**),[8]† from which mesOH is isolated following copper removal and extraction. By adapting the reactions used to synthesize analogous phenolate-[13] or phenol-containing[14] dinuclear copper(I) compounds, two new trinuclear copper(I) complexes possessing unsymmetrical Cu(I) coordination were prepared (Scheme 1). The bright orange (CH_2Cl_2; λ_{max} 370 nm, ε 16600 M^{-1} cm^{-1}) compound $[Cu^{I}_3(mesO^-)](ClO_4)_2$ (**3**) was prepared by diphenylhydrazine reduction of **2** (as a ClO_4^- salt), in the presence of Et_3N. When this reduction reaction is carried out with **2** (as a BF_4^- salt) in



Scheme 1



Scheme 2

the absence of base, a yellow compound, $[Cu^{I}_3(mesOH)](BF_4)_3$ (**4**), was isolated.‡ For each of these trinuclear complexes, two of the three copper ions possess features found in dinuclear analogues with phenol or phenoxide groups, $[Cu^{I}_2(xylOH)]^{2+}$ (Scheme 2) and $[Cu^{I}_2(xylO^-)]^+$.[13,14] Consistent with their compound formulations, **3** and **4** are diamagnetic (^1H and ^{13}C NMR spectroscopies).

Reaction of O_2 with **4** in CH_2Cl_2 at −80 °C leads to an intensely green colored solution dominated by strong 368 (ε 14000) and 408 nm (sh, ε 9500 M^{-1} cm^{-1}) charge-transfer (CT) absorptions. The latter band is characteristic of the μ-$^-$OAr/μ-1,1-$^-$OOH dicopper coordination observed for $[Cu^{II}_2(xylO^-)(^-OOH)]^{2+}$ {395 nm (ε 8000 M^{-1} cm^{-1}),[14] while the 368 nm absorption is characteristic of the intense LMCT observed for copper complexes $[\{Cu(Rpy2)\}_2(O_2)]^{2+}$ {λ_{max} 350–365 nm, $\varepsilon \geqslant 12000$ M^{-1} cm^{-1}},[15] with intermolecular μ-η^2:η^2-peroxo-dicopper(II) ligation (Scheme 2).¶ Thus, the oxygenation product of **4** is formulated as a hexanuclear species, $[\{Cu_3(mesO^-)(OOH)\}_2(O_2)]^{6+}$ (**5**), (Scheme 1). Consistent with this formulation, **5** is observed to be EPR silent (frozen CH_2Cl_2) and manometric O_2-uptake measurements (−80 °C, CH_2Cl_2) reveal a reaction stoichiometry of $Cu:O_2$ = 6 : 2.9 (±10%)‖

A related hexanuclear complex **6** also appears to form from O_2-reaction with **3**.‖ This product lacks the the protons available in **4**, thus leading to peroxo species $[\{Cu_3(mesO^-)(O_2)\}_2(O_2)]^{6+}$ (**6**) (Scheme 1) {(CH_2Cl_2, −80°C); λ_{max} 340 (ε 12000), 384 (sh, ε 11000), 482 (ε 6500), 594 nm (sh, ε 2500 M^{-1} cm^{-1})}. This is suggested to possess two peroxo Cu_2-O_2 moieties similar to that observed for $[Cu^{II}_2(xylO^-)(O_2^{2-})]^+$ {385 (ε 2900), 505 (ε 6000), 610 (sh, ε 6500 M^{-1} cm^{-1}},[13] and an intramolecular peroxo species again similar to that in $[\{Cu(Rpy2)\}_2(O_2)]^{2+}$. Accurate manometric O_2-uptake experiments were thwarted by the instability of **6**.

Interestingly, mixed-valent $Cu^{I}Cu^{II}_2$ clusters **7** and **8** were obtained *via* oxygenation of **3** at −80 °C in EtCN as solvent (Scheme 1). The spectrum that develops in the CT region following O_2-reaction with **3** consists of primarily only the 482 and 594 nm (sh) absorptions, again very similar to the spectrum expected for $[Cu^{II}_2(xylO^-)(O_2^{2-})]^{+}$[13] and that found for **6**. The lack of formation of a more intense band in the 340–380 nm regions indicates that the Cu^{I}(Rpy2) moiety in **3** does not react with dioxygen; this is as previously observed for discrete $[Cu^{I}(Rpy2)]^+$ complexes[15] and is explained by the strong nitrile (solvent) coordination, especially at low temperatures. Manometric measurements are also in accord with the formulation of **7**, since $Cu:O_2$ = 3 : 0.95 (±10%) (EtCN, −80 °C). Further confirmation comes from reaction of **7** with excess acid (HBF_4·Et_2O) and workup, which generates hydrogen peroxide in *ca*. 85% of the expected yield (1 H_2O_2 per molecule of **7**), as determined by iodometric titration. A hydroperoxo-containing mixed-valent cluster analogue, **8** (λ_{max} 395 mm), can be generated by addition of one equiv. of H^+ (HBF_4·Et_2O) to **7** (Scheme 1).

In summary, mes-OH as a trinucleating ligand affords novel tricopper(I) complexes **3** or **4**, in which an unsymmetrical ligation for the three copper ions occurs, as observed for the enzymes.[1,10] Based on previously established chemistry for phenoxide (or phenol) dicopper(I) compounds (Scheme 2), we have shown that phenoxide with peroxo- (or hydroperoxo-) dicopper(II) species form upon O_2-reactions with **3** or **4**, and in CH_2Cl_2 as solvent, this leaves the third copper ion to react with O_2 in an intermolecular fashion, affording hexanuclear complexes. In EtCN as solvent, the latter reaction is suppressed, and mixed-valent species form, in which a copper(I) moiety survives oxidation even in the presence of a nearby (hydro)-peroxo-dicopper(II) center. The reasons for this are currently unclear. Evidence for a related hydroperoxo-tricopper [including Cu(I)] entity has been presented by Solomon and co-workers,[1] as an intermediate in the four-electron reduction of O_2 by the enzyme laccase. Further investigations of tricopper(I)/O_2 reactivity patterns are in progress.

Financial support for this research has been made available from the National Institutes of Health, USA (GM28962).

Notes and references

† This product **2** is obtained if ClO_4^- or $CF_3SO_3^-$ are utilized as the counteranion (unpublished results). We previously[8] mistakenly identified **2** as the product formed when using PF_6^-, which is actually a bis-μ-F^- complex, $[\{Cu^{II}_3(mesO^-)(OH^-)(F^-)\}_2]^{6+}$. See also ref. 15(*a*) and S. C. Lee and R. H. Holm, *Inorg. Chem.*, 1993, **32**, 4745.

‡ Satisfactory analytical data (NMR and mass spectral for mesOH; C, H, N combustion analysis for complexes **3** and **4**) have been obtained.

§ A band assignable to the ν(O–H) stretch, expected for **4** in its IR spectrum, was not observed, probably due to interaction of the Ar–OH group with Cu(I) ion(s). The same phenomenon was observed for $[Cu^{I}_2(xylOH)]^{2+}$; for a bis PPh_3 adduct, the expected ν(O–H) stretch was detected.[14]

¶ Some decomposition to a bis-μ-F^- complex may also be occurring, since **4** contains BF_4^-, with fluoride. See footnote † above.

‖ The hexanuclear formaulation is also supported by the existence of the very similar mesO$^-$-containing hexanuclear compound **2** (with X-ray structure). See ref. 8 and footnote †.

Towards multianalyte molecule-based sensors: reactivity and photophysical behaviour of hemilabile ligand-containing Ru(II) bipyridyl complexes

Cerrie W. Rogers and Michael O. Wolf*

Department of Chemistry, University of British Columbia, Vancouver, Canada V6T 1Z1. E-mail: mwolf@chem.ubc.ca; fax: 604-822-2847

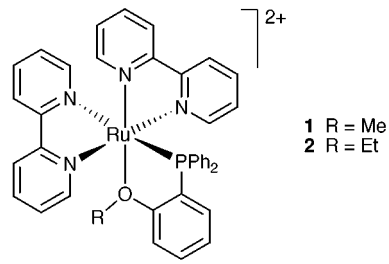
Received (in Bloomington, IN, USA) 25th August 1999, Accepted 7th October 1999

The concept of using hemilabile ligand-containing complexes as the basis for multianalyte sensors is introduced: the preparation of two such ruthenium complexes (1 and 2) and their reactivity towards a series of donor molecules is reported; differential photoluminescence and absorption responses are observed.

Molecule-based sensors are compounds designed to respond to specific analyte molecules by undergoing changes in readily-monitored physical properties. Ideally, molecule-based sensors should be sensitive to the amount and type of analyte present, while functioning in a reversible fashion. Many different and elegant strategies have been used to detect a variety of analytes, such as metal ions,[1] small anions,[2] gases,[3] biomolecules,[4] and pH.[5]

In this communication, we show how a new class of ruthenium complexes containing hemilabile ligands may be used as the basis for molecule-based sensors. Hemilabile ligands, which contain both substitutionally inert and labile moieties, provide a site for the binding of analytes to a metal center. Importantly, hemilabile ligands have been shown to allow the *reversible* binding of small molecules to metal complexes because of their chelating ability.[6] In a previous study, a rhodium carbonyl complex containing a hemilabile ligand was shown to selectively detect carbon monoxide in a mixture of gases.[3b]

In our approach, multiple analytes may be distinguished *via differences* in the response of a tailor-made complex to different analytes. Two such complexes, $[Ru(bpy)_2(PO)](PF_6)_2$ [PO = 2-(diphenylphosphino)anisole (**1**) and 2-(diphenylphosphino)-phenetole (**2**)], have been prepared and their reactions with a



series of analytes examined in solution. In these complexes, the PO ligands are hemilabile because of weak coordination of the ether moiety to the metal, and the bpy groups provide an optical handle. The absorption and emission properties of ruthenium polypyridyl complexes are well-known to be sensitive to the nature of the other ligands on the metal.[7] The bpy ligands also serve to prevent isomerization, a common occurrence with six-coordinate Ru complexes bearing hemilabile ligands.[6]

Complexes **1** and **2** were prepared† by reacting the appropriate PO ligand with 1 equivalent of $[Ru(bpy)_2(Me_2CO)_2](BF_4)_2$. Metathesis to the hexafluorophosphate salts yielded **1** and **2** as yellow powders which are soluble in polar organic solvents and stable for > 10 days in air-saturated solution. The ^{1}H NMR spectrum of **1** obtained at −80 °C (CD_2Cl_2) was unchanged from the spectrum at 25 °C; thus, either the opening-and-closing of the PO ligand does not occur on the NMR timescale, or the opening-and-closing is still fast at −80 °C. Two-dimensional ^{1}H correlation spectroscopy and NOE experiments established that the coordination of the PO ligand in **1** is bidentate.

The reactions of **1** and **2** with a variety of small molecules have been explored. The complexes react rapidly and irreversibly with one equivalent of acetonitrile, resulting in upfield shifts of the methoxy or ethoxy ^{1}H and phosphine ^{3}P NMR resonances of the hemilabile ligand. On the other hand, no reaction occurs with the oxygen donors ether, acetone and methanol.

The complexes **1** and **2** also react with sulfur donors such as ethanethiol, dodecanethiol, dimethyl sulfoxide and dimethyl sulfide. In these cases, the analyte-bound complexes are in equilibrium with the corresponding analyte-free complexes. The equilibrium is conveniently monitored by ^{1}H and ^{31}P NMR since the analyte-bound complexes also show upfield shifts of the methoxy or ethoxy ^{1}H and phosphine ^{31}P NMR resonances of the hemilabile ligand (data for reactions with **1** are shown in Table 1). The reversibility of the reaction of these analytes with **1** and **2** was established by varying the concentration of analyte in solution; this results in the expected changes in the ratios of analyte-bound to analyte-free complex as equilibrium is reestablished.

The equilibrium constant (K) is sensitive to the nature of the analyte and the hemilabile ligand. For example, of the sulfur donors examined, dimethyl sulfide binds with greatest affinity. We also observed differences in analyte affinity between **1** and **2**; for instance, all the sulfur donors bind with higher affinity to **2**. The equilibrium constant for dimethyl sulfide binding to **2** (300 ± 60 M^{-1}) is significantly higher than for binding to **1** (50 ± 10 M^{-1}). These differences suggest that sensor complexes can be designed to react specifically with certain analytes and may be used to distinguish analytes with closely related structures.

Both the analyte-free and analyte-bound complexes are luminescent at 77 K in 2:1 ethanol–acetone. The emission spectrum of **1** contains a band with λ_{max} at 600 nm (Fig. 1A), and the spectrum of **2** is similar; these complexes are both weak red emitters by eye. Addition of CH_3CN to **1** or **2** results in a dramatically more intense, blue-shifted (bright yellow) emission, as shown in Fig. 1B for **1**. Addition of DMSO and

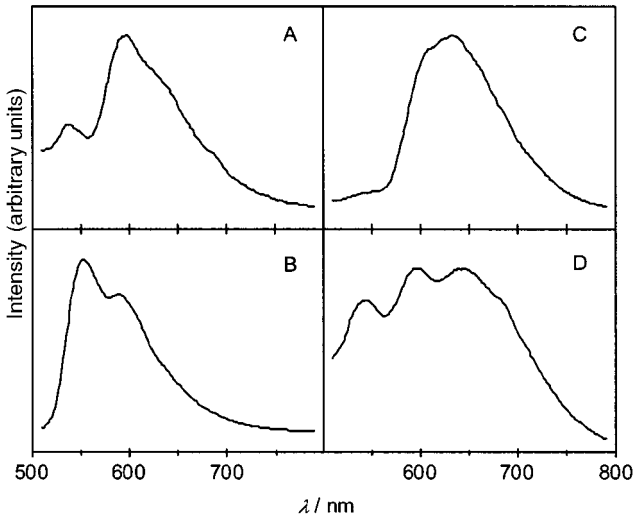

Fig. 1 Emission spectra of complexes at 77 K in 2:1 ethanol–acetone. (A) **1**; (B) **1** with 100 equiv. acetonitrile added; (C) **1** with 100 equiv. DMSO added; (D) **1** with 100 equiv. dodecanethiol added.

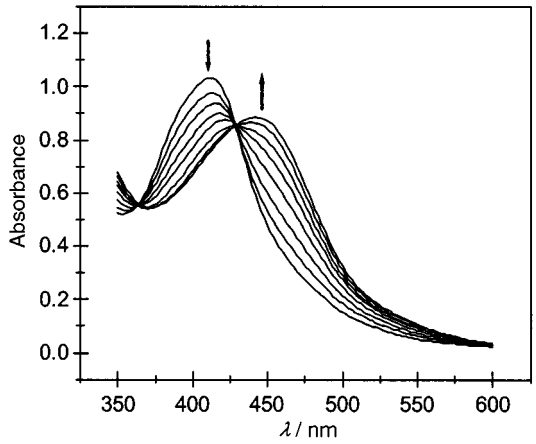

Fig. 2 Visible absorption spectra of **1** in acetone (1.47×10^{-4} M) upon addition of DMSO (0–13 000 equiv.).

dodecanethiol to **1** or **2** also results in shifts in the emission spectra (Fig. 1C and D), but minimal changes in intensity.

Certain analytes also react with **1** and **2** to yield colour changes. For example, of the analytes tested, only DMSO results in a significant colour change with **1** and **2** (Fig. 2 shows this effect for **1**). In this case, the concentration-dependent red shift of the visible absorption spectrum may be used to ascertain the amount of the analyte in solution. It may also be used to distinguish DMSO from related species that do not result in an absorption shift, such as other sulfur donors that produce only very slight colour changes.

These results show that emission characteristics, in combination with absorption, may be used to identify and quantify analytes by reaction with complexes such as **1** and **2**. Selectivity, sensitivity, and room temperature luminescence output are currently being optimized by varying the structures of the hemilabile ligand and ancillary ligand set. Studies are ongoing to incorporate these complexes into thin films to enable the development of solid-state sensors.

We thank the Natural Sciences and Engineering Research Council (NSERC) of Canada for financial support of this work.

Inter-anion O–H···O interactions are classical hydrogen bonds

Thomas Steiner

Institut für Chemie – Kristallographie, Freie Universität Berlin, Takustraße 6, D-14195 Berlin, Germany. E-mail: steiner@chemie.fu-berlin.de

Received (in Cambridge, UK) 23rd July 1999, Accepted 4th October 1999

Inter-anion O–H···O interactions have consequences on the covalent bonding of the donor and acceptor moieties that are typical for strong hydrogen bonding; in contrast to published views, they are classified as strong hydrogen bonds, with bond orders of H···O of the magnitude 0.25 valence units.

Of all types of hydrogen bonds, O–H···O is by far the best investigated.[1] At H···O distances larger than about 1.6 Å, hydrogen bonds are primarily electrostatic interactions with only a relatively small charge transfer contribution. With reducing distance, the interaction gradually gains a quasi-covalent nature.[2] The extreme case of the centred hydrogen bond, O···H···O, in which the proton is equally shared between two O-atoms, can be considered as two half covalent bonds.[3] Intermolecular O–H···O hydrogen bonds can be formed between uncharged molecules, but can involve also ions, in particular O–H···O^-, $^+$O–H···O, $^+$O–H···O^-, $^-$O–H···O and $^-$O–H···O^-. Inter-anion hydrogen bonds are frequently observed between ions like HSO_4^-, $H_2PO_4^-$, HPO_4^{2-}, related inorganic anions, and numerous hydrogen carboxylates like hydrogen oxalate, hydrogen fumarate and so on. On the basis of structural and IR spectroscopic data, they are usually considered as strong. An example of a well-studied system is the hydrogen sulfates, which have been extensively investigated by X-ray diffraction and vibrational spectroscopy.[4]

Recently, the usual interpretation of inter-anion O–H···O interactions as hydrogen bonds has been seriously challenged.[5] For the O–H···O interaction in potassium hydrogen oxalate, $K^+[HC_2O_4]^-$, it has been argued that it does not represent a hydrogen bond despite the short O···O distance of 2.52 Å and the linearity of the geometry. As the reason, it is stated that the electrostatic inter-anion repulsion would prevent a stable anion–anion bond. On the basis of *in vacuo* computations on hydrogen oxalate dimers, it is stated that contacts between hydrogen oxalate ions are destabilizing in all geometries, and the geometry found in the crystal is adopted because it is the least destabilizing one. In this view, the O–H···O interaction does not 'link' the ions, but still organises them in space because the anions adopt the 'least destabilizing' mutual arrangement. Because this theoretical paper challenges a large part of the hydrogen bond literature, in particular of the literature on strong hydrogen bonds, a close look at the experimental data is appropriate.

The crystal structure of potassium hydrogen oxalate **1** has been determined by X-ray[6,7] and neutron[8] diffraction. The structure is layered, as shown in Fig. 1(*a*) for the neutron diffraction data. The anions are arranged in infinite chains, and the chains are linked by potassium ions coordinated to the O-atoms. The O–H group of each anion is oriented at a carboxylate O-atom of the next anion in the chain. The published IR absorption spectrum shows the typical features of a strong hydrogen bond (not commented upon in ref. 5).[6] The covalent bonding is quantitatively described by the bond distances given in Fig. 1(*a*). The O–H bond is elongated almost 0.09 Å compared to the typical gas-phase values of monomeric carboxylic acids [0.972(5) Å in formic acid,[9] 0.971(2) Å in acetic acid[10]]. Such a lengthening is inherent to strong hydrogen bonds,[2,3] and is a consequence of weakening of the covalent O–H bond by the bonding H···O interaction. A further indication of the bonding nature of H···O is found in the bond lengths of the carboxylate group. The O–H···O interaction is directed at the O-atom that is *cis* with respect to O–H of the accepting molecule. The corresponding C–O bond is 0.017 Å longer than the C–O bond of the O-atom that does not accept an O–H···O interaction. This means that the acceptor C–O bond is weakened by the O–H···O interaction, as it must be in a strong hydrogen bond.

A second hydrogen oxalate crystal structure has been determined by neutron diffraction, and is very informative here. In dimethylammonium hydrogen oxalate **2**, the anions also form infinite chains linked by short O–H···O interactions [Fig. 1(*b*)].[11] The geometry of the O–H···O contact is very similar to that in **1**, with the covalent O–H bond even being slightly longer, and H···O slightly shorter. Unlike **1**, the interaction is directed at the carboxylate O-atom that is *trans* with respect to O–H of the accepting molecule. Again, the C–O bond of the accepting O-atom is longer than that of the other carboxylate O-atom. The main difference of **1** and **2** is in the interaction pattern of the cations. In a layer of **1**, each K^+ ion coordinates to O-atoms of three anions, two of which are successive in a chain. This could support an argument (implicitly made in ref. 5) that the strong O···K^+···O interaction pulls together the anions within the chains, forcing them to make a short contact that they would otherwise avoid. In **2**, on the other hand, each cation

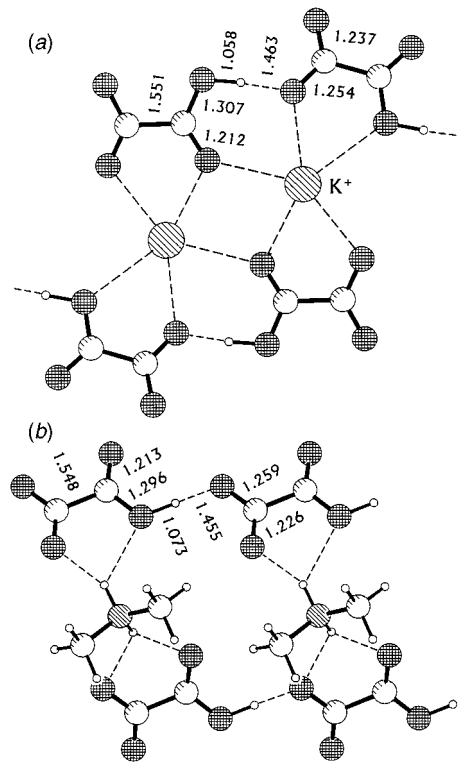

Fig. 1 (*a*) Neutron crystal structure of potassium hydrogen oxalate, determined by Moore and Power (ref. 8). (*b*) Neutron crystal structure of dimethylammonium hydrogen oxalate, determined by Thomas (ref. 11). Distances are given in Å.

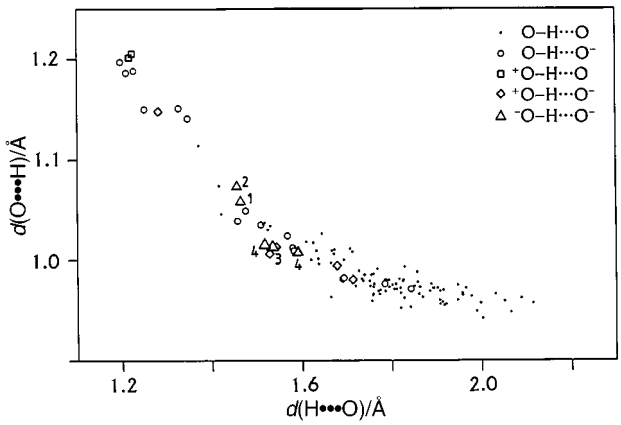

Fig. 2 Lengthening of the covalent O–H bond in O–H···O hydrogen bonds. Scatterplot of data from 125 hydrogen bonds in 66 ordered and error-free neutron crystal structures with $R < 0.06$ (CSD, update 5.16 with 190 307 entries). For the cases $^{+}$O–H···O, $^{+}$O–H···O^{-} and $^{-}$O–H···O^{-}, R values up to 0.09 were allowed. In hydrogen bonds classified as $^{-}$O–H···X, the donor is part of an anion where the negative charge is either delocatized or formally very close to the O–H group. The symbols marked as **1**, **2**, **3** and **4** correspond to the compounds with the same identifiers mentioned in the text.

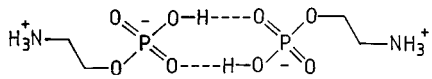

Fig. 3 Structure of 2-aminoethyl phosphate anion dimer.

forms N^{+}–H···O^{-} hydrogen bonds with only two anions, which belong to different chains. There is no anion–cation–anion bridge that could pull the anions together along the chains.

It is of interest to compare the lengthening of the O–H bond in **1** and **2** with the related lengthening in undisputed O–H···O hydrogen bonds of various kinds. Fig. 2 shows the correlation of the O–H and H···O distances in 125 O–H···O interactions found in neutron diffraction crystal structures extracted from the Cambridge Structural Database[12] (details are given in the legend). The overall correlation is as repeatedly published.[2,3,13] It is of importance that the data for different kinds of hydrogen bonds [O–H···O, O–H···O^{-}, $^{+}$O–H···O, $^{+}$O–H···O^{-}] all obey a common function r(O–H) = $f[d$(H···O)]. The data for inter-anion O–H···O interactions, indicated by triangles, *obey this function too*. Four relevant neutron diffraction studies are available: the hydrogen oxalates **1** and **2**, 2-aminoethyl phosphate,[14] **3**, and putrescine diphosphate[15] **4**. The latter two structures are also very interesting. In **3**, the anions form dimers, as shown in Fig. 3, and in **4**, the dihydrogen phosphate ions even form a layer where the anions are connected by interionic O–H···O interactions.

Fig. 2 guides directly to the valence model of the hydrogen bond.[2,3] In this model, O–H and H···O are attributed bond orders or 'valences' s, which depend strictly on the interatomic distances. In hydrogen bonds, the sum of valences at the H-atom is conserved, *i.e.* $s_{O–H} + s_{H···O} = 1.0$. In hydrogen bonds with long H···O, $s_{H···O}$ is small so that $s_{O–H}$ is only slightly reduced from unity, and O–H is only slightly elongated. If H···O is short, however, $s_{H···O}$ becomes large, leading to a large reduction of $s_{O–H}$ and a pronounced elongation of the O–H bond. According to Fig. 2, this is valid for inter-anion O–H···O interactions in the same way as for all other O–H···O hydrogen bonds. For various types of hydrogen bonds X–H···A, the distance dependence of $s_{X–H}$ and $s_{H···A}$ has been parametrized by fitting model functions against structural data (ref. 16 and references therein). Using the most recent parametrization for the case O–H···O,[16] one obtains for the O–H···O interaction in **1** the bond orders $s_{O–H} = 0.73$ and $s_{H···O} = 0.26$. This means that the H-atom is bonded with about ¾ of a valence unit to one O-atom, and with ¼ to the other. The whole interaction O–H···O is, therefore, well inside the quasi-covalent regime of strong hydrogen bonds.[2]

The experimental data discussed above do not indicate any behaviour of inter-anion O–H···O interactions that would fundamentally differ from classical hydrogen bonds. On the contrary, the covalent bonding on the donor as well as on the acceptor sides shows the normal features of strong hydrogen bonding. The effects on the covalent geometries are strong, and indicate that the O–H···O interaction in **1** and related compounds is in the regime of quasi-covalent hydrogen bonds, in which the central hydrogen atom is involved in two bonds of essentially covalent nature.

The author thanks Professor Wolfram Saenger for giving him the opportunity to carry out this study in his laboratory.

Mononuclear tris(2-mercapto-1-arylimidazolyl)hydroborato complexes of zinc, [Tm^{Ar}]ZnX: structural evidence that a sulfur rich coordination environment promotes the formation of a tetrahedral alcohol complex in a synthetic analogue of LADH

Clare Kimblin, Brian M. Bridgewater, David G. Churchill and Gerard Parkin*

Department of Chemistry, Columbia University, New York, NY 10027, USA. E-mail: parkin@chem.columbia.edu

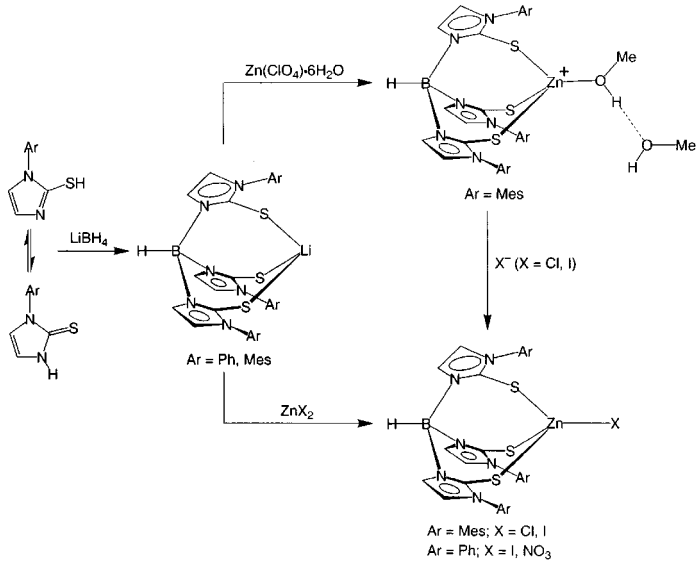
Received (in Bloomington, IN, USA) 12th August 1999, Accepted 30th September 1999

The tris(2-mercapto-1-mesitylimidazolyl)borate ligand, [Tm^{Mes}]$^-$, has been used to synthesize {[Tm^{Mes}]Zn-(HOMe)}$^+$, a stable monomeric tetrahedral zinc–methanol complex which resembles the proposed alcohol intermediate in the catalytic cycle of the mechanism of action of liver alcohol dehydrogenase.

The active sites of many zinc enzymes are composed of tetrahedral zinc centers surrounded by a water molecule and a combination of nitrogen, oxygen and sulfur donors derived from amino acid residues of the protein backbone, and may be generally represented as {[$N_xO_yS_z$]Zn^{II}(OH$_2$)}, where $x + y + z = 3$.[1] Although structurally similar, it is evident that the compositions of the {[$N_xO_yS_z$]Zn^{II}(OH$_2$)} active sites are highly varied, ranging from nitrogen rich carbonic anhydrase (CA), {[N$_3$]Zn^{II}(OH$_2$)}, to sulfur rich liver alcohol dehydrogenase (LADH), {[NS$_2$]Zn^{II}(OH$_2$)}.[1] Correspondingly, the chemistry performed by each of these enzymes is distinctly different: for example, CA is a hydrolytic enzyme, whereas LADH is responsible for the oxidation of alcohols.[1] In order to understand why Nature has elected to use different amino acid residues to promote different chemical transformations of zinc enzymes, it is essential to understand how the chemistry of zinc is modified by various donor groups. Here, we describe the syntheses of tetrahedral zinc complexes in a sulfur rich environment of relevance to LADH chemistry,[2] including the structural characterization of an alcohol complex.

Although a large number of [S$_3$] donor ligands are known, many of these are unsuitable for modeling aspects of bioinorganic zinc chemistry since they do not have the ability to inhibit the formation of six-coordinate sandwich complexes. For example, crown thioethers, such as 1,4,7-trithiacyclononane, are insufficiently sterically demanding and do not provide a protective pocket about a metal center that prevents the formation of six-coordinate sandwich complexes.[3] Tripodal thioethers, such as Rabinovich's {MeSi(CH$_2$SMe)$_3$},[4] and Riordan's [RB(CH$_2$SMe)$_3$]$^-$ (R = CH$_2$SMe, Ph, Fc)[5] and [PhB(CH$_2$SR)$_3$]$^-$ (R = Ph,[6] Bu^t [7]) offer much more potential for providing well defined and sterically encumbered coordination sites than their cyclic counterparts. However, of these ligands, only the *tert*-butyl substituted [PhB(CH$_2$SBu^t)$_3$]$^-$ derivative has been reported to be a 'tetrahedral enforcer';[7] thus, a methyl substituent on sulfur does not prevent the formation of six-coordinate compounds, *e.g.* [RB(CH$_2$SMe)$_3$]$_2$Co (R = CH$_2$SMe, Ph).[5a,b]

We are particularly interested in the application of sterically demanding tripodal ligands in which the sulfur atoms are devoid of additional substituents: ligation of this type should more closely resemble that of the negatively charged cysteine thiolates (RS$^-$) at the active site of LADH[1] than would coordination of a thioether (RSR) function. Thus, we considered that modification of Reglinski's tris(mercaptomethylimidazolyl)borate ligand [Tm^{Me}]$^-$,[8] by incorporation of bulky substituents on the imidazolyl rings, could provide a coordination environment that would allow for the isolation of monomeric species of relevance to the mechanism of action of LADH, such as four-coordinate alcohol complexes. Indeed, the aryl substituted ligands [Tm^{Ph}]$^-$ and [Tm^{Mes}]$^-$ are readily obtained by heating LiBH$_4$ with 3 equivalents of 2-mercaptophenylimidazole and 2-mercaptomesitylimidazole,[9] respectively (Scheme 1).



Scheme 1

A critical step in the proposed mechanism of action of LADH involves displacement of water from the active site to give a tetrahedral zinc–alcohol complex, {[NS$_2$]Zn^{II}(HOR)}, as an essential intermediate.[1] Despite their relevance, however, there are no mononuclear tetrahedral zinc complexes of aliphatic alcohols listed in the Cambridge Structural Database,[10] even though there are a substantial number of five- and six-coordinate derivatives.[11] It is, therefore, significant that the cationic alcohol complex {[Tm^{Mes}]Zn(HOMe)}$^+$ may be obtained by reaction of Li[Tm^{Mes}] with Zn(ClO$_4$)$_2$ in methanol (Scheme 1).

The molecular structure of {[Tm^{Mes}]Zn(HOMe)}$^+$ has been determined by X-ray diffraction (Fig. 1), which demonstrates that the [Tm^{Mes}] ligand adopts a propeller configuration.[12] Solution ^{1}H NMR spectroscopic studies indicate that this configuration is also rigid on the NMR time-scale at room temperature. For example, the two *ortho*-methyl groups of each mesityl substituent are chemically inequivalent in the ^{1}H NMR spectrum, thereby indicating that both inversion of the propeller configuration and rotation about the C–N bond are slow on the NMR time-scale.

The zinc coordination geometry in {[Tm^{Mes}]Zn(HOMe)}$^+$ resembles aspects of that in LADH. For example, the Zn–O and average Zn–S bond lengths in {[Tm^{Mes}]Zn(HOMe)}$^+$ {1.993(3) and 2.32[1] Å, respectively} are comparable to those in the

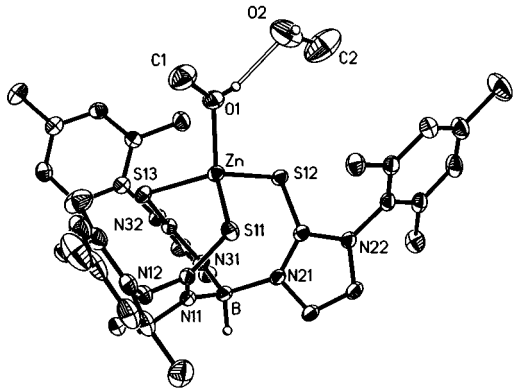


Fig. 1 Molecular structure of $\{[Tm^{Mes}]Zn(HOMe)_2\}^+$ (counter ion omitted for clarity). Selected bond lengths (Å) and angles (°): Zn–O(1) 1.993(3), Zn–S(11) 2.338(1), Zn–S(12) 2.320(1), Zn–S(13) 2.313(1); O(1)–Zn–S(11) 111.37(9), O(1)–Zn–S(12) 105.56(1), O(1)–Zn–S(13) 109.68(9).

$C_6F_5CH_2OH$ adduct of LADH (2.0 and 2.2 Å, respectively).[13] Also noteworthy is the observation that the hydroxy group of the coordinated alcohol of $\{[Tm^{Mes}]Zn(HOMe)\}^+$ participates in a hydrogen bonding interaction with an additional molecule of methanol. This interaction may be viewed as mimicking the hydrogen bond network at the active site of LADH which serves as a relay for proton transfer to the solvent.[13,14] In fact, the hydrogen bonded O···O separation of 2.58 Å between $\{[Tm^{Mes}]Zn(HOMe)\}^+$ and MeOH is effectively identical to that between the zinc bound alcohol at the active site of LADH and Ser–48 (2.6 Å).[13]

The facile isolation of a tetrahedral alcohol complex $\{[Tm^{Mes}]Zn(HOMe)\}^+$ using the tripodal $[S_3]$ tris(mercaptomesitylimidazolyl) ligand is particularly interesting given that the tripodal $[N_3]$ donor tris(imidazolyl)phosphine ligand $[Pim^{Bu^t,Pr^i}]$ yields a zinc hydroxide complex, $\{[Pim^{Bu^t,Pr^i}]ZnOH\}^+$,[15] upon reaction with $Zn(ClO_4)_2$ in methanol. Furthermore, tris(pyrazolyl)hydroborato zinc hydroxide complexes $[Tp^{RR'}]ZnOH$ have also been synthesized using methanol as solvent, in accord with the fact that simple alkoxide derivatives $[Tp^{RR'}]ZnOR$ are extremely sensitive to hydrolysis.[16] In contrast, ^1H NMR spectroscopy and mass spectrometry demonstrate that solutions of $\{[Tm^{Mes}]Zn(HOMe)\}^+$ in methanol are reasonably stable in the presence of water.

The above observations strongly indicate that the sulfur rich coordination environment provided by $[Tm^{Mes}]$ stabilizes alcohol binding to zinc. As such, it suggests that one of the reasons why LADH utilizes a sulfur rich coordination environment is to increase the stability of the required alcohol intermediate with respect to that of an aqua species.[17] In support of this notion, there is only one other structurally characterized complex listed in the Cambridge Structural Database which contains methanol coordinated to a tetrahedral zinc center, and it also possesses a sulfur rich $\{[S_3]Zn(HOMe)\}$ coordination environment; this entity is, however, a portion of a complex polymeric structure, *catena*-$(\mu$-SPh$)[(\mu$-SPh$)_6Zn_4$(MeOH)(SPh)].[18]

Although not readily displaced by water, the methanol ligand in $\{[Tm^{Mes}]Zn(HOMe)\}^+$ is displaced by anions to give neutral $[Tm^{Mes}]ZnX$ derivatives, which may also be obtained by the direct reaction of $Li[Tm^{Mes}]$ with ZnX_2 (Scheme 1). The corresponding $[Tm^{Ph}]ZnX$ (X = I, NO_3) derivatives may be obtained in an analogous manner. The molecular structures of $[Tm^{Mes}]ZnX$ (X = Cl, I) and $[Tm^{Ph}]ZnX$ (X = I, NO_3) have been determined by X-ray diffraction, thereby confirming the monomeric nature of the complexes.[12] It is also worth noting that the nitrate ligand in $[Tm^{Ph}]Zn(ONO_2)$ is coordinated in a unidentate, and not bidentate, manner, thus demonstrating that the $[Tm^{Ph}]^-$ ligand strongly favors tetrahedral coordination in zinc chemistry.

In conclusion, a monomeric tetrahedral zinc–alcohol complex has been obtained using the anionic $[Tm^{Mes}]^-$ sulfur rich donor ligand. The successful isolation of $\{[Tm^{Mes}]Zn(HOMe)\}^+$, and its stability towards water, suggest that sulfur rich coordination sites promote the formation of alcohol adducts. Thus, because such species are essential intermediates in the mechanism of action of LADH, one of the reasons why LADH possesses a sulfur rich active site may be to promote the binding of alcohol to zinc at the active site.

We thank the National Institutes of Health (Grant GM46502) for support of this research.

A mesoporous ruthenium silica hybrid aerogel with outstanding catalytic properties in the synthesis of *N*,*N*-diethylformamide from CO_2, H_2 and diethylamine

Leo Schmid, Markus Rohr and Alfons Baiker*

Laboratory of Technical Chemistry, Swiss Federal Institute of Technology, ETH Zentrum, CH-8092 Zürich, Switzerland. E-mail: baiker@tech.chem.ethz.ch

Received (in Cambridge, UK) 27th August 1999, Accepted 12th October 1999

A mesoporous ruthenium silica hybrid aerogel containing well dispersed bidentate $RuCl_2[Ph_2P(CH_2)_3PPh_2]_2$ complexes, synthesized using a sol–gel method, affords turnover frequencies up to 18 400 h^{-1} and 100% selectivity from CO_2, H_2 and diethylamine for the formation of *N*,*N*-diethylformamide.

Utilization of carbon dioxide in chemical synthesis has been fostered owing to its abundance, easy handling and non-toxicity.[1] Among several other syntheses the preparation of formic acid derivatives such as methyl formate and *N*,*N*-dimethylformamide have received considerable attention.[2,3] The first successful catalytic syntheses were exclusively based on homogeneous catalysts.[4] The technical potential of this approach is limited by the difficulties in catalyst separation and product recovery steps. This prompted us to search for a heterogeneous catalytic variant of these syntheses.[5–8] In our previous studies the mono- and bi-dentate group VIII metal phosphine complexes were covalently incorporated into microporous silica based xerogels. A considerable improvement in the stability of the active ruthenium complex could be achieved by employing biadentate complexes.[5,8] Although all of these catalysts showed high activity at 100% selectivity to the desired dimethylformamide the intrinsic activity of the free active complexes could not be reached owing to unfavourable microporous structure of the xerogel materials. Here, we report for the first time, the successful synthesis of a mesoporous hybrid aerogel catalyst and compare its catalytic behaviour with the corresponding microporous xerogel. It is shown that the activity of the mesoporous material outperforms the intrinsic activity of the free active ruthenium complex and that of the microporous catalyst by a factor of more than six.

The bidentate ruthenium phosphine complex $RuCl_2(dppp)_2$ **1** [Fig. 1, dppp = $Ph_2P(CH_2)_3PPh_2$] was prepared according to the procedure described in the literature.[9] The synthesis of the corresponding functionalized sol–gel precursor **2** (Fig. 1) and its ligand has also been described in detail.[8]

The hybrid gel catalysts **3a** and **3b** were synthesized from the functionalized precursor **2** by immobilizing this complex within a silica matrix and applying a sol–gel process. To a mixture of 15.22 g (0.10 mol) tetramethylorthosilicate (TMOS) and 7 ml tetrahydrofuran, 1.03 g 65% HNO_3 in 8.81 g H_2O and 27 ml tetrahydrofuran was added dropwise. Subsequently, 0.727 g (5×10^{-4} mol) of **2** in 20 ml tetrahydrofuran was slowly added. After stirring the homogeneous mixture overnight, 4.05 g (0.015 mol) trihexylamine in 15 ml tetrahydrofuran was added dropwise to the solution over 10 min. Within 1 h a solid gel had formed which was aged for 7 days. During this time the tetrahydrofuran which was released from the gel was replaced by ethanol. The gel was dried either by extraction of the solvent with supercritical CO_2 at 22.0 MPa and 41 °C, affording aerogel **3a** or by slow evaporation of the solvent, producing xerogel **3b**. Finally, the gels were washed with acetone and dried in vacuum at 100 °C. All steps, including aging, crushing, washing and drying, were carried out under an argon atmosphere.

^{31}P and ^{29}Si NMR investigations were carried out as described previously.[8] Nitrogen physisorption measurements of the specific surface area and mean pore diameters of the gel catalysts were performed at 77 K using a Micromeritics ASAP 2010 instrument.[6] For catalytic tests a 500 ml stainless steel reactor was used.[7] The products were analyzed by a GC equipped with a TCD and a fused silica capillary column (Supelco SPB-1).

To establish the undestructive incorporation of the active sites, solid state ^{31}P CP MAS NMR measurements for the hybrid gels **3a** and **3b** were compared with liquid ^{31}P NMR investigations of the precursor **2**. The spectra corroborated that no significant change of geometry in the coordination sphere of the phosphorus atoms had taken place. In the spectra of the solid materials, side bands were observed owing to the rotational frequency of the sample during measurements, and the peaks were broader in comparison with liquid ^{31}P NMR results for precursor **2**. Based on earlier EXAFS measurements of immobilized monodentate ruthenium phosphine complexes, which showed that these precursors were incorporated as isolated single entities,[6] it was assumed that cluster formation

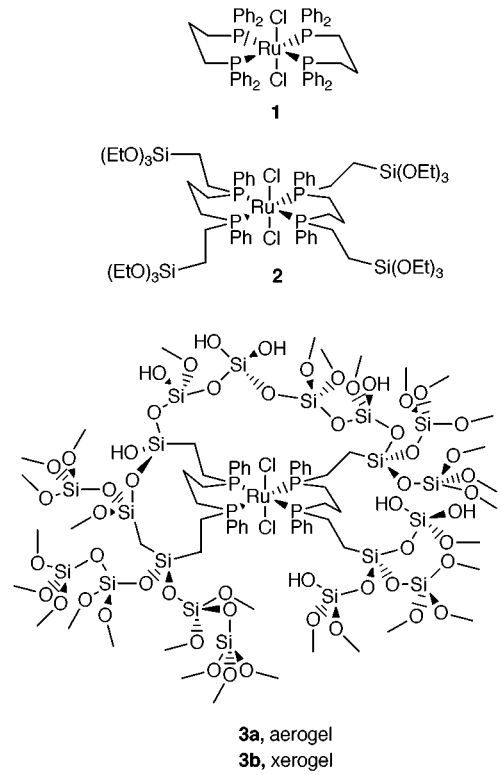

Fig. 1 Ruthenium phosphine complex **1**, which shows good activity and selectivity in the synthesis of formic acid derivatives, is functionalized by silyl ether groups (**2**) and immobilized within a silica matrix affording aerogel **3a** or xerogel **3b**, by different drying procedures.

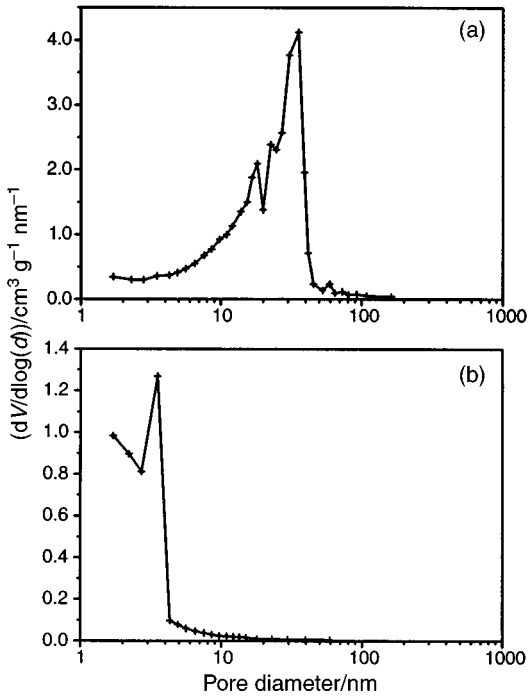

Fig. 2 Pore size distribution of aerogel **3a** (a) and xerogel **3b** (b).

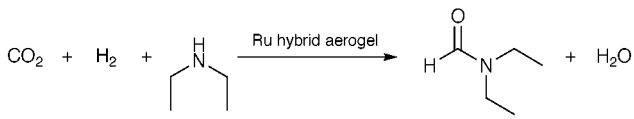
could be excluded also for bidentate complexes. ^{29}Si MAS NMR with single pulse excitation indicated a similar degree of condensation (cross linkage) for aerogel **3a** and xerogel **3b**. Textural properties of the synthesized hybrid gels **3a** and **3b** were investigated by means of nitrogen physisorption and results are shown in Fig. 2. As expected, supercritical drying of the gel applied to **3a** led mainly to mesopores, whereas for xerogel **3b**, dried by thermal evaporation of the solvent, the pore size distribution shifted to much lower values [Fig. 2(b)]. Corresponding t-plots (not shown) indicated a pronounced deviation from linearity for the xerogel between thickness 0.4 to 0.8 nm, which corroborated the presence of micropores.[10] For aerogel **3a**, exhibiting a low amount of micropores, the deviation was much less pronounced. The measured BET surface areas for xerogel **3b** and aerogel **3a** were 1000 and 670 $m^2\ g^{-1}$, respectively. Aerogel **3a** exhibited a nearly four times higher pore volume (1.74 $cm^3\ g^{-1}$) than xerogel **3b** (0.44 $cm^3\ g^{-1}$).

The hybrid gel catalysts **3a** and **3b** were tested in the synthesis of *N*,*N*-diethylformamide from CO_2, H_2 and diethylamine (Scheme 1). A fractional factorial design, including the



Scheme 1 Synthesis of *N*,*N*-diethylformamide from CO_2 as a C_1-building block with heterogeneous hybrid gels as catalysts.

Table 1 Kinetic data for aerogel **3a** under different reaction conditions. Corresponding results for xerogel **3b** are quoted for comparison

	T/°C	Total pressure/ MPa	Amount of catalyst/ 10^{-7} mol	Turnover frequency/h^{-1}
3a	90	18.0	7.5	4780
3a	110	14.0	2.5	12000
3a	110	18.0	2.5	15300
3a	110	18.0	7.5	18400
3b	110	18.0	7.5	2210

main parameters: temperature, total pressure, amount of catalyst, amount of diethylamine, initial hydrogen pressure, and type of stirrer has been carried out with the aerogel **3a**. The most influential parameters were: amount of catalyst, temperature and total pressure. Some results of the kinetic studies are summarized in Table 1. Note, that depending on the conditions, turnover frequencies up to 18400 h^{-1} were obtained with the mesoporous aerogel **3a**, whereas under the same conditions the microporous xerogel **3b** afforded a value of only 2210 h^{-1}. This improvement is attributed to the favourable textural properties of the aerogel eliminating intraparticle diffusion limitations. In both cases, a selectivity of 100% towards the desired product was found. Surprisingly, the measured turnover frequency, 3130 h^{-1}, for precursor **2** under similar reaction conditions was also significantly lower than that of the aerogel. The reason for this unprecedented increase in activity upon heterogenization is, as yet, not clear. Presumably electronic influences of the silica matrix may play a role. These new aerogels which combine stability with favourable textural properties should also be suitable for the synthesis of higher *N*,*N*-dialkylformamides from CO_2, H_2 and the corresponding dialkylamines.

Convenient preparation of mononuclear and dinuclear ruthenium hydride complexes for catalytic application

Stefan Busch and Walter Leitner*

Max-Planck-Institut für Kohlenforschung, Kaiser-Wilhelm-Platz 1, 45470 Mülheim an der Ruhr, Germany. E-mail: leitner@mpi-muelheim.mpg.de

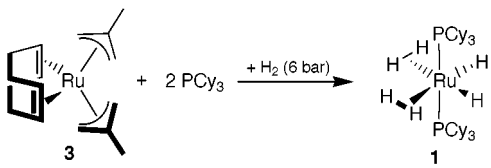
Received (in Cambridge, UK) 12th August 1999, Accepted 12th October 1999

A mixture of commercially available [Ru(cod)(η^3-C_4H_7)$_2$] and PCy_3 reacts with H_2 to give [$RuH_2(H_2)_2(PCy_3)_2$] in high yields, whereas [Ru{$Cy_2P(CH_2)_3PCy_2$}(η^3-C_4H_7)$_2$] leads to [{$Cy_2P(CH_2)_3PCy_2$}$RuH(\mu$-H)$_3$Ru(H_2){$Cy_2P(CH_2)_3PCy_2$}] under identical conditions; this new synthetic procedure provides convenient access to this type of ruthenium hydrides for investigation of their potential in catalytic reactions like the Murai-reaction.

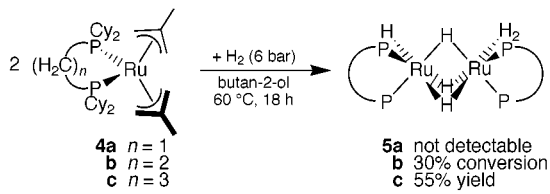
The mononuclear ruthenium hydride [$RuH_2(H_2)_2(PCy_3)_2$] **1**[1,2a] and the related binuclear complex [$(PCy_3)_2HRu(\mu$-H)$_3$Ru(H_2)(PCy_3)$_2$] **2**[2] have received considerable attention because of the unique possibility to study η^2-coordinated dihydrogen ligands[3] together with terminal and bridging hydrides in the same coordination sphere. Recent research has demonstrated a remarkable potential of **1** for C–H activation[4] and as a catalyst precursor in C–C bond forming processes, such as olefin metathesis[5] and Murai-type couplings.[6,7]

A major obstacle to a broader investigation of the catalytic properties of **1** and **2** is their time consuming synthesis, involving the highly air sensitive and not readily accessible [Ru(cod)(cot)][8] as a key intermediate. An alternative route to **1** starting from polymeric [$Ru(cod)Cl_2]_n$ was reported recently.[5,9] The generation of complexes $RuH_2L_2(PR_3)_2$ (L = neutral donor ligand) by hydrogenation of [Ru(cod)(η^3-C_4H_7)$_2$)] in the presence of PR_3 and L was described in a patented procedure, but never disclosed in the open literature.[9] None of these methodologies has been applied to the synthesis of derivatives of **1** and **2** bearing chelating bidentate phosphine ligands, which might be of particular interest for catalytic applications.[10]

We now report a very convenient one-step preparation for **1** starting from commercially available [Ru(cod)(η^3-C_4H_7)$_2$)] **3**† (Scheme 1) and the application of the same procedure to the synthesis of derivatives of **2** bearing chelating phosphines (Scheme 2). Preliminary results on the use of **1** in Murai-type coupling reactions are also given.



Scheme 1 One-pot synthesis of **1** by hydrogenation of **3** in the presence of PCy_3.



Scheme 2 Hydrogenation of ruthenium bis(allyl) complexes **4a–c** containing chelating phosphine ligands.

For the synthesis of **1** the air stable components **3** and PCy_3 are placed in a thick-walled glass reactor in 1 : 2 stoichiometry. The reactor is evacuated, purged with argon and the solvent is added. The suspension is pressurised with hydrogen (6 bar) and heated for the appropriate reaction time. After cooling to room temperature, the precipitate is collected by cannula filtration, washed twice with small portions of pentane and dried in a hydrogen stream. Under optimised conditions colourless and spectroscopically pure **1** is obtained in almost quantitative yield (Table 1).

Table 1 Optimisation of reaction parameters for the synthesis of **1**[a]

T/°C	Reaction time /h	Yield (%)	Solvent
30	18	47	Pentane
60	18	97	Pentane
60	6	75	Hexane
60	9	85	Butan-2-ol
60	18	93	Butan-2-ol
60	24	83	Butan-2-ol
85	5	74	Butan-2-ol

[a] **3**: 0.375 mmol, PCy_3: 0.75 mmol, solvent: *ca.* 3.5 cm^3.

Applying the same methodology to the mononuclear complex **4c**[11] bearing the chelating dcpp ligand resulted in clean formation of the dinuclear hydride-bridged ruthenium complex **5c**, which was isolated in 55% yield as a bright orange microcrystalline powder (Scheme 2). The structural assignment of **5c** is based on elemental analysis and the excellent agreement of its spectroscopic data with those of **2**.[2]‡

The size of the chelating ring has a strong influence on the reactivity of complexes **4a–c** (Scheme 2): complex **4b** remained

[a] Substrate: 0.2 mmol, **1**: 0.02 mmol, ethylene: *ca.* 45 mmol (30 bar), solvent: pentane (2.5 cm^3), $V_{Reactor}$:11 cm^3. [b] Determined by GC–MS analysis after 24 h.

largely unreactive and gave low, but clean conversion to **5b** (< 30%).‡ ^{31}P-NMR monitoring of the reaction of **4a** with H_2 indicated also a very slow reaction. Two different phosphorus containing products were formed, but there were no unambiguously detectable signals in the hydride region of the ^{1}H NMR spectrum.

Preliminary results of some Murai-type couplings using **1** as catalyst precursor are summarised in Table 2. In agreement with Chaudret's recent findings, the alkylation of acetophenone with one molecule of ethylene proceeded smoothly in presence of **1** (10 mol%) under mild conditions.[6]§ Appreciable amounts of the dialkylated product were formed at 50 °C. Most notably, coupling of 2-α-styrylpyridine and ethylene occurred readily to give a mixture of mono- and di-alkylated products at 30 °C. This coupling has been previously reported only for rhodium catalysts under much more forcing conditions.[12]

Further evaluation of the new procedure for the synthesis of ruthenium hydrides and detailed investigation of their catalytic behaviour are under way.

Financial support by the Max-Planck-Society and the Deutsche Forschungsgesellschaft is gratefully acknowledged. We thank Dr Tom Baker (Los Alamos National Laboratory) for helpful discussion.

The organo-pillared porous magnetic framework $Co_4(SO_4)(OH)_6(H_2NC_2H_4NH_2)_{0.5}\cdot 3H_2O$

Apinpus Rujiwatra,† Cameron J. Kepert‡ and Matthew J. Rosseinsky*†

Inorganic Chemistry Laboratory, Department of Chemistry, University of Oxford, South Parks Road, Oxford, UK OX1 3QR. E-mail: m.j.rosseinsky@liv.ac.uk

Received (in Cambridge, UK) 9th September 1999, Accepted 8th October 1999

The organo-pillared octahedral–tetrahedral (O/T) layer solid $Co_4(SO_4)(OH)_6(H_2NC_2H_4NH_2)_{0.5}\cdot 3H_2O$ is robust to loss of water molecules within the galleries, thermally stable to 300 °C and orders as a metamagnet below 14 K.

Pillared layered solids are an increasingly important class of materials of interest in the areas of sorption, separation and catalysis, as exemplified by the study of layered double hydroxides (positive layer charge),[1] smectite and other classes of clay (negative layer charge)[2] and the metal phosphonates (neutral layers).[3] Here, we report the direct synthesis and structural characterisation by single crystal X-ray diffraction of a novel type of layered hydroxide derived by organic pillaring of the namuwite[4,5]/basic zinc sulfate structure.[6] The multi-component nature of the new solid, its hydration/dehydration behaviour and the straightforward low temperature synthesis all suggest a broad family of such magnetic porous materials should be accessible.

Hydrothermal synthesis is a widely exploited low-temperature route to new solids.[6] Initial attempts to prepare microporous cobalt sulfates with a variety of amine templates at pH of below 7 led to the formation of dense, stable mineral phases such as $Co_3(SO_4)_2(OH)_2\cdot 2H_2O$ which only contain octahedral cobalt.[7] Increasing the pH of the initial synthesis gel from 7.7 to 10.8 led to precipitation of a brown sol (amorphous to X-rays) which on hydrothermal treatment for three days at 180 °C yielded small blue crystals of $Co_4(SO_4)(OH)_6(H_2NC_2H_4NH_2)_{0.5}\cdot 3H_2O$.§ Single crystal X-ray diffraction¶ showed the structure of this phase to arise from the stacking of layers formed by edge-sharing $Co^{II}(OH)_6$ octahedra regularly decorated by tetrahedral Co^{II} sites located above and below the layer at the 1/7 of the octahedral sites which are vacant (Fig. 1). Layer neutrality is completed by sulfate groups projected out from the layer which share one oxygen atom with three neighbouring CoO_6 octahedra and give the layer composition $Co_3^{oct}(SO_4)(OH)_5\cdot Co^{tet}(OH)$.

The coordination at the pseudo-tetrahedral metal site pulled out of the layer consists of three basal hydroxide anions (whose orientation is stabilised by hydrogen bonding to the neighbouring sulfate group) with the apical site occupied by the amine group of the bidentate ethylenediamine ligands. These organic units thus link two adjacent layers covalently *via* the decorating tetrahedral cobalt cations (Fig. 1). The synthesis pH controls whether cobalt is able to adopt this tetrahedral co-ordination.

The void space between the O/T layers separated by the en pillars contains three waters of crystallisation located by hydrogen bonding. The free dimensions of the channels between the pillars are 4.7 × 2.8 Å, occupying 16.5% of the crystal volume. One of the interlayer water molecules is readily lost at ambient temperature as elemental analysis indicates only two water molecules per formula unit. The difference from the composition derived from the low temperature crystallographic study is due to kinetic trapping of this water by the supporting oil at the low measuring temperature. The thermal analysis data in Fig. 2 shows that the remaining interlayer water is lost in two steps at *ca.* 100 and 200 °C to yield $Co_4(SO_4)(OH)_6(H_2NC_2H_4NH_2)_{0.5}\cdot H_2O$ [(b) c = 9.426 Å at 100(2) °C] and the fully dehydrated phase $Co_4(SO_4)(OH)_6(H_2NC_2H_4NH_2)_{0.5}$ [(c) c = 9.339 Å at 200(2) °C], respectively. The retention of the en pillars within the framework up to 200 °C was confirmed by the characteristic vibrational spectrum of the methylene group. Further heating leads to loss of the organic pillars as confirmed by loss of the methylene bending vibrations (Fig. 2, inset) and formation of Co_2O_3 *via* an unidentified crystalline intermediate above 450 °C. Water loss to stage (c) is fully reversible as demonstrated by TGA and *in situ* X-ray powder diffraction measurements of $Co_4(SO_4)(OH)_6(H_2NC_2H_4NH_2)_{0.5}$ on cooling from 200 °C to room temperature in water-saturated gas streams: the c-parameter increases sharply on cooling below 60 °C as water is reabsorbed within the interlayer region (Fig. 2 inset).‖

The *ca.* 1 Å decrease in the c parameter is consistent with a slippage of the layers occurring within the *ab*-plane. The bridging en units, having an N···N distance of 3.1 Å, may facilitate this interlayer compression if there is a tilting of the C–C bond resulting from a 120° rotation about each of the C–N bonds and change in N–C–C–N torsion angle from 60 to 180°.

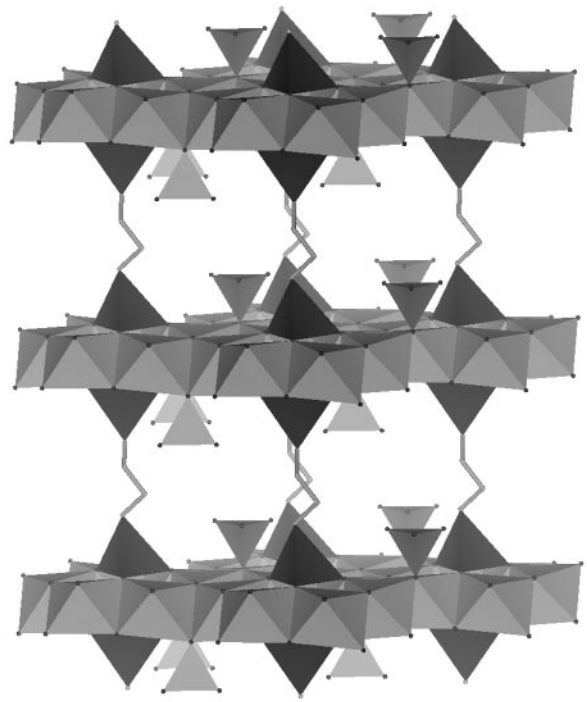

Fig. 1 The octahedral–tetrahedral (O/T) cobalt hydroxide layers of $Co_4(SO_4)(OH)_6(H_2NC_2H_4NH_2)_{0.5}\cdot 3H_2O$ are connected to each other by ethylenediamine pillars through the tetrahedral cobalt ions. The sulfate anions are the light grey tetrahedra decorating the layer. The interlayer water molecules, which can be removed while retaining the structure, are omitted for clarity.

‡ Present address: School of Chemistry, University of Sydney, NSW 2006, Australia.

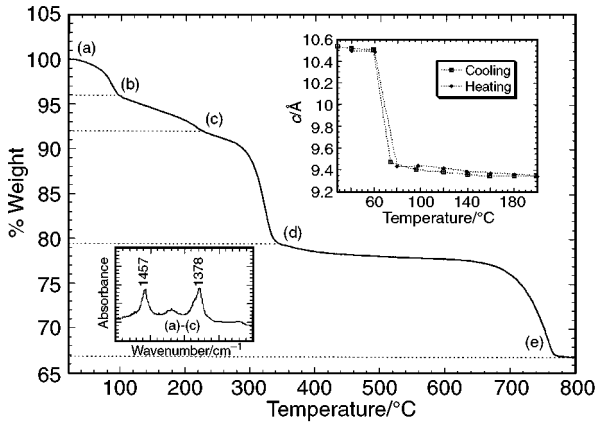

Fig. 2 TGA data under flowing nitrogen for $Co_4(SO_4)(OH)_6(H_2NC_2H_4NH_2)_{0.5}\cdot 2H_2O$ (a), showing loss of the interlayer water to yield the dehydrated pillared phase at (c). Insets show the temperature dependence of the *c*-parameter on heating and cooling in H_2O saturated helium and the IR spectra showing bending and stretching modes of the methylene groups (at 1457, 1378 and 2952, 2891 cm^{-1}).

The loss of 3D ordering with desolvation, as seen by the retention of only the 00l reflections, indicates there is no long range correlation in the direction of the resulting slippages for neighbouring sets of layers.

The magnetic susceptibility obeys the Curie–Weiss law above 190 K with an effective magnetic moment of 4.92(1) μ_B per cobalt, and a Weiss constant of −43(1) K. The downturn in the ZFC magnetisation at 14 K is consistent with antiferromagnetic ordering below this temperature.** Deviation from linearity in $M(H)$ below 190 K indicates the development of short-range order well above this temperature. The magnetisation isotherm at 5 K (Fig. 3) and the corresponding first derivative curve (dM/dH) indicates metamagnetic behaviour with a saturation moment of 1.07 μ_B per Co at 5.0 T and 5 K. Manipulation of the metal sites, pillar and tetrahedral oxyanion

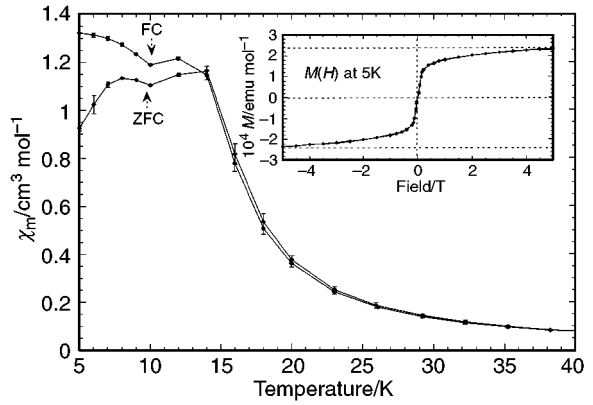

Fig. 3 Temperature dependent molar susceptibility (per mole of cobalt ions: ZFC and FC data collected in an applied field of 100 G). The field dependent magnetisation at 5 K is shown as an inset. The hysteresis at 5 K yields r_m of 336(9) emu mol^{-1} and H_c of 55(1) G.

based on this structure promises enhancement of void volume size, guest sorption and magnetic behaviour in this new class of magnetic porous material.

§ *Experimental*: $Co_4(SO_4)(OH)_6(H_2NC_2H_4NH_2)_{0.5}\cdot 3H_2O$ was synthesised hydrothermally from a mixture of $Co(NO_3)_2\cdot 6H_2O$ (98% Aldrich), H_2SO_4 (98% aq.), ethylenediamine (99% Aldrich) and concentrated aqueous 6 M KOH (pellet, 85+% Aldrich) in a molar ratio 1 : 2 : 0.6 : 5.4 : 100. The initial pH of the mixture was <2 and became about 11 after addition of concentrated $KOH_{(aq)}$, then decreasing gradually to 8 after stirring for 1 h. A dark brown sol was obtained at this stage. The reaction was performed (180 °C, 3 days, autogeneous pressure) in a sealed hydrothermal bomb (22 cm^3 bomb volume and 70% fill factor) fitted with a Teflon liner. Blue plate-like (0.30 × 0.20 × 0.05 mm) crystals mixed with monophasic powder of the same product obtained were washed and rinsed with deionised water and acetone respectively. The elemental analytical formula was $Co_4(SO_4)(OH)_6(H_2NC_2H_4NH_2)_{0.45}\cdot 2.2H_2O$. Found: C, 2.16; H, 2.82; N, 2.52; Co, 47.10; S, 6.41. Calc. C, 2.32; H, 3.11; N, 2.70; Co, 45.51; S, 6.19%.

¶ Diffraction data collection was conducted at 150 K with an Enraf-Nonius DIP2000 diffractometer equipped with fine-focus molybdenum X-ray tube and a graphite monochromator. *Crystal data*: $CH_{16}Co_4NO_{13}S$, M = 517.93, trigonal, space group $P\bar{3}$ (no. 147), a = 8.298(1), c = 10.519(2) Å, U = 627.3(2) $Å^3$, Z = 2, μ(Mo-Kα) = 5.43 mm^{-1} 3396 reflections measured, 875 unique (R_{int} = 0.054) which were used in all calculations. The en pillar and surrounding water molecules are disordered about a threefold axis and were modelled with 1/3-occupation. $R(F)$ = 0.0881 and $R(F^2)$ = 0.2193 for all data. CCDC 182/1437. See http://www.rsc.org/suppdata/cc/1999/2307/ for crystallographic files in .cif format.

‖ Powder diffraction data collection was carried out using a Phillips X-ray diffractometer with Cu-Kα radiation to confirm the purity of the bulk synthesis. High temperature data were collected for 30 ⩽ T/°C ⩽ 400 using a Siemens D5005 X-ray diffractometer with Cu-Kα radiation from a Gobel mirror multilayer monochromator: the sample was under a He or He–H_2O stream within an Anton-Parr HTK1200 high-temperature cell.

** Susceptibility measurements on a monophasic polycrystalline sample were made using a Quantum Design MPMS-SQUID magnetometer with a sample mass of 31.5 mg. Field cooled (FC) and zero-field cooled (ZFC) measurements were performed in applied fields of 100 and 1000 G over the temperature range of 5–300 K.

FTIR data were collected with a Nicolet Magna-IR 560 spectrometer with samples as self-supporting pellets.

Thermogravimetric analysis and differential scanning calorimetry (TGA-DSC) data were collected on a Rheometric Scientific STA 1500 instrument for 20 ⩽ T/°C ⩽ 800 under a nitrogen flow with a heating rate of 2 °C min^{-1}.

A new route to incompletely-condensed silsesquioxanes: base-mediated cleavage of polyhedral oligosilsesquioxanes

Frank J. Feher,* Raquel Terroba and Joseph W. Ziller

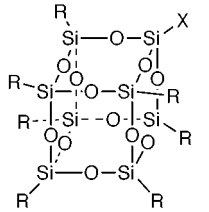
Department of Chemistry, University of California, Irvine, CA 92697-2025, USA. E-mail: fjfeher@uci.edu

Received (in Bloomington, IN, USA) 2nd August 1999, Accepted 7th October 1999

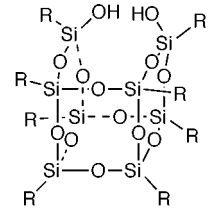
Readily available $R_8Si_8O_{12}$ frameworks react selectively with aqueous Et_4NOH to afford discrete incompletely-condensed silsesquioxanes: reaction of $R_8Si_8O_{12}$ (2a, R = c-C_6H_{11}; 2b, R = Bu^i) with Et_4NOH first produces *endo*-D_2-$R_8Si_8O_{11}(OH)_2$ (3a, R = c-C_6H_{11}; 3b, R = Bu^i), which reacts further with Et_4NOH to produce *endo*-C_2-$R_8Si_8O_{10}(OH)_4$ (5a and 5b) and *endo*-C_3-$R_7Si_7O_9(OH)_3$ (4a, R = c-C_6H_{11}; 4b, R = Bu^i); the reactions of Et_4NOH with $Me_8Si_8O_{12}$ (2c), (c-C_6H_{11})$_7$(H)Si_8O_{12} (2d) and (c-C_6H_{11})$_7$(OH)Si_8O_{12} (2d) also produce the corresponding trisilanols (*i.e. endo*-C_3-$R_7Si_7O_9(OH)_3$ (4a, R = c-C_6H_{11}; 4c, R = Me).

Incompletely condensed polyhedral silsesquioxanes are versatile precursors to a wide range of Si/O and Si/O/M frameworks.[1–7] For many years, the pool of incompletely condensed silsesquioxanes available in synthetically useful quantities was limited to a small number of compounds available *via* hydrolytic condensation of trifunctional silanes possessing relatively bulky organic groups.[8–15] Recently however, our discovery that fully-condensed $[RSiO_{3/2}]_n$ frameworks, such as (c-C_6H_{11})$_6Si_6O_9$ (**1**) and (c-C_6H_{11})$_8Si_8O_{12}$ (**2a**), can be selectively cleaved by strong acids provides access to many useful new incompletely-condensed frameworks.[16–18] In this paper, we report that base catalyzed cleavage of polyhedral silsesquioxanes can be similarly selective. For the first time, cleavage of a single Si–O–Si linkage in $R_8Si_8O_{12}$ can be achieved directly with complete retention of stereochemistry at Si to afford *endo* disilanols with structure **3**. Under more vigorous conditions, cleavage of additional Si–O–Si linkages occurs to produce tetrasilanols with structure **4** and trisilanols with structure **5**.

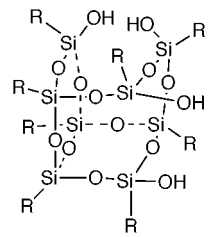
The reaction of **2a** with aqueous Et_4NOH in THF occurs over a period of several hours at room temperature. The first product to appear in the ^{29}Si NMR spectrum was D_2-symmetric disilanol **3a**, which was identified by its characteristic ^{29}Si NMR resonances at δ −60.4, −67.2, and −69.8 (2:2:4).[16] When the reaction is performed at 25 °C for 1 h with 1.1 molar equivalents of 35% aqueous Et_4NOH, **3a** is obtained as the only reaction product in *ca.* 80% yield (along with 20% of unreacted **2a**). At longer reaction times, resonances for **3a** are gradually replaced by resonances for two additional products. One of these products is C_3-symmetric trisilanol **5a**, which exhibits three resonances at δ −60.1, −67.7, and −69.4 (3:1:3) in the ^{29}Si NMR spectrum.[9] The second product, which exhibits four ^{29}Si resonances at δ −59.3, −61.5, −69.8 and −71.3 (2:2:2:2), as well as prominent peaks at *m/z* 1117.36 $[M + H]^+$ and 1139.37 $[M + Na]^+$ in its electrospray mass spectrum, is most consistent with C_2-symmetric tetrasilanol **4a**. For a typical reaction performed in THF at 25 °C, the ratio of unreacted **2a**:**3a**:**4a**:**5a** was 26:34:17:23 after 9 h and 6:18:26:50 after 15 h. When the reaction was performed in refluxing THF or methyl isobutyl ketone, all of the starting material was consumed within 3 h to produce **5a** in 47% crude yield (23% isolated yield).† The balance of the product mixture exhibited a very broad featureless ^{29}Si NMR spectrum typical of silsesquioxane resins. Samples of **3a** and **5a** prepared by the above procedure were identical in all respects to authentic samples prepared by other means.[9,16]



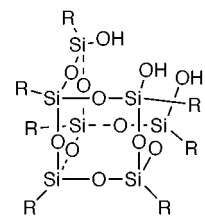
2a R = X = c-C_6H_{11}
b R = X = Bu^i
c R = X = Me
d R = c-C_6H_{11}; X = H
e R = c-C_6H_{11}; X = OH



3a R = c-C_6H_{11}
b R = Bu^i
c R = Me



4a R = c-C_6H_{11}
b R = Bu^i



5a R = c-C_6H_{11}
b R = Bu^i
c R = Me

A number of other $R_8Si_8O_{12}$ frameworks react similarly with Et_4NOH. For example, the reactions of **2d** and **2e** with aqueous Et_4NOH (1.1 equiv., THF, reflux, 1 h) both afford **5a** in good (> 50%) yield. These results clearly demonstrate that Si centers possessing H or OH groups are much more readily extracted from the Si_8O_{12} framework than Si centers possessing relatively bulky, electron-rich cyclohexyl groups.

We have only begun to explore the scope and generality of base-mediated silsesquioxane cleavage reactions, but it is already clear that this approach will provide access to a large number of useful new compounds, including many incompletely-condensed frameworks with substituents other than cycloalkyl groups. For example, the reaction of Et_4NOH with (Bu^i)$_8Si_8O_{12}$ (**2b**) appears to produce isobutyl analogs of **3**, **4** and **5**. This reaction is approximately an order of magnitude faster than the reaction of (c-C_6H_{11})$_8Si_8O_{12}$ (**2a**), and it eventually produces a good isolated yield of **5b**,‡ which was identified on the basis of compelling multinuclear NMR data and a single-crystal X-ray diffraction study.§ Similar results are observed with (vinyl)$_8Si_8O_{12}$, (cyclopentyl)$_8Si_8O_{12}$ and $Et_8Si_8O_{12}$. Even $Me_8Si_8O_{12}$ (**2c**), which is notoriously difficult to functionalize because of its very low solubility in organic solvents,[19] reacts with aqueous Et_4NOH to produce an incompletely-condensed framework with spectroscopic features expected for $Me_7Si_7O_9(OH)_3$ (**5c**).¶ The isolated yield is relatively low (< 10%), but the fact that inexpensive and readily available **2c** can be used to produce incompletely-condensed fragments of discrete polyhedral silsesquioxanes has important

implications for many potential applications—particularly the use of polyhedral silsesquioxanes as precursors to hybrid inorganic/organic polymers.[2]

The susceptibility of $R_8Si_8O_{12}$ frameworks to base-catalyzed redistribution and non-selective degradation is well established,[20,21] but the results described above are unprecedented, apparently quite general and of considerable practical importance: it is now possible to prepare synthetically useful quantities of incompletely-condensed silsesquioxanes by selectively removing Si atoms from fully condensed $R_8Si_8O_{12}$ frameworks. Our efforts to expand the scope of this methodology—including our efforts to use spherosilicates as feedstocks—will be reported in due course.

These studies were supported by Hybrid Plastics (Fountain Valley, CA) under an Advanced Technologies Program grant from the National Institute of Standards and Technology, and the National Science Foundation.

Note added in Proof: The reactions of **2a** and **2b** with Et_4NOH have been optimized to produce high isolated yields of disilanols **3a** (77%) and **3b** (98%). Similarly selective cleavage reactions have also been achieved with $R_8Si_8O_{12}$ with R = *c*-C_5H_9 and vinyl.[22]

Notes and references

† Preparation of $Cy_7Si_7O_9(OH)_3$ **(5a)**: A solution of $Cy_8Si_8O_{12}$ (500 mg, 0.46 mmol) and 35% aqueous Et_4NOH (0.2 mL, 0.49 mmol) was refluxed in THF (5 mL) for 4 h then neutralized with dilute aqueous HCl. Evaporation of the volatiles afforded a white solid, which was dissolved in Et_2O and dried over anhydrous $MgSO_4$. Filtration and partial evaporation of the solvent afforded **5a** as a white microcrystalline solid in 23% yield. The product is indistinguishable from authentic **5a** prepared *via* the hydrolytic condensation of $CySiCl_3$.

‡ Preparation of $Bu^i_7Si_7O_9(OH)_3$ (**5b**): A solution of $Bu^i_8Si_8O_{12}$ (400 mg, 0.46 mmol) and 35% aqueous Et_4NOH (0.2 mL, 0.49 mmol) was refluxed in THF (5 mL) for 4 h then neutralized with dilute aqueous HCl. Evaporation of the volatiles afforded a resinous white material, which was dissolved in Et_2O and dried over anhydrous $MgSO_4$. Filtration and evaporation of the solvent afforded crude **5b** as a tacky white solid. Recrystallization from toluene–acetonitrile gave pure **5b** as colorless crystals. Yield 142 mg (39%). Selected characterization data: Anal. Calc. for $C_{28}H_{66}Si_7O_{12}$ (found): C, 42.49 (42.62); H, 8.41 (8.52)%. $^{29}Si\{^1H\}$ NMR (99.3 MHz, C_6D_6, 25 °C) δ −58.5, −66.9, −68.3 (s, 3:1:3); 1H NMR (500 MHz, C_6D_6, 25 °C) δ 7.0 (br s, 3 H, OH), 2.21 (m, 7 H, –CH–), 1.24 (d, J = 6.6 Hz, 18 H, CH_3), 1.21 (d, J = 6.6 Hz, 18 H, CH_3), 1.17 (d, J = 6.6 Hz, 6 H, CH_3), 0.97 (d, J = 7.1 Hz, 6 H, CH_2), 0.95 (d, J = 7.1 Hz, 6 H, CH_2), 0.92 (d, J = 7.0 Hz, 2 H, CH_2), $^{13}C\{^1H\}$ NMR (125.8 MHz, C_6D_6, 25 °C) δ 25.7 (s, CH_3), 25.6 (s, CH_3), 25.5 (s, CH_3), 24.1, 24.05, 24.0 (s, 3:1:3 for CH_2), 23.4, 23.0, 22.6 (s, 3:1:3 for CH). MS (ESI, 100% MeOH): *m/z* 791.16 $[M + H]^+$, 80%); 813.08 $[M + Na]^+$, 100%).

§ Like many polyhedral silsesquioxanes, trisilanol **5b** crystallizes from many solvent systems as well formed but poorly diffracting (even at 158 K) crystals. Attempts to obtain a high quality set of diffraction data were unsuccessful, but a marginal set of data was eventually collected from a large crystal obtained from toluene–acetonitrile. Although the quality of the structure does not warrant a discussion of metrical data, it clearly identifies the trisilanol as *endo*-C_3-[(c-$C_4H_9)_7Si_7O_9(OH)_3$]. Crystal data for **5b** obtained by recrystallization from toluene–acetonitrile: $C_{28}H_{66}O_{12}Si_7$, M = 791.44, monoclinic, space group $P2_1/n$, a = 14.089(3), b = 21.336(5), c = 14.750(3) Å, α = γ = 90°, β = 100.119(4)°, V = 4365.1(17) Å^3, T = 158 K, Z = 4, ρ_{calcd} = 1.204 Mg m^{-3}, μ = 0.268 mm^{-1}, $F(000)$ = 1712, λ = 0.71073 Å, crystal dimensions 0.60 × 0.60 × 0.40 mm, 3.40° ⩽ 2θ ⩽ 57.5°; of the 45556 collected reflections, 10644 are independent, and these were used for the refinement of 424 parameters; R_1 = 0.166, wR_2 = 0.468 with $R_1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $wR_2 = (\Sigma w(F_o^2 - F_c^2)^2/\Sigma w(F_o^2)^2)^{0.5}$. CCDC 182/1444.

¶ Selected characterization data for **5c**: $^{29}Si\{^1H\}$ NMR (99.3 MHz, C_6D_6, 25 °C) δ −56.8, −64.5, −67.4 (3:1:3); MS (ESI, 100% MeOH) *m/z*: 496.96 ($[M + H]^+$, 100%); 518.86 ($[M + Na]^+$, 75%).

Superior amine catalysts for the Baylis–Hillman reaction: the use of DBU and its implications†

Varinder K. Aggarwal* and Andrea Mereu

Department of Chemistry, University of Sheffield, Brook Hill, Sheffield, UK S3 7HF. E-mail: v.aggarwal@sheffield.ac.uk

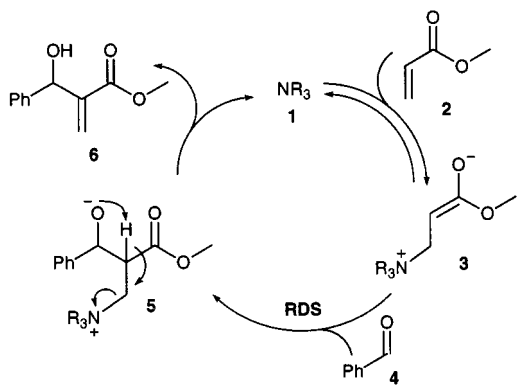
Received (in Cambridge, UK) 27th September 1999, Accepted 8th October 1999

DBU, which is normally regarded as a hindered and non-nucleophilic base, is in fact the optimum catalyst for the Baylis–Hillman reaction, providing adducts at much faster rates than using DABCO or 3HQD; the scope of the Baylis–Hillman reaction is enhanced using this catalyst and implications of this finding are discussed.

The Baylis–Hillman reaction has great synthetic utility as it converts simple starting materials into densely functionalised products.[1] However, it suffers from low reaction rates (especially for acrylates) and this often limits the range of substrates that are tolerated. Whilst acceleration can be achieved by physical methods this usually requires specialised apparatus. We recently described a chemical method for accelerating the reaction: the use of $La(OTf)_3$ and triethanolamine as cocatalysts, which provided up to 40 fold rate increase over the use of DABCO alone.[2]

Structural variations of the amine catalyst have been probed and DABCO and 3-hydroxyquinuclidine (3-HQD) provide the highest rates. Indeed, if the optimum features of the catalyst are that it should be nucleophilic and unhindered, it is hard to imagine superior ones.[3] Here we describe our study on the nature of the catalyst and the discovery that much higher rates can be achieved with alternative structures.

The rate-determining step of the Baylis–Hillman reaction is the reaction of the aldehyde **4** with the ammonium enolate **3** (Scheme 1).[3] This enolate is formed by conjugate addition of the nucleophilic amine **1** to the Michael acceptor **2** (a reversible process) and therefore to obtain faster rates, higher *concentrations* of the enolate are required. Amines which can shift the equilibrium towards the enolate **3** by stabilising this species should achieve this. We therefore screened a range of amines which all had the potential for the positive charge on nitrogen to be stabilised through conjugation with another heteroatom (Table 1). Of the aromatic heterocyclic catalysts (entries 1, 2) only DMAP gave any Baylis–Hillman adduct,[4] but at a rate only slightly higher than DABCO (Table 2, entries 1, 3). None of the amidine catalysts (entries 4, 5) were stable under the reaction conditions except for DBU **7**, which not only gave a clean reaction but also the fastest rate (Table 1, entry 6; Table 2, entry 6). The substituted guanidine gave a lower yield due to a competing side reaction involving the acrylate (entry 7).



Scheme 1

In comparison with other commonly used catalysts (Table 2), DBU was over an order of magnitude faster than the current best catalyst (3-HQD, entry 4) and superior to the DABCO–$La(OTf)_3$–triethanolamine system that we have developed (entry 2).[2] Even at 10 mol% loading, DBU was superior to both stoichiometric DABCO or 3-HQD (Table 2, entry 5).[5]

We investigated the scope of the DBU-catalysed Baylis–Hillman reaction by reacting benzaldehyde with a range of Michael acceptors (Table 3), and methyl acrylate (Table 4) and cyclohex-2-en-1-one (Table 5) with a range of electrophiles.

Notable examples from Table 3 include a fast reaction with *tert*-butyl acrylate (entry 3; DABCO gives 65% yield after 28 d[6]), and a very rapid reaction with cyclohex-2-en-1-one (entry 5).[7] Methyl vinyl ketone (MVK) is not a suitable substrate with DBU (*vide infra*) but, in any case, is a fast reacting substrate with other catalysts (*e.g.* DABCO).

Notable examples from Table 4 include reaction with 4-anisaldehyde which gave a good yield after just 2 days (entry 5; DABCO gives 90% after 20 d[8]), reaction with the notoriously difficult, hindered and deactivated 2-anisaldehyde (entry 4) and

[a] Reactions conducted on 2 mmol scale using 1:1:1 ratio of carbonyl compound: acrylate: DBU. [b] Low yield due to decomposition of aldehyde. [c] Reaction performed in presence of 0.05 equiv. $La(OTf)_3$. [d] Product found to be unstable in presence of high concentration of catalyst. [e] 0.1 equiv. DBU used.

Table 5 Reactions of aldehydes with cyclohex-2-en-1-one[a]

Entry	Aldehyde	*t*/h	Yield (%)
1	Benzaldehyde	0.5	60
2	2-Anisaldehyde	50 min	70
3	Cyclohexanecarbaldehyde	7	73
4	Trimethylacetaldehyde[b]	21	75

[a] Reactions conducted on 2 mmol scale using 1:1:1 ratio of aldehyde: cyclohex-2-en-1-one : DBU. [b] 1.2 equiv. cyclohex-2-en-1-one and 0.05% $La(OTf)_3$ used.

for the first time reactions with pivaldehyde (entry 7)[9] and trifluoroacetophenone (entries 8, 9). Pivaldehyde required $La(OTf)_3$ to promote the reaction as no adduct was obtained without it. $La(OTf)_3$ often enhances the rates and gives higher yields of adducts (Table 4, entry 7; Table 5, entry 4) but when used with benzaldehyde a less clean reaction was observed and the additional acceleration was minimal. Aldehydes with enolisable protons gave low yields of Baylis–Hillman adducts because of competing aldol reactions.[10]

Notable examples from Table 5 include high yielding reactions with all the difficult aldehydes (2-anisaldehyde, entry 2; pivaldehyde, entry 4; even the aliphatic enolisable aldehyde cyclohexanecarbaldehyde, entry 3), demonstrating the effectiveness and superiority of this catalyst. Again $La(OTf)_3$ (5 mol%) was required in the reaction with pivaldehyde (entry 4); in its absence 44% yield of adduct was obtained after 4 days. Evidently with faster reacting enones compared to acrylates, enolisable aldehydes are better tolerated.

There is one example of the use of DBU as a catalyst for the Baylis–Hillman reaction although no comment was made on its rate.[11,12] The focus of the paper was on α-alkylation of enones with acrylates as acceptors and it was proposed that DBU acted as a base rather than a nucleophile, with the reaction occurring *via* a diene enolate rather than a β-enolate. This was supported by their observation that reaction between MVK and acetaldehyde only returned starting material. Our observation that

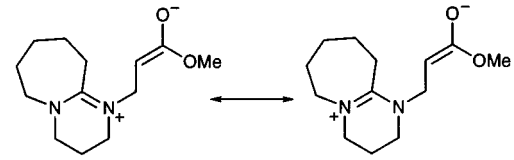

Fig. 1

acrylates work extremely well with DBU as a catalyst indicates that enolisation is *not* a requirement and that the reaction must proceed *via* the β-ammonium enolate derived from DBU and the acrylate. Furthermore we have not been able to reproduce some of their results: when we repeated the reaction between MVK and acetaldehyde we obtained polymeric material instead, no MVK was returned.

We were surprised that DBU worked so well as it is considered to be a non-nucleophilic hindered base; features that are diametrically opposite to what is normally required of amine catalysts for the Baylis–Hillman reaction. DABCO, for example, is one of the best amine catalysts and is an unhindered, nucleophilic base. The incorporation of substituents α to nitrogen result in substantial reduction in rates and this has been ascribed to the lower nucleophilicity of the base due to steric hindrance.[13] In fact, a more likely explanation is that the additional substituent contributes substantial steric hindrance to the β-ammonium enolate intermediate **3** which results in a shift in the equilibrium back to starting materials. In contrast, with DBU the intermediate β-ammonium enolate is stabilised through conjugation (Fig. 1), which increases its equilibrium concentration, and this results in significantly enhanced rates. These studies reveal that to achieve high rates in the Baylis–Hillman reaction the nucleophilicity of the amine is much less important than factors which stabilise the intermediate β-ammonium enolate.

We thank the EPSRC for financial support for this work.

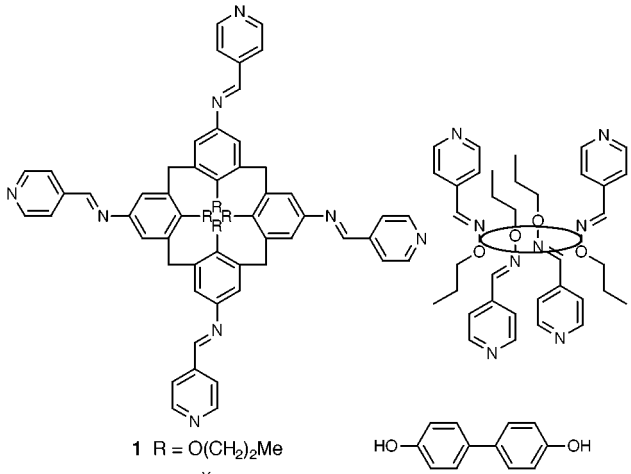
Received (in Basel, Switzerland) 18th August 1999, Accepted 13th September 1999

The synthesis of 1, characterized by a calix[4]arene backbone in 1,3-alternate conformation bearing four pyridines acting as hydrogen bond acceptors, was achieved and its solid state structure studied by X-ray diffraction on a single crystal; in the presence of 4,4′-biphenol 6 acting as a dihydrogen bond donor, compound 1 formed infinite single strand helical 1-D molecular networks which upon lateral association were packed in the crystalline phase as quintuple helices.

Molecular networks are formed by molecules possessing complementary interaction sites oriented in a divergent mode. One may tune the dimensionality (1-, 2- or 3-D) and the topology of molecular networks through the interplay between complementary components. Recently, much effort has been invested in obtaining a variety of molecular networks such as inclusion,[1] hydrogen bonded[2] or coordination networks.[3] Concerning 1-D networks, the formation of helical assemblies is a subject of current interest[4,5] and the understanding of lateral interactions between helical 1-D networks remains a challenge. Examples of helical arrangements in a variety of supramolecular assemblies have been reported.[6–8]

Here, we report the synthesis of a new building block **1** characterized by a calix[4]arene backbone in 1,3-alternate conformation and bearing four pyridine groups as hydrogen bond acceptors, as well as the structural analysis of the free ligand and of its helical hydrogen bonded molecular network obtained in the presence of 4,4′-biphenol **6**.



We have been interested in the formation of molecular networks using both H-bonds and electrostatic charge–charge interactions.[9] Molecular units possessing four H-bond acceptor sites occupying the apices of a pseudo-tetrahedron may be used for the formation of helical networks in the presence of H-bond donors possessing two divergently oriented polarised hydrogen atoms. The design of such a tecton may be based on a preorganised moiety such as a calix[4]arene backbone which offers the possibility of anchoring four H-bond acceptors in an alternating mode below and above its main plane. This type of unit is obtained using both the upper- and lower-rims of calix[4]arene. By transforming all four OH into OPr groups, the 1,3-alternate conformation was imposed, whereas by amination of the upper rim, four pyridines as H-bond acceptor groups were introduced through imine junctions. The choice of the imine functionality in *E* configuration connecting pyridines to the calix unit was based on the design of **1** which requires that pyridines should be oriented perpendicularly to the main plane defined by four CH_2 groups of the calix. Using the above mentioned strategy, calix[4]arene derivatives in 1,3-alternate conformation bearing catechol[10] or four nitrile groups[11] have been reported. An analogue of compound **1** with the calix unit in cone conformation was previously prepared.[12]

Dealing with the hydrogen bond donor part, 4,4′-biphenol **6** which possesses two phenolic groups oriented in a divergent mode and thus capable of forming an infinite hydrogen bonded molecular network was chosen.

Starting with **2**,[13] its tetra-alkylation with PrI in refluxing benzene and in the presence of Bu^{t}OK produced the desired compound **3** after crystallisation.[14] The latter, upon *ipso*-

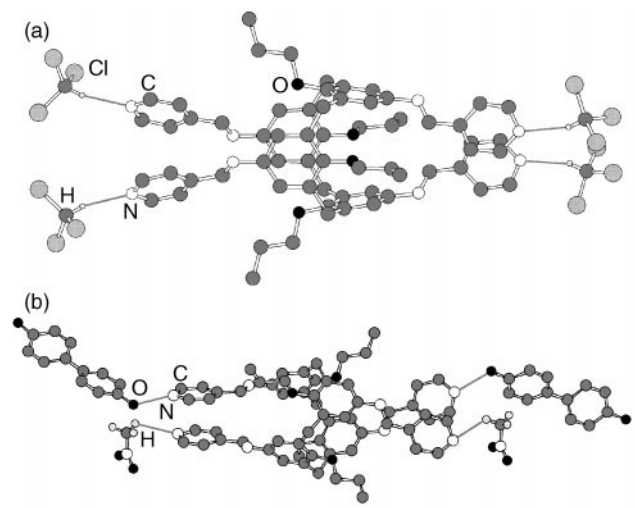


Fig. 1 (a) X-Ray structure of **1**. H atoms except for $CHCl_3$ are omitted for clarity; (b) a portion of the X-ray structure of $(\mathbf{1}\cdot\mathbf{6})_n$ H-bonded network showing the surroundings of **1** and **6**. H atoms except for $MeNO_2$ are omitted for clarity.

† Dedicated to Jean-Marie Lehn on the occasion of his 60th birthday.

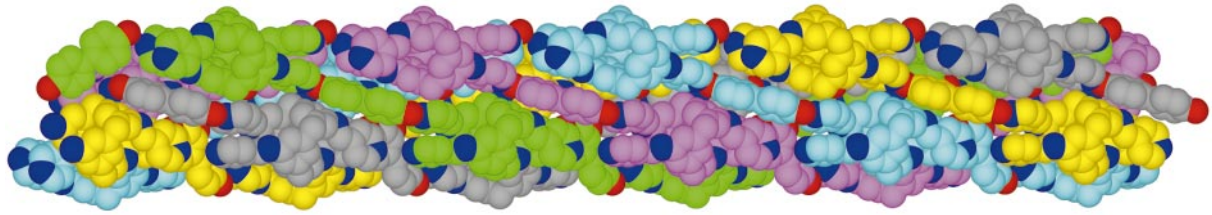

Fig. 2 A portion of the X-ray structure of (**1**·**6**)$_n$ hydrogen bonded network showing the formation of a quintuple helical arrangement comprised of five right handed helical strands represented in different colours for clarity. H atoms, O(CH$_2$)$_2$Me groups and MeNO$_2$ molecules are not shown (for distances and angles see text).

nitration,[14] gave the tetra-nitro compound **4** which was reduced to the amino compound **5** using $SnCl_2$ in EtOH.[10] Finally, treatment of **5** with 4.2 equiv. of 4-pyridylcarbaldehyde in EtOH at 80 °C in the presence of a catalytic amount of AcOH for 12 h afforded compound **1** in 52% yield after crystallisation from $CHCl_3$–MeOH.

The structure of **1** was confirmed by X-ray diffraction on a single-crystal obtained upon cooling from 80 to 25 °C a mixture of $MeNO_2$ (2 ml) and $CHCl_3$ (1 ml) containing compound **1** (2 mg).‡ As expected, compound **1** adopts a slightly pinched 1,3-alternate conformation [Fig. 1(a)]. The imine groups are in *E* configuration with an average C=N distance of 1.256 Å and C–N=C and C–N=C–C dihedral angles of 117.5 and 172.2° and −172.2° respectively. Interestingly all four pyridine units are hydrogen bonded to a $CHCl_3$ molecule with C···N and N···H distances of 3.233 and 2.338 Å respectively and an NHC angle of 156.8° demonstrating the H-bond acceptor feature of the pyridine units.

Upon slow cooling of a $MeNO_2$ (3 ml) solution of **1** (2 mg) and **6** (1.6 mg) from 80 °C to room temp., single crystals were obtained. X-Ray diffraction‡ revealed the formation of a network composed of **1**, **6** and $MeNO_2$ molecules in 1:1:1 ratio. The H-bond acceptor **1** and donor **6** form by mutual bridging a single stranded helical network which crystallises in the non-centric space group $P4_1$ or $P4_3$ [Fig. 1(b)]. The reason for the spontaneous chiral separation remains unclear. The pitch of the helix which extends along the *z* axis is composed of four **1**, four **6** and four $MeNO_2$. For each calix unit, among the four pyridines present, two of them, located on opposite sides of the backbone, participate in the formation of a helical arrangement through strong H-bonds with N···O distances of 2.703 and 2.776 Å. For the remaining two pyridines, each is located in close proximity to one $MeNO_2$ molecule with C···N distances of 3.290 and 3.312 Å. The observed helical structure is derived from the primary structure of ligand **1** which possess a S_4 screw axis. Rather interestingly, probably for best compacting reasons, five helical strands of the same handedness associate laterally in a helical fashion leading to a quintuple helical braid (Fig. 2). The formation of the braided arrangement is probably due to the uncharged nature of **1** and **6** as well as edge-to-face interactions between the pyridine units of **1** and the phenyl groups of **6** which operate in conjunction with van der Waals interactions. Finally, the quintuple helices associate laterally to form the crystal.

In conclusion, using a tetra-H-bond acceptor possessing an S_4 screw axis and a divergently oriented di-H-bond donor, a quintuple helical arrangement was obtained in the crystalline phase. The formation of the supramolecular assembly may be described as the result of molecular organisation at three different levels. The formation of a single stranded H-bonded helical network (first level), the formation of the quintuple helical braided network (second level) and the lateral association of braided networks into the compacted solid (third level). The role of the H-bond donor length and the thickness of H-bond acceptor on the pitch as well as the number of braided strands is currently under investigation.

Therefore, all atoms were kept with isotropic temperature factors and 2724 data with $I > 2\sigma(I)$ were used for refinements. Attempts to determine the absolute configuration using the Friedel's pair method failed. R = 0.099, R_w = 0.120. CCDC 182/1427. See http://www.rsc.org/suppdata/cc/1999/xxxx/ for crystallogrpahic files in .cif format.

Received (in Cambridge, UK) 27th July 1999, Accepted 8th October 1999

The reaction of $PPh_4[(\eta^5\text{-}C_5Me_5)WS_3]$ with 3 equiv. of $[Cu(MeCN)_4]PF_6$ in MeCN yielded an unusual high nuclearity W/Cu/S cluster $[\{(\eta^5\text{-}C_5Me_5)WS_3\}_3Cu_7(MeCN)_9](PF_6)_4$ 1, which in turn gave rise to a 2D polymer $[(\eta^5\text{-}C_5Me_5)WS_3Cu_3Cl(MeCN)(pz)]PF_6$ 2 upon treatment with pyrazine in MeCN in the presence of LiCl.

The transition metal-mediated self-assembly of inorganic clusters and extended macromolecular structures is of intense interest to chemists, and a remarkable range of polynuclear structures have emerged.[1–4] Homoleptic acetonitrile complexes $[M(MeCN)_m]^{n+}$ have often been used as convenient precursors for such molecular ensembles of transition metal compounds, since they undergo facile substitution of MeCN and adduct formation with N-donor ligands.[5] On the other hand, we have been interested in construction of new heterometallic sulfide clusters based on the organometallic trisulfide complex anions of group 5 and 6 metals, $[(\eta^5\text{-}C_5Me_5)MS_3]^{2-}$ (M = Nb, Ta)[6,7] and $[(\eta^5\text{-}C_5Me_5)MS_3]^-$ (M = Mo, W).[8,9] As a part of such a study, a series of $(\eta^5\text{-}C_5Me_5)M/M'/S$ clusters, consisting of tungsten and coinage metal atoms (M′), have been synthesized.[10–16] For instance, treatment of $[(\eta^5\text{-}C_5Me_5)WS_3]^-$ with CuNCS, CuBr, CuCl and $[Cu(PPh_3)_2]NO_3$ resulted in the formation of various $(\eta^5\text{-}C_5Me_5)W/Cu/S$ clusters with the nuclearity varying from WCu_3 to W_3Cu_9.[12–16]

In an attempt to expand the scope of the cluster syntheses, we examined the reaction of $PPh_4[(\eta^5\text{-}C_5Me_5)WS_3]$ with $[Cu(MeCN)_4]PF_6$, and isolated a triply-fused incomplete-cubane cluster $[\{(\eta^5\text{-}C_5Me_5)WS_3\}_3Cu_7(MeCN)_9](PF_6)_4$ **1**. Furthermore, we constructed a 2D polymeric structure $[(\eta^5\text{-}C_5Me_5)WS_3Cu_3Cl(MeCN)(pz)]PF_6$ **2** by treating **1** with pyrazine (pz) in the presence of LiCl. We report herein the synthesis and structures of these cluster/polymer compounds.

Compounds **1** and **2** were synthesized by the following procedures. When $[Cu(MeCN)_4]PF_6$ (0.17 g, 0.45 mmol) was added to a red MeCN (20 ml) solution of $PPh_4[(\eta^5\text{-}C_5Me_5)WS_3]$ (0.11 g, 0.15 mmol) under Ar, the solution darkened immediately. After stirring the solution overnight at room temperature, it was concentrated and layered by Et_2O, from which dark red cubic crystals of **1** were obtained in 76% yield. Complex **1** (0.052 g, 0.02 mmol) was then treated with 1 equiv. of LiCl in MeCN for 1 h at room temperature. 1 equiv. of pyrazine was added to the resulting homogenous solution which was stirred for 10 min. Subsequent work-up similar to that used for crystallization of **1** generated dark red plates of **2** in 67% yield. Compounds **1** and **2** are both stable toward oxygen and moisture and soluble in MeCN and DMSO.†

X-Ray analysis of **1**‡ revealed that a discrete cluster complex $[\{(\eta^5\text{-}C_5Me_5)WS_3\}_3Cu_7(MeCN)_9]^{4+}$ is accompanied by four PF_6^- counter anions. Being tetracationic, the cluster is considered as composed of three W(VI) and seven Cu(I) metal ions, and thus no redox process occurred during the cluster forming reaction. As shown in Fig. 1, the tetracationic cluster contains three $(\eta^5\text{-}C_5Me_5)WS_3$ units linked by two copper atoms, Cu(3) and Cu(5), and five more coppers chelate the sulfur ends to form a $W_3Cu_7S_9$ core. While the bridging coppers

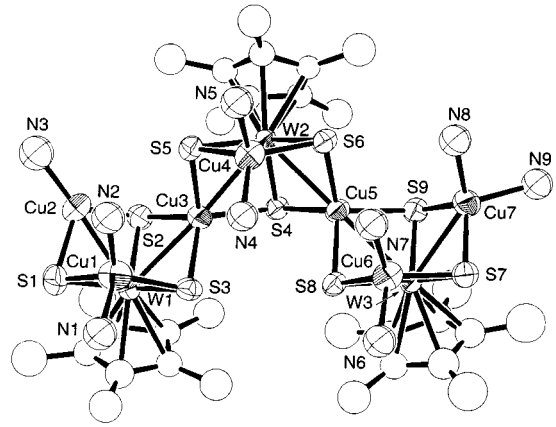

Fig. 1 Structure of the complex tetracation of **1**, with labelling scheme and 50% thermal ellipsoids. The MeCN molecules coordinated at the Cu atoms are represented by the pivotal N atoms only for clarity.

are tetrahedrally surrounded by four sulfurs, a total of nine acetonitrile molecules further coordinate to the latter five coppers to complete their coordination geometries. Alternatively, the core geometry of **1** can be viewed as a corner-shared triply-fused WCu_3S_3 incomplete cubane cluster. Interestingly, the resulting cluster structure is unsymmetric in that Cu(2) coordinates only one acetonitrile while each of the other coppers coordinates two acetonitrile molecules. It is rather surprising that one copper, Cu(2), assumes a trigonal planar coordination geometry with N(MeCN) and two μ_3-S atoms, despite the fact that the cluster was synthesized and recrystallized using MeCN as a solvent. The geometry of each incomplete WS_3Cu_3 cube of **1** is similar to those of the related double incomplete cubane clusters $[PPh_4]_2[(\eta^5\text{-}C_5Me_5)WS_3Cu_3X_3]_2$ (X = Br, Cl), as are the W–(μ_3-S) bond lengths.[12,14] It is noteworthy here that the W–Cu distances of **1** can be classified into three groups; a short W(1)–Cu(2) bond of 2.620(3) Å, long W–Cu(3,5) bonds of 2.759(3)–2.779(3) Å, and the remainder of W–Cu bonds with intermediate distances of 2.695(3)–2.720(4) Å. The observed trend of W–Cu bond lengths correlates with the number of bonding interactions at the Cu centers. The long W–Cu distances occur at Cu atoms, Cu(3) and Cu(5), each of which interacts with four S ligands and two W atoms, while the short W–Cu distance is observed for Cu(2) which interacts with three ligands and one W atom.

Compound **2**‡ has a 2D sheet structure in the crystalline state as shown in Fig. 2, which stacks along the crystallographic *b* axis. Fig. 3 displays the repeating unit of the 2D network and its connectivity. The cluster components, $[(\eta^5\text{-}C_5Me_5)WS_3Cu_3(MeCN)]$, are linked by pyrazine through interactions with Cu(1) and Cu(2′), to form zigzag chains extending along the *a* axis where the orientation of the $[(\eta^5\text{-}C_5Me_5)WS_3Cu_3(MeCN)]$ unit is alternating. The chains are then connected by μ-Cl at Cu(2*) and Cu(3) along the *c* axis. In the pyrazine linkage, two Cu–N bond distances are virtually the same, Cu(1)–N1 1.96(1)

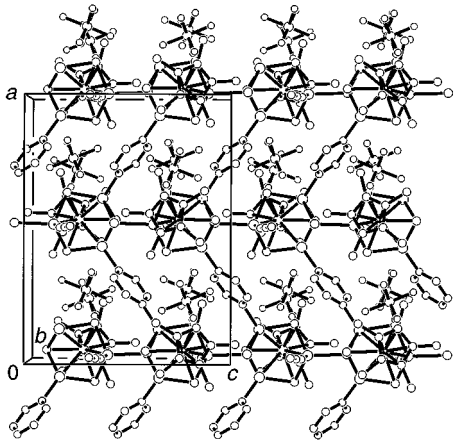

Fig. 2 Extended 2D layer structure of **2** looking down the *b* axis.

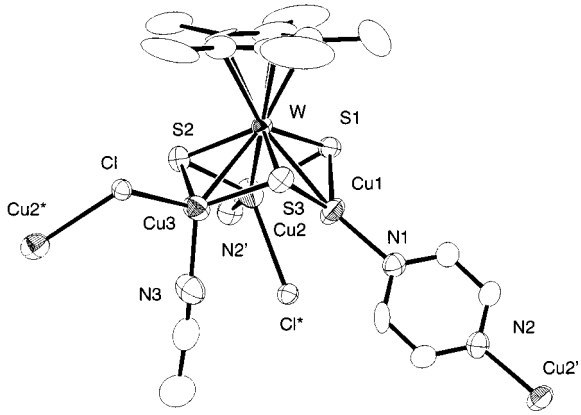

Fig. 3 Structure of a repeating unit of **2** with 50% thermal ellipsoids.

Å *cf.* Cu(2′)–N2 1.99(1) Å, while the μ-Cl bridge occurs in a less symmetric fashion with a Cu(2*)–Cl–Cu(3) angle of 106.8°, and the bonding with Cu(3) is substantially stronger, Cu(2*)–Cl 2.584(4) Å *cf.* Cu(3)–Cl 2.418(4) Å. The resulting 2D network forms a parallelogrammic mesh, and each cavity is filled by a PF_6^- anion. The surfaces of each layer are covered with η^5-C_5Me_5 rings, and the thickness of the layers is estimated to be *ca.* 9.9 Å. The layers are separated by *ca.* 3.5 Å, and no inter-layer bonding interactions were observed. The W(VI) and Cu(I) oxidation states are again retained in **2**, and the geometry of the WS_3Cu_3 incomplete cubane unit resembles closely those of **1** and $[PPh_4]_2[(\eta^5\text{-}C_5Me_5)WS_3Cu_3X_3]_2$.[12,14] Of the three copper atoms, Cu(1) is coordinated by three ligands, N(pz) and two μ_3-S atoms, and the W–Cu(1) distance is relatively short [2.654(2) Å]. On the other hand, Cu(2) and Cu(3) are coordinated by four ligands, N(pz or MeCN), μ-Cl and two μ_3-S atoms, and the W–Cu interactions are slightly weaker [2.673(2) and 2.722(2) Å].

The triply-fused incomplete-cubane $W_3S_9Cu_7$ framework of **1** is broken during the reaction with LiCl and pyrazine, providing a WS_3Cu_3 incomplete-cubane cluster as a building block of the stacked sheet structure of **2**. A key factor of this transformation is coordination of labile MeCN molecules at Cu in **1**. The formation of the intriguing 2D layer structure of **2** suggests that the construction of various types of 2D/3D extended structures will be made possible by reactions of **1** with appropriate hooking ligands such as 4,4′-bipyridine and dicyanoquinodiimine, *etc.*

Nitric oxide release from *S*-nitrosoglutathione (GSNO)

Darren R. Noble, Helen R. Swift and D. Lyn H. Williams*

Chemistry Department, University of Durham, South Road, Durham, UK DH1 3LE.
E-mail: d.l.h.williams@durham.ac.uk

Received (in Cambridge, UK) 30th September 1999, Accepted 11th October 1999

In the presence of Cu^{2+} (10^{-5} M) very little NO is generated from GSNO at ~10^{-3} M at pH 7.4, whereas the reaction is quantitative at ~10^{-6} M; this is explicable in terms of the complexation of Cu^{2+} by the product GSSG.

Interest in the biological chemistry of nitric oxide (NO) continues to expand as its range of known biological functions increases. *S*-Nitrosothiols (RSNO) are currently believed to play an important part *in vivo* in the storage and transport of NO.[1] Additionally, RSNO species, particularly *S*-nitrosoglutathione (GSNO), have wide applicability as NO donors.

It has been something of a puzzle that very little NO appears to be generated from GSNO in solution at pH 7.4 when it is at a concentration of ~1×10^{-3} mol dm^{-3}, whereas this nitrosothiol has been, and continues to be, widely used as a NO donor in a variety of experiments, both *in vitro* and *in vivo*. Indeed GSNO has been used for this purpose medicinally.[2] Most of the experiments relating to mechanistic studies of this reaction have followed the disappearance, spectrophotometrically, of the band at ~340 nm, characteristic of all RSNO species. Because of the relatively low extinction coefficients at this wavelength (~10^3 mol dm^{-3} cm^{-1}), suitable concentrations for conventional spectrophotometers are in the range 10^{-3}–10^{-4} mol dm^{-3}. The reaction mechanism has been shown[3] to involve [eqns. (1) and (2)] reaction with Cu^+ generated by reduction of Cu^{2+} by thiolate ion; the former is

$$2Cu^{2+} + 2RS^- = 2Cu^+ + RSSR \quad (1)$$

$$Cu^+ + RSNO = Cu^{2+} + RS^- + NO \quad (2)$$

often present as an impurity at low concentration levels, and the latter is always present at low concentration, because of the slight reversibility of RSNO formation from nitrous acid and a thiol.[4] We,[5] and others,[6] have shown that even at these millimolar concentrations, reaction can, however, be made quantitative by the addition of further amounts of Cu^{2+} or thiolate ion. For example the half-life for effectively quantitative decomposition of GSNO (5×10^{-4} mol dm^{-3}) containing added Cu^{2+} (5×10^{-5} mol dm^{-3}) and glutathione (GSH) (5×10^{-5} mol dm^{-3}) is ~15 min. Addition of the metal ion chelator EDTA stops the reaction completely.

We now report results from the direct measurement of NO produced from GSNO over a range of initial concentrations of GSNO (3×10^{-6} to 4×10^{-4} mol dm^{-3}), all at pH 7.4, and in the presence of added Cu^{2+} (1×10^{-5} mol dm^{-3}). Measurements were made using a commercial NO probe (WPI ISO-NO Mark II), which was calibrated using NO generated from nitrous acid and ascorbate. The results are quite dramatic, and are presented in Fig. 1 as the percentage yield NO as a function of time, generated from the different GSNO concentrations. At the lowest concentrations studied it is clear that the yield of NO is essentially quantitative, whereas as the [GSNO] is increased this yield falls, until at 4×10^{-4} mol dm^{-3} the yield of NO is only ~5%.† The last trace confirms the result (~5% decomposition) obtained spectrophotometrically at this concentration. Again no reaction occurred when EDTA was added. A similar result was obtained without added Cu^{2+}, relying on the impurity Cu^{2+} levels in the water/buffer components, but reaction rates were somewhat less.

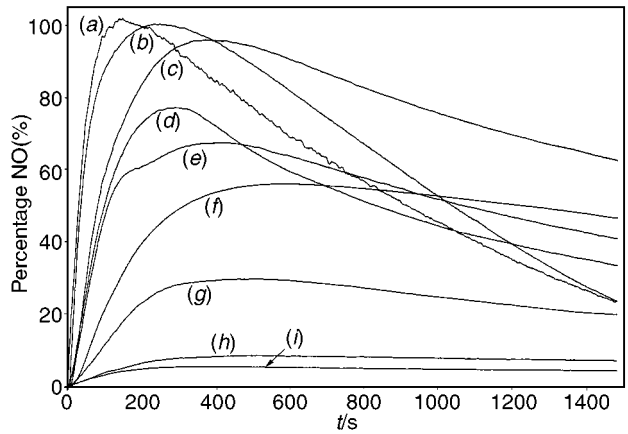

Fig. 1 The percentage NO generated from GSNO in the presence of added Cu^{2+} (1×10^{-5} mol dm^{-3}) as a function of the initial [GSNO]: (*a*) 3.0×10^{-6}, (*b*) 6.2×10^{-6}, (*c*) 1.2×10^{-5}, (*d*) 2.0×10^{-5}, (*e*) 2.3×10^{-5}, (*f*) 3.1×10^{-5}, (*g*) 7.4×10^{-5}, (*h*) 2.2×10^{-4} and (*i*) 3.7×10^{-4} mol dm^{-3}.

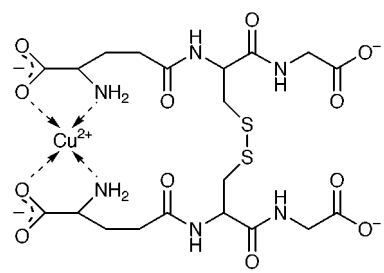
An explanation of these unusual results can be obtained if we consider the possibility that the organic product, the oxidised form of glutathione (GSSG), itself complexes the Cu^{2+} ions. Such complexes are well-known,[7] and have been identified spectrally. The suggested structure for the 1:1 complex with GSSG (absorption maxima at 250 and 625 nm) is given as **1**, but at higher [Cu^{2+}] a 2:1 complex has also been isolated and its crystal structure established.[8] The characteristic shoulder at 250 nm could be observed in the final spectrum from GSNO decomposition in our experiments.

To test this idea more directly we carried out the reaction of GSNO (3×10^{-6} mol dm^{-3}) in the presence of increasing amounts of added GSSG in the range 1×10^{-5} to 2×10^{-4} mol dm^{-3}). The results are given in Fig. 2. It is clear that, over this range, the percentage yield of NO decreases progressively from ~90 to ~10%.

Exactly the same pattern (not shown) was found for the reaction studied spectrophotometrically, *i.e.* at higher [GSNO], with added Cu^{2+} and GSH, when again addition of GSSG progressively stopped the reaction at incomplete conversion.

This explains our present set of results. The product GSSG is in effect acting as a metal ion chelator (for Cu^{2+} in this case), preventing reaction from occurring as the copper is removed from solution. It is to be expected that this effect is more marked



1

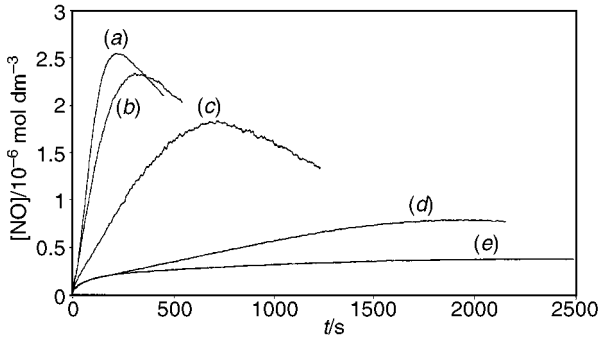


Fig. 2 The percentage NO generated from GSNO (3.1×10^{-6} mol dm^{-3}) in the presence of added Cu^{2+} (1×10^{-5} mol dm^{-3}) as a function of added GSSG: (*a*) 0, (*b*) 1.0×10^{-5}, (*c*) 2.0×10^{-5}, (*d*) 5.0×10^{-5} and (*e*) 2.0×10^{-4} mol dm^{-3}.

at the higher [GSNO], since more GSSG is then generated. Obviously the addition of more Cu^{2+} under these conditions will help promote reaction, as will the addition of GSH, since we propose that thiol/thiolate will be able to generate Cu^{+} from the GSSG–Cu^{2+} complex. We have tested this by addition of GSH to a solution of GSSG–Cu^{2+}, when the low extinction absorbance peak at 625 nm disappeared, and when the specific Cu^{+} chelator neocuproine[9] was added, the characteristic absorbance at 453 nm was immediately formed, corresponding to 82% conversion to Cu^{+}. So added GSH not only generates Cu^{+} from Cu^{2+} to start off the reaction, but also can generate Cu^{+} from the product GSSG–Cu^{2+} complex, allowing reaction to go on to completion. In the absence of added GSH however, when its concentration is very low, the inequality [GSSG] > [GSH] soon applies in the early stages of the reaction, and Cu^{+} cannot be retrieved from the GSSG–Cu^{2+} complex and reaction effectively ceases.

Higher concentrations of added GSH (1×10^{-4} to 1×10^{-3} mol dm^{-3}) inhibit NO formation from GSNO, probably since GSH–Cu^{+} complexes[10] are formed. Much higher thiolate concentrations lead to a totally new reaction where the main nitrogen product is ammonia and not NO.[11]

It has also been suggested[6] that the Cu^{+}-promoted decomposition of GSNO does not involve reoxidation of Cu^{+}, since no complex formation occurred when the specific Cu^{2+} chelator cuprizone was added. We found that Cu^{2+} is complexed more strongly to GSSG than it is to cuprizone, since when Cu^{2+} was added to equal concentrations of cuprizone and GSSG, no cuprizone complex is formed. However, we also find that cuprizone does stop the reaction of *S*-nitroso-*N*-acetylpenicillamine (SNAP), added either at the start or after ~60% reaction. In this case the disulfide does not have an inhibiting effect on the reaction.

We have looked briefly at the decomposition characteristics of *S*-nitrosocysteine (SNC). In contrast to the behaviour of GSNO, SNC decomposes quantitatively to give NO and cystine, even at the higher millimolar concentrations. When we examine the decomposition as a function of initial [SNC], we find that there is no great change, either in the rate of reaction, or in the NO yield over the range 3×10^{-6} to 1×10^{-3} mol dm^{-3}. The absence of the glutamyl residue here does not allow complex formation as in **1**.

It is probable the unreactivity of *S*-nitrosocaptopril at millimolar concentrations arises from the Cu^{2+}-complexing ability of the product disulfide since it contains a similar arrangement of atoms as in the glutamate residue in glutathione. This hypothesis remains to be tested.

A necessary consequence of our present results is that no structure–reactivity conclusions can be drawn from the rate constants (measured over a range of [Cu^{2+}]) of different RSNO structures, *when they have been measured at the millimolar concentration level*. This includes a series of rate constants reported earlier by us.[12] We no longer need to invoke the requirement of bidentate coordination of Cu^{+} with the nitroso group and a free amino group. GSNO and SNC have comparable decomposition reactivities at micromolar concentrations. The apparent greater reactivity of SNC at millimolar concentrations is not due, as previously thought, to the enhanced reactivity of SNC (because of the possibility of strong bidentate coordination of Cu^{+}), but rather due to the much reduced reactivity of GSNO due to the strong chelation of Cu^{2+} by the product GSSG. This effect was also found to be a major factor in the decomposition characteristics of a novel *S*-nitroso sugar derivative.[13]

We thank the EPSRC for a Research Grant which supported this work.

Notes and references

† Ideally the NO traces should level off when reaction is effectively over. The falling away must represent loss of NO either by oxidation or some other reaction.

Porphyrinogen tetraanion functioning as a polymetallic assembler: nickel-*meso*-octaethylporphyrinogen binding four transition metal ions at the periphery

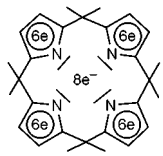
Lucia Bonomo, Euro Solari, Géraldine Martin, Rosario Scopelliti and Carlo Floriani*

Institut de Chimie Minérale et Analytique, BCH, Université de Lausanne, CH-1015 Lausanne, Switzerland. E-mail: carlo.floriani@icma.unil.ch

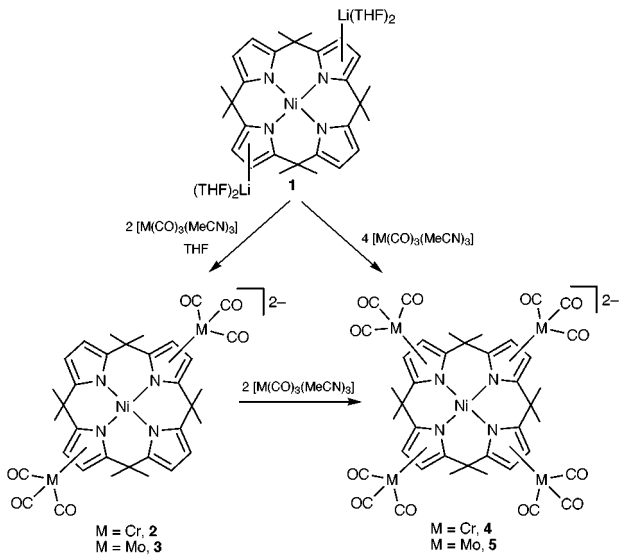
Received (in Basel, Switzerland) 6th September 1999, Accepted 15th October 1999

Nickel(II)-*meso*-octaethylporphyrinogen dianion behaves as a π-extended ligand binding four M(CO)$_3$ [M = Cr, Mo] fragments at the periphery, so that the porphyrinogen can assemble five metal centers around itself.

The interest in polymetallic frameworks is exponentially increasing in the domain of discovering cooperative metallic properties, *i.e.* magnetic or chemical reactivity, and, in general, in the context of materials science.[1] One of the molecular approaches to extended polymetallic structures is focused on organic fragments which, by displaying a variety of bonding modes, can assemble the maximum number of metal ions around themselves, as shown in the pioneering work by Constable and co-workers.[2] Such an assembly may function as a building block for extended structures. In this context, we should mention the *meso*-octaalkylporphyrinogen tetraanion,



which binds the metal both by the use of the N_4 core and the pyrroles functioning similarly to cyclopentadienyl anions in the periphery.[3–6] A peculiar property of such dimetallic systems is the electron transfer occurring between the ligand and the peripheral metals.[4] The present report deals with the maximum exploitation of the metal binding ability of the porphyrinogen tetraanion making use of its 32 available electrons for binding up to five metal ions.[3e,5]



Scheme 1

The synthetic sequence is displayed in Scheme 1. The reaction of the nickel-porphyrinogen dianion **1**[6] with 2 mol $[M(CO)_3(MeCN)_3]$[7] [M = Cr, Mo] led to the dimetallated forms **2** and **3**,† which can be further metallated to **4** and **5**,‡ thus forming polymetallic porphyrinogen complexes (65–80%). Each pyrrole functions as an η^5 binding site in the two step reaction and displaces the three labile acetonitriles from the group VI metals. Although the complexes are displayed in Scheme 1 as anions, they occur as ion-pairs in the solid state with lithium cations binding to the oxygens of the carbonyls.[8] The IR spectra in the solid state are somewhat complicated by

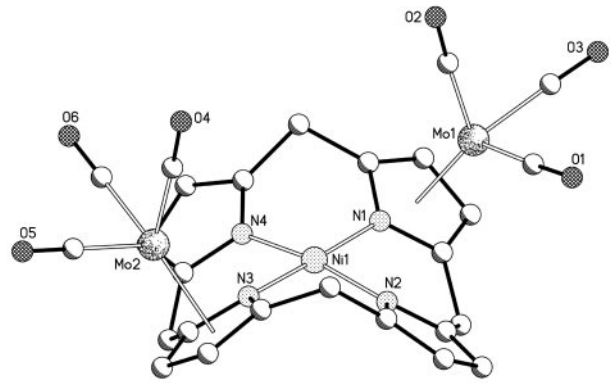


Fig. 1 A plot showing the dianion of compound **3**. Selected bond distances (Å): Ni1–N_{av} 1.877(3), Mo1–η^5(Pyr) 2.087(2), Mo2–η^5(Pyr) 2.091(2), Mo1–C_{av} 1.918(5), Mo2–C_{av} 1.903(6), C–O_{av} 1.177(6), out of plane Ni1–N_4 0.069(2). η^5(Pyr) indicates the centroid.

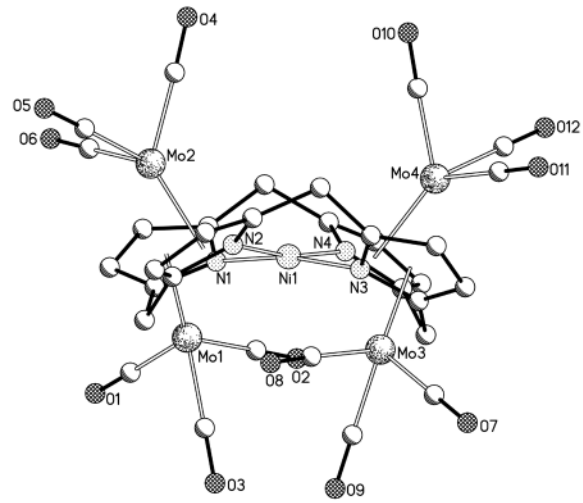

Fig. 2 A plot showing the dianion of compound **5**. Selected bond distances (Å): Ni1–N_{av} 1.874(3), Mo1–η^5(Pyr) 2.079(2), Mo2–η^5(Pyr) 2.086(2), Mo3–η^5(Pyr) 2.084(2), Mo4–η^5(Pyr) 2.087(2), Mo1–C_{av} 1.929(5), Mo2–C_{av} 1.926(5), Mo3–C_{av} 1.921(5), Mo4–C_{av} 1.922(5), C–O_{av} 1.173(6), out of plane Ni1–N_4 0.002(2). η^5(Pyr) indicates the centroid.

the lowering of the local symmetry due to solid state effects and the lithium–oxygen interactions, while in solution all complexes have C–O stretching vibrations according to a C_{3v} symmetry or very close to it. Further characterization has been carried out using ^{1}H NMR and X-ray analysis for both **3** and **5**, the structures being displayed in Figs. 1 and 2, respectively, with some relevant structural parameters provided in the captions.§

The first two $M(CO)_3$ fragments bind η^5 to two *trans*-pyrroles and are arranged *syn* to each other. The porphyrinogen displays a saddle-shape conformation, with the usual trend in the structural parameters. The overall conformation of the ligand does not change significantly moving from **3** to **5**, with the four $M(CO)_3$ fragments η^5-bonded to the four pyrroles. The sequence is up and down, so that two are bonded at the upper face and two at the bottom face. The structural parameters of the Ni-porphyrinogen moiety[6a] are not particularly affected by the presence of the $Mo(CO)_3$ fragments. In both complexes some of the lithium cations are associated with the carbonyl oxygens O1 and O4 in **3**, and O9 in **5**. Complexes **2**–**5** show how the nickel-porphyrinogen complex is a very versatile π-ligand for a variety of M(0) complexes, and how one can proceed from **2**–**5** to build up extended polymetallic structures.

Notes and references

† *Synthesis* of **3**. $[Mo(CO)_3(MeCN)_3]$ (6.10 g, 20.14 mmol) was added to a solution of **1** (9.03 g, 10.07 mmol) in THF (220 cm^3), resulting in a yellow–brown solution which was stirred at room temperature for 24 h. The solvent was evaporated and Et_2O (200 cm^3) was added to the obtained orange oily residue. The mixture was stirred overnight to give a yellow powder which was collected and dried *in vacuo* (9.60 g, 80%). Crystals suitable for X-ray diffraction were grown in Et_2O. (Found: C, 55.05; H, 5.41; N, 4.35. **2**·$Li_2(THF)_3$, $C_{54}H_{72}N_4Li_2Mo_2NiO_9$, requires: C, 54.70; H, 6.12; N, 4.35%). ^{1}H NMR (d_8-THF, 400 MHz, 298 K) δ 6.08 (d, J = 2.93 Hz, 2H, C_4H_2N), 6.01 (d, J = 2.93 Hz, 2H, C_4H_2N), 5.50 (d, J = 2.93 Hz, 2H, C_4H_2N), 5.41 (d, J = 2.93 Hz, 2H, C_4H_2N), 4.98 (dq, J_{gem} = 13.2 Hz, J_{vic} = 7.34 Hz, 2H, CH_2), 3.82 (dq, J_{gem} = 13.6 Hz, J_{vic} = 7.34 Hz, 2H, CH_2), 3.55 (m, 12H, THF), 2.87 (dq, J_{gem} = 12.8 Hz, J_{vic} = 7.34 Hz, 2H, CH_2), 2.72 (dq, J_{gem} = 13.2 Hz, J_{vic} = 7.34 Hz, 2H, CH_2), 2.32 (m, 4H, CH_2), 2.18 (m, 4H, CH_2), 1.46 (m, 18H, THF + CH_3), 1.32 (t, J = 7.34 Hz, 6H, CH_3), 1.20 (t, J = 7.34 Hz, 6H, CH_3), 0.89 (t, J = 7.34 Hz, 6H, CH_3). FEATURE ARTICLE

Building molecular wires from the colours of life: conjugated porphyrin oligomers

Harry L. Anderson

Department of Chemistry, University of Oxford, Dyson Perrins Laboratory, South Parks Road, Oxford, UK OX1 3QY. E-mail: harry.anderson@chem.ox.ac.uk

Received (in Cambridge, UK) 25th May 1999, Accepted 13th July 1999

Conjugated porphyrin polymers are giant supramolecular chromophores with extraordinary electrooptical and nonlinear optical properties. Close collaboration between synthetic organic chemists, chemical physicists and theoreticians has yielded new insights into the electronic structure of these remarkable materials. Alkyne-linked oligomers have been most intensively investigated. Several strands of independent work show that the unusual electronic behaviour of these materials can be attributed to strong ground state interporphyrin conjugation, which is amplified in the excited states, and in the oxidised and reduced forms.

Many porphyrin oligomers have been studied as models for natural photosynthetic systems[1] and as enzyme mimics.[2] Most of them are not conjugated; that is to say there is no significant π-overlap between the macrocycles, and their electronic absorption spectra resemble those of their components. Recently several research groups have created conjugated porphyrin oligomers, in which the porphyrin π-systems merge to form giant supramolecular chromophores.[3–14] Conjugated oligomers derived from small heterocycles, such as thiophene, are useful semiconductors,[15] so it is interesting to compare conjugated oligomers derived from larger, more polarisable, aromatic units such as porphyrins. This Feature Article highlights the emerging design principles, and structure–property relationships, for materials of this type, and focuses on interporphyrin conjugation: how to maximise it, how to measure it, and how to use it to make advanced optoelectronic materials.

Harry Anderson is a Lecturer at the Dyson Perrins Laboratory (Organic Chemistry), which is part of the Department of Chemistry at the University of Oxford. He graduated from the University of Oxford in 1987 and did his PhD at the University of Cambridge, with Professor Jeremy Sanders, then spent three years as a Research Fellow, funded by Magdalene College, in Cambridge and one year working with Professor François Diederich at ETH Zürich, before taking up his current post in 1994. His research interests include many aspects of synthetic supramolecular chemistry, with particular emphasis on dyes and conjugated electronic materials.

Porphyrins as building blocks for electronic materials

The word *porphyrin* is derived from the Greek *porphura* meaning purple, and all porphyrins are intensely coloured.[16] The electronic absorption spectrum of a typical porphyrin, such as zinc octaethylporphyrin ZnOEP **1** (Fig. 1) consists of a strong transition to the second excited state ($S_0 \rightarrow S_2$) at about 400 nm (the Soret or B band) and a weak transition to the first excited state ($S_0 \rightarrow S_1$) at about 550 nm (the Q band). Internal conversion from S_2 to S_1 is rapid so fluorescence is only detected from S_1. The B and the Q bands both arise from π–π* transitions and can be explained by considering the four frontier orbitals (the 'Gouterman four orbital model'): two π orbitals (a_{1u} and a_{2u}) and a degenerate pair of π* orbitals (e_{gx} and e_{gy}). The two highest occupied π orbitals happen to have about the same energy. One might imagine that this would lead to two almost coincident absorption bands due to $a_{1u} \rightarrow e_g$ and $a_{2u} \rightarrow e_g$ transitions, but in fact these two transitions mix together by a process known as configurational interaction, resulting in two bands with very different intensities and wavelengths: constructive interference leads to the intense short-wavelength B band, while the weak long-wavelength Q band results from

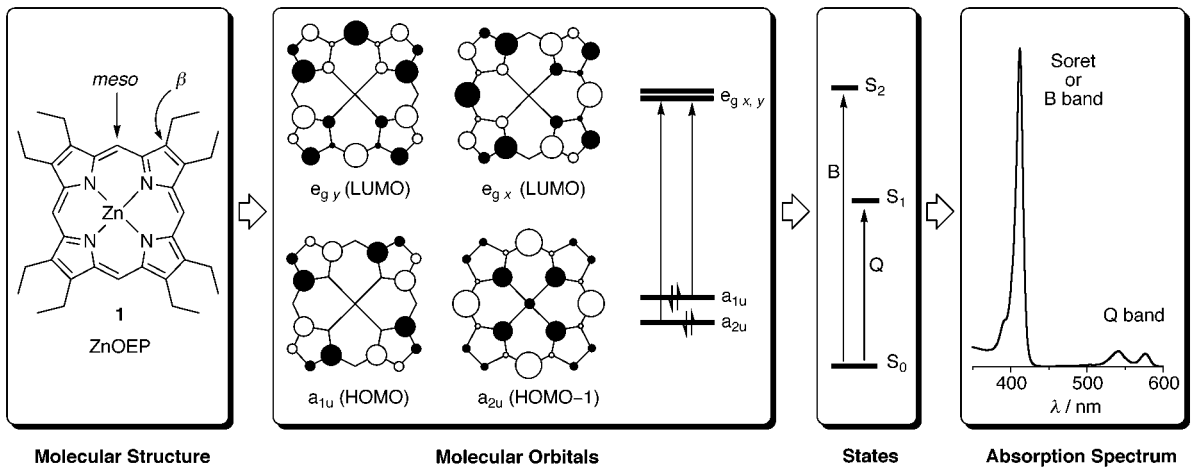

Fig. 1 The four Gouterman molecular orbitals explain the absorption spectra of simple porphyrins, such as **1**.

destructive combinations. The two types of position on the porphyrin periphery are referred to as *meso* and *β*. The a_{1u} orbital has nodes at all four *meso* positions whereas the a_{2u} orbital has high coefficients at these sites (Fig. 1).

Many synthetic porphyrins have *meso*-aryl substituents. These cause only a slight perturbation to the electronic structure, because there is minimal π-overlap between the aryl ring and the porphyrin, due to the large aryl–porphyrin dihedral angles, which result from steric interactions with the *β*-hydrogens. The distribution of aryl–porphyrin dihedral angles for some *ortho*-unsubstituted, *β*-unsubstituted *meso*-aryl porphyrins from the Cambridge Crystallographic Database (CCD)[17] is shown in Fig. 2. The zinc(II), copper(II), nickel(II) and free-base porphyrins have similar distributions of dihedral angles (mean = 73°; standard deviation = 9°). *meso*-Phenylene-linked porphyrin oligomers do not exhibit significant conjugation because of this non-planarity.[1c–f] Directly *meso–meso* bonded porphyrin oligomers are non-conjugated for the same reason.[1f,18] Lindsey and co-workers have investigated a system of *meso–meso* diphenylethyne-linked porphyrin oligomers, which have been called 'molecular photonic wires' because of their efficient inter-porphyrin energy transfer.[1c,d] However, these porphyrin oligomers are not conjugated (so they are not 'molecular wires' in the sense used in this review) because of the *meso*-aryl twist discussed above; their absorption spectra are almost identical to those of the corresponding monomers.[1d] Conjugation was intentionally minimised in the design of these systems to avoid electron-transfer quenching.

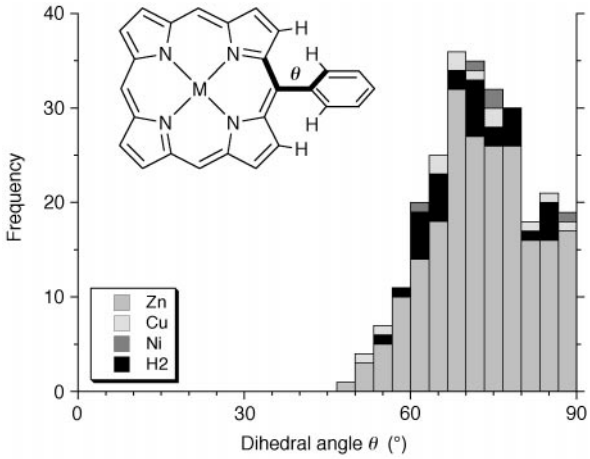

Fig. 2 Distribution of dihedral angles in *meso*-aryl Zn^{II}, Cu^{II}, Ni^{II} and free-base porphyrins, from the CCD, excluding structures with *R* factor > 10% or with disorder (ref. 17).

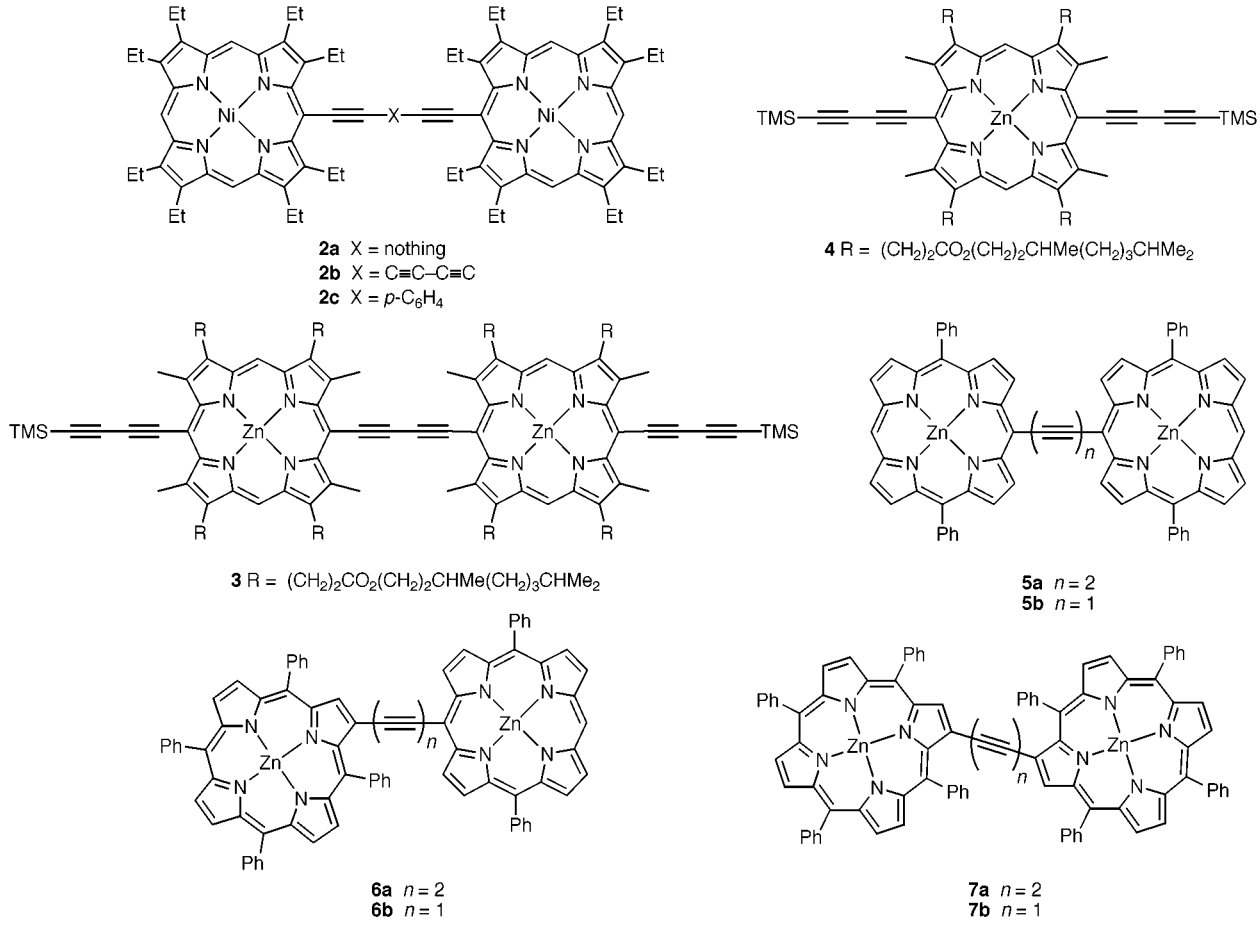
Types of conjugated porphyrin oligomers and their electronic spectra

The first conjugated porphyrin dimer **2a** was reported by Arnold *et al.* in 1978,[4a] although its unusual properties were not explored until the 1990s, at about the time that Anderson[3a] and Therien[13a–c] reported related *meso*-butadiyne-linked zinc dimers **3** and **5**–**7** respectively. The UV-visible absorption spectra of these dimers all exhibit broadly split B bands and unusually intense red-shifted Q bands, indicating substantial porphyrin–porphyrin conjugation; Fig. 3 compares the absorption spectra of dimer **3** with monomer **4**, which is an ideal model compound because of the identical local porphyrin environment. Polarised spectroscopy[3c] has shown that the more red-shifted components of both the B and Q bands (B_x and Q_x) are polarised down the acetylenic axis of the molecule, whereas the blue-shifted components (B_y and Q_y) are polarised in the perpendicular in-plane direction. Exciton coupling theory would predict some B_x/B_y splitting of this type, but the magnitude of the splitting is far greater than this theory predicts.[3a]

Conjugated porphyrin dimers make challenging subjects for quantum mechanical calculation, even with modern semi-



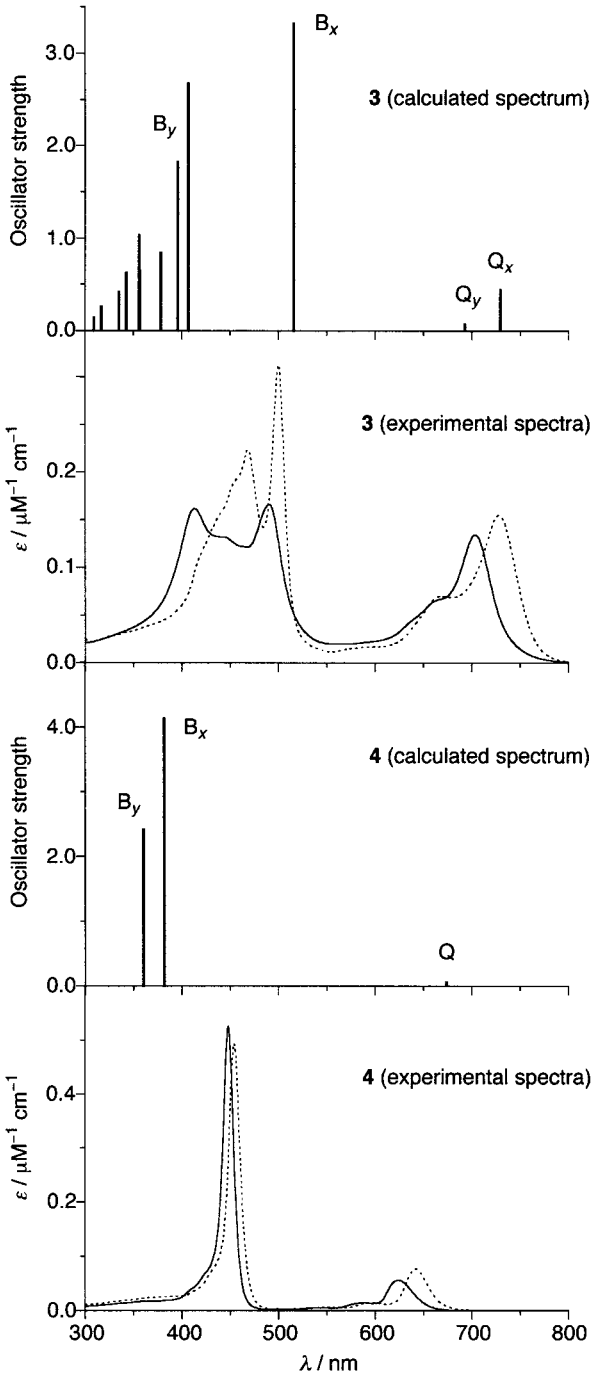


Fig. 3 Experimental and calculated electronic absorption spectra of **3** and **4**. Experimental spectra were recorded in CH_2Cl_2 (plain) and in 1% pyridine–CH_2Cl_2 (dashed) [refs 3(*a*), (*i*)].

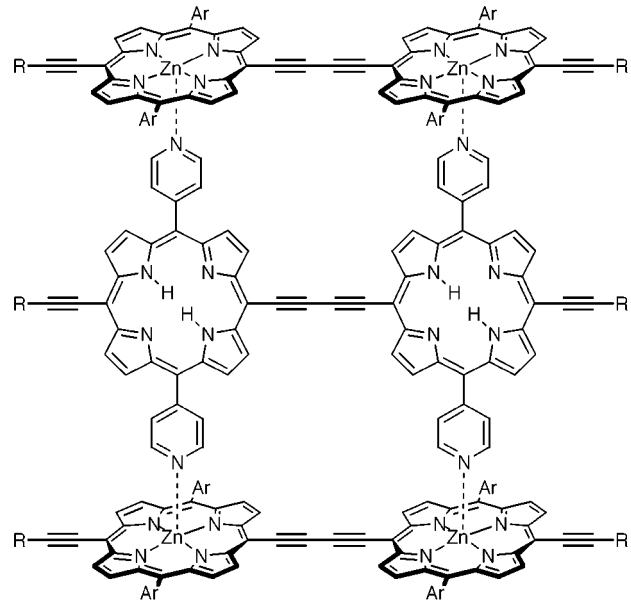
empirical techniques. Computational studies have shed light on the electronic absorption spectra of **2**[4e] and **3**.[3i] In both cases the lowest energy transitions were found to be between orbitals delocalised over the entire π-system. Beljonne *et al.* used a combination of the Hartree–Fock Intermediate Neglect of Differential Overlap (INDO) and Single Configurational Interaction (SCI) techniques[3i] to calculate the electronic transitions for **3** and **4** shown in Fig. 3. The dimer **3** was too big for complete geometry optimisation, so its ground state structure was constructed using coordinates from **4**. Satisfactory agreement with the experimental spectra could only be achieved by assuming a reduction in bond length alternation in the central butadiyne in the excited state geometry of **3**, which is evidence of increased conjugation in the excited state. These calculations reproduce the observed B_x/B_y splitting, as well as the red-shift and intensification in the Q_x band.

Beljonne's calculations assumed, for simplicity, that the two porphyrin macrocycles in **3** are coplanar. NMR and UV spectra indicate that a range of dihedral angles are populated when **3** is dissolved and disaggregated, whereas in the bimolecular aggregate $\mathbf{3}_2$ (which is formed in CH_2Cl_2 in the absence of amine ligands) the dimer units tend to lie flat.[3a] The planar aggregated conformation is characterised by a larger B_x/B_y splitting, as illustrated in Fig. 3, which compares the spectra of **3** (in 1% pyridine–CH_2Cl_2) with $\mathbf{3}_2$ (in CH_2Cl_2). The same effect is observed in the supramolecular triple strand array $\mathbf{8{\cdot}9}_2$.



$\mathbf{8{\cdot}9}_2$ R = Si(*n*-$C_{12}H_{13})_3$, Ar = 3,5-$Bu^t_2C_6H_3$

Formation of this assembly tends to hold both dimers **8** and **9** in planar conformations, resulting in increased B_x/B_y splitting and weighting the Q_x band towards longer wavelengths.[3n] Stranger *et al.* have used density functional theory (DFT) to calculate the electronic structure of **2a** as a function of the dihedral angle θ about the butadiyne axis.[4e] Fig. 4(*a*) shows contour plots of the π orbitals ($8b_{1u}$ and $9b_{3g}$) and π* orbitals ($10b_{1u}$ and $10b_{3g}$), which are derived from the a_{2u} and e_{gx} orbitals of the porphyrin monomer unit. The Walsh diagram in Fig. 4(*b*) shows how these molecular orbitals, and the total energy, change with dihedral angle θ. The contours for the $8b_{2g}$, $8a_{1u}$, $6b_{2g}$ and $6a_{1u}$ orbitals are not shown because these are non-delocalised orbitals derived from the e_{gy} and a_{1u} orbitals of the monomer, which have nodes along the butadiyne link. When θ = 90° the molecular orbitals converge to four Gouterman-type orbitals. The gap between the $10b_{1u}$ LUMO and the $9b_{3g}$ HOMO decreases with decreasing θ, as the molecule becomes more conjugated. The calculated potential energy surface is fairly flat for θ = 0–60°, but then rises steeply near the staggered conformation to about 60 kJ mol^{-1} at 90°. This implies that there should be substantial librational freedom, but not free rotation at room temperature. MOPAC calculations[13c] gave a much smaller estimate for the rotational barrier in **5a** (2.5 kJ mol^{-1}).† If these rotational barriers could be determined experimentally, they would give a direct measure of the interporphyrin resonance energy; this has yet to be achieved. The electronic spectra of **2a** indicate that it becomes more planar and more conjugated at lower temperatures. The crystal structure of dimer **9** shows it is completely planar in the solid state.[3m]

Therien and co-workers prepared a short ethyne-linked dimer **5b**, as well as a linear trimer of this type.[13a] Species **5b** has a similar absorption spectrum to **5a**, but with slightly stronger electronic coupling. Ultra-fast pump-probe measurements show that the first excited state of **5a** relaxes to a planar conformation

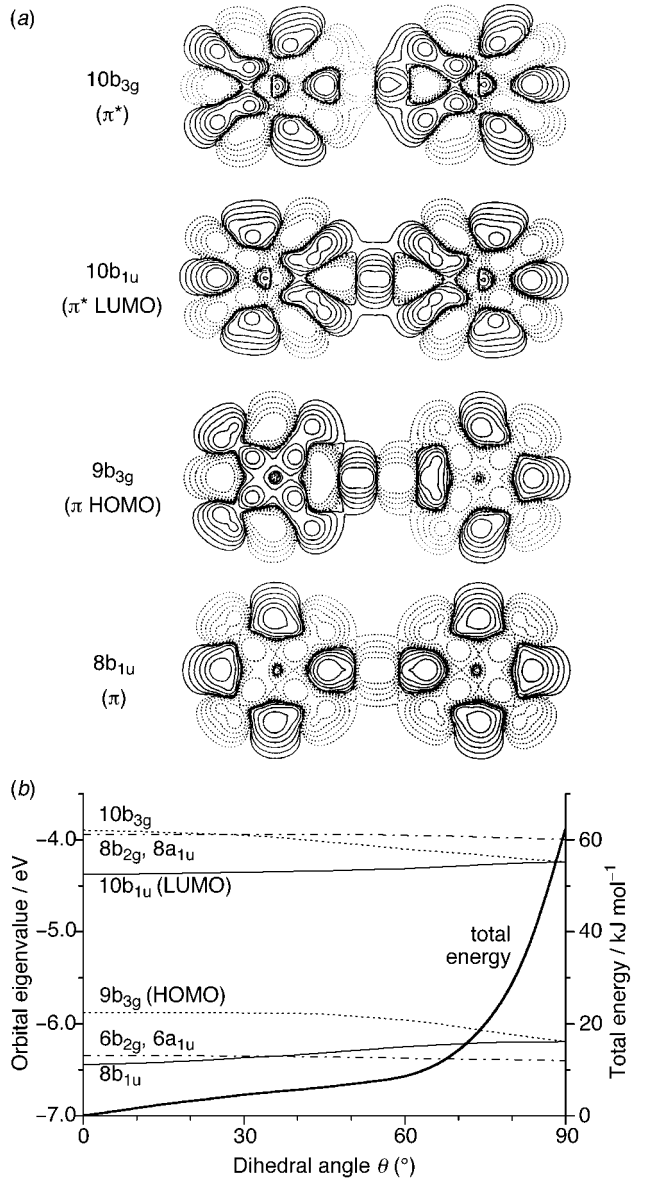


Fig. 4 (*a*) Contour plots for frontier orbitals of **2a** and (*b*) Walsh diagram showing how the energy of these orbitals (and the total energy) vary with the dihedral angle θ about the butadiyne, from DFT calculations (reprinted with permission from ref. 4(*e*); copyright 1996 American Chemical Society).

on a 30 ps time-scale.[13e] Arnold *et al.* have continued this sequence by studying the octatetrayne-linked dimer **2b**. Doubling the length of the alkyne spacer has a subtle effect on the absorption spectrum, and does not dramatically reduce the interporphyrin electronic coupling.

Comparison of *meso–meso*, *meso–β* and *β–β* linked dimers **5a**–**7a** and **5b**–**7b** shows that *meso-meso* connectivity confers maximum electronic coupling[13c] (*β–β* linked analogues of **2a** demonstrate the same effect[4b,7]). In the ethyne-linked series, poor conjugation in the *meso–β* and *β–β* linked dimers can be attributed to steric clashes, forcing the molecules into orthogonal conformations, whereas in the butadiyne-linked series the effect can only be due to the smaller frontier orbital coefficients at the *β*-positions (Fig. 1).

Examples of higher alkyne-linked conjugated porphyrin oligomers include polymer **10** (with 10–15 macrocycles)[3b] and hexamer **11** (an 83 Å long molecular wire).[3m] These oligomers continue the trends set by the dimers, and exhibit strongly red-shifted and intensified Q bands. For example **10** has a Q absorption band at 873 nm which is more intense than its Soret band (in 1% pyridine–CH_2Cl_2). The whole series of oligomers from monomer to hexamer **11** show a gradual evolution in electronic spectra with increasing chain-length.[3m] Rigid-rod porphyrin oligomers tend to be rather insoluble, but the isodecyl ester side chains of **10** give it excellent solubility, provided an amine is present to ligate the zinc sites. High quality transparent thin films of this polymer are easily prepared from solution (either of pure **10** or as a blend with a transparent polymer matrix). It is remarkable that the absorption spectra of these solid films are sharper than the solution spectra, suggesting that some type of ordered J-aggregate is probably formed. The excellent film forming properties of this conjugated porphyrin polymer have made it suitable for solid state electronic and photophysical investigations. It is a p-type semiconductor and photoconductor.[3d,h,j]

Many conjugated porphyrin dimers have been reported with unsaturated bridges linking alkyne-substituted *meso*-positions, such as **2b**,**c**.[4g] Taylor *et al.* have shown that a 9,10-diethynylanthracene bridge provides even stronger conjugation than a direct butadiyne-link, as judged from the emission spectra;[3l] this can be attributed to stabilisation of the quinoidal/cumulenic resonance canonical by the 9,10-anthrylene unit. The crystal structure of a 1,4-diethynylthiophene bridged dimer has been reported by Arnold *et al.*, and, like **9**, it is planar in the solid state.[4c] Diederich and co-workers have studied a series of (*E*)-

1,2-diethynylethene bridged oligomers **12a**–**c**. The Q band of the dimer **12b** is substantially red-shifted and intensified relative to the monomer **12a**, whereas the spectra of **12b** and **12c** are very similar, indicating that in this series, saturation of the electronic properties is already reached at the dimer.[6] Polymers with 1,4-diethynylarylene bridges **13a**,**b** have been investigated by Jones and co-workers.[8] Although 1,4-diethynylphenylene bridges do not provide optimum conjugation, these polymers are highly conjugated, with intense red-shifted Q bands.

Alkynes seem to provide the ideal way of making conjugated connections between porphyrins. *meso–meso* (*E*)-1,2-Ethene linked dimers also display intriguing conjugation. Chachisvilis *et al.* have shown that dimer **14** exists in solution partly (about 20%) as a conformer with strong conjugation (broad split Soret; Q band at 800–900 nm), although most of the material adopts twisted conformations with very little electronic coupling, and this non-conjugated conformer dominates the absorption spectrum.[12] A trimeric analogue of **14** has been prepared by Higuchi *et al.*,[14] while Vicente and Smith have synthesised hexatriene linked dimers of this type,[11a] but ethene-linked dimers without β-substituents, which should be more conjugated, have yet to be investigated.[13b] Smith's group have also synthesised conjugated planar β-alkene linked chlorophyll dimers.[11b] Officer and co-workers have prepared a β–β butadiene linked dimer, but it does not appear to be significantly conjugated.[10]

Edge-fused structures represent an alternative strategy for ensuring coplanarity and achieving extended π-overlap between porphyrin macrocycles. This approach has been explored by Crossley and co-workers, using 1,4,5,8-tetraazaanthracene bridges as in the tetramer **15**.[5] The interporphyrin electronic coupling in these structures seems to be weaker than in the *meso–meso* alkyne-bridged oligomers discussed above, probably because of the smaller frontier orbital coefficients at the β-positions of a porphyrin, and because the tetraazaanthracene bridge tends to act as an isolated aromatic unit. More strongly coupled analogues include a benzo-bridged dimer reported by Kobayashi *et al.*[9] Smith's group have recently prepared a directly edge-fused trimer **16**[11c] and an amazing benzo-bridged pentamer **17**,[11d] using an ingenious Diels–Alder route. This new synthetic methodology is likely to lead to rapid progress, but so far the electronic coupling in edge-fused oligomers is much less well characterised than that in *meso–meso* alkyne linked compounds.

Electrochemical evidence for conjugation

Conjugation causes splitting in the π and π* levels, reducing the HOMO–LUMO gap. The simplest manifestations of this are a red-shift, and a broadening, in the electronic spectra, as discussed above. The HOMO–LUMO gap can be approximated to the energy of the longest wavelength absorption or emission band. This is referred to as the 'optical gap' E_g. The HOMO–LUMO gap can also be estimated from the difference between the first oxidation and reduction potentials, E_1^{Ox}–E_1^{Red}; the 'electrochemical gap'. Electronic communication in a conjugated porphyrin oligomer also splits the redox potentials. It is widely assumed that the magnitude of this splitting provides a measure of the conjugation, but this may be misleading, as discussed below.

Table 1 summarises the redox characteristics of some conjugated porphyrin dimers, and reference monomers. There is close agreement between optical gaps (E_g in eV) and electrochemical gaps (E_1^{Ox}–E_1^{Red} in V). In general alkyne links reduce the HOMO–LUMO gap by lowering the LUMO (*i.e.* make E_1^{Red} less negative) rather than raising the HOMO (reducing E_1^{Ox}), because alkynes are electron-withdrawing. Comparison of the redox potentials of **2a**–**c** with those of NiOEP, confirms that the C_8 link in **2b** provides about as much conjugation as the C_4 link in **2a**, whereas the $C_2(p\text{-}C_6H_4)C_2$ link in **2c** is relatively insulating.[4h]

Arnold *et al.* have recently reported spectroscopic and electrochemical data on a range of analogues of **2a** with other divalent metals (Co, Cu, Zn, Pd and Pt) in place of Ni.[4k] The metallation state of this dimer has a surprisingly large effect on the porphyrin–porphyrin electronic coupling. The conjugation is greatest in the Ni_2 dimer and weakest in the Zn_2 complex. This accounts for the fact that the spectrum of **2a** resembles that of the $\mathbf{3}_2$ aggregate even when **2a** is not aggregated. Spectroelectrochemical studies have shown that doubly reduced dianions such as $[\mathbf{2a}]^{2-}$ exhibit an extraordinarily intense peak ($\varepsilon > 10^5\ M^{-1}\ cm^{-1}$) in the near-IR at about 1000 nm. Putting two electrons into the $10b_{1u}$ π* orbital (which is bonding with respect to the porphyrin-porphyrin link; see Fig. 4) enhances the interporphyrin electronic coupling and stabilises the $[\mathbf{2a}]^{2-}$ dianion. Thus strong conjugation can *reduce* the splitting between the $[\mathbf{2a}]/[\mathbf{2a}]^-$ and $[\mathbf{2a}]^-/[\mathbf{2a}]^{2-}$ reduction potentials. The same argument accounts for a small splitting in the oxidation potentials, since the $9b_{3g}$ π orbital is anti-bonding with respect to the interporphyrin link. Arnold has developed this idea and used the spectroelectrochemical data on a range of dimers to construct an empirical frontier orbital model for these systems.[4k]

The redox potentials of the (*E*)-1,2-ethene linked dimer **14** indicate that it is strongly conjugated,[4d] with an electrochemical gap of only 1.44 V, whereas its electronic spectra show that only about 20% of the material is in conjugated conformations,[12] as discussed above. This implies that the radical cation and radical anion of this dimer are more conjugated than the neutral molecule. The stabilising effect of conjugation is greater when it results in charge delocalisation, so radical cations and anions tend to adopt more planar conformations than neutral molecules. This effect is illustrated by the crystal structure of the [Cu(TPP•)][$SbCl_6$] radical cation,[19] which exhibits a remarkably small porphyrin–aryl dihedral angle of 41° (compared to the average dihedral angle of 67° for neutral *meso*-phenyl copper porphyrins, Fig. 2).

Nonlinear optics

Just as the stretchiest rubber bands show the greatest deviations from Hooke's law, for a given force, so the most polarisable materials show the greatest optical nonlinearities, for a given electric field. Materials which show large nonlinearities for weak electric fields can be used in all-optical and electro-optical switching devices. The nonlinear relationship between the polarisation *P* and the electric field strength *E* is represented by eqn. (1), where $\chi^{(1)}$ is the bulk linear polarisability, and $\chi^{(2)}$ and $\chi^{(3)}$ are the second and third order nonlinear optical (NLO) susceptibilities (higher terms in E^4 *etc.* are normally ignored).

$$P = \chi^{(1)}E + \chi^{(2)}E^2 + \chi^{(3)}E^3 \quad (1)$$

[a] Redox potentials are in V *vs.* Fc/Fc^+; $E_1^{Ox} - E_1^{Red}$ is the electrochemical gap; E_g is the optical solution gap from the longest wavelength absorption; see references for solvents and conditions; NiOEP is the Ni^{II} analogue of **1**; ZnDPP is 5,15-diphenylporphyrin Zn^{II}.

Conjugated porphyrin oligomers have extremely polarisable π-systems, resulting in strong NLO behaviour. Second order behaviour ($\chi^{(2)} \neq 0$; *e.g.* second harmonic generation and the Pockels effect) is only exhibited by non-centrosymmetric structures, which excludes most porphyrin oligomers, although Therien has predicted[13d] that structures such as **18** should have very high $\chi^{(2)}$. Third order behaviour ($\chi^{(3)} \neq 0$; *e.g.* third harmonic generation and the DC Kerr effect) does not require non-centrosymmetry, so is relevant to most of the materials discussed here.

Electroabsorption spectroscopy has shown that polymer **10** has a peak resonant third order NLO response ($|\chi^{(3)}| = 1.0 \times 10^{-15}$ m^2 V^{-2} at 850 nm)‡ which is stronger than those of other conjugated polymers.[3b] This peak response occurs near the wavelength region relevant for telecommunications applications; fibre optic systems commonly operate at 1300 nm. $\chi^{(3)}$ is frequency dependent and in this case it is resonance-enhanced at 850 nm due to Q band absorption. Denning and co-workers have used degenerate four wave mixing (DFWM) to test the NLO behaviour of **10** (both in solution and as a thin film) at 1064 nm, where the absorption is very low.[3o] The off-resonance response at this wavelength ($|\chi^{(3)}| = 3 \times 10^{-17}$ m^2 V^{-2})‡ is stronger than those for most other materials. Fig. 5(*a*) shows the strength of the DFWM signal for a thin film of **10**, as a function of the input light intensity, compared to the background signal. A cubic power dependence is maintained up to a damage threshold of 640 MW cm^{-2}. The DFWM experiment involves irradiating the sample with three laser beams; if the sample has significant $\chi^{(3)}$, these beams interact to create a fourth beam. The time response can be tested by delaying one of the probe beams,

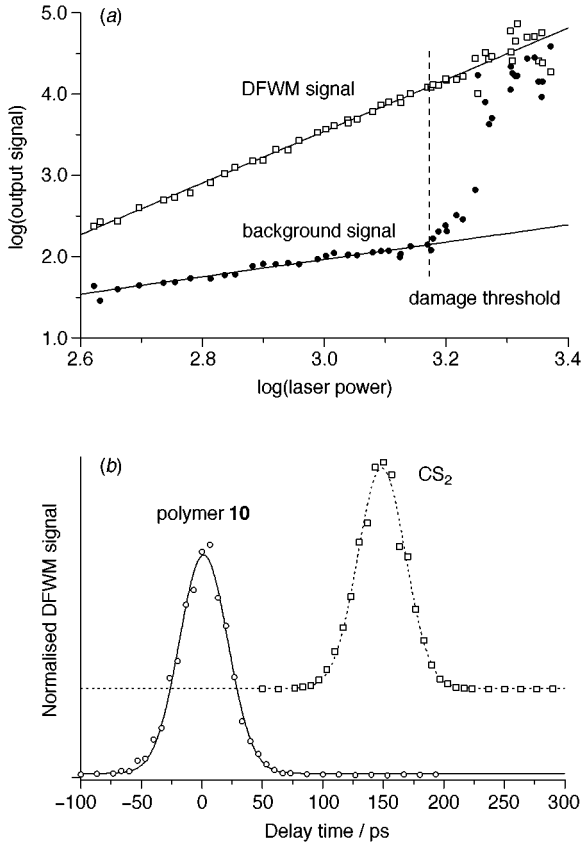

Fig. 5 DFWM measurements on a neat film of polymer **10** at 1064 nm: (*a*) log–log plot of the power dependence of the DFWM and background signals and (*b*) time resolved signals for the polymer film, compared with that for a CS_2 reference (offset for clarity by 150 ps); the smooth curves are fits for a Gaussian function to the data. Both sets of measurements were carried out in the *xyyx* polarisation which minimises non-electronic contributions to the DFWM signal [ref. 3(*o*)].

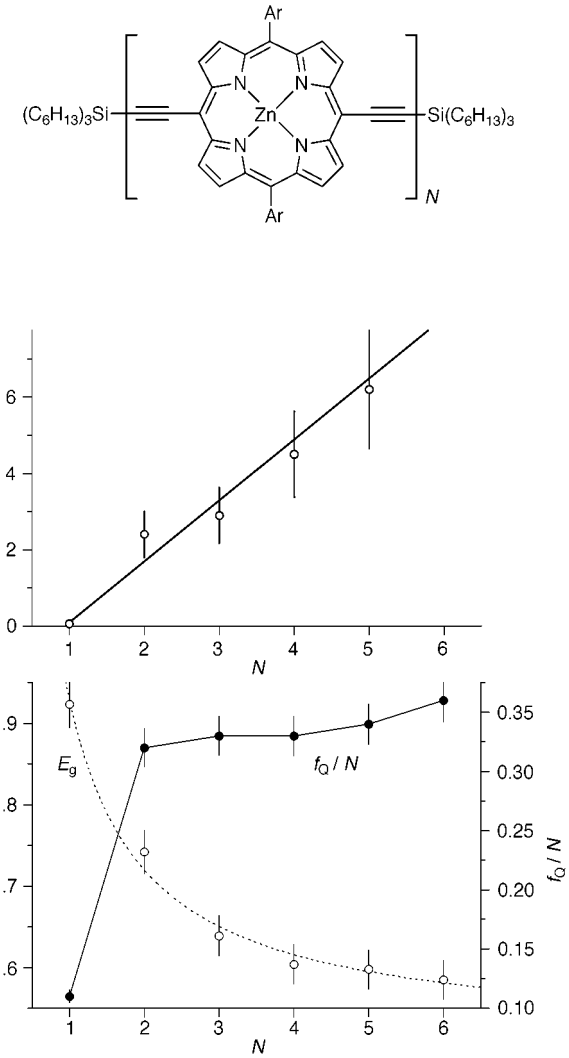

Fig. 6 Variation in (*a*) γ/N and (*b*) *E*g and f_Q/N with the number of macrocycles *N*. All these measurements were made in $CHCl_3$ containing 1% quinuclidine. γ is the magnitude of the *xyyx* tensor from DFWM at 1064 nm. E_g and f_Q are the centre of gravity and oscillator strength of the Q band. The E_g data are fitted to the theoretical curve for $E_g \propto N^{-1}$ [ref. 3(*p*)].

giving results such as those shown in Fig. 5(*b*), for a thin film of **10**, compared with a CS_2 reference. In both cases the response is limited by the pulse width of the laser (45 ps). The decay time of the nonlinearity is much shorter than the excited state lifetime, demonstrating that the mechanism involves a genuine third order electronic polarisation. This type of ultra-fast response is essential for switching applications.

The evolution of the susceptibility per macrocycle, γ/N (the molecular equivalent of $\chi^{(3)}$) with increasing chain length *N* in a series of oligomers of type **12**, has also been investigated using DFWM at 1064 nm.[3p] γ/N increases by almost two orders of magnitude between the monomer and the dimer, then rises linearly from the dimer to the pentamer, with no sign of saturation, as shown in Fig. 6(*a*). Fig. 6(*b*) compares the evolution of the optical band gap E_g and the *Q* band oscillator strength per macrocycle f_Q/N. E_g shows the expected linear dependence on $1/N$, and changes little between the tetramer and the hexamer. f_Q/N rises dramatically on going from the monomer to the dimer, but then hardly changes. γ/N shows a much greater chain length dependence than these classical measures of conjugation. A strong dependence of γ on chain length is also found in other conjugated polymers.[15,20] In non-conjugated *p*-phenylene-linked porphyrin oligomers γ/N is almost independent of the chain length.[18] The polymer **10** has a value of γ/N which is about five times that of the pentamer, consistent with its chain length of $N \approx 10$–15, from small angle neutron scattering. Even in **10**, the optical nonlinearity is about an order of magnitude too low for practical applications. It seems likely that higher molecular weight polymers, and polymers with stronger conjugation, will have stronger NLO behaviour, which will be useful in fabricating ultra-fast switching devices.

Another important type of third order NLO behaviour is optical limiting. When the excited state of a compound absorbs light more strongly than its ground state, the absorption coefficient increases with increasing light intensity. Such materials can limit the transmitted intensity of a light beam, while exhibiting high transmittance at low intensity. They can be used to protect eyes and optical sensors from intense lasers, without significantly obscuring vision. Conjugated porphyrin oligomers such as **3** and **10** show strong nonlinear optical absorption of this type,[3e,k] on a picosecond time-scale, due to photoinduced absorption by long lived triplet states. The molecular design criteria for optical limiting are no better understood than those for maximising $\chi^{(3)}$, but the high oscillator strength and abundance of low energy excited states in these materials are likely to contribute towards both types of third order optical nonlinearity.

Conclusions and outlook

Nonlinear optical applications have been highlighted because they relate directly to conjugation, and because conjugated porphyrin oligomers out-perform all other organic materials in this field. Other applications include biomimetic light harvesting,[13a] molecular-scale electronic components,[5h] and gas sensors.[3g,4f,g,j] All these applications require the porphyrin oligomers to be fabricated into thin films or monolayers, so the

surface chemistry of these compounds is being investigated by several groups.[3f,4f,g,j,5e,g]

Conjugated porphyrin oligomers constitute an active area of research (*ca.* 60 publications in the last 6 years), yet only a few structural types have been explored, and only a few compounds have been subject to detailed photophysical and electrochemical scrutiny. Those structures which have already been investigated in detail have revealed extraordinary electronic and NLO behaviour, resulting mainly from their high polarisability, intense oscillator strength, low HOMO–LUMO gap and abundance of low energy excited states. The strong inter-porphyrin conjugation in the neutral ground states of these oligomers is amplified in their excited states, and in their oxidised and reduced forms. This is a new area of exploration, and it is still easy to design new highly conjugated structures. For example an azo link is almost as sterically unencumbered as an alkyne, and has less bond length alternation. Azo-linked dimers are likely to show strong conjugation, and related structures have been predicted to have strong NLO activity.[21] Hush *et al.* have predicted that *f*-coronene bridged oligomers such as **19** should exhibit phenomenal porphyrin-porphyrin electronic coupling.[5h] The area is full of challenges for both synthetic chemists and theoreticians.

Kinetic control of stereoselectivity of halide substitution in arene ruthenium pyridyloxazoline complexes; a rare case of net inversion†

Adam J. Davenport, David L. Davies,* John Fawcett, Shaun A. Garratt and David R. Russell

Department of Chemistry, University of Leicester, Leicester, UK LE1 7RH. E-mail: dld3@le.ac.uk

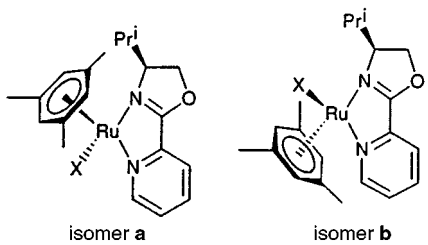
Received (in Cambridge, UK) 30th September 1999, Accepted 19th October 1999

Reaction of [RuCl(Pr^i-pymox)(η^6-mes)]$^+$ 1b [Pr^i-pymox = 4-isopropyl-2-(2-pyridyl)-1,3-oxazoline, mes = 1,3,5-trimethylbenzene] with $AgSbF_6$ then with halide gives [RuX(Pr^i-pymox)(η^6-mes)]$^+$ (X = Cl 1, Br 2, I 3), each as a mixture of diastereomers, the kinetic product being formed preferentially with net inversion of configuration at the metal; the structures of 2a and 2b have been determined by X-ray crystallography.

The stable well defined geometry of half-sandwich complexes makes them useful substrates for the study of the mechanism, particularly the stereochemistry, of substitution reactions at a chiral metal centre.[1] In addition, arene ruthenium complexes are becoming increasingly important in asymmetric catalysis.[2] In order to optimise the enantioselection of such complexes it is important to understand the factors that control diastereoselectivity, the tendency for epimerisation at the metal and the stereochemistry of substitution reactions.

Arene ruthenium(II) complexes have low-spin d^6-configuration and ligand exchange is usually dissociative, as found for anation of $[Ru(H_2O)(bipy)(\eta^6\text{-arene})]^{2+}$.[3] The stereoselectivity of substitution is determined by the stereochemical stability of the five-coordinate intermediate, partial epimerisation at the metal occurs in some cases.[4] In many cases kinetic control of asymmetric induction is hard to prove since the interconversion of the product diastereomers is relatively facile under the reaction conditions, this has lead to erroneous conclusions about stereoselectivity.[5] Nelson and coworkers reported that substitution of some cyclometallated arene ruthenium complexes occurred, in all cases, with preferential retention of configuration, and with very high selectivity in the case of halide exchange.[6]

Coordination of pyridyloxazolines to an '(arene)RuX' fragment can in principle give rise to two isomers (**a** and **b**). Treatment of $[RuCl_2(mes)]_2$ with Pr^i-pymox in refluxing methanol, gave $[RuCl(Pr^i\text{-pymox})(\eta^6\text{-mes})]SbF_6$ as one diastereomer which was shown by X-ray crystallography to have the isopropyl pointing towards the chloride (**1b**) rather than the π-bound ring.[7] Abstraction of chloride with $AgSbF_6$ in acetone–water gives $[Ru(H_2O)(Pr^i\text{-pymox})(\eta^6\text{-mes})][SbF_6]_2$ which reacts with KCl, KBr or NaI in methanol at room temperature to give the halide complexes $[RuX(Pr^i\text{-pymox})(\eta^6\text{-mes})]SbF_6$ (X = Cl **1**, Br **2**, I **3**).†



† ^{1}H NMR spectra and satisfactory elemental analyses are available as electronic supplementary information (ESI): See http://www.rsc.org/suppdata/cc/1999/2331/

The ^{1}H NMR spectrum of a crude sample of **2** shows the presence of two diastereomers in an approximate ratio of 75 : 25. Careful recrystallisation allowed separation of the two diastereomers and their structures were determined by X-ray diffraction.‡ Isomer **2b** (Fig. 1) has the isopropyl pointing towards the halide, the same as found previously for the chloride,[7] whilst isomer **2a** (Fig. 2) has the isopropyl pointing towards the π-bound arene. The Ru–N(1), Ru–N(2), distances and the N(1)–Ru–N(2) angle are statistically the same in each isomer and with the chloride **1b**.[7] The Ru–Br bond is slightly longer in isomer **2b**

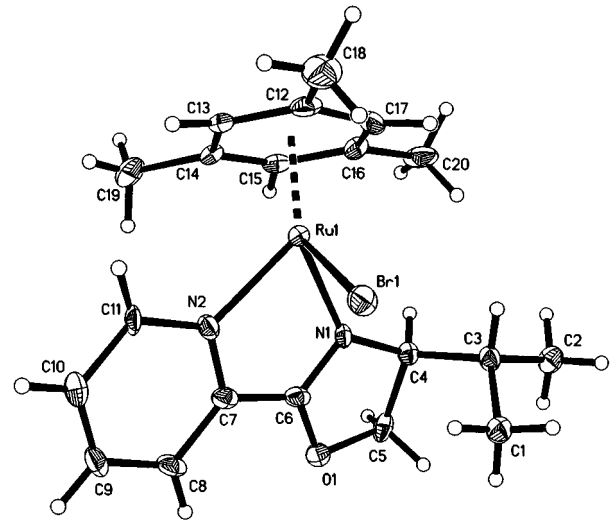


Fig. 1 Molecular structure and atom numbering scheme for the cation of **2b**. Selected bond distances (Å) and angles (°): Ru–N(1) 2.122(11), Ru–N(2) 2.103(10), Ru–Br 2.532(2); N(2)–Ru(1)–N(1) 76.3(4), N(1)–Ru–Br 89.3(3), N(2)–Ru–Br 82.1(3).

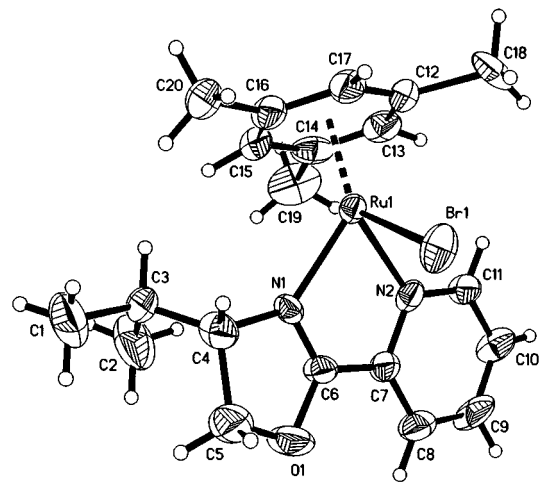

Fig. 2 Molecular structure and atom numbering scheme for the cation of **2a**. Selected bond distances (Å) and angles (°): Ru–N(1) 2.096(10), Ru–N(2) 2.097(13), Ru–Br 2.522(2); N(2)–Ru–N(1) 76.4(5), N(1)–Ru–Br 82.9(3), N(2)–Ru–Br 85.6(4).

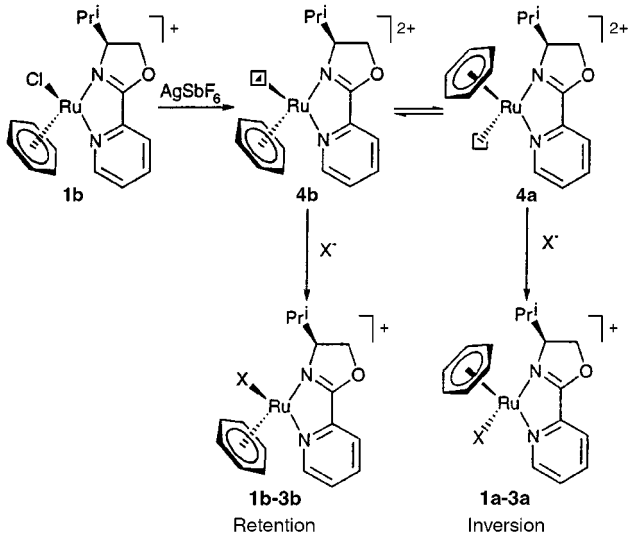
than in **2a**. In addition, the N(1)–Ru–Br and N(2)–Ru–Br angles are 89.3(3) and 82.1(3)°, respectively, in **2b**, *i.e.* the oxazoline end of the ligand is inclined slightly away from the bromide to relieve steric congestion between the isopropyl and the bromide; whilst in **2a** the corresponding angles are 82.9(3) and 85.6(4)°, *i.e.* with the pyridine end inclined away from the bromide to minimise steric congestion between the isopropyl and the π-bound arene. The ^{1}H NMR of the crystals showed that **2a** was the major product in the initial mixture.

The chloride (**1**) and iodide (**3**) were formed similarly and the ^{1}H NMR spectra of the crude products show two isomers in a similar 75 : 25 ratio. The ^{1}H NMR spectra, and a crystal structure for **3a**, showed that isomer **a** was preferred in each case. Thus, for **1**, by forming the complex at room temperature we have been able to isolate the kinetic product (**1a**) whilst the preparation in refluxing methanol gave exclusively the thermodynamic isomer (**1b**).[7]

The ^{1}H NMR spectra of crystals of **1a**–**3a** in CD_2Cl_2 showed only the presence of isomer **a**, no trace of isomer **b** was seen even after several days at room temperature. Similarly, the ratios of mixtures of isomers did not change within a few days in CD_2Cl_2 solution. Hence, the configuration at the metal is stable in this solvent. However, in more solvating solvents such as d_4-MeOH or d_6-acetone the isomer ratios were observed to change slowly over a period of days at room temperature or more rapidly at higher temperature, in each case isomer **b** being thermodynamically preferred by at least a ratio of 95 : 5.

Thus, these two-step substitution reactions are unambiguous examples of kinetic control of stereoselectivity with the favoured pathway being a rare case of formal inversion at the metal.[8] We propose the mechanism shown in Scheme 1. Abstraction of halide by Ag^+ provides the aqua/solvent species **4**, epimerisation of which will be much faster than for the halide coordinated species. Species **4a** is expected to react faster since attack of the halide occurs preferentially from the side opposite the oxazoline substituent, *i.e.* the least sterically hindered approach, giving **1a**–**3a** with the isopropyl pointing towards the π-bound arene rather than the halide. The rate of epimerisation of **1**–**3** in methanol is sufficiently slow that it can not account for the amount of isomer **b** formed, *i.e.* the reaction is not forming exclusively isomer **a** followed by epimerisation to isomer **b**. A more precise study of the selectivity, including the effects of different substituents on the oxazoline and the arene and a more detailed kinetic analysis of the reactions will be reported elsewhere.



Scheme 1 (i) □ represents a vacant coordination site or a solvent molecule. (ii) Methyl substituents on the arene have been omitted for clarity.

We thank the University of Leicester (S. A. G.) and EPSRC (A. J. D.) for studentships and Johnson Matthey for a loan of $RuCl_3$.

Novel peptidomimetic structures: enantioselective synthesis of conformationally constrained lysine, ornithine and alanine analogues from pyroglutamic acid

Rajesh Goswami and Mark G. Moloney*

The Department of Chemistry, Dyson Perrins Laboratory, University of Oxford, South Parks Road, Oxford, UK OX1 3QY. E-mail: mark.moloney@chem.ox.ac.uk

Received (in Liverpool, UK) 3rd August 1999, Accepted 27th September 1999

Conformationally constrained lysine and ornithine analogues, and an L-Ala-L-Ala dipeptide analogue, are available from pyroglutamic acid.

The synthesis of conformationally constrained amino acids is of considerable current interest;[1–4] in addition to their intrinsic interest as ligands for a wide variety of biological receptors, incorporation of these structural elements into peptide chains can be used to generate novel structures of relevance to biological or materials application.[5] Although structurally restricted analogues of a number of amino acids have been described,[6–10] the ω-amino acids have generally only recently begun to attract attention. However, modified lysine chimeras, derived from pyroglutamic acid,[11] and from proline,[9] and a peptidomimetic which includes a conformationally restricted lysine analogue[12] have all recently been reported, as have ornithine[13] and arginine analogues.[14] The synthesis of cyano[15] or indole[16] substituted glutamate analogues has also recently been described.

We have used the readily available lactam **1a** as a template for manipulation to a variety of functionalised pyrrolidinones[17–20] and recently shown its application to the synthesis of conformationally restricted glutamates[21] and aminopyrrolidones.[22] We report here the extension of this versatile approach to the synthesis of several other conformationally restricted amino acids. The well-defined conformation of pyroglutamic acid has been investigated in detail[23] and its application as a template for peptidomimetics previously proposed;[24] the pyrrolidone ring simultaneously restricts τ_1, τ_2 and τ_3 to very limited ranges (from a simple molecular modeling energy minimised structure,[25] these are −144, +23 and −17° respectively) and defines the *cis*-amide bond (Fig. 1).[26]

The lysine chimera was obtained as follows: the enolate of lactam **1a** was treated with $BrCH_2CN$ (Scheme 1), unusually to give exclusively the *endo* adduct **2** in 55% yield;[27] similar alkylations generally proceed under thermodynamic control to give the *exo* product.[19] The *cis* stereochemistry of **2** and **4** was assigned on the basis of NOE data. Reduction of the nitrile function with $NaBH_4$–$CoCl_2$ gave the corresponding amine **3** in 76% yield, and this intermediate was easily converted to the product **4** in a four step (protection, deprotection, oxidation and *in situ* esterification) sequence in 16% overall yield.

The ornithine chimera was obtained from lactam **1b**. Selenenation and elimination to the known enone **5** followed by conjugate addition of the Reformatsky reagent derived from $BrCH_2CN$ gave adduct **6a** in 69% yield as a single diastereomer, as shown by ^{13}C NMR spectroscopic analysis. This strategy has proved to be very successful for manipulation of this position of a pyrrolidone ring.[21] Hydrolysis and decarboxylation using $(Bu_3Sn)_2O$[28] readily afforded the product **6b** in 68% yield, and

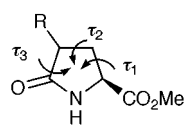

Fig. 1

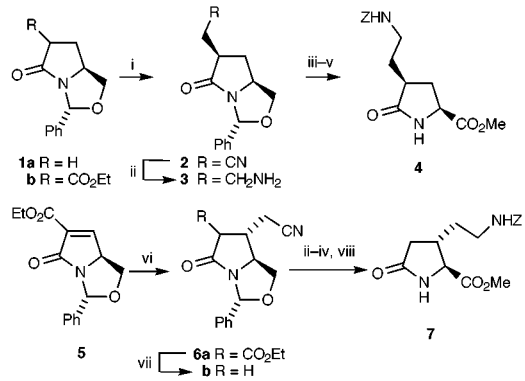
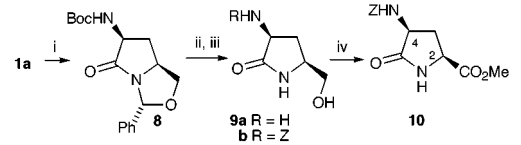


Scheme 1 *Reagents and conditions*: i, LDA, THF, −78 °C then $BrCH_2CN$ (55%); ii, $NaBH_4$, $CoCl_2$, EtOH; iii, ZCl, Et_3N; iv, TFA; v, RuO_2, $NaIO_4$ then CH_2N_2 (34%); vi, Zn, DMPU, $BrCH_2CN$ (69%), room temp.; vii, $(Bu_3Sn)_2O$, toluene, Δ, 16 h (68%); viii, PDC, DMF, then CH_2N_2 (35%).

a similar sequence to that described above gave the product **7** in 14% yield over the four steps. In this case, however, application of RuO_4 in the final oxidation step did not give the desired product, and this step was successful only with PDC/DMF. The *trans* relative stereochemistry of **6a** and **7** was again shown by NOE data.

The presence of an internal amide bond suggested that amination at the C-7 position of **1a** could be used to generate an unusual dipeptide mimetic. Related aminopyrrolidones, aminopiperidones and larger ring heterocycles have recently attracted interest as enzyme inhibitors[29] and peptidomimetic structures.[30–33] Amination of the enolate of lactam **1a** with $(PhO)_2P(O)N_3$ followed by treatment with Boc_2O gave the amino lactam **8** in 50% yield (Scheme 2); surprisingly, the *endo* product, whose stereochemistry was subsequently established, was obtained exclusively. Acidic release of the protecting groups, and reprotection of the C-4 amino function as its benzyloxycarbonyl (Z) derivative, gave the product **9b** in 51% yield over the two steps. Oxidation and esterification in the usual way then gave the product **10**, which was a single stereoisomer at room temperature by NMR analysis, and whose *cis* stereochemistry was shown by NOE spectroscopy. Molecular modeling of the *N*-acetyl analogue **11** of compound **10**[25] demonstrated that two well defined conformations existed, differing by 2.3 kcal mol^{-1} in energy, with the two substituents either pseudodiequatorial or diaxial, and the latter being the more stable; since a 2.7 kcal mol^{-1} energy difference corresponds to a 99:1 ratio of species at equilibrium,[34] the



Scheme 2 *Reagents and conditions*: i, LDA, THF, −78 °C, then $(PhO)_2P(O)N_3$, then Boc_2O, −78→O °C (50%) ii, TFA, CH_2Cl_2, room temp., 1 h (quant.); iii, ZCl, DMF–THF, Et_3N, 0 °C, 3 h (51%); iv, PDC, DMF, 40 °C, 12 h, then CH_2N_2 (28%).

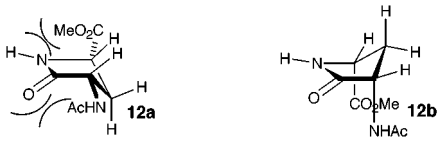


Fig. 2 Conformations of **12a** and **12b**.

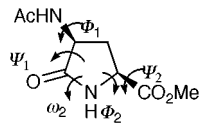
minor diequatorial conformer would not be expected to be observable at room temperature by NMR analysis, and ^{1}H NMR VT analysis provided no evidence for the diequatorial conformer even at 223 K. The stability of the diaxial conformer could be attributed to the presence of A-strain[35] between the two substituents and the planar amide system; the importance of torsional strain in five- and six-membered ring heterocycles for the control of stereochemistry has been investigated in detail,[36] although its importance in lactams has only recently been appreciated.[37] Thus, the diaxial conformer minimises the interations of the relatively bulky C(2) and C(4) substituents with the planar amide function (which would occur in the diequatorial conformer **12a**) by placing C(2)-H and C(4)-H in an eclipsing conformation with the lactam system **12b** (Fig. 2). Using the energy minimised structure for **11**, some calculated dihedral angles are given in Table 1; the diaxial conformer most closely resembles a Type VIa (*cis*) β-turn.[38] Thus, this compound could be considered to be a conformationally restricted L-Ala-L-Ala dipeptide analogue, with the central amide bond constrained in the *cis* orientation, and the pyrrolidone ring capable of providing a reverse turn in an attached peptide chain; as such it represents a potential low molecular weight non-hydrophobic turn inducer. A related aminopyrrolidone has also been reported to induce Type II′ β-turn folding in a short peptide, and to exhibit hypoglycaemic activity.[39]

Table 1 Dihedral angles for energy minimised[a] conformations of **11**



Conformation	Ψ_1 (°)	Φ_2 (°)
Diequatorial	−139	+137
Diaxial	+94	−97

[a] Structures optimised with Chem3D Pro 3.5, available from Cambridge Scientific (MM2 parameters).

In view of the increasing interest in the use of variously modified proline derivatives for subtle conformational control in short peptide sequences,[40–44] the ready synthetic accessibility of enantiopure functionalised pyrrolidones may enable their application as amino acid surrogates particularly where well-defined conformational restriction is required.

We thank The Felix Foundation for funding of a scholarship to R. G., the EPSRC Chemical Database Service at Daresbury[45] and the EPSRC National Mass Spectrometric Service Centre at Swansea.

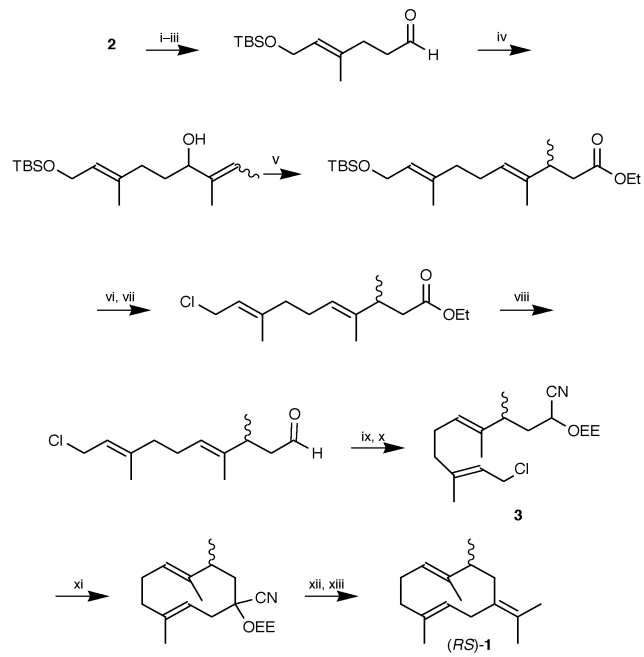
Received (in Liverpool, UK) 29th September 1999, Accepted 13th October 1999

The structure of the sex pheromone produced by the male sandfly *Lutzomyia longipalpis*, from the Lapinha Cave (Minas Gerais State) region of Brazil, previously proposed tentatively as the novel homosesquiterpene 9-methylgermacrene-B, is confirmed and the absolute stereochemistry defined as *S* by comparing physical and biological properties of the synthetic enantiomers with the natural product.

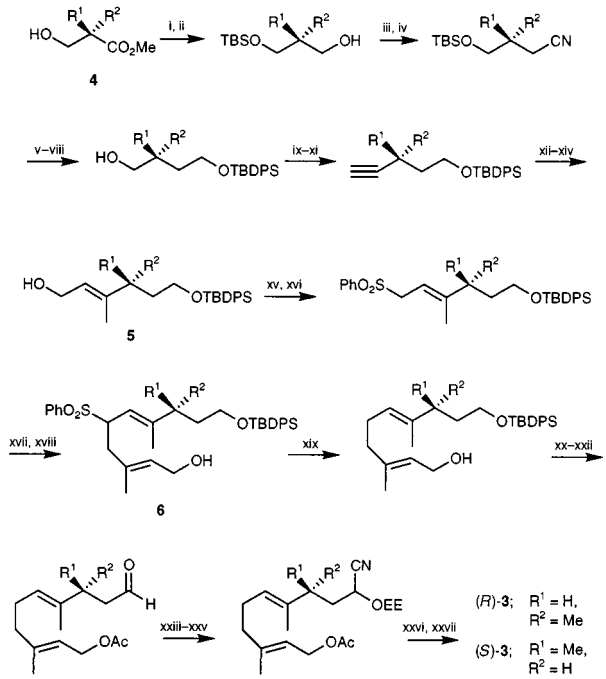
The sandfly *Lutzomyia longipalpis* (Lutz and Neiva) (Diptera: Psychodidae) is the vector of the protozoan parasite *Leishmania chagasi* (Cunha and Chagas) (Kinetoplastida: Trypanosomatidae), the causative agent of visceral leishmaniasis in the New World. Male *L. longipalpis* release a sex pheromone, from glands on the tergites of the abdomen,[1] which is highly attractive to females.[2] The sex pheromone gland of *L. longipalpis* from the Lapinha region (Minas Gerais State) in Brazil produces one principal volatile component that is responsible for the attraction of females.[3] It was proposed, mostly on the basis of mass spectrometry on natural material and on products from microchemical reactions, that the pheromone comprised the novel homosesquiterpene 9-methylgermacrene-B **1**.[4] The sex pheromones of other sympatric and allopatric populations of *L. longipalpis* are different;[5] for example, that from the Jacobina region of Brazil (Bahia State) has been confirmed as another novel sesquiterpene, 3-methyl-α-himachalene, with relative stereochemistry defined as 1*RS*,3*RS*,7*RS*.[6] The purpose of this work was to test the proposed structure for the Lapinha *L. longipalpis* sex pheromone by synthesis of 9-methylgermacrene-B and to define the absolute stereochemistry at C-9 by comparison between the natural product and the synthetic enantiomers (*R*)-**1** and (*S*)-**1**.

The overall synthetic approach adopted has recently been developed for sesquiterpene germacrene-B and involves the establishment of the cyclodecadiene ring system by an intramolecular alkylation before finally elaborating the isopropylidene group.[7] Initially, the racemic 9-methylgermacrene-B (**1**) was prepared as in Scheme 1 from geraniol **2**, in order to test the initial structural hypothesis for this pheromone.[4] The NMR data from racemic **1**† were similar to the limited data obtained originally for the natural product.[4] Co-injection on GC‡ (siloxane column) of racemic **1** with the natural product gave one enhanced peak (18.22 min). The mass spectrum of synthetic compound by GC-MS§ was similar to that published for the natural product.[4] Having confirmed the structure of the pheromone as 9-methylgermacrene-B **1**, the enantiomers were then synthesised by the same cyclisation approach but with methyl 3-hydroxy-2-methylpropionate **4** as chiral precursor, *i.e.* (*S*)-**4** to (*R*)-**1** and (*R*)-**4** to (*S*)-**1** as in Scheme 2. The enantiomers of **4** were obtained commercially and (*R*)-**1** was synthesised first, hence some improvements in yield for (*S*)-**1**. The chiral syntheses required introduction of two stereogenic double bonds at **5** and **6** which were both achieved with an *E*/*Z* ratio of >99% by NMR and the final products possessed an ee of >95%. Both (*R*)-**1** and (*S*)-**1** gave NMR and mass spectra essentially the same as for racemic **1**,†§ as expected, and with $[\alpha]_D^{18}$ + 61.4 and $[\alpha]_D^{20}$ −61.3 ($CHCl_3$), respectively. On chiral GC‡, the *R* and *S* isomers of **1** eluted in that order (38.04, 38.20 min) and, when co-injected with racemic **1**, the natural product gave enhancement of the second peak, defining the absolute stereochemistry of the pheromone as (*S*)-9-methylgermacrene-B (*S*)-**1**. It should be noted, as explained previously,[4] that the pheromone is not stable and readily undergoes acid catalysed cyclisation and a Cope rearrangement to the corresponding elemene structure on heating, hence the requirement for cold on-column injection or low injector port temperatures for GC.‡

Bioassays¶ involving attraction of female *L. longipalpis* and conducted in a Y-tube olfactometer resulted in racemic **1** giving 77% attraction compared with 72% (though not statistically significantly different) for an equivalent amount of the natural product. Attraction to (*S*)-**1** was 67% compared with 56% to the (*R*)-**1** isomer. The response to (*S*)-**1** was not significantly different from that of the natural pheromone, whereas the response to the (*R*)-**1** isomer was significantly lower (χ^2 p =



Scheme 1 Yields are for routes to (±)-**1**, and from compound **3** to **1** also are quoted for routes to (*R*)-**1** then (*S*)-**1** in that order. *Reagents and conditions:* i, TBSCl, imidazole, DMF, 96%; ii, MCPBA, $CHCl_3$, 74%; iii, $HIO_4.2H_2O$, Et_2O, THF, 52%; iv, CHMe=CMeMgBr, THF, 55%; v, $CH_3C(OEt)_3$, $C_2H_5CO_2H$, 71% (*E*/*Z*: 98:2); vi, PPTS, MeOH, 87%; vii; Ph_3P, CCl_4; viii, DIBAL-H, CH_2Cl_2; ix, TMSCN, KCN, 18-crown-6, then $BnNMe_3F$, THF, H_2O; x, CH_2=CHOEt, C_6H_6; xi, NaHMDS, THF, 19% (5 steps), 47%, 42%; xii, PPTS, MeOH then aq. NaOH, Et_2O, 18%, 51%, 50%; xiii, Me_2CBr_2, Sm, $CrCl_3$, SmI_2, THF, 56%, 60%, 64%.



Scheme 2 Yields are quoted for routes to (*R*)-**1** then (*S*)-**1** in that order. *Reagents and conditions:* i, TBSCl, imidazole, DMF, quant., 99%; ii, DIBAL-H, CH_2Cl_2, 85%, 94%; iii, TsCl, Py; iv, NaCN, DMSO, 79%, 84%, 2 steps; v, DIBAL-H, CH_2Cl_2; vi, $NaBH_4$, EtOH, 58%, 65%, 2 steps; vii, TBDPSCl, imidazole, DMF, 89%, 99%; viii, AcOH, THF, H_2O, 84%, 86%; ix, Swern oxidation; x, PPh_3, CBr_4, CH_2Cl_2, 87%, 93%, 2 steps; xi, BuLi, Et_2O, 98%, 98%; xii, Me_3Al, Cp_2ZrCl_2, CH_2Cl_2, H_2O; xiii, BuLi, hexane; xiv, $(CH_2O)_n$, THF, 80%, 80%, 3 steps; xv, PPh_3, CCl_4; xvi, $NaSO_2Ph$, DMF, 76%, 83%, 2 steps; xvii, BuLi, THF, HMPA then (*E*)-$TBSOCH_2C$-$Me{=}CHCH_2Cl$,[8] 78%, 87%; xviii, AcOH, THF, H_2O, 85%, 81%; xix, [$PdCl_2$(dppp)], Super-Hydride, THF, 82%, 81%; xx, Ac_2O, Py, 87%, 95%; xxi, TBAF, THF, 90%, 83%; xxii, Dess–Martin oxidation, 75%, 87%; xxiii, TMSCN, KCN, 18-crown-6; xxiv, $BnMe_3NF$, THF, H_2O; xxv, CH_2=CHOEt, TsOH, C_6H_6, quant., 94%, 3 steps; xxvi, H_2CO_3, MeOH, 87%, 86%; xxvii, LiCl, MsCl, DMF, *s*-collidine, 95%, 90%.

0.009). Thus, while the *S* isomer of **1** is highly active, the *R* isomer is itself also active but does not appear to interfere with the activity of its antipode. This will reduce the need to create highly stereochemically pure (*S*)-**1** for field development of the pheromone in control of these important disease vectors.

The demonstration that the sex pheromone produced by male *L. longipalpis* from the Lapinha region is (*S*)-9-methylgermacrene-B, (*S*)-(*E*,*E*)-7-isopropylidene-4,9,10-trimethylcyclodeca-1(10),4-diene (*S*)-**1**, would suggest that the absolute stereochemistry of that from Jacobina would be (1*S*,3*S*,7*S*)-3-methyl-α-himachalene, since the C-3 methyl is analogous in putative biosynthetic terms to the C-9 methyl of the homogermacrene **1** and the relative stereochemistry has already been established,[6] but this will be reported separately when the hypothesis has been fully tested.

¶ Virgin female sandflies were removed from larval rearing pots within 10 h after eclosion to ensure that they were unmated. They were provided with a saturated sugar solution on cotton wool and subsequently maintained for 5–6 days in Barraud cages (18 × 18 × 18 cm). Bioassays were conducted in a glass (9 mm internal diameter) Y-tube olfactometer. Zero grade air was passed (2 ml min^{-1}) through two charcoal filters into the test and control arms (10 cm long). The olfactometer was connected to the air supply by Teflon tubing. A filter paper disk (1.5 cm diameter) was inserted into the Teflon tubing at the connection with the olfactometer test and control arms. During bioassays, pheromone extracts or synthetic chemicals in hexane were placed on one of the filter paper disks and hexane in the same quantity as for the test arm was placed on the other filter paper disk. The female sandfly was introduced into the third arm (10 cm long) of the olfactometer and its response observed for 5 min.

Communication 9/07910F

Immobilization of $Rh(PPh_3)_3Cl$ on phosphinated MCM-41 for catalytic hydrogenation of olefins

Shin-Guang Shyu,* Sheau-Wen Cheng and Der-Lii Tzou

Institute of Chemistry, Academia Sinica, Taipei, Taiwan, ROC. E-mail: sgshyu@chem.sinica.edu.tw

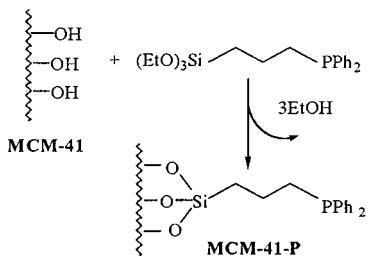
Received (in Cambridge, UK) 7th September 1999, Accepted 13th October 1999

The complex $Rh(PPh_3)_3Cl$ immobilized on MCM-41 modified with $(OEt)_3Si(CH_2)_3PPh_2$ results in a stable hydrogenation catalyst with turnover frequency (TOF) three times higher than that of $Rh(PPh_3)_3Cl$ in the hydrogenation of cyclohexene.

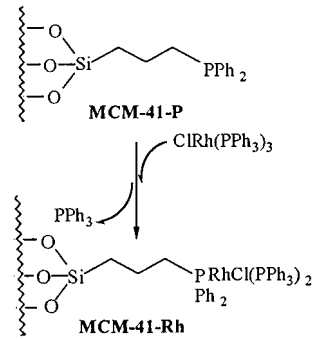
Immobilization of homogeneous catalysis by anchoring the catalyst (usually a metal complex) on a solid support has been studied extensively in the past two decades.[1,2] Recent developments on the mesoporous material MCM-41 provided a new possible candidate for a solid support for immobilization of homogeneous catalysts.[3] MCM-41 has a regular pore diameter of *ca.* 50 Å and a specific surface area $> 700\ m^2\ g^{-1}$.[4] Its large pore size allows passage of large molecules such as organic reactants and metal complexes through the pores to reach to the surface of the channel.[5] In addition, the regular pore size of MCM-41 can provide shape selectivity not provided by silica gel.

Homogeneous catalysts RhR_3Cl (R = Ph, C_8H_{12}) have been successfully immobilized on solid supports through anchoring ligands [*e.g.* $-(CH_2)_nPPh_2$] (n = 1, 2) which are chemically bonded to the surface of the support.[6] For Rh(III) complexes, enhancement of reactivity after immobilization was also reported.[7] By using the same method, $Rh(PPh_3)_3Cl$ was chemically attached on the surface of MCM-41. The resultant catalyst was characterised by various spectroscopic methods, and its catalytic activity evaluated. Herein, we report the preparation, characterisation and catalytic reactivity of this heterogeneous catalyst.

MCM-41 was prepared by hydrothermal reaction of SiO_2 and $Me_3(CH_2)_{15}NMe_3Br$.[8] A powder X-ray pattern indicates that the resultant mesoporous material has a pore diameter of *ca.* 43 Å. MCM-41 was contacted with water for 10 h in order to convert the surface to Si–OH which was further reacted with $(OEt)_3Si(CH_2)_3PPh_2$ to produce a phosphinated MCM-41(MCM-41-P) (Scheme 1).[9] Energy dispersive spectroscopy (EDS) of MCM-41-P clearly indicates that the mesoporous material contains phosphorus.† Solid state ^{31}P NMR of MCM-41-P showed a signal at δ −23.2. This further indicates the ligand has been successfully anchored to the material. The complex $Rh(PPh_3)_3Cl$ was reacted with MCM-41-P in benzene at room temperature overnight (Scheme 2). After filtration, the resultant yellow particles were washed with benzene until the filtrate was colourless. EDS showed that the sample contained Rh.‡ Solid state ^{31}P NMR of the sample showed three signals [Fig. 1(b)]. One of these corresponds to the unreacted anchoring ligand while the other two are assigned to the anchoring ligand and triphenylphosphine ligand coordinated to the Rh complex since they are shifted relative to the ^{31}P signal of $Rh(PPh_3)_3Cl$. However, exact assignments cannot be concluded. These observations indicate that Rh has been successfully immobilized on the mesoporous material.



Scheme 1



Scheme 2

Catalytic hydrogenation of cyclohexene to cyclohexane was used to test the catalytic activity of the hybrid complex MCM-41-Rh under 150 psi of hydrogen at 75 °C in a Parr reactor. After one cycle, the mixture was filtered and the catalyst was recovered on a filter paper. The filter paper was then cut into small pieces and used as a catalyst in the next cycle of hydrogenation. After fifteen cycles, the catalyst was still active (Fig. 2). The TOF for the first cycle was lower than that of the second cycle. This indicates that it takes some time to activate

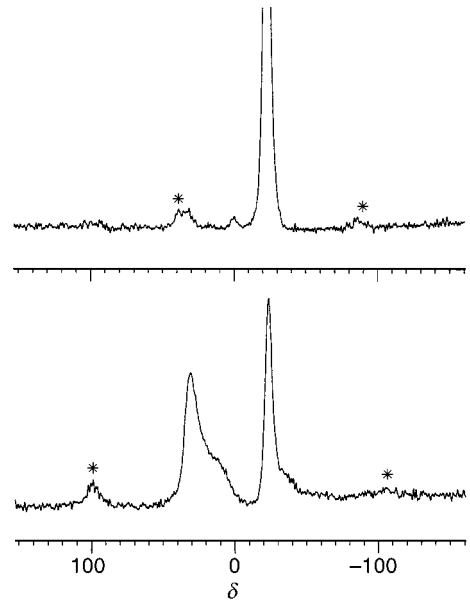


Fig. 1 Solid state ^{31}P NMR spectra of (a) MCM-41-P and (b) MCM-41-Rh. ^{31}P one-pulse experiments were performed on a Bruker AMX 400 spectrometer at a ^{31}P frequency of 161.98 MHz at room temperature. Chemical shifts were referenced to Na_2HPO_4 at 0 ppm. Signals arising from side bands are marked with asterisks.

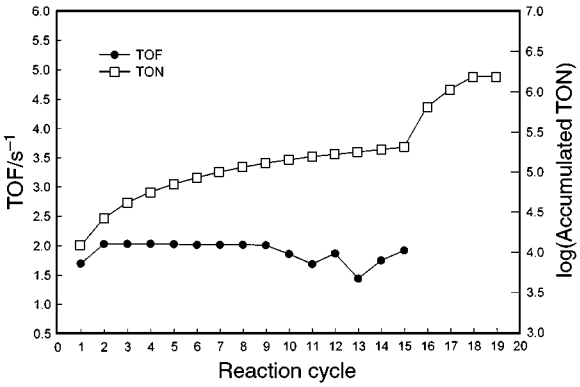

Fig. 2 Turnover frequecy (TOF) and accumulated turnover number (TON) for hydrogenation of cyclohexene by MCM-41-Rh under 150 psi of hydrogen at 75 °C. Product yields were determined by GC. For cycles 1–14, each cycle took 2 h and the solution concentration (cyclohexene in benzene) was 1.6 M. For cycles 15–18, pure cyclohexene was used. The catalyst was prepared by immobilization of 5.01 mg (5.41×10^{-3} mmol) of $Rh(PPh_3)_3Cl$ on 17.1 mg of MCM-41-P.

the catalyst to its best performance level. After the first cycle, the TOF reached *ca.* 2.0 s^{-1} and remained steady up to ten cycles.§ In order to estimate the TON, the hydrogenation of cyclohexene was carried out in pure cyclohexene. The total turnover number was $> 10^6$.¶

In order to evaluate the possibility of leaching,[10] solvent was removed from the reaction solution and benzene (3.0 ml) was added to the reactor to dissolve any possible remaining Rh complex. The UV spectrum of the solution was then recorded. The solution was then filtered through silica gel which can remove any Rh complex and the UV spectrum of the filtrate was run. The difference in absorbance between these two measurements should correspond to absorbance of leached Rh complex. The concentration of leached Rh complex was calculated according to the reported ε value (≈ 6000) at 360 nm of $Rh(PPh_3)_3Cl$.[11] The calculated amount of leached Rh complex is 1.4×10^{-9} mol *i.e. ca.* 0.3% of the Rh complex in the original catalyst.‖

The hydrogenation reaction was also carried out at ambient temperature under 1 atm of hydrogen. The catalyst was prepared by immobilization of 15.5 mg (1.68×10^{-2} mmol) of $Rh(PPh_3)_3Cl$ on 51.0 mg of MCM-41-P. For the first few hours, the catalyst was inactive. This indicates again that some time is required to activate the catalyst. The TOF is *ca.* 150 h^{-1} after subtracting the activation period from the total reaction time.

In order to evaluate the relative activity of MCM-41-Rh, hydrogenation of cyclohexene to cyclohexane with an equivalent amount of $Rh(PPh_3)_3Cl$ was carried out under the same reaction condition (150 psi hydrogen, 75 °C) and theTOF of the reaction was 0.7 s^{-1}. Hence, the TOF of MCM-41-Rh is *ca.* three times that of $Rh(PPh_3)_3Cl$.

The reason for the higher TOF for the hybride catalyst relative to the homogeneous catalyst is not clear. Similar observations were reported when a solid support such as SiO_2 was used for the immobilization of homogeneous catalysts.[7]

Received (in Cambridge, UK) 2nd September 1999, Accepted 19th October 1999

The first X-ray absorption spectrum of the rare Cr(IV) oxidation state has been obtained for the complex with the ehbaH ligand [ehbaH = 2-ethyl-2-hydroxybutanoate(1−)] in frozen aqueous solution (14 K), showing that at pH = 3.5 and in a large excess of the ligand, the predominant form of Cr(IV) is the five-coordinate oxo complex, $[Cr^{IV}O(ehbaH)_2]^0$.

Considerable interest[1,2] has been generated in the aqueous chemistry of Cr(IV) owing to its potential role as an active intermediate in Cr(VI)-induced genotoxicities.[3,4] The structure of a relatively stable Cr(IV)–ehba complex,[5] which has been studied in detail with respect to its reactivity with biomolecules,[6] has been the subject of considerable debate.[7–9] Alternative structures proposed contain either one multiple and four single Cr–O bonds (as in the crystallographically characterised $Na[Cr^{V}O(ehba)_2]$),[10] or six single Cr–O bonds [as in Cr(III)-ehba complexes].[8,9] To differentiate between these possibilities, XAS[5] of the Cr(V/IV/III)–ehba complexes in frozen solutions (14 K) were obtained. To our knowledge, this is the first XAS study of a Cr(IV) complex.

The K-edge XAS was recorded using the Australian National Beamline Facility at the Photon Factory, Tsukuba, Japan.[11] The Cr(IV) solutions were prepared by the addition of 10 mM Cr(VI) to 1.0 M ehba buffer containing 0.10 M As(III) (pH 3.5, 20 °C)[2] and were frozen in liquid N_2 at 50 ± 5 s after mixing, which corresponded to 88 ± 2% of total Cr existing in the Cr(IV) form (measured by UV–VIS spectroscopy).[2,11] The solution of Cr(V) was prepared by dissolving 10 mM of $Na[Cr^{V}O(ehba)_2]$[12] in ehba buffer (1.0 M, pH 3.5, 20 °C). The reaction of 10 mM $Na[Cr^{V}O(ehba)_2]$ with 50 mM of $FeSO_4$ (1.0 M ehba buffer, pH 3.5, *ca.* 1 min at 20 °C) resulted in quantitative formation of a Cr(III)–ehba complex.[13] The solutions of Cr(V) and Cr(III) were stable for at least 15 min at 20 °C (UV–visible spectroscopy) and were frozen in liquid N_2 at *ca.* 2 min after preparation. Photodamage of the samples during the exposure to X-rays was minimized by: (i) using cryogenic conditions (14 K);[14] (ii) moving the beam to a fresh spot on the sample after each set of five scans; and (iii) changing to a fresh sample after 12 h of exposure. The absence of significant photodamage was evident from (i) the absence of observable colour changes in the samples after 12 h of exposure;[15] and (ii) the absence of significant changes in the pre-edge and edge features of the XAS.[11] Averaging, background subtraction and the calculation of theoretical XAFS spectra were performed using the XFIT software package,[16] as described previously,[17] and appropriate constraints and restraints.[11,18] Most of the errors in the determined XAFS bond lengths estimated from the Monte Carlo analysis of the noise in the data[16] did not exceed the conservative systematic error of 0.02 Å.[17] HyperChem software[19] was applied for building the molecular models used to initialise the MS XAFS calculations.

The XANES[5] spectrum of the Cr(IV) complex is compared with those of the Cr(V) and Cr(III) complexes in Fig. 1. In agreement with literature data,[20] the edge energy increases along the series Cr(III) < Cr(IV) < Cr(V). The pre-edge region of the Cr(III)–ehba complex features two weak absorption maxima (symmetry-forbidden 1s → 3d transitions), characteristic for octahedral Cr(III) complexes.[21] By contrast, a more intense pre-edge peak was observed in the XANES of the Cr(IV)–ehba complex, when the edge jump was normalised. This feature gains intensity from a decrease in symmetry from an octahedral geometry and/or an increase in π bonding compared to Cr(III).[21] The pre-edge absorbance for the Cr(IV)–ehba complex is *ca.* three times less intense than that for the Cr(V)–ehba complex (Fig. 1).

The SS fits of the XAFS spectra were used to compare the coordination numbers and the Cr–O bond distances in the first coordination shells of the Cr(V/IV/III)–ehba complexes.[11] Acceptable models are those possessing both low goodness-of-fit values (R < 8%) and physically reasonable values of the threshold energy E_0, the scale factor S_0^2 and the Debye–Waller factors σ_i^2.[11] As expected, the first coordination shell of the Cr(III)–ehba complex was best fitted by the model containing six single Cr–O bonds,[22] and that of the Cr(V)–ehba complex is best fitted by the model containing four single (1.85 Å) and one multiple (1.55 Å) Cr–O bond.[23] Notably, additions of extra [*i.e.* seventh for Cr(III) and sixth for Cr(V)] long (2.2 Å) Cr–X distances to the models significantly improved the R values, but led to unreasonably high σ^2 values.[11] This feature probably reflects the influence of more distant coordination shells.

The best fit for the first coordination shell of the Cr(IV)–ehba complex includes: (i) two Cr–O bonds with lengths (1.89 Å) corresponding to those of the Cr–O(carboxylato) bonds in $Na[Cr^{V}O(ehba)_2]$;[10] (ii) two longer (2.07 and 2.26 Å) Cr–O bonds, assigned to the protonated alkoxo groups of the ligand;[24] and (iii) one short (1.55 Å) Cr–O bond, corresponding to the oxo ligand.[10] As for Cr(V)–ehba, addition of a sixth long (≥2.0 Å) Cr–O bond to the model, though improving the R value slightly, led to unreasonably high σ^2 values.[11] Any models including only single Cr–O bonds (≥1.7 Å), similar to the alternative structure proposed,[8] gave very poor fits.[11] The best model for

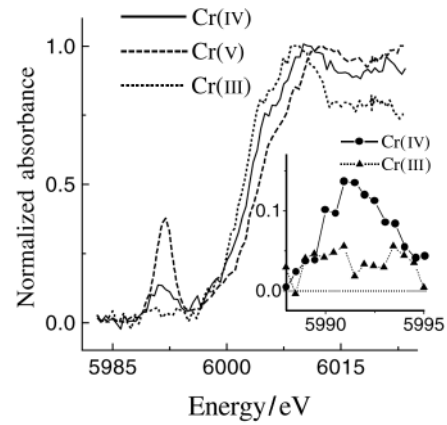

Fig. 1 XANES spectra of frozen (14 K) 10 mM solutions of Cr(V/IV/III)–ehba complexes in 1.0 M ehba buffers, pH 3.5 (average of 20 scans).

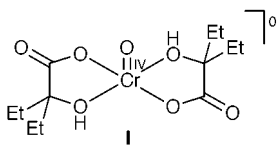
† Electronic supplementary information (ESI) available: refer to ref. 11. See http://www.rsc.org/suppdata/cc/1999/2339/

Cr(v)–ehba (*i.e.* with deprotonated alkoxo groups of the ligands) was unsuitable for Cr(IV)–ehba.[11] Thus, comparisons amongst the SS XAFS fits of the first coordination shells for the Cr(V/IV/III)–ehba complexes are consistent with a five-coordinate oxo complex structure **I** for the Cr(IV) complex.



I

When the XAFS of **I** was fitted using MS that included all non-hydrogen atoms[11] a good fit resulted (Fig. 2, R = 18.5%), including significant contributions (⩾10%) of 34 MS paths.[11] In the MS XAFS calculations, bond lengths and angles within the ligands were restrained to be consistent with those within the ehbaH ligand of the crystallographically characterised NH_4-[$V^{IV}O$(ehba)(ehbaH)] complex,[3] but the angles involving the O donors of **I** were allowed to change freely. The refined structure of **I** was of a distorted trigonal-bipyramidal geometry,[11] similar to those of the Cr(V) and V(IV) ehba complexes.[3,10] However, further studies are required to establish the reliability of the bond angles in **I** determined from the MS XAFS calculations. The Cr–O bond lengths determined from the MS analysis (1.56, 1.89, 1.90, 2.06 and 2.24 Å), were the same, within the experimental error, as those determined by SS calculations.

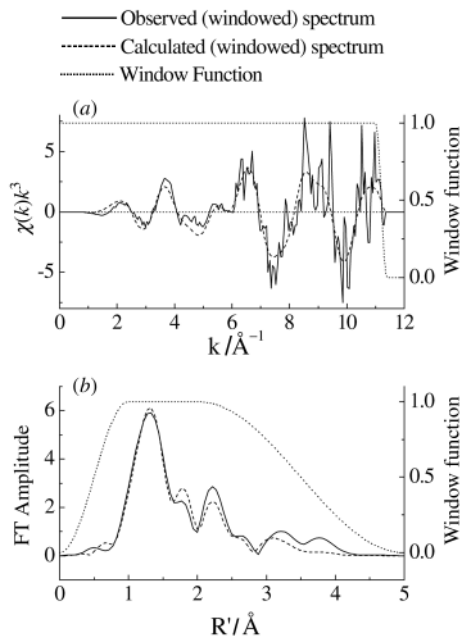


Fig. 2 (a) XAFS spectrum and (b) its Fourier transform for 10 mM **I** (1.0 M ehba buffer, pH 3.5, 14 K, average of 60 scans).

Thus, the SS and MS fitting of the XAFS data, together with the XANES and previous UV–VIS spectroscopic and kinetic studies,[1,2,6] point to **I** as the structure for the Cr(IV) complex under the reaction conditions, while an alternative structure ([$Cr^{IV}(OH)_2$(ehbaH)$_2$])[1,8] is eliminated by the XAFS data.

This work was performed at the Australian National Beamline Facility (ANBF) with support from the Australian Synchrotron Research Program, which is funded by the Commonwealth of Australia under the Major National Research Facilities program. The authors thank Dr James Hester (ANBF) and Mr Colin Weeks (University of Sydney) for assistance with the XAS experiments, Assoc. Professor Trevor Hambley (University of Sydney) for helpful advice on the data analysis and the Australian Research Council for funding.

21 P. J. Ellis, R. W. Joyner, T. Maschmeyer, A. F. Masters, D. A. Niles and A. K. Smith, *J. Mol. Catal. A: Gen.*, 1996, **111**, 297.
22 The Cr–O bond lengths in the Cr(III)–ehba complex, determined from SS XAFS calculations (1.94 Å),[11] are in agreement with the proposed structure of this complex.[13] The Cr–O bond lengths in [$Cr^{III}(OH_2)_6$]$^{3+}$ (determined from MS XAFS calculations) are 1.97 Å (H. Sakane, A. Muñoz-Páez, S. Díaz-Moreno, J. M. Martínez, R. R. Pappalardo and E. S. Marcos, *J. Am. Chem. Soc.*, 1998, **120**, 10 397).
23 The different Cr–O bond lengths in Na[$Cr^{V}O$(ehba)$_2$] involving the carboxylato and alkoxo moieties (1.90 and 1.80 Å, respectively)[10] are not distinguished by SS XAFS when $k \leqslant 11$ Å^{-1} since the resolution in bond lengths is 0.15 Å.[17] These data are in agreement with the results of SS and MS XAFS calculations for solid Na[$Cr^{V}O$(ehba)$_2$] (T. Maschmeyer, G. Barr-David, P. A. Lay and A. F. Masters, to be submitted).
24 The V–O(alcohol) bond length in NH_4[V^{IV}(ehba)(ehbaH)] is 1.95 Å.[3] The presence of unusually long (> 2 Å) Cr–O bonds in **I** is consistent with the ease of loss of one ehbaH ligand in solution.[1,2]

Oxidative steam reforming of methanol over CuZnAl(Zr)-oxide catalysts; a new and efficient method for the production of CO-free hydrogen for fuel cells

S. Velu, K. Suzuki* and T. Osaki

Ceramics Technology Department, National Industrial Research Institute of Nagoya, 1-1 Hirate-cho, Kita-ku, Nagoya 462-8510, Japan. E-mail: ksuzuki3@nirin.go.jp

Received (in Cambridge, UK) 31st August 1999, Accepted 15th October 1999

Steam reforming of methanol in the presence of air over CuZnAl(Zr)-oxide catalysts derived from hydrotalcite-like hydroxycarbonate precursors offers CO-free hydrogen suitable for fuel cells with about 100% methanol conversion at around 230 °C.

Hydrogen is forecast to become a major source of energy in the future.[1] Hydrogen fueled vehicles using fuel cells [*e.g.* polymer electrolyte membrane fuel cell (PEMFC)] are under development in an effort to reduce CO_2 emissions which accelerate global warming. In addition, fuel cell-powered vehicles, using hydrogen fuel, do not emit any environmental pollutants, such as NO_x, SO_x and hydrocarbons. For use in fuel cells for mobile applications, hydrogen is typically produced through steam reforming of methanol (SRM) [eqn. (1)] over CuZn-based catalysts.[2] Recently, partial oxidation of methanol (POM) [eqn. (2)] has also been suggested as a route for hydrogen extraction from methanol.[3] Unfortunately, both of these reactions produce considerable amounts of CO (> 100 ppm) as a byproduct. For application in PEMFCs, even traces of CO (> 20 ppm) in the reformed gas deteriorates a Pt electrode and the cell performance is dramatically lowered.[4] Currently, second stage catalytic reactors are being used to remove this CO by the water-gas-shift reaction [eqn. (3)], CO oxidation or methane formation. However, the addition of further steps for fuel gas refinement would lower the total efficiency of the propulsion system. Hence, in order to utilize hydrogen fuel for fuel cells, it is highly desirable to develop a process that can produce hydrogen without CO in the reformed gas.

$$CH_3OH + H_2O \Leftrightarrow 3H_2+CO_2 \quad \Delta H = +49.4 \text{ kJ mol}^{-1} \quad (1)$$

$$CH_3OH + 1/2O_2 \Leftrightarrow 2H_2+CO_2 \quad \Delta H = -192.2 \text{ kJ mol}^{-1} \quad (2)$$

$$CO + H_2O \Leftrightarrow H_2+CO_2 \quad \Delta H = -39.4 \text{ kJ mol}^{-1} \quad (3)$$

In the present study, we have performed the SRM reaction in an oxidizing atmosphere (in the presence of air) over a series of novel CuZnAl(Zr)-oxide catalysts obtained by calcining the CuZnAl(Zr)-hydroxycarbonates containing hydrotalcite (HT)/aurichalcite phases, at 450 °C for 5 h. We demonstrate here for the first time that under the reaction conditions employed, a combined steam reforming–partial oxidation of methanol, termed herein after as "oxidative steam reforming of methanol (OSRM)", reaction takes place to produce CO-free hydrogen with about 100% methanol conversion at 230 °C.

CuZnAl(Zr)-hydroxycarbonate precursors with different Cu:Zn:Al atomic ratios were synthesized by a coprecipitation method at room temperature using a mixture of NaOH and Na_2CO_3 as precipitants.[5] The (Cu+Zn)/Al(Zr) atomic ratio in the starting solution was varied from 2 to 4. The Cu surface areas (S_{Cu}), Cu dispersion (D) and the Cu crystallite sizes (t_{Cu}) were calculated by the TPR-N_2O passivation experiment as described in the literature.[6] Catalytic test reactions were performed in a packed-bed micro-reactor (4 mm i.d.) using 90 mg of the catalyst (particle size 0.30–0.355 mm) in the temperature range 180 to 290 °C at atmospheric pressure. Liquid methanol (for the POM reaction) or premixed water and methanol with a H_2O/CH_3OH molar ratio of 1.3 (for the SRM and OSRM reactions) was fed into the pre-heater at a rate of 1.6 or 2.5 $cm^3\ h^{-1}$ by means of a micro-feeder. Synthetic air (20.2 vol.% O_2 in N_2) at a rate of 10 to 20 $cm^3\ min^{-1}$ and Ar (carrier gas, 43 $cm^3\ min^{-1}$) flows were adjusted by means of a mass flow controller. The reaction products were analyzed on-line using two gas chromatographs equipped with TC detectors and porapak Q and molecular sieve 13 X columns. The performance of the catalyst was evaluated after 25 h of on-stream operation.

The physicochemical properties of the catalysts used in the present study are summarized in Table 1. Initially, a systematic study on the POM reaction was performed over a series of CuZnAl-oxide catalysts without Zr (CZAZ-A through CZAZ-D). Among them, the catalyst CZAZ-C exhibited the best performance. Hence, this catalyst was chosen first to be examined for its catalytic performance in the SRM and OSRM reactions. Fig. 1 compares the catalytic performance of the CZAZ-C catalyst in the POM, SRM and OSRM reactions. As will be noted, the methanol conversion is lowest in the SRM reaction at low temperatures and the conversion rate increases rapidly with increasing reaction temperature. The conversion reaches about 100% at around 290 °C where the selectivity of CO is < 5 mol% (CO concentration ≈ 200 ppm). Interestingly, when air was passed through during the SRM reaction, the conversion approaches 100% at a lower temperature of about 230 °C, without any detectable CO in the reformed gas. Because of the high methanol conversion of about 100%, the H_2 production rate in the OSRM reaction increased by a factor of two compared to that obtained from the SRM or POM reactions. It is of great significance that CO only started forming above 260 °C in the SRM reaction, while it started forming above

[a] CH_3OH: 8.8 cm^3 min^{-1}; H_2O: 11.4 cm^3 min^{-1}.

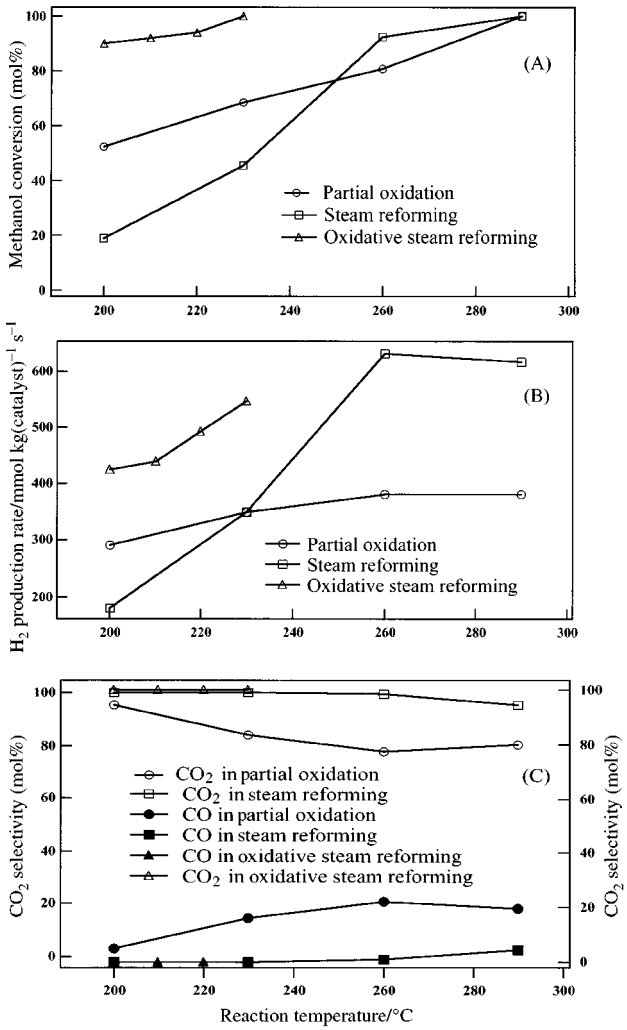

Fig. 1 Effect of temperature on catalytic performance of CZAZ-C catalyst in the partial oxidation, steam reforming, and oxidative steam reforming of methanol; (A) methanol conversion, (B) H_2 production rate, (C) carbon selectivity.

200 °C in the POM reaction. However, in the OSRM reaction, since excess water is present in the feed mixture, the situation is highly favorable for the water-gas-shift reaction [eqn. (3)] to transform CO into CO_2 and H_2.

For the purpose of evaluating the performance of various CuZnAl(Zr)-oxide catalysts in the OSRM reaction, the methanol conversion was reduced by increasing the flow rate of the $CH_3OH + H_2O$ feed mixture to 2.5 cm^3 h^{-1} and the results were collected during 25 h of continuous operation. Table 2 summarizes the catalytic performance of a series of CuZn-Al(Zr)-oxide catalysts in the OSRM reaction. It can be seen that the catalytic activity increases with decreasing Al content in the sample. It is also interesting to note from Table 2 that the best catalytic performance was obtained over the catalyst containing Zr instead of Al (CZAZ-F), indicating that Zr is an effective support for CuZn-based oxide catalysts compared to Al in the OSRM reaction. The undesirable byproduct CO is virtually not produced (or only traces are formed) and catalyst deactivation is insignificant over most of the catalysts (except CZAZ-A). Another interesting feature which will be noticed in Table 2 is that a ratio of H_2 production rate/CH_3OH conversion rate of around 2.5 is obtained over all the catalysts. However in the SRM [eqn. (1)] and POM [eqn. (2)] reactions the H_2 production rate/CH_3OH conversion rate ratios would be 3 and 2, respectively. The value of 2.5 obtained for the OSRM reaction suggests that a combined partial oxidation–steam reforming of methanol is taking place under the present experimental conditions. Hence, the overall reaction can be represented by eqn. (4), which is a combination of eqn. (1) and 2. Eqn. (4) satisfies the H_2 production rate/CH_3OH conversion rate ratio of around 2.5 observed in the present investigation.

$$2CH_3OH + H_2O + 1/2O_2 \Leftrightarrow 5H_2 + 2CO_2 \quad (4)$$

It is clear from the results presented in the present study that the OSRM reaction over these novel CuZnAl(Zr)-oxide catalysts is a very efficient and convenient method for the production of CO-free hydrogen suitable for fuel cells. Besides producing CO-free hydrogen, the OSRM reaction has an additional benefit in that the reaction is exothermic, thereby minimizing energy consumption. A detailed investigation is in progress into the optimization of the catalyst formulations and the reaction operating parameters to further improve the catalytic performance.

Received (in Bloomington, IN, USA) 6th September 1999, Accepted 7th October 1999

A caesium aluminophosphate compound synthesized *via* high-temperature, solid-state methods reveals a new composition for a layered AlPO structure; it exhibits a non-Löwensteinian framework which contains linear Al–O–Al linkages in six-rings of alternating Al_2O_7 and PO_4 groups.

In spite of the large number of aluminophosphates known (*ca.* 250 compounds), the only established compositions adopted by layered structures consisting of AlO_4 and PO_4 tetrahedra are $[Al_3P_4O_{16}]^{3-}$, $[AlP_2O_8]^{3-}$, $[Al_2P_3O_{12}H_x]^{(3-x)-}$ (x = 1,2), $[Al(HPO_4)_2(H_2O)_2]^-$, and $[Al_4P_5O_{20}H]^{2-}$.[1] Their frameworks are built up from either 4 × 6, 4 × 8, 4 × 6 × 8, or 4 × 6 × 12 rings. The title compound exhibits a new framework formula, $[Al_2P_2O_9]^{2-}$, which contains an equal number of Al and P atoms. The single crystal structure reveals an unusual feature with respect to the direct Al–O–Al linkages and, in turn, a new type of 4 × 6 aluminophosphate (AlPO) network. All the above mentioned AlPOs, except the current compound, show frameworks avoiding direct Al–O–Al linkages between AlO_4 tetrahedral units; for zeolites (aluminosilicates) this is known as Löwenstein's rule.[2] According to the Löwensteinian structure, each Al is coordinated through oxygen to four Si (or P) and *vice versa* (the 4:0 ordering scheme). Theoretical calculations predict that the formation of Al–O–Al linkages (in the 3:1 ordering scheme, for example) is energetically unfavorable.[3] The experimental findings on compounds prepared by hydrothermal routes, such as the organically templated AlPO synthesis, support this claim.[1] However, calculations based on the lattice energy of an ionic model by Bell, Jackson, and Catlow,[3b] suggest that the energy loss due to the direct linkages could be overcome by thermal energies. This prediction is confirmed by some scattered examples of non-Löwensteinian frameworks prepared by high-temperature methods.[4] Among these exceptions, there are about 45 out of over 2,450 reported aluminosilicates, but only two aluminophosphates. These include sodalite,[4a] a common example for aluminosilicates, as well as metal-containing $MAlPO_5$ (M = Mg, Fe).[4b,c]

Crystals of $Cs_2Al_2P_2O_9$, **1**, were grown by high-temperature, solid-state methods using CsCl flux,[5] and the structure was characterized by single crystal X-ray diffraction methods.[6] As shown in Fig. 1, **1** adopts a layered structure where the aluminophosphate slabs are held together by electropositive Cs^+ cations. The extended AlPO slab consists of alternately arranged Al_2O_7 and PO_4 groups sharing corner oxygen atoms. Each slab adopts a mixed four- and six-ring (4 × 6) network [Fig. 2(a)]. The 4-ring (2Al + 2P) structure is made up from alternating 2 × AlO_4 and 2 × PO_4 groups while the 6-ring (4Al + 2P) is built of 2 × Al_2O_7 and 2 × PO_4 groups. The Al–O–Al linkages [highlighted by solid lines in Fig. 2(a)] exist in the form of Al_2O_7 units in between rows of fused 4-ring units. The latter form a corrugated $Al_2P_2O_4$ chain [Fig. 2(b)], in which the 4-ring units are in a chair configuration.

The aluminium powder may facilitate a chain 'zipping' process *via* oxidation intercalation *en route* to the formation of AlPO slabs.[5] The 4-ring chain shown in [Fig. 2(b)] resembles the so-called precursor structure for extended lattices.[1a] In our study, aluminium powder was employed along with an oxidant, potassium superoxide. This approach is unconventional compared to commonly employed methods using aluminium oxide (or hydroxide) as starting material.[5] For the mechanism, one can imagine the processes of bond breaking *via* dissociation of the Al–O–Al linkages of Al_2O_3, prepared *in situ* in this case,

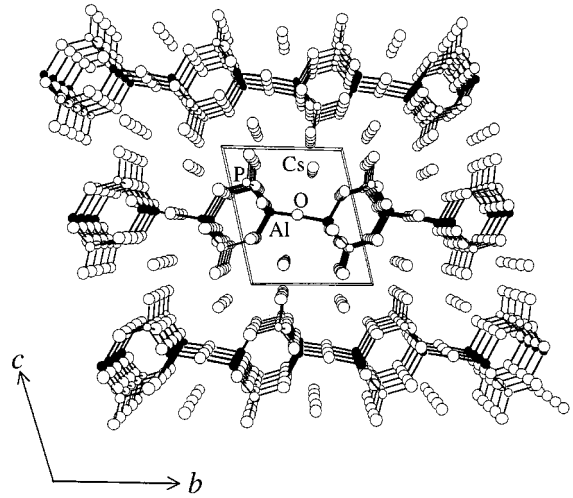

Fig. 1 Projected view showing the layered structure of **1**. The small filled and open circles, as for Fig. 2, represent Al^{3+} and P^{5+} cations, respectively, and the large open circles represent O^{2-} (bonded) and Cs^+ (non-bonded) ions.

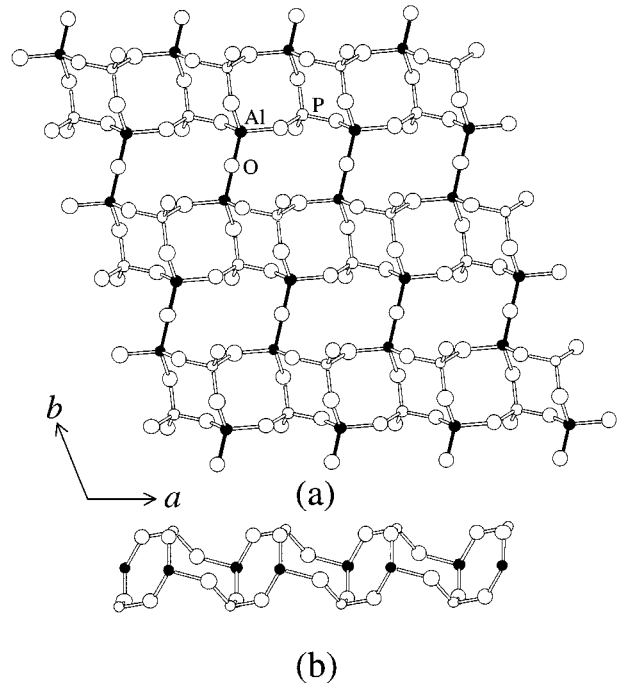

Fig. 2 (a) A partial structure of the $[Al_2P_2O_9]^{2-}$ slab. The linear Al–O–Al linkages are highlighted with thick lines. (b) A side view of fused 4-ring units, see text. The terminal oxygen atoms are omitted for clarity.

followed by bond formation with phosphorus cations through bridging oxygens. While the idea of this reaction pathway is intuitively sound, the framework formation could bypass the formation of Al_2O_3 to undergo simultaneous layer formation *via* oxidative 'zipping' of partially oxidized AlPO chains. Direct heating of a mixture of Al_2O_3 or $Al(OH)_3$, P_2O_5 and CsOH at 800 °C in an open system does not, in fact, yield **1**. Addition of CsCl as a flux results in an as yet unidentified phase, whose PXRD patterns show a close resemblance to those of **1**. Further investigation into the role of aluminium powder is underway.

The title compound reveals a new type of 4 × 6 network and a fascinating framework of interconnected 4-ring chains. Prior to this research, four 4 × 6 network structures were known that adopt the above mentioned $[Al_3P_4O_{16}]^{3-}$ and $[HAl_2P_3O_{12}]^{2-}$ compositions.[1c,7] Fig. 3 presents all the 4 × 6 networks, including the current example, in which only Al^{3+} and P^{5+} cations are shown. The network structures are adopted by, for example, $(NH_3CHMeCH_2NH_3)_3[Al_6P_8O_{32}]\cdot H_2O$ for network type (a), $Co(en)_3[Al_3P_4O_{16}]\cdot 3H_2O$ and *trans*-$Co(dien)_2[Al_3P_4O_{16}]\cdot 3H_2O$ for type (b), $(2\text{-}BuNH_3)_2[HAl_2P_3O_{12}]$ for type (c), $(C_5N_2H_9)_2(NH_4)[Al_3P_4O_{16}]$ for type (d), and **1** for type (e). It should be noted that the major difference among the frameworks consisting of these networks concerns the tetrahedral units. The framework of **1** is comprised of Al_2O_7 units while the others consist of AlO_4 interlinked with PO_4 units only. The networks (a)–(d), therefore, possess the 4 : 0 ordering scheme while network (e) has the 3 : 1 scheme. In addition, the networks (a) and (d) consist of short, (3- and 5-, respectively) edge-shared, four-ring units while (e) contains parallel chains of fused four-rings.

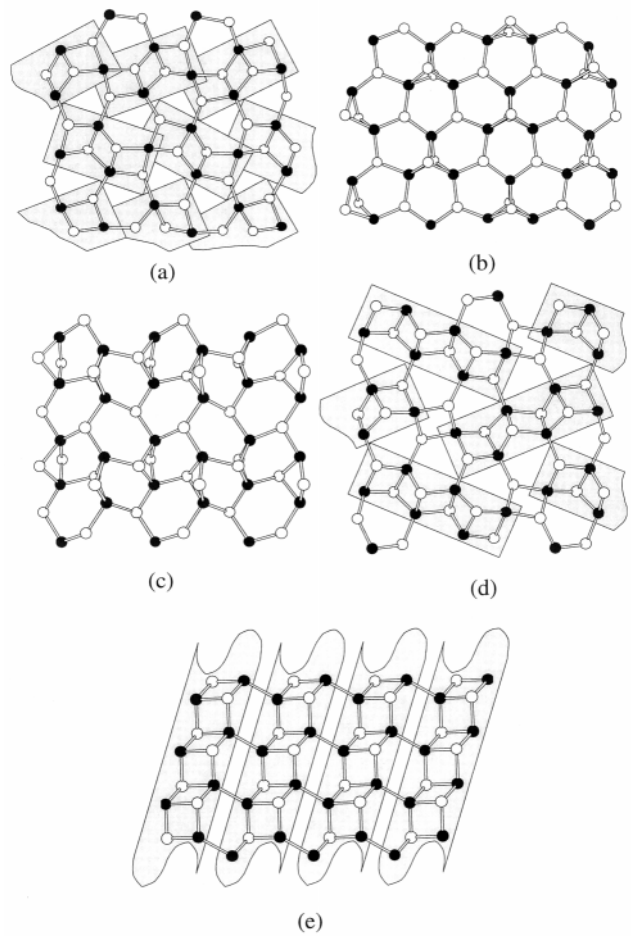

Fig. 3 Five types, (a)–(e), of 4 × 6 Al–P–O frameworks. Aluminum atoms (●) and phosphorus atoms (○) are linked by oxygen bridges (not shown). In (a)–(d), strict alternation of Al and P is observed, whereas in (e), the 3 : 1 ordering scheme is shown. The fused 4-ring units in (a), (d), and (e) are highlighted, see text.

The Al–O–Al linkage in **1** reveals two unusual features; namely, a linear bond angle and a fairly short $Al\text{–}O^b$ (O^b : bridging oxygen in the Al_2O_7 unit) bond. The $Al\text{–}O^b\text{–}Al$ angles are usually nonlinear and are much smaller than 180°. In the frameworks of two previously mentioned non-Löwensteinian compounds, $MgAlPO_5$ and $FeAlPO_5$, for instance, the $Al\text{–}O^b\text{–}Al$ angles are 129.8(2)° and 131.8(2)°, respectively.[4b,c] Also, the $Al\text{–}O^b$ bond in **1**, (1.69 Å) is shorter than the three Al–O^t (O^t : terminal oxygen in the Al_2O_7 unit) bonds, (1.75–1.76 Å). Based on chemical intuition, the linear bond angle and short bridging oxygen to aluminium bond distance suggest possible π character. It would be interesting to look at the thermal behavior of the framework in relation to the $Al\text{–}O^b\text{–}Al$ linkage.

Financial support for this research (DMR-9612148) and access to the single crystal X-ray diffractometer from the National Science Foundation is acknowledged. We thank Professor Myung-Hwan Whangbo for his insightful discussions.

5 0.0540 g of Al (2.0 mmol), 0.1422 g of KO_2 (2.0 mmol), 0.0795 g of CuO (1.0 mmol) and 0.1419 g of P_2O_5 (1.0 mmol) were ground and mixed with the flux CsCl. The charge to flux ratio was 1 : 2 by weight. The reaction was carried out in a carbon-coated quartz ampoule. The mixture was heated up to 500 °C over 24 h, and isothermed for 6 h, followed by heating to 800 °C, and isothermal treatment for an additional 4 d. The reaction was cooled slowly to 500 °C over 72 h, followed by furnace cooling to room temperature. Colorless columnar crystals of **1** (*ca.* 60%), as well as some other unidentified black and white polycrystalline phases (*ca.* 40%), were retrieved from the flux by washing the products with deionized water using suction filtration. EDAX shows no contamination from potassium, chlorine, and copper in this crystalline phase, as the presence of the latter is attributed to CuO used for the synthesis of Cu-containing AlPO. An alternative reaction of $2Al/2KO_2/P_2O_5/4CsCl$ without adding CuO resulted in a slightly lower yield of **1**, *ca.* 50%.

6 *Crystal data* for **1**: $Cs_2Al_2P_2O_9$, M = 525.7, triclinic, space group $P\bar{1}$ (No. 2), a = 4.925(2), b = 7.121(2), c = 8.066(2) Å, α = 96.51(2)°, β = 107.12 (2)°, γ = 108.68(2)°, V = 249.3(1) Å^3, Z = 1, D_c = 3.502 g cm^{-3}, μ(Mo-Kα) = 7.835 mm^{-1}, λ = 0.71073 Å, 3.50° < 2θ < 55.00°. Final R = 0.024, R_w = 0.035, GOF = 1.36 were obtained for all the data and 71 parameters. The final Fourier map had a minimum and maximum of −1.04 and 1.60 eÅ^{-3}, respectively. CCDC 182/1446. $Ru(bpy)_3$-based artificial receptors toward a protein surface: selective binding and efficient photoreduction of cytochrome c

Hiroshi Takashima, Seiji Shinkai and Itaru Hamachi*†

Department of Chemistry and Biochemistry, Graduate School of Engineering, Kyushu University, Fukuoka 812-8581, Japan. E-mail: itarutcm@mbox.nc.kyushu-u.ac.jp

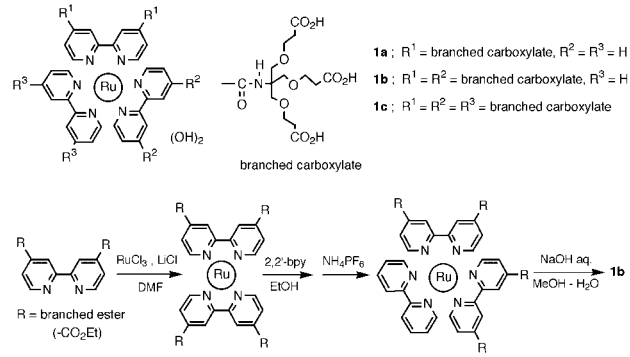
Received (in Cambridge, UK) 21st September 1999, Accepted 20th October 1999

The binding properties of a series of $Ru(bpy)_3$ complexes to cytochrome c are described; these compounds act as selective cytochrome c receptors and one derivatie is shown to be a photodriven modulator of the cytochrome c redox state.

Site-specific recognition on a protein surface, including a definite α-helix or β-sheet structure, with an artificial molecule is one of the major goals of recent bioorganic chemistry. A few ligands and receptors have been synthesized to bind proteins by using non-covalent and multi-point forces *via* hydrogen bonding, electrostatic or hydrophobic interactions.[1] However, design of such receptors is generally difficult because protein surfaces are relatively larger than conventional target molecules in host–guest chemistry. We recently demonstrated that lipid bilayer surfaces are promising for domain selective binding of a protein *via* electrostatic interaction.[2] However, more sophisticated interactions are not expected in such a molecular assembly since the spatial juxtaposition of interaction points is not elaborately carried out. Instead we made an attempt to utilize the coordination sphere of ruthenium tris-bipyridine complexes [$Ru(bpy)_3$], asymmetric functionalization of which is effected by simple coordination chemistry.[3] In this communication, we describe the binding properties of a series of $Ru(bpy)_3$ complexes to cytochrome c (Cyt-c) and the efficient electron injection which occurs through photoinduced electron transfer (ET) in their non-covalently linked systems.

The poly-anionic $Ru(bpy)_3$ complexes **1a**–**c** (Scheme 1) were constructed *via* the corresponding Ru bis-bpy complexes as intermediates. The bpy ligand bearing dendritic carboxylate moieties was synthesized according to the modified method in the literature.[4] All compounds were satisfactorily identified by NMR, IR, MALDI-Tof-mass spectroscopy and elemental analysis.‡ The photophysical properties of **1a**–**c** were investigated by absorption and emission spectroscopies, and emission lifetime experiments in a phosphate buffer (pH 7.0). The peak shapes and intensities (ε value at absorption maximum) in the UV-visible spectra of **1a**–**c** are similar to those in the spectrum of the original $Ru(bpy)_3$ complex, except for the 10 nm red-shifted λ_{max} of the MLCT band. This is due to the electron-withdrawing groups at the 4,4′-positions of the bpy ligand. The emission spectra are almost identical to that of the original $Ru(bpy)_3$ complex (λ_{em} 610 nm) upon excitation at the corresponding MLCT band (λ_{em} 615 nm for **1a**, 630 nm for **1b, 1c**). The emission lifetimes of $Ru(bpy)_3$, **1a** and **1b** were determined to be in the range 600–800 ns under anaerobic conditions (ex. 480 nm, em. 610 nm), whereas the lifetime of **1c** is elongated (1500 ns) by the cage effect due to the introduced branching on the three bpy ligands.[5]

The affinity of **1a**–**c** for various proteins was estimated by ultrafiltration binding assays. After incubation of the mixture containing a $Ru(bpy)_3$ derivative (3 μM) and a protein (9 μM) in buffer solution at pH 7.0 (10 mM phosphate) for 1 h, the solution was subjected to ultrafiltration [centricon-10 (Amicon), centrifuge at 7000 rpm, 25 °C]. The protein-bound



Scheme 1 Structures of $Ru(bpy)_3$-based poly-anionic complexes, **1a**–**c**.

$Ru(bpy)_3$ was not filtered and the fraction of the non-bound $Ru(bpy)_3$ component was determined by monitoring the filtrate spectrophotometrically. The results are summarized in Fig. 1. Obviously, the fraction of protein-bound $Ru(bpy)_3$ increases with an increase in the number of introduced carboxylate groups. Poly-anionic **1c**, bearing 18 carboxylates can bind to the Cyt-c surface 10 times more tightly than the original $Ru(bpy)_3$ complex. The surface of Cyt-c is positively charged at neutral pH, since the isoelectric point (pI) is 10.0.[6a] It is reasonable to assume that the poly-carboxylate clusters of the $Ru(bpy)_3$ complexes can bind to a cationic domain of the Cyt-c surface. Myoglobin (Mb, pI = 7.0), horseradish peroxidase (HRP, pI = 8.0), and cytochrome b_{562} (Cyt-b_{562}, pI = 5.0) were also used as target proteins under the same conditions.[6] The $Ru(bpy)_3$ derivatives pass through the ultrafiltration membrane in these cases, indicating that all Ru complexes examined here exhibit much lower affinities for these proteins, than for Cyt-c. It is clear that the poly-anionic $Ru(bpy)_3$-based complexes **1a**–**c** selectively bind to the Cyt-c surface.

Based on the redox potentials of Cyt-c [0.26 V (Fe^{3+}/Fe^{2+}) *vs.* NHE] and $Ru(bpy)_3$ [−0.86 V ($Ru^{3+}/{}^*Ru^{2+}$) *vs.* NHE], ET from the excited state of $*Ru^{2+}(bpy)_3$ to oxidized Cyt-c is energetically favorable.[3b,7,8] Thus, we studied the photoreduction of Cyt-c by visible light. Upon steady-state photoirradiation [high

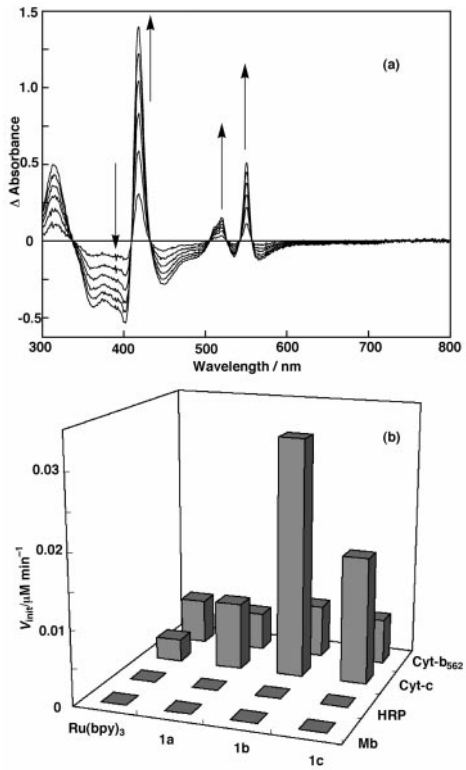

Fig. 2 (a) Time-course changes of the difference absorption spectra upon steady-state photoirradiation. (b) Summary of the initial rates (V_{init}) of photoreduction of various hemoproteins catalyzed by Ru(bpy)$_3$ derivatives.

pressure Hg-lamp (λ > 450 nm)] of a degassed solution consisting of Cyt-c (9 μM), a Ru complex (3 μM) and EDTA (10 mM),[3a,9] absorption bands at 520 and 550 nm attributable to the Q-bands of reduced Cyt-c(II) appeared [Fig. 2(a)]. The initial rates (V_{init}) are summarized in Fig. 2(b). Compared with the original Ru(bpy)$_3$ complex, it is apparent that **1a**–**c** accelerate the photoreduction of Cyt-c. Interestingly, the most effective ET relay was achieved by **1b**, having 12-carboxylates, not by **1c**, having 18-carboxylates. This suggests that not only the number of carboxylate groups, but also the asymmetric spatial orientation around the Ru center are crucial in the net photoreduction efficiency. On the other hand, no acceleration was observed for Mb, HRP and Cyt-b$_{562}$ as substrates of photoreduction, showing good agreement with the results of the binding experiments.

In the present photoreduction system, the Ru complexes should inject electrons into positively charged Cyt-c and simultaneously abstract electrons from negatively charged EDTA. In order to clarify the effect of asymmetric geometry, the ET quenching rates (k_{ET}) of the excited Ru complex by a cationic or anionic quencher were separately investigated by emission lifetime measurement. Since the sacrificial donor EDTA which is used in the photoreduction study has three negative charges at pH 7.0, the $Fe(CN)_6^{3-}$ anion was chosen as the negatively charged quencher.[10] The rate constant, k_{ET}, was calculated by the Stern–Volmer equation and decreases in the order Ru(bpy)$_3$ (k_{ET} = 1.5×10^{10} M^{-1} s^{-1}) > **1a** (4.2×10^9 M^{-1} s^{-1}) > **1b** (2.4×10^8 M^{-1} s^{-1}) > **1c** (8.9×10^7 M^{-1} s^{-1}), showing that ET becomes less efficient with the increasing number of carboxylate residues on the Ru(bpy)$_3$ derivatives.[11] On the other hand, when Cyt-c was used as a cationic quencher, the tight binding of **1c** and **1b** with Cyt-c prevented us from analyzing ET rates as a dynamic quenching mechanism.[12] Instead, pseudo intramolecular ET rates were determined: k_{ET} = 1.9×10^6 s^{-1} for **1c** and 1.8×10^6 s^{-1} for **1b**. In the case of **1a** and Ru(bpy)$_3$, ET rates were estimated from a typical dynamic quenching as follows: 8.3×10^9 M^{-1} s^{-1} for **1a** and 4.1×10^9 M^{-1} s^{-1} for Ru(bpy)$_3$. Thus, at a low concentration of Cyt-c (9 μM), the apparent rate constants are in the order **1c** = **1b** > **1a** > Ru(bpy)$_3$, which is almost opposite to the case with $Fe(CN)_6^{3-}$. These results suggest that the net photoreduction efficiency is controlled by a balance between the accessibility of the Ru complexes to Cyt-c and to sacrificial EDTA.

In conclusion, we have demonstrated that a Ru(bpy)$_3$ derivative **1b** which has an asymmetric charge distribution acts not only as a Cyt-c receptor, but also a photo-driven modulator of the redox state of Cyt-c. The present findings are anticipated to provide access to a combinatorial library of coordination chemistry to generate new Ru(bpy)$_3$-based function modulators which can selectively control protein activity.

8 Although the redox potentials of **1a**–**c** have not been determined thus far, it was reported that the presence of amide groups at the 4 and 4′ positions of bpy positively shifts the redox potential of both $*Ru^{2+}/Ru^{3+}$ and Ru^{2+}/Ru^{3+}. Still, this ET reaction seems favorable, since the potential shift was reported to be within only 0.3–0.4 V; see V. Skarda, M. J. Cook, A. P. Lewis, G. S. G. McAuliffe, A. J. Thomson and D. J. Robbins, *J. Chem. Soc., Perkin Trans. 2*, 1984, 1309. Details are now under way in our laboratory.

9 No obvious effect on the photoreduction was seen in the control experiments; (i) in the absence of Ru(bpy)$_3$ derivatives and (ii) under dark conditions.

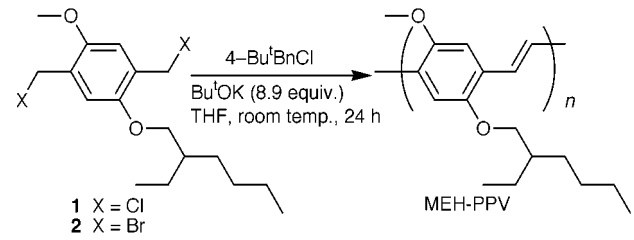
Received (in Corvallis, OR USA) 7th September 1999, Accepted 8th October 1999

A comparison of 1,4-bis(bromomethyl)- and 1,4-bis(chloromethyl)-2-(2′-ethylhexyloxy)-5-methoxybenzene as monomers for the modified Gilch route to poly[2-methoxy-5-(2′-ethylhexyloxy)-*p*-phenylenevinylene] was made; the bis(bromomethyl) monomer was found to give substantially higher yields of MEH–PPV with consistently higher molecular weights and narrower polydispersities than the corresponding bis(chloromethyl) monomer.

There is currently renewed interest in poly(*p*-phenylenevinylene) (PPV) and its derivatives due to the potential these polymers have for application in organic light-emitting diodes.[1–3] The two main routes to these polymers, the precursor route and the side chain approach, were developed to address the processability problems of PPV due to low solubility. The precursor approach involves the formation of a soluble precursor polymer that after fabrication can be converted to the final conjugated polymer using solid state thermal or photochemical processes. Both the sulfonium precursor route[4,5] and the halogen precursor route[6,7] have successfully addressed the lack of processibility of insoluble PPV and led to the production of electroluminescent devices from PPV films. The precursor approach, however, has some inherent problems.[2,8,9] The precursor polymers themselves can contain segments where elimination has occurred in 5–50% of polymer. The ill-defined nature of the precursor polymers due to such premature elimination makes their synthesis, storage and subsequent processing difficult. The lack of stability of the sulfonium precursor to PPV has caused problems such as gelation of the precursor polymer and difficulties in processing. Conversion of the precursor polymer to the conjugated form is also expensive and prone to the formation of defects in the resulting polymer due to incomplete elimination and side reactions with the eliminated species. The side chain approach addresses the solubility problems of PPVs by using monomers substituted with solubilizing groups. Ideally, the monomers are then converted directly into the corresponding soluble conjugated polymer that is processible by standard procedures. In 1966 Gilch reported a route to PPVs using the direct polymerization of bis(halomethyl)benzenes in the presence of excess base.[10] Although the polymerization *via* the Gilch route of bis(halomethyl)benzenes substituted with solubilizing groups should lead to soluble PPVs, in practice the preparation of poly[2-methoxy-5-(2′-ethylhexyloxy)-*p*-phenylenevinylene] (MEH-PPV) and poly(2,5-dihexyloxy-*p*-phenylenevinylene) *via* this route led to the gelation and precipitation of the products.[6,11,12] Hsieh *et al.* report that they were able to minimize gelation in the preparation of MEH-PPV by following the procedure of Wudl *et al.*, in which the Bu^{t}OK is added slowly and intermittently.[13,14] The MEH-PPV obtained by Hsieh in this manner, however, could not be filtered through a 0.5–1.0 μm filter indicating microgel formation.[14] Hsieh reports that microgel formation in the production of MEH-PPV has been an under-reported but significant problem in its synthesis. In our laboratory we had indeed encountered a similar problem when exploring a side chain route to MEH-PPV using a modified McMurry reaction of the corresponding dialdehyde. The polymer produced in the reaction appeared to be soluble, but was unfilterable through 0.45 μm filters. Hsieh's report was the first we encountered that addressed the problem of microgel formation in the preparation of MEH-PPV. Hsieh solved this problem in the preparation of MEH-PPV with the development of a modified Gilch route that uses the non-polymerizable additive 4-*tert*-butylbenzyl chloride **3** to control molecular weight and prevent microgel formation.[14] Having 1,4-bis(bromomethyl)-2-(2′-ethylhexyloxy)-5-methoxybenzene **2** in hand, we were curious whether replacing bromine for chlorine would affect polymerization using the modified Gilch route. We found that the polymerization of **2** *via* the modified



Scheme 1

Table 1 Conditions and results of the polymerization of **1** and **2**

Monomer	[Monomer][a]/ mol l^{-1}	Molar ratio **3**:monomer	M_w[b]/10^{-3}	M_n[b]/10^{-3}	Polydispersity	Yield (%)
1[c]	0.03	0.06	331	66.5	5.0	35
1[c]	0.04	0.06	199	39.1	5.1	39
1[c]	0.06	0.06	164	26.9	6.1	56
1	0.03	0.06	125	16.7	7.5	30
1	0.04	0.06	110	23.8	4.6	46

2	0.03	0.06	274	84.6	3.2	77
2	0.04	0.06	200	70.3	2.8	79
2	0.06	0.06	146	39.7	3.7	86

[a] 8.9 equiv. of Bu^{t}OK (1.0 mol l^{-1} in THF) was added all at once to an ice-water cooled solution of monomer in THF. [b] Relative to polystyrene in THF. [c] Hsieh *et al*. results for **1** (ref. 14).

Gilch route produced significantly different results than those reported by Hsieh for 1,4-bis(chloromethyl)-2-(2′-ethylhexyloxy)-5-methoxybenzene **1**.†

The polymerizations of both **1** and **2** (Scheme 1) were repeated under the reaction conditions that gave the highest molecular weight and the highest yield of MEH-PPV reported by Hsieh for the modified Gilch route (Table 1).[14] Products were isolated after a single precipitation of the reaction mixtures in methanol. We obtained results similar, but not identical, to those of Hsieh for **1** (Table 1). Overall, our molecular weights were lower, but followed the same trend of decreasing with increasing concentration of **1** in THF. The decrease, however, was less dramatic in our hands. We observed a wider range of polydispersities and obtained yields both slightly better and significantly worse than those reported by Hsieh. All the products were readily soluble in THF, $CHCl_3$ and CH_2Cl_2 and easily filterable through 0.45 μm filters. When 4-*tert*-butylbenzyl chloride was not added to the polymerization of **1**, we did encounter problems in filtering solutions of the polymer through 0.45 μm filters, indicating microgel formation, and obtained extremely low yields. The same procedures were then repeated for **2**. Under all three reaction conditions higher molecular weight material was obtained in significantly higher yield than we observed with **1**, Table 1. The molecular weights that we observed for the polymerization of **2** were similar to those reported by Hsieh for **1** and significantly higher than we observed for **1**. Polydispersities were narrower than those both Hsieh reported and we observed with **1**. Typical data for the elemental analysis of MEH-PPV produced from **2** (C, 77.61; H, 9.23; Br, 0.01%) shows very good agreement with that calculated for $[C_{17}H_{24}O_2]_n$ (C, 78.42; H, 9.29%) and very low bromine content. When no 4-*tert*-butylbenzyl chloride was added to the polymerization of **2**, both the yield and the molecular weight decreased but neither insoluble product nor microgel formation was observed, suggesting that the leaving group helps to prevent microgel formation but does not give as good results as the use of **2** with 4-*tert*-butylbenzyl chloride. ^{1}H NMR, UV, fluorescence and IR spectra of MEH-PPV produced from **1** and **2** are essentially the same and do not vary more than different polymerization runs using **1**. Relative quantum yields, as measured by a ratio of absorbance at 337 nm to integrated fluorescence intensity, did not vary as a function of method of preparation.

In conclusion, the modified Gilch route using the bis(chloromethyl)benzene **1** does indeed give soluble MEH-PPV in poor to moderate yields. Moderate to excellent yields of soluble MEH-PPV were obtained using the bis(bromomethyl)benzene **2**. Both **1** and **2** gave similar products. Elemental analysis data show products from **1** had slightly higher purity (99.5% compared to 99.0%) compared to **2** and had similar halogen content. Products from **2** consistently had higher molecular weights, narrower polydispersities and higher yields than the corresponding reactions with **1** in our hands. We conclude that the bromo monomer **2** gives significantly better yields with consistently higher molecular weights and narrower polydispersities of a comparable quality MEH-PPV than monomer **1** using the modified Gilch route and is recommended when the use of benzyl bromides is convenient.

Acknowledgment is made to the Donors of The Petroleum Research Fund, administered by the American Chemical Society, the Camille and Henry Dreyfus Start-up Grant Program for Undergraduate Institutions, the National Science Foundation under Grant No. CHE-9701800 and the Howard Hughes Medical Institutes Grant to Hope College for funding. We also gratefully acknowledge Dr Stephanie Schaertel, Joseph Gannon and Sarah Smolinski of Grand Valley State University for determining quantum yields of our samples.

Notes and references

† Monomer **2** was prepared from the alkylation of 4-methoxyphenol in the presence of base followed by bromomethylation with paraformaldehyde in HBr and acetic acid (ref. 15) Monomer **1** was prepared by Hsieh in a similar manner (ref. 12). We prepared monomer **1** from **2** using a halogen exchange reaction.
